Abstract

Photodynamic therapy (PDT) is a clinically approved, minimally invasive therapeutic procedure that can exert a selective cytotoxic activity toward malignant cells. The procedure involves administration of a photosensitizing agent followed by irradiation at a wavelength corresponding to an absorbance band of the sensitizer. In the presence of oxygen, a series of events lead to direct tumor cell death, damage to the microvasculature, and induction of a local inflammatory reaction. Clinical studies revealed that PDT can be curative, particularly in early stage tumors. It can prolong survival in patients with inoperable cancers and significantly improve quality of life. Minimal normal tissue toxicity, negligible systemic effects, greatly reduced long-term morbidity, lack of intrinsic or acquired resistance mechanisms, and excellent cosmetic as well as organ function-sparing effects of this treatment make it a valuable therapeutic option for combination treatments. With a number of recent technological improvements, PDT has the potential to become integrated into the mainstream of cancer treatment. Introduction

Despite progress in basic research that has given us a better understanding of tumor biology and led to the design of new generations of targeted drugs, recent large clinical trials for cancer, with some notable exceptions, have been able to detect only small differences in treatment outcomes.1,2 Moreover, the number of

new clinically approved drugs is disappointingly low. These sobering facts indicate that to make further progress, it is necessary to put an emphasis on other existing but still underappreciated therapeutic approaches. Photodynamic therapy (PDT) has the potential to meet many currently unmet medical needs. Although still emerging, it is already a successful and clinically approved therapeutic modality used for the management of neoplastic and nonmalignant diseases. PDT was the first drug-device combination approved by the US Food and Drug Administration (FDA) almost 2 decades ago, but even so remains underutilized clinically.

PDT consists of 3 essential components: photosensitizer (PS) (see Table 1 for the definitions of specialty terms), light, and oxygen. None of these is individually toxic, but together they initiate a photochemical reaction that culminates in the generation of a highly reactive product termed singlet oxygen ($^1O_2$) (Table 1). The latter can rapidly cause significant toxicity leading to cell death via apoptosis or necrosis. Antitumor effects of PDT derive from 3 interrelated mechanisms: direct cytotoxic effects on tumor cells, damage to the tumor vasculature, and induction of a robust inflammatory reaction that can lead to the development of systemic immunity. The relative contribution of these mechanisms depends to
a large extent on the type and dose of PS used, the time between PS administration and light exposure, total light dose and its fluence rate (Table 1), tumor oxygen concentration, and perhaps other still poorly recognized variables. Therefore, determination of optimal conditions for using PDT requires a coordinated interdisciplinary effort. This review will address the most important biological and physicochemical aspects of PDT, summarize its clinical status, and provide an outlook for its potential future development.

Basic Components of PDT

PDT is a 2-stage procedure. After the administration of a light-sensitive PS, tumor loci are irradiated with a light of appropriate wavelength. The latter can be delivered to virtually any organ in the body by means of flexible fiber-optic devices (Fig. 1). Selectivity is derived from both the ability of useful PSs to localize in neoplastic lesions and the precise delivery of light to the treated sites. Paradoxically, the highly localized nature of PDT is one of its current
limitations, because the treatment is ineffective against metastatic lesions, which are the most frequent cause of death in cancer patients. Ongoing research is focused on finding optimal PDT conditions to induce systemic immunity that might, at least to some extent, obviate this limitation in the future. PDT can be used either before or after chemotherapy, radiotherapy, or surgery without compromising these therapeutic modalities. None of the clinically approved PSs accumulate in cell nuclei, limiting DNA damage that could be carcinogenic or lead to the development of resistant clones. Moreover, the adverse effects of chemotherapy or radiation are absent. Radioresistance or chemoresistance do not affect sensitivity to PDT. Excellent cosmetic outcomes make PDT suitable for patients with skin cancers. There are no significant changes in tissue temperature, and the preservation of connective tissue leads to minimal fibrosis, allowing retention of functional anatomy and mechanical integrity of hollow organs undergoing PDT. Selected patients with inoperable tumors, who have exhausted other treatment options, can also achieve improvement in quality of life with PDT. Finally, many PDT procedures can be performed in an outpatient or ambulatory setting, thereby not only alleviating costs, but also making the treatment patient-friendly. The only adverse effects of PDT relate to pain during some treatment protocols and a persistent skin photosensitization that has been circumvented by the newer agents.

**Photosensitizers**

Most of the PSs used in cancer therapy are based on a tetapyrrole structure, similar to that of the protoporphyrin contained in hemoglobin. An ideal PS agent should be a single pure compound to allow quality control analysis with low manufacturing costs and good stability in storage. It should have a high absorption peak between 600 and 800 nanometers (nm) (red to deep red), because absorption of photons with wavelengths longer than 800 nm does not provide enough energy to excite oxygen to its singlet state and to form a substantial yield of reactive oxygen species. Because the penetration of light into tissue increases with its wavelength, agents with strong absorbance in the deep red such as chlorins, bacteriochlorins, and phthalocyanines offer improvement in tumor control. It should have no dark toxicity and relatively rapid clearance from normal tissues, thereby minimizing phototoxic side effects. Other pertinent desirable properties of PS agents have been summarized elsewhere. Although the interval between drug administration and irradiation is usually long, so that the sensitizer is given sufficient time to diffuse from normal tissues, reports now suggest that the tumor response may be sometimes better when light is delivered at a shorter drug-light interval when PS is still present in the blood vessels, thus producing marked vascular damage. Some reports suggest that a pronounced inflammatory response and necrotic cell death after illumination are important in the immune-stimulating function of PDT, whereas others suggest that PSs that produce more apoptosis and less inflammation are suitable for applications such as brain tumors, where swelling is undesirable. Recent findings show that certain PDT-induced apoptotic cell death mechanisms are highly immunogenic and capable of driving antitumor immunity as well. Finally, the light-mediated destruction of the PS known as photobleaching was previously thought to be undesirable, but some reports suggest that this property may make light dosimetry less critical because overtreatment is avoided when the PS is destroyed during the illumination.

The first PS to be clinically employed for cancer therapy was a water-soluble mixture of porphyrins called hematoporphyrin derivative (HPD), a purified form of which, porfimer sodium, later became known as Photofrin. Although porfimer sodium is still the most widely employed PS, the product has some disadvantages, including a long-lasting skin photosensitivity and a relatively low absorbance at 630 nm. Although a photodynamic effect can be produced with porfimer sodium, efficacy would be improved by red-shifting the red absorbance band and increasing the absorbance at the longer wavelengths. There has been a major effort among medicinal chemists to discover second-generation PSs, and several hundred compounds have been proposed as potentially useful for anticancer PDT. Table 2 displays the most promising PSs that have been used clinically for cancer PDT (whether approved or in trials). The discovery that 5-aminolevulinic acid (ALA) was a biosynthetic precursor of the PS protoporphyrin IX has led to many applications in which ALA or ALA esters can be topically applied or administered orally. These are considered to be “prodrugs,” needing to be converted to protoporphyrin.
to be active PSs. Many hypotheses have been proposed to account for the tumor-localizing properties in PDT. These include the preponderance of leaky and tortuous tumor blood vessels due to neovascularization and the absence of lymphatic drainage known as the enhanced permeability and retention effect. Some of the most effective compounds bind preferentially to low-density lipoprotein (LDL), suggesting that upregulated LDL receptors found on tumor cells could be important.

There have been targeting studies in which PSs are covalently attached to various molecules that have some affinity for neoplasia or to receptors expressed on specific tumors. The intention is to rely on the ability of the targeting vehicle to control localization factors so that the PS can be chosen based on its photochemical properties. These vehicles include monoclonal antibodies, antibody fragments, peptides, proteins (such as transferrin, epidermal growth factor and insulin), LDL, various carbohydrates, somatostatin, folic acid, and many others.

**Light Sources**

Blue light penetrates least efficiently through tissue, whereas red and infrared radiations penetrate more deeply (Fig. 2). The region between 600 and 1200 nm is often called the optical window of tissue. However, light up to only approximately 800 nm can generate \(^1\)O\(_2\), because longer wavelengths have insufficient energy to initiate a photodynamic reaction. No single light source is ideal for all PDT indications, even with the same PS. The choice of light source should therefore be based on PS absorption (fluorescence excitation and action spectra), disease (location, size of lesions, accessibility, and tissue characteristics), cost, and size. The clinical efficacy of PDT is dependent on complex dosimetry: total light dose, light exposure time, and light delivery mode (single vs fractionated or even metronomic). The fluence rate also affects PDT response. Integrated systems that measure the light distribution and fluence rate either interstitially or on the surface of the tissues being treated are so far used only in experimental studies.

Both lasers and incandescent light sources have been used for PDT and show similar efficacies. Unlike the large and inefficient pumped dye lasers, diode lasers are small and cost-effective, are simple to install, and have automated dosimetry and calibration features and a longer operational life. Such lasers are now being specifically designed for PDT.

Abbreviations: ALA, 5-aminolevulinic acid; AMD, age-related macular degeneration; Ce6-PVP, chlorin e6-polyvinylpyrrolidone; HPD, hematoporphyrin derivative; HPPH, 2- (1-hexyloxyethyl)-2-devinyl pyropheophorbide-a; MACE, mono-L-aspartylchlorin-e6; mTHPC, m-tetrahydroxyphenylchlorin; nm indicates nanometers; SnEt2, tin ethyl etiopurpurin.
sources with relatively narrow spectral bandwidths and high fluence rates. Lasers can be coupled into fibers with diffusing tips to treat tumors in the urinary bladder and the digestive tract. Inflatable balloons, covered on the inside with a strongly scattering material and formed to fit an organ, are also commercially available. It is quite feasible to implant a light source in solid organs deep in the body under image guidance. The choice of optimal combinations of PSs, light sources, and treatment parameters is crucial for successful PDT.

Photophysics and Photochemistry
Most PSs in their ground (ie, singlet) state (Table 1) have 2 electrons with opposite spins located in an energetically most favorable molecular orbital. Absorption of light leads to a transfer of one electron to a higher energy orbital (Fig. 3). This excited PS is very unstable and emits this excess energy as fluorescence and/or heat. Alternatively, an excited PS may undergo an intersystem crossing (Table 1) to form a more stable triplet state (Table 1) with inverted spin of one electron. The PS in triplet state can either decay radiationlessly to the ground state or transfer its energy to molecular oxygen ($O_2$), which is unique in being a triplet in its ground state. This step leads to the formation of $^1O_2$, and the reaction is referred to as a Type II process. A Type I process can also occur whereby the PS reacts directly with an organic molecule in a cellular microenvironment, acquiring a hydrogen atom or electron to form a radical. Subsequent autoxidation of the reduced PS produces a superoxide anion radical ($O_2^-$). Dismutation or one-electron reduction of $O_2^-$ gives hydrogen peroxide ($H_2O_2$), which in turn can undergo one-electron reduction to a powerful and virtually indiscriminate oxidant hydroxyl radical ($HO^*$). Reactive oxygen species (ROS) generation via Type II chemistry is mechanistically much simpler than via Type I, and most PSs are believed to operate via a Type II rather than Type I mechanism.

Mechanisms of PDT-Mediated Cytotoxicity
The lifetime of $^1O_2$ is very short (approximately 10-320 nanoseconds), limiting its diffusion to only approximately 10 nm to 55 nm in cells. Thus, photodynamic damage will occur very close to the intracellular location of the PS. Porfimer sodium is a complex mixture of porphyrin ethers with variable localization patterns mostly associated with lipid membranes. Of the other PS agents in current use, the mono-L-aspartyl chlorin e6 (NPe6, talaporfin) targets lysosomes; the benzoporphyrin derivative (BPD) targets mitochondria; m-tetrahydroxyphenylchlorin (mTHPC, temeporfin) has been reported to target mitochondria, endoplasmic reticulum (ER), or both; and the phthalocyanine Pc4 has a broad spectrum of affinity, although mitochondria are reported to be a primary target. Other agents that have been
developed can have multiple targets. Specific patterns of localization may vary also among different cell types.

PDT can evoke the 3 main cell death pathways: apoptotic, necrotic, and autophagy-associated cell death (Fig. 4). Apoptosis is a generally major cell death modality in cells responding to PDT. Mitochondria outer membrane permeabilization (MOMP) after photodynamic injury is controlled by Bcl-2 family members and thought to be largely p53-independent. Mitochondria-associated PSs, photodamage to membrane-bound Bcl-2, can be a permissive signal for MOMP and the subsequent release of caspase activators such as cytochrome c and Smac/DIABLO, or other proapoptotic molecules, including apoptosis-inducing factor (AIF). Lyosomal membrane rupture and leakage of cathepsins from photo-oxidized lysosomes induces Bid cleavage and MOMP.

Phototoxicity is not propagated only through caspase signaling but involves other proteases, such as calpains, as well as nonapoptotic pathways. Typically, inhibition or genetic deficiency of caspases only delays phototoxicity or shifts the cell death modality toward necrotic cell death. Recent evidence suggests indeed that certain forms of necrosis can be propagated through signal transduction pathways. The molecular mechanisms underlying programmed necrosis are still elusive, but certain events including activation of receptor interacting protein 1 (RIP1) kinase, excessive mitochondrial ROS production, lysosomal damage, and intracellular Ca\(^{2+}\) overload are recurrently involved. Severe inner mitochondria membrane photodamage or intracellular Ca\(^{2+}\) overload could promote mitochondrial permeability transition, an event that may favor necrotic rather than apoptotic phototoxicity.

Photodamage of cells can also lead to the stimulation of macroautophagy (hereafter referred to as autophagy). This is a lysosomal pathway for the degradation and recycling of intracellular proteins and organelles. Autophagy can be stimulated by various stress signals including oxidative stress. This process can have both a cytoprotective and a prodeath role after cancer chemotherapies, including those involving ROS as primary damaging agents. Recent studies delineate autophagy as a mechanism to preserve cell viability after photodynamic injury. PSs that photodamage the lysosomal compartment may compromise completion of the autophagic process, causing incomplete clearance of the autophagic cargo. Accumulation of ROS-damaged cytoplasmic components may then potentiate phototoxicity in apoptosis-competent cells. A better understanding of the interplay between autophagy, apoptosis, and necrosis and how these processes lead to improved tumor response will be a requisite to devise better therapeutic strategies in PDT.

**Cytoprotective Mechanisms**

Numerous publications have reported cytoprotective mechanisms that cancer cells exploit to avoid the cytotoxic effects of PDT. The first mechanism identified was based on the large variation observed in the level of antioxidant molecules expressed in cancer cells. Both water-soluble antioxidants (eg, some amino acids, glutathione [GSH], or vitamin C) and lipid-soluble antioxidants (eg, vitamin E) are present at variable levels in many cancer cell types, explaining the large variation in PDT sensitivity. A second mechanism is associated with expression in cancer cells of enzymes that can detoxify ROS. Although there is no specific cellular enzyme that can directly detoxify \(\text{O}_2\), enzymes involved in other ROS metabolism can influence the cytotoxic effect.
of PDT. For example, superoxide dismutase (SOD) overexpression or treatment with SOD mimetics have been shown to counteract the cytotoxic effect of PDT. An increase in SOD activity has also been observed in various cancer cell types after PDT, and this is associated with a decrease in GSH peroxidase and catalase activities. The third cytoprotective mechanism involves proteins whose encoding genes are themselves induced by PDT. Many categories can be specified but most of them are part of signaling pathways that can regulate PDT-induced apoptosis or participate in the repair of lesions induced by oxidative stress. NF-κB inhibition by overexpression of the IkBα super-repressor or by the use of pharmacological inhibitors strongly sensitizes cancer cells to apoptosis induced by PDT. Other stress-related transcription factors induced by PDT include activator protein 1 (AP-1), hypoxia-inducible factor (HIF), or nuclear factor-like 2 (Nrf2). PDT was shown to upregulate heme oxygenase-1 (HO-1) expression, and the mechanism is dependent on Nrf2 nuclear accumulation and on p38 mitogen-activated protein kinase (p38MAPK) and phosphoinositide 3-kinase (PI3K) activities. Because of the antioxidant activity of HO-1, it can be envisioned that Nrf2-dependent signal transduction can control cellular protection against PDT-mediated cytotoxic effects.

PDT was found to induce expression of various heat shock proteins (HSPs) for which a protective role in PDT has been described. For example, transfection of tumor cells with the HSP27 gene increased the survival of tumor cells after PDT. Similarly, increased HSP60 and HSP70 levels are inversely correlated with sensitivity to the photodynamic treatment. The simplest explanation for these observations is the ability of HSPs to bind to oxidatively damaged proteins. Moreover, the intracellular function of HSPs is not only restricted to protein refolding. Many HSPs “client” proteins play a critical role in the regulation of prosurvival pathways. PDT also leads to increased ubiquitination of carbonylated proteins, thereby tagging them for degradation in proteasomes, which prevents the formation of toxic protein aggregates.

**Antivascular Effects of PDT**

Photodynamic perturbation of tissue microcirculation was first reported in 1963. A study by Star et al utilized a window chamber to make direct observations of implanted mammary tumor and adjacent normal tissue microcirculation in rats before, during, and at various times after PDT sensitized with HPD. An initial blanching and vasoconstriction of the tumor vessels was followed by heterogeneous...
responses including eventual complete blood flow stasis, hemorrhage, and, in some larger vessels, the formation of platelet aggregates. Observations performed on excised tissues from murine models demonstrated a wide range of vascular responses, including disruption of blood flow to subcutaneous urothelial tumors and to normal rat jejunum, breakdown of the blood-brain barrier in the normal brain of mice, and endothelial cell and organelle damage in subcutaneous tumors and normal tissue.51,52

Other studies demonstrated that tumor cells treated with a potentially curative photodynamic dose in vivo were clonogenic if removed immediately from the host.53,54 Progressive loss in clonogenicity was seen when tumors were left in the host for increasing durations; this corresponded to progression of PDT-induced hypoxia as determined radio-biologically. Hypoxia sufficient to preclude direct tumor cell killing was identified at subcurative PDT doses. These studies suggested a central role for vascular damage in governing the tumor response to PDT in mouse models.

Many reports cited above directly implicate the endothelium as a primary target for PDT in vivo; this stimulated research into the relative sensitivity of endothelial cells to PDT and the responses of endothelial cells that could initiate the various phenomena at the vessel level. Gomer et al55 showed that bovine endothelial cells were significantly more sensitive to PDT with porfimer sodium than smooth muscle cells or fibroblasts from the same species. This increased sensitivity, assessed by clonogenic assay, was not a result of increased porfimer sodium accumulation. Sensitivity to HPD-mediated PDT of bovine aorta endothelial cells and human colon adenocarcinoma cells was investigated by West et al.56 Exponentially growing endothelial cells were significantly more sensitive to PDT with porfimer sodium than smooth muscle cells or fibroblasts from the same species. This increased sensitivity, assessed by clonogenic assay, was not a result of increased porfimer sodium accumulation. Endothelial cell responses to sublethal doses of PDT may also contribute to vascular changes observed in tissue.

Increased vessel permeability to albumin in the rat cremaster muscle during and after PDT with porfimer sodium was reported by Fingar et al.57 More recently, intravital fluorescence imaging has been used to demonstrate treatment-induced increases in tumor vessel permeability for PDT with verteporfin and talaporfin.58,59 In a pioneering study, Synder et al60 showed that 2-(1-hexyloxyethyl)-2-devinyl pyropheophorbide-a (HPPH) PDT induction of increased tumor vascular permeability resulted in enhanced accumulation of Doxil (Centocor Ortho Biotech Products, Horsham, Penn), a liposome-encapsulated formulation of doxorubicin. When Doxil was administered immediately after PDT, tumor control and selectivity were potentiated significantly relative to either modality alone. In a study motivated by the need to deliver chemotherapeutic agents to the brain adjacent to a tumor, PDT with ALA was used successfully to transiently disrupt the blood-brain barrier in normal rat brain in vivo.61 These and other aspects of vascular-targeted PDT represent important current research directions.

PDT and the Immune Response

Inflammation and Innate Immunity
PDT frequently provokes a strong acute inflammatory reaction observed as localized edema at the targeted site.4 This reaction is a consequence of PDT-induced oxidative stress. Thus, PDT can be ranked among cancer therapies (including cryotherapy, hyperthermia, and focused ultrasound ablation) producing chemical/physical insult in tumor tissue perceived by the host as localized acute trauma. This prompts the host to launch protective actions evolved for dealing with a threat to tissue integrity and homeostasis at the affected site.62 The acute inflammatory response is the principal protective effector process engaged in this context. Its main task is containing the disruption of homeostasis and ensuring removal of damaged cells, and then promoting local healing with restoration of normal tissue function.

The inflammation elicited by PDT is a tumor antigen nonspecific process orchestrated by the innate immune system.62 The recognition arm of this system, in particular pattern recognition receptors (Table 1), is responsible for detecting the presence of a PDT-inflicted, tumor-localized insult revealed to its sensors as the appearance of “altered self.”62 PDT appears particularly effective in rapidly generating an abundance of alarm/danger signals, also called damage-associated molecular patterns (DAMPs) (Table 1) or cell death-associated molecular patterns (CDAMPs), at the treated site that can be detected by the innate immunity alert elements.62
The onset of PDT-induced inflammation is marked by dramatic changes in the tumor vasculature, which becomes permeable for blood proteins and proadhesive for inflammatory cells. This occurs even with those PSs that mainly target tumor rather than vascular cells, where the inflammatory process is predominantly initiated by signals originating from photo-oxidative damage produced in perivascular regions with chemotactic gradients reaching the vascular endothelium. The inflammatory cells, led by neutrophils and followed by mast cells and monocytes/macrophages, rapidly and massively invade tumors undergoing PDT (Fig. 5). Their primary task is to neutralize the source of DAMPs/CDAMPs by eliminating debris containing compromised tissue elements, including injured and dead cells. Damage and dysfunction of photodynamically treated tumor vasculature frequently results in vascular occlusion that serves to “wall off” the damaged tumor tissue until it is removed by phagocytosis, thereby preventing the spread of the disrupted homeostasis. Depletion of these inflammatory cells or inhibition of their activity after PDT was shown to diminish therapeutic effect. Among cytokines involved in the regulation of the inflammatory process, the most critical role in tumor PDT response is played by interleukin (IL)-1β and IL-6. Blocking the function of various adhesion molecules was proven also to be detrimental to PDT response. Conversely, blocking anti-inflammatory cytokines such as IL-10 and transforming growth factor-β can markedly improve the cure rates after PDT.
PDT and Adaptive Immunity

Numerous preclinical and clinical studies have demonstrated that PDT can influence the adaptive immune response in disparate ways; some regimens result in potentiation of adaptive immunity, whereas others lead to immunosuppression. The precise mechanism leading to potentiation versus suppression is unclear; however, it appears as though the effect of PDT on the immune system is dependent upon the treatment regimen, the area treated, and the photosensitizer type.66,70 PDT-induced immune suppression is largely confined to cutaneous and transdermal PDT regimens involving large surface areas.70,71

PDT efficacy appears to be dependent upon the induction of antitumor immunity. Long-term tumor response is diminished or absent in immunocompromised mice (Table 1).64,72 Reconstitution of these animals with bone marrow or T cells from immunocompetent mice (Table 1) results in increased PDT efficacy. Clinical PDT efficacy also appears to depend on antitumor immunity. Patients with vulval intraepithelial neoplasia (VIN) who did not respond to PDT with ALA were more likely to have tumors that lacked major histocompatibility complex class I molecules (MHC-I) (Table 1) than patients who responded to PDT with ALA.73 MHC-I recognition is critical for activation of CD8\(^+\) T cells and tumors that lack MHC-I are resistant to cell-mediated antitumor immune reactions.74 VIN patients who responded to PDT had increased CD8\(^+\) T-cell infiltration into the treated tumors compared with nonresponders. Immunocompromised and immunocompetent patients with actinic keratoses and Bowen disease had similar initial response rates to PDT; however, immunocompromised patients exhibited greater persistence of disease or the appearance of new lesions.75

Canti et al.76 were the first to show PDT-induced immune potentiation, demonstrating that cells isolated from tumor-draining lymph nodes of PDT-treated mice were able to confer tumor resistance to naïve mice (Table 1). Subsequent studies demonstrated that PDT directed against murine tumors resulted in increased immune cell infiltration into distant untreated tumors that was accompanied by tumor regression.78 PDT of basal cell carcinoma (BCC) increased immune cell reactivity against a BCC-associated antigen.79

The mechanism whereby PDT enhances antitumor immunity has been examined for the past several decades. PDT activates both humoral and cell-mediated antitumor immunity, although the importance of the humoral response is unclear. PDT efficacy in mice and humans is reduced in the absence of CD8\(^+\) T-cell activation and/or tumor infiltration.64,73,80 Therefore, most mechanistic studies have focused on the means by which PDT potentiates CD8\(^+\) T-cell activation. It is clear that induction of antitumor immunity after PDT is dependent upon induction of inflammation.81 PDT-induced acute local and systemic inflammation is postulated to culminate in the maturation and activation of dendritic cells (DCs). Mature DCs are critical for activation of tumor-specific CD8\(^+\) T cells and the induction of antitumor immunity.82 DCs are activated in response to PDT69 and migrate to tumor-draining lymph nodes, where they are thought to stimulate T-cell activation.69,83 Generation of CD8\(^+\) effector and memory T cells is frequently, but not always, dependent upon the presence and activation of CD4\(^+\) T cells.84 PDT-induced antitumor immunity may or may not depend on CD4\(^+\) T cells and may be augmented by natural killer cells.80

PDT-mediated enhancement of antitumor immunity is believed to be due, at least in part, to stimulation of DCs by dead and dying tumor cells, suggesting that in vitro PDT-treated tumor cells may act as effective antitumor vaccines.85 This hypothesis has been proven by several studies using a wide variety of PSs and tumor models in both preventive and therapeutic settings.67,85-87

Mechanistic studies showed that incubation of immature DCs with PDT-treated tumor cells leads to enhanced DC maturation and activation and an increased ability to stimulate T cells.85,88 PDT of tumor cells causes both cell death and cell stress,4,89,90 and it is hypothesized that the activation of DCs by PDT-treated cells is the result of recognition of DAMPs/CDAMPs that are released/secreted/exposed by PDT from dying cells.91-93 HSP70 is a well-characterized DAMP that interacts with the
danger signal receptors, Toll-like receptors 2 and 4, and is induced by PDT. The level of expression of HSP70 in PDT-treated tumor cells appears to correlate with an ability to stimulate DC maturation and the initiation of inflammation. Furthermore, opsonization of photodynamically treated tumor cells by complement proteins increases the efficacy of PDT-generated vaccines. PDT therefore induces multiple danger signals capable of triggering antigen-presenting cell activation and antitumor immunity.

The implications of PDT-induced antitumor immunity and efficacious PDT-generated vaccines are significant and provide an exciting possibility for using PDT in the treatment of metastatic disease and as an adjuvant in combination with other cancer modalities. Several preclinical studies demonstrated that PDT is able to control the growth of tumors present outside the treatment field, although others have failed to demonstrate control of distant disease after PDT. PDT was also shown to be an effective surgical adjuvant in patients with non-small cell lung cancer with pleural spread.

**Combinations of PDT With Other Therapies**

Combinations of various therapeutic modalities with nonoverlapping toxicities are among the commonly used strategies to improve the therapeutic index of treatments in modern oncology. Two general approaches may increase the antitumor effectiveness of PDT: 1) sensitization of tumor cells to PDT and 2) interference with cytoprotective molecular responses triggered by PDT in surviving tumor or stromal cells. Any interactions between PDT and PDT-sensitizing agents will be confined to the illuminated area. Therefore, the potentiated toxicity of the combinations is not systemic. This should be of special importance in elderly or debilitated patients who tolerate more intensive therapeutic regimes poorly. Moreover, considering its unique \(^1\)O\(_2\)-dependent cytotoxic effects, PDT can be safely combined with other antitumor treatments without the risk of inducing cross-resistance.

There have been few studies on combinations of PDT with standard antitumor regimens published to date. PDT can be used in combination with surgery as a neoadjuvant, adjuvant, or repetitive adjuvant treatment, preferably fluorescence image-guided to confine illumination to the most suspicious lesions. PDT has also been successfully combined with radiotherapy and chemotherapy (Table 3).

Another approach to promote PDT efficacy involves increased PS delivery or impaired loss from tumor cells. The first approach involves conjugation of PSs to various tumor-targeting molecules as is described above. This may be important in the treatment of tumors where large surface areas are illuminated and hence increased tumor selectivity is desired (eg, superficial spreading bladder cancer or metastases to the peritoneum and pleural cavity). The use of compounds that impair PS efflux has also been demonstrated to effectively sensitize tumor cells to PDT, although such approaches seem to be limited to those PSs that are the substrates of outward transport systems such as ABCG2. Another approach involves increased conversion of ALA or its esters into protoporphyrin IX by iron-chelating agents.

The development of novel target-specific antitumor drugs has enabled examination of a number of concept-based combinations that in various molecular mechanisms sensitize tumor cells to the cytotoxic effects of PDT. Proteins are major targets for oxidative reactions because they constitute nearly 70% of the dry weight of cells. Oxidized proteins can be refolded by molecular chaperones (Table 1) such as HSPs. Inefficient restoration of their structure leads to accumulation of misfolded proteins and their aggregation, which precipitates cell death. Accumulation of damaged or misfolded proteins within ER triggers a process called ER stress, which can be ameliorated by unfolded protein response or can lead to cell death. Therapeutic approaches that interfere with refolding or removal of oxidized proteins can be used to sensitize tumor cells to PDT. For example, modulation of HSP function with geldanamycin, a HSP90 inhibitor, sensitizes tumor cells to PDT. Bortezomib, a proteasome inhibitor successfully used in the treatment of hematological disorders, potentiates the cytotoxic effects of PDT by aggravation of ER stress. Moreover, several apoptosis-modulating factors such as rapamycin, Bcl-2 antagonists, ursohexycolchic acid, or ceramide analogues have been shown to increase PDT-mediated cancer cell death (Table 3).
### TABLE 3. Combinations of PDT and Various Therapeutic Modalities in Cancer Treatment: A Comprehensive Summary

</table>
Transformed cells deeply seated within the tumor mass receive suboptimal light doses and survive due to induction of numerous cytoprotective mechanisms. Targeting enzymes participating in ROS scavenging (such as superoxide dismutase, HO-1, or nitric oxide synthase) with selective inhibitors has been shown to improve the antitumor activity of PDT. Antivascular effects of PDT can be further potentiated by cyclooxygenase (COX) inhibitors, antiangiogenic or antivascular drugs, or monoclonal antibodies targeting factors promoting neovascularization (such as vascular endothelial growth factor), significantly improving tumor growth control after PDT. Finally, combining PDT with agents that target signal transduction pathways such as the anti-epidermal growth factor receptor agent cetuximab may also improve the efficacy of PDT. Moreover, combining 2 different PSs in one treatment regimen leads to simultaneous targeting of tumor as well as vascular cells. The use of agents that enhance the efficacy without increasing the normal tissue effects of PDT, thereby improving the therapeutic index, will represent a major focus of clinical research going forward.

Clinical PDT

The clinical use of PDT for cancer dates to the late 1970s, when there was a study published on the effects of HPD plus light in 5 patients with bladder cancer. In 1978, Dougherty et al reported the first large series of patients successfully treated with PDT using HPD. Complete or partial responses were observed in 111 of 113 malignant lesions. Of the large variety of tumors examined, none was found to be unresponsive. Since this early work, there have been over 200 clinical trials for PDT.

Recent systematic reviews revealed that PDT can be considered a reasonable option in the treatment of malignant and premalignant nonmela-noma skin lesions. It is also useful in the treatment of Barrett esophagus and unresectable cholangiocarcinoma (CC). However, its effectiveness in the management of other types of tumors has not yet been unequivocally proven. The major reason for this is that only a few adequately powered randomized controlled trials have been performed to date. Systematic analysis of the literature is limited due to lack of optimal PDT parameters (illumination conditions or PS dose) that could be comparable among these studies.

PDT produces mostly superficial effects. Due to a limited light penetration through tissues, the depth of tumor destruction ranges from a few millimeters to up to 1 centimeter. This apparent disadvantage can be favorably exploited in the treatment of superficial diseases, such as premalignant conditions (mucous dysplasia, actinic keratosis), carcinoma in situ (CIS), or superficial tumors (such as malignant pleural mesothelioma or intraperitoneal disseminated carcinomatosis). Moreover, PDT can be used supplemental to surgery, to irradiate the tumor bed, and to increase the probability of long-term local disease control.

Skin Tumors

PDT using porfimer sodium and ALA and its derivatives has been extensively studied in the treatment of both premalignant and malignant skin tumors. In the definitive setting, PDT is currently approved in the United States, Canada, and the European Union (EU) for the treatment of actinic keratosis (AK) and approved in the EU and Canada for the treatment of BCC. PDT has demonstrated efficacy in treating squamous cell carcinoma.
(SCC) in situ/Bowen disease and has also been used with some success to treat extramammary Paget disease. However, the results of PDT for SCC of the skin using topical PSs have been disappointing, with recurrence rates of greater than 50%.156,157

**PDT for AK and PDT for SCC In Situ/Bowen Disease**

Successful results for PDT of nonhyperkeratotic AK have been achieved with systemically administered porfimer sodium as well as topically applied ALA and methyl-ALA (MAL). Twenty randomized controlled trials that reported the use of PDT in the treatment of AK have been identified. Kennedy et al158 introduced topically applied ALA for the treatment of nonhyperkeratotic AK with complete response rates for AK lesions exceeding 75%. In a placebo-controlled trial, PDT with ALA showed a significantly superior complete response rate compared with placebo PDT using vehicle plus light (89% vs 13%; \( P < .001 \)).159 Similar results were obtained using PDT with MAL.160,161 Other studies have compared PDT for AK with cryotherapy or topical fluorouracil (5-FU) cream. In one study, 119 subjects with 1501 AK lesions of the scalp and face were randomly assigned to receive PDT with MAL to either the left- or right-sided lesions with cryotherapy used to treat the contralateral side.162 Twenty-four weeks after therapy, both treatment groups showed a high response rate (89% for PDT with MAL vs 86% for cryotherapy; \( P = .2 \)), but PDT with MAL showed superior cosmetic and patient preference. Similar results have been found in other large randomized trials of PDT with MAL versus cryotherapy, with complete response rates for both ranging from 68% to 81% for cryotherapy and 69% to 92% for PDT with MAL.19,160,161,163 In conclusion, multiple trials have demonstrated complete response rates of 70% to 90% with good to excellent cosmetic outcomes in greater than 90% of patients for PDT of AK. In a randomized study comparing 5-FU cream with PDT using either ALA or MAL in the treatment of AK, equivalent complete response rates were found with comparable or superior tolerability for PDT.164,165 Current studies have focused on novel PS drugs and reformulations of ALA, such as nanoemulsion or patch-based applicators, that may increase the complete response rate for AK at 12 months to greater than 95%.166

The results of PDT with ALA in the treatment of patients with Bowen disease (SCC in situ) have been equally positive and to date were reported in 6 randomized clinical trials. Randomized controlled trials comparing PDT with ALA or MAL with cryotherapy or 5-FU cream reveal complete response rates of 82% to 100% for PDT versus 67% to 100% for cryotherapy or 79% to 94% for 5-FU at 12 to 24 months.167-169

**PDT for BCC**

Other indications for PDT with ALA include superficial and nodular BCC.170-172 Six randomized clinical trials have reported the results of PDT for nodular BCC; 5 evaluated PDT efficacy in the treatment of superficial BCC, and 2 were performed in patients with mixed superficial and nodular BCC. In the largest single institution experience with 1440 nodular and superficial BCCs, PDT using systemically administered porfimer sodium showed an initial (6-month) complete response rate of 92%, with a recurrence rate of less than 10% at 4 years.173 At this same institution, a 92% complete response rate was achieved with PDT with topical ALA in 330 patients with superficial BCC, but the response rate dropped to 71% in 75 patients with nodular BCC.173 In a multicenter randomized trial of PDT with MAL versus cryotherapy for superficial BCC, complete response rates at 3 months were 97% and 95%, respectively, with 5-year recurrence rates of 22% and 20% for PDT with MAL and cryotherapy, respectively.174 In this study, the excellent-to-good cosmetic outcome was 89% for PDT with MAL and 50% for cryotherapy. However, when topical PDT is compared with surgery for BCC, topical PDT with ALA or MAL consistently shows an increase in the recurrence rate compared with surgery for both superficial and nodular BCC. A randomized controlled trial of PDT with MAL versus surgical excision in 196 patients with superficial BCC showed a 9.3% recurrence rate for PDT versus a 0% recurrence rate for surgery at 12 months.175 However, the good-to-excellent cosmetic outcome was 94% and 60% for patients treated with PDT and surgical excision, respectively. Similarly, in trials of PDT versus surgery for nodular BCC, recurrence rates are less than 5% for surgery versus 14% to 30% for PDT with MAL.176-179 As with superficial BCC, cosmetic effects are consistently shown to be more favorable.
with PDT with ALA. In summary, PDT can be an appropriate and effective treatment alternative to cryosurgery or surgical excision for selected patients with BCC.

Head and Neck Tumors

PDT has been successfully employed to treat early carcinomas of the oral cavity, pharynx, and larynx, preserving normal tissue and vital functions of speech and swallowing.\(^{180}\) Multiple institutions have published small series of results demonstrating the efficacy of PDT for head and neck cancer.\(^{181}\) Only one small clinical trial was randomized and compared PDT with porfimer sodium with chemotherapy (5-FU and cisplatin) in the treatment of nasopharyngeal carcinoma.\(^{182}\) Although no details on randomization procedures or blinding were provided, the clinical response was better with PDT \((P = .001)\), and there was improvement in the Karnofsky performance score. Biel reported the largest series of over 300 patients accrued over a 15-year clinical time period and treated with porfimer sodium-mediated PDT.\(^{183}\) Among the treated lesions, there were predominantly SCCs of the oral cavity, pharynx, or larynx, but also Kaposi sarcoma, melanoma, and SCC in the head and neck area. The treatment protocol most commonly involved the administration of 2.0 mg/kg of porfimer sodium 48 hours prior to irradiation with 630 nm of light from an neodymium yttrium aluminum garnet (Nd:YAG) pumped dye laser. The light fluences delivered ranged between 50 and 75 joules per square centimeter \((J/cm^2)\) for oral cavity, nasopharyngeal, and skin lesions and 80 J/cm\(^2\) for laryngeal tumors.\(^{184}\)

Among the reported group, 133 patients presented with recurrent or primary CIS, T1N0, and T2N0 laryngeal carcinomas and were treated with PDT with curative intent. After a single PDT procedure, the patients were followed on average for 96 months and at 5 years demonstrated a 90% cure rate. The second group of patients who underwent PDT consisted of 138 patients with CIS and T1N0 SCCs of the oral cavity. Similarly, one PDT treatment was delivered and the patients were followed for up to 211 months. All patients were reported to achieve complete pathological and clinical responses and the cure rate at 5 years remained at 100%. PDT was also used for patients with more advanced stages of oral cavity lesions. Fifty-two patients with T2N0 as well as T3N0 SCC also received a single PDT treatment that led to complete pathological and clinical response, affording a 100% cure rate at 3 years.

Overall, over 500 patients with early stage oral cavity, larynx, pharynx, and nasopharynx lesions were treated with porfimer sodium-based PDT worldwide with similar success.\(^{184-187}\) The small number of patients experiencing recurrences were usually salvaged with either repeated PDT or surgical resection. Complications observed in these series were limited to cutaneous photosensitivity, and local pain after therapy was usually controlled by oral analgesics.

The intense development of a second generation of PSs has led to their entering clinical application in head and neck lesions as well. Several series have reported on the use of the second-generation PSs such as ALA and temeporfin.\(^{188,189}\) The large mult center phase 2 trials evaluated the application of temoporfin-mediated PDT in the treatment of primary oropharyngeal cancers. The study by Hopper et al\(^{188}\) of patients with early oral cancer, in whom the tumors measured up to 2.5 cm in diameter, reported a complete response rate of 85% (97 of 114 patients) at 12 weeks and a disease-free survival rate of 75% at 2 years. In another study by Copper et al.,\(^{190}\) PDT was used in the treatment of a total of 27 patients with 42 second or multiple primary head and neck tumors. Cure rates for stage I or in situ disease were 85% versus 38% for stage II/III disease.

Perhaps the most interesting study reported the application of temeporfin-mediated PDT for advanced disease. A total of 128 patients with advanced head and neck cancer were treated with a single PDT session.\(^{191}\) The patients included in this study had failed conventional therapy or were unsuitable for such treatment. PDT delivered 96 hours after temeporfin administration allowed for 100% tumor mass reduction in 43% of lesions and the remaining lesions were reduced by at least 50%. In this trial, tumor mass reduction was measured for each lesion by multiplying the lesion’s length by its width. The 100% tumor mass reduction represented a complete local tumor clearance. Greater than one-half of the treated patients also achieved substantial quality-of-life benefit. Overall, the complete response rates as determined for every patient according to the World Health Organization criteria were 13%, but interestingly, this figure rose to 30%
when the total surface area of the tumor could be illuminated and the depth estimate was less than 1 cm. A relatively limited study that has been conducted with ALA for head and neck lesions reported results that were slightly inferior to those observed with porfimer sodium and temeporfin.189,192,193

Taken together, the data from phase 1/2 trials strongly suggest that PDT could be an effective primary and alternative treatment modality for patients presenting with early head and neck tumors and that further research in this area, including randomized trials, is needed.

Digestive System Tumors

The application of PDT in the gastrointestinal (GI) tract has been divided into 2 groups: PDT of the esophagus and beyond. Barrett esophagus and various grades of dysplasia and early esophageal cancer are the best-studied PDT applications in the GI tract.194,195 Premalignant conditions such as Barrett esophagus with high-grade dysplasia are theoretically ideal for PDT.196 These are superficial and large mucosal areas that are easily accessible for light. Barrett esophagus is the development of an intestinal-type metaplasia in the esophagus and is associated with gastroesophageal reflux disease. Dysplasia may arise in the setting of Barrett esophagus and can lead to the development of adenocarcinoma. Although historically the standard treatment was distal esophagectomy, this treatment is associated with significant morbidity and a 3% to 5% mortality rate. Therefore, endoscopic ablative therapies have become attractive alternatives for patients with Barrett esophagus, including argon plasma coagulation and PDT.

Seven randomized clinical trials have been reported to evaluate PDT in patients with Barrett esophagus with high-grade dysplasia or superficial carcinoma. Most were relatively small, included fewer than 50 patients, and did not clearly report on study methods. Therefore, it is premature to state whether PDT is superior, equivalent, or inferior to other ablative treatments. The most frequent adverse effects included prolonged skin photosensitivity and esophageal strictures, especially when using porfimer sodium. However, the frequency of the latter does not appear to be higher compared with argon plasma coagulation. There is insufficient information on the clinical factors that might be useful in predicting the likelihood of strictures after PDT.

A total of 102 patients with Barrett esophagus and high-grade dysplasia (69 patients) or mucosal adenocarcinoma (33 patients) were treated with PDT using porfimer sodium as an alternative to esophagectomy (median series follow-up time of 1.6 years). After treatment with PDT, there was complete ablation of glandular epithelium with one course of PDT in 56% of patients. Strictures requiring dilation occurred in 20 patients (20%) and were the most common serious adverse events. PDT failed to ablate dysplasia or carcinoma in 4 patients, and subsequent esophagectomy was curative in 3 of these patients. The authors concluded that PDT is a highly effective, safe, and minimally invasive first-line treatment for patients with Barrett dysplasia and mucosal adenocarcinoma.197 Corti et al followed 62 patients with esophageal cancer who were treated with HPD-mediated PDT.198 Eighteen of these patients had CIS (Tis), 30 had T1 tumors, 7 had T2 tumors, and 7 had recurrence of tumors at the anastomotic site from prior surgery. Radiation was delivered to selected patients. The complete response rate after PDT alone was 37% (23 of 62 patients) and was 82% (51 of 62 patients) after PDT and radiation. The complete response rate to PDT alone was the highest in Tis/T1 patients (44%) compared with T2 patients (28%). Patients with recurrence at the anastomotic site did not respond to PDT. The median local progression-free survival was 49 months for patients with Tis/T1 lesions, 30 months for patients with T2 lesions, and 14 months for patients with recurrent tumors. Of those who had a complete response, 48% remained disease free through the follow-up period (range, 3 months–90 months). Three cases (5%) of esophageal stricture and 1 case (<2%) of tracheoesophageal fistula were reported. Based upon these data, the authors concluded that PDT was effective for early stage esophageal cancer and also demonstrated that radiotherapy could be used in those patients who did not respond completely to PDT. What is also clear from these studies is that in tumors with a greater depth of penetration (T2 or greater), PDT is not an optimal treatment option. A randomized, phase 3 trial of porfimer sodium-mediated PDT for Barrett esophagus and high-grade dysplasia has been performed by the International Photodynamic Group for High-Grade Dysplasia in Barrett’s Esophagus.199 Patients were randomized to treatment with
omeprazole (37 patients) or omeprazole with PDT (128 patients). At 5 years, PDT was significantly more effective than omeprazole alone in eliminating high-grade dysplasia (77% [106 of 138 patients] vs 39% [27 of 70 patients]; $P < .0001$). A secondary endpoint of preventing progression to cancer showed a significant difference ($P = .027$) with approximately one-half the likelihood of cancer occurring in the PDT arm (21 of 138 patients [15%] vs 20 of 70 patients [29%]). There was also a significantly ($P = .004$) longer time to progression to cancer favoring PDT. It is based upon these data that the US FDA approved porfimer sodium-mediated PDT for patients with Barrett esophagus and high-grade dysplasia who do not undergo surgery. It should be noted that a recent Cochrane review concluded that radiofrequency ablation has significantly fewer complications than PDT and is efficacious at eradicating both dysplasia and Barrett esophagus. Long-term follow-up data are still needed before radiofrequency ablation should be used in routine clinical care.

These phase 2 and 3 trials of PDT for high-grade dysplasia demonstrate that this therapy prevents the development of invasive carcinoma and is a safe and reliable treatment option. Despite this positive assessment, there are certain challenges. Stricture formation, potential skin phototoxicity, severe chest pain, and nausea are quite problematic. It is believed, however, that with improved dosimetry and new PSs those limitations could be overcome.

PDT has been applied to a variety of tumor types in the GI tract beyond the esophagus. Early clinical studies from Japan of PDT in the stomach suggested great promise, but regrettably have not been followed by randomized clinical trials to date. PDT for early duodenal and ampullary cancers and advanced adenomas has also been investigated in pilot studies that indicated promising results, but further work is required to optimize the treatment conditions. The most promising results have been achieved in CC. Case reports of PDT for CC began to emerge in the 1990s, and in 1998, Ortner et al published an uncontrolled, observational pilot study of 9 patients with inoperable CC treated with porfimer sodium-mediated PDT. In a follow-up study, 70 patients were treated, including 20 who were randomized to PDT followed by bilateral plastic stenting. The median survival in the PDT plus stenting group was a remarkable 493 days compared with only 98 days in the group treated with stenting alone. Patients’ quality of life also improved significantly. Other studies have shown similar results. Although only 2 clinical trials for CC were randomized, both reached a similar conclusion, namely that PDT has a therapeutic effect on nonresectable CC. The most common complication was cholangitis, which developed in every fourth patient undergoing PDT plus stenting, which was higher than the rates observed in control patients treated with stenting alone. Other rare adverse effects reported include cholecystitis, abscess formation, pancreatitis, biliary leakage, and biloma. Consequently, a multicenter clinical trial has been recently initiated to obtain regulatory approval in the United States and Canada.

Among other applications for PDT in the GI tract, there are studies of PDT for unresectable pancreatic cancers and numerous reports that have examined using PDT to eradicate colon polyps as well as to palliate bulky colon and rectal cancers. The use of PDT in these tumors is still considered experimental because there are not high-level data to support the routine use of PDT for these indications at this time. In addition, PDT may have efficacy in treating hepatocellular carcinoma, which remains one of the most common forms of cancer worldwide. Early results from clinical trials have been quite promising, and a phase 3 study is currently underway to evaluate the efficacy of talaporfin-mediated PDT using interstitial LEDs compared with institution-specific standard treatment.

### PDT for Intraperitoneal Malignancies

As with pleurally disseminated malignancies, the treatment of patients with peritoneal carcinomatosis or sarcomatosis is typically palliative in nature. PDT has the potential to combine the selective destruction of cancerous tissue compared with normal tissue with the ability to treat and conform to relatively large surface areas. Moreover, the intrinsic physical limitation in the depth of visible light penetration through tissue limits PDT damage to deeper structures, thereby providing additional potential for tumor cell selectivity. This is especially true after surgical debulking (cytoreduction), where the residual tumor is microscopic or less than 5 mm in depth.
A phase 1 trial of intraoperative PDT after maximal surgical debulking that was performed with 70 patients, mostly with recurrent ovarian cancer carcinomatosis or peritoneal sarcomatosis, resulted in a 76% complete cytologic response rate with tolerable toxicity. In the follow-up phase 2 study, patients were enrolled, stratified according to cancer type (ovarian, GI, or sarcoma), and given doses of porfimer sodium and light at the maximally tolerated dose that was defined in the phase 1 trial. As in the phase 1 trial, intraperitoneal PDT was associated with a postoperative capillary leak syndrome that necessitated fluid resuscitation in the immediate postoperative period that was in excess of the typical fluid needs of patients who receive surgery alone. Other than the capillary leak syndrome and the skin photosensitivity, the complication rates were similar to the complication rates typically observed after similarly extensive surgery in the absence of PDT. With a 51-month median follow-up, the median failure-free survival and overall survivals for the patients who received PDT were 3 months and 22 months, respectively, in ovarian cancer patients; 3.3 months and 13.2 months, respectively, in GI cancer patients; and 4 months and 21.9 months, respectively, in sarcoma patients. Six months after therapy, the pathologic complete response rate was 9.1% (3 of 33 patients), 5.4% (2 of 37 patients), and 13.3% (4 of 30 patients) for the patients with ovarian cancer, GI cancer, and sarcoma, respectively. The median survival of almost 2 years in the patients with ovarian cancer and over 1 year in the patients with GI cancer suggested some benefit from this treatment compared with historical controls. In the patients with sarcoma, the prolonged overall survival was primarily due to patients with sarcomatosis from GI stromal tumors who were treated with imatinib when it became available. Given the narrow therapeutic index of PDT in the treatment of peritoneal carcinomatosis, this therapy has the potential to benefit patients but requires further study.

Urinary System Tumors
Prostate Cancer
Patients with prostate cancer who elect to undergo definitive radiotherapy have limited options for salvage therapy for isolated local failure. Moreover, first-line, definitive management of early stage prostate cancer with either surgery or ionizing radiotherapy has significant associated morbidities due to the proximity of normal structures such as nerves, bladder, and rectum. The intrinsic limitation in the range of PDT-mediated damage imposed by visible light has the potential to selectively treat the prostate while sparing the surrounding normal tissues. By adapting the techniques developed for interstitial brachytherapy with radioactive seeds, light can be delivered to the entire prostate gland using interstitial, cylindrically diffusing optical fibers. Unlike chemotherapy or radiotherapy, the mechanism of cell killing by PDT is not dependent on DNA damage or cell cycle effects, decreasing the chances of therapy cross-resistance and eliminating late normal tissue effects such as second malignancy. All of these factors combine to make prostate cancer an attractive target for clinical trial development.

Several groups have published clinical trial results for prostate PDT using second-generation PSs. In a pilot study of temeporfin-mediated PDT, 14 patients who experienced biopsy confirmed local failure after definitive radiotherapy for early stage prostate cancer were treated using up to 8 implanted, interstitial, cylindrically diffusing optical fibers. Of these patients, 13 were considered to have received a high light dose (≥50 J/cm²). Response of prostate-specific antigen to therapy was observed in 9 patients and a complete pathologic response was observed in 5 patients. One patient developed a urorectal fistula after a rectal biopsy was performed 1 month after PDT. Four patients developed stress incontinence and 4 patients developed decreased erectile function. In a follow-up report of definitive temeporfin-mediated PDT as first-line therapy, 6 patients with organ-confined, Gleason score 6 prostate cancer were treated with 4 to 8 interstitial fibers with implants designed to cover only the areas of the prostate with biopsy proven disease. Four of these patients had a second PDT session due to biopsy confirmed persistent disease at 3 months of follow-up. Although the treatment was relatively well tolerated, and all patients showed evidence of necrosis on postprocedure imaging or biopsy, all 6 patients had biopsy confirmed residual disease after PDT.

Another group has studied motexafin lutetium (MLu) as a PS for PDT of the prostate. In the phase 1 trial, 17 patients with biopsy confirmed,
locally recurrent prostate cancer after definitive radiotherapy were treated with increasing doses of 732 nm (red) light using interstitial fibers. The primary goal of this trial was to determine the maximally tolerated dose and dose-limiting toxicities of MLu-mediated prostate PDT, and one important secondary goal was to begin to develop the capability to perform real-time measurements of tissue optical properties, tissue levels of oxygen, and PS to eventually allow real-time light fluence modulation that would provide a more homogeneous dose of PDT to the entire prostate gland. As in the temeporfin study, one patient developed a urorectal fistula that was attributed to inhomogeneity of the light dose. The remainder of toxicities observed in these patients were mild to moderate and consisted of urinary toxicities, including stress incontinence. Although not designed to measure efficacy, a significant difference was found in time to biochemical failure (prostate-specific antigen recurrence) between the low and high PDT dose cohorts, providing some evidence of biochemical and pathologic disease response to PDT.

Another group has investigated vascular-targeted PDT using palladium (Pd)-bacteriopheophorbide (padoporfirin)–mediated PDT and a short drug-light interval. In the phase 1 trial, 24 patients with biopsy confirmed local failure after definitive radiotherapy for prostate adenocarcinoma were treated with padoporfirin-mediated PDT using 2 interstitial fibers. This study demonstrated that vascular-targeted PDT could be safely performed in this patient population. In the follow-up phase 2 study, 28 patients were treated with increasing light doses. After 6 months of follow-up, less residual cancer was noted on biopsy as the light dose increased. All had negative biopsies at follow-up if greater than 60% of the prostate was determined to be avascular by post-PDT magnetic resonance imaging (MRI). Toxicities were significant, with 2 patients developing urorectal fistulas. This study demonstrated the potential for pathologic complete response over a short-term follow-up. Together, these studies suggest that although PDT to the prostate is feasible, comprehensive treatment of the entire gland will be necessary, and improved techniques and dosimetry will be critical in providing an acceptable toxicity profile.

**Bladder Cancer**

Bladder cancers, which are often superficial and multifocal, can be assessed and debulked endoscopically. In addition, the geometry of the bladder should allow for improved and homogeneous delivery of light. These factors make superficial bladder cancer an attractive target for PDT. In general, early response rates (2 months–3 months) to PDT have been observed in approximately 50% to 80% of patients, with longer term (1 year–2 years) durable responses noted in 20% to 60% of patients. It should be noted that many of the patients treated in these studies had recurrent disease that developed after standard therapies such as bacillus Calmette-Guérin (BCG).

Early studies used HPD-mediated PDT. In one study, focal HPD-mediated PDT was used to treat 50 superficial bladder transitional cell carcinomas (TCCs) in 37 patients and achieved a 74% complete response rate. Another study used HPD-mediated PDT to treat the entire bladder wall for 34 patients with refractory CIS of the bladder and achieved a 73.5% complete response rate at 3 months. However, by 2 years, 77.8% of these patients experienced disease recurrence. In these studies, treatment of superficial bladder cancer with PDT is generally well tolerated, with dysuria, hematuria, and skin photosensitivity being the most common acute toxicities. However, bladder wall fibrosis/diminished bladder capacity has been and continues to be a problem in some treated patients. With improved dosimetry and the use of porfimer sodium as a PS, other investigators have achieved durable complete response rates as high as 60% for patients with refractory bladder CIS or superficial TCC. Studies of locally applied (intravesical) ALA demonstrate that similar durable complete response rates of 52% to 60% at 2 years to 3 years can be achieved for patients with treatment-refractory bladder CIS without the prolonged skin photosensitivity experienced when using systemic porfimer sodium.

Although most of the patients treated with bladder PDT are refractory to BCG, one randomized controlled study has compared a single porfimer sodium-mediated PDT with multiple BCG treatments (induction plus maintenance) and found that these therapies are equivalent in durable treatment response. Studies combining intravesical
immunotherapies such as BCG or chemotherapies such as mitomycin C with PDT showed that these therapies may significantly enhance the PDT responsiveness of bladder tumors.\textsuperscript{238,239} Despite these promising results, PDT for bladder cancer remains largely investigational with limited use. PDT for bladder cancer is approved in Canada and in some EU nations but has not been approved by the US FDA.

**Non-Small Cell Lung Cancer and Mesothelioma**

PDT for non-small cell lung cancer (NSCLC) was first used in 1982 by Hayata et al to achieve tumor necrosis and reopening of the airway.\textsuperscript{240} PDT for lung cancer is particularly useful for 1) patients with advanced disease in whom PDT is used as a palliation strategy\textsuperscript{241-243} and 2) patients with early central lung cancer when patients are unable to undergo surgery.\textsuperscript{244,245} PDT is considered to be more specific and lesion-oriented compared with other available modalities and produces less collateral damage, and therefore fewer complications. Indeed, a randomized trial of PDT versus Nd:YAG laser therapy for obstructing NSCLC lesions showed equal initial efficacy for these 2 treatments, with a longer duration of response noted for PDT.\textsuperscript{243} PDT plus palliative radiation also appears to increase the time to bronchus reocclusion when combined compared with radiation alone.\textsuperscript{109,246}

In patients with early stage lung cancer, PDT has been used to successfully treat patients for whom surgery is not feasible. In one phase 2 study, 54 patients with 64 lung carcinoma lesions underwent porfimer sodium-mediated PDT and showed an 85% complete response rate with a 6.5% local failure rate at 20.2 months.\textsuperscript{245} Other studies have supported these excellent results, with complete response rates averaging 73% in studies totaling 359 patients.\textsuperscript{246-248} For radiographically occult lung cancers, results are equally good, with one typical study showing a complete response rate of 94% with 80% local control at 5 years.\textsuperscript{249} Second-generation PSs have also been used in early stage lung cancer treatment. Recently, Usuda et al\textsuperscript{250} reported a series of 70 cancer lesions measuring 1.0 cm or less in diameter and 21 lesions measuring greater than 1.0 cm in diameter treated with PDT with talaporfin. The complete response rates were 94.3% (66 of 70 patients) and 90.4% (19 of 21 patients), respectively. PDT with talaporfin was capable of destroying the residual cancer lesions observed after the mass of large tumors had been reduced by electrocautery. Another report\textsuperscript{251} described the results of 529 PDT procedures performed on 133 patients who presented with NSCLC (89 patients), metastatic airway lesions (31 patients), small cell lung cancer (4 patients), benign tumors (7 patients), and other (unspecified) lung conditions (2 patients). The lesions were most commonly located in the main stem bronchi (71 patients). Most patients received 2 treatments during a 3-day hospitalization and returned in 2 weeks for 2 additional PDTs. The authors concluded that PDT can be safely and effectively used in the described setting, leading to improved dyspnea in selected patients. The small number of randomized clinical trials in patients with NSCLC and insufficient reporting on study methods and treatment outcomes do not enable us to draw firm conclusions regarding PDT efficacy and safety. PDT remains a very promising therapeutic approach in the treatment of NSCLC.

NSCLC with pleural spread is incurable with standard treatment modalities such as surgery, chemotherapy, or ionizing radiotherapy, and median survival rates in these patients typically range from 6 to 9 months. Surgery alone has been unsuccessful in obtaining local control and does not extend survival beyond palliative chemotherapy, which remains the standard of care for the treatment of this disease. Based on promising phase 1 study results, a pilot phase 2 trial of porfimer sodium–mediated PDT was performed to investigate the efficacy of combined surgery and PDT for patients with either recurrent or primary NSCLC with pleural spread, the majority of whom had N2 lymph node involvement and bulky pleural disease.\textsuperscript{101,252} In this study, local control of pleural disease at 6 months was achieved in 11 of 15 evaluable patients (73%) and the median overall survival for all 22 patients was 21.7 months. These results are highly encouraging in this population of patients and suggest that additional investigation in this area is warranted.

Malignant pleural mesothelioma (MPM) is a cancer of the pleura that, similar to NSCLC with pleural spread, has no currently available curative options. In a phase 2 study of porfimer sodium-mediated PDT after extrapleural pneumonectomy for MPM, patients with stage I and II disease
experienced a median survival of 36 months with a 2-year survival rate of 61%, whereas patients with stage III and IV disease experienced a median survival time of 10 months. Both of these rates were significantly improved compared with historical series of surgery alone. However, in a single randomized phase 3 study of surgery versus surgery with PDT, patients received treatment similar to that described above but did not appear to benefit from the addition of PDT to surgery. This trial was potentially underpowered and also involved surgical debulking that could leave disease of up to 5 mm in thickness as opposed to a macroscopically complete resection. Trials of intraoperative PDT using temoporfin showed that temoporfin PDT is feasible and has potentially acceptable toxicity. One important finding in these studies of resection with PDT for MPM is that a lung-sparing, tumor debulking surgery can be combined with PDT to achieve local control rates similar to those observed with extrapleural pneumonectomy. Indeed, a more recent study of macroscopically complete, lung-sparing surgical debulking followed by intraoperative porfimer sodium-mediated PDT for patients with locally advanced MPM found a median survival that had not been reached with a 2.1-year median follow-up in patients after radical pleurectomy with PDT. Thus, PDT for MPM needs to be further evaluated in clinical trials of lung-sparing surgery.

Brain Tumors

PDT is currently undergoing intensive clinical investigation as an adjunctive treatment for brain tumors. The major tumor lesions particularly suitable for PDT treatment are newly diagnosed and recurrent brain tumors due to their high uptake of PSs. Since the early 1980s, close to 1000 patients worldwide have received PDT for brain lesions. Perria et al reported one of the earliest attempts to use PDT to treat the postresection glioma cavity in humans, and Kaye et al reported a phase 1/2 trial involving 23 patients with glioblastoma multiforme (GBM) and anaplastic astrocytoma (AA). Other brain lesions treated with PDT included malignant ependymomas, malignant meningiomas, melanoma and lung cancer brain metastasis, and recurrent pituitary adenomas. The initial trials provided encouraging results, and the authors concluded that PDT can be used as an adjuvant therapy in patients with brain tumors. The PSs used to date were various formulations of HPDs (porfimer sodium) and ALA as well as temoporfin. The light sources used to activate those PSs included lamps, dye lasers, gold vapor potassium titanyl phosphate dye lasers, and diode lasers.

Currently, PSs are being evaluated both as intraoperative diagnostic tools by means of photodetection (PD) and fluorescence-guided resection (FGR) (Table 1) as well as during PDT as an adjunctive therapeutic modality. All 3 approaches take advantage of the higher uptake of PS by the malignant cells and are used intraoperatively. The most recently published trials that employed PD, FGR, and PDT provided additional encouraging results, but the initial delay in tumor progression did not translate to extended overall survival. Stylli et al reported the results of a total of 375 patients treated at the Royal Melbourne Hospital. Among the 375 patients, the majority consisted of those with newly diagnosed (138 patients) and recurrent (140 patients) GBMs. Additional histological types included newly diagnosed (41 patients) and recurrent (46 patients) AAs. Patients received 5 mg/kg of HPD 24 hours prior to surgery and the light dose was 70 to 260 J/cm². In the follow-up, the mean survival for both types of GBM was between 14.3 and 14.9 months, and approximately 28% to 41% of patients survived more than 2 years. For AA, the mean survival was between 66.6 and 76.5 months and 57% to 73% of patients survived more than 3 years.

Muller and Wilson reported the results of a prospective randomized controlled trial using adjuvant porfimer sodium-mediated PDT in the study group. The 96 patients treated for supratentorial gliomas with PDT with porfimer sodium at St. Michael's Hospital in Toronto, Ontario, Canada were randomized to 2 groups that received either 40 J/cm² or 120 J/cm². The patients who received the higher dose (48 patients) survived on average for 10 months, whereas the 49 patients in the low-dose group survived on average 9 months; the difference between both groups was not statistically significant (P = .05).

Stummer et al reported the results of the ALA study group, a multicenter prospective randomized controlled trial in Germany. This trial compared the effectiveness of ALA-based FGR with...
conventional surgery. The 322 patients with suspected malignant gliomas were followed for 35.4 months. Patients randomized to the FGR group demonstrated much better time to progression (5.1 months) compared with the controls (3.6 months), which translated into a greater survival of 16.7 months versus 11.8 months, respectively. However, the difference in overall survival was not statistically significant.

Eljamel et al reported a single-center, prospective randomized controlled study that employed the techniques of ALA-based FGR, protoporphyrin IX spectroscopy, and fractionated porfimer sodium-mediated PDT in patients with GBM.271 The PDT was delivered up to 500 J/cm² in 5 fractions. Among the 27 recruited patients, 13 received FGR and PDT and demonstrated a mean survival of 52.8 weeks compared with 24.6 weeks in the control group. The mean time to tumor progression was 8.6 months in the FGR and PDT group compared with 4.8 months in the control group.

The current standard therapies that include surgery, radiotherapy, and chemotherapy afford a median survival of approximately 15 months and although there are limited data comparing PD, FGR, and photodagnosis with those standard therapies, the initial results from randomized trials are encouraging. It remains to be seen whether PDT for brain tumors remains a palliative or, at most, an alternative treatment modality. The new classes of PSs, the better understanding of dosimetry, and further improvement in technology may significantly change the currently achieved clinical outcome. In addition, preclinical data indicating that protracted light delivery may increase the therapeutic index of PDT in the brain combined with newer technologies such as implantable LED-based light delivery systems could lead to significant improvements in treatment outcomes.258

Barriers for Adoption of PDT Into Routine Clinical Practice

Despite being first described in the early 1900s,272 the use of PDT to treat cancer patients has been relatively slow to enter mainstream clinical practice. Even when used clinically, PDT for cancer remains in many cases an alternative or palliative treatment or is used within the context of a clinical trial. For the PDT novice, the array of associated technologies such as lasers, applicators/fiber optics, and power meters along with the need to perform manual calculations for dosimetry can be daunting. When performed with the assistance of a radiation oncologist or medical physicist with some training in optical methods and dosimetry, this difficulty can be overcome more easily. Another potential problem is the scarcity of phase 3 clinical trials that could demonstrate the superiority of PDT over other modalities.151 Although more randomized trials of PDT are needed, other technologies and therapies with a similar deficiency in phase 3 data have been much more readily adopted by clinicians. Finally, the first-generation PSs exhibited a prolonged skin sensitivity to visible light, and this likely limited the use of these drugs in the palliative setting, especially for patients with a life expectancy of fewer than 6 to 12 months. However, better understanding of dosimetry, LED and diode-based laser technologies with simplified user interfaces, and new PSs with a decreased duration of skin photosensitivity, combined with mechanistic studies that may allow patient- or tumor-specific selection of therapy, suggest that PDT has the potential to finally make the transition to obtain widespread clinical use in the oncologic community.

Novel Strategies in PDT

Two-Photon PDT

The standard method in PDT is to use an organic PS, activated by continuous light, administered as an acute, high-dose single treatment. There are several fundamentally different approaches that are currently under preclinical investigation, involving different photophysics, chemistry, and/or photobiological mechanisms. In 2-photon PDT, short (approximately 100 femtosecond) laser pulses with very high peak power are used, so that 2 light photons are absorbed simultaneously by the PS. Because each photon only contributes one-half of the excitation energy, near-infrared light can be used to achieve deeper tissue penetration. The subsequent photochemistry and photobiological effects are the same as in 1-photon PDT. Starkey et al reported 2-cm effective treatment depth in tumor xenografts; this is considerably greater than what would typically be achieved by 1-photon activation.273 Alternatively, if the laser beam is strongly focused, then the
activation volume may be extremely small. This may be exploited to target individual blood vessels, reducing damage to adjacent tissues. Both approaches have used novel PSs designed to have very high 2-photon cross-sections. Potentially, either strategy could overcome light attenuation limitations, particularly in pigmented tumors such as melanoma.

Metronomic PDT

In metronomic PDT (mPDT) both the drug and light are delivered at very low dose rates over an extended period (hours–days). This can result in tumor cell-specific apoptosis, with minimal tissue necrosis. To date, the main focus has been in glioma to minimize direct photodynamic damage to adjacent normal brain and secondary damage from the inflammatory response to PDT-induced tumor necrosis. Dose-dependent tumor responses have been demonstrated in vitro and in an intracranial model using ALA and an implanted optical fiber source.

It is not known if this concept applies to other PSs or organ sites. There is evidence that the molecular pathways in mPDT may be different from those of acute, high-dose PDT.

PDT Molecular Beacons

The concept of PDT molecular beacons (MBs) derives from the use of MBs as fluorescent probes with high target specificity. The PS is linked to a quenching molecule, so that it is inactive until the linker is cleaved by a target-specific enzyme (Fig. 6). Alternatively, the linker may be an antisense oligonucleotide (hairpin) loop, which is opened by hybridization to complementary mRNA.

PDT MBs were first demonstrated using a caspase-3 linker between pyropheophorbide and a carotenoid quencher, achieving 8-fold and 4-fold quenching and unquenching, respectively, as demonstrated by the 1O2 yield. Subsequently, matrix metalloproteinase (MMP)-based beacons were reported in vitro and in vivo, with high selectivity between MMP-positive and MMP-negative tumors. Hairpin-type beacons targeted to raf-1 mRNA had even higher tumor-to-nontumor specificity and almost complete restoration of the PDT efficacy upon hybridization in human breast cancer cells in vitro. The most important characteristic of MBs is that tumor selectivity no longer depends solely on the PS delivery, but also on the tumor specificity of the unquenching interaction and the selectivity of the beacon to this interaction. Recently, asymmetric hairpin beacons were described to balance high quenching efficiency with 2-step activation (cleavage and dissociation) to enhance tumor cell uptake.

FIGURE 6. Photodynamic Therapy Molecular Beacons. A peptide linker that is a substrate of a cancer-associated enzyme (e.g., a protease) is conjugated to a photosensitizer (PS) and a singlet oxygen (1O2) quencher. The proximity of the PS and quencher ensures inhibition of 1O2 generation during irradiation of normal cells. In the presence of an enzyme, the substrate sequence is cleaved and the PS and quencher are separated, thereby enabling photoactivation of the PS. Hv indicates light: O2, molecular oxygen.
Nanotechnology in PDT

Nanoparticles (NP) have several potential roles in PDT: for PS delivery, as PSs per se, and as energy transducers. Liposomal NPs are used clinically for delivery of the water-insoluble PS verteporfin. The potential advantage of NPs is that a high “payload” can be delivered and they can be “decorated” with multiple targeting moieties such as antibodies or peptides. Other approaches include biodegradable polymers and ceramic (silica) and metallic (gold, iron oxide) NPs; magnetic NPs, in which an applied magnetic field enhances localization to the tumor; and hybrid NPs that allow both PDT and either another therapeutic strategy such as hyperthermia or an imaging technique such as MRI. NP delivery of 2-photon PSs has also been reported, because these typically have very poor water solubility. Materials that themselves generate \( ^1O_2 \) upon photoexcitation include silicon NPs and quantum dots. The latter may also be linked to organic PSs, where they absorb the light energy with high efficiency and transfer it to the PS. Upconverting NPs have been investigated, in which relatively long wavelength light (near infrared) is absorbed and converted to shorter wavelength light that activates the attached PS. These concepts illustrate a general advantage of NP-based PDT in that the photophysical and photochemical properties of the PS can be uncoupled from the delivery and activation processes. A final recent approach is the encapsulation of a PS inside polymeric NPs that in turn are incorporated into liposomes containing a second drug such as an antiangiogenic agent (or vice versa). This codelivery increases the therapeutic synergy of the 2 modalities.

Photochemical Internalization

A large number of technologies have been developed to enhance translocation of macromolecular therapeutics (Table 1) into the cytosol. These technologies are mainly designed to enhance cellular uptake of macromolecules via endocytosis and stimulate their endosome-to-cytosol translocation. Photochemical internalization (PCI) was specifically designed to enhance the release of endocytosed macromolecules into the cytosol. It is based on the use of PSs located in endocytic vesicles, as shown in Figure 7. PDT-generated \( ^1O_2 \) induces a release of macromolecules from the endocytic vesicles into the cytosol. The physicochemical requirements of the PSs utilized in PCI are strong amphiphilicity hindering their penetration through membranes and the presence of a hydrophobic region necessary for sufficiently deep penetration into cell membranes to efficiently produce \( ^1O_2 \) in a membranous environment. The unique properties of the PCI process may be used to activate the therapeutics only in the

---

**FIGURE 7.** The Principles of Photochemical Internalization (PCI) Technology. The photosensitizer (PS) and the therapeutic compound (D) in this example linked to a monoclonal antibody as a targeting moiety are delivered to the target cells. The PS and D are both unable to penetrate the plasma membrane and both are thus endocytosed, initially reaching the endocytic compartments (endosome). The photosensitizers used in PCI are integrated into the membranes of the endocytic vesicles. Upon light exposure, the PS becomes activated and forms singlet oxygen \( (^1O_2) \) oxidizing membrane constituents, resulting in rupture of the endocytic membranes, allowing D to reach the cellular compartments where its therapeutic targets are located (\( T_1 \) or \( T_2 \) [nucleus]). In the absence of light, the therapeutic compound may be degraded in the lysosomes. \( O_2 \) indicates molecular oxygen.
light-exposed area while unexposed normal tissues are spared. PCI has been shown to increase the biological activity of several molecules that do not readily penetrate the plasma membrane, including type I ribosome-inactivating proteins (RIPs), immunotoxins, plasmids, adenoviruses, various oligonucleotides, dendrimer-based delivery of chemotherapeutics, and unconjugated chemotherapeutics such as bleomycin and doxorubicin. In addition, PCI allows for the use of therapeutics without intrinsic properties for endosome-to-cytosol translocation. An example is the use of the highly toxic RIP diphtheria toxin (DT). In a PCI-based treatment regimen, DT may be replaced with type I RIPs such as gelonin and saporin, which exert low translocation efficiency, thereby reducing the side effects from the toxins. The clinical documentation of the therapeutic effects of macromolecular therapeutics for intracellular targets on solid tumors is, however, limited. An ongoing phase 1/2 clinical trial evaluating PCI of bleomycin has been reported to result in encouraging tumor responses. Of 14 patients treated to date (SCC of the head and neck, adenocarcinoma of the breast, chondroblastic osteosarcoma, and skin adnexal tumor), complete clinical regression was observed in all evaluable tumors within a few weeks after treatment, although 2 recurrences were noted at the 3-month follow-up (unpublished data). The treatment has left the healthy tissue underneath the tumor largely unaffected, indicating high specificity for the tumor tissue. These promising properties of PCI technology have the potential to enhance the antitumor efficacy and to exert a high grade of specificity due to the combination of targeted therapeutics with light-activated cytosolic delivery induced by PSs preferentially accumulating in solid tumors.

Conclusions

PDT is still considered to be a new and promising antitumor strategy. Its full potential has yet to be shown, and its range of applications alone or in combination with other approved or experimental therapeutic approaches is definitely not exhausted. The advantages of PDT compared with surgery, chemotherapy, or radiotherapy are reduced long-term morbidity and the fact that PDT does not compromise future treatment options for patients with residual or recurrent disease. Due to a lack of natural mechanisms of $1O_2$ elimination and a unique mechanism of cytotoxicity, mutations that confer resistance to radiotherapy or chemotherapy do not compromise antitumor efficacy. Moreover, PDT can be repeated without compromising its efficacy. These are significant limiting factors for chemotherapeutics and radiotherapy. Finally, many conventional antitumor treatments carry a risk of inducing immunosuppression. PDT-induced immunogenic cell death associated with induction of a potent local inflammatory reaction offers the possibility to flourish into a therapeutic procedure with excellent local antitumor activity and the capability of boosting the immune response for effective destruction of metastases. The interdisciplinary uniqueness of PDT inspires specialists in physics, chemistry, biology, and medicine and its further development and novel applications can only be limited by their enormous imagination.
