Introduction

Determining the load-power relationship for given resistance exercises could be useful for quantifying performance changes after training and to identify the training load to maximize power output. It has been recommended that to improve power, athletes should use this load that maximizes power output. However, it has been recently demonstrated that for some exercises, the power profile was relatively similar across a wide range of loads. As a consequence, near maximal power output could be produced at very different loads [1, 2]. However, performing a squat at 20% or 80% of the 1RM, despite producing the same power output, results in very different neuromuscular activity and according to training specificity theory, working with 20% or 80% 1RM loads will result in differential training objectives as well as neuromuscular adaptations.

Recently, Quievre et al. [4] have suggested splitting total power output into two components: one linked to the force of gravity (gravity power, Pg) and one linked to the system mass resulting acceleration (acceleration power, Pa). It may be that differentiating total power output into these Pg and Pa and noting their effects, results in a different interpretation of the load-power relationship and therefore the loading and adaptational effects to muscle. We have hypothesised that profiling Pg, Pa, and Pg-Pa relationships could inform programme design to better effect as to the loads to use for specific power training objectives.

Métodos

- 15 healthy males: 22±3y, 1.76±0.12m, 72±13kg
- Concentric Bench Press exercise
- Inertial dynamometer [1]
  - Linear PositionTransducer
  - Accelerometer
  - Labview software
- Direct measurements and constants
  - Displacement (x),
  - Acceleration (a),
  - Gravity acceleration (g)
  - Time (t),
  - Mass (m)
- Calculated measurements
  - Velocity (v = dx/dt)
  - Net Force (Pn=ma+mg)
  - Mechanical power (Pm=PaV)
- Acceleration and Gravity power concept
  - Pa = (ma+mg)V = mav + mgv = Pa + Pg
  - Gravity power = Pa = mav

Results

The three different types of power outputs presented very different profiles revealed by curves analysis as well as by the load-power relationship. Pa and Pm significantly decreased from 35 to 50% of 1RM, but not in the same way: the reduction in power increased with load for Pa while it was almost constant for Pm. Pm significantly increased from 35 to 50% and decreased from 70 to 95% of 1RM. These effects were observed from the curve that Pa has a substantial influence on P at 15% of the 1RM but not at 95%, while Pm is almost totally influenced by Pg.

Discussion & Conclusions

The results indicate that Pa, Pm, and Pg are not affected in the same way when load was increased, confirming the previous study of Quievre et al [4]. These findings question the value of traditional power-load profiling and the use of these profiles in training load selection. Researchers have highlighted that in the squat jump and power clean, P presented little change over a wide range of loads [1, 2]. According to Harris et al [2], in these specific cases, profiling the P-load relationship may not be that important. With the introduction of Pa and Pg concept, it appears that using a light or heavy load should result in different training outcomes. For coaches, profiling Pa-load and Pm-load relationships could be more relevant than the classical P-load relationship in order to determine which amount of load they have to use in their power training programme. Obviously, load selection should depend on sport characteristics and the relative importance of Pa and Pm during decisive actions.

The introduction of the Pa and Pg concept should lead to new considerations regarding power output and the load to be selected to maximize muscle performance.
