ABSTRACT

We present photometric observations of four transits in the WASP-17 planetary system, obtained using telescope defocussing techniques and with scatterers reaching 0.5 mmag per point. Our revised orbital period is 4.0 ± 0.6 s longer than previous measurements, a difference of 6.6σ, and does not support the published detections of orbital eccentricity in this system. We model the light curves using the JKTEBOP code and calculate the physical properties of the system by recourse to five sets of theoretical stellar model predictions. The resulting planetary radius, \( R_p = 1.932 ± 0.052 ± 0.010 \) R\(_\text{Jup}\) (statistical and systematic errors respectively), provides confirmation that WASP-17 b is the largest planet currently known. All fourteen planets with radii measured to be greater than \( 1 \) R\(_\text{Jup}\) are found around comparatively hot (\( T_{\text{eff}} > 5900 \) K) and massive (\( M > 1.15 \) M\(_\odot\)) stars. Chromospheric activity indicators are available for eight of these stars, and all imply a low activity level. The planets have small or zero orbital eccentricities, so tidal effects struggle to explain their large radii. The observed dearth of large planets around small stars may be natural but could also be due to observational biases against deep transits, if these are mistakenly labelled as false positives and so not followed up.

Key words: stars: planetary systems — stars: fundamental parameters — stars: individual: WASP-17

1 INTRODUCTION

Ongoing surveys for transiting extrasolar planets (TEPs) have detected an unexpectedly diverse set of objects, such as HD 80606 b, a massive planet on an extremely eccentric orbit \((e = 0.9330 \pm 0.0005, \) [Hebrard et al. 2010]]; super-Earths on very short-period orbits like CoRoT-7 b and 55 Cnc e \((\) [Léger et al. 2009]; [Winn et al. 2011]]; WASP-18 b with a mass of \(10 \, M_{\text{Jup}}\) and an orbital period of \(0.94 \, \text{d}\) \((\) [Hellier et al. 2009]; WASP-33 b, a very hot planet revolving around a metallic-lined pulsating A star \((\) Collier Cameron et al. 2010]; a system of six planets transiting the star Kepler-11 \((\) Lissauer et al. 2011]; and a planet orbiting the eclipsing binary star system Kepler-16 \((\) Boyle et al. 2011].

Among these objects, WASP-17 b stands out as both the largest known planet and the first found to follow a retrograde orbit \((\) Anderson et al. 2010, hereafter A10]. However, the reliability of its radius measurement was questionable for two reasons. Firstly, it rested primarily on a single high-quality transit light curve, whereas it is widely appreciated that correlated noise can afflict individual light curves whilst remaining undetectable in isolation \((\) e.g. [Gillon et al. 2007]; [Adams et al. 2011]. Correlated noise is clearly visible in the residuals of the best-fitting model for this transit \((\) fig. 2 in A10]. Secondly, the orbital eccentricity, \(e\), was poorly constrained, and this uncertainty in the orbital velocity of the planet has major implications for the interpretation of the transit light curves.

The WASP-17 discovery paper \((\) A10] presented three measurements of the planetary radius, \(R_b\), based on models with different assumptions. The preferred model \((\) Case 1] was a straightforward fit to the available data, yielding \(R_b = 1.74^{+0.26}_{-0.23} \, R_{\text{Jup}}\) and \(e = 0.129^{+0.106}_{-0.068}\). The test of Lucy & Sweeney \((\) 1971], which accounts for the fact that a measured eccentricity is a biased estimator of the true value, indicates a probability of only 83\% that this eccentricity is significant. Case 2 incorporated a Bayesian prior on the stellar mass and radius to encourage them towards a solution appropriate for a main-sequence star, and resulted in \(R_b = 1.51 \pm 0.10 \, R_{\text{Jup}}\) and \(e = 0.237^{+0.089}_{-0.069}\). The third and final model, Case 3, did not use the main-sequence prior but instead enforced \(e = 0\), and yielded \(R_b = 1.97 \pm 0.10 \, R_{\text{Jup}}\). The measured size of the planet is clearly very sensitive to the treatment of orbital eccentricity.

[Triaud et al. 2010] and [Bayliss et al. 2010] subsequently confirmed the provisional finding that WASP-17 b has a retrograde orbit, from radial velocity observations obtained during transit. [Triaud et al. 2010] also obtained improved spectroscopic parameters for the host star. They assumed \(e = 0\) and found \(R_b = 1.986^{+0.089}_{-0.074} \, R_{\text{Jup}}\). [Wood et al. 2011] have detected sodium in the atmosphere of WASP-17 b, using echelle spectroscopy obtained outside and during transit.

[Anderson et al. 2011, hereafter A11] used an alternative method to constrain the orbital shape of the WASP-17 system: measurements of the time of occultation of the planet by the star in infrared light curves obtained by the Spitzer satellite. To first order, the orbital phase of secondary eclipse (occultation) depends on the product \(e \cos \omega\) where \(\omega\) is the longitude of periastron \((\) Kopal 1959]. A11 obtained \(e \cos \omega = 0.00352 \pm 0.00075\) and \(e = 0.028^{+0.015}_{-0.014}\) finding \(e \cos \omega\) to be significantly different from zero at the 4.8σ level. Inclusion of the Spitzer data, alongside existing observations, led to the measurement \(R_b = 1.991 \pm 0.081 \, R_{\text{Jup}}\). This was achieved without making assumptions about \(e\) or \(\omega\), so represents the first clear demonstration that WASP-17 b is the largest planet with a known radius. One remaining concern was that the orbital ephemeris of the system had to be extrapolated to

![Figure 1. Light curves of WASP-17. The error bars have been scaled to give $\chi^2_e = 1.0$ for each night, and in some cases are smaller than the symbol sizes.](http://www.sao.org/act/facilities/lasilla/telescopes/dip5)
at ESO La Silla, Chile (Table 1). Our approach was to defocus the telescope and use relatively long exposure times of 100–120 s (see Southworth et al. 2009a,b). This technique results in a higher observing efficiency, as less time is spent on reading out the CCD, and therefore lower Poisson and scintillation noise. It also greatly decreases flat-fielding noise as several thousand pixels are contained therefore lower Poisson and scintillation noise. It also greatly decreases flat-fielding noise as several thousand pixels are contained therefrom A10, of which 12 are from observations with Super-

3 LIGHT CURVE ANALYSIS

The analysis of our light curves was performed identically to the Homogeneous Studies approach established by the first author. Full details can be found in Southworth (2008, 2009, 2010, 2011). Here we restrict ourselves to a summary of the analysis steps.

The light curves were modelled using the \texttt{JKTEBOP} code \cite{southworth2004}. The star and planet are represented by biaxial spheroids, and their shape governed by the mass ratio. We adopted the value 0.0004, but our results are extremely insensitive to this number. The salient parameters of the model are the fractional radii of the star and planet (i.e. absolute radii divided by \( R_A \) and \( r_B \), and the orbital inclination, \( i \). The fractional radii were parametrised by their sum and ratio:

\[
r_A + r_B = \frac{r_B}{r_A} = \frac{R_B}{R_A}
\]

as the latter are less strongly correlated.

3.1 Orbital period determination

Our first step was to obtain a refined orbital ephemeris. Our own four datasets were fitted individually and their errorbars rescaled to give \( \chi^2 = 1.0 \) with respect to the best-fitting model. This step is necessary because the uncertainties from our data reduction pipeline (specifically the \texttt{APER} algorithm) tend to be underestimated. We then re-derived the times of mid-transit for the three datasets which covered complete transits. Monte Carlo simulations were used to assess the uncertainties of the measurements, and the resulting errorbars were doubled based on previous experience \cite{southworth2012a}.

We augmented our three times of mid-transit with 13 measurements from A10, of which 12 are from observations with Super-WASP \cite{pollacco2006} and one is from their follow-up Euler
The reduced timings, which confirms the caveat from A10 that these may have optimistic errorbars.

3.2 Orbital eccentricity

As emphasised in Sect. 1, the possibility of an eccentric orbit is an important consideration for WASP-17. The radial velocity measurements of the star do not strongly constrain eccentricity; the radial velocity curve of the star has an amplitude not much greater than the size of the errorbars on the individual measurements.

The observed shape of the transit is not useful because it covers only a very small phase interval (an essentially ubiquitous situation for TEPs; see Kipping 2008). The only precise constraint on orbital shape was obtained by A11, from two occultations observed using Spitzer. They found the phase of mid-occultation to be $0.50224 \pm 0.00050$, allowing a detection of a non-zero $e \cos \omega$ at the 4.8σ level.

Our revised period is $4.0 \pm 0.6$ s larger than that found by A11, a difference of 6.6σ, which affects the phase of mid-occultation. The actual occultation times are not given by A11, but an effective time can be inferred from the dates of the observations and the orbital ephemerides utilised. We performed this calculation and then converted the result back into orbital phase using our new ephemeris. This procedure incorporates the necessary conversion from the UTC to the TDB timescales. We found the phase of occultation to be 0.50066, which is consistent with phase 0.5 at about the 1σ level. The Spitzer results can no longer be taken as evidence of an eccentric orbit in the WASP-17 system. This emphasises the importance of accompanying occultation measurements with transits, in order to avoid uncertainties in propagating ephemerides from different observing seasons.

To confirm this result, we obtained a time measurement which represents the actual times of the Spitzer occultations by repeating the analysis by A11. We found 2454949.5422 ± 0.0016 on the HJD(UTC) timescale. After converting to the TDB timescale this equates to the phase 0.50059 ± 0.00043, which is equivalent to an $e \cos \omega$ of only 0.00093 ± 0.00068. This differs from zero at the 1.4σ level, which we do not regard as convincing evidence of orbital eccentricity (see also Anderson et al. 2012). Further observations with Warm Spitzer would be useful in confirming the phase of mid-occultation of WASP-17b.

The possibility of transit timing variations as might arise from the light-time effect induced by a body on a wider orbit around WASP-17 Ab, but a periodogram of the residuals from Table 3 does not show any peaks above the noise level. We therefore proceeded under the reasonable assumption that the orbital period is constant.

### 3.3 Light curve modelling

We modelled the three complete transits from the Danish Telescope simultaneously using the JKTEBOP code. The partially-observed transit provides a confirmation of the transit depth, but is less reliable than the other ones and has little effect on the solution, so was not included in further analysis. The $\chi^2$ of the fit to the three light curves is 1.22, which indicates that they don’t agree completely on the transit shape. Such a situation may arise from astrophysical effects such as starspot activity (which can cause changes in the transit depth without altering the shape), instrumental effects such as correlated noise in the photometry, and analysis effects such as imperfect transit normalisation. Importantly, our possession of three independent transits mitigates against all three eventualities, making the resulting solutions much more reliable than those based on a.
Table 4. Parameters of the fit to the light curves of WASP-17 from the JKTEBOP analysis (top lines). The parameters adopted as final are given in bold. Alternative parameters with various constraints on orbital eccentricity and orientation are included, labelled with the $\cos \omega$ and $\sin \omega$ values are given to show explicitly the measurements or assumptions relevant to each analysis.

Figure 3. Phased light curves of WASP-17 from the Danish telescope (upper) and the Euler telescope (lower), compared to the best fits found using JKTEBOP and the quadratic LD law. The residuals of the fits are plotted at the bottom of the figure, offset from zero.

Single transit. The excess $\chi^2$ causes larger errorbars to be obtained for both error analysis algorithms (see below) so is accounted for in our final results.

Light curve models were obtained using each of five limb darkening (LD) laws, of which four are biparametric (see Southworth [2008]). The LD coefficients were either fixed at theoretically predicted values or included as fitted parameters. We found that fitting for one LD coefficient provided a significant improvement on fixing both to their theoretical counterparts, but that fitting for both led to ill-conditioned models with no further improvement in the quality of fit. We therefore adopted the fits with the linear LD coefficient fitted and the nonlinear LD coefficients set to its theoretical value but perturbed by ±0.05 on a flat distribution during the error analyses (corresponding to case ‘LD-fit/fix’ in the nomenclature of Southworth [2011]). This does not cause a significant dependence on stellar theory because the two LD coefficients are very strongly correlated (Southworth et al. [2007a]). The results for the linear LD law were not used as linear LD is known to be a poor representation of reality.

Errorbars for the fitted parameters were obtained in two ways: from 1000 Monte Carlo simulations for each solution, and via a residual-permutation algorithm. We found that the residual-permutation method returned larger uncertainties for $k$ but not for other parameters, indicating that red noise becomes important when measuring the transit depth. The final parameter values are the unweighted mean of those from the solutions involving the four two-parameter LD laws. Their errorbars are the larger of the Monte-Carlo or residual-permutation alternatives, with an extra contribution to account for variations between solutions with the different LD laws.

We also modelled the Cousins $I$-band light curve from the Euler Telescope presented by A10, in order to provide a direct comparison with our results. The LD-fit/fix option was also the best, and correlated noise was found to be important for all photometric parameters. A plot of the best fit is shown in Fig. 3 and the corresponding parameters are tabulated in Table 4. The agreement between the Danish and Euler data is poor, especially for $k$. The Danish results should be more reliable as they are based on three transits and correlated noise was found to be important for all photometric conditions. The Euler data are more scattered, cover only one transit with a gap near midpoint, and were obtained from an alt-az telescope so suffer from continual changes in the light path over the duration of the observing sequence. We therefore adopted the Danish results as final.

Table 4 also shows a comparison between our photometric parameters and the theoretical coefficients predicted by the JKTEBOP code available from http://www.astro.keele.ac.uk/jkt/codes/jktld.html.

Table 6. Final physical properties of the WASP-17 system (with statistical and systematic errorbars) compared to published measurements. Eccentricity is included to illustrate the difference approaches taken to obtain each set of results.

4 THE PHYSICAL PROPERTIES OF WASP-17

The physical properties of the WASP-17 system can be obtained from the adopted photometric parameters (Table 5), the orbital velocity amplitude of the star ($K_A = 52.7 \pm 2.9 \text{ ms}^{-1}$; Triaud et al. 2010), its effective temperature ($T_{\text{eff}}$) and metallicity ($[Fe/H]$), and a constraint from theoretical stellar evolutionary models. Full details of our approach can be found in Southworth (2009, 2010).

One immediate problem faced here is the diversity of the published $T_{\text{eff}}$ measurements of WASP-17 A: A10 find 6550 $\pm$ 100 K from analysis of echelle spectra; Triaud et al. (2010) obtain 6650 $\pm$ 80 K from similar observations, and Maston et al. (2011) deduce 6500 $\pm$ 75 K from the InfraRed Flux Method (IRFM; Blackwell & Shallis 1977; Blackwell et al. 1990). We adopted $T_{\text{eff}} = 6550 \pm 100$ K as this encompasses all three determinations but leans towards the IRFM value, which should be the method with the least dependence on stellar theory and analysis technique. The corresponding metallicity is $[Fe/H] = -0.325 \pm 0.009$ (A10).

Our approach was to guess a value of the orbital velocity of the planet ($K_b$) and combine it with the photometric parameters and $K_A$ to calculate the physical properties of both bodies using standard formulae (e.g. Hilditch 2001). The predicted properties of the star for the calculated mass were then found via interpolation in a set of theoretical model predictions. $K_b$ was iteratively adjusted to find the best agreement between the known $K_A$ and calculated $K_b$, and between the measured and predicted $T_{\text{eff}}$ values. This was done...
for ages ranging from zero to the point at which the star evolves to log $g < 5$. All asymmetric errorbars have been averaged, and the statistical and systematic errorbars have been added in quadrature, in order to fit into the Table.

(2009); (8) Mandushev et al. (2007); (9) Hebb et al. (2009); (10) Joshi et al. (2011); (11) Enoch et al. (2010).

For a summary of the physical properties of WASP-17, which are in good agreement overall but contain some optimistic errorbars.

5 WHAT CAUSES SUCH LARGE PLANET RADII?

We have measured the radius of WASP-17 b to be $R_b = 1.932 \pm 0.053 R_{\text{Jup}}$ (adding the statistical and systematic errors in quadrature), confirming its status as the largest planet currently known. We also find no significant evidence for orbital eccentricity, removing an additional contribution to the uncertainties of the measured properties of the system.

For a summary of the physical properties of WASP-17 system (Table 6) were therefore calculated from the results obtained using the other four model sets (Claret, $Y^2$, Teramo and VRSS). Table 6 also contains results from published studies of WASP-17, which are in good agreement overall but contain some optimistic errorbars.
that they orbit host stars with radii above 1.6 \( R_{\text{Jup}} \). This list has been boosted by the addition of two objects, OGLE-TR-56 and WASP-14, based on major revisions to their radii by Southworth (2012). The newly-discovered systems WASP-78 and WASP-79 (Smalley et al. 2012) are not included here as the radii of their planets are uncertain. We now discuss the properties of the fourteen planets with radii above 1.6 \( R_{\text{Jup}} \).

Firstly, Fig. 4 shows that their orbital period distribution is not exceptional, and that they are consistent with the known correlation between period and surface gravity (Southworth et al. 2007b). The masses of all but two of them (OGLE-TR-L9 and WASP-12) are in the interval 0.4–1.0 \( M_{\text{Jup}} \). These objects also do not represent a high-eccentricity population: all have orbits which are (or are almost) circular. Tidal heating (Bodenheimer et al. 2003; Jackson et al. 2008; Ibata & Burrows 2009) is therefore not a viable proposition to explain their large radii. Orbital misalignment may be relevant: WASP-14 is misaligned (Johnson et al. 2009), WASP-17 is retrograde (Traub et al. 2010), and TrES-4 is axially aligned (Narita et al. 2010). Thus two of the three planets with obliquity measurements are misaligned.

However, a notable feature of the fourteen large planets is that they orbit host stars with \( T_{\text{eff}} > 5900 \text{ K} \) and \( M_{\text{*}} > 1.15 \text{ M}_\odot \). This establishes a connection between a bloated planet and a hot star. Fig. 5 and Fig. 6 show that the large planets are preferentially associated with hotter and more massive host stars. The association does not work the other way: such stars also possess TEPs with smaller radii representative of the general planet population. A correlation with host star \( T_{\text{eff}} \) was suspected but not found. An important factor in bloating planets above their expected size therefore seems to be the \( T_{\text{eff}} \) of their host star. This may be due to the enhanced UV flux from such stars, but such a possibility does not explain why less inflated planets are found around stars with \( T_{\text{eff}} > 5900 \text{ K} \).

A similar situation occurs with irradiation: the large planets have high \( T_{\text{eq}} \)'s (or equivalently large specific incident stellar fluxes) of 1600 K or more, but so do many other smaller planets. The connection between inflated radii and high \( T_{\text{eq}} \) is well-known (see Baraffe et al. 2010; Enoch et al. 2012, and references therein) but the simultaneous existence of small planets with high \( T_{\text{eq}} \) is not yet understood. Laughlin et al. (2011) quantified the correlation between the radius anomaly (observed radius versus those predicted by the models of Bodenheimer et al. 2003) of TEPs and their \( T_{\text{eq}} \)'s, in the form of a power law. Whilst their fig. 2 exhibits appreciable evidence for this claim, the large planets discussed here remain outliers even in that diagram.

We have searched for values for the chromospheric activity indicator \( \log R'_{\text{HK}} \) (Noyes et al. 1984) for the host stars of our large planets. Knutson et al. (2010) give values of \( -5.331 \) for WASP-17, \( -5.099 \) for Kepler-7, \( -5.104 \) for TrES-4, \( -5.500 \) for WASP-12, and \( -4.923 \) for WASP-14. These \( R'_{\text{HK}} \) values are representative of inactive stars, suggesting a correlation between inflated planetary radii and low chromospheric activity. HAT-P-32 and HAT-P-33 possess values of the related S index (Vaughan et al. 1978) which indicate a low activity level, despite their comparatively high rotation rates and velocity jitter (Hartman et al. 2011). HAT-P-40 and HAT-P-41 have similarly quiet \( \log R'_{\text{HK}} \) values of \( -5.12 \) and \( -5.04 \) (Hartman et al. 2012).

Therefore eight of the fourteen stars in question have measured activity indicators, and all suggest low chromospheric activity. Perhaps the increased high-energy photon flux from more active stars acts against large planetary radii. Knutson et al. (2010) found a correlation with the atmospheric properties of planets, in that inactive stars possess planets with temperature inversions whereas planets around active stars do not have inversions. However, Hartman (2010) found no correlation between \( \log R'_{\text{HK}} \) and

6 Data taken from the Transiting Extrasolar Planet Catalogue (TEPCat), available at: http://www.astro.keele.ac.uk/jkt/tepcat/

7 It has been noticed that orbital eccentricity is correlated with planet mass (Southworth et al. 2009c) but plots of planet radius versus eccentricity (not shown here) indicate that there is – if anything – a deficit of large-radius eccentric planets.
planet radius, so the low values for the fourteen host stars in question may be an artefact of their $T_{\text{eff}}$ distribution. Another possibility to explain the large planetary radii is that the more massive stars, around which the larger planets are found, have shorter main-sequence lifetimes. They will therefore be on average younger than the less massive TEP host stars. The large planets could simply be at an earlier stage of their evolution. This is, however, at odds with the low activity levels of the host stars, which implies that they are not particularly young. The models by Fortney et al. (2007, their fig. 5) show that it is possible for planets to be 2.0 $R_{\text{Jup}}$ or above if they are young (of order $10^7$ yr) and low-mass (less than 1 $M_{\text{Jup}}$). These criteria are not satisfied by any of our large planets. Explaining the radii of the large TEPs is therefore only viable if there is a large systematic error in our estimation of the age of their host stars, which is unlikely but certainly not impossible.

5.1 Can observational biases explain the properties of large planets?

An important question is whether the correlation between large planets and hot and massive host stars is real, or is it merely a phantom arising from observational selection effects? The correlation could easily be suspected to arise from detection biases as a function of transit depth. Fig. 6 shows a plot of the radii of the host stars versus their planets. We have overlaid dotted lines to indicate loci of approximately constant transit depth, calculated using JKTEBOP and assuming quadratic LD with both coefficients equal to 0.30. The subset of planets discovered via space telescopes are down-played in Fig. 7, as these should be much less biased against finding systems with shallow transits. It is immediately clear that the large planets do not stand out in this diagram as having unusually deep, and therefore easily detectable, transits.

Fig. 7 shows that most known TEPs have transit depths of about 1–3%. Firstly, we are straightforwardly biased against finding small planets around hotter (and therefore bigger) stars, as the transit depths in these systems are small. The relative paucity of small planets around big stars is plausibly explained by lower detection probabilities for transits less than 0.5% deep. Secondly, the absence of large planets around small stars might be explicable by either natural rarity or a bias against deep transits. Such objects may have a low follow-up priority within planet-search consortia if it is believed that deep transits are associated with false positives such as eclipsing binary star systems. As an example, if WASP-17 b orbited an unevolved 0.9 $M_{\odot}$ star then the transit depth would be roughly 5%.

None of the observables discussed above pre-determines the existence of big planets. They are found only around hotter stars, but some such stars possess small planets. They have quite high $T_{\text{eff}}$, but so do many smaller planets. They do not give rise to unusually deep or shallow transits, which rules out the more simple observational biases, and the metallicities of their host stars are not exceptional. The question of what causes their bloated radii remains unsettled.

6 SUMMARY AND CONCLUSIONS

Whilst WASP-17 was widely regarded to be the largest known planet, its radius was uncertain as it was based primarily on one follow-up transit light curve which shows moderate correlated noise. In this work we present three new high-precision transit light curves, obtained using telescope-defocussing techniques, and improve the measurement of its radius.

We have refined the orbital ephemeris of the system using our new data, which increase the temporal baseline by 3.1 years. Our revised orbital period is $4.0 \pm 0.6$ s longer than previous measurements, a difference of 6.6σ, and this change is sufficient to bring the observed time of occultation (A11) into line with that expected for a circular orbit. Further observations would allow this result to
be checked. In the case of WASP-17, circularity of the orbit favours a larger value for the planetary radius.

We have modelled our new data, along with the single follow-up light curve presented in the discovery paper (A10), using the JKTEBOP code. We paid careful attention to the treatment of limb darkening and to obtaining reliable uncertainties. The physical properties of the system were then derived using our new photometric and published spectroscopic results. Remaining uncertainties and discrepancies in the existing $T_{\text{eff}}$ and $\rho R^3$ measurements of the host star impose a bottleneck on the quality of the resulting properties, and new radial velocity observations would also be useful in refining the measurement of the planet’s mass and therefore its density.

WASP-17 b is the largest known planet, with a radius of $R_b = 1.932 \pm 0.053 R_{\text{Jup}}$. Another eleven planets are known with radii greater than 1.6 $R_{\text{Jup}}$. They are found only around comparatively hot ($T_{\text{eff}} > 5900$ K) and massive ($M_*/1.15 M_\odot$) stars, and have correspondingly high equilibrium temperatures ($T_{\text{eq}} > 1600$ K with the exception of Kepler-12) and equivalently incident fluxes. But other stars of similar mass and $T_{\text{eff}}$ possess smaller planets, whilst other planets with similar $T_{\text{eq}}$ (or equivalently specific incident flux) do not have such enlarged radii. One possible discriminating feature is that all eight of the fourteen host stars with measured activity indicators are chromospherically inactive.

The set of fourteen large planets do not have unusual transit depths. However, planets of this size around cooler stars may have an anomalously low discovery rate if their deep transits (of order 5%) discount them from detailed follow-up observations. High-precision radial velocity measurements are expensive in terms of telescope time, so dubious TEP candidates with unexpectedly deep transits may be prematurely rejected as false positives. A re-evaluation of such candidates will either yield scientifically valuable discoveries, or dismiss the existence of large planets around small stars.

The fourteen planets with radii greater than 1.6 $R_{\text{Jup}}$ all have circular (or nearly circular) orbits, so their large size cannot easily be attributed to tidal heating. Of the three published measurements of the axial alignments of these planets, one reveals a retrograde orbit, one a misaligned orbit, and one indicates alignment. Observations of the Rossiter-McLaughlin effect on the remaining eleven systems could either verify or discount the possibility that axial alignment is a relevant aspect of large planets.

ACKNOWLEDGMENTS

The reduced light curves presented in this work will be made available at the CDS (http://cdsweb.u-strasbg.fr/) and at http://www.astro.keele.ac.uk/~jkt/.
