Material & Methods

- Leaf-off and leaf-on LiDAR datasets are used to produced raster metrics at plot-scale. Plots are characterized by LiDAR variables calculated from the rasters (131 variables).
- Reference data are collected by a systematic sampling inventory with visual evaluation of tree girth, in 0.1ha plots. Principle is counting the number of stems by species & by 4 girth classes. Structure types are defined by the percentage of small, medium & large trees (5 types). Composition types are defined by the percentage of oak and beech (4 types).
- Unsupervised methods are used in an exploratory way: analyzing the within-cluster variability and discussing about the 2 typologies relevance. Supervised methods, especially random forests, are first used to identify reliable variables for forest types classification.

Unsupervised methods
- Aim: identification of natural groups within the meaning of LiDAR variables
  - Preprocessing data with PCA
  - Decrease the dataset dimension
  - Selection of the first 30 components (≈ 90% explained variance)
  - Partitioning classification
  - Hierarchical classification
  - 5, 10 & 15 clusters

Supervised methods
- Aim: Test the efficiency of supervised data mining methods with LiDAR data to identify forest types
  - Use of random forest to assess variables importance
  - Implementation of 2 variants of random forest
  - randomForest (RF) R package
  - cforest (CF) R package
  - Analysis of the variables ranking
  - Analysis of the quality of classification
  - Discussion about the 2 methods
  - Variables Selection

Figure 2: Schema of the 2 parallel classification approaches to analyze the potential of LiDAR data to identify forest types.

cforest() is a variant of the classical random forest concept, based on conditional inference for variable selection. cforest was developed to overcome RF typical bias with highly correlated predictors and predictors varying in their scale measurement.

This typological approach is complemented by an estimation model of basal area (Figure 5).

B.A. (m²/ha) = -0.444 + 2.711 * x₁ - 18.87 * x₂ + 1.47 * x₃ + 17.39 * x₄
with:
- x₁ = std(Height Std of vegetation points)
- x₂ = Mean(Height elevation 70th-95th percentile)
- x₃ = Mean(Height elevation 67th-95th percentile)
- x₄ = std(Height 90th percentile)

Figure 5: Basal area estimation model (R² = 0.8039 & Residual standard error = 2.62). Several models were fitted, based on raster metrics at plot level and have to be compared and validated.

Results

- The within-cluster variability shows an important mix of the different structure & composition types (Figure 3).
- RandomForest (RF) results are poor comparing to Cforest (CF) results, especially for structure types (global error ≈ 60 %).
- Global, producer & consumer accuracies are better for composition & for leaf-off dataset (Figure 4).
- For composition, RF seems to better discriminate Beech stands (producer error ≈ 15 % for a global error ≈ 40 %).
- The variables highlighted by RF et CF are different. The 4 most important variables for CF are:
  - For structure: Max Height of veg. points, 90-95th percentil. of height of veg. points, Std Height of veg. points, % Between 10-20 m high.
  - For composition: Std Height of veg. points, Mean intensity of veg. points, Height coef. var. of veg. points, Std intensity of veg. points.

Perspectives

- Analysis of the results sensibility & validation with additional plots (also for basal area model).
- Performing k-nn & CART analysis.
- Reflexion on the relevance of the two typologies and possibly development of new ones.
- Injection of new raster variables (selection of the return number).
- Variables calculated directly from the raw point clouds have to be investigated.
