PREFACE

Dear Colleagues,

In your hands are the *Proceedings* of the 7th International Scientific Agricultural Symposium "AGROSYM 2016", which I hope you will find useful in your research, education and professional activities and endeavors.

AGROSYM 2016 themes cover all branches of agriculture and are divided into seven sessions: 1) Plant production, 2) Plant protection and food safety, 3) Organic agriculture, 4) Environmental protection and natural resources management, 5) Animal husbandry, 6) Rural development and agro-economy, and 7) Forestry and agroforestry.

Keynote papers dealt with organic agriculture from different perspectives as well as international cooperation in agricultural and rural development, climate change and forestry. Organic farming is a holistic production management system of agricultural, food and other products, combining good agricultural practices, a high degree of biodiversity, conservation of natural resources, and application of high standards of animal welfare.

Food production, food security and production of raw materials for other industries determine multiple environmental, economic and social roles of agriculture (including crop production, animal husbandry, forestry and fisheries) in all countries, both developed and developing ones, as well as its multi-functionality; including its contribution to rural development. This is clearly highlighted in the numerous contributions included in these *Proceedings* alongside the challenges that agriculture sector is facing and the negative impacts of industrial agriculture on the environment.

I do believe that the research results reported here will be significant in the dissemination of knowledge to the wider audience about the importance of agriculture as a strategic sector in many countries.

AGROSYM 2016 made an important contribution to the agriculture theory, knowledge and practice in different areas. During the four-day symposium on October 6-9, 2016, over 1100 contributions were presented (either as oral or poster presentations) to more than 1000 participants representing 78 countries.

The *Proceedings* comprise an edited selection of the papers submitted to the symposium. Each paper included in the *Proceedings* was positively reviewed by referees.

AGROSYM 2016 was made possible through the commitment and contributions of a wide range of partners and sponsors. Many thanks to all authors, reviewers, session moderators and colleagues for their help in editing these *Proceedings*. Special thanks go to all co-organizers for their unselfish collaboration and comprehensive support.

East Sarajevo, 05 October 2016

Abstract

Selection of perennial forage grasses is aimed at improving the economic and environmental sustainability of cattle and sheep production. Tolerance to drought conditions, water use efficiency, persistence and high forage yields are the major traits that determine the adaptability of the tested genotypes. This study was conducted at the experimental site of the ITGC institute in Sétif during the cropping seasons 2005/06, 2006/07 and 2007/08 with the objective to evaluate the performance of 13 varieties of perennial grasses, belonging to two species: *Festucaarundinacea*Schreb. And *Dactylisglomerata* L. in a semi-arid region. Characterization has focused on various morphological traits in order to assess their adaptability to drought prone environments. The results showed the existence of a wide range of variability due to the diversity of responses of the evaluated varieties of both species, particularly regarding biomass production, production cycle, persistence and water use efficiency, which is considered as one of the most important factors in the success of artificial grasslands in semi-arid areas. These results show high potential for the selection of a plant material adapted to the specific conditions of the semi-arid areas of the Algerian high plains. Indeed, this study allowed us to discriminate the most adapted genotypes characterized by high performance, good height growth, earliness in heading and good persistence.

Keywords: *Festuca arundinacea* Schreb., *Dactylis glomerata* L., *morphological traits, drought.*

Introduction

The use of perennial grasses in the semi-arid Mediterranean environment requires a high capacity to survive the severe thermal and water stress of summer and the ability to provide a high biomass yield in autumn-winter (Copani*et al*., 2012). Among the perennial grass species of common interest across the Mediterranean basin, tall fescue (*Festuca arundinacea* Schreb.)and cocksfoot (*Dactylis glomerata* L.) are of paramount importance (Mousset, 1995). However, these species have mostly been bred in and for more temperate climates, and the attempt to simply introduce cultivars selected under different conditions into the Mediterranean region has repeatedly proven unsuccessful. Therefore, all the attempts of introduction of high yielding genotypes bred in temperate climates should be preceded by studies about their adaptation to semi-arid conditions.On the basis of the importance of studies that evaluate yield adaptation to Mediterranean locations of both species, the present study was undertaken to compare 13 cultivars (6 *Dactylis glomerata* L. and 7 *Festuca arundinacea* Schreb.) in an Algerian drought prone environment for yield and other relevant phenotypic traits, in order to identify the best adapted plant material.

Material and Methods

The field trial was carried out over three consecutive cropping seasons (*i.e.*, 2005/2006, 2006/2007, 2007/2008) at the Agricultural Research Station of the Field Crop Institute of Sétif (Algeria) (1081 m a.s.l.; 36°12′N, 5°24′E), which has a long-term mean annual rainfall of 387 mm. The soil is classified as clayloam, with 45% clay, 41% silt, 13.9% sand, and 1% organic matter, and pH (H_2O) 8.2. The climate is temperate continental, and varies from arid to semi-arid. The monthly rainfall and mean monthly temperatures recorded at the experimental site during the trial are shown in Figure 1. The trial was run under rain-fed conditions, except for the sward establishment year, in which 40 mm irrigation was given in March 2006, after a severe drought spell. The soil was prepared in the autumn of 2005, after chickpea as the previous crop. Before ploughing, 18 kg/ha P was applied as triplesuperphosphate fertiliser (18% P, 9% S), as the standard application for cereal production in the area.

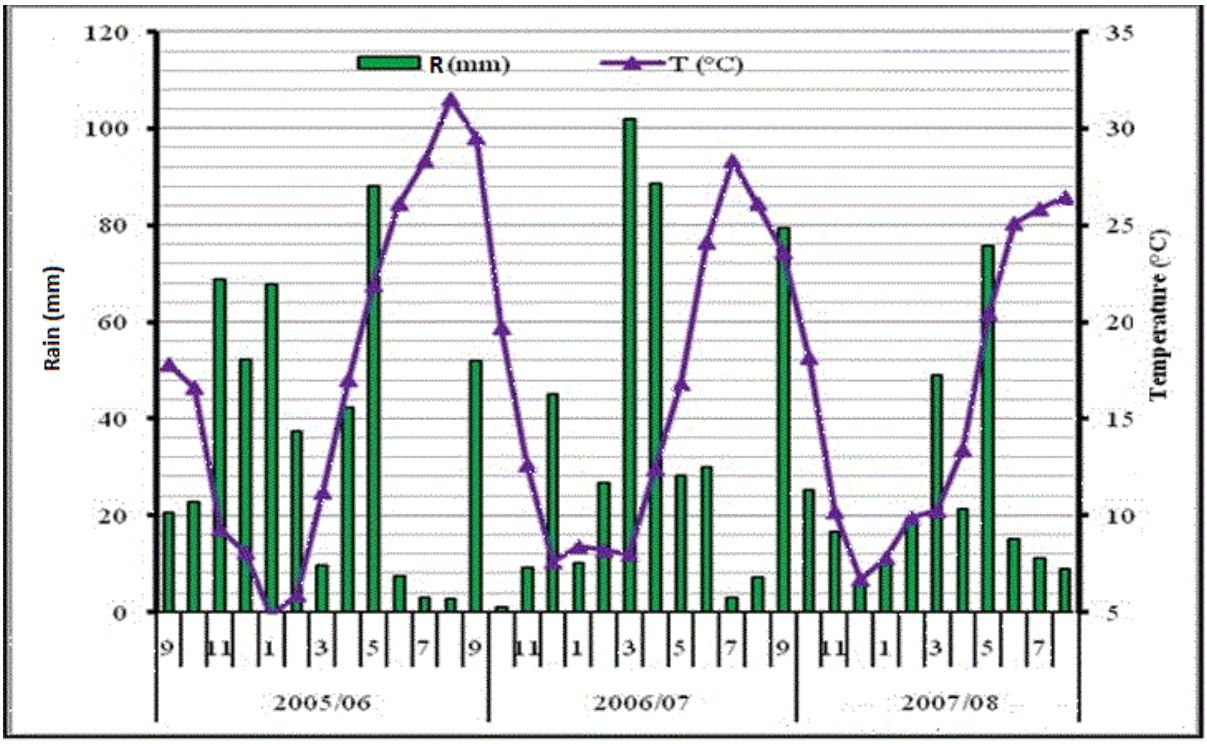

Figure 1. Mean monthly temperatures and rainfall recorded at the experimental site (Sétif, Algeria) for the years of the study.

The six cultivars of cocksfoot and seven of tall fescue obtained via the "PerMed" European project (Mefti*et al.*, 2014) were endophyte free (E-), except E-542 (E+), which is 'Flecha' infected by the endophyte AR542. Each grass cultivar was hand sown in a Lattice design in October 2005 on a 10-row plot, with 2.5-m-long rows and 0.20-m spacing between the rows. Nitrogen fertiliser was applied in November 2006 and in March 2006, 2007 and 2008, at a rate of 35 kg/ha of N asurea (35% N).

Measurements

The inner six rows were harvested to determine dry matter yield after drying a sample of 500g in a forced air oven at 70 °C for 48 h at each harvest (autumn and spring).The heading date (HD) was recorded in spring on undisturbed rows in each plot, and expressed as the number of days from 1 January needed to reach 50% heading of the plot. Recovery from each cut (REC) was expressed as the row cover percentage; i.e., the percentage of the row space occupied by living grown tissue. This was measured after each harvest, to determine the persistence of each of the cultivars.

Soil water measurements were carried out with a neutron probemoisture meter (CPN Corp., Pacheco, CA, USA) twice a year: at the start of the cropping season in September, and just after the last cut in May-June. The measurements of the water content were made in plot soil to a depth of 100 cm, where we observed that most root biomass was concentrated. The moisture readings were calibrated against the soil water content, which was determined gravimetrically for each soil depth layer, as: 0-20 cm, 20-40 cm, 40-60 cm, 60-80 cm and 80-100 cm, and converted to volumetric measures. The total water evapotranspired (TWU) by the crop was then estimated according to Chen *et al.* (2003), as:

$TWU = ASW_{09} + Rainfall - ASW_{06}$(1),

whereASW_{09} is the available soil water at the start of the productive season, measured in September, *Rainfall* is the accumulated rainfall during the season, which was recorded at the national weather station located 5 km from the experimental field, and ASW_{06} is the available soil water measured just after the last harvest in May-June.

The WUE was expressed as kg forage dry-matter yield per hectare accumulated between the two harvests/mm total water evapotranspired (*TWU*), according to Chen *et al.* (2003), as: $WUE = DMs/TWU$ (2).

The field-collected data during the three cropping seasons were analysed using the balanced **generalised linear model** (GLM) subroutine of the Systat12 software (Systat Software, Chicago, IL, USA), as a factorial in randomised complete block design.

Results and Discussion

Persistence and earliness

Variations among the cultivars and years for row cover (REC) reached significance of at least $P<0.01$ in both of the seasons over the 3 years of the experiment, but there were no significant effects of species, or for the double and triple interactions (Table 2). The mean of the sward persistence averaged over the years, ranged from 46.24% (cocksfoot 'Ottava') to 71.33% (tall fescue 'Tanit') in autumn, and from 46.62% (tall fescue 'Sisa') to 69.31% (cocksfoot 'Jana') in spring. (Table 1).

The number of days to flowering showed highly significant differences between the genotypes (G), years (Y), G × Y, and G × SP(species) × Y interactions ($P<0.001$; Table 2). The swards took a longer time to flower during the first year of establishment, compared to the second and third years, with the mean number of days to flowering averaged over the genotypes of 134.6 (cocksfoot, 137.0; tall fescue, 131.0) in 2005/2006, compared to 113.7 days and 101.8 days in 2006/2007 and 2007/2008, respectively . Tall fescue cultivars 'Flecha' and 'E-542' showed the earliest flowering dates across the years (109 days), while the cocksfoots 'Jana' and 'Delta-1' and the tall fescues 'Tanit' and 'Lutine' were the latest to head over the 3 years of the study (Table 1).

Dry-matter yields

The dry-matter yields were relatively low during the autumn compared to the spring harvests, with a 3-year average of 0.48 t/ha for the autumn harvest (DMa) for both cocksfoot and tall

fescue, and 1.12 t/ha for the spring harvest (DMs) for cocksfoot *versus* 1.50 t/ha for tall fescue (Table 1). The analysis of the variance of DMa accumulated across the years of the study did not indicate any differences between species, or genotypes, or any interactions, with a significant effect of year only (Table 2). For the spring dry-matter yield (DMs), the ANOVA was highly significant ($P<0.001$) for species, genotype and year effects, together with a significant triple interaction (*i.e.*, genotype × species × year; Table 1). The mean DMs across the 3 years indicated that 'Flecha' (1.77 t/ha), 'E-542', 'Centurion' and 'Fraydo' were the top yielding cultivars, all of which are tall fescues, with cultivars of tall fescue being generally higher yielding in spring than cocksfoot. The lowest yielding cultivar was the cocksfoot 'Ottava', with a mean spring biomass harvest of only 0.87 t/ha (Table 1). When the individual years were examined, the yields for the second year were higher for both species, while the third year was the lowest also for DMs. The tall fescue 'Flecha' was the highest yielding cultivar in year 1 (2005/2006; 1.92 t/ha), while it gave the same yield as the tall fescues 'E-542', 'Centurion', 'Lutine', 'Fraydo', and as the cocksfoot 'Medly' in the second year (2006/2007).

Water-use efficiency

The WUE varied significantly between the years, species, genotypes, G × Y, and G × SP × Y year interactions (Table 2). For individual years, the establishment year (2005/2006) showed far less efficiency in terms of water use for all of the cultivars tested, with 'Flecha' showing the highest WUE of all the tall fescue and cocksfoot cultivars. The WUE was higher in the second year (2006/2007), with nearly identical effects in the two grass species. Indeed, the cocksfoot 'Kasbah' showed the lowest WUE during the first year (2005/2006; together with 'Delta-1', 'Ottava' and 'Lutine'), but ranked second for WUE for the third year (2007/2008), after 'E-542'. Tall fescue cultivars 'Flecha', 'E-542' and 'Fraydo' showed generally high WUEs for each year than cocksfoots.

Table 1.Three-year means for the agronomical traits for the cocksfoot and tall fescue cultivars.

Species	**Cultivar**	**Dry-matter yield**		**Recovery**		**HD**	**WUE**

Prolonged summer droughts and poor management practices adversely affect persistence; and as a result, swards are short-lived and require frequent re-establishment (Malinowski *et al*. 2005).However, increased persistence was not always shown to be of benefit in terms of production. In fact, a comparison between the two tall fescue cultivars has been done by Hayes *et al*. (2012) showed that the more summer active cultivar, Demeter, failed to persist beyond year 1; cv. Fraydo, by contrast, persisted to at least year 3; however, the cumulative herbage production during the entire experimental period of cv. Demeterwas 59% greater than that of cv. Fraydo.

For our results, Flecha was selected in difficult conditions in Argentina (Pecetti*et al*., 2011). It has at least two characters that contribute to its drought tolerance (i) the deep root system plays a large role in enhancing plant survival (Volaire, 2008) , and (ii) the development of an extensive senescent leaves around young tillers during the summer, increasing the survival of tillers under drought conditions (Norton *et al.* 2006). Poor persistence of cocksfoot variety Ottava and tall fescues CVs Lutine and Sisa, is related to their non summer dormancy. Their origin in temperate regions of Europe explains also the difficulties of adaptation despite their good performance during the first two years.

Heading date, which is dependent on both genotype and environment has led to distinguish a late heading year, corresponding to the year of installation where endophyted Flecha, Flecha and Centurion were the earliest varieties with a period of 123, 127 and 128 days, respectively, while Medly, delta 1 and Lutine were the latest to head. In earlier year Flecha, endophyted Flecha, Fraydo and Medly were the earliest with periods ranging from 95.0to98.0days, while Delta1 is the latest with a heading date of 110 days.

Dry-matter yield is a very important trait determining the choice of perennial grass cultivars. Humphreys et al. (2006) reported that increasing dry-matter yield was the main objective of grass breeding programmes and breeding has achieved mean productivity increases of 0.5% per year. In the present study, there were differences in dry-matter yield between the cultivars studied. This variation arose from differences in the forage dry-matter yield per annual cycle and differences in cultivar (G) production across the years. The autumn dry-matter yield (DMa) was constantly lower than DMs, and this was explained by the decrease in soil moisture content (data not shown). In fact, in such drought-prone Mediterranean environments a commonly observed phenomenon is that autumn rains arrive very late and rainfall in summer may be completely absent.

In the present study, WUE varied greatly between the years, and also between varieties within the individual years. The WUE, which is defined as the ratio between the plant dry-matter production and the water transpired, represents a measure of the ability for a plant to perform well under incipient drought (Thomas, 1997). Blum (2009) considered that the WUE is an

important determinant of the yield under stress, and even as a component of the crop drought resistance. In the present study, the highest yielding varieties also had high WUE.

Conclusion

These traits showed the possibility to select an adapted material of *Dactylisglomerata* and *Festucaarundinacea* to specific conditions of the semi-arid areas of the Algerian high plains, where annual rainfalls rarely exceed 400 mm per year. Flecha, Fraydo and Kasbah showed superior adaptation for the measured traits. There was evidence for better drought tolerance of earlier-heading varieties.

POSSIBILITY OF PEPPER PRODUCTION BY DIRECT SOWING

Goran PERKOVIĆ[1*], Aleksandra GOVEDARICA-LUČIĆ[1], Saša LALIĆ[2]

Abstract

The aspiration for economic, yielding and qualitative production has led to the introduction of the improved technology for pepper cultivation by direct sowing of seed with the application of the specific machinery and a suitable protection from pests. The aim of the pepper production by direct sowing is neither an early harvest nor big fruits. It is a high yield, a single harvest and the simple economic cultivation practices. In pepper production by a direct sowing the period of disease is avoided, and a possibility of the occurrence of a disease is a lot lower in comparison to the peppers that are produced from seedlings. The share of human labor during the production is much smaller and the greatest part of cultivation practices is done by machinery; the production is more simple and safer, and the yield and quality of fruits are at the level of the yield of a classical production of pepper from seedlings. The advantage of pepper production by direct sowing is also reflected in the achievement of plant spacing per hectare that is by even 4 to 6 times larger compared to the classical system of cultivation. Such a cultivation system introduces a low yield per a plant, but a high total yield. Beside all these statements, the pepper production by direct sowing is little present on the plots in Semberija because of many restrictions in the production.

Key words*: pepper, direct sowing, seedling, yield, a number of plants.*

Introduction

Production of pepper from seedlings is the most common production system, but more rational technologies of pepper production by direct sowing are being more and more accepted. The main disadvantages of cultivation of pepper from seedlings are large total costs, significant energy consumption, bigger risk of disease occurrence and very high involvement of human labor. The total yield depends on the quality of seedlings. The seedling production requires very high level of skills, as well as constant investing in new technologies of the production of seedlings.

The pepper production by direct sowing does not require any additional investments, equipment or building of additional facilities. Because of these facts, the pepper production by direct sowing is coming to be more and more interesting and widespread. The results of the trial can be added to this, as well as production practices which speak in favor of production by direct sowing. The pepper that is planted late gives a lower yield as a rule. The reduction of the yield will occur if we plant the seedlings that are not suitable for seeding because they are underdeveloped, too young or they have overgrown the optimal phase for seeding. The results of Lazić (1975) confirm that in the production of the pepper by direct sowing higher yields are realized than in the production of pepper from seedlings if the planting happened after 20th of May, so called the late phase. We specially have to emphasize the advantages of a thicker plant spacing of pepper in the production by direct sowing which also Zatyko (1979) points to in his researches. He points out that the advantage of pepper production by direct sowing is that we achieve larger plant spacing by an area unit, even by 4 to 5 times larger compared to the planting which gives a low yield per a plant, but a high total yield per area

unit. Therefore, the aim of this research is that we, beside determining the most yielding way of pepper production, make an analysis of ecological conditions and the effect of the applied cultivation practices on the reduction of unfavorable conditions.

Material and methods

The studies about possibilities of pepper production by direct sowing have been carried out on a soil which belongs to grey and brown non-calcareous chernozem and which is at the same time the most prevailing soil at the territory of Semberija region (entity of Republic of Srpska, Bosnia and Herzegovina).

A general trait of this soil is weak acid reaction with the PH value of 6.41 and it is also characterized by relatively low content of humus substances that ranges from 2.37 to 2.71%. The soil has good physical properties, emphasized crumbly structure but it is typical that during the process of production in unfavorable climatic conditions a crust occurs. The soil is well provided with nutrients, the content of basic nutritive substances does not represent a limitation in the production.

The preparation of soil has been done with the application of standard mechanization and with the usual pattern of cultivation practices which is a standard in pepper production at the territory of Semberija. During autumn, cow dung and mineral fertilizer NPK 8:16:24 were applied. Ploughing down was done after spreading of fertilizer at the depth of 25 to 30 cm. During spring, the other part of mineral fertilizer NPK 15:15:15 was applied in the plot after which the preparation of soil for sowing and planting was approached to. The direct sowing on an open field was done on 5th of April and the planting of seedlings from container and bare roots seedlings was done on 10th of May. Sowing and planting were done with the 55-cm row distance. The trial was set by 4-replicate randomized complete block design and the Palanačka Babura variety was used in the trial. With the aim of solving the task, a trial with the direct sowing of pepper on an open field was carried out but the trial also included the variants of pepper cultivation from the different ways of seedling cultivation namely the seedlings from a container and the bare roots seedlings. All of the applied cultivation practices were common for all the variants of the trial. At the end of the trial, the level of yield was being determined, and the results obtained were compared to results from the literature.

Results and discussion

The success in the production of pepper largely depends on the series of factors. For a successful production of pepper it is necessary to provide fertile soil with good structure, harvest the best preceding crop, cultivate the soil well and apply, on good time, the necessary measures of care during the vegetation. During performing of the trial, it was obvious that the applied cultivation practices affect the yield, but also that the ecological conditions have a great influence, which Wells (1967), Somos (1984) and Marković (1998) also concluded in their researches.

The results of the researches of Špaldon et al. (1972) indicate that pepper in the early stages goes through the basic phases of organogenesis, especially of generative organs. In this period, the pepper must have optimal conditions for growing and development in order to make a yield as great as possible.

Table No. 1 An average pepper yield by different means of production t/ha

Means of production	I	II	III	AVERAGE VALUE
Papper from direct sowing	31	30	40,80	33,93
Pepper from bare root seedlings	31,60	36	48,24	38,61
Papper from seedlings from container	32,48	40,16	60,64	44,42

Table 1: *Experiments source results*

The table above clearly indicates that the highest yield, in all of the three years of examination, was achieved in the production of pepper from container seedlings. It is obvious that the yield achieved is significantly higher compared to the other means of pepper cultivation. If we compare the average yields within some means of pepper cultivation, we will see that there are significant differences within some means of pepper cultivation in the sense of the level of the yield, which depends on the year of examination. It is a general conclusion that the pepper yield is a very variable trait which depends on the series of factors and that it is changeable depending on the means of production, but it also depends on the conditions of production within the individually observed ways of production.

The highest average yield was achieved in the pepper production from container seedlings which was 44.42 t/ha. During the cycle of research, the lowest yield was obtained in the first year of the trial, 32.48 t/ha, and the highest yield was achieved in the third year (60.64 t/ha) where the difference is 28.16 t/ha.

In the pepper production by direct sowing on an open field the lowest yields were obtained in all of the three years of examination. The average yield was 33.93 t/ha and the lowest yield was obtained in the second year (30 t/ha) while in the third year it was highest (40.8 t/ha) just like in all other variants of the trial, where the difference is 10.8 t/ha. Just like in the case of the seedlings from container, during the production of pepper from bare root seedlings the lowest yield was obtained in the first year (31.6 t/ha), while it was highest in the third year of the trial (48.24), with the difference of 16.64 t/ha. The average yield of the pepper cultivated from the seedlings from container (44.42 t/ha) was higher for 10.49 t/ha than the yield of the pepper cultivated by the means of direct sowing, and it was higher for 5.81 t/h than the yield of the pepper cultivated from the bare root seedlings.

Based on the data above, we can see that the variations of the yield by years of examination within some ways of cultivation were more pronounced than they were among the different ways of cultivation. An emphasis should be put on a cause which was long rainy and non-rainy periods followed by significant oscillations of high and low temperatures that were followed by unfavorable relative air humidity.

The results presented confirm so far researches which emphasize that the pepper production from container seedlings has numerous advantages.

By producing the pepper from seedlings, we obtain higher yields; is this enough for a clear recommendation? What are the possibilities and perspectives like for the pepper production by direct sowing? Which moments do the producers have to pay a special attention to? The success in the production of pepper by direct sowing is related to the soil and the climatic conditions during the process of production. The most fertile structural soils should be chosen for the pepper production. Fertile alluvial soils and chernozems, the soils with good water and

air regime, good physical and chemical properties are the most favorable soils for pepper production by direct sowing. The soil has to have a good aeration because the roots of peppers are sensitive to the lack of oxygen. The soils that are liable to forming of a crust make the pepper production more difficult, and exactly such soils occupy the largest part of arable land in Semberija.

The largest part of human labor use is related to breaking a crust especially in the period after the sowing and in the first stages after cropping up when pepper is most sensitive to the occurrence of crust. During this period, the efficient breaking of crust is possible only with regular irrigation of the sown plots.

The stoppage in cropping up and the speed of the passing of the first phases of growing and development is mostly related to occurrence of crust which in the final result leads to the decrease of yield.

The pepper from direct sowing requires greater involvement of human labor in the first part of vegetation, while in the production of pepper from seedlings greater involvement of human labor is in the second part of vegetation.

The first part of vegetation is a critical period in the production of pepper by direct sowing and it is necessary to pay more attention to it in that period.

The data from literature confirm our results and observations.

In order to make the yield of pepper from direct sowing as great as possible, the preparation of the soil must be as high-quality as possible and the sowing as early as possible. It is best to do the sowing from the end of March till 10th April, which matches with the conclusions from the researches done by Marković (1988). Gvozdenović et al (2006), just like Marković (2001), in their researches, confirm our facts that starting from the choosing of soil and all the way to the care of pepper all the measures for the cultivation practices have very large influence on the yield.

During the researches, we came to a clear conclusion that ecological conditions have very large influence on the yield, and that the measures of cultivation practices must be adapted to the ecological conditions which Marković (1995) also concluded in his researches.

The results of the research show that the yield of pepper from direct sowing was significantly higher in the third year of the trial.

It is necessary to emphasize that satisfactory yields can be achieved in the production of pepper by direct sowing, which was also a conclusion of the researches of Lazić et al (1971).

Conclusion

On the basis of the practical results and observations that have been noticed, the following conclusions can be made:

There are favorable agro-ecological conditions, at the territory of Semberija region, which give a firm basis for a successful cultivation of pepper by direct sowing on an open field.

The conditions for the production are not ideal (only favorable), but with intensified cultivation practices, timely and coordinated care measures, pepper can be very successfully produced directly from seed.

For a successful production of pepper, a special attention should be paid to choosing a high-quality soil, which, above all, must be very fertile, with good structure and other favorable physical and chemical properties.

The research also shows that in this production great attention must be paid to the high-quality cultivation of soil and measures for care of crops.

An important factor for the success in the pepper production by direct sowing are climatic conditions during the vegetation which cannot be influenced, but with a right choice and timely applied measures for cultivation practices, their negative effect can be reduced.

The pepper yield depends on numerous factors during the production, but in this production a satisfactory yields can be easily achieved.

The yield of pepper by direct sowing is lower than the production from seedlings, but it also has a series of advantages which are reflected in easier and simpler cultivation practices followed by higher economic profitability of production.

PHYSIOLOGICAL RESPONSES OF POTATO EXPOSED TO DROUGHT STRESS: STOMATAL CONDUCTANCE, LEAF WATER POTENTIAL AND GROWTHPARAMETERS

Mirjana JOVOVIĆ[1]*, Zorica JOVANOVIĆ[2], Radmila STIKIĆ[2]

[1]University of East Sarajevo, Faculty of Agriculture, Bosnia and Herzegovina
[2]University of Belgrade, Faculty of Agriculture, Serbia

Abstract

The aim of this study was to investigate the mechanisms which are responsible for the growth inhibition of plants under drought conditions and it is carried out by measuring the plant growth parameters and water regime. The research was carried out under controlled conditions andpotato (Solanum tuberosum L.) cultivar Liseta was used for investigation. During the vegetative period the plants were grown by the applied two different irrigation regimes:optimal irrigation - soil is watered every day until the optimum water capacity and soil water content in the substrate at field water capacity was 36% and water deficit -the drought caused by interruption of watering the substrate in the tuber initiation stage. The results of this study show that drought caused the reduction of the leaf and stem growth (leaf area, dry weight of leaves and stem) and development. On the basis of the results of measured water regime parameters (water content in a substrate, leaf water potential and stomatal conductance) and their correlative relationships it was confirmed that the decrease of water content in a substrate caused induction and interaction of both types of signals (chemical and hydraulic signals).

Key words:*water,drought, stomatal conductance, leaf, water potential*

Introduction

In the face of increasing frequency of extreme climatic events, crop plants are often exposed to multiple abiotic stresses at the same stage of growth (Walter et al., 2012).As a result of global climate change and excessive pollution have decreased the amount of water available for agricultural production. Drought stress becomes a significant stress factor that may limit agricultural production worldwide. Therefore, improving drought resistance of plants is difficult to achieve without understanding the effect of drought on plants.

Drought particularly affects the breeding and productivity of crops, especially vegetables, including potatoes. Potato is an important crop worldwide and due to its sparse and shallow root system is very sensitive to soil drying (Yuan et al., 2003). In potato like in many agricultural crops yield depends on how much dry matter is partitioned to reproductive organs (tubers). Even mild levels of water stress reduce potato productivity by limiting canopy expansion and increasing senescence rate and by the delay of tuber initiation and bulking (Fabeiro 2001; Lahlou et al., 2005; Hassanpanah, 2010).

Drought mainly affects the plant–water relations on cellular even the whole-plant level, resulting in reductions of leaf water potential and stomatal conductance (Rampino et al.,2006; Neumann, 2008).The traditional view of drought is that soil drying induces restriction of water availability and decreasing water and turgor potentials. Changes in plant water regime and the development of water deficits in leaves present a hydraulic signal of drought that lead the reduction of leaf growth (Dodd 2009). However, many results indicated that leaf growth could be reduced without any changes in leaf water status (Bahrun et al., 2002; Schachtman and Goodger, 2008; Fernandez et al., 2003) and that these changes are linked with soil water status. This kind of reaction requires

that the plants have some mechanism to sense the soil water availability. A number of experiments done in control and field conditions have shown that primary sensors of soil drying are roots which produce different chemical signals. Many experiments (Reddy et al., 2004; Davies at al., 2002, Liu et al., 2006) confirmed that this chemical signal is a stress hormone ABA that is a produce in roots in the response to soil drying. Abscisic acid is is transported via xylem to the shoots and caused stomatal closure and reduced leaf area. As a aditional signals in the plant response to soil drying can be changes in concentrations of others hormones (cytokinins), mineral composition and pH of xylem sap (Schachtman and Goodger, 2008; Wilkinson and Davies, 2008, Vystskaya et al., 2009) increasing of xylem pH has been suggested as a drought signal that reduces the leaf elongation rate through an ABA-dependent mechanism (Wilkinson, 1999).The impact of drought on physiological processes of plants is complex and depends on its intensity, duration, and of plant species exposed to stress.Drought has an effect on almost all processes in the plant and growth process is most sensitive to the water deficit. In drought conditions shoot growth inhibition is associated with the closure of stomata and caused a decrease in transpiration (Wilkinson and Hartung,2009). Reducing of stomatal conductance in early stages of water stress inhibits transpiration ratemore than it reduces the intercellular CO_2 concentration. The objective of a present study were to investigate the mechanisms responsible for the potato growth inhibition under drought conditions, measuring parameters plant growth, water regime and compared these results with control.

Materials and methods

Experimental design

Potato (Solanum tuberosum L.) cultivarLiseta was used for investigation. In the experiment under controlled conditions, we studied the effect drought of potato plants at an early phenological phase of growth. Potato tubers are uniform and germinated tubers were sown in containers with soil as substrate (Potground H, Klasmann-Deilmann, Germany). Plants were grown in phytotronic chamber at a temperature 25/18° C, relative humidity 70% and light intensity 300 $\mu molm^{-2}s^{-1.}$ After planting, all plants were watered up to the field water capacity. During the vegetative period the plants were grown by the applied two different irrigation regimes:

- Optimal irrigation - soil is watered every day until the optimum water capacity and soil water content in the substrate at field water capacity was 36%;
- Water deficit -the drought caused by interruption of watering the substrate in the tuber initiation stage.

Experimental measurements

Measurements of plant water regime parameters included leaf water potential (Ψl) and stomatal conductivity. The leaf water potential (Ψl) was measured using the pressure chamber (Scholander et al., 1965), while stomatal conductivity was measured using diffusion porometer AP4 (Delta-T Devices).Soil water content measurements was done by using teta probes (ML2X, Delta - T Device Ltd., United Kingdom) at a depth of 20 cm.

During the experimental period we measured parameters of growth and productivity (leaf area, dry weight of leaves and stem). Leaf area was determinate destructively by sampling leaves from plants and scanning by scanner (Mustec Scan Express A3 USB). Plant biomass (leaf and stem dry weight) was measured after oven drying to constant weigh at 80°C. The measured traits have been analyzed for statistically significant differences by Students unpaired t - tests (Sigma Plot 6.0 for Windows –SPW 6.0, Jandel Scientific, Erckhart, Germany).

Results and discussion

Water content in the substrate and plants water status

Changes in water content in substrate or soil water content, leaf water potential and stomatal conductance in the control and plants exposed to drought during the experiment are shown in Fig 1.The values of water content in the substrate in control plants during the study period were maintained at approximately the same level. Water content in the substrate at the beginning of the experiment was 35.5%, and then was a slight increased in 9-th day, where they recorded the maximum value of 37.6% and a gradual decrease until the end of the study where the water content was 33%.

Maximum values of water in the substrate in plants exposed to drought were at the beginning of the measurements, 33.5%, and then the value of the 5-th day fell to 30.6% and had a more pronounced decrease in the last day of drought where values were 16.7%. Tests of the water content in the substrate during the experiment under controlled conditions, showed that the values of water content in the substrate in plants exposed to drought were significantly lower than in control plants .Water content in control plants kept close to field water capacity, while in the plants exposed to drought decreased from the beginning of experiment untill the end of the study where the reduction of water content in the substrate was 49% compared to control. Similar results were obtained by Liu et al., (2005).

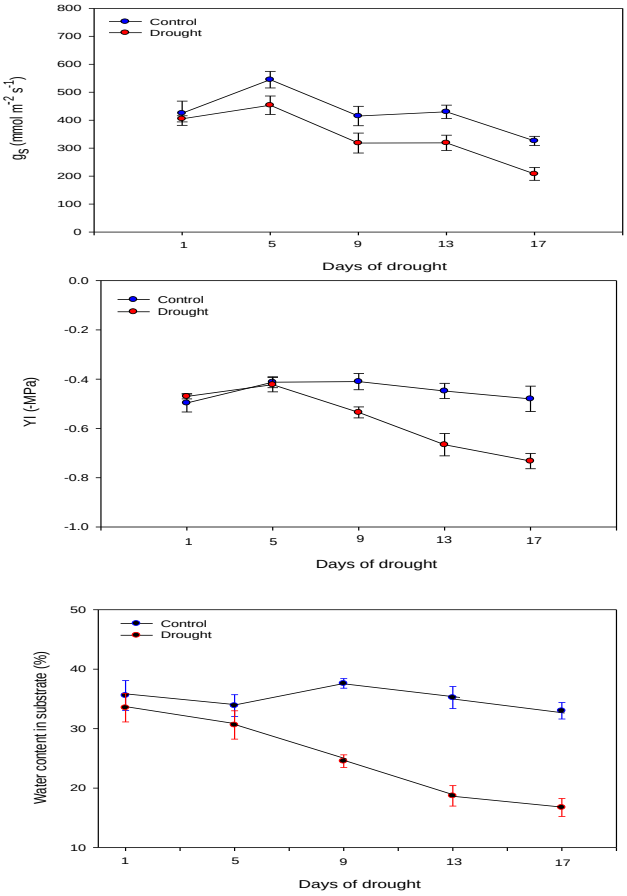

Fig. 1. Changes in water content, stomatal conductance (g_s) and leaf water potential (Ψl) in the control and plants exposed to drought during the experiment

During the experimental period, stomatal conductance and leaf water potential in both applied irrigation regimes followed the changes of water content in the substrate. Our results measuring stomatal conductance and leaf water potential was accompanied with a change in water content in the substrate. The results showed that leaf water potential in controlled and plants exposed to drought was similar untill the 5-day (0.41 and -0.42 MPa). Drought caused a statistically

significant reduction in leaf water potential at the end of study where water potential in droughted plants was reached -0.73 MPa which is 34% of reduction compared to control. The results of stomatal conductance in control and drought plants had similar trend as a water potential, an increase up to 5-th day, and decreased at the end of experiments. Maximum values for both, controled and drought exposed plants were at 5-th day (545.0 and 453.6 mmol $m^{-2}s^{-1}$). Stomatal conductance in both treatments decreased untill the end of experiment (326.0 and 208.0 mmol $m^{-2}s^{-1}$). Results showed statistically significant reduction of 37% in stomatal conductance compared to the control. Our results are consistent with the majority of published papers on which the conditions of water deficit has been a reduction of stomatal conductance (Liu et al., 2006, 2008). The results of Liu et al., (2005) showed that the soil drying effect on the reduction of stomatal conductance and leaf water potential of potato, but also increase xylem ABA. Misson et al. (2004) found that g_0 decreases with declining the pre-dawn leaf water potential. In study of Ahmadi et al., (2009) measurements of the leaf water potential on potato resulted that a lower leaf water potential leads to a higher gs .The decrease in stomatal conductance may occur before there is a drop in the substrate water content and leaf water potential. Such reactions of plants indicates a non-hydraulic (chemical) signals of stress.Correlation analysis (Fig.3) found a linear relationship of water potential and stomatal conductance (coefficient of 0.72) and water potential and water content in the substrate (coefficient 0.85), indicating the presence of hydraulic drought signal. By reducing the water content in the substrate there was a decrease in leaf water potential. These results are consistent with studies Tarideu et al., (1996) where the reduction of leaf water potential leads to decrease in stomatal conductance with increasing number of dry days. Also in the later stages of drought we found a positive correlation between water content in the substrate and stomatal conductance (Fig.2) indicating the presence of chemical signals and drought. The correlation coefficient is 0.57 and determined the linear decreasing dependence, the reduction of water content in the substrate was accompanied by a significant decrease in stomatal conductance.

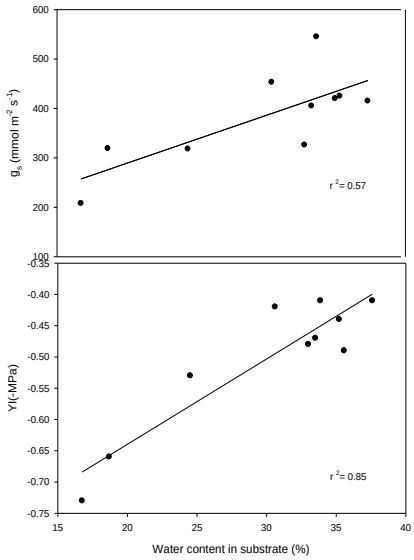

Fig.2. Correlation between water content in the substrate and water potential (A) and water content in the substrate and stomatal conductance (B)

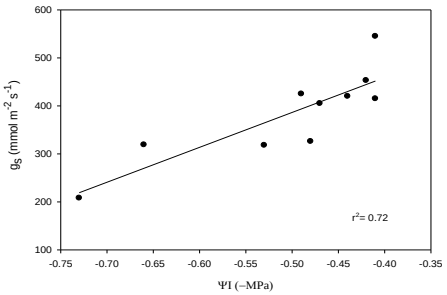

Fig.3. Correlation between stomatal conductance (g_s) and leaf water potential (Ψl)

Growth parameters

During the experiment under controlled conditions, measurement of physiological parameters as leaf area and dry leaf and stem biomass were measured at an early phenological phase of growth.Leaf area was increased in controlled plants the during the entire period and maximum values of 4250 cm^2 were recorded at the end of the experiment (Tab. 1). In plants exposed to drought leaf area was increased until the 9-day and maximum values were 3250 cm^2, and then there was a reduction untill the end of the period, where the leaf area was 2903 cm^2. The t-test showed a statistically highly significant reduction in leaf area in droughted plants by 55% compared to the control.The results show that the leaf dry weight at the beginning of the studies were similar in control and plants exposed to drought (12.4 g and 12.1 g, respectively). During the experiment, there has been an increase in dry weight in controls so that at the end of the experiment, leaf dry weight of the control plant was 24.5 g. In plants under drought conditions there was a decrease in values ranging of 9 days starting with the drought and on the end of experiment they reached a value of 11.0 g. Drought caused a statistically significant reduction in leaf dry mass by 55% compared to the control plants. The results of measurements of stem dry weight at the start of measurements for both control and drought plants were 9.1 g and 8.5 g. Dry weight of stem values were rising to 9-th day for both tested treatments, and then there was a decline in the value of plants exposed to drought increasing the number of days of drought. At the end of the experiment, dry weight of stem plants in plants exposed to drought was 10.25 g, which presents statistically significant reduction of 41% compared to control plants.

Decrease in leaf expansion decrease the use of carbon and energy, and a higher proportion of the plant assimilates is distributed to the root system and support further root development. A reduction of dry weight aboveground portion probably comes because the less inhibited root growth in relation to shoot growth and an increases translocation of biomass from aerial parts of the roots of potatoes. Similar to our results, has recieved Mingo et al., (2004) in studies on tomato. The cause of the reduction in growth under drought conditions, an increase in activity of cell wall hydrolytic enzymes, especially antioxidants (Aganchich et al., 2007), which can induce or cause lignification inactivation of auxin leading to suspension growth.

Table 1. Results of plants leaf area, dry weight of leaf, dry weight of stem in the control and plants exposed to drought

Days of drought	Leaf area		Dry weight of leaf		Dry weight of stem	
	Control	Drought	Control	Drought	Control	Drought
1	2350±150.16	2298±298.85	12.4±0.35	12.1±0.10	9.1±0.9	8.0±0.05
5	2969±235.75	2813±186.68	14.1±0.85	14.5±0.50	10.8±0.7	11.3±0.6

13	3950±50.00	3090±239.07	13.0±1.00	18.0±1.00	14.9±0.90	11.55±0.55
17	4250±250.0	2903±119.45	11.0±0.60	24.5±1.50	17.4±0.60	10.25±0.75

Conclusion

In the experiment under controlled conditions results measurements of stomatal conductance and leaf water potential followed a change of water content in the substrate. These results showed that the test plant at the end of the experiment were exposed to a significant degree of drought stress.On the basis of the results of measured water regime parameters (water content in a substrate, leaf water potential and stomatal conductance) and their correlative relationships it was confirmed that the decrease of water content in a substrate caused induction and interaction of both types of signals (chemical and hydraulic signals).

The results of measurements the parameters of plant growth showed that in plants exposed to drought significantly decreased plant biomass that can be explained by reduction of dry weight of plants and plant leaf area.Measurement results showed that the drought has led to a reduction that is probably due to the translocation of dry matter to the roots, as well as the reduction of leaf area. The results investigated plants growth parameters are indirectly indicate that the effect of the drought influenced assimilate synthesis and partitioning, which is of importance for understanding the impact of drought on the yield of the tested plants.

Abstract

The removal of sugar beet haulm is a topical research-and-technology problem of the sugar beet growing industry. Solving it would facilitate a considerable increase in sugar yield per hectare of the harvested crop acreage. The use of haulm as a source in the biogas production further increases the priority of this problem. Therefore, finding an optimal design and kinematic parameters of anew feeling unit for the standing root scalper on the basis of a theory onthe impact interaction between apassive feeler and standing beet root crowns during their scalping is a high-priority task for scientists. This paper presents new analytical research onthe process of interaction between the passive feeler and the beet root crown. Thus, the impact momentum has been determined and the conditions needed for the effective feeling and scalping of the standing root's crown without dislodging the root from soil have been established. The numerical calculation of the derived analytical expression performed on a PC has facilitated the plotting of a curve, which shows the efficient root crown feeling to be at a travelling speed of $V = 2$ m s^{-1}and a comb feeler elevation angle of $\alpha = 0.3$ rad (or 17°).

Keywords: *sugar beet root, harvesting, scalper, modelling, constructive and kinematic parameters.*

Introduction

Today's sugar beet root harvesting technologies involve initial chopping of the bulk of the haulm followed by final scalping of the standing root's crown prior to lifting the root from the soil (Gu et al., 2014; Sarec et al., 2009; Wang & Zhang, 2013; Wu et al., 2013). Therefore, the efficient performance of the majority of beet harvesters depends on how sensitively and accurately the feeling of the roots standing in the row with their crowns rising to different heights above the soil surface is done (Gruber, 2005; Schulze Lammers, 2011). This applies to most of the haulm gatherers, root crown after-cleaners, scalpers and certain designs of lifting tools (Schulze Lammers&Schmittmann, 2013). In international practice, various mechanical feeling devices are now widely used, which feel the standing beet roots and adjust the elevation of the tools accordingly, as required. They can be passive feelers, active (powered, drum-type) and even combined ones. However, the requirements of achieving the needed performance level under various harvesting conditions, design simplicity and reduced metal and power intensity are not always met.

A lot of studies have recently been published covering the issues of the removal of residual sugar beet haulm after the total topping of the standing roots with the cutting apparatus (Pogorely et at., 1983; Bulgakov 2002, 2011; Bentini et al, 2005; Zhang et al., 2013). These studies dealt with root crown cleaners of different designs: vane, ring, sector and drum as well as paraboloid types. The most widely used standing root crown cleaners are those which do not require noticeably accurate and sensitive feeling of each of the beet root crowns rising to different heights above the soil surface in the row. The processes of haulm harvesting are

largely similar for sugar beet and fodder beet, but only experimental studies have been carried out with regard to fodder beet haulm harvesting (Pogorely&Tatyanko, 2004).
The aim of this study was to find the optimal constructive and kinematic parameters of a feeling unit for the standing root crown scalper on the basis of the development of a theory of the impact interaction between the passive feeler and standing root crowns during their scalping.

Materials and methods

This research used methods of generating mathematical models of operation of agricultural machines and their tools with the use of fundamental provisions of mathematics and theoretical mechanics, principles of program construction and numerical computation on PCs..
We have developed a new passive-type design of standing sugar beet root crown scalper. Its design and process flow schematic model are presented in Fig. 1. It comprises frame 1 rigidly attached to the rear part of the main frame of the haulm gatherer (which performs total chopping of the bulk of the haulm with no prop and no feeler) above each row of root crops and vertical support 2 with the tools, which is connected to frame 1 by two pairs of link rods 3 and 4 in the parallelogram linkage. Link rod 3 has a screw mechanism to adjust its length. Vertical support 2 holds passive runner-type feeler 5 attached to its bottom at an adjustable elevation angle of α and flat passive knife 6 with a length of l attached behind the feeler and vectored at an angle of γ to the line of travel (V). All moving members of the scalper are connected to each other with hinge joints 8, while link rods 3 and 4 are in addition connected with spring mechanism 7.

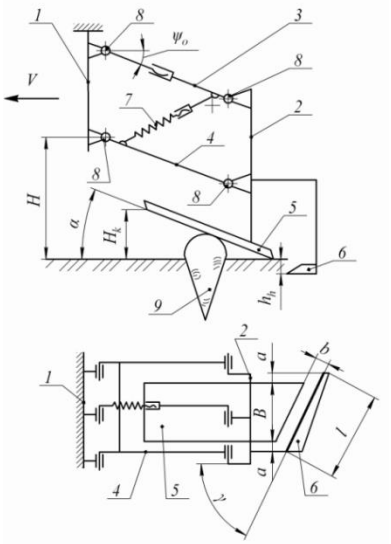

Fig. 1.Design and process flow schematic model of the root crown scalper: 1 – frame, 2 – support; 3 and 4 – link, 5 – passive runner-type feeler, 6 – flat passive knife, 7 – spring mechanism, 8 – hinge, 9 – root.

The root crown scalper operates as follows. During its movement along the planted row of sugar beet roots, feeler 5 runs into root 9 and while travelling over its crown raises vertical support 2 with knife 6 upwards. By the time, when the rear part of the feeler reaches the tip of the crown, knife 6 finally settles at the needed scalping height. During the following translational movement of the scalper, knife 6 scalps flat the root crown.
Depending on the clearances h_h and b, the root crown scalping height changes. The values of the clearances are stipulated by the statistical sizes of the sugar beet roots and adjusted individually for each beet field. Spring mechanism 7 is employed to dampen the galloping of

the scalper's moving part, when it travels over the root crowns reaching different heights, – it presses feeler 5 down to root crown 9.

Based on the statistical dimension and mass properties of the sugar beet roots and their positions in the planted rows, some of the main design parameters of the scalper can be assumed as required by the design or calculated using relatively simple established dependencies. Thus, the feeler's width B is assumed to be within B = 160…210 mm; H_k – feeler 5 front end setting height is selected to be greater than the elevation of sugar beet root 9 above the soil surface level and it cannot be less than 150...170 mm; H – elevation of lower hinge joint 8 in the parallelogram carrier is selected in accordance with the design and it must be within 250...350 mm. At the same time, the elevation H must be sufficient to provide a haulm gatherer transport clearance of at least 300 mm. The length of feeler 5 depends on the maximum elevation of root crown 9 and can be determined using the following dependency:

$$L_k = \frac{H_k}{\sin\alpha} \quad (1)$$

The vertical clearance h_K between knife 6 and feeler 5 depends on the elevation of the beet root crown and must be within 10...50 mm. The horizontal clearance b between feeler 5 and knife 6 depends on the maximum diameter of the crown of root 9 and ranges within b = 0...80 mm. The angle γ must ensure secure sliding of the scalped root crown and other crop residues off the blade of knife 6. This can be found from the following formula:

$$\gamma = 90^o - \varphi, \quad (2)$$

whereφ – angle of repose of haulm on the knife blade $45^o > \varphi > 40^o$.

The length l of knife 6 can be derived from the following dependency:

$$l = \frac{B+2a}{\cos\varphi}, \quad (3)$$

where$a$ – overlap of knife 6 and the width of feeler 5, selected according to the design.

The effective operation of such a design of haulm gatherer can be expected only when the force parameters of the interaction between the passive feeler and the root crown comply with the requirement to avoid dislodging the latter from the soil in the course of operation and ensure minimum damage of the roots under high travel speed.

In the next section we build a mathematical model of the interaction between a passive feeler and a root crown rigidly fixed in the ground. As the operation of a scalper always involves the feeler striking at the root crown, it would be necessary to study the effect that the design and force parameters of the scalper have on its performance quality.

Theory and modelling

Let's analyse the process of interaction between the passive feeler and the root, when the former moves along the planted row of sugar beet and makes contact with the latter's still standing crown at point A (Fig. 2). It is assumed that the feeler inclined at an angle α to the horizontal strikes the beet root crown during its translational movement.

Let's find the total force Q acting on the beet root crown, when the feeler strikes it. The force will be equal to the algebraic sum of the projections of all forces applied at contact point A on axis n:

$$Q = F_{s.t.} + mg\cos\alpha + P_n + F \quad (4)$$

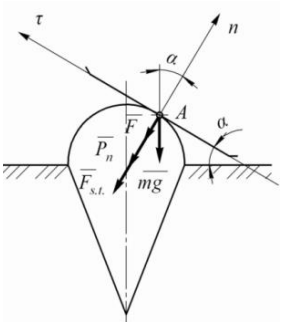

Fig. 2. Force diagram of interaction between passive feeler and beet root.

Now we are going to generate the differential equation of motion of the feeler running into the beet root crown. According to the fundamental law of dynamics (Dreizler&Lüdde, 2010), the following differential equation can be given:

$$m\frac{d\bar{V}}{dt}=\bar{Q} \qquad \text{or} \qquad m d\bar{V}=\bar{Q}dt \tag{5}$$

where*m* – reduced mass of the beet root crown scalper at point A.
Taking the integral of equation (6) from $t = 0$to $t = \tau$,(whereτ– time of action of the impact), we obtain:

$$\int_{\bar{V}_p}^{\bar{V}} m\, d\bar{V}=\int_0^{\tau}\bar{Q}\,dt \tag{6}$$

or

$$m\left(\bar{V}-\bar{V}_p\right)=\int_0^{\tau}\bar{F}_{s.t.}\,dt+\int_0^{\tau}\bar{P}_n\,dt+\int_0^{\tau}\bar{F}\,dt+\int_0^{\tau}\overline{mg}\cos\alpha\,dt, \tag{7}$$

whereV_p – the feeler's speed before the impact; V – the feeler's speed after the impact.
According to the mean value theorem from the integral calculus course (Pogorely et al., 1983), the following can be derived:

$$m\left(\bar{V}-\bar{V}_\rho\right)=\int_0^{\tau}\bar{F}_{s.t.}\,dt+\bar{P}_{n.med.}\cdot\tau+\bar{F}_{med.}\cdot\tau+\overline{mg}\cos\alpha\cdot\tau, \tag{8}$$

where$P_{n.med..}$ – mean value of force P_n on interval [0, τ]; $F_{med..}$– mean value of force Fon interval [0, τ].

As $\tau \to 0$ in case of an impact, we have:

$$m\left(\bar{V}-\bar{V}_p\right)=\bar{S}+\lim_{\tau\to0}\bar{P}_{n.med.}\cdot\tau+\lim_{\tau\to0}\bar{F}_{med.}\cdot\tau+\lim_{\tau\to0}\overline{mg}\cos\alpha\cdot\tau, \tag{9}$$

where impact momentum

$$\bar{S}=\lim_{\tau\to0}\int_0^{\tau}\bar{F}_{s.t.}\cdot dt \tag{10}$$

The three last limits in expression (9) are equal to zero, because $P_{n.med.}$and$F_{med.}$vary arbitrarily, while force $mg\cos\alpha$ does not change at all, hence, in time interval [0, τ], where $\tau \to 0$, we can consider them to be almost constantly finite quantities.

Thus, taking into consideration expressions (10), we finally obtain:

$$m\left(\bar{V}-\bar{V}_p\right)=\bar{S} \tag{11}$$

where$S$ – impact momentum vector directed along the common normal line n drawn through the feeler and the root crown at contact point A.

If we know such values as ε – coefficient of restitution for the impact of the feeler on the root crown and α – angle between the impact direction and the feeler plane, then we can find the impact momentum in accordance with the established theory of impact (Bulgakov, 2002).

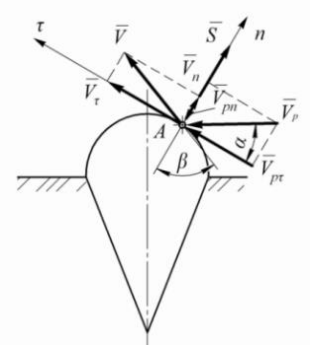

Fig. 3.Equivalent schematic model of impact of the feeler on a beet root crown.

To find them, let's examine again the impact of the feeler on the root crown. We have drawn an equivalent schematic model, in which a system of coordinates $A\tau n$ is shown as well as the vectors of speed before and after the impact of the feeler on the root crown (Fig. 3). In this model, as mentioned earlier, V_p– the feeler's speed before the impact; V – the feeler's speed after the impact; S – impact momentum vector.

After mathematical transformations, we obtain the following equations:

$$\varepsilon = \frac{V_p \cos\alpha \cos\beta}{V_p \sin\beta \sin\alpha} = \frac{\cos\alpha}{\cos\alpha} \cdot \frac{\cos\beta}{\sin\beta} = \frac{\cot\beta}{\tan\alpha} \qquad (12)$$

if $\cot\beta = \varepsilon\tan\alpha$, then $\beta = \cot^{-1}(\varepsilon\tan\alpha)$;

$$S = m(1+\varepsilon)V_p \sin\alpha \qquad (13)$$

where$m$ – reduced mass of the beet root crown scalper at point A,

$$F_{s.t.} \approx 6m(1+\varepsilon)V_p^2 \sin\alpha, \qquad (14)$$

where$m$ – reduced mass of the scalper at point A; ε – coefficient of restitution; V_p – travelling speed; α – feeler's elevation angle, and

$$\alpha = \arcsin \frac{-(P_n + F) + \sqrt{(P_n + F)^2 + 240\, m(1+\varepsilon)V_p^2}}{12m(1+\varepsilon)V_p^2}. \qquad (15)$$

Results and discussion

Thus, we have analytically found the law that allows us to determine the optimal kinematic and design parameters for the feeling unit of a standing root crown scalper. To put these equations to use it is necessary to know the reduced mass of the scalper – m, the coefficient of restitution of the feeler striking on the beet root crown – ε, and the forces – P_n and F, which will depend on the specific engineering solution.

Now we can carry out the numerical calculation of expression (15). The calculation will be based on the following values of the constituent parameters: P_n = 98 N, F = 18 N, m = 18 kg, ε = 0.72. Considering the condition $0 < \alpha < \pi/2$, we obtain the interval $0 < \alpha < 1.006$ rad or 0

$<\alpha<$ 57.667°, on which effective values of the speed V_p exist. The curve generated as a result of the numerical calculations is presented in Fig. 4, where the values of angle α in radians are shown.

From the graph in Fig. 4, we can conclude that the efficient feeling of root crowns takes place at a travel speed of V = 2 m s^{-1}and a comb feeler elevation angle of α = 0.3 rad (or 17°).

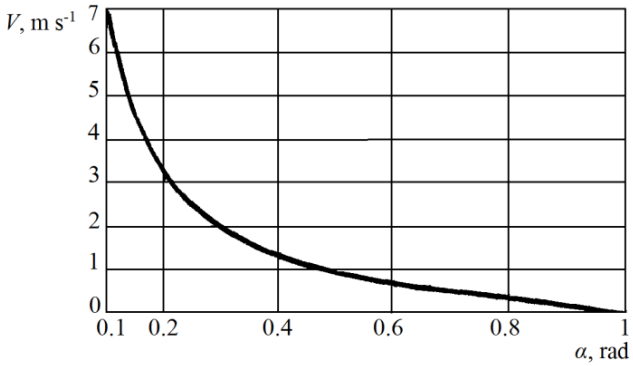

Fig. 4. Relation between feeler elevation angle α and translational motion speed V_p (Bulgakov, 2002).

We have tested the operating efficiency of the new design of the sugar beet root crown scalper experimentally under field conditions. Fig. 5 shows the appearance of a row of roots after the scalper made a pass along it (the white line shows the centre line of the planted row of sugar beet).

It has been found that, despite the impact interaction between the passive feeler and the beet root, dislodging of the latter from the ground is virtually absent.

Meanwhile, the main measure of quality of the scalper's operation is the amount of the tops left on the beet root crowns, which in the test were collected from a unit of area of the planted row equal to 1 m^2 and weighed on electronic scales.

Fig. 5.Row of sugar beet roots after scalping.

The results obtained from the field trial and processed on a PC enabled us to plot diagrams that showed the dependencies between the amount of the haulm (uncut parts) left on the root crowns after their scalping and the design and kinematic parameters (Fig. 6). The angles of inclination of the passive feeler of the root crown scalper were set within a range of α = 15…17^o, the cutting height varied within a range of 0.03…0.12 m, while the translational movement speed V changed from 1.2 m s^{-1} to 2.0 m s^{-1}.

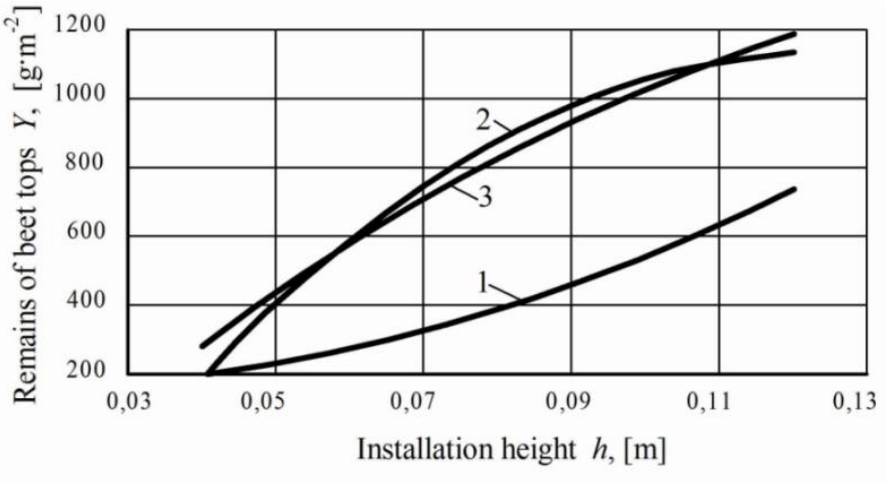

Fig. 6. Amount of haulm left on beet roots *Y*as a function of preset cutting height *h* and translational movement speed *V*: 1 – *V*= 0.7 m s^{-1}; 2 – *V*= 1.2 m s^{-1}; 3 – *V*= 2.0 m s^{-1}.

Figure 6 shows that the dependencies of haulm remaining on installation height and speed were close to linear. When the cutting height *h* was set below 0.03 m, the scalper became virtually inoperative; hence, the lowest value of this design parameter should be within a range of 0.05 m to 0.07 m. Using other values of this design parameter resulted in a considerable increase of the amount of haulm (uncut parts) left on the beet root crowns. Although the highest quality of sugar beet root crown scalping with the removal of haulm remains was achieved at a scalper travelling speed of 0.7 m s^{-1}, the process parameters stipulate that the working speed (which has to conform with the haulm gatherer's working travelling speed) should be close to 2.0 m s^{-1}, which would increase, the amount of haulm left on the root crowns.

The overall measures of quality of the sugar beet root crown scalping performed by the new design scalper were, according to the results of the field experimental studies, as follows: root dislodging from soil – 0…0.5%, root mass loss – 2.0…2.5%, root crown surface damage – 0…1%, amount of normally scalped crowns – 95…98%.

Conclusions

A new design of standing sugar beet root crown scalper has been developed, its experimental analysis and field testing have produced positive results supporting the operating efficiency and high quality of the tool.First, the analytical mathematical model of the process of interaction between a passive feeler and a sugar beet root crown was generated. For this purpose, the force diagram of the interaction between a passive feeler and the spherical surface of a beet root crown and the equivalent schematic model of their impact was drawn out. All forces acting during the impact contact and the speeds before and after the impact were applied at the points of contact in these diagrams. Thereafter, the impact momentum was determined and the conditions needed for the effective feeling and scalping of the standing root's crown without dislodging the root from the soil were established.The numerical calculation of the derived analytical expression performed on a PC facilitated the plotting of a curve, which showed efficient root crown feeling to be at a scalper travelling speed of V = 2 m s^{-1} and its passive comb feeler elevation angle of α = 0.3 rad (or 17°).

The obtained values of the design and kinematic parameters of the scalper that removes the haulm remains off the root crowns allow us to achieve operation quality measures (root dislodging from soil – 0…0.5%, root mass loss – 2.0…2.5%, root crown surface damage – 0…1%, amount of normally scalped crowns – 95…98%).

Abstract

Winter wheat is a very important field crop on the arable lands in Croatia and Bosnia and Herzegovina (B&H).Wheat production is often characterized by significant yield variations, as affected by unfavorable weather conditions. The aim of this study was to analyze wheat yield in relation to weather data (precipitation and mean airtemperature) in Croatia and B&H in the 2012/2013, 2013/2014 and 2014/2015 growing seasons.The data from four meteorological stations in Croatia situated in the east and north of the country and data from four stations in the northern B&H were analyzed. Average wheat yields were 4.9, 4.2 and 5.4 t ha^{-1} (Croatia), and 3.9,2.9 and3.5 t ha^{-1}(B&H),for harvest in 2013, 2014 and 2015, respectively.The 2013/2014 growing season was less favorable for winter wheat growingas precipitationsums in the October-June period were considerably higher compared to the long-term reference mean (1961 – 1990), while mean air temperatures were significantly higher. The main cause of lower yields in 2014 for both countries was excessive precipitation in the period April-June, in some places also accompanied with floods. In the remaining two growing seasons, precipitations in both countries were mainly favorable distributed and temperatures somewhat lower compared to the 2013/2014 season.

Key words:*wheat yield,precipitation, temperature, Croatia, Bosnia and Herzegovina*

Introduction

Winter wheat is a very important field crop on the arable lands in Croatia, where is the second ranked crop, and Bosnia and Herzegovina (B&H) as well.Degree of arable land utilization becomes a serious problem of agriculture in both countries, because significant share of arable land is unfarmed.In the 2001-2010 period, wheat was grown in Croatia on 184 500ha on average with the mean yield 4.42 t ha^{-1}, and on about 74 000 ha in B&H with average yield 3.12 t ha^{-1}. According to the available statistical data (FAOSTAT, 2016, CBS, 2016) yield variations among years for mentioned ten year period were from 2.96 to 5.50t ha^{-1} in Croatia and from 2.26 to 3.78 t ha^{-1} in B&H.Such yield variation is attributed to weather conditions, especially precipitation and temperature regimes. The lower yields of wheat are usually connected to precipitation deviation, either by excessive precipitation in autumn/winter period or drought periods in growth stages from stem elongation to ripening (Dencic*et al*., 2000; Gupta *et al*., 2008; Marijanovic*et al*., 2010; Pepo and Kovacevic, 2011; Jolankai and Birkas, 2013;Majdancic*et al.*, 2016).Variation of yields among years is also associated with recently climate change which has often adverse influences on field crops yields (Adams, R. M.*et al*., 1998; IPCC, 2007; Kovacevic*et al*., 2013).

Aim of this study was survey of wheat yield in relation to weather data (precipitation and mean air-temperature) in Croatia and B&H in the 2012/2013, 2013/2014 and 2014/2015 growing seasons with emphasis on climate change.

Material and methods

Meteorological data, precipitation and mean air-temperatures were provided by courtesy of State Hydrometerological Service in Zagreb (Croatia), Federal Hydrometeorological Institute in Sarajevo (entity of Federation of Bosnia and Herzegovina) and Hydrometerological Institute of Republic of Srpska in Banja Luka (entity of Republic of Srpska, Bosnia and Herzegovina).Data were collected from eight meteorological stations of which four are in Croatia (Osijek, Bjelovar, Sisak and Varaždin), and four in B&H(Bijeljina, Tuzla, Banja Luka and Bihać). Those towns are situated in the east, the central and the north part of Croatia in Pannonian region and in northern Bosnia, representing the main wheat growing area in both countries. Meteorological data were compared with reference long term mean (1961-1990). Database of FAOSTAT and Croatian Bureau of Statistics were used as sources of data forwheat harvested areas and yields for analyzed period.

Results and discussion

The average wheat harvested area in Croatia in the decade 2001-2010 were 184 500 ha, while in the last three year period 2013-2015 it was about 167 000 ha or by 10% lower, indicating decreasing trend of wheat growing. In B&H also some reduction of wheat growing area is present (Table 1). It can be observed that higher wheat yield is achieving in Croatia as average wheat yield in the decade period were 4.42 t ha^{-1} in Croatia, while 3.12 t ha^{-1} in B&H. In the analyzed three-year period, average yields of wheat were also byalmost 30 % higher in Croatia. Great yield variability was found, not only between countries, but also among three years, especially in the last growing season. Average wheat yield in the 2015 in Croatia was quite above average (5.4 t ha^{-1}) andby 22% highercompared to the previous ten-year mean, while in the 2014 it was 4.2 or by 5% lower. The highest annual yield of wheat in B&H inanalyzed three-year period was 3.9 t ha^{-1} in 2013. The lowest yield in both countrieswas recorded in 2014 (Table 1).

Table 1. Arable land and gardens (ALG), wheat harvested area (ha) and wheat yields (t ha^{-1}) in the growing seasons 2012/2013 to 2014/2015 and averages for the 2001-2010 period in Croatia and Bosnia and Herzegovina

Year of wheat harvest	Croatia			Bosnia and Herzegovina		
	ALG	Wheat		ALG	Wheat	
	ha	ha	t ha^{-1}	ha	ha	t ha^{-1}
Mean 2001-2010	859 800	184 500	4.4	1 014 800	73 700	3.1
2013	874 800	204 500	4.9	1 010 000	67 600	3.9
2014	811 100	156 100	4.2	1 011 000	67 600	3.0
2015	841 900	140 700	5.4	1 029 000	61 900	3.5
Mean 2013-2015	842 600	167 100	4.8	1 016 667	65 700	3.1

The analyzed region is characterized by typical continental climate (Bertić, 1987). Precipitation quantities are increasing from the east to the west and from the north toward south, what was confirmed also in our study. Long-term mean (LTM) values of precipitation in October-June period for diagonal-positioned towns Osijek (NE point) and Bihać (SW point) is 482 mm and 982 mm, respectively (Table 2). In the lowland area of the northern Croatia there is tendency of temperature decreasing from the east toward to the west (Osijek 7.9°C and Varaždin 7.2°C), while in the tested sites of B&H this tendency is somewhat lower (Bijeljina 8.3°C and Bihać 8.0°C).

In accordance with global warming, three growing seasons included in our study were warmer compared to LTM in average by 1.2°C, 2.4°C and 1.9°C, respectively (averages of all eight sites for the October-June period). Increased mean air-temperatures are recorded in all months

of winter growing season, but they were particularly high during winter period (Table 3).At the same time, precipitation was higher byaround 20 % in all three growing season (Table 4).

Table 2. Reference values of long-term means (LTM; 1961-1990) for precipitation (mm) and mean air-temperatures (°C) in selected sites in Croatia and B&H

LTM (1961-1990)		Month of wheat growing season									Sum (mm)/ Mean (°C)

	°C	11.3	6.3	1.7	0.3	2.3	6.1	10.7	15.1	18.3	8.0

Sum of precipitation and theirs monthly distribution was different among analyzed localities and years (Table 3), but the 2013/2014 growing season was very specific regarding winter wheat growing andless favorable compared to the other two season. Consequently, in both countries the lowest yield was achieved in the 2014 (Table 1).Precipitation and temperature in the October-June period for this season quite deviated from LTM, especially regarding precipitation distribution, so the main cause of lower yields in 2014 for both countries was excessive precipitation in the period April-June, in some places also accompanied with floods. The greatest deviation was found for Tuzla region, where in that three-month period was recorded more than a double sum of precipitation in comparison with reference LTM (590 *vs.* 279 mm). In Banja Luka precipitation was higher by 79 %, inBijeljina by 71 %, in Osijek by 66 %, and in Sisak by 59 %.In the east Croatia wheat yield reduction is usually associated to precipitation surplus during autumn and winter period or drought stress in the spring period (Iljkić*et al*., 2010.). The least affected regions by the flood or excessive water supply were the areas of Bihać in B&H and Varaždin in Croatia (Table 3).

At the same time, in 2013/2014 growing season mean air-temperatures were unusually high, particularly during winter and early spring period from December to March. It is well known that in typical continental climate January is the coldest month with mean temperatures around or below 0 °C (Table 2), but in 2014 the mean value of air temperature forthat month in all eight analyzed localities ranged from 4°C to more than a 6°C (Table 4). Values of mean air-temperatures for that growing season varied from 9.8 °C (Varaždin) to 10.4 °C (Bijeljina, Banja Luka).

Wheat top dressing with nitrogen as well as protection from weeds and diseases are applied later, due to long rain periods.

In the remaining two growing seasons, in both countries precipitation was mainly favorable distributed and temperatures something lower compared to the 2013/2014 (Tables 3 and 4).

Table 3. Monthly values of precipitation in eight selected sites in Croatia and B&H during winter wheat growing seasons 2012/2013 to 2014/2015

Locality	Year	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	June	Sum (mm)

Bijeljina	2012/13	52	62	5	58	63	74	28	182	57	581
	2013/14	62	69	4	31	36	73	83	252	67	677
	2014/15	56	13	76	58	63	74	28	182	57	607
Tuzla	2012/13	72	34	89	82	80	80	31	168	74	710
	2013/14	58	96	2	29	39	72	187	339	64	886
	2014/15	94	23	76	77	101	142	211	217	236	1177
Banja Luka	2012/13	88	78	146	94	116	89	63	120	54	848
	2013/14	68	156	1	52	74	91	214	218	97	971
	2014/15	117	42	83	111	91	79	54	118	61	756
Bihać	2012/13	130	166	193	169	221	160	88	98	73	1298
	2013/14	107	339	20	92	176	144	187	199	87	1351
	2014/15	189	101	97	61	70	139	218	225	295	1395

Precipitation in the October-June period in 2012/2013were lower in the east-positioned Bijeljina, Osijek and Tuzla (average 656 mm) compared to the remaining five towns (average 928 mm), particularly in Bihać (1298 mm), while values of mean air-temperature ranged from 8.2 °C in Varaždin to 9.8 °C in Bijeljina. However, in the remaining six towns, mean air-temperature was higher with range from 8.9 ^{o}C to 9.5 ^{o}C. In that season, the highest yield in B&H is achieved (3.9 tha^{-1}) or by 25 % higher compared to the decade (2001-2010) average (Table 1).

In general, the growing season 2014/2015 was the most suitable for wheat growing in Croatia compared to the previous two season, and very high average wheat yield achieved (Table 1), while in B&H excessive precipitation in some places (Tuzla 1177 mm and Bihac 1395 mm)probably led to reduced yields in B&H. For example, precipitation in the same period in Osijek, Bjelovar,Sisak and Varaždin was lower (Table 3). Regarding the temperature regime, in Tuzla was something colder (mean 9.0 ^{o}C) than in remaining towns (from 9.4 ^{o}C in Varaždin to 10.0 ^{o}C in Sisak). Weather conditions were more favorable for wheat growing particularly in the eastern part of Croatia. For this reason, average yields of wheat in some places in the east Croatia were about 8.0t ha^{-1}to more than 9 t ha^{-1}(personal communication).

Table 4. Monthly values of mean air temperatures in eight selected sites in Croatia and B&H during winter wheat growing seasons 2012/2013 to 2014/2015

	2013/14	13.6	7.1	3.6	6.4	6.0	9.0	12.3	14.9	19.5	10.3
	2014/15	13.5	9.7	4.8	4.0	1.2	7.1	11.6	17.3	20.0	9.5

Conclusions

Great wheat yield variability was found, not only between countries, but also among three analyzed growing season. Yields of wheat in Croatia and B&H are under considerable impacts of weather characteristics, mainly precipitation and temperature regimes.In general, balanced monthly distribution as well as temperature regime without excessive cold or warm periodscharacterized favorable growing seasons, whereas precipitation deviations toward extremes in combination with the higher temperatures in the winter and/or spring are accompanied with the lower yields.The main cause of lower yields in 2014 for both countries was excessive precipitation in the period April-June, in some places also accompanied with floods. Generally, higher wheat yield is achieving in Croatia.

Abstract

The majority of smallholdersin Bosnia and Herzegovina (B&H), who areengaged in fruit production,have a lack of experience regarding irrigation in general.Irrigation systems are usually installed without proper guidelines, design, operation and maintenance practices andfarmers are not familiar with scheduling techniques and proper management. This often results in poor irrigation efficiency and unsustainable production. Due to increasingly common transfer from extensive to intensive production systems and theincreased frequency of drought periods, especially during the vegetation months, fruit producers in the central-eastern, hilly areas of B&H are becoming increasinglyaware of the importance of irrigation.

To resolve the previously mentioned issues, we propose a simple tool for real-time irrigation scheduling called *Irrigation Charts*. These charts are based on the *Food and Agriculture Organization* (FAO) methodology for computing crop water requirements, which considers crop characteristics, length of the growing season, soil properties and climate data (precipitation, temperature, humidity, insolation and wind speed). The charts for day-to-day apple irrigation guide the usershow to adjust the irrigation interval to the actual weather conditions throughout the growing session. As the pilot study, irrigation charts for intensive apple production atthe central-eastern hilly areasof B&H were developed by using climate data from four meteorological stations: Zenica, Sarajevo, Goražde and Foča.With Irrigation Charts, apple producers will be able to achieve better irrigation efficiency, better quality and quantity of yields, leading tobetter and sustainable position in the local market.

Keywords:*Irrigation, Chart, Irrigation calendar, Scheduling, Apple.*

Introduction

The performance of apple in terms of crop yield, fruit size, fruit quality, storability, and long-term productivity are highly dependent on irrigation and irrigation management. Irrigation level and water status are known to affect yield and yield components: crop yield, fruit size and quality, growth habit, precocity, and long-term productivity (Steduto, et al., 2012).

To avoid crop water stress, the root zone depletion should not exceed the threshold value for no stress (lower limit). If so, the depletion will be larger than readily available water (RAW) and the crop will experience water stress. On the other hand, to avoid water losses, the soil water content in the root zone after an irrigation event should not exceed field capacity (upper limit). By altering the irrigation interval during the season, one is able to keep the root zone depletion between the lower and upper limit (Reas, et al., 2002).

In Bosnia and Herzegovina (B&H) agriculture is highly vulnerable to climate change. Higher temperatures and changes in precipitation are reducing crop yields and increasing the likelihood of short-term crop failures and long-term production declines (Žurovec, et al.,2015). The positive linear trend of soil moisture deficit that have recently had its record value (315 mm in 2012) was determined in central B&H, indicating the urgent need to start with climate change adaptation, otherwise, agriculture of the area and therefore the people engaged in it, will face significant negative consequences (ŽurovecJasminka, et al.,2015).

Due to increasingly common transfer from extensive to intensive production systems and the increased frequency of drought periods, especially during the vegetation months, smallholder fruit producers in the central-eastern, hilly areas of B&H are becoming increasingly aware of the importance of irrigation. Due to the lack of experience, their irrigation systems are usually installed without proper guidelines, design, operation and maintenance practices and farmers are not familiar with scheduling techniques and proper management.

In this paper, we outline a methodology to develop, present and use irrigation scheduling charts (calendars) that give smallholder farmerssimple guidelines on how to adjust their irrigation during the growing session to the actual weather conditions.

Irrigation charts are based on information concerning the actual weather conditions, local and technical aspects of the used irrigation systems and the crop response to water. The combination of all these information results in an irrigation calendar that is specific for a given location and adjustable to the actual weather conditions (Jabloun, et al., 2007).

Materials and methods

In this paper, tool for real-time irrigation scheduling called *Irrigation Charts* (Reas, et al., 2000; 2002; Jabloun, et al., 2007) was used to create apple irrigation calendars. These calendars are based on the *Food and Agriculture Organization* (FAO) methodology for computing crop water requirements (Allen, et al., 1998), which considers climate data, crop characteristics, length of the growing season and soil properties.

The development of irrigation calendars requires a good knowledge of the meteorological conditions of the region, especially the reference evapotranspiration (ETo) levels that can be expected in a 10-day period.

The ETo is derived from monthly climatic data of the central-eastern B&H by means of the FAO Penman-Monteith equation (Allen et al. 1998) usingFAO *EToCalc* software. Irrigation calendars are created throughout a soil water balance technique using *CROPWAT* 8.0 (Smith, et al., 1994) software.

Apple varieties Idared (I) and Gala (G) are chosen for this research, which are frequently grown in the study area. The data on the lengths and start dates of vegetation periods were collected at producers' fields. Crop evapotranspiration (ETc) is calculated by multiplying ETo by Kc for certain apple growth stage.We used FAO crop coefficients for mature apple trees in intensive production, with active ground cover in thearea with killing frosts (Allen et al., 1998).

To represent the meteorological conditions for the central-eastern hilly areas of B&H,we used the data from meteorological stations (MS)Zenica, Sarajevo, Goražde and Foča (Table 1), provided by *Federal Hydrometeorological*and *Republic Hydrometeorological Institute*.

Table 1. Location and length of time series for used meteorological stations (MS)

MS	Longitude	Latitude	Altitude	Used time series	No. of years
Zenica	17° 54´	44°12´	344m.a.s.l	1966-2015	50
Sarajevo	18° 25´	43°52´	630m.a.s.l	1966-2015	50
Goražde	18° 59´	43° 40´	345m.a.s.l	1972-91	20
Foča	18° 48´	43° 30´	260m.a.s.l	1962-63; 1986-90; 2006-2015	17

Rainfall and ETo levels that are expected in 2 (2/10), 4 (4/10), 6 (6/10) and 8 (8/10) years out of 10, were statistically derived from the 10-day rainfall and ETo records with the help of *RAINBOW* (Reas, et al., 1996) software. By combining various probability levels of ETo and rainfall, four weather conditions are distinguished; hot weather conditions without any rainfall (2/10 ETo and no rain), dry (4/10 EToand 8/10 rain), normal (mean ETo and rain) and humid (6/10 ETo and 2/10 rain) weather conditions.

The critical depletion or factor p is a function of the evaporation power of the atmosphere and it depends of ETo level. In this study, p was calculated based on methodology by Allen et al. (1998), for all four ETo levels.
Soil characteristics in the analyzed area are represented through available water content in one meterlayer amounting 200 mm of totally available water (TAW), which is in average 100 mm of RAW.At the beginning of the vegetation period, the soil water content is considered to be at field capacity (FC) as a result of a pre-irrigation or spring rainfall.
The charts are developed for drip irrigation, which is the most frequently used method of irrigation in intensive apple orchards in the central-eastern hilly areas of B&H.
For the design of apple irrigation scheduling charts, the application depth is considered as fixed. Fixed application depths in combination with a variable irrigation interval results in an efficient use of the irrigation water (Reas, et al., 2000). Since the net irrigation water requirement during the peak period at this area is about 7 mm/day, 70 m^3/ha is selected as the net application depth in this study. The gross application depth, the irrigation depth applied by the producers, will be determined in an operation phase when irrigation efficiency at field level will be considered.

Results and discussion

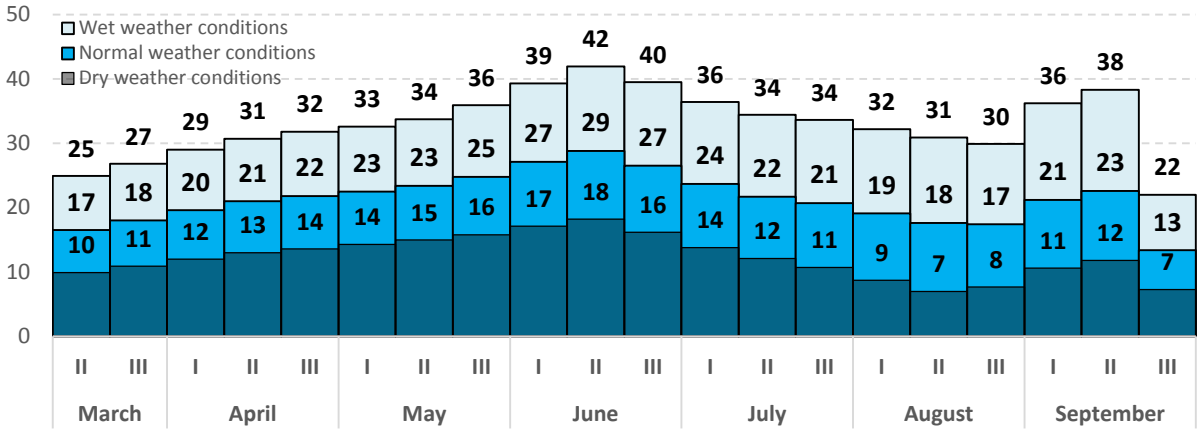
The used crop coefficients (Kc_{ini}.,Kc_{dev}.,$Kc_{mid.}$ and Kc_{end}) and field collected data on length of the growing stages for four locations and two varieties are presented in table 2.

Table 2. Crop coefficients (Kc) and their starting dates for apple growth stages

Location	Variety	Kc for growth stage				Total (days)
		Kc_{ini}	Kc_{dev}	Kc_{mid}	Kc_{late}	
		0.5	0.5-1.2	1.2	1.2-0.95	
		Growth stage (date)				
Zenica	I	16.04.	01.05.	14.06.	16.09.	166
	G	09.03.	30.04.	24.05.	24.08.	175
Sarajevo	I	20.04.	04.05.	16.06.	19.09.	165
	G	10.03.	07.05.	31.05.	26.08.	176
Goražde	I	15.04.	28.04.	11.06.	13.09.	166
	G	08.03.	05.05.	29.05.	23.08.	172
Foča	I	14.04.	27.04.	10.06.	11.09.	165
	G	06.03.	04.05.	30.05.	21.08.	173

The designed irrigation schedule charts (calendars) consist of dependable rainfall graphs (Graph 1-4) and drip irrigation interval tables (Table 3-7). The charts present guidelines for adjusting the irrigation interval to the actual weather conditions for the specific apple varieties (I – Idared; G – Gala) and locations.For the irrigation charts to be used, it is necessary to daily monitor rainfall on field. Simple manual rain gauge can be used to measure rainfall on the field. In order to determine the actual weather conditions, farmer records the daily amounts of rainfall and creates a summarized decade rainfall, which is then compared with dependable rainfall for that decadeon specific location (Graph 1-4).Depending on location, irrigation interval can be used from irrigation interval tables for the previously determined weather conditions (Table 3-7). The orchards should be irrigated according to the interval between two irrigations calculated in the table for the particular weather conditions until the end of that decade or change in weather conditions. In our case, the irrigation interval is the number of days between irrigations, which should settle the irrigation water requirements of 7 mm. The farmer should continue to monitor daily rainfall during the vegetation period and adjust irrigation interval based on actual weather conditions.

For MS Zenica, decade rainfall amounts expected during dry, normal and wet weather conditions are shown in Graph 1. Indicative irrigation intervals are given in Table 3, for the four considered weather conditions in a certain decade and for two apple varieties.

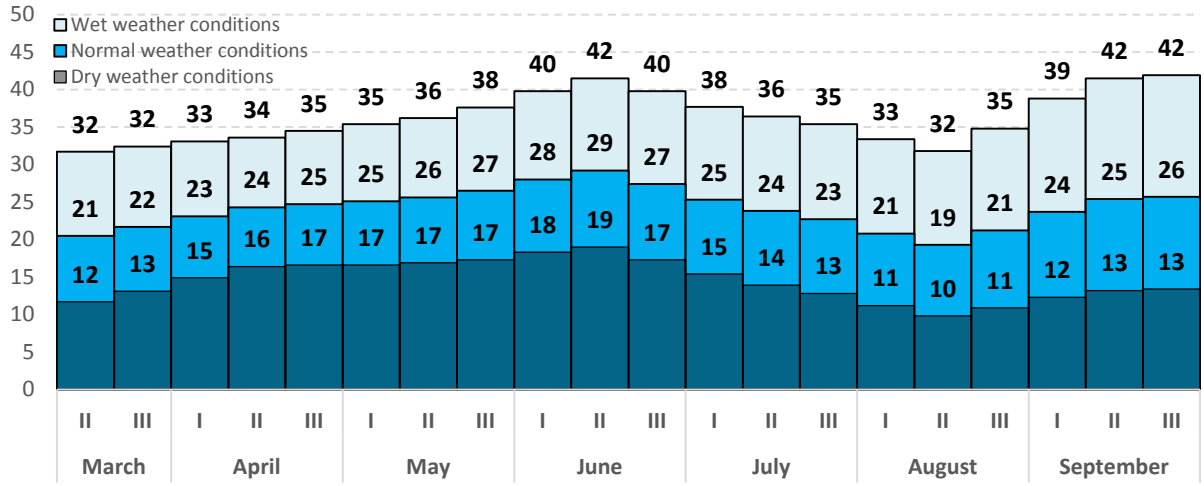


Graph 1. Dependable rainfall at Zenica MS (mm/decade)

Table 3.Apple, drip irrigationintervalsfor MS Zenica in days

	Month	March			April			May			June			July			August			September		
	Decade	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III
Gala	Hot + Dry									2		1					2					
	Dry										3	2	1		2		3					
	Normal												2		3		5					
	Wet																5					
Idared	Hot + Dry									3		1					2			3		6
	Dry										5	2	1		2				3	5		
	Normal												4		3		4		5			
	Wet																5					

For the area of MS Sarajevo, dependable decade rainfall amounts are given in Graph 2, and irrigation intervals for Idared and Gala apple varieties in Table 4.



Graph 2. Dependable rainfall at MS Sarajevo (mm/decade)

Similar values of rainfall for dry, normal and wet weather conditions between MS Zenica (Graph 1) and Sarajevo (Graph 2) are determined.

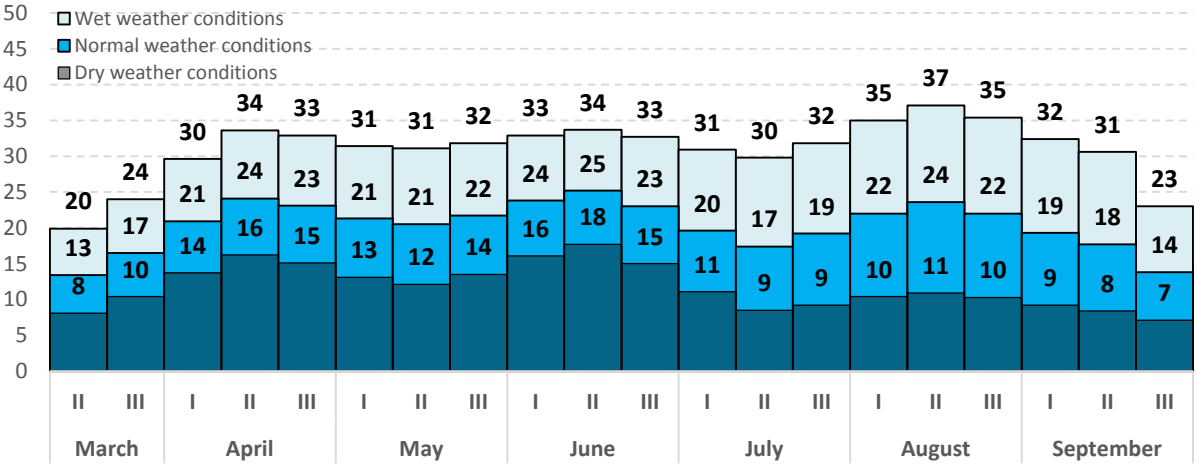
The total length of growing periods of two analyzed apple varieties (Idared and Gala) are differentiated only by few days (165-176), while the growth stages (Table 2) vary sometimes

more than a month.As result, significant differences in the need and intensity of irrigation between apple varietiesare noticeable.

Table 4. Apple, drip irrigation intervals for MS Sarajevo in days

	Month	March			April			May			June			July			August			September		
	Decade	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III
Gala	Hot + Dry									3	1								2			
	Dry												5	2	1	2						
	Normal														5	2	3	4				
	Wet																					
Idared	Hot + Dry												10	2	1					2		5
	Dry													3	2		1	2		3	4	
	Normal															3	2	3		6	10	
	Wet																					

For the area of MS Goražde, dependable decade rainfall amounts are given in Graph 3, and irrigation intervals in Table 5.

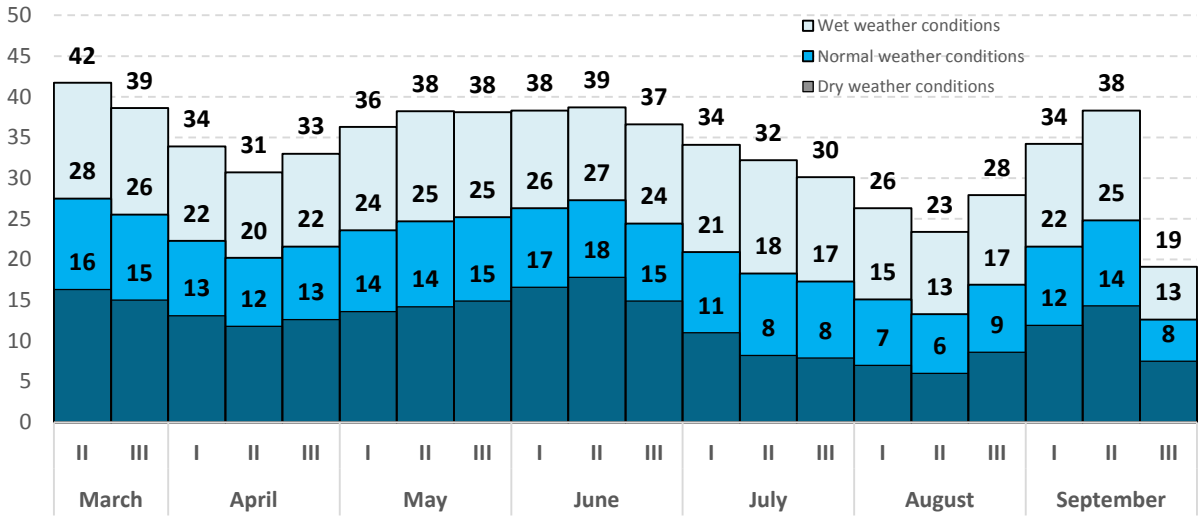


Graph 3. Dependable rainfall at MS Goražde (mm/decade)

Table 5. Apple, drip irrigation intervals for MS Goražde in days

	Month	March			April			May			June			July			August			September		
	Decade	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III
Gala	Hot + Dry									4	1								2			
	Dry												3	1			2					
	Normal													4	2			3				
	Wet														10	3	4	10				
Idared	Hot + Dry										2	1							2	4		
	Dry											2	1				2		8			
	Normal													5	2	1	2	3	4			
	Wet															5		10				

Compared to other MS rainfall for dry, normal and wet weather conditions at MS Foča are slightly lower, especially for August.



Graph 4. Dependable rainfall at MS Foča (mm/decade)

Table 6. Apple, drip irrigation intervals for MS Foča in days

	Month	March			April			May			June			July			August			September		
	Decade	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III	I	II	III
Gala	Hot + Dry									2			1						2			
	Dry										3	2				1			2			
	Normal												5	2			1	2	3			
	Wet															2						
Idared	Hot + Dry												1							2	3	
	Dry											5		1					2	3		
	Normal													2		1			2	3		
	Wet															2				4		

By comparing irrigation intervals between analyzed locations,we can say that the largest needs for irrigation is at the MS Foča. At this location,daily irrigation for both varieties during the normal weather condition is required by the third decade of June and lasts for the next two or three decades. In MS Goražde daily irrigation is required only for Idared and only in the third week of June under normal conditions, while MS Sarajevo and Zenica do not have any decade with daily irrigation requirements.

Conclusion

Based on the analysis of dependable rainfall for four locations, similar values of rainfall for dry, normal and wet weather conditions between MS Zenica and Sarajevowere determined.Compared to them,values for MS Goražde and Foča are slightly lower.

Growing periods of two analyzed apple varieties (Idared and Gala) are differentiated by few days (165-176).However, significant differences in the need and intensity of irrigation are noticeablefrom the irrigation intervals charts.

The largest needs for irrigation is at the MS Foča, where daily irrigation for both varieties during the normal weather condition is required by the third decade of June and lasts for the next two or three decades. In MS Goražde daily irrigation is required only for Idared and only in the third week of June under normal conditions, while MS Sarajevo and Zenica do not have any decade with daily irrigation requirements.

Based on the results of this study, significant differences in the need and intensity of irrigation between locations and varieties in the central-eastern hilly area of B&H highlight the importance of irrigationapproach in the local level and the need ofsimple tools such as the Irrigation Chart.

EFFECT OF LIMING OF THE CONTENT OF TOTAL SUGARS, TITRATABLE ACIDS AND pH IN DIFFERENT WINE GRAPE VARIETIES

Krasimir TRENDAFILOV, Mladen ALMALIEV*

Agricultural University-Plovdiv, Bulgaria
*Corresponding author: mladenalmaliev@abv.bg

Abstract

In a two-year field experiment, the effect of liming with $Ca(OH)_2$ was studied at rates of 1; 2,5 and 5 t/ha on the content of total sugars, titratable acidity and pH in the grapes of varieties Sauvignon Blanc, Chardonnay, Cabernet Sauvignon and Merlot, planted on Chromic luvisols in the land of Mezek village, Svilengrad municipality, Bulgaria. The grapes of all varieties were studied immediately after harvest in technological maturity, simultaneously with the mass harvesting of the variety in the vineyards, where was the lime experiment. Generally in the white varieties, liming causes increase in the level of total sugars. Relatively stable is the tendency to reduce the content of titratable acids, simultaneously with increase of the lime rate. During the second year, increase in the content of total sugars and reduction of the level of titratable acids in the white varieties was found only in the highest applied ameliorative lime rate of 5 t/ha. Liming affects technological indicators of the grapes mainly in the white studied varieties and causes an increase in the content of total sugars and reduce the titratable acidity.

Key words: *Liming, Wine grape varieties, Sugars, Titratable acids*

Introduction

The creation of large vineyards in the wide area of Sakar mountain in southeastern Bulgaria in recent years, and the fact, that the most of them not only entered in active fruiting, but also established themselves as brands of the wine market, has led to expansion of the vineyards area, as a result were planted and areas with limited suitability for this type of production. The soil in these terrains are usually located on hilly areas, which as a result of erosion, there is too wide variety of their properties. This affects the depth of the soil profile, soil texture, amount and type of skeletal materials and their distribution in the depth of the soil profile and other factors with significant impact on the quality of the vineyards. In fact, the diversity of the region in regard to the following characteristics is its essential feature and defines its individuality.

The soil acidity, considered in this context also characterized by very wide variety of the elements, which determining them.

The concept of the chemical amelioration of the vineyards, in the research area must be built precisely on the requirement to provide minimum sufficient calcium and magnesium levels in the soil, which are necessary to overcome the deficit of them as nutrients and ions, defining the point and sustainability of acid-alkaline balance in the soil (Totev and Palaveev, 1979).

The practice of planting large part of modern plantations of vineyards in the country on genetically acid soils, the proven in recent years unfavorable affect of the soil acidity of on the quality of wine grapes (Soyer et al., 1995) and higher requirements of the modern and most often introduced pad combinations to the soil quality (Roberto, et al., 1991) resumed the actuality of this task, and its technological complexity called the need to test new chemical meliorants for liming.

Materials and methods

The studies have been conducted in a two-year field experiment in vineyards in Mezek village, Svilengrad municipality, Bulgaria. The the experiment was set by the method of Shanin, 1965, as in the distribution of the variants was included control variant without fertilization and liming, variant without liming, but with combined nitrogen, phosphorus and potassium fertilization, and three increasing rates of liming with hydrated lime (BS EN 459-1 CL 90-S) - 1, 2,5 and 5 t/ha.

The content of CaO in the used by us hydrated lime, determined after reaction of the starting material with HCl and a subsequent titration with NaOH, at bromtimolblau indicator was 94%. Each variants was in three repetitions. The experiment was set after the end of the third vegetation. All varieties included in the study were planted on the pad Berlandieri X Riparia, selection Openhaim 4 (SO4). Meliorants were applied in the period from August to September. One month after liming were applied phosphorus and potassium fertilizers, in the form respectively of triple superphosphate and potassium sulphate, and nitrogen fertilizer in the form of NH_4NO_3 was applied in February, before the next vegetation.

The grapes of the four varieties were studied immediately after harvest in technological maturity, simultaneously with the mass harvesting of the variety in the vineyards, where was the lime experiment.

Harvested grapes was analyzed to determine the content of total sugars (BDS 7169:1989), titratable acids in the grapes (fresh weight) were analyzed titrimetrically with NaOH in indicator phenolphthalein and pH in grapes of wine varieties.

Results and discussion

The effect of liming on the content of total sugars, titratable acidity and pH of the grapes was studied. The data are shown in Table 1. The effect of the factor "liming" on the main technological indicators of the grapes was evaluated by ANOVA of replications, formed for each of the studied four varieties. In the role of factor variables are set the year of sampling (first and second) and the applicable rate of liming (0, 1, 2,5 and 5 t/ha).

The liming has a proven effect on the content of total sugars and titratable acids, but did not affect the pH of the grapes of variety Chardonnay. The impact on the amount of the sugars increased on average by about 1,5-2% total for limed varieties, as the effect was tangible in high lime rates – 2,5 and 5 t/ha. As a result of liming, the titratable acids decreased from 6 to about 3 mg/l by increasing the rate of the ameliorant, as dependence was with characteristics approaching to linear. Proven differences between the measurements in two consecutive years of measurement were not found.

In the variety Sauvignon Blanc, statistically proven differences between limed variants and the variants without liming were not found in terms of the three studied indicators. There is a tendency to increase the content of total sugars, but the tendency is disturbed by the result, obtained by applying the rate of 2,5 t/ha lime material, which found lower sugar content compared to the control variant without liming. If excluded this value, the difference between limed variants and the variants without liming becomes essential.

In the variety Merlot, the average content of total sugars content is increased with increase of the lime rate, but the titratable acidity and pH of the grapes reduced. These tendencies are prominent, but the differences between limed variants and the variants without liming indicators were not statistically proven under the criteria of the set level of guarantee probability of 95%.

In the variety Cabernet Sauvignon, in the variants with liming was found statistically proven lower levels of total sugars, compared with the control variant. The difference was on average less than 1% between limed variants and the variants without liming. Liming did not lead to proven differences in terms of titratable acidity and pH of the grapes for this variety.

Table 1. Contents of total sugars [%], titratable acids [mg] and pH of the grapes of varieties Chardonnay, Sauvignon Blanc, Merlot and Cabernet Sauvignon, depends on the liming rate with hydrated lime

Year	Direction of growth	Variety	Hydrated lime (t/ha)	Total sugars %	Titratable acids (mg)	pH (grape)
1	2	3	4	5	6	7
1	White	Chardonnay		21.6	7.41	3.57
			1	21.4	6.76	3.20
			2.5	24.1	4.37	3.60

			5	22.2	5.84	4.30
		Merlot		25.0	5.51	3.93
			1	24.9	5.22	3.50
			2.5	26.3	5.61	4.30
			5	26.9	4.77	4.20
2	White	Chardonnay		21.2	7.36	3.50
			1	20.4	6.49	3.20
			2.5	22.5	4.85	3.50
			5	21.9	3.80	3.20
		Sauvignon Blanc		21.5	5.39	3.57
			1	22.5	5.63	3.60
			2.5	20.9	7.28	4.30
			5	23.1	5.74	3.40
	Red	Cabernet Sauvignon		23.3	5.66	4.23
			1	20.9	5.23	4.10
			2.5	20.4	5.53	4.10
			5	21.6	5.16	4.10
		Merlot		24.6	6.04	3.80
			1	24.9	5.42	3.60
			2.5	24.3	5.58	4.00
			5	26.1	4.14	4.00

The contradictory results, obtained about the effect of the liming on the composition of the grapes, assessed separately for each of the studied varieties gave us the idea to analyze the effect of conducted liming on a more generalized samples, as unite white and red varieties and apply the same model of variance single factor analysis at a level of guarantee probability of 95%, however separate the replications, formed by the two years of sampling.
The results can be summarized as follows:

Overall in white varieties liming in the specified level of significance, caused proven increase in the level of total sugars, as in the control variant without liming was average 21,75%, in liming at rate of 1 t/ha – 22,40%, and in higher rates reached respectively 23,05 and 24,2%. The effect on the titratable acidity and pH of the grapes was unproven at the specified level of significance.

During the second year, increase in the content of total sugars and decrease of the level of titratable acidity in white varieties was found only at the highest applied ameliorative lime rate of 5 t/ha. In the other variants with lower lime rates applied did not affect the studied indicators of the grapes.

Proven effect of liming on the indicators, characterizing the composition of the grapes in the red varieties was not found, as well in the first and in the second year of the study.

The unbalanced application of high rates of calcium containing ameliorants in the soils, characterized by strong deficit of bases in exchange easily mobile exchangeable form in the complex can lead to higher than optimum ratio between the two elements in the foliage. The application of calcium containing ameliorants increases the degree of heterogeneity of the calcium content in the foliage. The reason for it is probably due to positional inaccessibility of the lime materials in the soil.

The increased rate of absorption of Ca in the foliage of the vines leads to increase the intensity of the entrance of magnesium, independently, that its level in the soil did not change. (Valcheva and Trendafilov, 2015), which lead to proven change in the technological indicators of the grape, mainly in the white studied varieties.

Conclusions

Overall in white varieties liming caused proven increase in the level of total sugars, as in the control variant without liming was average 21,75%, in liming at rate of 1 t/ha – 22,40%, and in higher rates reached respectively 23,05 and 24,2%. The effect on the titratable acidity and pH of the grapes was unproven at the specified level of significance.

Liming affects technological indicators of the grapes mainly in the white studied varieties and causes an increase in the content of total sugars and reduce the titratable acidity. In red varieties proven dependencies in this direction was not found.

Relatively stable is the tendency to reduce the content of titratable acids, simultaneously with increase of the lime rate.

During the second year, increase in the content of total sugars and reduction of the level of titratable acids in the white varieties was found only in the highest applied ameliorative lime rate of 5 t/ha.

Abstract

This research was conducted to compare feed quality characteristics of some silage corn varieties in the irrigated experimental field of the Agricultural Research and Application Center of Igdir University in 2015. In research, ten silage corn varieties were established according to randomized complete blocks experimental design with three replications.CP (Crude protein), NDF (Neutral Detergent Fiber), ADF (Acid Detergent Fiber) ADL (Acid Detergent Lignin), DMD (Dry matter digestibility), DE (Digestible energy), ME (Metabolizable energy), DMI (Dry matter intake), and RFV (Relative feed value) of corn varieties were determinedand results varied significantly between varieties. According to results following values were found for different varieties: CP 8.72% (OSSK-602) with 5.98% (HİDO), NDF 52.18% (OSSK-644) with 39.51% (TK-6060), ADF 23.37% (HİDO) with 14.72% (72 MAY 80), ADL 3.71% (OSSK-602) with 1.57% (TK 6063), DMD 74.55% (72 MAY 80) with 66.83% (HİDO), DE 3.46 Mcal kg^{-1} (72 MAY 80) with 3.13 Mcal kg^{-1} (HİDO), ME 2.84 Mcal kg^{-1} (72 MAY 80) with 2.57 Mcal kg^{-1} (HİDO), DMI 3.04% (TK 6060) with 2.30% (OSSK 644) and RFV 62.18% (TK 6060) with 56.80% (HİDO).According to these results OSSK-602, 72MAY80, Shemall and RX-9292 varieties have been found to be most suitable varieties for this area and animal feed.

Key Words:*Silage corn, nutrient content, animal feed.*

Introduction

When compared with the developed countries, low proportions of areas cultivated with fodder crops within the field crop production in Turkey together with erroneous management of pastures that does not follow proper pasture management principles and lack of improvement in pasture areas, have resulted in an increase in the gap between the amount of coarse fodder demanded by farms and the amount of produced coarse fodder. This has resulted in improper nutrition of animals. The demand for quality coarse fodder is especially high in Turkey during winters. Because of this science people and producers have been looking for alternatives which can give much higher yields of feedstuff per unit area cultivated with fodder crops. Corn is an advantageous plant, which has been gaining importance throughout the World as well as in Turkey, for overcoming this gap in coarse fodder production, since it produces higher amounts of green material per unit area, has higher amount of calories and since it is suitable for silage productionand mechanized agriculture(Kılıç, 1986; Ayaz et al., 2013).

Besides its usage in human nutrition and in various industries, increasing preference of Corn(Zea mays L.) plant as a source of silage material in animal nutrition has resulted in an increase in corn farming and corn production amounts both in Turkey and in the World. As of today, the total corn cultivation area around the World totals to 183 Million hectares and the total amount of silage corn produced is 1.008 Million tons. Meanwhile, total cultivation area of fodder crops among all cultivated field crops in Turkey 1.862.758 hectares and the share of corn cultivated areas within the total is 22.71%, which amounts to 423.123 hectares. Total amount of silage corn produced from this area is 19.7 Million tons (Anonymous, 2015a).

As known, silage is the process of acetifying fresh or wilted plant material containing humidity, dry matter and soluble carbohydrates through lactic acid fermentation under anaerobic conditions. Properly prepared silage feed conserves a great proportion of the nutritional value of the green plants and provides a succulent feed material for the animals during winters. Although silage can be made with many feed material and low-quality grass, plants with high carbohydrate content are preferred. Thus, the quality of silage is closely related to nutritional content rather than morphological and physiological characteristics of the produced feedstuff. Suitability of the content of feedstuff for silage production is determined through chemical analyses.

The aim of this research was to determine the nutritional content of 10 silage corn varieties for animal nutrition produced under the conditions of Igdir province (Turkey).

Material and Methods

The research was conducted in experimental field of the Agricultural Research and Application Center of the Igdir University in 2015. Ten (10) corn varieties(72 MAY 80, OSSK-644, TK-6063, OSSK-596, TK-6060, HİDO, RX- 9292, 71 MAY 69, SHEMALL, OSSK-602) were used in the research.Varying climatic conditions of Igdir Province, where the research was carried out, during 6 months in 2015 are given in Table 1. According to Table 1, monthly average amount of precipitation is 30 mm, monthly average temperature is 23.2^{o}Cand monthly average relative humidity ratio is 44.2. Trial area is classified as clay-loamy soil, highly-alkaline (pH: 8.6),lightly saline (EC: 1.37 dS/m),low in organic matter (1.20%) and rich in lime content(CaCO3: %22.27).Moreover, available phosphorus and potassium contents of the soil are determined as 51.7 ppmand 852.4, respectively (Erdogan, 2013).

Table 1.Some Climatic Features of Igdir Province in 2015 (Anonymous, 2015b)

Months	Monthly Total Precipitation (mm)	Monthly Average Temperatures (^{o}C)	Monthly Average Relative Humidity (%)
March	52.0	11.0	50.8
April	44.1	16.4	47.7
May	41.5	21.3	52.9
June	27.8	28.5	40.0
July	0.3	31.8	33.6
August	14.3	30.2	40.7
Average	30	23,2	44,2

The research was established according to randomized complete blocks experimental design with three replications. Seeds were sownon 04.04.2015 by hand using markers with 70 cm row spacing and 15 cm intra-row spacing distance. Each parcel area in the study was set as 17.5 m^2 (5 m x 3.5 m). 80 kg/ha Nand80 kg/ha P_2O_5phosphorus was applied at the sowing and an additional amount of 80 kg/ha Nfertilizerwas applied when the plants reached 50 cm of height.

Moisture content of the soil was regularly measured with soil moisture measurement device and the plants were started to be irrigated only after 50% of the available field moisture capacity was utilized. Irrigation was carried out by sprinklers until the plants reached a height of 40-50 cm, and by furrows thereafter. Hoeing and weed prevention were carried out when the plants reached 10-20 cm of height, and hoeing and middlebreaking were conducted with the second application of nitrogen when the plants reached 40-50 cm of height. Harvest was

carried out on 09.07.2015 and all plant samples taken from each parcel were first weighed fresh, then kept out in the open air for a while and then dried in a drying oven set at 70^{o}C until their weights were stabilized. After drying, grass samples were ground in order to enable them to pass through 1 mm sieve and feed samples were readied for quality analyses (CP, NDF, ADF, ADL, DMD, DE, ME, DMI and RFV).

Nitrogen (N) content of the samples of used materials was determined using Kjeldahl Method and obtained %N values were multiplied by 6.25 coefficients to determine CP (Crude Protein) content (AOAC, 1990). NDF (Neutral Detergent Fiber), ADF (Acid Detergent Fiber) and ADL (Acid Detergent Lignin) contents, on the other hand, were determined by the method suggested byVan Soest et al. (1991).

Dry Matter Digestibility (DMD) was determined using the formula (DMD (%) = 88.9 – (0779 x % ADF) suggested by Oddy et al. (1983). DMD values were used in the regression equation (DE = 0.27 + 0.0428 x DMD) developed by Fonnesbeck et al. (1984) to determineDE (Digestible Energy) values. After this, Metabolizable Energy (ME) was calculated using the formula (ME = 0.821 x DE) developed by Khalil et al. (1986).Dry-Matter Intake (DMI) and Relative Feed Value (RFV) were found using the equations suggested by Sheaffer et al., (1995) (DMI= 120/NDF and RFV= [DMD x DMI]/1.29, respectively).

The data were exposed to GLM (General Linear Models) with SPSS (version 20) on the basis of main effects. Mean separation were performed by using Duncan test.

Results and Discussion

CP (Crude protein) (%)

CP ratios were varied significantly between the varieties. CP ratios of corn varieties varied between 5.98 and 8.72 and were found to be statistically significant. The highest CP ratios were observed in OSSK 602 (8.72%) and SHEMALL (8.09%) while the lowest were seen in HİDO (5.98%) variety.In a study conducted by Erdal et al. (2009), the highest and the lowest CP ratios for different varieties were determined as 8.2%and 7.4%, respectively. In another study, average CP ratios of corn plants were reported to be varying between 5.5%and8.1%(Akdeniz et al., 2004). All these results are in parallel to our findings.

CP is particularly important in silage corn production. CP must not be lower than 7.0% in silage corn. In our research carried out under the ecological conditions of Igdir, it was observed that CP ratios of all corn varieties studied were over 7.0%.

NDF (Neutral Detergent Fiber), ADF (Acid Detergent Fiber) and ADL (Acid Detergent Lignin) (%)

High contents of NDF, ADF and ADL ratios in fodder crops adversely affect the quality and, thus, preference of the feedstuff. Presence of these structures also decreases the digestibility of the crop. Because of these reasons, it is known that NDF, ADF and ADL are undesired structures in fodder crops (Temel et al., 2015). NDF, ADF and ADL ratios of 10 corn varieties tried under Igdir conditions were varied between 39.51-52.18%, 14.72-23.37% and 1.57-3.71%, respectively and significant differences were observed among varieties. The highest NDF ratio was measured in TK 6060 (39.51%) variety. The lowest ADF ratios were observed in 72 MAY 80 (14.72%)and TK 6060(15.06%)varieties. The lowest ADL ratio was 1.57% and was observed in TK 6063 variety. In many studies conducted under different ecologies, NDF, ADF and ADL ratios of the investigated plants were reported to show significant differences and it was explained that these differences may be a result of different genotypes. NDF, ADF and ADL ratios of different varieties are reported to be varying between 38.2-46.0%, 28.3-37.7%and 8.03-15.1%, respectively (Canbolat and Karaman, 2009), 46.6-55.9%, 24.9-32.6%and 6.3-8.1%, respectively (Canbolat, 2012), 44.4-59.5%, 26.3-31.5%and 2.6-5.0%, respectively (Ergul et al. 2001). In addition, it was reported that the

NDF content for corn plant is determined as 53.2%, while ADF ratio is 30.1% and ADL ratio 6.3% (Canbolat, 2012).

Table 2.CP, NDF, ADF, ADL, and DMDRatios of Investigated Corn Varieties According to Dry-Matter Content

Varieties	CP (%)	NDF (%)	ADF (%)	ADL (%)	DMD (%)
72 MAY 80	7,38 ab	45,43 ab	14,72 e	2,28 bc	77.0 a
OSSK 644	7.39 ab	52,18 a	19,96 abc	2,59 b	73.0 ab
TK 6063	6,08 b	44,73 ab	22,19 ab	1,57 c	71.0 b

Mean	7,23	46,47	18,70	2,35	73.8

* Values indicated with different letters are significantly different at P<0,05

DMD (Dry matter digestibility) (%)

DMD (Dry matter digestibility)values were determined to differ significantly between corn varieties. DMD ratios of the varieties were ranged between 70.3%and 77.0%. The highest DMD ratio was observed in 72MAY80 variety with 77.0%while the lowest was determined in HİDO variety with 70.3%. As known, DMD values are calculated based on ADF contents of the feedstuff. As it can be seen in Table 2, ADF contents were varied among corn varieties and thus the differences in DMD ratios is thought to be a reflection of this variation. In other research conducted with different forage species, DMD ratios were determined as 76.6-87.3% (Ergül et al. 2001), 59.5-66.8% (Canbolat and Karman, 2009)and 63.6-69.5% (Canbolat, 2012).

DE (Digestible energy) and ME (Metabolizable energy) (Mcal kg^{-1})

Significant differences were observed among DE (Digestible Energy) and ME (Metabolizable Energy) values of varieties studied in the trial. Looking at Table 3, it can be seen that DE and ME values of corn varieties ranged between 3.13-3.46 and 2.87-2.84 Mcal kg^{-1}, respectively. The highest DE and ME amounts were observed in 72MAY80 variety as 3.46 and 2.86 Mcal kg^{-1}, respectively while the lowest DE and ME amounts were detected in HIDO variety as 3.13 and 2.57 Mcal kg^{-1}, respectively.In other studies conducted with different fodder crops ME amounts were reported to vary between 9.3-11.1 Mcal kg^{-1} (Canbolatve Karaman, 2009), 9.1-10.9 1 Mcal kg^{-1} (Canbolat, 2012) and 10.22-11.08 Mcal kg^{-1} (Metcalf et al. 2008).

DMI (Dry matter intake) (%)

Dry Matter Intake (DMI) ratios of corn varieties were observed to vary between 2.30% and 3.04%. Statistical comparisons among means showed that the highest DMI ratio was detected in TK 6060 variety with 3.04% while the lowest ratios were seen in OSSK 644, OSSK 602 and 71 MAY 69 varieties with 2.30%, 2.45%and 2.46%, respectively.

RFV (Relative feed value)

Relative Feed Values (RFVs) of the corn varieties investigated in the study were varied between 131.3and 182.0. According to the results of Duncan Multiple Range Test which was conducted to determine the differences between RFVs of corn varieties, the highest RFV of 182.0 was measured in TK 6060 variety while the lowest value of 131.3 was detected in OSSK-644 variety (Table 3).Considering together with Table 2, it can be seen that varieties with higher content of cell wall components as NDF, ADF and ADL, which make digestion difficult, have lower RFVs and RFVs of such varieties are negatively influenced by presence of higher amounts of such components. However, since RFVs of all investigated varieties found to be over 100, it was determined that all feed obtained from these varieties are of high quality. In other studies conducted in different regions with different plants RFVs are found to be ranging from 120.3-159.9 (Canbolat and Karaman, 2009), 105.8-138.7 (Canbolat, 2012), and 75.6-119.5 (Jahansouz et al. 2014).

Table 3.DE, ME, DMI and RFV Ratios of Corn Varieties

Varieties	DE (Mcal kg^{-1})	ME (Mcal kg^{-1})	DMI (%)	RFV
72 MAY 80	3,46 a	2,84 a	2.64 ab	158,3 b

Mean	3,31	2,72	2,61	150,69

* Values indicated with different letters are significantly different at P<0,05.

Conclusion

Some nutritional valuesof 10 corn varieties, which are widely-sowing, those are important for animal nutrition, were determined with this research. In addition to productivity per unit area values of the varieties,knowledge of nutritional (quality) characteristics and selection of fodder crops to-be-produced in different regions according to these criteria is very important for animal nutrition.

According to the findings of the study, when Crude Protein (CP), which is one of the most important quality characteristics for animal nutrition, considered, OSSK-602 variety should be preferred.For many other nutritional characteristics (NDF, ADF, ADL, DMD, DE, ME, DMI and RFV) TK-6060, 72MAY80, SHEMALL and RX-9292 varieties are determined to be more preferable than other species.

Abstract

The first-year of a lemon verbena (*Aloysia triphylla* L.) crop's growth and productivity as affected by irrigation was investigated under field conditions in central Greece. In April 2015, winter cuttings of lemon verbena were transplanted to an experimental field installed in Nea Aghialos, Magnesia, central Greece. The experimental design was a completely randomized design with three drip irrigation levels (0, 50, and 100% of potential evapotranspiration) in four replications. The growth and final productivity of the crop was measured in three destructive samplings of the crop during the summer of 2015. The results demonstrated the paramount effects of irrigation on lemon verbena productivity and final yield already in the first year of crop establishment.

Keywords: *lemon verbena, irrigation, growth, evapotranspiration.*

Introduction

Lemon verbena, (syn.: Aloysia citriodora A. citrodora Palau, A. triphylla, Lippia citriodora L. triphylla) is an evergreen perennial aromatic plant. It likes warm moist conditions with plenty of sunlight. When exposed to frost, it becomes deciduous. belongs to the Verbenaceae family. The genus Lippia (Verbenaceae) brings together about 200 species and lemon verbena is native in Latin America as well as North Africa (Morocco), and was introduced to Europe during the 17th century (Carnat et al., 1999; Botta, 1979; Rotman and Mulgura Romero, 1999). Lemon verbena is an aromatic perennial shrub that is valued for its medicinal use (as a tea or tincture) as a digestive aid, antimicrobial, antispasmodic, analgesic, diuretic plant; besides, it is used as a treatment for cold, insomnia and anxiety (Botta, 1979; Carnat et al., 1999; Rotman and Mulgura Romero, 1999). Antioxidant and antibacterial qualities of Aloysia citriodora have been found in its essential oil, tea and tincture (Bilia et al., 2008; Cowan, 1999; Pereira and Meireles, 2007; Ohno et al., 2003; Sartoratto et al., 2004). This aromatic plant has a widespread market in the western world (Di Leo Lira, et al.,2013), its compounds have widespread uses in foods, cosmetics and household products (Catalan and Lampasona, 2002; Santos-Gomes et al., 2005). The essential oil contained in the plant and its leaves are used in the perfume industry and the production of flavored beverages and food preparations (Pascual, Slowing, Caretero, Mara, & Villar, 2001). In the United States, lemon verbena is listed in Generally Regarded As Safe (GRAS) for human consumption in alcoholic beverages (Gomes, Oliveira, Vicente, & Ferreira, 2006). Whereas very low researches have been applied on enhancement of medicinal plants production, presenting the appropriate planting methods is very important for increasing the quantity and quality of medicinal plants (Farooqi & Sreeramu, 2001). The purpose of trading production of medicinal plants is obtaining further amount of biomass in area (Nematian, Dalvandi, & Shariati, 2014). In view of the commercial value of lemon verbena, and considering that plants can display significant genetic biodiversity and variations in their morpho type due to differences in the edaphic or climatic conditions of their habitat (Molina et al.,2003), it is very important that these factors are studied and somehow controlled to ensure better yields.

The purpose of this study was to evaluate the effect of nitrogen fertilization on the growth parameters of a lemon verbena crop.

Materials and methods

Crop establishment

The experiment was set up in the rural area of Nea Aghialos in Central Greece (39°16'02.3"N 22°47'47.5"E) on May 5, 2015. The soil of the experimental plots was a sandy loam one with a pH of 6.8 and an organic carbon (C) of 1.5 g kg^{-1}. Lemon verbena cuttings (40 days old) were obtained from a local nursery. The soil was prepared and divided into plots; each of them was 4,2 m χ 2,4 m and contained three drip rows. The cuttings were transplanted on May 5. Distance between plants and distance between rows were both 60 cm. Twelve plots containing a total of 216 plants were arranged in a completely randomized design with irrigation being the main factor and nitrogen fertilization the factor split into sub-plots. Each experimental unit consisted of three rows of plants, 0.6 m apart, with the two outer rows serving as buffers while plants were spaced at 60 cm apart.

Fertilization

A nitrogen dressing was manually applied (100 kg ha^{-1}) in the form of a urea fertilizer on June 9 of 2015.

Irrigation

The amount of irrigation water was equal to 0% (rainfed – 110 mm), 50% (281 mm) and 100% (562 mm) of the recorded evaporation values of a class-A pan. Irrigation water was applied by drip irrigation system and the irrigation interval was seven days. Surface drip irrigation system consists of an irrigation pump connected to sand and screen filter and a hydraulic fertilizer injection pump was used. The actual water discharge rate was 8 L h^{-1} along the drip lines. Weed control was carried out via application of a polyethylene transpiring mulch as this material has demonstrated a 100% efficiency in weed control among other tested mulches according to Hoeberechts et al (2004).

Harvesting and Drying

Harvests (destructive samplings) were carried on transplant – May 5, June 29, July 29 and finally August 28. Two plants per plot were harvested and all aerial parts of the plants were cut 10 cm above ground and the following growth parameters were determined: plant height, fresh weight of leaves/plant and fresh weight of stem/plant. LAI was measured via destructive methods using a calliper. The same parameters were determined after drying plant material in dark storage rooms on specially designed shelves. This method of drying was chosen as it is the method most commercial growers in Greece actually use. The results of the three final harvests are demonstrated in this paper.

Statistical analysis

All recorded values of this experiment were statistically analyzed using analysis of variance through the Genstat Program. Means were compared using revised L.S.D. test at 0.05 levels. The first harvest was not subjected to analysis of variance due to extensive rainfall during June.

Results and discussion

During the second harvest (29/07/2015) none of the variables were significantly affected by irrigation volume. During the third and final harvest (28/08/2015) irrigation volume significantly increased LAI and dry leaf yield (Figure 1, 2). LAI means were 0.72, 1.47, 1.98 (Figure 2) and dry leaf yields were 0.87, 1.34 and 1.9 t ha^{-1} (Figure 1) for treatments I1, I2 and I3 respectively. Plant height remained unaffected by irrigation volume throughout the experiment. The LSD test showed that dry leaf yields of treatment I3differed greatly than the rest during the final harvest (Table 1). Moreover the LSD test showed differences between all

irrigation volumes regarding LAI during the final harvest. Finally, an interesting effect of water deficiency was that plants started shedding leaves after the second harvest and LAI was lower at the time of the third and final harvest while leaf color shifted to yellow.

Figure 1 Dry leaf yield (t ha^{-1}) means grouped by irrigation volume during the experiment.

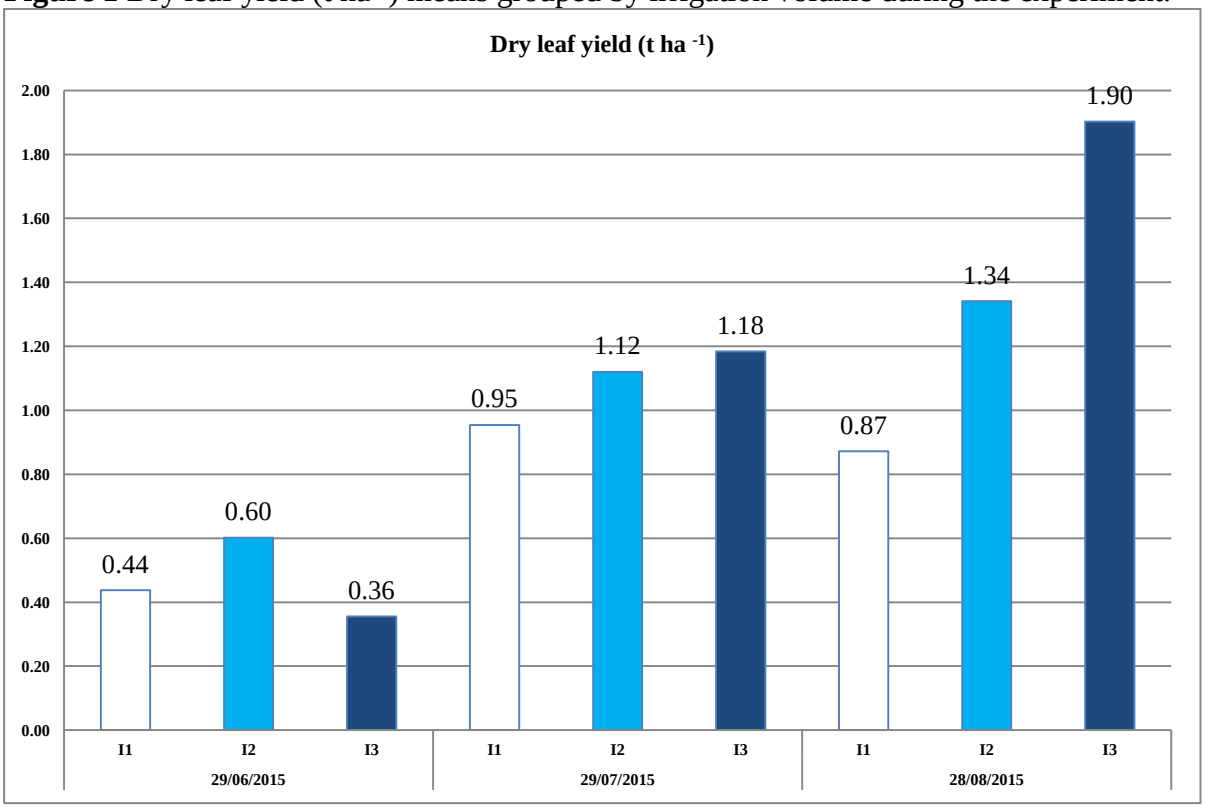

Figure 2 LAI (leaf area index) means grouped by irrigation volume during the experiment.

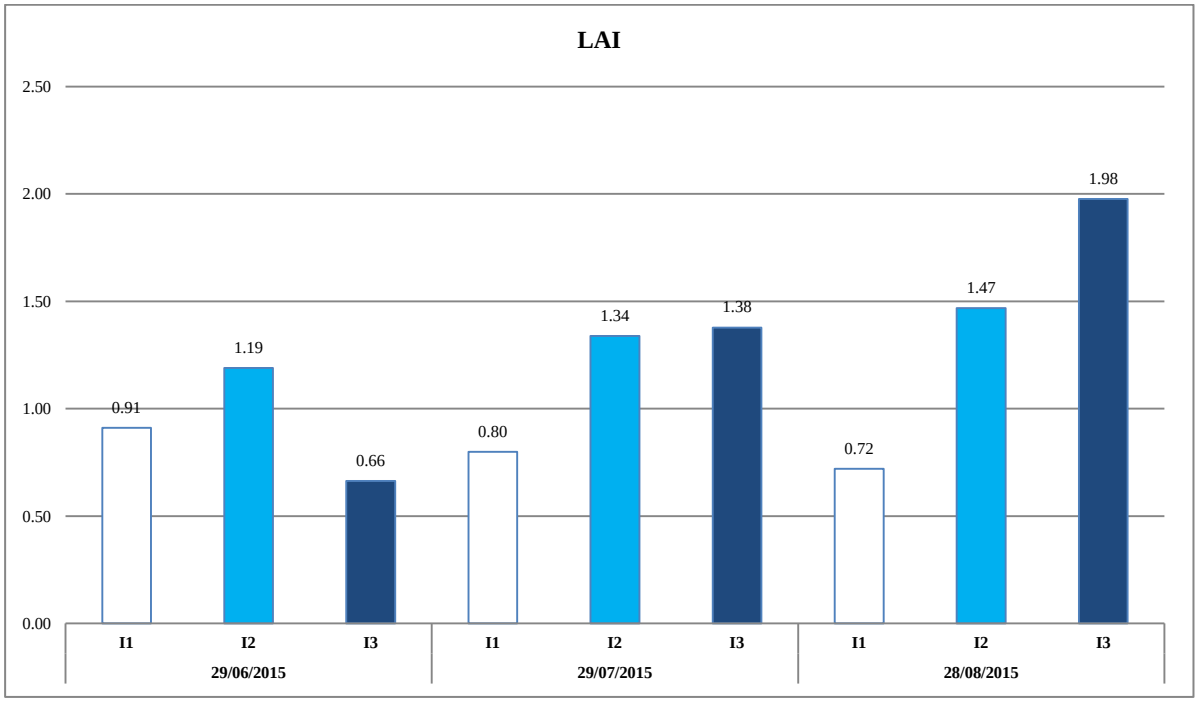

Table 1. Means of vegetative growth data of lemon verbena as affected by different irrigation volumes during the experimental season.

Harvest date	Nitrogen treatment	Plant height (m)	LAI	Dry stem yield (t ha^{-1})	Dry leaf yield (t ha^{-1})
29/06/2015	I1	0,49	0,91	0,21	0,44
	I2	0,52	1,19	0,31	0,60
	I3	0,51	0,66	0,17	0,36
29/07/2015	I1	0,88a	0,80a	0,77a	0,95a
	I2	0,87a	1,44a	0,92a	1,12a
	I3	1,01a	1,38a	0,98a	1,18a
28/08/2015	I1	0,98a	0,87a	1,34a	0,87a
	I2	1,06a	1,47b	1,83a	1,34a
	I3	0,99a	1,98c	2,19a	1,90b

Conclusions

During the establishment year of the, irrigation had a significant effect on plant growth. Future experiments for consecutive growing seasons and in different soil types are recommended in order to assess the prospects of lemon verbena cultivation in Greece and the possible financial interest of the crop. It seems that water is a vital input for lemon verbena crops in central Greece as lack of it leads to a smaller vegetative period. As water becomes scarce in the Mediterranean and nitrogen fertilization is always a cost for producers, these inputs should be carefully calculated in terms of sustainability and cost efficiency.

A STUDY OF THE EFFECTS OF DIFFERENT BIO-FERTILIZERS AND AMMONIUM PHOSPHATE LEVELS ON THE YIELD OF SUNFLOWER

Morteza BARMAKI*

Department of Agriculture and Natural Resurses, University of Mohaghegh Ardabili, Ardabil, Iran.
*Corresponding author: barmakimorteza@gmail.com

Abstract

Sunflower (*Helianthus annuus* L.) is one of the main crops producing the oil requirements of the Iran. This experiment was conducted in Ardabil plain to study the effects of different biological and chemical nutrition systems on Sunflower (Sanbro cultivars) yield, in 2013. A factorial field experiment in a randomized complete block design with three replications was done. The first factor was ammonium phosphate levels (zero, 150 and 300 kg ha^{-1}) and the second factor was seed inoculation with Mycorrhiza (*Glumus etanicatum*), Azotobacter, Mycorrhiza plus Azotobacter as bio-fertilizer and control without any bio-fertilizers. The results showed that grain and oil yield of sunflower were significantly affected by ammonium phosphate levels and biofertilizers as well. Also, there were interaction effects between ammonium phosphate levels and bio-fertilizer types on oil percentage and oil yield. Applying the highest levels of ammonium phosphate (300 kg ha^{-1}) had the maximum grain yield (4584.1 kg ha^{-1}) and the minimum (2708.3 kg ha^{-1}) was obtained from control. The application of mycorrhiza as bio-fertilizer on grain yield of sunflower was more effective than Azetobacter and increased it to more than 500 kg ha^{-1}. Means comparison of interaction effects between Ammonium phosphate and bio-fertilizer showed that combination use of 300 kg ha^{-1} of ammonium phosphate with both types of bio-fertilizers compared to control without any fertilizers could triple the oil yield.

Keywords: *Sunflower, Bio-fertilizer, Chemicals, Yield, Ardabil*

Introduction

Sunflower (*Helianthus annuus* L.) is one of the main suggested oil crops to solve edible vegetable oil shortage in the world that seeds contain 24-49% of oil and the cake contains 25-35% of protein (Henen, 2011). In Iran, sunflower is also one of the main crops producing the oil requirements of the country. It has an important position in crop rotation system of many Iranian farmlands so achieving a sustainable system for sunflower cultivation would be of great value in agricultural management in the region. Overuse of different chemical fertilizers is one of the causes for the degradation of environment and soil. Bio fertilizers are the newest and most technically advanced way of supplying mineral nutrients to crops. Compared to chemical fertilizers, their supply nutrient for plant needs, minimizes leaching, and therefore improves fertilizer use efficiency (SeyedSharifi, 2009). Bio-fertilizers play vital role for increasing the number of microorganisms and accelerate certain microbial process in plants which can change the available form of many nutrients for crops (Abou-Khadrah *et al*., 2000). Bio-fertilizers such as Azotobacter, have a positive effect on growth, yield and yield component of many crops. Fertilizer management is one of the most important factors in successful cultivation of crops affecting yield quality and quantity (Tahmasbi *et al*., 2011_). Phosphorus and nitrogen are essential elements required in sunflower cropping which can significantly affect seed yield and oil content (Zubillaga *et al*., 2002). The symbiosis of plant roots with mycorrhizal fungi is known to be one of the most ancient and widespread plant strategies to enhance nutrient acquisition and to cope with environmental stress (Brachmann and Parniske, 2006). The intra-radical mycelium of these soil fungi proliferates in the root

cortex of the host plant. Extra radical Mycorrhizal fungi hyphae spread in the soil around the root and provide the surface area by which the mycorrhizal fungi absorbs nutritional elements such as phosphorus (P), nitrogen (N), zinc (Zn) or copper (Cu) for transport and transfer to the host plant (Smith and Read, 2008). Therefore this study was designed to evaluate the influence of a biofertilizers containing Azotobacter and Mycorrhiza (*Glumus etanicatum*) in addition to Ammonium phosphate levels on sunflower cropping in the region of Ardabi, north west of Iran.

Materials and methods

This experiment was conducted in Ardabil plain on the research field of University of Mohaghegh Ardabili (Iran), with longitude of 48°15' and latitude of 38°15' and cold semi-arid climate (Emberger method) to study the effects of different biological and chemical nutrition systems on Sunflower (Sanbro cultivars), in 2013. A factorial field experiment was done in a randomized complete block design with three replications. The first factor was Ammonium phosphate levels (zero, 150 and 300 kg ha^{-1}) mixed with the soil before planting, and the second factor was seed inoculation with Mycorrhiza (*Glumus etanicatum*), Azotobacter, Mycorrhiza plus Azotobacter as bio-fertilizer and control without any bio-fertilizers.There were 5 rows with 6 meters long in any of 27 plots with 0.6 m row spacing. At maturity, two outer rows for each plot, 50 cm from each end of the plots, were left as borders and the middle 4 m^2 of the three central rows were harvested. Seeds oil was determined by Sucsilate machine .Then oil yield was determined by following formula:

Oil yield= % oil × seed yield

All data were subjected to analysis of variance (ANOVA) and differences among treatment means were tested by Duncan's multiple range test (at $P \leq 0.05$) using MSTAT-C software.

Results and discussion

The results showed that grain and oil yield of sunflower were significantly affected by ammonium phosphate levels and biofertilizers as well. Also, there were interaction effects between ammonium phosphate levels and bio-fertilizer types on oil percentage and oil yield (table 1).

Applying the highest levels of ammonium phosphate (300 kg ha^{-1}) had the maximum grain yield (4584.1 kg ha^{-1}) and the minimum (2708.3 kg ha^{-1}) was obtained from control (table 2). Soleimani (2008) reported that application of nitrogen fertilizer increased grain yield of safflower. The positive effect of phosphorus fertilizer on the yield of sunflower by Zubillaga *et al.* (2002) have been reported.

The application of mycorrhiza as bio-fertilizer on grain yield of sunflower was more effective than Azetobacter and increased it to more than 500 kg ha^{-1}(table 3). Soleimanzadeh *et al.* (2010) has stated that application of mycorrhiza had an appropriate performance and could increase grain yield and oil production of sunflower to an acceptable level, so it could be considered as a suitable substitute for chemical phosphorus fertilizer in organic agricultural systems.

Means comparison of interaction effects between ammonium phosphate and bio-fertilizer showed that combination use of 300 kg ha^{-1} of ammonium phosphate with both types of bio-fertilizers compared to control without any fertilizers could triple the oil yield (table 4). Ekin (2010) reports that application of chemical fertilizer with bio-fertilizer in sunflower cropping was more profitable than single usage. Observation of sunflower oil percentage in means comparison didn't show a clear trend.

Table 1. Analysis of variance for Grain yield, oil yield and Oil percentage of sunflower under application of Ammonium phosphate levels and bio-fertilizers

Dependent variable	Df	Independent variable (mean square)

Error	16	294788/5	5/72	27460/7

*and ** show significant difference at 5 and 1%, respectively

Table 2: Effect of Ammonium phosphate levels on grain yield of sunflower

Ammonium phosphate level (kg ha^{-1})	Grain yield(kg ha^{-1})
0	2708.3 c
150	3521.0 b
300	4584.1 a

Means with the same letters are not significantly different (Duncan's multiple range test)

Table 3: Effect of bio-fertilizer types on grain yield of sunflower

Bio-fertilizer type	Grain yield(kg ha^{-1})
Mycorrhiza	4164.7 a
Azotobacter	3661.4 b
Control	2887.2 c

Means with the same letters are not significantly different (Duncan's multiple range test)

Table 4: Interaction effects between Ammonium phosphate levels and bio-fertilizer types on oil percentage and oil yield of sunflower

Ammonium phosphate level (kg ha^{-1})	Bio-fertilizer type	Oil percentage	Oil yield
0	Mycorrhiza	40.82 bc	1586.2 bc
	Azotobacter	43.55 ab	1250.3 d
	Control	41.85 abc	612.3 e
150	Mycorrhiza	42.13 abc	1522.5 bc
	Azotobacter	38.21 c	1403.7 cd
	Control	41.84 abc	1325.1 cd
300	Mycorrhiza	44.78 a	**2203.5 a**
	Azotobacter	45.11 a	**2008.2 a**
	Control	39.50 bc	1462 b

Means with the same letters in each column are not significantly different (Duncan's multiple range test)

Conclusion

This research emphasizes the dominant role of chemicals with nitrogene and phosphorus in oil crops production.Using mycorrhiza and Azotobacter as bio-fertilizers with ammonium phosphate can increase the sunflower quantity and quality characteristics specially the oil yield. Biofertilizers are very safe because they do not pollute the environment. They can be very functional in sustanable agriculture.

Abstract

The objective of the study was to determine quality changes for different carrot cultivars during 5-month cold storage. Seven popular carrot cultivars were investigated: 'Abledo' F_1, 'Bastia' F_1, 'Karotan', 'Kazan' F_1, Sirkana' F_1, 'Trafford' F_1 and 'Warmia'. The observations were performed in monthly regime, from mid-October (harvest time) till mid-March, i.e. in five terms. The roots were stored at the temperature of 0-1°C and RH 98%. The following items were determined: nitrate (NO_3), soluble solids (^{o}Brix) and β-carotene contents, juice colour in CIE L*a* b* system. The results showed that soluble solids content differed among the cultivars and the highest content was characteristic to 'Kazan', followed by 'Bastia'. Generally, an increase of soluble solids content during storage was observed. Nitrate content in the roots was generally on a low level and during the storage the content showed a decreasing tendency, but related to the cultivars. The lowest nitrate content showed 'Abledo', 'Bastia', 'Karotan' and 'Sirkana', and the highest content was found in 'Trafford'. The β-carotene content in the roots showed small decreasing tendency during storage, but after 3 months small increase was observed. The highest content was found in 'Abledo' and 'Kazan'. The L* (lightness) and a* (redness) decreased during storage, however at the end of storage small increase of a* parameter was observed. The highest a* was characteristic to 'Kazan' and 'Karotan'. The b* (yellowness) decreased during storage, however at the end of storage small increase of the b* was observed. The highest b* value was noted for 'Kazan'. The cultivar was characterized also by very high β-carotene and soluble solids contents, low content of nitrate and high a* and b* parameters. 'Karotan' was also very good in this respect.

Keywords: *carrot, cultivars, cold storage, quality*

Introduction

Carrot (*Daucus carota* L.) is an important vegetable crop, consumed during the whole-year period, in fresh or processed form. High biological value of carrot is mainly due to the presence of carotenoid compounds in the roots. The main carotenoid in carrots are α-carotene and β-carotene, which account for more than 90% of their total content (Mayer-Miebach and Spiess 2003). Carotenoid content is highly differentiated among carrot cultivars and ranges usually from 4 to 25 mg 100 g^{-1} f.w. (Rubatzky et al,1999). According to Skrede et al. (1997) and Seroczyńska et al. (2006), high carotenoid content in resulted in more reddish and darker colour of plant flesh tissue.

Soluble sugars are the main storage compounds in carrots. They account for 34-70% of dry weight of the roots. Sucrose is the predominant sugar in the roots at their full maturity, and the amount reaches 3.6% f.w. Growing method or storage conditions affect the content of sugars in carrots (Lee 1986, Seljasen et al. 2001, Gajewski et al. 2007).

Carrot roots are prone to nitrate accumulation during the vegetation. Nitrate accumulation by vegetable plants is of high importance to a consumer due to potential negative influence on health. According to the Joint FAO/WHO Expert Committee on Food Additives, the acceptable daily intake of nitrate (NO_3) is on the level of 3.7 mg/kg of body weight per day, what is the equivalent to 222 mg of nitrate per day for adult of 60 kg of body weight (Santamaria 2005). Several factors which affect nitrate accumulation in different plants, including fertilization, environmental conditions and harvest date, were investigated by several authors (Gutezeit and Fink 1999, Santamaria 2005, Kona 2006).

Storage conditions are among the main factors influencing degradation of carrots quality during postharvest (Seljasen, 2001). Mature carrots can be stored in regular cold stores for 4–6 months, depending on the cultivar and roots initial quality. Recommended storage conditions for carrots are: temperature of 0–1^{o}C and 95–98% RH (Brecht, 2003). According to Kidmose et al. (2004) and Koca and Karadeniz (2008), carotenoid content in carrot roots is little affected by storage. Sometimes even an increase of carotenoid content is observed (Kopas-Lane and Warthesen 1995). According to Suojala (2000) an increase of hexoses and decrease of sucrose contents take place during storage of carrots.

The objective of the study was to determine quality changes for popular 7 cultivars of carrot during 5-month storage in a cold store, at recommended thermal and humidity conditions. In the study we determined following quality traits: soluble solids (^{o}Bx), nitrate (NO_3), β-carotene contents, as well as juice colour parameters in CIE L*a*b* system.

Material and Methods

In the study 7 carrots cultivars, listed below, were investigated. Carrot roots were obtained from a farm localized in Tomaszów Lubelski region (south-east part of Poland). The plants were grown in humus-rich black soil on ridges and fertilized with standard doses of NPK fertilizers. Harvest time of the roots was mid-October.

Characteristics of the cultivars (data provided by Rijk Zwaan seed company): 'Abledo' F_1 - cultivar with long, conical-shaped root, of high carotenoid, sugars and soluble solids contents. Good for making juice and for freezing. Shows low tendency to nitrate accumulation and is resistant to diseases of the leaves. 'Bastia' F_1 - a new cultivar, of conical-shaped roots, intensive roots colour and of high content of sugars and soluble solids. The cultivar is recommended for juice production and freezing. 'Karotan' – cultivar in 'Flakkee' type, high content of carotenoid, sugars and dry matter, and low tendency to nitrate accumulation. Standard cultivar for processing industry. 'Kazan' F_1 - cultivar of slightly conical root shape. Roots of dark orange colour, with unprominent core. Resistant to fungi diseases and good for freezing. 'Sirkana' F_1 - cultivar in 'Nantes' type, roots of intensive orange colour. Resistant to diseases of leaves. Good for production of juice and shredded roots. 'Trafford' F_1 - cultivar in 'Flakkee' type. High content of sugars and soluble solids. Long roots, of intensive orange colour. Good for freezing and juice production. 'Warmia' - cultivar in 'Flakkee' type, with high content of sugars and soluble solids. Resistant to leaves diseases caused by *Alternaria* sp. Roots used for drying and freezing, show low tendency to nitrate accumulation.

The roots were transported from the farm and put to the experimental cold store at the University in plastic 20-kg crates (5 crates/cultivar). One crate with carrots was a replicate. Storage conditions were: temperature of 0-1°C, 98% RH, ambient atmosphere.

The experiment was established as the two-factorial, in 5 replicates. The first factor (A) was the cultivar (7 cultivars) and the second one (B) was storage duration - directly after harvest, after 1-month storage, after 2-month, after 3-month, after 4-month, after 5-month.

Following chemical analyses and measurements were performed: nitrate (NO_3) content in the roots, beta-carotene content, juice colour in CIE L*a* b* system, soluble solids content. Analyses were performed in 5 replicates.

Soluble solids (^oBx) content was determined with the digital refractometer (Index Instruments, UK). To obtain the juice, 6 randomly selected healthy carrot roots were chosen for one replicate.

Nitrate (NO_3) content in the roots was determined spectrophotometrically with Fiastar 5000 Analyzer (Tecator, Sweden). 10 g of fresh finely fragmented roots were extracted on laboratory shaker with 100 ml 2% acetic acid + charcoal for 30 min. Extracts were filtered. Data were shown as mg NO_3/kg f.w.

The β-carotene content was determined with spectrophotometrical method. Carotenoid compounds were extracted from the roots with hexane and light absorbance was determined with the wavelength 450 nm, using UV-1201V (Shimadzu, Japan) spectrophotometer. 5 g of fresh roots was finely fragmented with 30 g sodium sulfite Na_2SO_4. 50 mL of hexane was added and the solution was put to dark place for 24 h. Then 2 mL of the extract was taken and 8 mL of hexane was added. Absorbance was measured at wavelength 450 nm, using UV-1201V (Shimadzu, Japan) spectrophotometer. Carotenoid content, expressed as β-carotene, was determined with the calibration curve. Data were shown as mg·100 g^{-1} f.w.

To determine carrot juice colour MiniScan XE (HunterLab, USA) spectrophotometer was used (the measure conditions: D65, 10^o Observer). There were determined: L* - lightness, a* - redness, b* - yellowness. The juice was obtained with a professional juice maker and the measurements were done in 5 replicates.

Statistical analysis was performed with Statgraphics 4.1.Plus™ software, using two-way ANOVA. Tukey's HSD test was used to determine significance of differences between means, with probability level P>0.95.

Results and Discussion

To obtain good quality carrots during prolonged period after harvest, i.e. in winter and spring months, optimal storage conditions should be applied. However, as it is reported by many authors (Suojala 2000, Seljasen 2001, Brecht 2003, Koca and Karadeniz, 2008), quality degradation of the roots during storage is observed, even at cold-store conditions. In the study we tried to determine how the cold-store conditions affect some quality parameters of carrots cultivars which are grown for processing industry purposes, especially.

Table 1. Determined quality traits of carrot cultivars (means of storage periods)

Cultivars	Soluble solids (^oBx)	Nitrate (mg NO_3 kg^{-1})	β-carotene (mg/100 g)	L*	a*	b*
Abledo	11.3 a	38 a	16.1 c	45.4 a	26.7 ab	31.7 ab
Bastia	13.0 b	58 b	12.6 a	45.6 a	25.8 a	31.4 a
Karotan	11.2 a	60 b	14.6 b	45.6 a	27.5 b	32.0 b
Kazan	14.8 c	74 b	16.0 c	47.1 b	28.6 c	34.0 c
Sirkana	11.5 a	61 b	13.0 a	46.0 ab	25.8 a	31.7 ab
Trafford	11.6 a	102 c	13.6 a	45.2 a	26.1 a	31.7 ab
Warmia	11.9 a	106 c	12.8 a	45.3 a	26.8 ab	31.3 a

Note: means which differ significantly according to Tukey's HSD test at P>0.95 are marked with different letters

The data obtained are shown as the means for the cultivars in Tab. 1, and as the means for the storage periods - in Tab. 2. Also values for each cultivar at all storage terms are shown in Tab. 3. As regards soluble solids content, it can be seen that it was differentiated among the cultivars. The highest soluble solids content was characteristic to 'Kazan' F_1, followed by 'Bastia' F_1 (Tab. 1). An increase of the content during storage of the roots took place (Tab. 2).

It could be explained partly by water loss from the roots as the result of transpiration, as well as by starch hydrolysis to simple sugars. The water loss was about 5-6% of carrots mass after 5-month storage (data not shown). Suojala (2000) reported increase of hexoses in carrots during prolonged storage. Hexoses accumulation during storage was explained by starch enzymatic decomposition.

Based on means of storage terms, it can be noted that the cultivars of the lowest nitrate content were 'Abledo' F_1, 'Bastia' F_1, 'Karotan' and 'Sirkana' F_1, and of the highest content 'Trafford' (Tab. 1). Nitrate content in the roots was generally on low level in all terms of storage (Tab. 2). However, differences between cultivars were observed (Tab. 3). During storage nitrate content showed decreasing tendency, but related to the cultivars. The amount of nitrates was generally low compared to reccomended tolerable amounts of nitrate in carrots (Santamaria 2005, Kona 2006).

The highest β-carotene content was found for 'Abledo' and 'Kazan' cultivars (Tab. 1). The β-carotene content in the roots showed small decreasing tendency during storage period, but after 3 months of storage small increase of β-carotene was observed (Tab. 2). Similar tendency for carotenoid content increase for stored carrots was also reported by Lee (1986) and Kopas-Lane and Warthesen (1995).

The highest L* value (lightness) was characteristic to 'Kazan' and 'Sirkana' cultivars (Tab. 1). The L* values showed decreasing tendency during the storage period (Tab. 2). As regards a* values, the highest values were observed for 'Kazan' and 'Karotan' cultivars. The a* values decreased during storage period, however after 5 months of storage small increase of a* value was observed, in general. The highest b* values were noted for 'Kazan'. The b* values decreased during storage of carrots, however after 5 months small increase of the b* parameter was observed. The a* and b* values for carrots are good indices of carotenoid presence in the roots and are very important parameters taken into account in the case of carrots used for processing industry (eg. for juice concentrate production, freezing and drying) (Seroczyńska et al. 2006).

Table 2. Determined quality traits of carrots in relation to storage period (means of cultivars)

Storage period	Soluble solids (^{o}Bx)	Nitrate (mg NO_3 kg^{-1})	β-carotene (mg 100 g^{-1})	L*	a*	b*

Note: values which differ significantly at P>0.95 are marked with different letters

Conclusion

Investigated carrot cultivars differed significantly in respect of contents of β-carotene, nitrate (NO_3), soluble solids, as well as juice CIE L*a*b* colour parameters. 'Kazan' F_1 was characterized by very high β-carotene and soluble solids contents, low content of nitrate, high

a* and b* juice colour parameters, what indicates especially good suitability of this cultivar for concentrate production. 'Karotan' was also very good cultivar in this respect.

Storage of carrots in cold store conditions for 5 months influenced following changes of quality: β-carotene content decreased in a low degree in the case of all cultivars, nitrate content showed also a tendency to decrease. The L*, a* and b* colour parameters of the juice decreased slightly and soluble solids content showed a tendency to increase during storage.

PROBLEMS OF PEACH WINTER HARDINESS IN THE STEPPE CRIMEA

Tatyana LATSKO

Nikitsky Botanical Garden (NBG), Yalta, Russian Federation
Corresponding author: cr_way@mail.ru

Abstract

Culture *Prunus persica (L.)* Batsch came to the Crimea and began to develop at the end of the 19th century. Since then, it has won high popularity among the amateur gardeners, and eventually has become a commercial fruit crop. Agro ecological conditions of the Crimean region, especially the southern coast are favorable for the cultivation of this crop. Unfortunately the areas suitable for the peach are limited. The steppe part of Crimea, with large spaces, suitable for horticulture, is often subjected to cold invasions from the north, damaging the generative buds of peach and destroying the potential yield. Extreme critical temperatures occur in winter period (20-30% years) and in the spring (25%). The intensive peach breeding has been carried out from mid-20th century till nowadays. One of the main breeding in the NBG is to create resistant to cold samples. As parental forms were used Domestic and foreign winter-hardy cultivars: Veteran, Pushystiy Ranniy, Crimskiy Feyerverk etc. Over 100 created peach cultivars are included in the Register and regionalized. In the late 50's, the peach had spread in the steppe part of the Crimea, and then in the southern regions of Ukraine. Assessment of winter hardiness of hybrids was carried out by means of laboratory and field methods in test years. As a result of researches, winter-hardy peach cultivars and hybrids have been selected, and they have been recommended for commercial fruit growing and breeding. These included 'Osvezhayuschiy', 'Demerdzhinskiy' and 'Kandidatskiy' *etc.*

Keywords: *Prunus persica*, winter hardiness, cultivar, hybrids, breeding.

Introduction

Culture *Prunus persica (L.)* Batsch came to the Crimea and began to develop at the end of the 19th century. Since then, it has won high popularity among the amateur gardeners, and eventually has become a commercial fruit crop. Agro ecological conditions of the Crimean region, especially the southern coast are favorable for the cultivation of this crop. Unfortunately the areas suitable for the peach are limited. The steppe part of Crimea, with large spaces, suitable for horticulture, is often subjected to cold invasions from the north, damaging the generative buds of peach and destroying the potential yield. Extreme critical temperatures occur in winter period (20-30% years) (Antyufyev *et al.*, 2002) in time of the deep rest and in the spring (25%) before and after flowering in different phase's development of generative organs (Latsko, 2015). There are risks of spring frost damage of the peach and in warmer countries, such as Spain (Iglesias, 2013). Significant results in the study of plant adaptation mechanisms to adverse or extreme environmental factors are achieved. Physiological and biochemical processes in various sustainability peach cultivars grown in different soil-climatic regions of the Crimea were studied (Yelmanova, 2010). Extensive research on a peach and breeding carried out since the mid 20th century to the present day (Smykov *et al.*, 2010). More than 100 peach cultivars were established, most of them are regionalized (Nikolić, 2013).

In the late 50's peach recently launched to the steppe part of Crimea, and then to the southern regions of Ukraine: Kherson, Odessa, Zaporozhye and Mykolayiv. The area of peach distribution in the Crimea, in the south of Russia and Ukraine is due, primarily, the temperature factor and the low winter hardiness (Smykov, 1990; Latsko, 2005).

It is believed that temperatures (-21°C) – (-27°C), causes the death of peach generative buds at stage sporogenous tissue in the Crimea. According to other authors, the critical temperature range for the peach in a period of deep dormancy (from December to January 1-20) in the Crimea is (-22) - (-24) °C (Orehova and Latsko, 2001). Many of the commercial cultivars of peach had insignificant damages of flower buds at lower frost (-25) - (-26) °C in the Moldova (Sokolov and Sokolova, 1987). In connection with the above the study of the peach gene pool and search for the most resistant to frost cultivars and hybrids are highly relevant for the further breeding of peach and promotion of culture in steppe regions. The aim of this work is to evaluate damage of generative buds of the peach collection in test winters, to identify the most resistant samples and to recommend them for commercial or scientific use.

Materials and M

The object of the study was resistance to negative air temperatures of peach cultivars and hybrids. Evaluation of winter hardiness is carried by laboratory and field methods in test years according to Sedov and Ogolcova (1999) and Methodical recommendations (Smykov, 1990; Yelmanova, 2010). Research was conducted in 1992-2016 years at the collection garden, which was located on the border of the steppe and foothill soil-climatic zones of the Crimea. The climate is dry, moderately hot, with short, unstable winter and return spring frosts (Antyufeyev *et al*., 2002). Planting distance was 6 × 3 m.

Protection from pests and diseases were carried by technologies and systems adopted in the steppe Crimea. Land was kept under fallow, irrigation was performed by furrows, one times during the growing season in the amount of 300 m^3/ ha and once before the winter. Observation and analysis of weather conditions was carried out by a meteorological station of the Steppe department NBG (Ryabov, 1999). Peach cultivars are distributed into five groups according to the degree of damage of flower buds: high winter hardiness (0-10.4%), winter-hardy (10.5-30.4%), mid winter-hardy (30.5-60.4%), low winter hardy (60.5-90.4%), not winter-hardy (90.5-100%).

Results and Discussion

Resistance to cold remains a major problem for Russia in breeding peach. Winter hardiness of plants is a vast concept, combining many complex and simple signs, which are determined by polygenes and oligogenes (Hesse, 1975; Latsko, 2005, 2012). These include the ability to hardening frost resistance vegetative and generative parts of structures in a period of deep dormancy (December-January), resistance to late spring frosts of flower buds (buds, pistils), as well as resistance to low temperatures roots (rootstock). Winter hardiness, in the narrow sense, it is the resistance of plants to low temperatures, that is cold resistance. Winter hardiness in a broader sense include the ability of plants to hardening, frost resistance of various tissues and parts of plants in different stages of ontogeny. Some authors believe (Pomology, 1997), that the winter hardiness – a stability not only to the low temperatures, but also to the entire range of the cold season of adverse factors. These include especially the temperature regime, the drying effect of wind, ice and sunburn, especially in the southern area of horticulture. The commercial value of the cultivar is determined, first of all yield of fruits, and flower buds are the beginnings of a future harvest. The article will be considered primarily this aspect of winter hardiness, namely stability of generative buds or flower buds to winter and spring air negative temperatures.

There are 15 extremely cold years for the study in the 1972-2016 periods in the steppe Crimea (34% years): 1972, 1976, 1979, 1980, 1982, 1985, 1989, 1990, 1994, 2002, 2006, 2007, 2010, 2012, and 2015. Return spring frosts recorded 16 times (36% years): 1972, 1980, 1981, 1985, 1988, 1989, 1990, 1991, 1992, 1993, 1994, 1999, 2004, 2009, 2012 and 2016. The lowest temperature was fixed at 02.21.1985 (-28.8°C). The scale and depth of the damage are

maximized this year. Generative and vegetative buds, twigs, bark and wood have been damaged. Cambium remained at the level of the skeletal branches of the first order of more winter-hardy cultivars. Very low negative temperature (-27.1° C) was registered 23.01.2006. Peach plants were at this time in a deep state of rest or an exit from it. Damage to generative buds was highest. The extent of frost damage to the vegetative parts of plants varied depending on the by cultivars. Bark, cambium, wood, core and of thin shoots or shoots terminations was mostly damaged by 4 points (on 5-point scale). The greatest damage was observed in of timber: 1-4 points. Cultivars of American origin were badly damaged of timber (3-4 points): Flacar, Harbrite, Hardbound, Harbella, Slanche and the nectarine Anderson. Vegetative buds were not injured. The cambium is intact in most cultivars. It is helped to keep plants, having made renewal pruning up to skeletal branches.

09.01.2002 the frost was registered (-24.6°C). The plants were in a state of deep physiological rest, i.e. in the period of its maximum frost resistance. Examination of flower buds after exposure to such cold identified frost resistant cultivars and hybrids of peach: G.Lebedev, Osvezhayuschiy, Posol Mira, Favorite Morettiny, Comanche, Early Red Haven, Reliance, C4/210, C4/110, C8/163, C4/38 and C4/57. Field evaluation of the peach in general confirmed the results of laboratory tests. A number of cultivars and forms showed high hardiness: Ak-Cheftalyu-2, Baten Kaisev, Iftihor, Ranniy-84, Panniy-85, nectarines Yevpatoriyskiy and Zee Gold. Winter-hardy cultivars include Candidatskiy, C1/227, Alma-Atinskij , Start, Peach Sungen de Toamna, Superba de Toamne, Pegaso, Mireille, Fairhaven, NSF2, mutants Sovetskiy 37-167 and 63-30, nectarines Ichunskiy, May Grand and Fantasia.

23.02.2007 the late winter frosts (-19.1°C) was marked. The duration of the frost period was 162 hours from 21 to 28 February. At first glance, not very a low temperature, but it struck a powerful irreversible damage: flower buds of all cultivars were damaged by 100%.

The winter 2006/2007 was unique. It has demonstrated effect of several factors hardiness: autumnal hardening, an early exit from the physiological rest, the frost resistance of flower buds in February, resistance to prolonged cold exposure. These factors have been reinforced pre-drought and frost of the previous year (23.01.2006 -25.6ºC). Trees have been weakened. Even the most winter-hardy cultivars were severely damaged. Not only generative buds, but also vegetative parts of the plant were damaged: bark, wood, core, infrarenal tissue.

10.01.2010 January frosts (-21.1)° C, that were close to the critical temperature negative for medium-hardy cultivars, had a great influence on the crop of peaches. Damage assessment showed that it is not winter-hardy and low hardy cultivars were severely damaged generative buds (60-100%). These include ‘Kremlevskiy’, ‘Ryabovskiy’, hybrid ‘84-2445’ etc. High winter hardy and hardy cultivars have had little or poor (30%), moderately hardy – average (30-60%) and significant (60%) damage to of flower buds. Medium and minor damage generative buds have not affected the yield of peach. These cultivars bloomed well in spring on 4-5 points (for a 5-point scale). These include ‘Posol Mira’, ‘Red Haven’, ‘G.Lebedev’, ‘Nikitskiy Podarok’ et al (Table.1). Damage to the flower buds cultivar Ryabovskiy estimated on 74%, significantly influenced the force of flowering (2 points) and reduced yield. Sorts Osvezhayuschiy and Clown are characterized by profuse the formation of generative buds. Despite the considerable them destruction of (61 and 74.8%, respectively), a good harvest is marked. ‘Iftihor’, ‘Posol Mira’, ‘Red Haven’ also refer to this category cultivars with the profuse formation of generative buds. This fact has significant advantages when choosing cultivars for orchards.

Average damage of flower buds were somewhat smaller in the garden near the v.Lobanovo (Dzhankoy, Crimea), although the cold there was stronger by one degree. ‘Red Haven’ had 28% damaged buds there, compared with 48% – in the v.Novyi Sad. Probably less frost damage of generative buds is associated with better agricultural background, plants be healthier physiologically and young plants (Tabl. 1).

[1] average value on a 5-point-scale;
[2] Evaluation of frost resistance generative buds.

Winter 2012 was a very interesting and special. The peculiarity of it is that frosts occur in a very short time, in February, so it was very cold (-19° – -23° C). The February cold spell was preceded by several warming and cooling in the December and January. In 02.02.2012 temperature have reached their extreme the value – (-23.6°C) on the stage of forced rest. The destructive action of the frost was accompanied by strong north-easterly winds, which blew continuously from 1 to February 10, with a force of 14 to 34 m / sec. In such unfavorable for fruit crops weather conditions chance for harvest did not remain. Flower buds of most cultivars of peaches and nectarines have been damaged to the maximum extent; they have survived only in very winter-hardy cultivars. The nature of damage is browning of pistils and anthers. 576 cultivars and forms of all were examined. 8 cultivars and perfect forms highlighted with power of flowering, estimated at 4 points, 9 – with the flowering of 3 points, 29 – with the flowering of 1-2 score and 85 – with a single flowering (on a 5-point scale). So, more than 60 winter-hardy cultivars and hybrids had allocated in extreme temperature conditions, the first decade of February 2012 (-19° – -23.6°) C. High winter hardy cultivars include Demerdzhinskiy, Candidatskiy, Crimskiy Feyerverk, Sochnyiy, Yubileyniy Ranniy, Sun Crest, Ranniy-84, Melitopolskiy Yasnyiy, elite forms C7/6, 10487, C16/87, hybrids 84-2468, 84-2445, №5714, *etc*.

The minimum air temperature (-24.1ºS) was recorded 08.01.2015. Evaluation of flower buds 30 cultivars and 20 hybrids of peach were carried out by means of laboratory and field methods. Selections of hybrid families with one or two hardy parents, such as Valiant's Crimean Fireworks were evaluated. Most samples had hundred percent damages of flower buds. Some generative buds of hybrids №80-426 (Valiant's Favorite Morettini) and №84-485 (Red Haven's Starking) had remained intact (5.3 and 0.7% respectively).

In 2016 are marked January frosts (-15,8°C) and spring frosts depth of -6.5°C and -8.5°C with an interval of 3 days 16.03 and 19.03.2016 (Table 2).

[1]Tight flower bud
[2]Loose flower bud

January frosts hadn't detrimental effect on the generative buds of peach, nectarine and peach decorative, as they were not deep enough (-15.8°C). Flower buds frost resistance of 12 cultivars and four hybrids of peach in the phase of formation of pollen (the appearance of the petals, tight or loose bud) were tested. Cultivars with high resistance to negative air temperatures (-6,5°C), and (-8,5°C) at this developmental stage were obtained. These include 'Nikitskiy Podarok', 'Osvezhayuschiy', 'Pushistyiy Ranniy', and '10607'. Percentage generative buds damage them was 3.7, 8.6, 8 and 13.9%, respectively. Cultivars 'Demerjinskiy', 'Startovyiy' have also shown relatively high cold resistance (damage to flower buds up to 30%) compared to 'Zolotaya Moskva' (79%), 'Rumyanyiy Nikitskiy' (74%) and 'Crimskaya Osene' (70%).

Latest returnable spring frosts were recorded 06.05.99 (-2.2)ºC. Such extreme temperature weren't more than 100 years ago. Virtually all of sets were damaged by that frost, and the harvest was destroyed. Return spring frosts of depth -10.4° C were fixed in April 2004 (04.04.04). Peach plants were in the phase of a "pink loose bud". In this year was allocated one cultivar of nectarine Crimchanin.

In 2009, two waves of cold weather were marked April 11-13 (-5° C) and April 21-23 (-6° C). The second wave of cold was greater in absolute value. With all other things being equal, cultivars with the rose-type flower (Candidatskiy, Crimskiy Feyerverk, C 7/6, C 16/87 and other) had less damage than ones with the campanula-type flower.

Some peach cultivars were allocated in test years with various extreme temperature factors, for example: Demerjinskiy, Osvezhayuschiy, Crimskiy Feyerverk, Posol Mira, Startovyiy, Yubileynyiy Ranniy and etc. These cultivars are adapted well to agro-climatic conditions of

the steppe Crimea. They were characterized by the high yield, the excellent taste and good biochemical parameters of fruits.

Conclusions

Evaluation of winter hardiness cultivars and forms of the peach gene pool of Nikitsky Botanical Gardens based on years of research is given, and very hardy specimens were identified. These include cultivars and advanced selections of peach Demerdzhinskiy, Ranniy 84, Andrey Lupan, Osvezhayuschiy, Candidatskiy, C7/6, C16/87ES, Melitopolskiy Yasnyiy, Nikitskiy Podarok, Comanche, Reliance, Sun Crest, '10487', '11417', '9978', '6312', ' 6610', '6331', '9381', '80-429', '172-88' and others. They are recommended for the state cultivar testing, for commercial use or for breeding. Thus, the creation and selection of hardy and very winter-hardy cultivars of peach allows them to grow in conditionally favorable regions of the steppe Crimea and Russia, where low winter-hardy cultivars of peach are not profitable.

Abstract

The paper presents the results of studies on important agro biological characteristics of the variety Pinot Noir, during the growing season in 2013 and 2014, in Trebinje. The tests of agrobiological characteristics which were done included: phenological properties, fruitfulness of buds and shoots and yield. During the years 2013 and 2014 a significant influence of climatic factors on the phenological characteristics of the studied varieties was observed. The observed climatic factors have influenced the development of a large number of fruitful shoots (12) and bunches per vine (14) in 2013 compared to 2014, when the number of fruitful shoots was 10.5 and the number of bunches per vine was 13.4. During 2014 there was a larger number of clusters per bud (1.12) and per fruitful shoot (1.59) compared to 2013. The yield of grapes per bud (110 g) and per fruitful shoot (137.5 g) was higher in 2013, compared to 2014 when the grape yield per bud was 84 g and the yield per fruitful shoot was 120 g. The higher yield of grapes per vine (1.65 kg) and per hectare (7638.88 kg/ha) was also recorded in 2013, while in 2014 the yield per vine of 1.26 kg and the yield per hectare of 5832.54 kg/ha was determined.

Keywords: *Pinot Noir, phenological characteristics, fertility of buds and shoots, yield*

Introduction

Due to climatic conditions, vine occupies a wide area of distribution. *Vitis* varieties are grown in zones of moderately - continental, subtropical and Mediterranean climate (*Žunić and Garić,* 2010). Climatic conditions (solar radiation, heat accumulation, rainfall, frost, temperature, humidity, etc.) have a strong impact on viticulture, affecting grapevine growth, chemical and sensory characteristics of the wine. Out of all the climatic factors, temperature appears to be one of the most important (*Ruml et al.*, 2012). 'Pinot Noir' originates from the Burgundy region in France which means that its adaptation is very specific to this environment. Now 'Pinot Noir' has become an international variety and it is grown in a large number of viticultural regions all around the world (*Ranković-Vasić et al.,* 2015). The reconstruction of the vineyards in the area of Herzegovina started in the last decade and new varieties have been introduced since then, Pinot Noir variety is one of them.

The aim of this study was to investigate the basic agro biological properties of this variety and the possibility of its cultivation in climatic conditions of the city of Trebinje and other wine regions of similar agro ecological conditions.

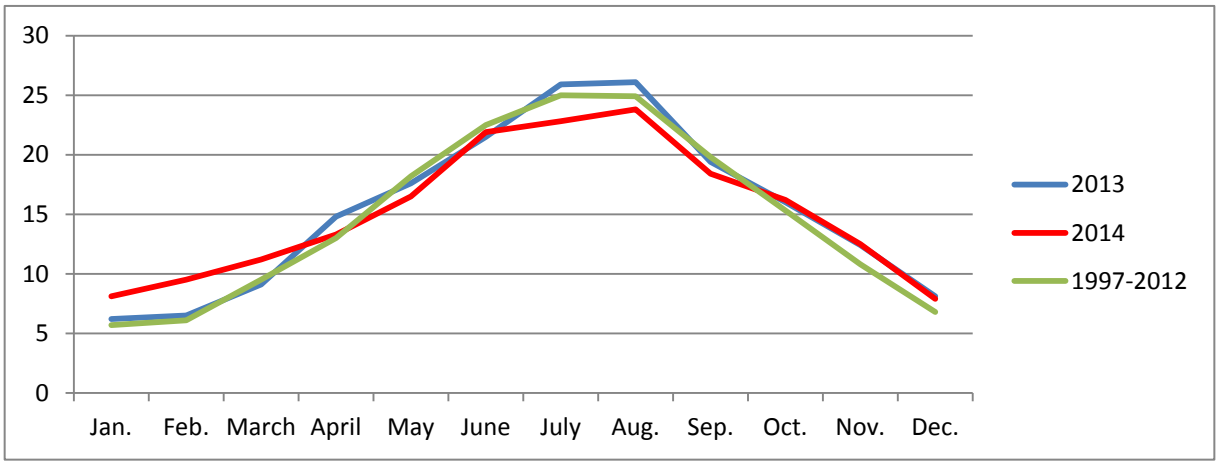
Material and methods

The research of agrobiological characteristics of Pinot Noir variety was carried out during the growing season in 2013 and 2014, in Trebinje area (Entity of Republic of Srpska, Bosnia and Herzegovina). The experiment was set up at the location of Zasad polje. This vineyard was founded in 2008 at an altitude of 273 m. The distance between plantings was 2.4 x 0.9 m. 10 vines were selected for the research, and each vine served as a separate experimental unit in the research. During the pruning, 15 buds were left on the vine. Basic measures of pruning were applied during the two years of research in experimental plantation, as well as basic measures for the protection of the most important causes of disease and pests. During the research, the "drop by drop" method of irrigation was used on the plantations. Agrobiological

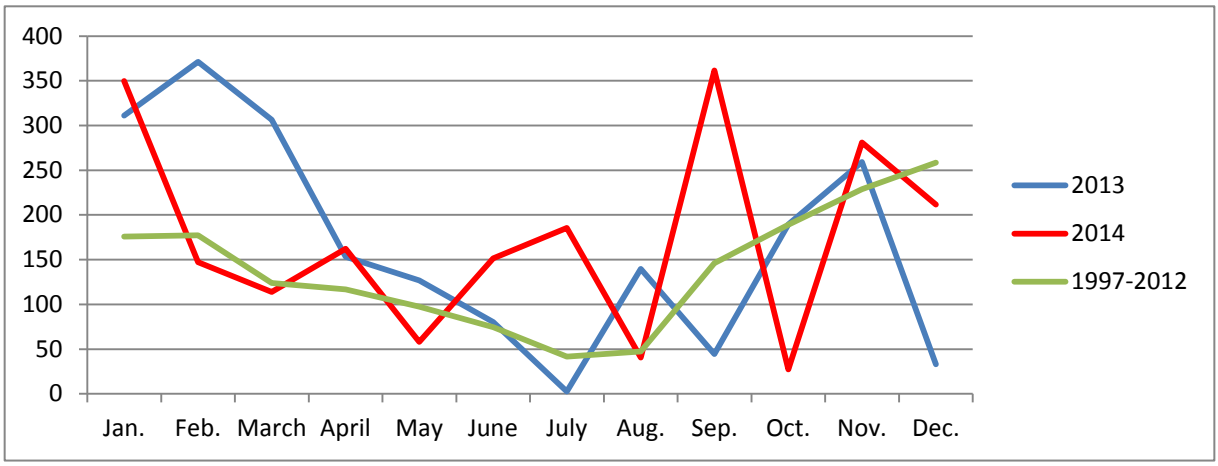
characteristics of the variety which were investigated were: phenological characteristics, fertility of buds and shoots and yield. Phenological observations were carried out on the basis of monitoring and inspecting of the pheno-phases in the annual cycle of development of the vine. Phenological characteristics of the variety which were monitored were: the beginning of tearing, the beginning of budding, beginning, fullness and end of blooming, duration of flowering, the growth of berries, the beginning of a hinge and maturing of berries. The load of fruitful buds significantly has an impact on productivity and the development of vines. The indicators of fertility of buds and shoots which were studied were: the number of buds per vine, the number of fertile shoots, number of bunches per bud, the number of bunches per vine and the number of clusters per shoot. The yield of analyzed variety of grape is registered by specifying different categories of fertility: per bud, per bearing shoot, (expressed in g / bud, and bearing shoot) per vine (expressed in kg / vine) per unit area (kg / ha). The data from Hydrometeorological Institute of the Republic of Srpska was used for the analysis of meteorological conditions observed during the two years.

Results and discussion

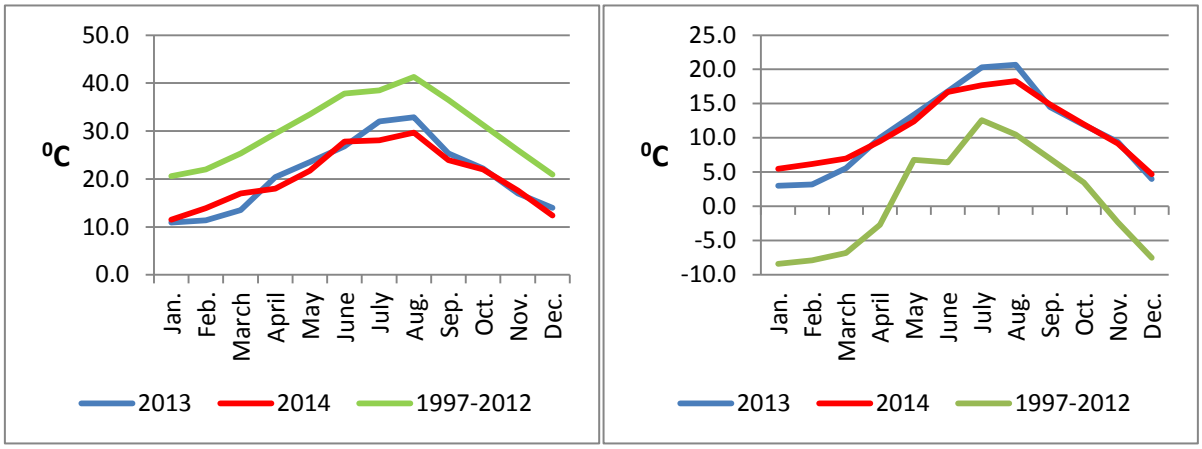
Trebinje is located in a zone of altered Mediterranean climate. It is characterized by a large number of sunny days (260), low relative humidity and cloudiness, rains in winters and warm summers. Autumn is significantly warmer than spring, the snow falls very rarely, and when it falls, it does not stay for too long. The relief of the municipality is dominated by the mountain Leotar, the river Trebišnjica, and Trebinje field and Popovo field. Compared to long-term averages (1997-2012) both observed years were warmer and had more rainfalls (Graph 1. and Graph 2.). The average monthly air temperature for the period from January to March was significantly higher in 2014, while in the period from April to September temperatures were higher in 2013. Average maximum temperature in July and August, and the average minimum temperature increased in 2013, while in January, February, and March average maximum and minimum temperatures were higher in 2014 (Graph 3.). In February and March of 2013, rainfall was considerably higher than in 2014, while in June, July and September rainfall was considerably higher in 2014. During 2014 there was 70 mm more rainfall than in 2013.



Graph 1. - Average monthly temperature for the period of 1997-2012 as well as for 2013 and 2014 years.



Graph 2. - Average monthly rainfall for the period of 1997-2012 as well as for 2013 and 2014 years.



Graph 3. – Average monthly maximum and minimum temperatures for the period of 1997-2012 as well as for 2013 and 2014 years.

Monitoring of phenological development of the vine varieties in certain agro ecological conditions is of great importance from the point of analysis of fruiting and quality of grapes. The course of duration of certain stages in the annual cycle of development of Pinot Noir variety in conditions of Trebinje area can be seen from the data presented in Table 1.

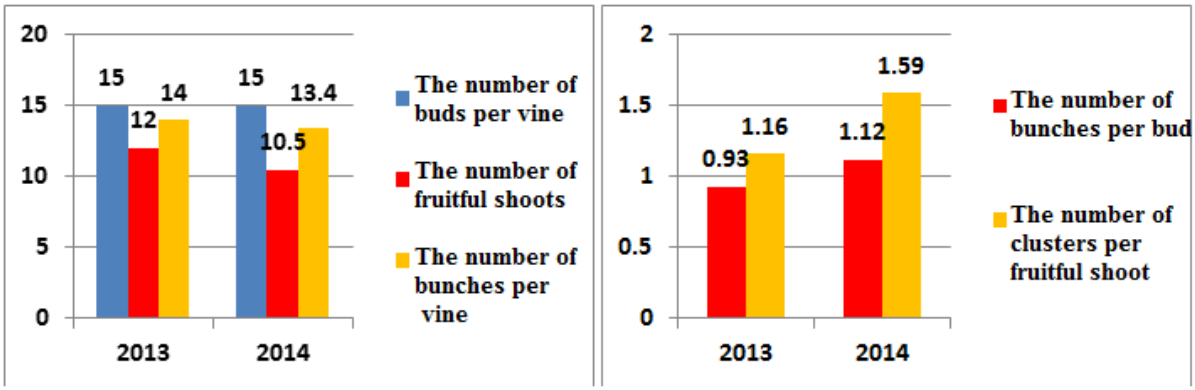
Analysis of data from Table 1. shows that pheno-phase of tearing started earlier in 2014 (March 10). This happened because of the slightly higher temperature during the month of March in 2014 (Graph 1. and Graph 3.). The results, which are shown in Table 1. showed that Pinot Noir variety had earlier beginning of budding in 2014 (March 15). The range of vegetation movement and the opening of buds, amounted to 16 days. The beginning of flowering began earlier in 2013 (May 19), when the temperature was slightly higher than in 2014 and than the average of several years (Graph 1.). The beginning of flowering of this variety began somewhat later compared to the results cited by *Garić et al.* (2007) for the conditions of Aleksinac sub-region, which can be explained by different climatic conditions. Pheno-phases of full flowering occurred 5 to 10 days after the beginning of flowering, May 23 in 2013 and May 25 in 2014. End of flowering occurred on 31 May in both years. The blossoming of studied varieties in average lasted for y11 days. Pheno-phase of berry growth lasts from beginning of the seeding of the berries and lasts until the beginning of their maturation, the hinge of the grapes. Berry growth pheno-phase in 2014 began on June 5, and in 2013 it began a little later (June 12). Pheno-phases of the hinge (Table 1.) started earlier in

2014 (July 20). The moment of getting to full maturity varies greatly from year to year, and depends even more on the range in which the variety is grown and climatic conditions (*Artem et Antoc,* 2013). The full maturity of this variety occurred earlier in 2013 (August 30), while in 2014, due to heavy rainfall, it occurred somewhat later (September 8) (Graph 2.).

Table 1. – Beginning time of certain pheno-phases of Pinot Noir variety

Pinot Noir	2013	2014
The beginning of tearing	26.03.	10.03.
Beginning of budding	01.04.	15.03.
Beginning of blooming	19.05.	22.05.
Full blooming	23.05.	25.05.
End of blooming	31.05.	31.05.
Duration of blooming (days)	13	9
Growth of berries (6-7 mm)	12.06.	05.06.
Hinge	22.07.	20.07.
Full maturity	30.08.	08.09.

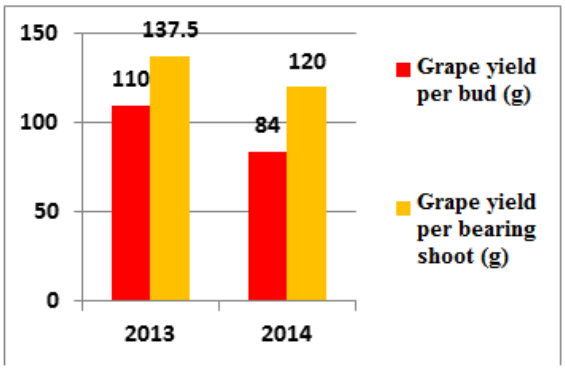
The degree of the load with fruitful buds significantly impacts on productivity and the development of vines, yield and quality of grapes (*Nakalamić and Marković,* 2009). Based on the data presented in Graph 4., the analysis of the search results can be carried. During pruning 15 buds were left on each vine. The number of fruitful shoots depended on the weather conditions in certain years. The number of fruitful shoots is higher in 2013 (Graph 4.). The number of clusters per bud and fruitful shoot was within the limits stated by *Avramov* (2001) and *Garić et al.* (2007). The number of clusters per vine was satisfactory for achievement of normal yield of grapes.



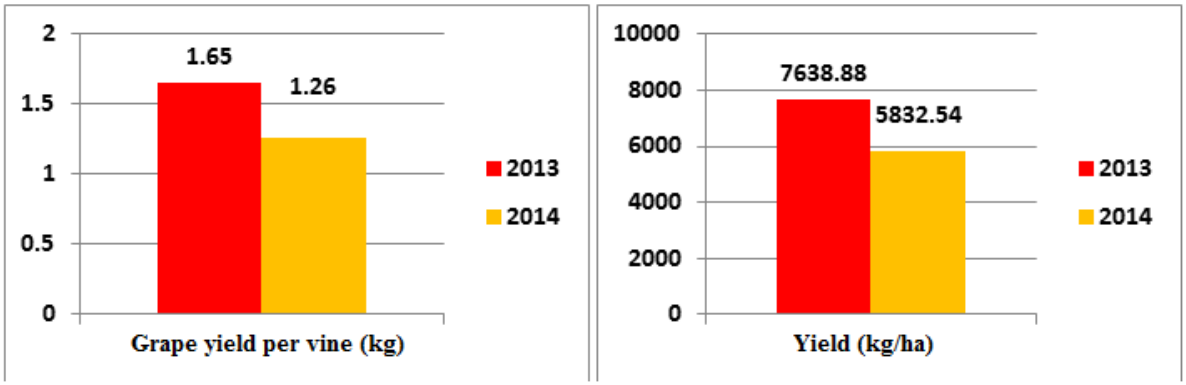
Graph 4. – Fruitfulness of buds and shoots

Grape yield depends on several factors, among which the biological characteristics of grown varieties, environmental conditions and the way of growing grapes stand out. In one variety in the same agro ecological conditions, the yield varies depending on the age of the plant, as well as vegetative and fruitful potential of vines. The variation in yield in native vineyard

during the years is 10% to 20%, depending on the meteorological conditions and applied agro-techniques (*Nakalamić and Marković,* 2009). Based on the analysis of the data presented in Graph 5., it can be seen that the yield of grapes per bud (110 g) and productive shoot (137.5 g) was higher in 2013 compared to 2014, when the yield per bud was 84 g, and the yield per bearing shoot was 120 g. Higher yield of grapes per vine (1.65 kg) and per hectare (7638.88 kg / ha) was also recorded in 2013, while in 2014 the yield per vine of 1.26 kg and the yield per hectare of 5832.54 kg / ha was recorded, Graph 6. These results are consistent with results of *Burić* (1995), *Avramaov et al*. (2001) and *Ranković-Vasić et al.* (2011).



Graph 5. – Grape yield per bud and bearing shoot



Graph 6. – Grape yield per vine and per hectare

Conclusions

Based on the results presented on agro biological properties of Pinot Noir variety cultivated in agroecological conditions of Trebinje the following conclusions can be formed:

- A significant impact of climatic factors on the beginning time of pheno-phases this variety is detected.
- The observed climatic factors influenced the development of a large number of productive shoots, bunches per vine, grape yield per bud, grape yield per bearing shoot, grape yield per vine and per hectare in 2013 compared to 2014.
- In 2014, a larger number of clusters per bud and per productive shoot were detected compared to the year 2013.
- Pinot Noir variety shows positive properties in agroecological conditions of Trebinje city area.

Abstract

Chicory (*Cichorium intybus* L.) is an important medicinal plant used traditionally to cure various diseases. The whole plant contains various medicinally important compounds and the concentrations of the compounds vary in different tissues. Callus induction and shoot regeneration of Chicory using leaf and petiole explants were investigated by studying the effects of different combinations of plant growth regulators. Leaf and petiole explants were cultured on MS medium supplemented with different concentrations of IAA/KIN and NAA/TDZ. In leaf and petiole explants highest callus induction were obtained in the medium containing 0.3 mg l^{-1} IAA with 0.5 mg l^{-1} KIN and 0.6 mg l^{-1}NAA with 0.02 mg l^{-1}TDZ.The results showed that the highest regeneration percentage and the number of regenerated shoots were obtained in the medium containing 0.1 mg l^{-1}IAA with 1.5 mg l^{-1}KIN in leaf and petiole explants. In addition, the highest regeneration percentage and the number of regenerated shoots were obtained in the medium containing 0.1 mg l^{-1} NAA with 0.5 mg l^{-1} TDZ in leaf explant and no regenerated shoots were produced in the presence of NAA and TDZ in all combination tested in petiole explant.

Keywords: *Cichorium intybus* L., *Callus induction, Explant, Plant growth regulators, Regeneration.*

Introduction

Chicory (*Cichorium intybus* L.) belonging to Asteraceae family is commonly known as witloof chicory (Bais and Ravishankar, 2001). The leaves and the roots of this medicinal plant are edible and commonly used as salad and some varieties are cultivated for coffee substitute after roasting the roots. In folk medicine, the plant is used for the treatment of diarrhea, spleen enlargement, fever, and vomiting. Antihepatotoxic activity on damaged rat's liver sections (Zafar and Ali, 1998) and anti-bacterial activity of this crop (Petrovic *et al*., 2004) has been recently reported. The alcoholic extract of Chicory is also used against pyrorrhea or gingival inflammation (Patel and Bhatt, 1985) and contains large numbers of pharmaceutically important phytochemicals including sesquiterpene, lactones, glycosides flavonoids, coumarins, anthocyanins, organic acids, and cytokinins (Bais and Ravishankar, 2001) Rehman *et al*., (2003) reported *in vitro* regeneration from leaf explants and various hormonal combinations. Nandagopal *et al*.,(2007) studied *in vitro* regeneration of Chicory from cotyledon explants and different combinations of plant growth regulators. Yucesan *et al*., (2007) developed a protocol for the regeneration of plantlets from leaf and petiole explants of witloof chicory. Geun- Won *et al*., (2009) also studied *in vitro* regeneration for genotypes, Radcchio and Italiana of *Cichorium intybus* L. var *foliosum*, using leaf and petiole explants. Lastly, Maroufi *et al*., (2012) studied *in vitro* regeneration of *Cichorium intybus* var. *sativum* from leaf and cotyledon explants and different combinations of plant growth regulators.

The aim of the present investigation was optimization of callus induction and shoot regeneration from leaf and petiole tissues of landrace genotype of Chicory (Esfahan) and this

protocol will effectively be used in *Agrobacterium* mediated gene transformation for Chicory breeding.

Materials and Methods

Esfahan genotype (Pakan Bazr Ltd) was used in this investigation. Seeds of chicory were first washed with running tap water for 30 min then seeds were surface sterilized by dipping in 70% ethanol for 90 s and rinsed with sterile distilled water, followed by immersing in 5% sodium hypochlorite solution for 25 min and thereafter rinsed for 30 min with sterile distilled water. Sterilized seeds were germinated on MS medium (Murashige and Skoog, 1962) supplemented with 0.8% agar and 3% sucrose. The basal medium used in this investigation was MS (Murashige and Skoog, 1962). For shoot regeneration, leaf and petiole explants (5 mm segments) excised from 4-week-old sterile seedlings were cultured on MS medium containing different concentrations and combinations of IAA/KIN and NAA/TDZ in two separate experiments. The cultures were incubated in a growth chamber at 25 ± 2°C under 16/8 h (light/darkness) photoperiod using white fluorescent light. Experiments were performed factorial based on completely randomized design and four replicates per treatment with 8 explants for each replicate were used. The percentage of callus induction and shoot regeneration were calculated for the leaf and petiole explants that had been cultured for 4 weeks. Data was subjected for analysis of variance (ANOVA) and compare means using SPSS 16.0.

Results and Discussion

The effect of different concentrations and combinations of the selected plant growth regulators were investigated on callus induction from leaf and petiole explants (Table 1 and 2). In consistent with the results presented in Table 3 and 4, explants cultured on medium containing either no plant growth regulators (control) or cytokinins alone produced no callus at all and other different concentrations of IAA/KIN and NAA/TDZ, callus formation from leaf and petiole explants was observed in all hormone combinations after 2 week. In leaf and petiole explants highest callus induction were obtained in the medium containing 0.3 mg l^{-1}IAA with 0.5 mg l^{-1}KIN and 0.6 mg l^{-1}NAA with 0.02 mg l^{-1}TDZ (100%).

Leaf and petiole explants excised from 4-week-old sterile seedlings were cultured on MS medium containing different concentrations and combinations of KIN with IAA and NAA with TDZ. Explants cultured on medium containing no plant growth regulators (control treatment) and IAA and NAA alone produced no shoots at all in both types of explants. The combination of 0.1 mg l^{-1} IAA and 1.5 mg l^{-1} KIN was the most successful of the treatments tested, producing a mean of 2.4 shoots per explant at 71% shoot regeneration frequency in leaf explant and mean of 1.13 shoots per explant at 62.5% shoot regeneration frequency in petiole explants. In leaf explants mean number of shoots per explant was achieved nearly twice more than the petiole explant. The results also showed that the highest regeneration

percentage and the number of regenerated shoots were obtained in the medium containing 0.1 mg l^{-1} NAA and 0.5 mg l^{-1} TDZ in leaf explants (75% regeneration shoots and 3.1 shoots per explant respectively) (Figure 1). No regenerated shoots were produced in the presence of NAA and TDZ plant growth regulators in all combination tested in petiole explant. To identify the relationship between callus induction and shoot regeneration, Pearson's correlation coefficient was computed. Pearson's correlation coefficient identified that callus induction was correlated with shoot regeneration. These variables were positively correlated (0.848), and the correlation was statistically significant at the 0.01 level.

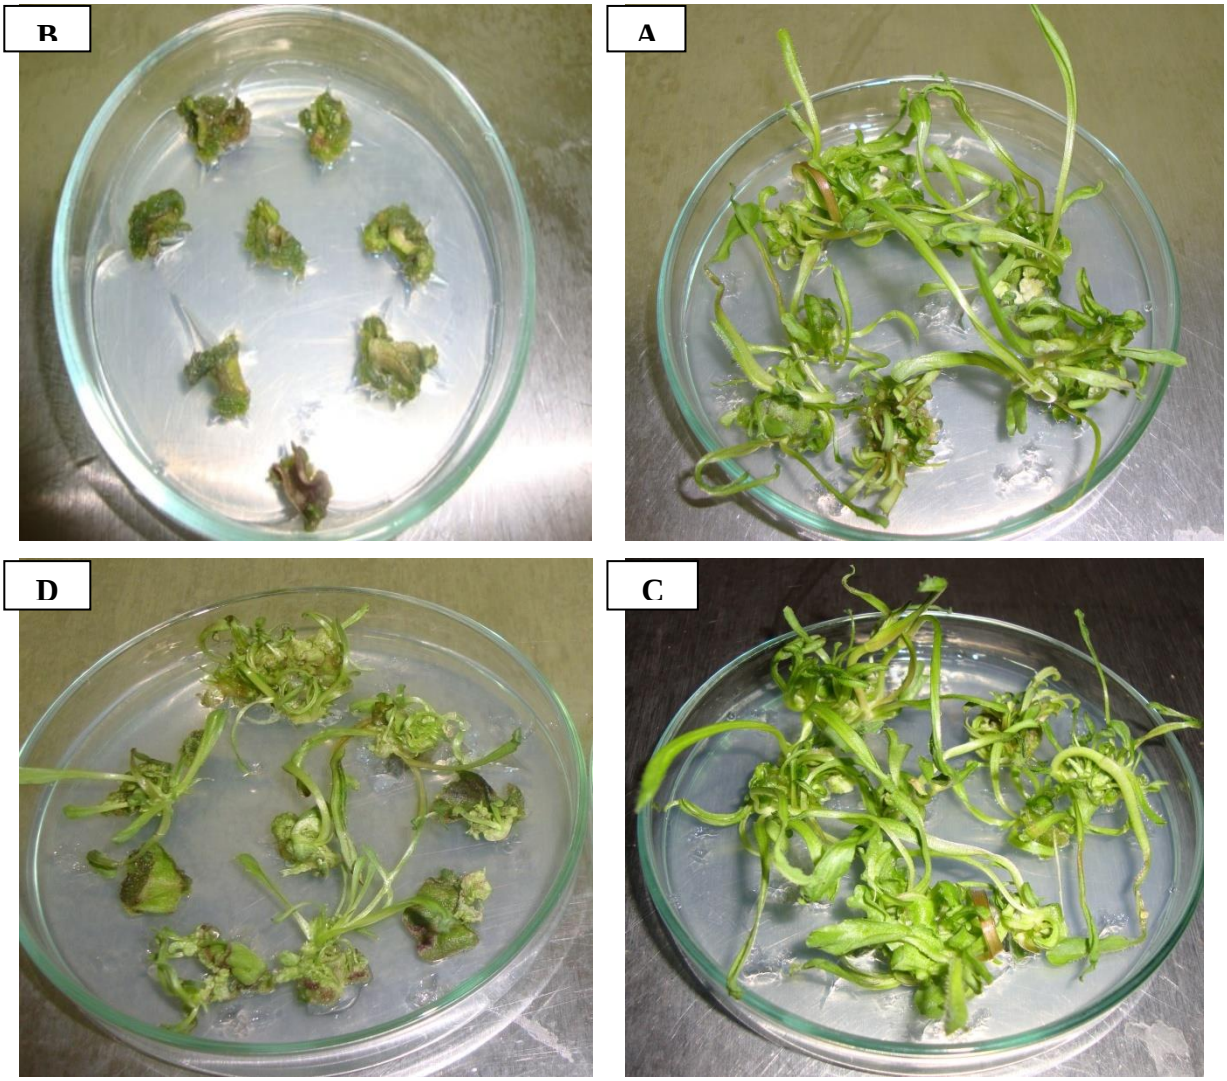

Figure 1.A: Effect of NAA and TDZ on leaf explant regeneration B: Effect of NAA and TDZ on petiole explant callus induction C: Effect of IAA and KIN on leaf explant regeneration D: Effect of IAA and KIN on petiole explants regeneration

Callus induction and shoot regeneration are *in vitro* tissue culture methods, which depend on environmental conditions and plant growth regulators. Optimization of these factors is essential to establish a high frequency of callus induction and shoot regeneration and gene transfer to this plant. Plant growth regulators and types of explant are the most important factors for callus induction and shoot regeneration phases (Mineo, 1990). The application of different concentrations of plant growth regulators had a significant influence on callus development and organogenesis. The response of explants to form callus was seen within two

weeks incubation on callus inducing medium containing different plant growth regulators for both explants (leaf and petiole) of chicory. The same observations were reported by Nandagopal and Ranjitha (2007). In this study, the combinations of IAA/KIN and NAA/TDZ showed a positive effect on cell division for both leaf and petiole explants. Lim *et al*., (2003) obtained maximum callusing for both explants leaf and petiole of chicory in combination 0.1 mg l^{-1} IAA and 0.2 mg l^{-1} TDZ. Yucesan *et al*., (2007) reported that NAA alone or in combination with 6-BAP produced considerably more callus with green-to-yellowish and highly friable callus. Velayutham *et al*., (2007) reported that a higher frequency of callus was observed on MS medium supplemented with NAA (1.86 mg l^{-1}) in combination with BAP (0.45 mg l^{-1}). In shoot inducing phase, shoots were produced within three to four weeks. The number of induced-shoots was found to vary in the different combinations of IAA/KIN or NAA/TDZ. High promotion of shoot regeneration in the presence of IAA/KIN or NAA/TDZ in this study is compatible with several reports for different chicory cultivars by Park and Lim (1999); Velayutham *et al*., (2007); Nandagopal and Ranjitha (2006); Yucesan *et al*., (2007); Hyeon-Jeon *et al*., (2009); Geun-Won *et al*., (2009); Maroufi *et al*., (2012).

Both direct and indirect shoot regeneration require plant cells to undergo dedifferentiation and redifferentiation, both of which are known to be affected by not only exogenous plant growth regulators but also endogenous content of the hormones (Trigiano and Gray, 2000). Different tissues may have different levels of endogenous hormones and, therefore, the type of explant source would have a critical impact on the regeneration success. In our study, when leaf and petiole explants were compared, it was clear that leaf explants were much more productive for shoot formation than petiole explants, in the combinations of IAA/KIN producing nearly two times more shoots (2.4 shoots per explant compared to 1.13, respectively). In the combinations of NAA/TDZ, highest regeneration percentage and the number of regenerated shoots were 75% regeneration shoots and 3.1 shoots per explant respectively in leaf explants. No regenerated shoots were obtained in the presence of NAA and TDZ plant growth regulators in all combination tested in petiole explant. Park and Lim (1999); Yucesan et al., (2007); also found that leaf segments were more productive for both callus and shoot development than petiole segments although there was a clear genotypic variation among the eight *Cichorium intybus* cultivars tested. Karam and Al-Majathoub (2000) reported that the cells most competent to differentiate into shoots are located at the petiole base, but to express their totipotency, they are dependent on some factors contributed by the leaf. An increased amount of vascular tissue and thus levels of endogenous hormones and metabolites in the leaf might be responsible for the increase in shoot regeneration ability.

WILD ALMOND SPECIES IN TURKEY AND USE OPPORTUNITIES

Safder BAYAZIT[1*], Oguzhan CALISKAN[1]

[1]Mustafa Kemal University, Faculty of Agriculture, Department of Horticulture, Antakya, Hatay, Turkey
*Corresponding author: sbayazit@mku.edu.tr

Abstract

Due to the suitable climatic conditions, Turkey is one of the most important growing center for wild and domesticated species/varieties of almond. Because of the adaptability of wild almond species to severe environmental conditions and resistance to drought, salinity and some pest and diseases, these can be used as rootstock for almond cultivars and in breeding programs for rootstock improvement in Turkey. In this review, we evaluated to the distribution of *A. orientalis, A. turcomanica, A. arabica and A. webbi* almond species in Turkey and its potential as a multi-purpose crop. These species are naturally widespread as genetic resources in many regions of Turkey. Seedlings of these species can be used for as dwarf rootstocks for almond cultivars due to them are growing weak. In addition, the species show a great tolerance to abiotic stresses such as drought, salinity, low soil fertility and low winter temperatures; therefore the species may present an important genetic resource to be used for development of new cultivars and rootstocks that are more adapted to differ climate change in almond breeding programs.

Keywords: *wild almond, species, rreeding, rootstock*

Introduction

Turkey is located at a significant position in the world from the viewpoint of plant genetic resources and genetic diversity. It is scientifically agreed that two of the centers of diversity and centers of origin; the Near Eastern and the Mediterranean overlap at Turkey. Turkey is the meeting ground of three phytogeographical regions; Euro-Siberian, Mediterranean and Irano-Turanian. Due to its great variety in geomorphology, topography and climate, Turkey has large diversity of habitats so it is very rich in plant species and endemism. Based on the information given by Davis et al. (1988) the number of native ferns and seed plant species were stated as 8.745 by Kaya et al. (1998), 2.763 of which are endemic. In addition to these figures about 1.000 new species were listed by Güner et al. (2000). Altogether the number comes to a total of approximately 10.000.

The cultivated almond [*Prunus dulcis* (Mill.) D.A. Webb syn. *P. amygdalus* (L.) Batsch] belonging to *Rosaceae* family, subfamily *Prunoideae,* is originated from Central Asia (Grasselly, 1976). Wild populations of almond species representing a wide range of morphological characteristic have been widely spread in these areas (Browicz and Zohary 1996; Kester and Gradziel 1996). Turkey is especially rich in native germplasm of these wild species such as *A. orientalis, A. turcomanica, A. webbii* and *A.arabica* that are naturally distributed throughout the country (Bayazit, 2007; Bayazit et al., 2011). These wild species relative of almond play a socio-economical and ecological role in this region (Bayazit, 2007). They not only have been used as direct consumption, but also have been used as a rootstock, and in semi-desert areas to control soil erosion and to stabilize water sheds (Mortazavi 1986). Wild species also provide an extended germplasm for breeding improved cultivars, contributing useful traits such as late bloom, self fertility, and drought and salinity tolerance (Denisov 1988; Gradziel *et al.* 2001). Recent studies have been performed using morphological and pomological, molecular markers for the genetic characterization of these Turkish wild *Amygdalus* species (Martinez-Gomez *et al.* 2003; Bayazit, 2007).

The genus *Amygdalus* L. contains some 26 well defined species (Table 1), as well as a long list of additional binomials.

Properties and distribution of the almond species in Turkey

There are several wild almond species in Turkey included *Amygdalus orientalis* (Mill.), *Amygdalus turcomanica* (Lincz.), *Amygdalus fenzliana* (Fritsch) Lipsky, *Amygdalus trichamygdalus* (Hand.-Mazz.) Woronow, *Amygdalus arabica* (Olivier), and *Amygdalus webbii* (Spach). These species offer a great value for the almond improvement; we studied the distribution area on Turkey and morphological and pomological properties of these almond species. Distribution areas and properties of naturally grown almonds species in Turkey are provided below.

***Amygdalus trichamygdalus* (Hand.-Mazz.):** A narrowly distributed East Anatolian species, and one of the least known members of the *Communis* group. Only a few scattered stands of this wild almond have been discovered up to date in eastern Turkey and in adjacent areas in Iran. They grow on limestone slopes and in rock gorges at 1250-1900 (-2100) m elevation. Spineless shrubs up to 3 m tall (sometimes small trees) closely resembling *A.*

communis but with characteristic short-petioled leaves, bearing relatively large (3.0 × 2.0 cm) compressed fruits (Browicz & Zielifiski, 1984).

***Amygdalus fenzliana* (Fritsch) [Syn.: *Prunus fenzliana* Fritsch]:** A subspinescent shrub usually 2-3 m tall (and more rarely a small tree up to 4 m height), with rather large (2.5 x 1.5 cm) tomentose fruits. A Caucasian element extending to northeast Turkey and northwest Iran and Armenia growing mainly in stony or rocky slopes occupied by sparse xerophytic woody vegetation or in open steppe communities, mostly between 700-1800 m altitude **(**Browicz & Zielifiski, 1984**).** Nuts are small, flat, and hard shelled. The shell surface has sparse, shallow holes. Kernels are bitter **(Kester et al., 1991).**

***Amygdalus webbii* Spach, [Syn.: *A. salicifolia* Boiss. & Bal.]:** Much branched spinose shrubs or small trees usually attaining the height of 2-3 m. A very variable wild almond in terms of leaf size and fruit shape, with linear oblong to lanceolate leaves and relatively small fruits. A Balkano-Anatolian species, extending to Puglia district in south Italy and to Sicily. It was also reported growing spontaneously in Spain (Felipe & Socias i Company, 1977). According to the Vlasic (1977). This primarily European species occurs in a range extending from western Turkey into the balcan peninsula including Greece, Bulgaria, and Yugoslavia. *A. webbii* grows in open sunny places in limestone rocks or gravelly slopes from sea level up to 900 m altitude. Few stands were recorded up to 1200-1600 m (Browicz& Zielifiski, 1984).

***Amygdalus graeca* Lindley, [Syn.: *A. discolor* (Spach) *Prunus discolor* (Spach)]:** A shrub or small tree 1-4 m tall, resembling A.*orientalis* in its growth form but more spinescent and with glabrous dorsal leaf surface. The main range of *A. graeca* is in southwest Anatolia and in some of the adjacent Greek Islands, particularly Rhodos. *A. graeca* reappears in Aleppo district, Syria and near Ankara, Turkey, but in these localities it is represented only by few stands. *A. graeca* is a xerophylous shrub growing on rocky calcareous slopes mainly in phrygana-type vegetation. In few places (in Anatolia) it occurs side by side with *A. orientalis.* However such contacts are relatively rare since *A. graeca* is distinctly a low altitude plant, growing mainly at altitudes ranging from 10 to 500 m (Browicz & Zielifiski, 1984).

***Amygdalus kotschyi* Boiss. & Hohen., [Syn.: *Prunus kotschyi* (Boiss. & Hohen.)]**: A small subspinescent shrub scarcely 30-45 cm tall, characterized by very dense, soft, long, yellowishgrey hairy cover on the shoots, leaves and fruits. A montane species confined mostly to the Zagros mountain range of west Iran and north Iraq as well as few sites in southeast Anatolia. It grows on limestone rocks, bolders and screes and in dry and open places in the upper margins of the oak and pistachio park-forest zone, and also in the thorny cushion-type vegetation above the forest belt, in altitudes between 1800 and 2500 m **(**Browicz & Zielifiski, 1984).

***Amygdalus carduchorum* Bornm., [Syn.: *Prunus carduchorum* (Bornm.)]:** A small subspinescent shrub 0.5-1.0 m high with narrow, lanceolate or linear leaves and with globose or ovate-globose slightly compressed up to 15 mm long fruits. A narrowly distributed montane species, restricted to a small area in Norh Iraq on the border between Turkey, Iraq and Iran. It occurs mainly close to the upper limits of the oak park-forest belt, and in the zone of the thorny cushion-type vegetation above it, growing on rock slopes and screes, in open places or in degraded oak forests in altitudes between 1500 and 3000 m (Browicz & Zielifiski, 1984).

***Amygdalus arabica* Olivier, [Syn.: *A. spartioides* Spach, *Prunus spartioides* (Spach)]:** *A. Arabica* is a Near Eastern plant. Its range covers southeastern Anatolia, Iraq and Syria. An erect, broom-like shrub up to 1.5-2.5 m in tall, characterized by stiff, long, permanently green, glaborous, angled branches. Throughout most of the year the shrubs are leafless since they shed their leaves at the beginning of the dry season. This almond grows on dry bare limestone rocks and sandstone cliffs, both in lowland and in hilly terrains. In the

northern parts of its distribution it occurs in degraded oakwoods, while in the more arid south it enters forest-steppe, steppe and semi-desert formations. *A. arabica* is also found in sandy places and in wadi beds. Its altitude range is between 150-1200 m, rarely up to 1500 m (Browicz& Zielifiski, 1984).In Turkey, this species can be found in rocky and mountainous areas (about 400 m to 1500 m), steppes, and semiarid to arid habitats. They may grow in a wide range of habitats including stony to sandy slopes, dry valleys of Adıyaman and Gaziantep cities in southeastern region (Atlı, 2008).

***Amygdalus spinosissima* Bunge. [Syn.: *Prunus spinosissima* (Bunge)]:** A very prickly shrub, 1.5-2.0 m tall or rarely a small tree. The first year twigs are purple-red and lustrous, the older twigs are grey while the bark of well developed trunks is almost black. The fruits are variable, up to 2 cm long. Two subspecies have been recognized in this almond: Relatively taller forms (subsp. *spinosissima),* with long-ovate to ovate lanceolate and more or less flattened drupes occur in the eastern part of this species range. Somewhat lower forms (subsp. *turcomanica* (O. Lincz.) Browicz.), with smaller and globular fruits grow in the west part of the range (Browicz & Zielifiski, 1990).

***Amygdalus turcomanica* Linczis:** Essentially the same species as *A. spinosissima* but grows at a lower elevation (Denisov, 1988). Typically, the plants are small bushes (1 to 1.5 m) very thorny and adapted to extreme xerophytic conditions of Gaziantep and Şanlıurfa cities of Turkey. Leaves are very small and dark green color. Nuts are very small and generally round shape (Bayazit, 2007).

***Amygdalus orientalis* Duhamel, [Syn. *A. argentea* Lam., *Prunus argentea* (Lam.) Rehder]:** A subspinescent shrub 1-2(3) m tall, characterized by white tomentose shoots, leaves and fruits, particularly when of young age. The fruits are very variable in size and shape_ *A. orientalis* is a Near East species. In northeast Iraq and in south and central Anatolia it is one of the most common wild almond species. Specimens with large (up to 3 cm) and much flattened fruits occur in the southern part of its distribution range. *A. orientalis* mainly occupies open, sunny niches such as sandy hills covered with steppe or steppe forest vegetation, loose gravel and limestone cliffs or rock slopes. *A. orientalis* is a low altitude plant, growing mainly in altitudes between 600 and 1200 m (Browicz & Zielifiski, 1984) nuts are small, hard shelled and have grooved (Kester et al., 1991). According to the Bayazit and Küden (2007) *Amygdalus orientalis* is widely grown in Middle and Southeast Anatolia while *A. turcomenica* is prevalent in the Southeast Anatolia region. Nut weights of *A. orientalis* types were higher than those from *A. turcomenica* types in Birecik, Şanlıurfa. Types of *A. orientalis* had higher kernel weight and nut length and lower shell thickness compared to types of *A. turcomenica*. Types of *A. orientalis* from Middle Anatolia had higher nut and kernel weight, nut width and length, shell thickness compared to types from Southeast Anatolia region. All types had bitter kernel in both species and regions (Table 2).

Table 2. Fruit quality and pollen characteristics of important almond species (Bayazit et al., 2011; Bayazit et al., 2012)

Potential usage of almond species for horticulture

Several almond species such as A. orientalis (Mill.), A. turcomanica (Lincz.), A. fenzliana (Fritsch) Lipsky, A. trichamygdalus (Hand.-Mazz.) Woronow, A. arabica (Olivier), and A. webbii (Spach) are found in Anatolia. Some of these species has been partly domesticated and they might offer some possibilities for horticultural utilization. For example, Kester and Gradziel (1996) reported that immense possibilities exist for rootstock improvement through the use of other almond species either by direct selection within the species or by their hybridization with almond cultivars. Thus, these species are important germplasm sources of almond and their wide genetic diversity present among related almond species provides an enlarged pool of available germplasm that has not been sufficiently exploited. There is not any important restriction regarding hybridization and backcrossing of species in almond breeding studies involving the species present in Anatolia.

Successful almond production under different ecological region and conditions requires breeding of resistant individuals. For these purposes; *A. davidiana* (Carr.) and *A. mira* Koehne are used for disease resistance of peach and self-fertile cultivars of almond,

A. orientalis is used for cold resistance and self-fertile cultivar breeding of almond,

A. bucharica Korschinsky is used self fertile cultivars of almond, cold resistance breeding of cultivars and crown development control of almond,

A. kuramica Korschinsky is used for development of self-fertile types and breeding disease resistance of almond,

A. webbii (Spach) is used for breeding self-fertile cultivars and crown development control of almond (Kester and Gradziel, 1996; Gradziel *et al*., 2001). In contrast with most other almond species, at least some populations (or individuals) of *A. webbii* are self-fertile (Socias i Company, 1990). It was suggested that also the rare self-compatible almond cultivars acquired their self-fertility through hybridization with local *A. webbii* (Socias i Company, 1990).

Among the wild almond species of Turkey, *A.orientalis* is present at the Central and Southeast Anatolia Regions, while *A. turcomanica* is present in Southeast Anatolia Region. High lime content along with very low yearly precipitation (around 340 mm) is typical for Southeast Anatolia Region. Being present under these conditions suggest that these species might be tolerant against unfavorable soil conditions such as lime, rocky soil and drought. The plants of *A. orientalis* present under Central Anatolia Region had an average plant height of 151 cm while they had an average of 238 cm plant height under and Southeast Anatolia Region (Bayazit and Küden, 2007). These averages suggest that this is a relatively short species and might have a potential for a dwarfing rootstock. Indeed, Atlı (2008) reported that *A. orientalis* can be utilized as a rootstock for cultivated almond without any incompatibility problem. The researchers also reported that while 'Nonpareil' grafted on 'Texas' gave an accumulative yield of 83.8 kg at the end of the 4-yr period, 'Nonpareil' grafted on *A. orientalis* gave 351.1 kg for the same time interval. Both *A. turcomanica* and *A. orientalis* are known as late flowering almond species. Bayazit (2007) reported that the flowering date of *A.turcomanica* was 3-7 d later than those of *A. orientalis* suggesting a possible avoidance against late spring frosts as well.

Conclusion

Turkey is one of the genetic centers for almond species. In the present, more than 9 *Almond* species have been identified in Turkey. Especially, *A. orientalis, A. webbi* and *A. turcomanica* genotypes are found to be promising for rootstocks breeding programs. Seeds and seedlings are also serving as rootstocks for almond cultivars. Shrubs of this species show great tolerance to abiotic stresses such as drought, salinity, low soil fertility and low winter temperatures; therefore these species may present an important genetic resource to be used in

breeding programs to generate new cultivars and rootstocks that are more adapted to climate change. Another feature of this almond species are to be dwarf compared to *A. communis*. Therefore also be used in breeding dwarf rootstock.

Abstract

Among the flowering trees, ornamental peaches are important as landscape dominants in early spring. The genetic similarity of 23 ornamental peach genotypes, originated from *Prunus mira, P. davidiana, P. persica* and *P. kansuensis* was studied by AFLP-analysis. Eight (8) combinations of primer/enzyme were used in the study. Totally, 162 fragments including 90 (56.2%) polymorphic ones were obtained. Primer combinations with three selective nucleotides (E41/M59, E36/M61, E45/M59) were the most informative. Jaccard similarity coefficient ranged from 0.52 to 1. The analysis by the method of principal coordinates demonstrated that *P. persica* cultivars were quite similar and clustered in two compact groups on the graph. The first group included pink-flower cultivars 'Yu Tao', 'Vesna', 'Yugoslavsky Decorativny' and 'Assol'. The second group combined 'Manific' and its seedlings, 'Iransky Decorativny', 'Iransky Pestrotsvetkovy', 'Bi Tao' and 'Sahong Tao', with red, pink and variegated colorings, similar in the shape of flowers. Wild species *P. mira* and its cultivar 'Lel', *P. davidiana* and its cultivars 'Alba' and 'Belosnezhka', hybrid of *P. kansuensis* 'Malenky Prince' were at a significant distance from *P. persica* cultivars, on the graph. Hybrid cultivars 'Zhisele', 'Ruthenia', 'Decorativny Ryabova', 'Mily' and 'Lubava' were intermediate between wild species and *P. persica* cultivars but more similar to the group of wild peaches. Thus, AFLP-analysis demonstrated genetic remoteness of wild species from *P. persica* cultivars, the close relationships between wild peach and 8 hybrid cultivars originated from those species and also 2 groups of closely related *P. persica* cultivars obtained from different regions of introduction.

Key words: *breeding, DNA, cultivar, hybrid, identification*

Introduction

Ornamental peaches have been grown since ancient times in China and other countries in South-East Asia. From there they spread to Persia, and then to the gardens of European countries, where are cultivated for more than three centuries (Bean, 1950). Since the late of 19th century peaches from China began to be collected on the American continent (Werner and Okie, 1998). Showy flowering peaches with double flowers of white, rose, red and variegated colors found its admirers and it is widespread in the world. Now these plants can be found in every country, wherever the cultivation of peaches exists. In the Botanical gardens and breeding centers new and original varieties have been obtained (Hu and Zhang, 2001; Komar-Tyomnaya, 2015; Yoshida M. *et al*., 2000; Jacobson, 1996; Dumitru *et al.*, 2006). As a result of the introduction and breeding programmes considerable gene pool of ornamental cultivars was accumulated, genetic relationships of which are not always precisely known. There are cases when the cultivar falls into the collection without a name, under a wrong name or name information is lost, and the descendants of the varieties continue to engage in breeding practice. Modern methods of DNA-genealogy help to establish the validity in such cases. One of them is the method of analysis of amplified fragment length polymorphism (AFLP-analysis). AFLP-analysis is informative and effective method for studying genetic polymorphism at intraspecific and interspecific levels, determination the

degree of relationship of different cultivars groups of varieties, as well as in other practical purposes. The positive results of using this method for ornamental peach has been demonstrated by D. Hu *et al.* (2005) in the study of ornamental peach taxa from the collections of the Beijing Botanical Garden (China), National Institute of Fruit Tree Science (Tsukuba, Japan), the JC Raulston Arboretum, and North Carolina State University (USA). The aim of this study was to investigate the genetic similarity of the genotypes of ornamental peach from the collection of Nikita Botanical Garden (NBG-NSC), the relationship between them were unknown, questionable, or required confirmation.

Materials and methods

Plant material. The genetic similarity of 23 ornamental peach genotypes, originated from *Prunus mira*, *P. davidiana*, *P. persica* and *P. kansuensis* were included in the study. The 13 accessions bred in Nikitsky Botanical garden, had famous parents or at least a female form (Table 1). Other everywhere accessions were obtained from various regions in different years. The real name of some of them was not always known and it was given by us conditionally according to the region of introduction. All plants are characterized by upright crown and semi-double or double flowers, with the exception *P. mira*, *P. davidiana*, *P. davidiana* 'Alba' and 'Decorativny Ryabova' with five petals.

DNA extraction. DNA was extracted from leaves of germinated cuttings of peach plants by the method of Puchooa (2004).

AFLP-procedure. AFLP-analysis was performed by the standard method (Vos *et al*., 1995). Genomic DNA of each sample hydrolyzed with restriction enzymes EcoRI and Me (NEB). In this study we used different combinations of EcoRI/Me primers with one selective nucleotide on the 3'end for the first round PCR, with three or four selective nucleotides for the second round). Primer sequences are given on the Standard List for AFLP® Primer Nomenclature. Fractionation of amplification products was performed by polyacrylamide gel electrophoresis. Electrophoresis in polyacrylamide gel was carried out in the chamber Sequi-Gen® GT Sequencing Cell (BIO-RAD) using the 3000/300 POWER SUPPLY (BIO-RAD), with small deviations from the protocol of the manufacturer. As a buffer system was used TBE. Gel was showed by the method 3 of Benbouza *et al.* (2006).

AFLP data analisis. The presence (absence) of the amplification products on the gel were detected visually, the results are recorded in a binary matrix (1 is the presence of a fragment, 0 – no). Statistical data processing was performed using the program PAST 1.67 b, which carried out the calculation of the Jaccard similarity coefficient between pairs of samples. Based on the matrix of similarity the analysis was done by the method of Principal Coordinate Analysis.

Results and discussion

In general, the resulting AFLP-analysis of 23 samples of ornamental peach using 8 primer combinations 162 fragment were obtained, of which 90 (56.2%) were polymorphic (Table 2). The number of DNA fragments detected by various primer combinations ranged from 17 to 30. The largest number and the clearest specters were obtained by use E41 / M59 primer combination. Combinations of primers with three selective nucleotides were more informative. The number of polymorphic fragments ranged from 6 to 23 for one primer combination. The level of polymorphism ranged from 35.3% (for the primer combinations E45 / M50) to 76.7% (for the primer combinations E41 / M59).

Table 1. Species, cultivars and hybrids of ornamental peach, studied by the method of AFLP-analysis.

Species, cultivars and hybrids	Country of origin	Parentage	Number in the study
***Prunus davidiana* and cultivars**			
P. davidiana	China	*P. davidiana*	21
P. davidiana var. alba	China	*P. davidiana* var. alba	1
'Belosnezhka'	Russia, NBG-NSC	*P. persica* 'Vostorg' x *P. davidiana* var. alba	2

E45/M59	14	9	64.3
In total	162	90	56.2

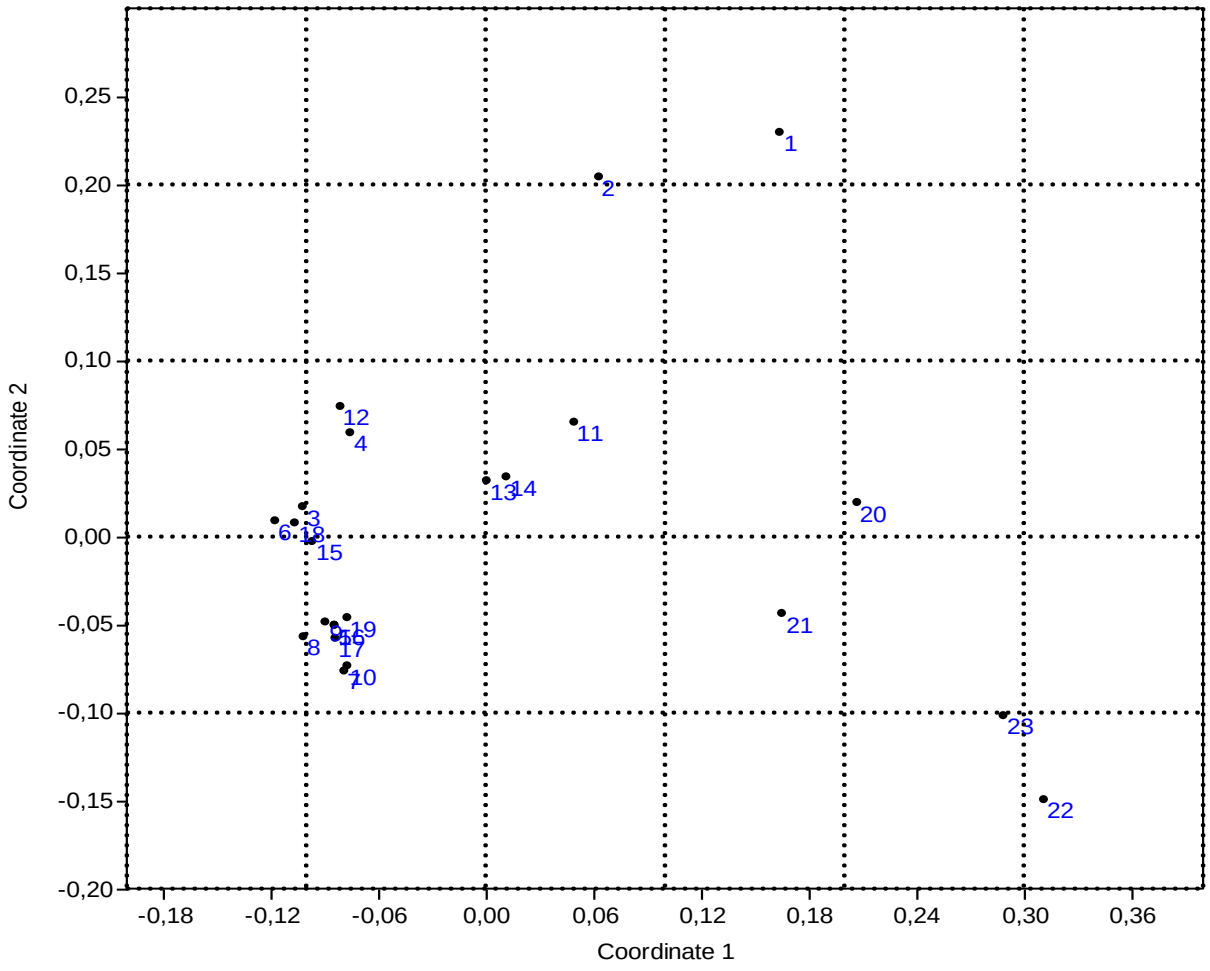

Fig. 1. Principal Coordinate Analysis of ornamental peach according to AFLP-analysis.

Jaccard similarity coefficient ranged from 0.52 (between *P. kansuensis* 'Malenky Prince' and complex hybrid of *P. mira* and *P. persica* 'Lyubava') to 1 (between cultivars *P. persica* 'Manific' and 'Iransky Decorativny'). This result is quite expected; typically varieties differences are smaller than differences between species.

Data obtained by us are consistent with the results of other authors. Thus, D. Hu and |X. Zhang (Hu and Zhang, 2005) in the study of 51 samples of ornamental peaches showed that the genetic differences ranging from 0.044 (between *P. persica* cultivars) to 0.4 (between *P. persica* and *P. davidiana*).

The method of Principal Coordinate Analysis showed that the cultivars with *P. persica* morphotype are quite similar and form on the graph two compact groups. The first group includes pink-flowers cultivars 'Yu Tao', 'Vesna', 'Yugoslavsky Decorativny', 'Assol', despite the fact that they have different geographical origins and vary in shape of a flower. Of these, the most important for us was to determine the genealogical relationship of cultivar 'Vesna', which by the breeding book was listed as a descendant of *P. mira* (F_4 *P. mira* free polination). AFLP-analysis showed a significant distance of these two samples, which is also confirmed by the lack of significant morphological similarities between them.

The second group of *P. persica* cultivars combined 'Iransky Decorativny', 'Iransky Pestrocvetkovy', 'Bi Tao', 'Sahong Tao', 'Manific' and his seedlings 'Adalary v Snegu'. This group of cultivars is characterized, above all, by a similar form of the flower, which is called peony or wide-chrysanthemum and oval petals, which number is counted from 35 to 60 and even more. Their corolla color may be monochrome, for example, purple-red, like 'Manific', or variegated, such as pink with red in 'Iransky Pestrocvetkovy', or white with red and pink in 'Adalary v Snegu' and Sahong Tao'. Seedlings from open pollination of this cultivars group, as a rule, have a variegated coloring. Probably, these varieties have a common ancestor. Cultivar 'Iransky Decorativny' is characterized by pink flowers, but sometimes the petals have mild white strokes. Seedlings from open pollination of this cultivar have red flowers, very similar to the flowers 'Manific'. Considering the high genetic similarity coefficient (1), the nature of the flower color splitting and morphological similarity, we assume that the 'Manific' is a direct descendant of 'Iransky Decorativny'.

Wild species *P. mira* and its cultivar 'Lel', *P. davidiana*, *P. davidiana* ‘Alba’ and its cultivar 'Belosnezhka', *P. kansuensis* hybrid 'Malenky Prince' are at a considerable distance from the cultivars of *P. persica* on the graph. In addition, in AFLP-spectrum of these samples several unique fragments were revealed.

Hybrid varieties 'Zhizele', 'Ruthenia', 'Decorativny Ryabova', 'Mily' and 'Lyubava' occupy an intermediate position between wild species and cultivars of *P. persica*, but still, closer to the group of wild peaches. This is confirmed by their morphological characteristics described by us previously (Komar-Tyomnaya, 2015).

Conclusion

AFLP-analysis allowed revealing genetic relationship between the studied samples of ornamental peach. The genetic distance of wild species of *P. mira* and *P. davidiana* from cultivars of *P. persica* was confirmed. Closely relationships between 8 hybrid cultivars and wild species of peach, whose descendants they are, were confirmed. 2 groups of closely related *P. persica* cultivars obtained from different regions of introduction were determined. The obtained data have significant theoretical and practical value. They help to organize the collection funds for taxonomic and geographical criteria; give an idea about the history of the varieties spreading and allow to orientate better in the genotypes selection for crossings, etc. This is always actual for the botanical gardens and breeding centers.

WATER–YIELD RELATIONS OF MAIZE IN SEMIARID CLIMATE CONDITIONS

Borivoj PEJIĆ[1]*, Ksenija MAČKIĆ[1], Vladimir SIKORA[2], Livija MAKSIMOVIĆ[2], Jan BOĆANSKI[1], Ivica DJALOVIĆ[2]

Abstract

Deficit irrigation creates water stress that can affect the growth and development of maize plants. Effects of water stress on maize include the visible symptoms of reduced growth, delayed maturity and reduced crop yield. A field study was carried in 2015 in order to determine the water – yield relationship of maize in the Vojvodina region, a northern part of the Republic of Serbia. Maize sensitivity to water stress was determined using a yield response factor (K_y). To assess the irrigation effects on maize yield, irrigation water use efficiency (I_{wue}) and evapotranspiration water use efficiency (ET_{wue}) were determined. Irrigation has significantly increased the yield of maize. The yield in irrigation conditions (11698 kg ha^{-1}) was 39.3% higher as compared with control without irrigation (8395 kg ha^{-1}). K_y value of 0.52 in the growing season indicates that maize is moderately sensitive to water stress under semi-arid climate conditions of Vojvodina region. The amounts of water used on evapotranspiration under irrigated (ET_m) and non-irrigated conditions (ET_a) were 512 and 234 mm, respectively. The values of I_{wue} and ET_{wue} were 1.16 and 1.19 kg m^{-3}, respectively. K_y, I_{wue} and ET_{wue} can be used as a good basis for maize growing in the region in terms of optimum water use, and also for the improvement of crop technology.

Key words: *Maize, Water stress, Water use efficiency, Yield*.

Introduction

Maize (*Zea mays* L.), one of the most important field corps, is grown on approximately 24% of areas cultivated with cereals (about 155 million ha). Furthermore, the participation of maize in grain production amounted to approximately 30% (i.e. about 609 million tons), while the average yield was 4.97 tha^{-1} in the period 2006–2015 (FAO Statistical Yearbook, 2015). In Vojvodina, a northern part of the Serbia Republic, maize is the dominant field crop, grown on average in 640,000 ha, or about 42% of the total arable land. The average yield in the period 2006-2015 was 5.0 t ha^{-1}, with a significant variation from 2.94 to 6.44 t ha^{-1} (Statistical Yearbook of Serbia, 2015), correlated, first of all, with the sum and distribution of precipitation..

It is generally considered that maize is resistant to drought and that maize plants use water economically. Nevertheless, maize consumes great amounts of water due it is large vegetative mass, high yields and a long growing season. In the case of water deficiency, maize successfully overcomes drought, but yields less, because plants consume less readily available categories and forms of water from the soil (Bošnjak et al., 2005). Based on long-term experiments carried out under the conditions of Vojvodina, Bošnjak et al. (2005) pointed out to maize yields lower by 28.7% as a result of a deficit of easily available soil water with a remark that yield can be lower by 147–159% in extremely dry years in relation to yields recorded under irrigation conditions. Cakir (2004) emphasizes the yield amount of 15 t ha^{-1} under irrigation conditions in north-western parts of Turkey, while the amount of 5 t ha^{-1} under rainfed conditions. A striking example of low yields of maize (ranging from 1.22 to

4.63 t ha^{-1}) under rainfed conditions is provided by studies carried out by Vasić et al. (1997) in the arid region of eastern Serbia. The effect of irrigation on the increase of maize yields depends on weather conditions of the year, primarily on the sum and distribution of precipitation. In dry years, it can be great (Bošnjak and Pejić, 1994), while in wet years, it can be very modest or even it can be omitted (Pejić et al., 2011).

The actual evaluation of stress related to the yield due to soil water deficit during the maize growing season can be obtained by the estimation of the yield response factor (K_y), that represents the relationship between a relative yield decrease ($1–Y_a/Y_m$) and a relative evaporation deficit ($1–ET_a/ET_m$). In fact it is the amount of yield (Y) lost per unit of evapotranspiration (ET) loss. A larger Ky value indicates larger yield losses due to water deficit. Doorenbos and Kassam (1979) estimate 1.25 of K_y for the maize growing season. Vaux and Pruitt (1983) suggest that it is highly important to know not only the K_y values from the literature but also those determined for a particular crop species under specific climatic and soil conditions. This is because K_y may be affected by other factors besides soil water deficiency, namely soil properties, climate (environmental requirements in terms of evapotranspiration), growing season length and inappropriate growing technology. In order to approach the implementation of any idea on the intensive utilization of agroecological conditions or the development of new procedures for the irrigation regimes of crops, it is necessary to know precise water needs of plants, i.e. potential evapotranspiration (ETP). Water requirements of maize under agroecological conditions of the Vojvodina region vary from 450 to 540 mm (Bošnjak, 1982, Vasić, 1984, Pejić, 2000).

The estimation of water use efficiency in relation to evapotranspiration (ET_{wue}) can show a more realistic evaluation of irrigation effects, i.e. of the irrigation regime applied in maize crops. Also, the importance of analyzing ET_{wue} is illustrated by the efforts of numerous studies that consider the total water use for evapotranspiration towards transpiration use as to the productive part of water to plants (Howell et al., 1997). The parameter ET_{wue} mostly depends on precipitation amount and distribution and establishes whether the growing period is favorable for plant production or not. Wang et al. (1996) pointed out that crop yield depends on the rate of water use and all the factors that increase yield and decrease water used for ET favorably affect the water use efficiency. Howell (2001) indicated that ET_{wue} generally is highest with less irrigation, implying full use of the applied water and perhaps a tendency to promote deeper soil water extraction to make better use of both the stored soil water and the growing-season precipitation. An even clearer estimation of irrigation effects and the applied irrigation regime can be obtained by the evaluation of irrigation water use efficiency (I_{wue}). If the irrigation regime is not synchronized with water needs of crops, water and physical properties of soil and weather conditions, the effect of irrigation can fail, that is the I_{wue} values can be bellow the optimum. The parameter, I_{wue}, generally tends to increase with a decline in irrigation if that water deficit does not occur at a single growth period (Howell, 2001).

The objective of the study was to estimate the yield response factor (K_y) and on the basis of this factor to analyze a seasonal maize response to water stress and in such a way to obtain additional information that can be useful in the improvement of maize growing practices under climate conditions of Serbia. The established values of ET_{wue} and I_{wue} will be used in analyses of the applied irrigation regime and effects of irrigation on maize yields with the aim to use water more efficiently in irrigation practice. Estimated values of water use on maize evapotranspiration will be compared with previously established water requirements by maize under agroecological conditions of Serbia.

Material and Methods

The experiment with irrigated corn was conducted at Bački Petrovac experimental field of Institute of Field and Vegetable Crops in Novi Sad (N 45° 19`, E 19° 50`) on the calcareous

chernozem soil on the loess terrace in 2015. Over the 1964 to 2014 period, the annual mean air temperature, precipitation and relative humidity were 11.2^{0}C, 598.7 mm and 76% respectively. According to the Hergreaves climate classification system, the study area is classified as arid in the summer period, from Jun to August (Bošnjak, 2001). In the growing season (16 April to 25 August), the mean air temperature and total rainfall were 20.2^{0}C and 220 mm respectively. As expected, rainfall is not sufficient for maize production. For this reason, irrigation is needed for acceptable yields of maize grown in the region. The amount of water added by irrigation was 285 mm (Fig. 1, Tab. 2). Maize hybrid NS 6030 was used for the trials. The row spacing was 0.70 by 0.24 m. The size of the experiment unit was 50.0 m^2 (2.1 x 24.0 m) and was replicated three times.

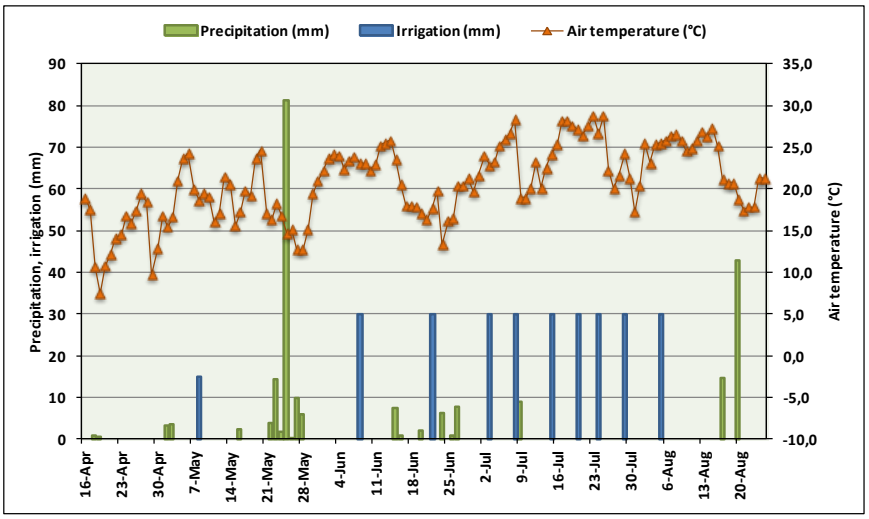

Figure 1. Irrigation schedules, irrigation water applied and meteorological data for the experimental year

The trial was established in a system of random blocks and adapted to technical specifications of drip irrigation system. The plants were irrigated with a lateral row per plant row with drippers spaced every 0.1 m. The drippers had an average flow of 1.4 1/h under a pressure of 70 kPa. The trial included irrigated and non-irrigated, control variants. Irrigation was scheduled on the basis of water balance method using reference evapotranspiration (ET_o) and crop coefficients (k_c). ET_o was calculated by Hergreaves equation (Hergreaves and Samani, 1985).

$$ET_o = 0.0023(T_m+17.8)\left(\sqrt{T_{max}-T_{min}}\right)R_a$$

ET_o – reference evapotranspiration (mm day^{-1}), T_m – the average daily air temperature (^{0}C), T_{max} – the maximum daily temperature (^{0}C), T_{min} – the minimum daily temperature (^{0}C), R_a – the extraterrestrial radiation (mm d^{-1}).

Daily water used on plants evapotranspiration (ET_d) was calculated by multiplying ET_o with kc values (according to FAO, 2015) for initial stage 0.3–0.55, crop development stage 0.7–0.85, mead season stage 1.05–1.2 and late season stage 0.8–0.9 (Fig. 2).

$$ET_d = ET_o \cdot k_c$$

Irrigation started when readily available water in the soil layer of 40 cm was completely absorbed by plants.

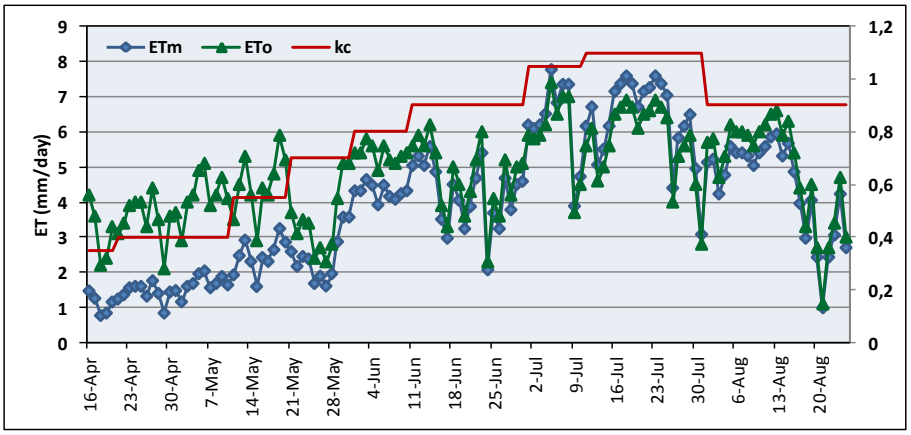

Figure 2. Daily evapotranspiration and crop coefficient of maize

Yield response factor: The yield response factor (K_y) for total growing season was determined using the Steward's model (Doorenbos and Kassam, 1979) as follows:

$$\left(1-\frac{Y_a}{Y_m}\right) = K_y \left(1-\frac{ET_a}{ET_m}\right)$$

Where: Y_a = the actual harvested yield (non-irrigated, kg ha^{-1}), Y_m = the maximum harvested yield (under irrigation, non limiting conditions, kg ha^{-1}), K_y = the yield response factor, ET_a = the actual evapotranspiration (mm) corresponding to Y_a, ET_m = the maximum evapotranspiration (mm) corresponding to Y_m, $(1–ET_a/ET_m)$ = the relative evapotranspiration deficit, and $(1–Y_a/Y_m)$ = the relative yield decrease.

Water productivity: Irrigation water use efficiency (I_{wue}, kg m^{-3}) and evapotranspiration water use efficiency (ET_{wue}, kg m^{-3}) were estimated as Bos (1981, 1985).

$$I_{wue} = \frac{Y_m - Y_a}{I}$$

$$ET_{wue} = \frac{Y_m - Y_a}{ET_m - ET_a}$$

Where: I = the amount of irrigation water applied (mm)

All recommended agronomic practices were applied for cultivation and plant protection at the experimental site. A total of 130 kg N/ha, 75 kg P_2O_5/ha and 75 kg K_2O/ha fertilizer was applied according to recommendations based on the results of the soil analysis. The technological maturity of the crop was detected on 25 August, but maize was harvested by hand on 30 September. Precipitation and air temperature data were obtained from Meteorological Station located at Bački Petrovac experimental field (Figure 1). Grain yield was expressed in kg ha^{-1} adjusted to 14% moisture content. Statistical processing of data was done by the analysis of variance (ANOVA) and testing the obtained results by the Fisher's LSD test ($P< 0.05$ levels between the means).

Results and Discussion

Irrigation has significantly increased the yield of maize. The yield in irrigation conditions (11698 kg ha^{-1}) was 39.3% higher as compared with control without irrigation (8395 kg ha^{-1}) (Tab. 2). Results are in agreement with many studies conducted in a wide range of environments which confirm that irrigation can significantly affect the yield increase of maize

(Istanbulluoglu et al., 2002, Cakir, 2004, Pejic et al., 2010, 2011, 2013). In the study period, evapotranspiration rate in irrigation conditions (ET_m) and in rainfed control variant (ET_a) was 512 mm and 234 mm respectively (Tab. 1 and 2). The calculated value of maize ET_m of 512 mm is in accordance with values previously recorded for the agroecological conditions of the Vojvodina region. Bošnjak (1982), Vasić (1984), Pejić (2000) determined in field plots that water requirements of maize for the conditions of Vojvodina varied from 460 to 530 mm. Škorić and Berić (1994) have determined for the same climate conditions by the calculation over reference evapotranspiration (ET_o) and crop coefficients (k_c) that water requirements for normal growth and development of maize amounted to 523 mm. Stegman (1986) reported similar values of seasonal water use of maize for North Dakota of 432–514 mm. The calculated values of the deficit in readily available soil water of 278 mm (Tab. 1) point to the fact that the genetic potential for yield of otherwise very high-yielding maize hybrids will not be fully realized, since the amount of precipitation determines the potential yield levels.

Table 1. Water balance of maize

Elements	Month					
	April	May	Jun	July	August	Growing season
ET_m (mm)	19	62	120	195	116	512
P (mm)	1	126	25	9	59	220
Δ	-18	+28	-60	0	0	
r (mm)	30	12	60	0	0	
ET_a (mm)	19	62	85	9	59	234
d (mm)	0	0	35	186	57	278
s (mm)	0	16	0	0	0	16

ET_m– the maximum evapotranspiration–irrigated (mm), P – monthly rainfall sum (mm), Δ ± – difference in rainfall (P) and ET_m represents deficit or suficit after consuming or filling the reserve of readily available water, ET_a– the actual evapotranspiration – rainfed (mm), d – deficit of readily available water (mm), s – suficit (mm)

Agriculture in Vojvodina indubitably lacks water as one of the cornerstones of crop production (Vučić, 1976). The value of K_y of 0.52 recorded for the maize growing season (Tab. 2) is lower than values established by other researchers based on results obtained under arid climatic conditions (Doorenbos and Kassam, 1979, 1.25 FAO publication, Howell et al. 1997, 1.47 for Bushland in Texas, Cakir, 2004, 1.36 for arid conditions of Turkey). Obtained K_y value of 0.52 is in accordance with results obtained under moderate climate. Furthermore, Kanber et al. (1990) and Istanbulu et al. (2002) have established values of 0.93 and 0.76 for coastal areas of Turkey. Pejić et al. (2009) point out that the K_y value of 0.65 determined for climate conditions of Vojvodina is the result of weather conditions, first of all, of precipitation amount and their distribution. Value of 0.52 in the growing season indicates that maize is moderately sensitive to the soil water deficit under climatic conditions of Vojvodina. On average, relative evapotranspiration decrease was 73%, resulted with yield reduction of 28% (Tab. 2).

Table 2. Yield response factor and water productivity of maize

ET_m	ET_a	Y_m	Y_a	$1–Y_a/Y_m$	$1–ET_a/ET_m$	K_y	I	I_{wue}	ET_{wue}
512	234	11698[a]	8395[b]	0.282	0.732	0.52	285	1.16	1.19

The best method to describe the role that irrigation has in water use efficiency (WUE) in irrigated agriculture is by expressions given by Bos (1981, 1985). Many researchers have evaluated water use efficiency in different ways (Bos, 1985, Howell, 2001, Payero et al.,

2006). Consequently, care should be taken when comparing WUE values. Gained results under given agroecological conditions can be compared only in the approximately same temporal distance, because not only genetic potential of yielding was smaller more than 30 years ago (Pejić, 2013), but also growing practices have been significantly modified (Videnović et al., 2007). Irrigation water use efficiency (I_{wue}) and evapotranspiration water use efficiency (ET_{wue}) determined in the period of investigation was 1.16 kg m^{-3} and 1.19 kg m^{-3}, respectively (Tab. 2). Obtained values are congruent with results of Yazar et al. (2009) gained for the conditions of the Mediterranean climatic conditions in Southern Turkey, for the maize irrigated by drip system (I_{wue} 1.61 kg m^{-3}, ET_{wue} 1.54 kg m^{-3}). Pejić et al. (2010) determined for the conditions of Vojvodina region I_{wue} and ET_{wue} 1.8 kg/m^3 to 2.8 kg/m^3, respectively. Robertson et al. (1980) recorded maximum values of I_{wue} (4.5 kg m^{-3}) for the conditions of Florida noting that the highest maize yields were recorded when I_{wue} ranged from 2.0 to 3.0 kg m^{-3}.

Conclusion

Based on obtained results it can be concluded that irrigation significantly influenced yield of maize in semi-arid climatic conditions of the Vojvodina region. The yield in irrigation conditions (11698 kg ha^{-1}) was 39.3% higher as compared with control without irrigation (8395 kg ha^{-1}). Evapotranspiration rate in irrigation conditions (ET_m) and in rainfed control variant (ET_a) were 512 mm and 234 mm respectively. The value of K_y in this study of 0.52 indicates that maize is moderately sensitive to the soil water deficit under climatic conditions of Vojvodina. I_{wue} and ET_{wue} were 1.16 kg $m^{-3}$and 1.19 kg m^{-3} respectively. These results could be used as a good platform for maize growers in the region in terms of improvement of the cropping technology, optimum utilization of irrigation water and for the planning, design and operation of irrigation projects.

Abstract

Sweet basil is a species with high environmental requirements, especially temperature conditions. Therefore, in Polish climate, its cultivation in the field is difficult. The solution of the problem may be e.g. modern fertilizers that positively influence on the general condition of the plants so that they can increase their yield. In this work, morphological and developmental traits (plant height, number of lateral shoots per plant, number of leaves) as well as the yield and quality of sweet basil herb were determined. Herb was collected twice: in July and in September (regrowth). The raw material was assessed in respect of essential oil content and its chemical composition, as well as flavonoids and polyphenolic acids content. Plant height ranged average from 31.65 to 32.50 cm, the number of lateral shoots from 10.01 to 10.73 pcs, the number of leaves per plant from 59.73 to 68.88 pcs. Mass of herb depended only on the term of harvest and for the first harvest it was 121.92 g dry mass·m^{-2}, for second harvest – 314.69 g dry mass·m^{-2}. Essential oil content ranged from 0.620 to 0.72 ml·100g^{-1}. Its main components were: linalool, 1.8 cineol and eugenol. Flavonoids content ranged from 0.31 to 0.39 g·100 g^{-1}, polyphenolic acids from 0.63 to 1.48 g·100g^{-1}.

Keywords: *Basil, growth stimulator, biometric features, essential oil, polyphenolics*

Introduction

Medicinal plants have been the main source of drugs for a long time and the knowledge of their application and activity was passed down from generation to generation. Currently, interest in herbal medicines is very large and still increasing (Keh-Shaw *et al.*, 1993; Newman and Cragg, 2007). Many medicinal plants are also used as spices, and their medicinal and aromatic properties have a beneficial effect on the digestion process and absorption of nutrients. Such a plant is sweet basil, *Ocimum basilicum* L., used not only as a spice plant, but also as an aromatic, medicinal and cosmetic agent (Loughrim and Kasperbauer 2001; Aburjai and Natsheh, 2003; Makri and Kintzios, 2007; Khan *et al.*, 2011). In connection with such a comprehensive use of basil, the request for raw material and seeds of this specie is constantly increasing. In turn to get raw material of very good quality it is important to develop effective and safe for the environment and consumer method to control growth and development of that plant. Still looking for a modern means of production, which would mitigate the negative effect of the climate on yields of thermophilic plants, making them less sensitive to stress conditions. In order to improve these processes bio-stimulators can be used. They do not affect directly life processes of plants, but the impact on their metabolism. They provide macro- and micronutrients, thereby causing an increase in resistance to diseases and pests. The use of growth stimulants can play an important role in increasing the yield and quality of crops, as well as in improving the health and the overall condition of plants (Dyśko, 2008).

The aim of the experiment was to evaluate the effect of the Nano-Gro® on the growth of sweet basil (*Ocimum basilicum* L.). It included the characteristics of morphological and development traits as well as yield and quality of the basil herb. The quality of the above raw

material was determined on the basis of chemical analyzes, including the content of essential oil and its chemical composition, as well as flavonoids and polyphenolic acids content.

Materials and Methods

Seedlings to establish the experiment were produced in the greenhouse of Department of Vegetable and Medicinal Plants, Warsaw University of Life Sciences (SGGW) (Poland), from seeds bought in the garden shop. When the seedlings have developed one pair of true leaves they were transplanted into multipalets. After the formation four pairs of true leaves the plants were planted into a field at a spacing 30x40 cm, on plots of 5 m^2, in the first decade of June 2014 and 2015. The experiment was set in four replications, randomized block.

Experiment factors:

- Variants of Nano-Gro® application

Variant 1 (V1) - seeds/plants were not treated Nano-Gro® - control

Variant 2 (V2) - seeds were not treated Nano-Gro®. After germination, when the seedlings were reached approximately 2 cm in height, plants were sprayed the above preparation.

Variant 3 (V3) - seeds were treated Nano-Gro® (soaking for 30 seconds directly before sowing). After quilting seedlings to multipalets, plants were sprayed of Nano-Gro®.

Variant 4 (V4) - seeds were treated Nano-Gro® (as above). Directly after planting in the field, the seedlings were sprayed Nano-Gro®

Solutions of Nano-Gro® for seed soaking and plants spraying were prepared according to the manufacturer's instructions on the package.

- Term of observation of morphological and development traits.

In each plot 5 plants were randomly selected (20 plants for each combination), for observations of morphological and developmental characteristics. Research was carried out in 4 stages of plants development: the vegetative stage (third decade of June), before flowering (first decade of July), in full flowering stage (third decade of July) and the after flowering plants (third decade of August). At any term of observation plant height, number of lateral shoots, number of leaves per plant and mass of one plant were measured.

- Term of herb harvest

Herb was harvested twice. The first harvest was carried out in the second decade of July, when the plants were at the beginning of flowering. All the plants of plot (except the selected for observation) were cut down about 10 cm above the ground. The second harvest was made in the first decade of September (regrowth - the plants were in the vegetative phase). Raw material from both harvests was dried in drying chamber at 35 °C and air-dry mass of the herb received. The results were calculated per 1 m^2.

In the air-dry herb, the content of essential oil and its chemical composition as well as the content of flavonoids and polyphenolic acids were determined.

The content of essential oil was determined by steam distillation, according to a method described in Polish Pharmacopoeia X (2014**).** Separation of essential oil compounds was performed by gas chromatography (HP Model 6890) in the following conditions: temperature of detector – 250°C, temperature of injector – 220°C, temperature programme – 60°C – 220°C, 5C·min^{-1}, capillary column – Carbovax 20m x 0.32 mm, 25m x 0.2 mm. Identification of essential oil components was carried out by comparing their time of retention with adequate standards.

The content of polyphenolic acids and flavonoids were determined according to Polish Pharmacopoeia X (2014)

Total content of polyphenolic acids (calculated as caffeic acid) was made from aqueous solution with Arnov reagent, in the presence of 1n HCL and 1n NaOH. Absorbance of the obtained solution was measured at 490 nm length wave.

Total content of flavonoids were quantified by using the chelating properties of the molecules towards $AlCl_3$, with quercetin used as standard. The raw materials was extracted with acetone.

The hydrolysis of flavonoids was done by using of hydrochloric acid (28 $g \cdot l^{-1}$). Flavonoids were extracted from acetone extract witch ethyl acetate. Absorbance of the obtained flavonoids solution was measured at 425 nm length wave.
The presented results (except essential oil composition) are the mean from the two-year experiment. Chromatografical analysis of essential oils were made only in 2014.
The results were subjected to statistical evaluation using ANOVA 1 and ANOVA 2 programmes and Tukey's test at the significance level α=0.05.

Results and Discussion

Sweet basil (*Ocimum basilicum* L.) is a popular aromatic, medicinal, spice and cosmetic plant (Loughrim and Kasperbauer, 2001; Aburjai and Natsheh, 2003; Khan *et al*., 2011). In connection with such diverse possibilities of its use, the demand for its raw material (herb), is constantly increasing. However, the cultivation of this species in Polish climatic conditions is not easy, due to the high thermal requirements of this plant. Therefore it is necessary to search for such methods of cultivation that would mitigate the negative effects of our climate making sweet basil less sensitive to stress conditions. This role may fulfill modern fertilizers, which besides a favorable impact on yield also improves the overall condition of the plant. An example of such a measure is the Nano-Gro® preparation (Wallace, 2006). In this experiment we analyzed the effect of the Nano-Gro® on the growth and yield of sweet basil, as well as on the content of selected chemical components of the herb: essential oils, flavonoids and polyphenolic acids. Numerous studies point to the positive impact of the above preparation on the yield of agricultural plants, fruit, vegetables and flowering plants but there is no information about its direct impact on the behavior of the herbal plants, including sweet basil. Effects of other bio-fertilizer and bio-stimulators (e.g. Kadostim and Nitroxin) on morphological traits of sweet basil were studied by Rahimi *et al*., (2013). Preparations influenced stimulating inter alia, on the height of basil plant analyzed by these authors. Plants treated by these fertilizers were clearly higher in comparison with the control plants. Kwiatkowski and Juszczak (2011) also observed that spraying of basil plantation such preparations as Asahi SL and Titanite resulted in about a 12% increase in plant height, compared to the control plants. The above-mentioned bio-stimulators also had a significant effect on the growth of the shoots relative to the control group (for Asahi SL -16.7; for Titanite - 15.5%). In the present study no significant differences were observed in plant height and number of lateral shoots between the control and plants treated with Nano-Gro®. Similar results obtained Rosłon et al (2011) for such bio-fertilizers as Aminoplant, Goëmar Goteo and Goëmar BM86 used in the cultivation of sweet basil. Application of Nano-Gro® significantly influenced only on the number of leaves, with the proviso that clearly more leaves was observed in the case of control plants compared with these treated above preparation. On the examined characteristics significant impact had only term of observation. In all variants of experiment, the highest plants, with the highest number of lateral shoots and leaves were observed in the last period of observation (Table 1, Table 2, Table 3).

Table1. The influence of Nano-Gro® application and term of observation on height of plants [cm]

Variant of Nano-Gro® application	Term of observation				Mean
	Third decade of June	First decade of July	Third decade of July	Third decade of August

Application of Nano-Gro® not significantly impact the growth of plant height and number of lateral shoots. However, there was a significant influence on the increase in the number of leaves. Clearly more leaves during vegetation were created by plants from the variant 3 (139.70 pcs), only slightly less control plants, substantially less leaves, however, created plants in variant's 2 and 4 (Table 4).Wallace (2006) testing Nano-Gro® on another herbal specie - tobacco observed that tobacco plants treated above preparation grew faster compared with the control plants, produced also about 30% more leaves.

Evaluation of yielding of sweet basil showed that the use of Nano-Gro®, irrespective of the application way, does not affect the mass of herb. It is true that the highest air-dry mass of herb was obtained for variant, wherein seeds was soaked and plants was sprayed Nano-Gro® after planting in the field (the average of 225.30 $g \cdot m^{-2}$), but it was not significantly higher mass, compared to control plots. Different results obtained Rahimi *et al*. (2013), who showed that the use of biological fertilizers such as Fosnutren and Nitroxin significantly increases total fresh and air-dry mass of basil herb. In this experiment on the tested parameter significantly affected only the term of harvest. Plants collected in the flowering stage (the first term of harvest) gave two and a half lower mass of the dry herb, compared with plants collected in the second term (regrowth). That was respectively 121.92 and 314.69 $g \cdot m^{-2}$ (Table 5).

Table5. The influence of Nano-Gro® application and term of harvest on air-dry mass of herb [$g \cdot m^{-2}$]

In the cultivation of herbs draws attention not only on the yield but also the quality of obtained raw material. Herb of sweet basil is primarily investigated for content of essential oil. Hussain et al. (2008) report that the essential oil content in above raw material is from 0.5% to 0.8%. The results obtained in this experiment were similar. Content of essential oil ranged from 0.58 to 0.73 $ml \cdot 100\ g^{-1}$. The highest content of this component was determined for variant 4, while the lowest - for plants from untreated seeds, sprayed after germination (variant 2). However, there were not found significantly differences in the content of essential oil depending on the variant of application Nano-Gro®. This parameter is not significantly affected also by term of harvest of raw materials, but a higher content of essential oil was characterized by the material collected in the second term (regrowth). Effects of other bio-fertilizer (Aminoplant, Goëmar Goteo and Goëmar BM86) on the content of essential oil in the sweet basil herb studied Rosłon *et al*., (2011). Of the three above-mentioned preparations only Goëmar Goteo significantly influenced the content of essential oil (decreased it). The chromatographic analysis of obtained essential oils showed that the important components in

the tested oils, irrespective of the variant of Nano-Gro® application were linalool, 1.8-cineol, eugenol and eugenol derivatives. Similar results were obtained by many authors (Lee *et al*., 2005; Hussain *et al*., 2008;Carović-Stanko *et al.*, 2010) (Table 6, Table 7).

Table 6. The influence of Nano-Gro® application and term of harvest on essential oil content (ml·100 g^{-1})

Besides essential oil an important components of the sweet basil herb are polyphenols, including flavonoids and polyphenolic acids (Javanmardi et al., 2003; Lee and Scagel 2009). The presence of flavonoids was pointed out many authors (Grayer *et al.*, 1996, Harnafi *et al*., 2009). In the present study we demonstrated that the application of Nano-Gro® significantly affect the content of these compounds. The highest content of flavonoids were characterized by control plants (average 0.39 g·100g^{-1}), the lowest – for plants from seed treated and sprayed preparation Nano-Gro® after planting them in the field (average 0.31 g·100g^{-1}). The content of these compounds influenced also term of harvest. Significantly more flavonoids were determined in the raw material obtained from first term of harvest in compare to the second harvest. Analyzing, in turn, the results on the content of phenolic acids it was observed that significantly more of these compounds there are in plants from variant 4 than in the other variants, including control plants. Higher content of polyphenolic acids also was observed in the raw material collected in the second term (regrowth) (Table 8, Table 9).

Table 8. The influence of Nano-Gro® application and term of harvest on flavonoids content [g·100 g^{-1}]

Conclusions

The obtained results indicate that the yield of sweet basil and quality of obtained raw material most of all is affected by proper cultivation and optimally chosen term of harvest of raw material. Preparation Nano-Gro® used in the sweet basil cultivation not significantly affected both the morphological features as well as herb yield and its quality. Application of the above preparation in the cultivation of basil is not justified.

Acknowledgement

We would like to thank AGRARIUS Ltd. per financial support and the opportunity to test preparation Nano-Gro® in the cultivation of medicinal plants.

Abstract

Micro-propagation, callus and antimicrobial activity developed efficient protocols of *R. graveolens* were used under controlled conditions to overcome limitations of the conventional propagation methods. MS medium supplemented with different plant growth regulators IBA, IAA, 2,4-D and NAA using different concentrations of 0.0, 0.4, 0.8, 1.2, 1.6, 1.8 and 2.0 mg/l were evaluated for their effects on adventitious root induction. Our result showed that the highest number of new root (3.25 cm) was obtained using MS medium with 0.4 mg/l 2,4-D. Whereas, using 0.2 mg/l 2,4-D resulted in highest root length per explants. In our research the Antimicrobial activity of different extract types and volume (40 or 80 µl) was studied using agar-well diffusion assay against five bacterial species of three gram positive bacteria (*Staphylococcus aureus, Bacillus cereus, Micrococcus latus*), two gram negative bacteria (*Escherichia coli, Salmonella typhmurim*), and four fungal species (*Alternariasolani, sclerotiniasclerotiorum, Fusariumoxosporium,* and *Verticillium dahlia).* Results indicated that all tested extracts at different volume revealed antimicrobial activities against all tested bacterial species and did not display antifungal activity against *Alternariasolani, Sclerotiniasclerotiorum* and *Verticillium dahlia* except *Fusariumoxosporium*.

Key words: *In vitro, Ruta Graveolens, Antimicrobial, Ex Vitro*

Introduction

Ruta graveolens is an important medicinal plant belongs to the family *Rutaceae* and is a small aromatic perennial shrub, which grows throughout Jordan and is native to the Mediterranean region (Khouri and El-Akawi, 2005). It is currently used by many people in Jordan as an aphrodisiac, fertility promoting agent antispasmodic, diuretic, sedative, and analgesic effects and externally for its antirheumatic effect (Khouri and Akawi, 2005). In addition, it's have antifungal properties that could be beneficial to agriculture and medicine (Ojala *et al.*, 2000). Previous study by (Ojala *et al*., 2000) indicated that extract of *R. graveolens* showing high toxicity against *Rhizoctonia solani*. Furthermore, growth of *Heterobasidium annosum* was inhibited, whereas that of *Phytophtora cactorum* was promoted by the extracts. The antifungal activities of six natural coumarin compounds were weak, except for the inhibitory effect against *Fusarium culmorum* (Ojala *et al.,* 2000). Moreover, *R. graveolens* showed antimicrobial activity against some bacterial species *Escherichia coli, Streptococcus pneumonia, Salmonella typhi, Klebsiella pneumonia* and *Proteus vulgaris*. Karouei *et al.,* (2011) showed that root ethanolic extract of *R. graveolens* had antifugnal effects and prevented from *saprolegnia* growth. Furthermore, (Dababneh and Khalil, 2007) reported that *Achillea santolina* extract inhibits growth of *Fusarium oxysporum* and

Rhizoctonia solani of about 42%. Moreover, the volatile oil has a pungent smell and bitter taste, and possesses antibacterial activity against *Micrococcus pyogenes* and *Escherichia coli* (Anonymous, 2003).

In vitro propagated medicinal plants provide a ready source of uniform, sterile, and compatible plant material for biochemical characterization and identification of bioactive constituents (Mahmoud *et al.*,). Faisal *et al.*, (2005) reported direct shoot bud induction in nodal segments of *R. graveolens* through axillary shoot multiplication. In addition, secondary metabolites from tissue cultures may be more easily purified because of simple extraction procedures and absence of significant amounts of interfering pigments, which it will minimize the cost of purifying and producing such valuable compounds (Nalawade and Tsay, 2004). Therefore, the goal of this study is to determine the effect of different *in vitro*, *ex vitro* and callus of *R. graveolens* extracts against some microbes as a possible alternative to antibiotic drugs.

Materials and methods

Source material and explants preparation

In vitro cultures were established at the Al-Balqa Applied University before being used in laboratory. Seed were collected from five years old *R. graveolens* from the Al-Sareeh, Irbid, Jordan (about 600 meters above sea level, 32.3306° N latitude and 35.8951° E Longitude).

Shoot induction, callus formation, *in vitro* rooting and acclimatization

Plantlet were subcultured onto 250 ml Erlenmeyer flask containing about 60 ml MS medium supplemented with 30 g/L sucrose and 0.3 mg/l BAP, 0.05 mg/l IBA and 1.0 mg/l GA3 in order to multiplication of plant *in vitro*. Calli were initiated from leaves on MS media supplemented with 1.0 mg/L 2,4-D or NAA. Moreover, in order to induce root, microshoots with 10 mm length were subcultured on MS medium containing indole-3-butyric acid (IBA), indole acetic acid (IAA), 2,4-Dichloromethoxy acetic acid (2,4-D) or naphthalene acetic acid (NAA) at 0.0, 0.4, 0.8, 1.2, 1.6, 1.8 or 2.0 mg/l, and 0.2 mg/l in case of NAA and 2,4-D with the supplemented of 0.5 g/L charcoal. After that In vitro rooted plantlets were removed from the medium, wash in a water bath at 25-30 °C and transplanted to plastic pots containing sterile autoclaved mixture of 1 peat: 1 perlite and covered with transparent plastic bag.

Secondary metabolites extraction

Healthy callus, ex vitro and in vitro plants of *R. graveolens* were dried at 80 ^{0}C. The dried plant materials were separately extracted at room temperature with absolute ethanol and methanol separately at 10:1 (v/w) (Green, 2004). The mixture was placed at room temperature for two days with occasionally shacking to dissolve secondary metabolites properly. The extracts were then filtrated on Whatman no. 1 filter paper. In order to remove the solvents the filtrate place in water path at 40 ^{0}C to dryness.

Microbes culture

Five bacterial species were used in this research work, and these are listed as follows: three gram positive bacteria (*Staphylococcus aureus, Bacillus cereus, Micrococcus latus*) and two gram negative (*Escherichia coli, Salmonella typhmurim*) cultured on nutrient agar. These species were obtained from the laboratory of microbiology, Yarmouk University, Jordan. Four fungal species were included in this study and these are listed as follows: *Alternaria solani, sclerotinia sclerotiorum, Fusarium oxosporium,* and *Verticillium dahlia* Fungi cultured on potato dextrose agar (PDA) were obtained from Plant Pathology Laboratory from Jordan University of science and Technology.

Antibacterial activity assay

Antimicrobial activity against the test organism was performed using the agar diffusion method (Perez *et al.,* 1990). The bacterial species were spreaded on nutrient agar plates with sterile swap. Plates were divided into 4 quadrates, wells were made on the plates with a sterile cork borer of 6 mm diameter to contain the different extracts, R. graveolens extract aliquots (40 µl and 80 µl) at (250 µg/µl) concentration were added into wells and left for one hour to diffuse, then the plate were incubated at 37 °C for 24 h. The antibiotic Oxytetracycline were used as positive control and prepared in (250 µg/µl) and their antimicrobial activity was tested in the same manner, also the solvent dimethylesulfoxide DMSO (negative control) was added, the zones of inhibition was measured in mm at the end of the incubation period. Microbial growths were determined by measuring the diameter of the zone of inhibition and were compared with standard antibiotic (oxytetracycline).

Antifungal activity assay by the agar well diffusion method

An aliquot of 100 µl spore suspension ($1x10^8$ spores/ml) of each isolate were streaked in radial patterns on the surface of complete media plates. Plates were divided into 4 quadrates, wells were made on the plates with a sterile cork borer of 6 mm diameter to contain the different extracts, R. graveolens extract aliquots (40µl and 80 µl) at (250 µg/µl) concentration were added into wells and left for one hour to diffuse, then the plates were incubated at 30 °C for 48 h. The antifungal (Cyclohexamine; positive control) was prepared in (250 µg/µl) and their antimicrobial activity was tested in same manner, also the solvent dimethylesulfoxide (DMSO) (negative control) was added, the zones of inhibition were measured in mm at the end of the incubation period. Microbial growths were determined by measuring the diameter of the zone of inhibition and were compared with standard antifungal (Cyclohexamine).

Experimental design and statistical analysis

Data were subjected to one-way analysis of variance ANOVA; differences between individual means were determined by least significant difference (LSD) test at 0.05 level of probability.

Result and discussion

***In vitro* shoot formation and callus induction**

All established cultures gave healthy shoots when sub-cultured on the multiplication medium. Initially small yellowish calli developed on the cut ends within 7 days of inoculation which subsequently covered the entire surface of the explants with the used of 2,4-D and NAA. After two months better callus texture, color and maximum fresh weight were obtained when MS media was supplemented with 2.4-D or NAA (figure, 1) our results agreed with Al-Ajlouni *et al.*, (2015).

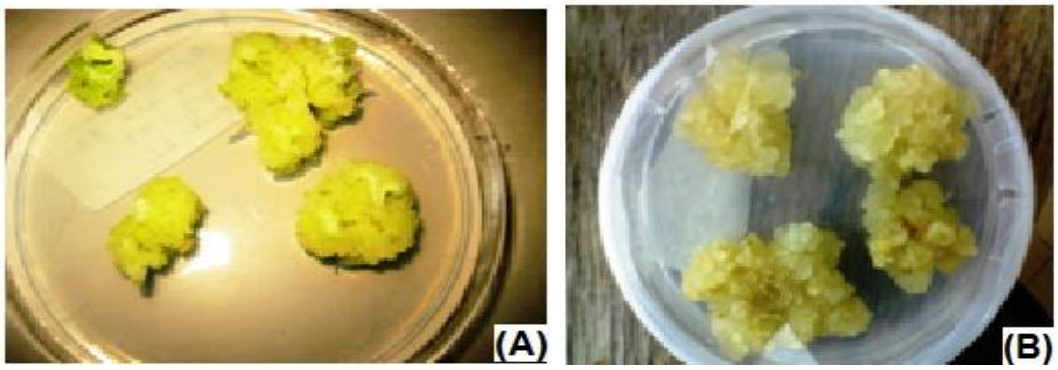

Figure1: (A) Callus formation after six weeks of culture on full strength media supplemented with 2mg/l 2,4-D, (B) Callus subculture on MS with 1mg/l 2,4-D.

In vitro root formation and acclimatization

Table (1) shows effect of different auxins concentration on root formation. The use of auxins hormones enhance shoot formation compared with the controls. Maximum root number was obtained on medium supplemented with 0.4 mg/l IBA, where the means root number was 1.6. Maximum root length (0.55 cm) was obtained on medium supplemented with 1.2 mg/l IBA. Bohidhar *et al*., (2008) reported that IBA induced root formation on MS media supplemented with 0.5mg/l IBA. Faisal *et al*., (2005, 2006) had reported rooting of microshoots of *R. graveolens* on MS media supplemented with IBA (0.1 mg/l). Using IAA maximum root number (1.6 roots per explants) was obtained at 0.4 mg/l IAA. Moreover, maximum root length (0.44 cm) was occurred on medium containing 0.4 or 1.2 mg/l IAA (Table 1). No callus formation appeared at the base of each cutting. This has also been found in previous studies, where in vitro shoots of *Artemisia herba alba* were reported to root with a supplement of IBA, IAA or NAA (Shatnawi *et al*., 2011). Gurudeeban *et al*., (2012) reported that *R. graveolens* was rooted on MS media supplemented with 0.5 mg/l IAA. On the other hand, Bohidhar *et al*., (2008) reported that no healthy roots were observed on MS media containing IAA. The number of roots formed per microshoots was affected by the concentration of 2,4-D. Maximum root number and long root were obtained from MS media supplemented with 0.4 mg/l 2,4-D where the means number of new root and root length was 3.25 and 0.96 cm. Callus was induced on MS media with different concentration of 2,4-D. Root initiation was appeared from the bases of shoots after incubation on solid MS medium containing NAA. Maximum root number (1.15 root/ex-plant) with 0.41 cm length of was obtained on MS medium containing 1.2 mg/l NAA. However, number of roots per explant varied with increasing NAA concentration and ranged from 0.2 to 1.15 (P=0.05) (Table 1). The role of NAA in root induction of in vitro derived shoots has been well documented.Survival of the rooted plants was up 100% under acclimatization conditions in the greenhouse (Data not shown).

Table 1: Effect of different concentration of Auxins on roots formation of *in vitro* grown *Ruta graveolens* after six weeks growth periods.

Auxins type / Conc. (mg/L)	Number of new root *				Maximum root length*

Antibacterial activity

The control (negative) by using Dimethylsulfoxide (DMSO) alone failed to suppress all involved bacterial growth and therefore had negative results. Results obtained show that the reference antibiotic Oxytetracycline exhibited positive results shown as zone of inhibition (11.33 mm) (figure 2 and figure 3). It is clear that *Micrococcus latus* showed high sensitivity to all extract culture types of *R. graveolens* compared to other bacterial species were used. The *in vitro* extract had the highest antibacterial activity in all cases (13.00 mm and 12.33 mm) using 80µl from ethanolic and methanolic respectively (figure 2 and figure 3F). Our results confirmed the observation of Ivanova *et al.*, 2005 who reported that extracts of *R.*

graveolens showed antibacterial activity against *Staphylococcus aureus, Staphylococcus epidermidis* and *Bacillus cereu* , while no activity was shown against *Escherichia coli.* Moreover, and Ojala *et al*., (2000) reported that extracts using methanol solvent were more active than those extracted by ethanol against *Bacillus* spp. and *S. aureus*. LI Fang, (2001) reported that the alcoholic extract of *R. graveolens* have the same weak bacteriostasis on the following bacteria: *Streptococcus purulent, Micrococcus luteus, Staphylococcus aureus, Streptococcus B, Streptococcus pneumoniae, Pseudomonas aeruginosa, Escherichia coli* and *Salmonella species.* In contrary, the results of this study showed that *Micrococcus luteus* and *Salmonella typhmurim* were highly affected with alcoholic extract. Moghadam *et al.*, (2012) reported that ethanol extract of *R. graveolens* has no inhibitory effect on *staphylococcus aureus*. It seems that there might be more antibacterial components in methanol and also in pure ethanol extract from callus, *in vitro* and *ex vitro*. Furthermore, Pandey *et al.*, (2011) also reported that extracts of *R. graveolens* stem using ethanol showed the most potent antibacterial activity against *S. aureus* and *B. subtilis*.

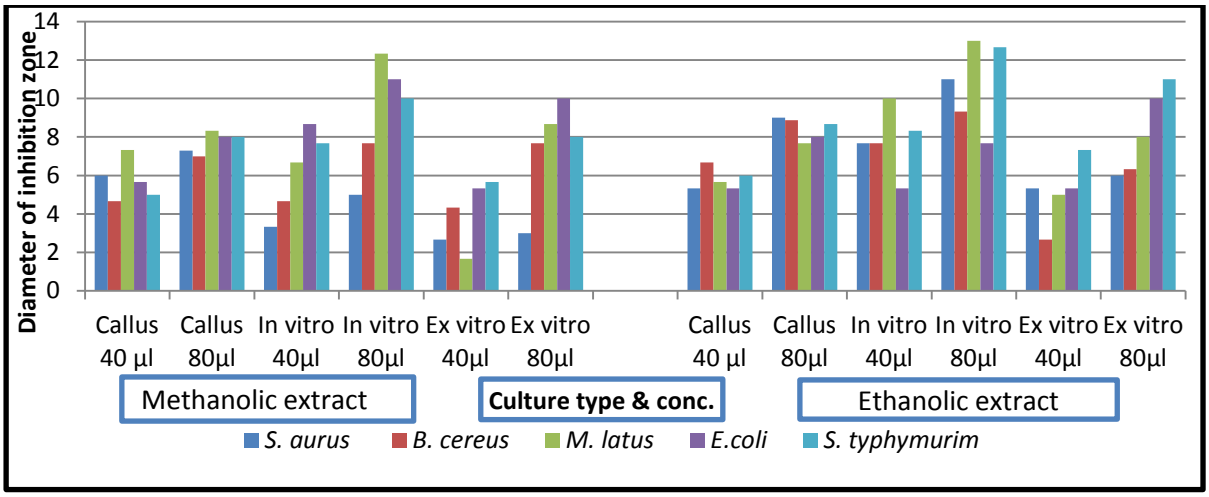

Figure 2: Antibacterial activity of different culture types of *Ruta graveolens* against five bacterial species at different volume (40 µl and 80 µl) using well diffusion method.

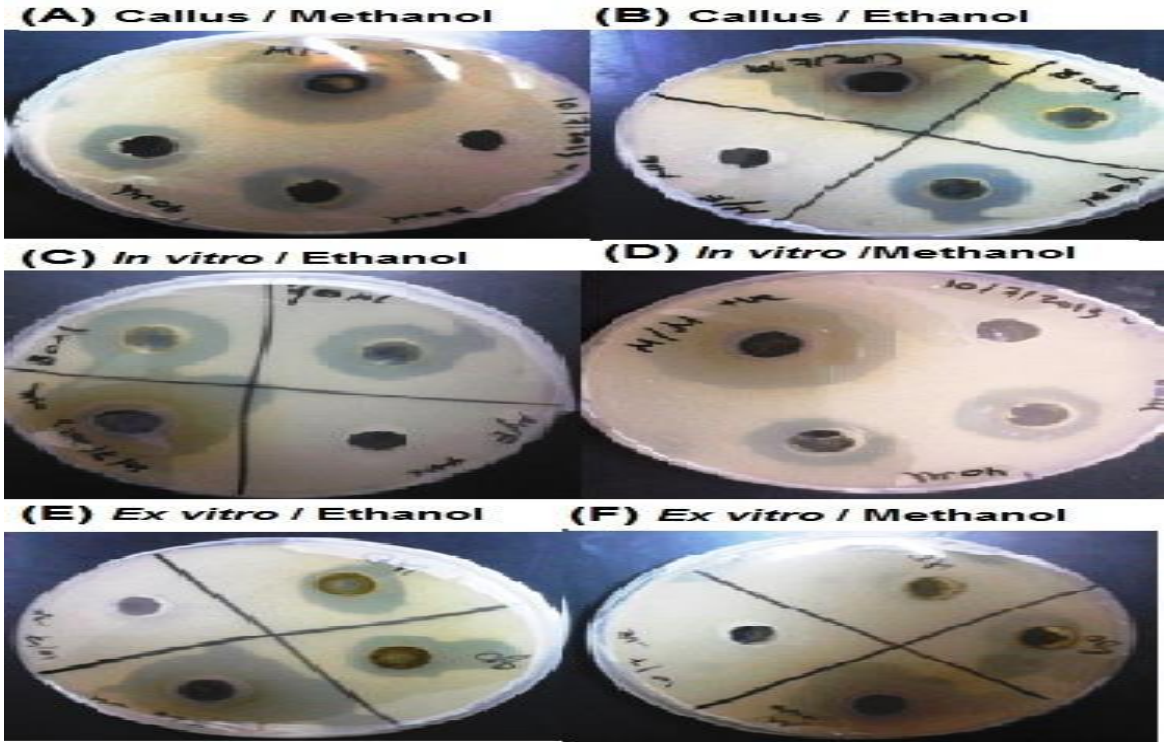

Figure 3: Agar well-diffusion assay of *R. graveolens* extracts against *M.latus*, (A) activity of callus extracted by methanol, (B) activity of callus extracted by ethanol, (C) activity of *in vitro* extracted by ethanol, (D) activity of *in vitro* extracted by methanol, (E) activity of *ex vitro* extracted by ethanol and (F) activity of *ex vitro* extracted by methanol. Inhibition zone was observed around the well.

Antifungal activity

In vitro ethanolic extracts was shown the highest activity against *Fusarium oxosporium*, it was 12.33 mm and 10.33 mm inhibition zone in *in vitro* methanolic extracts (Figure 4). The antifungal of callus extract against *Fusarium oxosporium* was in methanol 8.66 mm and in ethanol was 9.00 mm at 80 µl. *Ex vitro* extract was also had inhibitory effect on *Fusarium oxosporium*, it was in ethanolic extract 8.67 mm and in methanolic extract was 7.67 mm at 80 µl, Figure (4). Meepagala *et al.*, (2005) reported that the ethylacetate extract from roots of *R.graveolense* had shown fungicidal activity against several agriculturally important pathogenic fungi like *Colletotichum fragariae*, *C.gloeosporioides*, *C.acutatum*, *Botrytis cineara* and *Fusarium oxysporium.* Moreover, Pandey *et al.*, 2011 reported that ethanolic extract of *R. graveolens* stem showed moderate antifungal activity except *Fusarium oxosporium*, it was high inhibition activity. *Saprolegnia* also prevented from growth by root ethanolic extract of *R. graveolens* (Karouei *et al.*, 2012).

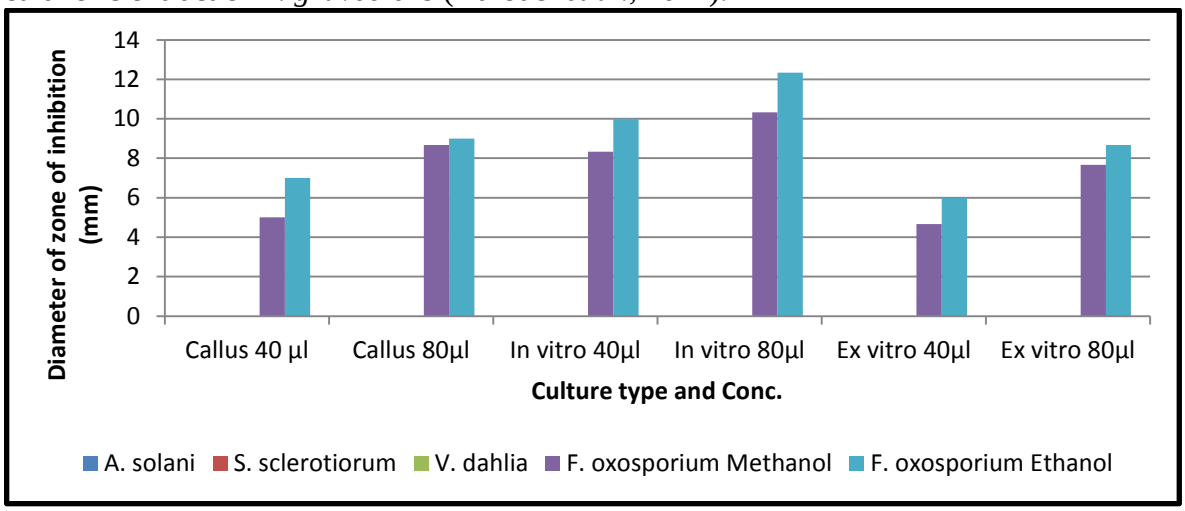

Figure 4: Antifungal activity of different culture types of *Ruta graveolens* against four fungal species at different volume (40 µl and 80 µl) using well diffusion method.

In vitro extracts shows to give high antimicrobial activity against tested bacterial and fungal species, it may due to presence of high concentration of toxic compounds as results in HPLC analysis (Al-Ajlouni *et al.*, 2015).

Conclusion

Adventitious roots were successfully induced from shoot tip segments of *R. graveolens* on MS medium supplemented with 0.4 mg/L IBA. In addition, callus was successfully induced from leaf segments on MS media supplemented with 4.0 mg/L NAA under dark condition. For the antimicrobial activity of *R. graveolens* would help for development of a new alternative medicine system which has no side effects. *R. graveolens* stem extracts possess a broad spectrum of activity and open the possibility of finding new clinically effective antimicrobial compoundsfor *R. graveolens.*

Abstract

This paper presents the results of a two-year study of six Dutch potato varieties in agroecological conditions of northern Montenegro. The two-year average of the highest number of tubers were found in the variety Arnova (8.4), while the lowest tuber number was obtained in varieties Arrow (6.8), Rudolph (6.8) and Riviera (6.9). Increasing the number of tubers in the variety Arnova compared to other varieties was statistically significant. Varieties Rudolph (116.5 g) and Kuroda (100.5 g) gave averagely biggest tubers. The average weight of tuber of other varieties studied was approximately at the same level, and ranged from 80.4 g, for the cultivar Arrow to 88.6, for the Arnova. Rudolph and Kuroda were, compared with all other varieties, had significantly larger tubers. The highest yield in trials was on plots planted with varieties Rudolph - 33.7, Kuroda - 32.0 and Arnova -31.5 tha^{-1}. The lowest yield was measured at variety Arrow - 23.2 tha^{-1}. Yields of varieties Rudolph, Kuroda and Arnova were compared to all other investigated varieties statistically significant. This research showed that the highest yields of tubers in agroecological conditions of mountain climates are achieved by growing medium late and middle early varieties of potatoes.

Keywords: potato*, tuber number, tuber weight, yield*

Introduction

Potato is among the most important and most profitable crops in many countries of the world. On a global scale, after rice, wheat and maize, potato is the fourth largest source of food. The economic importance of potato in Montenegro is very significant, especially for the mountainous area where it is predominantly grown.

Potato is a plant of temperate climate and is grown in almost all latitudes. However, the best zone for potato growing is considered the area of temperate zone (40-60^o north latitude), as well as areas under 40° of north latitude at high altitudes (Muminović et al., 2014). Due to the very pronounced polymorphism, potatoes easily adapt to different environmental conditions. Thanks to this feature, potato is now grown even in poor production conditions and high altitudes, even where the cultivation of other agricultural crops is not possible (Jovović et al., 2015).

Potatoes prefer chilly nights, but nights like that are less and less. The increasing climate variability poses a serious threat to its further cultivation. Climate change has increasingly negative impact on potato crop production leading to large seasonal fluctuations in the amount and quality of yields. Therefore, in the future potato production is gradually moving from the warmer south to colder northern areas and higher mountain regions (Jovović et al., 2016).

The systematic study of the different genotypes in different environmental conditions is of great importance resulting with wider selection of varieties adapted to the specific conditions (Yang, 2002). Yields of potatoes, in addition to the variety, greatly depend on the agro-ecological conditions, but also on nature of interaction between genotype and environment. The reaction of individual varieties to different environmental conditions is conditioned by

their genetic predisposition. Knowing very complex relations existing between genotype and environment is of paramount importance when selecting varieties (Jovović et al., 2012).
As different production areas are governed by very different environmental conditions, variety performance is different as well. Therefore, knowledge on the productivity of potato varieties and their reactions to the specific conditions of production regions is one of the most important preconditions for achieving high and stable yields (Momirović et al., 2000). Consequently, the study of the productivity of different potato varieties in different agro-ecological conditions has outstanding practical significance. In this way, there is very reliable information about the cultivated varieties that will allow maximum utilization of genetic resources and thus achievement of high and stable yields (Yang, 2002).
The aim of this study was examination of yield and other indicators of productivity for six Dutch potato varieties in mountain areas of Montenegro.

Materials and methods

The study of the productivity of six promising Dutch potato varieties was carried out during 2013 and 2014 in Kolašin, on the alluvial-deluvial soil at an altitude of 900 m. Varieties with different length of vegetation and skin colour were tested - early varieties: Riviera (1) and Arrow (2); medium early: Tresor (3) and Arnova (4) and medium-late varieties of red epidermis: Kuroda (5) and Rudolph (6).
The experiments were conducted in a completely randomized block design, with 4 replicates and the surface of the single experimental plot of 15 m^2. Planting of potatoes was carried out on May 20 2013 and 15 May 2014, by hand, at a distance of 70 x 33 cm, with the resulting density of 43300 plants per hectare. The basic tillage, pre-sowing preparation and fertilization were conducted as standard agricultural practices for potato crop. The protection of crops from weeds, pests and disease-causing agents was conducted timely. Potato harvesting was carried out on 15 September in both years.

Table 1. Chemical characteristics of soil in the experimental field

Depth (cm)	pH		$CaCO_3$	Humus	Soluble mg/100 g	
	H_2O	nKCl	%	%	P_2O_5	K_2O
40	6,29	5,55	1,1	4,53	2,4	16,0

Table 2. Meteorological condition during the experiment

Year	Month					Average
	May	June	July	August	September	
Air temperature (^{0}C)						
2013.	12,4	15,7	18,1	18,4	12,7	15,5
2014.	11,3	15,3	17,3	17,5	12,8	14,8
Precipitation sum (mm)						Total
2013.	301,3	125,0	32,9	67,8	118,3	645,3
2014.	96,6	150,3	114,7	69,1	233,2	663,9

Determination of the number of tubers and their mass was performed after complete maturation on average sample of 10 potato plants from a row in each repetition. Total yield per hectare was calculated according to the theoretical categories of crop density.
Soil in experimental plots has favourable water and air properties, high humus content, low phosphorus and calcium and moderate potassium content (table 1). Meteorological data for the experimental period are given in table 2. Statistical analysis was performed by the method of factorial analysis of variance (ANOVA), and the score difference between the mean values using LSD test.

Results and discussion

The measurement results given in Table 3 show that the largest number of tubers in the experiment was found in variety Arnova - 8.4 (7 in 2013 and 9.8 in 2014), while the lowest tuber number was measured in Arrow - 6.8 (6.2 and 7.3), Rudolph - 6.8 (7.2 and 6.3) and Riviera - 6.9 (6.3 and 7.4). In two-year average, variety Arnova had significantly higher number of tubers compared with other varieties. The significant increase in the number of tubers was determined in varieties Kuroda (7.5) and Tresor (7.3) compared to Errow (6.8), Rudolph (6.8) and Riviera (6.9).

Table 3. Results of studies for Dutch varieties

	2013-14.	0,327	0,444
Average tuber weight (g)	2013.	5,921	8,034
	2014.	14,415	19,556
	2013-14.	6,765	9,179
Yield (t.ha^{-1})	2013.	1,833	2,487
	2014.	3,956	5,367
	2013-14.	2,021	2,742

The average number of tubers is a very important parameter of productivity on which depends the production per plant of potatoes, and finally the total yield per unit area (Bugarčić et al., 2000). The variability of the number of tubers, except genetic differences between the varieties of potato, largely depends on the interaction between genotype and environmental factors (Nacheva, 2006). In compared studied years, slightly higher average number of tubers was found in 2014 as a result of higher rainfall in June, when potato plant tuberisation is occurring.

Tuber size is an important parameter of productivity and is basically a varietal characteristic, but above all it depends on the level of agricultural practices, soil type and weather conditions during the vegetation period (Jovović et al., 2011). In two-year studies, plots with the highest average tuber weight measured, were planted with varieties Rudolph (116.5 g) and Kuroda (100.5 g). The smallest tubers were measured in varieties Arrow, Tresor and the Riviera (80.5, 81 and 83 g). Analysis of variance of the average tuber weight showed a highly significant increase in tuber weight of varieties Kuroda and Rudolph as compared to other varieties. Differences in tuber weight between Rudolph and Kuroda are also statistically significant. Increase in number of tubers in the variety Arnova compared with varieties Arrow and Tresor was statistically significant.

Number and size of tubers depend on the number of primary shoots formed on single plant. Bigger number of primary shoots, bigger number of tubers formed, but not their weigh too (Butorac and Bolf, 2000). The results of this study are correlated with this statement.

The highest yields were obtained in experiments on plots cultivated with varieties Rudolph - 33.7, Kuroda - 32.0 and Arnova - 31.5 tha^{-1}, while the lowest yielding varieties were Arrow -

23.2, Riviera – 24.3 and Tresor - 25.3 tha^{-1}. Rudolph, Kuroda and Arnova as compared to other varieties yielded a significantly higher tuber yield. Arrow, Riviera and Tresor yields were statistically highly significant. The significant increase in yield was found in the variety Tresor compared with Arrow, as well as between varieties Rudolph and Arnova. As 2014 had a slightly greater quantity and a better distribution of rainfall during the growing season of potato, and lower average air temperatures, it resulted with higher yields in this year (29.9 in 2014 and 26.7 tha^{-1} 2013).

Proper selection of varieties could significantly reduce adverse environmental effects. For these reasons, the study of potato varieties in the mountain area of Montenegro should continue.

Conclusion

Based on said above it can be concluded:

- With proper variety selection, high potato yields can be achieved even in mountainous areas of Montenegro.
- In two-year studies, the highest yielding varieties were Rudolph - 33.7, Kuroda – 32.0 and Arnova - 31.5 tha^{-1}, while the lowest yields were measured in plots planted with varieties Arrow - 23.2, Riviera - 24.3 and Tresor and - 25.3 tha^{-1}.
- The largest number of tubers per plant was determined in cultivar Arnova (8.4), while the lowest tuber number was found in varieties Arrow and Rudolph (6.8). The number of tubers in the variety Arnova compared to other varieties was statistically significant.
- Tubers with the highest average weight were obtained from varieties Rudolph (116.5 g) and Kuroda (100.5 g), while the smallest tubers were measured in the varieties Arrow and Tresor (80.5 and 81.0 g).
- The highest yields are achieved growing medium late and medium early potato varieties in mountainous area of Montenegro.

IN VITRO SHOOT AND ROOT REGENERATION IN ERCIS CABBAGE (BRASSICA OLERACEAE VAR. CAPITATA)

Ferit ERTAŞ, Burcu TUNCER*

Department of Horticulture, Faculty of Agriculture, Yuzuncu Yil University, Van, Turkey
*Corresponding author: brctuncer@gmail.com

Abstract

Ercis head cabbage which is a population local to the Van province of Turkey was tested for ability to regenerate shoots and roots *in vitro*. Cotyledon and hypocotyl explants were excised from 7 day old *in vitro* seedlings, germinated on Murashige and Skoog (MS) medium, and cultured on MS medium supplemented with benzylaminopurine (BAP) (0.5 mg/l, 1.0 mg/l, and 2.0 mg/l) and naphthaleneacetic acid (NAA) (0, 0.05 mg/l, and 0.1 mg/l). The highest shoot regeneration (100%) was achieved in hypocotyls explants with MS7 (MS + 2 mg/l BAP) and 91.6% with MS6 (MS + 1 mg/l BAP + 0.1 mg/l NAA), MS4 (MS + 1 mg/l BAP), and MS3 medium (MS + 0.5 mg/l BAP+ 0.1 mg/l NAA). The MS4 medium (5.2 shoot/explant) was the most successful in terms of the number of shoots per explant. The highest shoot regeneration from cotyledon explants was obtained from MS1 (MS + 0.5 mg/l BAP) and MS9 (MS + 2 mg/l BAP + 0.1 mg/l NAA) mediums with 91.6%. In hypocotyls explants, indirect shoot regeneration was induced in all media combinations and the rate of regeneration was found to be higher than in cotyledon explants. In root regeneration trials, 4 different indolebutyric acid (IBA) doses (0 mg/l, 0.5 mg/l, 1.0 mg/l and 1.5 mg/l) were tested on 1/2 MS medium, and 100% rooting was achieved from the control and 0.5 mg/l IBA doses.

Keywords: *Regeneration, Cabbage, Hypocotyl, Cotyledon*

Introduction

Cabbage vegetables of the *Brassicacea* family are economically significant vegetable species. This family includes approximately 350 genera and 3000 species (Şalk et al., 2008). The total production of *Brassica* group vegetables in Turkey is 935,230 t, 492,610 t of which is white head cabbage (Anonymous, 2014). Turkey is as rich in terms of its cabbage genetic resources as it is in cabbage production (Balkaya et al., 2005). Different types of cabbage are cultivated in each region in Turkey. For example leaf cabbage is cultivated in the Black Sea Region while white head cabbage is cultivated in Eastern Anatolia, and red head cabbage is cultivated in Western and Southern Regions of Turkey. The Ercis cabbage is a local head cabbage population that is cultivated in the Van province of the Eastern Anatolian Region of Turkey. Due to its loose and large head (average of 1.0 kg) and thin leaf properties it is more suited for stuffing or pickling, and is a significant source of income for the region's population.

Currently in breeding studies on *Brassica* species, biotechnological methods and genetic transformation approaches are widely used in addition to traditional plant breeding methods. However the success of these approaches depends on the use and development of an effective and suitable system of *in vitro* regeneration. Therefore studies are required to optimize the regeneration system for every species, in fact for every genotype. Cotyledon (Daud et al., 2015) and hypocotyl explants (Hazrat et al., 2007; Cristea et al., 2010; Gerszberg et al., 2015) taken from seedling cultivated *in vitro* are widely used in plant regeneration and genetic transformation studies on *Brassica* species.

Munshi et al. (2007) have reported that the highest shoot regeneration in cotyledon and hypocotyl explants taken from 7 day old *in vitro* seedlings of head cabbage (*B. oleracea* var. *capitata*) was observed on 1/2 MS containing 0.5 mg/l BA and that 98% rooting had been

achieved on 1/2 MS fortified with 0.5 mg/l IBA. In a study performed on 8 different head cabbage *(Brassica oleracea* var. *capitata)* varieties, it is stated that the highest shoot regeneration in 5 varieties was obtained from the MS + 8.88 µM BAP + 0.53 µM NAA medium in 10 day old hypocotyl and cotyledon explants cultured *in vitro*, and that hypocotyl explants had been more successful in terms of callus stimulation and organogenesis. The same researchers have also stated that rooting was achieved in all varieties and that an increase was observed in the number of healthy and strong roots in the MS + 5.37 µM NAA medium (Gerszberg et al., 2015).

Sharma et al. (2014) have tested 36 different hormone combinations in head cabbage *(Brassica oleracea* L. var. *capitata)*. They have reported that the highest shoot regeneration in cotyledon explants had been obtained from the MS + 1.5 mg/l BAP + 0.50 mg/l NAA and MS + 2 mg/l BAP + 0.25 mg/l IAA medium, and that 90% root regeneration was achieved from MS + 0.1 mg/l IBA as rooting medium. Daud et al. (2015) have used stalk, root, leaf, and leaf stem explants taken from 7 day old seedlings of head cabbage that had developed *in vitro*. They have determined that plantlets had been obtained more quickly from calluses obtained from stalk and root explants cultured in the MS + BAP (1 mg/l) + NAA (0.5 mg/l) medium. In another study that had been performed on 2 genotypes of head cabbage, it is stated that the maximum shoot regeneration in hypocotyl explants taken from 5 day old seedlings developed *in vitro* had been observed on MS containing 9.1 µM zeatin and 2.8 µM IAA (Cristea et al., 2010).

The present study was undertaken to investigate the effect of MS medium formulations and different explant types (cotyledon and hypocotyl) on shoot and root regeneration in Ercis cabbage. This is the first report on *in vitro* regeneration of Ercis head cabbage.

Material and methods

Seeds belonging to the 'Ercis cabbage population' obtained from the Ercis district of Van province in Turkey have been used in the study. The seeds were washed several times under tap water, eliminating inorganic materials from the seeds. Then they were kept for 30 seconds in 70% ethyl alcohol within a laminar flow container, washed several times with double distilled water, removing ethyl alcohol. The seeds were then kept for 15 minutes in 20% commercial sodium hypochlorite solution to which a few drops of Tween-20 had been added, and finally washed by being shaken in double distilled water 3 times, 6 minutes each time. The sterilized seeds were germinated in hormone-free MS (Murashige and Skoog, 1962) medium (30 g/l sucrose, 7 g/l agar, PH: 5.8) within 6 cm glass Petri dishes (6-7 seeds/Petri dish). Cotyledon and hypocotyl explants were excised from 7 day old seedlings, and cultured on MS containing various concentrations of BAP (0.5, 1.0, and 2.0 mg/l) and NAA (0, 0.05, and 0.1 mg/l). All the cultures were kept under a 16 h photoperiod (3000 lux, approx.) regime at 23 ± 2°C. Shoots that reach an approximate length of 3 cm were transferred to 1/2 MS rooting medium containing IBA (0, 0.5, 1.0, and 1.5 mg/l) in 4 different concentrations. 4 weeks later, the number of shoot per explant and percentage, average shoot length, the number of roots obtained per explant and percentage and the average root length was calculated in the cultures.

Shoot regeneration trials were conducted with 3 repetitions for each application, and root regeneration trials were conducted with 6 trials. Variance analysis was performed in comparisons of properties investigated in the trial. The level of statistical significance was taken as 5% in calculations, and the SPSS (ver. 13) statistics package software was used for calculations.

Results and discussion

In vitro shoot regeneration trials, cotyledon and hypocotyls explants were excised from 7 day old *in vitro* seedlings, and cultured in the MS medium in 9 different hormone combinations

containing BAP and NAA (Table 1). The swelling and growths that occurred in explants 7-9 days after being planted in the MS medium were determined as development, and the number of explants which had shown development were recorded. Shoot regeneration was achieved from all explants that had observed development and growth. Hypocotyl explants were found to be more successful than cotyledon explants in terms of explant development and shoot regeneration, except in the MS1 (0.5 mg/l BAP) and MS9 (2 mg/l BAP + 0.1 mg/l NAA) mediums. While all explants (100%) registered growth in the MS7 (2 mg/l BAP) medium in hypocotyl explants, this was followed with MS6 (1 mg/l BAP + 0.1 mg/l NAA), MS4 (1 mg/l BAP), and MS3 (0.5 mg/l BAP + 0.1 mg/l NAA) with a 91.6% percentage of regeneration. MS9 (2 mg/l BAP + 0.1 mg/l NAA) was found to be the least successful medium with a 58.3% rate of regeneration.

In cotyledon explants, the highest shoot ratio was obtained in MS1 (0.5 mg/l BAP) and MS9 (2 mg/l BAP + 0.1 mg/l NAA) mediums with a 91.6% rate of regeneration, and this was followed by MS4, MS5, and MS8 in that order. MS6 and MS7 mediums were found to be least successful in terms of shoot regeneration with a 41.6% rate of regeneration. Indirect shoot regeneration was occurred in all medium combinations in hypocotyl explants (Figure 1). The rate of callus formation ranged between 41.6 – 100% in hypocotyl explants, and between 0-33.3% in cotyledon explants (Table 2).

Table 1. Effect of BAP and NAA in the MS medium on the number of shoots per explants, regeneration rate and on shoot length.

Medium	Hormone (mg/l)		Shoot number/explant and regeneration rate (%)				Shoot length (cm)	
	BAP	NAA	Hypocotyl	R.R (%)	Cotyledon	R.R (%)	Hypocotyl	Cotyledon
MS1	0.5	0	3.16 bc	83.3	2.92 ab	91.6	1.83 bc	2.33 a
MS2	0.5	0.05	3.75 b	83.3	0.66 c	50.0	3.80 a	1.60 ab
MS3	0.5	0.1	4.42 ab	91.6	0.75 c	58.3	2.60 ab	1.60 ab

R.R.: Regeneration rate

While the highest number of shoots per explant was obtained from the MS4 (5.25 shoot/explant) medium in hypocotyl explants, this was followed by the MS3 (4.42 shoot/explant), MS6 (4.33 shoot/explant), and MS7 (4.33 shoot/explant) mediums that are included in the same statistical group, in that order. The MS9 medium was found to be the least successful environment in terms of the number of shoots per explants (Table 1). In many studies conducted on cabbage, it is reported that the composition of the medium and type of explant are influential on shoot regeneration, and that hypocotyl explants yield more successful results as compared to other explant types in terms of the rate of shoot regeneration (Munshi et al., 2007; Dai et al., 2009; Ravanfar et al., 2009; Pavlovic et al., 2010). Figure 1 shows shoot formation from cotyledon and hypocotyl explants.

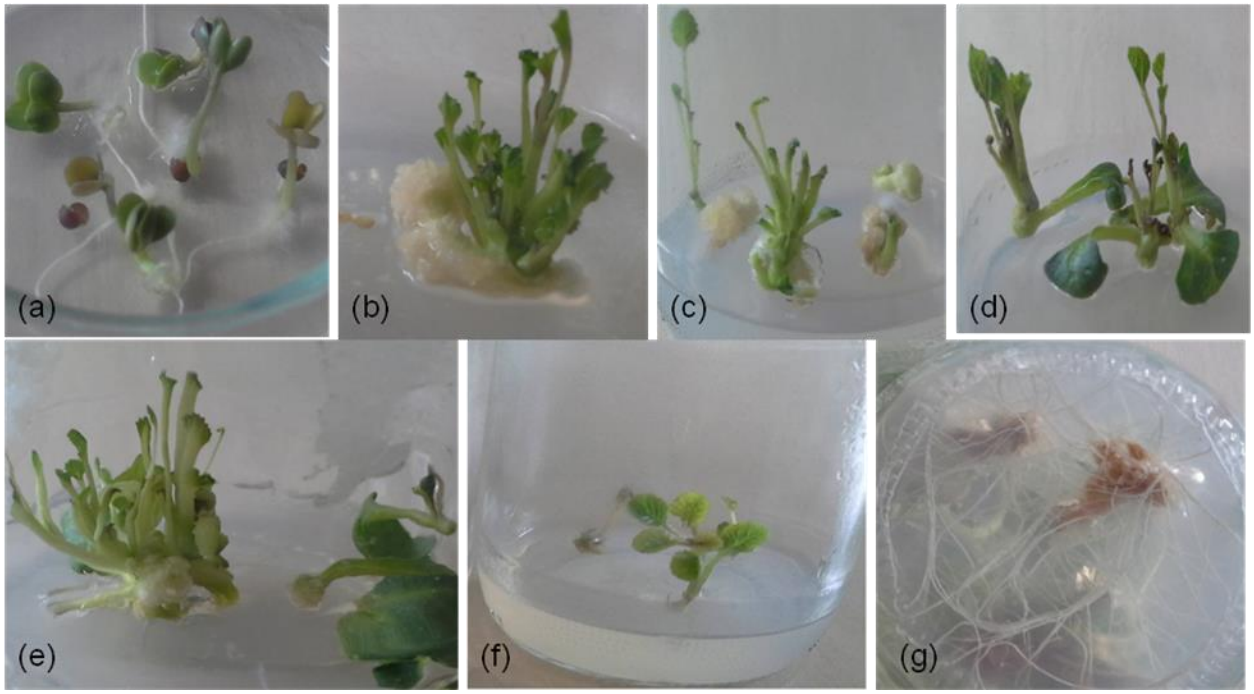

Figure 1. In Ercis head cabbage, (a) 7 day old in vitro germinated seedlings, (b, c) indirect shoot formation from hypocotyl explants, (d, e) direct shoot formation from cotyledon explants, (f) plants transferred to rooting medium, (g) root formations in rooting medium.

Table 2. Effect of BAP and NAA in the MS medium on the rate (%) of callus formation

Medium	Hormone (mg/l)		Callus formation rate (%)	
	BAP	NAA	Hypocotyl	Cotyledon
MS1	0.5	0	66.6	0.0
MS2	0.5	0.05	91.6	16.6
MS3	0.5	0.1	100.0	16.6
MS4	1.0	0	100.0	0.0
MS5	1.0	0.05	91.6	0.0
MS6	1.0	0.1	66.6	8.3
MS7	2.0	0	58.3	25.0
MS8	2.0	0.05	41.6	33.3
MS9	2.0	0.1	50.0	33.3

The results of our study also have been found to support this literature, and more successful results have been obtained from hypocotyl explants in terms of shoot regeneration. A statistically significant decrease has been determined in the number of shoots obtained from cotyledon explants. While the highest number of shoots was obtained from the MS9 (3.75 sürgün/eksplant) medium, this was followed by the MS1 (2.92 shoot/explant) and MS4 (2.58 shoot/explant) mediums. The number of shoots that was obtained from other medium combinations were found to be low, and the differences between them were found to be statistically insignificant (Table 1). It has been determined that various doses of are BAP (1.0 – 3.5 mg/l) and NAA (0.1-0.5 mg/l) are generally used in shoot regeneration studies in studies conducted on various *Brassica* species (Basak et al, 2012; Sharma et al, 2014). Shoot length

ranged between 1.0 – 3.8 cm in shoots developing from hypocotyl explants, and 1.0 – 2.33 cm in shoots developing from cotyledon explants (Table 1).

Literature scans performed have indicated that various doses of IBA (0 – 1.0 mg/l) or NAA (0.1 – 4.0 mg/l) are generally used as rooting medium on *Brassica* species, and that the results obtained are successful (Munshi et al, 2007; Ravanfar et al., 2009; Sharma et al., 2014; Daud et al., 2015; Gerzberg et al, 2015). In our study, considering these literature statements, the shoots obtained were transferred to rooting mediums containing various doses of IBA (0 mg/l, 0.5 mg/l, 1.0 mg/l, and 1.5 mg/l) in a 1/2 MS medium. The impact of various concentrations of IBA on the number of roots obtained per shoot, root length, and the rate of regeneration are shown in Table 3. The highest number of roots per shoot (14.16 root/shoot) was obtained from the 0.5 mg/l IBA dose. The number of roots per shoot decreased in other doses, while the differences between the doses were found to be statistically insignificant (Table 3). While a higher result in terms of root length was obtained from the control group to which no hormones had been added, no positive effects on root length of increased IBA doses were found.

Table 3. Effect of various concentrations of IBA in the 1/2 MS medium on rooting

Hormone (mg/l) IBA	**Root number/shoot**	**Root length (cm)**	**Regeneration rate (%)**
0	8.50 b	2.35 a	100
0.5	14.16 a	1.82 ab	100
1.0	8.30 b	1.78 ab	83.3
1.5	8.16 b	1.56 b	66.6
LSD.05	**1.84**	**0.66**	

Conclusion

It has been concluded that in future studies that will be conducted on *in vitro* shoot regeneration in the 'Ercis' head cabbage genotype, it would be beneficial to use hypocotyl explants taken from 7 day old sterile seedlings, and make trials with a higher number of repetitions using 0.5 – 2.0 mg/l doses of BAP in the MS medium. In terms of *in vitro* rooting, it is recommended that no hormones be added to the nutrient medium, or that a dose of 0.5 mg/l IBA not be exceeded in future studies.

MICROMORPHOLOGY OF POLLEN GRAINS OF SOME GRAPE CULTIVARS

Zeliha GÖKBAYRAK*, Hakan ENGIN

Department of Horticulture, Faculty of Agriculture, Çanakkale Onsekiz Mart University, Çanakkale /TURKEY.
*Corresponding author: zgokbayrak@comu.edu.tr

Abstract

Micromorphological characteristics of the pollen grain are one of the most important parameters to identify plant material. Pollen grains in various species are characterized by surface features, the length of polar axis (*P*) and the equatorial axis (*E*) of grain and *P/E* ratio. In this study, pollen grains of two cultivars of *Vitis vinifera* (Cardinal and Cabernet Sauvignon) collected from South Marmara of Turkey were examined for their micromorphological characterization through scanning electron microscopy. The length of polar axis (*P*), the equatorial axis (*E*), and *P/E* ratio were compared. There is no difference in size between 'Cabernet Sauvignon' and 'Cardinal' cultivar. Pollen from both cultivars is about 25 µm. The *P/E* ratio was 1.09 in 'Cabernet Sauvignon' and 1.08 in 'Cardinal'. The pollen grains shape is classified as elliptical-oval.

Keywords: *Vitis vinifera, Pollen Grains, Micromorphology, SEM*

Introduction

Palynology has presented considerable opportunities for cultivar identification in grapevines, besides its importance in plant taxonomy (Marasalı et al 2005). The elements of the pollen aperture complex, such as polar and equatorial axes and exine ornamentation are used in the description of the pollen (Roytchev 1995). Roytchev (1997) stated that shape, depth and size of the surface ornamentations and most of the pollen aperture complex traits are cultivar-spesific. Using pollen morphology in identification has become more important since the advent of the scanning electronic microscope (SEM) (Roytchev et al. 1994; Fogle, 1977; Cargnello et. al, 1980; Hebda et.al., 1988; Perveen and Qaiser, 2003; Engin and Unal, 2007). Vallania et al. (1996) reported differences in exine ornamentation that could be useful for cultivar identification in *Vitis vinifera* L. Liu et al. (1997) observed pollen morphology of 10 Vitis species with SEM and found that there were some differences in the size and shape of the pollens.

The objective of this study was to investigate in detail the pollen morphology of two cultivars of *Vitis vinifera* using SEM.

Material and methods

Pollens of the grape cultivars, 'Cabernet Sauvignon' and 'Cardinal' (*Vitis vinifera* L.) were utilized as plant materials. The vines were located at the experimental vineyard at the Dardanos Campus of Canakkale Onsekiz Mart University (Turkey). Inflorescences were collected in the morning hours at the 23rd stage (full bloom) of Eichorn and Lorenz (1977) classification. Inflorescences were brought into lab and all unopened flowers were emasculated and later, anthers were collected in petri dishes. Anthers were allowed to burst for 24 hours at room temperature. The pollen was further dried up at room temperature for 14-16 hours, put into brown glass vials. Samples were stored in a refrigerator at +4 °C until examined.

Preparation of pollen for analysis was performed by mounting two-layer transparent tape on the object carrier on the microscope and applying pollen with a brush. Prepared using methods described by Engin and Unal (2007) for scanning electron microscopy (SEM).

Coating of pollen samples was performed with a layer of gold using Sputter-Coater BAL-TEC SCD 005. Observation of the prepared samples was carried out with a scanning electron microscope (SEM) JEOL JSM-7100F (Tokyo, Japan) at 15 kV. Sixty pollen grains from both of cultivars were examined for their size and shape. Morphological characters measured were; length of polar axis (*P*), length of equatorial axis (*E*) and ratio of polar axis to equatorial axis (*P/E*).

The experiment was carried out in three replicates. In each replicate, ten pollen grains were analyzed. The statistical analysis was performed using statistical analysis software MINITAB software (Minitab Inc., ver.16) to determine differences in *P*, *E*, and *P/E* ratio. Significant differences between the mean values was determined using Tukey's test for significance at $p \leq 0.05$.

Results and discussion

Based on the analysis conducted by SEM, pollens from both cultivars, 'Cabernet Sauvignon' and 'Cardinal', are similar. The pollen grains can be characterized as elliptical-oval with a smooth exine surface (Figure 1). There were no perforations on the surface of pollen grains of the cultivars. The surface of the exine of both of cultivars was striate, with more or less parallel longitudinal ridges (Figure 2), which agrees with the results obtained by Marasalı et al (2005). The ridges were more parallel in 'Cabernet Sauvignon' and less parallel in 'Cardinal'. Perforation of the exine was not more pronounced compared to other cultivars reported in the work of Roytchey et al (1994) who found that the perforation on the pollen surface in seedless grapes are more clear. This indicates that perforations in the grape are cultivar specific.

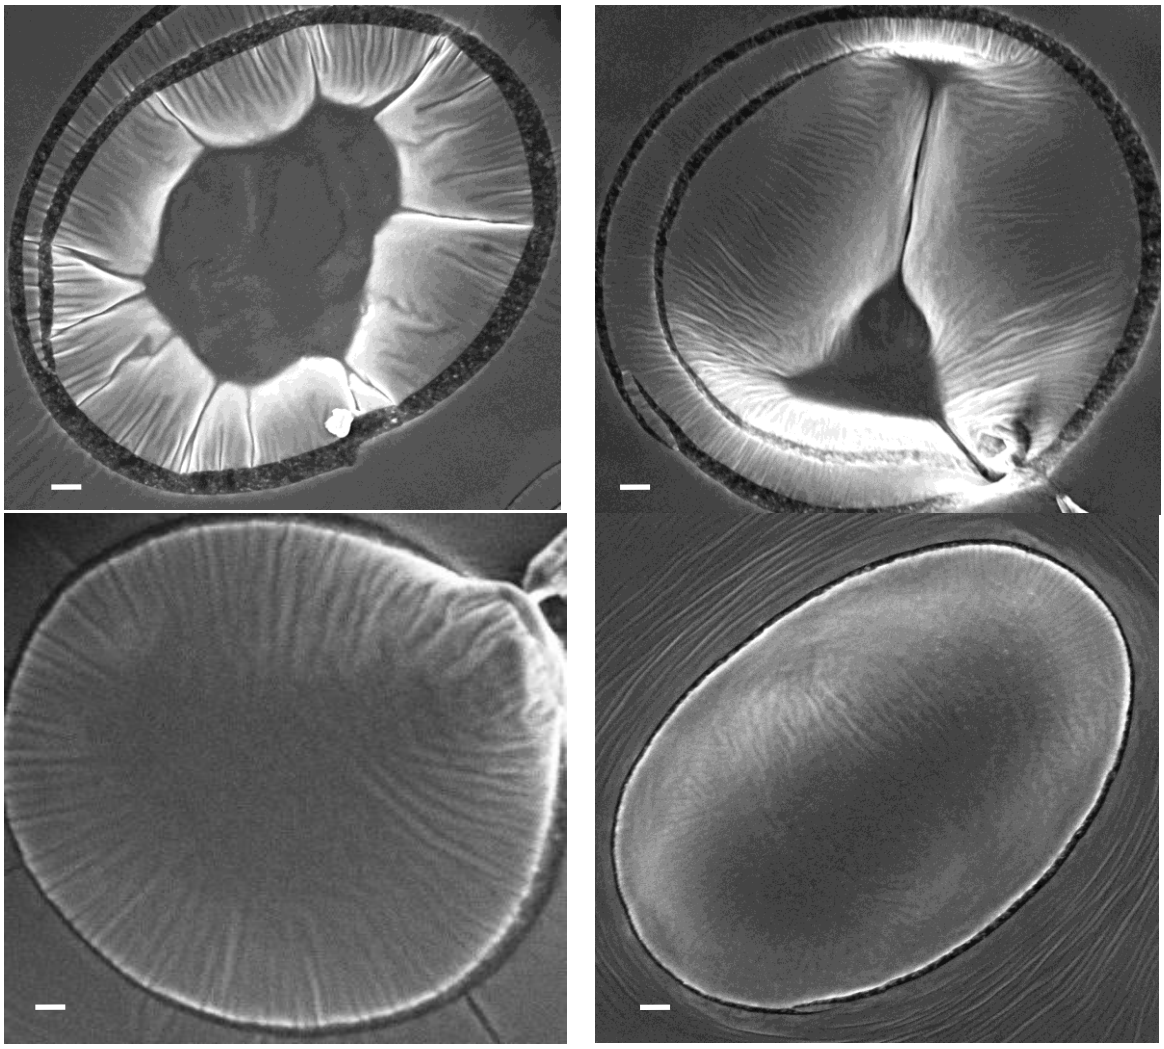

Figure 1. Pollen grain from ‘Cabernet Sauvignon’ flowers (left) and from ‘Cardinal’ flowers (right) in grape (*Vitis vinifera* L.). Bars: 1 μm.

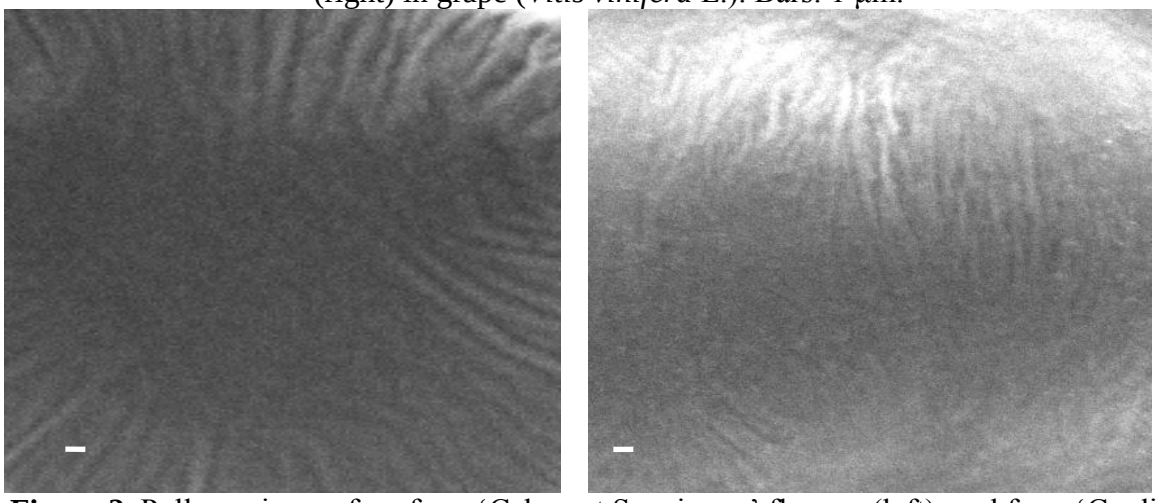

Figure 2. Pollen exine surface from ‘Cabernet Sauvignon’ flowers (left) and from ‘Cardinal’ flowers (right) in grape (*Vitis vinifera* L.). Bars: 1 μm.

Length of the axes (*P* and *E*), ratio of polar axis to equatorial axis (*P/E*) of pollen grains from ‘Cabernet Sauvignon’ and ‘Cardinal’ flowers were demonstrated in table 1.

Table 1. The measured characteristics of pollen grains in grape (*Vitis vinifera* L.). 'Cabernet Sauvignon' and 'Cardinal' flowers.

	Polar axis (*P*) μm		Equatorial axis (*E*) μm		*P/E* ratio	shape
	Variation range	Mean value	Variation range	Mean value		
Cabernet S.	21.84-36.40	27.22	18.48-33.04	24.92	1.09	prolate
Cardinal	21.84-33.60	27.12	16.24-27.44	24.97	1.08	prolate
Grape (Mean)		24.94		27.17		

The size and shape of pollen grains of 'Cabernet Sauvignon' and 'Cardinal' did not differ significantly. The maximum length of pollen grains was determined in the 'Cabernet Sauvignon' cultivar (36.40 μm) and the lowest in both cultivars (21.84 μm). The width of pollen grains ranged from 16.24 μm (Cardinal) to 33.04 μm (Cabernet Sauvignon). The pollens were medium sized. In relation to the results reported by Marasalı et al (2005), the polar axis values obtained in our studies were higher in both of cultivars. Estimation of the axes might change with mounting medium (Punt etal. 2003).

According to findings of Sotonyi et al. (2000), the dimensions of the pollen grain are, to a large extent, genetically determined and of great importance for cultivar characterization. In accordance with the classification given by Erdtman (1969), the shape of pollen grains varies on the basis of the ratio of the pollen grains polar axis to equatorial axis from prolate (length/width ≤2) to perprolate (length/width >2). From this point of view, the pollen grains of both cultivars are prolate (*P/E* = 1.08-1.09). A certain degree of homogeneity for *P* and *E* values and ratio were observed. Generally, the *P* and *E* values measured in the 'Cabernet Sauvignon' and 'Cardinal' pollens changed within a very small range. Marasalı et al (2005) determined that the cultivars studied had small range of *P* and *E* values, but the shapes changed from suboblate prolate-spheroidal. Inceoglu et al (2000) stated that pollens of *Vitis sylvestris* ranged from prolate-spheroidal and subprolate pollen shape.

Conclusion

Morphological characteristics of pollens did not show significant differences among these grape cultivars. These properties are the most influential for classification of cultivars into particular groups. The pollen of the investigated cultivars were medium sized with a smooth exine surface. The shape of the pollen grains was elliptical-oval (prolate). The pattern of the exine of both of cultivars was striate, with parallel longitudinal ridges.

Abstract

Caraway (*Carum carvi* L.) is a plant from the Apiaceae family (Umbelliferae). It has two forms: annual (*C. carvi* var. *annua*), which usually grows in warm climates, and biennial (*C. carvi* var. *biennis*), which grows in cooler climates. In our region, the biennial caraway is usually grown, because it has higher seed yield and essential oil content. However, introducing the annual caraway to agroecological conditions of Serbia has the purpose of shortening the production cycle of this plant as the biennial variety is not profitable during the first year, requires significant investment and occupies space. The purpose of this research was to determine the duration of the vegetation period, the requirements for temperature, moisture and insolation of annual caraway during the phenological stages. The experiment was conducted during two years at three locations in Vojvodina Province. The sowing-harvest period of annual caraway lasts from 136-177 days, requires above 3000 degree days, whereas the amount of precipitation needs to be a minimum of 200 mm, and number of sunshine hours between 1250 and 1480. There is a strong relationship between temperature, precipitation and insolation that influences the development rate during the caraway vegetation period.

Keywords: *caraway, production cycle, temperature, moisture, insolation*

Introduction

Caraway (*Carum carvi* L.) is a plant from the Apiaceae family (Umbelliferae). It has two forms: annual (*C. carvi* var. *annua*), which usually grows in warm climates, and biennial (*C. carvi* var. *biennis*), which grows in cooler climates. However, both forms have the tap root system, white or pale yellow, 15−20 cm long and 1−2 cm thick. Caraway germinates with two lanceolate descending cotyledons, while the first true leaf is feathery and unequally divided. The leaves of the leaf rosette and lower leaves are on long petioles, with 6−12 lobes that are double or triple pinnate. The leaves on the stem are arranged alternately, and the leaves at the top are thread-like. Biennial caraway forms only the leaf rosette in the first year, which consists of 7−18 leaves usually up to 20 cm long. With the end of the vegetation period the above-ground part dies, while the root winters. In the spring, the development of the plant starts early, and 4−5 weeks after the first shoots appear, a flower stem develops. The vegetation period of this form of caraway usually lasts 440−460 days. In contrast, annual caraway forms a leaf rosette with fewer leaves (usually up to five), and the umbel quickly starts developing. The vegetation period lasts 140−160 days. The flower stem is upright with a branching upper part, each branch ends in an umbel, which consists of 5 to 16 primary rays – umbelletes. The flowers consist of five petals which are white or pale pink with tips bent upward (Aćimović 2016).

Caraway fruit (*Carvi fructus*) is a schizocarp, a seed (reproductive plant organ) and drug (medicinal raw material) as well as spice at the same time. The fruit is gray brown in color, 3−7 mm long, 1−1.25 mm wide, with a crescent curve. Usually, a schizocarp separates spontaneously into two mericarps. Each mericarp has nine longitudinal ridges, between which are the channels with essential oil. Caraway fruit contain from 1 to 6% of essential oil (*Carvi aetheroleum*) that gives caraway its characteristic aroma (Sedláková et al. 2003). There are approximately 30 compounds in caraway essential oil, among which carvone and limonene account for about 95%. Other components are present in small proportions (Bouwmeester et al. 1995). These two components have a wide range of applications.

The biennial caraway is usually grown in our region, because it has higher seed yield and essential oil content. However, introducing annual caraway to the agroecological conditions of Serbia has the purpose of shortening the production cycle of this plant as the biennial variety is not profitable during the first year, requires significant investment and occupies space. The purpose of this research was to determine the duration of the vegetation period, the association of annual caraway productivity with temperature, moisture and insolation during the phenological stages.

Material and methods

The seed used in this study was an annual local ecotype of caraway seed. The field experiment was carried out during 2011 and 2012 at three localities in Vojvodina Province, Serbia: Mošorin (latitude 45°18'5"N; longitude 20°09'32"E), Veliki Radinci (latitude 45°02'26"N; longitude 19°40'15"E) and Ostojićevo (latitude 45°53'16"N; longitude 20°09'31"E).

The climate in Vojvodina Province is moderate continental with some tendencies towards continental. The whole region is located in a semi-arid area where variations in the amount of precipitation, air temperature and other important climatic elements are substantial over the years. The weather conditions in 2011 and 2012 indicate that they were moderately (2011) to severely dry (2012) in during the active growing season (April–September), in relation to long-term averages. Temperature conditions during both years, at the three localities, were similar, but there were significant variations in the amount and distribution of rainfall between the locations and years. Meteorological data were obtained from the meteorological stations nearest to the experimental fields, and are shown in Figure 1.

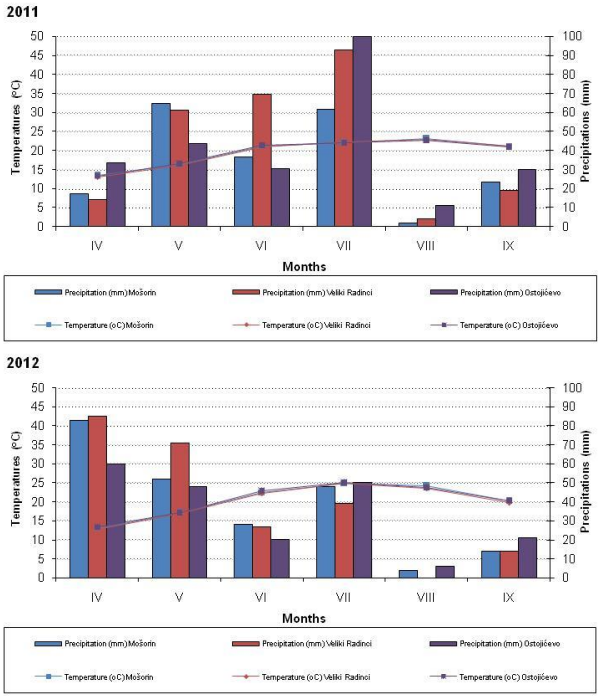

Figure 1. Average daily temperatures (°C) and precipitation (mm) during 2011 and 2012 at three localities

Caraway seed was sown in the first decade of April (optimal time in Serbian agroecological conditions), with row spacing of 0.35 m, and density of 200 plants/m^2. The size of the experimental plots was 5 m^2. Weeds were controlled by hoeing and weeding when needed. Measures of protection from diseases and insects were not used. Harvest was carried out by hand in the phase of full maturity. In 2011, the harvest was performed in the middle of September, and in 2012 because of water deficit and high temperatures the vegetation period was shortened and the harvest was performed in the last decade of August.

The development of the caraway plant was checked daily. Four phenological stages were determined: (1) germination, (2) stem elongation, (3) flowering and (4) fruit formation and maturation. The exact occurrence of these stages was registered both years at the three localities. The duration of each phenological stage was measured in days. Optimum parameters necessary for the cultivation of annual caraway were obtained by comparing the duration of each stage with the sum of effective temperatures (GDD) which present a sum of average daily temperatures above 5 °C, sum of precipitation and insolation.

Results and discussion

The growth and development of an annual caraway plant is shown in Figure 2, while the duration of phenological stages in both experimental years in three experimental fields is shown in Figure 3. The vegetation period of annual caraway lasted from 136 to 177 d. It lasted longer in 2011 (an average of 169.0 d) than in 2012 (140.7 d). The germination period lasted 14−19 d, and the period from germination to stem elongation, i.e. leaf rosette formation, was the longest (between 40 and 51 d). Caraway needed 16−27 d from the start of stem elongation to flowering. Flowering lasted 15−29 d, and fruit formation and maturation 40−51 d. All phenological stages during 2012 were shorter on average by 5.7 d compared with 2011, which in the end resulted in the shortening of the total vegetation period by 28.3 d.

Figure 2. Growth and development of *Carum carvi* var. *annua*

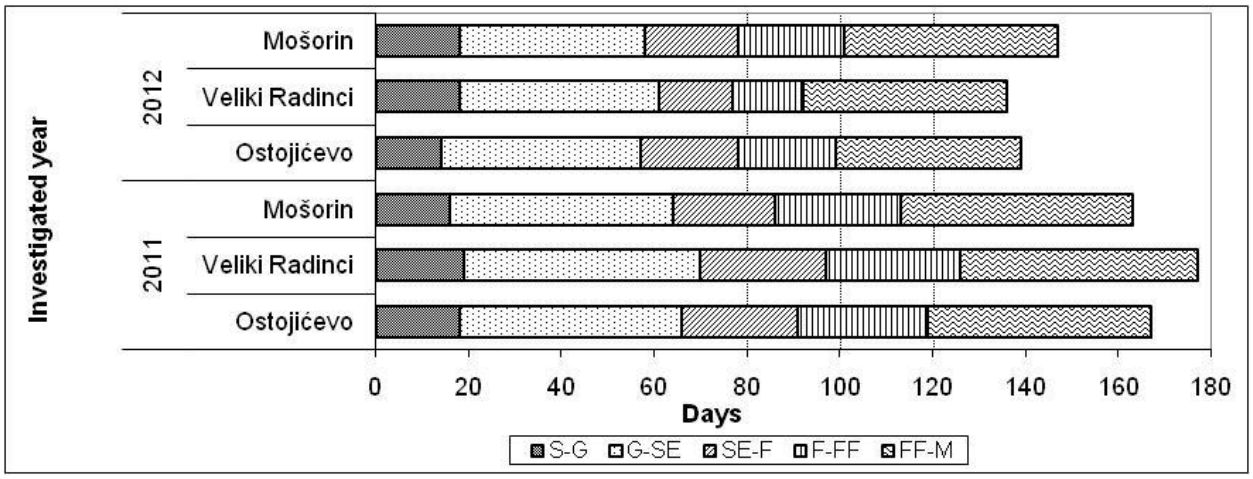

Figure 3. Duration of phenological stages of annual caraway during 2011 and 2012 at three localities (S−sowing, G−germination, SE−stem elongation, F−flowering, FF−fruit formation and maturation, H−harvest).

The GDD during phenological stages of annual caraway in both years is shown in Figure 4. In 2011, which was more favorable for caraway yield formation, the average sum of effective temperatures was 3207 °C (3048−3317 °C). During 2012, the sum of effective temperatures was lower by 13.2% and the average was 2783 °C (2693−2960 °C). During the period from sowing to germination, the sum of effective temperatures was 170 °C (in 2011), and 179 °C (in 2012). For the period from forming a leaf rosette until maturation, the sum of temperatures was lower in 2012 in comparison with 2011. In 2012, during the period of leaf rosette formation, a sum of effective temperatures lower by 63 °C was recorded when compared with the previous year. During the period of flowering, this difference was 83 °C, in the period of fruit formation 212 °C, and during maturation 75 °C. However, during the second year, the mean daily temperatures were higher on average by 1.2 °C. Higher average daily temperatures could have caused shortening of the caraway vegetation period in the second year of the study.

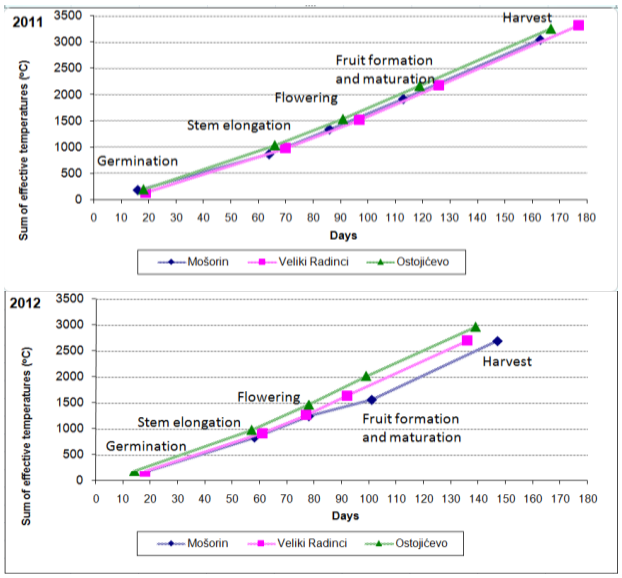

Figure 4. The sum of effective temperatures (GDD) during phenological stages of annual caraway in 2011 and 2012 at three localities

Precipitation during the vegetation period in 2011 was 20% higher on average than in 2012. Also, the precipitation in the first year was better distributed during the vegetation period. However, the lowest precipitation was noted from sowing to germination. Nevertheless, the seed used moisture reserves from the winter period, so this deficit had no negative influence on germination. During the rest of the 2011 growing season, rainfall was evenly distributed and sufficient for the formation of high yield.

In 2012, in the period from sowing to germination there was enough rainfall (34–50 mm) which enabled uniform and fast germination of caraway seed. Also, during the period of leaf rosette formation (from germination to stem elongation) the quantity of rainfall was optimal. However, in the period from stem elongation until flowering, there was a significant rainfall deficit. The dry period continued during the stage of fruit formation, which had a negative impact on the thousand fruit mass and germinability. In the period of fruit maturation there was an average of 47 mm of rainfall, but it had no effect on the increase of fruit yield. Thus, drought in the generative stages had a negative effect on the caraway fruit yield formation.

The influence of insolation on the duration of the caraway vegetation period and some phenological stages are shown in Figure 5. During the caraway vegetation period in 2011, the average duration of insolation was 1442 h. In 2012, the average number of sunshine hours was lower by 117, amounting to 1325 h. Compared with 2011, in 2012, a higher number of sunshine hours was recorded only in the period of leaf rosette formation. In all other phenological stages, the amount of insolation was smaller in the second year.

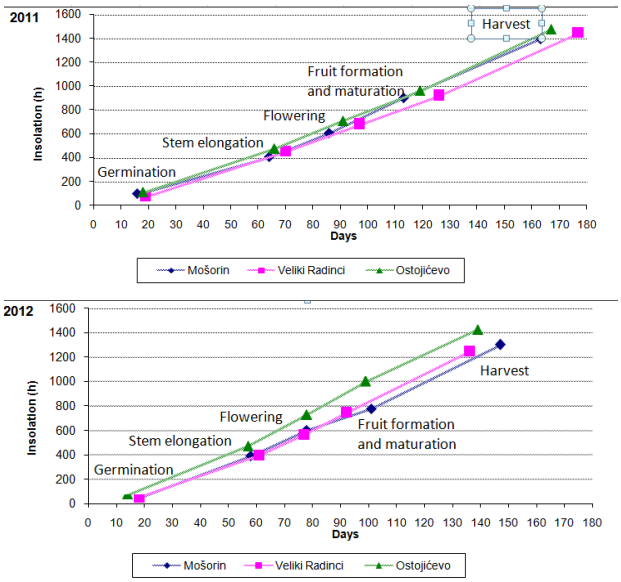

Figure 5. Insolation (h) during phenological stages of annual caraway in 2011 and 2012 at all three localities

Weather conditions influenced qualitative parameters of caraway fruits such as essential oil content, oil component ratios, thousand fruit mass, and seed germination (Aćimović et al. 2014; Aćimović et al. 2015). Weather conditions also influenced morphological parameters such as plant height, umbel diameter, number of umbels per plant, as well as whole plant mass, yield of fruits per plant, and harvest index.

Fruit yield per plant was strongly influenced by weather conditions in 2011 and 2012 (Table 1). In the favorable year (2011), the yield of fruits per plant was 4.25 g, while in the dry year (2012) it was significantly lower (only 0.96 g). The yield of fruits per plant is determined by the number of umbels per plant, number of fruits per umbel and thousand fruit mass. All these parameters were significant higher in 2011 than in 2012.

During a dry year in Hungary, the yield of annual caraway fruit per plant was very low, ranging between 0.02−0.82 g, while in moderate drought conditions it was slightly higher, reaching 1.73 g (Valkovszki 2011). In Tunisia the yield of fruit per plant was between 0.70−1.33 g, while in Lithuania it was 1.1−2.9 g (Laribi et al. 2010; Petraityte 2005).

Whole plant mass was also significantly influenced by weather conditions (Table 1). In the favorable year, across the three trial locations average mass per plant was 10.02 g, while in the dry year it was only 4.21 g, a reduction of 58%. In a study by Laribi et al. (2010), whole plant mass was reduced by 20 to 40%, depending on the drought level. These results demonstrate that water deficit is a factor limiting the growth and development of caraway.

Harvest index shows the division of photosynthesis products between fruits and vegetative parts of a plant. In 2011 harvest index was 43.16%, but only 22.65% in 2012.

Table 1. Fruit mass per plant, whole plant mass and harvest index of annual caraway depending on weather conditions of the year (mean ± SD)

	Fruit mass per plant (g)	Whole plant mass (g)	Harvest index (%)
2011	4.25±1.02	10.02±2.58	43.16±1.09
2012	0.96±0.47	4.21±1.89	22.65±2.07
Average	**2.61**	**7.12**	**32.91**

Conclusion

There is a strong relationship between temperature, precipitation and insolation that influences development rate during the caraway vegetation period. However, these parameters primarily affected harvest index, as well as yield of caraway fruit.

Abstract

In this study, 38 different mulberries genotypes collected from Tokat region in Turkey were used. ISSR-PCR analyses were carried on the DNA of genotypes isolated using mini-CTAB extraction method. The levels of polymorphism between genotypes were determined using the UBC-ISSR primers. A total of 96 bands were obtained from 15 UBC ISSR primers. Out of 96 bands, 80 bands were polymorphic. The number of bands obtained per primer ranged between 4 and 11, the average number of bands were determined as 6.4. The average number of polymorphic bands per primer was 5.33. Similarities and differences between genotypes have been studied at the molecular level. The data used for statistical analysis were obtained by the evaluation of ISSR bands. Similarity coefficient and UPGMA dendrogram were built using the Basic Coordinates Analysis. According to the dendrogram, the genotypes have been divided in two main groups, one small and other large group. While the small group was only comprised of black mulberry genotypes, the large group included white mulberry, weeping mulberry and wild white mulberry genotypes. Different mulberry species have been divided into different sub groubs within the large group. The polimorfizm level within the species was lowest in black mulberry genotypes, and this was followed by weeping mulberry, white mulberry and wild white mulberry genotypes, respectually.

Keywords: *Mulberry, molecular, genotype, marker, ISSR*

Introduction

Mulberry is a perennial fruit species belongs to the genus *Morus* of the family Moraceae. (Datta, 1992, Anonymous, 2006). *Morus*, a genus of flowering plants in the family Moraceae, deciduous trees commonly known as mulberries, growing wild and under cultivation in many temperate world regions. The origin of mulberry is Asia (Awasthi et al., 2004). Over 150 species names have been published, and although differing sources may cite different selections of accepted names, only 10–16 are generally cited as being accepted by the vast majority of botanical authorities. *Morus* classification is even further complicated by widespread hybridisation, wherein the hybrids are fertile. Mulberry trees are either dioecious or monoecious and sometimes will transform from one sex to another. The flowers are held on short, green, pendulous, nondescript catkins that emerge in the axils of the current season's growth and on spurs on older wood. They are wind pollinated and some cultivars will set fruit without any pollination (Anonymous, 2009).

Black, red, and white mulberry are widespread in southern Europe, the Middle East, northern Africa and Indian subcontinent, where the tree and the fruit have names under regional dialects. The most important mulberry species are *Morus alba* (white mulberry), *Morus australis* (Chinese mulberry), *Morus indica* (Indian mulberry), *Morus microphylla* (Texas mulberry), *Morus nigra* (Black mulberry), *Morus rubra* (Red-purple mulberry) and *Morus serrata* (Himalian mulberry) (Tutin, 1996; Vijayan et al., 2004). The mulberry plants are deciduous and are produced for their fruit and leaves in all parts of Turkey (Anonymous, 2005). The species *M. alba*, *M. nigra* and *M. rubra* are common in Turkey (Ercisli, 2004;

Ercisli and Orhan, 2007; Özgen et al., 2009). The main mulberry production areas of Turkey are Black Sea Region and Eastern and Central Anatolian Regions.

Turkey has very old mulberry cultivation, and mulberries are one of the main fruits grown by Turkish farmers. The four mulberry species (*Morus alba, Morus nigra, Morus rubra, Morus laevigata*) can be seen in different agro-climatic regions in Turkey. There is no registered mulberry cultivar in Turkey but each region has its own local genotypes which propagated by budding or grafting over many years (Ercisli and Orhan, 2008).

Tokat Province of Turkey, at the mid Black Sea region of Anatolia, has a hot-summer Mediterranean climate with considerable maritime and continental influences. Most parts of province are suitable for mulberry production, and some species of mulberry spread over the province. Although there is no intesive mulberry production by producers, one or two mulberry trees can be seen almost in every orchard, especially near by homes.

The aim of this research is to determinate diversity of mulberries grown in North Anatolia (Tokat Province) between or within species by ISSR markers.

Material and Methods

Plant Material; For research purposes, a total of 38 different mulberries genotypes from Tokat region in Turkey were used. Out of total number 15 belongs to black, 13 to white, 5 to pendulous, 2 to everbearing mulberry and 3 to wild mulberry,.

DNA extraction; Total genomic DNA was extracted according to the CTAB method (Doyle and Doyle, 1987). DNA sample concentration was determined using a fluorometer employing a Hoechst dye (Hoefer Inc., San Francisco, CA, USA), and the DNA samples were diluted to a final concentration of 10 ng/µl with 1 × TE buffer and stored at −20 °C prior to polymerase chain reaction (PCR) amplification**.**

ISSR amplification**;** 15 primers that produced clear and reproducible fragments were selected out of a hundred UBC primers, which were previously tested for further analyses (Table 2). ISSR amplification was performed in a 20 µl volume containing 20 ng genome DNA, 1 × Taq buffer, 2.0 mM $MgCl_2$, 0.2 mM dNTPs, 0.75 µM primer, 0.5 units of Taq DNA polymerase. The amplification reaction consisted of an initial denaturation step at 94 °C for 5 min, followed by 45 cycles of 45 s at 94 °C, annealing at 50 °C–56 °C for 45 s, extension at 72 °C for 90 s, and ended with extension at 72 °C for 7 min. The amplified products were resolved electrophoretically on 2.0% agarose gels run at 100 V in 1.0 × TBE buffer, visualized by staining with ethidium bromide (0.5 µg/ml), and photographed under ultraviolet light (Charters at al., 1996, Rafalski at al, 1996) The amplifications were repeated twice and only clear repetitive bands were used in data analysis, and molecular weights were estimated using a 100 bp DNA marker (Vivantis).

Data analysis; The amplified fragments were scored for band presence (1) or absence (0) with all the accessions studied. Similarities and differences between genotypes have been studied at the molecular level. The data used for statistical analysis were obtained by the evaluation of ISSR bands. Similarity coefficient and UPGMA dendrogram were built using the Basic Coordinates Analysis.

Results and Discussion

On the basis of the number, intensity and reproducibility of ISSR bands 15 primers were selected out of a hundred UBC primers, which were previously tested (Cekic at al., 2001). Bands with the same mobility were treated as identical fragments. Weak bands with negligible intensity and smear bands were both excluded from final analysis. Each primer was evaluated for total band number (TBN), polymorphic band number (PBN) and the ratio of polymorphism(PR= PBN/TBN X 100).

The number of scored bands varied from four to eleven with an average of 6,4 bands per primer and an average of 5,33 polymorphic bands per primer. In total, 80 bands out of 96 derived from 15 primers were polymorphic.

Table 1. Band number, Polymorphic band number and Polymorphic band ratio(%) in mulberry genotypes

	ISSR Primer Code	Primer Sequence and Anchors	Band Number	Polymorphic Band Number	Polymorphic Band Ratio(%)

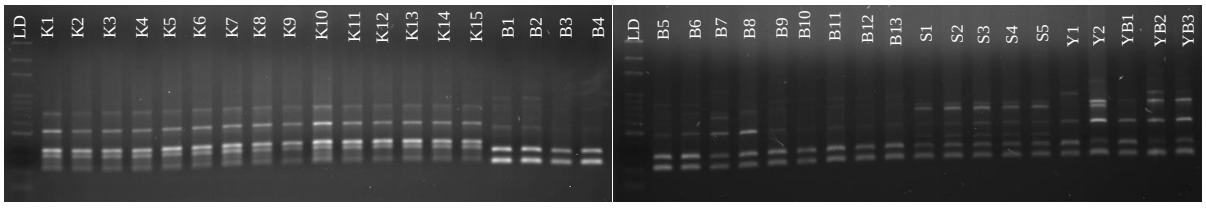

Figure 1. Agarose gel of polymorphic DNA amplification profiles of different mulberry genotypes ((K: Black mulberry, B: White mulberry, S: Pendulous mulberry, Y: Everbearing mulberry(Long season harvesting), YB: Wild mulberry) obtained with UBC ISSR primer 811. (LD: 100 bp LADDER -Vivantis)

Cluster analysis: Genetic similarity among varieties was estimated using dissimilarity coefficient matrix based on ISSR bands scored. Pairwise values of dissimilarity coefficients ranged from 0.27 for genotypes with the same scored bands to 1.00 for the most similar genotypes. The dendrogram was constructed based on the similarity matrix, using UPGMA method (Rohlf, 1992). The 38 mulberry genotypes were divided into two main clusters (Figure 2), in which black mulberry genotypes in one group and the rest of the genotypes falling under the other group. While the first major group contained only black mulberries, the second major cluster was further separated into subgroups. The first subgroup contained black mulberry genotypes, respectively which showed very close ISSR profile exhibited the highest genetic similarity ranges (0,95-1,00). On the other hand, the similarity of the second varied 0.75 to 0.96, in which different mulberry species (White mulberry, Pendulous mulberry,

Everbearing mulberry, Wild mulberry) seperated in different clusters at various stages (Figure 2).

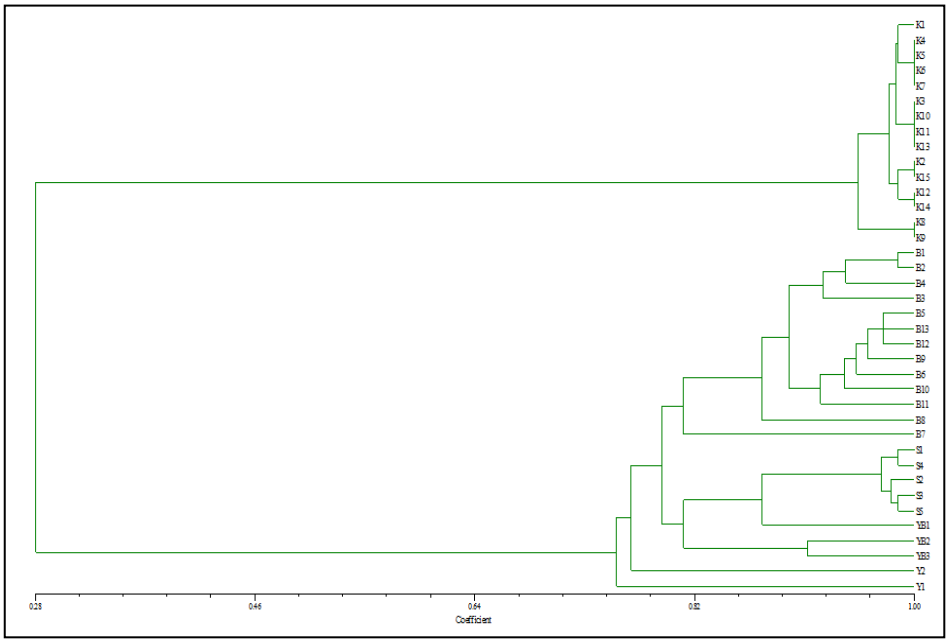

Figure 2. Dendrogram showing genetic relationships among value of ISSR markers for mulberry genotypes (K: Black mulberry, B: White mulberry, S: Pendulous mulberry, Y: Everbearing mulberry(Long season harvesting), YB: Wild mulberry)

Also, the principle component analysis generally put the genotypes into different clusters as paralel to morfological differences of the mulberry species.

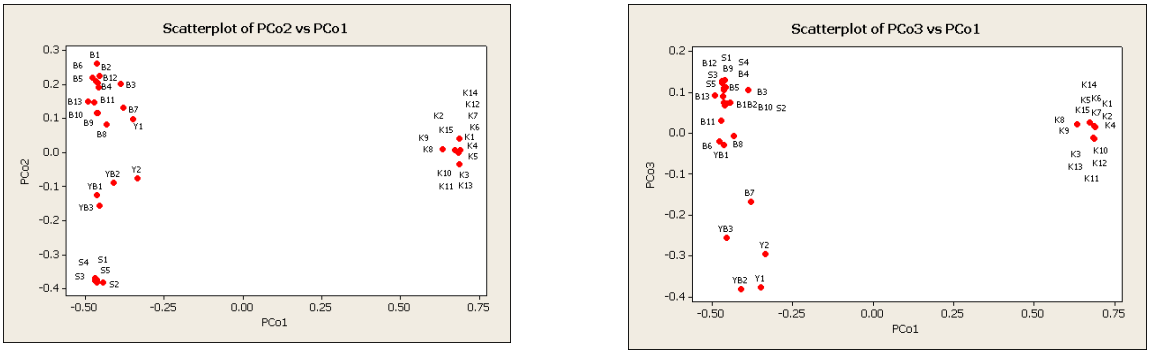

Figure 3. The principle companent analysis of mulberry genotypes according to 15 ISSR primers

Conclusion

Screening of the 38 genotypes of different mulberry species revealed that banding profiles obtained with fifteen ISSR primers were enough to distinguish the diversity between species or within the species. The results indicated that the ISSR technique is effective to develop genotype-specific banding patterns valuable for genotype identification. Since ISSR-PCR technique does not require previous DNA sequence information and uses very small quantity of DNA, it is considered as one of the most widely used techniques for genotypeidentification and genetic diversity studies. These results mean that molecular tools are more reliable than the phenotypic observations for evaluating variations and monitoring genetic stability.

Abstract

With the dramatically increment of human population, demand for food will increase significantly. In order to enhance food amount, there is a need for utilization of all available ways to produce food. One of those ways is the exploitation and utilization of production unsuitable and less productive soil. Solonetz is a type of soil characterized by increased alkaline reaction, high sodium content and unfavorable water-physical characteristics. Solonetz is mainly used as a destitute pasture, covering about 135 million hectares, about 20 million hectares in Europe, while in Serbia occupies about 80,000 hectares, mainly in Vojvodina. Trials were set up at two localities that differ in agro-ecological conditions, especially in terms of land. The experimental field of the Novi Sad Institute of Field and Vegetable Crops has been used as control part of the trial having normal growth conditions on chernozem soil. The other locality is in the village of Kumane in Banat. The aim of perennial trials conducted on chernozem and solonetz types of soil is to select usable genetic variation from the existing wheat gene pool and to create a novel genetic variability for the halomorphic soil growing conditions. Multiyear results show that desirable genetic variability could be selected within the existing genetic variation and that novel genetic variability of the enhanced tolerance to abiotic stress conditions of high sodium content and higher alkalinity could be selected in progenies of suitably chosen parents.

Key words: *wheat, abiotic stress, solonetz, breeding, genetic variation.*

Introduction

Agricultural production intensification has almost reached the border at given technology development. However, there is still a space to increase food production by utilizing agriculturally less suitable land. There is a space of 2.7 billion ha potentially useful to some degree for broadening food harvest area. One of the ways for broadening land for food production is putting in use types of soil with less favorable conditions for crop production. Solonetz represent the type of soil characterized with a high content of sodium, alkaline reaction and clayey subsurface horizon. Appears, normally, in a steppe climate. Commonly is utilized as rangeland or just lies idle. There is about 135 million ha of solonetz in the World. In Europe, solonetz covers about 0.5%. Concerning Serbia, about 3.6% of arable land is solonetz soil (Miljković, 1996). About 67% is settled in Vojvodina (Belić *et al*., 2012; Djordjević and Radmanović, 2016). The crops growth on the soil as solonetz, represents abiotic stress environment for plants that reflects their yield and overall production. Consequently, beside the reclamation practice, a novel, better adapted genetic variability is needed. A desirable genetic variability could be found in taxonomically distant organisms, wild relatives, landraces, older varieties that had been of a good adaptability, but not suitable for an intensive agricultural production, green revolution type, and among novel varieties bred for the modern agricultural practice. A new genetic variability could be created vertically through gene recombination using classic hybridization methods, or by horizontal gene transfer using gene insertion by means of transgenic technology (Munns *et al*., 2012; Jiang *et al.*, 2014, respectively). A crop of choice for targeted agro-ecological production conditions is

an important decision. Hexaploid wheat (*Triticum aestivum L.*) meets the requirements. Wheat has moderate salt tolerance level (Arshad, 2008). It is plays a key role in food supply, as well. Wheat is durable, adaptable, having genes (*Nax*) for Na^+ exclusion in its ancestry (Borelli *et al.*, 2011). This cultivar is not very demanding and costly in respect of crop care during the vegetation, and has broad genetic variability among cultivated varieties, and its wild relatives, like closely linked *Aegilops* sp. (Colmer *et al.*, 2006). The aim of the article is to present a survey of long-standing efforts to single out a desirable genetic variability in bread wheat, as well as, *in situ* obtained novel genetic variability, under selection pressure of high potassium content, and overall abiotic stress conditions of solonetz soil.

Materials and methods

The wheat cultivars of the Institute of Field and Vegetable Crops in Novi Sad, have been put in long-standing trials, established at two localities: Kumane village (45.5219940N, 20.1949190E, altitude 73m, pH = 9.86) on solonetz soil, and Rimski Šančevi experimental field of the Institute of Field and Vegetable Crops in Novi Sad (45.3249360N, 19.8428830E, pH=6.86) on chernozem, as a parallel control trial. Plant traits, the yield components, were followed, as well as, grain yield per unit area. Phenotypic expressions of individual plant traits, and the grain yield, were selection criteria for desirable genotype selection in an existing germplasm, as well as, in novel genetic variability. The existing genetic variability was tested in a randomized block design (RCBD) trial with three replications, in 1m long rows 20 cm apart. The wheat varieties in RCBD were parallel observed in micro trials established at the locality of Kumane that were to simulate a wide production conditions with 1m wide and 150m long rows, with the 12.5cm, space between rows. Fifty kilograms of NPK 15:15:15 fertilizer was applied along with sowing, and 150kg of Potassium ammonium nitrate was additionally applied in spring. In order to follow the reaction of genotypes, reclamation was partly applied with 25t/ha and 50t/ha of phosphor-gypsum. Elementary statistics, as well as, models for sources of variation identification and quantification with the emphasis on genotype by environment interaction have been calculated for studied traits. The mode of inheritance has been established using t-test.

Results and discussion

Germplasm testing sample - criterions and variability. *In situ* breeding program was developed in two phases. The first phase was forming and testing a germplasm that has been selected. The general idea was to use available Serbian wheat genetic variability, since Serbia has a well developed wheat breeding programs. The institution of the first choice was the Institute of Field and Vegetable Crops (IFVC) and its wheat varieties. IFVC is settled in the town of Novi Sad area that is about 60km from *in situ* breeding programe in the village of Kumane sharing very similar climatic and weather conditions. Moreover, IFVC Experimental field in Rimski Sancevi (RS) has a chernozem soil type that could be used as quality bases for control part of trials. Having Kumane (solonetz soil type) and the experimental polygon and RS (chernozem) as a control, the variation of abiotic environmental conditions has been diminished, except the soil type difference that was in a scope of the investigation.

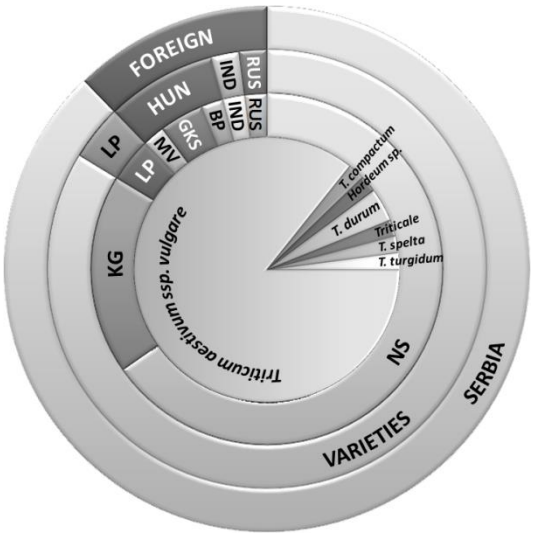

Figure 1. Genotypes in *in situ* breeding program established on solonetz soil, where all varieties were roughly classified according to the country of origin (Serbia and foreign) in the outer cycle. Secondary classification is on varieties and local populations (LP) within genotypes from Serbia and countries of origin within the group of foreign varieties Hungary (HUN), India (IND), Russia (RUS). Thirdly, the breeding institutions or origin - Novi Sad (NS), Kragujevac (KG), Local populations (LP), Martonvasar (MV), Szeged (GKS), Bred Population (BP). The inner split is accordin to taxa.

The selection criterion for the first set of wheat varieties for testing to adaptability to abiotic stress growth conditions of halomorphic soil was the overall adaptations to target environment of steps. That is the reason that 63.3% of all tested varieties (49), through years, have been originated in IFVC wheat breeding program. In a later stage of testing, 10 wheat varieties from the former Small Grains Research Center in Kragujevac were included (20.4%). Consequently, the predominant share of 87.8% represented wheat varieties from Serbia, as well as, bread wheat (*T. aestivum spp. vulgare*) up to 85.7%. The rest were local populations of wheat, barley and some other *Triticum* species. Among these occasionally tested genotypes, two are of special interest - Old Banatka, as local population obtained by instinctive selection and largely grown in Vojvodina at the beginning of XX Century, and Bankut 1205, tall old bred Hungarian variety that replaced local wheat populations in Vojvodina by the quarter of the previous century (fig. 1).

Genetic variability of genotype sample populations tested in different environments. The representative sample population was formed out of total germplasm collection that has been tested through years. The part of the trials conducted in the agro environment of the IFVCNS experimental field in Rimski Sancevi was used as a pillar of a behavior of corresponding tested sample comparison, in the part of the trial conducted i Kumane. The conditions in Rimski Sancevi could be characterized as normal, conducted on chernozem. Kumane part of the trial was conducted on solonetz soil. Having in mind geographical closeness of these two sites (about 60km), the difference in soil type could be considered as a major source of phenotypic variation. The genotype by environment interaction (GEI) was the main source of total variation particularly closer observed. Two types of GEI variation were looked for - the small GEI over all the environments, followed by acceptable yield average, as well as, higher GEI value that shows a positive reaction of the particular genotype to reclamation by phosphor gypsum. For example, the wheat variety Pobeda is a perfect example of the first selection criterion, holding a small GEI and the yield in Kumane about 48% of the yield achieved in Rimski Sancevi, with no obvious effect of reclamation. The wheat variety Renesansa exhibited quite different GEI variation, reacting to reclamation by enhancing the yield positively correlated to the level of reclamation. Varieties Simonida and NSR-5 behaved the same way, where the later one had expressed very positive reaction to reclamation. The third type was “economic variation”. That kind of reaction exhibited varieties Evropa 90 and Rapsodija, in a smaller extent. Both of them had a higher grain yield under 25t/ha phosphor gypsum reclamation treatment, than under 50t/ha. The fourth GEI interaction pattern could be described as “durable one”. Triticale variety Odisej had the best performance in a part of the experiment conducted on solonetz with no amelioration. A similar way behaved local wheat population Banatka, and old breaded variety Bankut 1205, as well as, modern variety Cipovka and facultative bread wheat Nevesinjka.

This reaction is particularly interested because is kind of unexpected. However, local population Banatka was grown in this part of Vojvodina for decades up to the WWI and could be considered as well adapted by the instinctive selection. The variety Bankut 1205 was Hungarian breaded variety that successfully replaced Banatka in the region, for a while. The variety Nevesinjka is a special facultative durable genotype, because it came from a part of breeding program that was conducted in former SFR Yugoslavia for particular requirements of national defense. The standard for that kind of variability was *Triticale* Odisej. Varieties Pobeda, Nevesinjka, Banatka 1205, local population Banatka had on characteristic incommon. They used the best their yield potential in abiotic stress conditions of solonetz with no reclamation, realizing 47-54% of the grain yield they gave in normal production conditions of even more expressive in that way (65%), fig 2.

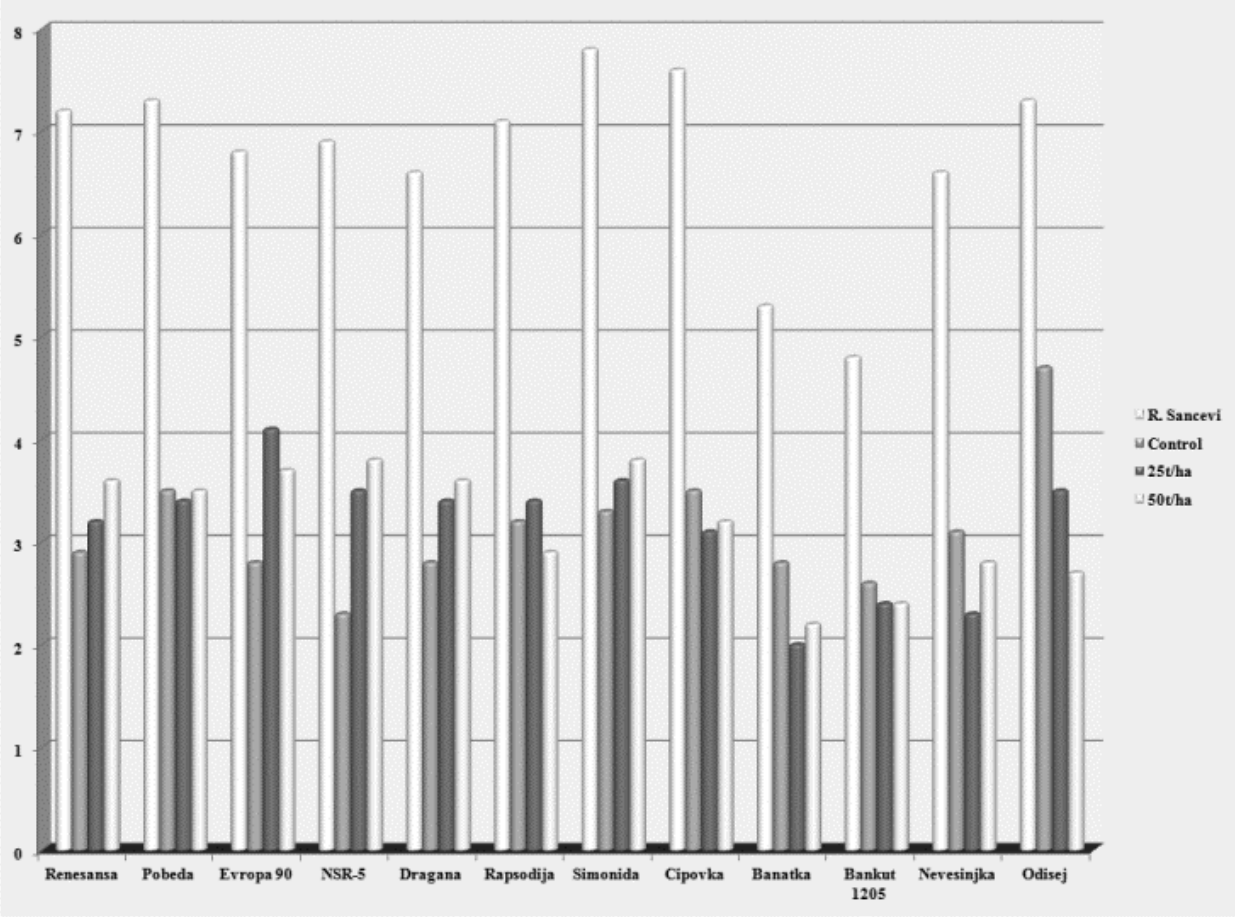

Figure 2. The grain yield (t/ha) of 12 genotypes (11 bread wheat varieties + *Triticale* Odisej) compared in 4 environments - Rimski Sancevi (chernozem soil type), and Kumane (solonetz soil type) with control and two reclamation treatments (25t/ha and 50t/ha of phosphor gypsum)

Rimski Sancevi. Triticale Odisej was

According to previously reported results, diminished soil productivity enhances cross over interaction, more over the effect of reclamation highly depends on overall agro-ecological conditions. The differences in grain yield between the control and 25t/ha of phosphor-gypsum reclamation varied from 8 to 24% depending on year and genotype tested, while grain yield on solonetz soil was between 41 and 52% comparing to the yield on chernozem (Dimitrijević, *et al*., 2009; Dimitrijević, *et al*., 2011).

The variation of the grain yield components. In order to perceive the effect of the soil type, as pure as possible, a representative sample of genotypes (11 entries out of 49) was tested on different soil types, humoglay and solonetz, at the same locality by year, to lessen abiotic

environmental factors as the variation source (Dimitrijević, *et al*., 2009; Petrović, *et al*., 2013). Humogley exhibits less favorable water-physical properties, while solonetz represents sodium reach, alkaline soils with a subsurface clay horizon. The pattern that could be observed is that length traits (plant height, and spike length) were of higher average value on humoglay that could be considered as more favorable environment concerning soil type. Mass parameters (spike weight, and grain weight per spike), on the contrary, were of higher mean values on solonetz soil type. In the same time mean values of the number of grains per spike were about at the same level. A plant puts an effort to secure embryo with nutrients in order to provide a better start to its offspring. Denčić *et al.* (2000) affirmed the view that some individual plant traits, like grain weight per spike, have a significant positive direct effect on grain yield in abiotic stress conditions.

Crosses and progenies. After multiyear varietal screening, several wheat varieties were selected as parents for crosses. The criterions of parental selection were: small GE interaction - the reaction as stable as possible, but followed by acceptable mean values of traits - grain yield components, as well as, grain yield and good reaction to soil proclamation. Wheat varieties Renesansa, Pobeda, Pesma, Sara, and Partizanka have been selected for the first set of crosses.

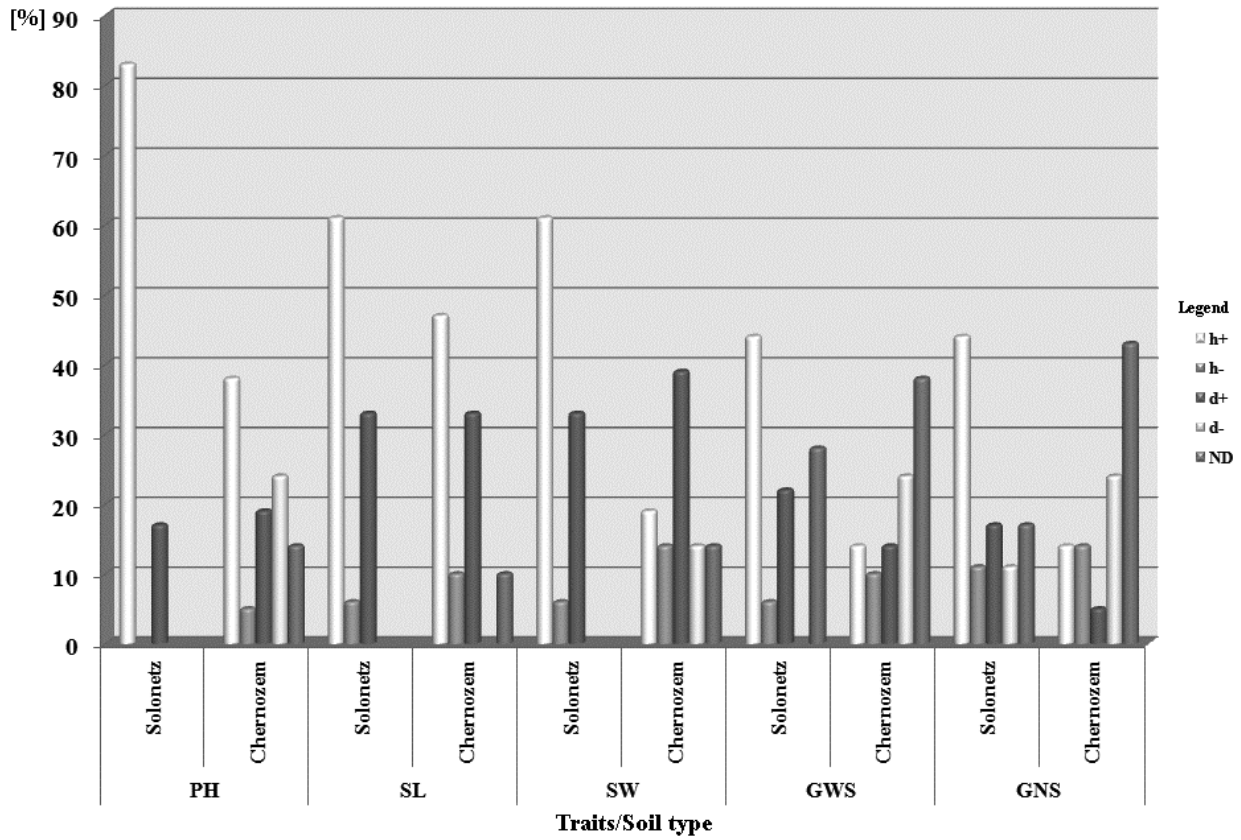

Figure 4. The mode of inheritance of five traits, the yield components, - plant height (PLH) in cm, spike length (SL) in cm, spike weight (SW) in g, grain weight per spike (GWS) in g, and grain number per spike (GNS) in F_2 progenies of 5 bread wheat varieties crosses compared in Kumane (solonetz soil type), and Rimski Sancevi (chernozem soil type)

Progenies of crosses were parallel sown on chernozem and solonetz soil, with full awareness of genetic variability in early progenies, F_2 in particular. Variability of the grain yield components, as well as, the mode of inheritance was followed. In three years period a certain pattern could be observed. The mode of inheritance in F_2 progenies grown on solonetz soil was positive heterotic effect, predominantly, for all traits that were followed (fig. 4). As

previously reported by Dimitrijevic et al. (2012, 2013), a genetic variability in F_2 for all examined traits, the yield components (plant height, spike length, spike weight, grain weight per spike, and grain number per spike), on solonetz soil, where a positive heterotic effect was denoted, was not only at the same level as on chernozem, but also of higher mean values. Having in mind that the selection criterion in early offspring could not be based on the grain yield *per se*, but on traits of individual plants, as phenotypic markers, the results of the trials are encouraging. There is a space within the existing wheat genetic variability, as well as, within newly created genetic variation to select perspective genotypes for growing in halomorphic soil conditions.

Conclusion

A discussion on advances and setbacks of *in situ* breeding programs has been going on within a breeder's community, for decades. That goes for breeding programs established in stressful growing conditions, in particular. *Ex situ* breeding for special purposes is more secured, harvest is reliable and better, however has to be combined with lab and markers, and still it's outcome is unreliable depending on a number of variation sources of multivariate nature. *In situ* breeding has its setbacks, as well. The harvest is not certain and commonly is of smaller quantity. The process is time consuming, as well, and could appear more expensive, particularly because parallel trials in normal conditions are recommendable. However, working in very conditions requires no or very limited lab assistance and MAS, since the environment is truly the same as in wide production in that environment. Plants adapt from the very beginning and their reaction is very and thru. Environmental conditions influence total genome. Genes are not isolated units. They work together, as a genome in a whole. The thru environment is, wherever is possible, better solution than MAS. MAS could follow predominantly major genes; the rest is statistical estimation of minor genes highly depending on the environment and genome interaction. Lab testing gives pure gene effects and intra genome interaction, but lacks the environment and the effect of plant population that is very important for plant breeding. According to the results of this program, a desirable and useful genetic variation could be selected effectively, using a classical plant breeder's approach.

Abstract

Sustainable crop production nowadays is assumed crucial for agriculture to survive. Not only does it mean environmentally friendly protection or renewal of agricultural-natural resources (no spent substrate, less CO_2 footprint, less water consumption), but also for growers and consumers this means producing foodstuff without chemical inputs. Whenever feasible, sustainable agriculture relies upon crop rotations, crop residues, animal manures, off-farm organic wastes, mechanical cultivation, mineral-bearing rocks, and aspects of biological pest control to maintain the soil and its tillage, to supply plant nutrients, and to control insects and weeds. In this study we evaluated possibility of combined cultivation of edible mushrooms and vegetables as a sustainable, vertical system of growing. Mushroom compost (MC) was spawned with *Agaricus subrufescens*. Overgrown mushroom compost, produced in plastic bags was released, shredded and formed in 20-30 cm high heaps in the cultivation container. Cultivation substrate – garden compost (GC) was placed between rows and on top of MC, and used instead of peat as casing. This prevents MC from drying out and is necessary for fructification as a water holding layer. Cowpea (*Vigna unguiculata)* was planted in between rows. Climbing plants formed shades for mushroom and created specific microclimate. CO_2 produced by mushrooms in respiration process is used by plants for plant tissue production.
Results of experiment show the potentiality incorporating plant (legumes) cultivation system with mushroom growing. Yield of cultivated mushrooms was similar to control, however increase in yield of beans compared to control was observed.

Keywords: *crop growing, fungi, substrate, sustainability, legumes.*

Introduction

Yearly losses of food around the world are estimated in range of 1.3 billion tones. In Europe and North America food waste is dominated by consumer waste and it range 95–115 kg of food each year, while in African and Asian areas it is 6-11 kg a year (FAO, 2011). This process influence human-generated greenhouse gas emissions (it is 6% to 10 %) (Vermeulen et al., 2012). Anaerobic digestion (AD) of organic matter generates biogas for energetic purposes and influence on decreasing of atmospheric emissions of methane (Horn et al. 1994). Zhang et al. (2007) and Bouallagui et al. (2003) indicate that food waste is a needed substrate for anaerobic digesters it is high biodegradable and increase methane production.
Biogas projects which process biological wastes are established in many countries as a policy of decreasing greenhouse production and waste management. A great deal of byproducts such as biogas slurry (BS) is produced during the process. Recycling of biogas byproducts via vegetable production can be sustainable, multi beneficial approach regarding agriculture and environment. The BS contains abundant nutrients and phyto-beneficial substances. Many authors claimed biogas slurry can be used in plant production (Alam and Chong 2010, Hasselgren 1998, Michitsch et al. 2008). In his study, Liu et al. (2009) describes approach on the utilization of BS in soilless vegetable cultivation. The commercial use of the AD byproducts is, still, little known and developed worldwide due to unstable or low yields of

vegetables. The main problems appearing when biogas byproducts are used as a component for plant nutrition is unstable composition which varies during the year (Govasmark et al. 2011). This instability can influence growth and yields of vegetable crops. It is crucial for vegetable cultivation to optimize composition of biogas byproduct if used commercially.
The choice of plants was triggered by leaf surface area and ability of the plant to be formed (i.e. climbing plants). This is due to form plants into shades for mushroom and to create specific microclimate. *Vigna unguiculata* (cowpea) is one of several species of widely cultivated genus *Vigna*, however the most important food legume crops in semiarid tropics of Asia, southern Europe, Central and South America (Singh at al. 2003). This plant is warm-weather crop; drought tolerant is well adapted to drier regions. Cowpea is shade tolerant, so is compatible as intercrop with maize, millet, sorghum, sugarcane, and cotton (Blade et al. 1997). This makes cowpeas an important component of traditional intercropping systems, especially in the complex and elegant subsistence farming systems of dry savannas in sub-Saharan Africa. In these systems the haulm (dried stalks) of cowpea is a valuable by-product, used as animal feed. According to the USDA food database, the leaves of cowpea plant have the highest percentage of calories from protein among vegetarian foods (Rangel et al. 2003, Phillips at al. 2003, Shaw 2007).
Agaricus subrufescens is a Brazilian mushroom which is popularly known as a sun mushroom widely used not only as a gourmet foods but also as medicine. The Almond mushroom is a heat loving species (23-27°C) and lower humidity requirements (75-85%), Chang (2008). The mushroom contains among others, bioactive polysaccharides and protein complexes (PSPC) which vitalize production of interferon and interleukin and is used in the cancer treatment (Nakajima et al. 2002). What is more it was also found to have beneficial activity in the treatment for AIDS, diabetes, hypotension and hepatitis (Mizuno 2002, Endo et al. 2010, Oliveira Lima et al. 2011). The growing interest in cultivation of this species and its requirements suiting with the cowpea was triggering the choice for our experiment.
The conducted experiment was performed in the scope of Food to Waste to Food (F2W2F) project focused on closing "loop" in biogas and food production. Soap bubbles isolated greenhouse was build, which differ from traditional greenhouse both in better energy savings and in recycling CO_2 from biogas production. Additionally digestate, liquid-like wastes after anaerobic digestion in biogas production was used for plant and mushroom cultivation. Many authors indicated on difficulties with proper yielding and environmental safety in food production combined with digestate. Yet, in most of our experiments yields were comparable with control treatments (mineral fertilizers), we focused on local recycling and safety both for human health and environment.
The following experiment was a preliminary trial of possible incorporation of combined cultivation system of mushroom and plants. The aim of research was to show the prospect of horizontal cultivation structure for future implementation in ecological design and cultivation.

Materials and Methods

Mushroom compost preparation
Compost substrates (wheat straw, shredded paper, chicken manure) were gained from local sources (farm areas near Drammen, Norway). Straw and chicken manure were derived from local farms, shredded office paper – collected from offices in the neighborhood area (local businesses – City of Drammen). The digestate from anaerobic digestion (AD) of source separated household food waste was separated using a decanter centrifuge. The resulting digestate solid was added to *phase I* substrate, and further prepared according to commercial *Agaricus* production.
First substrate components were mixed according to substrates dry matter (DM): straw – 18%, paper 36%, chicken manure – 3%; gypsum 3% and digestate – 40%. Later substrate was

composted in rotating composter drums. After few days compost loses volume due to heat generation and was mixed and moved to insulated containers with controlled flow of air through the substrate (to obtain similar conditions as in commercial bulk systems; 70-80ºC and 6-9% O_2 v/v). The substrate was turned (reloaded) subsequently again twice at an interval of 2 days, giving total of 10 days for *phase I*. The compost was loaded into a miniature *phase II* tunnel for pasteurisation. The temperature was gradually increased to 60ºC through 24 hours and maintained for 6 hours of pasteurisation, then decreased to 55ºC, for another 6 hours and subsequently to 50ºC where it was maintained for conditioning until ammonia (NH_3 gas) had dissipated (below 10 ppm).

Substrate incubation

Polypropylene 50 micron, autoclavable plastic bags (capacity of 7 liters, flat size 38 cm wide x 57 cm high), with four linear ventilation filters were applied were filled with approximately 3 kg of composted, pasteurized compost and left for cooling to room temperature (approx. 22ºC). Substrate was inoculated with granular spawn of *Agaricus subrufescens* (Mycelia BVG) on wheat grain as amount of 3% of fresh substrate weight. The bags were sealed with adhesive tape and shaken by hand until the spawn appeared evenly distributed. The spawning was performed in stable controlled conditions, at 25ºC.
Overgrown mushroom compost (MC), was released, shredded but not too much and formed in little heaps in cultivation container (number of rows depends on the container). The heaps were 20-30 cm high (for mycelium to easily grow and prevent compost from drying out). In between the rows proper cultivation substrate, here garden compost (GC) was placed. Garden compost was also placed on the top of MC, and used instead of peat as a casing. This prevents MC from drying out and was necessary for mushroom fructification as a water holding layer.

Combined cultivation design

Cultivation container was aluminum table sized 100x100 cm. MC were formed in 2 rows. The cowpea plants (*Vigna unguiculata)* were planted in 3 rows in between MC rows. The plants were grown in such way to shade mushrooms and also to allow easy harvesting of legume. The air humidity for fruit body development was held at 85-95%. The CO_2 produced by mushrooms was used by plants and converted to O_2. Cultivation room was aired not to allow CO_2 concentration to exceed 1000 ppm (higher CO_2 levels inhibit mushroom primordia formation). Water was applied by individual dripping system which was placed on top of mushroom heap, watering both mushrooms and plants. Later in cultivation vermicompost, for nutrition addition, was applied on the top of mushroom heap. The dripping water was making a leakage and nutrition was washed out to plants. Mushrooms appeared on the top and also can appear on the sides of heap, 2-3 weeks beginning of cultivation (after mycelium recovered and fully overgrown casing soil). Temperature during this period (esp. inside the MC heap should remain between 22-25ºC). The mushroom harvest was led until the end of cultivation period of legume plants 8-10 weeks. The legumes were collected gradually when ripe.
Experiment have been performed in 3 replications of spring-summer season 2013, cultivation time was 8-10 weeks in greenhouse conditions. Daytime temperature was maintained on 21-25°C, decreased in nighttime to 17-19°C.
When comparing the experimental results, the analysis of variance for one factorial experiments was applied (ANOVA, level of significance α=0.05).

Results and discussion

In following experiment we examined possibility of combined cultivation of legume plant – *Vigna unguiculata* and mushroom – *Agaricus subrufescens*. The trial shows yield of both examined objects depended on cultivation system. Yield of almond mushroom, *A. subrufescens* was slightly higher in the control trial; however statistical difference between combinations was insignificant. In the contrary, there was great difference of yield of cowpea – *V. unguiculata.* The legume plant yielded significantly higher in the combined cultivation system than in the control cultivation system (Fig.1-2).

Average yield of *A. subrufescens* from control trial was 84 g/kg^{-1} of substrate, and in combined cultivation design showed 62 g/kg^{-1}. This corresponds with research of other scientists on almond mushroom. Eira et al. (2005) and Llarena-Hernandez et al (2013) report yield of *A. subrufescens* to reach 80-200 g/kg^{-1} fresh substrate. The average yield of cowpea is reported to reach 1.8-3.0 kg/m^2. In our experiment yield was much lower than reported in literature; however it was significantly increased in combined cultivation system (Blade et al. 1997, Phillips et al. 2003, Rangel et al. 2003, Singh et al. 2003). In literature there are several research describing combined cultivation of different mushroom-plant systems (not mentioning omnipresent mycorrhiza dependence between higher plants and mushrooms). *Stropharia rugoso-annulata* is grown together with maize – 20% of yield increase, while combination of *Hypsizygus ulmarius* and Brussel sprouts because 25% of yield increase (Wang et al. 1984, Dallon 1987, Levanon and Danai 1995, Maher et al. 2000, Mullen and McMahon 2001, Williams et al. 2001, Prabu et al. 2014). Mushroom hyphae wrap around roots and increase water and minerals availability for plants – which lead to higher biomass production – higher yields. In the other hand, mushroom compost is nutrient rich product, highly assimilable by plants. Yield increase in cowpea can be explained by high nitrogen content ($1m^3$ of MC contain same amount of N present in cow manure). MC contain also around 20% of calcium carbonate, therefore regardless of pH has great potential for substrate deacidification (Niżewski et at. 2006). Lower mushroom yield could be caused to rich casing material (vermicompost), critical moment in *A. subrufescens* production, which might inhibit fruiting bodies development (Zied et al.2012).

This trial experiment show the potential of vertical cultivation in terms of CO_2 production/disposal as well as waste treatment and limited space needed for cultivation. However further investigation should be performed in order to evaluate more possibilities of plant-mushroom combination.

Conclusions

Combined cultivation of plant (legumes) and mushroom was possible. Yield of cultivated mushrooms was similar to control. Yield of cowpea was higher compared to control.

PEACH CUTIVARS RESEARCH AND BREEDING IN NIKITA BOTANICAL GARDEN

Anatoliy SMYKOV*, Olga FEDOROVA, Tatyana SHISHOVA, Juliia IVASHCHENKO

Nikita Botanical Garden - Federal Research Center of RAS, Yalta, Russian Federation
*Corresponding author: fruit_culture@mail.ru

Abstract

Peach breeding was focused on obtaining cultivars with high commercial properties, enhanced adaptability to frosts, drought and fungus diseases. Gene fund is the basis for breeding. Peach collection on the southern coast of Crimea, owned by Nikita Botanical Garden, includes 483 cultivars, 103 elite hybrid forms and above 2000 hybrid seedlings. Gene fund has been formed by means of introduction and inclusion of cultivars and forms from own breeding. Gene fund is systematized on grounds of belonging to certain ecogeographycal groups and ecotypes, among them were recognized carriers of economical valuable features and was showed efficiency of their selection amid diverse cogeographycal groups for use in the breeding. Evaluation of selected varieties and their comparison with the cultivar model based on cluster analysis allowed to determine the degree of similarity between them after a complex of characteristics. Together with intraspecific (direct, reciprocal and back-crossing as also inbreeding) was effected distant (interspecific, intergeneric) hybridization, without and with treatment of pollen by mutagens. Clone selection of somatic mutations was effected without and with treatment of vegetative buds and seeds by mutagens. As a result of cultivars research and breeding were selected 28 new peach cultivars, afterwards included into Plant Varieties Register of Russia and Ukraine.

Keywords: *gene fund, ecogeographycal groups, ecotypes, hybridization, cultivars*.

Introduction

Common Peach (*Persica vulgaris* Mill.) is one of the most important stone fruit crops cultivated in Southern Russia. In the Republic of Crimea it occupies an area of 2.63 thousand ha, which amounts to 25.2% of the total area of fruit crops. The peach is notable for excellent commercial properties of fruits, a bride range of ripening terms and is in great demand in the market. But the existing assortment of this culture includes too little early maturing cultivars, especially with yellow flesh, and late ripening terms. It is necessary to increase the resistance of cultivars to adverse abiotic and biotic factors of the environment and improve the commercial properties of fruits.

At present, the most significant is the classification of Ryabov I.N. (1953), based on botanical and geographical peach groups. Within the peach *Persica vulgaris* Mill. selected two kinds of varieties: with pink flowers - P. vulgaris var. Rosaeflorae Riab. and bell flowers P. vulgaris var. Campanulaeflorae Riab. Among varieties with bell-flowered dominated the middle and late ripening, and about equally there were varieties with white and yellow colored flesh. They belong to the Iranian eco-geographical group of varieties. Among the varieties with pink flowers were many early ripening samples. Varieties of early, middle and late ripening are distributed in roughly equal proportions with white colored flesh forms. They belong to the North Chinese eco-geographical group of varieties.

The main base for breeding is the gene fund of fruit crops, used by NBG, is formed by cultivars and forms, wich were introduced from various natural regions of the CIS, Europe and America, and by self-bred forms and varieties (Plugatar, 2016; Ryabov, 1969; Smykov,

2001; Smykov, 2008; Smykov, 2015;Hesse, 1981;Infante et al.,2008;Ogundiwinet al., 2009;Sansavini, 2006).
In this regard, the aim of research was to develop theoretical foundations for improving the techniques used in peach varieties research and breeding as a basis for optimization of the breeding process and the development of new cultivars for commercial horticulture in Crimea and southern Russia.

Materials and Methods

The material of the research was a peach gene fund, represented by 483 cultivars, bred and introduced by Nikita Botanical Gardens and by 103 elite forms, as well as more than 2 thousand hybrid seedlings. Research were carried out for 2000 - 2015 years. For a comprehensive assessment of varieties the gene fund was systematized by eco-geographical groups and ecotypes with the definition of the incidence of economically important traits in each group and ecotype. The research on the gene pool and on the breeding process was carried out according to the techniques by NBG (Smykov and Lishchuk, 1999), the "Programme and technique for research on varieties of fruit, small-fruit and nut crops" (Sedov, 1995), "Programme and technique for breeding of fruit, small-fruit and nut crops" (Sedov and Ogoltsova, 1999).

Results and Discussion

The breeding was based on the scheme developed and used by us. Gene fund has been formed by means of introduction and inclusion of self-bred cultivars and forms. Together with intraspecific (direct, reciprocal and back-crossing as also inbreeding) was effected distant (interspecific, intergeneric) hybridization, with and without dust treatment with mutagens (Sedov and Ogoltsova, 1999). Embryos from the seeds of early maturing maternal varieties were grown up by the in vitro culture (Department of Biotechnology).
Clone selection of somatic mutations was performed without and with treatment of vegetative buds and seeds by mutagens. To stimulate development in the in vitro culture, the immature embryos were irradiated at small doses (Smykov and Lishchuk, 1999).
The obtained hybrid seedlings and clones were studied on the complex of economically valuable traits in greenhouses and breeding garden during a several of years after the fruiting. Selected elite forms were grafted into rootstock and planted in amount of 5-10 plants in the collection garden for a comprehensive assessment according to the technique of primary research, involving specialists from other departments (biotechnology, biochemistry, phytopathology, agroecology and athers.) (Sedov, 1995).
The forms, with better economical valuable features than used cultivars have been passed in State service of varieties test, and then were passed to the firms for production testing. Last stages of the breeding process are the patenting entry in the Russian Register of Breeding Achievements and conclusion of license agreements with nurseries for industrial reproduction of new cultivars.
Accomplished researched allowed to identify diverse eco-geographical groups, ecotypes and cultivars with high intensity of blossom (the North-Chinese ecogeographycal group, the European ecotype of North-Chinese group, 16 cultivars), with late blossom (North-Chinese group, the European ecotype of the North-Chinese group, 17 cultivars), with long-lasting blossom, (the Iranian group, the American ecotype of the Iranian group, 22 cultivars), with early bearing age (the Iranian group, the European ecotype of the Iranian group, 60 cultivars), high-yielding (North-Chinese group, Transcaucasian ecotype of the Iranian group, 14 cultivars), early ripening (Iran group, the American ecotype of the Iranian group, 60 cultivars), late ripening (North-Chinese group, Transcaucasian ecotype North-Chinese group, 6 cultivars), with high commercial properties (Iranian group, the European ecotype of the

Iranian group, 111 cultivars), with high adaptability to frost (North- Chinese group , European ecotype Northern-group, 14 cultivars), to drought (Iranian group, the Central Asian ecotype of North-Chinese group, 32 cultivars), to leaf curl (*Tarphina deformans*Tul.) (North-Chinese group, the Central Asian ecotype of the North-Chinese group, 4 cultivars), to powdery mildew (*Sphaerotheca pannosa* Lev. var. *persica*Woronich) (North-Chinese group, Chinese ecotype of the North- Chinese group, 10 cultivars).

In our investigations we used the developed by us cultivar model criteria, based on 35 features: a tree with a moderate growth of 1.8-2.0 m, narrow revertive-pyramidal compact shape of the top, early productivity (starting from the second year after planting), a long deep rest period (over 100 days), a late blossom (more than 50 days after the start of the growing season), plenty blossom (5 points), long-lasting blossom (over 18 days), high-yielding (above 50 kg per tree and 10 kg per 1 $м^2$ of the top projection), a high productivity factor of leaf apparatus (CPWL above 3.0), high resistance to frost: flower buds damaging do not exceed 10 per cent (1 point), a very low susceptibility to leaf curl (0.5 points), to powdery mildew (0.1 points), high drought tolerance (5.0 points), the duration of the yielding period over 20 years.

Average fruit weight amounts to 120 - 150 g, round in shape, fruit have a poor pubescence, yellow, melting or non-melting, dens flesh, carmine-dark-red surface colouring, which covers 100 percent of the fruit surface, a little (less than 4 g) stone, free stone, have an excellent appearance and taste, have universal using, high content of biologically valuable substances: dry substance (above 20 percent), sugars amount (above 12 percent), ascorbic acid (> 10 mg/100 g), leucoanthocyanins (above 120 mgt/100 g), flavons (above 24 mg/100 g), pectic substances (above 1.2 percent), carotin (above 1.6 mg/100 g).

For comparing the top 25 cultivars of peach, selected from the collection, by means of cultivar model based on 15 main features, we have used the cluster analysis technique (see table.). This technique allowed us to determine the degree of similarity between these cultivars and the cultivar model based on Euclidean distance. All objects are grouped into a classification tree, which is reflected in a dendrogram (figure 1).

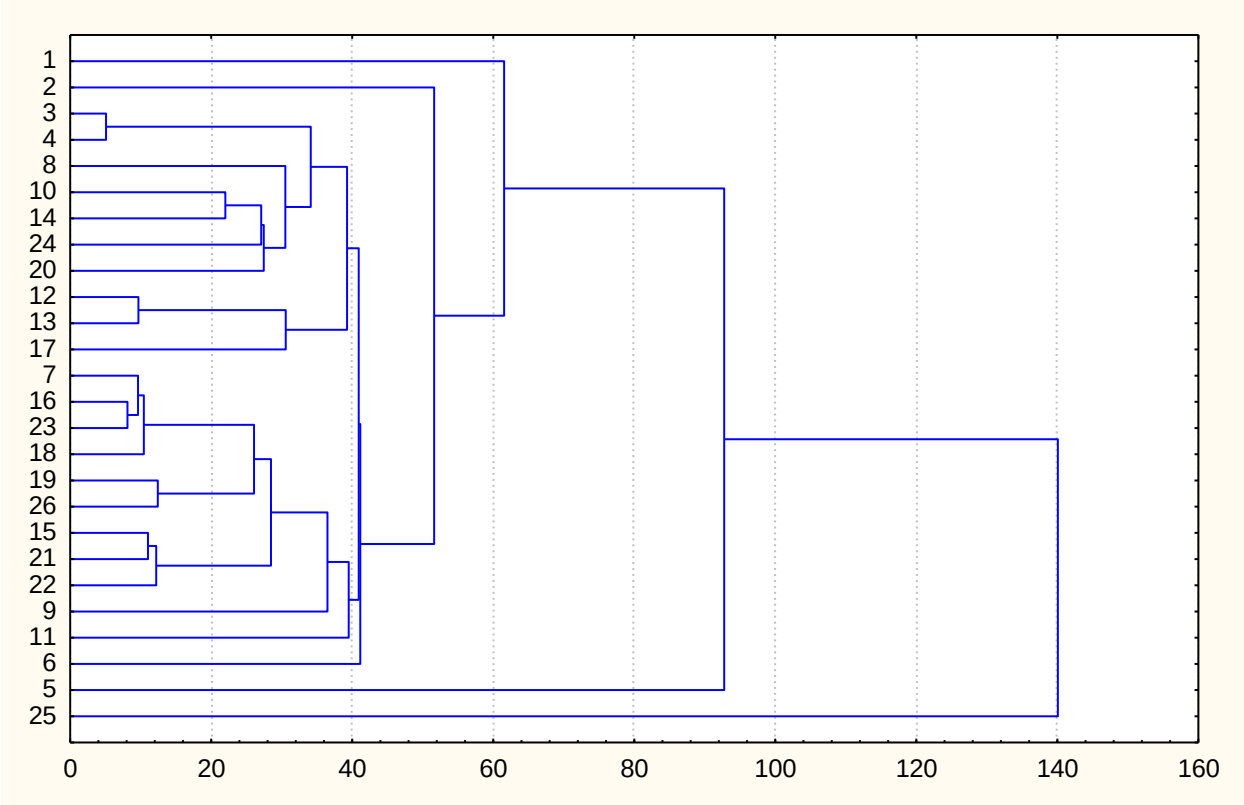

Figure 1. Cluster analysis of similarity between peach cultivars and cultivar model:

1. Cultivar Model, 2 Gagarinskiy, 3. Gartvis-72, 4. German Titov,
5. GorniyTsvetok, 6. DruzhbaNarodov, 7. Kodru, 8.KrasaKavkaza,
9. Kremlyovskiy, 10. Lebedev, 11.Muza, 12.Pamyat Simirenko, 13.Tyulpan,
14. Baby Gold-6, 15. Conharmony, 16.Early Coronet, 17.Early Red, 18. Elvira,
19. Golden, 20. Harbell, 21. Harken, 22. Monroe, 23.Redcap, 24.Redhaven, 5.Rihven, 26. Sun Beam

According to the similarity of the features and their values the cultivars, united in clusters (groups), are close: 1. Gartvis 72 и German Titov; 2. Lebedev, Baby Gold-6, Redhaven, Harbell; 3. PamyatSimirenko, Tyulpan; 4. Kodru, Early Coronet, Redcap, Elvira; 5. Golden, Sun Beam; 6. Conharmony, Harken, Monroe.

According to the complex of features as the most close to model (62 units of Euclidean distance) were marked eight cultivars: Gagarinskiy (51 units), Druzhba Narodov (42 units), Muza (39 units), Kremlyovskiy (37 units), Krasa Kavkaza (35 units), Early Red (30 units), Harbell (28 units), Redhaven (27 units).

To determine the interdependence between economically-valuable signs based on evaluation of 110 cultivars we perfomed a correlation analysis on 15 indicators and detected varying degree of their interrelation.

The highest correlation coefficient was observed between fruit quality - appearance (0.9) and the taste (0.83); ripening term - weight (0.5) and the percentage of surface colouring (-0.6); period and duration of blossom (-0.66); appearance and taste of fruits (0,55), and others.

Breeding was focused on developing new cultivars with low susceptibility to powdery mildew and leaf curl, with early and late ripening terms, high commercial properties and enhanced resistance to frost. The total namber of crossing combinations was 380.

Most combinations with a high percentage of seed formation was observed in crosses on the earliness with the participation of the middle ripening parent cultivars.
The most high-self-fertile and self-fertile cultivars belonged to the Iranian ecological-geographic group, and the American ecotype. In the high-self-fertile group were marked 13 cultivars , among self-fertile samples - 18 cultivars.
Hybridologycal analysis allowed to detect cultivars and forms - donors of qualitative signs: 14 donors of round shape, 19 - non-melting flesh, 3 - of white flesh colouring, 11 - of tender flesh density, 2 -free stone, as well as quantitative signs: 2 donors of early ripening, 4 - of medium terms, 7 - of the medium and large fruit , 8 - of a better colouing, 5 - of good taste of fruits, 9 - of high yields, 10 - of low susceptibility to leaf curl, 3 - of low susceptibility to powdery mildew, 2 - comprehensive donors of low susceptibility to diseases.
Through investigation seedlings from gene fund on fruits quality we selected 47 forms (the most of them (68,8 per cent) were obtained by crossing of cultivars belonging to different eco-geographical groups and ecotypes), with high productivity - 32, low susceptibility to leaf curl - 36, to powdery mildew - 38.
In the course of research was evaluated radiosensibility and the fertility of gamma-irradiated pollen of 23 peach cultivars, used in breeding programs.
Thereby were detected optimal doses and plants variation range after exposure of seeds to gamma-radiation in combination with growth substances «Fumar», IBA and by treatment of vegetative buds with chemical mutagens EI, NEU, NMU in combination with gamma radiation and these growth substances.
By means of radiation mutagenesis were detected 49 promising forms that were evaluated on a range of economically valuable signs.
Among them 13 radioforms were marked by frost resistance, 11 - by drought resistance, and 8 forms with high content of biologically valuable substances in fruits.
In the course of research have been studied the specifics of differential chromosome colouring in gamma-irradiated peach forms of cultivar Sovetskiy (figure 2).

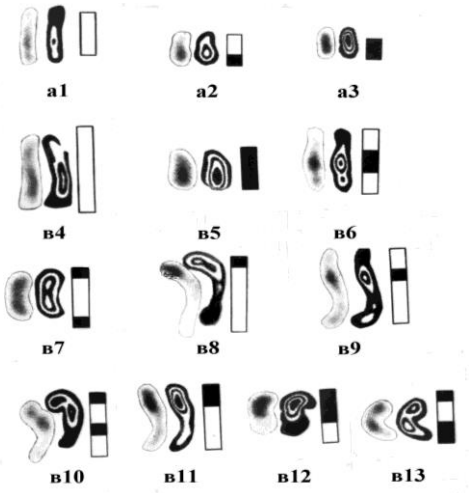

Figure 2.The classification of types of peach chromosomes at the stage of cell division prophase-prometaphase.

In variants with radiation, especially at a dose of 50 Gy, were marked differences in the ratio of hetero- and euchromatin blocks, changing area, the total optical density of the cell nucleus, the appearance of cells with micronuclei, bridges and polyploid set of chromosomes (Table).

Table. Abnormalities in the mitotic division of somatic cells in the irradiated peach.

Cultivar	Variant of radiation Gy	The number of studied cells	Area core		The total optical core density		Amo-unt of micro -cores	Amo-unt of cells with briges	Amo-unt of polyp -loid cells
			Pixel^2	V, %	sumg-rey	V, %			
Barkhatistiy (control)	0	100	2515.9	20.4	10.7	18.4	0	2	1
Barkhatistiy	50	96	2402.8	22.2	9.5	19.7	4	7	2

Kudesnik	50	112	5262.7*	32.5	26.8*	19.0	6	7	4

Significant differences with control at P = 0.95 for the core area and the total optical density

Based on the study of the gene fund, the selection of the source cultivars and forms for hybridization, evaluation of breeding material, we selected 28 new peach cultivars: Sonata Tavridy, Ulublenniy, PamyatnyiNikitskiy, Pontiyskiy, Granatoviy, Podarok Like, Strelets, Soprano, KrymskiyShedevr, Rodzinka, Karnavalniy, Lakomiy, Naryadniy, Nikitskiy, Otlichnik, NikitskiyPodarok, Dostoyniy, Kloun, Temisovskiy, KrymskiyDiamant, YuzhnayaGarmoniya, RumyanyiNikitskiy, Merkuriy, Serdolik, Ozhidaniye, KrymskiySonet, PivdennaFantasiya, Etyudniy, Persey, which have been included into Russian Register of Breeding Achievements (Division Republic of Crimea). Some of these cultivars are shown in figure 3.

Cultivar Pontiyskiy

Cultivar Pivdenna Fantasiya

Cultivar Yuzhnaya Garmoniya

Cultivar Rodzinka

Figure 3. Promising cultivars of peach.

Conclusions

Thus, the comprehensive study of the peach gene fund on the basis of dividing cultivars into according eco-geographical groups and ecotypes, determining their frequency of occurrence of valuable signs, the criteria of cultivar model, correlation interdependence between signs, selection of sources and donors of economically valuable properties, including them in crossing combinations on the principle of distant origin, application of radiation and chemical mutagenesis allowed to optimize the breeding process and to make it more effective. On this basis we obtained 28 new peach cultivars, which were included into Russian Register of Breeding Achievements.

Abstract

Rosemary (*Rosmarinus officinalis L.)* is an evergreen plant endemic and typical of the Mediterranean region. Rosemary has long been considered an important plant for its essential oil used vastly in the perfume and medicine industry. The plant has been reported to possess several medicinal properties. The first-year of a rosemary (*Rosmarinus officinalis L.)* crop's growth and productivity as affected by irrigation and N fertilization was investigated under field conditions in central Greece. In April 2015, winter cuttings of a native rosemary cultivar were transplanted to an experimental field installed in Nea Aghialos, Magnesia, central Greece. The experimental design was a 2^3 factorial split plot design with three drip irrigation levels (0, 50, and 100% of potential evapotranspiration) comprising the main plots, and three nitrogen dressings (0, 50, 100, kg N ha^{-1}) comprising the subplots in four replications (blocks). The growth and final productivity of the crop was measured in four destructive samplings of the crop during the summer 2015. The results demonstrated the paramount effects of both irrigation and nitrogen fertilization on thyme productivity and final yield already in the first year of crop establishment.

Keywords: *rosemary, irrigation, nitrogen, fertilization, evapotranspiration*

Introduction

Rosemary (Rosmarinus officinalis L.) is an evergreen woody aromatic herb with a characteristic aroma and lavender-like leaves. The plant is native to the Mediterranean region where it grows abundantly. Rosemary is cultivated on a large scale in Spain, Italy, France, Algeria, and Portugal for its essential oil. Morocco, one of the world's leading producers of rosemary oil, is second only to Spain and Tunisia in terms of volume of production (Bolens 1985). The leaves of rosemary are also used for culinary purpose and are reported to possess antioxidant properties. Rosemary is also used in food products.

Water availability plays an important role in plant growth and productivity (Singh and Goswamy, 2000). Deficit irrigation, one of the environmental stresses, is the most significant factor restricting plant growth and crop productivity in the majority of agricultural fields of the world (Abedi and Pakniyat, 2010). Field experiments on water requirements of rosemary in Egypt revealed that irrigation once every 14 days resulted in high herbage and oil yield (Kandeel, 2001). It was demonstrated that irrigation once a week is sufficient (Farooqui and Sreeramulu, 2001). Identifying growth stages of a particular cultivar under local conditions of climate and soil fertility allows irrigation scheduling to maximize crop yield and most efficient use of scarce water resources (Puttanna et al, 2010; Mahal and Sidhu, 2006).

Besides irrigation, Nitrogen fertilization is very important affecting leaf area index and dry herb yield of rosemary plants as shown in previous studies (Singh, 2013; Singh and Wasnik, 2013). Studies conducted in Italy (Sardinia) on fertilizer dose and weed management revealed that applying 80 kg N ha^{-1} coupled with hand weeding of the major weeds increased herbage yield and oil (Milia *et al*., 1996). Fertigation with water-soluble fertilizers (80% WSF)

coupled with micronutrients were reported to increase growth, yield and quality traits of rosemary (Vasundhara *et al*., 2002).
The objective of the present work is to determine the growth and productivity of rosemary under field conditions during the first year of establishment under optimum and sub-optimum irrigation and N-fertilization inputs in a typical Mediterranean site, e.g. central Greece.

Materials and methods

Crop establishment
The experiment was set up in the rural area of Nea Aghialos in Central Greece (39°16'02.3"N 22°47'47.5"E) on May 5, 2015. The soil of the experimental plots was a sandy loam one with a pH of 6.8 and an organic carbon (C) of 1.5 g kg^{-1}. Rosemary cuttings (43 days old) were obtained from a local nursery. The soil was prepared and divided into plots; each of them was 4,2 m χ 2,4 m and contained three drip rows. The cuttings were transplanted on May 5. Distance between plants and distance between rows were both 60 cm. Nitrogen was applied in three levels: N0, N50 and N100 (0, 50 and 100 kg ha^{-1} respectively) in the form of a urea fertilizer on June 9 of 2015. Thirty-six plots containing a total of 648 plants were arranged in a split plot design with irrigation being the main factor and nitrogen fertilization the factor split into sub-plots. Each experimental unit consisted of three rows of plants, 0.6 m apart, with the two outer rows serving as buffers while plants were spaced at 60 cm apart.
Irrigation
The amount of irrigation water was equal to 0% (rainfed – 110 mm), 50% (281 mm) and 100% (562 mm) of the recorded evaporation values of a class-A pan. The irrigation water was applied by drip irrigation system and the irrigation interval was seven days. Surface drip irrigation system consists of an irrigation pump connected to sand and screen filter and a hydraulic fertilizer injection pump was used. The actual water discharge rate was 8 L h^{-1} along the drip lines. Weed control was carried out via application of a polyethylene transpiring mulch as this material has demonstrated a 100% efficiency in weed control among other tested mulches according to Hoeberechts et al (2004).
Harvesting and Drying
Two plants per plot were harvested on three dates in the experimental season, all aerial parts of the plants were cut 5 cm above ground and the following growth parameters were determined: plant height, fresh weight of leaves/plant and fresh weight of stem/plant. LAI was measured via destructive methods using a calliper. The same parameters were determined after drying plant material in dark storage rooms on specially designed shelves. This method of drying was chosen as it is the method most commercial growers in Greece actually use. The results of the final harvest (28/08/2016) are demonstrated in this paper.
Statistical analysis
All recorded values of this experiment were statistically analyzed using analysis of variance through the Genstat Program. Means were compared using revised L.S.D. test at 0.05 levels.

Results and discussion

Irrigation effect on plant growth parameters including LAI, plant height and dry leaf weight
Irrigation had a significant effect on dry leaf weight. The I3 treatment gave higher dry leaf yields in all nitrogen treatments (0.50, 0.77, 1.21 t ha^{-1} for nitrogen treatments N0, N50 and N100 respectively) compared to lower volume of irrigation as it is apparent in Figure 3.
The same significant effect appeared in LAI measurements and the means were 0.3, 0.51 and 0.84 for nitrogen treatments N0, N50 and N100 respectively (Figure 1). Irrigation had no significant effect on plant height, although plant height trended to higher values as water volume increased (Figure 2).
.

Nitrogen effect on plant growth parameters including LAI, plant height and dry leaf weight

Nitrogen had a highly significant effect on dry leaf weight (F_{prob}<0.001). The N100 treatment gave higher dry leaf yields in all irrigation treatments (0.84, 0.93, 1.21 t ha^{-1} for irrigation treatments I1, I2 and I3 respectively) compared to lower levels of nitrogen per hectare as it is apparent in Figure 3. The same highly significant effect was witnessed in LAI measurements and the means were 0.64, 0.67 and 0.84 for irrigation treatments I1, I2 and I3 respectively (Figure 1). Nitrogen fertilization had no significant effect on plant height, although plant height trended to higher values as nitrogen per hectare increased (Figure 2).

The LSD test demonstrated that the I3N100 combination differed than the rest regarding LAI while treatment combinations I1N100, I2N100 and I3N100 were different than the rest when it came to dry leaf yield (t ha^{-1}).

Figure 3. Leaf area index (LAI) of plants, primarily grouped by irrigation level and secondly by nitrogen level.

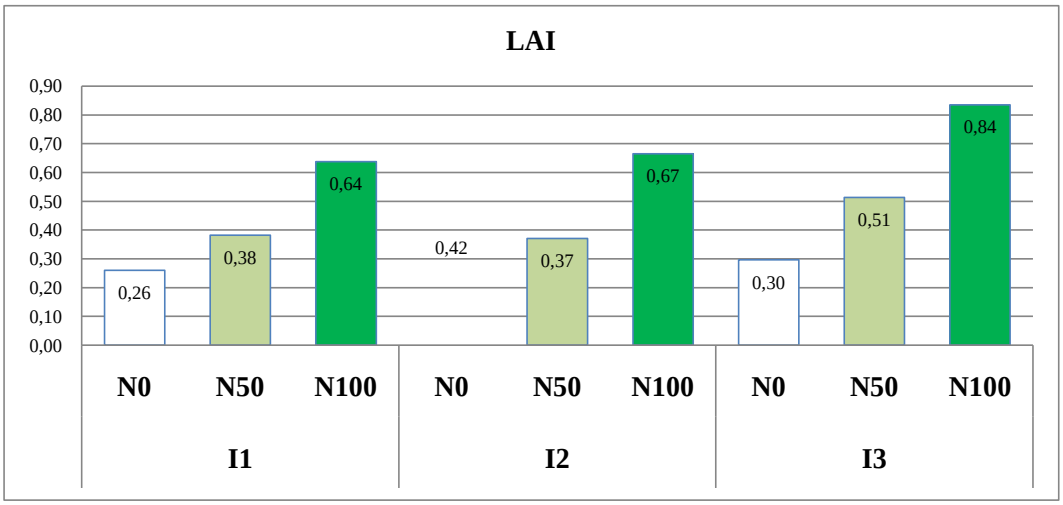

Figure 4. Plant height (cm) of plants, primarily grouped by irrigation level and secondly by nitrogen levels.

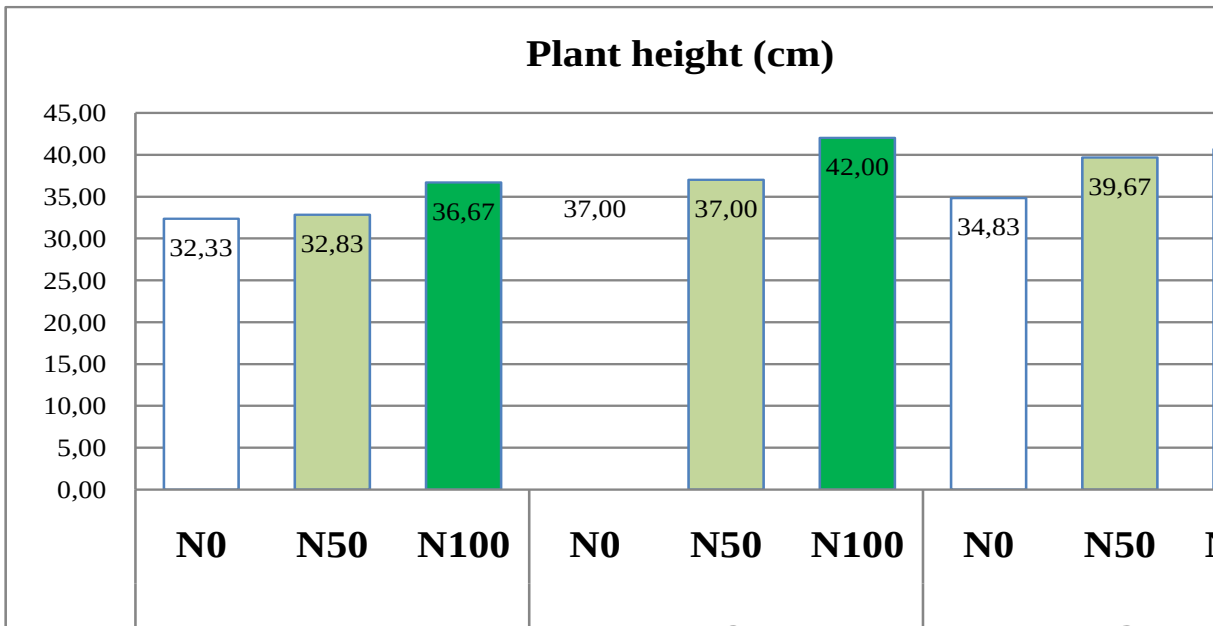

Figure 5. Dry leaf yield (t ha^{-1}) of plants, primarily grouped by irrigation level and secondly by nitrogen level.

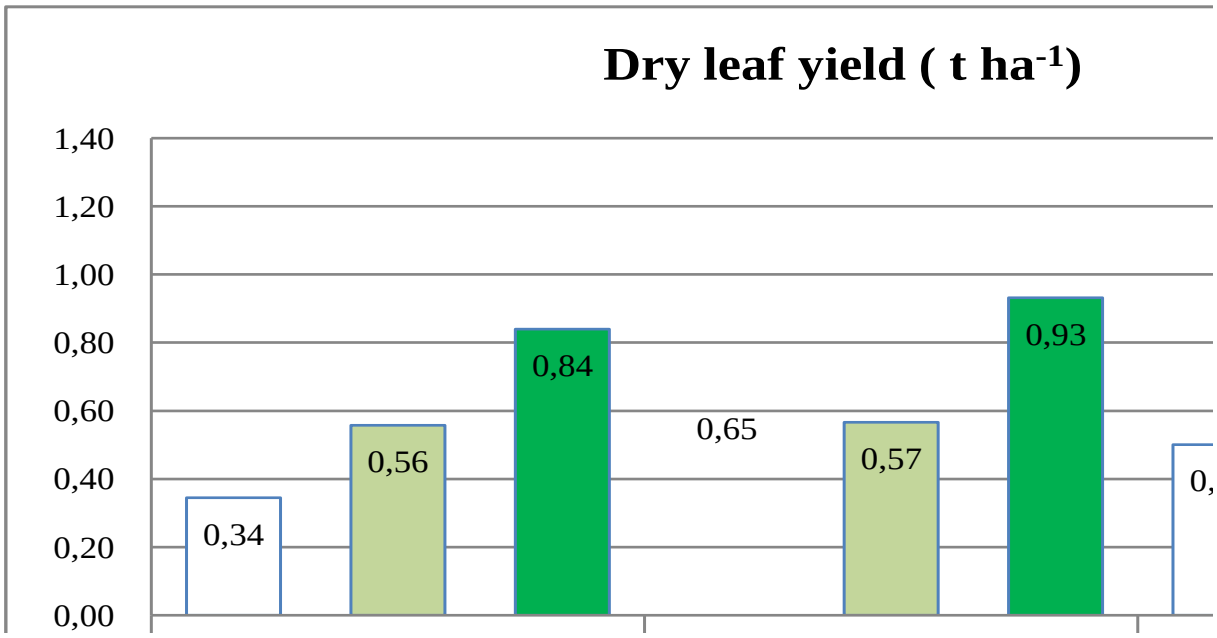

Table 2. Means of vegetative growth data of rosemary as affected by different water regimes and nitrogen fertilization level at the end of the experimental season.

Irrigation level	Nitrogen level	Plant height (cm)	LAI (Leaf Area Index)	Dry leaf yield (t Ha^{-1})
0%	N0	32,33a	0,26a	0,360a
	N50	32,83a	0,38b,c	0,557a
	N100	36,67a	0,63e	0,840b,c
50%	N0	37a	0,41c	0,654b
	N50	37a	0,37b,c	0,5670a
	N100	42a	0,66e	1,01c
100%	N0	34,83a	0,29a,b,c	0,501a
	N50	39,67a	0,51d	0,773b
	N100	40,67a	0,83f	1,21c

Means followed by different letters were significantly different according to revised L.S.D. test at 0.05 level.

Conclusion

During the first year of the crop's establishment, irrigation and nitrogen's paramount effects were demonstrated. Future experiments for consecutive growing seasons and in different soil types are recommended in order to assess the prospects of rosemary cultivation in Greece and the possible financial interest of the crop. As water becomes scarce in the Mediterranean and nitrogen fertilization is always a cost for producers, these inputs should be carefully calculated in terms of sustainability and cost efficiency. As soil erosion continues to be a problem in Greece (Kosmas et al, 2001), perennial crops like rosemary make suitable candidates for the eradication of the problem.

PRESENT AND FUTURE EFFECTS OF CO_2 ON VARIOUS FIELD CROPS: A GENERAL EVALUATION

Hakan ULUKAN*

[1]Department of Field Crops, University of Ankara, Faculty of Agriculture, Ankara, Turkey
*Corresponding author: ulukan@ankara.edu.tr

Abstract

It was generally examined and been informed the present and future effects of carbon dioxide (CO_2) on field crops which were grown on the earth as morphologically, physiologically, agriculturally, etc. in this poster presentation. As known, agricultural sector is very sensitive to the global warming effects on field crops. Almost in each country, agriculture is the second or first largest direct or indirect contributor for the global warming. Especially, this phenomenon contributes to unwanted effect(s) through the emission of carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), chlorofluorocarbons (CFCs), etc. Especially, from them CH_4 has the highest global warming potential that is about 300 times than the potential of CO_2, and about 20 times than that of the N_2O. It was found that the average temperature of the Earth would be rise up to (1.4–5.8 ^{0}C) by the 2100, and some agricultural practices (poly, mono and mixed cropping) and ecosystems (such as agro-forestry, agro-silvo-pastoral systems, landscape, aquaculture, rangelands, wetlands, fallows, etc.) will be affect at different levels. It was verified by the satellite images, increasing in the CO_2 concentration (Its level in March 2016 is 404.83 ppm) will make accelerate plant growth, increase of water use efficiency (WUE) and physiological/metabolic activity (ies), reduce the grain filling period, nutrient efficiency, incubation and flowering periods. The purpose of this paper is to give some important, valuable and practical information(s) on the present and future effects of carbon dioxide (CO_2) on various field crops.

Keywords: *Global Warming, CO_2, Field Crops, Water Use Efficiency.*

Introduction

Increase in the CO_2 concentrations will be profound effects on the various field crops growth and productivity (Reddy et al. 2010). It is expected to reach 550 ppm by 2050 according to IPCC, and a 75 % increase from 315 ppm measures in 1960 (Tausz et al. 2013), however and its (present) level is 407.40 ppm in 11 June 2016 (Anonymous, 2015a, 2015b).

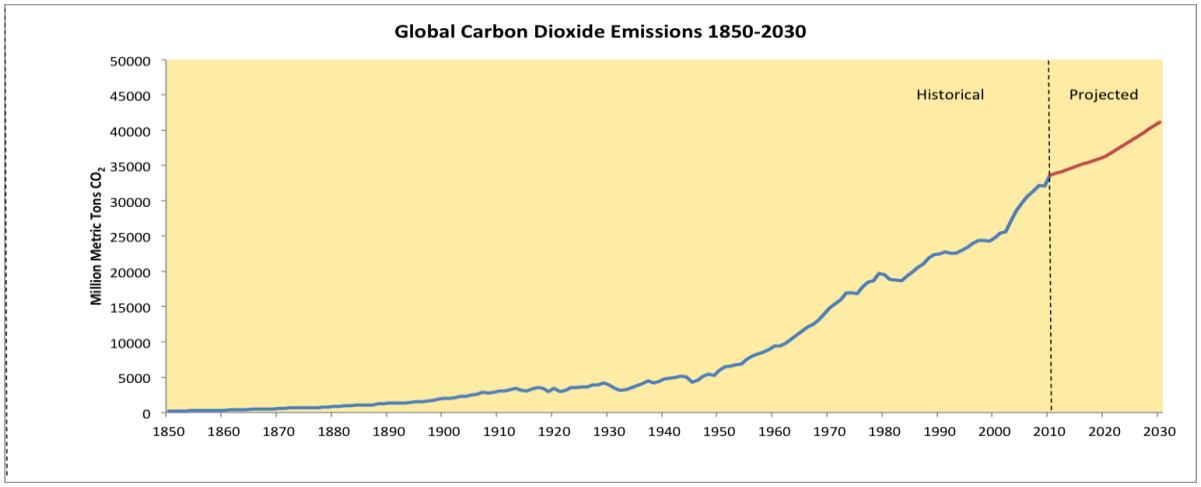

Figure 1. Global CO_2 emissions trend between 1850 and 2030 years (Anonymous, 2015c)

Plants are grouped into (3) classes as C_3 (e.g. wheat (*Triticum* ssp.), rice (*Oryza* ssp.), soybean (*Glycine* ssp.), potato (*Solanum* ssp.)), C_4 (maize (*Zea mays* L.), sorghum, sugarcane (*Saccharum* ssp.), trees, grain legumes, rice, potato, vegetables, millet, soybean) and CAM (e.g. pineapple (*Ananas comosus* (L.) Merr., Papaya (*Carica papaya* L.) according to their stable carbon isotopes' number at the end of photosynthesis. With the C_3 photosynthetic pathway, they often exhibit greater growth response relative to those with a C_4 (Prior et al. 2013). So, their reaction(s) differ from each other to the elevated CO_2. The C_3 plants under the elevated CO_2 have indicated photosynthetic acclimation, which might be due to soil and nutrient limitation associated with reduced root volume, some showed also significant increases in light-saturated rates of photosynthesis in the several C_3 plants. They have a lower water usage efficiency (*the WUE*) compared with the other C_4 field crops (Fuhrer, 2009). Under the elevated CO_2, it is exclusively assimilated and enhances growth 33% to 40% in the C_3 plants, but 10% to 15% increase in the C_4 plants (Tausz et al. 2013). The CAM and the C_4 plants use a series of enzymes that initially combine of the CO_2 (DaMatta et al. 2009), (*Crassulacean Acid Metabolism*) plants. They (The CAM plants) are inherently high in *the WUE*, due to their ability to open their stomata at night to take into the CO_2 (Ulukan, 2008).

Material and methods

Increasing in the CO_2 concentration can have a positive impact/s on yield by stimulating their photosynthesis and reducing of water losing via respiration. Since, this kind of the CO_2 acceleration role on yield level (*CO_2 fertilization*) is a strong effect esp. in the grain legumes and the C_3 plants (Zhai and Zhuang, 2009), but the *WUE* decreases when the CO_2 concentration increases (Dhakhawa and Campbell, 1998). The C_4 plants had higher *the WUE* than the C_3 plants due to their convertibility *of the WUEs'* for the photosynthetic components in the plants and it is (nearly) two times higher than that of the C_3's (Zhengbin et al. 2011). Studies showed that the CO_2 concentration increasing would have dramatic effects/results on the growth and development of various field crops (Romanova, 2005) in present, in future for *the WUE* esp. in the pulse crops (legumes) (Cutforth et al. 2007)). Studies have showed that the sensitivity of C_3 photosynthesis to temperature declines as plants become limited by the CO_2, much like the patterns exhibited by the C_4 plants (Ward et al. 2009). Gas accelerates the photosynthesis and its concentration is increasing, the productivity of C_3 plants do not drop (generally) in contrast increase by 36% (Uzmen, 2007), compared with 35-80% in the grain legumes (Ziska et al. 2001). Similarly, according to satellite imaginaries there will be shift for the harvest and threshing dates between five days and three weeks (Cutforth et al. 2007).

Results and Discussion

The future (elevated) CO_2 effect/s on various field crops will be/can be mentioned generally as follow(s) (Anonymous, 2010): *i*) Due to level of the CO_2 extreme meteorological events such as droughts, floods, hurricane, etc. will be/can be happen; *ii*) Because of them, crop production or agricultural production etc. will be/can be affected negatively; *iii*) Quality and quantity of the products, and its price will be/can be also negatively affected; *iv*) hungry, diseases, water scarcely, forest fire(s), etc. will be/can be burst at different level; *v*) phenological changes/lateness up to 4 or more weeks can be emerged in root ad tuber crops; *vi*) morphological deformations/disorders will be/can be seen on esp. roots (e.g. sugar beet) as discoloration and photosynthesis area losing; *vii*) With the interaction other meteorological, andropogenic and ecological parameters all possible hazards will be/can be arisen.

Table 1. Effect of elevated CO_2 to various field crops agronomical, botanical traits (Modified and adapted from
Krupa, 1997; Peet and 1997; Dhakhawa and Campbell, 1998; Tubiello and Ewert, 2002).

Trait	Elevated CO_2
Photosynthesis	Increase in the C_3 up to 100%; less happens or not in the C_4
Inhibition of photosynthesis by source-sink imbalance	*Response occurs in many species.*
Leaf Area and conductance	Decrease in the C_3 and the C_4 but the C_4 responds more
Leaf photosynthetic rates	*Increase in all plants on first exposure, the C_3 respond more than the C_4, little responses above 1000 ppm, and levels above 2000 ppm may be toxic.*
Leaf Anatomical and Biochemical Adaptation	Leaf area, weight per unit area, thickness, and number of mesophyll cell layers in many species
Leaf Thickness	*Increase*
Canopy Leaf Area	Usually increases
Branching, Flowering and Fruiting	*Initiation and/or retention of these organs is increased in many species*
Maturity	Increase happens early
Flowering	*There is a big difference in the C_3 and the C_4*
Fruit and seed	Increases in number and/or size fruits and seeds
Dry Matter Prod. & Yield	*Doubled (almost) in the C_3 but it is unclear in the C_4* *Increases 32% on average between 300 and 600 ppm for plants in favorable conditions.*
WUE	Increase in the C_3 and the C_4 more in the C_3
Species and Cultivars	*Different*
Susceptibility	Different
Susc. to Drought Stress	*Different*

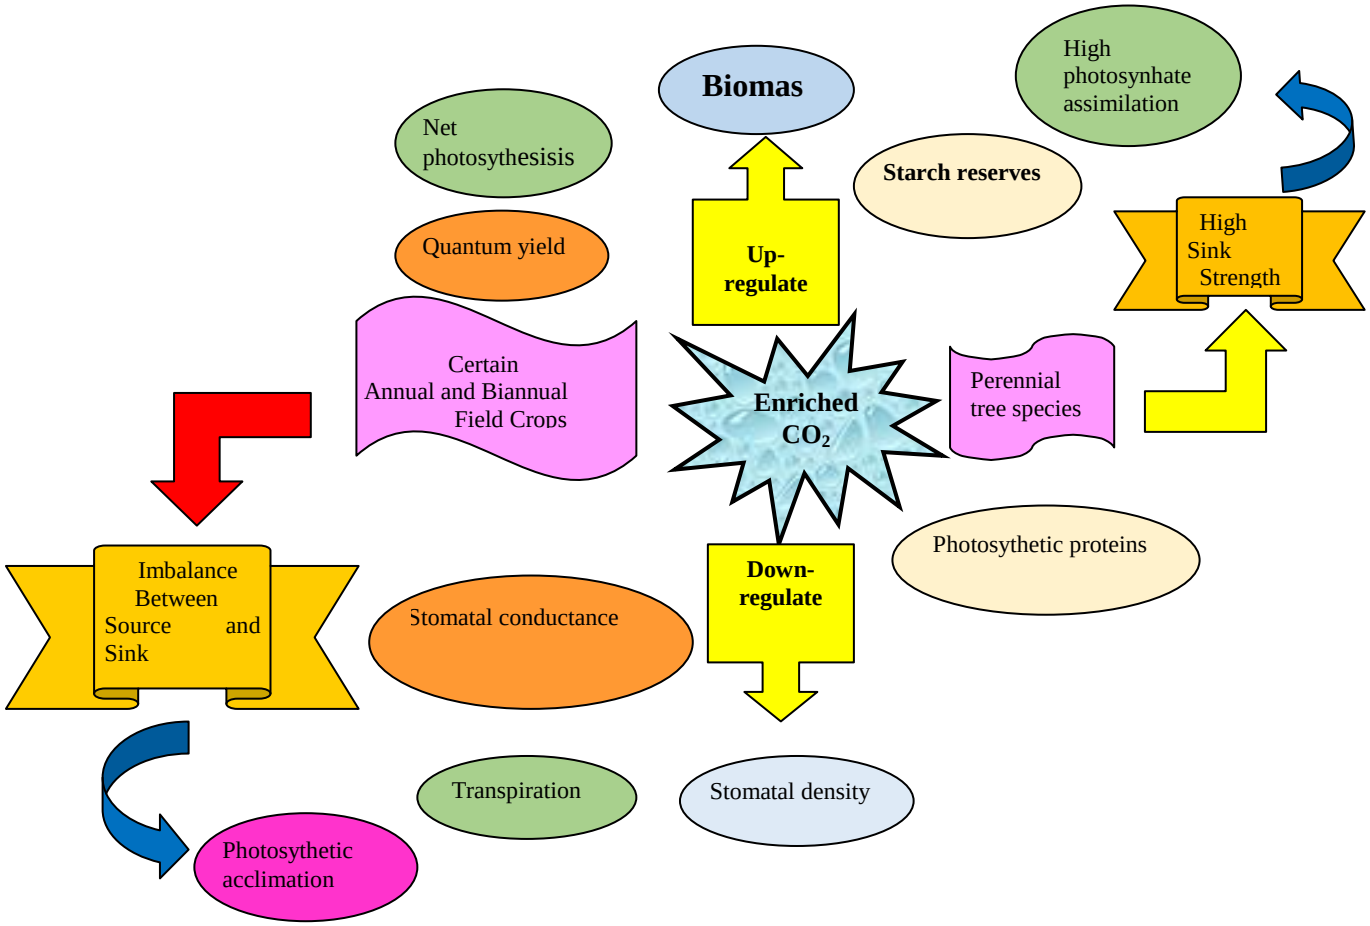

Figure 2. Schematic (biochemical) representation of the effects of elevated CO_2 on the various field crops' at biochemical level (Reddy et al. 2010).

High concentrations of CO_2 produces some morphological effects on growth such as increasing in the rate of photosynthesis, and in branching of both woody and herbaceous plants, greater stem elongation, in root/shoot (Peet and Krizek, 1997). For instances, it was seen elevated increasing the tuber formation in potatoes (*Solanum tuberosum* L.), recorded that stomatal conductivity trait is clearly reduce in corn (*Zea mays* L.) and bean (*Vicia faba* L.), but not in sunflower (*Helianthus annuus* L.).

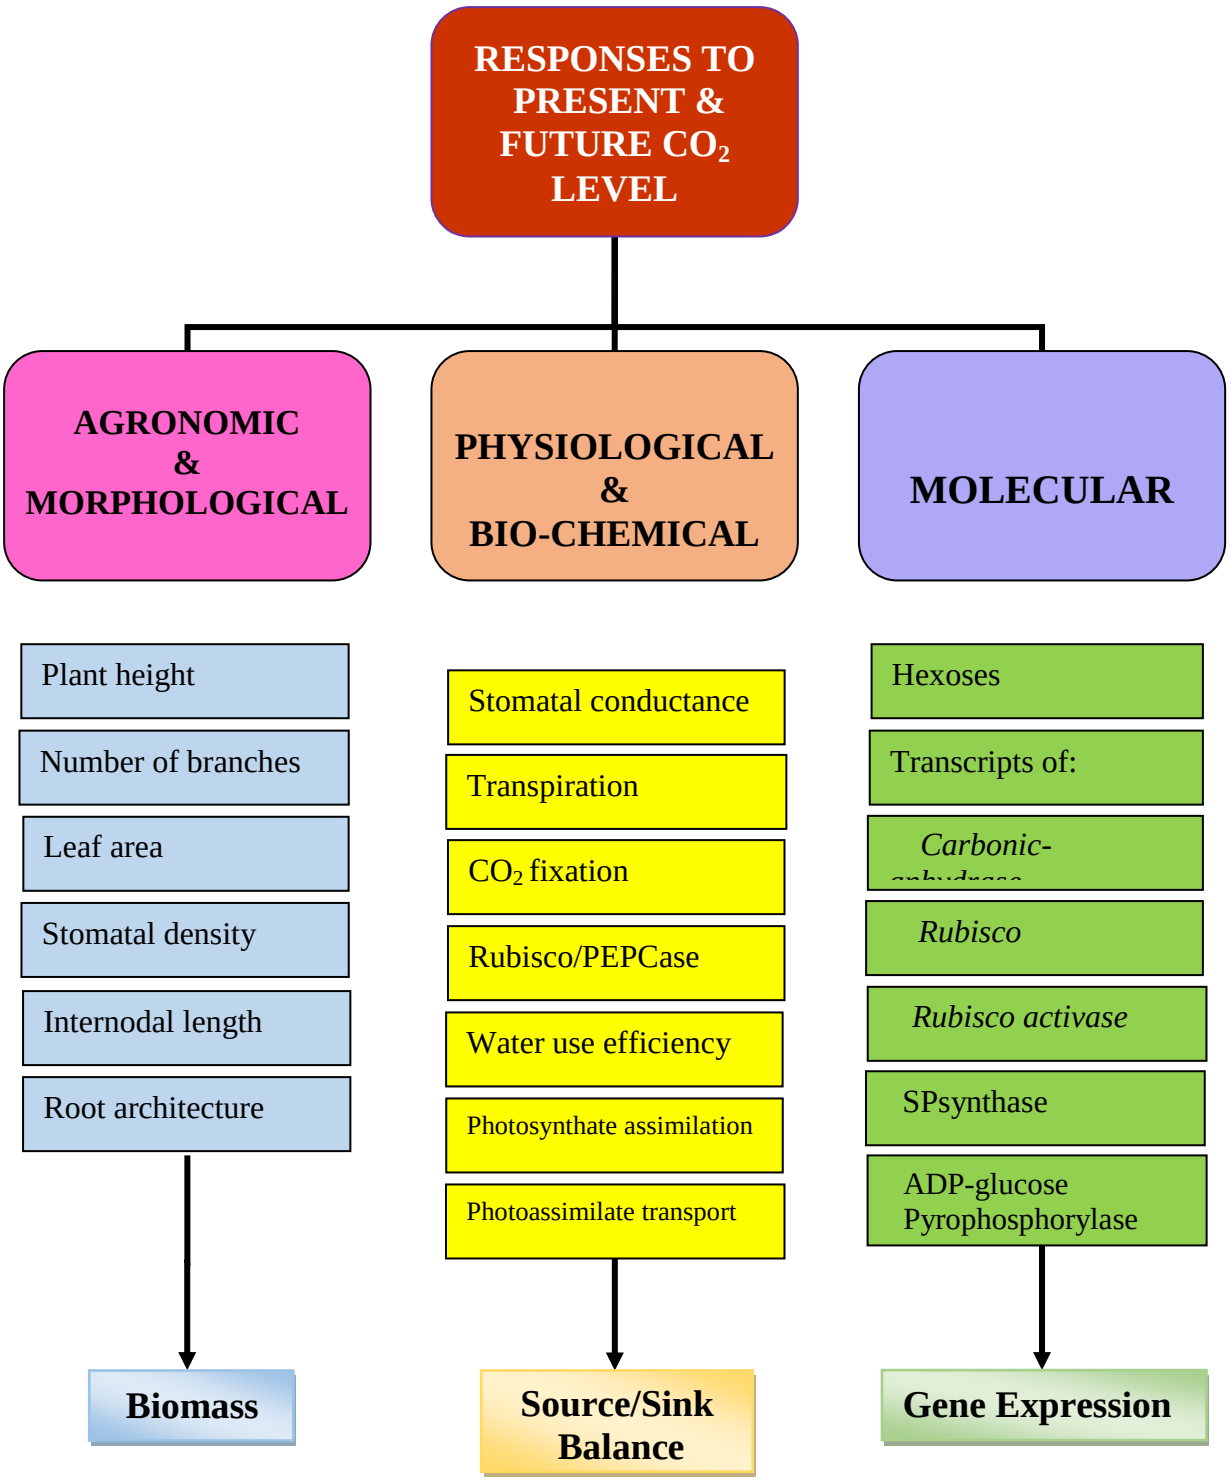

Figure 3. Agronomic & Morphological, Physiological & Bio-Chemical and Molecular Responses of the various field crops' at the present & future CO_2 level (Adapted from Reddy et al. 2010).

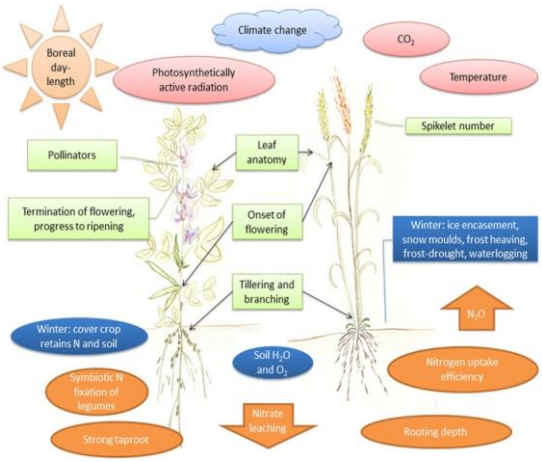

Figure 4. CO_2 effect of various field crops yield and yield components as a biological solutions cycle (Adapted from Frederick et al. 2011)

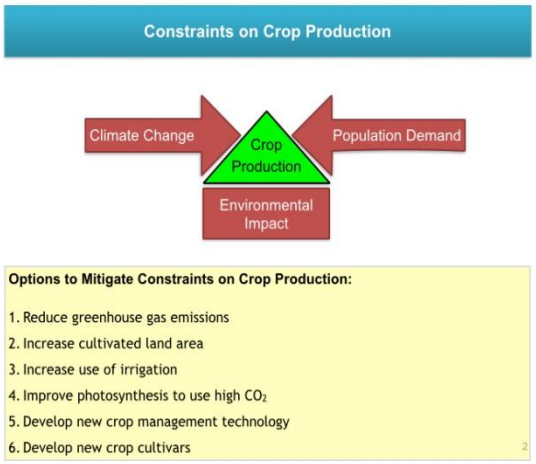

Figure 5. CO_2 effect to crop production and possible (From Anonymous, 2015d)

Conclusion

Elevated CO_2's, level of its increasing, present effects are getting sensed itself by various signs by anybody and in the future, it will be very sharp according to level of the elevated CO_2. In terms of the elevated CO_2 effect to the various field crops', due to belonging to the C_3, C_4 or CAM, responses will be different. But in any case, not only solely but also with other climatic factors such as (mainly) temperature, precipitation, *the WUE*, etc. morphologically, plant height (and yield (dry matter) components esp. such as number of branches, leaf area, stomatal density, roots (fibrous) some differences are seen. Especially these formations are very clear in industrial crops. Physiologically and biochemically changes are majority linked with the microscopic structure of the leaf that called "*stomata*". Esp. stomatal density, environmental temperature and hormonal/enzyme equilibrium (For ABA, Rubisco, etc.) is a very crucial. Additionally, molecular changes (gene expression) involved; but, details are not known clearly as today.

GROWTH AND PRODUCTIVITY OF LEMON VERBENA (*Aloysia triphylla* L.) AS AFFECTED BY NITROGEN FERTILIZATION IN CENTRAL GREECE: FIRST YEAR (ESTABLISHMENT) RESULTS

Konstantinos MARTINOS*, Elpiniki SKOUFOGIANNI, Nicholas G. DANALATOS

Laboratory of Agronomy and Applied Crop Physiology, Department of Agriculture, Crop Production and Rural Environment, University of Thessaly, Volos, Greece
*Corresponding author: kmartinos@agr.uth.gr

Abstract

Lemon verbena is an aromatic perennial shrub that is valued for its medicinal use as a digestive aid, antimicrobial, antispasmodic, analgesic, diuretic herb and it is also used as a treatment for cold, insomnia and anxiety. The first-year of a lemon verbena (*Aloysia triphylla* L.) crop's growth and productivity as affected by irrigation was investigated under field conditions in central Greece. During the spring of 2015, winter cuttings of lemon verbena were transplanted to an experimental field set up in Nea Aghialos, Magnesia, central Greece. The experimental design was a completely randomized design with three nitrogen dressings (0, 50, 100, kg N ha^{-1}) in four replications. The growth and final productivity of the crop was measured in three destructive samplings of the crop during the summer of 2015. The results demonstrated that nitrogen fertilization played a significant role on lemon verbena productivity and the final yield of the crop in the first year of crop establishment.

Keywords: *lemon verbena, fertilization, growth, nitrogen, evapotranspiration.*

Introduction

Lemon verbena, (syn.: Aloysia citriodora A. citrodora Palau, A. triphylla, Lippia citriodora L. triphylla) is an evergreen perennial aromatic plant. It likes warm moist conditions with plenty of sunlight. When exposed to frost, it becomes deciduous. belongs to the Verbenaceae family. The genus Lippia (Verbenaceae) brings together about 200 species and lemon verbena is native in Latin America as well as North Africa (Morocco), and was introduced to Europe during the 17th century (Carnat et al., 1999; Botta, 1979; Rotman and Mulgura Romero, 1999). Lemon verbena is an aromatic perennial shrub that is valued for its medicinal use (as a tea or tincture) as a digestive aid, antimicrobial, antispasmodic, analgesic, diuretic plant; besides, it is used as a treatment for cold, insomnia and anxiety (Botta, 1979; Carnat et al., 1999; Rotman and Mulgura Romero, 1999). Antioxidant and antibacterial qualities of Aloysia citriodora have been found in its essential oil, tea and tincture (Bilia et al., 2008; Cowan, 1999; Pereira and Meireles, 2007; Ohno et al., 2003; Sartoratto et al., 2004). This aromatic plant has a widespread market in the western world (Di Leo Lira, et al.,2013), its compounds have widespread uses in foods, cosmetics and household products (Catalan and Lampasona, 2002; Santos-Gomes et al., 2005). The essential oil contained in the plant and its leaves are used in the perfume industry and the production of flavored beverages and food preparations (Pascual et al., 2001). In the United States, lemon verbena is listed in Generally Regarded As Safe (GRAS) for human consumption in alcoholic beverages (Gomes et al 2006). Whereas very low researches have been applied on enhancement of medicinal plants production, presenting the appropriate planting methods is very important for increasing the quantity and quality of medicinal plants (Farooqi and Sreeramulu, 2001). The purpose of trading production of medicinal plants is obtaining further amount of biomass in area (Nematian at al., 2014). In view of the commercial value of lemon verbena, and considering that plants can display significant genetic biodiversity and variations due to differences in soil or climatic

conditions of their habitat (Molina et al.,2003), it is very important that these factors are studied and somehow controlled to ensure better yields.
The purpose of this study was to evaluate the effect of nitrogen fertilization on the growth parameters of a lemon verbena crop.

Materials and methods

Crop establishment

The experiment was set up in the rural area of Nea Aghialos in Central Greece (39°16'02.3"N 22°47'47.5"E) on May 5, 2015. The soil of the experimental plots was a sandy loam one with a pH of 6.8 and an organic carbon (C) of 1.5 g kg^{-1}. Lemon verbena cuttings (40 days old) were obtained from a local nursery. The soil was prepared and divided into plots; each of them was 4,2 m χ 2,4 m and contained three drip rows. The cuttings were transplanted on May 5. Distance between plants and distance between rows were both 60 cm. Twelve plots containing a total of 216 plants were arranged in a completely randomized design with irrigation being the main factor and nitrogen fertilization the factor split into sub-plots. Each experimental unit consisted of three rows of plants, 0.6 m apart, with the two outer rows serving as buffers while plants were spaced at 60 cm apart.

Fertilization

Nitrogen dressings were manually applied in three levels: N0, N50 and N100 (0, 50 and 100 kg ha^{-1} respectively) in the form of a urea fertilizer on June 9 of 2015.

Irrigation

The amount of irrigation water was equal to 100% (562 mm) of the recorded evaporation values of a class-A pan. Another 110mm of rain fell during the months of the experiment. Irrigation water was applied by drip irrigation system and the irrigation interval was seven days. Surface drip irrigation system consists of an irrigation pump connected to sand and screen filter and a hydraulic fertilizer injection pump was used. The actual water discharge rate was 8 L h^{-1} along the drip lines. Weed control was carried out via application of a polyethylene transpiring mulch as this material has demonstrated a 100% efficiency in weed control among other tested mulches according to Hoeberechts et al (2004).

Harvesting and Drying

Harvests (destructive samplings) were carried on transplant – May 5, June 29, July 29 and finally August 28. Two plants per plot were harvested and all aerial parts of the plants were cut 10 cm above ground and the following growth parameters were determined: plant height, fresh weight of leaves/plant and fresh weight of stem/plant. LAI was measured via destructive methods using a calliper. The same parameters were determined after drying plant material in dark storage rooms on specially designed shelves. This method of drying was chosen as it is the method most commercial growers in Greece actually use. The results of the three final harvests are demonstrated in this paper.

Statistical analysis

All recorded values of this experiment were statistically analyzed using analysis of variance through the Genstat Program. Means were compared using revised L.S.D. test at 0.05 levels. The first harvest was not subjected to analysis of variance because the date nitrogen application was too close to the harvest.

Results and discussion

During the second harvest (29/07/2015) LAI, dry leaf yield (t ha^{-1}) and dry stem yield (t ha^{-1}) were significantly affected by nitrogen fertilization level. LAI means were 0.85, 1.38 and 1.60 for treatments N0, N50 and N100 respectively. Dry stem yield means were 0.86, 0.98 and 2.27 t ha^{-1} for treatments N0, N50 and N100 respectively while dry leaf yield means were

0.76, 1.18 and 1.63 t ha^{-1} for treatments N0, N50 and N100 respectively. During the third and final harvest (28/08/2015) nitrogen fertilization significantly increased LAI and dry leaf yield (Figure 1, 2). LAI means were 1.13, 1.47, 2.08 and dry leaf yields were 1.16, 1.34 and 1.80 t ha^{-1} for treatments N0, N50 and N100 respectively. Plant height remained unaffected by nitrogen fertilization during the experiment. The LSD test showed that dry leaf yields of treatment N100 differed greatly than the rest during the final harvest (Table 1).

Figure 1. LAI (leaf area index) means grouped by nitrogen level fertilization level during the experiment.

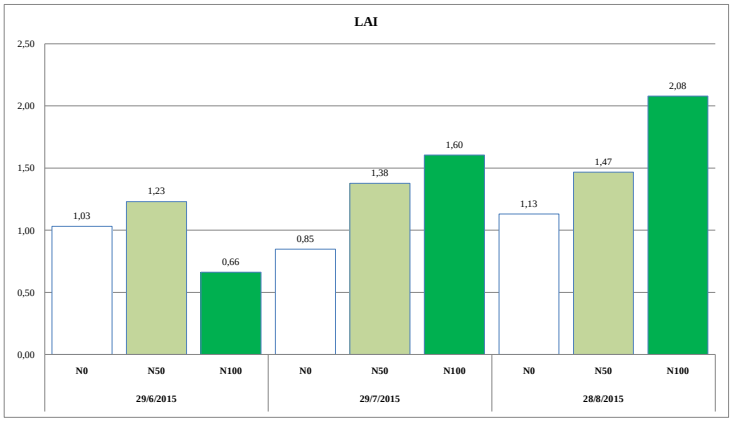

Figure 2. Dry leaf yield (t ha^{-1}) means grouped by nitrogen fertilization level during the experiment.

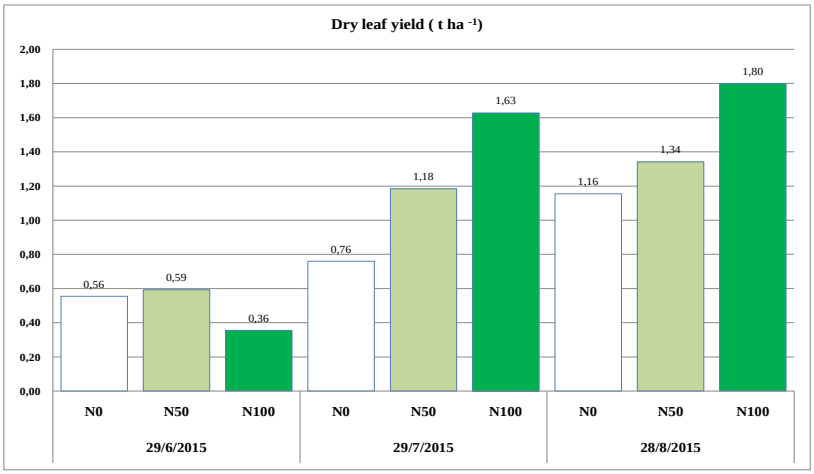

Table 1. Means of vegetative growth data of lemon verbena as affected by different nitrogen fertilization regimes and nitrogen during the experimental season.

Harvest date	Nitrogen treatment	Plant height (m)	LAI	Dry stem yield (t ha^{-1})	Dry leaf yield (t ha^{-1})
29/06/2015	N0	0,71	1,03	0,31	0,56
	N50	0,68	1,23	0,29	0,59
	N100	0,51	0,66	0,17	0,36
29/07/2015	N0	0,94a	0,85a	0,86a	0,76a
	N50	1,01a	1,38b	0,98a	1,18a
	N100	1,04a	1,60b	2,27b	1,63b
28/08/2015	N0	1,17a	1,13a	1,44a	1,16a
	N50	1,06a	1,47b	1,83a	1,34b
	N100	1,21a	2,08c	2,40a	1,80c

Means followed by different letters were significantly different according to revised L.S.D. test at 0.05 level.

Conclusion

During the first year of the crop's establishment nitrogen's paramount effects were demonstrated. Future experiments for consecutive growing seasons and in different soil types are recommended in order to assess the prospects of lemon verbena cultivation in Greece and the possible financial interest of the crop. As nitrogen pollution of underground water reserves has been prominent in the past years in Greece, this crop shows potential as it can prove lucrative with little nitrogen inputs when compared to other traditional crops of central Greece. Finally, soil erosion continues to be a problem in Greece (Kosmas et al, 2001), making perennial crops like lemon verbena a suitable candidate for the eradication of the problem.

GROWING TRITICALE BIOMASS AT VARIOUS NITROGEN FERTILIZATION RATES AND HARVESTING PHASES

Hristina NEDEVA*, Hristina YANCHEVA, Radka IVANOVA

Department of Crop Science, Faculty of Agronomy, Agricultural University, Plovdiv, Bulgaria
*Corresponding author: h_nedeva@abv.bg

Abstract

The study was carried out in the field of Crop Science Department at the Agricultural University–Plovdiv, during the period 2013-2015. The experiment was set up following blok method with four replications, and 20m^2 for each experimental plot. That is why the purpose of our study was to determine the green biomass yield in the triticale varieties Musala and Attila which are grown under different nitrogen fertilizer rates (N_0; N_{120}; N_{160}; N_{200}; N_{240}). The varieties are harvested in heading stage and milk maturity stage and are grown in the region of Central South Bulgaria. During the first year of our experiment, in the two stages of the harvesting cultivar Musala and entered the coming later than the Atila. During the second year of the study, in the two stages of the harvesting cultivar Atila and entered the coming later than the cultivar Musala. During both years of the experiment, average over the study period in the two stages of the harvesting higher green biomass yield average for the two years was obtained at Attila variety in both harvesting stages. Depending on the nitrogen fertilizer rates, in both harvesting phases and two cultivars highest yield was obtained with nitrogen fertilization $N_{200.}$ The higher rate among organs that form the plants at the coming to ear stage, followed by leaves and ears. At the milky ripeness stage, the share of stems and ears increases while the share of leaves decreases compared to the coming to ear stage. With increasing nitrogen fertilizer rate, the share of all studied indicators increases up to fertilizer rate N_{200} and then drops at N_{240}.

Keywords: *triticale, variety, nitrogen fertilization, yield.*

Introduction

In recent years, with the decline of livestock farming in Bulgaria the interest in growing cereals for biomass is decreasing. Therefore, studies in this field are very limited.

The increasing shortage of fossil fuels on global scale leads to growing interest in green biomass as a possible source of renewable energy. Biomass from various crops is more and more used for the production of biogas. The use of renewable energy sources of vegetal origin helps to protect the world biosphere, to solve issues relating to global air pollution, to preserve the planet's biodiversity threatened by anthropogenic factors, and to decrease the dependence of individual countries on fuel import. In the practice, the most commonly used crop is corn followed by some cereals, including triticale. Most studies, both at global and national scale, show that triticale is a high-yield crop and exceeds the other cereals in terms of biomass yield as well as in dry mass (Yoshihira et al., 2000; Oettler et al., 2001; Motzo et al., 2001; Rosenberger et al., 2002; Dekić et al., 2013; Bassu et al., 2013). Todorov's studies (2009) have shown that biomass yield from triticale in Bulgaria exceeds by 20% to 30% that of rye. When harvested during the coming to ear stage, it gives between 5 and 6 tonnes of raw material, which is equal to 1000 to 1200 kg of dry mass.

Various methods to increase the quantity of biomass have been tested. Many authors have tried growing triticale at various fertilization rates and harvesting at different stages for green feed (Tosheva, 1994; Tonev, 1995; Jansone et al., 2011; Kirchev et al., 2013).

Lately there have been very few studies in the area. Therefore, we set ourselves the objective to establish which of the studied nitrogen fertilization rates and harvesting stages for the two new tested varieties led to higher yield of green biomass.

Material and methods

The experiment was set in 2013/2014 and 2014/2015 at the experimental facility of the Plant-growing department of the Agricultural University of Plovdiv (Bulgaria), using the block method with test plots of 20 m^2 each, in 4 repetitions. Two varieties of triticale were tested: Musala, selected at the Institute for plant and genetic resources of Sadovo, and Attila, selected at the Institute for wheat and sunflower of General Toshevo. The crops were sowed after rape predecessor. The varieties have been grown at the following fertilization rates: N_0, N_{120}, N_{160} N_{200} and N_{240}/ha. Nitrogen fertilizers have been applied twice: once in the autumn during the soil preparation for sowing, and once in the spring, for nutrition, at first occasion. Green biomass yield was accounted for during the coming into ear and milky ripeness stages. Were identified the stages of development of the two varieties and the following indicators: weight of the whole plant (g), weight of the stem of one plant (g), weight of the leaves of one plant (g), weight of the ears of one plant (g), and ratio of the organs – stems/leaves/ears of one plant (%). Statistical data processing was carried out in fourfold repetition. The experimental results were processed by one-way ANOVA, with the authenticity of differences was determined by Student's t criterion at the following levels according to: ns - no evidence of a difference; Gd = 5,0%; Gd = 1,0%; Gd = 0,1%.

Results and discussion

Data characterizing the monthly average air temperature and the precipitations over the periods 2013/2014 and 2014/2015 are shown in figures 1.

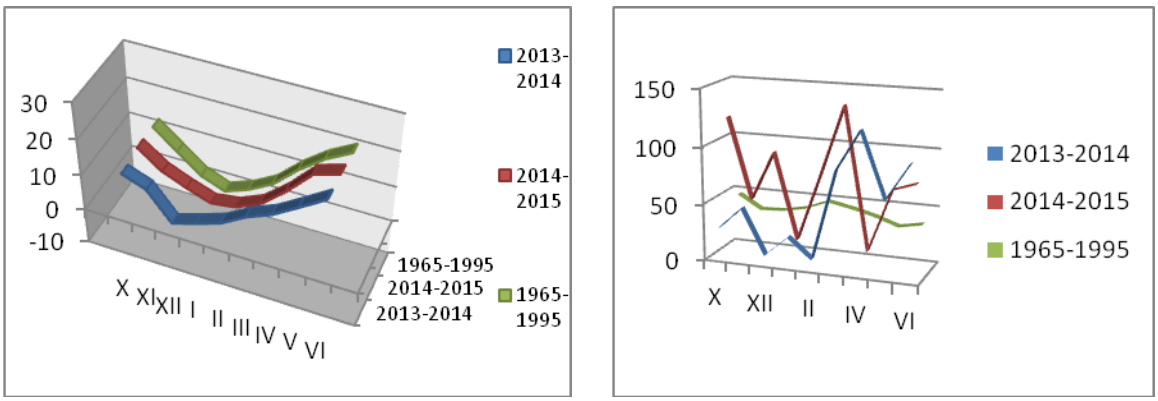

Fig 1. Average monthly temperatures / t^0C/ and rainfall / mm/ for the region of Central South Bulgaria, from 2013/2014; 2014/2015 and multiannual period

They show that during the two years of the study significant deviations from the daily average temperature for Central South Bulgaria compared to the multiannual period were not observed.

Relatively favourable daily average temperatures in the autumn and in the winter create conditions for optimal development of plants, their good tempering and successful overwintering. More important differences were observed in terms of precipitations during the two years of the experiment. The precipitations during the 2014/2015 (655.8 mm) significantly exceed both the precipitations during the former year (161.5 mm) and those of the multiannual period (236.8 mm). To the difference of the former year, the precipitations were evenly distributed over the whole period of vegetation. The total precipitation during the

first year of the experiment (494.3 mm) is less than that of the second year but more than the multiannual period. It should be noted that the distribution of precipitation was extremely uneven, especially with the large quantity (123.0 mm) in April. During both years of the experiment, the development stages in Central South Bulgaria occur at different times depending on the weather conditions and the specific features of tested varieties (Table 1).

Table 1. Phenological observations

Stages	Years			
	2013 /2014		2014/ 2015	
	Cultivars			
	Musala	Atila	Musala	Atila
Sowing	22.10.	22.10	16.10	16.10
Germination	31.10.	31.10	24.10	27.10
3 rd leaf stage	15.11.	15.11.	07.11	12.11.
Tillering	07.12.	07.12.	05.12	10.12.
Finish vegetation	14.12.	14.12	19.12	19.12.
Beginning vegetation	23.02.	23.02.	20.02.	20.02.
Stem elongation	23.03.	13.03.	25.03.	27.03.
Heading	25.04.	15.04.	27.04.	07.05.
Milk maturity stage	15.05.	29.04	11.05.	21.05.

Favourable weather conditions at the time of sowing during the two experimental years have secured quick germination of seeds (8 to 9 days). During the first year of our experiment, no genotypic differences between the tested varieties were observed up to the stage of stem elongation. All development stages occur simultaneously in the two tested varieties.

Genotypic differences in the development of these two varieties were only observed at the stem elongation stage when the weather factors such as temperature (6-7 °C) and precipitation (57.4 mm) were closer to the requirements of the Attila variety, which has been selected in Northern Bulgaria, i.e. in cooler and more humid climate. The increasing temperatures during the second and third 10-day period of March (11.5 °C and 10.7 °C) along with twice lower precipitations favour the development of the Musala variety and it enters the stem elongation stage just 10 days after the Attila variety.The high precipitation levels during the period of coming to ear and milky ripeness in Musala (157 mm) extended the period of coming to ear and milky ripeness and the variety enters these stages 10 and 14 days (25.04 and 15.05) later than the Attila (15.04 and 29.04 respectively).

During the second year of the study, higher daily average temperatures in November and December compared to the multiannual period created unfavourable conditions for the development of the Attila variety, which fell behind Musala by five days at the third leaf stage. 28 days later both varieties entered the tillering stage at which they overwintered.

During both years of the study, by mid-December with continuous drop of temperatures the crops suspended their vegetation.

Upon resuming vegetation (20.02.2015) the two varieties entered the stem elongation stage almost simultaneously. As a result of higher temperatures and absence of moisture in April, the Attila fell significantly behind in its development and entered the coming to ear stage 10 days later than the Musala. This trend remained unchanged over the following stage.

Biomass yield over the two years of the study, from the two varieties at different stages of harvesting and varying nitrogen fertilizer rates is shown in Table 2.

The results from our experiment show that depending on weather conditions biomass yield varies over the study years.

*Values with the same letters do not differ significantly

During the first year of the experiment, biomass yield from the Attila exceeded that of the Musala. The reason for that are the drastic differences in precipitations during the period of coming to ear for the Musala. The high precipitation level of 121.5 mm during the period of coming to ear of the Musala (25.04.2014) beat down the plants and resulted in lower yield.
The precipitation had no negative impact on the biomass yield of the Attila as it came to ear (15.04.2014) earlier than the Musala.
During the second year of our experiment, as a result of the drought in April that covered the coming to ear stage for the crops the biomass yield from the Attila was lower than that of the Musala. In the Attila variety, the yield varied between 24780 kg/ha and 36760 kg/ha whereas for the Musala it varied between 27580 kg/ha and 38150 kg/ha respectively.
During this stage, the lowest biomass yield was obtained from implementations without fertilization. With increasing nitrogen fertilizers rates, both during the two years of study and as average for the period the biomass yield increased. The highest yield was obtained at nitrogen fertilizer rate of N_{200} and at higher rates the yields decreased. The results from all implementations with fertilization and the control group have been mathematically proved. The results from all implementations have been proved by the N_{200} implementation. At later growth stages the yield significantly increased. When harvested at the stages of coming to ear and milky ripeness during the first year of the experiment, the yield from the Attila variety (38110 kg/ha and 46980 kg/ha respectively) exceeded the yield from the Musala variety (35000 kg/ha and 38840 kg/ha respectively). As a result from higher temperatures and lower humidity during the milky ripeness stage in the second year, the Musala outdid the Attila in terms of productivity. The results from all implementations with fertilization and the control group have been mathematically proved. The results from all implementations have been proved by the N_{200} implementation. At the coming to ear stage, the Musala exceeds the control by 24% in the N_{120} implementation and up to 38% in the N_{200} implementation while for the Attila these values vary between 22% and 40%. At the stage of milky ripeness, the Musala exceeds the control by between 10 and 18%, and the Attila by 14 to 29%.
Diagram 2 shows that stems have the higher rate among organs that form the plants at the coming to ear stage, followed by leaves and ears.

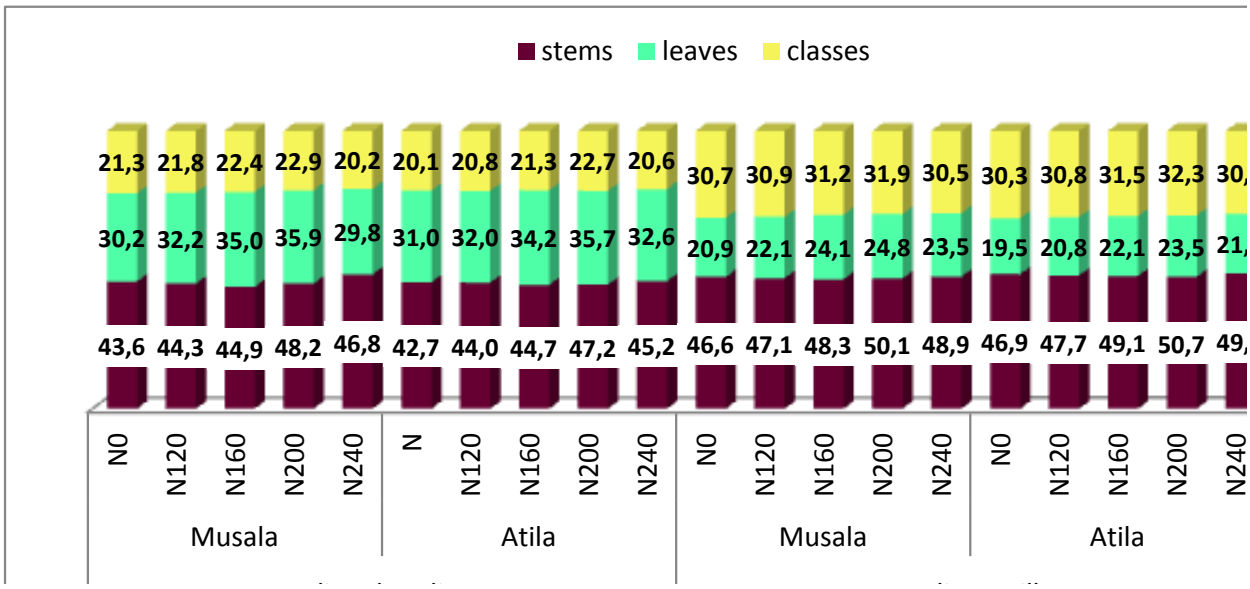

Fig2. Share of fresh biomass on triticale plant components, at different varieties of fertilization and heading and milk maturity stages

The percentage of stems from the total weight of the plant is the highest at the coming to ear stage. In average over the study period, the ratio of stems in the Musala variety (between 43.56% and 48.24%) exceeds that of the Attila variety (between 42.74% and 47.18%).
Leaves have a smaller share of the plant organs. The higher ratio of leaves in the Attila is due to the lower ratio of stems. The percentage of ears from the whole plant is the lowest with an average between 20.11% and 22.69% for the Attila and between 21.34% and 22.88% for the Musala variety over the whole period. With increasing nitrogen fertilizer rate, the share of all studied indicators increases up to fertilizer rate N_{200} and then drops at N_{240}. At the milky ripeness stage, the share of stems and ears increases while the share of leaves decreases compared to the coming to ear stage, which is due to fading and drying of the lower leaves.
In average over the period of the study, the ratio of stems for the Attila variety (between 46.88% and 50.68%) is a little bit higher than the ratio for the Musala variety (between 46.64% and 50.12%). The trend is inversed for leaves which have the lowest share during the milky ripeness stage. At that stage, ears have a higher ratio than leaves. The percentage is similar in both varieties with Musala slightly prevailing. In terms of fertilization rates, the trend remains the same as during the coming to ear stage.

Conclusions

During the first year of our experiment, in the two stages of the harvesting cultivar Musala and entered the coming later than the Atila. During the second year of the study, in the two stages of the harvesting cultivar Atila and entered the coming later than the cultivar Musala.
During both years of the experiment, average over the study period in the two stages of the harvesting higher green biomass yield average for the two years was obtained at Attila variety in both harvesting stages. Depending on the nitrogen fertilizer rates, in both harvesting phases and two cultivars highest yield was obtained with nitrogen fertilization $N_{20.}$
The higher rate among organs that form the plants at the coming to ear stage, followed by leaves and ears. At the milky ripeness stage, the share of stems and ears increases while the share of leaves decreases compared to the coming to ear stage. With increasing nitrogen fertilizer rate, the share of all studied indicators increases up to fertilizer rate N_{200} and then drops at N_{240}.

Abstract

Fig (*Ficus carica* L.) is a gynodiocius species which has male and female fruits on the different trees. Smyrna type figs are needed to pollination for the enough fruit set. Therefore, caprification (meaning the transfer of pollen grains from male trees to female trees by a vector, *Blastophaga psenes* L.) are commonly used for the figs. The aim of the study was to carry out and evaluate the effects of some applications on pollen germination of caprifig genotypes (*Ficus carica* var. *caprificus*). For this purpose, we investigated effects of light and dark conditions, pH of medium, sucrose, glucose and fructose levels and H_3BO_3, $Ca(NO_3)_2$, $MgSO_4$, KNO_3 concentrations in petri dishes on the temperature of 24°C for 24 h. Pollens from caprifigs were collected from anthers cracking on the June 10-25 from eastern Mediterranean region of Turkey. Germination rates of the caprifig genotypes were higher in the dark conditions (44.41%) compare to light conditions (30.65%). pH of medium were significantly affected on germination rates and optimal germination was obtained from pH 5.0 (56.39%). As a result, best condition for *in vitro* caprifig germination were in 1% agar+3% sucrose +100 ppm H_3BO_3+300 ppm $(CaNO_3)_2$+200 ppm $MgSO_4$+100 ppm KNO_3tests in pH 5.0 and dark conditions.

Keywords: *fig, caprifig, pollen, germination.*

Introduction

Fig tree (*Ficus carica* L.) is a typical species of Mediterranean countries. The *Ficus* species are gynodioecious and functionally dioecious. Trees producing only ovule bearing fruit are functionally female whereas trees producing only pollen are functionally male. Figs are typically pollinated by pollen-carrying wasps (Kjellberg et al., 1987).

The fig is an important fruit worldwide for dry and fresh consumption, and recently their nutritive and pharmacological values have been investigated.A major benefit of the Mediterranean diet is its high level of natural antioxidants derived from vegetables and fruits, including figs. In addition to contributing antioxidant vitamins, figs have some of the highest polyphenol levels in commonly available fruits. Traditional Mediterranean fruit and nut crops include grapes, olives, figs, almonds, hazelnuts, pistachios, pomegranates, apricots, and citrus (Caliskan and Polat, 2011; Caliskan, 2015).

The caprification is a common practice in all of fig grown regions and is known as an important factor affecting the quality of fig fruits (Condit, 1947). The main characteristics for the caprifigs (profichi crop) are as follows: Fruit size, amount of fruit number per shoot, ripening period, amount of gall and male flowers, amount of pollen production, pollen viability and germination ratios, include of the mammoni and mamme crops, and free from disease and pests (Aksoy et al., 2001; Caliskan et al., 2016).

In Turkey a large number of caprifigs can be found with a great diversity based on color, shape and ripening periods. Fig cultivation on the coastal region of the Mediterranean in Turkey has a long history and a promising future (Caliskan and Polat, 2012). The region is very important for fresh fig cultivation after Bursa province in Turkey. In this region, a lot of caprifig genotypes that are used for caprification are grown in natural population, but there are not found enough information included plant, fruit and pollinizer traits (Caliskan et al., 2016).
Stanley and Linskens (1974) indicated that there is a linear relation between pollen viability and germination capability in many fruit species. Some of the factors which influence pollen germination in plants are carbohydrate (sugar), boron, calcium, enzymes, plant hormones, magnesium, potassium, agar, pH and certain physical factors such as temperature and light. The requirements are species specific (Johri and Vasil, 1961). However, effects of different applications for pollen germination of caprifigs have not been investigated in detail.
The objective of this study was to determine effects of some applications on *in vitro* pollen germination of caprifig genotypes.

Material and methods

In the study some caprifig cultivars (‘Ak İlek’, ‘Armut İlek’, ‘Elma İlek’, ‘Hamza’, ‘Küçük Konkur’, and ‘Taşlık’) and genotypes (Hatay18, Hatay28, Hatay34, Hatay36, Hatay37, Osmaniye11) was used for pollen germination tests. The cultivars were obtained from Fig Research Institute, Aydın and the genotypes were selected from Hatay and Osmaniye provinces, Eastern Mediterranean Region of Turkey. Pollens collection was done according to the technique adopted by Storey (1975). Thirty profichis per genotype were harvested in full maturity period (10-25 June) and transferred to the laboratory. Ripe caprifigs were taken to a warm, dry place, split open longitudinally, and spread out to dry on aluminum foilat the laboratory bench. After 2-3 days, fruits were dried and all of anthers have dehisced. The pollens were taken in glass jars (100 ml). It was stored at +4°C in a refrigerator until use.

Table 1. Sucrose and nutrition levels used *in vitro* pollen germination of caprifig in 1% agarose

Medium	Nutrition	Medium	Nutrition
I	3% sucrose	**VIII**	5% sucrose +100 ppm H_3BO_3
II	5% sucrose	**IX**	3% sucrose +100 ppm H_3BO_3
III	10% sucrose	**X**	3% sucrose +300 ppm $Ca(NO_3)_2$
IV	15% sucrose	**XI**	3% sucrose +100 ppm KNO_3
V	20% sucrose	**XII**	3% sucrose +200 ppm $MgSO_4$
VI	25% sucrose	**XIII**	3% sucrose +100 ppm H_3BO_3+300 ppm $(CaNO_3)_2$+200 ppm $MgSO_4$+100 ppm KNO_3
VII	30% sucrose	**XIV**	%5 sucrose +100 ppm H_3BO_3+300 ppm $(CaNO_3)_2$+200 ppm $MgSO_4$+100 ppm KNO_3

In vitro germination was assessed with the petri-agarose method (Eti, 1991). Pollen germination was determined by placing a small drop of germinating media on a cover glass; pollen grains were sown on the drops with a clean brush. Components were subtracted from the medium or the levels modified as described in the Table 1 and 2.
In the pH tests, sucrose was dissolved first, then the other materials added, and the pH measured using pH meter and adjusted to 4.0, or to other values described in the Table 2, with dilute NaOH or HCI solution. The germination experiments, fresh pollen were evenly dusted onto germination solutions and incubated at 25°C constant temperature for 24 h. A pollen grain was considered to be germinated when the length of the pollen tube was equal to or

longer than the diameter of the grain. Germination was scored by a light microscope (Nikon Eclipse E200, Japan) in four random fields of three petri dishes for each caprifig genotype.

Table 2. Some application levels used *in vitro* pollen germination tests

Application	**Level**
Light	Light and Dark
pH	4, 4.5, 5.0, 5.5, 6.0, 6.5 and 7.0
Sugar (Glucose, Fructose and Sucrose)	3% and 5%
H_3BO_3	100 ppm in 3% and 5% sucrose
$Ca(NO_3)_2$	300 ppm in 3% sucrose
$MgSO_4$	200 ppm in 3% sucrose
KNO_3	100 ppm in 3% sucrose

Germination percentage (%) was evaluated by dividing the number of germinated pollen grains per field of view by the total number of pollen per field of view.
Data were analyzed using SAS software and procedures (SAS, 2005). Analysis of variance (ANOVA) tables were constructed with Tukey's Honestly Significant Difference (HSD) method at $p < 0.05$.

Results and Discussion

1. The effects of light and dark conditions on pollen germination: The light is one of the factors which influence pollen germination in plants and they the requirements are species specific (Johri and Vasil, 1961). According to our results, germination of caprifig pollens were significantly affected by the dark conditions (Figure 1). Pollen germination percentages were highest in the dark condition (44.41%) compared to the light condition (30.65%). Similarly, Hoyo et al. (2014) showed that light is not effective factor for the pollen germination.

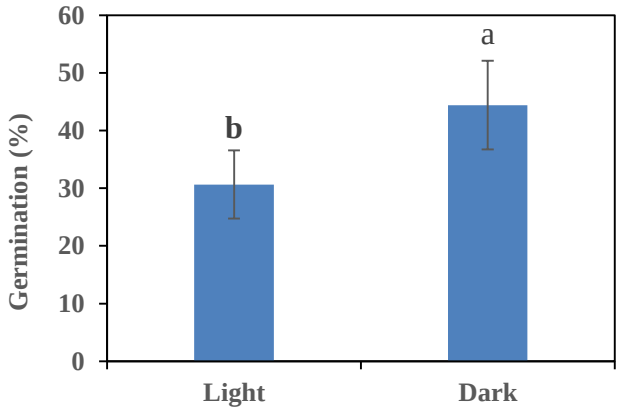

Figure 1. Effects of light and dark conditions on pollen germination. Bars show standard errors, the different letters show statistical significance on treatments.

2. The influence of different sugar compositions and levels on pollen germination: Two levels of sucrose, glucose and fructose plus nutrition medium were designed to evaluate the effect of sugars on pollen germination of caprifigs. Analysis of variance showed that there were statistically significant differences for both sugar compositions and levels (Figure 2). The highest pollen germination of caprifigs was detected in sucrose, followed by glucose and fructose. Levels of 3% (24.57%) and 5% (22.17%) of sucrose was shown to be the best sugar for pollen germination. Sucrose is generally considered to serve two functions in the medium, that of an energy source and an osmotic. The externally supplied sucrose maintains the

osmotic pressure and acts as a substrate for pollen metabolism (Hecker and McClintock, 1988). However, researchers showed that sucrose level can to be changed to fruit species (Ilgin et al., 2007; Bayazit et al., 2011).

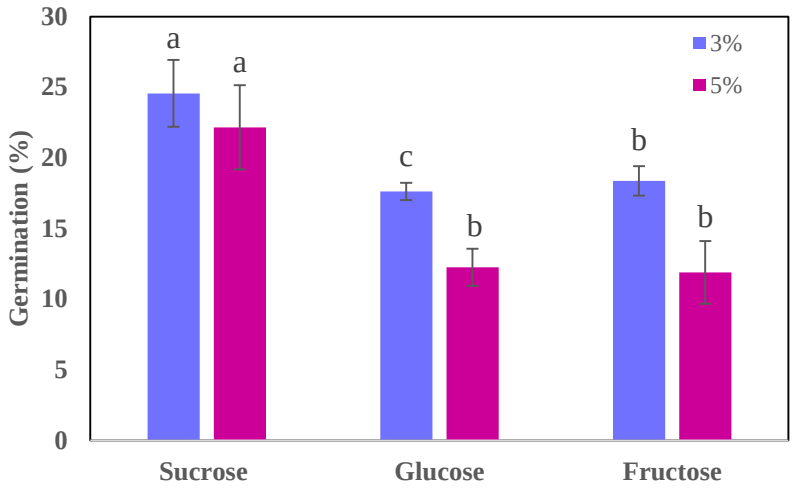

Figure 2. Effects of different sugar compositions and levels on pollen germination. Bars show standard errors, the different letters show statistical significance on treatments.

3. The effect of pH levels on pollen germination: pH has been reported to have a significant effect on pollen germination (Boavida and McCormick, 2007). Using our standard nutrition and agarose medium we varied the pH from 4.0 to 7.0. There was found that pollen germination percentage was the highest values 56.39% at pH 5.0 whereas, the lowest values of germination were 3.0% and 1.44% at pH 4.0 and 7.0 respectively (Figure 3).The results obtained from the present study showed that the acidity of germination media is one of the important factors related to pollen performance of caprifigs. Similarly, the pH of the germination medium has been shown to affect pollen germination in apple (Munzuroglu et al., 2003), banana (Soares et al., 2008) and pistachio (Acar et al., 2010).

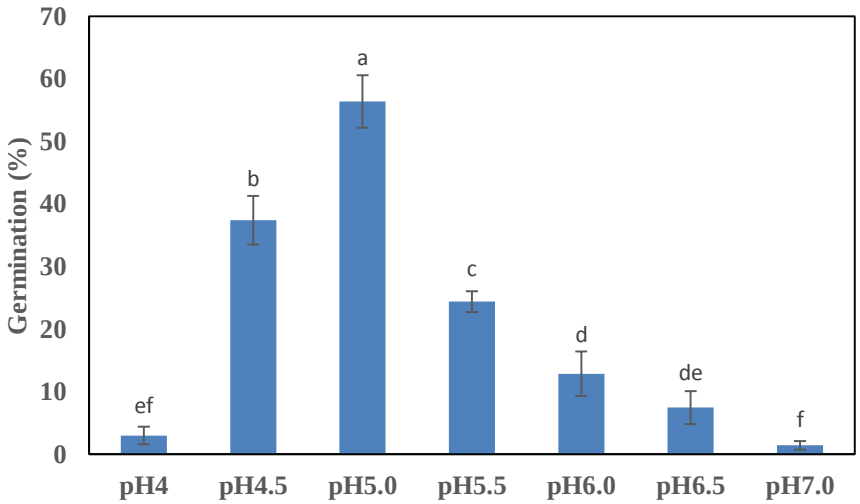

Figure 3. Effects of variation of pH on pollen germination. Bars show standard errors, the different letters show statistical significance on treatments.

4. Influence of some nutrition mediums on pollen germination: To determine the effect of the composition of the growth medium on caprifig pollen germination, we devised a series of

experiments of our medium including sucrose, boric acid (H_3BO_3), calcium nitrate [$(CaNO_3)_2$], and potassium nitrate (KNO_3). Effects of the nutritious on *in vitro* pollen germination of caprifigs summarized in Figure 4.The highest germination percentages were found in 3 % sucrose +100 ppm H_3BO_3+300 ppm $(CaNO_3)_2$+200 ppm $MgSO_4$+100 ppm KNO_3 (24.57% in XIII medium) and 5 % sucrose +100 ppm H_3BO_3+300 ppm $(CaNO_3)_2$+200 ppm $MgSO_4$+100 ppm KNO_3 (22.17% in XIV medium)(Figure 5). This result was in agreement with previous studies in caprifigs (Zeybekoglu et al., 1998). Increasing sucrose concentrations up to 5% improved pollen germination percentages whereas, germinations not detected with higher sucrose concentrations (20, 25 and 30%; V, VI and VII medium). This results showed the negative effect of higher sucrose concentrations on pollen germination as reported in caprifigs (Zeybekoglu et al., 1998; Ilgin et al., 2007). In addition, influence of potassium nitrate was not observed on pollen germination (XI).

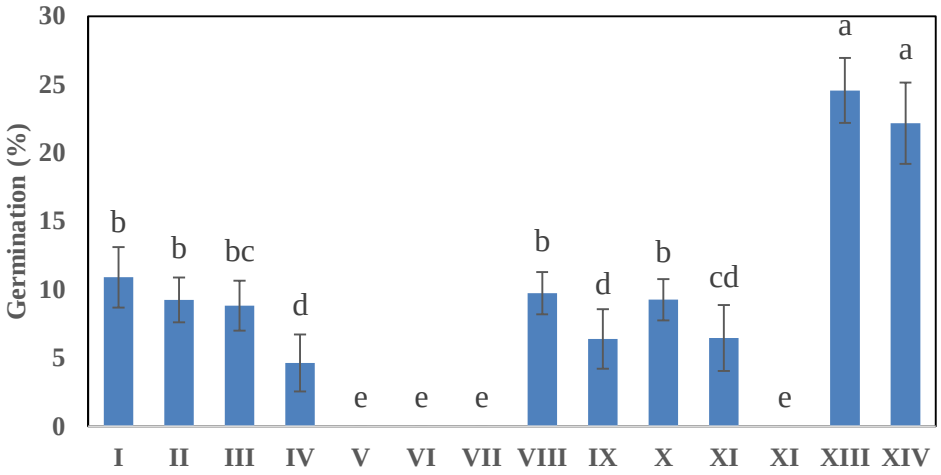

Figure 4. Effects of some nutrition mediums on *in vitro* pollen germination in 1% agarose. Bars show standard errors, the different letters show statistical significance on treatments.

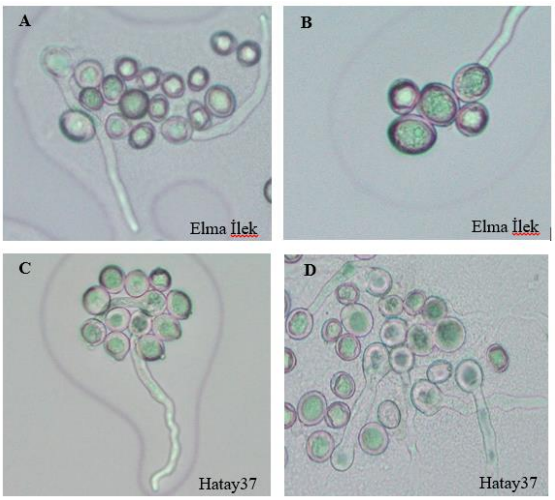

Figure 5. Pollen germination in Elma İlek cultivar and Hatay37 genotype XIII medium (A, C) and XIV medium (B, D) (40x)

Conclusion

The pollen quality is one of the desired parameter for the caprification. The germination tests also can be used to evaluate the pollen quality. In this study, the darkness, sugars, pH, and some nutritions on *in vitro* caprifig pollen germination were found to be highly significantly. As a result, best condition for *in vitro* caprifig germination were in 3% sucrose +100 ppm H_3BO_3+300 ppm $(CaNO_3)_2$+200 ppm $MgSO_4$+100 ppm KNO_3 tests in pH 5.0 and dark conditions in 1% agar.

Abstract

Regarding biodiversity the Black Sea region belongs to one of the richest regions of Turkey. Totally 2239 species are present in the East Black Sea region, 514 of them are endemic and the endemism ratio is ca. 23 %. More than half of the plants distributed at the East Black Sea region are present in the Rize province. 70 % of the plants are of medicinal and aromatic value. 4 Mentha species, 3 Origanum species, 3 Thymus species, 2 Salvia species, 2 Stachys species and 1 Calamintha species were collected from 19 different localities in Rize during 2015. A field nursery was established using collected material. Traits like plant height, number of branches, stem diameter, leaf area, dry drog weight, fresh drog weight, dry drog yield, fresh drog yield, seed weight and essential oil yield were determined. Principal Component Analysis was performed to assess the diversity regarding with the investigation of characters. Based on obtained data large diversity could be determined. Collected materials can be used as genetic resources for further investigations.

Keywords: *Lamiaceae, medicinal and aromatic plants, characterization.*

Introduction

Natural environment has been a sourceof medicinal agents for thousand of years, since healing wih plants dates back probably to the evolution of mankind (Mathe, 2015). As well known about 80 % of human in the World rely mainly on traditional medicines for their primary health care, while medicinal plants continue to play an important role in the health care systeme of the remaining 20 %. Partly based onther use in traditional medicine, an impressive number of modern drugs have also been isolated from natural plant species. Remarkably, even today there is no realdefiniion fro this special group of plants that has been accompanying mankind through history. Medicinal and aromatic plants form a numerically large group of economically important plants which provide basic raw materials for medicines, perfumes, flavours and cosmetics. These plants and their products not only serve as valuable source of income for small land holders farmers and entrepreneurs but also earn valuable foreign exchange by way of export facilities.

Turkey is one of the countries with richest plant diversity in the Mediterranean (Davis 1965-1986; Davis *et al*., 1988; Guner *et al*., 2001). A number of human races and tribes have settled here during different periods bringing in different cultures and customs. As a result of this we come across a great accumulation of knowledge of traditional medicine in the country. A recent survey of traditional and folk medicine in Turkey has revealed that most of these plants are still in use by the local inhabitants (Yesilada and Sezik, 2003).

Turkey is located in three biogeographical regions: Anatolian, Mediterranean, the Black Sea region, and their transition zones. Its climatic and geographical features change within short

intervals of space due to the country's position – a bridge between two continents. Thanks to its location, Turkey's biological diversity can be compared to that of a small continent: the country's territory consists of forests, mountains, steppe, wetlands, coastal and marine ecosystems and different forms and combinations of these systems. This extraordinary ecosystem and habitat diversity has produced considerable species diversity (Kahraman *et al*., 2011; Kahraman *et al*., 2012). Regarding biodiversity the Black Sea region belongs to one of the richest regions of Turkey. Totally 2239 species are present in the East Black Sea region, 514 of them are endemic and the endemism ratio is ca. 23 %. More than half of the plants distributed at the East Black Sea region are present in the Rize province. 70 % of the plants are of medicinal and aromatic value.
4 Mentha species, 3 Origanum species, 3 Thymus species, 2 Salvia species, 2 Stachys species and 1 Calamintha species were collected from 19 different localities in Rize during 2014. Different traits were determined, but only the differences between these species based on their essentail composition will be discussed.

Materials and methods

The research material was collected during 2015 in the Rize province (Turkey). The collected species, the localities and the altitudes are given in Table 1.

Table 1: Collected species and thEir localities

Essential oil analysis:

The essential oil composition of collected samples was done using an SHİMADZU GC/MS device. An 30 m column and related detection programme was used.

Statistical analysis:
Principal component and Biplot analysis was used to distinguiSh the collected samples regarding their essentail oil composition (Backhaus et al, 1989). Principal component and Biplot analysis was performed using XLSTAT2016 Trial Version. The collected samples were diversificated using all essential oil components, in Biplot only highly detected essential oil components were used. The calculated first two Principal Components are corresponding in % to the present variation regarding investigated trait.

Results and discussion

1. **Mentha species:** Fig.1 shows the distribution of investigated Mentha species based on most detected essential oils.

As can be seen in Fig. 1 Mentha species collected from different localities and altitudes showed different essential compositions. Specially in *M. longifolia* subsp. *longifolia* large varation was detected. The same can be sayed for *M. puligeum* collected from different localities and altitudes.

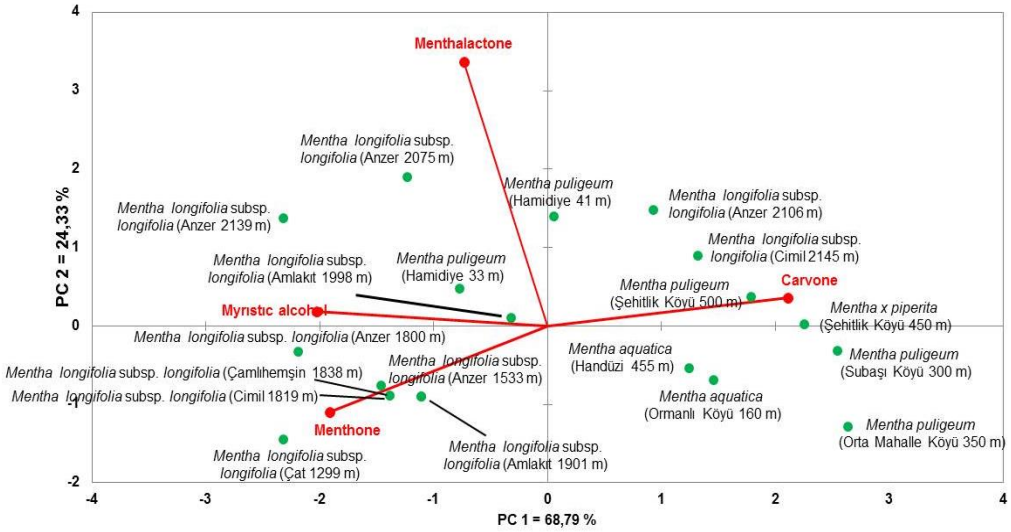

Fig. 1: Biplot analysis of Mentha species based on differentiating essential oils

The essentail oil menthone was detected specially in M. *longifolia* subsp. *longifolia*. Carvone, myristic alcohol and menthalactone was useful in seperating the other collected samples.

1. Origanum species: Fig.2 shows the distribution of investigated Origanum species based on most detected essential oils. *Origanum vulgare* subsp. *viride* samples collected from different altitudes of İkizdere and from Uğrak showed ifferent essential oil composition compared with the other Origanum species. Specially *Origanum vulgare* subs. *vulgare* collected from Cimil and *Origanum vulgare* subsp. *hirtum* collected from Çat showed different essentail oil compositions. *Origanum vulgare* subsp. *hirtum* collected from Çat and *Origanum vulgare* subsp. *viride* collected from İkizdere at 1533 altitude could be differentiated from other samples regarding Carvacrol.
Origanum vulgare subsp. viride collected from İkizdere at 787 altitude and from Uğrak could be seperated from other collected samples regarding the compounds İsoborneol and Myristic.

Origanum vulgare subsp. *vulgare* collected from Cimil stand out regarding Tymol from the other samples; *Origanum vulgare* subsp. *viride* collected from İkizdere at 314m altitude showed differences regarding Hmachalene alpha. The compund linaool was useful to separate all investigated samples.

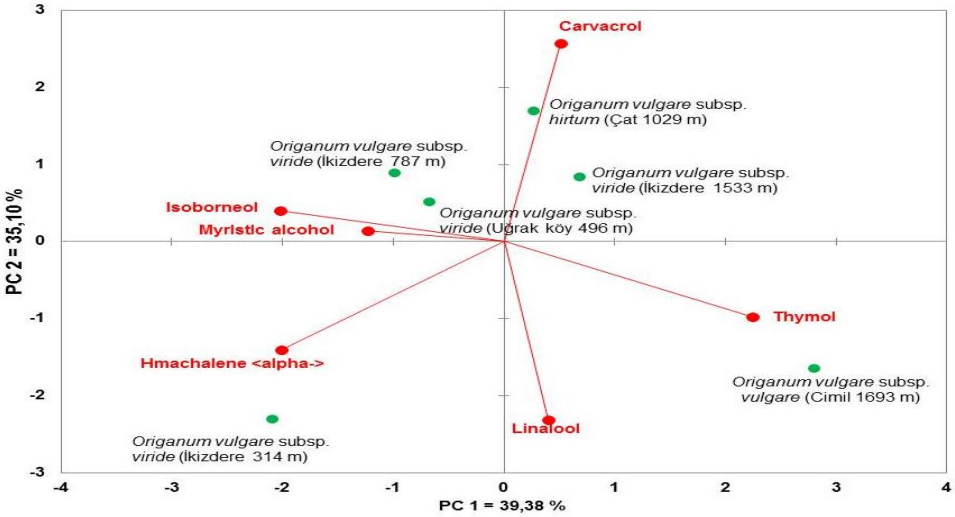

Fig. 2: Biplot analysis of Origanum species based on differentiating essential oils

2. Thymus species: Fig. 3 shows the Biplot analysis of collected Thymus samples based ontheir essential oil composition.

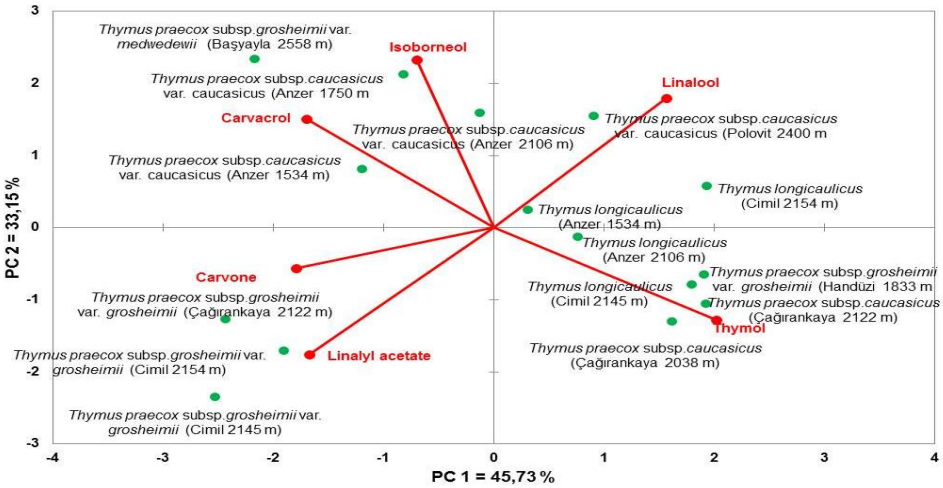

Fig. 3: Biplot analysis of Mentha species based on differentiating essential oils

T. praecox subsp. *grosheimii* var. g*rosheimi* samples collected from Cimil and Çağırankaya showed similar essentail oil compositions. Only the same species collected from Handüzi displayed similar composition with the species *T. longicaulicus* and *T. praecox* subsp. *caucasicus*. Further, *T. praecox* subsp. *grosheimii* var. *medwedewii* showed similar essentail oil composition with *T. praecox* subsp. *caucasicus* var. *caucasicus* samples collected from Polovit and different altitudes of Anzer.

T. praecox subsp. *grosheimii* var. *medwedewii* collected from Baş Yayla, *T. praecox* subsp. *caucasicus* var. *caucasicus* collected from Anzer and Polovit and T. *longicaulicus* collected

from Cimil and Anzer 1534 showed differentiation from the other samples regarding the essetial oil compounds Linalool, İsoborneol and Carvacrol.
Carvone and linalyl acetate were helpful to seperate *T. praecox* subsp. *grosheimii* var. *grosheimii* collected from Cimil and Çağırankaya from the other species. *T. Longicaulicus*collected from Cimil, *T. praecox* subsp. *caucasicus* collected from Çağırankaya and *T. praecox* subsp. *grosheimii* var. *grosheimii* collected from Handüzi were different from the other samples regharding Thymol.

3. Salvia, Stachys and Calamintha species: Fig. 3 shows the Biplot analysis of collected Salvia, Stachys and Calamintha samples based ontheir essential oil composition.

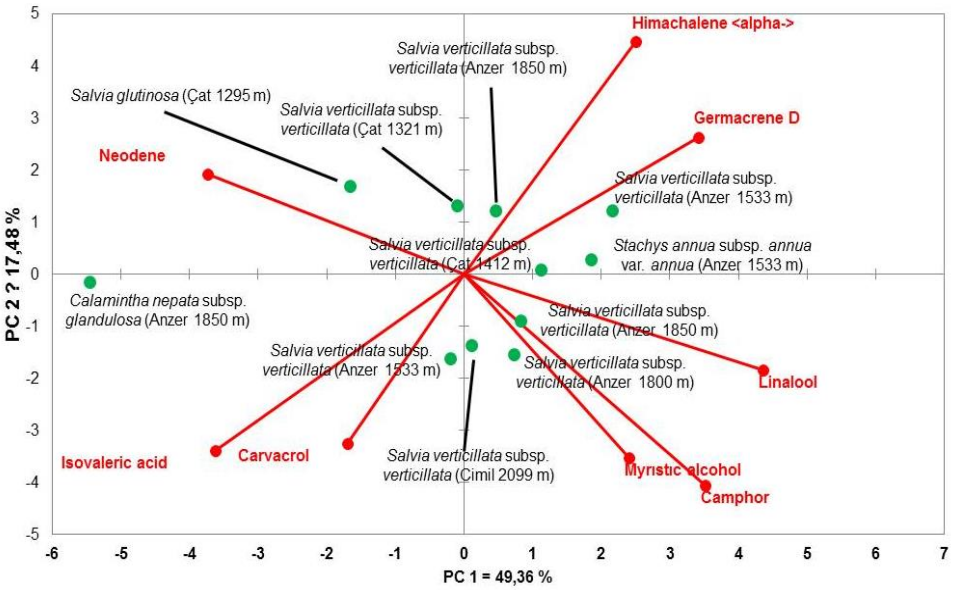

Fig. 4: Biplot analysis of Salvia, Stachys and Calamintha species based on differentiating essential oils

Salvia glutinosa, *Calamintha nepeta* subsp. *glandulosa* and *Stachys annua* subsp. *annua* var. *annua* differed from the other species regarding their essential oil composition. Samples of the species *Salvia verticillata* subsp. *verticillata* showed nearly similar essentail oil compositions.
Calamintha nepeta subsp. *glandulosa* differed from theother samples ragarding neoden, carvacrol and isovaleric acid. Further, *Salvia glutinosa* displayed different neodene composition. *Stachys annua* subsp. *annua* var. *annua* on the other side could be diffentiated based on germacrene D and linaool.
The presence, yield and composition of secondary metabolites in plants, viz. the volatile components and those occurring in essential oils, can be affected in a number of ways, from their formation in the plant to their final isolation (Figueiredo *et al*., 2008). Several of the factors of influence have been studied, in particular for commercially important crops, to optimize the cultivation conditions and time of harvest and to obtain higher yields of high-quality essential oils that meet market requirements.
Knowledge of the factors that determine the chemical variability and yield for each species are thus very important. These include: (a) physiological variations; (b) environmental conditions; (c) geographic variations; (d) genetic factors and evolution; (e) political/social conditions; and also (f) amount of plant material/space and manual labour needs. İn our case it could be stated that different species collected from different localities and altitudes showed variation regarding their essential oil compostion due to environmental conditions, geographic variations and genetic factors, which of course needs further investigation.

Conclusion

Medicinal plants and their various products can be viewed as an important commodity items for sustainable economic development of developing countries. There is globaly also need of organised marketing and trade of medicinal plants and their various products. To meet the internal and international demands, it has now become imperative to produce the quality raw materials in significant quantities. This can only be achieved to promote the domestication and cultivation of medicinal plants which have internal demand in large quantity and have export and import potential. During this study, the essential oil composition of different species of the Lamiaceae family were determined. Obtained data revealed that large variation exists based on the chemical compounds of species collected from different locations and altitudes. The investigated material will serve as genetic material for further breeding purposes.

ANTIFUNGAL ACTIVITY OF *SISYMBRIUM SOPHIA* EXTRACTS AGAINST PHYTOPATHOGENIC FUNGI

Yusuf BAYAN

Department of Plant Protection, Faculty of Agriculture, AhiEvran University, 40100,Kirsehir, Turkey
*Corresponding author: yusufbayan@gmail.com

Abstract

The purpose of this study was to assess the effectiveness of methanol and aquatic extracts from *Sisymbrium sophia* against the plant pathogens, *Fusarium oxysporum* f. sp. *radicis-lycopersici* (FORL) (Sacc.) W.C.Synder and H.N. Hans, *Rhizoctonia solani* J.G. Kühn., *Sclerotinia sclerotiorum* (Lib.) de Bary, *Verticillium dahliae* Kleb., and *Alternaria solani.* Various volumes of methanol and aquatic extracts were mixed with the sterile PDA in order to obtain different concentrations. Antifungal activity assessments were performed under in *vitro* conditions using 60 mm diameter petri dishes containing potato dextrose agar (PDA). Plant pathogen mycelial discs of 5 mm diameter were inoculated onto Petri dishes containing PDA medium (10 mL petri^{-1}).Then the mycelial growth inhibition (MGI) was calculated. Additionally, the antifungal activity of plant extracts was evaluated statistically. Methanol 100 mg, 200 mg 400 mg/mL and 5%, 10% and 20% aquatic extracts of plant extract doses were used respectively. *Sisymbrium sophia* methanol and aquatic extracts showed distinguished antifungal activity. These results revealed that methanol and aquatic extracts of *Sisymbrium sophia* could be of use for the future development of plant disease agents.

Keywords: *Antifungal effect, plant extracts, Sisymbrium sophia, Plant pathogenic fungi*

Introduction

Brassiaceae a major plant family with 390 genera and 3000 species, among which is *Sisymbrium sophia* L., syn *Descurainia sophia* (Shahina, 1994). The plant is shows distribution in the different regions of the world. Descurainia sophia high germination, particularly in late autumn and premature spring(Peng *et al*., 1997; Li *et al*., 2005). It is known as herb Sophia and tansy mustard. Propagated by seeds, it forms erect, furcate stem between 10 and 72 cm tall. *S. sophia* is an annual weed prevalently scattered in cultivated crops and forage throughout the world. Also, its special seed can be used for food, having medicinal and industrial properties (Anonymous, 2016).

The purpose of this study, determine *in vitro* antifungal activity of the methanol and aquatic extract obtained from *Sisymbrium sophia* L. to plant pathogenic fungi: *Alternaria solani, Verticililum dahliae, Rhizoctania solani, Fusarium oxysporum* f. sp *radicis-lycopersici* and *Sclerotinia sclerotiorum*.

Material and Method

Plant material

The above ground parts of *Sisymbrium sophia* were collected during 2015 and 2016 from the Kirsehir, Turkey.

Plant Extracts

Methanol Extracts: 100 grams of plant materials was put into a 1 liter Erlenmeyer flask containing 600 ml methanol. Mixture was left for 24 hours at room temperature and subsequently in an orbital shaker at 120 rpm. Extract was filtered using filter paper. The Rotary evaporator 40 ^{0}C was removed with the aid of solvents. The residual extract was used

to prepare a stock solution with 1% DMSO identified. Several concentrations to be used in the study (100, 200,400 mg /100 ml PDA) were prepared (Bayan and Akşit, 2016).

Aquatic Extracts: Dried plant materials were grinded and 20g of material was put in a glass vessel containing 100ml of distilled water and shaken for 24 hours at 120 rpm in an orbital shaker. Shaking mixture was then filtered through filter aid paper.Several concentrations to be used in the study (5%, 10%, 20% ml/100 ml PDA) were prepared (Yilar and Kadioğlu, 2016).

Fungal Culture: The plant pathogenic fungi used in this study were obtained from stock cultures of Department of Plant Protection, Faculty of Agriculture, Phytopathology laboratories at Ahi Evran University. Fungal cultures were plated in 90 mm Petri dishes containing 20 ml of potato dextrose agar (PDA) and incubated for 7 days at 23±2 ºC.

In- vitro antifungal activity of plant extracts

These assays were carried out to determine the effects of Sisymbrium sophia methanol and aquatic extracts against A. solani, F. oxysporum f. sp radicis-lycopersici, S. sclerotiorum, R. solani and V. dahliae. The obtained methanol and aquatic extracts were added to PDA at 40oC to at final concentrations of 100, 200 and 400 mg/ml and 5, 10 and 20% for each extracts respectively. The PDA was poured into 60-mm Petri plates (10 mL plate-1) and 5mm mycelial disc were placed onto the medium and incubated for 7 days at 25°C. Fungal development was recorded after 7 days. Inhibition in the development in fungal growth was calculated using the following formula (Pandey, 2009). PDA amended with synthetic Thiram 80% (Hektas, Turkey) was used at the indicated concentration for the disease a positive control. At the indicated concentration for the disease. All experiments were repeated twice and each with 4 replications.

Figure 1-2. The effect of *Sisymbrium sophia* L methanol and aquatic extract on the mycelial growth inhibition of *A. solani* (A.s.), *F. oxysporum* f. sp *radicis- lycopersici* (FOL), *S. Sclerotiorum* (S.s.), *R. solani* (R.s.) and *V. dahlhiae* (V.d.), Figure 2. 1-5 (5%, 10%, 20%, Negative control (N.C), Positive control (P.C))

In operating results; methanol and water extract: not fungi mycelium is blocking the development of 100%. However, compared to control, MGI is increasing as the concentration increases. The highest antifungal effect was observed in *S. sophia* methanol extracts in concentration of 400 mg mL^{-1} against *A. solani, S. sclerotiorum,V. dahliae R. solani and F. oxysporum f sp radicis- lycopersici,* which had MGIs of 72.22, 63.08, 61.18, 54.13 and 54.13%, respectively. Similarly, the highest antifungal effect was observed in *Sisymbrium sophia* L 20%aquatic extracts against *Verticilum dahliae, Rhizoctania solani, Alternaria solani, Fusarium oxysporum* f. sp *radicis- lycopersici,* and *Sclerotinia sclerotiorum* having MGI 73.12, 72.67, 71.08, 62.40 and 48.87%, respectively. Species within family Brassicaceae are reported to have anti-microbial activity has been identified (Panghal *et al*., 2011). The aqueous extract reported of *Sysymbriom irio* showed antibacterial activity (Khan *et a*l., 2011). *Sisymbrium sophia* L antipyretic, anti-inflammatory and analgesic activity plant extract has been determined (Mohamed and Mahrous, 2009). The effects of water extracts of different *Sisymbrium sophia L* parts obtained such as root, stem and leaves. The germination of wheat seeds have identified a preventive effect.

Conclusions

As a result, the plant methanol and aquatic extracts used in study were determined to have different level of antifungal effect. Antifungal activities opposite all test organisms have reduced mycelium growth at the grade of visible in a dose dependent way. Promising results were acquired from the use of plant extract plant pathogenic fungi controls.

Abstract

This study was conducted on five genotypes from the Fruit Research Institute (FRI), Čačak (Republic of Serbia) Apple Collection – 'Bošnjanka Sejanac', 'Jevtović Milutin', 'Jusuf Bećović', 'Tip 3' and 'Valjnika' – in order to determine the main biological properties. Flowering phenophase (onset, full and end of flowering), harvest maturity, pomological properties (morphometric and chemical) and disease susceptibility to scab [*Venturia inaequalis* (Cooke) Wint.], mildew [*Podosphaera leucotricha* (Ell. & Ev.)] and fireblight [*Erwinia amylovora* (Burnill)] were studied using Apple Descriptors, and standard morphometric and chemical methods. Regarding full flowering, the genotypes were classified from very early ('Jusuf Bećović') to late ('Tip 3' and 'Valjnika'). From the aspect of the fruit ripening time, all genotypes belong to the group of winter apples (from late September/early October to mid October). The average fruit weight ranged from 86.01 g ('Valjnika') to 135.21 g ('Tip 3'). The highest average fruit height and width were determined in 'Tip 3' and 'Jusuf Bećović' (58.51 mm and 68.12 mm, resp.), while the lowest was in 'Jusuf Bećović' and 'Valjnika' (50.77 mm and 56.67 mm, resp.). Regarding fruit quality among the assessed genotypes, the highest soluble solids content and total sugars were found in 'Jusuf Bećović' (15.10% and 12.83%, resp.). The highest content of total acids was found in 'Tip 3' (0.64%), accompanied with the lowest pH value (3.15%). 'Valjnika' showed low field susceptibility to scab and powdery mildew. All of the studied genotypes showed field resistance to fireblight, except for the 'Jevtović Milutin'.

Keywords: *Malus × domestica, autoshthonous genotype, biological properties, resistance*

Introduction

Apple (*Malus × domestica* Borkh.) is one of the most important fruit crops of temperate regions in the world with the cultivation history dating as early as 1000 BC (Zohary and Hopf, 2000). Apple germplasm is genetically and phenotypically diverse, due to the fact that multiple *Malus* species contributed to the cultivated apple and possession of self-incompatibility system leading to obligatory outcrossing. Brown (2012) stated that diversity within cultivated apple is a great benefit to breeders, as well as that older genotypes are used extensively to breed new, superior cultivars.

FRI, Čačak has a long tradition of collection, characterization, evaluation and utilization of indigenous apple genotypes, which can potentially provide useful genetic variability, especially for resistance and fruit quality traits (Marić *et al*., 2013). It is obvious that some of autochthonous apple genotypes carry useful genes which, if not preserved, will no longer be available. In recent years, there have been considerable advances in evaluation of autochthonous apple material at FRI, Čačak through the application of a uniform approach (Apple Descriptors) and the analysis of *ACS1* and *ACO1* genes encoding the enzymes that catalyse the two final reaction steps in the ethylene biosynthetic pathway (Marić *et al*., 2005), as well as *ETR1* gene encoding the ethylene receptor (Marić *et al*., 2007, 2015).

This work studied phenological and pomological properties, and field resistance to major causal agents of economically important diseases in five indigenous genotypes from the *ex-situ* Apple Collection of the FRI, Čačak.

Material and Methods

Five autochthonous genotypes ('Bošnjanka Sejanac', 'Jevtović Milutin', 'Jusuf Bećović', 'Tip 3' and 'Valjnika') from the Apple Fruit Collection of FRI, Zdravljak, near Čačak (Republic of Serbia) were analysed over a two-year period. The collection was established in 1986, at a spacing of 4 × 1.5 m. The apple genotypes were grafted on 'M26' rootstocks and planted three trees each.

The tree habit and fruit properties of the assessed genotypes were characterized using the Apple Descriptors of the International Board for Plant Genetic Resources (IBPGR, 1982).

The flowering phenophase was assessed by monitoring the onset, full and end of flowering (10% open flowers, 80% open flowers and 90% worn flowers, respectively) according to Wertheim (1996). The samples of 20 fruits in three replications per genotype were harvested randomly at the stage of physiological ripeness.

The fruit morphometric properties (fruit weight, height and width) were determined using the standard methods, whereas fruit shape index (height-to-width ratio) was calculated. The fruit chemical composition was assessed on the basis of the following parameters: soluble solids content – using the portable refractometer; total and invert sugars content – according to the Luff-Schoorl method (Egan *et al*., 1981); sucrose content – calculated as the difference between the total and invert sugars, multiplied by coefficient of 0.95; total acids content – expressed in malic acid (titration of 0.1 N NaOH with the presence of phenolphthalein as indicator); pH value of the fruit juice – using the CyberScan 510 pH meter.

The field susceptibility to causal agents of scab [*Venturia inaequalis* (Cooke) Wint.], powdery mildew [*Podosphaera leucotricha* (Ell. & Ev.)] and fireblight [*Erwinia amylovora* (Burnill)] was evaluated in accordance with the Apple Descriptors (IBPGR, 1982), on the scale from 1 to 9 (where 3 is low, 5 is medium and 7 is high susceptibility); the scale corresponds to the Van der Zwet scale and the portion of the tree blighted.

Fruit morphometric parameters were statistically analysed using the two-factor analysis of variance (ANOVA). The significance of differences among mean values was determined by Fisher's LSD multiple range tests at $P \leq 0.05$. Statistical analyses were performed using 'Statistica 10' software package (StatSoft, Tulsa, OK).

Results and Discussion

Based on Apple Descriptors (IBPGR), the assessed genotypes were characterised by the following biological properties:

'Bošnjanka Sejanac'. The tree is moderately vigorous, with spreading branches and intermediate to late blooming. It ripens in late September – early October. The fruit is small, flat-globose, of green ground colour and no overcolour. The flesh is of intermediate to good texture, pale greenish white, sweet to slightly acidic.

'Jevtović Milutin'. The tree is vigorous, with upright branches and intermediate to late blooming. It ripens in the first half of October. The fruit is small, globose-conical, of green-yellow ground colour with mottled dark red overcolour. The flesh is of a coarse texture, pale creamy white, sweet in taste.

'Jusuf Bećović'. The tree is moderately vigorous, with upright branches and very early blooming. It ripens in the second decade of October. The fruit is small to medium, flat, of a green-yellow ground colour and streaked with red blush. The flesh is of an intermediate texture, pale creamy white, slightly sweet in taste.

'Tip 3'. The tree is vigorous, with upright branches and late blooming. It ripens in the first half of October. The fruit is small, globose-conical, of green-yellow ground colour with mottled dark red overcolour. The flesh is of a coarse texture, pale creamy white, sweet in taste.
'Valjnika'. The tree is moderately vigorous, with upright branches and late blooming. It ripens in late September–early October. The fruit is small, globose-conical, of green ground colour and no overcolour. The flesh is of a coarse texture, whitish, slightly sweet in taste.
Blooming season of the assessed apple genotypes based on preliminary results over a two-year period is shown in Figure 1. The earliest average onset of blooming was recorded in 'Jusuf Bećović' (April 25th), while April 26th noted for the other apple genotypes. There was an approximately 7–day difference in full flowering between the earliest and latest genotypes. Among the studied local apple cultivars from southern Serbia, Mratinić and Fotirić Akšić (2011) reported a 16–day difference in full bloom. Regarding full flowering, the genotypes were classified into three groups, from very early – 'Jusuf Bećović' to late – 'Tip 3' and 'Valjnika'. Blažek *et al.* (2015) pointed out that late blooming apple genotypes should be favoured because of their capacity to avoid a risk of crop loss due to late spring frosts. Nevertheless, the late flowering of apple genotypes is in connection with reducing the risk of fire blight spread (Aldwinkle *et al*., 1976).

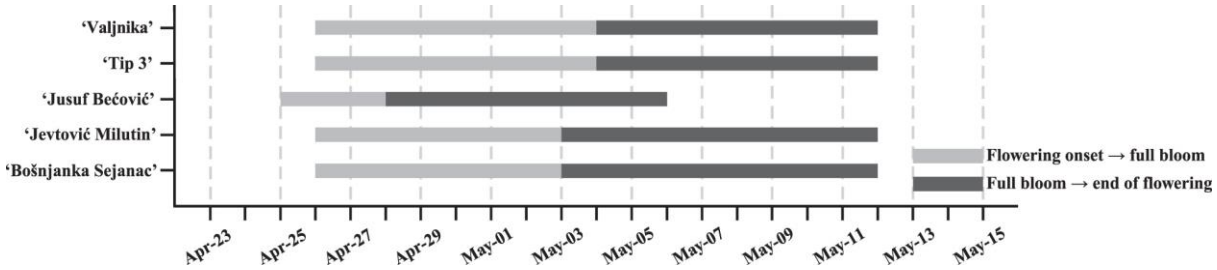

Figure 1. Flowering phenophase of the assessed apple genotypes.

Regarding the ripening time, the genotypes were classified into late ('Bošnjanka Sejanac' and 'Valjnika') and very late apples ('Jevtović Milutin', 'Jusuf Bećović' and 'Tip 3'). Apple is a climacteric fruit and its ripening is physiologically related to internal levels of ethylene. Based on studies of genes involved in ethylene biosynthesis and perception, Marić *et al.* (2005, 2007, 2015) reported the *ACS1*, *ACO1* and *ETR1* genotypes in some Serbian autochthonous apple genotypes and pointed out that the allele *d* of *ETR1* gene was identified only in the indigenous genotypes, i.e. 'Tip 3', but not in commercially grown apple cultivars.
Based on the fruit size, the genotypes were classified as small and small to medium, whereas the average fruit weight ranged from 86.01 g ('Valjnika') to 135.21 g ('Tip 3'). Variability in average fruit weight in autochthonous apple cultivars, as one of the most important properties, was confirmed by Gaši *et al.* (2011), Mratinić and Fotirić Akšić (2011) and Pirlak *et al.* (2003), who reported that the fruit weight varied from 97.90 g to 276.18 g, 70.0 g to 193.3 g and 49.5 g to 152.2 g, respectively. The statistical significance of the impact made by the variability factors interaction points to the fact that the expression of the genotype-specific properties related to the fruit weight, height, width and shape was modified by uneven influence of agro-ecological conditions prevailing in corresponding years (Table 1). Since apple is self-incompatible fruit crop, certain impact made by pollenizers (metaxenia effect) on the fruit morphometric properties is presumed (Kumar *et al*., 2005; Lukić and Marić, 2014), which could have also contributed to a total effect of manifestation of the variability factors interaction.

Table 1. Morphometrical properties of the assessed autochthonous apple genotypes.

The fruit chemical composition of the assessed autochthonous apple genotypes is shown in Table 2. The highest soluble solids content and total sugars were found in 'Jusuf Bećović' (15.10% and 12.83%, respectively), whereas inverted sugars and sucrose content ranged from 7.95% ('Bošnjanka Sejanac') to 9.52% ('Jevtović Milutin') and 2.65% ('Tip 3') to 3.75% ('Bošnjanka Sejanac'), respectively. The fruit of the 'Tip 3' genotype is characterised by the highest content of total acids (0.64%), accompanied with the lowest pH value (3.15%). Apple taste is mostly related to the balance between sugars and acids. According to Goodenough and Atkin (1981), the high quality dessert apples are in medium acid category (pH 3.2–3.5) and have a relatively high sugar content (14–16%), whereas the best cooking apples have high acidity (pH 2.8–3.2) and moderate sugar content (11–13%). Since the cultivars with sugar/acid ratio lower than 20 are suitable for processing, genotype 'Tip 3' can be recommended for this purpose, whilst 'Bošnjanka Sejanac', 'Jevtović Milutin', 'Jusuf Bećović' and 'Valjnika' are suitable for fresh consumption. Slightly higher values of soluble solids content (12.55–19.24%) of some autochthonous apple cultivars collected in southern part of the Republic of Serbia were stated by Mratinić and Fotirić Akšić (2011).

Table 2. Fruit chemical composition of the assessed autochthonous apple genotypes (average for a two-year period).

Genotype	Soluble solids (%)	Sugar content (%)			Total acids (%)	pH value
		Total	Inverted	Sucrose		
'Bošnjanka Sejanac'	13.98	11.89	7.95	3.75	0.49	3.28
'Jevtović Milutin'	15.05	12.45	9.52	2.78	0.26	3.71
'Jusuf Bećović'	15.10	12.83	9.45	3.68	0.47	3.16
'Tip 3'	14.05	11.33	8.54	2.65	0.64	3.15
'Valjnika'	14.50	11.83	8.09	3.63	0.13	4.43

The assessed apple genotypes showed a wide range of field susceptibility to scab, powdery mildew and fireblight (Figure 2). With regard to scab susceptibility, the genotypes can be classified into three groups, from 4–6% (2 on the scale) to 76–88% (7 on the scale). 'Valjnika' showed low field susceptibility to *Venturia inaequalis* (Cooke) Wint. (2 on the scale). Medium and high scab susceptibility was observed in one (6 on the scale) and three genotypes (7 on the scale), respectively. Regarding susceptibility to powdery mildew, the genotypes were divided into two groups, from 4–6% (2 on the scale) to 7–12% (3 on the scale). All of the studied genotypes showed low mildew susceptibility (ranging from 2 to 3 on the scale). The best performance in terms of field resistance to *Podosphaera leucotricha* (Ell. & Ev.) was observed in 'Jusuf Bećović' and 'Valjnika' (rated 2 on the scale). Field resistance to fireblight (rated 1 on the scale) was observed in all of the assessed apple genotypes, except for 'Jevtović Milutin'. This genotype showed medium susceptibility (rated 4 on the scale) to *Erwinia amylovora* (Burnill).

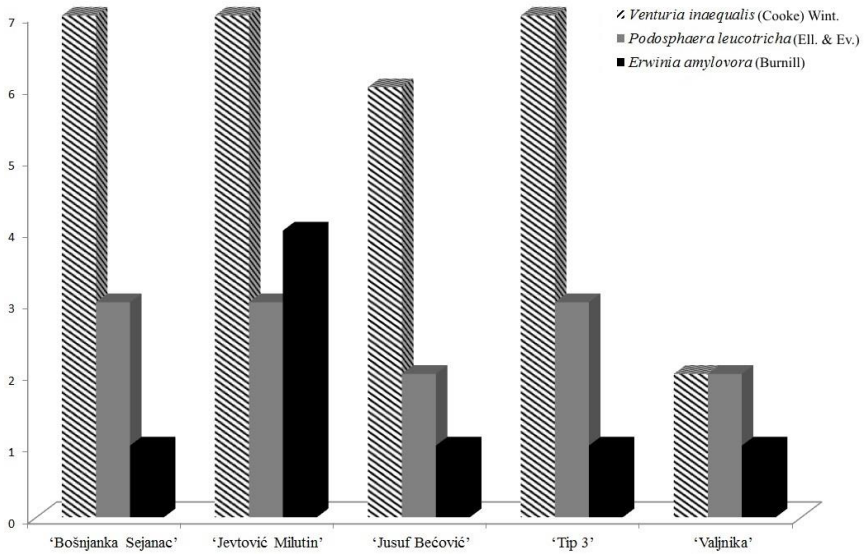

Figure 2. Susceptibility of autochthonous genotypes to causal agents of economically important apple diseases under field conditions.

Conclusions

The assessed autochthonous apple genotypes in this study with useful traits have substantial potential to be used as parents in future apple breeding programmes. Further studies should aim to continue research in the field of collection, evaluation using standard and novel molecular methods, as well as utilization of autochthonous apple genotypes for different purposes.

Abstract

Soybean is one of the most important legumes. Due to the extremely favourable chemical composition of the grain, surfaces under soybean in the world and in Republic of Serbia are showing a tendency to increase. Soybean is cultivated for the production of grain or green fodder, whole plant silage, in regular or second cropping. When cultivated for green fodder and silage, it is grown alone or in a mixture with maize, sorghum, and other crops. As green fodder it retains high quality proteins, vitamins and is useful in feeding livestock. In this study, two soybean varieties with different vegetation were examined in order to determine which one has higher biomass yields when grown as a second crop in agro-ecological conditions of Serbia intended for conservation by ensiling. Based on research results, it is evident that the variety had a statistically significant effect on plant height and dry matter yield. Average dry biomass yield was 5307.17 kg ha^{-1}. Higher dry biomass yield (6630.57 kg ha^{-1}), plant height (64.92 cm), the height of the first pod (7.76 cm) and weight of the plants (130.00 cm) was recorded in the variety with a longer vegetation (Valjevka) while the variety with short vegetation (NS Kaća) had higher percentage of dry matter. The differences obtained were significant, and indicate the possibility of achieving higher plants and higher yields of dry biomass by planting varieties with longer vegetation period as second crop.

Key words: *soybean, second crop, morphological characteristics, biomass yield*

Introduction

Soybean contains is widely used in the diet of humans and domestic farm animals, and in many industries. Soybean is one of the most important legumes that are used in the production of more than 20,000 products for human consumption, in nutrition of domestic farm animals and it is also used for industrial processing. Soybean has huge agro-technical character. Thanks to the symbiosis of soybean with a specific nitrogen-fixing bacteria, *Bradyrhizobium japonicum*, living on its root, it satisfies up to 70% of its nitrogen requirements, and also enriches the soil by this ingredient. Therefore, the soybean is highly valued as the preceding crop in the rotation for many other crops, especially cereals (Popović (2010, 2015), Popović et al. (2013) and therefore plays an important role in the system of climate smart agriculture.

As green fodder it contains high quality proteins, vitamins (A, B1, B2, C, D, E, K) and is useful in feeding livestock (Gagro and Herceg, 2005). All this makes soybean extremely valuable in nutrition of domestic farm animals, especially in combination with silage maize, which has low content of proteins of low biological value. Soybean is cultivated for the production of grain or green fodder, whole plant silage, as regular or second crop. For green fodder or silage it is grown alone or in a mixture with maize, sorghum, and other crops.

Terzić et al. (2001), state that the soybean grown in the system of intercropping with maize and cultivated as a second crop achieved by 16% higher yield (LER = 1.16) than when maize and

soybean crops are grown separately. Terzić et al., (2014) state that a mixture of maize and soybean formed more $MJha^{-1}$ compared to the mixture of soybean grown with sorghum.
Livestock consume readily soybean as fodder, particularly late maturation varieties/cultivars, leafy and with large habitus. Soybean in the green state has favourable impact on smell and taste of milk (Gagro 1997, Glamočlija et al. 2015, Zivanovic & Popovic, 2016).
Dinić et al. (1999) state that when biomass soybean silage is mixed with maize the ensiling of soybean is successful and that the share of soybean should not exceed 50%.
Market has a wide range of high yielding varieties that can be adapted to the purpose of cultivation. In the main sowing/planting, the varieties of longer vegetation (II, I and 0) are commonly used in regular cropping, and early varieties (00 and 000) in second cropping.
In the model of the second crop, varieties of shorter vegetation period are recommended so that they could mature before the end of the season. However, for ensiling, soybean before grains maturation is used and it should be further inquired which soybean varieties are better adapted to such a system of cultivation.
In this study, two soybean varieties were examined in order to determine which one has higher yields when grown as a second crop in agro-ecological conditions of Republic of Serbia and is intended for conservation by ensiling.

Material and methods

The studies were conducted in 2015, on the production areas of the Correctional facility for youth in Kruševac. Two varieties were planted: NS Kaća (000 MG) and Valjevka (0 MG). Varieties, NS Kaća and Valjevka, were created at the Institute of Field and Vegetable Crops in Novi Sad. For NS Kaća, the duration of the growing/vegetation period is about 105 days and for Valjevka 120 days. Varieties have coarse grain, with an average weight of 1000 grains of 180-200 g (Popović et al., 2016). The experiment was set up as a single factorial design–the varieties were the factor. The studies were conducted by a block system in five repetitions. Soybean was planted/sowed at a distance of 70 cm. The amount of 30 kg N, 30 kg P_2O_5 and 30 kg K_2O per hectare were incorporated into soil. The crop is grown under irrigation. The following parameters were observed in the research: plant height-stem-cm, height of first pod-cm, the weight of above ground parts of the plant-g, dry biomass yield-kg/ha, participation of leaves, stems and pods, %. The obtained results were analysed by descriptive statistics and analysis of variance using the statistical package Statistica for Windows 12. The most important characteristics are presented in tables and graphs.

Results and Discussion

Meteorological conditions during the trial

The required amount of water necessary during the soybean vegetation period ranges around 450 mm, and is especially important in the summer, June-August, when there were optimal amounts of rainfall (Popović, 2010). The vegetation period of 2015 (April-September) on the territory of Serbia was warmer with less precipitation compared to the multiannual average (Graph 1). Summer 2015 (June-August) was characterized by warmer weather than usual with much less rainfall in relation to multiannual average. In addition to the unfavourable quantity, also the distribution of rainfall during the summer was unfavourable.

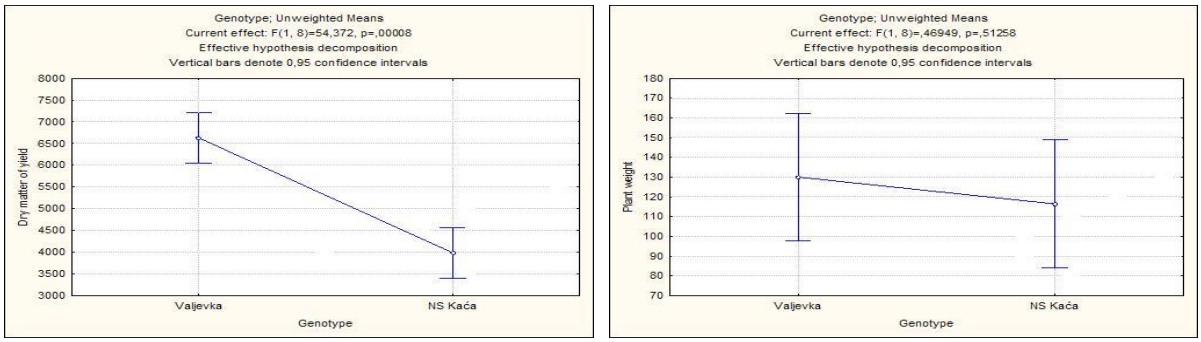
Dry matter of yield, kg ha^{-1} *						
NS Kaća	5	**3,983.76**	597.15	267.05	3242.2	4725.98
Valjevka*	5	**6,630.57**	536.32	239.85	5964.64	7296.51

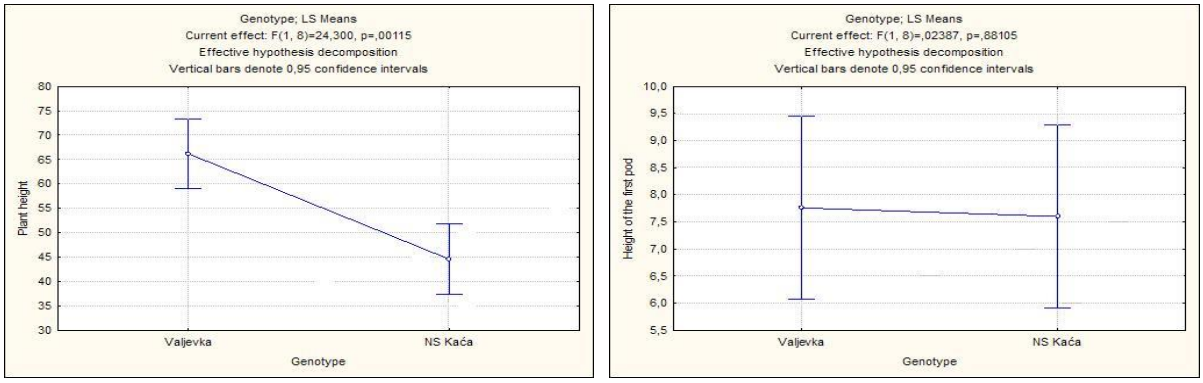
LSD	Plant height	Height of the first pod	Plant weight	Share leaf	Share stem	Share pod	Dry matter percentage	Dry matter of yield
0.5	10.11	2.39	45.77	0.015	0.019	0.123	1.924	827.74
0.1	14.70	3.47	66.59	0.021	0.027	0.179	2.799	1204.28

Significantly higher dry mass yield (6630.57 kg ha^{-1}), plant weight (130.00g), was recorded for the variety Valjevka compared to the cultivar NS Kaća (3983,76 $kgha^{-1}$), Graphs 2 and 3.



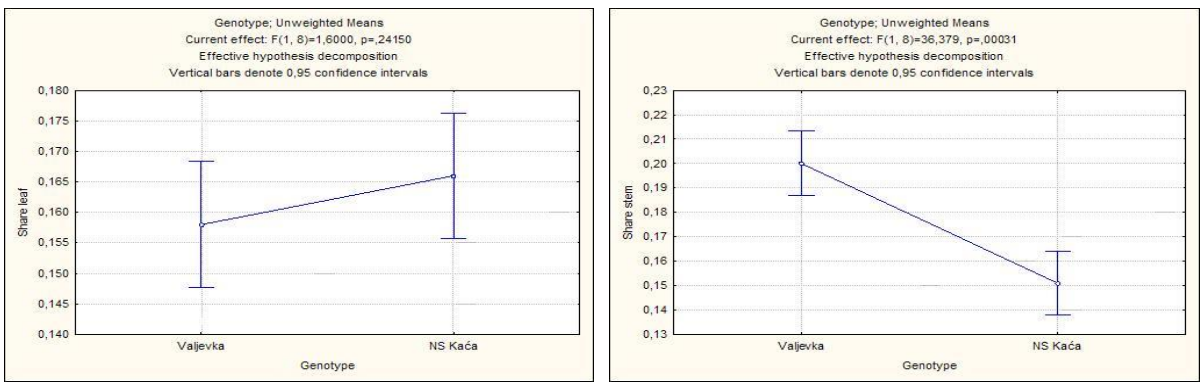
Graph 2 and 3. The effect of the variety on the plant weight and dry matter yield

The differences dry mass yield were significant, and indicated the possibility of achieving higher plants and higher yields of dry mass by planting varieties with longer vegetation period, Tab. 1. The results obtained by Terzić et al. (2001, 2003), are within the mentioned limits; the variety of shorter vegetation/growing period (Danica) grown as a second crop achieving 4563 $kgha^{-1}$.



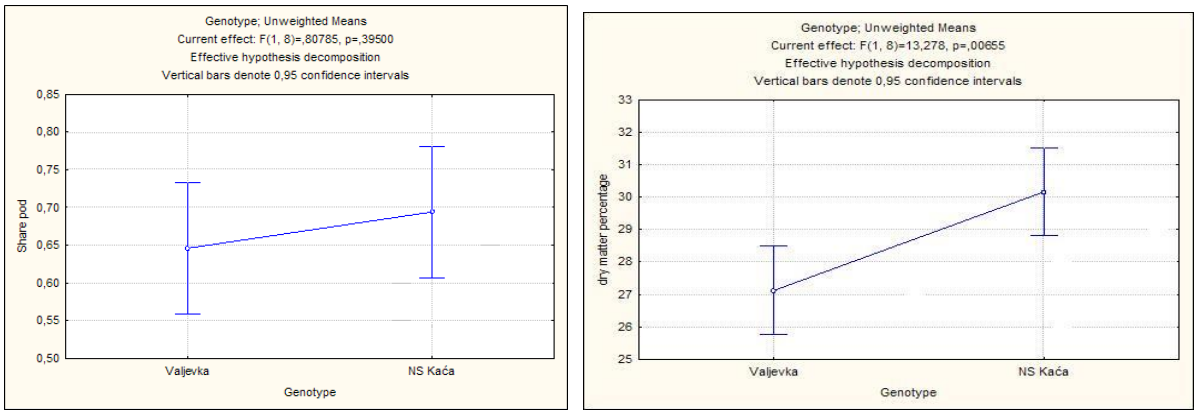
Graph 4 and 5. The effect of the variety on plant height and height if the first pod

Significantly higher plant height (64.92 cm), was recorded for the variety Valjevka compared to the cultivar NS Kaća (44.52 cm), Graph 4. The standard error for the height of the plants was, on average, 4.15, Table 1, Graphs 4. The average plant height was 54.72 cm, while the plant weight on average was 123.20 g. Weight plants showed a significant correlation with an overall yield (Tab.2). The standard error for the plant weight was on average 0.641, Table 1, Graph 3.



Graph 6 and 7. The effect of variety on the share of leaves and stems

NS Kaća variety had a higher share of pods (69.40%) compared to the variety Valjevka (64.60%), Graph 8. The cultivar Valjevka had a greater height of the first pod (7.76 cm), which is important because of the losses in the ensiling process. It is preferable that the height of the first pod is greater in order to reduce the losses. NS Kaća had higher share of leaves (16.60%) compared to the variety Valjevka (15.80%), Graph 6. The variety Valjevka had a statistically significantly higher share of stems (20.01%) compared to the cultivar NS Kaća (15.10%), Graph 7. Variety NS Kaća showed higher (30.16%) percentage of dry matter, than Valjevka (27.12%) Table 1 and Graph 9. The dry matter difference is statistically significant, but this not much of a influence on the quality of ensilage process.



Graph. 8 and 9. The effect of variety on the share of pods and dry matters

Correlations between studied traits/characteristics

Positive correlations between examined parameters of soybean are recorded in the study. The yield of dry matter was highly positively correlated with the plant height (r =0.76*). Also, a positive significant correlation was achieved between the height of plants and weight (r =0.64*), Table 2.

Table 2. Correlations between studied traits

Variable	*Dry matter of yield*	*Plant height*	*Height of the first pod*	*Plant weight*
Dry matter of yield	*1.00*	*0.76**	*0.24 ns*	*0.08 ns*
Plant height	*0.76**	*1.00*	*0.12 ns*	*0.64**
Height of the first pod	*0.24 ns*	*0.12 ns*	*1.00*	*0.14 ns*
Plant weight	*0.08 ns*	*0.64**	*0.14 ns*	*1.00*
*ns- non significant; * - significant at 0.5*				

Non-significant positive correlations were recorded between other investigated parameters, Table 2. Similar results were obtained in studies and Popović et al. 2012 and 2013. The authors state that the significant interactions of the examined factors suggest that the factors mutually synergized their effects ((p<0.05). Yield was positively correlated with oil content (0.37), the height of first pod (0.22) and the plant height (0.07) and negatively correlated with protein content (-0.34) and the 1000-grain weight (-0.27).

Conclusion

Based on the research results, in regard to the silage, and in order to obtain the better yield, the following can be concluded:

- Variety had a statistically significant effect on plant height and dry mass yield.

- Second crops can provide a significant amount of quality forage. The average dry biomass yield was 5307.17 kg ha^{-1}. Higher dry biomass yield (6630.57 kg ha^{-1}), plant height (64.92 cm), the height of the first pod (7.58 cm) and plant weight (129.25 cm) were recorded for the variety Valjevka while the variety NS Kaća had higher percentage of dry matter had.
- The variety NS Kaća had statistically significantly higher percentage of dry matter (30.16%) compared to the variety Valjevka (27.12%).
- Dry matter yield was highly positively correlated with plant height (r=0.76*). Also, a positive significant correlation was realized between the height of plants and weight (r=0.64*).
- Based on the test results of the study of two varieties of different vegetation period, grown as a second crop and intended for biomass production for silage, variety with longer vegetation showed better results in terms of yield per unit area, plant height, plant weight and height of first pod.

Abstract

Wheat production area is not to large but environmental factors varies across location. Biotic and abiotic stress affected grain yield and agronomic characters of wheat cultivars. This research was carried out to determine of the yield, some agronomic, quality and leaf disease traits of the bread wheat genotypes. This research was established with 25 genotypes in randomized completely blocks experimental design with 4 replications and at three locations in Edirne, Kırklareli and Lüleburgaz in Trakya region in 2007-2008 growing season. In this research, grain yield, days to heading and days to maturating, plant height, lodging resistance, thousand kernel weight, test weight, protein, sedimentation, leaf rust, powdery mildew, and relationship between these characters were investigated. According to the results it was found significant differences among location, genotypes and studied characters. The mean yield of the genotypes was 664.5 kg/da. Kate A-1 had the highest yield with 753.7 kg/da over three environments. Edirne was the highest yielding (808.3 kg/da) location. Grain yield was significantly negative correlated with protein ratio (r = -0.689**). There was a negative correlation between days to heading with TKW (r= -0.479*), protein content (r= -0.288) and sedimentation (r= -0.340). Also, it was found significant relation between days to maturating and protein content (r= -0.445*) and sedimentation (r= -0.514**). Plant height was also correlated with thousand kernel weight (r= 0.539**) and test weight (r= 0.731**). Leaf rust negatively affected TKW and test weight, also there was negative relation between leaf rust with days to heading and maturating, plant height. The higher infection of Leaf rust was determined in Edirne and there were differences among location and genotypes.

Key words: *Bread wheat, genotypes, yield, quality, leaf disease*

Introduction

Bread wheat is an important crop is grown in Trakya region (Turkey) and it covers 5-6% of the total wheat area of Turkey. Wheat production area is about 650.000 hectares and average wheat yield is almost 5.0 tons/ha per year in the region (Anonymous, 2012). Genotype-environment (GE) interactions are extremely important in the development and evaluation of plant varieties because they reduce the genotypic stability values under diverse environments (Hebert et al., 1995). Almost all breeding programs in the world aim to improve varieties with stable yields. The yield stability is generally grouped as static or dynamic stability (Pfeiffer and Braun, 1989). Consistency in yield has always been a problem in crop production due to the strong influence of environmental effects during the various stages of crop growth (Yan and Hunt, 2001; Viana and Cruz, 2002). In bread wheat varieties for irrigated environments, it must be decided whether to select directly in the irrigated or indirectly in a rainfed environment. In addition, it is concluded that thousand seed weight and test weight values of wheat will be selected by indirect selection in rainfed conditions (Tosun at al., 2006). In

wheat, grain yield and baking quality are dependent on the environment, genetic factors and the interaction between them (Yan; Holland, 2010; Coventry et al., 2011). On the other hand, both the quality and the content of the wheat protein are affected by the climatic conditions during wheat maturation (Johnson et al., 1972; Johansson and Svensson, 1988). Success of a wheat breeding program depends on the regional adaptability of the cultivars improved and adaptability of such cultivars in the target environments determined by its tolerance to biotic and abiotic stresses (Altay, 2012). Leaf rust caused by *Puccinia triticina* is one of the most important and widespread diseases of common wheat (*Triticum aestivum* L.) worldwide. It is adapted to a wide range of environments occurs wherever wheat is grown, and can cause significant yield and economic losses (Wamishe and Milus, 2004). The purpose of the present study was to investigate the some agronomical and quality characteristics of some widely cultivated varieties and advanced lines. In addition to some of biotics stress factors and relationship between these characters were investigated.

Materials and methods

The experiment was conducted at three locations in Trakya region (Turkey) in 2007-2008 growing seasons. Twenty five winter wheat genotypes, 6 of them were local check and 19 advanced lines, were examined under field condition, with RCBD with four replications. All plots were sown into 6 rows, and plot sizes were 6 m^2 at harvesting. In the experiment 500 seeds/m^2 was used at planting. Sowings were performed by using a plot drill and fertilizer was applied at three times. Also, chemical was used for weed control.

Table 1. Precipitation and temperature of the 2007-2008 growing year in three locations

Months	Rainfall (mm)			Mean temperature (^oC)		
	Edirne	Kırklareli	Lüleburgaz	Edirne	Kırklareli	Lüleburgaz
October 2007	40,5	56,8	22,0	15,2	16,1	15,4
November 2007	147,1	97,3	98,7	8,1	9,1	8,7
December 2007	85,0	53,0	55,0	2,7	3,6	3,2
January 2008	32,4	25,8	30,4	1,1	2,0	1,4
February 2008	2,8	0,3	6,7	4,4	4,4	4,3
March 2008	31,3	49,8	38,3	10,9	9,8	10,1

June 2008	45,7	68,4	90,4	23,3	22,4	22,7
Total/Mean	462,3	421,2	458,1	10,9	10,9	10,8

In this research; grain yield, plant height, days of heading and maturating were investigated. Also, 1000 kernel weights, test weight, protein ratio (Perten H. 1990) and sedimentation (Köksel et al., 2000; Anonymous, 1990) were investigated. The genotypes evaluated under natural field condition and reaction types and rust levels scored using the Modified Cobb scale (Peterson et. al., 1948; Roelfs et al., 1992; Saari and Prescott, 1975; Stubbs et al., 1986; Prescott et al., 1986) in three locations. A uniform epidemic was achieved and susceptible genotypes were rated as 80-100S. For powdery mildew (Jin Y., 2011; Mclntosh et al., 1995) determining double digit (00-99) scale was used. The statistical analyses of measurements data was performed by using statistics program and the differences among the means were compared with LSD at a 5% significant level (Kalaycı, 2005).

Results and discussion

The results of variance analysis are presented in Table 2. There was statistically difference among genotypes in yield according to all locations. The mean yield was 664.5 kg/da. According to location the highest yield were obtained in Edirne (808.3 kg/da) and the lowest yield in Kırklareli with 452.6 kg/da. The highest grain yields were determined in Kate A-1 cultivar with 753.7 kg/da. Other highest yielding genotypes were Gelibolu and entry number 22, 23 and 24 lines. Based on GxE interaction the highest yield was determined in Kate A-1 and Gelibolu cultivars with 936.8 kg/da and 903.0 kg/da respectively in Edirne location.

Wheat leaf rust is the most destructive and widespread diseases in Trakya region and susceptible cultivars leading to serious yield losses. There were differences among location according to leaf rust *(Puccinia recondita)* infection. There is a high incidence of wheat leaf rust in Edirne location because of suitable environmental condition in spring, and disease severities on susceptible varieties reached 80%. In Kırklareli and Lüleburgaz location there is generally a low incidence. Among genotypes ten genotypes were resistant in Edirne location including Tekirdağ cultivar. Nineteen genotypes were resistant to leaf rust in Kırklareli and fifteen genotypes were resistant, 6 genotypes moderately resistant to leaf rust in Lüleburgaz location. Five genotypes were resistant to leaf rust at three locations (Table 1).

Powdery mildew is considered of economic significance only in areas with high rainfall where the climate is favourable for disease. Powdery mildew caused by *Bluminera graminis* DC f. sp. *tritici* is an important disease of wheat (*Triticum aestivum*) growing area. Powdery

mildew disease usually occurs from February to April depending on the growing area, variety planted, and environmental conditions in Trakya region. There were differences among location and genotypes according to powdery mildew (*Bluminera graminis*) infection. In this study especially suitable environmental condition high infection of powdery mildew occurred in Kırklareli location. Five genotypes (entry number 16, 17, 18, 23 and 24 lines) and Tekirdağ cultivar tolerant to powdery mildew over three locations (Table 1).

Note: Significance at **: P<0.01 and *:P<0.05; GY: Grain yield (kg/da), DH: Days of heading, DM: Days of maturating, PH: Plant height (cm), LOD: Lodging resistance (1-9), TKW: Thousand kernel weight (g), TW: Test weight (kg), PRT: Protein ratio (%), SED: Sedimentation (ml), PM: Powdery mildew (0-99), LR: Leaf rust

In this study it was investigated in order to determining correlation coefficient of the characters. It was found significant relation among investigated parameters. There was slightly positive relation between grain yield and plant height (r=0.150), test weight (r=0.187) and negative relation with powdery mildew (r=-0.312). It was found significant negative relation between grain yield and protein ratio (r = -0.689). Days to heading was also negative correlated with thousand kernel weight (r= -0.479*), protein content (r= -0.288) and sedimentation (r= -0.340). Also it was found significant negative relation between days to maturating and protein content (r= -0.445*) and sedimentation (r= -0.514**). These results showed that earliness in genotypes have advantages for better quality. There was positive highly significant correlation between plant height and 1000-kernel weight (r= 0.539**) and test weight (r= 0.731**). Leaf rust in genotypes negatively affected almost all parameters yield, plant height, TKW and test weight, excepted protein ratio and sedimentation. Leaf rust was negative correlated with days to heading and days to maturating (Table 2).

Plant height is an important trait to evaluation genotypes especially for lodging resistance. Lodging is one of the mainly problem in Trakya region. In this study plant height ranged from 71.7 cm up to 115.0 cm and mean was 90.7 cm. Earliness is other important characters because of to grow forage crops within same growing cycle in the region. There was significant difference among genotypes according to earliness. Mean of the heading days was 125.6 days and maturating days 164.4 days. Heading days ranged from 120.3 days up to 133.3 days and maturating days from 161.7 to 170.3 days (Table 3).

Some quality parameters were investigated. These characters are affected by environmental conditions, agronomic practice and genotypic traits. Grain weight and test weight in wheat varies by cultivar x genotypes interactions. There was a wide variability both in thousand kernel weights and test weight. In this study 1000 kernels weights ranged between 27.5 g (Entry 18) and 44.0 g (Pehlivan). The mean thousand kernels weights was 35.9 g. (Table 3).

Test weight of the genotypes ranged between 75.4 kg and 82.8 kg, while mean test weight was 79.3 kg. The highest test weight was obtained from Bezostaya, which is followed by Kate A-1, Gelibolu and Pehlivan cultivars (Table 3). Table 3 shows mean and ranges of variation for protein ratio in all genotypes were evaluated during 2007-2008 at three locations. Protein ratio ranged from 12.0% to 15.0% among genotypes and mean protein was 13.5%. The highest protein ratio was measured in Bezostaya cultivar. Sedimentation ranged in genotypes from 33.7 ml to 54.3 ml and the highest test weight scaled in entry number 11 and Flamura-85 genotypes. The mean sedimentation was 44.3 ml (Table 3).

Figure 1. Relationship between some investigated characters

Grain yield, some physiological, agronomic and quality traits which was investigated in this study, was affected from environmental fluctuations. In this research these characters were examined and assessed for relationship amongst them. As it expected there was negatively relation between grain yield and protein ratio (R^2=0.474), and positive relationship between grain yield and plant height (R^2=0.473). It was found highly positive relation between plant height and lodging resistant (R^2=0.866), it means that genotypes which have short plant height resistant to lodging. There was negative relation between earliness and 1000 kernel weight (R^2=0.229) (Figure 1). Leaf rust in wheat negatively affected and decreased test weight and thousand kernel weight.

Conclusion

Wheat yield potential in Trakya region changes across region due to various environmental conditions. Because of various environmental conditions there was significant difference among genotypes and locations over studied characters. Grain yield was significantly negative correlated with protein ratio. There was a negative correlation between days to heading with thousand kernel weight, protein ratio and sedimentation value. Also, it was found significant relation between days to maturating and protein content and sedimentation value. These results showed that earliness in genotypes have advantages for better quality in Trakya region. Plant height was also positive correlated with thousand kernel weight and test weight. The higher infection of leaf rust was determined in Edirne and there were differences among location and genotypes. Leaf rust in genotypes negatively affected almost all parameters grain yield, thousand kernel weight and test weight. Leaf rust negatively affected and reduced 1000-kernel weight and test weight. Also, there was negative relation between leaf rust with days to heading and maturating so earliness in genotypes has disadvantages for rust disease in Trakya region.

Abstract

The yield of any crop is directly or indirectly a function of the interaction between the crop's genotype and the existing climatic and ecological factors. This study was carried out to determine the performances of some sesame cultivars under Igdir plain ecological conditions in Igdir - Turkey, 2012. Cumhuriyet-99, Kepsut-99, Muganlı-57, Orhangazi-99, Osmanlı-99, Tan-99, Tur-S-90 and Tur-S-203 varieties were used as trial materials. The study was conducted in the Randomized Blocks Experimental Design with three replications to investigate plant height, number of branch per plant, first pod height, pod length, pod width, number of pod per plant, number of seed per pod, 1000 seed weight and seed yield. Results of experiment revealed that all investigated properties showed significant differences among the genotypes. Plant height varied among 121.0-147.1 cm, number of branch 3.6-7.2, first pod height 43.6-67.1 cm, pod length 25.3-28.6 mm, pod width 4.8-6.5 mm, number of pod per plant 56.1-125.5, number of seed per pod 53.2-72.3, 1000 seed weight 2.85-3.67 g and seed yield 523.3-1005.9 kg ha^{-1}. The highest seed yields were obtained from Orhangazi-99 while the lowest seed yield was recorded from Tan-99.

Keywords: *Sesame, Sesamum indicum, variety, yield, yield components*

Introduction

Sesame (*Sesamum indicum* L., Pedaliaceae) is an important ancient annual spice and oilseed crop which is widely cultivated all over the world for its seeds. Sesame seeds contain about 40-60% (Doğan and Zeybek, 2009) oil and 20-30% of protein (Öz and Karasu, 2010). In general, it has high stability and quality oil which contains about 47% oleic acid (C18:1), 39% linoleic acid (C18:2), 9.0% palmitic acid (C16:0), 4.1% stearic acid (C18:0), and 0.7% arachidic acid (C20:0) (Weiss, 1983). As a "queen of oilseeds" (Al-Yemeni *et al.*, 2000), it was cultivated during ancient Harappan, Mesopotamian, and Anatolian eras, and throughout the Graeco-Roman world (Bedigian, 2003) for its high oil yield, mildness and pleasant taste (Al-Yemeni *et al.*, 2000) and also because of its rich and nutty flavor it is a common ingredient in cuisines across the world (Obiajunwa *et al.*, 2005). As a good source of protein and fat for humans and livestock (Adebisi *et al.*, 2005) sesame seeds are also used in baking and making candy, while its oil in addition to cooking is used in the manufacture of perfumes, pharmaceuticals, soaps, insecticides, paints (Alege *et al.*, 2013; Amara *et al.*, 2008).

Sesame has many species, most of them are wild and native to Turkey. The cultivated type is *Sesamum indicum which* originated in India and is tolerant to drought-like conditions, where other crops fail in Turkey. Sesame is known as a medicinal and spice oilseed crop in Turkish culture. Because of its high production cost and low yield, it has a limited production, therefore, its oil is not commonly used in meals in Turkey, instead, its seeds are mostly used in tahini and halvah production and also, sesame is the only condiment of world famous the Turkish bagel (simit). Despite, its most and widely consumption, the sesame production is far below the need of the country. Turkey sesame production deficit are tried to close by imports whereas even the half of annual needs of Turkey cannot be provided (Doğan and Zeybek, 2009; Şahin, 2014).

It is one of warm-season crops, and must be sown after last frost days; it adapts well to high temperatures, but it cannot tolerate waterlogged soil (Bedigian and Harlan, 1986). It need optimum 20-25 ^{o}C of soil temperature for germination. So in eastern Anatolia only some plain which has microclimate conditions ensure this temperature during germination in spring months. Therefore, it is necessary to determine the varieties with high seed yield in ecology where it can grow well. Iğdır plain is one of the most suitable one where sesame can easily be cultivated.

The aim of this study was to evaluate the best sesame cultivar which could be well adapted to conditions of Iğdır Plain (Turkey).

Material and Methods

Iğdır is a province in eastern Anatolia-Turkey, located along closed border with Armenia which follows Aras River, Azerbaijan (the area of Nakhichevan Autonomous Republic), and Iran. Its adjacent provinces are Kars to the northwest and Ağrı to the west and south. It occupies an area of 3.587 km². Because of its mountains, Eastern Anatolia average altitude is approximately 2 000-2 200 m. Therefore, it was called as "Roof of Turkey". Turkey's highest mountain, Mount Ararat (Ağrı Dağı) is in Iğdır, but much of the land is a wide plain far below the mountain which has lowest altitude (850 m) of Eastern Anatolia Region-Turkey. Therefore, it has a warmest climate in this part of Turkey where cotton can be grown.

The study was carried out at the trial field of Agricultural Research and Training Center (lat. 39° 55'-N, long. 44° 5'-E and the alt. 851 m above sea level) of the Iğdır University, Turkey during 2012 growing season in order to compare the sesame varieties adaptation performance according to some quantitative properties (plant height, number of branch per plant, first pod height, pod length, pod width, number of pod per plant, number of seed per pod, 1000 seed weight and seed yield).

The soil samples, where the research took place, were taken to identify physical and chemical characteristics of the research field which results are presented in Table 1.

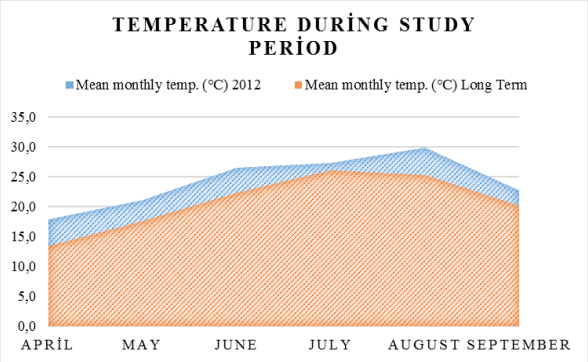
Table 1. The soil characteristics of the research field

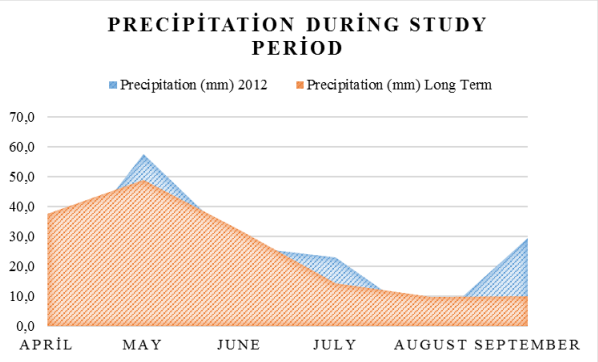
Soil texture (Type)	**EC** (mmhos/cm)	**pH**	**Lime** ($CaCO_3$) (%)	**Total N** (%)	**Organic matter** (%)	**Available plant nutrients (kg ha^{-1})**	
						P_2O_5	K_2O
Clay - Loam	1.85	7.99	11.81	0.98	2.1	34	271

As can be seen in Table 1, the soil type is clay-loam with a pH of 7.99 and low organic matter.

The meteorological data during the study periods in 2012 are presented in Figure 1. The averages of monthly mean temperatures during the growing period (April-September) consistently higher than Long Term (LT). The higher temperatures were observed during the reproductive stages. As

seen in Figure 2, the total precipitation (153.2mm) of 2012 was approximately similar to the long-term. Monthly precipitation differed in 2012 at the growth stages. During the vegetative stages (May, July and September), the crops received higher precipitation in 2012 than in LT. However, the plants received lower precipitation during reproductive stages (April, June and August) in 2012 compared to LT (Figure 2). The average of relative humidity (64.2 %) of 2012 was higher than the LT average (48.4).





The study was conducted with a total of 8 varieties containing yellow (Tur-S-90, Tur-S-203, Muganlı-57 and Orhangazi-99) and white (Cumhuriyet-99, Kepsut-99, Osmanlı-99 and Tan-99)(Tan, 2011) sesame groups in 2012 growing season in Iğdır Plain based on Randomized Complete Block Design with three replications. The experimental plots consisted of four rows 4 m in length 65 cm apart and were sown by hand at 30 May in 2012. Sprinkler irrigation was maintained immediately after sowing and thereafter used when necessary based on soil and plants conditions. Nitrogen, phosphorus and potassium were applied at a rate of 70kg ha^{-1} at sowing. The half of nitrogen fertilizer was applied during seedbed preparation, and the other was applied while the plant height was approximately 30 cm. After emergence, thinning was done to obtain row distances (15 cm) and weeding was applied before stem elongation manually.

Yield and yield components data were determined on 10 plants randomly selected from two middle rows in each plot where the harvesting areas determined after deletion of the plot sides and 30cm from the top and bottom of two middle rows.

The variance analysis of data for each properties and analysis of the randomized complete block design were computed using the IBM SPSS computer program (v.23.0). The LSD multiple range tests were used to test the significance of main effects at the 5 % level of probability. The Spearmen correlation equation between the traits mean as the dependent variables of sesame as the independent variable are calculated.

Results and Discussion

Table 2 shows the comparisons of varieties according to the plant height, number of branch per plant, first pod height, pod length, pod width, number of pod per plant, number of seed per pod, 1000 seed weight and seed yield.

Plant height: The means comparison for this trait (Table 2) indicated that sesame in 2012 was faced a more favorable thermal and moisture regime (Figure 1 and 2). The plant height had a significant (%5) difference among the varieties. This could be due to the differential response of varieties to environmental conditions based on their genetic variations (de la Vega, 1996). The plant heights differed from 121.0-147.1 cm. The highest plant was observed from Tur-S203

which had no statistically difference with Muganlı-57, Tur-S-90, Orhangazi-99 and Kepsut-99 (146.63, 146.50, 145.87 and144.47 cm), respectively and the shortest plants were obtained from Tan-99. Supporting evidences were reported by Öz and Karasu, (2010) who showed that Orhangazi-99 had maximum plant heights among 7 varieties and Tan, (2011) monitored that the plant heights changed between 110 – 128.9 cm.

Number of branch per plant: As can be seen in Table 2, number of branch/plant significantly (%5) varied among varieties. According to the means comparison, the maximum number of branches (7.17) was observed from Orhangazi-99 which had no statistically significant difference with the other varieties except Tan-99 which had the minimum number of branch/plant (3.63). These results are in concordance with Sağır *et al.*, (2010). Contrasting results were obtained by Öz and Karasu, (2010) who stated that the number of branch didn't changed according to the genotypes.

First pod height: Results obtained from the 8 varieties indicate that there exist wide variations among the varieties. The distance from the first pod down to the base of the plant was between 43.60 - 67.07 cm (Table 2) and was significant at %5 statistical level. The maximum height was observed from Tan-99 where the shortest plants were obtained from Orhangazi-99. The study results agree with the previous findings of Ansah *et al.*, (2015). The maximum height observed from Muganlı-57 while the minimum height determined from Cumhuriyet-99.

Pod length: The remaining one of morphological traits; pod length had significant (%5) differences among the varieties. The pod length was between 25.33-28.07 mm which had a good line Öz and Karasu, (2010) findings. The longest pods were screened from Orhangazi-99 while the shortest pods were observed from Tan-99. These differentials were in accordance with Alege *et al.*, (2013) who reported the pod length is stable to variations in soil fertility condition and are therefore under strong genetic influence.

Pod width: Table 2 shows that there were significant (5%) differences in the pod widths of varieties. As seen in Table 2, the highest pod width value (6.50 mm) was obtained from Orhangazi-99 while the lowest determined from Tan-99 (4.83 mm). These results has good line with Alege *et al.*, (2013) and Öz and Karasu, (2010) findings.

Number of pod per plant: In the present study, significant (5%) differences were occurred among varieties regards to number of pod/plant (Table 2). The highest number of pod/plant value (125.50) was obtained in plots of Orhangazi-99, where the lowest number of pod/plant (56.07) was produced from Muganlı-57 sown plots which had no statistically significant (5%) difference with Tan-99 (58.27) (Table 2). The results of study are in accordance with Öz and Karasu, (2010) who stated the number of pod had a significant effect on seed yield.

Number of seed per pod: According the data presented in the Table 2, the number of seed per pod had a significant (5%) differential among the varieties. The highest value (72.37) was obtained from Orhangazi-99 while the minimum values (53.20) were produced by Tan-99 variety (Table 2). Supporting evidence were reported by Lal *et al.*, (2016) who stated the number of seed per pod increased with increasing of pod length and width under optimum conditions as a morphologically reality.

1000 seed weight: In the present experiment, 1000 seed weight exerted significant (5%) differences among varieties (Table 2). The highest values (3.67 g) was obtained in Muganlı-57, where the minimum value (2.85 g) was observed in Kepsut-99 (Table 2). The supporting evidence had been reported by Li *et al.*, (2015) who stated the 1000 seed weight was mainly controlled by the maternal genotype under optimum conditions.

Seed yield: Seed yield is directly related to the number of branches, but the total number of pod/plant and the number of seed/pod has the greatest direct effect on seed yield (Lal *et al.*, 2016). The number of pod/plant is directly related to the number of flowers, but climatic conditions can affect the percentage of fertilized flowers. The short photoperiods can increase the number of pod/plant on early and medium-late genotype (Söğüt, 2009). The direct effect of the number of fruiting branches on seed yield in sesame was considerable, as shown by (Uzun *et al.*, 2002). On the bases of this, there was a highly significant (5%) difference in seed yield among eight varieties (Table 2). The maximum seed yield (1005.87 kg ha^{-1}) obtained from Orhangazi-99 variety where minimum seed yield (523.33 kg ha^{-1}) obtained from Tan-99 (Table 2). The supporting data were reported by Öz and Karasu, (2010).

LSD 0.05	**15.454**	**1.526**	**6.443**	**1.793**	**0.881**	**25.571**	**5.846**	**0.172**	**32.776**
CV %	**6.314**	**15.464**	**6.830**	**3.855**	**8.749**	**15.828**	**5.096**	**3.205**	**2.161**

Means with similar letters within each column for each treatment are not significantly different (LSD 5%).

The seed yield is the most important target in sesame cultivation, but also, the seed yield is under effect of lots of factors such as genotype, environmental (climatic and soil) conditions and the traits factors of farmers. Because of these reasons, the results of most sesame agronomic studies can be different.

Traits Correlations

The studied traits correlations are shown in Table 3. The correlations between plant height and number of seed/pod, pod length, pod width were observed positive and significant (5%). Number of branch/plant showed positive and highly significant (1%) correlation with number of pods/plant, number of seed/pod, pod width, seed yield and also significant (5%) correlation with pod length and 1000 seed weight but, had negative and highly significant (1%) correlation with first pod height. These results suggest that improvement in these properties could be with an increase in number of branch/plant (Lal *et al.*, 2016) with less first pod height.

The correlations of number of pod/plant with number of seed/pod, pod length and pod width are positive and significant (5%) and also had a positive and significant (1%) correlation with seed yield which suggest that the increase in these yield components could be with an increase in the number of seed/pod. But, a negative and significant (5%) correlation was screened with first pod height which suggested that an increase in number of pod/plant could be obtain with low first pod height.

The number of seed/pod was positive and significantly (1%) correlated with length of pods and seed yield while it had negative and significant (1%) correlation with first pod height. This indicates that the maximum length of pods and seed yield can be determined with a high number of seed/pod and low height of first pod.

The correlation of first pod height with pod length, pod width and seed yield was significantly (5% and 1%) negative which suggests that the first pod height could bring decrease in yield and yield parameters. Therefore, it will be a good step to improve a balance between these important components when breeding for high yield improvement in sesame (Lal *et al.*, 2016).

Pod length, pod width and 1000 seed weight were positive and significantly (5% and 1%) correlated with seed yield. This means that an increase in these parameters will occur high yield in sesame.

Table 3. The correlation values of plant parameters based on means of 8 varieties in 2012 growing seasons at Spearman

	Plant height (PH)	Number of branch/plant (NB/P)	Number of pod/plant (NP/P)	Number of seed/pod (NS/p)	First pod height (FPH)	Pod length (PL)	Pod width (PW)	1000 seed weight (TSW)	Seed yield (SY)

PL						1	0.320	0.010	0.413 *
PW							1	0.180	0.535 **
TSW								1	0.362 *
SY									1

**. Correlation is significant at the 0.01 level

*. Correlation is significant at the 0.05 level

Conclusions

According to results of the study, it can be concluded that to increase seed yield in sesame, the attributes like number of branch/plant, number of pods/plant number of seed/pod, pod length, pod width and 1000 seed weight should be increased to achieve potential yield of sesame in Iğdır plain conditions. And also, in order to cultivate sesame as an oil crop in conditions similar to the region of this experiment, Orhangazi-99 was recommended.

DRY MATTER YIELD AND FORAGE QUALITY OF PROMISING BITTER VETCH (*VICIA ERVILIA* (L.) WILLD.) LINES

Mehmet Salih SAYAR

Department of Crops and Animal Production, Bismil Vocational Training High School, Dicle University, 21500, Bismil, Diyarbakır, Turkey
*Corresponding author:msalihsayar@hotmail.com

Abstract

The major limiting factor to livestock production in Southeastern Anatolia region is the inadequate quality roughage supply. The introduction of leguminous forage species in crop rotation systems are of great importance. Accordingly; two years field trials (2008-09 and 2009-10) were conducted to determine performance of some promising bitter vetch lines, provided from International Center for Agricultural Research in Dry Areas, Aleppo, Syria (ICARDA) in highland of Southeastern Anatolia Region of Turkey. Field experiments of the study were designed according to randomized blocks design with three replications. According to two years average, the examined traits were ranged among the genotypes as follow; dry matter yield (DMY) 4.13-5.40 t ha^{-1}, dry matter crude protein content (CP) 16.53-18.52%, acid detergent fiber (ADF) 21.30-23.52%, neutral detergent fiber (NDF) 29.81-32.04%, dry digestible matter (DDM) 70.58-72.31%, dry matter intake (DMI) 3.75-4.03%, total digestible nutrients (TDN) 69.3-71.9, relative feed value (RFV) 205-226, calcium (Ca) content 0.42-0.71%, magnesium (Mg) content 0.20-0.23% potassium (K) content 3.01-3.22%, and phosphorus (P) content 0.29-0.31%. In the study; inverse relation was determined between the two growing season for dry matter yield and crude protein contents. Namely, crude protein content of bitter vetch genotypes were lower in high dry matter yield obtained growing season. Results of the study revealed that Ca, Mg, K and P contents of the bitter vetch forages are sufficient for the optimum performance of ruminants, and, the forages obtained from the bitter vetch lines are of the best quality, when by taking into consideration the RFV values of forages.

Key words: *Bitter vetch* (*Vicia ervilia (L.) WILLD), dry matter yield, forage quality, ADF, NDF*

Introduction

The genus *Vicia* (vetches) includes about 160 annual and perennial species distributed throughout temperate regions of Europe, Asia, and the Americas (Alkin *et al*., 1986; Maxted, 1995, Larbi *et al.,* 2011). According to Elci and Acıkgoz (1993) 59 of them find in native flora of Turkey, and 14 species of vetches are cultivated in arable land of Turkey. The most grown ones in Turkey are respectively *Vicia sativa* L. (common vetch) and *Vicia pannonica* Crantz (Hungarian vetch). *Vicia ervilia* (L) Willd. (Bitter vetch) is also important annual vetch species. It has been cultivated by farmers since ancient times in Anatolia.

Shortage of quality forages presents a serious problem to animal husbandry of the Southeastern Anatolia Region of Turkey, known as Upper Mesopotamia, is located within the 'Fertile Crescent'. Accordingly, livestock are fed predominantly by cereal chaff and straw, which have low nutritional values and are used as filler material to keep livestock from feeling hungry. However, in order to obtain animal products from the livestock in desired levels, they should be fed with quality roughage obtained from forage crop species (Sayar *et al.,* 2010). Bitter vetch is

highly resistant against adverse environmental conditions, drought and poor soil conditions. Hence it is cultivated almost in all parts of Turkey as a forage crops for both its high quality forage and its grains (Serin *et al*., 1997; Ayan *et al.*, 2006; Kaplan *et al*., 2014).

Objective of this study is to determine dry matter yield and forage quality of some promising bitter vetch (*Vicia ervilia* (L) Willd) lines in Hazro district, having higher altitude, lower winter temperatures and more rainy than central of Diyarbakır province.

Material and Methods

This study was conducted for two consecutive growing seasons (2008-2009, 2009-2010) in farmer's field of Sarıcanak village of Hazro district, Diyarbakır, Turkey (38°10'37 N; 40°45'41 E). The study materials consisted of seven promising lines and one control local bitter vetch population. The genetic materials and their origins are listed in Table 1. The promising lines (G1, G2, G3, G4,G5, G6) were provided from International Center for Agricultural Research in Dry Areas, Aleppo, Syria (ICARDA). The bitter vetch lines we used were previously determined to be promising as the result of trials previously conducted at the GAP International Agricultural Research and Training Centre (GAP IARTC), Diyarbakır, Turkey. In addition, one line (G7) and one local population (G8) were used as genetic materials. Since there was not any registered suitable bitter vetch cultivar in Turkey, we used the local population (G8) as a control cultivar.

The research fields were flat or near flat with very little erosion, and the soil layer had a deep or medium deep profile, and altitude of the research area was 815 m. The soil analysis of experimental area showed that, the experimental area soils (0-30 cm) had a clay loam structure, and were red-brown in color. Furthermore, the soils were rich in terms of calcium (16.45%) and potassium (520 kg ha^{-1} K_2O) contents, whereas organic matter (1.53%), phosphorus (30.5 kg ha^{-1} P_2O_5) and salt (0.063%) contents were relatively low. Also, due to the high limestone content, the pH status of the soils was slightly alkaline (pH: 7.67).

The Southeastern Anatolia Region is one of Turkey's seven census-defined geographical regions, and is characterized by a continental climate. In this region, summers are dry and hot, whereas winters are cool and rainy. Rainfall in the region is variable both within and among years. The experiments were conducted under rainfed conditions during 2008–2009 and 2009–2010 growing seasons. Monthly average temperature and total precipitation records during the study years, and the long-term averages, are summarized in Figure 1. The region's forage and seed yields obtained from annual legume crops depend greatly on the spring rainfall.

The experiments were conducted under rainfed conditions according to a randomized complete block design with three replications. Each plot consisted of six rows 5 m in length, and rows were spaced 20 cm apart. Diammonium phosphate fertilizer (DAP 18-46-00) (150 kg ha^{-1}) was applied in the experimental plots with the sowings. Weeds appearing in the experimental area were controlled by hand. The seeding rate was 200 seeds m^{-2} (Anonymous, 2001). The sowings were using an experimental drill. The sowing dates for first and second growing seasons were on November 06, 2008 and November 17, 2009 respectively.

In the experiments; after a half-meter at the beginning and end of each plot was neglected to account for edge effects, half of each plot was harvested separately in May to calculate fresh forage yield, and the fresh forages weighed as soon as possible without losing weight. Fresh forage samples were weighted for each plot (0.5 kg). Then, the samples were dried at 70 °C in a drying cabin for 48 hours for determining hay yields. In order to determine dry matter content of forages, milled 5 grams dried forages samples of each plots were dried at 105 °C in a drying oven, until the weight becomes constant.

After cooling the samples were weighed, dry matter percent was determined for each plot. Afterwards; determined dry matter percent by proportionalizing with fresh forage yield, dry matter yield was found for each plot. Dried forage samples pass through a 1 mm sieve. Crude Protein (CP), Acid Detergent Fiber (ADF), Neutral Detergent Fiber (NDF), Ca, P, Mg and P content of samples were determined by using Near Reflectance Spectroscopy (NIRS, 'Foss XDS') with software package program 'IC-0904FE' (Hoy *et al.,* 2002; Basaran *et al.,* 2011; Cinar, 2012). Dry digestible matter (DDM), dry matter intake (DMI), total digestible nutrients (TDN), and relative feed value (RFV) were calculated according to the equations of Schroeder (1994), as follows:

DDM% = 88.9 - (0.779 × ADF%)
DMI% = 120 / NDF
TDN% = 96.35 - (ADF% × 1.15)
RFV = (DDM% × DMI%) / 1.29

Also quality classes of the forages were determined according to Lacefield (1988). All statistical analyses of data were performed using the JMP 5.0.1 statistical software package (SAS Institute, 2002), and the differences between means were compared using least significant difference (LSD) test at the 0.05 probability level (Steel and Torrie, 1980).

Results and Discussion

The combined variance analysis over the 2 years showed that years, genotypes and genotype × year interaction were highly significant (P<0.01) for dry matter yield trait. Similarly, Bilgili *et al.* (2009) and Orak and Nizam (2005) reported that different environmental conditions among the growing conditions caused differed ranking of dry matter yield in various forage crops. Dry matter yield obtained in 2008-09 growing season (5.17 t ha^{-1}) was higher than that of in 2009-10 growing season (4.48 t ha^{-1}) (Table 2). Regular and higher rainfall amount and cooler temperatures in spring months can be specified as a cause of higher dry matter yield in 2008-09 growing season (Figure 1). Similarly, Karadag and Büyükburc (2004) and Sayar and Han (2014) reported that forage yield of annual forage legumes greatly depend on suitable climatic conditions, more rainfall and cooler temperatures of spring months in Turkey. The combined variance analysis over the two years showed that dry mater yields among the bitter vetch genotypes ranged from 4.13 to 5.40 t ha^{-1}. Respectively G8, G5, G6, G4 and G2, sharing the same statistical group, were found to be the most productive genotypes for dry matter yield. Previous studies, using bitter vetch genotypes under various ecological conditions reported that the dry matter yield ranged between 2.39 t ha^{-1} and 6.90 t ha^{-1} (Cakmakcı and Cecen, 1999; Mihailović *et al.,* 2006; Sayar, 2014; Basbag *et al.,* 2015). The reported bitter vetch dry matter yield data confirm our findings.

The combined variance analysis over the 2 years showed that genotypes and genotype × year interaction were not significant (P>0.05) for crude protein contents. This indicated no significant differences in terms of protein content among the genotypes, Moreover, the environmental conditions of growing seasons did not effected ranking of genotypes for crude protein content. However, a great significant differences were determined between growing seasons in terms of dry matter crude protein content of bitter vetch genotypes. The second year (2009-10) dry matter protein content (19.70%) was found higher than in that of the first year (2008-09) (15.34%). The striking point is that although the forage dry matter yield of the second year (2009-10) was found lower than the first year (2008-09), crude protein content in this year (2009-10) was found higher (Table 2). This can be explained by the inverse relationship between forage yield and forage

quality. Findings determined in this study related to dry matter crude protein content (14.09-20.55%) in bitter vetch genotypes complied with findings of Larbi *et al.* (2011) (14.6-17.2%). On the other hand, Kaplan *et al* (2014) reported that crude protein contents of bitter vetch genotypes changed between 22.12% and 24.96% at the beginning of flowering stage, and between 20.87% and 23.10% at full-bloom stage of the plants. Cited alfalfa (*Medicago sativa* L.) forage protein content ranged from 16.35 to 24.05% (Geren *et al*., 2009; Saruhan and Kusvuran, 2011), which indicates that crude protein contents of bitter vetch and alfalfa are almost equal.

Acid detergent fiber (ADF) and neutral detergent fiber (NDF) contents are important quality parameters of forages (Schroeder, 1994; Caballero *et al.*, 1995; Sayar *et al.*, 2014) Although ADF refers to the cell wall portions of a forage that are made up of cellulose and lignin, NDF refers to the total cell wall, which is comprised of the ADF fraction plus hemicellulose. As the ADF and NDF percentages increase, quality and digestibility of a forage usually decrease (Lacefield, 1988; Schroeder, 1994; Sayar *et al*., 2014). In the study; genotype × year interactions were found non-significant for ADF and NDF contents, also, there weren't found significant differences (P>0.05) among bitter vetch genotypes for the two traits. Although there weren't significant differences among growing seasons for ADF content trait, the NDF content in the second growing season (31.57%) was found higher than that of the first growing season (30.01%). In the study; ADF contents of forage dry matter in bitter vetch genotypes changed between 21.06% and 23.97%; NDF contents changed between 28.52% and 32.74% (Table 2). Similarly; Larbi *et al* (2011) reported that ADF contents of 25 bitter vetch genotypes changed between 20.0% and 23.0%, NDF contents varied between 33.5%-38.9%. Moreover; Kaplan *et al* (2014) cited that ADF contents of 16 bitter vetch genotypes varied between 20.41% and 22.57% at the beginning of flowering stage, and changed between 21.98% and 24.80% at full-bloom stage of plants, and NDF contents ranged from 25.10% to 31.64% at beginning flowering stage; ranged from 29.52% to 34.10% in the full-bloom stage. Accordingly, we determined a full conformity between data Kaplan *et* al. (2014) related to ADF, NDF contents and our data. However, there were a full agreement between our ADF contents data and Larbi *et al*. (2011) for ADF contents, their NDF contents were slightly higher than our findings.

There is inverse relation between ADF content of a forage and its dry digestible matter (DDM) and total digestible nutrients (TDN) values and likewise; similar relation has between NDF content of a forage and its dry matter intake (DMI) value. Namely, as ADF content of a forage increase, its dry matter digestibility and total digestible nutrients by livestock decreases, similarly, as NDF percent of a forage increases, intake amount of the forage by livestock decreases (Lacefield, 1988; Schroder, 1994; Sayar *et al.*, 2014). Also; RFV is an index combining the important nutritional components of intake and digestibility of forages. Although the index has no units, comparisons forage qualities of grasses, legumes, and intercropping mixtures can be made by using the index. A forage with 41% ADF and 43% NDF has 100 RFV value. The other forages can be evaluated with this value. As ADF and NDF percents decrease, the RFV value increases (Schroder, 1994). The combined variance analysis over the two years for DDM, DMI, TDN and RFV values indicated that differences among genotypes, and genotype × year interactions weren't significant (P>0.05) for these traits. However, significant differences were determined between growing years for DMI and RFV values (P<0.01), in contrast to DDM and TDN values (P>0.05). In the study, among growing years and genotypes DDM, DMI, TDN and RFV values had ranges as follows respectively; 70.26-72.27%; 3.67-4.21% ; 68.8-72.1% and 201-234 (Table 2 and Table 3).

By taking into consideration the RFV value of forages, Lacefield (1988) devoted the forages to quality classes. In this classification; if a forage RFV value is bigger than 151, it is accepted as

the best quality forage. In the study RFV values of all of the bitter vetch genotypes were higher than 151. Therefore, the forages obtained from the bitter vetch genotypes had the best quality.

Variance analysis of Calcium (Ca) content indicated that differences among years, genotypes, and genotype × year interaction were highly significant (P<0.01) for the trait. Ca contents of bitter vetch ranged from 0.28 to 0.80% among genotypes in the two years. According to two years mean, the highest Ca contents was determined in G8 (0.71%), and the lowest was determined in G6 (0.42%) (Table 3). Khan *et al.* (2007) reported that Ca content of pasture forages varied from 0.315 to 0.492% dry matter (DM). Their Ca content findings confirm our findings. Also, they cited that the forage Ca values were adequate for the optimum performance of ruminants. Similarly; Reuter and Robinson (1997) suggested Ca requirement for maintenance, growing and lactating sheep to be 1.200-2.600 mg kg^{-1} (0.12-0.26%). Temperate forages generally contain more Ca, Mg than those grown in the tropics (Khan *et al*., 2007). According to Sabah and Celik (2001) and Basbag *et al.* (2011) Ca deficiency leads to bone softening in young animal and bones deformations in the elderly ones. Additionally, it causes thin-shelled eggs in poultry. On the other hand, according to cited in Khan *et al* (2007) it is generally recommended that diets of livestock should have Ca:P ratio of about 1:1 to 2:1 (Underwood, 1981). Livestock will tolerate dietary Ca:P ratios of more than 10:1 without any serious effect provided the P intakes are adequate (Ternouth, 1990). In the study, bitter vetch Ca:P ratios were 2.25:1 for 2008-09 growing season and 1.23:1 for 2009-10 growing season (Table 3). These Ca:P ratios are adequate for the optimum performance of ruminants.

Variance analysis of magnesium (Mg) content indicated that differences among years, genotypes, and genotype × year interaction were found to be non-significant (P>0.05) for the trait. Mg contents of bitter vetch varied from 0.18 to 0.26% among genotypes in the two years (Table 3). Khan *et al.* (2007) reported that Mg content of pasture forages varied from 0.235 to 0.268% of dry matter (DM). Their determined Mg content findings completely consisted with ours. Also, they cited that their determined forage Mg contents in forages had slightly higher levels of Mg than the recommended requirement of 0.12-0.20% DM in the diet of ruminants (ARC, 1980, National Research Council, 1985). Magnesium is known as "anti-stress mineral". Since it helps to calm down in livestock, by reducing the hypersensitivity of the nervous system. Furthermore, it takes part in the mobilization of enzymes and the transformation sugar into energy in the blood. Also, Mg deficiency in the livestock causes "grass tetany" or "hypomagnesemic tetany, spasms in the legs, head backwards removal (Ensminger *et al*., 1990).

Variance analysis of Potassium (K) content indicated that differences among years, genotypes, and genotype × year interaction were found to be highly significant (P<0.01) for the trait. K contents of bitter vetch ranged from 2.80 to 3.47% among genotypes in the two growing seasons. According to two years mean, the highest K contents was determined in G7 (3.22%), and the lowest was determined in G8 (3.01%) (Table 3). In the same way; Başbag *et al.* (2011) reported that K contents of dry matter ranged from 1.54% to 3.82 % in different 10 vetch species. According to Khan *et al* (2007) 0.8% K content in dry matter is sufficient for normal animal requirements (ARC, 1980). Our K contents data is higher than the required amount (Table 3).

The combined variance analysis over the 2 years showed that genotypes and genotype × year interaction were non-significant (P>0.05), in contrast, statically significant differences were found between the two growing seasons in terms of phosphorus (P) contents in the bitter vetch genotypes. P contents of bitter vetch means varied from 0.27 to 0.32% among genotypes in the two years (Table 3). Our determined P contents in bitter vetch is in complete consistency with cited P contents data in various forages in MFC (2008). According to cited in MFC (2008) the phosphorus content of all forages from all pastures, both fertilized and unfertilized, is sufficient

to meet phosphorus requirements of all classes of cattle. However, the phosphorus content of forage from the unfertilized pastures was borderline.

Conclusion

Results of the study showed that the tested promising bitter vetch lines had potential to produce high quality forage when taking into account the examined forage quality parameters. Also, Ca, Mg, K and P contents of the bitter vetch forages are sufficient for the optimum performance of ruminants. As a result, introduction and cultivation the promising bitter vetch lines not only will provide high quality forage for livestock, but also will improve soil conditions for plant growing in the Southeastern Anatolia region.

Abstract

Global warming is an expression meaning rising temperature due to climate changes in the atmosphere. Our world has been facing the threat of global warming more and more for a few decades. According to studies, a global temperature increase of above 2 ^{0}C may cause problematic situations in many parts of the world. One of the problems caused by the global warming is the change in the floristic structure at different latitudes and altitudes of the earth due to rising temperatures. In this context, certain species, also known as invasive species and exotic species, have been encountered recently as new threats in cereal cultivation. These invasive species have been observed to negatively affect the bio region and the habitat in aspects of economics, environment and ecology. As long as these negative effects on agricultural production continue to threaten food security, it is inevitable that the estimated number of malnourished people (805 million) in the world will increase further. In this review paper, the floristic structure changes due to possible global warming and the foresights about invasive new species in cereal cultivation and related research results will be revealed.

Keywords: *Global warming, invasive species, changed floristic structure*

Introduction

Possible changes in the earth's atmosphere due to the global warming will threaten all aspects of the agricultural industry, especially crop production. Crop production industry is an important sector constituting the primary nutritional source for people, animals and all other living beings. As the production area of some plants will change, some plants will lead to new weed species which would infest the crops due to global warming. Being an important part of the ecosystem, weeds are cosmopolitan plants capable of adapting to various climatic and soil conditions, can survive and maintain the fertility even under extreme environmental conditions (Yıldırım and Ekim, 2003).

Due to their competitive abilities and genetic diversity, weeds can be easily adapted through the grassland areas of agricultural land, the archaeological area of the park, the wetlands of the sports fields of habitat, land and various environments from the roadside to railways (Özer et al., 2001). Unless necessary measures are taken against such species, product losses can be anywhere between 20 to 100% depending on the type of crop. Longitudes and latitudes which plants can grow would change due to increased temperature and atmospheric structural changes in the world. Some species will be exhibited as invasive character as a result of these changes (Atay et al., 2015).

Invasive plants (weeds), in general, are the species that grow better in areas where they moved because of the absence of natural enemies which is an important suppressor factor on the populations. Unlike other plants, their effect is not only in the cultivated areas, but also extremely wide area in natural ecosystems which have very different properties. With their settlements and

high adaptability in a short time they moved to areas with different ecological conditions are spreading into agricultural and non-agricultural areas (Atay et al., 2015).

Global Warming, Causes and Effects

Global warming is an expression meaning rising temperature due to climate changes in the atmosphere as a result of the activities of human. The amounts of certain gases in the atmosphere are increasing due to human activities such as increasing world population, the rapid development of industry, fossil fuel, the accumulated rubbish, waste water, transportation, deforestation and agricultural activities. These gases which keep a portion of the reflected beam from the sun to the earth or vice versa enable the earth to remain at a certain temperature. This warming effect and keeping the heat within the Earth atmosphere are called the greenhouse effect. Gases demonstrating this effect are called greenhouse gases. The most abundant greenhouse gases in Earth's atmosphere are: water vapor (H_2O), carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), ozone (O_3), and chlorofluorocarbons (CFCs). Some gases have indirect radiative effects (whether or not they are greenhouse gases themselves). This happens in two main ways. One way is that they break down in the atmosphere and produce other greenhouse gases. For example, methane and carbon monoxide (CO) are oxidized to give carbon dioxide (and methane oxidation also produces water vapor; that will be considered below). Oxidation of CO to CO_2 directly produces an unambiguous increase in radiative forcing although the reason is subtle. Without greenhouse gases, the average temperature of Earth's surface would be about −18 °C (0 °F), rather than present average of 15 °C (59 °F) in the solar system (Treut et al., 2007). Especially in the last 30-year period, the effects of global warming continue to increase due to triggering of the excessive fuel consumption, emissions of greenhouse gases increase in the atmosphere, increase in population and the depletion of the ozone layer.

According to the fifth assessment report of the Intergovernmental Panel on Climate Change (IPCC); each of the last three decades has been successively warmer at the Earth's surface than any preceding decade since 1850 (see Figure 1). In the Northern Hemisphere, 1983–2012 was likely the warmest 30-year period of the last 1400 years. The globally averaged combined land and ocean surface temperature data as calculated by a linear trend show a warming of 0.85 [0.65 to 1.06] °C, over the period 1880 to 2012, when multiple independently produced datasets exist. The total increase between the average of the 1850–1900 period and the 2003–2012 period is 0.78 [0.72 to 0.85] °C, based on the single longest dataset available. For the longest period when calculation of regional trends is sufficiently complete (1901 to 2012), almost the entire globe has experienced surface warming (IPPC., 2013).

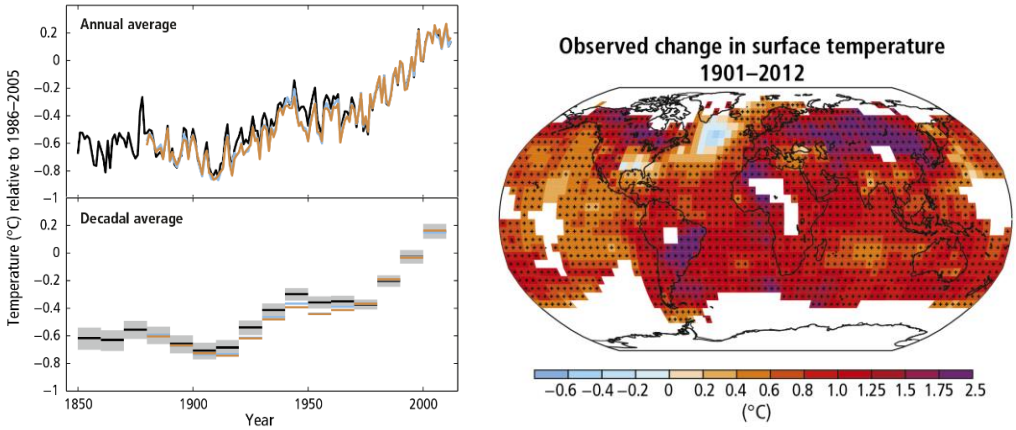

Figure 1. Observedchange in temperature

Global climate change has already had observable effects on the environment. Glaciers have shrunk, ice on rivers and lakes is breaking up earlier, plant and animal ranges have shifted and trees are flowering sooner. Effects of global climate change predicted by scientists in the past have started to take place: loss of sea ice, accelerated sea level rise and longer, more intense heat waves (Turkeş et al., 2000).

The Effects of Global Warming on Plants

Climate change is related to extreme weather events such as atmospheric CO_2 concentration, precipitation, temperature, solar radiation, floods, droughts, and erosion. As the most important input for photosynthesis reaction, carbon dioxide concentration directly and/or indirectly affect plant growth and productivity. While direct effect of rising CO_2 concentrations emerges increasing photosynthesis, indirect effect decreases water loss in plants. Water loss decreases and the rate of photosynthesis increases due to the closed stomata at high CO_2 concentration conditions. This so-called CO_2 fertilization process is a useful effect increasing the concentration of CO_2 in the atmosphere (Bongaart, 1994).

Temperature and humidity are the factors which play an important role in agricultural production. Increases in temperature extend the vegetation period especially in high altitude regions due to limited plant growth opportunities. Normally, plant vegetation period is shortened by rising temperature. Also, heated atmosphere shows a beneficial effect on the plant growth in semi-arid regions by holding more water vapour.

Droughts and other anticipated changes in precipitation may be particularly potent selective factors, especially in arid regions. To demonstrate the evolutionary response of an annual plant, *Brassica rapa*, to a recent climate fluctuation resulting in a multiyear drought, ancestral (predrought) genotypes were recovered from stored seed and raised under a set of common environments with descendant genotypes and with ancestor×descendant hybrids. As predicted, the abbreviated growing seasons caused by drought led to the evolution of earlier onset of flowering. Descendants bloomed earlier than ancestors, advancing first flowering by 1.9 days in one study population and 8.6 days in another. The intermediate flowering time of ancestor×descendant hybrids supports an additive genetic basis for divergence. Experiments confirmed that flowering time was heritable, and that selection intensities in the field were more than sufficient to account for the observed evolutionary change. Natural selection for drought escape thus appears to have caused adaptive evolution in just a few generations. A systematic effort to collect and store propagules from suitable species would provide biologists with materials to detect and elucidate the genetic basis of further evolutionary shifts driven by climate change. (Franks et al., 2007)

The rate of plant growth depends on temperature and CO_2 content. The rate of plant growth rises quickly depend on rising temperature and CO_2 concentration, and thus the vegetation period is shortened. The duration of the increased temperature accelerates the cereal grain filling period. Shortened grain filling period has negative effect on grain yield due to rising temperature (Bongaart, 1994). Increased evaporation from the soil and plants, increased extreme precipitation, extreme climatic conditions such as drought with increasing temperature are not desirable for most agricultural products. Likewise, increasing temperature decreases crop yield in the tropical and subtropical zones since most plants in these zones are already grown at a temperature close to the level of tolerance. More temperature increases could put the plants under temperature stress (Bongaart, 1994).

Global Warming, Invasive Species

It is predicted that the distribution of vegetation will take place at higher latitudes and higher altitudes due to global warming. This distribution will cause alien invasive species to emerge. These species, which can be more easily adapted to changing environmental conditions than the plant species found in the natural flora will easily spread. Invasive species distribution will change in accordance with different adaptation capacity, changeable genetic pattern and shortening growing period. Invasive species have significant negative effects on biodiversity, ecosystem function, agricultural productivity, and human health. Only, the estimated annual cost of invasive species exceeds $120 billion in the United States (Pimentel et al., 2005). It has been hypothesized that climate change will exacerbate the impacts of non-native species naturalization and subsequent invasion across communities.

A researcher groups identified that non-native species differ dramatically from natives in their ability to respond to climate change. Non-natives are significantly better able to track seasonal temperatures than native species. In particular, invasives track seasonal temperature variation better than natives and non-native non-invasives, although the difference between invasives and non-native non-invasives is not significant. Invasives have also significantly shifted their flowering time over the last 100 years to be 11 days earlier than natives and 9 days earlier than non-native non-invasives. Concordant with these phenological results, non-native and particularly invasive species have significantly increased in abundance since 1900 relative to the native flora. Finally, aside from having slightly larger flowers than natives, which is likely due to the fact that many non-natives are escaped ornamentals (Mack and Erneberg, 2002), non-native species showed no appreciable difference in the other traits their examined (Willis et al., 2010).

These results provide the strongest link to date between climate change and non-native species' naturalization and subsequent invasion at the community level. While the evolutionary and ecological mechanisms for these results require further investigation, these results nevertheless highlight the utility of phenological response as an important tool for assessing the likelihood of future naturalizations and subsequent invasions by non-native species. Specifically, these results indicate that information on flowering time tracking may allow us to determine if a non-native species is more likely to become naturalized in its introduced range. In addition, the likelihood that a non-native species will become invasive will benefit most from data on species flowering time shift. For example, in Concord, mayweed chamomile (**Anthemiscotula** L.) has greatly shifted its flowering time 23 days earlier since 1900. While mayweed chamomile has yet to be classified as an invasive in Massachusetts, this results from above suggest that it has a high potential of becoming invasive with continued climate change (Willis et al., 2010).

The Effect of Global Warming on Cereal Production

Cereals are today used in many fields from human and animal nutrition to industry. Also, cereals are major compounds in mankind’s basic necessities. It is inevitable that cereal production is likely to be affected first, considering vast production area in case of a possible threat of global warming on the Earth's surface. There are lots of scenarios about grain production in case of a global temperature rise.

The first scenario of rising temperatures is declining grain yield and quality due to reduced ripening time. Increased temperatures accelerate the grain filling period of cereals, therefore grain yield and quality characteristics vary. Wheat production area will also move to the polar regions due to rising temperature, and the size of wheat cultivable areas will decrease and consequently wheat production will decrease. Besides, the reduction of areas suitable for agriculture, yield of grain and other crops will lead to a decrease in the efficiency. Although some production rise will

occur at increasing temperatures and carbon dioxide levels, real losses will emerge in the coming period due to the increase of carbon accumulation and reduction of production area. According to a survey conducted in India about this subject, if a temperature increase of 4°Coccurs in terms of possible effects of global warming, it is assumed to decrease cereal production by 25-40%, rice production by 15-25%, wheat production by 30-35% (Mendelsohn, 2000).

Global warming and rising temperatures will increase the diseases and pests that threaten crop production. In this case, cereals will be directly affected with respect to yield and quality. In particular, invasive plants including weeds competing with crops will threaten production. Rice and corn mainly grown in irrigated conditions will be reduced with increasing temperature and the reasons such as decreasing of the water source, disappearance of water resources. Most produced and most important crops such as corn and rice in the world will face product losses due to possible global warming. These losses will create serious gaps in human and animal nutrition. In this case, wheat, barley and other species adapting to dry conditions will spread better.

Conclusion

Climate change will affect large geographical areas with similar characteristics. In recent years, staple grains absolutely necessary for human nutrition will become increasingly more important because of decreasing yield, changing growing zone, rising diseases and pests, rising weed threats and changing adaptability. Especially, contraction in grain zones where they can be grown and increasing pressure of invasive species will continue to threaten production in grain growing areas. Growing population and sufficient and balanced nutrition of the population, increasing demand for food, by adding to the threat of global warming, the world will be faced with intractable table every day.

As a number of changes in the earth atmosphere occur as a result of global warming, agriculture is the most affected one among all sectors which trying to conform to these changes. According to various scenarios in this regard, mankind will be confronted with hunger owing to some threat such as drought, pests and diseases, the spread of invasive species and desertification.

Many product groups, especially cereals will be under threat due to decreasing yield and quality with changing production zones. In the face of possible scenarios, international cooperation and strategies are more important than mankind's contribution alone. International partnership plans such as “climate change agreements”, “actions for the economic use of water resources” and “drought action plans” will be even more important. Environmentally friendly production techniques, especially applications reducing greenhouse gas emissions in the agricultural sector, will gain importance. It is inevitable that the grain growing system will change under these conditions. No-till farming, conservation tillage, strip tillage which are mainly based on the retention of water in soil environmentally friendly practices such as good farming, organic /ecological agriculture will be much more important to grow cereals.

INFLUENCE OF SALT AND OSMOTIC STRESS ON GERMINATION OF DIFFERENT DOMESTIC WHEAT (*Triticum aestivum L.*) CULTIVARS UNDER LABORATORY CONDITION

Branka GOVEDARICA, Igor ĐURĐIĆ, Tanja JAKIŠIĆ, Mirjana JOVOVIĆ, Vesna MILIĆ[1]

[1]University of East Sarajevo, Faculty of Agriculture, Vuka Karadjica 30, Bosnia and Herzegovina
Coresponding author: vesnamlc@yahoo.co.uk

Abstract

The aim of this research was to identify the cultivars of winter wheat which tolerate drought and increased salinity at the germination stage. The testing was carried out under controlled conditions with an aim to test reaction of 3 different cultivars of winter wheat to salinity and osmotic stress during the early stage of a seedling's growth. The test included examination of germination energy and percentage of germinated seeds. After being sterilized in 96% ethanol and rinsed with distilled water, 50 uniform seeds were transferred to Petri dishes (divided on genotype and treatment) filled with a solution (Mannitol and salt) in which the water potential was of almost 0 (control), -0.3 and -0.6 MPa. Alcohol Mannitol was used to create water stress and NaCl to create salt stress. Seedlings were incubated for 7 days at 25°C. The results showed that the benchmark water potential (under the influence of Mannitol and salt), in which all varieties can germinate and have a good growth of seedlings, is of -0.3 MPa, i.e. of the low stress. Under the stronger stress (-0.6 MPa) all the varieties showed reduction in all measured parameters. Bosanka cultivar showed the best result of germination and germination energy under the influence of water and salt stress when compared to other cultivars. An exception was the cultivar Orion where stress conditions had inhibited germination energy and germination, when compared to other cultivars. Reasons for stronger resistance, or sensitivity, of certain varieties may be numerous and further studies conducted on this or other varieties of wheat would contribute to understanding and explanation of these differences.

Keywords: *germination, cultivars, Mannitol, salt, drought.*

Introduction

Successful production of cultivated plants occurs as a result of a number of metabolic and physiological processes, and one of initial and the most important is the seed germination. Productivity analysis is done primarily by measuring seed germination, where a large number of genotypes can be tested simultaneously and also determine their resilience on different stress factors. Knowledge of these processes and individual genotypes resilience can contribute to achieving the potentials of fertility in certain agro-ecological conditions.

Drought, increased salt concentration as well as other abiotic factors, adversely affecting the quality (*Wang et al*, 2011*; Roy et al*, 2011) and the amount (*Dolferus et al.*, 2011) all produced grains, including wheat, which in the future could create very big problems since grains are important food for most of the world population. Salinization of land can create external osmotic potential that can limit the absorption of water by the seed, or the sodium and chloride ions can accumulate in the seed that germinates, and has a toxic effect. The salinity of the soil affects the germination of both sides, either as osmotic stress or a toxic effect of ions.

The selection of genotypes that tolerate drought and salt stress in this stage is therefore important, especially if the tolerance in the germination stage correlated with tolerance to drought and salt, with the period of grain filling (*Jovovic et al.*, 2015). Therefore, it is necessary through various surveys to better meet the physiological and biochemical processes that make the plant tolerant to drought.

The selection of genotypes that can tolerate the stress of draught and salts is important. Drought and increased concentration of salts lead to drop in photosynthesis rate, decrease in biomass and yield (*Bala et al*., 2006; *Hniličkа et al*., 2007). Laboratory research of drought impact, as well as impact of other environmental stress factors, on tolerance mechanisms have an advantage compared to field experiments, when it is necessary to keep track of changes caused by just one stress factor.

Materials and methods

The tests included examination of germination parameters of three different winter wheat cultivars (Jelena, Bosanka and Nova Bosanka) under controlled conditions. The seeds were selected in the Agricultural Institute of the Republic of Srpska. The experiment was set up in the laboratory of the Faculty of Agriculture in East Sarajevo. Only completely healthy and clean seeds were left for testing. Then the seeds were sterilized in 96 % alcohol for 30 seconds, then washed with distilled water several times, and 50 uniform, healthy seeds were transferred into sterile Petri dishes. The cups were with double layer of filter paper, soaked in saline certain concentration (Mannitol and salt, Table 1.), and it dissolves with water potential close to zero were controls, then, -0.3 and -0.6 Mpa (*Braccini et al*., 1996). 15 ml of solution was poured into each Petri dish. Control Petri dishes were with distilled water. Alcohol Mannitol was used to induce water stress and sodium chloride to induce stress of salt. The experiment was set with four replicates per each treatment and each variety separately. Seedlings were incubated in an incubator (Binder) for 7 days at a temperature of 25°C, till the appearance of the first true leaf. As the start of germination was recorded the day when the primary roots reached a length of 2 mm. During the experiment we measured germination energy on the 4^{th} day of the experiment, where we numbered all germinated seeds to that period and expressed in percentage compared to the total number of seeds. On the 7^{th} day of the experiment, i.e., at the appearance of the first leaf, we measured total number of germinated seeds in relation to the total number of seeds from one variant.

Table 1. Amounts of sodium chloride and Mannitol used to obtain different levels of water deficit

ΨO the level of MPa	NaCl (g/l distilled water)	Mannitol (g/l distilled water)
0	0	0
-0.3	4.20	22.29
-0.6	8.40	44.58

Traits measured were energy of germination (EG), germination percentage (GP), seed vigor testing (SVT) radicle length (RL), plumule length (PL), and the ratio of radicle to plumule (radicle/plumule – RL/PL).

Statistical analysis was made by MSTAT-C and Excel and the data were analyzed through variance analysis method and means compared by using Duncan's multiple range test at 5% probability level.

Results and discussion

The effects of different NaCl salt and the alcohol Mannitol on germination energy, germination percentage, percentage strong seeds, radicle length, plumule length as well as the ratio of radicle to plumule in all three domestic cultivars (Bosanka, Nova Bosanka and Jelena) is depicted in table 2., as well as charts 1, 2, 3, 4, 5 and 6. All of the tested qualities had the best values in control variety. Nova Bosanka cultivar in control variety had the biggest germination energy, germination percentage, seed vigor testing, radicle length, pulmule length, while the Bosanka cultivar had the largest ratio of radicle to plumule. Differences that are determined were statistically significant. In the Nova Bosanka cultivar there were increases in germination energy and pulmule lenght with the increase of salt concentration, and the same case was with Bosanka cultivar where slightly bigger pulmule was found in a bigger salt concentration, while the similar deviations were not noted for other tested parameters. *Hadi et al*. (2007) reported that seed germinating rate will be declined when salt content increased. The Jelena cultivar appeared to be the most sensitive because, with increase of salt concentration, it had the lowest germination energy, germination percentage, radicle lenght, pulmule, as well as the ratio between radicle to pulmule, while the Bosanka cultivar, with the increase of salt concentration had the smallest seed vigor testing. De Lima and Torres (2009) reported similar results and concluded that the effect of salt stress depends on the plant species. Salt stress affects many physiological aspects of plant growth. Increasing the concentration of salt in the growth medium results in an increase in shoot and root respiration.

Table 2. Mean comparison of the traits of wheat (by Duncan's multiple range test)

Conc. (g)	Variety	EG (%)	GP (%)	SVT (%)	RL (cm)	PL (cm)	RL/PL (cm)
0 (control)	Bosanka	88 b	97.75a	67.75c	6.85b	4.93b	1.39a
	Nova Bosanka	96.5a	99a	82.25a	7.95a	6.90a	1.15b

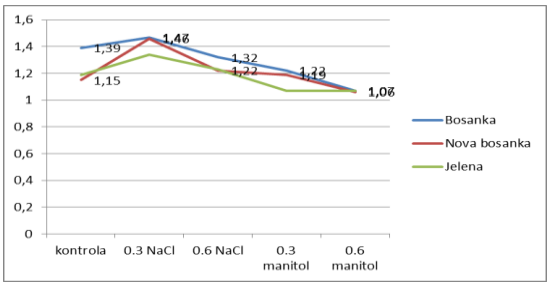

Fig. 6. Effect of NaCl and Mannitol on the ratio of radicle to plumule (radicle/plumule – RL/PL)

For winter crops, which include winter wheat, land for sowing may contain more salt at the time of sowing due to high evapotranspiration during the previous summer, where salt migrates to the surface of the land, and as the seed sown at 10 cm depth that part and contains the most salt. To seed germinated in such medium, must have strong vigor, that he survive and passed through a layer of salt on the surface land (*Huang et al*., 1995).

Alcohol Mannitol is used to induce water stress (*Chen et al*.,2010), as osmoticum in the germination test because it does not damage the embryo and causes the inhibition of seed germination by affecting the adoption of water energy.

By analyzing the effects of increase in mannitol concentration for all cultivars we determined best results in control variety, while the increase of Mannitol concentration caused tested qualities to decrease (germination energy, germination percentage, perantage strong seds, radicle length, pulmule length as well as radicle to pulmule ratio). The Nova Bosanka cultivar proved to be the most resilient to all tested treatments, compared to other cultivars.

Yang et al. (2010) in tests on Picea asperata published that with increasing water potential and the degree of stress tends to fall germination percentage and germination index, especially at -0.6Mpa.

The results showed a significant difference between cultivars with different treatments. Changes in water potential to more negative, cause the reduction in germination, proven *Pratap and Sharma* (2010) in studies on seed Stronger deficit of water has led to highly significant reduction in the percentage of germination of all cultivars. In -0.6 MPa worst result had Vigna, where energy and germination percentage was inhibited by increasing the osmotic potential.

Conclusion

Based on the examination of the effect of stressful conditions, different strengths of the osmotic potential and salinity, it can be concluded that all the varieties showed a reduction of all measured parameters, in medium (-0.6MPa) and it could be an indication of their sensitivity to stressful conditions.

Cultivar Nova Bosanka showed significantly better result of germination percentage, energy of germination, seed vigor testing, radicle length and plumule length, while the cultivar Bosanka showed significantly better result ratio of radicle to plumule (radicle / plumule) in conditions of water deficit and salinity, as compared to other tested cultivars.

We can conclude that the limit values of water resources when plant, under the influence of mannitol and sodium chloride, in all varieties can germinate quite well and have a good increase in seedling were at -0.3 MPa, i.e. in low stress.

Abstract

The objectives of this study were to compare the effect of different regimes of sprinkler irrigation of maize on its productivity and water use efficiency, on experimental fields of the Maize Research Institute of Zemun Polje, Serbia. Four irrigation regimes were studied: full irrigation (I_{100}), 75% of I_{100} (I_{75}), 50% of I_{100} (I_{50}), and no irrigation (I_0), in 2007 and 2008. The crop water use efficiency (CWUE), irrigation water use efficiency (IWUE) and evapotranspiration water use efficiency (ETWUE) are used to assess the water productivity of each studied treatment. The efficiency of the same treatment differs between the study years as it depends on seasonal water availability, weather conditions and their impact on grain yields. In general, CWUE increases with irrigation. In the two growing seasons, IWUE and ETWUE decreased with increasing ETa and the amount of water added by irrigation. On average, treatments I_{50} and I_{75} resulted in similar or higher WUE and ETWUE than treatment I_{100} in both years. IWUE rose as the amount of irrigation water increased in 2007, whereas the opposite was the case in the drier year 2008. Under the agroecological conditions such as exist in Vojvodina, treatments with 50% and 75% of I_{100} compare very well to full irrigation, in terms of productivity, such that they represent a sustainable irrigation strategy for improving the water productivity of maize, with an average of 43% and 27% less irrigation water, respectively, in which case the grain yields are reduced by 17% and 10%, respectively, on average.

Keywords: *Water management, Water stress, Crop water productivity, Irrigation water use efficiency, Evapotranspiration water use efficiency, Silty-clay soil*.

Introduction

According to the UN Food and Agriculture Organization (FAO, 2003), 93 developing countries are expected to increase their agricultural production in the period from 1998 to 2030 by 49% in rainfed areas and 81% in irrigated areas. A large portion of the agricultural output will come from irrigated farmlands, three-fourths of which are in developing countries. Compared to the year 1962, irrigated areas in these countries doubled by 1998. However, FAO estimates that irrigated farming in the 93 countries will actually expand by only 23% in the period 1998–2030. Still, given intensified farming, the assessment is that areas of effectively harvested irrigated crops will grow by 34%. This means larger areas need to be irrigated to produce more crops with currently available water resources.

Serbia's Province of Vojvodina (land area 21,506 km^2) is one of its most important agricultural regions. Farming is increasingly irrigated and maize is the main crop (grown on 640,000 ha). Precipitation levels in this region vary from year to year. The perennial average in the growing season is about 384 mm (Kresović *et al*., 2016). The perennial average actual evapotranspiration (ETa) of maize is 540 mm, much greater than the amount of rainfall in the growing season

(Kresović *et al*., 2014). As such, irrigation is needed to compensate for the rain deficit and sustain a high grain yield (GY). Water is most often scarce in July and August, when maize undergoes flowering, pollination and grain-filling.

Irrigation water is an increasingly limited resource in many areas of southern Europe and that necessitates proper irrigation scheduling to maximize water use efficiency (WUE) and profits (Di Paolo and Rinaldi, 2008).

According to Ali and Talukder (2008), maximized yield per unit of water (water productivity, WP), not yield per unit of soil (soil productivity), is the better strategy for rainfed crop farming. In such circumstances, a more efficient management approach is required for increasingly scarce water resources. Water and nutrient deficits often hinder crop growth and the production potential of agroecosystems, given that most crops are sensitive to a short supply of water and nutrients in different critical stages of growth. On the other hand, excessive soil moisture tends to increase farming costs and pollute the environment (as fertilizers and other agrochemicals are carried away). As such, improving water productivity (WP), also referred to as water use efficiency (WUE), is very important in agriculture. The widespread opinion is that increasing water productivity in agriculture is key for mitigating water scarcity and addressing environmental challenges.

According to literature sources, water productivity varies not only between regions but between fields as well, because it depends on many factors such as crop rotation, cropping pattern, climate, irrigation treatment, water/soil/crop management practices, genetic potential of the hybrid, and agritechnology (Gregory *et al*., 2000; Hatfield *et al*., 2001; Ali and Talukder, 2008; El-Hendawy *et al*., 2008; Katerji and Mastrorilli (2009); Djaman and Irmak, 2012). Additionally, the same crop can exhibit different CWUE responses to full and deficit irrigation and rainfed conditions, in different stages of growth on the same location.

Reports on WUE of different crops, including maize, show that variable efficiency between different regions, for the same crop, justifies local determination of this indicator. Ko and Piccinni (2009) found that maize grain yield increases with increasing irrigation and believe that deficit irrigation at 75% ET (evapotranspiration) is an acceptable strategy that reduces grain yield by 10% while increasing CWUE.

Given that WUE of the same crop differs between regions, a local database of CWUE, IWUE and ETWUE needs to be developed (Djaman and Irmak, 2012). The data and information can help better estimate crop yield response to the amount of water added by irrigation in local farming conditions. Therefore, the objective of the present research was to determine and compare CWUE, IWUE and ETWUE of maize under full and deficit sprinkler irrigation and rainfed conditions in the agroecosystem of Vojvodina.

Material and Methods

Site description

Experimental research was conducted on the trial fields of the Maize Research Institute of Zemun Polje in 2007 and 2008. The study area features a moderate continental climate influenced by the Mediterranean. The main characteristics of this climate are severe winters and long and warm summers. The perennial average amount of precipitation is 638 mm, of which 384 mm during the growing season. The perennial average air temperature is 11.9^{o}C and in the growing season 18.6^{o}C. The precipitation total during the growing season of 2007 was 105 mm lower, and in 2008 about 159 mm lower, than the perennial average, while the air temperature was 0.9^{o}C and 0.7^{o}C higher, respectively. Figure 1 shows average monthly air temperatures and precipitation

levels in 2007 and 2008. The experiment was conducted on carbonate, silty clay chernozem, whose field capacity was 0.34 m^3 m^{-3} and wilting point 0.15 m^3 m^{-3} (Kresović *et al*., 2016).

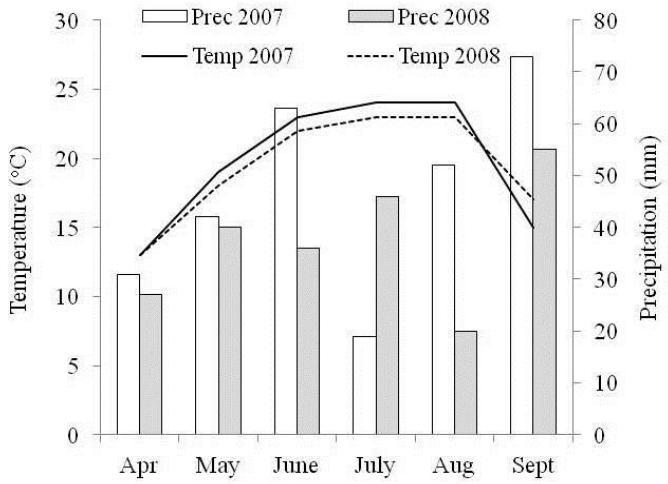

Figure 1. Average monthly temperatures and precipitation levels in the growing seasons of 2007 and 2008.

Experiment plan

Four irrigation treatments were studied: full irrigation (I_{100}), 75% of I_{100} (I_{75}), 50% of I_{100} (I_{50}), and no irrigation (I_0). The setup was of a randomized block design, with four replications. The basic plot size was about 150 m^2 and the harvested area 10 m^2.

The crop was semi-late maize hybrid ZPSC 684 (FAO 600), selected at the Maize Research Institute of Zemun Polje. The sowing density on all experimental plots was 55,000 plants per hectare (70 cm x 26 cm). Sowing was completed in the last decade of April and the harvest at the beginning of the second decade of October. Identical agrotechnical measures were undertaken on all plots, as needed. At the end of maturity, two central rows, 7.14 m long, were hand-picked from each plot. Grain yield was reported at 14% moisture.

Irrigation was applied by a portable sprinkler irrigation system with sprinkler heads on a square (12 m x 12 m) grid (model RINKA). The irrigation depth and time were determined based on the soil moisture in the effective zone of the root system (0–60 cm deep). Soil water content was measured periodically throughout the growing season (from the beginning of sowing to harvest), on each experimental plot, in 10 cm layers up to a depth of 100 cm, using thermogravimetric methods.

Water use efficiency indicators

The literature proposes different WUE estimation formulas (Tanner i Sinclair, 1983; Boss, 1980, 1985; Katerji *et al*., 2010). CWUE, IWUE and ETWUE were selected to assess the efficiency and productivity of maize in different irrigation treatments. CWUE was the quotient of grain yield (*Y*) and crop water demand, expressed as seasonal actual evapotranspiration (ETa) (Boss, 1980, 1985):

$$CWU = Y/ETa \quad (1)$$

where the CWUE, Y and ETa units are kg m^{-3}, kg m^{-2} and mm.

ETa was determined using the soil water balance equation:

$$ETa = P + I + U + Ron - Roff - D \pm SW \quad (2)$$

where P is precipitation (mm), I is the amount of water added by irrigation (mm), U is the upward flux of soil water (mm), *Ron* is the surface runoff to the field (mm), *Roff* is the surface runoff from the field (mm), D is deep percolation (mm) below the root zone, and ΔSW is the change in stored water in the soil cross-section (mm).

Although a useful indicator in many analyses and assessments of WUE, CWUE does not take into account the role of irrigation. To determine the impact of irrigation on crop water productivity (CWP), Bos (1980, 1985) proposed two new indicators – ETWUE and IWUE:

$$ETWUE = (Y_i - Y_r)/(ET_i - ET_r) \quad (3)$$

$$IWUE = (Y_i - Y_r)/I_i \quad (4)$$

where ETWUE and IWUE are expressed in kg m^{-3}, Y is the yield by treatment (kg m^{-2}), ET and I are the seasonal actual evapotranspiration and the amount of water added by irrigation per treatment (mm), and subscripts i and r denote the level of irrigation (or lack thereof).

The effect of the studied irrigation treatments on maize grain yield, CWUE, IWUE and ETWUE were analyzed applying the variance method and LSD test for significance levels of 5% and 1%. SPSS 17.0 software was used.

Results and Discussion

Effect of irrigation treatment on maize grain yield

In the studied irrigation treatments, the maize grain yield varied, on average, from 10.7 to 16.3 t ha^{-1} in 2007 and from 8.7 to 14.3 t ha^{-1} in 2008 (Fig. 2). The most distinct yield variation between the study years was noted in the rainfed treatment because the yield depended mostly on the seasonal amount and distribution of rainfall. The rainfed yield peaked at 10.7 t ha^{-1} in the relatively wet year 2007. A linear correlation was established between grain yield and watering depth; yield grew as irrigation increased from I_0 to I_{100} (Fig. 2). However, when the values for the two years are combined, the plot of grain yield vs. irrigation depth exhibits a quadratic function (R^2 = 0.744). On average, irrigation increased grain yields in both years by about 40, 51 and 63% at I_{50}, I_{75} and I_{100}, respectively. The results of the present research are similar to those reported by Széles *et al*. (2012) for maize irrigated by a Valmont linear system in the extremely dry year 2007 in Hungary, where the soil and climate conditions are comparable. However, for the growing season of 2008, which featured sufficient rainfall for maize (484 mm) and a favorable distribution, those researchers reported that irrigation reduced yields (by –1.9 t ha^{-1} on average), compared to the rainfed treatment, to a significance level of 0.1%. Other studies have also found that maize grain yields increased considerably with increasing amounts of irrigation water (Di Paolo and Rinaldi, 2008; Aydinsakir *et al*., 2013; Rudnick and Irmak, 2013).

In the present research, CWUE exhibited erratic variations from I_0 to I_{100} (Fig. 3). CWUE varied from 3.35 to 3.90 kg m^{-3} (average 3.59 kg m^{-3}) in 2007 and from 2.77 to 3.27 kg m^{-3} (average

3.02 kg m^{-3}) in 2008. In the growing season of 2007, CWUE increased with irrigation depth, reached maximum values in treatment I_{50} and then gradually declined as the amount of water added by irrigation increased. In 2008, CWUE increased with irrigation in treatments I_{50} and I_{75}, and then rapidly declined, reaching the lowest value of 2.77 kg m^{-3} in treatment I_{100}. Contrary to 2008, the rainfed maize exhibited the lowest CWUE – 3.35 kg m^{-3} in 2007. One of the reasons for CWUE variation between the years in the same treatments was the dependency on seasonal water supply, effect of water supply on water extraction, and climate conditions and their effect on yields. According to Irmak *et al*. (2016), a broad CWUE range during the year translates into a high potential for maintaining or increasing agricultural output. The results presented here are considerably higher than the CWUE interval from 0.80 to 1.60 kg m^{-3} described in FAO 33 (Doorenbos and Kassam, 1979), which shows that maize grown in the agroecological conditions that prevail in Vojvodina uses water sparingly.

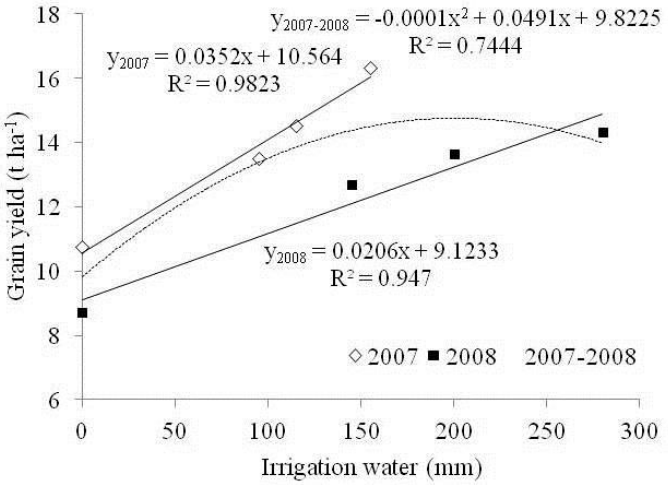

Figure 2. Maize grain yield vs. seasonal irrigation.

Effect of irrigation treatment on CWUE

Katerji *et al*. (2010) determined that CWUE varied depending on the year and location in Mediterranean ecological conditions and that the interval was from 1.34 to 1.81 kg m^{-3}. Djaman and Irmak (2012) applied different deficit irrigation treatments in Nebraska and reported CWUE values from 1.89 to 2.58 kg m^{-3}, the lowest achieved under rainfed conditions. Rudnick and Irmak (2013) reported similar CWUE values. In conditions similar to those that exist in Vojvodina, after a three-year study in Romania Stan and Năescu (1997) recorded CWUE values from 1.19 kg m^{-3} to as much as 3.78 kg m^{-3}, depending on the area and the maize hybrid. Results similar to those reported in the present paper (2.14–3.99 kg m^{-3}) were recorded by Kang *et al*. (2000) in arid conditions in northwestern China, with alternating furrow irrigation of maize. El-Hendawy *et al*. (2008) reported a much smaller CWUE interval, from 0.35 to 1.45 kg m^{-3}, for maize grown on sandy soil with subsurface drip irrigation in Egypt. The results reported in the present paper concur with the opinion of Taner and Sinclair (1983), who claim that maize CWUE is higher (> 2.5 kg m^{-3} on average) in humid than in relatively dry regions.

The regression analysis in Fig. 4 shows a linear CWUE increase with grain yield (R^2 = 0.85) and irrigation (R^2 = 0.92) in 2007, while the CWUE decreased linearly with grain yield (R^2 = 0.96) and irrigation (R^2 = 0.96) in 2008. By contrast, Djaman and Irmak (2012) determined a linear CWUE increase with increasing yield in both study years (2009 and 2010). Contrarily to our

study, the cited researcher reported quadratic relationship between maize CWUE, grain yield and seasonal irrigation in both years.

Effect of irrigation treatment on IWUE

IWUE variation did not exhibit a clear pattern with regard to the irrigation treatments (Fig. 3). In 2007, IWUE increased (by about 24%) with increasing amounts of irrigation water, peaking in treatment I_{100}. However, in 2008, IWUE decreased considerably (by about 37%) with decreasing irrigation and was the lowest in treatment I_{100}. In 2007, IWUE varied from 2.92 kg m^{-3} (I_{50}) to 3.61 kg m^{-3} (I_{100}) (average 3.28 kg m^{-3}). In 2008, it varied from 1.99 kg m^{-3} (I_{100}) to 2.73 kg m^{-3} (I_{50}) (average 2.39 kg m^{-3}). IWUE was therefore higher in 2007 (average 3.28 kg m^{-3}) than in 2008 (average 2.39 kg m^{-3}). In the relatively drier growing season of 2008, IWUE was much higher in the stress treatments (I_{50} and I_{75}) than in treatment I_{100}. The reason might be inefficient water use and inefficient repositioning of grain assimilates with increasing water supply. Lower IWUE in 2008 in treatment I_{100}, compared to 2007, could be a result of the fact that the percent grain yield increase was smaller than the increase in the amount of applied irrigation water. Compared to CWUE, IWUE exhibited much higher variability and much higher IWUE values throughout the range in 2008, compared to 2010 (Fig. 3).

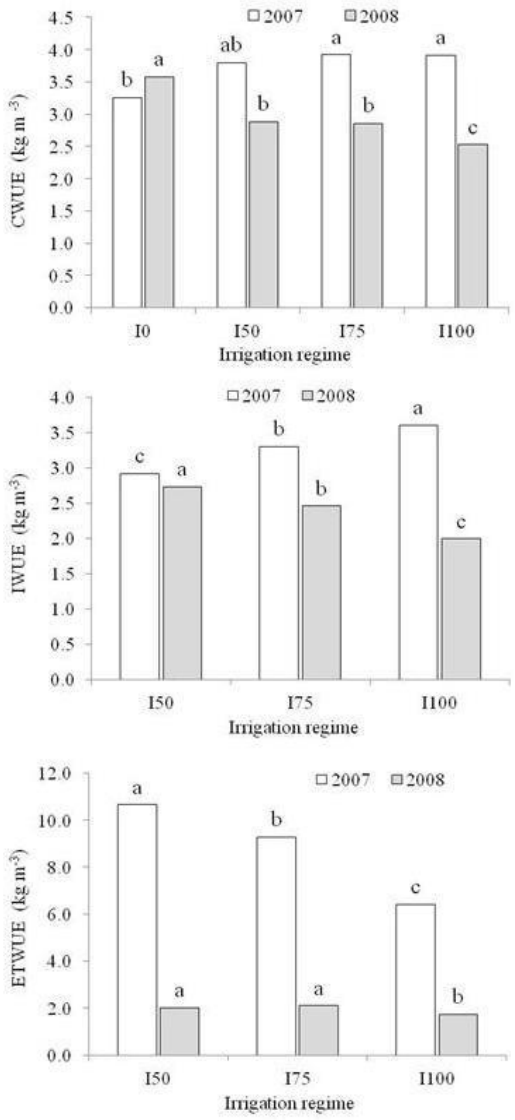

Figure 3. CWUE, IWUE and ETWUE indicators of maize in different irrigation treatments. Histograms with the same letters do not differ considerably at significance level $P < 0.05$ according to LSD test.

Similar IWUE trends and values have been reported in the literature. Djaman and Irmak (2012) compared CWUE, IWUE and ETWUE of maize under full, deficit and no irrigation in South Central Nebraska and found that IWUE varied from 3.63 kg m^{-3} (100% FIT – fully irrigated treatment) to 5.90 kg m^{-3} (50% FIT) in 2009, and from 2.52 kg m^{-3} (50% FIT) to 3.24 kg m^{-3} (75% FIT) in 2010, with a center pivot irrigation system. Their results in 2009, regardless of treatment, were higher than those of the present research. In soil and climate conditions similar to those of the present study Pejić *et al*. (2011) reported that the IWUE interval was from 0.47 to 3.00 kg m^{-3} (average 1.72 kg m^{-3}). Similar to the 2008 results reported in the present research, other studies noted that IWUE decreased with increasing amounts of irrigation water (Di Paolo and Rinaldi, 2008; Djaman and Irmak, 2012). The cited researchers found IWUE to be higher than CWUE. Additionally and contrary to other reports on research undertaken primarily in arid and semi-arid areas, in the present research stored soil moisture played a key role in rainfed grain

yields. The results of the present study are similar to those of Rudnick and Irmak (2013). In their research, CWUE was higher than IWUE and IWUE was much lower and varied from –0.08 kg m^{-3} to 1.78 kg^{-3}.

Figure 4 shows a linear increase in IWUE with grain yield (R^2 = 0.95) and irrigation (R^2 = 0.93) in 2007, while the IWUE decreased linearly with grain yield (R^2 = 0.94) and irrigation (R^2 = 0.99) in 2008. In contrast to our results, Djaman and Irmak (2012) reported a quadratic IWUE decrease with increasing yield. The cited researcher reported that IWUE decreased quadratically with irrigation amount in 2009, but in the 2010 IWUE was inversely related to irrigation. Evett et al. (2006) reported a quadratic increase of IWUE with declining irrigation depth, and their IWUE values ranged from 2.0 to 4.5 kg m^{-3}.

Effect of irrigation treatment on ETWUE

IWUE provides valuable information about the effect of irrigation on grain yield increase, compared to rainfed treatment. However, IWUE can be inconsistent because of potential out-of-purpose use of irrigation water (e.g. runoff, deep percolation, soil water retention, etc.) (Rudnick and Irmak (2013). Another expression – ETWUE (Bos, 1980, 1985) has been proposed to better assess the effect of irrigation water. In the present research, ETWUE of maize varied from 6.42 kg m^{-3} at I_{100} to 10.65 kg m^{-3} at I_{50} in 2007 (Fig. 3). In 2008, the ETWUE interval was much smaller, from 1.73 kg m^{-3} at I_{100} to 2.10 kg m^{-3} at I_{75}. Similar to CWUE and IWUE, ETWUE was higher in 2007 than in 2008. ETWUE was higher than CWUE in all treatments in 2007 because of the smaller ETa difference between the irrigated treatments and rainfed treatment. Contrary to 2007, in the drier year 2008 ETWUE was much lower than CWUE in all treatments.

The two-year average ETWUE rapidly declined with increasing amounts of water added by irrigation. There were much greater differences between I_{75} and I_{100} in 2007 than in 2008. ETWUE was the highest at ETa of 356 mm in 2007 and 478 mm in 2008. This means that in the reported experimental, climate and agrotechnical conditions, the maximum achievable ETWUE is at an ETa lower than that with full irrigation in a dry year, such as 2008. Consequently, I_{75} and I_{50} are sustainable practices of deficit irrigation under the given experimental conditions.

In general, the 2008 results are consistent with those reported by Howell (2001), who found that ETWUE was generally the highest with the least irrigation. The results of the present research are similar to those of Irmak *et al*. (2016), who reported that ETWUE of maize grown on silty clay soil in the USA varied from 1.4 to 11.3 kg m^{-3}. However, it was much higher that reported by Pejić *et al*. (2011), who determined an ETWUE of maize between 0.67 and 2.34 kg m^{-3} (eight-year average 1.50 kg m^{-3}), and Rudnick and Irmak (2013) who reported ETWUE from –0.14 to 3.65 kg m^{-3}. Similar to the results of the present research, Djaman and Irmak (2012) applied different deficit irrigation treatments to maize and recorded ETWUE values from 4.65 to 6.73 kg m^{-3}, but there was no clear-cut trend.

One of the reasons why ETWUE varies to a large extent between studies is because it is the most dependent on the amount and distribution of rainfall (Pejić *et al*., 2012). Howell (2001) stated that the highest ETWUE was generally achieved with the least amount of irrigation water, meaning that the applied irrigation water was fully utilized. In effect, ETWUE shows whether the growing season favors plant production.

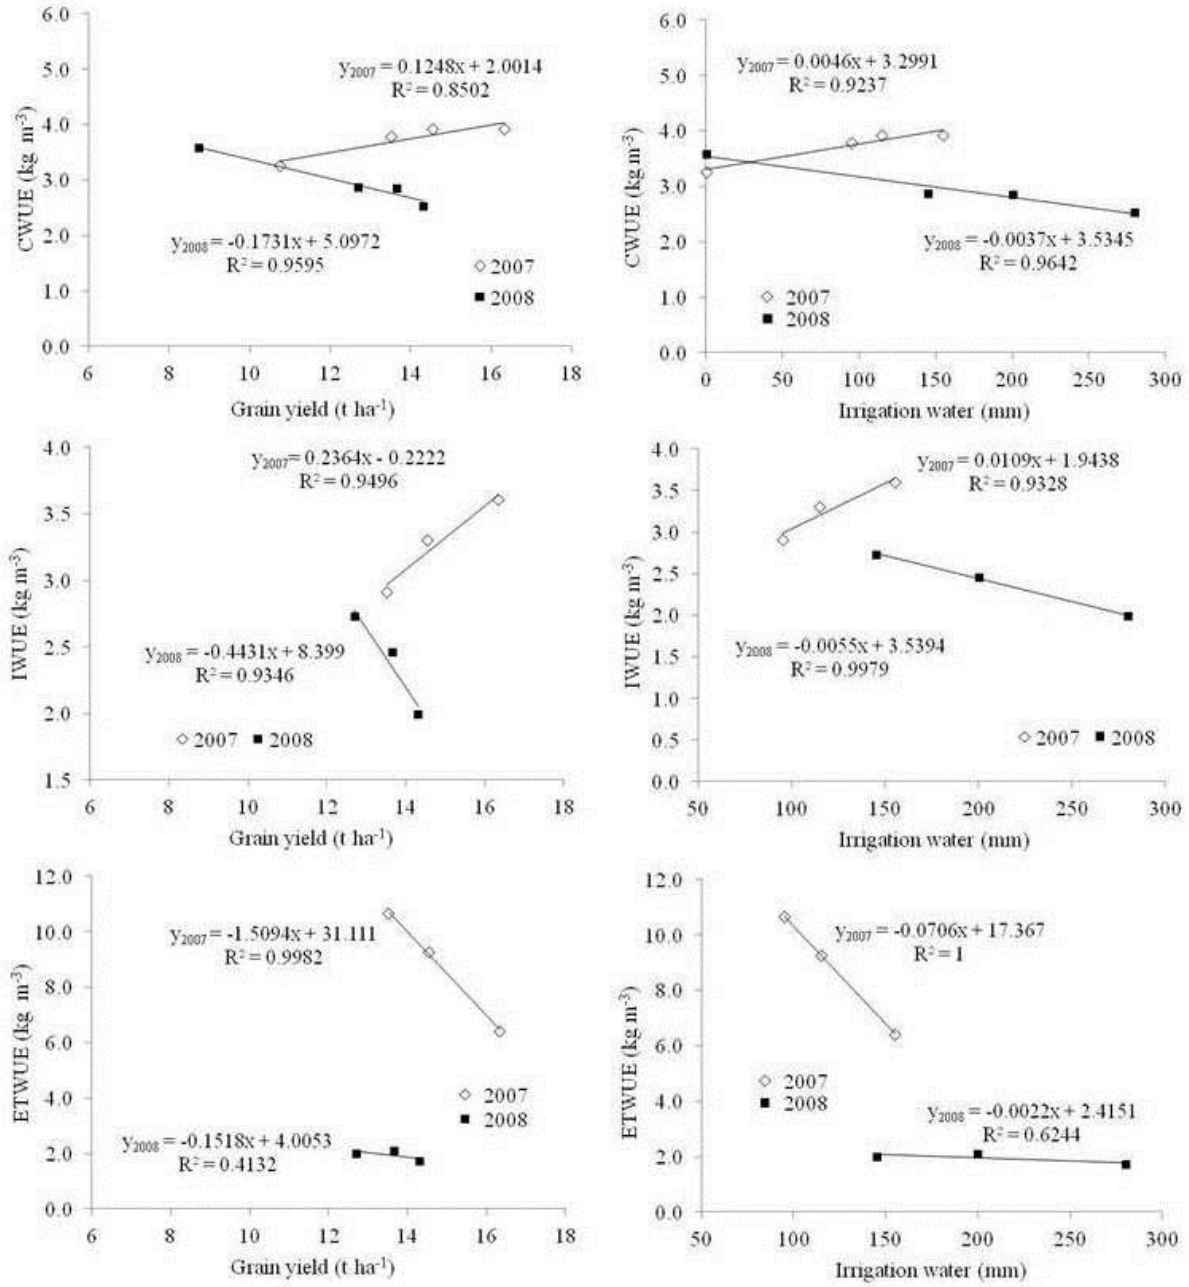

Figure 4. Correlation between grain yield (left) and irrigation (right) vs. crop water use efficiency (CWUE), irrigation water use efficiency (IWUE), and evapotranspiration water use efficiency (ETWUE).

In the present research, ETWUE inversely correlated with grain yields and irrigation amounts. The year 2007 exhibited a steeper regression curves than in 2008 (Fig. 4). Djaman and Irmak (2012), in the year 2009 of their experimental research, also determined a linear decrease in ETWUE with increasing yield and irrigation amounts. Contrary to results of 2009, these authors observed a gradual increase of IWUE with increasing grain yield and irrigation in 2010.
Differences in CWUE, IWUE and ETWUE across years are partially due to weather differences.

Conclusions

The results of the present study show that in Vojvodina, irrigation is of vital importance as a means of increasing maize output and WUE. Higher grain yields were achieved in 2007 than in 2008, but the percent yield increase in all irrigation treatments, compared to the rainfed treatment, were much higher in the dry year 2008 than in the wetter year 2007. Treatments I_{50} and I_{75} recorded relatively high yields, comparable to full irrigation. The finding is that deficit irrigation is a sustainable strategy for increasing CWP of maize, when 50% or 25% less water is used in the given experimental, soil and crop management, and climate conditions. In brief, the study shows that maximizing CWUE, IWUE or ETWUE should be the primary objective of maximizing crop water productivity with irrigation of maize in regions that feature soil and climate conditions and apply agritechnologies similar to those in Vojvodina.

Abstract

Cowpea, with its temperature and drought resistance, is one of the best legume plants and more adaptable to dry environments compared to the common bean. Flowering and pollination period of common bean has suffered due to recent temperature increases in our region. Expected temperature increases in the forthcoming years will further affect bean cultivation, and thus will lead to widespread cultivation of cowpea thanks to its substitution of bean in foods as either in the dry seed or fresh pod form. In this study, 16 cowpea genotypes (14 lines and 2 registered varieties) from four different environments (2 years and 2 locations) were evaluated for genotype (G) x environment (E) interactions and for stability parameters of regression coefficient and mean square of deviation from the regression. The effects of genotype, environment and GxE interactions on seed yield, plant height and biological yield were highly significant. It was found that 5 lines for plant height, 4 lines and 1 registered variety for biological yield and 4 lines for seed yield were stable. The seed yield of genotypes was 126-226 kg da^{-1}.

Keywords: *Cowpea, genotype x environment interaction, stability*

Introduction

Cowpea is grown in a total of 11.2 million ha area in the world (FAO, 2014). It is a remarkable plant, particularly for its low soil requirements and drought resistance and can also be included in crop rotation as a type of legume. It has been reported that it can grow under humid and semi-arid conditions and even under conditions with no precipitation due to its resistance to drought. From this point of view, cowpea is an important plant that can make positive contributions to the Middle Black Sea Region, similar to the examples in the world, with its integration into the system via studies on crop rotation and organic rice cultivation. As a superior legume in terms of temperature and drought tolerance in semi-arid and tropical regions of the world (Hall *et al.*, 2003; Hall, 2004), cowpea is a remarkable plant in Turkey where the temperature continuously increases and the water sources decline due to global climate change. It was noticed that cowpea had a better resistance to drought in such areas compared to that of beans, therefore it was more advantageous both for using as food and animal feed (Gençkan, 1983).

Organic vegetable producers in the United States of America have difficulty providing sufficient nitrogen to their crops. A nematode resistant cowpea cultivar grown in rotation could be used to enhance the fertility of the soil and suppress weeds and nematode pests. Young and tender leaves are prepared as a pot herb in a manner similar to that of spinach in the USA and Africa that is the largest growing area in the world (Ronde and Spreeth, 2007).

Although it has not been evaluated in agricultural statistics for the recent years, cowpea has a cultivation area of 3040 ha in Turkey. and is mostly cultivated in the Aegean, Mediterranean and Southern Eastern Regions of Turkey. The previous studies conducted in our region determined that adaptation requirements of cowpea fit to the Samsun conditions and the plant is suitable for

both monocrops and intercropping in the region (Bozoğlu and Gülümser, 1995). As a result of our selection studies initiated in 1996 for variety registration, which we consider the first step to agricultural development, 14 lines were determined as promising for dry seed cultivation purposes. In their pursuit of determining candidate variation lines, plant breeders carry out replicated trials revealing genotype x environment interactions, and thus find the most stable varieties that are least affected from the fluctuations occurring in the given environmental conditions. As a result of these trials, stable lines and adaptation classes of the lines are determined (Bozoğlu and Gülümser, 2000).

This study aimed to determine the genotype x environment interactions and stability of 14 cowpea lines selected in the region as well as to determine the candidate genotypes suitable for the Middle Black Sea Region in Turkey.

Materials and Methods

The experiments were carried out in two locations that represent the Middle Black Sea Region: Amasya represents the continental climate of the interior region, whereas Samsun represents the moderate climate of the coastal region.

In the Amasya region soil texture was: with high levels of phosphorus and potassium, clay loam, alkaline, slight salt weak organic matter, medium lime for the first year; medium organic matter and without lime in the second year. In the Samsun region soil texture was: with high levels of phosphorus and low levels of potassium, clay, neutral, without salt, medium organic matter, without lime for both years. Some climate data from locations for both years and the long term period are shown in Table 1.

Table 1. Some climate data from experiment locations

		May	June	July	August	September	Total or Mean
Rainfall (mm)							
Amasya	**Long term**	56.2	13.7	12.8	19.5	43.1	145.3

Amasya	**Long term**	17.7	21.3	25.3	24.9	19	21.64
	First year	17.8	20.9	25.5	26.1	20.7	22.2
	Second year	14.8	20.4	20.9	25.6	17.9	28.5
Samsun	**Long term**	15.3	20	23.1	23.2	19.8	20.3
	First year	15.7	19.3	23.4	24.8	20.4	20.7
	Second year	14.4	20.8	22	24.9	19.7	20.4

Fourteen lines determined by individual plant selection from the population that was collected from different regions of Turkey and two registered varieties were the materials of this trial (Karagöz, Akkız). The experiments were set up as randomized complete block design with three replications and carried out in two locations (Amasya- Gokhoyuk and Samsun-Kampus) for two years. Sowing was done on the last week of May for both years in the Samsun-Kampus region; the second week of May of the first year and the last week of May of the second year in the Amasya-Gokhoyuk region. Row spacing was 60 cm with intervals of 15 cm between plants and five rows per plot. Four kg per decare of nitrogen fertilizer was used at the emergence time of plant. Irrigation

was conducted for three times in the Samsun location; for four times in the first year and three times in the second year in the Amasya location. Agronomic observation and measurements were determined for 10 plants chosen randomly from each plot. Analysis of variance using the MSTATC program was performed after data was collected over the years and locations. LSD test was used for grouping the characteristics that were deemed significant. In accordance with Finlay Wilkonson (1963) and Eberhard Russell (1966), stability parameters to be calculated were selected as the regression coefficient (b_i) and deviation from regression (S^2d) with TARIST computer program. A stable genotype is above the general average, regression coefficient is equal to 1, and deviation from regression is zero or close to zero. Confidence limits (CL) for the regression coefficient and the mean of trial were calculated and showed in the stability graph as 9 different adaptation classes (Bozoğlu and Gülümser, 2000). The genotypes that are in the medium compliance group for all environments are accepted as stable (Arshad, 1990).

Results and Discussion

GxE interaction variance should be significant in order to determine the stability and adaptation classes of candidate variation genotypes selected via long breeding studies (Özbek, 1990). Analysis of variance for this study showed that GxE interactions, the number of pods per plant, the number of seeds per pod, 100-seed weights and crude protein ratio in the seed were not significant, whereas plant height, biological yield, seed yield and harvesting period values were statistically significant. Location, genotype mean values and multiple comparison test results for the number of pods per plant, the number of seeds per pod, 100-seed weights and crude protein ratio in the seed properties are shown in Table 2, whereas the mean values and stability parameters for plant height, harvesting period, biological yield, dry seed yield are shown in Table 3.

The number of pods in the plant were statistically different in both locations and the genotypes (Table 2). The average trial value for Amasya, which represents the warmer and inner areas of the region, was 13.3 and it significantly differed ($P<0.01$) from the Samsun location (9.8) by the sea. The control variety Akkız had the highest number of pods (15.6), whereas the G_{11} line had the lowest values (7.9). Gülümser *et al.* (1989) reported that the number of pods in the plant varied between 6.7 and 10.0 under the conditions of Samsun. On the other hand, Karasu (1999) determined the number of pods in the plant as 29.4-40.6, whereas Adiphala *et al.* (2001), in their study on eight cowpea genotypes, determined the number of pods in the plant between 19 and 41. Geetha and Varughese (2001), in their study conducted in India, reported the number of pods in the plant between 51.7 and 60.4, whereas Umaharan *et al.* (1997) reported values between 21.0 and 30; Negri *et al.* (2000) in their study on 13 cowpea varieties, reported the number of pods in the plant between 14.9 and 39.2.

Cowpea is highly variable in terms of pod length and the number of seeds in the pod vary depending on this parameter. However, the genotypes used in this trial were selected from materials suitable for dry agriculture, and therefore pod length and the number of seeds in the pod varied in a narrow range. The number of seeds per pod varied between 8.6 and 9.1 in the control variety, whereas it varied between 8.4 and 10.6 in the genotypes (Table 2). Omoigui *et al.* (2006) determined the number of seeds per pod in cowpea between 7.0 and 11.4, whereas Magloire (2005) reported these numbers between 6.6 and 12.9. In two different studies conducted in India, it was reported that the number of seeds per pod was the character which was least affected from the environment and it was one of the characters with the highest degree of inheritance (Singh *et al.*, 2006; Suganthi and Murugan, 2008). Muli and Saha (2000), in their study conducted at two different locations, used eight cowpea varieties and determined that the pod lengths varied between 13.0 and 20.3 cm

.

One of the most important agronomic properties that affect the yield is 100-seed weight. In the present study, 100-seed weight values differed only between the genotypes whereas no statistically significant differences were found between the environmental conditions. Thousand-seed weight of the genotypes varied between 11.8 and 22.6 g. The control variety Karagöz was in the same group with the line that has the highest weight value, whereas Akkız was the genotype with the lowest weight value. Olapade *et al.* (2002), in their study on cowpea, determined the 100-seed weight between 9.9 and 24.4 g, whereas Omoigui *et al.* (2006) determined the 100-seed weight between 12.3 and 29.3 g.

Legumes are protein rich plants and contain high levels of protein in their dry seeds. The degree of inheritance of protein is very high, therefore it is not much affected from the environmental factors. Indeed, in our study, it was found that the environmental factors had no effect on the protein ratio. In the genotypes, protein ratio varied between 18.7 and 21.9 %. Akkız genotype had the highest protein ratio. Ten genotypes were statistically in the same group with Akkız. Gençkan (1983) reported that the protein ratios in cowpea varieties were between 23 and 31%. Özturan and Gülümser (2004) determined the highest protein ratio as 22 %. Ünlü (2005) determined the protein ratios in cowpea between 29.32 and 41.79 %. In a study conducted at two different locations that represent the Middle Black Sea Region, where one of them represented the temperate climate whereas the other represented the continental climate, plant height of cowpea genotypes varied between 65.6 and 107.7 cm.

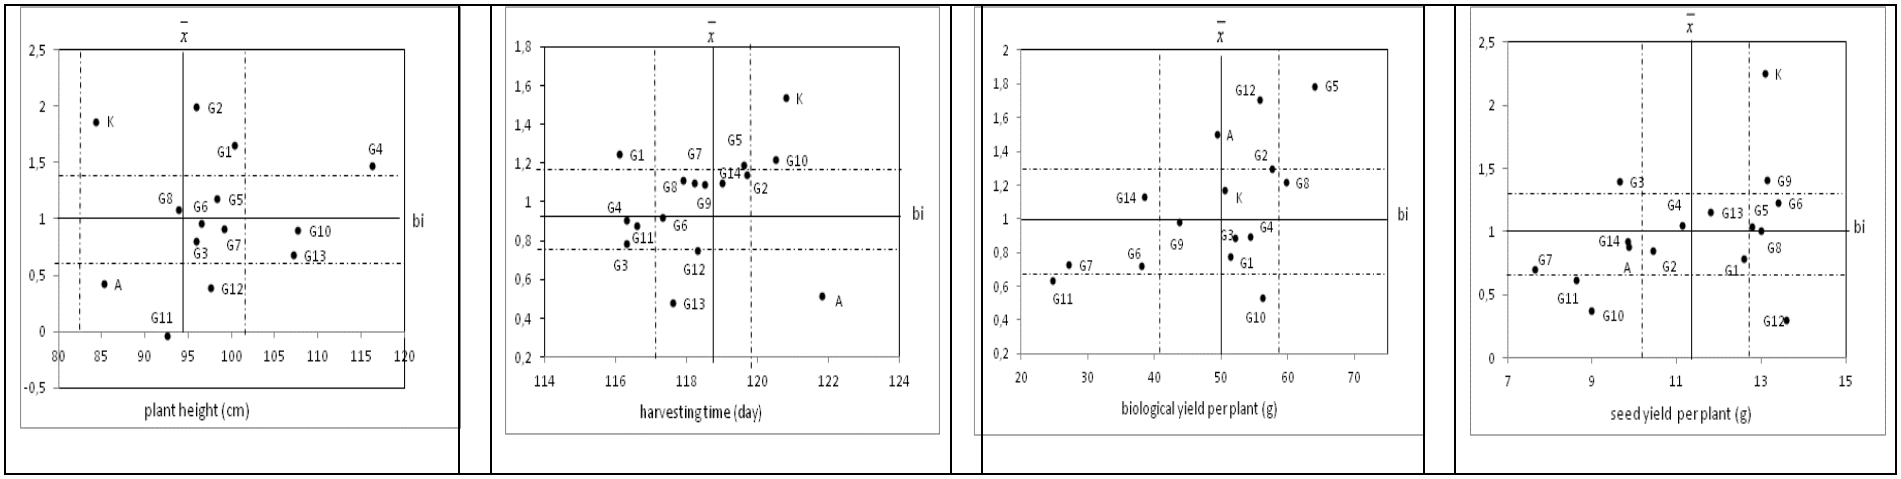

Figure 1. Adaptation classes of some properties of cowpea genotypes

The mean value for the trial was 92.5 cm. To comply with the field agriculture, genotypes that have the longer height and require any support are not preferred. Plant height is a character that is affected from environmental factors and height in cowpea can vary depending on the conditions. Therefore, stability is very important in terms of height. As a result of the stability test conducted (Figure 1), the G_3, G_5, G_6, G_7, G_8 genotypes were found to be stable. Ceylan and Sepetoğlu (1980) determined the plant height in cowpea between 52.3 and 161.3 cm. In addition, the researchers have determined that plant heights and the number of side branches varied depending on the genotype. Gülümser *et al.* (1989), in their study conducted under the ecological conditions of Samsun, have reported that the plant heights of cowpea varieties changed between 74 and 136 cm.

Cowpea is a temperate climate legume that demands high temperatures and thus, can extend its vegetation in areas with mild climate characteristics such as the Middle Black Sea Region. The average vegetation period in the present study was 118 days. Therefore, the dry harvests in the region were carried out in September. For a region that receives heavy rains in autumn, dry harvesting period should not be prolonged in order to eliminate harvest losses and facilitate an easy harvest. The stability tests showed that the G_6, G_7, G_8, G_9 and G_{12} genotypes were stable during the harvest period. It was determined that the control variety Karagöz can adapt well to good environmental conditions, whereas Akkız can adapt well to bad environmental conditions.

Ceylan and Sepetoğlu (1980), in their study on domestic and foreign cowpea genotypes in Bornova, determined that vegetation periods of the genotypes differed and the number of days between first sprouting and ripening was 88-192 days in 1976 and 77-109 days in 1977. Gülümser *et al.* (1989), in their study conducted under the ecological conditions of Samsun, have reported that vegetation period of cowpea varieties changed between 127 and 152 days.

Legumes, whose seeds are used for human nutrition while the remaining straws can be used as animal feed, are rich sources of nitrogen. Therefore, determining the biological yields of plants is important. Biological yield per plant varied between 24.7 and 69.0 g. The average for the trial was found as 49.5 g. The Karagöz, G_1, G_2, G_3, G_4 and G_9 genotypes were found stable.

Seed yield is an important character for all types of field crops, and as a legume whose seeds are consumed as food, that applies to, cowpea as well. For the materials suitable for fresh consumption, it is also important to determine the dry seed yield in terms of sowing seeds. Yield per plant varied between 8.6 and 13.6 g. This value corresponds to 950-1510 kg for the number of plants in one decare. The average value for the trial was 11.2 g and the values for 8 genotypes were higher than the average value. The G_1, G_2, G_4 and G_{13} genotypes were stable, whereas the G9 and Karagöz commercial varieties had a good adaptation to good environment, whereas Akkız had a poor adaptation to all environmental conditions (Figure 1). Ceylan and Sepetoğlu (1980) determined that seed yields of the genotypes were 146.6-271.1 kg/da in 1976 and 21.4-267.1 kg/da in 1977. Gülümser *et al.* (1989), in their study conducted under the ecological conditions of Samsun, reported that the seed yield in cowpea varieties changed between 129 and 169 kg^{-1}da.

Conclusion

The stability analysis of fourteen lines that were used as dry seeds and tested as 2 control varieties from 2 years and 2 locations showed that the lines 2, 4 and 13 were the most stable. The control variety Karagöz had a good adaptation to good environment, whereas Akkız had a poor adaptation to all environmental conditions (Figure 1). In light of these information, and particularly for the seed yield, plant height, biological yield values, the genotypes G_4 (with black hilum rings) and G_{13} (with brown hilum rings) can be recommended as the candidate variation

line. The Karagöz, one of two of our registered varieties had black hilum, whereas Akkız, the other registered variety, had white hilum. In addition, there are also other cowpea varieties that are defined as brown color type and have brown hilum and one of the lines we recommended also have this characteristic.

Abstract

Peppermint is one of the most popular medicinal plants cultivated in Poland. Over the years, the demand for herbs, leaves and essential oil of this species is very high and still increasing. Therefore, it has been looking for methods for improving the yield and the quality of the raw materials. The aim of this study was to analyze morphological and developmental characteristics (e.g. plant height, number of leaves, number of lateral shoots per plant) of peppermint plants treated and untreated with NANO-GRO® preparation. Evaluation of yield and quality of the herb including essential oil content and its chemical composition, were analyzed. The influence of harvest time of raw material and the impact of different methods of application NANO-GRO® were determined. Herb was collected twice: in first decade of July and in third decade of August (regrowth). Plant height ranged from 43.44 to 76.94 cm, the number of lateral shoots from 0.91 to 9.69 pcs, the number of leaves per plant from 19.30 to 92.76 pcs. Method of application of NANO-GRO® did not significantly affect plant height, while it increased the number of leaves and lateral shoots. Different variants of NANO-GRO® application significantly affect the mass of dry herb. This parameter was also influenced by the date of harvest of raw material. All factors used in experiment influenced the content of essential oil in peppermint herb.

Keywords: *Morphological features, yield of herb, essential oil, menthol*

Introduction

Peppermint (*Mentha x piperita* L.) is one of the most popular herbal plant cultivated in Poland. Its raw material e.g. herb, leaves, essential oil and its main component – menthol are components of many tinctures or extracts used mainly in disorders of the digestive system. They have also astringent, antiseptic, antypyretic, antispasmotic, antimicrobial, stimulant and anti-aging properties (Ali *et al.*, 2002; McKay and Blumberg, 2006; Para *et al*., 2013). The demand for above raw materials is very large therefore many years people was working on increasing the yield of peppermint and improving the quality of herb obtained from this species. It should be emphasized that the climatic conditions in Poland are conducive to the cultivation of peppermint, but there are also some dangers that make the growing of mint may be unreliable (frost in snowless winters, drought, the attack of fungal diseases, etc.). Therefore innovative solutions are quest that will avoid these risks as well as will have stimulating influence on the growth and development of plants peppermint. The answer to such goals can be modern fertilizer preparations. They contain a number of components, which influence on plant metabolism and stimulate their growth whereby increasing the yield. In addition to the effects on metabolic processes, these preparations additionally increase plant resistance to external conditions, among others, frosts, drought, salinity, disease and other infections. Such preparation is organic fertilizer NANO-GRO®, which according to the information of manufacturer's affects the growth of the aboveground part of plants and the development of the root system. Usage of this preparation

results in stimulation of the natural resistance of plants to abiotic stress. This leads to the production of growth hormones (auxin, gibberellins, cytokinins). This, in turn, makes the absorption of nutrients and water is getting better, which increases the yield and improves the quality of obtained raw material (Dyśko, 2008). So far, the action of the preparation was studied on vegetables and cereals, and the results confirmed stimulating effect NANO-GRO® on the ability of seed germination, growth, development and yield of the test plants, as well as to strengthen their resistance to adverse environmental conditions (Janas, 2011; Jankowski *et al*., 2012).

The aim of this study was to evaluate the effect of the preparation NANO-GRO® on growth, development and yield of peppermint, as well as to determine the impact of the above fertilizer on the quality of the yield of raw material (herb), i.e. the content of essential oil and its chemical composition. The impact of term of herb harvest on the tested parameters also was evaluated

Materials and Methods

The investigation was carried out on experimental field at the Department of Vegetable and Medicinal Plants'Warsaw University of Life Sciences – SGGW (Poland) in 2014 and 2015. Seedlings for plantation establishment were prepared in a greenhouse. Rhizome-shoots seedlings were collected from the plantation located at the Experimental Field in early spring 2014 and 2015 and were placed in boxes filled with a mixture of peat and sand (1:1). In the second decade of May seedlings were planted in a field on the plots of $5m^2$ in the spacing of 30x40 cm. The experiment was randomized block with 4 replications.

The experimental factors were: method of application of NANO-GRO® and the term of peppermint herb collecting.

Four different methods of application NANO-GRO® were used:

Variant I (V1) - control - seedlings were planting in the boxes, and then (after their rooting) in the field, without the application of NANO-GRO®.

Variant II (V2) - before planting in the boxes, seedlings were soaked for 60 sec. in a solution of preparation NANO-GRO®, after that rooted cuttings were planted in the field.

Variant III (V3) - seedlings were planted in boxes, without soaked of solution of NANO-GRO®. When the two pair of real leaves were created, the plants were sprayed of NANO-GRO®.

Variant IV (V4) - seedlings rooted in boxes, without soaked of solution of NANO-GRO®. Immediately after planting them in the field, the plants were sprayed above preparation.

Solutions of NANO-GRO® for seedlings soaking and plants spraying were prepared according to the manufacturer's instructions on the package.

In each plot 5 plants were randomly selected (20 plants for each combination), for observations of morphological and developmental characteristics. Research was carried out in 4 stages of plants development: the vegetative stage (first decade of June), before flowering (third decade of June), in full flowering stage (second decade of July) and the after flowering plants (third decade of August). At any term of observation plant height, number of lateral shoots, number of leaves per plant were measured. Herb were harvested twice. The first harvest was carried out in the second decade of July, when the plants were at the full flowering phase. All the plants of plot (except the selected for observation) were cut down about 10 cm above the ground. The second harvest was made in the third decade of August (regrowth - the plants were in the vegetative phase). Raw material from both harvests was dried in drying chamber at 30 °C and air-dry mass of the herb was received. The results were calculated per 1 m^2.

In the air-dry herb, the content of essential oil and its chemical composition were determined.

The content of essential oil was determined by steam distillation, according Polish Pharmacopoeia X (2014).
Separation of essential oil compounds was performed by gas chromatography (HP Model 6890) in the following conditions: temperature of detector – 250°C, temperature of injector – 220°C, temperature programme – 60°C – 220°C, 5C·min^{-1}, capillary column – Carbovax 20m x 0.32 mm, 25m x 0.2 mm. Identification of essential oil components was carried out by comparing their time of retention with adequate standards.
The presented results (except essential oil composition) are the mean from the two-year experiment. Chromatografical analysis of essential oils was made only in 2014.
The results were subjected to statistical evaluation using ANOVA 1 and ANOVA 2 programmes and Tukey's test at the significance level α=0.05.

Results and discussion

Peppermint is one of the most important herbal plants. Its raw materials - herb, leaves, essential oil and menthol, are used in many areas of the polish economy (pharmaceutical industry, food industry, cosmetics industry and others), which makes the demand for its raw materials is very large, there is therefore a need to increase their production (Kołodziej 2008; Newerli-Guz and Kobylańska, 2013; Kiełtyka-Dasiewicz *et al*., 2016). To achieve this goal, it must increase the yield of this species and at the same time improve the quality of the herb of peppermint. This can be obtained by introducing new agronomic solutions, which include among others, the application of modern fertilizers that stimulates plant growth and development. One of such preparation is NANO-GRO® (Jędrszczyk and Ambroszczyk, 2016). NANO-GRO® preparation so far has been tested on cereals, vegetables and fruit plants, such research were not carried out on herbal plants. In the available literature we can find only the results of research on the use of other bio-fertilizer on growth of peppermint plants. Kołodziej (2008) for example, demonstrated stimulating growth of that plant, under the influence preparation Asahi SL. Also Rosłon *et al*. (2011) in studies on the effect on morphological features of peppermint such bio-fertilizers as Aminoplant, Goëmar Goteo and Goëmar BM86 demonstrated the positive impact of the first two preparations at the height of the plants of this species. In this experiment NANO-GRO® did not significantly affect this trait, although the highest plants were obtained when plants were sprayed above preparation after planting them in the field (V4) (approximately 61.40 cm), while the lowest were the control plants (V1) (an average of 57.99 cm). Tested trait depended only from term of observation. The lowest were the plants at the beginning of the growing season, the highest in the last period of observation (Table 1).

Table 1. The influence of NANO-GRO® application and term of observation on height of peppermint plants [cm]

Variant of NANO-GRO® application	Term of observation				
	First decade of June	Third decade of June	Second decade of July	Third decade of August	Mean
V1	43.61 d	47.89 cd	63.50 abc	76.94 a	57.99 A

Mean	44.32 C	49.87 C	66.86 B	75.40 A	

An important attributes affecting the mass of the peppermint herb are the number of produced lateral shoots as well as the number of leaves. On these parameters clearly influenced application NANO-GRO® and term of observation. The number of lateral shoots was higher in plants treated NANO-GRO® compared with the control plants. Assessing the impact of the method of application of NANO-GRO® has been observed that most of the lateral shoots produced plants in variant 4, the lowest in variant 3. In the case of the number of leaves significantly less leaves created control plants as compared to plants treated NANO-GRO®. Most number of leaves were determined in the case of plants for variant 4 (Table 2 and Table 3). Similar results were obtained by Kołodziej (2008) and Rosłon *et al.* (2011) for such preparations as Asahi SL, Aminoplant and Goëmar Goteo. As in the case of number of leaves and lateral shoots, the lowest results were obtained in the first period of observation, the highest in the last one.

Table 2. The influence of NANO-GRO® application and term of observation on number of lateral shoots of peppermint plants [pcs per plant]

No influence of application NANO-GRO® on mass of herb collected on the first term of harvest (full flowering phase) was observed, provided that the lowest mass was obtained for control plots (average 203.33 $g \cdot m^{-2}$) the highest for variant 2 (293.33$g \cdot m^{-2}$). Distinct differences in mass of herb whereas were observed in the second term of harvest (regrowth) where higher mass of herb was obtained from plots where the plants were sprayed NANO-GRO® immediately after planting in the field (V4). It was also found that a significantly higher mass of herb was obtained on the second term compared with the first term of harvest. Analyzed preparation significantly influenced also on total mass (sum first and second harvest). The highest mass of herb was obtained for variant 4 (total mass: 943.34 $g \cdot m^{-2}$), the lowest for the control and variant 2 (total mass: 840 $g \cdot m^{-2}$). It is possible that high mass of the raw material obtained in variant 4 is correlated with the highest number of lateral shoots and leaves obtained in this variant (Table 4).

Table 4. The influence of NANO-GRO® application and term of harvest on air-dry mass of peppermint herb [g·m^{-2}]

Peppermint herb is a raw material standardized for essential oil content, and therefore obtained raw materials was rated for the content of this substance. Qualitative and quantitative analysis of essential oil also was carried out. In this experiment, content of essential oil averaged 2.65 ml·100g^{-1}, which is consistent with the results obtained by many authors (Picuric-Jovanovic *et al.*, 1997; McKay and Blumberg, 2006; Kaul *et al*., 2001.). Significantly more essential oil was obtained in the raw material from variant 4, in comparison with other variants of experiment. It was also found that more essential oil was in the herb collected in the full flowering phase in comparison to the herb obtained from the regrowth (Table5). On the increase in the content of essential oil under the influence of other bio-fertilizer indicate also Rosłon *et al*. (2011).

Table 5. The influence of NANO-GRO® application and term of harvest on essential oil content (ml·100 g^{-1})

Variant of NANO-GRO® application	First term of harvest	Second term of harvest	Mean

V2	2.85 a	2.37 b	2.61 B
V3	2.85 a	2.30 b	2.58 B
V4	2.76 a	2.87 a	2.82 A
Mean	2.84*	2.45	

*p=0.05

Assessing, in turn, the chemical composition from investigated essential oils was found that in all variants major compounds were menthol and menthone. 1.8 cineole and terpinene-4-ol were also present in high amounts. This is consistent with results presented by other authors (McKay and Blumberg, 2006, Dimandja *et al*., 2000; Gherman *et al.*, 2000). In the case of menthone obtained results are in the range required by the FP X (2014), which determines the content of that compound from 14.0 to 32.0%. For the menthol - the requirements of above standards specify that it should be 30.0 to 55.0%. Results obtained in this work were lower only for control, in the case of essential oil from variant 2, 3 and 4 (for all variants where the NANO-GRO® was used) the percentage of menthol satisfy the requirements of this standard and was the highest for the oil in variant 4 (36.54%) (Table 6).

Table 6. Identified components of peppermint essential oil and their percentage share [for first time of harvest, 2014]

Variant of NANO-GRO® application				
Chemical compound	V1	V2	V3	V4
α-pinene	0,92	0,91	0,89	0,73

Conclusion

Application of NANO-GRO® significantly affects some morphological features of peppermint, for example the number of lateral shoots and the number of leaves. Under the conditions of this experiment the highest values for these parameters were obtained when the peppermint seedlings were sprayed NANO-GRO® directly after planting them in the field. In this variant the highest mass of herb was also obtained both for analyzed terms of harvest as well as for total mass. The raw material from plots where seedlings sprayed directly after planting them in a field characterized by a significantly higher content of essential oil and a high, consistent with the requirements of Polish Pharmacopoeia X (2014) participation of main component - menthol. Taking into consideration obtained results it can be said that properly chosen application of preparation NANO-GRO® in the cultivation of peppermint can increase the yield of this species and improve the quality of the herb. The recommended procedure that allows to obtain positive results is to spray rooted cuttings of this species directly after planting them in the field.

Acknowledgement

We would like to thank AGRARIUS Ltd. per financial support and the opportunity to test preparation NANO-GRO® in the cultivation of medicinal plants.

HAWTHORN SPECIES FROM TURKEY AND POTENTIAL USAGE FOR HORTICULTURE

Oguzhan CALISKAN*, Safder BAYAZIT, Kazim GUNDUZ

Mustafa Kemal University, Faculty of Agriculture, Department of Horticulture, Antakya, Hatay, Turkey
*Corresponding author: ocaliskan@mku.edu.tr

Abstract

In the review, we aimed to investigate distribution of hawthorn species from Turkey and potential usage for horticulture. Many hawthorn species are grown for their edible fruit in Asia, Central America, and the Mediterranean. Turkey is one of the genetic centers for hawthorn species. Due to its positive effects on the cardiovascular system, *Crataegus* genus has recently become quite a popular herbal medicine in phototherapy. Currently, more than 20 *Crataegus* species have been identified in Turkey, including *C. monogyna* Jacq., *C. pentagyna* Willd., *C. azarolus* L. (synonym *C. aronia*), *C. orientalis* M. Bieb., *C. rhipidophylla* Gaud. and *C. laevigata* (Poir) DC. In different regions of Turkey, hawthorn plants are known by many different names, including 'alıç', 'yemişen' and 'haziran'. They are usually utilized for scattered hedgerow planting in orchards and along road borders. In recent years, the hawthorn has become favored for both fruit size and sweet-sour fruit taste. Especially, *C. azarolus* genotypes are grown in regular orchards for fresh fruit consumption in Hatay and Mersin provinces, Eastern Mediterranean region of Turkey. The fruits has been sold at higher prices in the local markets. There is not yet found a standard hawthorn cultivar although some genotypes has perfect fruit quality characteristics. The most important limiting factor for the hawthorn growing is propagation. Hawthorns can be propagated either seeds or grafting. Generally, *C. monogyna* seeds that has higher seed germination than other species are used as rootstock for the *C. azarolus* genotypes. As a result, we can say that *C. azarolus* and *C. orientalis* will be potential as horticultural crops in the future.

Keywords: *Turkey, Hawthorn species, Horticulture, Fruit*.

Introduction

Crataegus species form a well-defined genus known as hawthorns that belongs to the tribe *Crataegeae* and subfamily *Maloideae* of the *Rosaceae*. The subfamily *Maloideae* comprises about 28 genera and 940 species of ecologically and economically important trees and shrubs (Evans and Campbell, 2002). The genus is placed in the subfamily *Maloideae* and it is closely related to the genera *Pyracantha* M.Roem., *Mespilus* L. and *Hesperomeles* Lindl. The latest phylogenetic analysis of the genus shows that it is closest to the genus *Mespilus* L. (Hummer and Janick, 2009). The genetic diversity center of the section *Crataegus* ranges from Turkey to Iran.

Crataegus fruit generally persists on the shrubs throughout winter and represents an important source of food for many birds and small mammals. In some parts of the world, humans also eat hawthorn fruit, and it is reported to have high flavonoid, vitamin C, glycoside, anthocyanin, saponin, tannin, and antioxidant levels as well as phenolics (Ljubuncic et al., 2005; Caliskan et al., 2012; Caliskan, 2015).

In most European, Mediterranean, and Asian countries, herbs and phytomedicines are treated as drugs to be used in conjunction with conventional medicines. Some of the most important natural health products are employed to treat cardiovascular ailments, and these substances account for

over 25% of phytomedicine sales in the European Union. These herbal treatments include products derived from *Crataegus* species, which are widely available in Europe, Asia, and North America. *Crataegus*-derived medicines can take the form of tinctures, tablets, teas, and aqueous extracts of the plant's leaves, flowers, and fruits (Edwards et al., 2012; Caliskan, 2015).

In Turkey, hawthorn plants are known by many different names, including 'alıç', 'yemişen' and 'haziran', and generally they are used for scattered hedgerow planting in orchards and along road borders. In recent years, the hawthorn has become favored for both fruit size and sweet-sour fruit taste. In this review, we aimed to investigate distribution of hawthorn species in Turkey and their potential usage for horticulture.

Distribution of the hawthorn species in Turkey

Many hawthorn species are grown for their edible fruit in Asia, Central America, and the Mediterranean, with *Crataegus monogyna* Jacq. being the species commonly cultivated in Mediterranean countries. Turkey is one of the genetic centers for *Crataegus*, but few studies have attempted to describe the *Crataegus* strains in Turkey. Browicz (1972) described some of Turkey's *Crataegus* species in Flora of Turkey and the East Aegean Islands, and studies by Donmez have contributed information about new and existing *Crataegus* species (Donmez, 2007). Currently, more than 20 *Crataegus* species have been identified in Turkey, including *C. monogyna* Jacq., *C. pentagyna* Willd., *C. azarolus* L., *C. orientalis* M. Bieb., *C. rhipidophylla* Gaud., and *C. laevigata* (Poir) DC (Table 1). In addition, there are some hybrid species in different ecological regions (Table 2). There is several research on the molecular characterization of the species. Yilmaz et al. (2010) showed that *C.* x *bornmuelleri* hybrids are very close to *C. orientalis* as genetically. In addition, Serce et al. (2011) indicated that *C. aronia* var. *aronia* genotypes are closely related to *C. aronia* var. *dentata* genotypes, however *C. monogyna* var. *azarella* genotypes are not included in same clustered with *C. aronia*.

Table 1. Hawthorn species are found in Turkey

Species	**Species**
C. tanacetifolia (Poir.) Pers	*C. meyeri* Pojark.
C. orientalis M.Bieb. Fl. taur.-caucas	*C. caucasica* C.Koch

C. azarolus L. Sp.	*C. heterophylloides* Pojark
C. pontica C.Koch Verh	*C. longipes* Pojark.
C. pentagyna Waldst. and Kit.	*C. microphylla* C.Koch
C. davisii Browicz	*C. rhipidophylla* Gand.
C. pseudoheterophylla Pojark.	*C. monogyna* Jacq.

Table 2. Hybrid hawthorn species in the flora of Turkey

Parents	**Hybrid species**
C. orientalis x *C. tanacetifolia*	*C.* x *bornmuelleri*
C. monogyna x *C. tanacetifolia*	*C.* x *yosgatica*
C. azarolus x *C. monogyna*	*C.* x *sinaica*
C. monogyna x *C. pentagyna*	*C.* x *rubrinervis*
C. microphylla x *C. rhipidophylla*	*C.* x *browicziana*
C. monogyna x *C. rhipidophylla*	*C.* x *kyrtostyla*

Donmez (2004) indicated that 30% of the species are hybrid in origin. In addition, Turkey have specific ecological conditions for the hawthorn species in the different regions. The regions have at least one characteristic species and other secondary or common species with local genotypes. There are no hawthorn species growing either in the high mountain zone or in forests far from habitation in Turkey. *C. monogyna* Jacq. is widespread in Turkey. It has been given as *C. monogyna* var. *monogyna* and var. *azarella*. Generally, hawthorn species are distributed in temperate zone areas of Turkey. However, some hawthorn species are growing in low altitudes (300-500 m) areas of subtropical conditions in Turkey.

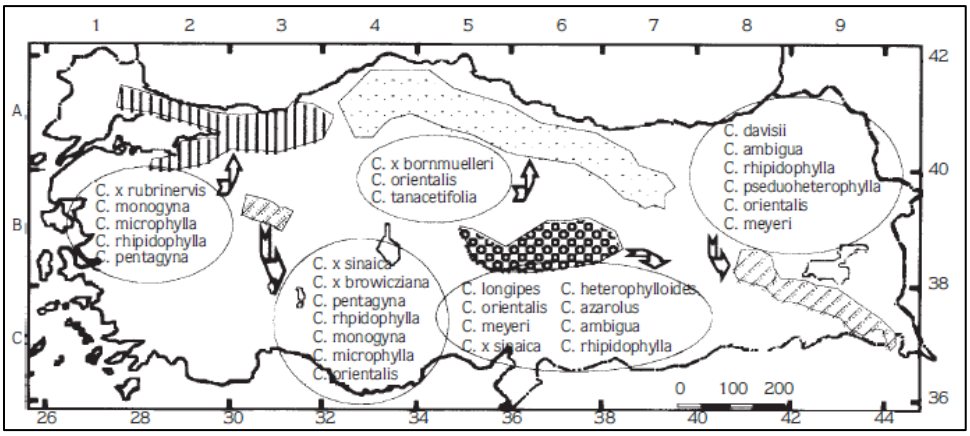

Figure 1. Distribution of the hawthorn species in Turkey (Donmez, 2004)

Traditional use

Crataegus species have been used since ancient times, and the antioxidant constituents of the plant may account for its therapeutic effects in the world. Several hawthorn species are also used as folk medicine. These species include *C. pinntifida* (China), *C. pubesens* (Mexico), *C. cuneata* (Japan), *C. laevigata* and *C. monogyna* (Europe), *C. oxycantha* and *C. aronica* (Middle East), *C. phaenopyrum* (America), and *C. ambigua* (Russia) (Ljubuncic et al., 2005; Caliskan, 2015).

In Europe, the fruit, leaves, and flowers of the plant were traditionally employed in the treatment of heart problems because of their antispasmodic, cardiotonic, hypotensive, and antiatherosclerotic effects, in addition to being ingredients in wine, jam, and candy (Ljubuncic et al., 2005; Caliskan, 2015). Common throughout Turkey, *C. monogyna* Jacq. is one of the species that is highly recommended in folk medicine, and in Spain and Portugal, its fruit is often consumed by shepherds, hunters, and children because it is considered to be "healthy" and nutritious (Carvalho, 2010). In Turkey, the leaf, flower, sprout, and root of *Crataegus* species have been used in traditional medicine to address various diseases such as cough, flu, asthma, stomach ache, rheumatic pain, nephritis, hemorrhoids, and cardiac diseases. The flowers and fruit of the hawthorn plant treat cardiovascular, hypertension, and diabetic diseases. Hawthorn vinegar is produced in some local areas of Turkey, and the fruits and flowers of hawthorn also are consumed as tea. Generally, hawthorn species are evaluated in Turkey as following;

a. *Crataegus azarolus*, *Crataegus orientalis and Crataegus monogyna* species are consumed for fresh fruits,
b. The fruits are used for marmalade,
c. The flowers and fruits are evaluated as medicinal plant for cardiovascular and high blood pressure disease,

d. Hawthorn seedlings are used as rootstock for apple, pear and loquat,
e. *C. monogyna* can be used as ornamental plant,
f. The fruits is used as a food source for forest animals,
g. Hawthorn wood is used in the furniture (especially, walking stick).

Potential usage of hawthorn species for horticulture

Fruit quality characteristics of important hawthorn species: The hawthorn fruits like a small apple, the thin skin covering a fleshy pulp. The color of the ripe fruit ranges from yellow, through green to red and on to dark purple-black. Fruit size varies from species to species. *Crataegus azarolus*, *Crataegus orientalis* and *Crataegus monogyna* species are very promising for the horticulture. The species are used for fresh fruit consumption in Turkey. In recent years, especially *C. azarolus* are grown in regular orchards in Hatay and Mersin provinces, Eastern Mediterranean region of Turkey due to the fruits has been sold at higher prices in the local markets. Most of the species are ripened their fruit in September and October months. *C. aronia* (syn. *C. azarolus*) genotypes has bigger fruit size whereas *C. monogyna* has smaller fruit size (Table 3). Mean seed numbers per fruit of hawthorn are ranged between 1.0 (*C. monogyna*) and 2.7 (*C. aronia*). *C. aronia* and *C. orientalis* are included more total soluble solids compared to *C. monogyna*. In addition, *C. orientalis* and *C. monogyna* has the red skin colors (positive a* values, lower while chroma and hue angle values) while *C. aronia* has the green-yellow skin color (Table 4). *C. aronia* and *C. orientalis* can be promising for horticulture based on the fruit quality characteristics and taste.

Table 3. Fruit quality characteristics of important hawthorn species (Serce et al., 2011)

Species	FW (g)	FD (mm)	FL (mm)	SN	SW (g)	TSS (%)	pH	Acidity (%)
Crataegus aronia var. *aronia*	3.4	17.8	15.8	2.5	0.7	14.8	3.1	1.6
Crataegus aronia var. *dentata*	8.5	24.7	21.7	2.3	1.3	16.0	3.2	1.4
Crataegus aronia var. *minuta*	9.2	24.6	20.6	2.7	1.9	22.5	3.5	1.5
Crataegus orientalis var. orientalis	4.1	18.7	18.8	2.5	0.9	22.5	3.3	1.5
Crataegus monogyna subsp. *azarella*	1.4	9.3	9.6	1.0	0.1	6.1	4.0	1.0

FW; fruit weight, FD; fruit diameter, FL; fruit length, SN; seed number per fruit, SW; seed weight, TTS; total soluble solids

Table 4. Fruit skin color characteristics of important hawthorn species (Serce et al., 2011)

Species	L*	a*	b*	*C*	*h*°
Crataegus aronia var. *aronia*	73.8	-1.2	52.4	53.0	91.7
Crataegus aronia var. *dentata*	76.8	-3.4	50.9	51.4	94.3
Crataegus aronia var. *minuta*	73.0	-1.5	55.9	56.2	91.6
Crataegus orientalis var. orientalis	54.3	30.0	36.8	47.9	51.1
Crataegus monogyna subsp. *azarella*	35.9	29.2	30.1	42.1	46.3

The high L* values indicate lightness. Negative a* values indicate green color and positive a* values indicate red color. The *C* value, shows color intensity. The h^o, a parameter that indicated to be effective in predicting visual color appearance.

Cultivars and growing areas: The hawthorn cultivars are grown as ornamental plants in the world due to the intensity of their flower production and the diversity of colors in their fruits

make them excellent cultivars for use as ornamentals in gardens and large landscaped areas. Generally, hybrids are used as ornamental. The hybrids are obtained from *C. laevigata* x *C. monogyna (*for example, 'Plena', Crimson Cloud', 'Rosea Flore Pleno', and 'Pauls's Scarlet' cultivars). 'Chapeado', 'Calpan Gold' 'Tempranero', 'Centenario', 'Eli' cultivars also used for ornamental plants in Mexico (Nieto-Angel et al., 2013). In China, about 150 cultivars used in the major hawthorn production areas are mainly from *C. pinnatifida* and late ripening cultivars are suitable for fresh consumption *(*Guo and Jiao, 1995). Li et al. (2015) indicated that hawthorn cultivar (*C. pinnatifida*) 'Dajinxing', is one of the most popular cultivar with wide adaptability across different hawthorn-growing regions of China.

Most popular hawthorn species is *C. azarolus* in Turkey. We have not yet a hawthorn cultivar(s) originated from Turkey. However, we can say that the cultivar(s) can be development in the coming years based on results of the resources on the hawthorns. In addition, genotypes of *C. azarolus* are planted as 4x5, 5x5 and 6x6 and drip irrigation are used in new hawthorn orchids. The plants are pruned as open center shape.

Caliskan et al (2012) reported some local hawthorn genotypes (*C. azarolus*) resources are found in Belen, Hatay province, Eastern Mediterranean region of Turkey. Since the 2008s, some promising genotypes have been selected (B3 and B7) and studies continues for commercial production (Serce at al., 2011). The genotypes are found to be commercially very promising because of its size (fruit weight >10 g), total soluble solids (TSS), total phenolic, antioxidant activity and antioxidant capacity. Genotypes of this species are grown in Benlidere (eight producers) and Kömürçukuru (two producers) districts, Belen, Hatay and fruits of this species have been sold in local markets at higher prices. Therefore, some farmers, especially in Belen County, are trying for the orchard establishment with plants of this species. The area is one of the most important hawthorn production center of Turkey, and hawthorn scions are taken form this area for the propagation. New hawthorn orchids are establishment in Kahramanmaraş, Malatya, Mersin and Aksaray provinces of Turkey. *C. orientalis* genotypes with big fruit size and reddish-orange skin color are also consumed as fresh fruit collected from natural populations. In addition, *C. monogyna* that is small fruit size and red skin color is evaluated as fresh fruit, but they fruits are not valuable seen based on horticultural potential. *C. monogyna* can be used for both rootstock and ornamental plants.

Propagation: Vegetative propagation of hawthorns by cutting is not a usefully method because of their rooting percentage is very lower. Grafting and budding can be used for propagation of hawthorns. T-budding is one of the most suitable vegetative propagation methods employed for a wide range of cultivars of hawthorns (Hartmann et al., 2002). Currently, we have not detail information about grafting and budding methods for hawthorn. Already, we are carried out an investigation for the effects of different grafting (whip grafting) and budding (T-budding and chip budding) methods in spring stage for *C. azarolus*. First results are showed that whip grafting method is highly successful at the March and April months for the hawthorns in the ecological conditions of Eastern Mediterranean region of Turkey (unpublished data). Seed propagation is used for rootstock, but a long time is needed for seed germination. For oneseed hawthorn, ISTA (1993) prescribes 90 days of incubation at 25 °C, followed by 9 months of moist-prechilling at 3 to 5 °C. Generally, *C. monogyna* seeds that has higher seed germination than other species are used as rootstock for the *C. azarolus* genotypes. In addition, hawthorn seedlings can be used as rootstock for apple, pear and loquat, but they are not common applications.

Main Problems of the hawthorn growing in Turkey: Basic problems for hawthorn growing are as follows:

a. The registered cultivar(s) are not yet found,

b. Standard method are not development to obtain seedlings,

c. The timing of grafting or budding methods are not unknown,

d. There are not found enough information about technical and cultural practices such as pruning shape, fertilization, irrigation etc.

e. There is no detailed information about diseases and pests in the hawthorns. However, fire blight disease can be severe in some years in the natural populations of Turkey.

Conclusion

Turkey is one of the genetic centers for hawthorn species. In the present, more than 20 *Crataegus* species have been identified in Turkey. Especially, *C. azarolus* and *C. orientalis* genotypes are found to be promising in front of fruit quality characteristics in horticultural sector. There is not development a standard hawthorn cultivar whereas some genotypes has perfect fruit quality characteristics. The most important limiting factor is propagation for the hawthorn growing. We can say that more detail studies are needed for the widespread of hawthorn growing in the future.

Abstract

The phenolic composition of Cynara scolymus L. was determined by analyzing the methanol extracts of the different morphological parts of the plant. More total phenolic compounds in calculation for gallic acid was noted in floral stem and receptacle and inner bracts of capitula. Artichoke plants accumulated 3.9 times less total phenolic compounds in outer bracts, while in leaves the content was more than 9 times lower. The dominant phenolic compound in leaves and floral stem of artichoke was chlorogenic acid. Significantly more chlorogenic acid was noted in floral stem and receptacle and inner bract, over 2.2 times more than in leaves and over 4.1 times more than in outer bracts of capitula**.** Cynarin was the main hydroxycinnamic acid in artichoke extracts, particularly in leaves extract. Apigenin represented the most abundant flavonoids in cultivated artichoke extracts, especially in capitula receptacle extract, and floral stem. The highest mean content of luteolin characterized leaves of artichoke than floral stem and receptacle with inner bracts capitula**.** Our results showed that the extraction of phenolic compounds from all morphological parts of artichoke can be integrated in an industrial value chain, involving nutraceutics and as animal feedstuff.

Introduction

An artichoke (*Cynara cardunculus* L. var. *scolymus* (L.) Fiori) belongs to the *Asteraceae* family and is a commonly cultivated plant in Southern Europe around the Mediterranean region (Sonnante et al. 2002). Globe artichoke is a perennial, rosette plant, widely cultivated for the large fleshy head or capitula (immature flowers). The edible parts of the artichoke are the tender inner leaves (bracts) and receptacle commonly known as 'heart' (Lombardo et al. 2010, Sałata and Gruszecki, 2010).

Artichoke plays an important role in human nutrition, especially in the Mediterranean area. In addition, artichoke contributes significantly to the Mediterranean agricultural economy, where more than 50% of the total word production is produced (FAO, 2016). Italy is a leading producer (about 470.000 t annually) followed by Spain (215.000 t), France (55.000 t) and Greece (25.000 t).

Plants produce a diverse array of organic compounds, that majority of which are not directly involved in growth and development. Such compounds, often referred to as secondary metabolites, generally have unknown functions, they are thought to benefit plants by mediating a wide range of interaction between plants and their environment (Kähkönen et al. 1999). Many secondary metabolites act a defensive agents against pathogens and herbivores and provide reproductive advantages as attractants of pollinators and seed disperses. There is also growing

evidence that secondary metabolites have a host of physiological activities related to protection against various form of environmental stress. The function of these secondary metabolites seems to be involved in plant defense against abiotic (i.e. UV irradiation, wounding) and biotic (pathogen attacks) stresses (Lombardo et al. 2012). In fact, the enzymatic steps involved in this pathway are under the control of corresponding genes which are induced by signal molecules involved in local and systemic defense signaling (Lombardo et al. 2010).

These compounds are generally classified into three major groups, based on their biosynthetic origin: terpenoids, alkaloids and phenolics (often referred to as polyphenols). The major classes of phenolic are the hydroxycynnamic acids, flavonoids, anthocyanins and tannins. According to many opinions, poliphenolic compounds found in artichoke plants, especially mono- and di-caffeoylquinic acids and flavonoids, decide about their health-enhancing and antioxidant properties (Kukić et al. 2008, Lattanzio et al. 2009).

Artichoke contains a high level of phenolic compounds, especially in capitula, as reported by several authors (Fratianni et al., 2007; Falleh et al., 2008; Pandino et al., 2011a). In available literature the wide therapeutic spectrum of poliphenolic compounds included in artichoke capitula is emphasized (Pandino et al., 2011a). The phenolics include cynarin (1,3-di-O-caffeoylqunic acid), luteolin, cynaroside (luteolin-7-O-glucoside), scolymoside (luteolin-7-rutinoside) and phenolic acids such as caffeic, coumaric, hydroxycinnamic, ferulic, and caffeoylqunic acid derivatives, mono- and dicaffeoylqunic acids (Pandino et al., 2011a).

The pharmacologic properties of artichoke is well documented in several in vivo and in vitro studies for the treatment of hepato-biliary dysfunction, dyspeptic syndromes, gastric diseases, as well as inhibition of cholesterol biosynthesis and low density lipoproteins (LDL) oxidation – agents responsible for arteriosclerosis and coronary hearth diseases (Speroni et al., 2003, Rossoni et al., 2005, Brat et al. 2006, Bundy et al., 2008, Lattanzio et al. 2009)

The aims of the undertaken research were to investigate the phenolic profile of different parts (outer, intermediate and inner bracts, and receptacle) of capitula artichoke.

Material and methods

Plant materials

The plant materials were artichoke globe plants cultivar ‘Symphony F1’ that is frequently cultured in Spain. Plants were cultured in the Cajamar Fields (Station in Paiporta, SW Valencia, Spain) in 2013 under standard growth conditions and management practices.

The seed was sown on 6 June 2012 and planted on 25 July 2012 in sandy clay loam soil (59% sand; 18% silt; 23% clay), pH=8.4, organic matter=1.29 %; CE (1:5)=0.168 dSm^{-1}. Average temperatures between August 2012 and May 2013 ranged between 26.5°C and 11.2°C, maximum temperatures between 31.6°C and 16.5°C, and minimum temperatures between 21.4°C and 4.6°C.

Plants were arranged in a completely randomized manner with three replicates of eight plants per plot. Fertilization and irrigation were performed following Pomares et al. (2004).Management of weed and pests was in accordance to standard commercial practices.

Plants were separated in stalk, capitula and leaves, and transported to the laboratory at 4ºC. At the laboratory, samples were washed, examined to eliminate damaged samples, were separated in receptacle with inner bracts (edible parts) and outer bracts (non-edible part) of capitula and floral stalk (non-edible part), freeze-dried, milled and stored in sailing bags until chemical analyses.

Samples preparation for HPLC analyses

The phenolic extract was obtained by solvent extraction with methanol (1:10) in a reflux condenser at the temperature of the solvent boiling point for 3 h. After percolation, the material was treated again with 80% methanol and was extracted twice for 2 h. Methanol extracts were joined, the solvent was evaporated, and the remains were eluted with hot water (50 ml). Water solutions were left in a refrigerator for 24 h. The separated tarry residues that contained ballasts were filtered and rinsed with distilled water. Having been obtained in this way, the filtrate was degreased by shaking 3 times with light petroleum (30 ml each). Then purified water solutions were extracted 10times with diethyl ether (20 ml each). Joined ether extracts were concentrated to a 100-ml volume and shaken 10 times with a 5% water solution of $NaHCO_3$ (10 ml each) to transform phenolic acids into salts that were readily soluble in water. Bicarbonate fractions, including phenolic acids salts, were acidified with 35% HCl to pH=3 In this way free phenolic acids were obtained, which were again extracted with diethyl ether by shaking with this solvent 10 times (10 ml each). Ether extracts were joined and dried with anhydrous Na_2SO_4. The solvent was then distilled until dry to give free phenolic acid fractions.

HPCL determination of polyphenols

HPLC separation was performed on a UFLC Shimadzu series instrument (Japan) coupled to a diode-array detector (DAD). Separation was performed in a Phenomenex Synergi Fusion-RP column (4μm, 250×4.6 mm i.d.; Phenomenex) with a sample injection volume of 20μL. The mobile phase was composed of acetonitrile (A) and water/formic acid (100/0.1, v/v) (B). A gradient programme was followed as so: 20% A (0 min), 25% A (10 min), 25% A (20 min), 50% A (40 min), 100% A (42–47 min), 20% A (49–55 min). The mobile phase flow rate was 1 mL/min; the chromatogram was recorded at 280 nm and 320 nm, and the spectral data for all the peaks were accumulated within the 190-400 nm range. Column temperature was controlled at 30°C (Gouveia and Castilho, 2012).

Statistics

The results of the polyphenolic content in the different artichoke head parts were statistically processed by Statgraphics Centuriun XV (Manugistics Inc., Rockville, MD, USA). The statistical analysis of polyphenols concentrations was done by an analysis of variance (one-way ANOVA). The least significance (LSD) procedure was used to test for the differences between averages at the 5% level of significance.

Results and discussion

The content of total phenolic compounds in different parts of inflorescences and leaves artichoke is presented in Table 1. More total phenolic compounds in calculation for gallic acid was noted in floral stem, mean 1550 mg 100 g dry weight, and receptacle and inner bracts, means 1538 mg 100 g dry weight Artichoke plants accumulated 3.9 times less total phenolic compounds in outer bracts, while in leaves the content was more than 9 times lower. The phenolic contents in different morphological parts of cultivated artichoke are the same trend of this described for different varieties of Cynara cardunculus L. (Fratiani et al. 2007, Pandino et al. 2011b, Ramos et al. 2014).

The qualitative content of phenolic acids was very different depending on the morphological parts of heads (table 2). Among identified phenolic acids, the highest share had derivatives of cinnamic acid: chlorogenic acid **(**5-O-caffeoylquinic acid**)** and cynarin **(**1,3-O-dicaffeoylquinic acid**).** Significantly more chlorogenic acid was noted in floral stem and receptacle and inner bract (815 and 677 mg 100 g^{-1} of DM respectively), over 2.2 times more than in leaves and over 4.1 times more than in outer bracts of capitula.

In an earlier research it was proved that artichoke plants accumulate more hydroxycinnamic acids in flower heads than in leaves (Romani et al. 2006; Fratianni et al. 2007, Ramos at al. 2014). The dominant compound was chlorogenic acid, known to have antioxidant activities and

anticarcinogenic properties (Rossoni et al. 2005). The large content of this substance explains its important role in biochemical reactions leading to form different poliphenolic compounds (Pandino et al. 2011b).

The content of cynarin in leaves was mean 26.7 mg 100 g^{-1} of DM and it was almost 2 times higher than edible parts of capitula (receptacle with inner bract). The less of this compound was marked in outer bracts and floral stems. Cynarin is considered the one with the highest capacity to inhibit cholesterol biosynthesis and LDL oxidation (Lattanzio et al. 2009).

The statistical analysis of normal and mean values of apigenin showed the highest content in receptacle with inner bract (742 mg 100 g^{-1} of DM) and floral stem (611.3 mg 100 g^{-1} of DM). The content of apigenin in leaves was 2.3 times lower, and in outer bracts it was 3 times lower than in in receptacle with inner bract.

The highest mean content of luteolin characterized leaves of artichoke (4.3). The content of luteolin in heads of artichoke was more even, the highest level of this compound was marked in receptacle with inner bracts (mean 2.3 mg 100 g^{-1} of DM) and floral stem (mean 2.0 mg 100 g^{-1} of DM), while less in outer bracts, mean 1.8 mg 100 g^{-1} of DM. This values agree with those reported by other authors (Pandino et al. 2011a, Lombardo et al. 2012). Pandino et al. (2011b) also reported that the artichoke leaves, in general, were rich in luteolin and apigenin while the main sources of caffeoylquinic acid isomers is the floral stem.

Table1. Total phenolic content from several morphological parts of artichoke (mg GAE·100 g^{-1} DW)

Flolar stem	Receptacle and inner bracts	Outer bracts	Leaves	Mean	α

Total flavonoids	**613.6±575**	**744.0±567**	**202.3±118**	**262.6±198**

Means with different letters for the same row are significantly different. Significance level (α):*** $p<0.05$; nd - not detected

Conclusions

The analysis of the most important polyphenols present in globe artichokes (i.e. chlorogenic acid, apigenin and cynarin) demonstrated the high content of these chemical species in Spanish cultivars 'Symphony F1'. The most abundant species was chlorogenic acid, followed by apigenin and cynarin. Apigenin and cynarin accumulated main in the receptacle and inner bracts, chlorogenic acid predominated in stems and in the receptacle and inner bracts. These data suggest the importance of those cultivar in not only the food industry, but also in the pharmaceutical one where industrial waste could be used to production concentrated phenolic extracts. Finally, the present work shows that extraction of phenolic compounds from all morphological parts of inflorescences artichoke can be good valuable material for herbal industry and nutraceuticals production. Regarding the large diversity of phenolic compounds found in flower heads the interest in their use for production of health-enhancing functional food increases.

A STUDY ON THE DETERMINATION OF YIELD PROPERTIES AND FACTORS THAT AFFECT THE YIELD IN COWPEA UNDER KIRSEHIR/TURKEY ECOLOGICAL CONDITIONS

Omer SOZEN[1*], Ufuk KARADAVUT[2]

1Department of Field Crops, Faculty of Agriculture, Kırsehir, Turkey
2 Department of Animal Science, Faculty of Agriculture, Kırsehir, Turkey
*Corresponding author: ekim_55@hotmail.com

Abstract

This study aimed to determine cowpea seed varieties that may be suitable for the production efficiency and affecting yield factors in Turkey's located Middle Anatolia Kırsehir ecological conditions. The study was conducted for 2 years in 2014-2015. In research, 4 cowpea varieties (Amazon, Sırma, Karagoz, Akkız) and control Nevsehir / Hacıbektas, obtained from the district domestic genotype 1, were used. Research was conducted in a randomized complete block experimental design with three replications. Sowing was performed on 10 May 2014 and on 8 May 2015. The local cowpea cultivars and genotypes according to the two-year average grain 50% flowering number of days 68-80 days, 50% pod connecting number of days 93-102 days, plant height 41-83 cm, pod number in plant 2-10 pieces/plant, pod length of 5-15 cm/pod, 100 seed weight and seed yield 11.46-18.75 g per plant between 1:21 to 6:19 g/plant ranged. As a result, number of pods per plant and seed per plant, plant and yield per plant and the number of days between the number of pods per pod connect with biological yield was found to be very important relationship. At the same time the first pod height, plant height and number of pods with one seed per plant were among the important relationships that were identified in both years. In cowpea breeding programs, in the number of pods per plant, yield per plant, number of pods per plant and has laid the biological traits could be used as selection criteria.

Key words: *Kırsehir, cowpea, local genotypes, yield, yield components*

Introduction

Cowpea is an important food legume as fresh and dry seed in human diet and as animal feed and green fertilizer for the improvement of soil fertility (Akcin, 1988). Depending on the cultivar and environment conditions, it contains 18-31.6% protein, 50-67% carbohydrates, 1.3% oil, 3.9% cellulose and 3.6% ash. Fresh pods and dry seeds of cowpea are used as edible legumes. Due to eating habits in human diet, priority is given to the consumption of animal-derived proteins. However, for a healthy diet, plant-derived proteins, as well as animal-derived proteins, should be consumed. Because, cowpea plant is rich in amino acids, lysine, tryptophan, carotene and B1 vitamin (Ozturk, 2010). Cowpea which is an edible legume is the third in legume production in the world following beans and chickpeas with 11.926.786 ha cultivation area, 6.224.698 tons of production and 52 kg/da yield. In Turkey, it is fifth in legume production following chickpeas, beans, lentils and broad beans with 1.941 ha cultivation area, 2.006 tons of production and 103 kg/da yield (FAO, 2013). Cowpea cultivation in Turkey is unsatisfactory. Cowpea cultivation should be developed and a cultivator culture should be established on this subject. As in other culture plants, it is of great importance, as well as other cultural applications, to use cultivars suitable to the ecological conditions for increasing the yield per unit area (Sert ve Ceyhan, 2012).

Ozturan and Gulumser (2004), in their study on Akkız and Karagoz cultivars, determined some yield properties including plant height, pod number in plant, yield per plant, seed yield, 1000-seed weight and crude protein have reported the highest seed yield as 273.1 kg^{-1}. The researchers obtained the highest seed yield per plant in Karagoz cultivar (69.0 g). Oztokat and Demir (2010), in their study on 31 different cowpea genotypes in Aegean region, determined the highest yield as 84.20 kg^{-1}. Vural et al. (2000), in their study, stated that growing condition is the most important factor that affects the yield. The researchers have reported that ecological conditions seriously affect the fertility. Tomer and Verma (1989) have reported that seed weight had a sufficient effect on the growth and development in cowpea. Gul (1996) has reported that the humidity should be high for the germination of cowpea. The researchers determined that cowpea may not germinate in soils where most of the legume types easily can.

Kırsehir is ecologically suitable for cowpea cultivation. However, the production level is not satisfactory due to the consumption habits of the producers. The aim of this study is to determine the genotypes of cowpea (line/variety) in terms of yield suitable for Kırsehir/Turkey ecological conditions which features all the characteristics of Central Anatolian ecological conditions.

Material and Methods

The present study aims to determine the yield and some agronomic properties of cowpea (*Vigna sinensis* L.) genotypes under Kırsehir/Turkey ecological conditions. The study was conducted for 2 years in 2014-2015 at trial farmlands located at Mucur country in Kırsehir. The altitude of Mucur country in which the study was carried out is about 80 m and it is located at 39°3'48.00"K latitude and 34°22'19.71"D longitude (Figure 1).

Figure 1. Locations where the conduct of the trials

Examining the analysis results for the soil used in the study, it was seen that the soil had a clayey-loamy structure with mild alkaline characteristics, saltless, calcareous, moderate in phosphorus, rich in potassium and moderate in organic substance for the every both years.

The average monthly temperatures and relative humidity ratios for both years were highly similar to those of long-term temperature and relative humidity values. However, examining the monthly total precipitation values, the total precipitation values for all months for both 2014 and 2015 were considerably higher compared to the long-term average values. Particularly, 161.4 mm precipitation value for June 2015 was 11 times higher than the long-term average values (Table 1).

The study was established according to the randomized complete block experimental design in three replications. Four cowpea standard cultivars (Akkız, Amazon, Karagoz, Sırma) and one native population, a total of five cowpea genotypes were included in the study. The seeds were sown in plots consisting of 4 rows which were prepared using a 5 m marker with 60 row spacings (5 x 2.40 m= 12 m^2) and 10 cm intra-row spacings manually between10 May 2014 and 8 May 2015. In addition to planting, the necessary fertilization (15 kg diamonium phosphateper decare)

was distributed among the plots homogeneously and herbicide application was carried out before planting and sprouting. Additionally, necessary irrigation was carried our during the required period for the plants. Harvest was carried out manually between 14 September 2014 and 11 September 2015. In each plot consisting of 4 rows, the 1st and the 4th rows of the plots and 50 cm distances from the starting point of each plot was removed as the edge impact and total harvesting was performed in the remaining area.

Flowering and pod setting values of all cowpea genotypes in all plots for the two years and phonological and agronomic properties including plant height (cm), first pod height (cm), the number of pods per plant (piece/plant), the number of seed per pod (piece/pod), the number of seed per plant (piece/plant), seed yield per plant (g), 100 seed weight (g), pod height (cm) and biological yield (g) for 10 plants randomly selected from each plot were determined according to Akcin (1974) and Gulumser (1981).

Table 1. Climate data for the Kırsehir.

Climatic Factors	Years	Months				
		May	June	July	August	September
Total Rainfall (mm)	2014	46.6	36	13	17	30.4
	2015	39.2	161.4	20.6	11.8	1
	ALY*	10.7	13.9	2.9	1	2.6
Average temperature (^{0}C)	2014	16.9	20.8	27.6	28.2	20.1
	2015	16.4	18.9	24.9	25.9	23.8
	ALY*	16.2	20.6	24.8	24.9	19.6
Average Relative Humidity (%)	2014	59.5	51.6	33.6	33.6	50.8
	2015	57.5	65.6	41.5	45.4	41.1
	ALY*	56.2	50.9	38.4	37.6	43.3

*ALY: Average Long Years

The combined data of the two years were subjected to the ANOVA using JUMP5.0 statistical software. The "LSD Multiple Comparison Test" was used for the comparison between the significant differences between the average values. The study comprised combined data of the each property examined for the both years.

Results and Discussion

50% The Number of Flowering and Pod Connecting Days

In terms of the average 50% number of flowering days for the both years, the differences between the cowpea genotypes were very significant ($P<0.01$). The genotypes with the longest 50% flowering periods were sırma and akkız genotypes with 75.9 days and 75.5 days, respectively (Table 2). The shortest 50% flowering period was determined in the native genotype with 69.5 days. The average 50% flowering period for all genotypes were 73.2 days. These results were in line with the results reported by Gulumser et al. (1989) who have reported that the flowering period for native cowpea genotypes varied between 66 and 73 days. Similarly, Buyukkılıç (1995), in their study conducted under Sanlıurfa conditions have reported that flowering period varied between 56 and 57 days. This was associated with the different ecological conditions in terms of humidity and temperature of the area that the study was conducted. Pod connecting and flowering periods are directly related to each other. 50% pod connecting period is described as the number of days for the plant until the date of 50% pod connecting. The average pod setting for the two years in the study was determined as 96.7 days and the differences between the

genotypes were statistically not significant (Table 2). The genotype with the longest pod connecting period was sirma with 99 days whereas the shortest pod setting period was determined in the native population with 94.5 days.

Plant Height

The average values of plant height for cowpea genotypes for the two years and the LSD groups are shown in Table 2. Analysis of variance revealed that the differences between the average plant heights of cowpea genotypes for the two years were very significant ($P<0.01$). The genotypes with the highest plant heights were sırma, amazon and native cowpea genotypes with 61.5 cm, 59.9 cm and 57.7 cm, respectively. The lowest plant heights were determined in akkız and karagoz genotypes with 45.8 cm and 47.6 cm, respectively. The average plant height was determined as 54.5 cm. The difference between the plant heights of the highest genotype and the lowest genotype was 15.7 cm. In a study on the determination of the effects of different intra-row spacings and via on seed yield and some agronomic properties of cowpea (*Vigna sinensis (*L.) *Savi*) cultivars under Hatay province ecological conditions, the plant height values varied between 33.22 cm and 60.37 cm (Sert, 2011). In another study on the determination of plant properties and ability of cowpea cultivars under Hatay ecological conditions, the differences between the plant height values of ecotypes were statistically significant (Atıs ve Yılmaz, 2005). The results obtained by the researchers were in line with the results obtained in the present study.

First Pod Height

Results for the analysis of variance for first pod height values of the cowpea genotypes and the LSD groups in the study are shown in Table 2. As seen in Table 2, the differences between the first pod height values of the genotypes were statistically significant ($P<0.05$). Examining the average values for the two years, first pod height varied between 21.3 cm and 25.4 cm. The highest first pod height values were determined in amazon and akkız genotypes with 25.4 cm and 25.1 cm, respectively.

These two genotypes were statistically located in the same group (a). The lowest first pod height was determined in native cowpea genotype with 21.3 cm. The average first pod height for the cowpea genotypes was 23.9 cm (Table 2). The higher first pod height values obtained in the present study was associated with high plant height values. Karasu (1999), in their study on the determination of the agronomic characteristics of some cowpea ecotypes under Isparta ecological conditions 1996-1997, have reported the first height between 17.8 cm and 22.7 cm. Although the variation was high, our results were within this variation.

Table 2. Two-year average of the investigated properties for cowpea genotypes

Genotypes	50% flowering number of days	50% pod connecting number of days	plant height (cm)	first pod height (cm)
sırma	75,9 a	99	61.5 a	24.5 ab
akkız	75,5 a	95.5	45.8 b	25.1 a
karagoz	74,5 b	96.5	47.6 b	23.4 ab
amazon	70,5 c	98	59.9 a	25.4 a
local	69,5 d	94.5	57.7 a	21.3 b
average	73.2	96.7	54.5	23.9
materiality	**	ns	**	*

ns, *, **=not significant and significant effect at 5 and 1 % respectively

The Number of Pods in the Plant

One of the most important components that affect the yield is the number of pods in the plant. As a result of the analysis of variance for the combined data of the two years, the differences between the genotypes in terms of the number of pods in the plant were significant (P<0.01). The groups formed in terms of the number of pods in the plant and LSD values are shown in Table 3.

Examining Table 3, it was seen that the number of pods in the genotypes varied between 3.7 and 6.5 pieces. Genotypes with the highest number of pods were akkız, amazon, sırma and native genotype with 6.5, 5.5, 5.5 and 5.5 pieces respectively. The genotypes were statistically located in the same group (a). The lowest number of pods were determined in karagoz genotype with 3.7 pods. The difference between the lowest and the highest number of pods (between sırma and akkız genotypes) was 2.8.

Ceylan and Sepetoglu (1983), in their study, have reported that the number of pods in cowpea genotypes varied between 2.1 and 26.5. On the other hand, Karasu (1999) have determined the number of pods in the plant between 29.4 and 40.6. In a study on the determination of the effects of different row spacings and via on seed yield and some agronomic characteristics conducted under Hatay ecological conditions in 2009, have reported the number of pods in the plant between 12.19 and 14.59 (Sert, 2011).

The number of pod obtained in the present study was lower than those obtained by other researchers. This was mainly associated with the decrease in plant growth in pod connecting period as well as the increase in high temperatures.

The Number of Seeds per Pod

The average number of seeds per pod values of cowpea genotypes and the groupings are shown in Table 3. Examining Table 3, the differences between the genotypes in terms of the number of seeds per pod were significant (P<0.01).

The number of seeds per pod varied between 4.1 and 5.6. The highest number of seeds per pod was determined in amazon genotype with 5.6 seeds. This genotype was statistically located in (a) group. This genotype was followed by akkız, sırma and karagoz genotypes with 5.3, 4.6 and 4.4 seeds, respectively. These three genotypes were located in the same group (ab). The lowest numbers of pods were determined in native genotype with 4.1 pods.

Clarke and Skeete (1982), in their study on arauca cowpea cultivars, have reported that, in five different plant spacing applications, planting spacing frequency had no effects on the number of seeds per pod and 100-seed weight. Bahceci (1987), in their study conducted under Cukurova ecological conditions, have reported that the number of seeds per pod increased as the intra row space increased.

In a study on the effects of different row spacings and nitrogen fertilization on the yield and yield components of akkıiz and karagoz cowpea cultivars under Samsun ecological conditions, the number of seeds per pod varied between 10.4 and 11 (Ozturan, 2003).

Pod Length

The average pod length values of cowpea genotypes for the two years are shown in Table 3. The differences between the genotypes in terms of pod lengths were found to be statistically not significant. Pod lengths of the genotypes in the study varied between 8.7 and 9.6 cm and other genotypes varied between these two genotypes.

The average pod length of the genotypes was 9.12 cm. The highest pod length value was determined in Amazon genotype with 9.6 cm whereas the lowest pod length values was in karagoz genotype with 8.7 cm. In a study on the determination of physiological and

morphological properties and yield and yield components of cowpea (*Vigna Sinensis L.*) ecotypes cultivated under Ordu ecological conditions, it has been reported that pod length values varied between 15.1 and 19.8 cm (Ozturk, 2010).
In another study on the determination of the most suitable variety and seed planting period for cowpea *Vigna unguiculata* (L.) Walp) under dry and aqueous ecological conditions of Isparta, the highest pod length value was determined in akkız cultivar with 16.19 cm whereas the lowest pod length values was determined in sarıgobek cultivar with 12.34 cm (Unlu, 2004). Pod length values obtained by the researchers were substantially higher than those obtained in the present study. This was associated with the increase in temperature and the decrease in humidity in the area that the study was conducted during pod setting period and the decrease in plant growth.

Table 3. Two-year average of the investigated properties for cowpea genotypes

Genotypes	the number of pods per plant	the number of seed per pod	pod length
akkız	6,5 a	5.3 ab	9.0
amazon	5,5 a	5.6 a	9.6
sırma	5,5 a	4.6 ab	9.0
local	5,5 a	4.1 b	9.3
karagoz	3,7 b	4.4 ab	8.7
average	5.34	4.8	9.12
materiality	**	**	ns

ns, *,**=not significant and significant effect at 5 and 1 % respectively

100 Seed Weight
The average 100 seed weight values of cowpea genotypes and statistical groupings are shown in Table 4. The effect of genotypes on 100 seed weight was statistically very significant ($P<0.01$). 100 seed weight values of the genotypes varied between 13.56 g and 16.94 g and the highest 100 seed weight value was determined in sırma genotype with 16.94 g. On the other hand, the lowest 100seed weight values were determined in native genotype and akkız genotype with 13.56 g and 14.24 g, respectively. These two genotypes were statistically located in the same group. The difference between the highest and the lowest 100 seed weight values was 3.38 g and the average 100 seed weight was 15.36 g. In a study on the determination of plant characteristics and adaptation capabilities in different cowpea ecotypes obtained from different parts of Turkey under Hatay ecological conditions, 100 seed weight value varied between 12.93 and 21.94 g (Atış, 2000). In a study on the determination of the most suitable cowpea cultivar (akkız, karnıkara and sarıgobek) and seed planting period under dry ecological conditions in Isparta, 100seed weight was reported between 12.55 and 21.53 g (Unlu, 2004).

Seed Yield per Plant
The average seed yield per plant values and statistical groupings are shown in Table 4 and the differences between the genotypes in terms of seed yield per plant values were very significant at 1% level.
Examining Table 4, seed yield per plant values varied between 1.916 and 3.003 g. The two genotypes with the highest seed yield per plant values were akkız and amazon cowpea genotypes with 3.003 g and 2.998 g, respectively. These two genotypes were statistically located in the same group (a). This was followed by sırma and native genotypes with 2.684 g and 2.382 g and these

two genotypes were statistically located in the same group (ab). The lowest seed yield per plant was determined in karagoz genotype with 1.916 g.
The difference between the highest and the lowest seed yield per plant values was 1.087 g. In a study conducted under Cukurova conditions, Bahceci and Engin (1989) have reported that the highest seed yield per plant values were determined in karagobek cultivar in 30 cm (44.03 g) and 25 cm (35.53 g) planting spacings, respectively, and in kırmızı cultivar in 25 cm (32.35 g) and 30 cm (28.30 g) planting spacings, respectively.
In another study conducted under Samsun ecological conditions, seed yield per plant values varied between 48.4 and 69 g (Ozturan, 2003). The seed yield per plant values obtained in the present study were lower than those obtained by other researchers. This associated with the effect of temperatures much above 30 °C in maturation period on seed maturation.

Table 4. Two-year average of the investigated propertiesfor cowpea genotypes

Genotypes	seed yield per plant	100 seed weight
akkız	3,003 a	14.24 c
amazon	2,988 a	15.81 b
sırma	2,684 ab	16.94 a
local	2,382 ab	13.56 c
karagoz	1,916 b	16.22 ab
average	2.594	15.36
materiality	**	**

ns, *, **=not significant and significant effect at 5 and 1 % respectively

Conclusion

The aim of the present study was to determine the yield properties and the factors that affect the yield in cowpea under Kırsehir/Turkey ecological conditions 50% flowering number of days, 50% pod connecting number of days, plant height (cm), first pod height (cm), the number of pods per plant (piece/plant), the number of seed per pod (piece/pod), seed yield per plant(g/plant), 100 seed weight (g) and pod length (cm) values were examined and compared with other studies.
In conclusion, the results obtained for the two years were not satisfactory to make a clear conclusion. However, the result obtained in terms of yield components in particular, the number of seeds, 100 seed weight and the yield per plant were promising for some cultivars. Indeed, high yields were obtained from akkız, sırma and amazon cultivars. In order to acquire better results on cowpea cultivation, it was concluded that the study should be conducted for a couple more years in Kırsehir and neighboring locations.
Considering the importance of edible legumes in human diet, there is need for research and development on the breeding and cultivation techniques for cowpea. These research studies will contribute to the development of agricultural production and hence the elevation of socio-economic structure.

GENOTYPIC SPECIFICS OF TRITICALE VARIETIES (*X TRITICOSECALE* WITTM.) AS A FUNCTION OF THE NITROGEN FERTILIZATION LEVEL

Hristofor KIRCHEV

Department of Crop Science, Faculty of Agronomy, Agricultural University, Plovdiv, Bulgaria
*Corresponding author: hristofor_kirchev@abv.bg

Abstract

A field experiments were conducted during three growing seasons, from 2012 to 2014, at the experimental field of Department of Crop Science in Agricultural University – Plovdiv. The experiment consisted of a randomized complete block design after predecessor rapeseed with three replicates and plots of 10 m^2 planted at a sowing rate of 550 viable seeds m^{-2}. Three triticale (×*Triticosecale* Wittm.) cultivars, one Bulgarian and two Spanish were studied – Rakita, Bulgarian standard, breeding at the Dobruja Agricultural Institute – Gen. Toshevo, Trujillo and Senatrit, created in Spain. Three nitrogen fertilization level has been studied – N_0, N_{80} and N_{160} kg ha^{-1} nitrogen expressed as ammonium nitrate – 1/3 of nitrogen was introduced after sowing, and the remaining 2/3 in early spring. To establish the productivity of the tested varieties of triticale under the influence of nitrogen fertilization were determined following parameters: grain yield, after plots were harvested at ripening and yield was expressed on a 13% grain moisture basis; number of spikes per m^2; plant height, cm; spike length, cm; number of spikelets per spike; number of grain per spike; mass of grain per spike, g; weigh of glumes per spike, g and spike harvest index, calculated as: (spike grain yield/total spike biomass) x 100.

Keywords: *triticale, variety, nitrogen fertilization, yield.*

Introduction

The combination of the resistance to biotic and abiotic stresses of rye with the high yield potential and good grain quality of wheat resulted in the man-made small grain Triticale (x *Triticosecale* Wittmack). This artificial plant is of interest due to its nutritional value which largely surpasses in many aspects those of wheat and rye. Triticale breeding programs are mostly focused on major economic traits such as grain yield, biomass yield, nutritional value, earliness and grain filling percentage (Grabovets and Popova, 2015; Moskalets et al., 2016; Priya et al., 2015; Stoyanov and Baychev, 2015).

Apart from the variety, many researches have been conducted on crop nutrients management and optimization. These studies (Bielski et al., 2015; Gerdzhikova et al., 2013a,b; Gerdzhikova, 2014; Jorgensen et al., 2007; Kolev et al., 2011; Kirchev et al., 2012; Kirchev et al., 2014; Madic et al., 2015; Wojtkowiak et al., 2015) have revealed the significant importance of nitrogen fertilizer optimization for triticale. Keeping in view the importance of nitrogen fertilization for triticale, the present study was conducted to evaluate the response of triticale varieties to various levels of nitrogen.

Material and methods

Field trials

A field experiments were conducted during three growing seasons, from 2012 to 2014, at the experimental field of Department of Crop Science in Agricultural University – Plovdiv

(42°08'26.2"N 24°48'21.1"E). The experiment consisted of a randomized complete block design after predecessor rapeseed with three replicates and plots of 10 m^2 planted at a sowing rate of 550 viable seeds m^{-2}.

Three triticale (*xTriticosecale* Wittm.) cultivars, one Bulgarian and two Spanish were studied: Rakita (Cooring x 35-131-5, a complete type triticale) Bulgarian standard, breeding at the Dobruja Agricultural Institute – Gen. Toshevo, Trujillo – derived from CIMMYT germplasm, a 'Juanillo' sister line (a complete type triticale) and Senatrit, released by the Spanish company SENASA, a substituted type.

Three nitrogen fertilization level has been studied – N_0, N_{80} and N_{160} kg ha^{-1} nitrogen expressed as ammonium nitrate – 1/3 of nitrogen was introduced after sowing, and the remaining 2/3 in early spring.

Estimation methods

To establish the productivity of the tested varieties of triticale under the influence of nitrogen fertilization were determined following parameters: grain yield, after plots were harvested at ripening and yield was expressed on a 13% grain moisture basis; NSM – number of spikes per m^2; PH – plant height, cm; SL – spike length, cm; NSS – number of spikelets per spike; NGS – number of grain per spike; MGS – mass of grain per spike, g; WGS – weigh of glumes per spike, g and SHI – spike harvest index, calculated as: (spike grain yield/total spike biomass) x 100.

Statistical analysis

The results were analyzed using the software package IBM SPSS Statistics 22. A two-way analysis of variance were used to determine the influence of various factors.

Results and discussion

The grain yield of studied triticale varieties under the influence of nitrogen fertilization, set over three harvest years is presented in table 1. In the first year of the study, lowest yield from the variants without nitrogen fertilization was obtained from variety Trujillo - 1.183 t ha^{-1}. Second in productivity is variety Rakita, and the highest yield was obtained from variety Senatrit - 1.353 t ha^{-1}. Under the average nitrogen rate of 80 kg nitrogen, highest yield was obtained from variety Trujillo - 3.030 t ha^{-1}, followed by Rakita, and the low productive is Senatrit - 2.847 t ha^{-1}. When fertilizing with 160 kg nitrogen per hectare, the low productive is variety Senatrit - 5.017 t ha^{-1}, followed by Trujillo and the highest yield was obtained from variety Rakita - 5.520 t ha^{-1}.

Table 1. Grain yields, t ha^{-1}

Varieties	Nitrogen fertilization	Years		
		2012	2013	2014
Rakita	0	1,220a	1,173a	1,350a
	80	2,943b	2,823b	3,060b
	160	5,520c	5,240c	5,747c
Trujillo	0	1,183a	1,153a	1,233a
	80	3,030b	2,933b	3,143b
	160	5,237c	5,033c	5,397c
Senatrit	0	1,353a	1,124a	1,447a
	80	2,847b	2,773b	2,943b
	160	5,017c	4,877c	5,177c
LSD 5%		*0.31*	*0.28*	*0.34*

*Values with the same letters do not differ significantly

In the second harvest year, with the variants without nitrogen fertilization lowest yield was obtained from variety Senatrit - 1.124 t ha^{-1}. Second in productivity is variety Trujillo and the highest yield was obtained from variety Rakita - 1.173 t ha^{-1}. Under the average nitrogen rate of 80 kg nitrogen highest yield was obtained from variety Trujillo - 2.933 t ha^{-1}, followed by Rakita, and the low productive is sort Senatrit - 2.733 t ha^{-1}. Under fertilizing with 160 kg nitrogen per hectare, most low productive is Senatrit - 4.877 t ha^{-1}, followed by Trujillo and the highest yield was obtained from variety Rakita - 5.240 t ha^{-1}.

Table 2. Analysis of variance.

Source of Variation	*df*	*MS*
N fertilization	2	360822,062*
Variety	2	579,728*
Interaction	4	842,877*
Within	18	15,704
Total	26	

* - statistical significant by P=0.05

In the harvest 2014, with the variants without nitrogen fertilization lowest yield was obtained from variety Trujillo - 1.233 t ha^{-1}. Second in productivity is variety Rakita, and the highest yield was obtained from variety Senatrit - 1.447 t ha^{-1}. Under the average nitrogen rate of 80 kg nitrogen highest yield was obtained from variety Trujillo - 3.143 t ha^{-1}, followed by Rakita, and the low productive is variety Senatrit - 2.943 t ha^{-1}. Under fertilizing with 160 kg nitrogen per hectare, most low productive is Senatrit - 5.177 t ha^{-1}, followed by Trujillo and the highest yield was obtained from variety Rakita - 5.747 t ha^{-1}.

Two-way analysis of variance (Table 2) can be seen strongly expressed influence as a variety of factors and factor nitrogen fertilization. The impact of both factors and the interaction between them is statistically significant.

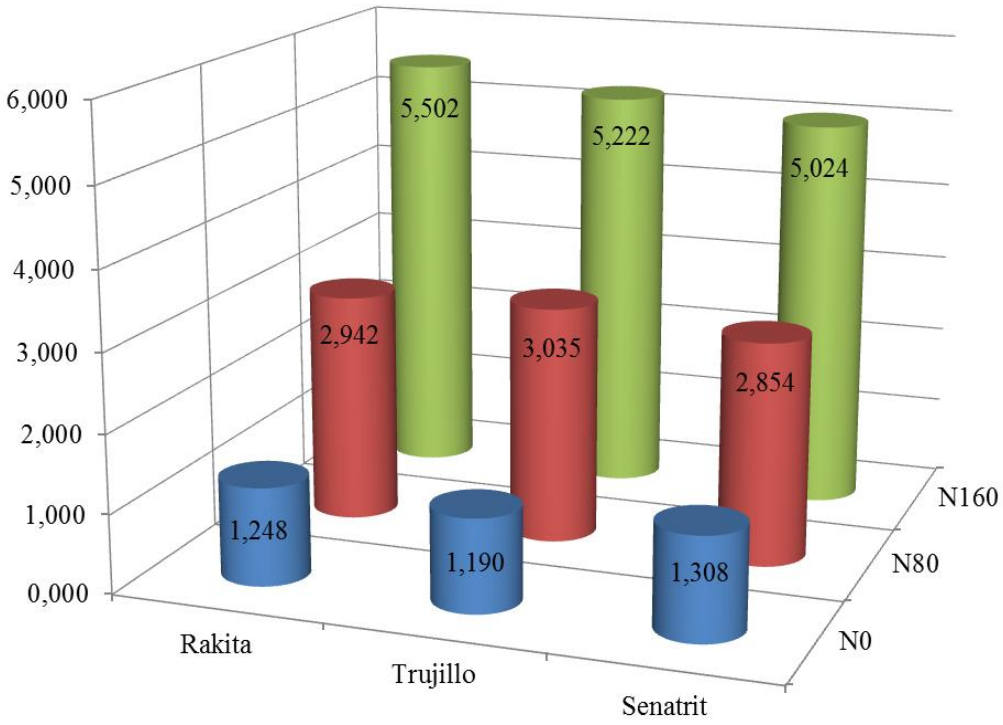

Figure 1. Average grain yields, t ha^{-1}

Average for the three years of the study variety Senatrit appears as the most productive in terms of nitrogen deficiency (N_0) - 1,308 t ha^{-1} followed by Rakita, and the lowest average grain yield was obtained from variety Trujillo - 1.190 t ha^{-1} (Fig. 1). In increasing nitrogen fertilization to 80 kg nitrogen, highest average grain yield is derived from a variety Trujillo - 3.035 t ha^{-1}, followed by Rakita, and the lowest average grain yield in these conditions of nitrogen nutrition is derived from a variety Senatrit - 2,854 t ha^{-1}. At the maximum tested nitrogen fertilizer rate of 160 kg highest average grain yield is derived from a variety Rakita - 5.502 t ha^{-1}, followed by Trujillo, and the low productive – variety Senatrit - 5.024 t ha^{-1}.

From the results it can be concluded that when nitrogen deficiency, variety Senatrit, being substituted type triticale, is manifested as more productive, than both complete type variety. The complete type varieties Rakita and Trujillo exerted their productive potential best at high nitrogen fertilization rates, while at nitrogen starvation they give very low yields.

The main structural elements affecting grain yield are presented in Table 3, the data is an average of the three harvest years.

In variety Rakita variation in the number of spikes is between 468 at no-fertilization variant and 688 at the maximum tested fertilizer norm. Most spikes in variety Trujillo are formed upon fertilization with N_{80} - 680 spikes, while at the variety Senatrit variation between three background of nitrogen fertilization is weakest. Exactly this variety forms most spikes with no fertilization with nitrogen - 488 spikes. At the maximum tested nitrogen rate of 160 kg nitrogen most spikes formed the variety that gave the highest grain yield in these conditions - variety Rakita (688 spikes).

The height of plants is significant different between the two types of triticale - at complete types varieties Rakita and Trujillo plant height varies between 90-110 cm, while the substituted type

triticale Senatrit is lower than the two complete type varieties. As expected, nitrogen fertilization leads to increase plant height and the all varieties of triticale.
Similar trends has and in the next linear parameter - length of spikes: Variety Rakita and Trujillo are characterized by longer spikes as variety Senatrit average of about 1-2 cm, and the increase in nitrogen rate leads to the formation of longer spikes in all three tested varieties. Longer spikes in complete type varieties Rakita and Trujillo are a sign that leads to the formation and more spikelets in the spike – between 23 and 27. In variety Senatrit this feature has a low performance – between 20 and 22 spikelets in the spike. Nitrogen fertilization leads to proven increases in this feature about 4 pieces in complete varieties, while the variety Senatrit increase in nitrogen rate up to 160 kg changing this feature with only 2 spikelets.

Table 3. Structural parameters of the plants (average for 3 years).

Varieties	N level	NSM	PH	SL	NSS	NGS	MGS	WGS	SHI

LSD 5%		*12,1*	*2,4*	*0,8*	*1.8*	*2.4*	*0.41*	*0.38*	*3.1*

*Values with the same letters do not differ significantly

The number of grains per spike with no fertilization with nitrogen variants is highest in the variety, gave the highest yield in terms of nitrogen deficiency – Senatrit. In this variety increasing nitrogen rate increases the grains per spikes by only 3 pieces. In complete type varieties, the number of grains in the spike vary between 41-48 grains, indicating that these two varieties the increasing of nitrogen rate leads to a significant increase in the number of grains per spike about 7 grains - double than the variety Senatrit.
The mass of grains per spike in all tested variants is greater than 1 gram, ranging between 1.28 g under no fertilization variant variety Senatrit and 1.95 g at fertilization with maximum nitrogen rates tested variety Rakita. In another sign of the spikes weight - the weight of glumes, the highest values occurred in varieties Senatrit and Trujillo. In variety Rakita glumes are the lowest weight.
The differences in accumulation of biomass in two main parts of the spike – grains and glumes leading to their different ratio, expressed as a harvest index of the spike (Hucl and Graf, 1992). Higher values of this indicator in complete type varieties: Rakita – between 69.47 and 74.80 and variety Trujillo – between 70.8 and 72.16. In variety Senatrit values are significant less – between 66.67 and 69.78.

Conclusions

Under nitrogen deficiency, variety Senatrit, being substituted type triticale, is manifested as more productive, than both complete type varieties. The complete type varieties Rakita and Trujillo exerted their productive potential best at high nitrogen fertilization rates, while at nitrogen starvation they give very low yields.

Variety Senatrit forms most spikes with no fertilization with nitrogen. Exactly at this variety variation between three backgrounds of nitrogen fertilization is weakest. At the maximum tested nitrogen rate most spikes formed the variety that gave the highest grain yield in these conditions – Rakita.

The height of plants is significant different between the two types of triticale – at complete types Rakita and Trujillo plant height varies between 90-110 cm, while the substituted type triticale Senatrit is lower. Similar trends has and in the next linear parameter - length of spikes.

The number of grains per spike with no fertilization with nitrogen variants is highest in the variety, gave the highest yield in terms of nitrogen deficiency – Senatrit. In this variety increasing nitrogen rate increases the grains per spikes by only 3 pieces. In complete type varieties the increasing of nitrogen rate leads to a significant increase in the number of grains per spike about 7 grains - double than the variety Senatrit.

The differences in accumulation of biomass in two main parts of the spike – grains and glumes leading to their different ratio, expressed as a harvest index of the spike. Higher values of this indicator in complete type varieties: Rakita and Trujillo. In variety Senatrit values are significant less.

GROWING POSSIBILITIES OF FORAGE RAPE WITH SOME ANNUAL CROPS

Zeki ACAR*, Suleyman ZEYBEK

Ondokuz Mayis University, Agricultural Faculty, Department of Agronomy, Samsun, Turkey
*Corresponding author: zekiacar@omu.edu.tr

Abstract

In Turkey, there are more than 14 million livestock as Animal Units. But, meat and milk production of livestock is very low compared to European countries. Main reason is lack of forage production in high quality. Some farmers have to feed livestock with straw and chaff during winter period. On the other hand, generally warm season main crops such as; corn, cotton, sugar beet, sesame, soya bean, rice, tobacco are grown in fertile and irrigated coastal areas in summer period. If we put some annual, and high yielding forage crops in quality such as forage rape, oat, vetch, forage pea into crop rotation system, it would be possible to increase high quality forage production. In 2015, we started to carry out a project aimed to determine yield and the other traits of forage rape, common vetch, Hungarian vetch, forage pea and oat grown alone and forage rape binary mixtures with others during winter period. According to the first year results, plant height of forage rape and the other crops decreased in mixtures. While branch number of forage rape increased into the mixture with common and Hungarian vetch, it decreased in the other binary mixtures. Stem diameters of forage rape increased in binary mixtures with legumes. All binary mixtures gave higher hay yield than sown alone, except oat. While hay yield was 5.90 ton ha^{-1} for sole forage rape, it increased to 9.44 ton ha^{-1} for forage rape + oat binary mixture. The early results showed that forage rape was very promising crop for forage production during winter period in northern coastal areas of Anatolia.

Keywords: *forage rape, vetch, oat, forage pea, hay production*

Introduction

Intercropping includes the simultaneous growing of two or more species in the same area for a significant period of time, but without necessarily being sown and harvested together. Intercropping is a practice that is used in low-input cropping systems especially in the developing countries (Lithourgidis *et al*. 2011a; Dordas *et al*. 2012). Intercropping can provide numerous benefits to cropping systems through increasing total yield and land use efficiency (Dhima *et al.* 2007); improving yield stability of cropping systems (Lithourgidis *et al.* 2006); enhancing light, water, and nutrient use (Lithourgidis *et al*. 2007); improving soil conservation(Anil *et al*. 1998); and controlling weeds, insects, or diseases (Vasilakoglou and Dhimna, 2008). Moreover, intercropping can facilitate mechanical harvest, whereas legumes in mixtures with cereals can improve the quality of forage (Javanmard *et al*. 2009). In temperate climates, intercropping has been more successful when used for forage production than for grain production (Anil *et al*. 1998). However, intercropping of legumes with cereals have the disadvantages of including extra work in preparing and planting the seed and the lack of tolerance to herbicides of the mixed crops (Anil *et al*. 1998).

Generally, intercropping legumes with cereals increases protein yield compared with cereals alone (Carr *et al*. 2004). However, there are contradictory data about the productivity of intercropping systems. In particular, many studies reported that intercropping legumes with

cereals provided more efficient utilisation of the available resources and increased productivity compared with each sole crop (Hauggaard-Nielsen *et al*. 2001; Agegnehu *et al*. 2006). On the other hand, in some studies there was no significant effect on forage yield (Lithourgidis *et al*. 2007, 2011*b*), whereas in other studies intercrops yielded lower DM as compared with cereal monocrops (Caballero *et al*. 1995; Lithourgidis and Dordas 2010).

Brassica species have been used as forage for centuries (Altinok and Karakaya, 2003). The exploitable features of *Brassica* crops include: (i) abundant forage at a time when most warm and cool-season grasses are unproductive (Wiedenhoeft and Barton, 1994) and (ii) high yields of readily consumed energy and protein compared with cereals and perennial grasses (Kay, 1975). Most *Brassica* species are relatively low in dry matter content, although their total dry matter production per unit area is high relative to most cereals and forage grasses. Not only they are high yielding crops, but they also have good nutritional quality (Rao and Horn, 1986). Forage rape is a short season (fast-maturing) crop (Altinok and Karakaya, 2003).

The aim of this study was to determine yield and the other morphological and chemical traits of forage rape, common vetch, Hungarian vetch, forage pea and oat grown alone and forage rape binary mixtures with others during winter period.

Material and Methods

The study was carried out according to randomized complete block design with 4 replicates at the experimental area of Agricultural Faculty in Samsun, Turkey in 2015-2016 growing period (From October to April). In the study Lenox cultivar of forage rape, Özkayrak cultivar of forage pea, Tarım 98 cultivar of Hungarian vetch, Nilüfer cultivar of common vetch and Faikbey cultivar of oat was used. Monthly temperature and rainfall data from October 2015 to April 2016 of the experiment site were 17.5, 14.5, 8.5, 7.5, 11.3, 10.4, 13.8 ^{o}C and 72.3, 31.3, 100.0, 88.1, 18.1, 63.4, 49.9 mm, respectively. The soil of the experiment site was rich in terms of organic matter and potassium and poor for phosphorus. Seed bed preparation was performed in October. Before seeding, 150 kg ha^{-1} DAP (27 kg N and 69 kg P_2O_5) was applied. The experimental plots consisted of 6 rows with 20 cm row spacing. At the mixture plots, forage rape and other species were sown in alternate rows. Experiment was established in October and harvested at the beginning of blossoming stage of forage rape at the end of April. Weeds were removed by hand pulling and hoeing when needed. No irrigation was applied. Forage samples taken from each plot were oven-dried at 60 ^{0}C and ground to pass through a 1 mm screen for chemical analysis. Crude protein, acid detergent fibre (ADF), neutral detergent fibre (NDF), Potassium (K), Magnesium (Mg), Calcium (Ca) and Phosphorus (P) contents of samples were determined by using near infrared reflectance spectroscopy (NIRS) with software program coded IC-0904FE. The data were subjected to analysis of variance (ANOVA) and, computation was performed by means of SPSS 10.0 V. (SPSS Inc., 1999). Means were separated using Least Significance Difference (LSD) test.

Results and Discussion

Significant ($P \leq 0.01$) differences amongst the treatments were figured out in terms of all investigated traits. The plant heights were found higher in forage pea and forage rape grown as sole crop. Plant height decreased in all species when they were grown in binary mixture (Table 1 and Figure 1). This reduce could probably be attributed to competition for light, water and plant nutrition inputs between different species. Plant height values of forage rape obtained from this study were about doubled compared to Altinok and Karakaya (2003) findings between 44 cm to 73 cm plant heights of forage rape sown in spring and summer in Ankara conditions. The reasons

of differences could probably be caused by cultivar effect and favourable climatic conditions in Samsun. Although there was no statistical difference, branch number of forage rape, forage pea and common vetch decreased in binary mixtures, while it increased for Hungarian vetch and oat (Table 1). Stem diameter of forage rape increased when it was grown in binary mixture with legume species. On the other hand, the same values for legume species decreased in binary mixture with forage rape. The highest stem diameter values were measured on forage rape compared to the other species (Table 1).

The highest hay yield was obtained from forage rape+forage pea, forage rape+oat and sole oat plots. In all binary mixture plots hay yield increased compared to their sole plots, except oat (Table 1 and Figure 2). Previous researchers indicated hay yield of forage pea as 2128 kg ha^{-1} (Darby, 2011); as between 5527 and 11529 kg ha^{-1} (Altinok and Karakaya, 2003). Generally mixtures had higher yields than monocrops (Dordas *et al*. 2012; Uzun and Asik, 2012). In consider botanical composition of binary mixtures, forage rape had significant dominancy to oat while Hungarian vetch and forage pea were dominant to forage rape (Table 1).

*There is no significant ($P \leq 0.01$) difference amongst the numbers had the same letter at the same column.
**The numbers belongs to the plant written in bold.

There were significant ($P \leq 0.01$) differences amongst the treatments in terms of all investigated chemical traits (Table 1). ADF contents of treatments varied from 25.83% to 37.15%, while NDF values were between 64.87% and 33.59%. Evaluating the species grown as solely, the rank from the highest to the lowest was oat, forage pea, Hungarian vetch (ADF values of forage pea and Hungarian vetch very close to each other), common vetch and forage rape. Fibre (ADF and NDF) level of the species generally decreased, except common vetch and forage rape grown in the mixture with Hungarian vetch (Table 2 and Figure 3). ADF content of forage rape was reported as between 19.0% to 20.3% while NDF was 19.7-24.3% (Darby, 2011; Westwood and Mulcock,

2012; Luo *et al*. 2014). ADF and NDF levels of forage rape obtained from this study were higher than previous results. The reason was probably differences of cultivar, climatic conditions and agricultural practices.

*There is no significant ($P \leq 0.01$) difference amongst the numbers had the same letter at the same column.
**The numbers belongs to the plant written in bold.

In terms of Ca and Mg ratios, the lowest values were obtained from oat. Ca content of forage rape was higher than legume species used in this study. On the other hand, Ca level of legume species grown in mixture with forage rape decreased. Mg values determined for treatments were very close to each other, except oat. K ratios of treatments altered between 3.15% and 2.24%. K values

of forage rape increased grown in mixture with the other species. The lowest K levels were determined in the hay samples obtained from forage pea plots. Although there were significant ($P \leq 0.01$) differences amongst the treatments for P content, all values were very close to each other and it varied from 0.43% to 0.38%. Except forage pea and forage rape grown in mixture with Hungarian vetch, all treatments were in the same statistical group (Table 2). Crude protein proportions of the treatments altered between 25.67% and 17.42%. The highest values were recorded in forage rape grown in mixture with common vetch and oat. The lowest was determined in oat, as expected. Crude protein ratios of forage rape increased when it was grown in mixture with the others (except Hungarian vetch) while the same value decreased for others grown in mixture with forage rape (Table 2 and Figure 4). Previous researchers indicated crude protein ratio of forage rape as 19.4% (Luo *et al*. 2014), 20% (Darby, 2011), 10-28% (Altınok and Karakaya, 2003). The results obtained from this research similar to previous researchers' findings.

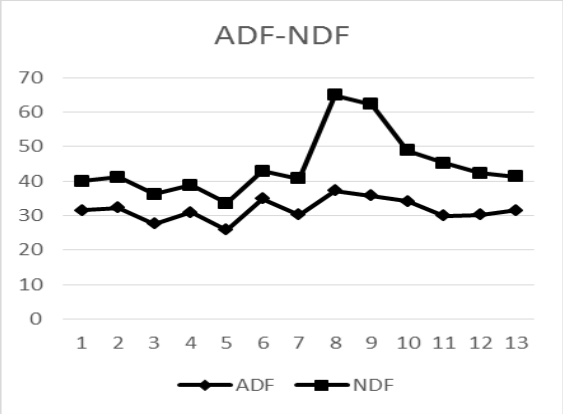

Figure 3. ADF and NDF contents of treatments

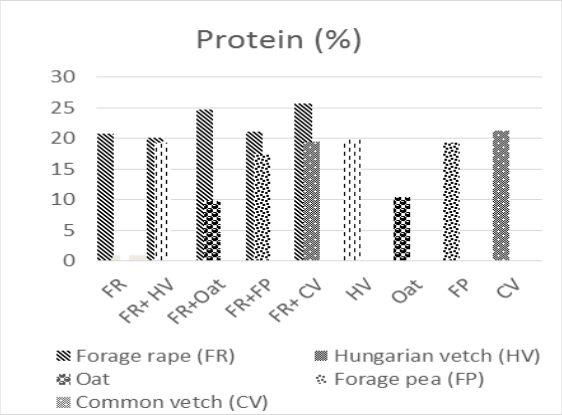

Figure 4. Crude protein contents of treatments

Conclusion

The results indicated that it could be possible to grow forage rape solely and in mixture with some other annual forage crops during the winter period in Samsun conditions. The hay yield of mixtures was higher than their solely treatments. Forage rape mixtures with forage pea and oat gave more than 9 t ha^{-1} highly nutritious and quality hay yield. The species involved in the mixtures increased both hay yield and crude protein ratio of forage rape.

THE EFFECT OF ORGANIC AND MINERAL FERTILIZATION IN DIFFERENT CROPPING SYSTEMS OF MAIZE

Milena SIMIĆ[1]*, Vesna DRAGIČEVIĆ[1], Nebojša MOMIROVIĆ[2], Milan BRANKOV[1], Igor SPASOJEVIĆ[1]

Abstract

Cropping systems of maize that are predominant in Serbia include continuous cropping, two crop rotation with winter wheat, and to a smaller extent, three crop rotation with winter wheat and soybean. The application of fertilizers, organic and mineral, is necessary in order to achieve higher yields. The typical sources of farmyard manure (FYM) are farms with the livestock production which are affected by present changes in agricultural owner's structure. Instead of FYM, soybean as a previous crop of maize, could play a role of a natural nitrogen soil supplier. The objective of the study was to evaluate the effects of the organic and mineral fertilizer application in different maize production systems on crop development and yield. The study was initiated in the experimental field of the Maize Research Institute Zemun Polje, Serbia in 2008/2009. The following production systems were evaluated: maize continuous cropping (MC), maize-winter wheat (MW), maize-soybean-winter wheat (MSW) and maize-winter wheat-soybean (MWS). In the autumn of 2008, cattle manure was applied in all production systems and in MC and MSW every third year, in MW each second year and, FYM was not applied in MWS rotation. Additionally, mineral fertilizers were applied in autumn and during early development stages of maize in spring in all cropping systems according to recommendation based on soil analysis. In 2015, after two completed three rotation cycles, the nitrogen content in the soil, leaf area, chlorophyll content, harvest index and the grain yield of maize were analysed. The highest chlorophyll content, harvest index and grain yield of maize were achieved in the rotation with winter wheat and when FYM was applied. Growing of maize in continuous cropping or without the application of organic fertilizers reduces grain yield.

Keywords: *Production system, maize, fertilisers, nitrogen, yield*

Introduction

Maize is the dominant crop in agricultural production in Serbia (Videnović *et al*., 2013a). The predominant production systems of maize is continuous cropping, two crop rotation with winter wheat, and to a smaller extent, three crop rotation with winter wheat and soybean, (Videnović *et al*., 2007). Rotation, as cropping system has many advantages, which are reflecting through better crop growth and yield (Videnović *et al*., 2013b). Its combined application with other cropping measures (tillage, fertilization, sowing, cultivation, etc.) could facilitate maximal growth and photosynthesis efficiency (Spasojević *et al*., 2014). Crop rotation, combined with application of herbicides or hoeing, had positive impact on maize yielding potential by increasing of leaf area index, chlorophyll and carotenoids content.

Results from the long-lasting study conducted in Zemun Polje, showed that grain yield of maize was the lowest in monoculture in 21 year average (6.75 t ha^{-1}), (Videnović *et al*., 2007). Adiku et

al. (2009) state that the crop rotation and residue management practices can significantly affect maize performances. Studies carried out by Stranger and Lauer (2008) showed that extended rotations involving forage crops, reduce N inputs, increase maize yield and are more sustainable than short-terms rotations or monoculture. For the region of central Serbia, contemporary maize growing systems should include a correctly applied crop rotation with legumes (soybean), conventional tillage with deep autumn ploughing, precisely determined plant density and application of fertilisers in the content and formulation adjusted to the requirements of the cultivated plant (Simić *et al*., 2016).

Application of fertilizers, organic and mineral, is necessary in order to achieve high, quality yields. The typical sources of farmyard manure (FYM) are farms with the livestock production. This type of agricultural economy is affected by present changes in the structure of land owner's. Instead of FYM, soybean as a previous crop of maize in three maize-winter wheat-soybean crop rotation, could play a role of a natural nitrogen soil supplier. It is known that each crop utilises nutrients from the soil to varying extent. Additionally, the composition and abundance of microbiota differ among various individual crops, which affect the scope of transformation of organic and mineral matters into forms available to plants. According to studies conducted in Zemun Polje, fertilizer application was the most effective in maize monoculture when yield has been increased for 0.76 t ha^{-1} (12.4%) after the application of 160 kg N ha^{-1}, even though the chernozem as a naturally fertile soil does not require intensive fertilization (Videnović *et al*., 2007).

The objective of the study was to evaluate the effects of the organic and mineral fertilizer application in different maize production systems on crop development and yield.

Material and Methods

The study was initiated in Maize Research Institute Zemun Polje, Serbia in 2008/2009 with the aim to evaluate effects of organic and mineral fertilizers application on maize growth and productivity in different production systems. The soil type at the experimental field is slightly calcareous chernozem with 53% sand, 30% silt, 17% clay; with good fertility and 3.3% of organic matter content and moderate drainage. The pH is 6.9 and soil structure is silty clay loam.

The maize hybrid ZPSC 606 was grown in the following production systems: maize continuous cropping (MC), maize-winter wheat (MW), maize-soybean-winter wheat (MSW) and maize-winter wheat-soybean (MWS). In the autumn of 2008, FYM was applied in all production systems and in MC and MSW every third year, in MW each second year and, FYM was not applied in MWS rotation. Additionally, mineral fertilizers were applied in the autumn and during early phases of maize development in the spring (Table 1). The amounts of mineral fertilizers were determined by the soil analysis. For weed control, herbicides isoxaflutole + acetochlor at the recommended dose of 1536 g a.i. + 105 g a.i. were applied.

In 2015, after completed the second three rotation cycle, nitrogen content in the soil, leaf area, chlorophyll content, harvest index and grain yield of maize were analysed during crop vegetation period.

The nitrogen content in the soil was evaluated at the beginning of growing season, in the spring 2015, in order to crate recommendation for further fertilizer applications. Maize leaf area and chlorophyll content were measured at the end of anthesis phase by sampling of three plants. Leaf area was determined with LI – 3100 area meter (LICor, Lincoln, NE, USA) and chlorophyll content (chlorophyll A+B) was determined with 70% acetone extraction by the method of Sarić *et al*. (1990). The maize grain yield was measured from two inner rows of each subplot and

calculated to 14 % of moisture. The experimental data were statistically processed by analysis of the variance (ANOVA) and analysed by the LSD-test (5%).

Meteorological conditions

Meteorological conditions during investigated period were different, (Figure 1). Year 2012 was characterised by the highest average temperature achieved in July and August (27.1 ℃ and 26.6 ℃, respectively). Moreover, the lowest precipitation amount, of only 4 mm was also obtained in August. Present conditions could affect grain filling, what could be also reflected on relative low values of grain yield.

The sum of precipitation was higher in 2009, 2010 and 2014 than in 2008, 2011, 2012 and 2013. The 2012 was extremely dry (June - 30.7 mm; August - 5.8 mm and September - 26.0 mm) and unfavourable for maize production. A dry spell during June-September period in 2012 year was especially important since it coincided with maize pollination and yield formation, Figure 1.

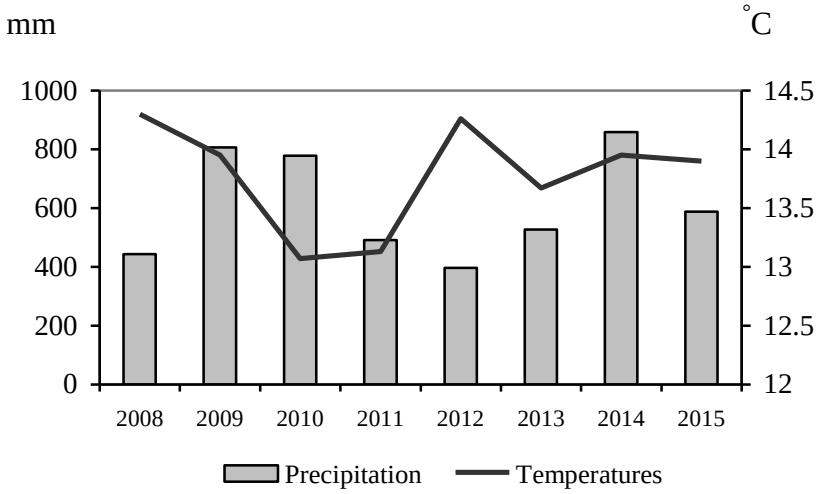

Figure 1. Meterological conditions 2008-2015

Results and Discussion

Soil analysis showed that nitrogen content had the highest values in first soil layer of 0-30 cm in almost all cropping systems (Table 2). Totally, the highest amount of soil nitrogen was detected in MW rotation (339.90 kg ha^{-1}), lower and similar values were in MC and MSW (192.86 and 197.80 kg ha^{-1}), while the lowest nitrogen content was in maize-winter wheat-soybean rotation (159.72 kg ha^{-1}). This is in accordance with farmyard manure frequency of application. The nitrogen content in the soil in MWS cropping system was not lowered significantly in comparison to MSW and MC taking in account the fact that cattle manure was not applied in MWS rotation. Nitrogen content in the first soil layer in this cropping system was even higher than in MC and MSW but in the deepest soil layer (60-90 cm) it was especially low in comparison to other rotations (19.99 kg ha^{-1}). This shows us that growing of soybean in rotation and as preceding crop of maize, can help in soil nitrogen supplying and even could replace application of organic fertilizers as nitrogen source up to the certain level. Additionally, intensive application of organic fertilizer, such FYM, is very important for soil fertility.

Table 2. Nitrogen content (kg ha^{-1}) in the soil of investigated cropping systems, spring 2015

Soil layer	MC	MW	MSW	MWS	Average
0-30	91.85	131.76	56.57	114.33	98.63
30-60	61.82	87.31	50.02	25.40	56.14
60-90	39.19	120.83	91.21	19.99	67.80
Total	192.86	339.90	197.80	159.72	222.57

The chlorophyll content in maize leaves and leaf area had highest values in MW rotation, (Figure 2). Chlorophyll content had almost equal values in both three crop rotations, while its content was the lowest in maize continuous cropping (44.2 SPAD units). Leaf area index, was also the lowest in maize continuous cropping (13385.2 cm^2 m^{-2}) and had the similar value in MW and MSW. In MWS rotation, chlorophyll content and leaf area were higher than in MC, even though fertilizers were not applied in MWS since the beginning of the production. This implicates that organic and mineral fertilizer application, as very important measure for maize production, and could be effective only in combined application with crop rotation especially with those involving legumes as natural nitrogen suppliers (Vári and Pepó, 2014). Leaf area index and relative chlorophyll content have primary roles in the yield forecast of maize in the early season (Vári and Pepó,

2014). Different levels of fertilization and crop rotation have a considerable impact on the maximum values of the leaf area, chlorophyll content and yields of maize.

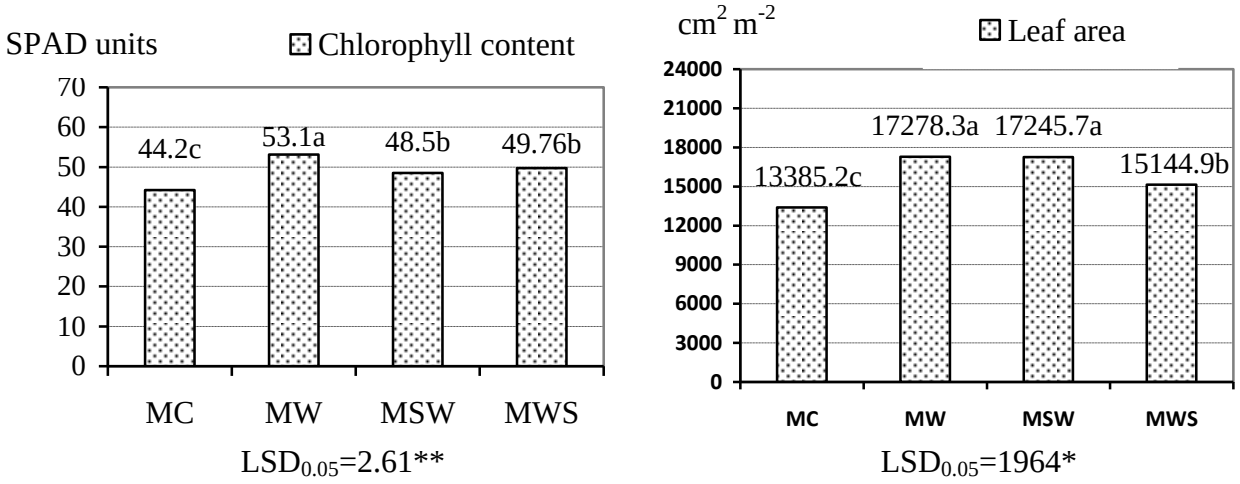

Figure 2. Chlorophyll content and leaf area of maize leaves in dependence of crop production system

Parallel with leaf area and chlorophyll content variations, harvest index and grain yield of maize have been changed within different cropping systems, (Figure 3). Differences in harvest index of maize were not significant between investigated crop rotations, but maize grain yield was noticeable highest in MW rotation. Regimes of mineral and organic fertilizer application, have increased maize grin yield by 30.66% in MW rotation, 20.58% in MSW and 18.10% in MWS in comparison to MC (5.79 t ha^{-1}).

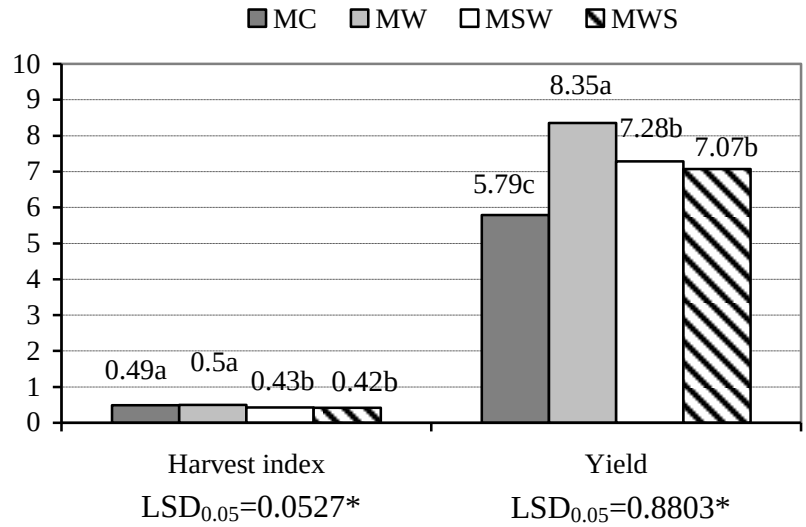

Figure 3. Harvest index and grain yield of maize (t ha^{-1}) in dependence of crop production system

The highest average maize yield (8.35 t ha^{-1}) was achieved with application of cattle manure and N fertiliser at the beginning of growing period when maize was grown in MW rotation. Nevertheless of the late maturing hybrid potential and high level of fertilizer application in the

maize monoculture, the highest yield did not reach more than 5.79 t ha^{-1}. This underlined the importance of all cropping practices and their integrated effects on maize production. In similar investigation conducted in Zemun Polje, the average maize yield was higher by 11.4 % in soybean–maize rotation, despite the amount of applied nitrogen fertiliser being reduced by 50 % (Videnović *et al*., 2013b). Average maize yields were not the highest in the treatment with the highest amount of fertilisers. It means that the application of greater rates of mineral fertilisers under the Zemun Polje conditions on chernozem soil is not economically justified (Videnović *et al*., 2007).

Conclusion

The values of all measured parameters were the highest in MW rotation which shows that old and the most present cropping system, based on old type of farm ownership and organisation, has advantage in maize production. But, in present time, with new system of farming land organization, crop rotation with legumes as nitrogen source, could be a good substituent and certainly takes advantage over maize monoculture.

Abstract

The purpose of this investigation was to determine the characteristics of Cabernet Sauvignon/Kober 5BB berries according to the position of the rachis (bunch). The berries from 5 bunches (a total of 871 berries) were divided according to the position on the rachis (top, middle and bottom) and weight of berries (two classes of weight: 1) less than or equals 1g and 2) between 1.01 and 1.50 g). Each of the berries was used to evaluate physical characteristics (fresh berry weight, fresh weight of skin, seeds and flesh and seed number). Soluble solids content and total titratable acidity was measured on must obtained by crushing berries, taking into account the rachis position. Data analysis of berry percentage distribution showed that there was a difference between each weight category and position. From the top to the bottom rachis position, a decrease in percentage of berry number occurred. With regard to physical characteristics, the analysis of the results indicated a highly significant difference in berry weight between the measured classes and a significant difference between the positions. The analysis of skin, seed weight and seed number also indicated that there was a highly significant difference among the two classes of berry weight. Concerning the compositional parameters, the highest content of soluble solids and total titratable acidity were found in the bottom part of the bunch. Berry variability is a factor influencing the yield and quality of grape and wine. Generally, it is difficult to obtain a uniform size of berries under filed conditions.

Key words: *Cabernet Sauvignon, berry position, berry weight, berry composition*

Introduction

Variations are a constituent part of all biological systems, and vineyards do not represent an exception what so ever. According to the quotations of Gray (2002), a variation in vineyard is present in more levels and evident among berries, bunches and vines. The same author claims that two components have the biggest significance in differences among berries: the size of a berry and the content of a berry. Variations in the size of a berry reflect on the yield and the quality, while variations in the content of a berry have influence on the taste and the quality of wine. Variations of physical and chemical characteristics among the berries on a bunch of grapes aren't usually taken seriously by many vine growers and wine producers (Pisciotta et al. 2013). Tarter and Keuter (2005) claim that the use of "traditional technique" of estimation ^{0}Brix in grapes, where the condition in the whole vineyard is based on one sample, isn't the best solution. According to these authors, the way of taking samples could be significantly improved if it would be clearly understood which berries in the bunch have ^{0}Brix that corresponds of ^{0}Brix in the whole bunch. The variation of a berry characteristics in a bunch is under the influence of production, among which irrigation has an important influence (Roby and Mathews 2004; Ferrer et al., 2014) as well as applied pruning (Holt et al., 2008). Mathews and Nuzo (2007) claim that the viticultural practices applied in vineyard (irrigation, pruning, thinning) in the purpose of yield

control can have much bigger significance in the defining of the quality of grapes and wine than yield or characteristics of berries. Berries in a bunch of grapes have different characteristics depending on their position, which has the influence on the grape quality and wine production (Melo et al. 2015).
The aim of this paper represents the Cabernet Sauvignon variety berries' characteristics analysis depending on their position in a bunch.

Material and Methods

Vitis vinifera L. cv. Cabernet Sauvignon grafted onto Kober 5BB samples were obtained from a seven year old vineyard, located in Banja Luka city area, in the ***northwestern region*** of Bosnia and Herzegovina. Rows were oriented North-South. ***The vines were trained*** on trellising systems Double Guyot. One typical bunch per vine was selected from five vines according to similar appearance and stored at about 20°***C before processing. The t***otal of 871 berries was sorted according to the position on the rachis by dividing the total rachis axis into thirds (top, middle and bottom) including berries on the wings. After that all the berries were separated from the pedicel, counted, weighed and divided into two classes according to the berry weight:1) less than or equal to 1 g and 2) between 1.01 and 1.50g. Each of the berries was used to evaluate other physical characteristics: weight of fresh skin, seed, flesh (g) and seed number. The content of soluble solids (Brix %) and titratable acidity (g/l tartaric acid) were analysed in the fresh must by means of standard method immediately after crushing the berries of every subgroup according to the position on the rachis. The berry percentage distribution for each weight class and position as well as the relative proportion of each part of the berry (flesh, skins and seeds) were calculated.

Statistical analysis

Data was analyzed through general linear models with significant difference established at $p<0.05$ level. Statistical analyses and graphical visualizations were made in R (R Core Team, 2016) and IBM SPSS Statistics 22 (IBM 2013).

Results and Discussion

The results of the berry percentage distribution for each position and weight class showed that the top part of the rachis had the most berries (41.23%), followed by middle (36.51%) and bottom part (22.26 %) (Table 1).

Table 1. The percentage of berry number for each position and weight class (based on total berries, n = 871)

Class of berry weight	1	2	Total
	≤ 1 g	1.01-1.50 g	
Rachis position	% of berry number	% of berry number	%
Top	21.00	20.23	**41.23**
Middle	18.53	17.98	**36.51**
Bottom	13.44	8.82	**22.26**
Sum	**52.97**	**47.03**	100.00

The results match those of Piscciota et al. (2013) and confirm the role of wings in determining the number of berries in some parts of the bunch. Also, different percentage distributions were found for each class of berry weight. Class 1 had higher percentage of berry number per position than class 2, consequently in the entire sample (52.97 % and 47.03%, respectively).

According to the results of relative proportion of skin, seed and flesh (Table 2), a different percentage distribution was found for each position and weight class. Approximately, participation of skin, seed and flesh in the fresh weight of the berry was (26%, 5% and 69%) along the rachis.
The found values of proportion of seed were similar to those reported by Roby et al. *(*2004).

Table 2. The relative proportion (%) of skin, seed and flesh for each position and weight class (based on total berries, n = 871)

Class of berry weight	1			2			Mean		
	≤ 1 g			1.01-1.50 g					
Rachis position	skin %	seeds %	flesh %	skin %	seeds %	flesh %	skin %	seeds %	flesh %
Top	25.16	4.80	70.04	25.13	5.59	69.28	25.15	5.20	69.66
Middle	27.34	4.78	67.88	23.89	5.28	70.83	25.61	5.03	69.36
Bottom	26.26	5.81	67.93	25.16	6.03	68.81	25.71	5.92	68.37
Mean	26.25	5.13	68.88	24.93	5.63	69.64	**25.49**	**5.38**	**69.13**

Berry characteristics

The analysis of berry mass has indicated that there was statistically highly significant difference in mass between the measured classes of berries and significant difference between the positions (Table 3, Figure 1).

Table 3. Berry characteristics in the two weight classes as a function of position on the rachis

Position	**Class**	Berry mass (g)			Flesh mass (g)			Skin mass (g)			Seed No.			Seed mass (g)

(**) and (*) indicates statistically significant ($p<0.05$*) or highly significant ($p<0.01$**) difference

The mass of the berries of class 2 is higher than the mass of the berries of class 1. From the top to the bottom rachis position there was a decrease in berry mass but there was no significant difference between the middle and top position.

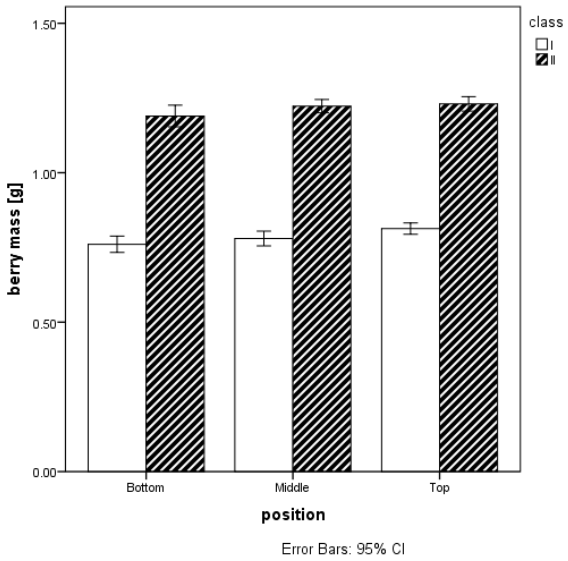

Figure 1. Berry mass (g) of a single berry in the two weight classes as a function of position on the rachis (vertical bars represent standard errors)

The analysis in terms of flesh mass showed a statistically significant influence of interaction between berry position and class on the flesh mass (Table 3, Figure 2). Top position in class 1 differs significantly from bottom and middle positions, between which there was no significant difference. In class 2 bottom position had significantly smaller flesh mass in comparison to middle and top positions, between which there was no statistically significant difference.

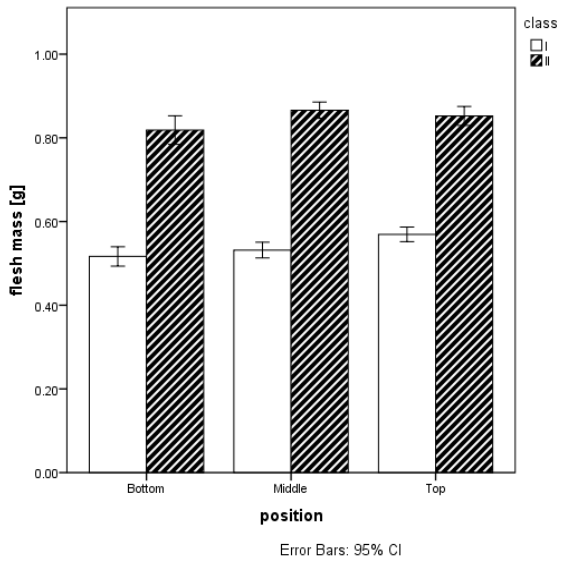

Figure 2. Average flesh mass (g) of a single berry in the two weight classes as function of position on the rachis (vertical bars represent standard errors)

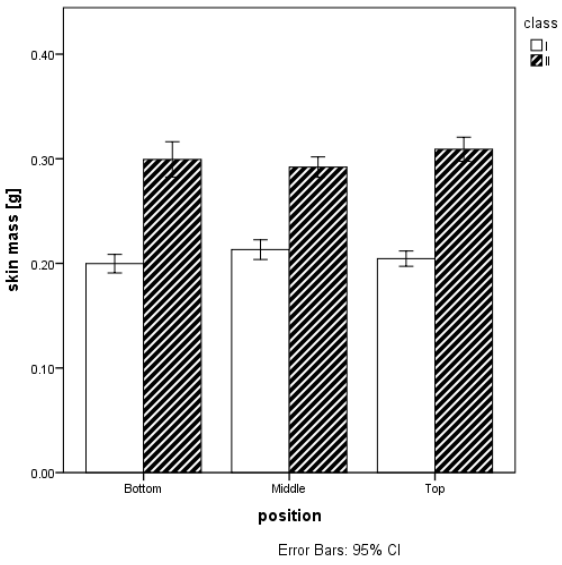

Figure 3. Average skin mass (g) of a single berry in the two weight classes as a function of position on the rachis (vertical bars represent standard errors)

Regarding the skin mass the analysis indicated that there was a significant interaction between positions and classes (Table 3, Figure 3). In class 2 there was statistically significant difference between top and middle position.

In seed number there was a highly significant influence of both position and class (Table 3, Figure 4). The berries of class 2 had more seed than the berries of class 1 and berries from the bottom part of the bunch had more seed than the other two parts.

Seed mass showed significant differences depending on the position and weight class. The results indicated that there was a significant influence of position and highly significant influence of class on seed mass (Table 3, Figure 5). In class 2 berries had bigger seed mass than the berries in class 1. Bottom position had bigger seed mass than the other two analysed positions.

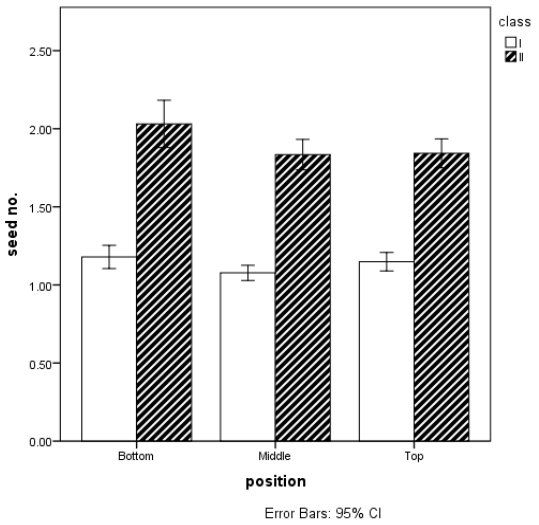

Figure 4. Average seed number of a single berry in two weight classes as a function of position on the rachis (vertical bars represent standard errors)

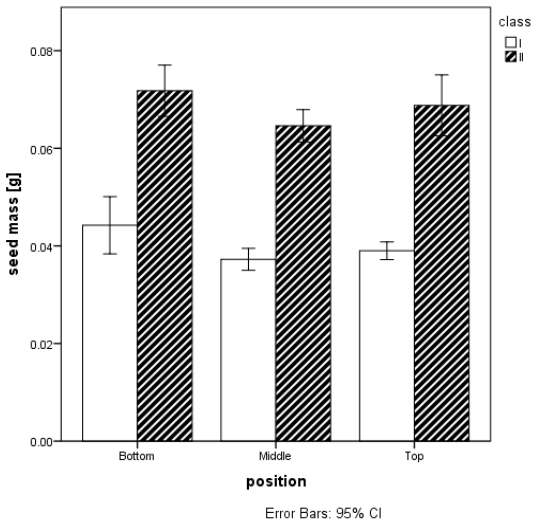

Figure 5. Average seed mass of a single berry in two weight classes as a function of position on the rachis (vertical bars represent standard errors)

Berry must analysis

The analysis of soluble solids content indicated that there was a highly significant influence of the position on the soluble solids content (Brix %) (Table 4, Figure 6).

Table 4. Soluble solids (Brix %) and total titratable acidity (TTA) at different position on the rachis

Position	Brix (%)			TTA (g/l tartaric acid)		
	mean	±	sd	mean	±	sd
Top	22.08	±	0.77	7.16	±	1.01
Middle	21.70	±	1.16	7.71	±	0.41
Bottom	22.89	±	0.59	8.22	±	0.74
$F_{position}$	6.93*			5.38*		

(*) indicate statistically significant ($p<0.05$*) difference

Tarter and Keuter (2005) had also indicated that there are differences in the content of soluble solids at Cabernet Sauvignon variety, depending on the position along the bunch. In this study, the berries from the bottom part of the bunch had significantly ($p<0.05$) higher soluble solids content in comparison to berries from the middle and top part, which differs from the results reported by Kasimatis et al. (1975) and Pisciotta et al. (2013).

The analysis of total titratable acidity (g/l tartaric acid) showed that there was statistically significant difference between different positions on the rachis (Table 4, Figure 7). There was a tendency of significant total titratable acidity decrease (p=0.04) from the bottom to the top position.

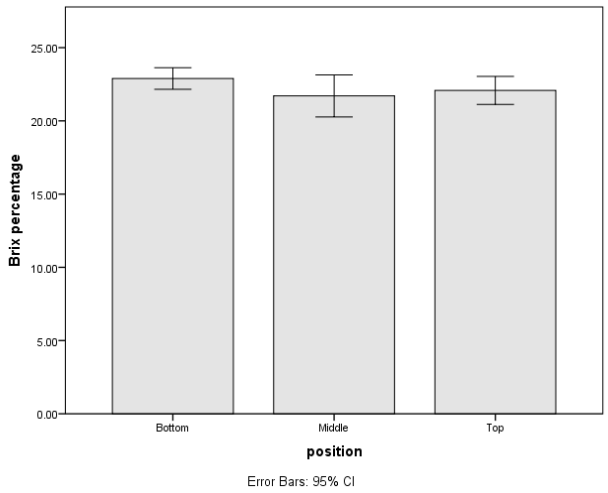

Figure 6. Average soluble solids content of berries (Brix %) at different position on the rachis (vertical bars represent standard errors)

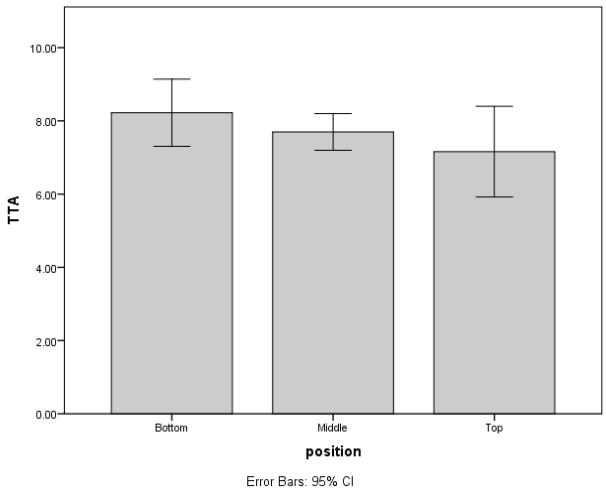

Figure 7. Average total titratable acidity of berries at different position on the rachis (vertical bars represent standard errors)

Conclusions

The analysis results showed that berries on the analysed parts of the rachis (top, middle, bottom) differed both regarding specific physical and chemical characteristics. Division of berries into two classes considering mass, clearly indicates existance of inequality of berries on the entire bunch. Since the appearance of inequalty of the berries and bunch, considering size, reflects on yield and the quality of grapes and wine, all further researches of causes and consequences of the phenomenon mentioned above are of multiple significance.

DETERMING THE POPULATION DYNAMICS INFESTATION OF TUTA ABSOLUTA MEYRİCK (LEPIDOPTERA: GELECHIDAE) BY DIFFERENT TRAPS ON TOMATO IN AYDIN PROVINCE, TURKEY

Muammer DEMIROZ, Ibrahim GENCSOYLU[1]*

1Department of Plant Protection, Faculty of Agriculture, Adnan Menderes University, Aydin Turkey
*Corresponding author:igencsoylu@adu.edu.tr

Abstract

The aim of paper was to investigate the population dynamics and infestation of *Tuta absoluta* (Meyrick) by using different traps on tomato field of glasshouse in 2010-2011 in Aydin province, Turkey. The study was conducted at the two growing seasons (Fall and Spring). Three different types of trap (Delta pheromone trap, pheromone+water pan and light trap) were used to evaluate the population dynamics during the experiment. At the end of the study, the highest population of *T. absoluta* was captured with 350 adult/trap in the pheromone+water pan trap in fall season and followed by 95 adult/trap in delta pheromone trap and 23 adult/trap in the light trap. After this time, the population decreased and continued at low amount (no more than 50 adult) in fall season. In spring season, the highest population was observed on two different sampling times. Pheromone+water pan trap captured 33 adults/trap and delta type pheromone trapped zero on 9 March 2011. On the other way, 40 adults/trap was captured in the pheromen+water pan and 18 adult/trap in delta pheromone trap on 14th May 2011. In contrast, the light trap was not efficient and not useful due to catching bees in the glasshouse. Infestation rate on leaves caused by the *T. absoluta* varied %10-66.7 and %5-100 in fall and spring season. On the other hand, the damage rate on the fruit varied %6.7-46.7 and %10-63 in fall and spring season. It is concluded that *T. absoluta* is major economically important pests, had four peaks for each season and gives 7-8 generations in both spring and fall tomato-growing seasons in the glasshouse. Pheromone+water pan trap with olive oil was 2.2-3.6 times more effective than the pheromone trap and 15 times more than the light trap. Therefore, it is more useful in management program against *T. absoluta*.

Keywords: *Tuta absoluta, tomato, traps, Aydın province in Turkey*

Introduction

Tomato is one of the most important vegetables in Aegean, Mediterranean and Marmara region in Turkey. The country is the fourth place on production with 12.516.000 ton after China, India and United States (Anonymous, 2016) and it is produced for fresh consumption under both greenhouse and open field areas in Turkey. There are many pests in tomato field. The tomato moth, *Tuta absoluta* Meyrick, is considered to be one of the most pests causing the damage in tomato fields. It was first recorded in Peru and widespread through South Africa in early 1900s and then has spread to Europa, Africa and Middle East countries (Van Der Straten et al., 2011; Tropea-Garzia et al., 2012) and finally recorded in Turkey (Kılıç, 2010). It has spread rapidly through Southern part (Mamay and Yanık 2012; Bayram et al., 2014) Mediterreanen (Erler et. al., 2010; Portakaldalı et al., 2012), Eastern (Marmara (Pehlavan and Kovancı, 2013; Çetin et al., 2014; Canbay et al., 2014) and Center Anatolia part of Turkey (Erdoğan et al., 2014).

The larva of *T. absoluta* can damage the plant and mine the leaves and produce large galleries. It overwinters eggs, pupae or adult and gives 10-12 generation. It is known as the most devastating

tomato pest and cause as much as 100% lost of production (Haji et al., 1995).Oztemiz (2013) mentioned that the tomato production decreased with the entry of the pest and the country economy lost 45 million euro due to the damage and caused 100% yield losses in greenhouse and open-field tomato. She also reported that 13 times pesticides were applied and chemical application is limited due to insect's nature of damage in the country.

In order to reduce the excessive use of insecticide various control measures should be applied against the pest due to more generations per year. One of the control technique was pheromone traps (Kılıç, 2010; Tropea-Garzia et al.,).

The aim of the study was to evaluate the effect of various traps and infestation rate on plant part in glasshouse in both spring and fall season.

Material and method

The study was conducted in three greenhouses of 800-1300 m^2 surface. The experiment was located at Kozalaklı Village far from Aydın-Center about 19 km. The tomato was planted on 3nd September 2010 and 20th January 2011. All cultural practices were conducted in according to farmer practices. Insecticides were not applied, but fungicides were conducted.

Three monitoring methods (Pheromone, pheromone+water pan and light trap) were applied to determine the population dynamics of *T. absoluta*. Pheromone traps was placed with 1, 5m above the ground level on 9 September 2010 whereas the pheromen+water pan and light were placed 0 45 cm above the ground level at the same day. The pheromone+water pan consist of pan (9 liter) with water and added olive oil. The pheromone connected with the iron wire into the pan. The traps were monitored weekly by the end of the harvest. The capsules changed monthly wh,ereas the sticky part was replaced weekly. The light traps were removed in spring season due to affect the bees in the greenhouse.

The sampling of infestation rate on the leaves and fruits were observed weekly. 60 leaves and all fruits were visually checked for each greenhouse. It started on 16 October 2010, 29 January 2011 and finished 15 January 2011 and 14 May 2011 for fall and spring season.

Results and Discussion

Seasonal flight activity of *T. absoluta* at different traps in fall season was shown in Figure 1. The first moth was captured on 16 October 2010 in pheromone trap and light trap.

The highest population was captured with 348 adults/trap in pheromone+water pan trap. After the two sampling date the population decreased. It is shown that it had four peaks in spring season. The first peak was noted with 90 adults/trap on 23. 10.2010 in pheromone trap, 348 adults/trap in pheromone+water pan trap and 25 adults/traps in light trap. The second peak was noted with 17, 26 and 24 adults on 4.12.2010 in the traps. The third was noted with 18, 26, and 25 adults on 1.1.2011 and the fourth peak was 10, 16,18 adults on 15.1.2011. in spring season. The flight activity was not observed by 26.2.2011 then increased with low amount. The adult in pheromone+water pan was observed earlier compared with pheromone trap. Four peaks were also recorded during the season. The first peak was observed on 12.2.2011 with 15 adults in pheromone+water pan trap and the second on 19.3.2011 with 33 adult, third on 16.4.2011 with 25 adult and the fourth on 14.5.2011 with 40 adults/trap (Figure 2). Light trap was not used due to catching the bees in the greenhouse

In this study pheromone+water pan trap captured more trap than the other traps. However, Pehlavan and Barış (2013) combined the water pan with the light source and they found that this kind of trap captured low amount due to evaporation of water in hot days. However, the reason for these differences is that the evaporation is low amount and also the olive oil was added into water in this experiment. 7-9 infestation peaks of infestation on the leaves, fruits and flight activities were occurred in both spring and fall season (from October to May). It means that the pest has 3-4 generations during each planting period in greenhouse. *T. absoluta* gave four generations in Tunisia, up to nine generations in Italy and 13 generations in Spain (Tropea-Garzia et al., 2012), South Africa (Barrientos et al., 1998). The data was also supported by Mamay and Yanık (2012), Pehlavan and Kovancı (2013) and Çetin et al., (2014). They mentioned that four peaks, or generations were occurred in open field tomato growing

The infestation on the leaves and fruits with *T. absoluta* in fall season is shown in Table 1.The first infestation on the leaves was observed with 33.3% on 16.10.2010. Four peaks of infestation were occurred in the greenhouses and infestation rate varied between %10-66.7%. The first fruit damage was observed at the beginning of November in greenhouses and varied 3.3-46.7% and three peaks of fruit damage were occurred. In spring season infestation on the leaves was not observed until 2.4.2011 in greenhouse 1 and 30.4.2011 in greenhouse 3. On the other hand, it was occurred through both seasons in Greenhouse 3. It varied 3.3-100% in greenhouses. Fruit damage rate was not observed on 23.4.2011 and reached to the highest level with 13.3% in greenhouses. However, it was observed with 16.7% on 2.4.2011 and reached to the highest level with 63.3% on 7.5.2011 in greenhouse 2 (Table 2). The rate was found more amounts compared with Pehlavan and Kovancı (2013). They found that infestation damage on the fruit was 1.45%. These differences should be varieties or favorable condition. The study was supported by Bayram et al., (2014). They reported that 3-5 maximum peak point was occurred and 100% tomato plant and fruit in Bismil, 60-90% plants, 20-30% fruits in Ergani County were damaged by the pest. Both fruit and leave damage increased toward the end of the season due to rising in temperature. This result also supported by Leite et al., (2004) Lacordaire and Feuvrier (2010), Allache and Demnati (2012).

Conclusion

It is concluded that *T. absoluta* is major economically important pests, had four peaks for each season and gives 7-8 generations in both spring and fall tomato-growing seasons in the glasshouse. Pheromone+water pan trap with olive oil was 2.2-3.6 times more effective than the pheromone trap and 15 times more than the light trap. Therefore, it is more useful in management program against *T. absoluta*.

3Center for Food Analysis, Zmaja od Noćaja 11, 11000, Belgrade, Serbia

Abstract

Cover crops has important role in sustainability, owing to protection from soil erosion and soil enrichment with organic matter. Bio-fertilizers are important for increase of soil and crop quality. The aim of experiment was to examine nutritional quality of sweet maize, sown at experimental plots after different cover crops: T1 - common vetch (*Vicia sativa* L.), T2 - winter oats, (*Avena sativa* L.), T3 - fodder kale (*Brassica oleracea* (L.) *convar. acephala*), T4 - field pea (*Pisum sativum* L.) + winter oats, T5 - dead organic mulch, T6 - common vetch + winter oats, T7 - field pea and control - uncovered during the winter, in combination with bio-fertilizer Uniker, during 2013/2014. Content of main antioxidants: phenolics, glutathione, vitamin C, carotenoids and phytic acid were determined in technological maturity. The highest content of carotenoids (2.48 µg g^{-1}) was obtained in T1 + Uniker combination, while the highest values of glutathione and phenolics were in T2 treatment (1927 nmol g^{-1} and 716 µg g^{-1}, respectively). T3 was characterized with the highest vitamin C content in combinations with and without Uniker (29.92 and 31.09 mg $100g^{-1}$) and control had the highest phytic P content (3.69 mg g^{-1}). Correlation consigned that increased kernel yield was followed by carotenoid increase and phenolics decrease in general, while application of Uniker induced increase of P_{phy} and decrease of vitamin C, parallel with grain yield increase.

Key words: *sweet maize grain, nutritional quality, antioxidants*

Introduction

Sustainable agriculture combines various cultural practices with aim to maintain agro-ecosystem stability and high crop productivity. From this point, great responsiveness was given to the cover crops, which protect soil from erosion, maintain balance of nutrients in soil, by increasing organic matter level, together with conservation of nutrients from loosing. This is particularly important for nitrogen, since cover crops hold back nitrogen from leaching through soil profile (Restovich et al., 2012). Dolijanović et al. (2012) underlined significantly higher sweet maize kernel yield achieved from the field with cover crops in relation to kernel yield achieved from the uncovered field. Uchino et al. (2009) and Dolijanović et al. (2012) also emphasized that the highest grain yields of soybean and sweet maize were obtained when they are grown after leguminous cover crops. It is also important to underline that excessive fertilization could decline nutritive value of crops, particularly when nitrogen fertilization, which increases nitrate level and decreases the level of vitamin C, soluble sugars and Mg and Ca in some crops (Wang et al., 2008). Other than that, low input agricultural strategies contribute to increased level of vitamins in vegetables, including sweet maize (Worthington, 2004; Crinnion, 2010). Application of catch crops has advantage to application of mineral and other organic fertilizers in increased vitamin C concentration in sweet maize kernels (Rosa, 2015).

What is more, by incorporation of cover crops residues into soil, microbiological activity is increasing. Microorganisms, present naturally in soil or introduced by application of microbiological fertilizers contribute to maintenance of soil fertility together with increase of crop yields (Mahdi et al., 2010).

Sweet maize, rich in carbohydrates is also good source of fibers, vitamins and minerals and it could have many health benefits, what is important in particular since it is mainly consuming fresh (Arnarson, 2015). It is also high in phenolics, with high antioxidant activity expressed among other maize genotypes (Das et al., 2014).

The aim of experiment was to test the reaction of sweet maize to application of different cover crops from the point of nutritional quality, i.e. variation in concentration of antioxidants like vitamin C, carotenoids, water soluble phenolics, glutathione and phytic acid expressed as phytic phosphorus.

Material and methods

A field experiment was carried out over 2013/14, at the Experimental Field of Maize Research Institute in Zemun Polje (44°52'N 20°20'E). The experiment was established as a block design with four replications with winter cover crops as treatment: T1 - common vetch (*Vicia sativa* L.), T2 - winter oats, (*Avena sativa* L.), T3 - fodder kale (*Brassica oleracea* (L.) *convar. acephala*), T4 - field pea (*Pisum sativum* L.) + winter oats, T5 - dead organic mulch, T6 - common vetch + winter oats, T7 - field pea and control - classical variant, uncovered during the winter.

The cover crops were sown at the end of October or in early November. Green mass of the cover crops were incorporated in the soil in early May. After that bio-fertilizer – Uniker (containing proteolytic and cellulolytic bacteria) was applied to accelerate mineralization of cover crops, which was followed by sweet maize (ZPSC 421*su*) sowing.

The kernels were harvested at the stage of milk maturity (end of August). The content of main antioxidants: phenolics, glutathione, vitamin C, carotenoids and phytic acid were determined. Phytic P (P_{phy}) and total glutathione (GSH) content were determined colorimetrically. Phytic P was determined by the method of Dragičević et al. (2011) and GSH by the method of Sari Gorla et al. (1993). Free soluble phenolics were determined by method of Simić et al. (2004), as well as carotenoids content (mainly containing of β-carotene) was also determined colorimetrically, after extraction with saturated butanol AACC (1995). Vitamin C was determined by iodometric titration (Rikovski et al., 1989). The experimental data were statistically processed by ANOVA (with LSD 5%) and by regression analysis.

Results and discussion

According to results present in Table 1, concentrations of all examined antioxidants in sweet maize kernels varied significantly toward cover crop treatment, as well as interaction cover crop x Uniker treatment. The highest variability was in carotenoid concentration, accordingly to the results of Khalid and Juvik (2009) who find high variability in carotenoid content in sweet maize kernels among various agro-ecological conditions. For GSH, the highest values were obtained at T5 treatment (with Uniker) and T7 (Ø); for phenolics, they were obtained in control (with Uniker) and T4 (Ø); for vitamin C, the highest values were acquired by T3 treatment (with Uniker) and T6 (Ø); for carotenoids, the highest values were obtained at T1 treatment (with Uniker) and T5 (Ø), and for P_{phy}, they were obtained by T6 treatment (with Uniker) and control (Ø). T1 (common vetch cover crop) was characterised with the lowest values of GSH (with Uniker) and vitamin C (in both, with and without Uniker application), while T2 (winter oats) was treatment with the lowest values of GSH and phenolics concentration (without Uniker) and P_{phy}

concentration (with Uniker) and T3 (fodder kale) is the treatment with the lowest values of carotenoids (in both, with and without Uniker application). Rosa (2015) find that cover crops were positively reflected on increase in vitamin C concentration, what is in this experiment present in treatments with fodder kale, field pea and combination of common vetch + winter oats. The positive impact of microbiological fertilizers is also observed on carotenoid lycopene and vitamin C accumulation in tomato fruits (Verma et al., 2015; Ochoa-Velasco et al., 2016). GSH content was mainly influenced by mulch and field pea, confirming that organic fertilizers, with available N forms are important for accumulation of this protein type (Dragičević et al., 2013). It is well known that fertilizers, together with other measures commonly used in organic farming, as low input agriculture contributes to increased level of vitamins in vegetables, including sweet maize, when compared to conventional farming (Worthington, 2004; Crinnion, 2010).

Table 1.Concentration of glutathione (GSH), phenolics, Vitamin C andphytic P (P_{phy}) in sweet maize grain influenced by different cover crops (T1 – T7) and bio-fertilizer (Uniker; Ø – without Uniker)

Variations in kernel yield were connected to variability in content of main antioxidants in sweet maize kernels, having significant and positive correlation of kernel yield with carotenoids and P_{phy} (R^2=0.3518 and R^2=0.3398, respectively; Figure 1), as well as significant and negative

correlation with phenolics and vitamin C (R^2=0.1764 and R^2=0.5926, respectively) in Uniker treatment. In parallel, Verma et al. (2015) find positive impact of effective microorganisms on yield and lycopene content of tomato fruits. Other than that, in treatment without Uniker, significant and positive correlation between kernel yield and carotenoids and vitamin C (R^2=0.2404 and R^2=0.5967, respectively; Figure 2) was observed, while significant and negative correlation was between kernel yield, phenolcs and GSH (R^2=0.2963 and R^2=0.4415, respectively). In the case of vitamin C, results obtained in the part of experiment without Uniker application indicate that proper nutrition reflects positive on increase of kernel yield and vitamin C concentration in kernels (Wang et al., 2008), as improved quality. This was especially underlined in treatments with fodder kale, field pea and combination of common vetch + winter oats (Table 1).

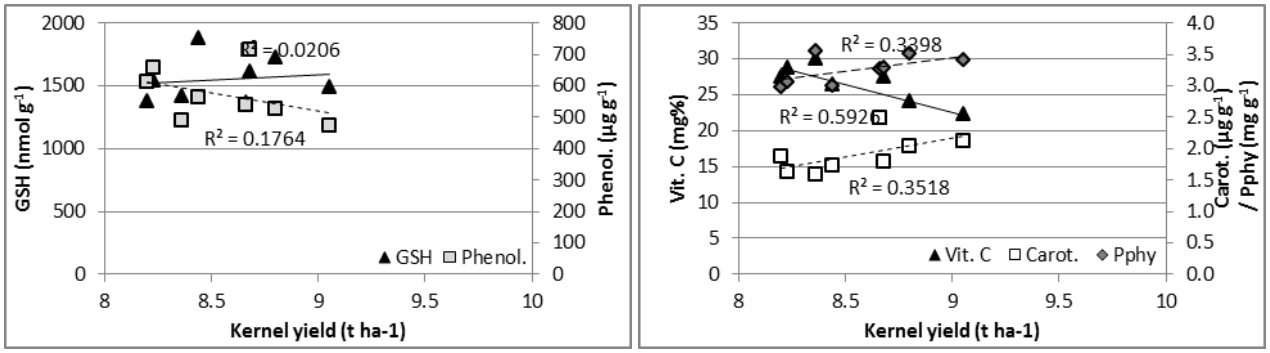

Figure 1. Interdependence between kernel yield and concentration of different antioxidants (GSH, phenolics, vitamin C, carotenoids and P_{phy}) in sweet maize grain in Uniker treatment

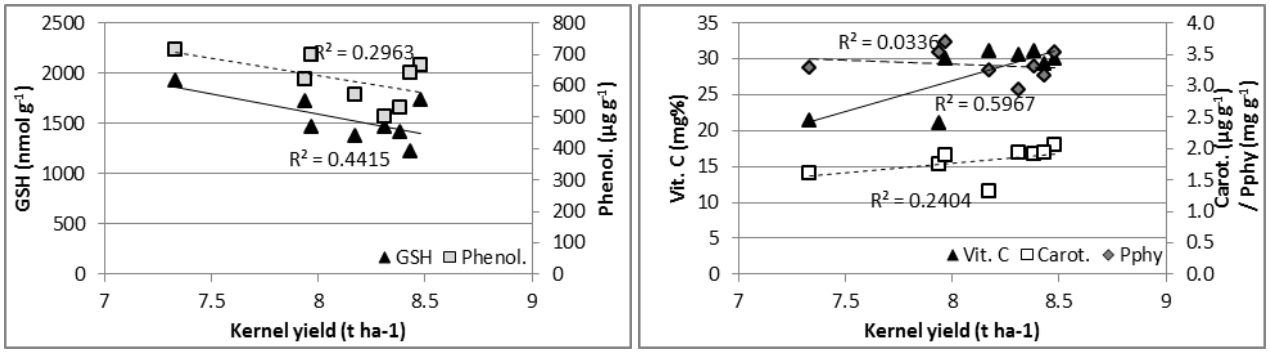

Figure 2. Interdependence between kernel yield and concentration of different antioxidants (GSH, phenolics, vitamin C, carotenoids and P_{phy}) in sweet maize grain in treatment without Uniker

Conclusion

Based on obtained results from research, it could be concluded that the highest variability was present in carotenoid concentration, among parameters examined. Uniker slightly increased carotenoid and GSH content, while it showed decreasing effect on phenolics content. Cover crop treatments expressed various effects, with the highest impact of dead organic mulch on GSH increase, fodder kale and field pea for vitamin C increase and common vetch for carotenoid increase. In general, increased kernel yield was followed by carotenoid increase and phenolics decrease, while application of Uniker showed diverse results, increasing P_{phy} and decreasing vitamin C, parallel with kernel yield increase.

Abstract

Investigations were carried out during the 2008/2009 and 2009/2010 year on stationary field trial, which was established in 1970 on the experimental field of the Center for Small Grains in Kragujevac. The objective of this study was to investigate the influence of mineral nutrition on the yield of winter wheat varieties Ana Morava. Trials were included control and seven fertilization variants with different combinations of NPK fertilizers. Investigation where showed a considerable variation of grain yield which were in dependence from mineral nutrition. The highest grain yields were the highest with mineral fertilizer in the combined 80 kg/ha N and 100 kg/ha P_2O_5 (3.976 t/ha). Over the two-year period, all investigated treatments of wheat achieved the highest average 1000-grain weight in the combined 80 kg/ha N and 100 kg/ha P_2O_5 (41.64 g). Analysis of variance was found highly significant effect of years on grain yield and 1000 grains weight. Different combinations of NPK fertilizers had the most highly significant influence on all characters, except for test weight. Analysis of variance for the impact of years and fertilization variants on investigated traits was found that doses of nitrogen in combination with NPK fertilizers significantly affected only on grain yield. Positive correlations were observed between grain yield and test weight in all treatments. Grain yield were significantly positively correlated with 1000-grain weight only in the 2008/09 ($r=0.44^{*}$) and 2009/10 ($r=0.55^{*}$).

Key words: *fertilization, yield, quality, wheat*

Introduction

New perspective wheat lines and varieties has more and better filled grain, higher yield, grain mass and farinaceous content, while proteins and lysine was smaller compared with older varieties (Đekić et al., 2014, 2015). Several factors are decisive in increasing wheat yields: the cultivar, cultural practices, agroecological conditions, local climatic and soil characteristics, mineral nutrition and adequate protection from plant diseases, pests and weeds. Wheat productivity and grain quality in Central Serbia are governed by a range of factors, notably climate, soil, genetics and crop nutrition. Soil acidity in wheat fields in Central Serbia has become a severe problem that leads to a significant decline in grain yield and quality of wheat (Đekić et al., 2013).

Mineral nutrition ofwheat grown on acid soil reaction is specific. The crucial importance play equilibred nutrition by nitrogen and phosphorus with higher impact ofphosphorus nutrient. The optimum rate of P application is important in improving yields of most crops (Jelić et al., 2013, 2014). In Serbia, farmers are using only nitrogen fertilizers for fodder crops while the use of P fertilizer is negligible. These crops are often grown on marginal lands. Hence, the production is low

and quality is poor. The absence of record yields indicates that an answer could be sought in soil, the main substrate for field crop production. Additionally, the major previous crops of small grains also suffer from negative nutrient balance. The use of incomplete production technology in previous decades had definitely affected the potential and actual soil fertility.
The objective of this study was to evaluate the effect of different fertilization systems on the grain yield and quality of wheat grown on a vertisol soil. The study was also aimed at optimizing fertilization for maximum profitability in the future wheat production of Central Serbia.

Materials and methods

Experimental design and statistical analysis
The study was carried out in a stationary field trial involving fertilization over a two years period from 2008/09 to 2009/10. Trials were first set up in the experimental fields of the Small Grains Research Centre in Kragujevac in 1970. Plot size was 50 m^2. The wheat cultivar used in the experiment was Ana Morava, the dominant cultivar in the production region of Serbia. This investigation included an untreated control and seven variants of fertilization: 1-80 kg/ha N, 2-60 kg/ha P_2O_5, 3-80 kg/ha N, 60 kg/ha K_2O, 4-80 kg/ha N, 60 kg/ha P_2O_5, 5-80 kg/ha N, 100 kg/ha P_2O_5, 6-80 kg/ha N, 60 kg/ha P_2O_5, 60 kg/ha K_2O and 7-80 kg/ha N, 100 kg/ha P_2O_5, 60 kg/ha K_2O. A non-fertilized variant served as a control. Total amounts of phosphorus and potassium fertilizers and half the nitrogen rate are regularly applied during pre-sowing cultivation of soil. The trial was set up in a randomized block design with five replications. Fertilization was regular and followed a long-time scheme.
On the basis of achieved research results the usual variational statistical indicators were calculated: average values, standard error and standard deviation. Statistical analysis was made in the module Analyst Program SAS/STAT (SAS Institute, 2000).

Soil conditions
The trial was set up on a vertisol soil in a process of degradation, with heavy texture and very coarse and unstable structure. The humus content in the surface layer of soil was low (2.22%). Soil pH indicates high acidity (pH in H_2O 5.19; pH in KCl 4.27), nitrogen content in soil is medium (0.11-0.15%), while the content of available phosphorus ranges from very low (1.7-2.9 mg/100 g soil) in the 4 variant (80 kg/ha N, 60 kg/ha P_2O_5) to very high (26.9 mg/100 g soil P_2O_5) in the 6 and 7 variants of fertilization. Available potassium contents are high, ranging from 19.5 to 21.0 mg/100 g soil K_2O.

Agroecologial conditions
This study was conducted over a three-year period in the Šumadija region, Central Serbia, on a Vertisol soil, at Kragujevac location, 173-220 m a. s. l. (44° 22′ N, 20° 56′ E), in a temperate continental climate having an average annual temperature of 11.5°C typical of Šumadija districts in Serbia and a rainfall amount of about 550 mm. The data in Table 1 for the investigated period (2008-2010) clearly indicate that the years in which the researches were conducted differed from the typical multi-year average of Kragujevac region regard the meteorological conditions.
The average air temperature in 2008/09 was higher by 1.48°C and 2009/10 was higher by 1.01°C. The sum of rainfall precipitation in 2008/09 was higher by 13.0 mm, where the sum of rainfall in 2009/10 was 616.2 mm higher than the average of many years and with a very uneven distribution of precipitation per months. Spring months April, May and June in 2009/10 were surplus of precipitation, what affected unfavorable on the crops. During the April in 2009/10 it

was 142.2 mm of rainfall, what was 90.7 mm more compared with the perennial average. During the month of June in 2009/10 it was 196.7 mm of rainfall, what was 117.4 mm more compared with the perennial average.

Results and discussion

The grain yield of wheat significantly varied across years, from 1.327 t/ha to 5.193 t/ha in 2008/09, from 1.178 t/ha to 3.049 t/ha in 2009/10.

Grain yield were the highest in the combined treatment 5 (80 kg/ha N and 100 kg/ha P_2O_5) with mineral fertilizer NP (3.976 t/ha). Results clearly show that yield components were significantly affected by fertilization (Table 2), the lowest values for grain yield and yield components were obtained in the untreated control. During the first year of investigations, the highest average value of 1000-grain weight achieved the 5 (80 kg/ha N, 100 kg/ha P_2O_5), 6 (80 kg/ha N, 60 kg/ha P_2O_5, 60 kg/ha K_2O) and 7 (80 kg/ha N, 100 kg/ha P_2O_5, 60 kg/ha K_2O) treatments (42.78, 42,64 and 42.42 g). During the second year of investigations (2009/10), the highest average value of 1000 grain weight achieved the 5 (80 kg/ha N, 100 kg/ha P_2O_5) and 7 (80 kg/ha N, 100 kg/ha P_2O_5, 60 kg/ha K_2O) treatments (40.50 g and 40.18 g). During the first year achieved the highest test weight at 7 treatment (71.73 kg/hl), while the lowest test weight was the control treatment (69.92 kg/hl). During the second year of investigations, the highest test weight at 7 (80 kg/ha N, 100 kg/ha P_2O_5, 60 kg/ha K_2O) treatment (72.93 kg/hl), followed by 6 treatment (80 kg/ha N, 60 kg/ha P_2O_5, 60 kg/ha K_2O) (72.73 kg/hl) and 4 (80 kg/ha N, 60 kg/ha P_2O_5) treatment (72.45).

The study showed that among investigated fertilization variants the highest grain yields were achieved in variant with 80 kg/ha N and 100 kg/ha. Usage of fertilizers and certain amendments on extremely acid soils in certain years, particularly those less favorable for production, almost certainly had different effects on grain filling, resulting in diverse relationships between productive and qualitative traits. Presented results confirm the opinion of many authors that the traits analyzed are genetically determined, but strongly modified by the nutrient status and weather conditions (Đekić et al., 2014; Jelić et al., 2013).Highly significant differences in grain yield at investigated wheat cultivar were found relative to the fertilization (Table 3).

Effect of the year x fertilization interaction on the traits analyzed				
Traits	Mean sqr Effect	Mean sqr Error	F(7. 64)	p-level
Grain yield (t ha^{-1})	1.750069	0.741714	2.359493*	0.032931
1000-grain weight (g)	1.858857	2.517750	0.738301	0.640356
Test weight (kg hl^{-1})	1.232857	4.497313	0.274132	0.961830

Based on the analysis of variance, it can be concluded that are highly significant differences in grain yield regard the year of investigation (F_{exp}=10.452**) and highly significant differences at 1000-grain weight (F_{exp}=27.828**). Highly significant differences in grain yield and 1000-grain weight regard the fertilization of investigation (F_{exp}=8.208** and F_{exp}=3.525**). In the dual interaction between the year and fertilization, significant effects were on grain yield.
Positive correlations were observed (Table 4) between grain yield and test weight in all treatments.

Table 4. *Correlation coefficients for the traits analyzed across treatments*

Correlations between the traits analyzed in the unfertilized control			
	Grain yield (t ha^{-1})	1000-grain weight (g)	Test weight (kg hl^{-1})
Grain yield (t ha^{-1})	1.00	0.23^{ns}	-0.20^{ns}
1000-grain weight (g)		1.00	0.26^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the 80 kg/ha N			
Grain yield (t ha^{-1})	1.00	0.58*	0.06^{ns}
1000-grain weight (g)		1.00	-0.17^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the 60 kg/ha P_2O_5			
Grain yield (t ha^{-1})	1.00	0.09^{ns}	-0.06^{ns}
1000-grain weight (g)		1.00	-0.37^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the 60 kg/ha K_2O			
Grain yield (t ha^{-1})	1.00	0.39^{ns}	-0.49^{ns}
1000-grain weight (g)		1.00	-0.51^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the 80 kg/ha N, 60 kg/ha P_2O_5			
Grain yield (t ha^{-1})	1.00	0.65*	-0.60*
1000-grain weight (g)		1.00	-0.50^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the 80 kg/ha N, 100 kg/ha P_2O_5			
Grain yield (tha^{-1})	1.00	0.59*	-0.05^{ns}
1000-grain weight (g)		1.00	0.14^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the 80 kg/ha N, 60 kg/ha P_2O_5, 60 kg/ha K_2O			
Grain yield (t ha^{-1})	1.00	0.26^{ns}	0.02^{ns}
1000-grain weight (g)		1.00	-0.42^{ns}
Test weight (kg hl^{-1})			1.00
Correlations between the traits analyzed in the 80 kg/ha N, 100 kg/ha P_2O_5, 60 kg/ha K_2O			
Grain yield (t ha^{-1})	1.00	0.64*	-0.47^{ns}
1000-grain weight (g)		1.00	-0.57*
Test weight (kg hl^{-1})			1.00

Pozitive and medium correlations were also found between grain yield and 1000-grain weight in the 1 treatment (r=0.58*) in the 4 treatment (r=0.65*), in the 5 (r=0.59*) and 7 treatment (r=0.64*).

Negative and medium correlations were also found between test weight and 1000-grain weight in the 7 treatment ($r=-0.57^{*}$).

Table 5. *Correlations between the traits analyzed during 2008-2010*

	Correlations in 2008/09			Correlations in 2009/10		
Traits	Grain yield, t/ha	1000-grain weight, g	Test weight, kg/hl	Grain yield, t/ha	1000-grain weight, g	Test weight, kg/hl
Grain yield (t ha^{-1})	1.00	0.44^{*}	0.40^{ns}	1.00	0.55^{*}	0.13^{ns}
1000-grain weight (g)		1.00	0.27^{ns}		1.00	-0.12^{ns}
Test weight (kg hl^{-1})			1.00			1.00

Testing the correlation coefficients between grain yield and 1000-grain weight of wheat (Table 5) was found positive and were significantly correlated between in 2008/09 and 2009/10. However, 1000-grain weight were significantly positively correlated with grain yield only in the first year ($r=0.44^{*}$) and second year ($r=0.55^{*}$). The results suggest that grain yield and quality formation is affected by both genetic and environmental factors (Đekič et al., 2015).

Conclusion

The highest grain yield had mineral nutrition by combination of two mineral elements N and P (80 kg/ha N and 100 kg/ha P_2O_5), as well by application three mineral elements N, P and K in rate 80 kg/ha N, 100 kg/ha P_2O_5 and 60 kg/ha K_2O. Regard the high importance of sufficient rainfall amounts during the spring months, particularly May for small grains production, the distribution and amount of rainfall over the growing season 2008/09 were considerably more favorable, what resulted with increment of yields during that year.

Statistically were highly significantly different between of year on the grain yield and 1000 grain weight were significantly different. Effect of fertilization on the grain yield and 1000 grain weight were highly significantly. Significantly positively correlated with yield and 1000 grain weight both in 2008/09 (0.44^{*}, respectively), and 2009/10 (0.55^{*}, respectively). Significant positive and medium correlations were observed between grain yield and 1000-grain weight in 1, 4, 5 and 7 treatments, and significant negatively medium correlations were observed between 1000 grain weight and test weight in 7 treatment.

Abstract

Bituminaria bituminosa (*Bitbit*) is a perennial species in *Bituminaria* genus. It naturally grows in open fields, road sides, eroded and slide areas and woodlands of soil pH 4.7-8.5. *Bitbit* plays important role in natural vegetation of the coastal areas in Turkey and keeps greenery throughout the summer period in northern and western areas. We have been carrying out studies on *Bitbit* since 2010. We have collected 86 genotypes from Central Black Sea Region of Anatolia. No fertilizer and water were applied throughout the study and hay and seed yields, agronomical, morphological and phenological traits of genotypes were investigated. It was observed that there were significant differences and diversity in terms of all aspects amongst the genotypes. In some genotypes, only one harvest was performed, but in others, two harvests were done in the same season. Hay yield obtained from the second harvest decreased sharply for all genotypes. In the first year, average hay yield per plant of genotypes was 7.81 g, but it reached to 351.6 g in the second year. When we evaluated all genotypes, average hay yield per plant was between 83-994 g in the second year. While average seed yield obtained per plant was 85.22 g, it exceeded 250 grams for some genotypes. Especially leaves of the plant are very rich in terms of Ca, Mg, K and P. At the early growing stages, leaf ratio was 70-80%, crude protein 23%, ADF 20%, NDF 30% and Relative Feed Value (RFV) value more than 150. Even though *Bitbit* plants contain some chemical compounds, they do not cause a detrimental effect on animal health and on quality of animal products. Considering the plant needs, it needs very little input to grow. Therefore, it might be very important for extensive livestock farming at summer and winter periods in Mediterranean Basin.

Keywords: *Bituminaria bituminosa, genotype, yield, quality, low input*.

Introduction

In Turkey, cultivated forage crops and plants existing naturally in pastures are cool season plants. Pasture plants are dormant or dry, because of high temperature and drought in June-September period which is resulting serious forage gap for the animals grazing on pasture. According to global climate changing scenarios, drought and high summer temperatures are expected in Turkey (Anon 2011). *Bitbit* is a perennial legume, improves the quality of pasture in the hot and dry periods while other species and grasses disappear or decrease their hay quality in the Mediterranean basin (Mendez and Fernandez, 1990; Pecetti *et al*. 2007). In northern parts of Turkey, *Bitbit* plants keep their greenery all over the year and livestock graze on this plant (Acar *et al*. 2016). Relative to annuals, perennials regrow more rapidly at the onset of autumn rains and are able to delay senescence in summer by better exploitation of residual soil moisture. In harsh environments, such as in Israel, *Bitbit* has been reported to withstand intensive grazing by cattle, being the only species with green matter in late spring (Gutman *et al*. 2000). In the Canary Islands a local ecotype called ‘tedera’ is traditionally used for feeding goats, either under grazing

or as hay (Ventura *et al*. 2000). *Bituminaria bituminosa* is usually considered of low palatability because of the strong smell that can be emitted by oil glands located on its foliage (whence its botanical name). Nonetheless, the 'tedera' population, for example, is reported to be of good palatability (Munoz *et al*. 2000), while high palatability and browse intake of the species throughout the year have also been reported (Otal *et al*. 1991). The nutritive value of *B. bituminosa* in terms of forage composition and digestibility has proved similar to or even better than that of other wild legumes (Viano *et al*. 1995). The presence of some secondary compounds (e.g. phenolic components) may have health-promoting effects due to their antioxidant properties (Pecetti *et al*. 2007).

Material and Methods

This study was carried out at 180 m asl. in Samsun between 2012-2015. Long term precipitation and temperature of experiment site were 830 mm and 13.8 ^{0}C. The same figures 2013 and 2014 years were 1019 mm, 15.85 ^{0}C and 620 mm, 14.7 ^{0}C. In the scope of the Project 86 *Bitbit* genotypes was collected from Samsun, Sinop and Kastamonu provinces. Regarding the altitude, *Bitbit* plants naturally grow from just nearby the sea (3 m) to south-eastern skirts of Mount Dranaz (985 m). After seed cleaning and germination tests, seeds were scarified and sown in small pots. In November of 2012, the seedlings were transplanted to the experimental field with 70 cm*70 cm spaces as 20 plants for each genotype. No fertilizer and water were applied throughout the study and observed hay and seed yields, morphological and phenological traits, crude protein, some minerals, ADF and NDF of genotypes. In 2013 spring stem elongation was observed in 41 genotypes but no stem elongation was observed in 45 of them. Two cuts were performed for 37 genotypes over 41 in 2013. In 2014, two cuts were performed in 55 genotypes and only one cut was done in 31 genotypes. Morphological measurements were realised on 10 plant samples for all genotypes. Then, five plants were randomly harvested in each plot at the 50% flowering stage. Plant samples (leaf and stem) were dried at 60 °C in oven till constant weight, and ground to pass through 1 mm screen. Chemical characters; dry matter, crude protein, ADF, NDF, ADP, Ca, Mg, K, P content of samples were determined by using Near Infrared Reflectance Spectroscopy (NIRS, "Foss 6500") with software package program "IC-0904F". Statistical analysis was performed with SPSS 17.0 program.

Results and Discussion

There was statistically significant variation amongst the genotypes in terms of plant height. Although, plant height values increased in 2014, variation level decreased (Table 1). There might be two reasons for the variation in the first year: i) genetic capacity of genotypes ii) no stems elongation. The variation in the second year could be attributed to genetic differences amongst the genotypes. Regarding the agronomical and morphological traits, perennial plants had highest values in the second year (Acar and Ayan, 2012). Increasing of plant height in 2014 might be attributed to the second year effect and climatic conditions that rainfall was higher in 2014 and it was hotter in 2014 compared to 2013. Plant height values obtained from the research were similar those that of some previous researchers 20-140 cm (Davis, 1970); 54-128 cm (Gulumser, 2011); 116.4 cm at blooming stage (Acar *et al*. 2016). While the first year branch number of *Bitbit* genotypes was 8.24, it increased to 17.75 in the second year. Similar to change of the branch number, stem thickness of genotypes increased from 5.42 mm to 7.91 mm in the second year (Table 1). The source of the increasing probably comes from second year effect and favourable climatic conditions in 2014. Branch number and stem thickness changed in the first and second year as 13.7-14.7 and 5.2-6.3 mm, respectively reported by Gulumser and Acar (2012). Opposite

of the first 3 morphological characters, leaflet sizes of *Bitbit* genotypes slightly decreased in the second year. The mean values of leaflet width and length were 23.6 and 50.4 mm in the first year and 23.6 and 49.1 mm respectively, in the second year (Table 1). Gulumser and Acar (2012) explained that leaflet width and length of some *Bitbit* genotypes were 21-24 mm and 45-45 mm in the first and second year, respectively. The results obtained from this study were slightly higher than their findings. The reasons of differences could probably be due to the climatic conditions and genetic variation of genotypes. Leaf numbers of *Bitbit* genotypes varied from 9 to 41 with 23.36 mean in the first year and between 21 and 80 with 48.67 mean in the second year. Increasing of leaf number in the second year was a consequence of plant height and branch number (Table 1). Parallel to increasing of leaf number, leaf ratio also increased. The first and second year average leaf ratio values were 63.31% and 70.04%, respectively (Table 1). Acar *et al*. (2016), reported that leaf ratio of *Bitbit* genotypes alters from 30.8% to 78.5% according to development stage. Leaf ratio values obtained from this research support Acar *et al*. (2016) findings.

Table 1. Some agronomic traits of *Bitbit* genotypes

Traits	**2013**			**2014**		
	Mean	**SE**	**Range**	**Mean**	**SE**	**Range**
Plant height (cm)	62.03	2.45	34.70 – 114.35	95.31	1.70	65.00 – 147.60
Branch number	8.24	0.50	2.00 – 18.00	17.75	0.65	8.00 – 39.00
Stem thickness (mm)	5.42	0.15	3.39 – 8.21	7.91	0.15	4.50 – 12.27
Leaflet width (mm)	23.62	0.75	15.89 – 36.87	23.58	0.60	10.65 – 37.25
Leaflet length (mm)	50.38	1.39	30.14 – 68.76	49.13	1.10	22.74 – 71.46
Leaf number	23.36	1.42	9.00 – 41.00	48.67	1.39	21.00 – 80.00
Leaf ratio (%)	63.31	1.97	32.23 – 88.08	70.04	0.53	56.15 – 82.16
Head number/plant	28.01	1.94	4.00 – 92.00	370.62	17.54	12.00 – 892.00
Flower number/head	15.01	0.41	7.00 – 24.00	13.37	0.32	7.00 – 20.00
1000 seed weight (g)	30.14	0.44	20.45 – 44.66			
Hard seed ratio (%)	92.20	0.48	97.64 – 76.67			

Head numbers per plant counted at *Bitbit* genotypes were 4-92 in the first year, while it changed from 12 to 892 in the second year. Mean values about head number were 28.01 and 370 the first and second year, respectively (Table 1). The increase of head number in the second year could be attributed to increase of plant height and branch number. Similar increase in the second year was observed by Gulumser and Acar (2012). In the contrary of head number, flower numbers per head decreased in the second year. While mean flower number was 15 in the first year, it declined to 13.4 in the second year. Parallel to average flower number, variation amongst the genotypes also declined (Table 1). The results similar to Gulumser (2011) that he determined the flower numbers as between 4.5 to 19.5 per head and Davis (1970) who indicated flower number 7-30. 1000 seed weight values were found between 20.45 and 46.66 grams with 30.14 gram mean according to genotypes. Average hard seed ratio was 92.20% and it ranged from 76.67% to 97.64% (Table 1). 1000 seed weight of *Bitbit* was reported between 20 and 29 grams by Correal *et al*. (2008) in Spain. The differences in environments and genotypes might affect the the variation in 1000 seed weight. Correal *et al*. (2008) found that hard seed ratios of Spanish *Bitbit* genotypes altered from 39% to 98%. Considering all investigated morphological characters, there were significant differences amongst the genotypes, except for hard seed ratio. These results could be promising to develop high yielding and high quality cultivars.

Table 2. Some chemical traits of *Bitbit* genotypes

Traits	2013			2014		
	Mean	**SE**	**Range**	**Mean**	**SE**	**Range**
Crude protein (%)	20.32	036	15.22 – 25.95	14.93	0.26	8.42 – 23.11
Ca (%)	1.53	0.02	1.23 – 1.88	1.62	0.01	1.31 – 1.86
K (%)	2.17	0.03	1.55 – 2.66	1.73	0.04	0.66 – 2.62
Mg (%)	0.44	0.01	0.35 – 0.56	0.45	0.01	0.37 – 0.56
P (%)	0.36	0.01	0.32 – 0.40	0.33	0.03	0.25 – 0.39
ADF (%)	33.93	0.99	23.69 – 43.91	32.72	0.35	25.48 – 41.64
NDF (%)	44.11	1.03	39.24 – 51.83	42.76	0.37	34.16 – 52.62

Crude protein ratios of *Bitbit* genotypes varied between 15.22% and 25.95% with 20.32% mean in the first year and it altered from 8.42% to 23.11% with 14.93% mean value in the second year (Table 2). Crude protein ratios of *Bitbit* leaves were higher than those in stems. The leaves and stems had 22.35-25.60% and 11.37-14.06% crude protein, respectively (Gulumser *et al*. 2010). Crude protein ratios of *Bitbit* genotypes varied from 23.41% at pre-elongation stage to 7.28% at seed setting stage (Acar *et al*. 2016). Some previous researchers determined crude protein ratio of *Bitbit* as 10.3-20.4% (Ventura *et al*. 2004; Pecetti *et al*. 2007). Calcium and magnesium contents of *Bitbit* genotypes increased from 1.53% to 1.62% and from 0.44% to 0.45%, in the first and second years respectively, while potassium and phosphorus contents decreased from 2.17% to 1.73% and from 0.36% to 0.33% (Table 2). These results supported to Ventura *et al*. (2004) that they reported calcium, phosphorus, magnesium and potassium ratios of *Bitbit* as 0.86-1.13%, 0.25-0.32%, 0.18-0.26% and 0.26-0.33%, respectively and Acar *et al*. (2016), those findings were 1.30-1.87% as calcium, 0.18-0.40% as phosphorus, 0.35-0.40% as magnesium and 0.51-2.59% as potassium. ADF and NDF ratios slightly reduced from 33.93% to 32.72% and from 44.11% to 42.76%, respectively in the second year (Table 2). These reduce could be attributed to increase of leaf ratio in the second year (Table 1). Gulumser (2011) explained that ADF and NDF ratios of *Bitbit* leaves were lower compared to stems. Similarities were found between these results and some previous researcher findings that they reported ADF and NDF values as 23.8-41.9% and 38.0-56.3%, respectively (Ventura *et al*. 2004; Pecetti *et al*. 2007; Gulumser and Acar, 2012).

Table 3. Some agronomical traits of *Bitbit* genotypes

Traits	2013			2014		
	Mean	**SE**	**Range**	**Mean**	**SE**	**Range**
Hay yield (g/plant)						
1. Harvest	5.78	0.45	1.04 – 14.92	295.38	15.89	83.31 – 780.90
2. Harvest	2.18	0.19	0.33 – 5.49	85.38	6.49	24.61 – 283.75
Sum	7.86	0.58	1.04 – 17.27	380.76	19.74	83.31 – 994.86
Seed yield (g/plant)	7.42	0.63	0.52 – 33.28	85.22	5.58	1.77 – 261.94

There was stem elongation on 41 genotypes out of 86 in the first year (2013). But, hay yield of the genotypes was quite low in the first year. While hay yield/plant altered from 1.04 g to 14.92 g at the first harvest, the data decreased to 0.33-5.49 g at the second harvest in 2013 (Table 3; Figure 1). In the second year (2014) all of the genotypes had stem elongation and two cuts were done in 55 genotypes. Hay yield figures significantly increased to 83-780 g at the first harvest of the second year. At the second harvest hay yields of the genotypes sharply decreased and the numbers were between 24.61 and 283.75 g. Considering total hay yield, more or less 1 kg hay

yield per plant was obtained from some genotypes in 2014 (Table 3). Acar *et al*. (2016) have reported that they took 205 g/plant hay yield as the average of 25 *Bitbit* genotypes. Decreasing yield after the first harvest is very common for all perennial forage crops (Acar and Ayan, 2012). Seed harvest was performed only for the first development of the genotypes in both years. Average seed yields were 7.42 g and 85.22 g/plant in the first and second years, respectively. Seed yield of some genotypes exceeded 250 g/plant in 2014 (Table 3; Figure 2). Similar to hay yield, seed yields of the genotypes were increased in the second year. Increasing of the yields in the second year could be attributed to second year effects for perennials and favourable climatic conditions.

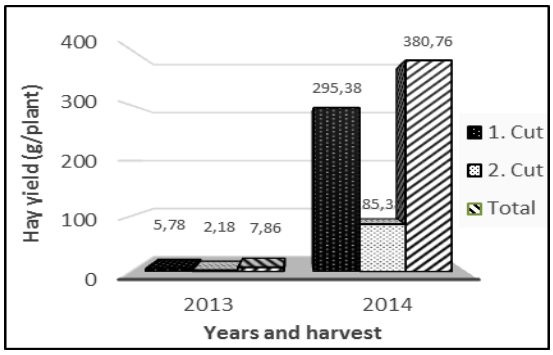

Figure 1. Hay yield of *Bitbit* genotypes

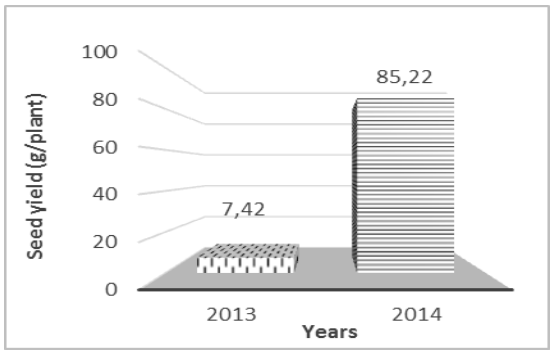

Figure 2. Seed yield of *Bitbit* genotypes

Table 4. Linear correlation amongst hay and seed yields and some other traits

Traits	Hay yield	Seed yield
Plant height	0.728**	0.277*
Stem thickness	0.188	0.249*
Branch number	0.251*	0.021
Leaf number	0.284**	0.242*
Leaf ratio	-0.335**	-0.209
Head number	0.243*	0.591**
Flower number	0.218*	0.369**
1000 seed weight	-0.097	0.248*
Seed yield	0.233*	-

There is a significant positive correlation between hay yield and branch number, head number, flower number, seed yield (P≤0.05); significant positive correlation between hay yield and plant height, leaf number (P≤0.01) and significant and negative correlation between hay yield and leaf ratio (P≤0.01). In terms of seed yield, correlation with plant height, stem thickness, leaf number and 1000 seed weight were positive and significant (P≤0.05); with head number and flower number, it was positive and significant at P≤0.01 level (Table 4). As plant height, branch number, leaf number and head number increase, hay yield also increased (Gulumser, 2011).

Conclusion

There was significant variation amongst the genotypes in terms of morphological and agronomical characters. In addition to high nutritious value, some of the genotypes have high forage yield. Although, almost all cool season plants dry, *Bitbit* genotypes kept greenery throughout the summer period. Considering the all results and global warming *Bitbit* could be a promising plant for forage production in Regions that have Mediterranean climate.

Abstract

Cocksfoot (*Dactylis glomerata* L.) is one of the most important cool season perennial grasses used for animal feed production on grasslands and pastures. It shows a high yield of quality forage as a component of different grass legume mixtures with more than five years of utilisation. Basic requirement for successful breeding of this species, as well as other, is variability of the initial material. The collection examined consisted of twenty two autochthonous populations of cocksfoot collected in hilly-mountainous areas of Serbia. Trial was conducted as spaced plant nursery with 30 plants per genotype in two years. The aim was to determine genetic variability for the most important phenological (heading date), morphological traits (plant height, length of leaf, width of leaf, the leaf number, panicle length and the number of tillers per plant) and dry matter yield per plant. Investigated material has demonstrated significant variability within the genotypes for all studied parameters. The highest average within population variability was determined for dry matter yield (CV 95%), while the lowest variability was determined for date of heading (CV 24%). The highest dry matter yield per plant was measured in the population of Čestobrodica 1, Grza and Boljevac 3 locality. The data were analysed by ANOVA. Among populations variability was high statistically significant for all investigated traits. Genetic diversity of examined cocksfoot autochthonous populations was illustrated by cluster analysis. High level of genetic variability in this collection indicates that the cocksfoot breeding process can make progress in the further.

Key words: *cocksfoot, variability, autochthonous populations, dry matter yield*

Introduction

Cocksfoot is one of the most important forage perennial grasses in Europe and Serbia also. Forage breeding of this species is very intense recent decades. As component of different sown grass-legume mixtures, it shows high and stable yield of quality forage (Balan et al., 2006; Kyriazopoulos et al., 2008). If it is cut frequently, the quality of cocksfoot dry matter can be compare with the quality of perennial ryegrass (Turner et al., 2005). Cocksfoot is a forage species with great adaptability, which has a good tolerance to frost, shade (Rodriguez-Barreira et al., 2008), heat and drought. It has good regrowth ability. In Serbia, cocksfoot (*Dactylis glomerata* L.) is a characteristic species of grasslands from the alliance *Arrhenatherion elatioris* with a different presence and covering. In natural habitats it occurs on various meadows in moderately moist soils, from lowland to mountain habitats over 1000 m a.s.l. (Sokolović et al., 2003) especially in shady places such as sparse woods, wood edges and abundant orchards.

First step in grass breeding process is the determination of genetic variability of breeding material. The existence of genetic variability in available breeding material influences the choice of breeding material and ensures success of a plant breeding program. Autochthonous populations demonstrate great adaptability to different macro and micro habitats varying in traits of adaptive significance and often can be used for direct phenotypic selection and for cultivars release (Posselt and Willner, 2007). The genetic variability of all the agronomical traits important for breeding represents a basic prerequisite for successful selection (Christie and Krakar, 1980). The primary aim in cocksfoot forage breeding is obtaining cultivars with a high yield and quality for livestock feed (Casler et al., 2000). The aim of this investigation was to define genetic variability of 22 cocksfoot autochthonous populations collected in hilly-mountainous areas of Serbia. The most important breeding criteria in cocksfoot breeding programs, as well as other forage grasses, were increasing of forage yield, disease resistance and drought and frost tolerance. One more objectives in many cocksfoot breeding programs on all continents are improvement of resistance to stem rust (*Puccinia graminis*) (Alderson and Sharp 1995). Since is cocksfoot regular component of grass-legume mixtures in Serbia, dry matter yield and quality, persistency and rust resistance and different maturity time is most important breeding criteria of this species.

Material and methods

A collection consisting of 22 autochthonous populations of cocksfoot was investigated during a two years period (2012 and 2013). Autochthonous populations have collected in hilly-mountainous areas of Serbia (Table 1.).

Table 1. Origin of the cocksfoot autochthonous populations

No	Collecting site	Altitude (m a.s.l)	Geographic latitude	Geographic longitude
1	Neradje	1083	43°28’	19°36’

21	Šuljagići	1106	43°38’	19°44’
22	Kremna	1018	43°42’	19°41’

Investigation was conducted in an experimental field of the Institute for Forage Crops, on degraded alluvium soil type. The trial was set up in a space plant nursery with plant to plant distance 60x60cm as a randomized block design with 30 plants per population in three replications. Heading date (HD) and morphological traits plant height (PH) (cm), leaf length (LL) (cm), leaf width (LW) (cm), the number of leaves per tiller (NLT), panicle length (PL) (cm), the number of tillers per plant (NTP) and dry matter yield (DMY) (g per plant) were investigated in 2 years; results are shown as two-year mean values. Heading date is presented as number of days from April the first. All morphological traits and dry matter yield per plant were measured at the full heading stage in first cut. All data were analysed by ANOVA. Differences between accessions were tested by the LSD test. Broad sense heritability (h_b^2) was calculated for all traits according to the formula

$$h_b^{\ 2} = \frac{\delta_g^{\ 2}}{\delta_f^{\ 2}} \cdot 100$$

($\delta_g^{\ 2}$-genetic variance; $\delta_f^{\ 2}$- phenotypic variance)

Cluster analysis was performed by the Ward method, using the Euclid distances (Statistica 8.0, Stat Soft.inc).

Results and discussion

Analyses of maturity, morphological traits which influence dry mater yield and quality, as well as biomass production of cocksfoot populations, showed high within population variability (Table 2.). Also, highly significant differences between cocksfoot autochthonous populations were determined for all studied traits (LSD values in Table 2.).

From the point of grass breeding, heading date is a very important trait, because accessions differing in this trait would enable creating of cultivars with diverse maturing time. This is of interest for the composition of mixtures for various terms and duration of utilization (Sokolović et al., 2010). The earliest heading dates were found in population Grza, while heading occurred last in population Neradje.

The average plant height in the first cut was 78.21cm, which is substantially similar to results published by Sokolović et al. (2016), who reported plant heights of 59.13–101.3cm, in average 76.64cm.

Leaf length and width and number of leaves per plant influence the forage quality by increasing the dry matter quality and improving the crude protein content. Populations Neradje, Balašević, Česma, M. Polje 2, Draglica, Kremna and Dupci 2 have a favourable ratio of leaf length and width and number of leaves per plant, which indicated that these populations have the best biomass quality.

In grasses, number of tillers per plant in the first cut (NTP) is the trait which has the highest impact on DMY, but number of tillers per plant also affects other important traits like seed yield. The highest NTP were found in populations Kremna (108.12), Boljevac 3 (107.75), Boljevac 2 (103.87) and Neradje (101.70). These are similar to the NTP reported by Sokolović et al. (2016), but higher than the published Babić et al. (2009) where the average number of tiller per plant was 49.26. Large variations in NTP between studies are expected, since the trait is highly affected by environmental conditions.

Dry matter yield per plant is one of the most important traits in the breeding process. The ultimate goal is to increase the yield of dry matter, or maintain the yield through improving of

other traits. The yield is very variable trait, influenced by a large number of genes, and largely depends on the present agroecological conditions. For the populations Čestobrodica 1, Grza and Boljevac 3 were scored the highest dry matter yield per plant (148.09, 135.84 and 123.49g). Average dry matter yield of collection was 109.33g per plant which is significantly lower compared to the results reported by Sokolović et al. (2016), where the two years average dry matter yield per plant was 142.58g.

Obtained results show a very high variability within populations for the most important traits, as indicated by the high coefficients of variation (Table 2.). Coefficients of variation were especially high in production traits such as number of tillers per plant (90.32%) and dry matter yield (95.03%), while heading date showed the lowest within population variability (23.99%).

Table 2. Average trait values and variability of cocksfoot autochthonous populations

Trait / Population	HD	PH cm	LL cm	LW cm	NLT	PL cm	NTP	DMY g/plant

Farma Zlatibor	33,00	67,22	20,80	0,78	3,00	15,35	81,09	96,84
Šuljagići	32,17	60,13	17,74	0,62	2,63	9,72	79,78	91,60
Kremna	32,13	86,89	22,90	0,95	2,58	15,29	108,12	107,48
Average	32,33	78,21	20,78	0,69	2,82	12,07	91,81	109,33
LSD 0,05	5,41	16,15	3,20	0,17	0,41	2,90	12,72	26,57
LSD 0,01	7,24	21,61	4,29	0,23	0,55	3,88	17,02	35,55
CV%	23,99	25,30	24,76	24,90	25,97	30,13	90,32	95,03
h_b^2%	12,33	34,52	55,30	38,75	18,62	56,49	58,77	53,51

HD - heading date (number of days from April the first); PH - plant height; LL - leaf length; LW - leaf width; NLT - number of leaves per tiller; PL - panicle length; NTP - number of tillers per plant; DMY - dry matter yield per plant

Broad sense heritability was high for number of tillers per plant (58.77%), panicle length (56.49%), leaf length (55.30%) and dry matter yield (53.51%) which indicates that an improvement of these traits could be possible and predictable in these collections. The lowest

broad sense heritability determined for heading date (12.33%) and number of leaf per tiller (18.62%). Broad sense heritability values was significantly less compared to the results reported by Babić et al. (2009), who found high broad sense heritability (over 70%) for all studied traits, especially for heading date where broad sense heritability was 93.0%.

In order to determine genetic distance between cocksfoot autochthonous populations a cluster analysis was performed. The cluster diagram showed three groups of accessions (Figure 1). The first group was formed by cocksfoot populations with high dry mater yield per plant. In this group, populations with highest dry matter yield per plant, Čestobrodica 1 and Grza make a separate subgroup.

Populations Česma, Tripkova, Crni Vrh 1, Borova Glava, Balašević and Čestobrodica 2 were clearly separated from other accessions by the values for all studied traits in range with average values for collection.

Populations Boljevac 1, Željin 1, Crni Vrh 2, M. Polje 1, Draglica, Farma Zlatibor and Šuljagići were the distant from the rest of the collection, due to minimum height of plants and the lowest dry matter yield per plant.

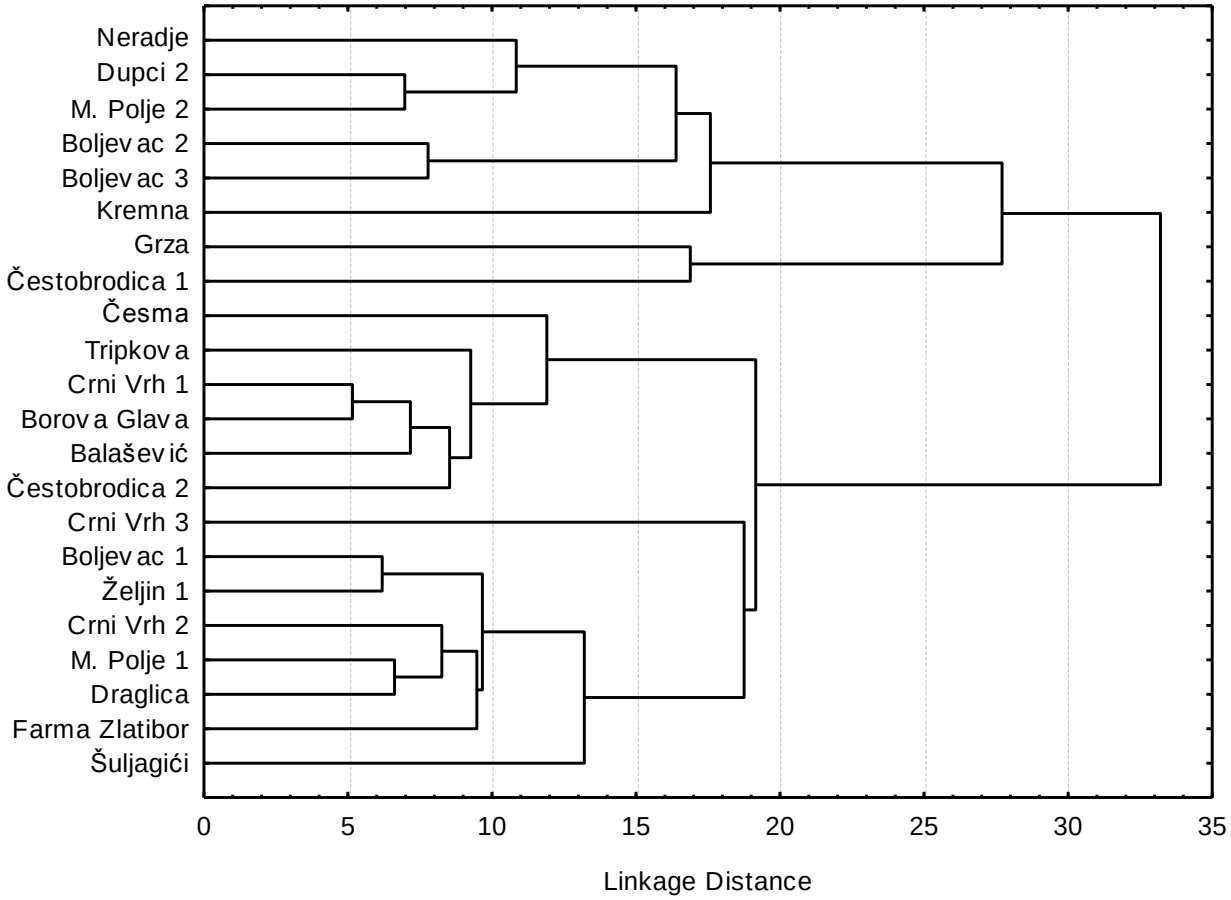

Figure 1. Dendrogram of cluster analysis of cocksfoot autochthonous populations based on eight traits

Conclusion

This study shows significant differences within and between cocksfoot autochthonous populations for studied traits. The highest number of tillers per plant and dry matter yield was obtained for populations Čestobrodica 1, Grza, Boljevac 3, Kremna, Boljevac 2 and Neradje. Populations Neradje, Balašević, Česma, M. Polje 2, Draglica, Kremna and Dupci 2 have the best ratio of leaf length and width, and the number of leaves per tiller, all components of dry matter quality. The average values, coefficients of variation and broad sense heritability for number of tillers per plant and dry matter yield indicate a high breeding potential of investigated autochthonous populations of cocksfoot for these most important traits in cocksfoot breeding process.

Abstract

Cultivated the grapevine *Vitis vinifera* subsp. *vinifera* is one of the leading horticultural plants in the world. It was domesticated from wild dioecious species *Vitis vinfera* subsp. *sylvetris*. Today, cultivated grape vines known to manifest a greater diversity and heterozygous in comparing with wild vines. The selection process through further and closer history took place in two directions: spontaneous in nature and with the active participation of men in order to increase productivity grape and berries, sugar content and total acids. Vegetative propagation, expressed hermaphroditism with spontaneous hybridization have contributed significantly to the diversity of varieties. Clonal selection has contributed more variety and adaptability improved quantitative and qualitative characteristics. Merlo is a typical example. In Bordeaux keeps about 300 potential clones, 13 were approved and widely diversity in the world. And in other countries were selected clones of variety Merlo, in our experiment we included clones R12, R5 and I-ISV-F-V4 from Italy, as we include two clones 181 and 348 origineted from Bordeaux. In addition to the yield and quality, we were interested indicators supplied the composition of the cluster and berries. The bigger cluster with low seeds in berry and low total acid is clone characteristic of the I-ISV-F-V4, while the per share of sugar in close clones 348 and R-12 chargers.

Key words: *Merlot, clone, yield, quality, composition of grape and berry*

Introduction

Variety Merlo is dominat red grapevine variety in Bordeaux and is grown on an area of 64416 ha or 65 % (van Leeuwen, 2014). Cabernet Sauvignon and Merlot are the two most common red varieties and it is estimated that each of the world cover 240 000 ha. The first description of the variety Merlo gave Odar (1850) and Rendu (1857) (cited by Boursiquot-u et al., 2009). Merlo exhibited less sensitivity to powdery mildew and thus explains the rapid expansion of the late nineteenth century, not only in France but also in other wine-growing countries. Quality manifested in a soft and easy recognizable red wine is another important factor. Reviewing Application of DNA with 20 SSR markers was found that a variety Merlo obtained by spontaneous crossing varieties Magdeleine Noire des Charentes (mother) and Cabernet Franc (father) in Bordeaux (Boursiquot et al., 2009). Mother's provenance is not completely confirmed, and therefore further research. The fact is that the ancient-old variety was created from a population where indiviue can not be identified at the genetic level. Therefore, there is diversity within the varieties manifested in, for example. the size of the berries, sugar accumulation capacity during ripening. Beginning in the sixties of the twentieth century clonal selection was

aimed at creating a virus free planting material, increased productivity, high class and quality (Lacombe et al., 2004; Sivčev et al., 2012). Clonal selection of cultivars of *Vitis vinifera* L. has led to significant improvements in viticulture, especially in terms of quality and quantity of grapes (Sivčev et al., 2011). The variation in phenology are conditioned by Jones and Davis (2000), genotype, climatic conditions and geographical location. To date, these climate changes have had a relatively positive impact on the quality of grapes and wine, which was reflected in earlier maturation of grapes, sugar and richer in polyphenols, with a smaller proportion of "plant" character and the whole high fertility (Ruml et al., 2012). Versatile consideration of viticulture in the world imposes and the fact that the clonal selection was focused primarily on widespread varieties that have led to the impoverishment of the election of new clones. This impoverishment in fact canceled out any possibility of selection of new clones in the future (Roby et al., 2014). Therefore, the preservation of genetic resources of primary task and incorporates institutional clonal selection, mass selection, and private clonal selection (Sivčev et al., 2011). Today a high level of production is not the primary producer requirements, adaptability clone to external factors and / or tolerance to the disease are the new essential requirements (van Leeuwen et al., 2013; Ruehl et al., 2015).

The quality of the grapes at harvest is an essential element of quality wines. Studies have shown that different clones of the variety may show significant differences in the chemical composition of berries. Some clones have the capacity to produce a wine with pronounced color, or the aromatic profile and content of phenol (Ferrandino et al., 2010). Simplified procedure for the introduction of new varieties / clones in Serbia does not negate the research work that includes new and indigenous varieties / clones (Ranković-Vasić et al., 2015).

The aim of this study was to evaluate and determine the basic production features three clones created in Italy (R-12, R-5 and ISV-4) and two originating from France 181 and 348.

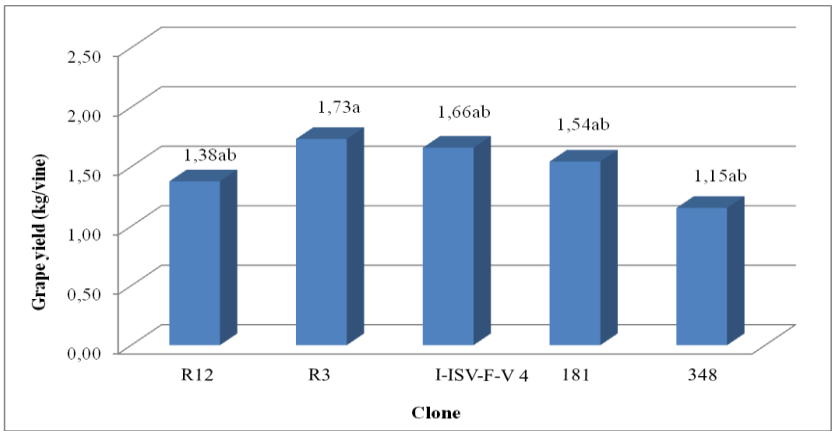
Materials and Methods

Studies have been conducted on the experimental field in Belgrade grape growing region (Experimental field 'Radmilovac' - Faculty of Agriculture, University of Belgrade) in the period between 2013 and 2015. So far, vineyard established between 2005 and 2006, with the planting space 3 x 1 m and this grapevine is in the form of asymmetric cordon with trunk of 0.8 m and loaded with 24 buds on average. The investigated clones were grafted at rootstock Kober 5BB. They differ by origin: Clones R12 and R3 come from Viva Cooperativa Raushedo, clone I-ISV-F-4 from Friuli Venezia Giulia both from Italy. Clones 181 and 348 came from France. Among the first admit clones in the year 1975 is clone 181 which it is grown and widely disseminate a total of 15 clones (INRA, 2007). The experiment included ten vines for each clone. In the vineyard were applied standard agricultural practices. The grape harvest was carried out at the stage of full ripening, is determined by the total number of bunches per vine, the yield of grapes per vine, sugar content, total acids in grape juice and weight of berries. The quality of grapes was determined on the basis of sugar content by Oechsle scale and total acid content was measured by titration method with n/4 NaOH in the must. The measured data were statistically analyzed using the software package Statistica (StatSoft, Inc.,Tulsa, OK, USA).

Results and discussion

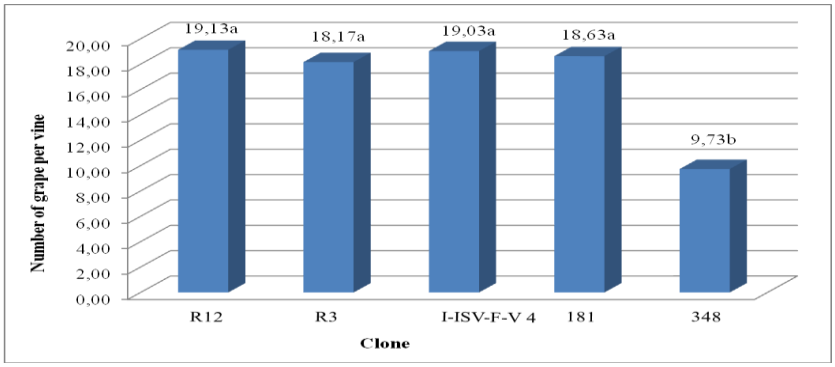
Variability in crop yield and quality in every situation on the ground and breeders have been trying to understand for centuries. Perhaps one of the most common examples of these problems is the production of wine grape varieties Merlot why was started with clonal selection just in the second half of the twentieth century. The objectives of breeding and selection are to correct

fertility varieties to eliminate negative characteristics of grape bunches and maintain quality (Ruehl et al., 2015). Clonal selection contributes to preserving the biodiversity, where there are two options to choose first the dominant clone and several supporting, time is maintained yield and quality in approximately the same level, without major variations from year to year. Another option is to take on a given plot combines several related by boat feature, or with different characteristics (Zamuz et al., 2007; Sivčev, 2011a).



Graf. 1 Mean values of grape yield per vine of the investigated Merlot clones (*average* 2013-2015)

In the graph. 1 the results shows the tested clones of Merlo. In three years the highest yield is achieved as a clone R3, per unit area of one hectare is 5700 kg. At the same time this clone showed the least variability in the examined period. Close the specified value of the clones I-ISV-F-V4 and 181. After the number of bunches allocated to clone 348 with extremely low values, only 9.73 per vine. The average number of bunches per vine was uniform clones R12, R3 I-ISV-F and 181 and was about 19 bunches per vine.



Graf. 2 Mean values of number of grape per vine of the investigated Merlot clones (*average* 2013-2015)

The results Dimovska et al (2011) realized in the period of full fruting are about the same compared with the clones R12, R3 I-ISV-F-V4 and 181, or clone with the lowest yield of the clone 348.

Comparing bunches noted that no major differences ie that the values in the range from 95-107 g (tab. 1). Merlot variety population as to the scores themselves Banjnain and Kulina (2015) has a

small bunch of an average of 95.5 g of Trebinje (Bosnia and Herzegovina). Comparative results Pajović et al. (2011) where they were involved Skopje vineyard and the vineyard of Montenegro indicate that there is no variation in the thickness of the bunch variety Merlot. The larger bunches with larger berries, which is observed in clones 181, while all three clones originating in Italy with regard to this value is very similar. The grape bunches, sometimes winged, are packed with blue-black sperical grapes that have moderately thick skin and juicy, plesant-testing pulp (Galet, 2002). Wine from Merlot has a remarkable quality that is expressed after two to three years of aging. This is another reason why this variety with several clones meet in wine-growing region of the Balkans from Slovenia, Istria, Croatian in the continental part, through Bosnia and Herzegovina, Montenegro, Serbia and Macedonia (Žunić and Garić, 2010).

Table. 1 Mean values of yield components and grape quality of the investigated Merlot clones (*average* 2013-2015)

Characteristic						
Clone	Grape yield ($kg \cdot vine^{-1}$)	Number of grape per vine	Bunch weight (g)	Berry weight (g)	Sugar content (%)	Titr. acidity ($g \cdot L^{-1}$)
R12	1.38 ab	19.13 a	95.33 b	1.03	22.20	6.40
R3	1.73 a	18.17 a	99.67 ab	1.17	21.47	7.00
I-ISV-F-V 4	1.66 ab	19.03 a	103.00 ab	1.03	21.87	5.77
181	1.54 ab	18.63 a	111.33 a	1.24	21.30	5.87
348	1.15 b	9.73 b	107.00 ab	0.91	21.70	6.17

Mean values followed by the same letter do not differ significantly according to LSD test at P = 0.05

The high sugar content of must was found in all clones and their differences are lower than one percent. Insignificant better quality grape clones which originated in Italy in comparearing from France. Van Leeuven (2014) highlights that in the six-year period in several locations in Bordeaux value of Merlot's quality is 223 g/L. Acidity expressed in tartrate in region from Belgrade the tested clones is within the limits of 5.77 and 7 g/L. Slightly in excess cause the contents of total acids is in clone R3 in comparison with clones I-ISV-F-v4 and 181. In Skopje region (Dimovska et al., 2011) clones of clones 181, 348, R 12, and R 3 are accumulated more sugars as compared with the Belgrade rejon. Temperature conditions during the ripening grapes have a dominant influence on the quality. In the first and third year of tests achieved better quality grapes compared to another year. Year 2014 was extremely rainy, cold, and caused a lower sugar content in must. By choosing the place at least a two to three clones within each variety in the same locality achieved the continuity in the quality of planting a proven health clones provides the longevity yet.

Conclusion

Our results were given new information on growing clones of Merlo originating from France and Italy in Belgrade vineyard area.

Data show that the clones R3 and I-ISV-F-V4 are the most desirable in terms of the amount yield. The combination of clone R12 with the highest sugar content in expanding and clone R3 with the highest and the clone I-ISV-F-V4 with the lowest share of total acid will significantly contribute to the harmonious relationship between that two features. Clones 181 and 348 differ in size berries and confirm the differences in yield that they should be equal treatment.

SOME PLANT PROPERTIES INTERACTIONS AND L-DOPA CONTENT OF FABA BEAN (*Vicia faba* L.) THAT DIFFERENT SOWING TIME

Nurdogan TOPAL[1*], Hatice BOZOGLU[2]

[1]Department of Field Crops, Faculty of Agriculture and Natural Sciences,University of Usak, Usak, Turkey
[2]Department of Field Crops, Faculty of Agriculture, University of Ondokuz Mayis, Samsun, Turkey *Corresponding author: nurdogan.topal@usak.edu.tr

Abstract

The study was carried out in Turkey's Samsun ecological conditions. The total of 26 genotypes (four of which cultivars) and two different sowing time (winter and early spring) were used in experiment that was conducted in a randomized block design with three replications. Winter sowing was made in November 2010 and spring sowing was made in March 2011. Winter and spring sowings effects was examined for biological yield, pod number, grain yield, protein content of the leaves, flowers and fresh fruit and L-Dopa (it is a metabolite used in the treatment of Parkinson's disease) content of the leaves, flowers and fresh fruit. L-Dopa content was determined by HPLC. The t-test was used for comparison of sowing times. According to t-test biological yield (t = 23.19 **), pod number (t = 15.54 **), grain yield (t = 21.752 **), crude protein content in leaves (t = 8.052 **) and the L-Dopa content in fruit (t = 3.801 **) were found with very significant differences regarding the sowing time and winter sowing came to the fore. Protein content of flowers (t = 7.58 **), protein content of fruit (t = 2.91 **), L-Dopa content of leaves (t = 2,831 **) and L-Dopa content of flowers (t = 5, 54 **) came to the fore for the spring sowing. When the results were evaluated, winter sowing seemed to be more advantageous than spring sowing.

Keywords: *Faba bean, Sowing time, L-Dopa, Yield components.*

Introduction

Faba bean, which is a cool season legume crops, is a multi-faceted plant used in human and animal consumptions (Crépon et al., 2010) and therefore it is a valuable product (Landry et al., 2016). According to Vavilov large grained faba bean origin is Mediterranean region. Turkey also is located in Mediterranean region (Özdemir, 2002). Faba bean cultivation is carried out in more than fifty five countries (Maalouf et al., 2013). The worldwide production is estimated to be aproximatly 3,398,330 tones, harvest area is estimated to be approximately 2,057,883 ha (FAOSTAT, 2013). And about %47of these areas are located in Asia and this continent produces about %47.16 of faba bean grains (Kazemi et al., 2016). In Turkey, Faba bean harvest area was 5,911 ha, faba bean yield was 2,525.3 kg/ha and faba bean production was 14,927 tones (FAOSTAT, 2014). Faba bean is also important plant for nutrient value. 100 g dry faba bean has 26-34 g of Nitrogen, 2-4 g of Crude fat, 15-24 of Diettary fibre, 40-50 g of Starch and 2.1-2.3 g of Sucrose (Guillon and Champ, 2002). Faba bean with high protein and dietary fiber content and low fat and sugar content primarily located in protective foods against diseases such as obesity and cancer. Beyond the agricultural and nutritive properties of Faba bean contains L-Dopa active ingredients used Parkinson's disease (Topal and Bozoglu, 2016). L-Dopa naturally located in different plant parts such as seedlings, green pods and beans is the precursor of the neurotransmitter dopamine. The pods are used in the treatment of some disease like Parkinson, hypertension, renal failure and liver (Randhir et al., 2002). The chemical name is (S) -2-amino-3-

(3,4-dihydroxyphenyl) propanoic acid, chemical formula $C_9H_{11}NO_4$ and a molecular weight of 197.19 g/mol. The half-life of L-Dopa is 0.75-1.5 hours. L-Dopa is converted into dopamine in the brain and body. In the absence of dopamine, dopamine found in certain plants such as faba bean and then not pass the blood-brain barrier, which is the precursor of dopamine and L-Dopa can pass this barrier. In the human and animal body, "L-Dopa decarboxylase" where an enzyme called L-Dopa is decarboxylated to dopamine by metabolizing meat has been identified (Wikipedia, 2016).

Parkinson's disease is a universal disease and shows an increase of 5-19 per hundred thousand in a year. In recent years, studies of Parkinson's disease is not unique to the elderly, they have revealed that the 21-40 age group starts seen in humans. Studies show that in the young period Parkinson's disease depends on genetic factors rather than environmental factors. Frequency of a Parkinson's disease varies by country. In Parkinson's disease related studies have demonstrated the important factor is race. The incidence of Parkinson's disease is higher in Europe and North America, in the mid-rate in China and Japan, while the black race in Africa is low (who, 2006). Today the number of Parkinson's disease patients is 5 million and Parkinson's patients will be between 8.7 and 9.3 million by 2030 (Dorsey et al., 2007). The number of patients with Parkinson's disease in Turkey is approximately 100 thousand and 10,000 new patients are diagnosed every year (PHD, 2016). Researchers have investigated motor effects of Faba bean on Parkinson's disease. In study, for the L-Dopa is natural source of faba bean and L-Dopa is a treatment factor of Parkinson's disease six patients were examined in this context. As a result, the broad bean is pharmacologically sufficient amount of L-Dopa and emphasized to be used in the diet of patients with Parkinson's (Kempster et al., 1993). L-Dopa an effective used in drug composition for Parkinson's disease. For example L-Dopa-a-lipoic acid (LD-LA) is a new drug for the treatment of Parkinson's disease. L-Dopa half-life in human plasma is fifty minutes (Aurizio et al., 2011). Protein, fat, carbohydrates, vitamins and minerals on the source of plants can exist also in a protective effect against some diseases and problems. The use of such plants in complementary medicine is increasing day by day. The importance of Faba bean used in the treatment of Parkinson's disease will increase because the incidence of Parkinson's will increase in the elderly population in 25 years (Topal and Bozoglu, 2009). Faba Bean is a cool season legumes and it originate from Turkey. It also could be sown winter or spring. In this study is investigated whether sowing time effects on some plant parts L-Dopa content.

Materials and methods

Trial was carried out at 41°21'50.6"N 36°11'26.6"E locations in Samsun in Turkey. The altitude of the trial area is 197 meters. Soil analysis show that clay structure, neutral pH (6.887), unsalted (EC = 0.523 ds / m), organic matter the medium (%2.681) and rich in phosphorus content (64 333 ppm P). A humid and mild climate-type provision in Samsun is ongoing. Samsun thirty-five-year average shows that lowest temperature of February (approx. 3.7 degrees), the highest temperature in the month of August (approx. 27 degrees), and the least rainfall of the month July.

As materials, in the experiment were used broad bean varieties which are registered in Turkey (Eresen-87, Filiz-99, Kıtıkı-2003, Lara), 22 genotypes. Experiments were conducted in a randomized block design with three replications. Winter sowing was made in November 2010 and spring sowing was made in March 2011. The samples of leaves were taken before flowering, flowers were taken during the fifty percent flowering and fruits were taken during the fifty percent pod binding were weighed. After this samples were dried (at 45 ^{0}C) and milled. Samples were kept at 4 centigrade degrees for chemical composition analysis. Protein analysis was made by Kjeldahl method (Kacar and İnal, 2008). L-Dopa assay method was made by Shivananda et

al.(2003). Analysis was carried out in Thermo Separation with automatic sampling HPLC device (Detector:UV-280nm; Mobile Phase: Sodium dihydrogen orthophosphate; Analytical column: C18, 4.6x 250 nm; Flow rate: 2 ml / min). There was used six L-Dopa Standard (S_1:0,002 g, S_2:0,004 g, S_3:0,008 g, S_4:0,016 g, S_5:0,032 g, S_6:0,064 g.) to get regression curve and formula. Analysis of variance in some plants properties and L-Dopa content of faba bean was used and the t-test was used for comparison of sowing times with SPSS-13 software package.

Results and Discussion

The average number of pods in winter and spring sowing were found respectively 11.81 and 4.60 and this difference was statistically significant (t=15.54**). The number of pods of genotypes ranged from 7.42-18.55 for winter sowing. For spring sowing, the number of pods of genotypes ranged from 3.31-7.15 and it was showed decrease of approximately %46. As a demonstrated in several studies carried out in legumes, the number of pods is one of the most important features directly associated with grain yield. Generally, the number of pods per plant affect grain yield positive (Mohamed, 1985; Ricciardi, 1985; Kıtıkı and Açıkgöz 1994; Bozoglu and Gulumser, 1994; Peksen and Gulumser, 2007). The number of pods per plant in Faba bean range from 1-9 (Akçin, 1988; Sehirali, 1988). Bozoglu and Gulumser (1994) reported that sowing time effect on pod number is important (P<0.01) and highest pod number derived from winter sowing on November 6 with 28.2 items. For pods numbers they also stated that November sowing was high rather than April. As a result of t-test it was found vary sowing time (t=23,19**). While biological yield per plant was 64,3 g at winter sowing and this value was reduced up to 15,91 g/plant at spring sowing. In winter sowing biological yield ranged between 45.42-101.89 g/plant. Differently in spring sowing biological yield ranged between 10.58-24.06 g/plant. Mwanamwenge et al (1999) reported that there was a strong relationship between biological yield and grain yield (r=0.89**).

While winter sowing grain yield was 27,92 g in spring sowing this figure reduced up to 5.98 g. Statistical result of the t-test showed that differences between winter and spring sowing (t=21.752**). Winter sowing productivity (29.65 g/plant) is high rather than spring productivity (5.97 g/plant). In the same ecology, previous studies reported that grain yield per plant ranged 15-79.7 g. (Bozoglu, 1989), 11.9-19.5 g. (Gulumser and Bozoglu, 1994), 32.3-49.6 g. (Peksen and Gulumser, 2007). These results are similar to our results.

According to the result of t-test there was significant differences among the sowing times for leaves (t=8.052**). The leaf protein ratio in winter sowing was found %42.01. For spring sowing leaf protein ratio was found %32.23. Mady (2009) reported that leaf protein rates varying ranges between percent 19-30. In their study Radwan et al (2010) reported that %30 total leaf protein ratio of faba bean. We think that differences in our study caused by cultivars. Significant differences were found between the sowing period in terms of protein content in flowers (t=7.58**). Flowers protein ratio was found %45.35 in spring sowing time and %36.26 in winter sowing time. Widely grown broad bean varieties have a strong apical dormancy and indeterminate growth. Therefore, there is a high potential blooming (Sepetoglu, 1994). However, the pods replacement rate of broad bean flowers is low. Bozoglu (2005) demonstrated that fruit binding rate changed between percent 10.2 and 27.1. T-test results about fruit protein ratio showed that there were significant differences among spring and winter sowing (t= 2.91**). In terms of fruits protein ratio spring sowing (%36.07) was higher than winter sowing (%32.30). Spring sowing fruit setting period is shorter than winter sowing and this shorter time leads to increased protein ratio proportionally. Because of short time, carbohydrates accumulate is low. Therefore spring sowing fruit protein ratio is higher than winter sowing.

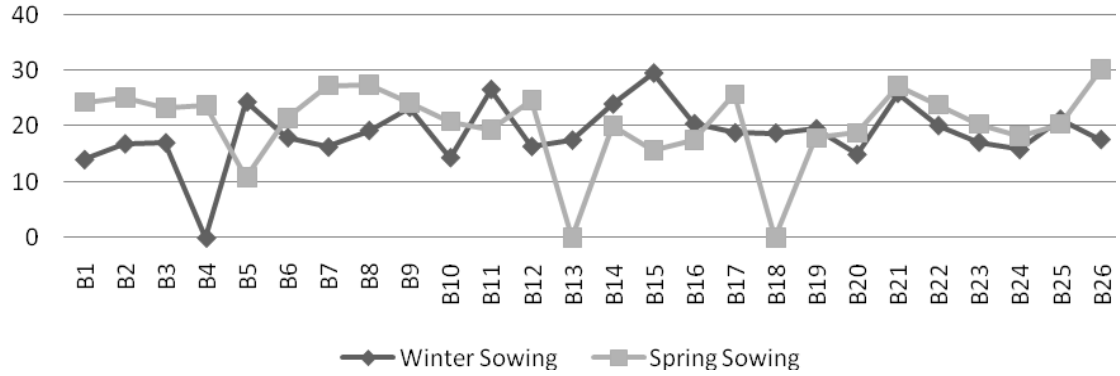
BY: Biological Yield, PN: Pod Number, GY: Grain Yield, PLC Protein Content of Leaves, PCFL: Protein Content of Flowers, PCFR: Protein Content of Fruits, LCL: L-Dopa Content of Leaves, LCFL: L-Dopa Content of Flowers, LCFR: L-Dopa Content of Fruits.

When examining relationships between features (table 1) there are positive and significant relationship between L-Dopa content of fruit and biological yield, pod number, grain yield, protein content of leaf. Additionally there are negative and significant relationship between proteins contents of fruit and pod number, biological yield, grain yield and protein content of leaves. Once and for all there are negative and significant relationship between L-Dopa content of fruit and protein content of fruit. In a study conducted by Peksen (2006), Faba bean populations were investigated for relationships among traits of faba bean and there were put forward positive and significant correlation between grain yield and pod number (0.700**) and biological yield (0.648**). In yet another study faba bean, there were found positive and significant relationship among pod number and grain yield (0.760**), biological yield (0.727**) and grain yield (0.896**) but there are negative and insignificant relationship protein content of seeds and other traits (Beser and Adak, 1999).

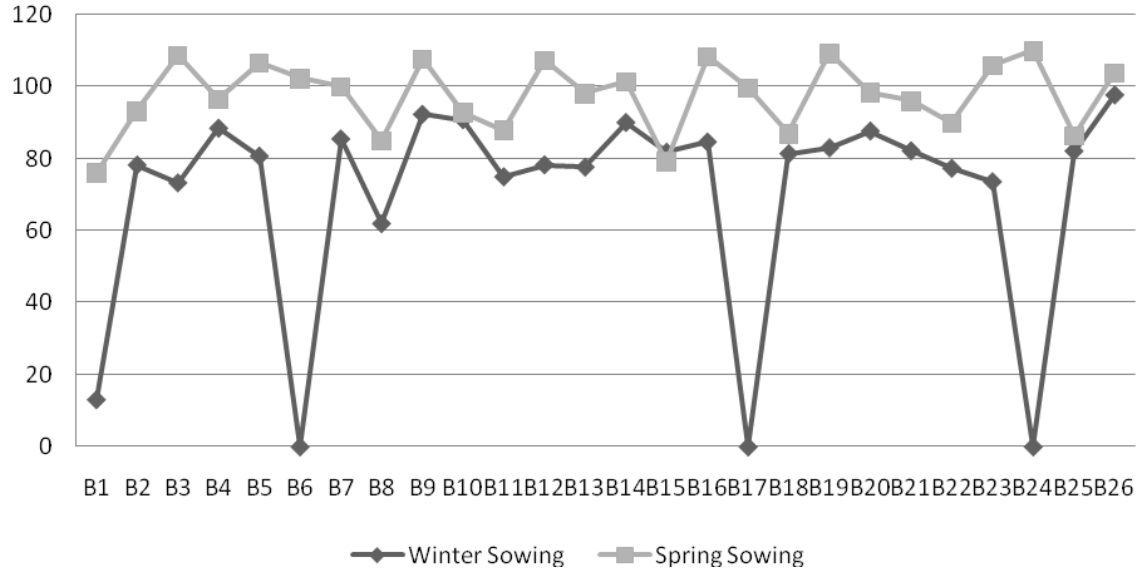
Leaves L-Dopa content were found 19.48 mg/kg in winter sowing and 22.45 mg/kg in spring sowing and these differences were statically significant (t=2.831**). Shetty et al (2003) reported that leaves L-Dopa content changed among 20 and 24 mg/g. When genotypes compared among themselves, B 15 (29.51 mg/kg) genotype is high from others at winter sowing, for spring sowing B 26 (30.32 mg/kg) genotype is high. In figure 1, leaves L-Dopa content of Genotypes are given. This result is higher than our result. It's also the reason why we think that the receipt of the leaves before flowering. This condition may be created difference.

Figure1. Leaf L-Dopa Content of Genotypes (mg/kg)



L-Dopa content of flowers was evaluated and it was observed that spring sowing (97.55 mg/kg) results was higher than winter sowing (78.93 mg/kg). According to t-test results this differences is significant (t=5.54**). In terms of flowers L-Dopa content, genotypes compared in its genotype B 26 (97.60 mg/kg) is high than others in winter sowing. B 24 (109.95 mg/kg) genotype is also high than others in spring sowing. Flowers L-Dopa content of Genotypes are given at Figure 2. Cenarruzabeitia et al (1978) stated that L-Dopa amount increased parallel with plant growth with it and they reported that the flower's organs with the highest L-Dopa so these flowers may be used for medical purposes.

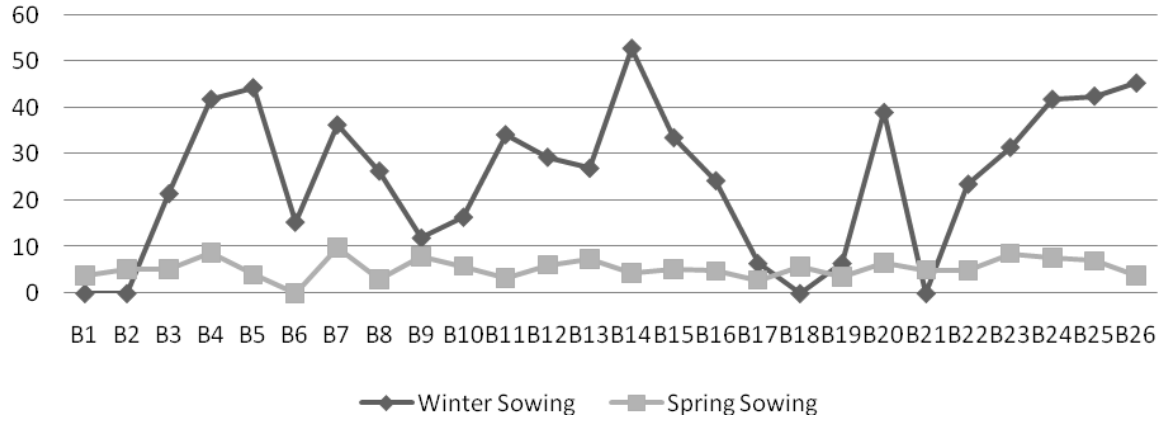
Figure2. Flowers L-Dopa Content of Genotypes (mg/kg)



L-Dopa was investigated in fruit used human consumption and it was determined 1.52-79.9 mg/kg in fruit. There was significant differences among sowing times (t=3.801**). While winter sowing L-Dopa ratio average was 29.59 mg/kg, spring sowing was 5.94 mg/kg. While B14 (52.73 mg/kg) genotype came to fore in winter sowing B7 (9.84 mg/kg) genotype came to fore in spring sowing. Fruit L-Dopa content of Genotypes are given at Figure 3. Holden (2006) reported that each 85 gram green pod contained 50-100 mg levedopa. Lattanzio et al (1983) found that per

dry matter of fruit contained %4 L-Dopa. We believe that our result differs with literatures due to different green pods harvest time.

Figure3. Fruit L-Dopa Content of Genotypes (mg/kg)



Conclusion

Our results are consistent with these findings. These data show us that L-Dopa content varying depending on the environment and climate conditions. If L-Dopa obtained from leaves and flowers spring sowing should be preferred if used fruit winter sowing should be preferred. Winter sowing is also recommended in terms of yield.

Abstract

Maize has large requirements for zinc and it is very susceptible to Zn deficiency, especially the inbred lines. The aim of this study was to analyze the response of maize genotypes to different fertilization treatments, as well as the zinc concentration in leaves and grain. The study included the following systems of fertilization: T_1: control – $P_{60}K_{60const}$; T_2: $P_{60}K_{60}$ + $N_{min\ spring}$; T_3: $P_{60}K_{60}$ + $N_{40\ autumn}$ + $N_{min\ spring}$; T_4: $P_{60}K_{60}$ + $N_{60\ spring}$; T_5: $P_{60}K_{60}$ + $N_{100\ spring}$; T_6: $P_{60}K_{60}$ + $N_{40\ autumn}$ + $N_{60\ spring}$ + Zn; T_7: $P_{60}K_{60}$ + $N_{40\ autumn}$ + $N_{80\ spring}$ + Zn; T_8: $P_{60}K_{60}$ + $N_{160\ spring}$ + Zn. Zn was applied as zinc sulphate ($ZnSO_4$), in the amount of 1.0 kg ha^{-1} with foliar spraying, in the fourth and sixth week after sowing. Average Zn content in maize leaves, across the treatments ranged from 44.4 mg kg^{-1} dry weight (DW) in 2011 to 41.2 mg kg^{-1} DW in 2012. Depending on the applied fertilization system, lower content of Zn in maize leaves (36.4 mg kg^{-1} DW), was found with application of $P_{60}K_{60}$ + $N_{60\ spring}$, and the highest (57.8 mg kg^{-1} DW) in the treatment $P_{60}K_{60}$ + $N_{40\ fall}$ + $N_{80\ spring}$ + Zn. Higher Zn content in grain was found in the NS 6030 hybrid (26.3 mg kg^{-1} DW) and NS 6010 (26.1 mg kg^{-1} DW) compared to NS 4023 (24.1 mg kg^{-1} DW) and NS 640 (25.3 mg kg^{-1} DW). On average, Zn concentration in the grain differed in 2011 (27.6 mg kg^{-1}) compared to 2012 (23.3 mg kg^{-1}). The lower Zn content in the grain was observed in T_1 (23.4 mg kg^{-1}) and the highest in T_7 (31.0 mg kg^{-1}). Future breeding programs should be focused on developing new genotypes suitable for mineral bio-fortification and with increased mineral bioavailability in grains.

Key words: *fertilization, maize hybrids, zinc, leaves, grain.*

Introduction

Maize has large requirements for zinc and it is very susceptible to Zn deficiency, especially the inbred lines. Zinc is a basic component for all plants, playing a key role as a structural constituent or regulatory co-factor of a wide range of different enzymes and proteins, maintaining the integrity of biological membranes and plant resistance (Rengel et al., 1999; Mengel & Kirkby, 2001; Cakmak, 2008). Zinc concentration is affected by a range of factors, including soil type, fertility, and moisture, environmental factors, soil pH (Zhao et al., 2011), genotype and interactions among the nutrients (Feila et al., 2005). Zn nutrition of plants is considered one of the major problems in the arid and semi-arid regions (Cakmak, 2008).

Understanding the dynamics of zinc uptake by maize is the basis for indicating the critical stages for accumulation of this micronutrient in the plant. However, most studies are usually focused only on the nutrient content in certain developmental stages and/or certain organs of the cultivated plants (Hossain et al., 2008; Izsaki, 2009).

Zinc fertilizer is widely used to increase yield (Potarzycki & Grzebisz, 2009) and to improve crop nutritional values (Jin et al. 2013). Most research on soil and foliar application of zinc focused on

alleviating its deficiencies, particularly on maize, wheat and rice cultivated in semiarid or arid regions (Cakmak, 2008). Crops can be supplied with Zn through direct application, via foliar fertilization or seed treatments (Gonçalves Júnior et al., 2007). Foliar application is one of the primary methods of applying Zn fertilizer and according to Cakmak et al. (2010) it improves Zn concentrations in cereals grain. Zhang et al. (2012) indicate that foliar Zn application for improving Zn concentration in grain is better than soil application. Knowledge of the different forms of zinc fertilizer and timing of foliar application is crucial for enhancing zinc in grain (Velu et al., 2014). Application of Zn in combination with NPK fertilizers increased Zn uptake from the soil to the grain, resulting in an increase in maize grain nutritional quality. Malakouti (2008) concluded that application of Zn with mixed fertilizers, particularly N-based fertilizers, could enhance Zn uptake. In studies with maize hybrids grown at different nitrogen (N) and water levels, Feila et al. (2005) found that N fertilization reduced grain concentrations of Zn and Mn, which was attributed to higher grain yield as a result of N application.

The aim of this study was to analyze the response of maize genotypes to different fertilization treatments, as well as the zinc concentration in leaves and grain.

Material and Methods

Site characterization, experimental design and plant analysis

Field experiments were conducted in 2011 and 2012 at the research experimental station of Institute of Field and Vegetable Crops, Novi Sad, Serbia (N 45° 19`, E 19° 50`). The soil at the study site is a typical calcareous chernozem. Soil sampling prior the trial establishment resulted with the following soil chemical properties in the 0–30 cm soil depth: pH 7.21, humus 2.90%, total N 0.260 g kg^{-1}, P_2O_5 17.8 mg kg^{-1}, and K_2O 24.0 mg kg^{-1}.

The experiment consisted of 8 treatment combinations in each of the two years: T_1: control – $P_{60}K_{60const}$; T_2: $P_{60}K_{60}$ + $N_{min\ spring}$; T_3: $P_{60}K_{60}$ + $N_{40\ autumn}$ + $N_{min\ spring}$; T_4: $P_{60}K_{60}$ + $N_{60\ spring}$; T_5: $P_{60}K_{60}$ + $N_{100\ spring}$; T_6: $P_{60}K_{60}$ + $N_{40\ autumn}$ + $N_{60\ spring}$ + Zn; T_7: $P_{60}K_{60}$ + $N_{40\ autumn}$ + $N_{80\ spring}$ + Zn; T_8: $P_{60}K_{60}$ + $N_{160\ spring}$ + Zn. Zn was applied as zinc sulphate ($ZnSO_4$), in the amount of 1.0 kg ha^{-1} with foliar spraying, in the fourth and sixth week after sowing. Maize seeds (*Zea mays* L. cv. NS 4023, NS 640, NS 6010 and NS 6030) were sown on 10 April, 2011 and 18 April, 2012. The distance between rows and plants was 75 cm and 24 cm, respectively. The experiment was set up in a completely randomized block design (RCBD) with four replicates. Maize was sown and harvested in the optimal agrotechnical terms. Plant tissue analyses included total Zn concentrations in leaves and grain samples. The ear–leaf of maize (25 leaves in the mean sample) was collected for chemical analysis at flowering stage (the second half of July). Zn concentrations were determined by inductively coupled plasma atomic emission spectroscopy after digesting the grain samples in a closed microwave digestion system in the presence of concentrated HNO_3 and H_2O_2 (HNO_3:H_2O_2 = 5:2, v/v).

Statistical analysis

The data were statistically processed by using the program STATISTICA series 12.6. A three–factor completely random design with a factorial combination was employed for analysis of variance (ANOVA). Assumptions for ANOVA were satisfied and the least significant difference (LSD) was calculated at $P \leq 0.05$. This allowed for treatment means to be compared using the Tukey's multiple comparison test.

Results and Discussion

Zinc (Zn) deficiency in plant tissues is a reflection of both genetic and environmental-related factors and is the most widespread problem in cereal crops worldwide. Response of maize genotypes to different fertilization treatments, and zinc concentration in the leaves and grain are given in Tab. 1, and Figures 1 and 2. Analysis of variance for Zn content in the maize leaves showed statistically significant effect of treatment (B) and hybrid (C) ($P < 0.01$) while the effects of the year (A) did not show statistical significance. By testing analysis of variance, statistically significant interaction effect between treatment and hybrids (B × C) ($P < 0.01$) was observed, while other interactions (A × B, A × C, and A × B × C) have not demonstrated statistical significance. Average Zn content in maize leaves, across the treatments for the study years, ranged from 44.4 mg kg^{-1} dry weight (DW) in 2011, to 41.2 mg kg^{-1} DW in 2012. Depending on the applied fertilization system, the lowest content of Zn in maize leaves (36.4 mg kg^{-1} DW), was found with application of $P_{60}K_{60}$ + $N_{60\ spring}$, and the highest (57.8 mg kg^{-1} DW) in the treatment $P_{60}K_{60}$ + $N_{40\ fall}$ + $N_{80\ spring}$ + Zn.

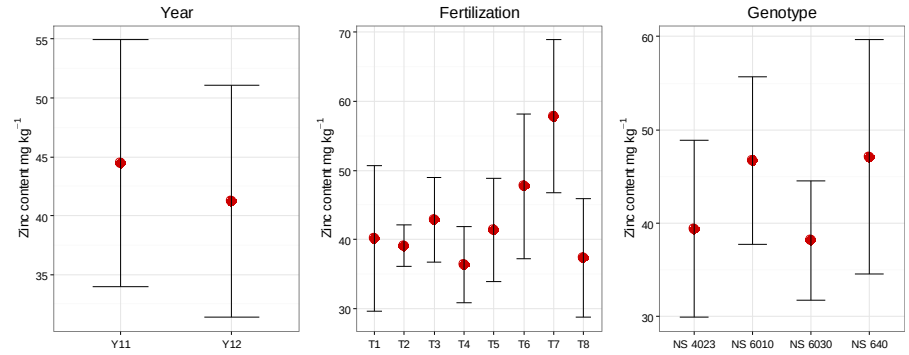

Figure 1. Variation of zinc content in maize leaves as influenced by individual factors

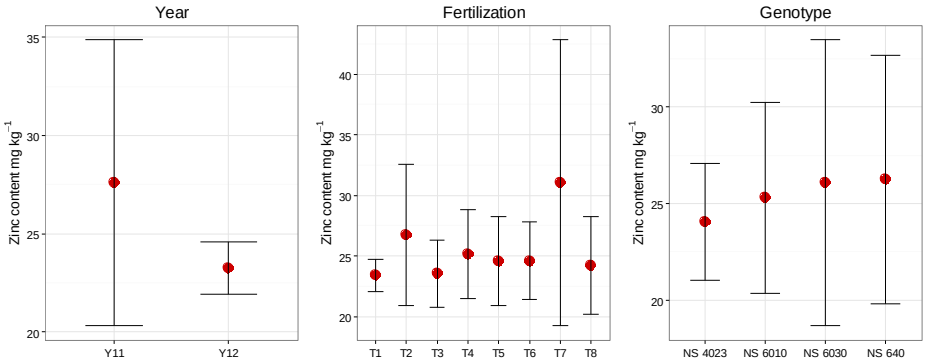

Figure 2. Variation of zinc content in maize grain as influenced by individual factors

The effect of fertilizers application rate on zinc concentration in the maize plants showed significant differences ($P < 0.01$), which is in agreement with Hosseini et al. (2007) who reported that foliar application of zinc fertilizer significantly affected nutrient concentration in maize plants. Maftoun and Karimian (1989) found that the uptake of zinc generally increased with increasing zinc rates, and was mainly due to an increase in either dry matter yield or zinc concentration in various plant parts. Thus, maize plants with a high zinc uptake capacity do not necessarily have a high zinc concentration in their leaf or shoot tissue (Banziger & Long, 2000). Cakmak et al. (1996) showed that Zn efficiency of cereals is mainly related to difference in acquisition of Zn by the roots. Korndörfer et al. (1995) also observed that Zn content in the maize leaf increased with doses of Zn applied to soil and the average content of Zn in the leaf varied from 13 mg kg^{-1} in the control to 23 mg kg^{-1} in the micronutrient treatment (4 kg of Zn ha^{-1}), and in the present study, Zn content varied between 15 mg kg^{-1} and 22 mg kg^{-1}.

Estimating variation of genotype in grain mineral concentration and bioavailability in relation to grain yield, according to the year, is important for maize production. Higher Zn content in grain was found in the NS 6030 hybrid (26.3 mg kg^{-1} DW) and NS 6010 (26.1 mg kg^{-1} DW) compared to NS 4023 (24.1 mg kg^{-1} DW) and NS 640 (25.3 mg kg^{-1} DW). In our trial, grain Zn concentration ranged from 27.6 mg kg^{-1} in 2011 to 23.3 mg kg^{-1} in 2012. The lowest Zn content in the grain was observed in T_1 (23.4 mg kg^{-1}) and the highest in T_7 (31.0 mg kg^{-1}) (Table 1, Figures 1 and 2).

The effect of soil Zn application on the grain Zn concentration is related to the soil characteristics that affect Zn availability, including pH and Ca concentration (Alloway, 2009). Zhang et al. (2012) indicated that the foliar application of 0.2%, 0.4%, and 0.5% $ZnSO_4 \cdot 7H_2O$ increased Zn concentration in grain flour by 60%, and 76%, respectively, compared with the control treatment.

Studies on maize also show increased zinc in grain between 4% and 16% with soil applied zinc (Wang et al., 2012). Potarzycki & Grzebisz (2009) reported that optimal maize grain yield was recorded with high Zn foliar spray concentration ranging between 0.25% and 0.37% of Zn. In a study with doses of Zn applied to soil in maize crop, Kanwal et al. (2010) verified a significant increase in the content of this micronutrient in maize grains (21.8 to 30.7 mg kg^{-1}). Brkić et al. (2003) also found the highest Zn concentration in grain of genotypes that included this line as a parent, indicating importance of inheritance for grain nutrient contents.

Conclusion

Maize is sensitive to Zn deficiency. Zinc is mostly deficient in soils and application of zinc fertilizer is required to explore its full potential. Application of zinc sources at different rates usually affects plant available zinc content of soil as well as the concentration and uptake of zinc by maize. Considerable influences of the factors: year and fertilization on maize leaves and grain Zn concentration were found. Foliar applied Zn products are effective for increasing Zn uptake in maize. Future breeding should be focused on developing new genotypes suitable for mineral bio-fortification and with increased mineral bioavailability in grains.

Abstract

Studies of fertilization effects were conducted in a stationary field trial on a degrading vertisol soil with low pH. Eight variants of mineral nutrition (N, P, K, NK1, NP1, NP2, NP1K1 and NP2K1) and untreated control (without nutrition) were tested in the experiment. The rates of nitrogen application were 80 kg N/ha, and they were applied either individually or in combination with two phosphorus rates and a potassium fertilizer. The wheat triticale cultivar used in the experiment was Trijumf. The highest grain yields under mineral nutrition involving a combination of three mineral elements NP2K1 (4.755 t/ha), NP2 (4.519 t/ha), NP1 (4.143 t/ha) and treatment NP1K1 (4.028 t/ha) have achieved satisfactory results, while the poorest results were achieved by the control and N treatmnets.

Key words: *fertilization, yield, quality, triticale*

Introduction

Triticale is cereal species gained by cross-breeding of wheat and rye. Thanks to its nutritive values higher than maize, electioneers and scientists for animal nutrition where recommended it for all animal species nutrition. Also, it could replace wheat very successfully in portions for animal nutrition (Đekić et al., 2012), regard the fact that food demands in the world are all the larger and more, and wheat yields and soils area less and less. Triticale is especially characteristic regard the high protein content in the grain and beneficial content of important amino acids regard the other cereals.

Triticale potential, grown under optimal conditions, regard the yield was approximately similar to wheat potential, and was much higher than wheat potential under unfavorable growing conditions (Browne et al., 2006). Wheat and triticale comparing presents that triticale accumulate more nitrogen than wheat in corn period and grain physiological maturation, what indicates that triticale is much appropriate culture for growing on nitrogen poor soils (Đekić, 2010). As species, it has important value on soils with marginal characteristics as dry or acid soils, and is also less demanded regard the fertilizers and other preparations which take place in agronomy.

Triticale presented high tolerance regard the acid soils, as well as god productive results on sandy soils (Đekić et al., 2010a; 2014). Soil acidity frequently affects agricultural production in Serbia. Triticale was planting where corn did not prosper, as well in the areas with moderate climate (Djekic et al., 2011b). It could be said that it inherited very good up to excellent tolerance regard the most important pathogens and small grains pests. Triticale presented high adaptability on local agro-ecological conditions, and it was influenced on stabile yield reaching.

New perspective triticale lines and varieties has more and better filled grain, higher yield, grain mass and farinaceous content, while proteins and lysine was smaller compared with older varieties (Đekić, 2010; Đekić et al., 2010b, 2011a).
Mineral fertilizers play a vital role towards improving crop yields but one of the main constraints in achieving proven crop potential is imbalanced use of nutrients, particularly low use of P as compared to N. The optimum rate of P application is important in improving yields of most crops (Đekić et al., 2014). In Serbia, farmers are using only nitrogen fertilizers for fodder crops while the use of P fertilizer is negligible. These crops are often grown on marginal lands. Hence, the production is low and quality is poor.
The objective of this study was to evaluate the effect of different fertilization systems on the grain yield and quality of triticale grown on a vertisol soil. The study was also aimed at optimizing fertilization for maximum profitability in the future triticale production of Central Serbia.

Materials and methods

Materials and field trials

The study was carried out in a stationary field trial involving fertilization over a two years period from 2007/08 to 2008/09. Trials were first set up in the experimental fields of the Small Grains Research Centre in Kragujevac in 1970. Plot size was 50 m^2. The wheat triticale cultivar used in the experiment was Trijumf, the dominant cultivar in the production region of Serbia. This investigation included an untreated control and eight variants of fertilization: N (80 kg N/ha), P (60 kg P_2O_5/ha), K (60 kg K_2O/ha), NK1 (80 kg N/ha, 60 kg K_2O/ha), NP1 (80 kg N/ha, 60 kg P_2O_5/ha), NP2 (80 kg N/ha, 100 kg P_2O_5/ha), NP1K1 (80 kg N/ha, 60 kg P_2O_5/ha, 60 kg K_2O/ha) and NP2K1 (80 kg N/ha, 100 kg P_2O_5/ha, 60 kg K_2O/ha). The trial was set up in a randomized block design with five replications. Fertilization was regular and followed a long-time scheme. Total amounts of phosphorus and potassium fertilizers and half the nitrogen rate are regularly applied during pre-sowing cultivation of soil. The remaining amount of nitrogen fertilizer is applied in a single treatment at the height of tilling towards the end of winter.
The crop was harvested at full maturity. Grain yield (t/ha) was harvested and reported at 14% moisture. Three parameters of grain quality, namely test weight (kg/hl) and 1000-grain weight (g) were analyzed. Thousand grain weight was determined using an automatic seed counter. Test weight is the weight of a measured volume of grain expressed in kilograms per hectoliter.
On the basis of achieved research results the usual variational statistical indicators were calculated: average values, error of the mean and standard deviation. Statistical analysis was made in the module Analyst Program SAS/STAT (SAS Institute, 2000).

Soil and weather conditions

This study was conducted over a two-year period in the Šumadija region, Central Serbia, on a vertisol soil, at Kragujevac location, in a rainfall amount of about 500 mm.
The trial was set up on a vertisol soil in a process of degradation, with heavy texture and very coarse and unstable structure. The humus content in the surface layer of soil was low (2.22%). The reduced humus content in field vertisols profiles suggests the necessity of using humification when planning fertilization systems and soil ameliorative operations to be used to maintain and improve the soil adsorption complex. Soil pH indicates high acidity ($pH_{(H2O)}$=5.19; $pH_{(KCl)}$=4.27), nitrogen content in soil is medium (0.11-0.15%), while the content of available phosphorus ranges from very low (1.7-2.9 mg/100 g soil) in the N and NK trial variants to very

high (26.9 mg P_2O_5/100 g soil) in the NPK variants of fertilization. Available potassium contents are high, ranging from 19.5 to 21.0 mg K_2O/100 g soil.

Table 1. *Middle monthly air temperature and precipitation amount (Kragujevac)*

Year	Months										Aver.
	X	XI	XII	I	II	III	IV	V	VI	VII	
Mean monthly air temperature (^oC)											
2007-08	10.8	4.5	0.6	2.5	4.5	8.1	12.6	17.3	21.8	22.4	10.51
2008-09	13.1	8.5	4.4	2.3	2.0	6.8	13.4	17.8	20.2	22.5	11.10
Average	12.5	6.9	1.9	0.5	2.4	7.1	11.6	16.9	20.0	22.0	10.18
The amount of rainfall (mm)											
2007-08	36.6	13.0	53.2	30.1	13.1	65.7	51.5	92.8	110.4	28.1	494.5
2008-09	57.7	76.9	40.3	16.8	46.0	137.8	25.2	31.3	30.6	29.7	492.3
Average	47.5	50.0	49.5	36.8	33.9	43.5	51.5	64.8	79.3	62.5	519.3

The average air temperature in 2007/08 was higher by 0.33°C and 2008/09 was higher by 0.92°C in relation to a multi-year average. The sum of rainfall precipitation in 2007/08 was lower by 24.8 mm, where the sum of rainfall in 2008/09 was 27.0 mm lower than the average of many years and with a very uneven distribution of precipitation per months. Spring months were surplus of precipitation, what affected unfavorable on the crops. During the Mart in 2008/09 it was 137.8 mm of rainfall, what was 94.3 mm more compared with the perennial average. During the month of June in 2007/08 it was 110.4 mm of rainfall, what was 31.1 mm more compared with the perennial average. Regard the high importance of sufficient rainfall amounts during the spring months, the distribution and amount of rainfall over the growing season 2007/08 were considerably more favorable, what resulted with increment of yields during that year. Apart from the rainfall deficiency during the spring months and the non-uniform distribution of rainfall across months, an increasing in average air temperatures was also observed.

Results and discussion

Fertilization had a significant effect on grain yield (Table 2). The average grain yield of triticale significantly varied across treatments and years, from 5.160 t/ha in 2007/08 to 4.198 t/ha in 2008/09 in treatment NP2. In the two-year period, was lowest in the unfertilized control (0.974 t/ ha) and significantly higher in fertilized treatments, ranging the highest average grain yield of all treatments investigated was achieved in the NP2K1 variant with the higher phosphorus rate (4.755 t/ha) and NP2 (4.519 t/ha).

The average grain yield in 2007/08 year was lowest in the unfertilized control (1.190 t/ha) and significantly higher in fertilized treatments to 5.160 t/ha (NP2) and 5.130 t/ha (NP2K1). During the second year of investigations (2008/09), the highest average value of grain yield achieved the NP2K1 treatments (4.380 t/ha) and 4.198 t/ha in NP2 treatment. NP2K1 fertilization induced a significant increase in grain yield as compared to the control for 3.781 t/ha.

The study showed that most investigated triticale cultivar achieved their highest grain yields less than 80 kg/ha nitrogen rate, phosphorus rate of 100 kg/ha P_2O_5 and potassium rate of 60 kg/ha K_2O (NP2K1) and NP2 treatment (80 kg N/ha, 100 kg P_2O_5/ha). Nitrogen, phosphorus and potassium application, particularly on acid soils poorly supplied with these nutrients, has a high effect on the grain yield of triticale and other cereal crops (Đekić et al., 2014; Jelić et al., 2013).

The sufficient amounts of rainfall during the spring months (Table 1), which are vital to successful triticale production, suggest that the distribution and total amount of rainfall during the growing season 2007/08 were considerably more favorable, resulting in an increased yield in this year as compared to the first year. The significantly lower yield in 2008/09 was due to a decline in total rainfall in the spring and its non-uniform distribution across months, accompanied by higher average air temperatures in these years. According to Đekić et al. (2010a; 2014), the best triticale yields with high quality grain are generated by warm, bright (high solar radiation) spring weather and cooler summer weather without excessive rains during grain filling.

	NP2K1	65.28	1.863	69.97	1.947	68.41	2.944

Thousand grain weight of triticale significantly varied across years, from 42.80 g to 47.64 g in 2007/08, from 37.16 g to 42.86 g in 2008/09. The control and P-treatment achieved the lowest average 1000 grain weight during the both years of investigation compared with other tested

treatments. During the both years of investigation the highest average value of 1000 grain weight achieved the NP1K1 treatment (47.64 g and 42.86 g). A number of authors (Browne et al. 2006; Đekić, 2010; Đekić et al., 2010b, 2014; Đurić et al., 2012) underline that 1000-grain weight is a cultivar-specific trait, with considerably higher variations being observed among genotypes than among treatments or environmental factors.

Table 2. presents average values for grain test weight across years and treatments. All testing fertilization variants had test weight greater than 65 kg/hl, except control, K and NK1 variants. During the first year achieved the highest test weight at N-treatmet (65.88 kg/hl), followed by NP1 and NP2 (65.68 kg/hl and 65.72 kg/hl), while the lowest test weight was the control (63.76 kg/hl). During the second year of investigations, the test weight of P was the highest with 69.99 kg/hl, while the slightly lower test weight was realized by NP2K1 (69.97 kg/hl) and NP1K1 (69.90 kg/hl). The average two-year value of test weight the highest at P (68.50 kg/hl), while the lowest average two-year value was at control treatment (66.05 kg/hl). Grain test weight showed a very significant dependence on year (Table 3). In all years, the use of different treatments induced a significant increase in grain test weight. Test weight is an indicator of grain quality, particularly grain monetary value (Đekić et al., 2014).

Table 3. *Analysis of variance of the tested parameters (ANOVA)*

Effect of year on the traits analyzed				
Traits	Mean sqr Effect	Mean sqr Error	F(df1.2) 1.88	p-level
Grain yield (t/ha)	4.8674	1.750393	2.7807	0.098959
1000 grain weight (g)	659.3440	5.356071	123.1022**	0.000000
Test weight (kg/hl)	373.9323	3.243677	115.2804**	0.000000
Effect of fertilization on the traits analyzed				
Traits	Mean sqr Effect	Mean sqr Error	F(df1.2) 8. 81	p-level
Grain yield (t/ha)	15.74848	0.40635	38.75622**	0.000000
1000 grain weight (g)	27.49528	11.24341	2.44546*	0.020097
Test weight (kg/hl)	5.84694	7.56297	0.77310	0.627383
Effect of the year x fertilization interaction on the traits analyzed				
Traits	Mean sqr Effect	Mean sqr Error	F(df1.2) 8. 72	p-level
Grain yield (t/ha)	4.8674	0.349590	13.9231**	0.000377
1000 grain weight (g)	659.3440	3.303333	199.5996**	0.000000
Test weight (kg/hl)	373.9323	3.123611	119.7115**	0.000000

Based on the analysis of variance, it can be concluded that there are very significant differences in 1000 grain weight regard the year of investigation (Fexp=123.102**) and highly significant differences at grain test weight (Fexp=115.280**). Highly significant differences in grain yield and significant differences in 1000 grain weight at investigated triticale cultivar were found relative to the fertilization. In the dual interaction between the year and fertilization, highly significant effects were in grain grain yield, 1000 grain weight and test weight (Table 3). The use of fertilizers and certain amendments on extremely acid soils in certain years, particularly those less favorable for production, almost certainly has different effects on grain filling, resulting in diverse relationships between productive and qualitative traits. The present results confirm the

opinion of many authors that the traits analyzed are genetically determined but are strongly modified by the nutrient status of the environment and weather conditions (Đekić et al., 2010a, 2014; Jelić et al., 2013).

Conclusion

Environmental conditions (weather and soil) and fertilization have a significant effect on grain yield and quality in triticale. Grain yield shows a tendency to increase in the years having a higher total amount and better distribution of rainfall during critical plant development stages.

Based on the gain results during two-year investigation on eight treatments fertilization, it can be concluded that the highest yield achieved the treatments NP2K1 (4.755 t/ha), NP2 (4.519 t/ha), NP1 (4.143 t/ha) and treatment NP1K1 (4.028 t/ha) have achieved satisfactory results, while the poorest results were achieved by the control and N treatmnets.

Considering the average yields value and test weight and 1000 grain weight in 2007/08 and 2008/09,, it was evidently that the yields and test weight were highly statistically significantly different between the year ($p<0.001$). The effect of environmental factors on grain quality was clearly evident. The physical quality of the grain declined in the years that were less favorable for triticale production. Effect of fertilization on the grain yield were highly statistically significantly and 1000 grain weight were statistically significantly. Interaction of the year and fertilization on the grain yield, 1000 grain weight and test weight were statistically significantly.

Abstract

This study was performed in the laboratory of the Kahramanmaraş Sütçü İmam University Faculty of Agriculture Department of Field Crops in Turkey. In this research were investigated karyological properties of some *Nigella* species and used three nigella species. These species were *Nigella damascene, Nigella sativa* species and *Nigella* Çameli registered varieties. The scope of karyological analysis examined the number of chromosome, the length of chromosome, relative length of chromosome, chromosome arm ratio, centromere index, centromere situation and idiograms of these species were performed. The somatic chromosome numbers were determined as 2n = 2x = 12 in all species. Karyotype analysis indicated that chromosomes of *Nigella* species generally have median region (m), subterminal region (st) and terminal point (T) karyotypes. Karyotype formula was observed as 5m+T in *Nigella damascene*, 5m+1st in *Nigella sativa* and 5m+1st in Çameli. Relative length was changed 9.60-19.40 in *Nigella damascene*, 9.45-20.26 in *Nigella sativa* 8.48-22.55 in Çameli. Karyological properties and the number of chromosome of three species were almost observed similar.

Keywords: *Nigella, chromosome, karyotype, black sesame.*

Introduction

The genus *Nigella* L. belong to the Ranunculaceae family and includes about 20 species distributed from the Mediterranean regions to West Asia (Hegnauer, 1973). The genus *Nigella* comprises about 13 species in Turkey (Davis, 1978, 1988). It is known as "çörek otu" in Turkish. *N.sativa* a seasoned plant is cultivated in several parts of the world. The seeds also known as black cumin or black caraway, have been use in Far Eastern Countries and many Middle Eastern as a natural remedy for over 2000 years (Kökdil *et al*., 2006). The seeds have antimalarial, insecticidal, antifungal antibacterial, and antitumor activates. The seeds are also reported to have carminative, antispasmodic, digestive, diuretic and antiseptic properties (Burits and Burcar, 2000; Morsi, 2000; Teicher, 2002; Ali and Blunden, 2003; Marsik *et al*., 2005; Saleh, 2006; Abdulelah and Abidin, 2007). *Nigella* is annual aromatic plant and its cultivation traced back more than 3000 to the kingdom of the ancient Egyptians and Assyrians (Jabeen *et al*., 2012). The seeds include 20.85% protein, 38.20% fats, 4.64%, moisture 4.37%, ash 7.94%, crude fiber 31.94% carbohydrate. It also contains campestrol, cholesterol, betasitosterol, stigmastrol (Riaz *et al*., 1996; Salma *et al*., 2007; Jabeen *et al*., 2012). The karyotype concept originated by the Russian school of cytogenetics. Karyotype provides basic information about morphology of an individual chromosome number, chromosomal homology and ploidy level in plants (Jabeen *et al*.**,** 2012).

Materials and Methods

N. damascena and *N. sativa* (Çameli registered varieties) seeds samples were obtained Eskişehir Transitional Zone Agricultural Research Institute and *N. sativa* seeds were obtained GAP Agricultural Research Institute. The karyological studies are conducted on the root tips

meristematic cells. The seeds were germinated on moist filter paper in petri dishes at 22°C. The actively growing root tips were pretreated with aqueous colchicine (0.05%) for 3 h at room temperature. Afterwards the root tips were fixed with Farmer (1:3 glacial acetic acid-absolute ethanol) for at least 24 h at 4°C, hydrolysed in 1 N HCl at 60°C for 8 min, then rinsed in tap water for 3-5 min. Finally they were stained in Feulgen for 1 h and mounted in 45% acetic acid (Elçi 1982; Gedik *et al*., 2016). Digital microphotographs from at least 5 well-spread metaphase plates were taken using Nikon E200 microscope, and were recorded with Nikon digital sight DS-Fi2 camera. The short arm (s), long arm (l) and total lengths (TKL) of each chromosome was measured and the relative lengths, arm ratios, and centromeric indices were determined from images of selected cells. Chromosomes were classified according to the nomenclature of Levan *et al.* (1964). The intrachromosomal asymmetry index (A1) and the interchromosomal asymmetry index (A2) are followed by Romero Zarco (1986).

Results and Discussion

The number of somatic chromosomes, ploidy level, karyotype formula, morphometric parameters, A1 and A2 values were determined for each taxa (Table 1). Idiograms of haploid chromosomes were drawn (Figure 2). The examined taxa and characteristics of somatic chromosomes are given below.

Nigella damascena L.

In previous studies conducted on this species the chromosome number was recorded as 2n=12 (Ghosh and Datta, 2006; Marks, 1975) and according to Hizume *et al*., (2013) the *Nigella* species are diploid and its genome (2n=12) has five pairs of long metacentric chromosomes and a short telocentric pair. In our study, the chromosome number was determined to be 2n=12. Chromosomes of the species had 5 median region (m) and 1 terminal point (T) centromeres. Metaphase chromosome length ranged from 9.15 to 18.47 μm and the ratio of the longest to shortest chromosome is 1.9:1. Chromosome arm ratios are measured as 1.13-7.32 μm. Centromeric index varies between 12.01 μm and 45.75 μm and relative lengths vary from 9.60 μm to 19.40 μm. The haploid chromosome length is 95.24 μm. (Tables 1-2, Figures 1-2).

Nigella sativa L.

Its chromosome number is 2n=12 and it consists of 5 median region (m), 1 subterminal (st) (Table 2). The shortest chromosome length is 9.42 μm and the longest chromosome is 20.18 μm. Total karyotype length is 99.62 μm. chromosome arm ratios are between 1.12 μm and 4.21 μm while relative lengths are between 9.45 μm and 20.26 μm. Centromeric index is between 19.18 μm and 46.96 μm (Table 2). Similarly, Ghosh and Datta (2006), Jabeen *et al.* (2012) found that *N. sativa* has 2n=12 chromosomes. According to Jabeen *et al*., (2012) three cultivars of *Nigella sativa* L., has been carried out to determine chromosomal position by using "Feulgen stain". The basic chromosomes number of x=6 have been found in all cultivars of *Nigella sativa*. The total length of chromosomes among the land races of Kohat, 10.84 μm to 4.50 μm, Faisalabad 10.00μm to 4.50μm and Kashmir 4.66 μm to 8.16 μm. The mean relative lengths of the chromosomes of this variety ranged from 19.82 μm to 8.92 μm.

Nigella sativa L. (Çameli registered variety)

The chromosome number was determined to be 2n=12. Chromosomes of the species had 5 median region (m) and 1 subterminal (st) centromeres. Metaphase chromosome length ranged from 8.55 to 22.74 μm and the ratio of the longest to shortest chromosome is 2.6:1. Chromosome

arm ratios are measured as 1.22- 4.61 µm. Centromeric index varies between 21.66 µm and 44.94 µm and relative lengths vary from 8.48 µm to 22.55 µm. The haploid chromosome length is 100.82 µm. ***N.*** *sativa* Çameli registered variety is the same karyotype formula with *N. sativa* (Tables 1-2, Figures 1-2).

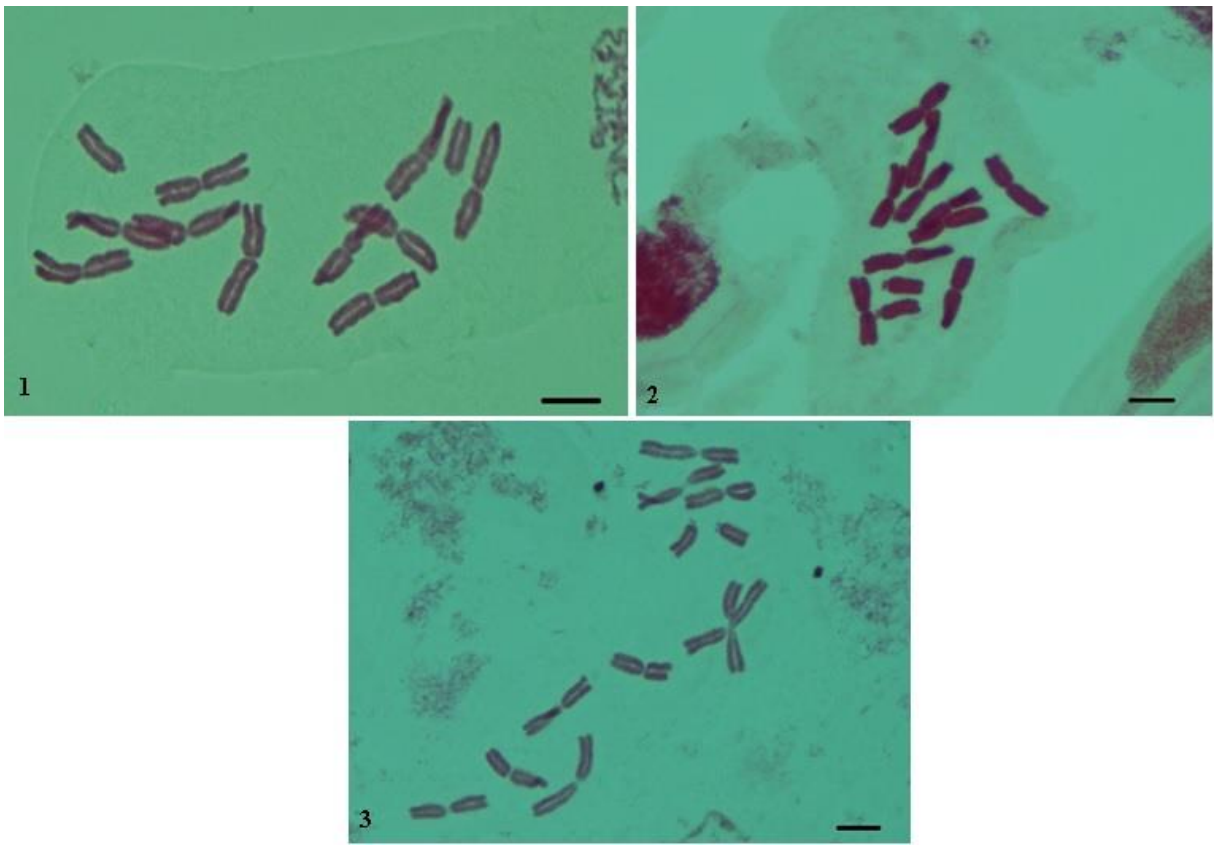

Figure 1. Somatic metaphases in *Nigella* taxa.1- *N. damascena*, 2- *N. sativa*, 3- *N. sativa* **(Ç**ameli**)** (Scala bar 10 µm).

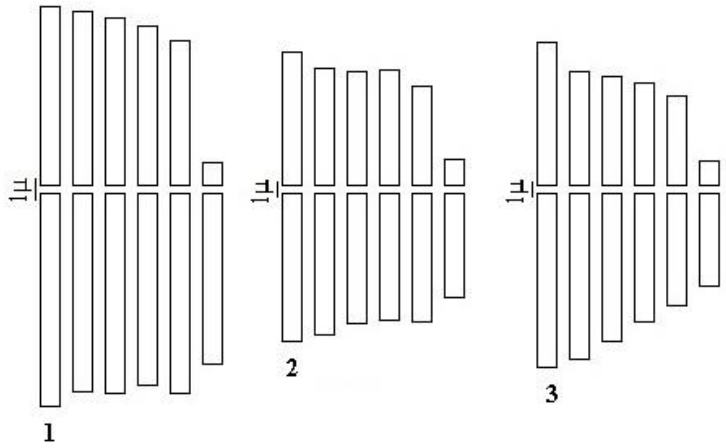

Figure 2. Haploid idiograms: 1- *N. damascena*, 2- *N. sativa*, 3- *N. sativa* **(**Çameli**)**

Table 1. Somatic chromosome number (2n), ploidy level, karyotype formula, ranges of chromosome length, total karyotype length (TKL), and asymmetry indexes (A1, A2) of Romero Zarco (1986) for the studied *Nigella* taxa.

Taxa	*2*n	Ploidy level	Karyotype formula	Chromosome length range (µm)	TKL (µm)	A_1	A_2

Conclusion

Present study represent detailed karyological results about the *N. damascena*, *N. sativa* and *N.sativa* Çameli registered variety. In this study it was found that the studied species 2n=12 chromosome numbers. While chromosome numbers the same as three species, the karyotype formula different from in *N. damascena* and the intrachromosomal asymmetry index (A1) and the interchromosomal asymmetry index (A2) are different in three species.

PROHEXADIONE-CALCIUM AFFECTS VEGETATIVE GROWTH AND YIELD OF PEPPER

Nusret ÖZBAY[1*], Recai METIN[2]

Abstract

Some crops like red pepper (*Capsicum annuum* L.) tend to stretch very early after germination especially if it is grown in low light environments. Therefore, the height of vegetable crop seedlings must be controlled by any possible way. The most common way to control plant height is to apply a plant growth retardant that inhibits stem elongation. This study was conducted to compare the effects of Prohexadione-Calcium (Pro-Ca) concentrations (0, 25, 50, 75, and 100 $mg.L^{-1}$) and application methods (seed soaking, foliar spray, and soil drench), on growth and quality of pepper seedlings and to determine any subsequent effects in the field on vegetative growth, flowering and yield. At field transplanting (42 days after planting), Pro-Ca concentrations higher than 25 $mg.L^{-1}$ and application methods except for seed soaking reduced seedling heights by 25-31%, leaf area size by 7-16 %, shoot fresh weight by 23-32%, shoot dry weight by 19-29%, root fresh weight by 10-22%, and root dry weight by 20-24%. No delay in flowering and fruit set time were found in pepper plants grown from Pro-Ca treatments. However, the 100 $mg.L^{-1}$ Pro-Ca treatment was found to decrease yield by 22%. These results indicate that lower Pro-Ca concentrations (25 and 50 $mg.L^{-1}$) can be used to control excessive elongation growth of pepper seedlings without yield loss.

Key words: *growth retardant, height control, application method, Capsicum annuum L.*

Introduction

Production of quality crops from transplants requires the use of uniform high quality transplants. Ideally, the acceptable transplants should be short and stocky with thick, strong stems and deep green color (Latimer, 1998). Some vegetable crops like peppers have the same tendency to early stretching as some bedding plant species do. Stretching and legginess in pepper transplants becomes a problem when field planting in the spring is delayed due to weather conditions. High light intensities at which the seedlings are grown, together with either low natural radiation levels during the rainy season and winter or high greenhouse temperature in summer, often result in batches of badly stretched seedlings being produced (Kim et al., 2008). In the field, lodging plants due to excessive vegetative growth results in yield losses. Tall vegetable transplants are also more difficult to transplant, more likely to break and are less compatible with transplanting machinery, than more moderately sized plants. In the greenhouse, plant stretching is an unwanted effect in plug production reducing plug quality and making it difficult to handle and perform mechanized transplanting (Magnitskiy et al., 2006). Plant height reduction is playing an important role in promoting yield and quality and decreasing the cost, space and labor (Kim et al., 2010). Therefore, managing transplant height is vital to the vegetable transplant production in both greenhouse and field plant production.

Commercial and experimental methods to control pepper transplant growth include applying plant growth regulators, regulating temperature during hardening or by controlling day and night

temperatures, and inducing mechanical (seismic) stress (Hatt Graham and Decoteau, 1995). Although various cultural practices can contribute to the production of acceptable transplants, chemical plant growth regulators provided one of the most convenient and consistent management methods. Pro-Ca is a novel plant growth regulator that inhibits the late stages of gibberellins (GAs) biosynthesis in plants, thus reducing the vegetative growth of the plant (Kim et al., 2007). Pro-Ca has low toxicity and persistence in the plant (Ilias and Rajapakse, 2005). Greene and Schloemann (2010) reported that inhibitory effects from an application of Pro-Ca lasted for about 28 days. Pro-Ca is very effective in controlling the growth of many fruit crops (Palonen and Mouhu, 2009) and may offer an alternative for use in vegetable transplant production.

This study was conducted to compare the effects of various Pro-Ca concentrations (0, 25, 50, 75, and 100 $mg \cdot L^{-1}$) and different application methods (seed soaking, foliar spray and soil drench), on the characteristics and quality of pepper transplants and to determine any subsequent effects in the field on vegetative growth and yield.

Material and Methods

Greenhouse and field experiments were conducted at the Horticultural Sciences Department Research Units, Kahramanmaras Sutcu Imam University, Turkey. Seeds of 'Sena' red hot pepper (*Capsicum annuum* L.) were obtained from Agricultural Research Institute, Kahramanmaras, Turkey (latitude: 37°35'N, longitude: 36°49'E, elevation: 502 m).

Seed soaking treatment

The seeds were surface disinfected in 1% NaClO solution for 10 min to eliminate possible seed-borne microorganisms, rinsed for 1 min under running tap water and dried for 30 min at room temperature. Pepper seeds were placed in covered transparent polystyrene boxes (10 cm x 10 cm x 4 cm) on double layers of filter paper (Whatman #1). Seeds were soaked for twenty four hours in an aqueous solution of Prohexadione-Ca (Regalis, BASF 125 10W containing 10% Prohexadione-Ca as the active ingredient) at 25, 50, 75 or 100 $mg \cdot L^{-1}$. Control seeds were similarly treated with the same amount of distilled water. After soaking, seeds were transferred to a sieve and then dried on filter paper at 20°C for 2 h to make the singulation of the seeds easier.

Greenhouse experiment

The greenhouse experiment investigated the effects Pro-Ca application methods and the concentrations on seedling growth parameters. Seedlings were grown in an unheated greenhouse at average day/night temperature of 29.5/19.8°C and relative humidity of 58%. Pro-Ca treated seeds (for seed treatment) and untreated pepper seeds (for foliar spray and soil drench application methods) were sown into 45-cell plastic trays (cell volume 75 cm^3) filled with a media consisting of peat and perlite in the ratio of 4:1 and grown on a greenhouse bench. Seedlings were watered regularly and fertilized with 20-20-20 N-P-K soluble fertilizer at a rate of 200 $mg \cdot L^{-1}$N once a week. As second application method, at emergence of the third true leaf (21 day after sowing), pepper seedlings from Pro-Ca untreated seeds were one-time sprayed with 0, 25, 50, 75, or 100 $mg \cdot L^{-1}$ Pro-Ca solutions containing of 0.1% Tween 20 (Sigma Chemical Co., St. Louis, Mo.) as a wetting agent. Water containing Tween 20 was applied to control plants. Pepper seedlings were sprayed on the foliage with Prohexadione-Ca soultion at five concentrations (0, 25, 50, 75 or 100 $mg \cdot L^{-1}$) to run-off, using a hand-held sprayer. At the time of spraying, plastic tray was covered with aluminum foil to protect growth regulator solutions with the substrate. As third application

method, Pro-Ca (20 mL per cell) was applied as a soil drench to the growing medium at emergence of the third true leaf. At 42 day after planting (DAP), the greenhouse experiment was discontinued and final seedling growth measurements were taken. Ten plants per treatment were randomly chosen from each replication to determine seedling height, internodes length, stem diameter, number of true leaves, leaf area (with a LI-3100C leaf area meter, LICOR, Lincoln, Nebraska, USA), shoot fresh and dry weights, and root fresh and dry weights (after drying samples in the oven set at 80°C until constant weight was reached).

Field experiment

Pro-Ca treated and untreated seedlings were transplanted into the field to investigate effects Pro-Ca on growth and yield parameters. The experimental plots were consisting of two rows of 10 plants each, with 20 plants per treatment with a drip irrigation tube down the center. Plant rows were spaced 50 cm apart on beds with 120 cm center and plants within each row were 50 cm apart (120 x 50 x 50 cm). Plants were grown to maturity with standard local field production practices (irrigation, disease/insect management, fertilizer rates, weed control, etc.). During field experiment, the effects of Pro-Ca were observed on plant heights (measured at 60, 90 and 120 DAP), number of fruits per plant, average fruit weight, and fruit yield in pepper. During field experiments average day/night temperature of 33.5/20.8°C and relative humidity of 45%.

Experimental design and statistical analysis

The experiment was a 5 x 3 factorial in a completely randomized design or randomized block design with three replications per treatment. Each experiment was repeated twice and yielded similar data. Therefore, the data from two experiments were combined and subjected to analysis of variance performed with SAS 9.1. (SAS Institute Cary, NC, USA) and mean separation was performed by Fisher's least significant difference (LSD) test when *F*-test was significant at $P \leq 0.05$.

Results and Discussion

Greenhouse experiment

With application of 50, 75 and 100 $mg \cdot L^{-1}$ Pro-Ca, seedling height was suppressed by 25%, 28% and 31%, respectively, compared to the control. There were significant differences in seedling height among Pro-Ca application methods, soil drench treatment having the highest reduction (37%). 100 $mg \cdot L^{-1}$ Pro-Ca also effectively reduced internode length by 27% as compared to control (Table 1). The Highest concentration of Pro-Ca (100 $mg \cdot L^{-1}$) resulted in reduction in shoot fresh weight and dry weight of pepper seedlings (by 32.14% and 27.72%, respectively) (Table 2). It was found that all Pro-Ca doses resulted in reduction in leaf area by up to 14% compared to control plants although there was a slight difference in the leaf number between Pro-Ca treatments and control plants (Table 3). Root fresh and dry weights were significantly decreased by all the Pro-Ca doses with the exception of 25 $mg \cdot L^{-1}$ (Table 3).

Field experiment

Pro-Ca treatments resulted in 17% reduction in plant height at 60 DAP, 14% reduction in plant height at 90 DAP, and 12% reduction in plant height at 120 DAP (Table 4). There were significant differences in plant height among Pro-Ca application methods, soil drench treatment having the highest reduction at 60, 90, and 120 DAP (26, 23.5 and 15% respectively). Low concentrations of Pro-Ca (25-50 $mg \cdot L^{-1}$) did not significantly affect number of fruits per plant

and total fruit yield. However, Pro-Ca at 100 mg·L^{-1} reduced number of fruits per plant by 17% and total yield by 21% (Table 5). No significant differences in mean fruit weight among Pro-Ca dosage treatments were found. Pro-Ca doses (75 and 100 mg·L^{-1}) reduced yield in pepper by 17% and 21%, respectively, whereas 25 and 50 mg·L^{-1}did not cause any change in yield in comparison with control.

In the present study, the application of Pro-Ca caused an immediate vegetative growth reduction, most dramatically demonstrated by a reduction in plant height and internodes length, compared with control treatment. This inhibitory effect of Pro-Ca diminished over time, and the difference in plant height and internode length between treated and control plants gradually decreased.

These results are in agreement with some previous studies (Rayirath et al., 2009; Kim et al., 2010; Guak, 2013). These findings also confirm Grossmann et al. (1994), who reported that the treatment of wheat seedlings with increasing Pro-Ca concentrations in hydroponics reduced plant height and fresh weight of shoots by up to 40%.

Soaking of faba bean seeds in solutions of Pro-Ca caused significant reduction in shoot height and shoot fresh weight. The reduction corresponded with increasing Pro-Ca concentration (Bekheta et al., 2009). The inhibitory effect of Pro-Ca on seedling height is further supported by other researchers for some other species, such as cabbage (Hamano et al., 2002), petunia and impatient (Ilias and Rajapakse, 2005), okra (Ilias et al., 2007), onion and garlic (Ouzounidou et

al., 2011). Pro-Ca inhibits gibberellin biosynthesis by blocking the 3ß-hydroxylation of GA_{20} to GA_1, resulting in reduced stem elongation (Rademacher, 2000). Application of Pro-Ca decreased the levels of GA_3 and IAA but increased the levels of ABA and cytokinins in faba bean seedlings, compared with their respective controls (Bekheta et al., 2009).

NS Not significant, * Significant at P<0.05, ** Significant at P<0.01, *** Significant at P<0.001, SS: Seed soak, FS: Foliar spray, SD: Soil drench. Means followed by the same letter are not significantly different at the 0.05 level, using Fisher's LSD.

Stem and leaf dry masses and stem length of okra were significantly enhanced by the application of exogenous GA_3, but Pro-Ca inhibited growth (Ilias et al., 2007). Prohexadione-Ca has a potential for effective control of vegetative growth in several plant species however, timing seems to be very important (Ilias and Rajapakse, 2005).

Pro-Ca treatments (higher doses) resulted in reduction in leaf number and leaf area compared to the control plants, which agrees with previous studies on Pro-Ca and some triazole group regulators (Glen and Miller, 2005; Medjdoub et al., 2007). It has been reported that Pro-Ca application decreased leaf number and leaf area of tomato plants compared to the control (Altintas, 2011). Reduced leaf area with increasing treatments is most likely due to the inhibition of gibberellin biosynthesis. Kang et al. (2010) reported that the endogenous bioactive GA_1 and GA_4 contents of Chinese cabbage drastically decreased with elevated Pro-Ca.

No delaying in flowering and fruit set time were found in pepper plants grown from Pro-Ca treatments (data not presented). These findings on pepper flowering and fruit set time are in line with Ilias et al. (2007), who reported that control and Pro-Ca treated okra plants took same time to bloom. In contrast, application of Pro-Ca (200 $mg \cdot L^{-1}$), 45 days after planting, delayed anthesis up to 11 days in petunia (Cerny-Koenig et al., 2005). This may be because of late application of retardant. Some yield parameters of pepper such as mean fruit weight and fruit yield were also reduced by the application of higher Pro-Ca treatments (especially with 100 $mg \cdot L^{-1}$) but not with the lower concentrations as mentioned previously.

These findings are consistent with those reported for apple plants by Miller (2002). Pro-Ca may be reducing fruit size primarily by slowing cell division during this active period of cell division in the pepper fruits. An alternative or contributing factor reducing fruit size could be reduced leaf area, which is true in our case. On the other hand, our results are contrary to some other studies.

Hytönen et al. (2009) reported that Pro-Ca treatment during the planting year resulting in a significant yield increases in strawberry during the following season. Similarly, Greene and Schloemann (2010) found that Pro-Ca increased total marketable yield without affecting mean fruit size. Asín et al. (2007) determined that Pro-Ca did not have any significant negative effect on yield of pear. It may be thought that the improving or negative effect of Pro-Ca depends on application time, doses, environmental conditions, species, cultivar, and even on individual plant.

Conclusion

Low concentrations of Pro-Ca appear to be effective at controlling vegetative growth yet appear to have minimal side effects. Based on our results it can be stated that lower Pro-Ca concentrations can be used to control excessive elongation growth of pepper seedlings without any major yield loss. Concentration ranging from 50 to 75 $mg \cdot L^{-1}$ can be used to achieve a 28 % height reduction. Several growth regulators are available to control plant height by controlling GA biosynthesis, but most of them have a long half-life. In contrast, Pro-Ca is a non-toxic growth regulator with a short half-life.

Abstract

Citrus fruits export is ranked as the 1st in fresh fruits and vegetable export in Turkey. In Turkey, the total citrus fruit productionis 3.975.873 tons in 2015. About 86.64% of the total citrus productions in Turkeyare in the Mediterranean Region.Orange production constitutes 45.70% with 1.816.798 tons of this production. Approximately 27.33% of orange production in Turkey is cultivated in Antalya province. In this study, four navel orange clones (numbers 3, 38, 39 and 86) and three navel orange varieties (‘Gillette’, ‘Navelina’ and ‘Tule Gold’) grafted onto common Sour orange and Troyer citrange rootstocks were used. Blooming dates (The first blooming, full blooming and the last blooming dates); flower and June drop (fruitlets) rates were examined by using Navel orange clones and varieties. Furthermore, some development parameters of the trees (canopy volume, stem diameter and canopy area) were alsostudied. The blooming period of Navel orange clone and varieties under Antalya seasonal conditionshas been determined and has ranged between the periods of April 7 to May 2. Although, flower and June fruit drop rates were not fundamentally affected by the rootstock, clones and varieties have influenced the flower and fruit drop rates. There wasn’t any statistical effect on the rootstock of flower drop and June fruit drop rates. However,significant positive correlations were observedregarding development parameters of the orange clones and varieties.

Keywords: *Citrus, blooming, June drop, Sour orange, Troyer*

Introduction

Citrus is one of the most important fruit tree crop in the world. Navel varieties, especially ‘Parent Washington Navel’ oranges are among the most popular citrus cultivar grown in Turkey. Navel orange production constitutes 74.33% of the 1.350.600 tons of total orange production in Turkey. Because of highsoil pH problems, the most popular rootstock use in citrus cultivation is sour orange. Besides, Troyer andCarrizocitranges which are hybrids between the trifoliate orange and the Washington navel orangehave also been used for orange production. Rootstocks may influence citrus growth and development, including yield, fruit quality, and tolerance to stress caused by biotic and abiotic factors (Filho*et al*., 2007). While 'trifoliate orange', 'Troyer' and 'Carrizo citranges' are also used, the main source of rootstock for Turkish citrus production is 'Sour orange'. The 'Sour orange' has been most desirable citrus rootstock in the world because of its adaptability to a range of soil conditions and excellent fruit quality production. However, the appearance of *Citrus tristeza virus* in the Mediterranean region (Kyriakou and Polykarpou, 1989) has necessitated a research program to replace'sour orange' with rootstocks tolerant totristeza for almost all the commercialcultivars (Tuzcu*et al*., 1998; Kaplankiran*etal*., 2005; Demirkeser*et al*., 2009).Rootstocks have had a substantial role in the development of the citrus industry in the world. The effect of rootstocks on citrus fruit production and fruit quality has been studied in many citrus producing areas (Continella*et al*., 1988; Economides and Gregoriou,

1993;GeorgiouandGregoriou, 1999;Georgiou, 2002; Roose*et al*., 1989; Rouse and Maxwell, 1970; Zekri, 1996, 1997, 1999, 2000; Salibe andMoreira, 1973; Crescimanno et al., 1981; Perez *et al*., 2005; Temiz, 2005; Turgutoglu *et al*., 2015; Kurt *et al*., 2014). Findings from their studies have revealed different and inconsistent conclusions. Therefore, it is reasonable to adopt rootstock recommendations from one part of the world to another without a thorough evaluation locally. Since environmental conditions and cultural practice are unique to each geographical location.

The aim of this study is to determine the blooming dates, flower and the June drop rates and development parameters of 4 navel orange clones(no's. 3, 38, 39 and 86) and 3 navel orange varieties('Gillette', 'Navelina' and 'Tule Gold') grafted onto common sour orange and Troyer citrange rootstock atAntalya, Western Mediterranean region of Turkey.

Materials and Methods

This study was carried out at BatıAkdeniz Agricultural Research Institute, Antalya (Turkey) during 2006-2007 seasons.Four navel orange clones (no's. 3, 38, 39 and 86) and three navel orange varieties ('Gillette', 'Navelina' and 'Tule Gold') were budded on the rootstocksof'sour orange' (*Citrus aurantium*L. var. 'Yerli') and 'Troyer citranges' (*Citrus sinensis*Osb.×*Poncirus trifoliate* Raf). The experimental design was completely randomized with four replications and a single tree per plot. The budded trees were planted in 1999 with 7×7 m spacing at the Fruit Research Station of West AkdenizAgricultural Research Institute,Antalya.The soil texture of the plot located in Antalya was sandy-clay. The soil was coarse textured (39% sand, 38% silt, 23% clay) and alkaline in the soil profile (pH 8.40 in 1:2.5 soil: water suspension).

The first and full blooming dates were recorded when 5-10% and 90-95% of the flowers have opened respectively. The last blooming date was recorded when 80-90% of the petal had dropped.Data collected from each branch included total number of flower and fruitlet per branch. Percentage flower drop rate was calculated as; number of the fallen flower / number of total flower x 100.The Percentage June drop rate was found as; number of the fallen fruitlet / number of total fruit set after blooming x 100.

In January (2006 and 2007), canopy height and canopy diameter in the two, three directions were measured after harvesting to obtain the mean diameter. The canopy volume was calculated from canopy height and spread and applying the formula: $CV= 4/3\pi ab^2$, where *a* is the major axis length/2, and *b* is the minor axis length/2 (Westwood, 1993). Additionally, stem diameterswere measured 10 cm above the bud union by scion trunk circumferences.

A completely randomized design with four replications was used. The data were recorded were subjected to ANOVA using SAS program (SAS, 2005) and means were compared with Duncan test at the 5% level of significance.

Results and Discussion

In most species under subtropical conditions, flowering takes place in spring and the subsequent formation of fruit extends until Midwinter (Iglesias *et al*. 2007).In Antalya, citrus bloom varies by year, typically occurring in 2-3 waves of flowering any time from the end of March through the beginning of April. In this study, blooming dates (The first blooming, full blooming and the last blooming dates) of Navel orange clones and varieties were found to be consistent with the above mentioned dates. In addition, blooming dates were not affected by rootstocks (Table 1).

Table 1. Blooming dates (The first blooming, full blooming and the last blooming dates) of navel orange clones and varieties

Types	Rootstocks	First bloomingdate	Full blooming date	LastBlooming date
3	Sourorange	9 Apri	24 April	28 April
	Troyercitrange	9 April	24 April	28 April
38	Sourorange	8 April	24 April	2 May
	Troyercitrange	8 April	24 April	2 May
39	Sourorange	9 April	24 April	2 May
	Troyercitrange	9 April	24 April	1 May
86	Sourorange	7 April	24 April	29 April
	Troyercitrange	7 April	24 April	29 April
Gillette	Sourorange	9 April	24 April	2 May
	Troyercitrange	9 April	24 April	2 May
Tule Gold	Sourorange	9 April	23 April	30 April
	Troyercitrange	9 April	23 April	30 April
Navelina	Sourorange	7 April	23 April	28 April
	Troyercitrange	7 April	23 April	28 April

The Navel orange clones and varietiessignificantly affected the flower drop and June drop rates, but not the rootstocks. The flower drop rate of clone 38 and Navelinavariety has lower than those of the other clones and varieties (Table 2). Similar results were reported by Yıldırım (2003) on 'Washington Navel' orange. The June drop rate of Tule Gold variety has the lowest compared to the others (Table 3). Fruit set rather than flowering is the step that limits yield in most citrus cultivars (Ruiz et al., 2001). The number of fruits finally harvested was less than 2% of the number of flowers formed, and values as low as 0.1% have been reported (Monselise, 1986). Bud, flower and ovary abscission occurmostly at the beginning of the cell division phase, whereas the fall of fruitlets and developing fruits is higher during the June drop. Generally, a small percentage of fruits overcome the June drop and less than 1% reached ripening (Iglesias et al. 2007).

Table 2. Theflowerdrop rate of navel orange clones and varieties (%)

Types	Rootstocks		Average of Types

According to our results, stem diameter, canopy volume and canopy area were not fundamentally affected by rootstock. Our findinghas in agreement withTuzcu*et al*. (1999) who reported similar results onValencia late' and 'Shaomuti' orange. However, our result is in disagreement with others (Yildirim, 2003; Georgiou, 2002) who reported opposite result in their studies.Clones 38 and 39 were similar and higher than others in terms of all three parameters (Table 4; 5; and 6).

Conclusions

Generally, there is noperfectrootstockevenfor specific situations. Bothroot stocks had similar features for investigated characteristics. Based on the presentresults, Troyercitrangeappeared to be promising along with sourorange. However, the most citrus producing areas in Antalya province are highly calcareous. Since Troyer citrange is sensitive tohighly calcareoussoils,Sourorangeeven though susceptible to the*citrus tristeza virus*,it might be preferredbecause of itshigh calcareous tolerance and adaptability to a wide range of soil conditions and excellent fruit qualityproduction. Additionally, thenavelclonesandvarieties used in this studycould also be recommendedfor both local and commercialorangeproductions.

Abstract

Turkish walnut cultivars are considerably early leafing and they are bear fruit on terminal buds. The most widely used breeding method in walnut variety breeding programs in Turkey was selection. Cross breeding method was used in only three studies. The new walnut variety breeding program was started in 2008. The aim of this breeding program is to provide new walnut cultivars by crossing for the Turkey walnut industry. The primary goal is to develop cultivars with late leafing, lateral fruit bearing, early harvest dates, and good nut quality. Thirteen crosses have been carried out in different three ecological conditions. The varieties with late leafing and good nut quality chosen as female parents were pollinated by varieties with lateral fruit bearing and high yielding. To ensure the highest possible germination, seed are straficated in cold room (4 °C). After stratification, germinated seeds were sowed in to plastic containers containing peat, perlite and soil for growth in the greenhouse. We have 1340 seedlings under evaluation in the breeding program. Leafing time of seedlings was observed in greenhouse at second year; and late leafing seedling were selected and planted in a breeding orchard. Leafing time of seedlings are determined and compared by 'Franquette', 'Serr' and 'Chandler' cv. during three years in breeding orchard. If no nuts have been produced by age four they are painted by red. The results showed that 189 genotypes were selected according to late leafing, and six genotypes early fruiting and late leafing. In 1340 hybrids observed, 33.52 % of seedling varied from medium late to late leafing. The data showed that there are correlation between the leafing time of first and third year.

Keywords: *Walnut, crossing breeding, cultivar*

Introduction

The Anatolia, English or Persian walnut (*Juglans regia* L.) is the most horticultural developed and widely cultivated of all the walnut species (*Juglans* L.) in the world**.** Turkey is reported to be the genetic origin of *Juglans regia* and wild trees of walnut are found in every parts of the country and trees exhibit considerable variation in respect of vegetative growth and fruit characters. Although there are many walnut variety breeding program in the world, the new walnut variety program begun in 1999 in Turkey. A lot of walnut variety breeding programs have been carried out in USA, France, Hungary, Italy and Spain; a few of these programs are still ongoing (Germain *et all*., 1985; Tulecke and McGranahan, 1994; Tamponi *et all*. 1997; Szentiványi and Szücs (2001); Anonymous, 2016).

Breeding of new walnut varieties is characterized by earlier fruiting, higher yield, lateral bearing, late leafing, good adaptability to different ecological conditions, good fruit quality and tolerant to pests and diseases. The ideal walnut cultivar should be relatively late leafing to escape spring frosts and the rains that spread walnut blight (*Xanthomonas campestris pv. juglandis*), precocious (yielding more than 500 kg/hectare in the fourth year), and vegetative vigorous with bearing on

both terminal and lateral shoots. The nut shell should be relatively smooth, well sealed, and make up no more than 50% of the nut weight. The nuts would fit the category of large or jumbo. The kernel would be plump and light colored, weighing about 8–9 g, and come out easily in halves. The tree would be at least moderately resistant to pests and diseases.

Turkish walnut cultivars have too early leafing out and most of them are susceptible to bacterial blight, and they bear fruit on terminal buds. The most widely used breeding method in walnut variety breeding programs in Turkey is by selection. The first breeding program was started in 1970 in Turkey (Ölez, 1971). At the first stage of the walnut breeding in Turkey, during 1970 to 2011 years, selection works have been made in populations that has been generated from seed. More than 200 promising types were selected among these trees [(Akça and Şen, 2001; Akca and Ozongun, 2004; Asma, 2012; Karadağ and Akça , 2011; Simsek et all; 2011; Kırca, et all., 2014; Akça *et all*., 2015; Yarılgaç and Yılmaz, 2016)**].** These selection works aimed to find new walnut types with high nut quality and yield. Also, the aim o this walnut variety breeding program was to obtain new selections combining lateral fruitfulness, late leaf break, resistance to pathogens (*Xanthomonas juglandis* and *Gnomonia juglandis*), regular yield, and high fruit quality. During the last 45 years, selections works carried out to find new walnut cultivars in Turkey. The selected types have a too early leafing out (Except Niksar1) and most of them are susceptible to bacterial blight and low yield. Therefore, this variety breeding program was started in 2008, in order to obtain new more productive cultivars with late leafing, higher nut quality and resistance to bacterial blight, early bearing. This paper reports the results gathered on leafing time characteristics.

Material and Methods

Twelve crosses have been done. The female parents consisted of Turkish, French and Californian varieties with late leafing (LL) and good nut and kernel quality. The male parents were lateral bud fruitfulness (LBF), early to medium late bud break and high fruit quality (Table 1). The female flowers were carefully bagged before receptive stage. After, the pollen of chosen parents was applicated to receptive flowers. Pollen applied flowers marked with different colored threads. Seed from these crosses is collected in the fall before nut drop, air dried before storing. To ensure the highest possible germination, after soaking 24 hours in a GA_3 solutions at 50 ppm, seed are straficated in cold room (4-5 °C). After strafication, germinated seed are planted in large tubes in containing peat, perlite and soil for growth in the greenhouse. The leafing time of each hybrid was noted and the seedlings which leafed out two-three weeks earlier than 'Franquette' were discarded. The selected selections were planted in the breeding orchard 4 x 4 m, on their own roots. By age 6, trees with low yield or other problems are cut down. Date of bud break is reach a length of about 2.5 cm of the terminal bud and pronounced leaflets and observing least 7-8 cm of shoot growth has been recognized as the date of the foliation (Ölez, 1971). Leafing times were grouped according to UPOV standards (Table 2) (Anonymous,1999).

Results and Discussion

The Turkish walnut cultivars have low yield potential. The yield is limited for the apical type of their bearing. Most of the Turkish cultivars are early leafing and very sensitive to spring frosts, when they grow under the continental climatic conditions. Therefore it is necessary to carry out a variety breeding program for developing new cultivars with lateral bearing, late bud-break, disease resistance and valuable economic traits of fruits.

During the first stage of the variety breeding program in Turkey (1998-2000), was used the national walnut genetic resources, in result of this research was not found walnut variety with late leafing according to 'Franquette' and 'Chandler' (Akça, 2001). But, during the last 10 years, the Californian and French walnut cultivars were used in crossing program. At the end of this new variety walnut breeding program are found excellent new walnut F_1 hybrids (Anonymous, 2012). Twelve crosses have been made so far and 1340 seedlings obtained in the new variety breeding program (Table 3).

Parents	Number of seedlings
'Şebin' x 'Akça 2'	75
'Şebin' x 60 NF 81	85
'Akça1' x 'Akça 2'	281
'Akça1' x 'Maraş12'	168

'Franquette' x 'Maraş12'	61
'Franquette' x 'Sütyemez1'	34
'Franquette' x 'Sütyemez2'	28
'Hartley' x 'Maraş12'	98
'Hartley' x 'Sütyemez1'	73
'Hartley' x 'Sütyemez2'	56
'Hartley' x 'Oğuzlar 77'	134
'Hartley' x 'Akça 2'	119
Total seedlings	1340

Table 3. Number of seedlings obtained from crosses

Distribution of walnut F_1 population's leafing time by parents (frequency %) were presented in Table 4. The percentage of medium, medium late and late leafing group of F_1 seedlings was observed as %50.72. The very early group (11.11%) of F_1 populations was only obtained in Hartley x Oğuzlar77 crossing. The distribution of F_1 population's leafing that is obtained from crossing late and very early parents was changed to used parent. For example medium, medium-late and late leafing percentage of F_1 population from crossing 'Franquette' x 'Maraş' 12 were determined as 20%, 14.29% and 28.58% respectively, but 38.00%, 32.00%, 6.00%, respectively male parent as 'Akça 1' was used.

Female Parents	Male Parents	Very Early (1)	Early (2)	Medium – Early (3)	Medium (4)	Medium –Late (5)	Late (6)

'Hartley' (4)	'Maraş12' (1)	-	12.12	30.30	39.39	12.12	6.06
Mean		1.39	12.04	35.85	27.20	11.52	12.00

Table 4. Distribution of walnut F_1 population's leafing time according to parents (frequency %)

Germain (1990) was obtained 2500 F_1 plant from used different French and Californian walnut parents. The percentage of medium late to very-very late leafing group was reported as 37.2% in this breeding program. Germain (1990), reported that used parent effected to the distribution of walnut F_1 population's leafing time.

Also, Szentiványi and Szücs (2001), examined to the inheritance of blooming time characteristics in 122 F_1 progenies from the cross A117 x Pedro, 125 ones from Pedro x A117, 34 ones from M10 x Pedro and 17 ones from T2 x Pedro. It was not observed the very late group of female blooming in F_1 population. Late female blooming group was changed between 6.25% to 21.43.

Conclusion

Among the 1340 hybrids, 198 F_1 hybrids have been preselected for the desired characters. They have been examined for further observations. The nut quality of preselected F_1 hybrid was observed much more than Chandler, Fernor, Hartley, Midland and Pedro (size, shell hardness, kernel percentage, color of kernel, proportion of waste, etc.). Superior pre-selections will be licensed before 2020. The early bore nuts was determined 'Hartley' x 'Oğuzlar 77', 'Hartley' x 'Maraş12' and 'Hartley' x 'Akça 2' combinations in 3th year after planting, the catkins has seen in their 4th-6th year.

Abstract

Malting barley thrives in temperate climates that exhibit small temperature fluctuations, especially during grain maturation, when the crop is particularly sensitive to heat stress. A field trial involving four two-rowed spring barley cultivars was conducted at the experimental field of the Secondary School of Agriculture and Chemistry, Kraljevo (Serbia) over a period of three years (2012-2014) to evaluate the variability of yield components (plant height, number of kernels per spike, kernel weight per spike and thousand-kernel weight) and grain yield in different growing seasons. The experiment was laid out in a randomized block design with three replications on a pseudogley soil acidic in reaction. Seeding rate was 450 germinable seeds m^{-2}. At tillering, 50 kg ha^{-1} nitrogen was applied. Calcium ammonium nitrate (CAN) with a nitrogen content of 27% was used for top dressing. The studied traits were significantly affected by weather conditions during the growing season. The effect of weather differed across cultivars. Grain yield, thousand-kernel weight, kernel weight per spike, number of kernels per spike and plant height were highest in all cultivars in the year characterized by moderate temperatures during grain filling and a high rainfall total in the second part of the growing season. The highest values for grain yield, number of kernels per spike and kernel weight per spike were obtained in 'Novosadski 448'.

Key words: *malting barley, climate, grain yield, yield components.*

Introduction

In Serbia spring barley goes through growth and development stages mostly under high temperature and water deficit conditions, especially during grain filling, which leads to a reduction in grain filling period, kernel size, kernel weight and, hence, grain yield and quality (Pržulj and Momčilović, 2002). Temperature and rainfall are not necessarily the most important factors that govern the level of production and grain quality in malting barley, since the harvested grain is often of poor quality when these factors are close to optimal (Pržulj et al., 2014). Therefore, the market is often lacking in barley that satisfies quality requirements of the malting and brewing industry (O'Donovan et al., 2011). In contrast, different soil and climatic conditions, especially temperature and moisture content during grain filling (Passarella et al., 2005) can cause a high variation in major grain yield components and, hence, total grain yield and quality of malting barley (Atlin et al., 2000; Paunović et al., 2007; Madić et al., 2009). Environmental conditions in Serbia and Southeastern Europe are considerably different from those in the barley belt of Western and Central Europe (Malešević and Starčević, 1992). Due to frequent heat waves during the growing season and considerable fluctuations in the amount and distribution of rainfall, there has been a tendency in Serbia for protein to accumulate in the barley grain and for kernel size to decrease (Malešević et al., 2010).

The objective of this study was to assess the effect of genotype and production conditions (year) on yield components and grain yield in spring malting barley grown on poorly productive soil.

Material and methods

Research was conducted in 2012-2014 at the experimental field of the Secondary School of Agriculture and Chemistry, Kraljevo in Serbia (experimental field of the Faculty of Agronomy, Čačak) on an acidic soil (pH_{H2O} 4.5, humus 2.18%, P_2O_5 7.50 mg 100^{-1} g and K_2O 15.5 mg 100^{-1} g soil). Four cultivars of two-rowed spring malting barley were used: 'Novosadski 448', 'Dinarac', 'Dunavac' and 'Lider'. The field trial was laid out in a randomized block design with three replications and a plot size of 5x1m. The total amount of the complex mineral fertilizer N:P:K (15:15:15) i.e. 300 kg ha^{-1} was manually broadcast before seedbed preparation. Seeding was performed by a seed drill designed for micro-trials at a rate of 500 germinable seeds m^{-2} and a spacing of 10 cm between rows and 3 cm in the row. Plants were fertilized at tillering by calcium ammonium nitrate (CAN - 27% N) at 50 kg N ha^{-1}. At full grain maturity, 30 plants were sampled from each plot for analysis of plant height, number of kernels per spike, kernel weight per spike and 1000 kernel weight. Prior to harvest, the number of spikes m^{-2} was determined. After harvest, grain yield from each plot was weighed and calculated as yield in kg ha^{-1}. Results were subjected to a two-way analysis of variance (cultivar, year). The significance of differences in means was assessed by Duncan's test (SPSS 1995).

Total rainfall was 263.5 m, 322.6 mm and 653.5 mm in 2012, 2013 and 2014, respectively. Substantial amounts of rainfall in April and May 2012 caused lodging in the barley crop, whereas drought and high temperatures occurred during grain filling and maturation. The year 2013 was characterized by humid and cold weather accompanied by a thick cover of snow in February and March, and high temperatures from mid April until harvest. Weather conditions in the 2014 growing season included high rainfall totals during the second part of the season and almost daily rainfall during grain filling. Extreme rainfall events with an average of 700 mm rainfall were recorded in most of Serbia during 2014 as the rainiest season in the last 45 years.

Results and discussion

The optimum plant height in breeding malting barley has not been precisely defined. There has been a tendency in selection work to create short-stem cultivars to eliminate plant lodging and its negative effects, given the weak mechanical tissue of the barley stem (Pržulj et al. 2010). The analysis of variance for plant height showed significant differences across cultivars and production conditions during the experimental years. Plant height was greatest in 2014, significantly lower in 2012, and lowest in 2013 (Table 1). Over the three-year period, the greatest average plant height was obtained in 'Lider', and the smallest in 'Novosadski 448'. The significant dependence of plant height upon year was confirmed by Gozdowski et al. (2012), who obtained the shortest stem in the year of deficient rainfall, whereas Knežević et al. (2014) stressed that plant height is primarily a cultivar-specific trait, with cultivars showing great differences as the result of differences in their genetic constitution.

Number of spikes is the most important yield component in all cereal crops; at the same time, it is the most unstable yield component under semiarid conditions in Southeastern Europe (Pržulj and Momčilović, 2004). Moderate air temperatures and favourable soil moisture in May and April 2012 enabled good tillering and led to the formation of a large number of spikes (812.3 m^{-2}). In 2013 and 2014, the number of spikes per unit area in 'Dinarac' was significantly higher than in the other cultivars. In 2012, 'Dinarac' exhibited higher values of this trait only when compared to 'Lider'.

Number of kernels per spike varied across years from 16.4 in 2013 to 21.5 in 2014 (Table 1). In all three years, 'Novosadski 448' had significantly more kernels compared to the other cultivars. The

significant effect of weather and cultivar on the number of kernels per spike was also reported by Gozdowski et al. (2012). Due to the high number of kernels per spike, 'Novosadski 448' exhibited the highest kernel weight per spike (Table 1). Kernel weight per spike in 'Novosadski 448' was significantly higher than in the other cultivars in all years except 2014, when it showed no significant difference from 'Lider'. 'Dunavac' had a significantly lower kernel weight compared to the other cultivars in all years.

**** F-test significant at 0.001*

Thousand kernel weight is a kernel size trait expressing kernel suitability for malting. The analysis of variance indicated significant differences among cultivars (Table 1). Across years, 1000-kernel weight was significantly higher in 2014 than in 2012 and 2013. The 2012 and 2013 growing seasons were characterized by dry and hot weather during grain filling. Plant lodging in 2012 did not lead to reduced 1000-kernel weight compared to the unfavourable year 2013, most likely due to higher soil water reserves from April and May. Thousand-kernel weight in 'Dinarac' was significantly higher than in the other cultivars, except 'Lider' in 2014. Climatic conditions are of particular importance during grain filling, since moisture deficiency and high temperatures during this period (Pržulj et al., 2014) result in reduced thousand-kernel weight. Weather conditions during the growing season had a significant effect on the traits analyzed in all barley cultivars. Yield and yield components as a function of weather conditions during the growing season were also reported by Malešević et al. (2010) and Glamočlija et al. (2011).

Grain yield was lowest in 2013, significantly higher in 2012 and highest in 2014 (Table 1). In the first two years, 'Lider' gave a significantly lower grain yield compared to the other cultivars. Garcia del Moral et al. (2003) observed that yield stability as affected by different environmental conditions is closely associated with kernel number per spike since a large number of kernels per spike ensures a large number of kernels per unit area even when the number of spikes is low. Upon formation of the number of spikes and number of kernels per spike during vegetative growth, yield is mostly determined by kernel weight (Wiegand and Cuellar, 1981).

Conclusion

The analysis of variance of spring malting barley genotypes showed significant differences in the studied traits among cultivars. Weather conditions during the growing season had a significant effect on these traits in all barley cultivars. Grain yield, thousand-kernel weight, kernel weight per spike, number of kernels per spike and plant height were highest in the year with moderate air temperatures during grain filling and a high rainfall total in the second part of the growing season. 'Novosadski 448' outperformed the other cultivars in terms of grain yield, number of kernels per spike and kernel weight per spike, but it had the lowest values for 1000-kernel weight and plant height. 'Dinarac' gave the highest number of spikes, highest 1000-kernel weight, and the lowest number of kernels per spike.

CHERRY BREEDING WORK AT FRUIT RESEARCH INSTITUTE – ČAČAK (REPUBLIC OF SERBIA)

Sanja RADIČEVIĆ[1*], Radosav CEROVIĆ[2], Slađana MARIĆ[1], Milena ĐORĐEVIĆ[1]

Abstract

Cherry breeding programme at Fruit Research Institute (FRI) – Čačak (Republic of Serbia) has had a long tradition since its initiation in 1960. The main method is the planned hybridisation within *Prunus avium* L. and *Prunus cerasus* L. Two sweet cherry (‘Asenova Rana’ and ‘Čarna’) and two sour cherry cultivars (‘Šumadinka’ and ‘Čačanski Rubin’) have been released in the previous period. Three new sour cherry cultivars (‘Sofija’, ‘Nevena’ and ‘Iskra’) were named and released in 2015, whereas a large number of hybrids are being intensively studied. Current sour cherry breeding work is based on the use of domestic genotypes, well adapted to the environmental conditions of the area (either obtained by planned hybridisation or autochthonous), and introduced genotypes – known sources of resistance, with a high cropping potential and good fruit quality. The investigations are also focused on different aspects of floral biology of these fruit species – flowering phenology, pollen quality, monitoring the pollen tubes growth in the pistil and cytoembryology. Cultivars’ specificities in reproductive behaviour as pollen donors/recipients were considered in order to find solutions for adequate choice of cultivars combinations that yield the best performance in terms of good fruit set and satisfactory yields. Decades-long research work on self- and cross-(in)compatibility in cherries was started by monitoring fruit set percentage under field conditions, and was later considerably advanced by observing pollen tubes growth in the pistil using fluorescence microscopy. In recent years, *S*-genotyping of domestic and foreign sweet cherry cultivars has also been involved, using consensus primers that amplify the two introns of *S-RNase* and allele-specific primers.

Keywords: *Sweet and sour cherry, breeding, new cultivars, floral biology, S-incompatibility*

Introduction

Sweet cherry (*Prunus avium* L.) and sour cherry (*Prunus cerasus* L.) belong to the *Rosaceae* family, *Prunus* genus and *Cerasus* subgenus. *P. avium* has a diploid genome, whereas *P. cerasus* is an alotetraploid species, originting as a result of natural hybridisation involving *P. avium* (producing unreduced gametes) and tetraploid *P. fruticosa* (ground cherry) (Dirlewanger *et al.*, 2007).

Cherries are among the most popular temperate fruit crops, due to their attractiveness in appearance, high nutritive value and suitability for both fresh consumption and different kinds of industrial and domestic processing. Compared to other temperate fruits, breeding improvements have been relatively slow, in particular in sour cherry. In recent time, the integration of the molecular markers in breeding programmes has had a strong impact on breeding achievements.

In the structure of fruit growing in the Republic of Serbia, cherry has an important place, especially in sour cherry production which, together with raspberry, represents the country’s most important exporting fruit (Cerović and Radičević, 2008; Budan *et al.*, 2013; Lukić *et al.*, 2016). The work on developing new cherry genotypes at Fruit Research Institute (FRI), Čačak resulted

in realization of two sweet cherry and five sour cherry cultivars, as well as numerous promising hybrids which are under the evaluation process. Using modern methods in investigation of fertilization biology and determination of *S*-genotype are important parts of cherry breeding work at FRI, Čačak.

In this paper, we refered to the most important achievements at FRI, Čačak in the field of cherry breeding, floral biology and identification of incompatibility alleles.

Planned hybridisation within *Prunus avium* L.

The work on breeding sweet cherries at FRI, Čačak has been in progress since 1960. The objectives were developing cultivars of differing ripening time, with large, high-quality fruits resistant to cracking, with early, abundant and regular bearing, moderate vigour and compact growth habit. Cultivars should have crisp flesh and deep red or yellow ground colour, high flesh/stone ratio, improved resistance to pests and disesaes, and hardiness to winter and late spring frosts (Milenković *et al.*, 2006). In 254 crosses, 40 cultivars were used as female parents (acceptors) and 56 as male parents (donors). The best progenies were originated from the crosses 'Majova Rana' × 'Drogan's Yellow', 'Emperor Francis' × 'Cassin's Early', 'Majova Rana' × 'Schrecken Bigarreau', 'Stella' × 'Van', 'Van' × 'Stella', 'Stella' × 'Bing' (Budan *et al.*, 2013). More than 5,000 hybrid seedlings were obtained, out of which 60 were designated as promising. Only 14 were singled out as elite, and certain number of them was tested in several localities in comparative cultivar trials. Two genotypes were released as cultivars – 'Asenova Rana' ('Drogan's Yellow' × 'Majova Rana') and 'Čarna' ('Majova' × 'Schrecken Bigarreau').

Planned hybridisation within *Prunus cerasus* L.

The work on the improvement sour cherry genotypes at FRI, Čačak, started concurrently with sweet cherry (1960). The breeding goals were to obtain self-fertile, highly cropping cultivars, with different ripening time, large and good quality fruits, suitable for freezing, industrial processing and fresh consumption, with favourable flesh/stone ratio, dark red or colourless juice that does not bleed at separation from the stalk (Milenković *et al.*, 2006). A special attention has been paid to obtaining genotypes tolerant/resistant to cherry leaf spot (*Blumeriella jaapii* (Rehm.) v. Arx.), brown rot (*Monilinia laxa* /Ader et Ruhl./ Honey ex Whetz.) and shot-hole (*Clasterosporium carpophilum* (Lév.) Aderh.) (Lukić *et al.*, 2012). In the first phase, planned hybridisation included 33 cultivars used as female parents and 52 as male parents, in 125 crosses. The best progenies were derived from the crosses 'Köröser Weichsel' × 'Heimanns Konserven Weichsel', 'Köröser Weichsel' × 'Richmorency', 'May Sour Cherry' × 'Heimanns Konserven Weichsel', 'Köröser' × 'Heimanns Rubin', 'Heimanns Konserven Weichsel' × 'May Sour Cherry' and 'Čačanski Rubin' × 'Heimanns Konserven Weichsel'. More than 20,000 hybrid seedlings were obtained, 80 of which were singled out as promising; 25 were designated as elite and evaluated in comparative varietal trials. Two of them are registered as cultivars – 'Čačanski Rubin' ('Shasse Morello' × 'Köröser Weichsel'), and 'Šumadinka' ('Köröser Weichsel' × 'Heimanns Konserven Weichsel').

In the second phase, 11 sour cherry genotypes were selected from the population of 3,000 hybrid seedlings (Cerović *et al.*, 1998; Nikolić *et al.*, 1999), and four of which have been singled out as elite, due to high quality fruits and a significant level of field resistance to economically most serious pests and causal agents of diseases (Radičević *et al.*, 2010). In 2015, three of them were released as new sour cherry cultivars (Radičević and Cerović, 2015):

'Sofija' ('Čačanski Rubin' × 'Heimanns Konserven Weichsel') – It is a mid-early ripening cultivar (the second decade of June under the West Serbia condition), with large to very large fruits (7.0 g on average), roundish in shape. The skin is ruby-red coloured, and the flesh is red,

sweet-subacid, of pleasant aroma and excellent quality. The juice is red. The stone is medium large, and stalk is very long, easily separating from the fruit, without leakage of juice. It is a regular and heavy cropper, showing a high level of field resistance to *Blumeriella jaapii*.

'Nevena' ('Köröser Weichsel' × 'Heimanns Konserven Weichsel') – The ripening time is mid-late (the beginning of third decade of June under the West Serbia condition). The fruit is large to very large (7.0 g on average), with dark red skin and flesh, of a pleasant aroma and high quality. The juice is intensly coloured. The stone is small to medium large, and the stalk is short to medium long. It is tolerant to *Blumeriella jaapii*. The fruits are of the excellent quality, good transportability, suitable both for fresh consumption and different kinds of processing.

'Iskra' ('Köröser Weichsel' × 'Heimanns Rubin') – The ripening time is mid-late (third decade of June under the West Serbia condition). The fruit is large to very large (7.5 g on average), of flattened-spherical shape, with light red skin colour, and whitish mesocarp of a pleasant aroma and excellent quality. The juice is light red, the stone is small, and the stalk is medium long. With the presence of adequate pollenisers, it is a regular and heavy cropper. It is tolerant to *Blumeriella jaapii*. The fruits are of a high quality, suitable both for fresh consumption and different kinds of processing.

The new breeding programme within *P. cerasus* at FRI started in 2011, and is in accordance with the requirements of the modern sour cherry production, both regarding the breeding objectives and the proper choice of parental genotypes. New sour cherry cultivars ought to possess a high cropping potential, and a fruit quality to suit the needs of industrial processing and fresh consumption (fruit size, low share of stone in the total fruit weight and easily detachable stone, as well as a high soluble solids content with a good balance of sugars and acids). Tolerance to *Blumeriella jaapii* is one of the major breeding goals. The relatively short span in the ripening time among the commercially important cultivars imposes a need to prolong the harvesting season, especially with earlier-ripening cultivars. Important goals are also self-fertility, and suitability for mechanical harvesting (medium vigour and upright growth of branches, even ripening time, fruit firmness and resistance to bruises, as well as easy detachment of stone and absence of juice leakage at separation of fruit from the stalk). The concept was significantly influenced by the fact that the pedigree of the commercially significant cultivars is dominated by a relatively small number of genotypes. Due to modern breeding trends imply the use of genetic potential from indigenous genotypes (predominantly from the South-Eastern Europe, which is characterised by a significant diversity within *P. cerasus*), the programme aims to unify the desired characteristics of the genotypes obtained from the planned hybrids population (domestic and introduced cultivars, promising hybrids) and from the natural populations (indigenous genotypes).

Floral biology investigation

In addition to conventional breeding method, the investigations at FRI, Čačak are also focused on the different aspects of fertilization biology in cherries.

Due to the fact that cherry genotypes are mostly self-incompatible, the knowledge of possibilites for cross-pollination and fertilization is essential for an adequate choice of cultivar combination that ensures abundant fruit set. Effective pollination among compatible cultivars is related to their flowering time (early, mid-early, mid-late and late flowering cultivars), which is an important part of floral biology investigation at FRI (Radičević *et al.*, 2008, 2012). Perennial overlap during the phenophase of full flowering for a period of 5–8 days is the crucial for a successful cross-pollination in commercial orchards (Cerović *et al.*, 2005); the overlap should be accompanied by a short span in the beginning of full flowering among the cultivars (2–3 days). On the basis of the average full flowering overlap in sweet cherry cultivars in West Serbia conditions and

classification of the cultivars among different incompatibility groups, recommendations for their effective cross-pollination and fertilization in sweet cherry orchards have been offered (Radičević *et al.*, 2011, 2015).

Pollen quality in cherries is one the key aspects of reproduction process which to a great extent influences its efficacy and consequently the realization of the cropping potential. Pollen vitality and *in vitro* germination is directly related to the regularity of the microsporogenesis process (Cerović, 1991a). Special attention has paid to investigation of temperature influence on pollen *in vitro* germination (Cerović and Ružić, 1992a). In different introduced sweet cherry cultivars, pollen germination *in vitro* can be the first indicator of their adaptability to agro-environmental conditions (Radičević *et al.*, 2012, 2013b), from the standpoint of regularity of phases within the fertilization process. On the other hand, the importance of pollen morphology in clarifying the classification of many plants has been recognized from taxonomists, paleobotanists and breeders. Examination of sweet cherry pollen grains by scanning electron microscope (SEM) has not only revealed differences in pollen size, coarseness, depth of ridges, striation of exine among the cultivars, but it could also be of a great importance for identification studies (plant breeders, gene banks) and helpful in studying the gene flow (Radičević *et al.*, 2013b).

Pollination experiments followed by monitoring the pollen tubes growth in the pistil by fluorescent microscopy and monitoring the fruit set are important parts of floral biology investigation at FRI, Čačak. Pollen tube growth *in vivo* shows the dependence with respect to pollen germination *in vitro* in sour cherry (Cerović and Ružić, 1992a) and sweet cherry (Radičević *et al.*, 2016). Our investigation showed that in cherries, the pollen-pistil interaction manifests through the gametophytic self-incompatibility system (Cerović, 1997; Bošković *et al.*, 2006; Radičević *et al.*, 2013a), but it occurs in compatible crosses too, so the pollen performance and final outcome of the fertilization represents overlapping effect of several factors – polleniser genotype, behaviour of pollenisers at different temperatures, the influence of pollinated cultivar on pollen performance, the influence of temperature on male-female relations (Radičević *et al.*, 2016).

Investigation of functionality of female flower elements conducted using fluorescent-microscopy and histological methods pointed to its dependence of genotypic factors and the temperature during the full flowering phenophase (Cerović, 1991b; Cerović and Ružić, 1992b; Cerović *et al*., 1999, 2014; Radičević *et al.*, 2016). The aforementioned factors were considered in the context of temperature conditions, bearing in mind the effects of global warming, and incidence of seasons with higher temperatures during the flowering in main cherry regions in the Republic of Serbia.

The study of *S*-allelic constitution in cherry genotypes

Cherries exhibits a S-RNase-based gametophytic self-incompatibility system, in which self-pollen rejection is controlled by alleles of the stylar (*S-RNase*) and pollen (*SFB*) specific genes. Diploid sweet cherry is generally self-incompatible, while tetraploid natural sour cherry genotypes include both self-incompatible and self-compatible types, although polyploidy per se does not result in self-compatibility. The *S*-genotype of cherry cultivar is an agronomically important trait, which provides useful information for breeders using it in crossing programmes and as genetic marker, and indeed for growers in order to achieve an effective pollination. In the recent period, determination of *S*-genotype of domestic and foreign sweet cherry cultivars using the consensus primers that amplify the first and the second introns of *S-RNase* (PaConsI-F + -R and PaConsII-F + -R, respectively) and allele-specific primers has been applied in the laboratory of Department of Pomology and Fruit Breeding at FRI, Čačak (Radičević *et al*., 2013a, 2015; Marić *et al*., 2014, 2015). The high polymorphism of *S-RNase* (25 alleles have been identified so far) has been used for cultivar identification and discrimination (Radičević *et al*., 2015; Marić *et*

al., 2015), determination of *S*-genotype and incompatibility group in some old cultivars which have not been published earlier, i.e. 'Majova Rana' (S_1S_4; incompatibility group IX), 'Junska Rana' (S_3S_9; incompatibility group XVI) (Marić *et al*., 2014, 2015) and assessment of self-(in)compatibility in some sweet cherry cultivars (Radičević *et al*., 2013a). Current work is focused on the analysis of segregating progenies in order to elucidate the nature of self-compatible behaviour in some sweet cherry genotypes, as well as on determination of *S*-allelic constitution in autochthonous genotypes and newly released sweet cherry cultivars and hybrids within breeding programmes in the Balkan region.

Conclusion

The new cherry genotypes, together with the ones that were released previously at FRI, Čačak, will represent an important base for the production of cherry fruits, as well as a base for further breeding programmes within *P. avium* and *P. cerasus*. The application of methods of reproductive and molecular biology within the conventional cherry breeding programme will improve efficiency in developing new cultivars by enabling proper choice of parental genotypes and early selection for adult traits.

Acknowlegdement

This work was conducted under Research Project *TR−31064: Development and preservation of genetic potential of temperate zone fruits*, supported by the Ministry of Education, Science and Technological Development of the Republic of Serbia.

Abstract

Traits of the F_1 generation of maize hybrid seed were observed in four SC combinations produced in two locations. Agro-ecological conditions for the production of hybrid seed in these locations during three years differed. The coefficient of variation for germination energy and seed germination was 0.71% in ZP 341 during the first year. Produced seed of all observed hybrids was of satisfactory quality. The analysis of data shows that seed germination and energy (2.56% CV) varied the most in the hybrid combination ZP 434 in the three-year experiment. According to the location assessment, established differences in traits were greater, and the coefficient of variation for both locations amounted to $0.9 \leq 3.21$. The effect of agro-ecological conditions differed over locations during the same production season. According to obtained results, agro-ecological conditions have an essential role on the formation of traits of hybrid seed. Based on gained results, the level of expression of the two observed traits in all four hybrids was high under all agro-ecological conditions. Moreover, effects of the factors (hybrid and location) on germination energy and seed germination were high.

Key words: *maize, location, germination, variability.*

Introduction

The necessary and appropriate number and arrangement of plants in a commercial maize hybrid crop can be provided primarily by sowing seeds of good physiological and physico-mechanical traits.

With regard to both scientific and technological research, germination represents a physiological trait of maize hybrid seed that depends on remaining physiologcal traits of embryos and seeds, but also on the environmental conditions under which the research is carried out. Seed germination is a complex biochemical, physiological and morphological process in the formation of a new plant. According to Ujević and Kovačević (1972), the process of seed germination is proceeded through three stages. Germination is a process encompassing enzyme activation, degradation of insoluble reserve materials, translocation and mobilisation of soluble substances and growth-inducing reactions. The studies preformed by McDonalda et al. (1994) point out that the most active water intake by seeds occur during the first six hours of imbibition and that is more pronounced in the embryo than in the endosperm. Physico-mechanical and physiological traits of maize hybrid seed depend on agro-ecological conditions during the seed formation and maturation. Shien and Mc Donald (1982) observed the influence of a seed size and shape in two maize inbred lines on seed quality and established that there is no dependence on a seed size. There are numerous studies published in our country relating to the significance of the seed size and shape and their effects on germination (Đukanović et al. 2003; Pajić et al. 1997). According

to results obtained by Chassot (2000), in the no-tillage system, the air and soil temperatures are probably the main physiological stress factor during the early maize plant development. Stone et al. (1999) determined that the soil temperature directly affected meristematic tissues of radicles and shoots.

All traits of maize hybrid seeds depend on a genotypic combination and the interaction of this combination and agro-ecological conditions during the growing season of the seed crop. Lee et al. (2002) showed significant differences in tolerance of genotypes to low temperatures; these differences were manifested during various developmental stages of roots and above-ground plant parts.

The research programme encompassed experimental studies of traits of the F_1 generation of maize hybrid seed, mathematical and statistical processing, evaluation and the analysis of obtained experimental data.

Material and Methods

Seed of the following hybrid combinations, produced in two locations, Banat1 (L1) and Banat2 (L2), was used as a material in this study: ZP 341, ZP 434, ZP 684 and ZP 704. The material was produced by the application of similar cropping practices. Production locations differed in ecological and agro-ecological conditions.

Production trials were established for each hybrid combination according to standards prescribed in the *Regulation on control of the seed production of agricultural crops* (Official Gazette of RS, issue 60/2006).

Agro-ecological conditions were monitored during the production process, while data were obtained from the nearest hydrometeorological stations.

Working samples of 1000 g each were drawn from the natural seed material (25-30 kg) and used for the analysis of germination energy and seed germination.

The determination of seed physiological traits (germination energy and germination) was done at the standard temperature regime and filter paper: t=20/30^{o}C ((16:8) light : dark (L:D) photoperiod, white light at higher temperatures), germination energy for 4 days and germination for 7 days.

Each of obtained parameters was processed by the statistical analysis by the application of the descriptive statistics for parameters at the annual level (the period from 2006 to 2010). Differences among four observed maize hybrids in two locations in Bačka were established by the analysis of variance for the factorial trial set up according to the randomised block design and by the LSD test at the probability levels of 5% and 1% (Hadživuković, 1973). In order to draw objective conclusions on effects of observed parameters on tested maze seed traits and the possibility to apply parametric tests (ANOVA and LSD-test), homogeneity of variance was tested by the Levene′s test.

Results and Discussion

Results of the three-year study on the impact of a location and a year of production on physiological traits, energy and germination, point out to the minor variability of observed traits. Germination and energy values were above 90%, while the coefficient of variation (CV) did not exceed 4%. The influence of the production location was higher than the effect of the production year. Furthermore, the differences among hybrid combinations were also determined. The least variation was in the hybrid combination ZP 704 during the first year of production (G1, Table 1).

Table 1. Average values and variations for germination energy and seed germination over years of production

Year		Germination energy (ek)				Seed germination (uk)			
		ZP341	ZP434	ZP684	ZP704	ZP341	ZP434	ZP684	ZP704
G1	Average	97.51	97.41	96.55	95.32	97.5	97.46	96.50	95.31
	CV	0.71	1.13	0.42	0.14	0.71	1.13	0.43	0.14
G2	Average	96.50	95.23	95.35	96.74	96.5	95.25	96.23	98.00
	CV	0.71	2.56	0.14	0.14	0.71	2.56	1.13	0.01
G3	Average	92.22	94.25	94.71	94.57	91.7	94.71	94.74	94.85
	CV	0.28	0.84	0.42	1.55	0.42	0.14	0.42	1.98

The production location L2 caused the greatest variation in the hybrid combination ZP 341, while the combination ZP 684 with the coefficient of variation of 0.9% in the location L1 had the least differences in values of traits presented in Table 2.

Table 2. Average values and variations for germination energy and seed germination over locations of production

Location		Germination energy (ek)				Seed germination (uk)			
		ZP341	ZP434	ZP684	ZP704	ZP341	ZP434	ZP684	ZP704
L1	Average	94,80	95,47	95,33	95,07	94,80	95,47	95,33	95,53
	CV	2,99	2,47	0,90	1,60	2,99	2,47	0,90	2,32
L2	Average	95,67	95,73	95,67	95,93	95,67	96,07	96,27	96,53
	CV	3,21	1,86	0,99	0,76	3,21	1,29	1,10	1,33

Observed factors have a smaller or a greater statistically significant effect on germination energy and seed germination, as well as on their partial effect of action. Hence, both factors and their interaction too affect changes in germination energy and seed germination. It was determined that many factors affected the process of maize seed germination either individually and or in interactions, while the obtained results referred to the seed as a whole (Dačić et al. 1997, Sabovljević et al. 1997, Tabaković et al. 2015.).

The year of production is a factor that affected both energy and germination in all hybrid combinations. Moreover, the interaction of the two factors was significant. The significance of the location on the expression of seed germination was observed in the hybrid combinations ZP 434, ZP 684 and ZP 704, while energy varied under the effect of this factor only in the hybrid combination ZP 704 (Table 3).

The partial effect of the year on the physiological traits was the highest in ZP 341 ($\eta 2$= 0.817, $\eta 2$=0.779). On the other hand, this effect of the location was small in all hybrid combinations and ranged from $\eta 2$= 0.001 to $\eta 2$=0.4639, while the interaction of factors with its partial effect caused the greatest variation in seed germination in ZP 434 ($\eta 2$=0.480) (Table 3).

The year of production as a factor had a significant effect on energy and germination in all hybrid combinations. Furthermore, the interaction of two factors was significant. Effects of the location on seed germination were significant in the following three hybrid combinations ZP 434, ZP 684 and ZP 704, while energy varied under the influence of this factor only the hybrid combination ZP 704 (Table 3).

The partial effect of the year on physiological traits was the greatest in ZP 341 ($\eta 2$= 0.817, $\eta 2$=0.779), while it was small in remaining hybrid combinations ranging from $\eta 2$= 0.001 to

η2=0.4639. In addition, the partial effect of the interaction of factors was greatest on seed germination in ZP 434 (η2=0.480) (Table 3).

Conclusion

All stated factors affect expression of traits of maize hybrid seeds to a different extent and in different ways: directly; more or less indirectly, through greater or smaller interactions and in altering ways;

Average values and variations of traits of maize hybrid seed represent a resultant of actions of all mentioned factors in all stated ways of their actions.

Results of the analysis of variance, i.e. values of the F-test and probabilities of these values, point out that the effect of certain factors is not the same for the expression of all seed traits and all hybrid combinations.

Abstract

In this study, 8 pop corn (*Zea mays* L. Everta) genotypes were used. Five ear characteristics of 8 pop corn genotypes (6 local pop corn genotypes and 2 local pop corn varieties) were examined. Local corn genotypeswere collected from Tokat -Erbaa district, Samsun-Bafra district, Ordu-Çamaş district, Ordu-Perşembe district, Ordu-Ulubey district and Konya in the Turkey in 2014. And also, local corn varieties were used such as Ant-Cin 98 and Nermin-Cin as proprietary in kinds. At this study, field and laboratory studies were completed in 2015. The experiment was conducted in 3 replicates according to a randomized block design. At this study, ear length, ear diameter, number of row per ear, number of kernel rows per ear, 1000-grain weight and popping volume were investigated. The ear length, ear diameter, number of row per ear, number of kernel rows per ear, 1000-grain weight and popping volume characters were determined ranging 16.87-18.40 cm, 32.67-36.33 mm, 11.60-20.13 units, 40.47-47.07 units, 94.33-224.40 g and 6.63-20.93 cm^3 g^{-1} respectively. Research results showed that there were not high variations in ear length, ear diameter, number of row per ear, number of kernel rows per ear from examination characteristics. However, number of row per ear, 1000-grain weight and explosion volume were determined statistically significant ($P<0.001$). The most number of row per ear value was obtained in Tokat-Erbaa district, 1000-grain weight's highest value was obtained in Ordu-Çamaş district and also highest popping volume value was obtained in Samsun-Bafra district. According to these results, the ear features of local corn genotypes have equivalent Ant-cin 98 and Nermin-cin varieties without number of row per ear, 1000-grain weight and popping volume features.

Keywords: *local pop corn, ear characteristics.*

Introduction

Maize (*Zea mays* L.) is one of the important cereals grown in all over the world and also maize is the third most widely circulated crop of the world, being grown in diverse seasons and ecologies with highest production and productivity among food cereals. Popcorn is different from other maize types with its popping ability. Popcorn has a special place in human nutrition of nutrient content as high fibre, vitamins and minerals it contains (Öztürk et al., 2016). It is also healthy and nutritious snack product with the stomach acid absorption, reducing the feeling of hunger, giving the feeling of satiety and being low in calories as a whole grain (Jele et al., 2014; Soni et al., 2014; Öztürk et al., 2016). Nutrional composition of popcorn showed that it contained 3.8 to 4.6% oil, 8.1 to 10.5% protein, and 61.0 to 67.9% starch (Soni et al., 2014). Popcorn explodes when exposed to heat treatment and produce flakes. Therefore, the use of popcorn (*Zea mays* everta Sturt.) as a snack food has been increasing continuously throughout the world.

Grain yield and popping volume are very important agronomic traits in popcorn as in other corn types. The most important factor effecting grain yield and popping volume in popcorn are

genotype (Sakin et al., 2005). Popping properties were mostly effected by physical properties of the popcorn kernels. Ear traits, kernel type, moisture level, kernel size, 1000 kernel weight, test weight, flake size and popping method are effective on popcorn quality parameters (Allred Coyle et al., 2000). Generally, popcorn germplasm has a narrow genetic basis. So that the higer yield and popping volume, new popcorn hybrids have almost completly replaced local varieties. It is provide by effectively a breeding programme. Landraces of maize represent a valuable genetic resources for breeding and genetics studies. Therefore, at the breeding programs is preferred local genotypes that maize populations are rich source of genetic variability, providing the necessary raw materials for maize breeding programs.

İn this study, we aimed that 8 difference local popcorn genotypes determinated of some ear characteristics and popping traits. And also, these traits were examined of availability.

Materials and Methods

The study was conducted in the research fields of the Eastern Mediterranean Gateway Zone Agricultural Research Institute in Kahramanmaras, Turkey in 2015. During flowering in maize, relative humidity is below 50%, maximum temperature is over 40 ° C and it seems to have little or no rainfall in Kahramanmaraş. Long-term average precipitation for this region was 25.3 mm/year. The amounts of total downfall in the vegetation periods of 166.5 mm/year was less than the long-term average. Plants were irrigated eight times until sowing to harvest. The average temperatures of the growing season was 24 °C. Soils of the research area had a texture classification of Sandy clay loam. The soils were slightly alkaline, medium in lime content, and very low in salt content. The soils were rich in available phosphorus (P) and potassium (K) (Anonymous, 2015). Thus, fertilizer of 25 kg N, and 10 kg P_2O_5 ha^{-1} was applied. To be used in the experiment 8 pop corn genotypes, (6 local pop corn genotypes and 2 local pop corn varieties) were obtained from Tokat -Erbaa district, Samsun-Bafra district, Ordu-Çamaş district, Ordu-Perşembe district, Ordu-Ulubey district and Konya in the Turkey in 2014 (Table 1). These genotypes were tested to determine grain yield and some ear characteristic in growing seasons of 2015. The experimental design was a randomized complete block with three replications. Seeds were sown in the first week of May in four-row plots, 5 m long, with 70 cm between rows. The standard maize growing technique was practiced. In this study, ear length, ear diameter, number of row per ear, number of kernel rows per ear, 100-grain weight and popping volume were investigated for genotypes. Harvest was made the first week of September. Ear length, ear diameter, number of row per ear, number of kernel rows per ear, 100-grain weight and popping volume were investigated. Popping expansion was measured in sample of 50.0 g of seeds. Popping tests were performed by using a hot air popping machine (Premier PPM 2021 900W). The moisture content of samples was 14±0.5% before popping. Popped samples were poured into a 2000 mL glass beaker, and volume recorded (Sakin et al., 2005). According to the analysis carried out in the investigation of properties, SAS program used for analyzing and Tukey test was used for grouping.

Results and Discussion

Ear length: There were not statistically significant ($p>0.05$) differences among the all of the genotypes the terms of ear length. The longest ear (18.40 cm) was obtained from Ordu-Perşembe district genotype and the lowest one (16.87 cm) was obtained from Konya Pop (Table 1).

Variations in ear characteristics of maize depend on genotype, environmental conditional and genotype x environmental interaction (Şener et al., 2004). Also, ear length trait affected by plant densities (Gökmen et al., 2001; Şener er al., 2004). According to previously studies were reported

that ear diameter have measured as 16.19-18.1 cm (Şener et al., 2004), 12.92-17.50 cm (İdikut et al., 2015), 17-20 cm (Tekkanat and Soylu, 2005), 15.7-16.9 cm (Gökmen et al., 2001), 13-17 cm (Sezer and Yanbeyi, 1997), 11-17 (Özkaynak and Samancı, 2003), 19-21 cm (Eşiyok et al., 2004), 17-19 cm (Öktem et al., 2004), 12-18 cm for dent corn (Saruhan and Sireli, 2005), 21-23 cm (Çetinkaya and Dura, 2010), 13.0-15.1 cm (İdikut et al., 2012) and avaraged 19 cm for firt crop, 18 cm for second crop on popcorn genotypes (Koca et al., 2010). In the previously studies were supported that our findings and difference the length of ear depends varieties, the environment and the process.

Ear diameter: There were not statistically significant ($p>0.05$) differences among the all of the genotypes to ear diameter. The thickest ear (36.33 mm) was obtained from Ordu-Ulubey district genotype and the thinnest one (32.67 cm) from Samsun-Bafra district (Table 1). Variations in ear diameter depend on genotype and environmental conditions as in ear length. According to previously studies were reported that ear diameter were measured at 24-29 mm in popcorn genotypes and 26-30 in hibrids (Özkaynak and Samancı, 2003), 42-43 mm (Eşiyok et al., 2004), 36-39 mm in dent corn (Saruhan and Sireli, 2005), 33-44 mm (Tekkanat and Soylu, 2005), 52-55 mm (Çetinkaya and Dura, 2010), 30.2-40.1 mm (Farsiani et al. 2011), 28.3-30.7 mm (İdikut et al., 2012), 40.2-50.2 mm (Peykarestan and Seify, 2012), 27-33 mm (İdikut et al., 2015). Mani and Dadari (2003) has announced the features that make the greatest contribution to the efficiency that one ear diameter. In the previously studies were supported that our results.

Table 1. Genotypes and kernel colour, ear length, ear diameter, number of row per ear, number of kernel rows per ear, 100- grain weight and popping volume values belonging to genotype.

Genotype No	Genotypes Sources	Kernel Colour	Ear Length	Ear Diameter	Number of Row Per Ear	Number of Kernel Rows Per Ear	1000-Grain Weight	Popping Volume
1	Ordu-Ulubey district	Yellow	17.87 ^{A}	36.33 ^{A}	16.37 ^{B}	47.07 ^{A}	185.50 ^{B}	6.63 ^{C}
2	Ant-Cin	Yellow	16.93 ^{A}	32.77 ^{A}	16.40 ^{B}	42.47 ^{A}	137.03 ^{C}	20.11 ^{A}
3	Konya	Yellow	16.87 ^{A}	33.60 ^{A}	15.87 ^{B}	40.47 ^{A}	143.87 ^{C}	16.17 ^{A}
4	Nermin-Cin	Dark yellow (Orange)	18.03 ^{A}	33.33 ^{A}	15.47 ^{B}	42.87 ^{A}	123.25 ^{C}	19.25 ^{A}
5	Tokat-Erbaa district	Light yellow	17.93 ^{A}	35.33 ^{A}	20.13 ^{A}	43.93 ^{A}	132.60 ^{C}	19.50 ^{A}
6	Samsun-Bafra district	Yellow	17.83 ^{A}	32.67 ^{A}	14.93 ^{BC}	43.40 ^{A}	94.33 ^{D}	20.93 ^{A}
7	Ordu-Çamaş district	Red	18.00 ^{A}	33.97 ^{A}	12.93 ^{BC}	43.87 ^{A}	224.40 ^{A}	9.05 ^{C}
8	Ordu-Perşembe district	Red	18.40 ^{A}	33.03 ^{A}	11.60 ^{C}	44.60 ^{A}	195.97 ^{B}	7.29 ^{C}
F and P values			F=0.93 P=0.5117	F=1.60 P=0.2047	F=12.73 P<.0001	F=1.78 P=0.1613	F=95.63 P<.0001	F=99.19 P<.0001

Number of row per ear: There were statistically significant ($p>0.01$) differences among the all of the genotypes to number of row per ear. The most number of row per ear (20.13 units) was

obtained from Tokat-Erbaa district genotype and the least one (11.60 units) from Ordu-Perşembe district genotype (Table 1). In the other studies have announced that the number of row per ear were 11-17 units in inbred popcorns and 13-15 units in hybrids (Todorovic et al., 2012), 12-16 units (İdikut et al., 2015), 12-14 units in popcorn genotypes and 13-15 units in hibrids (Özkaynak and Samancı, 2003), 15-17 units (Eşiyok et al., 2004), 13-17 units (Tekkanat and Soylu, 2005), 14.66-17.5 units (İdikut et al., 2012). Earlier studies on the number of ear rows were saved between 13-17 units. The genetic characteristics of corn varieties are affect on the number of ear rows. Therefore, our results were in agreement with earlier studies.

Number of kernel rows per ear: There were not statistically significant differences among the genotypes for number of kernel rows per ear. The most number of kernel rows per ear (47.07 units) was obtained from Ordu-Ulubey district genotype and the least one (40.47 units) from Konya popcorn genotype (Table 1). In the previously studies, the number of kernel row pere ar changed between 20-33 units for genotypes and 30-42 units in hibrids (Özkaynak and Samancı, 2003), 36-41 units (Eşiyok et al., 2004), 36-46 units (Tekkanat and Soylu, 2005), 22.7 - 51.0 units (Cengiz, 2006), 28.56-37.66 units (İdikut et al., 2012) and 29.32-40.86 units (İdikut et al., 2015). Our study results were consistent with earlier studies. Environmental conditions (temperature, water, nutrients) effects may be dominant genetic structure on number of kernel rows per ear. Therefore, the number of kernel rows per ear can be very variable.

1000-grains weight: There were statistically significant ($p<0.01$) differences among of the genotypes to 1000-grains weight. The highest 1000-grains weight (224.40 g) was obtained from Ordu-Çamaş district genotype and the lowest one (94.33 g) from Samsun-Bafra district genotype (Table 1). The weight of 1000- kernels was affected with genotype and environment condition. In the previously studies have reported that the weight of 1000- kernels was 132 g (Ulloa et al., 2010), 163.5-173.5 g (Peykarestan and Seify, 2012), 114-123 g (İdikut et al., 2012), 86-140 g in genotypes and 83-115 g in hibrids (Özkaynak and Samancı, 2003), 291-342 g in hibrids varieties (Öktem et al., 2004), 129-213 g in hibrid popcorn (Gökmen et al., 2007), 390-407 g in hibrids verieties (Çetinkaya and Dura, 2010), 309 g in first crop popcorn and 296 g in second crop popcorn (Koca et al., 2010) and 209-368 g in hibrids verieties (Kuşaksız, 2010). At the earlier studies were observed that the weight of 1000- grains on maize plant is change as variety, environmental condition and applied the method.

The our finding were consistent with some earlier studies. But it were not consistent with others, because used varieties at these studies were dent corn or flint corn.

Popping volume: There were statistically significant ($p<0.01$) differences among the all of the genotypes to popping volume. The highest popping volume (20.93 cm^3 g^{-1}) was obtained from Samsun-Bafra district and the lowest one (6.63 cm^3 g^{-1}) from Ordu-Ulubey district genotype (Table 1). Ant-Cin (20.11 cm^3 g^{-1}), Tokat-Erbaa (19.50 cm^3 g^{-1}), Nermin-Cin (19.25 cm^3 g^{-1}) and Konya genotype (16.17 cm^3 g^{-1}) have a high popping volume and these genotypes were determined that statistically same group with Samsun-Bafra district. İdikut et al. (2015) were reported that popping volume values were changed between 10-23 cm^3 g^{-1} on different local popcorn lines. At the other some searcher were announced that popping volume values were determinated as change between 38-48 cm^3 g^{-1} in hibrid genotypes (Öz and Kapar, 2011), 44.7-47.3 cm^3 g^{-1} (Sweley et al., 2012), 1288-25.75 cm^3 g^{-1} (Jele et al., 2014), 10-23 cm^3 g^{-1} (İdikut et al., 2015), 16-47 cm^3 g^{-1} in some single, three way and double cross popcorn hybrids (Sakin et al., 2005).

The factors affected popping volume are moisture content, popping temperature, popping method, kernel size, shape and weight, variety or genotype, kernel density, drying condition, and kernel damage (Ertaş et al., 2009; Ceylan and Karababa, 2001; Allred Coyle et al., 2000).

Ertas et al. (2008) were reported that popping volume is evolves at %12 moisture in popcorn and kernel size, shape and colour values are effects popping volume. We have obtained in our study results were very high. The reason of this may be that kernel weight will be popped kernels or popping method.

Conclusion

Overall, the study found significant variability among local popcorn genotypes for number of row per ear, 1000-grain weight and popping volume traits. The most number of row per ear was Tokat-Erbaa district genotype, the highest 1000-grain weight was Ordu-Çamaş district genotype, while the highest popping volume was Samsun-Bafra district. Amoung the genotypes don't found statistically significant variability to other traits. Therefore, the ear features of local corn genotypes have equivalent Ant-cin 98 and Nermin-cin varieties without number of row per ear, 1000-grain weight and popping volume features.

Abstract

Field pea grown for grain and forage is an important protein source which can improve milk and meat production. Along with common vetch, field pea is the most important annual forage legume in Central Serbia, and can substitute alfalfa, whose potential for expansion has been constrained by large areas of acidic soils. As a legume, field pea also plays a major role in field crop rotations, and has been increasingly used in conventional, integrated, organic and sustainable farming systems. Under dryland conditions, grain yield of spring pea cultivars 'NS-Junior' and 'Javor' was analyzed in 2011, 2012 and 2014 on an acidic soil receiving amendments. The field trial was established in Čačak (43°54'39.06" N, 20°19'10.21" E, 246m a.s.l.) on an alluvial soil acid in reaction (pH_{H2O} 4.8). The entire experimental field was fertilized with 300 kg ha^{-1} $N_{15}P_{15}K_{15}$. In addition to an untreated control, two liming treatments were applied, at rates of 3t ha^{-1} and 6t ha^{-1}. The experiment was laid out in a randomized complete block design with four replications. Plot size was $5m^2$ (1x5m). 'Javor' gave a significantly higher average grain yield compared to 'NS-Junior'. There was no significant difference between the control and lime treatments. In all three years, grain yield was significantly below the genetic potential of the cultivars, largely due to rainfall deficiency, delayed sowing dates, and very dry soil and air conditions during critical stages of plant growth and development.

Key words: *pea, protein, grain, production systems, yield*

Introduction

Growing field pea for grain and forage is part of the livestock development strategy, given the potential of field pea as a good source of protein to increase milk and meat production. This is of particular importance for livestock farmers in Central Serbia, as well as in other regions of the Balkans, who are facing problems associated with alfalfa production on acid soils. Along with common vetch, field pea is the most important annual forage legume on arable land in Serbia (Mihajlović et al., 2004). A major goal of selection programs on annual forage legumes is to create cultivars adaptable to diverse agroenvironmental conditions (Mihajlović and Mikić, 2010), given their significant effect on the percentage of seeds formed in different years and at different seeding dates (Erić et al., 2007).

The advantage of field pea over soybean is that its grain does not require heat treatment prior to feeding. All feed pea cultivars created in Novi Sad (Serbia) have low or very low trypsin inhibitor levels, which is in accordance with current European Union regulatory requirements (Mikić et al., 2009). Moreover, field pea is an important component of crop rotations as it contributes to soil fertility regeneration through its symbiotic relationship with nitrogen-fixing bacteria (Stoddard et al. 2009). The frequent occurrence of arid events has led to the need to use appropriate crop

rotations in dryland farming, along with other cultural practices, in an attempt to reduce the adverse effect of water deficiency during the growing season of the crop. Field pea is of great significance in organic and sustainable farming systems as it provides a rich source of protein and mineral elements (Ćupina et al., 2004, Corre-Hellou & Crozat, 2005, Lauk & Lauk, 2008). As other legumes, field pea plays an important role in organic farming since it reduces weed infestation, improves soil quality and acts as an excellent crop for companion planting, green manuring and environmental corridors (Bokan et al., 2016). Acid soils require amelioration for improvement of their productivity (Dugalić, 1997, Broćić, 1997, Bošković Rakočević, 2003, Bošković Rakočević and Bokan, 2005, Bokan et al., 2010).

Material and methods

A field trial was established in city of Čačak area (43°54'39.06" N, 20°19'10.21" E, 246 m a.s.l.) in Serbia) on an alluvial soil acid in reaction (pH_{H2O} 4.8), containing 3.18% organic matter, 0% $CaCO_3$, 22.08 mg P_2O_5, 30.0 mg K_2O 100 g^{-1} soil. The entire experimental field was fertilized with 300 kg ha^{-1} $N_{15}P_{15}K_{15}$. In addition to an untreated control, the experiment included treatments with 3t ha^{-1} and 6t ha^{-1} lime worked into the soil through secondary tillage using a disk harrow. The experiment was set up in a randomized complete block design with four replications. Plot size was 5m^2 (1x5m). Manual weed control was carried out twice. The crop was not irrigated during the growing season.

Two cultivars of spring field pea 'NS Junior' and 'NS Javor' were used. 'NS Junior' is of excellent quality, with a crude protein content of 25-28% in the grain. The cultivar is also intended for combined use (green forage and grain). It is the most common field pea cultivar in Serbia, since it produces grain yields of more than 5t/ha under favorable conditions. 'Javor' is grown for grain, and has an average crude protein content of 24.4 %. In three-year VCU trials, this cultivar gave an average grain yield of 5.41 t/ha (Erić et al., 2007).

Results were subjected to a two-way analysis of variance (ANOVA) using SPSS 4.5 software. The significance of differences between treatment means was assessed by the LSD test.

Climatic conditions

The average temperature in the experimental years was above the long-term average (Table 1). April, June and July in all three years were also warmer than average. Annual rainfall totals decreased by 222.6 mm in the first year and by 120.4mm in the second year, and increased by 201.8 mm in the third year compared to the long-term average. In the Republic of Serbia, 2011 was an extremely dry year. In the following year 2012, rainfall total increased by 107.2 mm in the region of Čačak, and this year seemed to be more favorable for the crop. However, only the rainfall total during April and May was higher than the long-term average, whereas only 56.9 mm of rain was received in the following three months. This indicates that 2012 also had an unfavorable distribution of rainfall. In 2014, rainfall total was 892 mm on an annual basis and 653 mm during the April-September growing season, with only August being close to the long-term average, whereas the rainfall total for the other months was higher than the long-term average. These values suggest that rainfall totals and rainfall distribution were the most favorable in the third year.

Table 1. Monthly precipitation, growing season precipitation and temperature in Čačak

Month	Air temperature (°C)				Precipitation (mm)			
	2011	2012	2014	Normal	2011	2012	2014	Normal
January	0.7	0.5	4.1	0	18.5	99.4	21.5	44.1

Results and discussion

The average grain yield in 2011 was 2.66 t/ha (Table 2). 'Javor' had a significantly higher yield (2.78 t/ha) compared to 'Junior' (2.54 t/ha).

Table 2. Effect of soil liming on grain yield (t ha^{-1}) of pea cultivars 'NS-Junior' and 'Javor' in 2011

Treatments	'Junior'	'Javor'	$\bar{x}$
Ø	2.55	2.84	2.70
3t	2.51	2.70	2.60
6t	2.57	2.79	2.68

LSD 0.05		Cultivar (A)	0.234
		Liming (B)	0.286
		A x B	0.485

In 2012, the average grain yield was 1.65 t/ha (Table 3). 'Javor' gave a significantly higher yield (1.93 t/ha) compared to 'Junior'(1.37 t/ha).

Table 3. Effect of soil liming on grain yield (t ha^{-1}) of pea cultivars 'NS-Junior' and 'Javor' in 2012

Treatments	'Junior'	'Javor'	$\bar{x}$
Ø	1.30	1.82	1.56

		Cultivar (A)	0.199
LSD 0.05		Liming (B)	0.244
		A x B	0.345

Climatic conditions during the experimental years (Table 1) indicate that 2011 was generally more unfavorable for the crop than 2012. Nevertheless, grain yield was higher in this less favorable year, one of the reasons being the decrease in rainfall by 53 mm in June 2012, which is a critical period for the supply of water required for intensive grain filling in field pea. Moreover, the soil water deficit in June was accompanied by high mean daily air temperatures. The mean monthly air temperature for June increased by 2.3°C compared to the long-term average, and by 1.6°C compared to 2011. The highest average grain yield of field pea was obtained in 2014 which had the most favorable climatic conditions (2.85 t ha^{-1}). This finding is in agreement with the production potential and properties of the studied cultivars (Erić et al., 2007).

In all three years, lime applied at 3t/ha and 6 t/ha to ameliorate the acid soil did not affect the grain yield of field pea compared to the control. This suggests the potential for growing field pea under such soil conditions. Liming has a long-term effect in improving soil chemical properties; therefore, its short presence in the soil had no effect on grain yield (Bokan et al., 2013). Low grain yields indicate that field pea development is significantly affected not only by soil but also by climatic factors during the growing season. As in other annual forage legumes, rainfall distribution is an important contributor to consistently high yields. Given the variable distribution of rainfall across months in the experimental years, grain yield stability can be achieved by irrigation as a regular cultural practice.

Conclusion

In all three years, grain yield was significantly higher in 'NS Javor' than in 'NS Junior'.

Ameliorative liming did not have a significant effect on the grain yield of the tested cultivars. This result confirms the potential for growing field pea on acid soils.

Grain yield increases for this annual forage legume can be expected to come from improved production technology. As a legume, field pea plays an important role in field crop rotations, and has been increasingly used in conventional, integrated, organic and sustainable farming systems. In the long run, amelioration of acid soils as an integral part of the agricultural development strategy should be consistently practiced through appropriate organic fertilization and lime application dynamics.

Abstract

White, red and yellow are the most common basic colours of maize, but other colour varieties exist, like blue, purple, brown and orange. Maize kernels with diverse colours have pigments and other substances with antioxidant capacity that can be highly beneficial for human health. This paper deals with results of the effects of different fertilizers on yield of maize hybrids with different kernel colour in two-year period (2014-2015). Trial was set up on chernozem soil type in the experimental field of Maize Research Institute in Zemun Polje, Serbia. Maize hybrids differing in the kernel colour developed at the Maize Research Institute, Zemun Polje, Belgrade, Serbia, were selected for these study: red maize ZP Rumenka, white maize ZP 655b and yellow maize ZP 633. The treatments of fertilization consisted of following variants: control, mineral fertilizer AN, microbiological fertilizer Uniker and organic fertilizer under the trade name „Humus Vita Stallatico". On the basis of two-year results it is obvious that meteorological conditions have very significant influence on maize yield. The second season had weather pattern less favourable for the maze production due to severe drought and very high temperature during flowering. According to results the yield of different maize hybrids was significantly different depend on varieties too. Fertilization showed no significant influence on maize yield in this experiment. All maize hybrids have greater yield in 2014 growing season compared with 2015. Red coloured hybrid ZP Rumenka had very significant lower yield then white and yellow hybrid in both years. The highest yields were recorded on treatments with the organic fertilizer in maize with red and yellow kernels.

Key words: *maize, different coloured kernel, fertilizer, yield.*

Introduction

Coloured maize has different pigments and other substances with antioxidant capacity that can be highly beneficial for human health. There is a clear relationship between pigment content and antioxidant capacity and several authors have reported that a higher content of pigment compounds in maize kernels is associated to higher antioxidant capacity (Lopez-Martinez et al. 2011; Žilić et al. 2012). Differences in pigment content are directly related to antioxidant capacity in maize kernels (Rodriguez et al. 2013). For example, red maize provides 20% more protein than white or yellow maize. It is rich in anthocyanins and flavonoids and contains 350% more antioxidants than common white or yellow maize (Žilić et al 2011). Red maize can be used in place of white and yellow sweet corn, though it does mature more quickly and can have a tendency to contain more starch than yellow and white varieties. Harvested immature and used soon thereafter, it can be hulled fresh for salads and soups.

Cropping systems aimed for high quality food production include all available measures that increase nutrients favorable for human health and growing of improved genotypes (Dragičević et al 2014). Menkir and Mazya-Dixon (2004) noticed low variations in β-carotene content in grain under the influence of environment, while the genotype was main source of variation. Lower level of phytate and higher level of β-carotene achieved in crops from organic production indicated higher nutritional quality of crops produced in this system (Dragičević et al 2013a). The aim of experiment was to compare conventional and organic production from the point of potential to improve yield of maize with different coloured kernel.

Materials and methods

A two year (2014-2015) field experiment was conducted at the Maize Research Institute in Zemun Polje, Belgrade, Serbia. Trial was set up on chernozem soil type in the experimental field. Maize hybrids differing in the kernel colour developed at the Maize Research Institute Zemun Polje were selected for this study: red maize ZP Rumenka, white maize ZP 655b and yellow maize ZP 633. The treatments of fertilization consisted of following variants: control (with no fertilizer), mineral fertilizer AN (ammonium-nitrate 34.4% N) in amount of 75 kg ha^{-1} N, microbiological fertilizer Uniker in amount of 10 l/ha and organic fertilizer under the trade name „Humus Vita Stallatico" in amount of 1.5 t ha^{-1}. Uniker is microbiological fertilizer witch consisted of following strains of bacteria: *Bacillus megaterium*, *Bacillus lichenioirmis* and *Bacillus suptilis*. It is applied by incorporation into soil prior to sowing, in order to improve soil microbiological activity and increase mineralization of organic matter. „Humus Vita Stallatico" is composted organic fertilizer made from cattle and poultry manure with high content of humified organic matter (48%) and fulvo (9%) and humic acid (10%). Content of nitrogen, phosphorus and potassium is nearly equal with over 3% for each macroelement. Grain yield of maize (t ha^{-1}) were determined after harvest.

Data was analyzed statistically using analysis of variance and $LSD_{0.05}$ were used for comparison, when main effects or interactions were statistically significant.

Results and discussion

Meteorological data on the experimental field during two years of trial are shown in table 1. The data shows better meteorological conditions for crops in the first year of this experiment. This year is characterized by big amounts of rainfall (annual sum was 858.4 mm) specially in May and July. Annual temperature mean 13.9 ^{o}C was significantly higher than long term temperature mean for Zemun Polje. Relatively high average monthly air temperature was in July and August 23.2^{o}C and 22.6 ^{o}C, respectively. The second year of experiment 2015 had significantly small amount and bad rainfall distribution compared with first year. Severe drought is appeared from June to August and caused very significant decrease of maize yield. Regarding temperature conditions in this period, extremely high temperature means is recorded in July (26.4 ^{o}C) and August, (25.7 ^{o}C).

The results of the effect of maize varieties with different coloured kernel and fertilizers on grain yield of these varieties are shown in table 2. On the basis of two-year results it is obvious that meteorological conditions have very significant influence on maize yield. The second season had weather pattern less favourable for the maze production due to severe drought and very high temperature during flowering. All maize hybrids have greater yield in 2014 growing season compared with 2015. According to results the yield of different maize hybrids was significantly different depend on varieties to.

B_1-control, B_2-mineral fertilizer, B_3-microbiological fertilizer, B_4- organic fertilizer
Means in columns followed by the same letter are not significantly different according to *LSD* values ($P = 0.05$)

Fertilization showed no significant influence on maize yield in this experiment. Red coloured hybrid ZP Rumenka had very significant lower yield then white and yellow hybrid in both years.
In 2014 fertilization treatments have no significant influence on red maize yield, but there were significant differences in yield on plots with white and yellow hybrids. Individually observed the highest yield was achieved in the yellow maize with microbiological 11.28 and organic fertilizer 11.17 t ha^{-1}. Also the highest grain yields were observed in the experiment on these treatments in both seasons. These results are similar to the results demonstrated by Dragičević et al (2013b) who concluded that in ecological production the highest yields and 1000 grain weight were obtained in Uniker treatment (microbiological fertilizer) with two times higher values in soybean, in relation to control. Oljača et al (2012) emphasized also that significantly higher yields of red maize Rumenka were obtained in combinations intercrop alternated rows with organic and microbiological fertilizers 3.38 and 3.25 t ha^{-1} respectivly.
In 2015 fertilization treatments have no significant influence on maize yield in all maize varieties but it is evident signifficant influence of maize hybrid. If we compare the interaction between two factors there were some significant differences. White maize gave significantly lower yield on control (2.42 t ha-1) and organic fertilizer treatment (1.21 t ha-1). While yellow one showed significant decrease of yield on mineral (1.64 t ha-1) and microbiological fertilizer treatment (2.73 t ha-1). On the plot with mineral fertilizer AN we obtain the lowest yield of yellow maize. This is the evidence that plants can not use mineral nutrients in extremely dry conditions. It is evident from the results that maize yield in all variant of hybrid and fertilization was at least two-fold lower in 2015 compare with 2014.
Drought is one of the major hazards affecting Serbia and drought is a normal part of the climate. This region will suffer from increased incidents of heat waves and droughts without possibilities for effectively shifting crop cultivation to other parts of the years. The results from the investigation performed by Kovačević et al (2012) shows the noticeable trend of decreasing moisture indices for the first twelve years of the new millennium compared to the last decade of the old one. This trend is particularly evident in the vegetative period of maize.

Conclusion

According to the obtained results during investigations of effects of fertilization and maize hybrids with different kernel colour on the grain yield the following conclusions can be made: meteorological conditions have very significant influence on maize yield. The second season 2015 had weather pattern less favourable for the maze production due to severe drought and very high temperature. It is evident from the results that maize yield in all variant of hybrid and fertilization was at least two-fold lower in 2015 compare with 2014. Fertilization showed no significant influence on maize yield in this experiment. If we compare the interaction between two factors there were some significant differences. The highest grain yields were observed in the yellow maize with organic fertilizer in both seasons. On the plot with mineral fertilizer AN we obtain the lowest yield of yellow maize. This is the evidence that plants can not use mineral nutrients in extremely dry conditions. In the fight against drought, regular and specific cultivation practices should be used along with an adequate assortment of plants with more tolerance to drought including soil tillage, particularly conservation tillage, proper fertilization and crop rotation.

STUDY OF THE LEAF AREA AND DRY MATTER IN NEW WHEAT VARIETIES DEPENDING ON THE APPLIED NITROGEN FERTILIZATION

Ivan YANCHEV*, Dafinka IVANOVA

Faculty of Agronomy, Agricultural University, Plovdiv, Bulgaria
*Corresponding author: ivan.yanchev@abv.bg

Abstract

The study discusses the influence of the empty area in the spring before sunflowers reach third-fourth leaf, and later on when the sunflowers surpass the wheat in height and serve as a green screen during its most important phases, i.e. from the end of shooting-up to the milk and wax ripeness. This study focuses on the formed leaf area during these phases throughout the years of the experiment, the influence of the strips, the effect of nitrogen fertilization, and the performance of the varieties as quality factors. The photosynthetic potential is characterized by the Leaf Area Index (LAI), and by the formation of dry matter relevant to the biological output of the respective growth and developmental phases. During the period 2013-2015 a field experiment is carried out on the research field of the Agricultural University-Plovdiv with two experimental crops – the first one consisting of ordinary sown common wheat, while the second one consisting of alternating strips of wheat and sunflower. The fertilization effect of four rates of nitrogen fertilization is studied, namely N_0, N_8, N_{16}, N_{24}, on the crops, while using three wheat varieties: Sadovo 1, Gea 1 and Sadovo 772. With the increase of the nitrogen fertilization rate, the leaf area and the dry matter increase too, more significantly at the third and fourth fertilization rate for both crops.

Keywords: *wheat, varieties, leaf area, fertilization.*

Introduction

The cultivar composition, representing various but consolidated agricultural properties, is intended to meet the equally various requirements of the market, the conditions of growth, the applied technological decisions, etc. (Akbar and Silva, 2012; Delibaltova and Kirchev, 2010; Ilievski et al., 2012; Man et al., 2012; Negassa et al., 2012). Throughout the whole country the most frequent crops preceding wheat are both, sunflower and corn. The droughts over the last years have led to the increase of the sunflower fields which is also, the better wheat preceding crop for a number of reasons (Delibaltova et al., 2014; Ivanova et al., 2010; Kirchev and Delibaltova, 2016; Tsenov et al., 2004; Tsenov and Kostov, 1999). The purpose, was to find out the productivity of new cultivars of common wheat grown in two different way– the first one consisting of ordinary sown common wheat, while the second one consisting of alternating strips of wheat and sunflower.

Thethe aim of investigation was to determine the influence of nitrogen levels and methods of sowing in the formation of leaf area and dry biomass in the vegetation.

Material and methods

The study is implemented during the period 2013-2015 at the Research Center of the Agricultural University – Plovdiv, Bulgaria. The first part of the experiment consists of a customary sown wheat, which is taken as a standard in the second stage of the experiment, where alternating strips

of sunflower and wheat are positioned perpendicularly to the most prevailing hot winds. Three-factor field experiment was carried out in order to find out the nitrogen mineral nutrition effect on the formed leaf area, on area of 1.0m^2 LAI^{-1} /LAI -Leaf Area Index/, and the formed dry biomass for three varieties of common wheat. The experiment is performed pursuant to the method of the fractional land plots, repeated four times, with dimensions of the land plot of 10.0m^2. The researched factors are: Factor A – method of sowing, i.e. ordinary and broad-strip sowing; Factor B – rates of nitrogen fertilization / N_0, N_8, N_{16}, N_{24} /; and Factor C – varieties, namely Sadovo 1, Gea 1 and Sadovo 772.The following characteristics are studied: number of plants on a unit of land, overall and productive bushiness, leaf area and dry biomass, expressed as biological output in the course of the different growth phases.

Results and discussion

On the basis of the leaf area formed by the varieties as a result of the interaction between the factors, as well as on the average number of plants per variants and years, we found out the Leaf Area Index (LAI).

Table 1. Surface of leaf (m m^{-2}) in analyzed varieties grown under differen N rate nutrition in differen years conditions.

	16	6,4	4,8	6,3	5,4	6,6	5,7	6,1	4,7	5,3	5,1	6,5	5,3
	24	6,6	5,1	6,4	5,5	6,5	5,5	6,2	4,9	5,3	5,1	6,1	5,6
Gea1	0	3,3	3,2	3,2	3,1	3,4	3,2	3,4	3,3	2,9	2,9	3,1	3,0
	8	4,6	4,0	4,2	3,8	4,4	3,9	4,4	4,0	3,7	3,7	4,1	3,4
	16	7,2	5,5	6,3	5,8	6,8	6,0	5,8	5,3	5,8	4,9	6,0	4,8
	24	6,6	5,0	6,1	5,6	6,8	5,6	5,7	5,1	5,8	5,0	6,2	5,1
Sadovo 772	0	3,7	3,4	3,1	2,9	3,4	3,3	3,7	3,3	2,7	2,7	3,3	3,1
	8	4,3	3,9	4,0	3,7	4,4	3,8	4,4	3,9	3,6	3,7	4,2	3,5
	16	6,2	5,3	5,5	5,4	6,4	6,0	5,3	5,3	5,5	4,9	5,6	5,4
	24	6,6	5,7	5,9	5,6	6,8	5,7	5,5	5,7	5,4	5,0	5,5	4,8
LSD 5%			*2.28*	*2.23*	*2.11*	*2.09*	*2.19*	*2.13*	*2.21*	*2.18*	*2.09*	*2.00*	*2.08*

The results for this characteristic in all varieties without applied nitrogen and with N_8 are under the minimal basic value of LAI of 5m^2. Values closest to it are achieved by the variety Sadovo, in broad-strip sowing, with N_8, namely LAI - 4.8m^2. At this norm of supply, the indicators of the broad-strip sown crops have better results, with the exception of the variety Sadovo 772, where the difference is insignificant, i.e. 4.3m^2 for the broad-strip sown crops and 4.4m^2 for the ordinary sown crops. In all varieties the differences in LAI are insignificant when nitrogen is not applied. Only on the basis of the soil fertility the achieved results are under 4.0m^2 on 1.0 m^2 of soil, which is under the accepted criterion for optical dynamic system. With the nitrogen rate increase

fromN_8 to $N_{16,}$ LAI sharply increases in all varieties in both methods of sowing. The differences remain insignificant with the increase of the fertilization rate to N_{24}, in which LAI is larger with 0.2-0.4m^2, however in some of the variants it is the same or lower. The comparison between the two types of sowing and the fertilization rates exhibit more significant differences, reaching most often to 1.0m^2, especially in the varieties Gea 1 and Sadovo 772. In the broad-strip sowing method, LAI for the variety Gea is 7.2 and it lowers to 6.6m^2 with the fertilization rate increase from N_{16} to N_{24}, while for the variety Sadovo 772 they are respectively 6.2 and 6.6m^2, whereas for the ordinary sowing method they are quite lower. For the variety Sadovo 1, regardless of the sowing organization, the values are 6.4 -6.1m^2 at N_{16} and 6.6- 6.2m^2 at N_{24}, which definitely demonstrates higher degree of plasticity.

Table 2. Variation of dry biomass (kg m^{-2}) in analyzed varieties grown under differen N rate nutrition in differen years conditions.

	24	1,5	3,3	1,5	3,3	1,5	3,4	1,5	3,1	1,5	2,6	1,4	2,9
LSD 5%			*0.25*	*0.82*	*0.16*	*0.66*	*0.18*	*0.76*	*0.22*	*0.78*	*0.14*	*0.62*	*0.16*

When studying the fertilization effect at N_0 and N_{24}, as a difference between the maximum and minimum values of the formed LAI, we found out that the differences are more substantial in the broad-strip sowing method, namely: Sadovo 1 – 3.1m^2, Gea 1 – 3.9m^2, and variety Sadovo 772 – 2.9m^2, versus 2.9m^2, 2.4m^2 and 1.8m^2 for the varieties in the case of the ordinary sowing method. The difference is again minimal between the data for the two types of sowing, i.e. for the variety Sadovo 1- from 3.1 to 2.9m^2, while for the new varieties it is more than 1, expressed at a less extent in the variety Sadovo 772 – from 2.9 to 1.8m^2, and at a greater extent in the variety Gea 1, with values 3.9 and 2.4m^2.

The results obtained demonstrate the influence of the larger nutritional area in the case of the broad-strip sowing method, as well as the influence of the warming of the ground air as a result of the warming of the empty strips that will be sown with sunflower. In the end of March and in the beginning of April, the values of the temperature on the leaves during midday hours is about

17^0C, while on the soil adjacent to the strips, the temperature reaches 32^0C. In the first year of the research, in the broad-strip sowing method, in the shooting-up phase, the variety Gea 1 accumulates greatest quantities of dry biomass, followed by the variety Sadovo 1 and variety Sadovo 772, while in the ordinary sowing method, the same varieties grown without fertilization, and at N_8 and N_{16} form the same quantity of dry substance. Only, with fertilization at N_{24}, the leading place for this indicator belongs to variety Sadovo 1 with 1 to 1.6 kg m^{-2}. With the increase of the fertilization rate from N_0 to N_{24} the accumulation of dry biomass increases in the both variants of sowing. During the shooting-up phase, the increase of the dry substance from N_0 to N_{16}, in the broad-strip sowing method is with 0.9 , 1.2 and 1.1 kg m^{-2}, respectively for the varieties Sadovo 1, Gea 1 and Sadovo 772, where the most significant difference is reported in the instance of the variety Gea 1. In the ordinary sowing method the results are similar. During the ear formation phase the largest dry substance is reported for the variety Gea 1, in the broad-strip sowing method and for variety Sadovo 772 in the ordinary sowing method, where for the first variety the effect of fertilization is expressed by 1.8 kg m^{-2} dry substance, while for the second variety it is expressed by 1.4 kg m^{-2}. The studied varieties increase their biomass while passing into the phase of ear formation. The values of this increase vary from 0.6 to 1.4 kg m^{-2} at the main background, and from 1.0 to 1.9 kg m^{-2} at the high fertilization rate, regardless of the sowing organization. Comparing the difference between the phases of the two varieties, a trend is discerned for bigger values in the broad-strip sowing method, where the dry substance formed during the period reaches 1.9 kg m^{-2}, while for the ordinary sowing method it is 1.6 kg m^{-2}.

During the second year of the experiment, in the broad-strip sowing method, in the phase of shooting-up, the largest quantities of dry biomass are formed at the high fertilization rates with preponderance for N_{16} , equal for the varieties Gea 1 and Sadovo 772 reaching 1.6kg m^{-2}, while for the variety Sadovo 1, it is 1.5 kg m^{-2}. During the same phase in the ordinary sowing method the values are highest for the variety Sadovo 772 reaching up to 1.6 kg m^{-2} at N_{16} , while for the standard and variety Gea 1, they are 1.4 kg m^{-2}. With the transition to the phase of ear formation, the dry biomass increases significantly, and the values are higher both versus the previous year, as well as versus the shooting-up phase. This is best presented by the differences in the effectiveness of the fertilization rates, which in 2013 formed over 2.0 kg m^{-2} of dry substance, while in 2014 it is from 1.3 to 1.8 kg m^{-2}. In 2015, again variety Gea 1 exhibits best responsiveness and the formed dry biomass versus the low fertilization rates is 2.4 kg m^{-2} for the broad-strip sowing method, and 2.1 kg m^{-2} for the ordinary sowing method. With regards to the difference between the phases, we found out that the achieved biomass is within the limits from 0.7 to 1.4 kg m^{-2} for the low fertilization rates, and from 0.8 to 2.3 kg m^{-2} for the high, whereas most often varies within the boundaries from 1.8 to 2.0 kg m^{-2}.

During the third year, both for the broad-strip and for the ordinary sowing method, the high fertilization rates influence significantly the formed quantity of dry biomass. At the main background and at second fertilization rate, the values do not reach 1.0 kg m^{-2} and they vary within the limits from 0.4 to 0.8 kg m^{-2}, while at third and fourth rate they exceed 1.0 kg m^{-2} within the limits from 1.3 to 1.6 kg m^{-2}. The varieties Gea 1 and Sadovo 772 most often outperform the standard in the broad-strip sowing method. The dry substance is constantly higher with several tenths, for the three varieties.

For the fertilization effect we judge on the basis of the difference between basic and maximal fertilization rate. The formed dry biomass most often moves around 1.0 kg m^{-2} in the two types of sowing, in the shooting-up phase, with values from 0.9 to 1.2 kg m^{-2}

With the setting in of the ear formation phase, the dry biomass increases more than twice. In the broad-strip sowing method a trend is forming towards more intensive absorption of the nutrients and the differences in the biomass reach 500 g m^{-2} versus the ordinary sowing method.
Variety Sadovo 772 forms most biomass, followed by Gea 1 and Sadovo 1, in the broad-strip sowing method, with maximal values from 3.2 to 3.4 kg m^{-2}, while in the ordinary sowing method no difference is observed between the varieties.
The fertilization effect on the varieties during the ear formation phase reaches up to 2.2 kg m^{-2}, where most often it is from 1.8 to 2.0 kg m^{-2} of dry biomass for the two types of sowing. The difference between the phases and the productivity with the increase of the fertilization rate follows the established trend. In the broad-strip sowing method they are within the limits of 0.8 and 1.9 kg m^{-2}, while in the ordinary sowing, they are lower, with values from 0.5 to 1.7 kg/m^2. The varieties Gea 1 and Sadovo 772 most often surpass the standard or are equal to it only in some of the fertilization rates. Fertilization increases the dry biomass during the shooting-up phase with values varying from 0.8 to 1.2 kg m^{-2} for the entire period, the same positive effect is maintained also during the phase of ear formation within the limits from 1.3 to 2.4 kg m^{-2}. In the different years the formed quantity of biomass in the shooting-up phase as a result of the increased fertilization rates, is relatively similar, due to the same influence of the climatic conditions on the foliar and stem mass, which is not so dynamic in the beginning of the phase. Setting in the ear formation phase, the growth and developmental rate is expressed by the fast increase of the dry biomass up to twice, but the values for the separate years are not the same. The highest fertilization effect is observed in 2014, in the broad-strip sowing method, followed by 2015 and 2013; the effect is similar for the ordinary sowing method, however with lower values of the formed dry biomass.

Conclusions

The fertilization effect for the basic rate and when applying N_8 kg m^{-2}, with regards to the formed leaf area expressed in m^2 per 1.0m^2 is under the accepted criterion for optical and dynamic system, equal at least to 5.0m^2 leaves per 1.0m^2 of sown area, while in N_{16} and N_{24} kg m^{-2} the leaf area is within the limits from 5.0 to 7.2 m^2 thus providing a more intensive synthesis of dry biomass during the two phases for the studied period.
Fertilization increases the dry biomass during the shooting-up phase, with values varying from 0.8 to 1.2 kg m^{-2} for the entire period, the same positive effect is maintained also during the ear formation phase, within the limits from 1.3 to 2.4 kg m^{-2}.
The highest fertilization effect is observed in the broad-strip sown crops, though this effect is similar in the ordinary sown crops, it shows lower values for the formed leaf area and the dry biomass.

EFFECT OF HEADING CUT POSITION AND DATE OF HEADING DURING EARLY SUMMER PRUNING ON THE OCCURRENCE AND PROPERTIES OF SYLLEPTIC SHOOTS IN APRICOT

Ivan GLIŠIĆ*, Dušan MIKIĆ, Tomo MILOŠEVIĆ, Gorica PAUNOVIĆ, Radmila ILIĆ

Faculty of Agronomy, Čačak, University of Kragujevac, Serbia
*Corresponding author: glishoo@yahoo.com

Abstract

This paper presents two-year results (2014 and 2015) of a trial on the effect of heading cut position and heading date on the occurrence and properties of sylleptic shoots in apricot. The research included cv. 'Hungarian Best' grafted on Myrobalan (*P. cerasifera,* Ehrh) seedling rootstock, and grown near Čačak (43°53'N latitude; 20°21'E longitude; 390 m a.s.l.), Western Serbia. Heading is aimed at reducing tree vigour and inducing the formation of sylleptic shoots that will develop into fruiting branches possibly by the end of the growing season. Shoots were cut back at three dates (D_1 - 5 June; D_2 - 20 June and D_3 - 5 July) and under two treatments i.e. treatment 1 (T_1) - just above the bud, and treatment 2 (T_2) - between buds. Inter alia, results showed a much greater % positive response in T_1 (82.21%) than in T_2 (52.88%), and the best performance at D_2. Number of sylleptic shoots was not significantly different across heading dates, but significant differences were found between the two heading cut positions. On average, T_1 and T_2 gave 2.12±0.24 and 1.17±0.13 sylleptic shoots, respectively. Significant differences were observed in sylleptic shoot length across heading dates; with the longest sylleptic shoots at D_1 - 9.39±0.91 cm, and the shortest at D_3 – 5.99±0.62 cm. Heading cut position had no significant effect on sylleptic shoot length. As regards the number of flower and vegetative buds per sylleptic shoot, results showed that early cutback dates (D_1 and D_2) mostly led to the formation of vegetative sylleptic shoots. A similar event was induced by heading treatment T_1.

Keywords*:* *Apricot, early summer pruning, sylleptic shoots*

Introduction

Pruning is one of the most important tree management practices, which ensures that trees are strong enough to support their load of fruit and that branches are properly angled to allow in sufficient sunlight for flower buds to form and for fruit to develop and ripen (Demirtas *et al.,* 2010). Pruning enhances fruit external and internal quality properties such as skin colour, total soluble solids/acidity balance, sugar accumulation etc. (Lord and Greene, 1982).

Summer pruning of apricot trees has been practiced for a long time in major apricot producing countries in Europe (Krška *et al.,* 2012). Šit (1958) was among the first researchers to stress the importance of summer pruning in apricots, and explained that heading at the end of May and in the first half of June stimulates the formation of sylleptic branches with flower buds flowering much later compared to those on unpruned shoots. Previous studies also showed that summer pruning has a positive effect on flower bud formation, improves fruit quality, controls tree development etc. (Kuden and Kaska, 1995; Demirtas *et al.,* 2010). Generally, summer pruning can be applied before and after harvest taking into account the development stage of flower buds. If shoots are cut back early before harvest, summer buds commonly develop into sylleptic shoots which produce flower buds (Šit, 1958; Demirtas *et al.,* 2010). Moreover, summer pruning

reduces tree vigour, stimulates the tree to come into bearing at an early age, and improves fruit quality (Son and Küden, 2002; Szklarz *et al.*, 2011).

However, in Serbia, summer pruning has only recently gained acceptance in apricot plantings, and is normally carried out after harvest until the last ten days in August i.e. during paradormancy (Milošević *et al.*, 2008; Jovanović *et al.*, 2010). The need to prune (especially summer prune) apricot trees has increased due to the fact that the highly vigorous Myrobalan seedling has become the dominant rootstock in Serbian plantings. Pre-harvest pruning which mostly involves shoots and inhibits their growth is practically not used or is scarcely used. Furthermore, timing of this pruning treatment has not been precisely defined. Therefore, the main objective of this study was to determine the optimum date of summer pruning, and the optimum heading cut position to stimulate the development of quality sylleptic shoots with flower buds.

Material and Methods

Research was conducted in an apricot planting at Miokovci during 2014 and 2015. The cultivar 'Hungarian Best' was used in the experiment. Trees were grafted on Myrobalan (*Prunus cerasifera* Ehrh.) rootstock and planted at a spacing of 6.0 × 4.0 m (416 trees ha^{-1}). Training system was the open centre with 3-4 primary scaffold branches.

In the open centre system, there is a tendency for main structural branches to become bare of shoots and for the fruit-bearing area to shift to the canopy periphery. To avoid this, summer pruning was applied as early as the second year after planting, and involved heading back shoots to 4-6 buds. Shoots were cut back at three dates (D) and under two treatments (T). Heading dates included D_1 on 5 June, D_2 on 20 June and D_3 on 5 July. Heading treatment involved heading back shoots just above the bud (T_1), and heading back shoots between two adjacent buds (T_2) (Fig. 1). At each heading date and in each treatment, 30 shoots were cut back in 3 replications, with 10 shoots per replication. Upon heading, sylleptic shoot formation was assessed.

Fig. 1. Heading treatments during early summer pruning

At the end of March of the following year, shoots were evaluated for their response to the heading treatment performed in June and July of the previous growing season (0 = no sylleptic branching on the headed shoot, 1 = one sylleptic shoot developed on the headed shoot, 2 = two sylleptic shoots developed on the headed shoot, etc.). Then, positive responses to heading were counted and expressed as % across heading dates and heading cut positions. The following morphological properties of sylleptic shoots were analyzed: sylleptic shoot length (cm), number of vegetative buds per sylleptic shoot and number of flower buds per sylleptic shoot.

Data were statistically averaged, and the mean absolute deviation was defined using the standard error of the mean (±SE). Statistical analysis and testing of the significance of differences were

performed by the analysis of variance and LSD test at the significance level $P \leq 0.05$ using the ANOVA statistical software (SPS Statistica, Software 5.0).

Results and Discussion

Results on the response of shoots to heading and the number and length of sylleptic shoots are presented in Table 1.

Table 1. Response of shoots to heading; number and length of sylleptic shoots

	Positive response of shoots to heading (%)	Number of sylleptic shoots	Length of sylleptic shoot (cm)
Heading date (A)			
D_1	59.91±8.14 b	1.67±0.15 ab	9.39±0.91 a
D_2	78.56±8.09 a	1.84±0.20 a	6.13±0.55 b

Results revealed a significant effect of heading date and heading cut position on percent positive response to heading (Table 1). Across heading dates, the highest percent positive response was obtained at D_2 – 78.56±8.09%, whereas the values at D_1 and D_3 were lower and exhibited no statistical difference. Overall, the percent positive response to heading at all dates was satisfactory (>50%), suggesting that early-summer pruning during June delivered positive results. These results are better if this operation is conducted until 20 June, which is in agreement with previous findings (Glisic *et al.*, 2015). As for the heading cut position, the response to heading was much better in T_1, i.e. when the shoots were headed back just above the bud (82.21±8.11% positive response). Milatović *et al*. (2015) reported that shoots in sweet cherry trees should preferably be cut back just above the bud during early-summer pruning to stimulate sylleptic branching. The results of the present study are consistent with this report.

In terms of the number of sylleptic shoots induced by heading, the best performance was achieved at D_2 – 1.84±0.20 and in T_1 – 2.12±0.24 sylleptic shoots per headed shoot. Length of sylleptic shoots showed significant differences across heading dates, ranging from the longest sylleptic shoots at D_1 – 9.39±0.91 cm to smaller lengths at D_2 and D_3 6.13±0.55 and 5.99±0.62

cm, respectively. Heading cut position had no significant effect on sylleptic shoot length. Milošević *et al*. (2011b) obtained significantly longer sylleptic shoots in apricot at early heading dates during early-summer pruning. A similar pattern was observed in the present experiment.
Number of flower and vegetative buds and their ratio per sylleptic shoot in apricot trees are given in Table 2.

Table 2: Number of flower and vegetative buds and their ratio

	Number of flower buds	Number of vegetative buds	Ratio of flower buds to vegetative buds
Heading date (A)			
D_1	1.73±0.19 a	3.81±0.31 a	1 : 2.27
D_2	1.00±0.10 c	3.58±0.40 a	1 : 3.70
D_3	1.42±0.12 b	2.95±0.21 b	1 : 1.75
Heading cut position (B)			
T_1	1.38±0.15	3.82±0.29 a	1 : 2.94
T_2	1.39±0.19	3.07±0.32 b	1 : 1.96
ANOVA			
A	**	*	
B	ns	*	
A × B	*	**	

Different lowercase letters within columns indicate the significance of differences between means at $P \leq 0.05$ according to LSD test

Results showed that heading date had a highly significant effect on the number of flower buds per sylleptic shoot, as opposed to the non-significant effect of heading cut position. Moreover, the effect of the heading date x heading cut position interaction as a variability factor was significant. Results ranged from 1.00±0.10 flower buds per sylleptic shoot at D_2 to 1.73±0.19 at D_1. Similarly, the number of vegetative buds per sylleptic shoot was significantly affected by heading date and heading cut position, and highly significantly affected by their interaction, and ranged between 2.95±0.21 at D_3 and 3.81±0.31 at D_1. The best ratio of flower buds to vegetative buds was at D_3 – 1:1.75 and under heading treatment T_2 - 1:1.96.
Milošević *et al.* (2011b) found that late heading dates generally result in short sylleptic shoots that exhibit a better ratio of flower to vegetative buds, which was confirmed by the present findings. Glisić *et al.* (2015) obtained similar results in cv. 'Roxana' and even more favourable values for the number of flower buds and the flower to vegetative bud ratio. This can be explained by the high yield potential of 'Roxana' (Milošević *et al.*, 2010). As for heading cut position, Guimond and Andrews (1998) reported that greater length of shoot left after pruning (corresponding to T_2 in this experiment) inhibited the growth and vegetative development of sylleptic shoots, as confirmed by the present results.

Conclusions

Heading the shoots of apricot cv. 'Hungarian Best' at early dates (1-20 June) led to a positive response, more sylleptic shoots and greater length of sylleptic shoots than at the later date (beginning of July). Heading just above the bud gave much better results compared to the heading cut between buds. In contrast, later heading and the treatment with a greater length of the shoot left above the bud had an inhibitory effect on vegetative growth, and led to the formation of a small number of mostly sylleptic shoots mainly of generative character.

Generally, the apricot cv. 'Hungarian Best' grafted on Myrobalan seedling exhibits a positive response to heading as part of early-summer pruning, especially if heading cuts are made in the first half of June and if shoots are cut back just above the bud.

Abstract

During 1998-2000, 2008-2012 and 2012-2015, the following controlled crosses were made to found new walnut genotypes with late leafing, lateral bud fruitfulness and high nut quality. In first variety breeding program, Turkish walnut selections were crossed with Payne and between their in 1998-1999: 'Niksar 1' × 'Niksar 2', 'Niksar 1' × 'Payne', 'Niksar 1' × 'Şebin', 'Turhal 1' × 'Niksar 2', 'Şebin' × 'Niksar 2'. 757 seedlings from controlled crosses were obtained in 1998 and 624 seedlings were obtained in 2000. In second variety breeding program, 'Niksar 1', 'Şebin', 'Hartley', 'Topak', 'Chandler', 'Akça 2', 'Oğuzlar 77', 'Franquette', 'Sütyemez 1', 'Sütyemez 2' and 'Maraş 12' walnut standard cultivars and selections were used in variety breeding program in between 2008-2012. We have 1340 seedlings under evaluation in this breeding program. In third variety breeding program, during 2012-2015, the following controlled crosses were made to found the new walnut genotypes with tolerant to bacterial blight, late leafing and lateral bud fruitfulness, high nut quality: 'Pedro' × 'Chandler', 'Pedro' × 'Fernette', 'Pedro' × 'Midland', 'Fernor' × 'Pedro', 'Fernor' × 'Chandler', 'Fernor' ×'Fernette', 'Fernor' × 'Howard', 'Fernor' × 'KZK1', 'Howard' × 'Fernor', 'Howard' × 'Chandler', 'Fernette' × 'Howard', 'Fernette' × 'Chandler', 'Fernette' × 'KZK 1', 'Chandler' × 'Kaman 1', 'Chandler' × 'KZK1'. A total number 1633 F1 seedling were obtained. The selected F1 seedlings were planted in the breeding orchard with a distance of 4 × 4 m on their own roots. The results of only phenological and pomological characteristics of controlled crosses 'Hartley' × 'Niksar 1' and 'Hartley' × 'Oğuzlar 77' will be presented in this paper. The kernel weight ranged between 8.2 g (55-60-89) to 11.80 g (55-60-) and kernel ratio (%) was changed between 50.0 (55-77-81) to 61.0 (55-60-37). The leafing time of selected genotypes is same with 'Chandler' and later than.

Keywords: *Walnut, crossing breeding, late leafing, nut quality*

Introduction

The important problem of walnut production is damage of spring frosts in Turkey. Turkish walnut cultivars are considerably early leafing and they bear fruits on terminal buds. The selection breeding method was the most widely used in walnut variety breeding of Turkey. A lot of selection study has been done among the rich native populations (Akça and Şen, 2001; Akca and Ozongun, 2004; Karadağ and Akça, 2011; Simsek *et all*; 2011; Asma, 2012; Kırca *et all*.,2014; Akça *et all*., 2015; Yarılgaç and Yılmaz, 2016).

It was not possible to found that is late leafing and lateral bud fruitfulness variety in seedling walnut population by selection breeding method due to the degree of heritability and contraindications of these two characteristics. The walnut varieties with lateral fruiting and late leafing walnut types same as Californian cultivars are not found from seedling population in

Turkey. ‘Şebin’, ‘Bilecik’, ‘Niksar 1’, ‘Şen 1’ and ‘Maraş 18’ walnut cultivars were important cultivars that were selected from seedling populations.

Cross breeding method was used in only three studies until today (Akça, 2001; Anonymous, 2012). The aim of this breeding program is to provide new walnut cultivars by crossing for the Turkey walnut industry. The primary goal is to develop cultivars with late leafing, lateral fruit bearing, early harvest dates, and good nut quality.

Most of the walnut production of Turkey comes from seedling trees, which give less and in homogeneity crop that cause low commercial value. However, in recent 15 years some regular orchards have been established by Californian and French cultivars. With respect to national varieties, main Californian (‘Chandler’) and French (‘Fernor’ and ‘Fernette’) cultivars are being used in these new orchards.

The primary objective of Turkish walnut scion breeding program is generation of new cultivars with late leafing, lateral bud fruitfulness, disease resistance, yield, and good kernel quality. In our walnut breeding program, late leafing parents were crossed with lateral bearing parents. In regions with late spring frosts in Turkey, late fruiting walnut varieties can be used economically. Therefore, the breeding of new varieties with high fruit quality that will not effected by spring frosts are required.

Material and Methods

During 1998-2000, 2008-2012 and 2012- 2015, the following controlled crosses were made to found new walnut genotypes with late leafing and lateral bud fruitfulness, high nut quality. In first variety program, Turkish walnut selections were crossed with Payne and between their in 1998 -1999: ‘Niksar 1’ x ‘‘Niksar 2’’, ‘Niksar 1’ x Payne, ‘Niksar 1’x ‘Şebin’, ‘Turhal 1’ x ‘Niksar 2’, ‘Şebin’ x ‘Niksar 2’. In second variety program, ‘Niksar 1’, ‘Şebin’, ‘Hartley’, ‘Topak’, ‘Chandler’, ‘Akça 2’, ‘Oğuzlar 77’, ‘Franquette’, ‘Sütyemez 1’, ‘Sütyemez 2’ and ‘Maraş 12’ walnut standard cultivars and selections were used in second variety breeding program in between 2008 - 2012. In third variety program, during 2012-2015, the following controlled crosses were made to found the new walnut genotypes with tolerant to bacterial blight, late leafing and lateral bud fruitfulness, high nut quality: ‘Pedro’ × ‘Chandler’, ‘Pedro’ × ‘Fernette’, ‘Pedro’ × ‘Midland’, ‘Fernor’ × ‘Pedro’, ‘Fernor’ × ‘Chandler’, ‘Fernor’ × ‘Fernette’, ‘Fernor’ × ‘Howard’, ‘Fernor’ × KZK1, ‘Howard’ × ‘Fernor’, ‘Howard’ × ‘Chandler’, ‘Fernette’ × ‘Howard’, ‘Fernette’ × ‘Chandler’, ‘Fernette’ × ‘KZK 1’, ‘Chandler’ × ‘Kaman 1’, ‘Chandler’ × ‘KZK1’. Based on the status of the bacterial blight diseases and leafing time will be determine in greenhouse in between 2016-2017. In order to inoculate plant, it will be use X*aj* isolates that the value of virulence is high and precise identification is right. The symptoms of bacteria on the leaf will be examined after than inoculations 14, 21 and 30 days and the disease symptoms will be scored according to 0-4 scale values.

The female flowers were carefully bagged before receptive stage. After, the pollen of chosen parents was squirted to receptive flowers. Pollen applied flowers marked with different colored threads. Seed from these crosses is collected in the fall before nut drop, air dried before storing. To ensure the highest possible germination, after soaking 24 hours in GA_3 solutions at 50 ppm, seed are straficated in cold room (4-5 °C). To ensure the highest possible germination, seed are straficated in cold room (4 °C). After stratification, germinated seeds were sowed in to plastic containers containing peat, perlite and soil for growth in the greenhouse. The leafing time of each hybrid was noted and the seedlings which leafed out two-three weeks earlier than Franquette were discarded. The selected selections were planted in the breeding orchard 4 × 4 m, on their own roots. By age 6, trees with low yield or other problems are cut down.

Nut and kernel weight, kernel percentage, nut dimension, shell thickness, kernel color and ease of kernel removal were evaluated using 25 nuts chosen randomly. The evaluation of selected superior genotypes was made according to UPOV (Anonymous, 1999). The results of only phenological and pomological characteristics of controlled crosses 'Hartley' × 'Akça', 'Hartley' × 'Oğuzlar 77' will be presented in paper.

Results and Discussion

Among the important goal of walnut breeding programs are late leafing, lateral bud fruitfulness, early yielding, shortness of vegetation period, early harvesting time, good fruit quality, high yield and resistance to bacterial blight. Similar walnut breeding programs have been carried out in USA, France, Hungary, Italy and Spain; a few of these programs are still ongoing (Germain *et all*.,1985; Szentivanyi1990; Tulecke and McGranahan, 1994; Tamponi *et all*. 1997, Anonymous, 2013).

Leafing time of F_1 selections were classified as early, medium-early, medium and, medium-late, group according to 'Franquette' cultivar in breeding orchard (Table 1). 'Chandler' walnut cultivar was classified medium early group in breeding orchard. The genotypes with medium, medium-early and medium –late are tolerant to late spring frost in Turkey walnut production.

Symptoms of bacterial blight (*Xanthomonas juglandis*) and anthracnose (*Gnomonia leptostila)* were examined in the breeding orchard. We have not observed bacterial blight and anthracnose symptoms on selected F_1 seedlings obtained from the first and second breeding programs.

Kernel weight, kernel percentage and shell thickness should be 6.0 to 8.0 g, 50 to 55%, and 0.7 to 1.5 mm respectively in promising new walnut cultivars according to Akça and Ozongun (2004).

In the selected F_1 genotypes, kernel ratio, kernel weight and nut weight changed from 50.0 – 61.0 %, 8.2 g – 11.8g, 13.9 g to 23.4 g, respectively. There is not very low (< 40%) and low (40–44%) kernel ratio among selected F_1 genotypes. Generally, kernel percentage of selected genotypes to be found high rather than 55%. Kernel color of all the selected F_1 were observed extra light and kernel ease of removal were determined very easy (Table 1).

Table 1. Pomological and phenological characteristics of F_1 selections

F_1 genotypes	Nut lenght (mm)	Nut width (mm)	Nut thickness (mm)	Nut weight (g)	Kernel weight (g)	Shell thickness (mm)	Kernel ratio(%)	Kernel color	Empty kernel percent (%)	Kernel ease of removal	Leafing time in breeding orchard	Leafing group according to 'Franquette'

Temponi *et all*. (1997), used ‘Sorrento’, ‘Serr’, ‘Payne’, ‘Chico’, ‘Pedro’, ‘Midland’, ‘Hartley’ ‘Gustine’ walnut cultivars in the new walnut crossing breeding program. A total number of 2500 seedlings were obtained in this walnut breeding program. In this study, kernel weight was ranged 4ç8 g (‘A1-1-33’ (‘Sorrento’ × ‘Serr’) to 7.2 g, (‘B1-8-4’ (‘Sorrento’ × ‘Chico’), kernel ratio changed from 43% (‘F-1-35’ (‘Sorrento’ × ‘Pedro’) to 60% (‘B1-7-4’ (‘Sorrento’ × ‘Chico’).
Szentivanyi (1990) reported that, a cross walnut breeding program was begun in the late 60’s with the Californian walnut cultivars (‘Pedro’, ‘Payne’ and ‘Tehama’) and Hungarian cv (‘Milota 10’, ‘Tiszasecsi’, ‘Alsoszentivani’). The new hybrids walnuts with late leafing are found in this program. Kernel weight changed to 5.10 g (‘T34-101’) to 9.80 g (‘A117-12’) g.
There has been an active walnut breeding program at UC Davis since 1948 ‘Chandler’, ‘Howard’, ‘Vina’, ‘Tulare’ and ‘Serr’ were selected by this program. Recently, ‘Sexton’, ‘Gillet’ and ‘Forde’ were released. According to report of walnut improvement 2013 of UC Davis, 86 scion selections are evaluated and propagated and over 4300 seedling are completed early evaluations. ‘Solano’ ‘Gillet’, ‘Sexton’ and ‘Forde’ walnut cultivars were obtained from this program. Kernel weight and kernel ratio of ‘Solano’ was reported as 8.0 g and 54% respectively. Also, kernel weight and kernel ratio of ‘Gillet’, ‘Sexton’ and ‘Forde’ was ranged, 8.5 g, 8.2 g and 9.0 g, 50%, 50% and 54% respectively (Anonymous, 2016a).
Germain (2004), reported that French walnut cultivars ‘Fernor’ and ‘Fernette’ were obtained from ‘Franquette’ × ‘Lara®’ crossing. The new walnut cultivars ‘Feradam’, ‘Ferouette’ and ‘Ferbel’ were obtained from France walnut breeding program. Also, H113/1, H113/4, H113/20, H107/23, HP 39 F1 selections are evaluated. ‘Feradam’ has very big nuts rather than ‘Ferbel’, ‘Ferouette’ (Anonymous, 2016b). Our promising walnut F_1 hybrids have high kernel weight, kernel ratio and kernel dimension better than the results of another walnut program.

Conclusion

The new international variety walnut breeding program can be started in EU countries. We have a lot of the new selections obtained variety walnut breeding program in Turkey. The new selections late leafing, lateral bud fruitfulness, high nut quality ant tolerance to bacterial blight, it will enable to development of walnut production of Turkey.

Abstract

This paper presents the results of a two-year study of six Dutch potato varieties in agroecological conditions of northern Montenegro. The two-year average of the highest number of tubers were found in the variety Arnova (8.4), while the lowest tuber number was obtained in varieties Arrow (6.8), Rudolph (6.8) and Riviera (6.9). Increasing the number of tubers in the variety Arnova compared to other varieties was statistically significant. Varieties Rudolph (116.5 g) and Kuroda (100.5 g) gave averagely biggest tubers. The average weight of tuber of other varieties studied was approximately at the same level, and ranged from 80.4 g, for the cultivar Arrow to 88.6, for the Arnova. Rudolph and Kuroda were, compared with all other varieties, had significantly larger tubers. The highest yield in trials was on plots planted with varieties Rudolph - 33.7, Kuroda - 32.0 and Arnova -31.5 tha^{-1}. The lowest yield was measured at variety Arrow - 23.2 tha^{-1}. Yields of varieties Rudolph, Kuroda and Arnova were compared to all other investigated varieties statistically significant. This research showed that the highest yields of tubers in agroecological conditions of mountain climates are achieved by growing medium late and middle early varieties of potatoes.

Keywords: *potato, tuber number, tuber weight, yield*

Introduction

Potato is among the most important and most profitable crops in many countries of the world. On a global scale, after rice, wheat and maize, potato is the fourth largest source of food. The economic importance of potato in Montenegro is very significant, especially for the mountainous area where it is predominantly grown.

Potato is a plant of temperate climate and is grown in almost all latitudes. However, the best zone for potato growing is considered the area of temperate zone (40-60^o north latitude), as well as areas under 40° of north latitude at high altitudes (Muminović et al., 2014). Due to the very pronounced polymorphism, potatoes easily adapt to different environmental conditions. Thanks to this feature, potato is now grown even in poor production conditions and high altitudes, even where the cultivation of other agricultural crops is not possible (Jovović et al., 2015).

Potatoes prefer chilly nights, but nights like that are less and less. The increasing climate variability poses a serious threat to its further cultivation. Climate change has increasingly negative impact on potato crop production leading to large seasonal fluctuations in the amount and quality of yields. Therefore, in the future potato production is gradually moving from the warmer south to colder northern areas and higher mountain regions (Jovović et al., 2016).

The systematic study of the different genotypes in different environmental conditions is of great importance resulting with wider selection of varieties adapted to the specific conditions (Yang,

2002). Yields of potatoes, in addition to the variety, greatly depend on the agro-ecological conditions, but also on nature of interaction between genotype and environment. The reaction of individual varieties to different environmental conditions is conditioned by their genetic predisposition. Knowing very complex relations existing between genotype and environment is of paramount importance when selecting varieties (Jovović et al., 2012).

As different production areas are governed by very different environmental conditions, variety performance is different as well. Therefore, knowledge on the productivity of potato varieties and their reactions to the specific conditions of production regions is one of the most important preconditions for achieving high and stable yields (Momirović et al., 2000). Consequently, the study of the productivity of different potato varieties in different agro-ecological conditions has outstanding practical significance. In this way, there is very reliable information about the cultivated varieties that will allow maximum utilization of genetic resources and thus achievement of high and stable yields (Yang, 2002).

The aim of this study was examination of yield and other indicators of productivity for six Dutch potato varieties in mountain areas of Montenegro.

Materials and methods

The study of the productivity of six promising Dutch potato varieties was carried out during 2013 and 2014 in Kolašin, on the alluvial-deluvial soil at an altitude of 900 m. Varieties with different length of vegetation and skin colour were tested - early varieties: Riviera (1) and Arrow (2); medium early: Tresor (3) and Arnova (4) and medium-late varieties of red epidermis: Kuroda (5) and Rudolph (6).

The experiments were conducted in a completely randomized block design, with 4 replicates and the surface of the single experimental plot of 15 m^2. Planting of potatoes was carried out on May 20 2013 and 15 May 2014, by hand, at a distance of 70 x 33 cm, with the resulting density of 43300 plants per hectare. The basic tillage, pre-sowing preparation and fertilization were conducted as standard agricultural practices for potato crop. The protection of crops from weeds, pests and disease-causing agents was conducted timely. Potato harvesting was carried out on 15 September in both years.

Table 1. Chemical characteristics of soil in the experimental field

Depth (cm)	pH		$CaCO_3$	Humus	Soluble mg/100 g	
	H_2O	nKCl	%	%	P_2O_5	K_2O
40	6,29	5,55	1,1	4,53	2,4	16,0

Table 2. Meteorological condition during the experiment

Year	Month					Average
	May	June	July	August	September	
Air temperature (^{0}C)						
2013.	12,4	15,7	18,1	18,4	12,7	15,5
2014.	11,3	15,3	17,3	17,5	12,8	14,8
Precipitation sum (mm)						Total
2013.	301,3	125,0	32,9	67,8	118,3	645,3
2014.	96,6	150,3	114,7	69,1	233,2	663,9

Determination of the number of tubers and their mass was performed after complete maturation on average sample of 10 potato plants from a row in each repetition. Total yield per hectare was calculated according to the theoretical categories of crop density.

Soil in experimental plots has favourable water and air properties, high humus content, low phosphorus and calcium and moderate potassium content (table 1). Meteorological data for the experimental period are given in table 2. Statistical analysis was performed by the method of factorial analysis of variance (ANOVA), and the score difference between the mean values using LSD test.

Results and discussion

The measurement results given in Table 3 show that the largest number of tubers in the experiment was found in variety Arnova - 8.4 (7 in 2013 and 9.8 in 2014), while the lowest tuber number was measured in Arrow - 6.8 (6.2 and 7.3), Rudolph - 6.8 (7.2 and 6.3) and Riviera - 6.9 (6.3 and 7.4). In two-year average, variety Arnova had significantly higher number of tubers compared with other varieties. The significant increase in the number of tubers was determined in varieties Kuroda (7.5) and Tresor (7.3) compared to Errow (6.8), Rudolph (6.8) and Riviera (6.9).

	2013-14.	2,021	2,742

The average number of tubers is a very important parameter of productivity on which depends the production per plant of potatoes, and finally the total yield per unit area (Bugarčić et al., 2000). The variability of the number of tubers, except genetic differences between the varieties of potato, largely depends on the interaction between genotype and environmental factors (Nacheva, 2006). In compared studied years, slightly higher average number of tubers was found in 2014 as a result of higher rainfall in June, when potato plant tuberisation is occurring.

Tuber size is an important parameter of productivity and is basically a varietal characteristic, but above all it depends on the level of agricultural practices, soil type and weather conditions during the vegetation period (Jovović et al., 2011). In two-year studies, plots with the highest average tuber weight measured, were planted with varieties Rudolph (116.5 g) and Kuroda (100.5 g). The smallest tubers were measured in varieties Arrow, Tresor and the Riviera (80.5, 81 and 83 g). Analysis of variance of the average tuber weight showed a highly significant increase in tuber

weight of varieties Kuroda and Rudolph as compared to other varieties. Differences in tuber weight between Rudolph and Kuroda are also statistically significant. Increase in number of tubers in the variety Arnova compared with varieties Arrow and Tresor was statistically significant.

Number and size of tubers depend on the number of primary shoots formed on single plant. Bigger number of primary shoots, bigger number of tubers formed, but not their weigh too (Butorac and Bolf, 2000). The results of this study are correlated with this statement.

The highest yields were obtained in experiments on plots cultivated with varieties Rudolph - 33.7, Kuroda - 32.0 and Arnova - 31.5 tha^{-1}, while the lowest yielding varieties were Arrow - 23.2, Riviera – 24.3 and Tresor - 25.3 tha^{-1}. Rudolph, Kuroda and Arnova as compared to other varieties yielded a significantly higher tuber yield. Arrow, Riviera and Tresor yields were statistically highly significant. The significant increase in yield was found in the variety Tresor compared with Arrow, as well as between varieties Rudolph and Arnova. As 2014 had a slightly greater quantity and a better distribution of rainfall during the growing season of potato, and lower average air temperatures, it resulted with higher yields in this year (29.9 in 2014 and 26.7 tha^{-1} 2013).

Proper selection of varieties could significantly reduce adverse environmental effects. For these reasons, the study of potato varieties in the mountain area of Montenegro should continue.

Conclusion

Based on said above it can be concluded:

- With proper variety selection, high potato yields can be achieved even in mountainous areas of Montenegro.
- In two-year studies, the highest yielding varieties were Rudolph - 33.7, Kuroda – 32.0 and Arnova - 31.5 tha^{-1}, while the lowest yields were measured in plots planted with varieties Arrow - 23.2, Riviera - 24.3 and Tresor and - 25.3 tha^{-1}.
- The largest number of tubers per plant was determined in cultivar Arnova (8.4), while the lowest tuber number was found in varieties Arrow and Rudolph (6.8). The number of tubers in the variety Arnova compared to other varieties was statistically significant.
- Tubers with the highest average weight were obtained from varieties Rudolph (116.5 g) and Kuroda (100.5 g), while the smallest tubers were measured in the varieties Arrow and Tresor (80.5 and 81.0 g).
- The highest yields are achieved growing medium late and medium early potato varieties in mountainous area of Montenegro.

Abstract

The aim of the study was to determine effects of both, different types of cytoplasm (*cms*-C, *cms*-S and fertile) and environmental factors, on the plant height of 12 maize inbred lines. The trial with inbred lines was set up in two locations (Zemun Polje - Selection field and Zemun Polje - Školsko dobro) in 2008 and 2009. Very significant differences in the plant height among inbred lines in dependence on the type of cytoplasm and the location were established by the analysis of variance. The average plant height varied from 161.8cm (L_{11}) to 220.5cm (L_1). In relation to the type of cytoplasm (*cms*-C, *cms*-S and fertile), the average values of the plant height very significantly varied (P≤1%). The plant height in inbred lines with fertile cytoplasm was very significantly higher ($Lsd_{0.01}$) (187.6cm) than in inbred lines with sterile *cms*-C (181.1cm) and *cms*-S (180.2cm) types of cytoplasm. Varying of average values of the plant height was very significant (P≤1%) in both years of investigation and locations. In 2008, the average plant height of inbred lines (173.98cm) was significantly lower than the average values recorded in 2009 (191.94cm). Very significantly higher values of the plant height were determined in the first location, Selection field (189.25cm) than in the second location, Školsko dobro (176.67cm).

Key words: *Cytoplasmic male sterility, inbred lines, plant height*

Introduction

Maize hybrids are the product of the cross between inbred lines derived in the process of selection by controlled self-pollination of selected genotypes until homosigosity is reached. In the hybrid maize seed production it is necessary to perform deta sseling on the female component in order to avoid self-pollination and reduction in heterosis of F_1 generation hybrids.

It is necessary that complete hybridisation between parental components is achieved otherwise heterosis will not be expressed in the F_1 generation. If complete hybridisation is not achieved self-pollinated female component will occur in produced seed and heterosis will not be fully used, while total yield per area unit will be reduced.

In the production of hybrid maize seed, it very often happens that complete hybridisation between parental components cannot be achieved during deta sseling even by the best producers. In order to achieve complete hybridisation it is necessary to remove all tassels in female component rows prior to pollen release. This job requires a great number of workers who should be engaged in a relatively short period of time (10-30 days). In addition to these workers, it is necessary to provide appropriate control and super control of quality of the job done, which means engagement of a large number of skilled workers.

Mechanical topping in the production of hybrid maize seed has been imposing from the beginning of this production. Experiments with mechanical topping had been performed by numerous researches (Dungan and Wudworth, 1939; Borgeson, 1943; Kiesslbach, 1945; Bauman, 1959; Hunter *et al*., 1973 and many others), while results of their studies were summarised by Huey (1971) and Trifunović (1975). Huey (1971) stated that mechanical toppers were not usable under poor weather conditions, and that they did not solve the problem of deta sseling on tillers and under developed plants, while leaf loss could not be lower than 2-3 even with the most attentive operation.

The possibility of successful solving problem of deta sseling in the hybrid maize seed production occurred when cytoplasmic male sterility in maize was discovered. The use of male sterile versions of the female component thoroughly eliminates the need to perform deta sseling, reduces the number of workers necessary for control, effectively improves production quality and significantly reduces costs and accompanying risks, and ultimately, in this way, the seed production becomes very attractive for producers.

The first description of male sterility was provided by Rhoades (1931). Further researches showed that cytoplasmic factors were responsible for sterility.

Cytoplasmic male sterile plants of the female component do not consume nutrients and energy to form and shed pollen, but to form the grain. Fertile pollen is a great recipient of mineral nitrogen, much more than any other part of the plant. It was estimated that sterile plants may save approximately 10-30 kg ha^{-1} of nitrogen, which is, instead of being used to form pollen, directed into female reproductive organs, thus resulting in the grain yield increase.

Kaeser *et al.* (2003) considers cytoplasmic male sterility (*cms*) a trait interesting for the maize seed industry, because it leads to lower costs of the hybrid seed production by eliminating the labour-intensive mechanical emasculation of parental lines.

In recent years, many hybrid seeds based on male sterile inbred lines have been produced with major *cms* types, *cms*-C and *cms*-S, replacing *cms*-T, which is susceptible to maize leaf pathogens.

The main goal in the commercial maize production is the highest possible grain yield, along with other favourable agronomic traits. Increasingly strong competition in the market of maize seed requires studies on the effect of the type of cytoplasm and its interaction with a genotype on yield and some morphological traits for the purpose of the production.

Material and Methods

Material and methods in performing field trials

Total of 12 maize inbred lines with three different types of cytoplasm was observed: 1) inbreds with the *cms*-C type, 2) inbreds with the *cms*-s type and 3) inbreds with fertile cytoplasm.

Two trials were set up in two locations (Zemun Polje - Selection field and Zemun Polje - Školsko dobro) in 2008 and 2009. The tree-replication trials were set up according to randomised block design. Each plot within the replication consisted of 4 rows. Fertile versions of inbred lines were sown in two border rows and these inbreds had a role of a pollinator for their sterile counterparts. Each row consisted of 12 hills with 4 seeds each. The within-row hill distance amounted to 40 cm, while the inter-row distance amounted to 70 cm. The elementary plot size was 5.6m².

The trial was set up under rainfed conditions. Cropping practices common for maize were applied during the growing season.

Thinning to two plants per hill was done in the 5-leaf stage. In order to avoid the effect of border plants, only plants from 10 inner hills were used in the analysis of agronomic traits.

The 12 observed inbred lines encompass the majority of maize germplasm that is used in the seed production of the Maize Research Institute. The comparison of probable pollen restoration into two observed *cms* types can point out to more suitable *cms* type for the seed production under conditions of our country.

Immediately prior to harvest, a total number of both, plants and lodged and broken plants, was great in all replications. Broken plants were all those plants that were broken below the upper-ear bearing node, while lodged plants were those in which the angle between the stalk and the ground was less than 45º.

Harvest was done at full ripeness.

Methods of experimental data processing

Statistical-biometrical data processing is based on means per replication. Differences among analysed maize inbred lines with various sources of cytoplasm (C, S and fertile), in two locations and during two years as well as their interactions were determined by the analysis of variance for the factorial trial set up according to the randomised block design, as wall as by the LSD test at the probability levels of 5% and 1% (Hadživuković 1991). In order to draw objective conclusions on effects of observed factors on tested traits of maze inbred lines and the possibility to apply parametric tests (ANOVA and LSD-test), homogeneity of variance was tested.

Results and Discussion

The average plant height of inbred lines ranged from 161.8cm (L_{11}) to 220.5cm (L_1) (Table 1). In dependence on the type of cytoplasm (*cms*-C, *cms*-S and fertile) these values very significantly ($P \leq 1\%$) varied. Inbred lines with fertile cytoplasm were on the average very significantly ($Lsd_{0,01}$) higher (187.6cm) than inbreds with sterile *cms*-C type (181.1cm) and *cms*-S type (180.2cm).Variation of average plant heights of all inbred lines was very significant ($P \leq 1\%$) in both years of investigations and both locations. The average plant height (173.98cm) was very significantly lower in 2008 than in 2009 (191.94cm). Furthermore, a very significantly greater plant height was obtained in the first location, Selection field (189.25cm) than in the second location, Školsko dobro (176.67cm), (Table 1).

If obtained values are compared with ones achieved by Sečanski (1999), it can be concluded that the heights were approximately equal ranging from 169 cmto 185cm.

The plant height does not depend only on genetic background of the trait, but also on many environmental factors and cropping practices (sowing density, soil type, presence of diseases and pest, meteorological conditions...).

According to two-year studies Todorović (1995), stated that the plant height was greater in observed hybrids than in observed inbreds, ranging from 194.30cm to 253.50cm vs. 165.60cm to 189.50cm.

Similar results were obtained in the study carried out by Radanović *et al*. (2015), which means that heterosis for this trait was very pronounced.

According to everything stated it can be concluded that the plant height is a very important trait that indirectly affects yield and is related to the duration of the growing season.

Conclusion

Based on two year studies of maize inbred lines with different types of cytoplasm the following conclusions may be drawn:

1. An inbred line, type of cytoplasm, year and location significantly affect the plant height.
2. The highest plant height was recorded in the inbred line L_1 (220.5cm).
3. The lowest plant height was recorded in the inbred line L_{11} (161.8cm).
4. The highest, i.e. lowest average plant height was detected in inbreds with fertile cytoplasm (187.6cm), i.e. cytoplasm S type (180.2cm), respectively.
5. The average plant height was significantly lower in the first year (173.98cm) than in the second year (191.94cm).
6. The average plant height was higher in the first location (189.25cm) than in the second location (176.67cm).

SOME EARLINESS ENHANCING METHODS IN SWEET CORN PRODUCTION

Ferenc OROSZ

Sapientia University, Department of Horticulture, 540485 Targu Mureş, Şoseaua Sighişoarei 1C, Romania
(Corresponding author: oroszferenc67@gmail.com)

Abstract

Aim of experiment, set up in 2014, was to study evolution of sweet corn growing period with application of some technological elements such as: propagation time, propagation method, floating row cover. The choosen variety was a conventional sweet corn hybrid, very early ripening 'Spirit'. The following growing technologies were compared: 1. direct sowing of plants with floating row cover, early period 2. direct sowing of plants without row cover, early period 3. plants transplantation with floating row cover, earlier period and 4. direct sowing of plants without row cover, normal period (regarded as control). The transplanted plants had shorter growing period by 9 days, compared to direct sowed covered treatment and were 26 days earlier harvested than control. The influence of above mentioned technological elements on some important morphological properties of sweet corn ears regarding: husked and unhusked ear weight, ear length, length of seeds and ear diameter was studied.

Key words: *earliness, sweet corn, transplantation, fleece covering*.

Introduction

Currently, Hungary is not considered as an influential country of the market considering the majority of the vegetables. The only exception is the sweet corn. Although the yield fluctuated, the growing area have grown continuously, in 2002 we gone before French and Hungary became the European leader in sweet corn growing. The impulsive force of great growth, was the canning and freezing industry. Based on its present growing area, the sweet corn is the vegetable which is grown on the greatest area in Hungary and after the sudden and sharp decline in 2003 this plant returned in a rise after 2006. According to the Hungarian Interprofessional Organization for Fruit and Vegetables and Product Board, with a growing area of over 30,000 hectares Hungary is presently the first in the EU. In the case of the former, however, the increase in fresh consumption partly counterbalanced the rate of decrease. In order to promote fresh consumption, as well as to maintain and increase the sweet corn exports, it is necessary to promote investigations able to ensure a further increase in the growing area and yields of sweet corn with the help of the experiences. Of the production technology elements, a number of researchers studied or are currently studying the sowing time of sweet corn. Early sowing is also recommended by Aldrich (1970) for the reason that the roots will penetrate deeper this way, from where they can get water even in periods of drought. The more intensive vegetative growth also takes place during the period of shorter daytime and this way the plants will be smaller and will be less prone to lodge. Several techniques are known in the art for the purpose of early fresh market shipments: seedling growing or direct sowing with temporary plant cover (Kurucz 1998; Hodossi 2004). Direct sowed sweet corn under fleece cover showed earlier ripening and gave better yields in the experiments of Kassel (1990). The plots under fleece cover reached harvest maturity 12 days earlier as compared to the plots with no cover. Besides, a greater number of missing plants was observed in the plots with no cover. As a result of the greater plant number

and the better ear set per plant yields were much higher in the plots with fleece cover. The most widespread method of seedling production is the use of soil blocks (Pereczes, 1999) which can also significantly increase earliness. According to the trials of Kurucz (1998) seedling growing advanced harvest by 2 weeks. According to Hodossi (2004) 10 to 12 day earliness can be achieved by planting seedlings grown in soil blocks and 6 to 8 day earliness by seedlings grown in trays. The measurements of Kassel (1990) revealed that the ears of direct sowed corn plants under floating row cover could be harvested 10 days earlier as compared to the plots planted with seedlings and having no cover. The combined application of seedling growing and floating row cover of plants can advance harvest by three weeks as compared to the traditional technology (Kurucz, 1998).

Materials and methods

The experiment was set up on an area equipped for irrigation at Tg. Mures, Mures County, situated in central part of Romania. Conventional, reliable and sufficiently known among growers sweet corn variety, Spirit, was used as a reference variety in the variety comparison trials of the Central Agricultural Office. Hybrid has short growing period of 85 days and yellow kernels. Average height of plants is 159 cm, average ear height is 37 cm, ear length 19.6 cm and average ear weight is 245 g. The variety was granted official recognitions in 1988 and has been the dominant variety of the early ripening category till now. In the year prior to the experiment the area was under wheat.

The following treatments, each with four replications, were applied during the experiment:

P1 = direct sowing of plants with floating row cover, early period (8^{th} April)
P2 = direct sowing of plants without row cover, early period (8^{th} April)
P3 = plants transplantation with floating row cover, early period (8^{th} April)
P4 = direct sowing of plants without row cover, normal period, regarded as control (25^{th} April).

For the frame structure of the treatments with cover we used ø 4.2 mm zinc coated wire coils. The fleece, 60 cm in width, was stretched over a small tunnel of 40 cm in height and then its edges (25-25 cm, respectively) were covered with soil using a hoe and the its ends were tied to the stakes hammered down. The construction of the frame structure and the setting out of the fleece cover were carried out at the same day as direct seeding and out planting.

For the purpose of seedling growing, the seeds were sown on 16^{th} March 2014, in trays with rigid walls having 3,7x4x5,4 cm size. For growing the seedlings, commercial mix made of white peat 10-20 mm, PG Mix 1 kg/m^3 + micro nutrients, bentonite 40 kg/m_3, pH 5,5-6,5 was used. The seedlings were planted out at the 3 to 4 leaf phenological stage. At the two propagation times the treatments P1 and P3 were covered with Novagryl floating row cover, having a weight of 19 g/m^2, (using the small tunnel technique) in order to enhance earliness. The stand was created to contain 60,607 plants per hectare, according to the recommendations of the owner of the variety, at a spacing of 110+40x22 cm in twin rows. Each plot had an area of 6x3,5m (8 parallel rows and 16 seeds sown in each row). Sowing depth was 3 cm. The edge was the respective outer rows of the 4 twin rows of the plot.

In October 2013, 35 t/ha of farmyard manure was worked into the soil with ploughing on area. Nitrogen fertilizer (120 kg/ha) was applied at the 6-7 leaf stage, the form of top dressing. The fertilizer application was worked into the soil with a rotary hoe.

Ears were harvested together with the husks, from the two central twin rows. Twenty ears were selected from each row and the following measurements were carried out:

weight of unhusked and husked ears (g),

total ear length (cm),
length of seeds (mm),
ear diameter (mm).
The statistical analysis of the results was carried out by using the programme *RopStat 1.1*. When the standard deviations were identical the mean values were compared by pairs using the *Tukey-Kramer* test, while in the case of the non identical standard deviations the means were compared using the *Games-Howell* test (Vargha, 2007).

Results and discussion

According to obtained results, harvesting time (measured in days) was the shortest in the treatment P3 and P2, merely 76, respectively85 days, i.e. the corns became ready for harvest 26, respectively 17 days earlier compared to P4 (control). In case of P1 treatment, harvesting began 12 days earlier compared to P4 (control).
Results of the one of the major characteristics in connection with yield rating, unhusked and husked ear weight, are summarised in Figure 1.

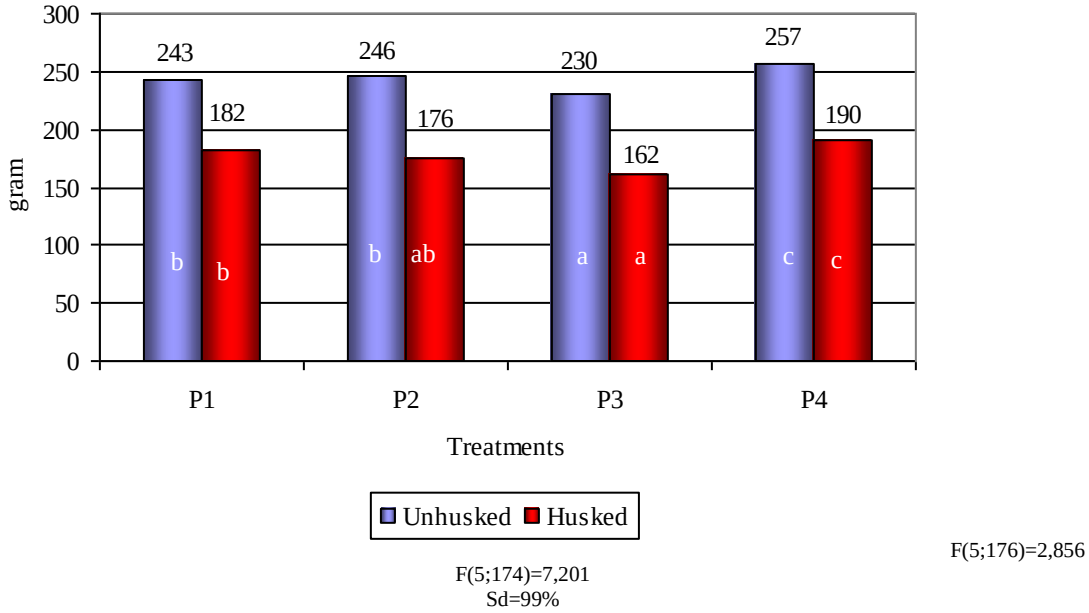

Fig. 1. Unhusked and husked ear weight (g).

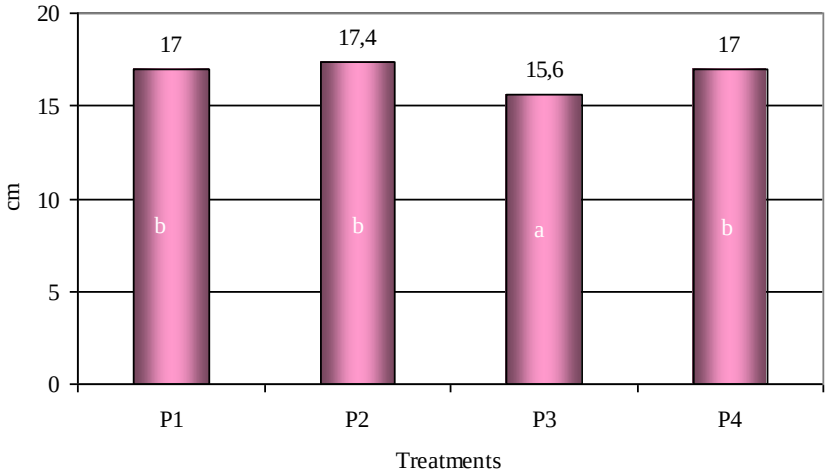
Analysing the data measured for unhusked ear yield, it is noticeable that the average weight of the ears of the earlier transplanted, covered treatment P3 was significantly (at $p<0.01$ level) lower as compared to earlier and later sowed, covered and uncovered treatments P1, P2 and P4 (control). Though there was some difference between the plants of the treatments P1 and uncovered, sowed, treatment P2 in unhusked ear weight, statistically this was not significant. Significantly highest value, supported statistically (at $p<0.01$ level), of unhusked ear weight was produced by ears of control treatment (P4). In case of husked ear weight the same tendencies were observed as in case of unhusked ear weight.
The data concerning, an important characteristics for market appeal (total ear length) are contained in Figure 2.



F(5;174)=11,000

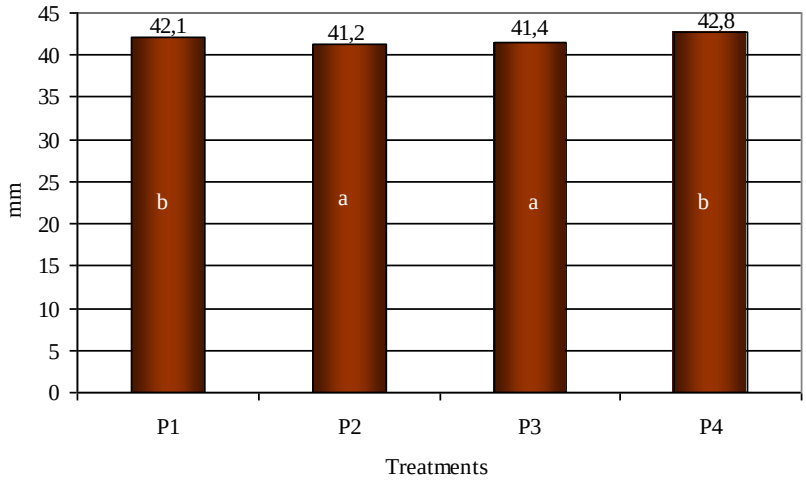
Sd=99%

Fig. 2. Total ear length (cm).

The length of the covered, earlier transplanted treatment P3 was significantly (at *p<0.01* level) shorter compared to the ear length of all treatments. No statistically demonstrable difference was found between ear lengths of covered, direct sowed P1, uncovered direct sowed P2 and P4 (control) treatments.

Total ear length, average ear length 19.6 cm as measured in the variety comparison trials, had been not achieved by the above mentioned treatments.

Other important characteristics for market appeal (total ear diameter), is presented in Figure 3.



F(5;174)=4,440

Sd=99%

Fig. 3. Total ear diameter (mm).

The measured values were significantly (at *p<0.01* level) higher in case of covered treatment P1 and P4 (control) treatment compared to uncovered sowed treatment P2 and covered transplanted treatment P3. The total ear diameter of transplanted, covered treatment P3 and uncovered earlier sowed treatments P2, have had no significantly differences..

Length of seeds is an important characteristic for yield quantity is presented on Figure 4.

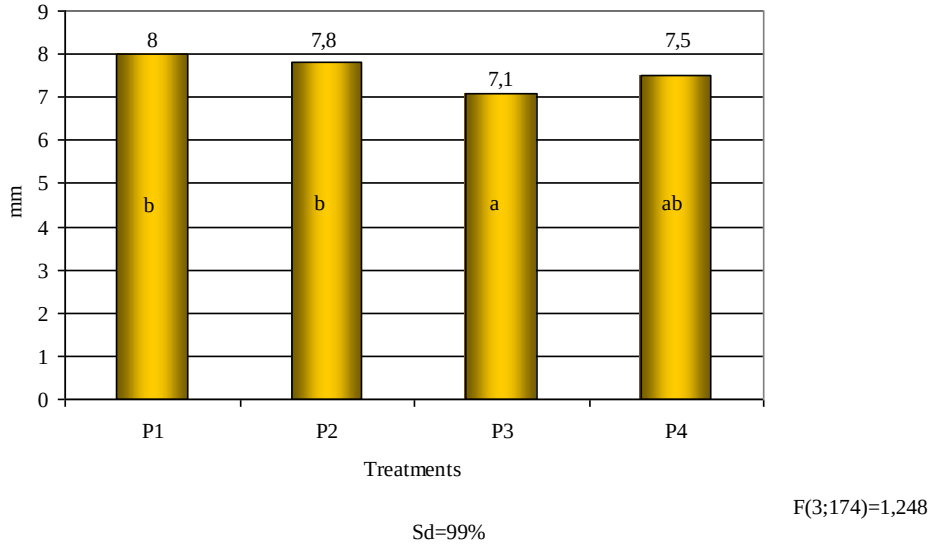


Fig. 4. Length of seeds (mm).

The measured values were significantly (at $p<0.01$ level) higher in case of covered and uncovered, earlier sowed treatments P1 and P2 compared to covered, earlier transplanted P3 treatment. Length of seeds of transplanted, covered treatment P3 and P4 (control) treatment was not found significantly differences.

Conclusions

Based on the results of the 2013 year experiment, the following conclusions can be made:
The growing period was significantly shortened with transplantation of sweet corn plants compared to direct seeded.
Harvest time occurred 26 days earlier in the case of earlier time transplanted and floating row covered (P3) application compared to normal time, direct sowed, uncovered, control (P4) treatment, and 9 days earlier compared to earlier time, direct sowed, covered P1 treatment. At the same time the floating row cover produce 6 days shortening in the growing season between P1 (direct sowing of plants with floating row cover) and P2 (direct sowing of plants with no row cover) treatments.
The fleece covering had favourable effect on studied morphological characteristics of plants that are transplanted and floated with row cover.
In case of direct sowed treatment (P2) the effect of covering had positive effect on unhusked and husked ear weight, length of ears, total diameter of ears, and length of seeds.

Abstract

The aim was to analyze the impact of foliar application of liquid organic fertilizer on the forage and seed yield of red clover (*Trifolium pratense* L.) in conditions of dense sowing on acid soil. The field experiment with varieties of red clover (K-39 – diploid, Amos - tetraploid) and fertilizing treatments (control, Bioplant flora) was set up in Čačak (Serbia) on the alluvium soil type, with acid reaction (pH_{H2O}=4.8). The experiment was designed using a randomized block design with three replications, with the plot size of 5x1m, row spacing of 20 cm and the amount of seed of 18 kg ha^{-1}. The foliar application of fertilizers (Bioplant flora, Plant DOO, Russia at a concentration of 0.4%, with the implementation of 250 l ha^{-1} of water) was carried out in the first and second growth in the second year of cultivation, once at the beginning of intensive growth and the second time two weeks after that. The first growth was used for forage production and the regrowth for seed production. The foliar application of liquid fertilizer influenced the significant increase in forage yield at tetraploid variety Amos. Irrespective of foliar application of liquid fertilizer, cultivar K-39 had a significantly higher number of inflorescences per stem, number of inflorescences m^{-2}, number of seeds per inflorescence, fertility of flowers and seed yield than variety Amos. Foliar application of liquid manure has affected a significant increase in the value of yield components, primarily fertility of flowers and seed number per inflorescence in cultivar K-39.

Key words: *red clover, Bioplant flora, yield, variety*

Introduction

Thanks to the high and stable yield, diverse use, relatively modest requirements for cultivation and good forage quality, red clover (*Trifolium pratense* L.) is an important plant species in the production of forage for livestock feed rich in proteins. In the Republic of Serbia as the most rational proved to be combined production of forage and seeds of red clover (Lugić et al., 1996), where for the production of seeds is used the second growth in the second year and sometime the second growth in the third year. Seed yield of red clover is mainly determined by the genetic base of the cultivar, environmental conditions of the area, time of cut the first growth, presence of insects pollinators as well as the interaction of genotype/environment (Steiner et al., 1995). Proper mineral nutrition, and the content of some macro and micronutrients in plants can also be a limiting factor for achieving high yield of red clover, especially when production takes place on acid soils, where certain macro and micro-elements are heavily accessible to the plants. According to Taylor and Quesenberry (1996) acid soils are cheracterized by a high prevalence of easily accessible form of aluminium, iron and manganese and reduced content of readily available phosphorus, calcium and molybdenum.

The aim of the research was to assess the impact of foliar application of liquid fertilizer Bioplant flora to forage and hay yield, seed yield and seed yield components of red clover in the second year of growing in one diploid and one tetraploid variety, on an acid soil near Čačak city (Serbia).

Materials and methods

The experiment was set up in 2012 on the estate of veterinary stations in Čačak (43º54'39.06"N, 20º19'10.21"E, 246m above sea level), on the alluvial soil type, acid reaction (pH H_2O 4.8), which contains 3.18% of organic matter, 0% $CaCO_3$, 22.08 mg P_2O_5, 30.0 mg K_2O 100 g^{-1} soil. Together with the basic treatment and after the first growing season, the land was fertilized with 300 kg ha^{-1} of $N_{15}P_{15}K_{15}$. Factorial experiment was designed using a randomized block design with three replications with plot size of $5m^2$ (5x1m). These cultivars of red clover were chosen for the trial: K-39 – diploid and Amos – tetraploid. Sowing was done in rows of 20 cm width and the amount of seeds of 18 kg ha^{-1}, which is according to Lugić et al. (1996) recommended in combined production. The crop is grown without irrigation. Foliar application of fertilizers (Bioplant flora, Plant DOO, Russia at 0.4%, with the implementation of 250 l ha^{-1} water) was carried out in the first and second growth in the second year of cultivation, once at the beginning of intensive growth and the second time after two weeks.

The analyses were carried out in the second year (2013). The first growth was cutting in the bud stage. Green forage yield was determined by measuring the total mass of the plots immediately after cutting and converted to forage yield in t ha^{-1}. After drying the metered sample to room temperature, the hay yield was recalculated (t ha^{-1}). The second growth was used for the production of seeds. In the field were determined following yield components: number of stems m^{-2} and number of inflorescences m^{-2} (counting the area of 0.2 m^2 per elementary plot), number of inflorescences per stem (counting on ten randomly selected strips from elementary plot). In the laboratory is determined by: flower number per inflorescence and seed number per inflorescence (on a sample of ten inflorescences per elementary plot) and thousand grains weight (based on weight 5x100 seeds separated from the same sample as the pods were). Fertility of the flowers was recalculated on the base of number of flowers and the number of seeds per inflorescence. The actual seed yield was determined on the basis of yield components (number of inflorescences per unit area, number of seeds per inflorescence, thousand grains weight) and recalculated on the seed yield in kg ha^{-1}.

The mean annual air temperature in 2013 was 13.0ºC, and the amount of annual rainfall 582.7mm. The average annual air temperature for the multi-year period (1992-2002) was 11.97ºC, and the average sum of annual rainfall 680.3mm.

The results were analyzed using analysis of variance of two-factor experiment (ANOVA) using SPSS 4.5 software. The significance of differences of the mean values of the varieties, foliar nutritions as well as interaction middles were tested with LSD test.

Results and discussion

The most of the European and Japanese manufacturers stand out the advantage of tetraploid varieties of red clover for forage production, which are characterized by higher and more stable yield as compared to the diploid (Tomaszewski, 1989; Jonsson, 1985). However, the obstacles to the wider introduction of tetraploid red clover cultivars into the production are a low yield and high cost of the seed (Vasiljević et al., 1999). In our experiment, in the first cutting in the second year of growing, regardless of foliar nutrition, the diploid cultivar K-39 had a significantly greater height of stem in relation to the tetraploid variety Amos (Table 1.). However, in terms of green forage yield, hay yield and content of hay compared to the green forage yield, the cultivars

had not any significant differences between themselves. Due to a very expressed drought in 2012 the crop was badly prepared, so in the first cutting in 2013 a very low forage yield was achieved.
A propper mineral nutrition of red clover, especially on acid soils, is one of the preconditions for the relization of a better yield potential. Foliar application of liquid fertilizer, has positively influenced the increase in the yield of green forage only in varieties of Amos, which usually has a higher potential for yield of forage.
In the second growth in the second year of cultivation, in our experiment, in terms of the number of stems m^{-2}, there were not any significant differences between the cultivars of red clover, as well as between the treatments (Table 2.). Irrespective of foliar application of liquid fertilizer, a significantly higher number of inflorescences per stem and number of inflorescences m^{-2}, had the diploid variety K-39 as compared to the tetraploid variety Amos.
Wilczek and Cwintal (2008) indicate that foliar fertilization of red clover with microelements can have a positive effect on the components of yield, and seed yield. The foliar fertilization in our experiment, had not any significant effect on the increase of inflorescences number per stem and inflorescences number m^{-2} in any of the varieties.

Table 1. Plant height, forage yield, the share of hay in relation to the total weight of forage and hay yield of red clover cultivars (K-39, Amos) as affected by foliar treatment (control – Ø, Bioplant).

		Plant height (cm)	Forage yield (kg ha^{-1})	Share of hay (%)	Hay yield (kg ha^{-1})
Cultivar	K-39	72,9 a	6,94	22,53	1,569
	Amos	55,5 b	6,38	20,72	1,301
Fertilization	Ø	64,2	5,63 b	22,84	1,292
	Bioplant	64,3	7,68 a	20,42	1,578
K-39	Ø	72,9	6,33 ab	23,79	1,503
	Bioplant	72,9	7,55 ab	21,27	1,634
Amos	Ø	55,5	4,94 b	21,88	1,08
	Bioplant	55,6	7,82 a	19,57	1,527

The values denoted with different small letters within columns for genotypes, foliar treatment and interaction are significantly different ($p<0,05$) in accordance with the LSD test.

Table 2. Seed yield components: stems number m^{-2} – SNM, inflorescence number per stem – INS, inflorescence number m^{-2} – INM, flower number per inflorescence – FNI, seed number per inflorescence – SNI, fertility – F (%), thousand seed weight – TSW (g) and seed yield – SY (kg ha^{-1}) in red clover cultivars (K-39, Amos) as affected by foliar treatment (control – Ø, Bioplant).

		SNM	INS	INM	FNI	SNI	F	TSW	SY
Cultivars	K-39	258	4,10 a	1111 a	83	35,5a	43,5 a	1,696 b	672 a
	Amos	254	2,23 b	562 b	80,9	11,7b	14,4 b	2,006 a	198 b
Foliar	Ø	282	2,83	769	82,6	20	24,4	1,962	315
treatment	Bioplant	230	3,5	876	81,3	27,2	33,5	1,777	555
K-39	Ø	297	3,57 ab	1041	84,5	26b	31,7 b	1,807 ab	475 b
	Bioplant	219	4,63 a	1181	81,5	45 a	55,4 a	1,586 b	870 a
Amos	Ø	267	2,10 b	552	80,7	14 c	17,2 bc	2,045 a	156 b
	Bioplant	242	2,37 b	571	81,1	9,4 c	11,6 c	1,967a	241 b

The values denoted with different small letters within columns for genotypes, foliar treatment and interaction are significantly different ($p<0,05$) in accordance with the LSD test.

In terms of the number of flowers per inflorescence, there also were not any significant differences between the varieties of red clover, or between the treatments. According to Julien (1956) and Miladinović (1978) between the genotypes of red clover there were large differences in the number of flowers per inflorescence.

Regardless of foliar nutrition, a significantly higher number of seeds per inflorescence was recorded in cultivar K-39 in relation to the variety Amos. This is due to significantly higher fertility of flowers in the variety K-39, which was expected, given that it is a diploid variety, as compared to Amos, the tetraploid one. Reduced fertility of tetraploid cultivars of red clover causes a compositive complex of factors: genetic, cytogenetic, embryogenic, flower morphology, climate and other factors. The most common causes of low seed yield are: reduce of number of productive stems, inflorescence number, and the number of flowers, as well as unfavorable conditions for fertilization by insects polinators (Vasiljević et al., 1999). Tube of coronal sheet (corolla) in tetraploid red clover is longer, which makes it difficult to polinate with honey bees (Nikovitz, 1985). That is why tetraploid flowers are usually pollinated through large bumble bees (Alekseyev, 1981). Wilczek and Cwintal (2008) reported that the number of seeds per inflorescence and fertility of flowers are the most important components of seed yield of red clover. Jevtić et al. (2007) i Wilczek and Ćwintal (2008) indicate that a major impact on fertility of the flowers and the number of flowers per inflorescence has the presence of insects pollinators. Wilczek and Cwintal (2008) state that in different years fertility of red clover flowers ranged from 51.2 to 69.8% and that a large amount of rainfall during flowering can significantly reduce fertility and harvested seed yield in relation to the potential seed yield.

Foliar application of liquid fertilizer influenced the significant increase of the number of seeds per inflorescence and fertility of flowers only in the variety K-39. The availability of trace elements is one of the factors that can greatly affect the seed yield of clovers (Stoltz and Wallenhammar, 2014). Foliar fertilization is an efficient way to supply plant with micronutrients, especially when their adoption through the root system is limited due to the drought and low soil pH (Mortvedt, 1994; Donald et al., 1998; Dordas, 2006). Since the flowers and seeds of perennial legumes don't transpirate, they are not able to supply themselves with mineral nutrients directly from the soil (Wilczek and Cwintal, 2011). This is a possible reason why in many studies there is a positive effect of foliar use of certain elements, just on the development of flowers and fruit. The reason for better reaction of the cultivar K-39 on the foliar nutrition is generally higher fertility of flowers (29.1%) and higher number of seeds per inflorescence (23.8%) as compared to the variety Amos, so the effect of foliar nutrition in this cultivar had a better expression.

Irrespective of foliar treatment, a significantly higher thousand grain weight had the cultivar Amos (2.0 g) as compared to the cultivar K-39 (1.7 g). The foliar application of liquid organic fertilizer did not significantly influence on the thousand grain weight in any of the cultivars.

Regardless of foliar nutrition, diploid cultivar K-39 had a significantly higher seed yield (672 kg ha^{-1}) in relation to the tetraploid cultivar Amos (198 kg ha^{-1}) as a result of primarily higher fertility of flowers and higher inflorescences number per unit area, and a higher number of inflorescences per stem. Obtained results are in accordance with the results (Vojin, 2007) according to which the diploid genotypes of red clover gave a significantly higher seed yield as compared to the tetraploid varieties. According to Montardo et al. (2003) and Herrman et al. (2006), the seed yield is in a positive corelation with the number of inflorescences per plant of red clover. The basis for increasing the seed yield potential according to the same authors is the increase of the number of inflorescence per plant. Herrman et al. (2006) have found a positive correlation between seed yield per plant and seeds number per plant, seed yield per plant and flower fertility, as well as the seeds number per inflorescence and fertility of flowers.

Foliar application of liquid organic fertilizer influenced the significant increase in actual seed yield only in cultivar K-39. It can be associated with better supply of plant with mineral nutrients, given that the soil with acid reaction and a positive effect of biostimulators, which the fertilizer contains on growth, ellongation of stem and inflorescence development, as well as greater

fertility of the flowers of this variety, which normaly has a higher potential for seed yield. Numerous other studies also point out the importance and role of foliar application of fertilizers on productivity of various species of plants (Nyomora et al., 1997; Perica et al., 2001; Asad et al., 2003; Donald et al., 1998).

Conclusion

Irrespective of foliar application of liquid organic fertilizer, cultivar K-39 had a significantly greater height of the stem, greater number of inflorescences per stem, number of inflorescences m^{-2}, number of seeds per inflorescence and significantly higher fertility of flowers than variety Amos. All this has resulted in significantly higher seed yield in cultivar K-39, regardless of foliar nutrition.

Foliar application of liquid organic fertilizer in the first growth in the second year of cultivation caused the significant increase in the forage yield in the tetraploid variety Amos. Also, foliar application of liquid fertilizer Bioplant flora in the second growth, influenced the significant increase in the value of yield components, primarily fertility of flowers and seed number per inflorescence in cultivar K-39, which normally has a greater potential for seed yield. This is the result of positive action of biostimulants and nutrients which the fertilizer contains on the growth and development of vegetative and generative organs.

COMPARATIVE TESTING OF MAIZE HYBRIDS (ZEA MAYS L.), CULTIVATED FOR GRAIN, UNDER NON-IRRIGATION IN CENTRAL NORTH BULGARIA

Vanya DELIBALTOVA

Department of Crop Science, Faculty of Agronomy, Agricultural University, Plovdiv, Bulgaria
*Corresponding author: vdelibaltova@abv.bg

Abstract

The experimental work was performed in the Central North Bulgaria region – city of Pavlikeni in the period 2012 - 2014. The experiment was performed on carbonate chernozem soil type by means of a block method with four repetitions; experimental field area - 15 m2, after the predecessor winter wheat. The following hybrids were tested; P8523, P9606, P9721, P0412 and P1114. The aim of the investigation was to establish the productivity of five maize hybrids for grain, grown under the conditions of central north Bulgaria. All the stages of the established technology for maize growing under non-irrigation conditions were followed. The experimental data was processed according to the method of dispersion analysis. The analysis of the results showed, that the highest values of elements of productivity - length of the cob, number of the row per cob, number of the grains per row, mass of the cob, mass of the grains per cob and mass of 1000 grains were reported in the hybrid P0412 and the lowest in P8523 hybrid. Under the conditions of North Central Bulgaria the highest yield was obtained in P0412 hybrid – 8163 kg/ha, and the lowest one – in P8523 hybrid – 6821 kg/ha. The percentage content of protein in grain was the highest in P1114 hybrid (10.8 %) and that of fats – in P0412 (5.19 %). The highest starch content was established in P8523 hybrid (77.05 %).

Keywords: *maize, elements of productivity, yield of grain, protein, fats, starch.*

Introduction

The production potential of hybrid maize is determined by the environmental factors as well as by the technology of growing (Calvino et al., 2003; Delibaltova, 2014; Niaz et al., 2014).

The agroecological and the climatic conditions in the separate regions of Bulgaria influence the development and productivity of plants (Liu et al., 2012; Stoyanova and Mihova, 2008; Zivkov and Matev, 2005). The right choice of the maize hybrids and the proper regional distribution, as well as their growing by strictly following the agrotechnical practices, are of vital importance for the yield amounts and the quality of the produce obtained (Chen et al.,2013; Dong et al.,2016; Kandil, 2013). That necessitates the constant introduction of new hybrids that are the most suitable and efficient for the separate microregions of Bulgaria (Delibaltova, 2009; Delibaltova and Ivanova, 2009). The aim of the investigation was to establish the productivity of five maize hybrids for grain, grown under the conditions of central north Bulgaria.

Material and methods

Field trials

The experimental work was performed in the Central North Bulgaria region – city of Pavlikeni in the period 2012-2014. The experiment was performed on carbonate chernozem soil type by means of a block method with four repetitions; experimental field area - 15 m2, after the

predecessor winter wheat. The following hybrids were tested; P8523, P9606, P9721, P0412 and P1114.

Ploughing-in of the stubble was performed in August after the forecrop was gathered, and deep ploughing at 25 - 28 cm was performed in October; pre-sowing cultivation with harrowing was performed twice in March and April. Fertilization was performed in autumn before deep ploughing, with 8 kg active substance phosphorus and 10 kg active substance potassium and before sowing with 18 kg active substance nitrogen. The sowing was performed in the second decade of April as the seeds were pre-processed against diseases and pests (by Vitavax – 250 ml / 100 kg seeds and by Diafuran 2.5 l / 100 kg seeds respectively), at crop density of 65000, 63000, 63000, 59000 и 59000 plants per ha for - P8523, P9606, P9721, P0412 and P1114 respectively. Herbicide Gardian3000 ml/ ha was applied before sowing and Merlin duo – 1500 ml/ha was applied during vegetation of maize for weed control. All the stages of the established technology for maize growing under non-irrigation conditions were followed. The indices height of the plants, height of the cob, length of the cob, number of the row per cob, number of the grains per row, mass of the cob, mass of the grains per cob, mass of 1000 grains, grain yield and protein, fats, starch content in grain were determined.

Statistical analysis

For the purpose of determining the quantity dependence between the studied indicators, the experimental data were processed according to the Anova Method of dispersion analysis, and the differences between the variants were determined by means of the Dunkan's Multiple Range Test (Dunkan, 1995).

Results and discussion

The period of study (2012-2014) comprised years, which differed significantly concerning the major meteorological factors (air temperature and precipitation sum) having an effect on maize productivity. The most favourable for the growth and development of the plants was reported to be 2014, followed by 2013 and the most unfavourable was 2012. The last experimental year (2014) was characterized by temperature values close to those established for many years and by enough and evenly distributed precipitations fully meeting the requirements of the hybrids for moisture from emergence till ripening. In the first year of the experiment (2012) the rainfalls were insufficient and unevenly distributed. The dryness during the critical stages of maize development had on the production possibilities of the plants.

The values of the morphological characteristics and the structural elements of the yield were presented in Table 1 in average for the three years. The studied hybrids differed significantly in the height of the plants. The lowest height was reported for the plants of hybrid P8523 (193.3 cm) and the highest were the plants of hybrid P1114– 241.7 cm. Referring to that characteristic P0412 hybrid fell behind P1114 by 2.6 % and P9721 surpassed P9606 by 4.3 %. The height of the first cob initiation as a characteristic determining the suitability level for mechanized maize grain harvesting varied from 63.2 cm in P8523 hybrid to 116.7 cm in P1114. Due to the lower height of the first cob initiation in P8523 and P9606, the regulation of the combine harvester is necessary for the better quality harvesting.

The analysis of the cobs showed that the late hybrid P0412 had the longest cobs – 23.7 cm and it surpassed P1114 by 7.7 %, the difference being statistically significant, while the medium lates P9721 and P9606 were surpassed by 11.8 and 20.3 %, respectively. The early hybrid P8523 formed cobs of the smallest length – 18.1 cm. The highest values of the characteristic number of rows in the cob were reported in P0412 hybrid – 16.5 rows and in the rest hybrids the number

varied from 13.1 (P8523) to 14.3 rows (P9721). It was statistically proven that P0412 hybrid surpassed by 15.9 % in average all the other studied hybrids.
Out of all the investigated hybrids the smallest number of grains in the row, in average for the three years, was established in hybrid P8523 – 38.2 and it fell behind the hybrids P9606, P9721 and P1114 by 7.3, 18.8 and 27.2 %, respectively, the biggest number of grains in the row being formed by hybrid P0412.

Table 1.Morphologic characteristics and structural elements of the yield of maize hybrids mean for the period 2012 – 2014

Hybrids	Height of the plants, cm	Height of the cob, cm	Length of the cob, cm	Number of the row per cob	Number of the grains per row	Mass of the cob, g	Mass of the grains per cob, g	Mass of 1000 grains, g
P8523	193.3 [a]	63.2 [a]	18.1 [a]	13.1 [a]	38.2 [a]	166.5 [a]	150.4 [a]	265.0 [a]
P9606	219.1 [b]	74.5 [b]	19.7 [b]	14.0 [a]	41.0 [b]	177.3 [b]	162.0 [b]	278.6 [b]
P9721	228.5 [c]	101.0 [c]	21.2 [c]	14.3 [a]	45.4 [c]	209.6 [c]	167.0 [b]	297.9 [c]
P0412	235.6 [d]	108.5 [c]	23.7 [d]	16.5 [c]	50.3 [e]	235.8 [e]	250.2 [d]	367.2 [e]
P1114	241.7 [e]	116.7 [d]	22.0 [c]	15.5 [b]	48.6 [d]	223.4 [d]	223.0 [c]	326.7 [d]
LSD 5 %	*5.38*	*8.01*	*1.52*	*1.42*	*2.77*	*10.2*	*7.80*	*11.5*

Cob weight in the late hybrids was from 223.4 to 235.8 g. P1114 hybrid fell behind P0412 by 5.5 % and the P9606 fell behind the hybrid P9724 by 18.2 %. The lowest values of that characteristic were reported in the early hybrid P8523 – 166.5 g. The differences between the hybrids were statistically significant.
The grain weight per cob in average for the period varied from 150.4 g in P8523 to 250.2 g in P0412. P1114 hybrid fell behind P0412 by 11.2 % (with statistical significance), however, both of them had higher grain weight per cob compared to P8523 – by 14.8 % and 16.6 %, respectively, as well as to P9606 and P9721 – by 13.6 % and 15.2 % in average. Grain weight per cob in P0412 was bigger compared to all the hybrids, the differences varied from 11.2 % to 16.6 % and they were statistically very significant. Like the other structural elements of the yield, 1000 grain weight characteristic also had the highest values established in hybrid P0412, i.e. 367.2 g. In the rest of the hybrids the values of that characteristic varied within the limits from 265.0 g (P8523) to 326.7 g (P1114). Data statistical processing showed that the differences between all the studied hybrids were significant.
The results obtained were presented in Table 2 and they showed that both by years and in average for the experimental period hybrid, P0412 surpassed in grain yield all the other hybrids included in the study. The higher grain yield of the hybrid was due to the higher values of its structural elements. The highest grain yields were obtained in the favourable for maize 2014 year when the temperature values and the precipitation sum fully met the plant requirements for warmth and moisture throughout the whole vegetation period. The yields obtained reached up to 11125 kg/ha in hybrid P0412. Referring to grain yield that hybrid surpassed the hybrids P1114, P9721, P9606 and P8523 by 17.4 %, 20.0 %, 21.9 % and 30.8 %, respectively, the differences being statistically significant.
In the second experimental year (2013) the grain yields obtained varied from 7240 kg/ha in the early hybrid to 8265 kg/ha in the late hybrid P0412, i.e. they were by 25.6 % lower in average in comparison with the previous year. Mathematical processing of data showed that hybrid P1114

significantly fell behind P0412 by 95 kg/ha, while hybrid P9606 fell behind P9721 by 118 kg/ha. The lowest yields were realized by hybrid P8523 – 7240 kg/ha.
In the first year of the study (2012) the meteorological conditions during the hybrid vegetation were extremely unfavourable and the plants were not able to attain their biological potential. The grain yields obtained were within the limits of 4720 to 5100 kg/ha. Statistically proven, the lowest ones were those of hybrid P8523 and the highest – of P0412.

Table 2. Grain yield – kg/ha

Hybrids	Stand density Plants/ha	Years of stady			Average for the period kg/ha
		2012 kg/ha	2013 kg/ha	2014 kg/ha	
P8523	65000	4720 [a]	7240 [a]	8503 [a]	6821
P9606	63000	4887 [b]	7564 [b]	9130 [b]	7194
P9721	63000	5000 [c]	7682 [c]	9270 [c]	7317
P0412	59000	5100 [d]	8265 [e]	11125 [e]	8163
P1114	59000	4974 [c]	8170 [d]	9472 [d]	7539
LSD 5 %		*43.2*	*66.1*	*51.4*	

The results of the hybrids P1114, P9721 and P9606 had quite close values and they were statistically insignificant.
During the period of study (2012-2014) P0412 hybrid realized the yield of 8163 kg/ha in average and it surpassed the hybrids P1114, P9721 and P9606 by 2.5, 2.0 and 4.3%, respectively. The grain yield obtained from P8523 hybrid was 4720 kg/ha and it was less than the yields from all the other hybrids included in the experiment by 3.5 to 8.1 %.
The results from analyses of variance over three years for the grain yield are presented in Table 3. It was found that the effects of Hybrids and Year on the yield grain were significant. The Interaction was also statistically significant.

Table 3. Analysis of variance.

Source of Variation	*SS*	*df*	*MS*	*F*	*P-value*	*η 2*
Hybrids	11823911,9	4	2955978,0	4834,07	0,000	34,7

Interaction	6701336,2	8	837667,03	1369,88	0,000	31,8
Residual	27517,0	45	611,49			

The nutritional and forage value of maize grain is determined to a great degree by the content of proteins, fats and starch. Data of the chemical analyses (Table 4) showed that the highest protein content in grain was established in hybrid P1114 – 10.8 %. It exceeded the hybrids P0412, P9721, P9606 and P8523 by 12.5 %, 16.1 %, 36.7 % and 29.3 %, respectively.

Table 4. Chemical composition of grain, mean of the period 2012-2014

Hybrids	%		
	protein	fats	starch
P8523	8.35[a]	4.15[b]	77.05[c]
P9606	7.90[a]	4.05[b]	75.52[b]
P9721	9.30[b]	3.49[a]	74.09[b]
P0412	9.60[b]	5.19[c]	71.80[a]
P1114	10.80[c]	4.67[b]	70.50[a]
LSD 5 %	*0,89*	*0,48*	*1,51*

The fat content varied from 3.49 % in P9721 to 5.19 % in P0412.
The medium early hybrid P9606 fell behind P8523 by 23.4 %, while the medium early hybrid P9721 fell behind the two late ones (P1114 and P0412) by 33.8 and 48.7 %, respectively.
The starch percentage was lowest in P1114 – 70.5 % and highest in P8523 – 77.05 %. The early hybrid exceeded the values of that characteristic established in the hybrids P9606, P9721 and P0412 by 2.0 %, 4.0 % and 7.3 %, respectively.

Conclusions

The characteristics plant height and height of the first cob initiation had the highest values in hybrid P1114 (241.7 and 116.7 cm) and the lowest in P8523 (193.3 and 63.2 cm).
The structural elements of yield – cob length, number of rows per cob, number of grains per row, cob weight, weight of the grains per cob and 1000 grain weight varied within a broad range, the highest values being reported in hybrid P0412. There was an obvious tendency of increase of those values in the direction of early to late hybrids.
Under the conditions of North Central Bulgaria the highest yield was obtained from P0412 hybrid – 8163 kg/ha, followed by P1114 – 7539 kg/ha and the lowest one – from P8523 hybrid – 6821 kg/ha.
The percentage content of protein in grain was the highest in P1114 hybrid (10.8 %) and that of fats – in P0412 (5.19 %). The highest starch content was established in P8523 hybrid (77.05 %).

Abstract

Oyster mushroom has lately been more produced worldwide due to its shorter growing season and fruiting, high resistance to diseases and pests, and low requirements for growing conditions. Growing oyster mushrooms is simple and many different substrates are used which contain cellulose, hemicelullose and lignine. The degradation of these components provides fruiting bodies of mushrooms and they are important for human nutrition. The process of growing mushrooms uses agricultural residues, so oyster mushroom cultivation directly helps the management of organic waste. Storing and burning organic waste have become a significant environmental issue and large quantities of biomass are unnecessarily being destroyed. The aim of this study was to grow oyster mushrooms on agricultural waste most abundant in Vojvodina Province – wheat and soybean straw and maize and sunflower stalks, used as individual substrates and in combination with wheat straw, which is most often used as oyster mushroom substrate. Isolated and determined oyster mushroom (*P. ostreatus*) strain was used (NS 77). The effect of substrate on the nutritive content of mushrooms was analyzed, as well as the content of water, proteins, fats, cellulose, ash and mineral elements. Determination of the effect of substrate on the content of nutrients in the oyster mushroom enabled control of the quality of mushrooms depending on the market demands.

Key words: *oyster mushroom, strain NS 77, substrate, nutritive value,*.

Introduction

Wide distribution of *Pleurotus* sp. use is mostly based on its growing on a wide array of substrates from unused lignocellulosic biomass waste from plant growing. In India it is grown on false banana tree and cut rice straw (Jandaik, 1974), cotton waste in Malesia (Tan, 1981) while Danai *et al*. (1989) report on mix from cotton straw and wheat straw in Israel. Sawdust supplemented with wheat bran or rice bran is used in the commercial cultivation in Japan (Wang *et al*., 2001). In Portugal it is grown on oat straw (Fernandes *et al.*, 2015), in Taiwan on sawdust, corncob, sugarcane bagasse (Hoa *et al*., 2015). Manzi *et al* (1999) added 15% of sugar beet waste to wheat straw in Italy. The prospects of wide use of oyster mushroom in the future is based on the easily-accessible and affordable substrates, its nutritive value and content of medicinally active compounds which benefit human health, while at the same time the unique taste (Bugarski *et al*., 2012). Nutritive value is similar to other plant species, with the addition of much higher protein content in oyster mushroom. According to Akyuz and Kirbag (2010) and Wani *et al.* (2010), protein content ranges between 17 g and 42 g per 100 g dried mushroom, while in fresh mushroom it is around 4% (Lin, 1999). The difference resulting from high water content which ranges from 87.5% to 92,5% depending on the strain, substrate and cultivation practices (Bugarski *et al*., 2012). Regarding mineral elements, oyster mushroom contains significant

quantities of P, K, Na, Se and Mg (Lin, 1999). Wang et al., (2001) reported similar nutrient contents in commercially grown mushrooms and wild mushroom species, but also quantitative and qualitative differences between different *P. ostreatus* strains and growing methods and conditions. Mshandete and Cuff (2007) state that, apart from the strain and substrate, the chemical composition depends on the growing stage and part of the mushroom as well. Inspired by these data, this study aimed to separately analyse the chemical composition in the cap and stalk. This study supposed that if the chemical composition of the mushroom stalk does not differ significantly from the chemical composition of the mushroom cap, the stalk could be dried, milled and used for cookery.

Material and Methods

In this three-year trial (2006-2009), strain of Pleurotus ostreatus NS 77 was grown on different substrates under production conditions, and the effect of chemical composition of the cap and the stalk was analysed. The strain NS 77 comes from the collection of the Institute of Field and Vegetable Crops in Novi Sad, Serbia. The mushroom is of standard shape, light grey, with a large number of small fleshy fruits on long stalks growing in clusters. The substrates were prepared individually or in the in the following combinations with wheat straw which is the substrate most often used in oyster mushroom cultivation in Serbia: 1. Wheat straw (S1) 2. Wheat straw 50% + Soybean straw 50% (S2) 3. Wheat straw 50% + Corn stalks 50% (S3) 4. Wheat straw 50% + Sunflower stalks 50% (S4) 5. Soybean straw (S5) 6. Corn stalks (S6) 7. Sunflower stalks (S7). Average mushroom samples were collected from each replication for chemical composition of caps and stalks were determined separately. Moisture percentage was determined according to Roy (1993). Cellulose was determined by the standard AOAC method and crude fats by the conventional Soxhlet method. N was determined on CNSH Elementar Vario III Analyser (KONIG, 1991) and multiplying by a conversion factor 4.375 was obtained a protein content. The plant material was mineralised according to the standard method ISO 551:1979. In order to test the differences between the treatments for chemical characteristics, the null hypothesis H_0: $\mu_i = \mu_j$ was tested for all values of chemical characteristics $i \neq j$ using the Tukey's test, at 95% level of significance. The interpretation of the graphics follows the geometrical principles of biplot (Kroonenberg, 1995). The data were assessed and visualized in R program (R Core Team, 2015).

Results and Discussion

Analysis of variance showed significant differences in water content depending on the substrate used for growing oyster mushroom (*P. ostreatus*) strain NS 77. The highest water content (Tab. 1) was found in oyster mushroom grown on S6 (92.11%), and the lowest in oyster mushroom grown on S4 (91.19%), which is in accordance with the results of Manzi *et al.* (1999) who reported the range between 85.2% and 94.7%, Akyuz and Kirbag (2010) (89.7%-90.3%) and Pardo-Gimnez *at al*. (2015) (91.9%- 92.4%).

Table 1. Content of nutrients (%) in the cap and the stalk of the strain NS 77

Sub	Content of nutrients in the cap					Content of nutrients in the stalk				
	Moisture	Protein	Fat	Cellu.	Ash	Moisture	Protein	Fat	Cellu.	Ash
S1	91.34^{ab}	21.52^{ab}	2.32^{a}	3.56^{a}	8.27^{a}	91.34^{ab}	6.93^{a}	0.99^{abc}	2.77^{a}	5.61^{a}
S2	91.56^{ab}	22.85^{ab}	2.20^{a}	3.61^{a}	9.47^{a}	91.56^{ab}	7.77^{ab}	0.85^{ab}	3.63^{a}	7.97^{ab}
S3	91.72^{a}	26.23^{a}	1.71^{a}	3.32^{a}	8.77^{a}	91.72^{a}	9.27^{ac}	1.60^{c}	3.97^{a}	7.24^{ab}
S4	91.19^{b}	19.80^{b}	1.97^{a}	2.77^{a}	8.31^{a}	91.19^{b}	6.73^{a}	0.61^{a}	2.54^{a}	5.52^{a}
S5	91.43^{b}	18.53^{b}	1.58^{a}	2.67^{a}	8.74^{a}	91.43^{b}	6.53^{a}	1.20^{abc}	3.60^{a}	7.24^{ab}
S6	92.11^{a}	25.89^{a}	1.28^{a}	3.25^{a}	9.30^{a}	92.11^{a}	10.87^{c}	1.16^{abc}	3.55^{a}	9.08^{b}
S7	91.18^{ab}	22.39^{ab}	1.96^{a}	2.74^{a}	8.76^{a}	91.18^{ab}	7.37^{ab}	1.53^{bc}	3.74^{a}	6.29^{a}

Note: a, b, c, - values designated with the same alphabetic lettering in a column are not statistically significant (Tukey's test of multiple comparisons)

Ash content in mushroom cap showed no significant difference in relation to different substrates and ranged between 9.47% in mushroom grown on S2, and 8.27% in mushroom grown on S1. Ash content in mushroom stalk showed significant differences in relation to different substrates and ranged between 9.08% in mushroom grown on S6 and 5.52% in mushroom grown on S4 or 5.61% in mushroom grown on S1 or 6.29% in mushroom grown on S1 (Tab. 1). This is in accordance with the reported 13.7-6.0% in Akyuz and Kirbag (2010), 6.7-8,4% in Wang *et al.* (2001), 5.9-6.42% in Patil *et al.* (2010), and 7.32-7.83% in Kortei *et al.* (2014).

Protein content showed significant differences in the cap and the stalk in relation to the substrate used. The mushroom cap showed significant differences regarding protein content in mushrooms grown on the S3 (26.23%) and S6 (25.89%) in relation to S5 (18.53%) and S1 and S7 (19.80%) as shown in Table 1. The mushroom stalk showed significant differences regarding protein content in mushrooms grown on S6 (10.85%) and S3 (9.24%) in relation to other substrates, especially S5 (6.52%), which had the lowest protein content. The results from the cap are somewhat lower than Deepalakshmi and Mirunalini (2014) who reported 17-42%, and higher than Kortei *et al.* (2014) who reported 10.48-10.80%. Cellulose was uniform in mushrooms grown on all substrates. Its content in the mushroom cap ranged from 2.67% in S5 to 3.61% in S2. Cellulose content in the mushroom stalk ranged from 2.54% in S4 to 3.97% in S3.

Depending on the substrate on which oyster mushroom was grown, there were no significant differences in fat content in the cap, and it ranged from 1.28% in S6 to 2.32% in S1. On the other hand, there were significant differences in fat content in the stalk, and it ranged from 1.60% in S1 or 1.53% in S7 and 0.61% in mix of S4 (Tab. 1). Fat content results in the stalk are similar to the results of Akyuz and Kirbag (2010) (0.5-1.3%).

There were significant differences in P content in mushroom cap and stalk in relation to the substrate used. P content in the cap showed significant differences in mushrooms grown on S6 (123 mg) in relation to S1 (85 mg), as shown in Table 2. P content in the stalk showed significant differences in mushrooms grown on S2 (68 mg) or S6 (67 mg) and S1 (26 mg), as shown in Table 3. The results are lower than reported in Wang *et al.* (2001),) and Manzi *et al*. (1999). There were no significant differences in Na content in the mushroom cap regarding different substrates, and it ranged from 6.15 mg in mushrooms grown on S3 to 31.02 mg in S1(Tab. 2). However, there were significant differences in Na content in the mushroom stalk which ranged from 17.22 mg in S3 to 56.94 mg in S5 (Tab. 3). Wang *et al.* (2001) reported Na content of 21.9 mg, and Manzi *et al.* (1999) reported Na content of 25.2-136.0 mg.

Similar results were found for Ca content in mushroom cap, which ranged from 2.23 mg in mushrooms grown on S7 to 3.19 mg in S2. There were significant differences in Ca content in mushroom stalk and it ranged from 1.97 mg in S4 to 2.99 mg in mushrooms grown on S6 (Tab. 2). The results are similar to lower values (2-36 mg) reported by Deepalakshmi and Mirunalini (2014), but are tenfold lower than 23.5-48.6 mg reported by Manzi *et al*. (1999).

Table 2. Content of minerals (mg/100 g dry matter) in the cap of the strain NS 77

Substrates	Ca	Cu	Fe	Mg	Mn	Na	P	Zn
S1	2.76^{a}	1.84^{a}	12.31^{a}	171.44^{a}	1.23^{a}	31.02^{a}	85.0^{a}	8.72^{a}
S2	3.19^{a}	2.02^{a}	8.08^{a}	175.83^{a}	1.32^{a}	11.41^{b}	121.0^{ab}	8.36^{a}
S3	2.83^{a}	2.18^{a}	10.08^{a}	153.43^{a}	2.07^{a}	6.15^{b}	108.0^{ab}	9.10^{a}
S4	2.67^{a}	2.07^{a}	13.66^{a}	161.89^{a}	1.31^{a}	10.98^{b}	96.0^{ab}	9.21^{a}
S5	2.80^{a}	2.03^{a}	7.62^{a}	164.52^{a}	1.33^{a}	15.85^{b}	119.0^{ab}	7.97^{a}

Table 3. Content of minerals (mg/100 g dry matter) in the stalk of the strain NS 77

Substrates	Ca	Cu	Fe	Mg	Mn	Na	P	Zn
S1	2.09^{a}	1.14^{a}	5.29^{a}	90.44^{a}	0.54^{a}	28.5^{a}	26.0^{a}	1.86^{a}
S2	2.75^{ab}	1.34^{a}	4.24^{a}	121.90^{bc}	0.56^{a}	33.3^{ab}	68.0^{b}	1.75^{a}
S3	2.58^{ab}	1.68^{a}	4.31^{a}	96.08^{ab}	0.59^{a}	17.2^{a}	43.0^{acd}	3.66^{a}
S4	1.97^{a}	1.24^{a}	4.36^{a}	70.58^{ab}	0.50^{a}	28.3^{ab}	38.0^{ac}	1.30^{a}
S5	2.36^{ab}	1.78^{a}	4.68^{a}	98.92^{abc}	0.70^{a}	56.9^{b}	54.0^{bcd}	2.55^{a}
S6	2.99^{b}	1.83^{a}	5.58^{a}	121.73^{bc}	0.68^{a}	21.4^{a}	67.0^{b}	3.67^{a}
S7	2.07^{a}	1.38^{a}	3.46^{a}	125.82^{c}	0.65^{a}	26.0^{ab}	57.0^{bd}	2.20^{a}

There were no significant differences in Mg content in the mushroom cap regarding different substrates, and it ranged from 153.43 mg in S3 to 178.41 mg in S6. However, there were significant differences in Mg content in the mushroom stalk which ranged from 90.44 mg in S1 to 125.82 mg in S7. The highest Mg content was found in the cap, which is similar to 181.9 mg reported by Wang *et al.* (2001) and 161.4-203.2 mg reported by Manzi *et al*. (1999). The contents of Fe, Mn, Cu, and Zn did not show significant differences in relation to the substrates on which oyster mushrooms were grown. Fe content in the cap ranged from 7.62 mg in S5 to 13.66 mg in S4, and Fe content in the stalk ranged from 3.46 mg in S7 to 5.58 mg in S6 (Tab. 3). Mean values of the results are similar to 7.1 mg which was reported by Wang et al. (2001), and 13.13-15.62% as reported by Patil *et al*. (2010). According to Vetter (1994), Fe content in the cap was 15.1 mg and in the stalk it was 13.7 mg. Mg content in the cap ranged from 1.23 mg in S1 to 2.07 mg in S3, and in the stalk it ranged from 0.5 mg in S4 to 0.7 mg in S5. The results are similar to 1.6 mg reported by Wang *et al*. (2001), higher than 1.13 mg in the cap and almost identical to 0.71 mg in the stalk as reported by Vetter (1994). Cu content in the cap ranged from 1.84 mg in S1 to 2.42 mg in S6, and in the stalk the results were uniform among different substrates but lower, and ranged from 1.14 mg in S1 to 1.83 mg in S6. The results in the cap are similar to 2.5 mg as reported by Wang *et al*. (2001), and 2.19 mg in the cap and 1.62 mg in the stalk as reported by Vetter (1994). Zn content in the cap ranged from 7.97 mg in S5 to 9.51 mg in S7, and in the stalk

it ranged from 1.30 mg in S7 to 3.68 mg in S6. The results are similar to 7.61-11.45% reported by Hoa *at al.* (2015) and somewhat lower than 13.7 mg as reported by Wang *et al.* (2001).

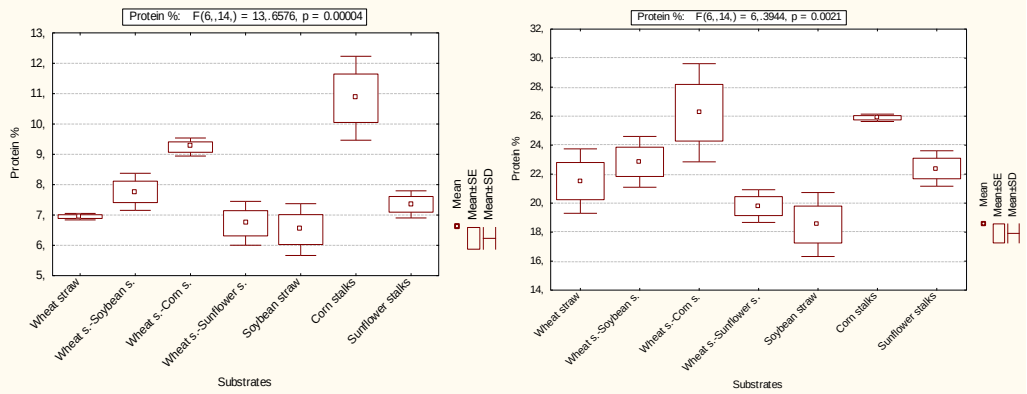

Figure 1. Protein content in stalk (%) Figure 2. Protein content in cap (%)

Cellulose content was similar in the cap and the stalk depending on the substrate, while the contents of protein, fat and mineral elements were mostly higher in the cap than in the stalk, with the exceptions of Zn and Na content. Zn content in the cap was 2.5 times higher in S3, and as much as 7 times higher in S4. Na content ranged from similar value in S1 to 3.6 times lower in S5, as shown in Tables 2 and 3. Higher content of mineral elements in the cap than in the stalk, with the exception of Na, was reported by Vetter (1994).

The highest and the lowest mean values of nutrients and minerals content, except Zn, are lower in the stalks than in the cap. Protein content is also lower in the stalks (Fig. 1) than in the cap (Fig. 2), but is identically distributed throughout the substrates.

The biplot shows that the first dimension explained 54.3% of the variability of samples, while the second dimension explained 17.6% (Fig. 3). Substrates with profiles similar to „the average substrate", i.e. with higher number of characteristics that respond to the most common category, are distributed near the coordinate origin. Among them, S2 stands out, in the vicinity of coordinate origin. Distances between the points for chemical elements and nutrients depend on the similarity of their profiles. Ideally, the parameters that belong to the same substrate are grouped at smaller distances, such as water, proteins, Ca, Zn, ash, and Cu, which form together a group of positive variables with high values for S6 and S3, while fat and cellulose have high values for S3 and S7. The substrate S6 contains only corn stalks, and S3 is the combination wheat straw + corn stalks. These two substrates had high quality and high yields of oyster mushroom.

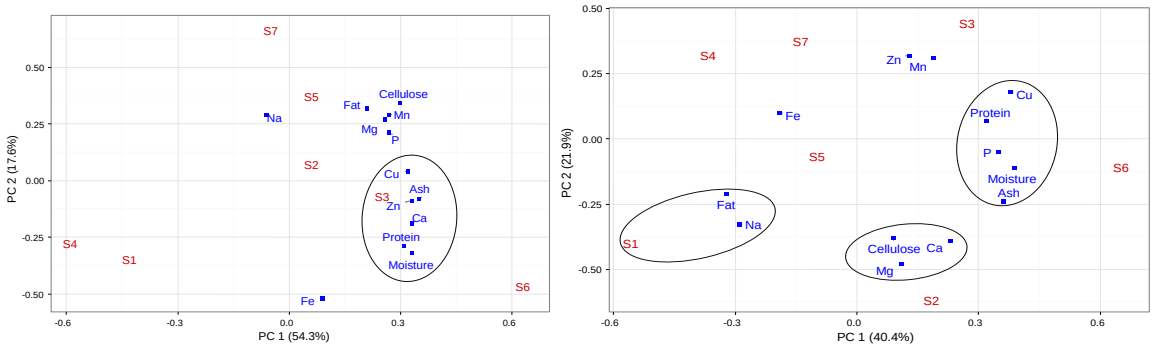

Figure 3 and 4. Biplot of nutrients and minerals content in the stalk and in the cap

The biplot (Fig. 4), shows that the first dimension explained 40.4% of the variability of the samples, while the second dimension explained 21.9%. Along both axes, S5 is situated in the coordinate origin of the biplot, being the substrate with the least variations of the assessed nutrients and minerals. Mg, Ca and cellulose comprise a group of positive variables with highest values for S2, while ash, water, P, proteins and Cu comprise a group of positive variables with high values for S6. S1 had the highest values of Na and fat, while S4 had the highest Fe content.

Conclusions

This study confirmed the initial assumption that chemical composition of oyster mushroom depends on the substrate it is grown on. The study found significant differences in the water content, protein content, P and Na content both in the cap and the stalk, depending on the substrate. Quantity of cellulose, Fe, Mn, Cu and Zn showed no significant differences in relation to the substrate on which they were grown. The contents of ash, fat, Mg, and Ca in the cap were uniform, while in the stalk the difference was significant in relation to the growing substrate. Content of nutrients and minerals in the fruiting body of the strain NS 77 was the lowest in S1, followed by S7 and S4, and it was the highest in S6 and S3 and S2. Corn stalk (S6) was the best substrate regarding water regime, protein content, ash content, P, Ca, Cu, Mn, Zn, and Mg. Therefore, it can be concluded that wheat straw can be used as a substrate only in combination with other crops, such as corn or soybean.

Abstract

Microorganisms present the biotic component of soil and their abundance is an indicator of soil quality. Content of organic matter, as an energy source for microbial metabolism, and chemical properties, especially pH value of the soil, are limiting factors that influence the activity of microbial populations. In order to find solutions of growing alfalfa and other crops on acid soils different agricultural measures are used, and biological measures such as the use of microbial inoculants for better utilization of resources for the development of plants and microorganisms are increasingly introduced. In this paper, the effects of microbial inoculants on the abundance of microorganisms in the rhizosphere soil of alfalfa (*Medicago sativa* L.) were studied. Alfalfa seed of cultivar Syntéza 1 inoculated with two nitrogen-fixing bacteria: rhizobium ((*Sinorhizobim meliloti)* and azotobacter *(Azotobacter chroococcum).* The above listed microorganisms were used individually and in joined cultures. After inoculation seed from each inoculum variant were planted in the pots filled with corresponding soil. The control variant was without inoculation. For the purposes of research two types of soil with different pH were used (the soil with increased acidity and with neutral reaction). The results Fishers LSD test show that the total number of microorganisms in the rhizosphere of alfalfa after inoculation in comparison with the control varied depending on the variant of inoculation and soil type.

Keywords: *microorganisms, alfalfa, inoculation*

Introduction

Soil is a system which is characterized by complex ecological interactions of organisms **(**Zaccardelli et al., 2013). In this system microorganisms play a significant role, they with their enzymatic systems, participate in 60-90% of the total metabolic activity in soil (Lee et al., 1994). Abundance, activity and diversity microorganisms in the soil are factors that determine its fertility (Milošević et al., 1999). The abundance of microorganisms ranges from tens to hundreds of billions in one gram of absolutely dry soil (Govedarica and Jarak, 1995). Stable composition of soil microbiocenoses is important for a correct functioning of this environment (Hawrot-Paw et al., 2016). The abundance of microorganisms in soil is influenced by many abiotic and biotic factors, primarily by soil type, content of organic matter (as an energy source for microbial metabolism), plant species, temperature, water, etc. (Milić et al., 2004).

In relation to the pH, micro-organisms dwell in environments with a wide range of pH from 1.7 to 9.0. The high abundance and activity of microorganisms is characteristic for the soils of neutral and slightly alkaline reaction and with a high content of organic matter. However, acid soils are characterized by low microbial activity (Diaz-Ravina et al, 1998).

In order to find solutions of growing alfalfa and other crops on acid soils different agricultural measures are used, and biological measures such as the use of microbial inoculants for better utilization of resources for the development of plants and microorganisms are increasingly introduced (Jarak et al., 2005). The successful introduction of inoculum strains in the soil depends on the number of indigenous populations, the activities of host plant, and other traits of the soil (Brockwell et al., 1995).

Soils with high acidity have negative effects on the abundance and activity of rhizobium and on the intensity of nitrogen fixation (Soto et al. 2004). To ensure the successful production of alfalfa on soils of high acidity, pre-sowing inoculation using *S. meliloti* strains results in satisfactory nitorgen-fixing activity in such soils. Rhizobium provide macrosymbionts with nitrogen and also synthesize polysaccharides, vitamins B_{12}, B_1, B_2 (Denison and Kiers 2004). In addition to the symbiotic nitrogen-fixers, the increase of nitrogen balance is achieved by the application of free nitrogen-fixers, primarily azotobacter which synthesize gibberellins, auxins, pyridoxine and nicotinic acid (Dobbelaere et al., 2003).

The aim of this study was to examine the effect of inoculation with rhizobium (*Sinorhizobium meliloti*) and azotobacter (*Azotobacter chroococcum*) as individually culture and combined cultures on the number of microorganisms in the rhizosphere of alfalfa grown in different soil types.

Material and Methods

The experiment was a two-factorial, where the first factor was the soil of different pH values and the second factor was the variant of microbial inoculation. For the purposes of research, were used two types of soil with different pH: the soil with neutral reaction pH 6.58 (KCl) - A and the soil with increased acidity pH 4.77 (KCl) – B (Tab. 1). Soil A is of alluvium type, and soil B is a cambisol. Chemical composition of the soil was determined by standard methods in the chemical laboratory of the Institute for Forage Crops in Kruševac.

Table 1. The chemical composition of the soil

Parameter / Soil	Total nitrogen, %	P_2O_5 mg/100g	K_2O mg/100g	Humus, %	pH/KCl
A	0.138	6.60	24.05	2.62	5.58
B	0.204	10.20	51.0	4.30	4.77

Research was conducted on alfalfa cultivar Syntéza 1, bred in the Plant Production Research Center (PPRC) in Pieštany.

The inoculation was done using the following inocula:

1. *Sinorhizobium meliloti* (10.8×10^{11} per ml);
2. *Azotobacter chroococcum* (28×10^{11} per ml)*;*
3. *S.meliloti + A.chroococcum;*
4. Control – no inoculation.

These microorganisms were from the collections of the Department of Microbiology of the Faculty of Agriculture in Novi Sad. The *S. meliloti* cultures were grown on YM substrate by Vincent, *A. chroococcum* cultures were grown on the liquid substrate by Feodorov (Jarak and Djurić, 2006).

The alfalfa seed was sterilized using the 0.2 % $HgCl_2$ solution and 70 % alcohol and rinsed several times with sterile tap water and afterwards submerged in the correct inoculum. After this, the seed of each inoculum variant was planted in the pots containing correct soil type. In each pot, 10 ml of the appropriate inoculum was added. After each alfalfa cut, three times during the

growing seasons, the total number of microorganisms in the rhizosphere was determined for each inoculation variant. This was done by streaking 10^{-6} dilution of soil suspension on soil agar - method of agar panels (Pochon and Tardieux, 1962). The incubation lasted for five days on 28° c. The number of grown colonies was calculated per 1g of absolutely dry soil.

The results were processed using the statistical package STATISTICA 8.0. The significance of the difference between the investigated treatments was determined by analysis of variance i.e. LSD test.

Results and Discussion

The total number of microorganisms, where bacteria were the most abundant, can be used as a general indicator of the biological activity in the soil and is extremely important for the creation and maintenance of soil fertility (Milošević et al., 2000). Alfalfa was grown on soils of different pH values: the soil with neutral reaction (A) and the soil with increased acidity (B). Each type of soil has the characteristic features of microbial processes that can be affected by different measures (Govedarica et al. 1997). The results of statistical analysis by Fishers LSD test show that the total number of microorganisms in the rhizosphere of alfalfa after inoculation varied depending on the inoculation and soil type (Tab. 2). The abundance and diversity of microorganisms in the soil influenced by physical and chemical properties - acidity, amount and type of organic matter, water, air and heat regime, structure and mechanical traits of soil, etc. (Jarak and Čolo, 2007).

After first cut of alfalfa, the total number of microorganisms was statistically different on all variants. Compared to control variants the number of microorganisms was higher on all treatments, except variant of application of combined cultures *S. meliloti + A.chroococcum.* The highest number of microorganisms recorded on treatment of inoculation with *A.chroococcum* in soil A. Examining the impact of the application of inoculation in soybean Cvijanović et al. (2012) have found that the total bacterial number was higher in the inoculated soil. Also, by bacterization of alfalfa on pseudogley the total number of bacteria can be increased (Jarak et al., 2002).

Table 2. The total number of microorganisms (log number) in the rhizosfere of alfalfa

Soil	Variant	I cut	II cut	III cut
A	*S. meliloti*	1,866 ^{c}	1,532 ^{b}	1,394 ^{g}
	A.chroococcum	2,297 ^{a}	1,298 ^{d}	1,406 ^{g}
	S. meliloti + A.chroococcum	1,374 ^{g}	1,430 ^{c}	1,650 ^{e}
	Control	1,529 ^{e}	1,562 ^{b}	1,566 ^{f}
B	*S. meliloti*	1,921 ^{b}	1,634 ^{a}	1,959 ^{b}
	A.chroococcum	1,603 ^{d}	1,164 ^{e}	1,768 ^{c}
	S. meliloti + A.chroococcum	0,999 ^{h}	1,667 ^{a}	1,685 ^{d}
	Control	1,435 ^{f}	1,463 ^{c}	2,226 ^{a}

Note: Mean values with the same superscript(s) are not significantly different according to Fisher's LSD test ($p < 0.05$)

After second cut of alfalfa, the highest number of microorganisms recorded in soil B applicated of monovalent inoculum *S. meliloti* and combined cultures *S. meliloti + A.chroococcum,* but in comparison with the control, number of microorganisms in soil A was lower by applying

A.chroococcum. Comparing to the control, the number of microorganisms in the soil A was statistically significant different in a negative sense on treatments inoculated *A.chroococcum* and *S. meliloti + A.chroococcum.* The treatment with inoculation with *S. meliloti* and control variant make homogeneous group (absence of a statistically significant difference). Large number of microorganisms is introduced into the soil by application of microbial inoculation that brings changes in the abundance and composition of the indigenous population (Andjelković et al., 2013).

In third therm, only in the treatment of soil A, where the mixture of rhizobium and azotobacter was applied, the total number of microorganisms was significantly increased compared to the control. In all other of the inoculation variants achieved statistically significant reduction in number compared to the control. Treatment with inoculation with *S. meliloti* and treatment with *A. chroococcum* in the soil A make homogeneous group (absence of a statistically significant difference). Microorganisms, from those applied inoculums, that can adapt to the conditions prevailing in the soil can help in the intensification of microbiological processes. As noted by Revellin et al. (2000), after application, microorganisms in the soil encounter whole new environmental conditions that may inhibit their activity.

Conclusion

The obtained results showed that the application of microorganisms can provide the different effects in two soils with different pH values collected from agricultural fields at different locations. As a result of the effect of various abiotic and biotic factors that exist in these soils, survival of introduced microorganisms was varied. In the rhizosphere of alfalfa cultivar Syntéza 1 the number of microorganisms varied depending of the variant of inoculation and the type of soil within one term of analysis. Also, the abundance of microorganisms on the same treatment at different time periods was different compared to the control during the growing season. There is no clear trend influence neither one of the factors applied. Application of microbial inoculation, as a biological measure, in order to improve soil and increase its productivity and production potential of crops is justified from environmental and economic aspects.

Abstract

There are numerous factors affecting pollen germination in plants. Plant growth regulators have produced different results on pollen germination both *in vivo* and *in vitro*. In this research, pollen viability using IKI test and effects of three different growth regulators (epibrassinolide, homobrassinolide and gibberellic acid) added into growth medium on the *in vitro* pollen germination of two wine grape cultivars (Cabernet Sauvignon and Merlot) were investigated. Pollen viability results showed that Cabernet Sauvignon contained more viable pollens (63.12% that Merlot (59.06%). Pollens collected from fresh flowers were sown on medium containing 1% agar and 20% sucrose using 'agar in petri dish' method. Results revealed that growth regulators did not affect germination in the cultivars, but the treatments had an overall increasing influence (about 25%). Although, in general, treatments produced similar ratios with the control group, 100 mgL^{-1} GA3, alone, and in combination with 0.01 and 0.001 mgL^{-1} epibrassinolide were found to cause significant increase. In addition, applying the lowest GA_3 concentration (25 mgL^{-1}) with 0.1 mgL^{-1} epibrassinolide provided the highest germination (23.54%). Only 0.001 mgL^{-1} homobrassinolide resulted in the almost the same ratio with the control group. Information obtained here show that effects of growth regulators change with the genotype, type of the hormones and composition of the basal growth medium.

Key words: *Vitis vinifera* L., *Pollen Germination, Gibberellin, Epibrassinolide,Homobrassinolide*

Introduction

For plant species in different families, *in vitro* germination of pollen has been investigated at genetical, physiological and biochemical levels. Pollen germination evaluated *in vitro* might validate germination *in vivo* (Hormoza and Herrero, 1999; Tunistra and Wedel, 2000).

In vitro germination introduces a way for pollens to germinate under specific nutrient medium and temperature conditions (Heslop-Harrison, 1979). Some studies also show effects of plant growth regulators added to the medium. Some researchers showed that auxins and gibberellins generally promote *in vitro* pollen germination and growth (Viti et al., 1990; Qi et al., 2010; Ruijin and Chuanlai, 2010), whereas inhibition occurred when cytokinins and abscisic acid were utilized (Hewitt et al., 1985; Tosun and Koyuncu, 2007).

Brassinosteroids are the least investigated growth regulators in terms of their effects of pollen germination and pollen tube growth. Kang and Guo (2011) through their extensive works in Arabidopsis showed that brassinosteroids are important in the regulation of reproductive growth. In addition, they were shown to improve pollen tube growth in *Camelia japonica* (Hewitt et al., 1985) and tomato (Singh and Shono, 2003). Gökbayrak and Engin (2015) indicated that epibrassinolide, an active form of brassinosteroid, were effective more than naphthalene acetic acid and less than gibberellic acid on increasing pollen germination in table grapes. On the other

hand, Ylstra et al (1995) reported in tobacco that 28-homobrassinolide completely inhibited pollen germination while 24-epibrassinolide did not stimulate it. There is both lack of information and contradicting results about effects of brassinosteroids on pollen germination.
This study was conducted to determine the effects of two brassinosteroid compounds, epibrassinolide and 22S, 23S-homobrassinolide, along with the other group growth regulator, gibberellins, on *in vitro* pollen germination and growth of wine grape cultivars.

Material and Methods

Pollens of the wine grape cultivars, 'Cabernet Sauvignon' and 'Merlot' (*Vitis vinifera* L.) were utilized as plant materials. All the cultivars are dark colored and late maturing, known to exhibit low fruit set under vineyard conditions. The vines were located at the experimental vineyard in the Dardanos Campus of Canakkale Onsekiz Mart University. Inflorescences were collected in the morning hours at the 23rd stage (full bloom) of Eichorn ve Lorenz (1977) classification. Inflorescences were brought into lab and all unopened flowers were emasculated and later, anthers were collected in petri dishes. Anthers were allowed to burst for 24 hours at room temperature.
Iodized potassium iodide staining was employed to test the viability of pollens. Potassium iodide (1 g) and iodine (0.5 g) were added to 10 ml distilled water. After completion of the staining, pollens stained dark brown or yellow/transparent were considered viable and non-viable, respectively.
The pollen germination capability was determined using epibrassinolide (EBR, Sigma E-1641), 22S, 23S-homobrassinolide (HBR, Sigma H-1267) and gibberellic acid (GA_3, commercial grade) at three concentrations with basic 1% agar + 20% sucrose medium. Concentrations applied were GA_3; 25, 50, 100 mgL^{-1}, EBR; 0.001, 0.01 and 0.1 mgL^{-1}, and HBR; 0.001, 0.01 and 0.1 mgL^{-1}. A total of 28 different treatments were carried out including the control, which included nothing but the basic medium. Appropriate amounts of freshly prepared solutions of growth regulators singly and in combinations of brassinosteroids with gibberellic acid were thoroughly mixed with the basal germination medium during cooling but before attaining a semisolid condition. Pollen was dusted on the media using a fine camel hair brush so as to provide a nearly uniform layer. Petri dishes after inoculation were incubated for 24 h at 26±1°C under room conditions. After the incubation period, the surface of the media was flooded with a fixative solution. This solution contained 20 parts glycerin, 5 parts formaldehyde, 3 parts glacial acetic acid and 72 parts water (Pfahler, 1967). Petri dishes were stored at room temperature and observations on percent germination were recorded from four different areas under a light microscope (Olympus CX41) at 10x magnification.
Statistical analysis was performed using MINITAB statistics package program (ver. 16) for one-way analysis of variance. Data was divided in two groups, one including sole applications of the three hormones and the other including combinations of the hormones. Control group was the same in the both groups. Differences among the meaningful treatments were tested using Duncan's multiple comparison analysis.

Results and Discussion

Pollen viability of the cultivars were tested with IKI staining and results showed that 'Cabernet Sauvignon' contained more viable pollens (63.12% that 'Merlot' (59.06%).

Results of testing effects of the plant growth regulators belonging to two distinct classes, gibberellins and brassinosteroids, on 'Cabernet Sauvignon' and 'Merlot' wine grape cultivars were evaluated in two groups for ease of interpretation of the results of the statistical analyses.

Statistical analysis of the sole applications of the hormones and the control showed that effects of the hormones affected *in vitro* pollen germination ratios of the cultivars (Table 1). However, in the pollens of 'Cabernet Sauvignon', there were no clear cut differences between the hormones and the control, except for 100 mgL^{-1} GA_3 treatment. 0.1 mgL^{-1} HBR showed the greatest effect among the brassinosteroids. In general, type of the brassinosteroid compound did not cause a marked effect on the pollen germination. One interesting result is that HBR caused less germination ratio than the control. This might be the result of totally random observations of the field views.

In 'Merlot' pollens, on the other hand, influence of the hormones compared to the control was more apparent and this effect was mostly dependent on the concentration of the hormone to which the pollens were exposed. The greatest germination was obtained from the 100 mgL^{-1} GA_3 application. 50 mgL^{-1} GA_3, 0.001 mgL^{-1} EBR and 0.01 and 0.001 mgL^{-1} HBR yielded similar ratios with the control.

Table 1. *In vitro* pollen germination ratios (%) of the wine grape cultivars (*Vitis vinifera* L.) exposed to different plant growth regulators

Growth regulators (mgL^{-1})	Cabernet Sauvignon	Merlot
GA_3 25	17.78 abc	20.85 ab
GA_3 50	20.20 ab	12.20 bcd
GA_3 100	22.42 a	23.63 a
EBR 0.1	11.85 abc	16.69 abc
EBR 0.01	11.01 bc	17.25 abc
EBR 0.001	13.47 abc	12.06 bcd
HBR 0.1	17.96 ab	16.32 abc
HBR 0.01	7.41 c	10.58 cd
HBR 0.001	9.95 bc	14.05 abcd
Control	10.75 bc	5.55 d

The second group of statistical analysis was done to possibly show any interactions of brassinosteroids in the presence of gibberellic acid at different concentrations (Table 2). 'Cabernet Sauvignon' pollens did not react to combination treatments and resulted in 10-35% germination ratios. 'Merlot' pollens were affected by the combination applications, although not to a great extent. Most of the hormone combinations did not yield great differences compared with the control group. However, it seemed that effects of epibrassinolide concentrations were more dependent on the GA_3 concentration. For instance, germination was more prominent with 25 mgL^{-1} GA_3 than with 50 or 100 mgL^{-1} GA_3. Effects of HBR were somewhat similar to the EBR concentrations, being higher at 25 mgL^{-1} GA_3 compared to the higher concentrations.

Table 2. *In vitro* pollen germination ratios (%) of the wine grape cultivars (*Vitis vinifera* L.) exposed to combination of different plant growth regulators

Growth regulators (mgL^{-1})	Cabernet Sauvignon	Merlot

mean	16.19	14.01

These cultivars are known for their poor fruit set and tendency to millendrage because of high pollination deficiencies (Kidman et al., 2013). Baby et al. (2016) report that *in vitro* pollen germination of these cultivars had similarities with their *in vivo* conditions and that pollens were less functional. Alva et al. (2015) indicated 'Cabernet Sauvignon' germination around 35% in 15% sucrose and calcium chloride containing medium that was kept in the dark. The difference (10.75% vs. 35%) might be due to the constituents of the medium. Sucrose is important for balancing internal and external pressure in organelles and different concentrations were found related to osmotic potential (Alcaraz et al., 2011).

Different studies on grape cultivars stated that high gibbrellins found on anthers and pollens affected pollen germination (Izhaki et al., 2002; Singh et al., 2002). Kimura et al. (1996) showed that pollen germination of cultivar 'Muscat Bailey A' was restricted with increasing gibberellin. Similar tendency was also observed for 'Kozak Beyazı' and 'Amasya Beyazı' grape cultivars, in addition effects of epibrassinolide were cultivar-dependent (Gökbayrak and Engin, 2015).

Conclusion

'Cabernet Sauvignon' and 'Merlot' are cultivars with generally low viability and germination ability. Information obtained here show that effects of growth regulators change with the

genotype, type of the hormones and composition of the basal growth medium. Brassinosteroids generally enhance *in vitro* pollen germination, but the effect is cultivar and type dependent.

Abstract

Oil is one of the most important organic substances required for human nutrition. Omega fatty acids play an important role in the body's physiological and biochemical activity of constructive and restorative functions and they are effective in the development of healthy tissue. Omega fatty acids consist of Omega-3, Omega-6 and Omega-9 and they have important function in the treatment of obesity, strengthening the immune system and the prevention of cholesterol and heart disease. Poly-unsaturated fatty acid/Saturated fatty acid rate (P / S) is an important quality factor. Higher P/S ratios increases the quality of oil. The most important plant sources for linoleic acid are; sunflower, safflower, soybean, corn, sesame, peanut, cotton and linolenic acid major sources are rapeseed and flax. The lack of omega fatty acids causes many diseases. Saturated fatty acids cause cardiovascular diseases and weight gaining due to fat accumulation. Omega fatty acids such as Omega-3, Omega-6 and Omega-9 have positive effect on health. For adequate and balanced consumption of oil fatty acids, consumers should have minimum and maximum limits. In this paper; the effects of omega fatty acids on human health will be discussed.

Keywords: *Fatty acid, Omega fatty acids, Omega-3, Human Health.*

Introduction

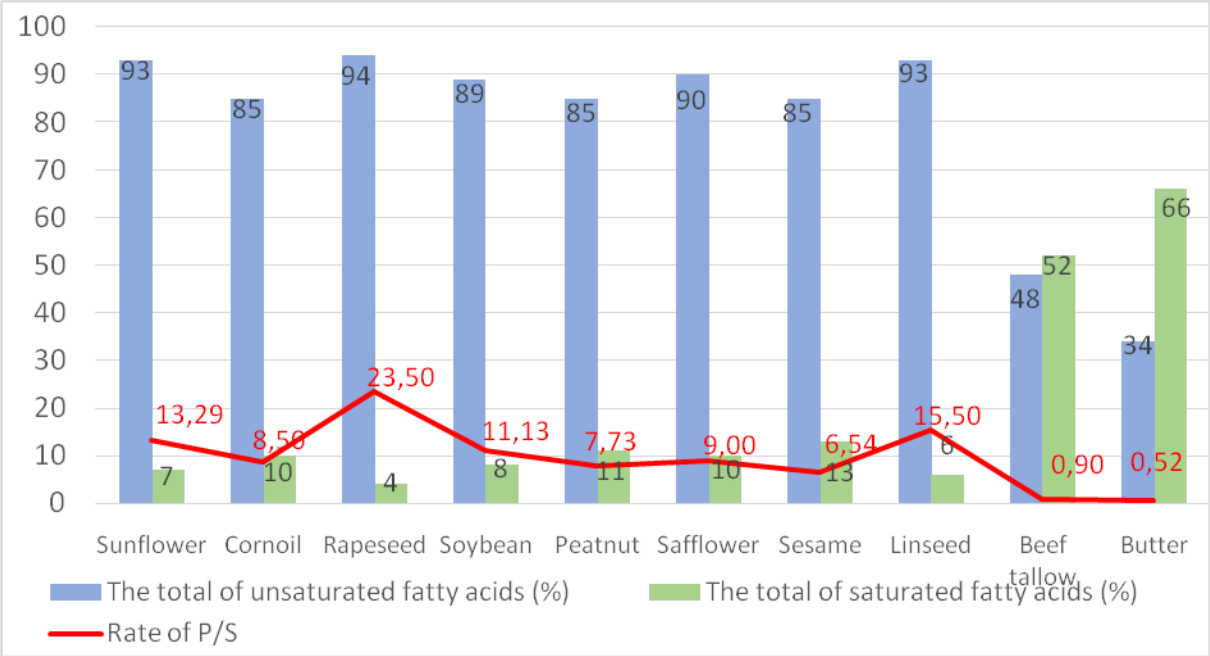
Oil is one of the most significant organic substances required for human nutrition. Oil is derived from plant or animal sources as a natural or refined product. The human body produces fat with the help of special enzymes for metabolic activity (Bayizit, 2003).

The main structural components of fats are called fatty acids. The physical, chemical and physiological properties of oil depend mainly on the type and amount of fatty acids (Kayahan, 2009). The importance of oil in terms of nutrition depends on the number of atoms, saturation degree, number of double bonds between carbon atoms and the position of hydrogen atoms in the molecule (Karabulut and Yandı,2006; Samur, 2006). Fatty acids are divided into five groups; i) Saturated fatty acids, ii) Unsaturated fatty acids, iii) Oxidized fatty acids, iv) Cyclic fatty acids and v) Acetylenic fatty acids.

The Effects of Omega 3 Fatty Acids on Human Health

In recent years, due to increased awareness of health and nutrition, and increased risk of disease, consumers have begun to prefer natural methods rather than synthetic chemical drugs. Several clinical trials indicate that vegetable nutrition reduces chronic diseases, obesity and risk of cancer. Researchers recommend more cereals, fresh fruit and vegetables as opposed to less fat content and animal meat in the diet. The quality of edible vegetable oils depends on the composition and iodine value of the fatty acids (Culbertson, 1954). The ratio of Poly-unsaturated fatty acid/Saturated fatty acid rate (P / S)is a known significant quality factor. Higher ratio presents higher oil quality (Figure 1).

Figure 1. Some vegetable and animal fats of some vegetable and animal fats and rates of P/S.



In the last century, the development of food industry affected food consumption and accordingly the fatty acid ratio in food has changed. The Omega-6 consumption trend increases, however the Omega-3 consumption trend decreases (Gómez Candela et al., 2011). The lack of omega fatty acids cause dry skin, asthma, growth retardation, diabetes, certain types of cancer and also learning deficiency (Lewis, 2000).

Omega fatty acids involve in the body's physiological and biochemical activity of constructive and restorative functions and they are effective for development of healthy tissue (Gogus and Smith, 2010).

Omega fatty acids have direct and indirect effects on the body. They indirectly improve the strength of the red blood cells, decrease the blood viscosity, increase the capillary oxygen use, heal heterogenic illnesses, remediate metabolic disorders, strengthen the immune system, decrease the risk of the heart attack and hypertension, and decrease neurotic disorders (Kaya et al, 2004; Leaf and Weber, 1988; Sarıca, 2003).

These fatty acids increase birth weight as well as preventing premature birth. Also, the last three months of pregnancy, during which the development of the fetal nervous system and angiogenesis is at its peak and is known to need a lot of Omega-3 (Gordon and Ratliff 1992). Moreover, a small increase in the consumption of Omega-3 fatty acids, reduces the risk of fatal coronary heart disease by 40-50%.

Vegetable Sources of Omega Fatty Acids

Many plants are used as a source of omega fatty acids. Certain plants are very popular across the world. These plants are sunflower, cotton, soybean, rapeseed, safflower, flax, sesame, peanut and corn.

Sunflower

The nutritional value of the sunflower oil is relatively higher than other oilseeds, because of the low saturated fatty acid rate due to high unsaturated fatty acids rate (Figure 1). For that reason, liquid sunflower oil is used in cooking and frying(Harris et al. 1978; Miller et al. 1987). High Omega-9 contained sunflower oil protects metabolic balance and decreases cholesterol. The poly-unsaturated fatty acid in sunflower oil plays an important role in brain functions, body growth and development. It is good for skin and hair health. Also, clinical studies have shown that hyperactive children with attention deficit hyperactivity disorder have low poly-unsaturated fatty acid levels. Researchers recommend sunflower oil for the hyperactivity disorder treatment.

Rapeseed

Rapeseed oil contains 65% oleic, 20% linoleic, 9% linolenic, 4% palmitic and 2% stearic acid. Rapeseed oil has an important role for the central nervous system, eye functions and thrombocyte metabolism. It lowers cholesterol levels and triglyceride levels and increases the viscosity of blood. Moreover, it strengthens the immune system and prevents the formation of atherosclerosis. Rapeseed oil is also preferred as the cooking oil due to less effect on taste.

Cottonseed

Cotton seedoil belongs to the oleic-linoleic acid group of oils due to its 13-44% oleic and 33-58% linoleic acid. The most important saturated fatty acid in this oil is palmitic acid and its rate is 17-29%.One of the most important unsaponifiable matter of vegetable-based oils is tocopherol due to the antioxidant effect. Crude cotton oil is oil rich in natural tocopherols. Heat resistance ofcotton oil is higher than other oils; therefore it is an ideal fat for frying. Cottonseed oil regulates bowel movements by softening the digestive system and resolves constipation problems. It enables the rapid repair of wounds in the skin. This oil has muscle relaxant properties. It is effective in reducing pain by stimulating blood circulation, so it is a good antipyretic.

Linseed

Linseed oil contains approximately 9-11% of saturated fatty acids (5-6% palmitic acid and stearic acid 4-5%) and 75-90% of unsaturated fatty acids (50-55% linoleic acid, 15-20% oleic acid, 10-15% linoleic acid) (Robbelen et al., 1989; Carter, 1993). Linseed oil is rich in Omega-3 fatty acids (alpha-linolenic acid) and has many positive effects on human health. Indeed, it has been determined that linseed oil reduces heart diseases and inhibits blood clotting. Omega-3 in flaxseed oil balances high blood pressure and raises good cholesterol. Especially, it has been scientifically proven that alpha-linolenic acid decreases the occurrence of chronic heart diseases. Besides; researchers recommend linseed for forgetfulness, stroke and cancer by consuming linseed oil over the salad or one spoon of seeds per day. In addition, it is a good source of protein, flavonoid, lignan and phenolic acid (Bernerand O' Donnell, 1998; Mazza, 1998; Korthals, 2002).

Safflower

Safflower seed contains 90% unsaturated fatty acids (oleic and linoleic acid). Safflower oil with high linoleic acid (over 70%) is one of vegetable oils that can be used for lowering high blood cholesterol and particularly treats the hardening of the arteries. It also strengthens the immune system. It protects against breast and prostate cancers. Safflower oil improves heart and cardiovascular health, increases muscle tissue, raises the good cholesterol (HDL), and regulates blood sugar levels. It has been determined that it regulates respiratory disorders and bloodstream. Safflower oil decreases the rheumatism pain if applied on to the affected area. Also, it is

preferred for the treatment of obesity due to its fat burning feature and fat storage blocker property of Omega-6.

Sesame

Sesame oil includes 47% oleic (Omega-3) and 39% linoleic (Omega-6). Sesame oil is heart-friendly cooking oil that lowers cholesterol levels. It inhibits some diseases by its secondary metabolites (such as sesamin, sesamol etc.). Sesame oil is a good essential fatty acid which is not produced by the body. Accordingly, sesame oil protects the skin from the harmful effects of the sun and it has an important role in aging. The zinc in sesame oil increases the collagen production of skin and it provides more elastic and softer skin. Sesame oil reduces the plaque formation on teeth and prevents dental problems. Sesame oil sterilizes the mouth when used as a mouth wash.

Soybean

The composition of soybean oil is20-34% oleic acid (Omega-9), a rate of 49-55% linoleic acid (Omega-6) and the rate of 4-12% linolenic acid (Omega-3). It has considerable benefits for the heart. Soybean oil is used for making mayonnaise, coffee cream, margarine as well as salad dressings in several products in the food industry. Soybean oil cause stronger food taste when fried because of the zero flavor. Fatty acids in soybean oil regulate fat and lipid metabolism in the human body, so it is recommended to people with diabetes, arteriosclerosis or coronary heart disease. It contains many essential amino acids and reduces the risk of breast cancer, colon cancer, prostate cancer and stomach cancer. The use of soybean oil externally causes brighter skin and nails. It prevents hair loss and promotes hair growth. Soybean oil strengthens the immune system. Soybean oil contains A, E, D, K, B vitamins, as well as iron, zinc, phosphorus, magnesium. It regulates bone resorption (osteoporosis).

Corn

Corn oil has 19-49% oleic acid and 34-62% linoleic acid. Corn oil is preferred for frying because of its high burning durability. Corn oil is a rich source of linoleic acid which is good for growth. Corn oil contains tocopherols. This substance with antioxidant effects is an important resource of vitamin E. Corn oil contains vitamins and minerals which are beneficial for health. It is recommended for the prevention of heart disease, diuretic properties and also to reduce kidney stones. According to the studies, phytosterols which inhibit the absorption of cholesterol from the gut have a large effect in reducing blood cholesterol levels. 100 grams of corn oil contains 968 mg of phytosterols. This is the biggest proportion in any vegetable oil.

Peanut

eanut oil contains 47% oleic and 38% linoleic acid. Liquid peanut oil has a clear appearance and very popular for its unique taste and smell. Due to the high content of oleic acid, peanut oil is very nutritional and has desirable physical properties. It is extremely resistant to high temperatures, and particularly preferred for foodstuffs to be stored for some time after frying. In this way, it helps to protect the antioxidant value of packaged products. Resveratrol content of peanut oil inhibits the development of cancer cells. Peanut oil is an alternative product for diabetics because of its sugar balance properties. Peanut oil can be used as a dietary supplement. For this purpose, one or two teaspoons of peanut oil consumption per day, depending on the body needs is recommended. Recent studies have shown that peanut oil accelerates the metabolism and provides appetite control. Dieticians recommended peanut oil to treat obesity and control weight.

Conclusion

In recent years, consumers have come to realize that food is not only basic nutrition to survive, but also for leading a healthy life. Fatty acids are very important for human nutrition. Saturated fatty acids cause fat accumulation and cardiovascular diseases. On the other hand, Omega-3, Omega-6 and Omega-9 fatty acids have positive effects on health. For adequate and balanced consumption of fat, fatty acids should be taken with defined limits and proportions. For a balanced diet, consumers should be educated about fatty acids.

POPULATION DYNAMICS OF APHIDS AND NATURAL ENEMIES ON DIFFERENT WHEAT CULTIVARS IN AYDIN PROVINCE, TURKEY

Yunus CAVDIR, Ibrahim GENCSOYLU[1]*

1Department of Plant Protection, Faculty of Agriculture, Adnan Menderes Universty, Aydin, Turkey
*Corresponding author:igencsoylu@adu.edu.tr

Abstract

The study was conducted to determine the population dynamics of aphids and natural enemies on different wheat varieties in Aydın Province, Turkey. Nine wheat varieties (Kiziltan, Atalay, Yaren, GAP, C1252, Tuten 2000, Ege, Turabi and Solen 2000) were used in the study. The experimental plot consisted of 8 m in length and 5 rows with three replicates. The sampling was begun on March 11, 2015 and finished at the end of harvest. The population densities of nymphs and adults of aphids were recorded at weekly intervals. Ten plants were randomly selected for each replicate and totally thirty plants for each variety was checked visually. Natural enemies were also recorded during the sampling of aphids. At the end of the study, three aphis species, *Sitobion avenae* (Fabricius), *Metopolophium dirhodum* (Walker) and *Rhopalosiphum padi* (L.), were recorded . *Coccinellie septempunctata* L. and *Chrysoperla carnea* (Stephens) as predators and *Aphidius rhopalosiphi* De Stefani Perez as a parasitoid were also recorded during the study. Population of aphids were reached to the highest population on May 6th 2015 with 4.2±2.2 on Turabi and followed with 3.7±0.5 on Solen 2000 variety. The population was not observed after the end of May. The mean number of aphids per year was statistically important and lowest on GAP, Tuten 2000, Ege (0.7±0.5), and followed by Yaren (0.8 ±0.5), Kiziltan (0.9±0.5), Atalay (0.9±0.8), Turabi (1.1±1.0), Solen 2000 (1.2±1.0) and C1252 (1.4±0.7). Natural enemies were observed from the first week of April to the end of May and more predators were recorded on Ege, Tuten 2000 and C1252 varieties. Parasitic rate was higher on Tuten 2000, Turabi and C1252. As a result, the population of aphids in the region was observed under the economic injury level. However, it seems to be a potential pest for the wheat and the three wheat varieties could be effective in managing against the aphids and important tool for IPM program.

Keywords: *Wheat varieties, Aphids, Natural enemies, Parasitoids, Predators, Turkey*

Introduction

Wheat (*Triticum aestivum* L.) is a main cereal crop of Turkey and cultivated over 78 668 874 decare with annual production of 22 600 000 tone in 2015 (Anonymous, 2015) and plays important role as a field crop in country economy. Aydın which is the western city of Turkey has important place in this production with this 220.996 decare . Wheat is attached by aphids that are small insect and causes serious damage by sucking cell sap, young shoots, injecting toxic salina into the tissues, distortion, leaf curling, twisting, wilting and also transmit the plant viruses and finally reduce the yield. They also result in glutenin and gladin content (Gianoli, 1999; Basky and Fonagy, 2003). Elmalı and Toros (1997) reported that *S. avenae* caused 2.25 % loose of crude protein, and average loss of 1000-grain weight for all varieties was 10.16%. *Sitobion avenae* (Fabricius), *Rhopalosiphum padi*, Linnaeus, *Metopolophium dirhodum* (Walker), *Rhopalosiphum maidis* (Fitch), *Schizaphis graminum* (Rondani), *Sipha maydis* (Passerini), *Sipha elegans* Del Guercio are the main aphids species in Turkey (Özder and Toros 1999; Toros et al., 2002; Yiğit et al., 2007;

Aslan, 2002). However, the aphid species varied according the regions in the country. Sertkaya and Yiğit (2002) reported that *R. padi* and *S. avanea* were recorded in Antakya. In addtion to the two aphids, Bilgin (2006) also mentioned that *S. gaminum* and *M. dirhodum* was found in Kahramanmaraş. On the other hand, *D. noxia* was found in Konya (Elmalı 1998) and Tekirdağ (Özder and Toros, 1999). *S. avenae* infests ont only upper leaves but also head, whereas *R. padi* prefers to colonize the leaf sheats and lower leaves of wheat plants (Gianoli, 2000).

Cereal aphid infestation may be limited by some management strategies. One of them is host plant resistance due to economical and environmentally effect (Webster and Inayatullah, 1984; Tyler et al., 1987). Aphid population density affected by abiotic and biotic factors such as both predator and parasitoits (Naeem et al., 2002). As natural enemies *Coccinella septmepunctata* (L.), *C. undecimpunctata*, *Synharmonia conglobata* (L.), *Adonia variegata* (Goeze), *Episyrphus baleatus* (DeGeer), *Metasyrphus corollae* (F.*)*, *Melanostoma mellinum* (L.*)*, *Meliscaeva auricollis* (Megeu), *Sphaerophoria scripta* (L.), *Chrysoperla carnea* (Stephens) *Lysiphlepus faborum (* Marchall*)* and *Ephedrus plagiator* and parasitoid, *Aphidius uzbektanicus* Luthetzki were found in wheat fields (Kıran, 1994; Yiğit et al., 2007). Also, Elmalı and Toros (1994) reported that 14 *Coccinellidae*, three Syrphidae, one Chamaemyiidae, one Miridae, two Nabidae species, were found as predators and 4 aphidiid and 1 aphelinid were determined as parasitoids. The also mentioned that the most common species was Coccinelidae species. In the region no study was conducted on aphids and their natural enemies. Therefore, the aim of the study was determine the aphid species and natural enemies on different varieties in Aydın province, Turkey.

Material and Methods

The study was conducted at Research Farm of Faculty of Agriculture, Adnan Menderes University, during 2014-2015 wheat growing season. The study site was located in the city of Aydın. Nine wheat varieties (Kiziltan, Atalay, Yaren, Tuten 2000, C1252, Turabi, Solen 2000) were sown on 19 November 2014. The experiment was 8 m in long with five rows and three replacates. Population of aphids and natural enemies were recorded from ten randomly selected tillers from each replication at the each week and 2 m space left to reduce the edge effect. The sampling was started on 11 March 2015 and lasted till the breakdown of the population in the field. The insect samples collected were transferred into the bottle. 70% ethanol was added to kill and preserve all insects for identification. Parasitoids in the experiment live through their larval stage mainly in the mummies of the aphids. The mummies were collected and transferred into the lab and reared for 20 day to lay and then send to specialist for identification. The wheat was cultivated in accordance with recommended agriculture practices and no insecticides were applied during the study. All data were analyzed by SPSS programme ($p<0.05$)

Results and Discussion

Three aphis species, *R. padi*, *S. avenae* and *M. dirhodum* were recorded in this study. The population of aphids species remained very low in March, started increasing in the first week of April and reached to the highest level on the first week of May. They were reached to the highest population on May 6th 2015 with 4.2±21.7 on Turabi and followed with 3.7±0.5 on Solen 2000 variety. The population was not observed after the end of May (Table 1). The mean number of aphids per year was statistically important and lowest on GAP, Tuten 2000, Ege (0.7±0.5) whereas it is more with 1.4±0.7 on C1252 (Table 3). The reason for this differences that C1252 and Turabi varieties have got late maturing wheat species and aphids feeds more time on this variety. Marek (2007) reported that 8.2 aphid/tiller did not affected head length, plant height and 1000-grain weight on Kyber 87 varieties.

Table 1. Mean number of aphids per tiller on different wheat varieties in 2015

Akhtar (2010) also reported that 12.6 and 14.4 aphid/tiller on Punjab-96 and Inqlab-91 reduced 3.96-7.36% yield. In the study the population has not reached to economic injury level. Therefore it seems to be present insect, but not harmful in the region. *D. noxia* was not found in the region and other region except middle part of Turkey (Altınayar, 1981; Elmalı, 1996). The reason is probably climatic condition.

Table 3. Mean number of aphid populations per year on wheat varieties during the 2015-2016 wheat- growing season.

03.06.15	0	0	0	0	0	0	0	0	0

Coccinellie septempunctata L. and *Chrysoperla carnea* (Stephens) as predators and natural enemies were observed from first week of April to the end of May and more predators were recorded on Ege, Tuten 2000 and C1252 varieties (Table 2). It seems that the most important predators is *C. septempunctata*. Krotova (1994) supported the study that he mentioned 17 species of coccinellids as predators of which *C. septempunctata* was the most important. As a

parasitoid *Aphidius rhopalosiphi* De Stefani Perez was recorded during the study. Parasitism percentage was not seen till middle of March then observed and reached different level on the varieties. The highest parasitism percentage was observed on Turabi variety with 21,4 % on late April and followed by Tuten 2000 (16%), Ege (12,5%), C1252 (11.1%), Yaren (10%), GAP and Solen (8.3%), Kiziltan (6.8%) and Atalay (2.9%) (Table 4). In contrary *A. uzbekistanicus* was recorded in other wheat field of the country (Aslan et al ., 2004; Yiğit el al., 2007; Yiğit and Sertkaya, 2007). Bilgin et al. (2008) mentioned that the highest parasitism percentage was 17.9-18.4% in Golia and Zenit cultivars and had important role on the suppression of *R. padi* in wheat. The study was supported by the references.

Conclusion

The observed population of aphids in the region was under the economic injury level. However, it seems to be a potential pest for the wheat. Natural enemies were also low, but if we increase the natural enemy population through its rearing in the laboratory at the peak level, we reduce the infestation and improve the wheat quality and yield. It can be concluded that the three wheat varieties could be effective in managing against the aphids and important tool for IPM program.

Acknowledgment

Thanks to Dr. Işıl Özdemir for identification of aphid species and Prof. Dr. Zeljko Tomanovic for identification of parasitoids.

RESULTS OF INVESTIGATION ON SOME BIO -MORPHOLOGICAL TRAITS OF BURLEY TOBACCO VARIETIES

Karolina KOCOSKA*, Ilija RISTESKI

University "St. Kliment Ohridski "- Bitola - Scientific Tobacco institute - Prilep,
Republic of Macedonia
*Corresponding author: karolina_kocoska@yahoo.com

Abstract

During 2009, 2010 and 2011 field trials were carried out in Scientific Tobacco Institute – Prilep (Republic of Macedonia) with three varieties of Burley tobacco (American fertile variety B-21(used as a check) and domestic varieties B-2/93 and Pelagonec CMS F_1). Investigations were made on diluvial soil, using randomized block design with 8 replications at 90 x 50 cm spacing. The obtained results were statistically processed by the method of analysis of variance and tested with LSD test. During the growing season, morphological measurements were made on 20 stalks of each variety. The following traits were included in the analyzes: time of flowering, length and width of the 5th , 10th and 15th leaf, stalk height and number of leaves. In most of these traits domestic varieties proved to be superior to the fertile variety B-21 Ø, with some advantage of the variety Pelagonec CMS F_1. Typical Burley characteristics make this variety attractive both for farmers and manufacturers. In present conditions, it can be used as initial variety for restarting the production of Burley tobacco in R. Macedonia, but it can be also interesting for neighboring countries and wider. The obtained results can help producers to make decision which genotype to use in the start of the production cycle.

Keywords: *tobacco, variety, Burley tobacco, leaves, stalks.*

Introduction

The share of Burley tobacco raw in technological blends ranges between 25 and 30%. Cigarette factories find this raw material attractive due to its flexible use. Burley leaves are characterized by high combustibility and filling capacity and good absorption of casings that improve the taste of tobacco blends. The production of Burley tobacco in Republic of- Macedonia started in the 60s of the last century on small areas intended for experimental purposes in Scientific Tobacco Institute-Prilep. Since then, the Department of genetics, selection and seed control together with the departments of Chemistry, Agrotechnics and Technology is working on creation of new varieties of Burley tobacco and finding the appropriate cultural practices in order to obtain raw material with higher use value. Analyzis of length: width ratio in the 5th, 10th and 15th leaf shows a tendency of increase from the lower to the upper insertions and that Macedonian varieties are characterized by larger leaf size.

Material and Methods

During 2009, 2010 and 2011 investigations were conducted in the field of Scientific Tobacco Institute – Prilep (Republic of Macedonia) with three varieties of Burley tobacco (American variety B-21and domestic male-sterile varieties B-2/93 and Pelagonec CMS F_1). Investigations were set up in randomized block design with 8 replications at 90 x 50 cm spacing on 657 m², with dimensions 5 m x 131.4 m. In each replication the 3 tested varieties were sown in 6 rows,

five of which were harvested and one was used for morphological investigations. The number of stalks of each variety per harvest was 45, and total number of stalks in the whole trial was 360. During the growing season, 10 stalks of each variety were used for morphological measurements of the 5th, 10th and 15th leaf, stalk height with inflorescence and total leaf number per stalk.

Results and Discussion

Plant height (cm) and leaf number per plant

Burley tobacco belongs to the group of high tobaccos, but this morphological trait depends on agro-ecological conditions, cultural practices, soil composition and the available moisture. The variety B-21 in 2009 (Table 1) was characterized by minimum height (124.9 ± 0.21), with d 1.30 standard deviation and variability coefficient of 1.04% (2009), 1.40% (2010) and 1.08% (2011). Macedonian variety Pelagonec was the highest and had the lowest variation coefficient compared to other two varieties, ranging from 0.27% in 2009, 0.45% in and 0.63% in 2011.

Table 1. Plant height with inflorescence, in cm

VARIETY	2009			2010			2011			Average	Relative difference
	$\bar{x} \pm s_{\bar{x}}$	σ	cV %	$\bar{x} \pm s_{\bar{x}}$	σ	cV %	$\bar{x} \pm s_{\bar{x}}$	σ	cV %		
B-21 ∅	124.9±0.21	1.30	1.04	131.2±0.29	1.83	1.40	125.8±1.12	1.36	1.08	127.3	100.00
B-2/93	167.6±0.15^{++}	0.97	0.58	177.0±0.22^{++}	1.39	0.79	178.0±1.27	2.13	1.20	174.2	136.84
Pelagonec	179.4±0.08^{++}	0.49	0.27	193.5±0.14^{++}	0.88	0.45	191.5±1.15	1.22	0.63	188.1	147.76

2009 LSD Stalk height 5% = 1.18 cm $^{+}$ 1% = 1.63 cm^{++}

2010 LSD Stalk height 5%= 1.65 cm $^{+}$ 1%= 2.29 cm $^{++}$

2011 LSD Stalk height 5%= 2.06 cm $^{+}$ 1%= 2.85 cm $^{++}$

According to the presented data, the average height ranges from 127.3 cm in the check variety B-21 to 188,1 cm in Pelagonec (47.76% higher compared to the check). Plants of B-2/93 variety were 174.2 cm high, i.e.36.84% higher than the check.

Stojanov, and Apostolova (1999), in their research of newly created Burley tobacco varieties reported that the average stalk height in variety B 1317 was 158 cm while in B-1351 it ranged between 165 and 170 cm.

Ristevski (2006) reported that average stalk height in several varieties of Burley tobacco ranged from 156 cm to 189 cm and the average number of leaves varies from 25.7 to 29.

Table 2. Leaf number

VARIETY	2009			2010			2011			Average	Relative difference
	$\bar{x} \pm s_{\bar{x}}$	σ	cV %	$\bar{x} \pm s_{\bar{x}}$	σ	cV %	$\bar{x} \pm s_{\bar{x}}$	σ	cV %		
B-21 ∅	26.6±0.15	0.92	3.45	27.0±0.11	0.70	2.59	27.0±0.10	0.65	2.42	26.87	100.00

Pelagonec	31.7±0.12^{++}	0.75	2.35	33.3±0.09^{++}	0.59	1.76	33.0±0.12	0.75	2.28	32.67	121.59

2009 LSD Leaf number
5%= 1.82^{+}
1%= 1.14^{++}

2010 LSD Leaf number
5%= 0.75 $^{+}$
1%= 1.04 $^{++}$

2011 LSD Leaf number
5%= 0.97^{+}
1%= 1.34^{++}

Data in Table 2 reveal correlation between number of leaves and height of the stalk. The highest leaf number of 32,67 was observed in variety Pelagonec, i.e. 21.59% more than the check. Leaf number of B 2/93 averaged 30.83, or 14.74% more than the check variety.

According to Uzunoski (1985), the introduced American variety Burley B-21 has variable height, ranging from 140 to 230 cm, and the average number of leaves is 24.

According to the results of two-year investigations it can be stated that the obtained data on stalk height and leaf number are typical of Burley tobacco. Climate conditions in 2010, characterized by higher humidity, directly influenced the increased stalk height and leaf number of the varieties included in the trial. In all three years, the investigated varieties showed 5 % significance and lower coefficient of variation compared to the check.

-Characteristics of the 5th leaf

According to its position, the 5th leaf belongs to the lower part of the plant. With different varieties of Burley tobacco it differs in several morpho-technological, chemical and tasting characteristics. Data presented in Table 3 reveal that leaf length in the first year of investigation (2009) was lower compared to 2010.

The average length of the 5th leaf was the lowest (43.80 cm) in the check variety B-21 and the highest (55.00 cm) in Pelagonec (25.57% more compared to the check).

Width of the 5th leaf was the lowest in the check B-21 (28.4 cm) and the maximum width was measured in the variety Pelagonec (38.4 cm, i.e. 33.80% more compared to the check). The average length:width ratio was the lowest in B 2/93 and Pelagonec (1.43) and highest in the check B-21. These data indicate that the check variety has slightly elongated form of the 5th leaf compared to other two varieties.

Ristevski (2006) in his investigation on six varieties of Burley tobacco in the region of Prilep during 1999-2001reported that the average length of the 5th leaf was 43-52 cm and the average width 27 - 34 cm.

Table 3. Morphological measurement of the 5th leaf

Varieties	Length of the 5th leaf				Width of the 5th leaf			Length : Width ratio		
	Year	Length	Average 2009/11	Index	Width (cm)	Average 2009/11	Index	L:W ratio	Average 2009/11	Index
B-21	2009	42.5	43.8	100.00	28.8	28.4	100.0	1.48	1.54	100.00
	2010	45.5			28.6			1.59		
	2011	43.4			27.8			1.56		
B-2/93	2009	48.3	50.0	114.16	34.9	34.4	121.12	1.38	1.45	95.00
	2010	50.9			34.3			1.48		
	2011	50.8			34.0			1.49		
Pelagonec	2009	53.7	55.0	125.57	38.7	38.0	133.80	1.39	1.45	95.00
	2010	55.2			37.1			1.49		
	2011	56.1			38.2			1.46		

Characteristics of the 10th leaf

Tenth leaf is positioned in the middle part of the stalk, where tobacco leaves are the largest in size. Characteristics of this leaf are resented in Table 4.

The lowest 10th leaf length (53.53 cm) was measured in the check variety B-21 and the highest (66.60 cm) was recorded in Pelagonec (24.41% higher index compared to the check). In respect of this trait, B 2/93 showed better results compared to the check, having a leaf length of 60.78 cm, i.e. 13.54% more than the check variety. In 2009 the lowest leaf width was measured in B-21 variety (29.5 cm) and the highest in varieties B 2/93 and Pelagonec (33.4 cm and 34.5 cm). In 2010 and 2011, the width of the leaves was higher and ranged from 36,8 cm in the check to 39,1 cm in varieties B 2/93 and Pelagonec.

The lowest average width of the 10th leaf (32.43 cm) was observed in the variety B-21 and the highest (37.27 cm) in Pelagonec (14.92% higher index compared to the check variety). In B 2/93, the average width of the 10 th leaf was 35.50 cm, i.e. 9.47% higher index compared to the check variety. Cavkaroski et al. (1991), in their trials with 10 varieties of Burley tobacco set up in the regions of Prilep and Bitola in 1988 and 1989, reported great variations in leaf size and height of the stalk under the influence of agro-ecological conditions and smaller variations in number of leaves per stalk.

Table 4. Morphological measurements of the 10th leaf

Varieties	Length of the 10th leaf				Width of the 10th leaf			Length : Width ratio		
	Year	Length	Average 2009/11	Index	Width (cm)	Average 2009/11	Index	L:W ratio	Average 2009/11	Index
B21	2009	50.4	53.53	100.00	29.5	32.43	100.00	1.77	1.68	100.00
	2010	56.2			36.8			1.53		
	2011	54.0			31.0			1.74		
B-2/93	2009	58.3	60.78	113.54	33.4	35.50	109.47	1.75	1.71	101.79
	2010	62.8			39.1			1.60.		
	2011	61.1			34.0			1.79		
Pelagonec	2009	63.2	66.60	124.41	34.5	37.27	114.92	1.83	1.79	106.55
	2010	68.8			39.1			1.76		
	2011	67.8			38.2			1.77		

Characteristics of the 15th leaf

The lowest average length of the 15th leaf was recorded in the check variety B-21 (53.97 cm) and maximum length (60.27 cm) in variety Pelagonec (i.e. 11.67% higher index compared to the check).

Also the variety B 2/93 showed better results, achieving 56.63 cm length of the 10th leaf and 4.93% higher index compared to the check.

The lowest leaf width was measured in 2011 in B-21 variety (22.5 cm) and maximum (29.8 cm) in variety Pelagonec (2010). The lowest average width of the 15th leaf (22.83 cm) was measured asgain in the check variety B-21 and the maximum width was observed in Pelagonec (28.60 cm, i.e. 25.27% more than the check variety.)

Ristevski I. (2006) reported that average leaf length of the six varieties included in the trial was 51 - 62 cm and the average width 24 - 33 cm.

Table 4. Morphological measurements of the 15th leaf

Varieties	Length of the 15th leaf				Width of the 15th leaf			Length : Width ratio		
	Year	Length	Average 2009/11	Year	Length	Average 2009/11	Year	Length	Average 2009/11	Year
B-21	2009	54.3	53.97	100.00	23.7	22.83	100.00	2.29	2.35	100.00
	2010	53.4			22.3			2.34		
	2011	54.2			22.5			2.41		
B-2/93	2009	55.5	56.63	104.93	25.8	26.90	117.83	2.14	2.10	0.89
	2010	57.6			27.9			2.06		
	2011	56.8			27.0			2.10		
Pelagonec	2009	58.7	60.27	111.67	26.8	28.60	125.27	2.19	2.11	0.89
	2010	61.3			29.8			2.06		
	2011	60.8			29.2			2.08		

The lowest average L : W ratio was recorded in the leaves of B 2/93 (2.10) and the highest in the check variety B-21, which has slightly elongated form compared to the other two varieties.
The analyses shows that L : W ratio of the 5th, 10th and 15th has a tendency to increase from the lower to the upper insertions, i.e. the leaves of upper insertions are characterized by slightly elongated form.
Climate conditions in 2010 were favorable for plants to form larger and wider leaves and thereby to give a better expressed length: width ratio in investigated varieties. The results obtained for L : W ratio in the 5th, 10th and 15th leaf are in accordance with our expectations and literature data.

Conclusions

The average height of varieties included in the trial ranged from 127.3 cm in the check variety B-21 to 188.1 cm in variety Pelagonec, which is 47.76% more compared to the check. The highest leaf number was recorded in Pelagonec (32.57) and the lowest in variety B-21 (26.87). Macedonian varieties are characterized by slightly higher leaf number.
The lowest average length (43.80 cm) and width (28.4 cm) of the 5th leaf was measured in the check B-21, and the highest length (55.00 cm) and width (38.0 cm) was recorded in variety Pelagonec (increase of 25.57 % compared to the check variety).
The lowest average length (53.53 cm) and width (32.43 cm) of the 10th leaf was measured in the check variety B-21 and the highest length (66.60 cm) and width (37.27 cm) was observed in Pelagonec, which is 14.27% higher index compared to the check.
The lowest average length (53.97 cm) and width (22.83 cm) of the 15th leaf was recorded in the check variety B-21 and the highest length (60.27 cm) and width (28.6 cm) was observed in Pelagonec, which is 25.27% higher index compared to the check variety.
Analyzis of length: width ratio in the 5th, 10th and 15th leaf shows a tendency of increase from the lower to the upper insertions and that Macedonian varieties are characterized by larger leaf size.

Abstract

In this paper, the stability of ten divergent wheat varieties was investigated, where two traits were analyzed: spike weight and grain weight per spike. The trial was conducted on the experimental field of the Center for Small Grains in Kragujevac during three growing seasons. The expressions of the analyzed traits were statistically significant and showed additive and non-additive sources of variation. The AMMI analysis showed significant effect of the genotype x environment interaction, where two main components were significant (PCA1 and PCA2). The first principal component (PCA1) expressed the largest share of the genotype x environment interaction. The genotypes reacted differently to different environmental conditions. Genotype Szegedi 765 had the highest value of analyzed traits, but moderate to low stability. Genotypes Sterna and Gruza expressed the highest stability, while genotype Mironovskaya 808 showed the highest instability in terms of both traits. The investigated genotypes had the highest stability in the second year of investigation, and the lowest stability in the first year. In terms of stability, these genotypes can be used in wheat breeding programs.

Key words: *Stability, AMMI, wheat, interaction, PCA*

Introduction

Wheat, as one of basic grains in the human diet, has always taken a central role in agricultural production. Wheat is mainly used in human nutrition as shown by the fact that it takes about 53% of total production in developed, and 85% in developing countries (Peña, 2007).

The main goal in a crop breeding program is the development of genotypes which are stable or adapted to a wide range of diversified environments (Farshadfar *et al.*, 2011). Stability is important for breeders in terms of changing ranks of genotypes under the influences of different environments, which can influence selection's efficiency. On the other hand, for famers, high yielding characteristics of genotypes are most important, regardless of the change ranks of genotypes (Crossa *et al.*, 2002). In wheat breeding programe it is important to identify genotypes which are adapted or stable to different environmental conditions (Hagos and Abay, 2013).

The genotype x environment (GE) interaction is major problem especially in the study of quantitative characteristics, which are influenced with few genes. Because of it, predictions and interpretation of genetic experiments are very complicated (Amiri *et al.*, 2013). The additive main effect and multiplicative interaction (AMMI) method proposed by Gauch (1992) was a significant advance in the analysis of genotype x environment interpretation. The AMMI model separates the additive variance from non-additive, multiplicative, variance, and includes the principal component analysis (PCA) to the interaction. This model explains in more detail the interaction pattern (Thillainathan and Fernandez, 2001).

The main objectives of this study are investigating stability of spike weight and grain weight per spike in different wheat genotypes and identifying stable genotypes by evaluating GE interaction using AMMI model and biplot analyses.

Material and Methods

The experiment was conducted in the experimental field of the Center for Small Grains in Kragujevac (Serbia) during three different vegetation seasons. Ten wheat genotypes (Arsenal, KG-56, Gruza, Mironovskaya 808, Norin 10, Rana Niska, Spartanka, Sterna, Osjecanka, and Szegedi 765) were evaluated in a randomized complete block design with three replications. Rare sowing was performed where seeds were sown in 1 m long rows, with 20 cm space between the rows and 10 cm distance between each seed in a row. Because of this rare sowing method, genotypes could express their maximal genetic potential for tillering and other spike characteristics. Genotype and environment interaction was tested using AMMI (Additive Main Effects and Multiplicative Interaction) proposed by Gauch (1992) and Zobel (1988). Biplot analyses were, also, created due to graphical visualization in the relationship between genotype and environment. AMMI and biplot analysis were performed using GenStat Trial Version 18.1.0.17005 (https://www.vsni.co.uk/).

Results and Discussion

Spike weight and grain weight per spike could be of the importance for grain yield formation. Saed-Moucheshi *et al*. (2013) established that spike weight had the highest correlation with yield in wheat. Results of AMMI analysis of mean spike weight and grain weight per spike showed significant differences ($p<0.01$) among the genotypes, the environments and GE interaction. The significance of GE interaction effects demonstrated that genotypes responded differently to variations in environmental conditions. AMMI analysis of spike weight showed that 20.98% of the total sum of squares was attributable to genotype effect, only 5.77% to environmental effects, and 11.65% to GE interaction.

Table 1. AMMI ANOVA for spike weight and grain weight per spike of ten wheat genotypes in three years

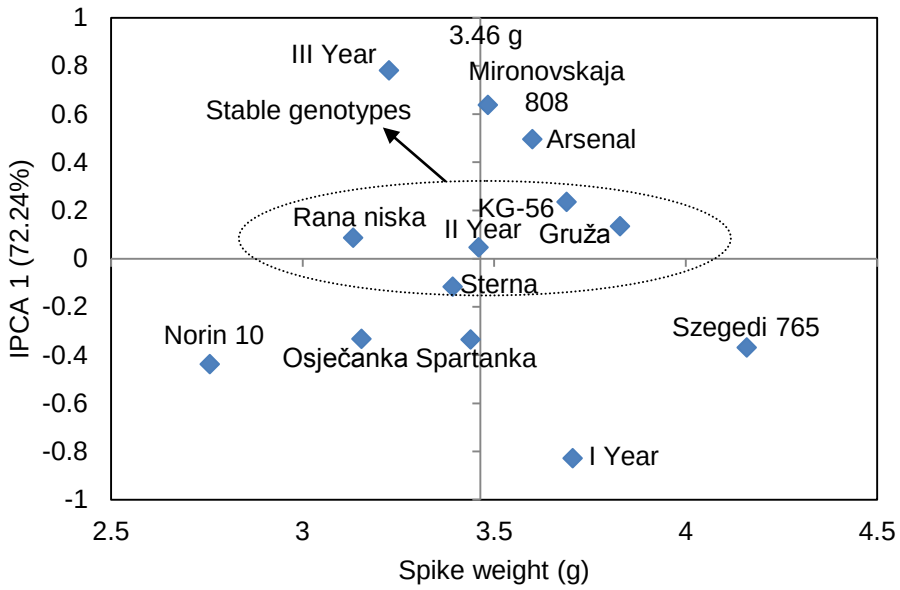
Source of variation	Spike weight				Grain weight per spike			
	df	SS	MS	F-value	df	SS	MS	F-value
Total	899	600.289			899	402.989		
Genotypes	9	125.93	13.998	32.92**	9	47.74	5.304	17.86**
Environments	2	34.63	17.317		2	34.84	17.418	
Interactions	18	69.96	3.886	9.14**	18	62.02	3.446	11.60**
IPCA1	10	50.54	5.054	11.89**	10	35.06	3.506	11.80**
IPCA2	8	19.42	2.428	5.71**	8	26.96	3.370	11.35**
Error	870	369.77	0.425		870	258.39	0.297	

** p<0,01

The AMMI analysis of variation for grain weight per spike showed that genotype accounted for 11.84% and environment for 8.64% of the total experiment variation. The GE interaction had the largest share in the total variation (15.39%) for grain weight per spike. Petrović *et al.* (2013) and Dimitrijević *et al*. (2005) also found a significant effect of GE interaction on grain weight per spike (Table 1).

In both analyzed traits, the first two main components (IPCA1 and IPCA2) were highly significant, which indicate that interaction was agronomically significant. The greatest contribution to genotype and environment interaction gave IPCA1, with participation of 72.24% for spike weight, and 56.53% for grain weight per spike of the interaction sum of squares (Table 1). The prediction assessment indicated that AMMI with only two interaction principal component axes was the best predictive model (Motamedi *et al.*, 2013).

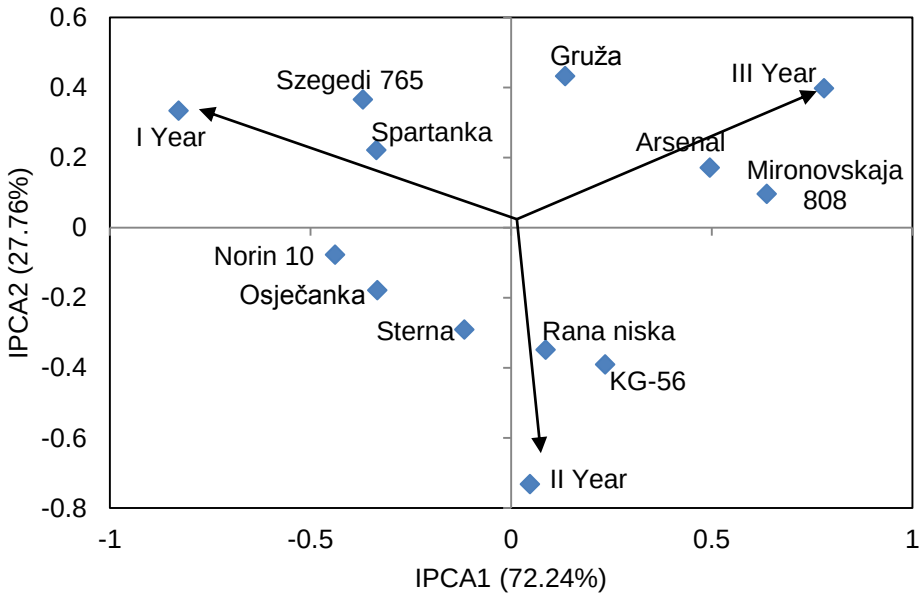
The GE interaction is considered in detail using AMMI 1 biplot. The genotypes that are located close to the origin, Rana Niska, Sterna, Gruža and KG-56, considered to be stable genotypes. These stable genotypes have good adaptation to a wide range of environments. In relation to all stable genotypes, genotype Gruža had the highest value of spike weight. Genotype Szegedi 765, with the highest value of spike weigh was middle stable genotype, which indicates that it is harder to achieve stability in genotypes with high value of certain trait. Saleem *et al.* (2015) reported that genotypes which showed yield above the grand mean yield were less stable than genotype which was close to the zero of PCA score with low yield. Also, middle stable genotypes are Norin 10, Osječanka, Spartanka, Szegedi 765 and Arsenal. Genotype Mironovskaja 808 is unstable and expresses the greatest interaction with the environment. Analysed genotypes had the highest stability in the conditions that prevailed in the second year (Graph 1).



Graph 1. AMMI 1 biplot for the spike weight of 10 wheat genotypes in three years

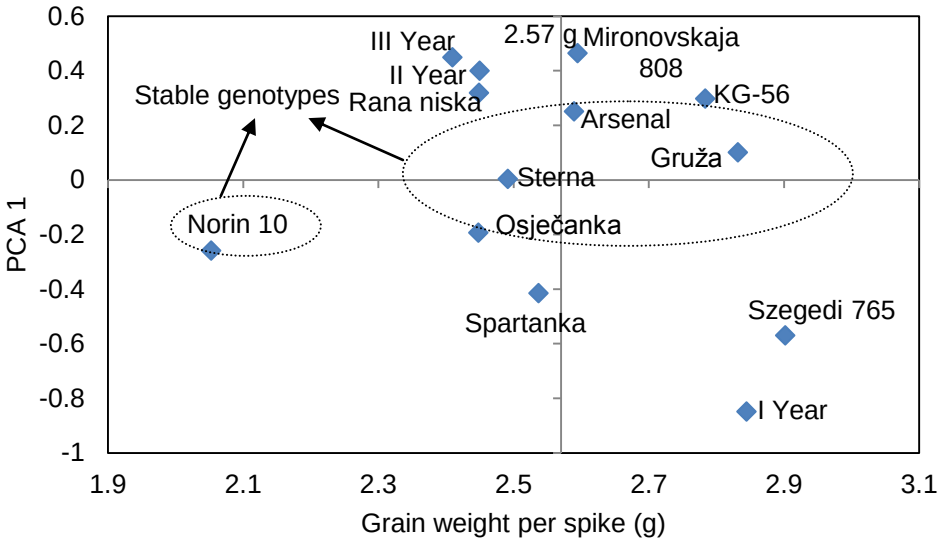
In order to obtain a more precise analysis of the GE interaction, the AMMI 2 biplot (IPCA1 *vs.* IPCA2) is created. Genotypes with large IPCA1 or IPCA2, or both, have high interactions, whereas genotypes with IPCA1 or IPCA2 scores near zero have low interactions for the corresponding axis (Motamedi *et al.*, 2013). Genotype Sterna is located the nearest to the biplot origin, which indicates that this genotype is the most stable. Stable genotypes are Rana niska, Spartanka, KG-56 and Gruža, as well. Genotype Mironovskaja 808 has the longest IPCA1 vector and thus expresses the greatest interaction with the environment. The distance from the origin to the points of environmental conditions indicate that no genotype has superior performance of spike weight in all environments. However, the genotypes that are close to a vector of specific environment considered to be stable for the given conditions. Therefore, genotypes Rana niska,

Sterna and KG-56 are close to a vector of environmental conditions in the second year. Genotypes Arsenal, Mironovskaja 808 and Gruža are close to a vector of the third year and considered to be stable in this year, while genotypes Szegedi 765, Spartanka, Norin 10 and Osječanka may be characterised by specific stability in environment of the first year (Graph 2).



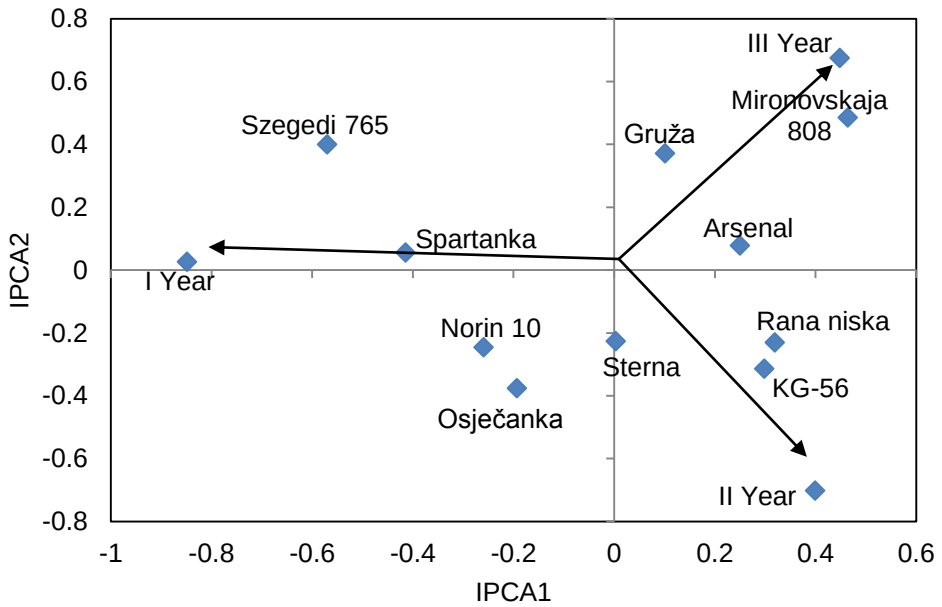
Graph 2. AMMI 2 biplot for the spike weight of 10 wheat genotypes in three years

Genotypes that are stable or less sensitive to environmental influences are found near the biplot origin, and in this case, these genotypes are Sterna, Gruža, Osječanka, Arsenal and Norin 10. Genotype Norin 10, in addition to being stable, is characterized by the lowest value of grain weight per spike, while the genotype Gruža has the highest value of this trait in relation to all stable genotypes. The middle stable genotypes are Rana niska and KG-56, while unstable genotypes are Mironovskaja 808, Szegedi 765 and Spartanka. Genotype Szegedi 765, with the highest value of grain weight per spike, is the most unstable genotype. Genotypes showed the greatest stability in the second year of investigation and the lowest one in the first year (Graph 3).



Graph 3. AMMI 1 biplot for the grain weight per spike of 10 wheat genotypes in three years

Genotypes Sterna, Arsenal, Norin 10, Gruža and Osječanka are located near biplot origin and are considered to be more stable in relation to other genotypes. According to Motamedi *et al.* (2013), the greater the PCA scores, either negative or positive, indicates that genotypes are more specifically adapted to certain environmental conditions. Therefore, genotype Mironovskaja 808, with high positive IPCA1 and IPCA2 values, is well adapted to the conditions in the third year, while genotype Szegedi 765 with high positive IPCA2 and high negative IPCA1 value is well adapted to specific conditions in the first year. Genotypes Arsenal and Gruža are close to a vector of the third year, while genotypes, Spartanka and Norin 10 are well adapted to conditions of the first year. The genotypes that are adapted to environment of the second year are Rana niska, KG-56 and Sterna (Graph 4).



Graph 4. AMMI 2 biplot for the grain weight per spike of 10 wheat genotypes in three years

Conclusion

The AMMI analysis showed significant effect of the additive and non-additive sources of variation on the expressions of the spike weight and grain weight per spike. No genotype has superior performance in all environments, but genotypes Gruža and Sterna are the most stable in wide range of environment. On the other hand, genotypes Mironovskaya 808, Szegedi 765 and Spartanka were located away from biplot origin and are considered specifically adapted genotypes to certain environments. Genotype Mironovskaya 808 expresses high instability for both analyzed traits. Genotype Szegedi 765 had the highest value, but moderate to low stability for both investigated traits. This indicates that it is very difficult to achieve stability in genotypes which are characterized by high values of the certain trait. Stable genotypes, which are adapted to wide range of environments can be used in plant breeding programs.

Abstract

Antioxidant activity of essential oil and extracts of rosemary on the oxidative stability of sunflower oil were determined. The essential oil and extracts of rosemary at the concentrations of 0.1%, 0.3% and 0.5% into sunflower oil were added separately. Antioxidant effect of essential oil and extracts of rosemary on the oxidative stability of sunflower oil were evaluated as connected with colour (Hunter *L*, *a* and *b*) and peroxide values. *L* value of the frying oil in which 0.5 % extract of rosemary was added is very close to *L* value of the raw oil. The value of *L* of the frying oil in which extract was added is less than the frying oil that essential oil added. Peroxide value of frying made with 0.3 % concentration of the rosemary essential oil increased less than that of made with the raw sunflower oil. Peroxdie value of frying made with 0.5% the rosemary extract decreased, too. In addition, viscosity and free fatty acid (FFA%) values of frying sunflower oil were determined. FFA% of the frying oils of 1. and 2. frying made with the sunflower oil in which 0.5 % essential oil of rosemary added increased less than that of 1. and 2. frying made with the raw sunflower oil.The essential oil of rosemary have been effected more from the extracts of rosemary on the oxidative stability of sunflower oil.

Keywords: *Rosemary, antioxidant activity, frying, sunflower oil*

Introduction

During the frying process, oils and fats are exposed to heat, air and moisture. These factors contribute to diminishing oil quality and changing the triacylglyceride structure (Ramalho & Jorge, 2008). During the deep fat frying process, oils and fats in the presence of atmospheric oxygen and high temperatures are used over and over again and are subjected to the maximum oxidative and thermal effect (Ulusoy & Ergin, 2006). The oxygen in deep-fat frying reacts with oil. The rate of oxidative degradation reactions increases as the concentration of oxygen and free radicals increases (Choe & Min , 1992).

Oxidative degradation occurring fats and oils leads to the formation of unwanted taste and odor, the emergence of a large number of compounds harmful to human health, a decrease in nutritional value (Akgül & Ayar, 1992; Quaglia, Comendador & Finotti, 1998).

Synthetic antioxidants have been used for over 50 years in manufacturing, packaging and storage of fats and fatty foods (Anwar, Ali, Hussain, Shahid, 2009). The use of synthetic antioxidants, such as butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA) and tertiary butylhydroquinone (TBHQ), in foods is discouraged due to their perceived carcinogenic and teratogenic potential and safety concerns. (Çoban & Patır, 2010). Generally consumers prefer natural antioxidants to synthetic ones. Therefore, for a long time to improve the properties of

foods, such as smell and taste, used as contribution spices, and natural aromatic plants has gained increasing importance (Criado, Motilva, Goni, Romero, 2005).
Within the spices, rosemary (*Rosmarinus officinalis L.*) is the one that presents the highest antioxidant ability. The compounds responsible for rosemary antioxidant activity are mainly phenolic diterpenes such as carnosol, carnosic acid, rosmanol, epirosmanol and isorosmanol (Ramalho & Jorge, 2008). 0,02 % rosemary methanolic extract was established that increased the oxidative stability of sunflower oil at 63˚ and 120 ˚C (Criado, Motilva, Goni, Romero, 2005).
The objective of this work was to study the antioxidant action of essential oil and extracts of rosemary on the stabilitiy of sunflower oil during deep-frying.

Material and methods

Material

Rosemary was obtained from the local spice seller in Konya (Turkey) As oil, refined sunflower oil was provided from market. Potatoes were obtained from the local market. All solvents were of analytical grade.

Methods

Isolation of essential oils of rosemary and extraction of extracts of rosemary

In the wake of rosemary was developed into a flour with blender 10 g (± 0,5 g) sample weighed and was put into 2x 250 mL erlenmayers and their mouths closed. With an interval of 20-30 minutes they are shaken, were stored in a night. Then, each one of all filtered from filter papers and ethanol extractions of spices were extracted with soxhlet device that tuned to 40 C. Dried and ground rosemary plant (about 100 g for each) were subjected to hydrodistillation for 3 h using a Clevenger-type apparatus and the oils obtained were dried over anhydrous sodium sulfate.

Deep fat frying process

The fry-pan (19x3,5 cm in size, no cover) was used for frying process. Oil sample was taken for comparison from the fry-pan. essential oil (0,1%, %0,3 and %0,5) and extract (0,1%, %0,3 and %0,5) of rosemary were used in the frying process. The fry-pan was put for frying process on the electric heater. Oil (220 mL) was introduced into a fry-pan before adding extract or essential oil. The potatoes were peeled, washed, cut as uniformly as possible, wiped, weighed (~53,5 g) and introduced into frying oil immediately. Deep-fat frying was carried out for both extract and essential oil of 0,1%, 0,3% and 0,5%, respectively, twice in same oil. Before each frying, fry-pan was cleaned. At the end of the frying process (the frying process takes 5-6 minutes), frying oil was filtered with filter paper and samples were taken for analysis. Oil samples were stored in the refrigerator until analysis.

Assessment of Instrumental Color

Chromameter was used for colour analysis. A little oil was put into a clean petri and the colour value of three different regions was read. A colorimeter (Minolta Chroma meter CR 400 (Minolta Co., Osaka, Japan)) was used to assess the oil color and the CIELAB colorimetric system was applied. Each time 20 ml of samples put into a glass Petri dish, and the liquid probe of the instrument was immersed into the dish sitting on the white tile, and readings of the CIE lab coordinates are recorded. The L^*, a^*, b^* values are average of ten readings. The colour brightness coordinate L^* measures the whiteness value of a colour and ranges from black at 0 to white at 100. The chromaticity coordinate a^* measures red when positive and green when negative, and

chromaticity coordinate b^* measures yellow when positive and blue when negative (Pagliarini, 1994).

Determination of viscosity of frying oil

35-45 mL sample of oil was put into the viscometer device. Value was recorded as mPas.

Determination of % free fatty acid of frying oil

The oil samples were weighed to 5 g fat ± 0.01 for determination of % free fatty acid of frying oil, thawed in 100 mL ether. a few drops of phenolplthalein were added and were shaked. Finally, it titrated with 0,1 N KOH (potassium hydroxide) solution, consumption was recorded. % FFA were calculated according to the following formula.

% FFA: (V/m) x 2.8

V: consumed KOH solution, ml

m: sample weight, g

Determination of peroxide value of frying oil

2-3 g oil sample was weighed in the erlenmayer. 10 mL chloroform, 15 mL acetic acid and 1 mL potassium iodide solution were added upon its and were shaken. Then, closing the mouth of it was kept in a dark environment for ~5 min. At the end of this period, 75 ml distilled water and a few drops of starch solution were added upon its and sample was titrated with 0,02 N sodium thiosulfate. Peroxide value were calculated according to the following Formula (Paul and Mittal,1997).:

Peroxide value: (V/m) x 2

V: used in titration sodium thiosulfate, ml

m: sample weight, g

Results and discussion

Physico-chemical properties of raw and frying oils are given in Table 1. Frying oils have been evaluated according to the Hunter color system (Ulusoy & Ergin, 2006). The colour values were expressed as *L* (brightness/darkness), *a* (redness/greenness) and *b* (yellowness/blueness) (Bansal, Zhou, Barlow, Lo, Neo, 2010). As shown in Figure 1(b), *L* value of the frying oil in which 0.5 % extract of rosemary was added is very close to *L* value of the raw oil. The value of *L* of the frying oil in which extract was added is less than the frying oil that essential oil added. While *a*-value of the frying oil that extract added highly significant decrease as shown in Figure 1(b), increase in the value of *a* of the frying oil that essential oil added less decreased as shown in Figure 2 (a). Increase in the value of *b* of 1. and 2. frying made with the sunflower oil in which 0.5 % essential oil of rosemary added is less (Figure 3 (a)). As for that *b*-value of the frying oils that extract of rosemary added has been an increase rather than (Figure 3 (b)). This increase is due to the color of dark green rosemary extract. b-value of the frying oil that the essential oil of rosemary added showed less increase than b-value of the frying oil that extract of rosemary.

Peroxide value of frying made with 0.3 % the rosemary essential oil increased less than that of made with the raw sunflower oil (Figure 6 (a)). Peroxide value of frying made with 0.5% the rosemary extract decreased, too (Şekil 6(b)). Whenever rosemary essential oil and rosemary extract compare, the essential oil seems to be more effective on the peroxide value of the frying oil.

Table 1. Physico-chemical properties of sunflower oil

	Colour	**Viscosity (mPas)**	**FFA%**	**Peroxide value Meq/Kg oil**

a) b)

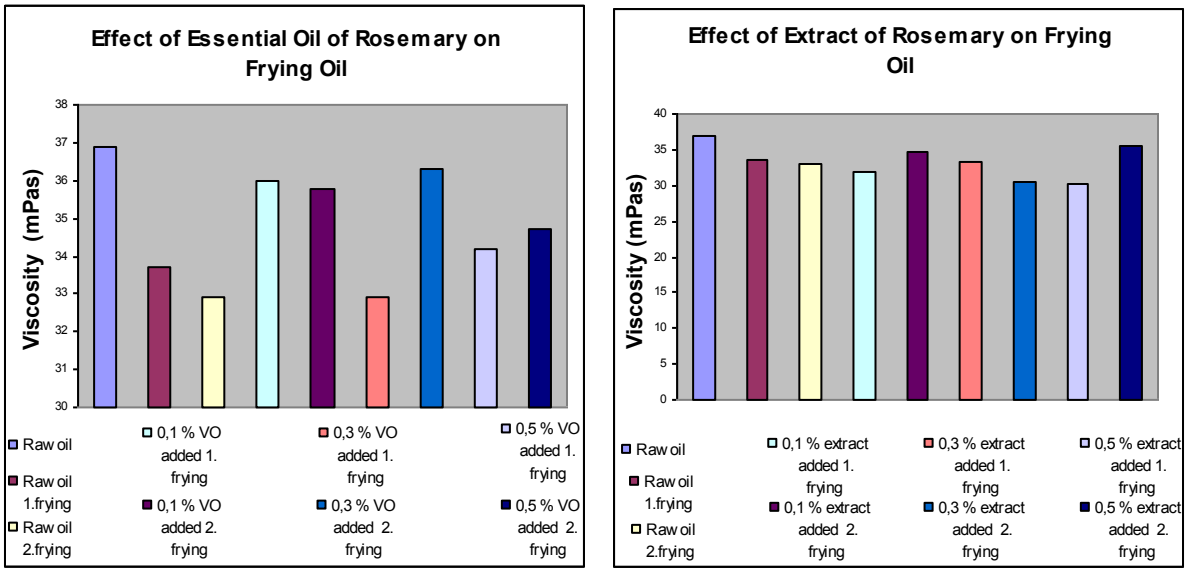

Figure 6: (a) Action of essential oil of rosemary on peroxide value of frying oil. **(b)** Action of extract of rosemary on peroxide value of frying oil.

The viscosity of the raw sunflower decreased as a result of frying. The viscosity of 1. and 2. frying made by adding 0,1 % essential oil of rosemary didn't far too decrease (Şekil 4 (a)). The frying made by adding extract, almost all concentrations, the viscosity of 1 and 2 frying oils are close to each other (Şekil 4 (b)).

The acid value is the number of milligrams of potassium hydroxide necessary to neutralize the free acids in 1 g of sample. The acid value can be estimated by multiplying the percent free fatty acid content expressed as oleic acid (Paul & Mittal, 1997).

As shown in Figure 5 (a), FFA% of the frying oils of 1. and 2. frying made with the sunflower oil in which 0.5 % essential oil of rosemary added increased less than that of 1. and 2. frying made with the raw sunflower oil. The fact that 0.1%, 0.2% and 0.3% rosemary extract had no effect on the FFA% are show in Figure 5 (b).

Conclusion

Peroxide value of frying made with 0.3 % the rosemary essential oil increased less than that of made with the raw sunflower oil. Peroxide value of frying made with 0.5% the rosemary extract decreased, too. In addition, viscosity and free fatty acid (FFA%) values of frying sunflower oil were determined. FFA% of the frying oils of 1. and 2. frying made with the sunflower oil in which 0.5 % essential oil of rosemary added increased less than that of 1. and 2. frying made with the raw sunflower oil.The essential oil of rosemary have been effected more from the extracts of rosemary on the oxidative stability of sunflower oil.

Abstract

This research was conducted to assess the effect of two irrigation methods (drip and furrow irrigation) and irrigation levels (25 %, 50 %, 75 % and 90 % of the water-holding capacity of the soil) on yield and yield components of grain corn (*Zea mays* L.) at the Agricultural Research and Extension Center, Igdır University from North East Turkey, in 2014. The experimental design was a split-plot arrangement with three replications on the soils of a clay silt loam. Plant height (185.0-253.3 cm), plant weight (583.3-930.0 g), stem ratio (47.2-57.4%), ear ratio (42.6-52.8%),ear weight (290.0-403.7 g), grain number in ear (350.7-640.0), ear length (24.0-28.7 cm), 1000-grain weight (359.5-450.6 g), crude protein ratio in grain (6.0-9.0%), and grain yield (10.0–25.2t ha^{-1}) were varied between. While the highest plant height, grain yield, 1000-grain weight, stem ratio, grain number in ear was obtained from drip irrigation method, ear ratio and crude protein ratio were obtained from furrow irrigation method. Grain yield and yields components except for ear and stem ratio in corn production were significantly decreased according to decreasing of the water-holding capacity of the soil. Furthermore, the highest and lowest yield and yield parameters were obtained at 25% and 90%, respectively in both irrigation methods. In an arid region where rain never falls during the growing season, the question when to irrigate is rather crucial. According to the results of the study, irrigation should start when available water fallen to 25or 50 percent.

Keywords: *Corn, Deficit Irrigation, Yield, Yield Conponents*

Introduction

Maize (Zea mays L.) ranks as the most important crop worldwide in terms of grain production; although wheat and rice are the most important for direct human consumption. Maize seeds are consumed by humans directly or after processing, and are often the main component of animal feed. Vegetable oil, sugar syrup, alcohol as biofuel, and feedstock for the manufacturing of plastic are commonly derived from maize seeds (Anonymous, 2016).

The total amount of water that a corn crop needs during the growing season may vary from 500-750 mm depending on factors such as weather conditions, plant density, fertility, soil type and days to maturity. Farm planners should have a basic understanding of the relationship between soil and water. Otherwise, they will have difficulty in evaluating the importance of such water-control practices as drainage, mulching, and irrigation. The most widely used form of irrigation scheduling is based on crop water use and soil water evaporation how two these processes, combined with precipitation and stored soil moisture, are used to determine irrigation needs. Magar (1995) reported that semi-arid and arid regions, drip irrigation is particularly well as plants increase in water consumption, 60% water saving compared to surface irrigation, the yield has been provide 30% increase. Water is usually the cruelest natural factors limiting expansion and development of agriculture in this region of Turkey. Igdır has approximately 256 mm

(Anonymous, 2015), amount of precipitation does not to meet the needs of corn. Moisture stress anytime after planting can affect plant development and reduce yield potential. The any amount of yield loss is dependent on the growth stage of the corn when moisture stress occurs. Öner at al. (2012) found that grain yield per unit area t h^{-1} were between 9.3-15.1 t h^{-1} in Adapazarı, 7.8-12.9 t h^{-1} in Adana and 9.1-12.2 t h^{-1} in Samsun, Turkey.

Karasu at al. (2015) stated that deficient irrigation decreased grain yield and yield components except fort the percentage of crude oil and crude protein of the grain, but improved the efficient use of irrigarion water. Also, they stated that relationship of the grain yield and and its componets were positively significant.

The goal of study was to evaluate the impacts of irrigation methods and irrigation levels on yield and its components on Zea mays L. (71MAY69) in order to recognize and optimize water irrigation regimen when having limited water resources.

Material and methods

A field experiment by drip and furrow irrigated grain corn (*Zea mays indendata* 71MAY69) was conducted on the at the Agricultural Research and Extension Center of Igdır University ,lies at latitue, 44º 48 E, longitude 40º and altitude 800-900 mabove sea level, in Eastern Anatolia, Turkey. The effect of various consumptive water level on corn yield of maize was studied. The experimental design was split plot with three replications. The main plots of irrigation methods irrigation (drip irrigation and furrow irrigation), the levels of irrigation water included 25%, 50%, 75% and, 90% of the water-holding capacity of the soil. The grain cultivar was sown at a seeding rate of approximately 92.500 seeds ha^{-1} by hand at 5-6 cm depth by hand after barley harvesting on 9July 2014. The plot size was 5 x 3.5 m, row spacing of 70 cm and crop distances on each row, 1.5 m apart from each other plot, three meters wide left between blocks as buffer zone, and total plot area was 17.5 m^2. Soil samples were taken before the set up the experiment from the soil layers 0 to 30 and 30 to 60 cm to determine determine selected physical and chemical properties ofthe experimental field at the beginning of the experiment (Table 1). Soil lime, soil pH, soil electrical conductivity, potassium, phosphorus, organic matter at 30 cm soil depth was % 6.53, 7.98, 1.8 dS m^{-1}, 0.3 t ha^{-1}, 0.008 t ha^{-1}, 1.6% and experimental soil texture was clay-loam. Irrigation treatments included: drip and furrow was set up in main plot and irrigation level 25%, 50%, 75% and 90 %) in subplot as pointed at Table 3. The irrigation water amount treatments were distributed randomly in the subplots of each main plots. First irrigation was applied to all plots using a sprinkler irrigation system to bring the soil water content in 0-90 cm soil depth up to field capacity. Water content in the soil profile at 0.3 m depth increments were directly measured several times during the growing season. The common dripline design was one lateral for two rows of crop, dripper spacing was 70 cm with dripper flow rate 4 l/h in drip irrigation method. Water was filtered using 150 mm diameter screen filter. Soil moisture accounting is used to calculate the soil-water balance in the root zone throughout the growing season. The water-tansiometer equipment was used for calculating the amount of irrigation water of all treatments. Irrigation was applied when the soil moisture content decreased to 25% (a total of 1380 mm with 13 applications), 50% (a total of 1025 mm with 10 applications), 75% (a total of 812 mm with 6 applications) and 90% (a total of 614 mm with 4 applications). The amount of nitrogen (N) application 250 kg ha^{-1} N (ammonium sulphate with 21% N) which has divided into two applications (before planting) and (the plants were reached to 40-50 cm with anchor). The all of the phosphorus, triple super phosphate, 100 kg ha^{-1} P were given all plots before planting and weeds were cleared out during the growing season, by hand and hoe.

Some yield and yield component parameters were determine; those include: plant height (cm), plant weight (g), ear length (cm), ear weight (g), ear ratio (%), stem ratio (%), 1000-grain weight (g), grain number in ear, crude protein ratio (%) and grain yield (t/ha^{-1}). Plant height values were measured on randomly selected 20 plants in the centre of every plot before harvest. Randomly selected plants were cut at ground level, the ears were separated from thestover. The ears of plant without husk were used for determining of ear length and weight and grain number per ear and thousand-grain weight.

Statiscal analysis

Variance analysis of data obtained in the experiment, Duncan Multiple Comparison Tests SPSS (17.0) was made according to the package.

Results and discussion

Evaluation of Yield components

Plant height and plant weight

Yield components of grain cornshuch as plant height, plant weight, ear length, ear weight, ear ratio of maize grown under different irrigation methods and levels of irrigation are presented and stem ratio, 1000-grain weight,grain number in ear, crude protein ratio and grain yield are shown inTable 3 and Table 4, respectively.

Table 3. Different irrigations and their levels on grain corn yield and components in 2014

Irrigation method	Irrigation Levels % 25	% 50	% 75	% 90	Irragation methods Means

Note: Means followed by the same letter are not significantly different at the p = 0.05 level using Duncan test

The effect of irrigation methods and irrigation levels were statistically significant at plant height of grain maize. Effect of drip irrigation on plant height (232.9 cm) has been more thanfurrow irrigation method (218.7 cm) at the end of trial. On the other hand, the effect of different irrigation water amounts was significant and plant height reduced also showed parallel as means of watering scarcity of irrigation levels has also decreased (Table 3). In addition this according to interaction of irrigatlion method x water levels, the lowest plant height was found from the furrow irrigation at 90% of water deficiet (Table 3).

Variance analysis indicates that the weight of the plant according to irrigation methods have not been statistically significant, while levels of irrigation water affected plant weight owing to the fact that the increased plant weight. The lower water application during the vegetative growth stage for furrow irrigated method contributed to shorter plant heigth and plant weight but in no

significant difference in plant weight compared to irrigation methods. Our results are in close agreement with those of Dagdelen at al. (2008) and also these were similar to those of Bozkurt et al. 2006; Kang et al., 2000; Yazar et al. 2002; Kirnak et al., 2002; Vartanlı and Emekliler 2007; Vural and Dagdelen, 2008; Karasu et al. 2015).

Ear length, weight and ratio

As shown in Table 3, data obtained from the investigation showed that both ear length and ear weight were not significantly affected by furrow and drip irrigation method. Ear lengths were 28.2, 28.2, 27.2 and 25.2 cm in the levels of irrigation water 25%, 50%, 75% and, 90% of water deficit, respectively. Significant diffirences between irrigation methods were found in term of the ear ratio for combined data of irrigation levels. The ear rate, 48.6% in furrow irrigationwas significantly higher than 45.1%, drip irrigation system. However, variance analysis demonstates that levels of watering in the end of the experiment could not significantly leads to ear ratio of plant (Table 3). Our findings showed that when the irrigation levels decreased, the ear lenghth, weight and ratio decreased. In similar study, Bolanos and Edemedes (1996) indicated that any decrease in irrigation intervals may directly alters factors such as ear width, ear length, leaf surface area, plant height and seed yield.

In maize plant, due to decrease watering during the growing period, lesser biomass is produced and ultimately yield is reduced. These results were consistent with the results of Ertek and Kara (2013); Oktem et al. (2003); reported that the highest fresh ear yield of sweet corn was 13.66 t ha^{-1} for the 2-day irrigation frequency with 100% evapotranspiration (ET) water application by a drip system. However, corn has been reported to be very sensitive to drought. Water stress can affect growth, development, and physiological processes of corn plants, which can reduce biomass and, ultimately, grain yield due to reduction in the number of kernel per ear (cob) or the kernel weight (Payero et al., 2009; Aslam at al. 2012). Koca. Y. O and Erekul (2011b) indicated that lentgh among of 18.9-24.8 cm, the number of grain per cop among of 514-812, a thousand of grain weight among of 243-330 g.

Stem ratio,%

Results of the experiment showed that, stem ratio in drip irrigated method was higher than the furrow irrigation method and statsisticaly was significant. As average of the irrigation methods, had no effect on stem ratio of the irrigation levels. In additon to, irrigation treatments also results in differences between methods. At the applications of deficit irrigation, the values cosiderable decreased (Table 4). Kiziloglu et al. (2009) reported that water deficit (20% field capaicty) resulted in alower cob, leaf, stem and total fresh yields. Moosavi, S.G. (2012) showed that water deficit stress and N fertilizer level significantly affected leaf area index at silking stage, ear length, grain number per ear, 1000-grain weight and grain yield. Stem diameter, ear diameter and harvest index were only affected by irrigation treatments.

1000-grain weight

Results of the experiment, Table 4 show that 1000-grain weight was higher 416.3 g in drip irrigation method compared to furrow irrigation method with 393.9 g as average of irrigation treatments. In both furrow irrigation and drip irrigation, as the field capacity decreases, 1000-grain weight decreased depending on the irrigation levels. 1000-grain weight significantly interacts with irrigation treatments. Maximum 1000-grain weight was reported at 75% water treatment of drip irrigation while there was 375.5 the same point of furrow. However, when the lowest grain weight was obtained from irrigation of falls to 90% of water-holding capacity of the soil. It is important to keep moisture adequate, but not excessive, even in the late stages of corn development because kernel weight continues to increase. Similarly, Bozkurt et al. (2006)

pointed out that the grain yield per cob varied from 153.3 g for deficit irrigation to 194.9 g for full irrigation treatments and 1000-kernel weight varied from 178.0 to 306.2 g among treatments. Some experiments have shown that drip irrigation does not increase 1000 seed weigth to well management surface irrigation (Harde at al. 1982; Kirtok, 1998). Kebede at al. (2014) showed that reducing soil moisture from 100% FC (fully irrigated) to 75% FC of a silt loam soil starting at the silking growth stage in corn did not reduce yield significantly compared to yield from the 100 % FC, while saving a significant amount of water. Moosavi, S. G.(2012) found that the highest grain number per ear, 1000-grain weight and grain yield were obtained under optimum irrigation treatment, and irrigation stop at 10-leaf, tasselling and grain-filling stages decreased grain yield by 52.8, 66.4 and 44.9%, respectively; and it decreased grain number/ear by 45.9, 59.3 and 30.1%, respectively.

Grain number in ear

Grain number is cosidered as an important factor in production of graind corn. Experiments shows thatmain effects of the furrow irrigation and drip irrigation methods and irrigation levels were significant on grain number in ear as shown in Table 4. In present study, number of grain decreased depends on deficit of water-holding capacity of the soil. In addition, Variance analysis illustrate that grain number was affected irrigation methods and deficit of water levels interaction. The highest number of grain per ear were obtained from drip irrigation system. Number of kernels per ear decreased with increasing deficiency in irrigation water (Table 4). This could be due to stress that affected grain formation as reported by Ahmad et al. (2002). However, we should keep in mind that grain number in corn plant is not stable and mainly changes with factors such as, planting season, climate, region, soil properties and cultivar. The findings obtained in our research provided similar results were reported by Pandery at al. (2000a); number of kernels is closely associated with yield of maize and the number of kernels per ear is a yield component that varies markedly with stress (Fischer, K.S. and F.E. Palmer. 1984); Harder at al. (1982) mentioned that water stress caused failure of kernel development, its number, size and weight. Pandery at al.2000, alo stated that kernels per ear were reduced from 20% to nearly 50% due to water stress. Yazar et al. (1999) concluded that kernel number decrease is the primary effect of water deficit on corn grain yield. Tabatabaei and Dadashi (2013) indicaded that the effect of drought stress on grain and biological yields was significant at 1% probability level and the maximum grain yield of about 10.1 ton per hectare was obtained in 100% water requirement. Also, they indicated that about 88% of grain yield variation was related to the grain number per ear.

Crude protein ratio,

%Statistical analysis results for crude protein ratio were significant between furrow and drip irrigation methods and crude protein ratio in grain (8.1%) for furrow method was higher than crude protein ratio (7.6%) for drip method (Table 4). Similarly, both crude protein rate in furrow and drip irrigation decreased as shown the number of grains per ear and 1000 grain weight due to reduced irrigation treatments. These results suggest that soil moisture in both irrigation methods can be depleted to 75% irrigation is applied without significantly decreasing crude ratio of per ear. According to the results of the research by Vartanlı ve Emeklileler (2007) changed between 6.21-8.65 % for the crude protein ratio. Our results were closely to results of grain protein rate 8.28% –10.87% by (Ayrancı and Sade, 2004) but were not similar with findings by Koca and Erekul (2011) grain yield among of 11.3-16.8 t ha^{-1} and protein rate among of 9.8 %-13.5. Deficit irrigation decreased grain yield and yield components except the percentage of crude oil and crude protein of grain, relationships between the grain yield and each yield component were positively significant.

Grain yield, t/ha^{-1}

The results of analysis of variance shoved that the irrigation significantly effect ed the grain yield of corn (Table 4). Drip irrigation method did increase yield of corn grain higher than the furrow irrigation system and was obtined 22.8 kg/ha^{-1} grain yield from drip system in this investiagion. However, irrigation levels (25%, 50 %, 75 % and 90 % of the water-holding capacity of the soil) affacted on yield of grain corn (*Zea mays* L. 71MAY69) and grain yield were 25.0, 22.3, 20.3 and 14.9 kg/ha^{-1}, respectively. The highest grain yield about 25 ton per hectare was obtained 25% of field capacity in both irrigation method. However, a slightly interaction was observed between in both irrigaton method at 25% water treatmet. Furthermore, grain yield has declined to about 40% when the irrigation level decrease from 25% to 90% of the water-holding capacity of the soil. On

the other hand, 17 % more grain yield was obtained from drip methtod according to the furrow irrigation. Drought severe stress reduced grain yield by compared to the optimum irrigation condition, this reduction was mainly due to reduction in grain number per ear and average grain weight (Table 4). Hammad at al. (2011) assert that water stress at six and twelve leaves stage simultaneously decreased grain yield 30% while water stress at grain filling stage decreased 20% yield. Our results are quite consistent with the results of the researchers by Kuşcu et al. (2012) concluded that the average grain yields varied from 5.5 to 16.5 t ha^{-1} and 25% deficit. According to Vartanlı and Emekliler (2007) found that grain yield were 15.8-19.0 t ha^{-1} and 288.5-320.0 cm for the plant height. Bozkurt at al. (2011) stated that average corn grain yields varied from 1.93 to 10.4 t ha^{-1} related to amount of irrigation water and irrigation levels had statistically effect on fresh and dry ground biomass production of corn. Koca at al. (2010) stated that means of grain yield components, agricultural and quality characteristics of first crop product were higher than those of second crop product. Also, differences are present among grain yield, the number of grain per. Dagdelen at al. (2008) cited that the grain yield increased with irrigation water amount, and the highest average grain yield (11.1 t ha^{-1}) were obtained from the well irrigated treatment. Karasu at al. (2015) conducted that the highest value of grain yield was found to be 18.3 t ha^{-1} in the I 125 treatment, which represents excessive water.

Conclusion

Grain yield and yields components decreased according to decreasing of the water-holding capacity of the soil. Irrigation levels significantly affected the grain yield, all some morplogical and quality characters studied in present study except for ear and stem ratio of grain corn plant. Drip irrigation method provided highest plant height, grain yield, 1000-grain weight, stem ratio, grain number in ear. Irrigation of grain corn in Igdır ecological conditions should start when available water fall 25% or 50 percent. In particular, owing to fact that problems drainage and salinity of soils in this region, drip irrigation should be further explored as an effective means to control quantity of irrigation water.

AGRICULTURAL MECHANIZATION IN FIELD CROPS IN THRACE REGION OF TURKEY

Bahattin AKDEMIR

Namik Kemal University Faculty of Agriculture Department of Biosystems Engineering, Tekirdag, Turkey
*Corresponding author: bakdemir@nku.edu.tr

Abstract

Instead of one of the well- developed industrial area of Turkey, Thrace Region has important agricultural production. Objective of this research is to determine mechanization chain for field crops in Thrace Region of Turkey. Agricultural machinery type, size, specifications application time of agricultural practices and amount of agricultural inputs were determined for wheat, sunflower, canola, maize, sugar beet and rice. Fuel consumption of each procedure and time requirements of field operations were determined from survey, research studies and articles. In addition, production costs were calculated. As an example: fuel consumption and time requirement of machinery operations were 107.5 l/ha and 3 h/ha for sunflower. In addition, human labour and requirements were determined 3.2 h/ha for field operations of sunflower production. From tillage to harvest of the sunflower, there are 13 field operations. These are plough, cultivator, harrow, centrifugal fertiliser spreader, planting, roller, fertilisation with centrifugal fertiliser spreader, hoeing, 2 times herbicide application, and harvesting. The results can be used to manage next year growing strategies such as field traffic, agricultural input requirements.

Keywords: *Mechanization, field crops, Thrace Region, Turkey*

Introduction

European part of Turkey is gradually well developed region of Turkey (Figure 1). Instead of one of the well- developed industrial area of Turkey, Thrace Region has important agricultural production. Thrace Region has important agricultural production. A large portion of Thracian land is used as cultivation land. The most important means of livelihood in Edirne and Kırklareli provinces are agriculture and the agriculture industry. In Tekirdag province, which has an intense industrial production, a great part of the people living especially in the inland and western parts deal with work based on agriculture (Trakya Kalkinma Ajansi, 2016).

Figure 1. Thrace Region of Turkey (FAO, 2016)

Agriculture is the one of the important income sources in Edirne, Kirklareli and Tekirdag Cities in Thrace Region. Agricultural production value of the Region was obtained from plant production in 79.13% and animal production 20.87%. Wheat, sunflower and rice are the most important crops in this Region. In addition, canola, sugar beet, grape, apple have been growing. Mean size of farm area is approximately 7 ha. Instead of the mean size is higher than Turkey's average farm size 5 ha, 37% of farms are lower than 5 ha. in Thrace Region. Economic income of the farmers is small because of small scale farms and non irrigated agricultural crop production (TUIK, 2016)

Mechanization chain is important for machinery selection and determines problems in crop production. Objective of this research is to determine mechanization chain for field crops in Thrace Region of Turkey. Field operations, agricultural machinery type, size, specifications application time of agricultural practices and amount of agricultural inputs were determined for wheat, sunflower, canola, maize, sugar beet and rice. Fuel consumption of each procedure and time requirements of field operations were determined from survey, research studies and articles. In addition, production costs were calculated.

Materials and methods

Wheat, sunflower, rice, canola, maize for silage, and sugar beet widely produced in Thrace region were selected for determining of agricultural mechanization. Agricultural machinery type, size, application time of agricultural practices and amount of agricultural inputs were determined for wheat, sunflower, canola, maize, and rice. Field operations, machine type, time, speed, effective machine capacity, fuel consumption and human labour requirement were determined by using question with farmers in Thrace Region. Fuel consumption of each procedure and time requirements of field operations were determined from research studies, articles and surveys. Machine size and type, field size, soil type and working conditions etc. affect fuels consumption, effective machine capacity and labour requirement. In this research a sample data were given for an average size farm in Thrace Region. Daily working hour accepted as 10 hour per day. Field efficiency data of the agricultural machines were taken from Canakci (1999), Resim (2005) and ASABE (2016). Collected data were used to calculate effective field capacity (h/ha), total fuel consumption (l/ha) and total man labour requirement as (h/ha).

Results and discussions

Results of the study are given in Table 1 for wheat, in Table 2 for sunflower, table 4 for paddy, Table 4 for maize, and Table 5 for canola. Field operations of the crops investigated in this article have been made by agricultural machineries. Total fuel consumption was determined as 118 l/ha for wheat, 107.5 l/ha for sunflower, 110 l/ha for paddy, 144l/ha for maize, 145.5 l/ha for canola and 116.50 for sugar beet. Total man labour requirement 3.93 h/ha for wheat, 3.72 h/ha for sunflower, 4.78 h/ha for paddy, 3.13 h/ha for maize, 4.08 h/ha for canola, 7.44 h/ha for sugarbeet.

	FUEL (%)	**38.89**	4.86	5.56	4.86	45.83	100.00
	MAN LABOUR (h/ha)	2.16	0.18	0.34	0.18	0.29	3.14
MAIZE-SILAGE	**MAN LABOUR (%)**	**68.71**	5.67	10.83	5.67	9.11	100.00

According to the fuel consumption and man labour requirement; soil preparation is the first field operations for all selected field crops. Percentages of the soil tillage operations in all field operations are higher than 50% for all crops. If farmers want to energy consumption should focus on soil preparations.

Conclusions

Agricultural mechanization is an indicator of agricultural input use in crop production. In addition, it is very important for production cost and energy balance analyses in farm management. From these results; it can be seen that agricultural machineries use for most field operations of field crops in Thrace Region, Turkey. Agricultural machinery usage is necessary to realise crop production in large areas but machinery usage should be good managed otherwise increases production cost and decrease profitability. Big percentage of fuel has been using for soil preparation including hoeing (Table 6). Farmers generally use conventional agricultural practices for soil tillage. Reduced tillage method and/or direct drilling method should be used to decrease machinery use consequently decreasing soil compaction and fuel consumption.

In Turkey, more than 65 % of the farmers are small farmers. As an example mean size of the land is 6.8 hectares and mean numbers of parcels are 6.9 (Ministry of Development, 2014). This is not good for sustainable crop production even most of field operations have been done by agricultural machineries. One of problem is right machinery use. If farmers don't arrange agricultural machinery right, it is create environmental and health problems. Last 10 years farmers get 50% support from Government for some selected agricultural machineries. This support caused increasing agricultural mechanization level for all farmers in Turkey. The problems are small scale farm, small field plots, and young people don't want to work in agricultural (Ministry of Food, Agriculture and Livestock, 2016). Education level of farmers is lower than general mean education level in Turkey and they are using more developed machines. In the contrary, there are many agricultural engineers in Turkey and they are waiting to work in agricultural production. In a survey, mean age determined as 51 for Thrace Region and percentage of primary school education was 66% (Trakya Development Agency, 2013). Government started to put into practice a National Financial Programme to encourage young people to be farmer.

Abstract

Leaf emergence represents externally visible trait that is results of externally not visible leaf primordial initiation. Final leaf number initiated in the apex and the rate of leaf emergence determine of pre-anthesis phases. The aim of this study was to determine the effect of year and cultivars on final leaf number (FLN) in winter barley. In the present study no consistent differences were found in the FLN between 6-rowed and 2- rowed cultivars. FLN differs among barley varieties sown in the field at different years and was controlled by all three factors; cultivar, year and their interaction. Contribution of year in FLN variation was highest, about 74%. This can be explained as a direct effect of the year on the rate of leaf appearance or as an indirect effect of an ontogenetic decline in the rate of appearance. Low value of interaction showed stability of leaf number from year to year. Considered across the growing seasons (GSs), the early cultivar Novosadski 581 had the lowest (11.3) and the late cultivar Kredit the highest (14.7) FLN. In average the early cultivars had one leaf less than the late ones. Earliness is rather the result of leaf number reduction than grain filling reduction. FLN across cultivars and GSs was 13.5. Quadratic equation fitted best the relationship between GDD requirement and FLN per main stem, with R^2>0.99. In our investigation, the FLN was positively correlated with GDD accumulated till flag leaf completion, while the effect of precipitation was less important. The tested cultivars showed significant variability in FLN, which can be used for selecting most adaptable genotypes.

Keywords: *Barley (Hordeum vulgare L.), final leaf number, phenology, polynomial regression, correlation*

Introduction

The rate of organ emergence and the duration of developmental phases are key components of plant fitness to its environment. An understanding of the effect of environment on leaf emergence is necessary for modeling crop growth (Pržulj and Momčilović, 2011). Leaf production phase from crop emergence to flag leaf appearance integrates the effects of vernalization and photoperiod. Leaf appearance in small cereals is result of leaf primordium initiation and leaf primordium extension and both processes in normal growing conditions are controlled mainly by temperature (Slafer and Whitechurch, 2001; McMaster, 2005). The final number of initiated leaf primordium is proportional to the time from sowing to double ridge (Robertson *et al*., 1996; Pržulj *et al*., 2013). At the time of seedling emergence, the shoot apex has five to seven leaf primordia and this is considered to be the range in minimum final leaf number per wheat plant (Robertson *et al*., 1996).

Kirby (1992) showed that variation in the final leave number (FLN) produced by winter wheat in the field in response to sowing date and location could be explained, in part, by differences in

exposure to low temperature during the phase when leaf primordia were being initiated. FLN depends upon the rate and duration of leaf initiation. The vernalization response is important for fitting the plant life cycle to the environment in which it is grown, so that it can make the best use of the seasonal opportunities for growth and avoid adverse climatic factors. The major effect of vernalization is to shorten the duration of the phase of leaf primordia production (Griffiths *et al*., 1985). Air temperature is the main factor affecting the leaf number and phyllochron (Rickman and Klepper, 1991).

Researchers have concentrated on understanding how environmental factors, first of all temperature and photoperiod and then water and nutrition, affect the FLN. Only a few studies have evaluated cultivar effect on the FLN. In this research, we studied the effect of cultivar and year on FLN of winter barley.

Materials and Methods

Cultivars and crop management. Twelve barley cultivars which differed in origin, pedigree and agronomic traits were used in this study. A 6-year experiment was conducted from 2002/03 to 2007/08 growing seasons (GS) at the experimental field of Institute of Field and Vegetable Crops in Novi Sad (45°20'N, 15°51'E, altitude 86 m) on a chernozem soil and under rainfed conditions. The experiment was conducted in a randomized complete block design with 3 replications in each year. The plots were 1.2m wide and 10m long, with 0.20m spacing between rows. Planting density in all GSs was 300 viable seeds per m^2 for six-rowed barley and 350 viable seeds per m^2 for two-rowed barley. To avoid negative effects of diseases and pests, the experiments were sprayed with the fungicide Tilt 250 EC in Zadoks phase 64 and the insecticide Karate zeon applied when needed. Weed control was performed by hand. To determine the FLN on the main stem, including the flag leaf, recording was done according to the Haun scale on three tagged plants in each replication. GDD was calculated for each of the phases as $Tn=[(T_7+T_{14}+2T_{21})]/4$, where T_7, T_{14}, and T_{21} are temperatures at 7 AM, 2PM and 9 PM, respectively (Pržulj, 2001). Base temperature was 0° C.

Statistical analysis. All data were subjected to the analysis of variance using Statistica 9.0 program (StatSoft, Tulsa, OK, USA). When differences among earliness groups, duration of developmental phases and agronomic traits were tested, four cultivars from each group were considered as replication as samples for detection of developmental phases.

Weather conditions. The average temperatures at the level of the long-term average and abundant rainfall in October 2002 allowed a rapid crop development and fast progression through vegetative phase. The early reproductive phase continued in the spring under conditions of extreme drought and low temperatures. Excessive rainfall, several-fold above the annual average, and average temperatures accompanied the emergence stage in the 2003/04 GS. The completion of the generative phase next spring unfolded under normal conditions. In the 2004/05 GS, both temperature and rainfall conditions were favorable during the vegetative phase. The remainder of the GS continued under favorable conditions. In the 2005/06 GS, barley germination and the vegetative stage took place under a drought, while the generative phase in November and December unfolded under favorable conditions. The generative phase that continued next spring took place under conditions of high temperature fluctuations, while high temperatures and water deficit coincided with the jointing stage. Drought and high temperatures in October and November 2006 obstructed winter barley emergence and the development of the vegetative phase. Favorable rainfall and temperatures during December and the subsequent winter months enabled the plants to accumulate the necessary amounts of effective temperatures and compensate for the previous delay in development. The end of the generative phase took place under high temperatures and excess rainfall. In the 2007/08 GS, the germination, vegetative

phase and the beginning of the generative phase unfolded under somewhat low temperatures and a large surplus of water.

Results and Discussion

Duration of developmental phases in barley includes a chain of coordinated interdependent processes. Leaf emergence represents externally visible trait that is results of externally not visible leaf primordial initiation. Final leaf number initiated in the apex and the rate of leaf emergence determine of pre-anthesis phases. Phenological development and phyllochron is result of genetics and many environmental factors (McMaster, 2005). FLN was controlled by all three factors, cultivar, year and their interaction (Table 1). Contribution of year in FLN variation was highest, about 74%. It means that the tested cultivars were genetically similar in leaf number. Low value of interaction showed stability of leaf number from year to year. Considered across the GSs, the early cultivar Novosadski 581 had the lowest and the late cultivar Kredit the highest FLN (Table 2). In the cultivar Novosadski 581, early maturity was due to a reduction in FLN (Table 2) and a short phyllochron (Table 3). Juskiew *et al*. (2003) found that earliness was due to accelerated postanthesis growth rather than reduction in leaf number and phyllochron.

E-early, M-medium, L-late, 2R- two-rowed, 6R- six-rowed

Even though the cultivar x year effect for FLN was significant and participated in total variation with 7.2% (Table 1), the FLN variability within a cultivar-year was rather small (Table 2).
Although differences in FLN was observed among the cultivars (Table 1, 2), no relationship could be established in the rank of the cultivars for the FLN. For example, the early cultivar Kompolti-4 had one of the highest FLN in 2002/03 GS and one of the lowest in 2005/06 GS (Table 2). The average FLN for the barley main stem was 13.5. In the present study no consistent differences were found in the FLN between 6-rowed and 2- rowed cultivars, although García del Moral and García del Moral (1995) had showed that 6-rowed barley cultivars have less tillers per plant because they have less leaves per main stem. Arisnabarreta and Miralles (2004) also didn't found differences in the FLN between 6-rowed and 2- rowed barley cultivars.

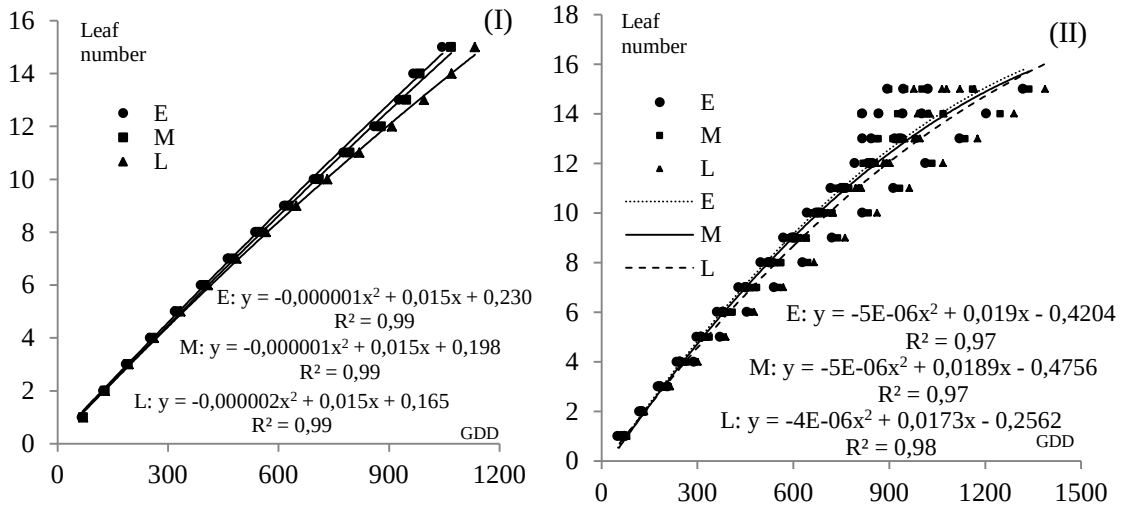

Figure 1. (I) Leaf number development in four early (E), four medium (M) and for late (L) winter barley cultivars across six GSs (II) Leaf number development of three winter barley maturity classes (E-early, M-medium, L-late) in different GSs. Each point represents the average of four cultivars belonging to a maturity group in individual GS. There are six points for each leaf per maturity group

Table 3. Mean squares of FLN per main stem for three maturity classes (early, medium, late) of winter barley

Heritability		0.71

**-significant at the 0.01 level, ns- non significant

Across GSs and maturity classes, the early maturity group completed the FLN fastest (Figure 1I). Quadratic equation fitted best the relationship between GDD requirement and FLN per main stem, with R^2>0.99. Also, quadratic equation fitted best the relationship between leaf number development across cultivars in the same maturity group and GS, with R^2>0.97 (Figure 1, II). In our investigation, the FLN was positively correlated with GDD accumulated till flag leaf completion, while the effect of precipitation was less important (data not

shown). When the cultivars were sorted according to earliness, each cultivar representing a replication, then maturity classes and years determined FLN (Table 3). The interaction maturity class x year was not significant for FLN, i.e., the early cultivars always had lowest FLN and the late ones always had highest FLN and longest PHY regardless of the year (Table 3, 4). Across the studied GSs, the early cultivars had 12.9, medium early 13.5, and late 13.9 main stem leaves (Table 4).

In our investigation, the FLN was positively correlated with GDD accumulated till flag leaf completion (Table 5), while the effect of precipitation was less important. The identification of genetic variability on leaf area is a crucial step on plant breeding. (Royo *et al*., 2004). This is particularly important in species with a narrow genetic background, which may be a result of the selection pressure applied in breeding programs. Understanding of how changes in photosynthetic area may be affected by environmental conditions, particularly drought stress under field conditions, could provide a basis for evolving superior high yielding varieties. Some studies have been conducted to understand the growth of leaves as affected by factors such as temperature, photoperiod, available water, nitrogen etc. Genotype by environment interactions should be taken into account to determine the optimum breeding strategy in a target environment.

Table 4. FLN per main stem for three maturity classes (E-early, M-medium, L-late) across six GS

	GS						
Maturity class	2002/03	2003/04	2004/05	2005/06	2006/07	2007/08	Average
E	12.5	13.5	11.8	12.8	13.5	13.2	12.9
M	14.0	13.5	12.7	13.0	14.5	13.5	13.5
L	14.2	13.8	13.2	14.0	14.5	14.2	13.9
Average	13.6	13.6	12.6	13.2	14.2	13.7	13.5
		Year	*Maturity cl.*	*Y x G*			
	0.05	*0.76*	*0.54*	*1.31*	*CV 6.9%*		
LSD	*0.01*	*1.01*	*0.71*	*1.75*			

Increases in the potential yield of barley requirs an increase in the photosynthetic area in early growth stages, in order to increase the incident radiation intercepted by the crop and the total biomass produced. In barley higher grain yields under drought stress conditions is associated with higher leaf area index at the end of tillering. However, since leaf area is determined by factors such as phenology, leaf number, potential leaf size and stem morphology, any effect of drought on these factors would modify leaf area. In fact, the earliest response of plants to drought is adaptation of the expansion rate of the leaves, which is important through its control of radiation interception and water use during the grain filling period. Before anthesis, the reduction in leaf area index and intercepted radiation under stress is a consequence of dicreased leaf expansion and changes in leaf display, whereas after anthesis this reduction is mainly a result of progressive leaf senescence.

Table 5. Simple correlations between final leaf number (FLN) and temperature and precipitation during some phenological growth stages (PGS)

PGS	GDD from E till DR	Precipitation from E till DR	GDD during DR	Precipitation during DR	GDD during J	Precipitation during J
FLN	0.35**	-0.25*	0.34**	-0.27*	0.79*	-0.16

E-emergence, DR- double ridge, J- jointing

Conclusion

The average final number of leaves on the main stem of winter barley under the conditions of the Panonnian Plain was 13.5. The early cultivars had one leaf less than the late cultivars. Earliness is rather the result of leaf number reduction than grain filling reduction.

Abstract

The purpose of this study is to determine the vegetative growth, yield, phenological, pomological and morphological characteristics of six apple cultivars grafted on M9 and MM 106 rootstocks under ecological conditions of Sanliurfa in 2007-2012. According to the findings of the study, full blooming occurred between March 25th (Anna/M9) and April 07th (William's Pride/MM 106). The fruits were harvested between July 10th (Vista Bella/M9) and August 12th (Mondial Gala/MM 106). The average fruit weights of the cultivars were determined as 140.9 g (Summer Red/MM 106) and 193.4 g (Anna/M9). Average total soluble solid content ranged between 12.7% (in Jersey Mac/MM 106) and 17.2% (in Mondial Gala/MM 106), while the highest of titratable acidity was observed as 0.76% in Vista Bella/MM 106. Trunk cross-sectional area of six apple cultivars at the end of the 9th year ranged between 54.4 cm^2/tree (Anna/M9) and 102.5 cm^2/tree (William's Pride/MM 106). Anna/M9 has taken the first row with respect of cumulative yield (167.34 kg/tree) and the yield of fruits per cm^2 of trunk cross-sectional area (3.08 kg/cm^2) in the first nine cropping years.

Introduction

Apple, growing especially in cold temperate climates, is the most commonly relished species among temperate climate fruits (Ozcagiran et al., 2005). Anatolia is one of the native lands of apple. It was taken to Greece and Italy from the Anatolian region by the Greeks and Romans and therefrom spread out to the rest of Europe.

Cultivation of apple is widespread in the areas within cold temperate climates between latitudes 30° and 50° in the North and South of the Equator (Soylu, 2003). In Turkey, apple is cultivated in areas of altitude over 500 m in the Aegean Region and over 800 m in the Mediterranean and the Southeastern Anatolia Regions (Ozcagiran et al., 2005).

Apple is the most commonly produced kind among the temperate climate fruits in the world. According to FAO (2013) data, Turkey is the third largest apple producer after China (39.7 million tons) and the USA (4.1 million tons) within an estimated global production level of approximately 80.1 million tons. Turkey has a 3% share in the world's apple production with 2.5 million tons. Yet, Turkey lags far behind by exporting 126.000 tons of apple (1.48%) (FAO, 2013) considering the global apple exports of 8.5 million tons exports. Among the reasons why Turkey takes a back seat in apple exports are insufficient technical infrastructure and lack of high-grade apple varieties preferred by the global market (Ozongun et al., 2014). Despite the adaptation and introduction studies on apple varieties in certain periods, more persistent studies in relation to apple varieties, including the varieties demanded in foreign trade, are necessary

considering the numerous varieties of apple introduced to the market every year (Ozongun et al., 2014).

Apple production has been continuously increasing in Turkey, which has productive areas for apple cultivation. In fact, the number of apples cultivated increased from 2,400,000 tons to 3.128.450 between 2000 and 2013. However, due to the adverse climate conditions in 2014, this number fell back to 2.480.444 ton indicating a decline of 20.8%. In Turkey, 26% of the apple production is made in Isparta, 13% is made in Karaman; 9% is made in Antalya; 7% is made in Denizli, and 5% is made in Nigde (Anonymous, 2016a). In Turkey, apple cultivation was practiced using strong-growing apple varieties that were budded on seedling rootstocks until the 1970s. In the later years, it was maintained using modern fruit growing techniques, in which weak-growing apple varieties known as spurs are grafted on various weak-growing rootstocks. As of the 2000s, there has been a significant increase in garden facilities with varieties grafted on the M9 rootstock and new garden facilities using apple varieties grafted on the M9 and MM 106 rootstocks are still being established. From the early years of planting, increasingly more abundant and high-grade products have been harvested; cultural procedures such as pruning, thinning, pest and disease control, as well as harvesting have been implemented more easily and affordably, and higher-grade products in terms of fruit size and color have been obtained by means of clonal rootstocks that are weak or slow-growing (Oz et al., 1994). Consequently, clonal rootstocks have become widespread in place of seedlings. Nowadays, highly dwarf, dwarf and semi-dwarf clonal rootstocks such as M27, M9, M7, M26, and MM 106 are increasingly used in modern fruit growing.

Today, M9 is the most commonly used dwarf rootstock in the world. Apple saplings grafted on M9 rootstocks need support beginning from their planting and they start yielding fruit the following year. The size of the saplings grafted on these rootstocks is 20-40% of what is grafted on seedlings (Ozcagiran et al., 2005). MM 106, which is an M9 and Northern Spy hybrid, has a solid root system that can hold the soil and shorten 25-40% of the apple varieties grafted on it. It is the second most commonly used rootstock in apple cultivation after M9 (Jackson, 2003; Ozcagiran et al., 2005). In Sanliurfa, apple production varies year by year, but it is around 400-500 tons a year. In order to improve and increase apple cultivation in Sanliurfa, which lags behind in apple production compared to the rest of Turkey, rootstocks and apple varieties appropriate for the ecology of the city should be determined. This study aims to identify the phenological and pomological features of certain apple varieties grafted on M9 and MM 106 rootstocks, as well as their yield performance in Sanliurfa, which has a rich potential for apple cultivation in Turkey.

Material and Methods

The present study was implemented on four-year-old Anna, Jersey Mac, Mondial Gala, Summer Red, Vista Bella and William's Pride apple varieties grafted on M9 and MM 106 in the Research and Application Orchard of the Department of Horticulture at the Faculty of Agriculture at Harran University ($37^{o}10'$ N and $38^{o}59'$ E; 535 m. a.s.l.) between 2007 and 2012. Varieties budded on M9 were planted in 5x2.5 m distances and varieties budded on MM 106 were planted in 5x5 m distances. The garden, where the study took place, was irrigated using drip irrigation. As from their planting, the trees were trained in accordance with the central leader training system. Technical and cultural procedures such as fertilizer application and pest and disease control were regularly implemented and fruit thinning was not performed. According to the climate data (Table 1), the average temperature in Sanliurfa was 19.1 ^{o}C, while the highest temperature was 45.2 ^{o}C, and lowest temperature was -4.7 ^{o}C. Additionally, the areal

precipitation was 389 mm, while the average daily evaporation amount was 14.74 mm between April and October, where the average relative humidity value was 49.1% (Anonymous, 2016b). The soil in the experiment garden (0-40 cm) was generally heavy textured. It had 58.5% clay, 18.5% silt, 1.27% organic matter and a pH of 8.12. The level of potassium in the soil was high, whereas the levels of nitrogen and phosphorus were low (Anonymous, 2012).

Table 1. Mean monthly climate data of Sanliurfa, 2007-2012 (Anonymous, 2016)

Months	Temperature (°C)			Relative Humidity (%)	Precipitation (mm)
	Max.	Min.	Average		
Jan.	17.5	-4.7	4.5	71.1	99.4
Feb.	20.0	-4.0	7.9	72.2	58.5
March	23.6	1.8	12.2	65.6	6.2
April	28.5	4.0	17.8	53.0	81.1
May	39.1	11.0	23.8	33.6	17.4
June	44.0	17.8	30.8	29.2	0.3
July	43.7	20.3	32.2	31.7	0.3
Aug.	45.2	20.0	33.4	29.8	
Sep.	42.0	12.0	27.2	38.9	
Oct.	34.2	9.8	21.0	40.1	42.5
Nov.	26.8	2.2	11.4	58.2	26.2
Dec.	18.5	-4.3	6.8	65.6	23.3

The following sections include observations and measurements conducted, and methods implemented on the apple varieties discussed in this study:

Phenological observations: Phenological stages and morphological characteristics were recorded as per BBCH scale (Meier et al., 1994). Bud swelling (BBCH stage code 01), bud breaking (BBCH 07), first blooming (BBCH 60), full blooming (BBCH 65), post blooming (BBCH 69) and fruit harvest dates (BBCH 07) were separately specified for each variety/rootstock combination.

Pomological traits: Twenty fruits were collected from each variety/rootstock combination in order to measure width (mm), length (mm), weight (g), flesh firmness (Effegi penetrometer FT–011; Effegi-Italy) (with the 11.1 mm tip of the penetrometer), the amount of soluble solids content (SSC) (%) (Atago Palette Series Model PR-101a digital refractometer; Atago Co. Ltd., Tokyo, Japan), pH of the fruit juice and titratable acidity (%), and calculate volume (cm^3) of the fruit.

Yield and vegetative traits of the tree: The yearly yield average per tree (kg/tree), the cumulative yield per tree (kg/tree) and yield of fruits per 1 cm^2 of the trunk cross-sectional area (TCSA) were recorded during the dormant season of 2007 (mainly in March). In the last year of the trial (2012), in order to calculate the trunk cross sectional area (TCSA), trunk circumference was measured from about 15 cm above the graft union with a hand caliper at the end of the growing season and the measurement was converted to TCSA in cm^2. Finally, yield efficiency (yield per tree/TCSA) was measured as yield per tree divided to TCSA in late growing season.

Statistical Analysis: According to the randomized blocks experimental design, the study was organized in three repetitions, one tree for each repetition. JMP 8.0 package program was used to compare the results obtained from the study. "Duncan's Multiple Range Test" ($p<0.05$) was used in comparing the differences between the averages.

Results and Discussion

Table 2 shows conditions the phenological observation results regarding Anna, Jersey Mac, Mondial Gala, Summer Red, Vista Bella, and William's Pride apple varieties grafted on M9 and MM 106 in Sanliurfa conditions.

During the study, spring frost damage was not encountered often on the flowers under Sanliurfa conditions. However, in some regions of Turkey, late frosts in spring can cause significant damage. For this reason, it is crucial to know the exact blooming dates of the varieties in garden facilities.

In the trial, the earliest bud swelling was encountered in the Anna variety (March 6th) grafted on M9 and MM 106 and the latest bud swelling was encountered in Vista Bella/M9, Jersey Mac/M9, and Jersey Mac/MM 106 (March 11th). The earliest bud breaking was observed in the Anna/M9 variety (March 11th) and the latest bud breaking was observed in William's Pride/M9, William's Pride/MM 106, and Jersey Mac/MM 106 (March 17th). The earliest variety to bloom was Anna/M9 (March 20th), while the latest blooming was observed in William's Pride/MM 106 (March 31st). Anna/M9 and Anna/MM 106 were the first completely blooming varieties (March 25th and 27th). They were followed by Mondial Gala/M9 and Summer Red/M9 (April 02nd). The latest to bloom completely was William's Pride/MM 106 (April 07th) (Table 2).

Table 2. Phenological data of the apple cultivars (average of 2008-2012).

Cultivars	Rootstocks	Bud swelling	Bud breaking	First Bloom	Full bloom	End of flowering	Fruit maturation
Anna	M9	6 Mar.	11 Mar.	20 Mar.	25 Mar.	2 Apr.	13 Jul.
	MM 106	6 Mar.	12 Mar.	22 Mar.	27 Apr.	3 Apr.	15 Jul.
Mondial Gala	M9	10 Mar.	15 Mar.	27 Mar.	2 Apr.	9 Apr.	08 Aug.
	MM 106	10 Mar.	16 Mar.	28 Mar.	3 Apr.	10 Apr.	12 Aug.
Vista Bella	M9	11 Mar.	16 Mar.	28 Mar.	3 Apr.	10 Apr.	10 Jul.
	MM 106	8 Mar.	14 Mar.	28 Mar.	4 Apr.	13 Apr.	13 Jul.
William's Pride	M9	10 Mar.	17 Mar.	30 Mar.	5 Apr.	13 Apr.	17 Jul.
	MM 106	10 Mar.	17 Mar.	31 Mar.	7 Apr.	15 Apr.	20 Jul.
Jersey Mac	M9	11 Mar.	16 Mar.	28 Mar.	3 Apr.	10 Apr.	15 Jul.
	MM 106	11 Mar.	17 Mar.	29 Mar.	4 Apr.	12 Apr.	17 Jul.
Summer Red	M9	10 Mar.	15 Mar.	27 Mar.	2 Apr.	9 Apr.	17 Jul.
	MM 106	10 Mar.	16 Mar.	28 Mar.	5 Apr.	12 Apr.	20 Jul.

When Table 2 is examined, it may be seen that the varieties in the Sanliurfa city center were in the harvest phase between the second week of July and the second week of August. The Vista Bella/M9 variety (July 10th) was the first variety to reach harvesting maturity while the Mondial Gala/MM 106 variety (August 12th) was the lastone.

Burak et al. (1994) reported the bud swelling, bud breaking, first blooming, full blooming, post blooming dates for the Jersey Mac variety grafted on seedling rootstock between 1990 and 1994 in Yalova conditions as 15/3, 29/3, 16/4, 19/4 and 30/4 respectively. The apple adaptation study conducted in the research garden of Kentucky University (USA) pointed out that the William's Pride variety was in the green tip phase between March 10th and 29th, in the pink flower phase between March 31st and April 04th, in the initial blooming phase between March 31th and April

11th, in the post blooming phase between April 14th and 18th, and in initial fruit set phase between April 19th and 22nd April (Masabni and Wolfe, 2007).

Atay et al. (2010) reported that Jersey Mac, Galaxy Gala and Braeburn varieties grafted on MM 106 rootstock under the conditions of Egirdir were in the full blooming phase in 20, 22 and 20 April in 2006 and reached the full blooming phase on 28 April, 1 May, and 28 April in 2007. Researchers stated that Jersey Mac, Galaxy Gala and Braeburn varieties were in the harvest phase in periods of July 30th –August 03rd; August 27th –August 31st and October 22nd in 2007. In Apple Variety Adaptation Trial carried out between 2003 and 2009 in Egirdir Directorate of Research Station for Fruit Growing, the performances of ten apple varieties grafted on MM 106 were investigated. For the varieties studied, bud swelling occurred between March 21st and 25th, bud breaking occurred between March 29th and April 01st, first flowering occured between April 19th and 25th, full blooming occurred between 24th-27 th April, post blooming occured between May 01st and 05th, and the harvest stage occurred between August 23th (Rubinstein) and November 14th (Cripps Pink (Pink Lady™)) (Ozongun et al., 2014).

According to the results of phenological observations conducted between 2003-2009 on Mondial Gala apple variety grafted on M9, M26, MM 106, and MM 111 rootstocks, the bud swelling occurred between 20th-25th March; the bud breaking occured between March 29th and April 05th; the initial blooming occurred between April 17th and 21st; the full blooming occured between April 23rd and 29th April; the post blooming occurred between May 01st and 07th; and the harvest occurred between August 25th and September 01st (Ozongun et al., 2016). The initial blooming, full blooming and harvest periods of Jersey Mac apple variety grafted on MM 106 under Samsun's ecological conditions were March 27th – April 08th, April 10th - 22th, and July 07th - 08th respectively (Ozturk and Ozturk, 2016).

Both in Turkey and in other countries, phenological observations on apple varieties yielded varying results. This shows that blooming in apple varieties differs depending on the ecological conditions of fruit growing regions. In the fruit-growing region, annually varying climatic factors are the most important reason behind the changes in blooming time and period of fruit trees. In fruit growing, blooming (full blooming) time and period differs based on the variety, rootstock, ecology and cultural procedures, while high temperatures, especially during the blooming period, shorten the blooming period (Jackson, 2003). The latitudes, longitudes and the altitude of the fruit growing region, hot and cold winds, rootstocks and cultural procedures considerably affect the blooming period (Karacali, 2004).

The average yield value of variety/rootstock combinations per tree by years during the trial period is provided in Table 3. According to the data, the highest cumulative yield value belonged to the Anna/M9 combination (167.34 kg) between 2007 and 2012. It was followed by the Anna/MM 106 (131.07 kg) and William's Pride/MM 106 combinations (122.01 kg). The lowest value belonged to the Mondial Gala/M9 variety (92.17 kg). At the trial, the trunk cross-sectional area values were established between 54.35 cm^2 (Anna/M9) and 112.73 cm^2 (Mondial Gala/MM 106). Considering the yield amounts (yield effect) per trunk cross-sectional area unit, the highest value was obtained once again from the Anna/M9 variety (3.08 kg/cm^2) as in the cumulative yield. It was followed by the Anna/MM 106 variety (2.12 kg/cm^2), the Vista Bella/M9 variety (1.73 kg/cm^2) and the William's Pride/M9 variety (1.62 kg/cm^2). The lowest value belonged to the Mondial Gala/MM 106 variety (0.87 kg/cm^2). According to the decare yield value calculated based on the six-year cumulative yields of different apple varieties grafted on M9 and MM 106 rootstocks, the Anna/M9 (13.39 ton) combination ranked first. It was followed by the Anna/MM 106 (10.49 ton) combination. The lowest value belonged to the Mondial Gala/M9 (7.37 ton) combination.

Crassweller and Smith (2011) reported that until the 10th fruit growing season, the cumulative yield ranged between 85.5 (Ginger Gold - Trellis) and 152.5 kg/tree (Fuji - offset V-axe); the cumulative yield effect changed between 2.00 (Gala-Slender Spindle) and 2.92 kg/cm^2 (Ginger Gold – Vertical Axe); and the decare cumulative yield changed between 13.23 ton/da (Ginger Gold-Trellis) and 21.76 ton/da (Ginger Gold – Vertical Axe) in Crimson Gala, Ginger Gold and Fuji apple varieties, which were grafted on M9 rootstock, where four different training systems were tried in Pennsylvania (USA) conditions. A cumulative yield changing between 48.40 (Budagowski 9) and 67.00 kg/tree (M.9 EMLA), TCSA changing between 19.29 (Budagowski 9) and 35.15 cm^2 (Supporter 4) (at the end of the 7th season) and the yield value per trunk cross-sectional area (yield effect) changing between 0.71 (Supporter 4) and 1.02 kg/cm^2 (Pajam 1) were obtained between 2008 and 2010 from the Granny Smith apple variety grafted on rootstocks of nine varying strengths (M.9 T 984, M.9 T 337, Jork 9, Mark 9, Budagowski 9, M.9 EMLA, Pajam 1, Pajam 2 and Supporter 4) in Macedonia in 2004 (Gjamovski and Kiprijanovski, 2011).

Table 3. Cumulative yield, cumulative yield efficiency and trunk cross-sectional area of apple cultivars budded on M9 and MM 106 rootstocks.

Cultivars	Rootstocks	Cumulative yield (kg tree^{-1}) (2007-2012)	Trunk cross-sectional area in 2012 (cm^2)	Cumulative yield efficiency (kg cm^{-2})	Cumulative yield (ton da^{-1})
Anna	M9	167.3 a	54.4 g	3.1 a	13.4 a
	MM 106	131.1 b	61.9 fg	2.112 ab	10.5 b
Mondial Gala	M9	92.2 d	90.6 bc	1.0 c	7.8 i
	MM 106	97.9 cd	112.7 a	0.9 c	7.8 g
Vista Bella	M9	111.3 bcd	64.9 efg	1.7 bc	8.9 e

Significance		**	**	***	*

In Egirdir (Isparta) Fruit Research Institute, ten apple varieties grafted on MM 106 rootstock produced decare cumulative yield values between 8.3 tons/da (Top Red) and 19.40 tons/da (Cripps Pink (Pink Lady TM)) at the end of a seven-year variety adaptation trial. The same study showed that the cumulative yield value per tree was between 87.92 kg/tree (Rewana) and 233.78 kg/tree (Cripps Pink (Pink Lady^{TM})), while the yield value per trunk cross-sectional area was between 0.97 kg/cm^2 (Rewana) and 3.69 kg/cm^2 (Scarlet Spur) (Ozongun et al., 2014). On ten-year-old Mondial Gala varieties grafted on M9 and MM 106 rootstocks under Egirdir conditions, the trunk cross-sectional area between 67.75 cm^2 and 109.12 cm^2, the yield per tree between 37.44 and 95.5 kg and the yield value per trunk cross-sectional area between 5.25 and 3.25 kg/cm^2 were obtained (Ozongun et al., 2016). In the same study, the tenth-year cumulative decare

yield values of Mondial Gala/M9 and Mondial Gala MM 106 rootstock/variety combinations ranged between 35.17 tons/da and 31.88 tons/da.

Fruit characteristics regarding six apple varieties on trial are given in Table 4. In terms of the features examined, significant statistical differences were detected among the varieties. The varieties examined during the study had an average fruit weight between 140.94 (Summer Red/MM 106) and 193.42 g (Anna/M9), fruit width between 67.87 (Anna/MM 106) and 77.86 mm (William's Pride/MM 106), fruit height between 57.35 (Mondial Gala/MM 106) and 81.98 mm (Anna/M9) and fruit volume between 150.45 (Summer Red/MM 106) and 234.58 cm^3 (Anna/M9).

In terms of fruit flesh firmness, the Mondial Gala/M9 variety (25.65 libre) had the highest value and the Vista Bella/M9 variety (14.86 libre) had the lowest value. In terms of water-soluble solid matter, the Mondial Gala/MM 106 variety (17.2%) had the highest value. It was followed by Mondial Gala/M9 (17.1%). The lowest value belonged to the Jersey Mac/MM 106 (12.7%) variety (Table 4). In terms of pH, Anna/MM 106 had the highest value with 4.81, while William's Pride/M9 had the lowest value with 2.70. The titratable acidity of the examined apple varieties ranged between 0.21% (Mondial Gala/MM 106) and 0.76% (Vista Bella/MM 106).

Atay et al. (2010) reported that in Galaxy Gala and Jersey Mac apple varieties grafted on MM 106 under Egirdir conditions, the fruit weight was between 150.14 and 135.71 g; the fruit flesh firmness was between 6.01 and 8.90 kg/cm^2; water soluble solid matter was between 13.19% and 12.36%; pH was between 3.41 and 3.09, and titratable acidity was between 0.38% and 0.55%. In a variety adaptation trial on ten apple varieties grafted on MM 106 rootstock under Egirdir (Isparta) conditions, the weights of the varieties were between 162 g (Rubinstein) and 287 g (Crown Gold); their width was between 69 mm (Early Red One) and 84 mm (Novaja); their length was between 57 mm (Gala Selecta) and 77 mm (Topred); their flesh stiffness was between 6.94 kg/cm^2 (Crown Gold) and 9.55 kg/cm^2 (Cripps Pink (Pink Lady^{TM})); their pH was between 2.48 (Cripps Pink (Pink Lady^{TM})) and 4.14 (Topred); their titratable acidity was between 0.31% (Topred) and 1.12% (Cripps Pink (Pink Lady^{TM})), and their water soluble dry matter was between 12.20% (Scarlet spur) and 16.40% (Cripps Pink (Pink Lady^{TM})) (Ozongun et al., 2014). In Celarevo (Serbia), the average weight (g), width (mm), water soluble dry matter (%) and titrable acidity (%) values of Gala apple variety grafted on M9 rootstock were 174.4 g, 75.0 mm, 12.4% and 0.16%, respectively (Radiojevic et al.., 2014).

Table 4: Fruit quality characteristics of apple cultivars on M9 and MM 106 rootstocks. Values show the average between 2010-2012.

Cultivars	Rootstocks	Fruit width (mm)	Fruit length (mm)	Fruit weigh t (g)	Fruit volume (cm^3)	Fruit firmnes s (lb cm^{-2})	SSC (%)	pH	TA (%)
Anna	M9	71.1	81.9	193.4	234.6	18.6	14.4	3.5	0.5
	MM 106	67.8	75.9	181.1	190.5	19.6	15.0	4.8	0.5
Mondial Gala	M9	70.5	62.3	154.4	167.1	25.7	17.1	3.6	0.3
	MM 106	68.7	57.4	147.0	162.7	24.9	17.2	4.4	0.2
Vista Bella	M9	74.8	60.4	165.9	206.3	16.9	13.5	3.0	0.5
	MM 106	75.1	64.3	166.6	217.5	21.7	13.7	3.1	0.7
William' s Pride	M9	75.6	65.2	171.2	216.5	21.7	14.0	2.7	0.4
	MM 106	77.9	65.8	183.7	223.1	21.3	14.6	3.6	0.3
Jersey Mac	M9	77.9	61.4	162.7	206.0	18.3	13.3	2.9	0.6
	MM 106	76.6	64.9	178.4	214.4	18.2	12.7	3.5	0.4
Summer Red	M9	69.2	65.4	145.7	160.5	20.2	14.3	3.7	0.6
	MM 106	70.1	62.7	140.9	150.5	22.6	15.0	2.8	0.5

Edizer and Bekar (2007) indicated that the average fruit volume of ten local apple varieties (Tavar, Yağlıkızıl, Arapkızı, Elifli, Demir, Yer Elması, Ekşi Elma, Gelin Elma, Alyanak, and Pehrizoğlu) bred in the central district of Tokat were between 48.00 cm^3 (Yer Elması) and 309.50 cm^3 (Alyanak).

The weight, width, length, flesh firmness, soluble solids content, juice pH and titratable acidity (TA) levels of the Mondial Gala apple variety grafted on M9 and MM 106 under Egirdir conditions were between 147 and 148 g, 69.04 and 67.65 mm, 61.73 and 60.86 mm, 9.25 and 9.64 kg/cm^2, 13.03% and 12.48%, 3.70 and 3.66, and 0.30% and 0.35%, respectively (Ozongun et al., 2016). On some apple varieties bred under Samsun conditions, the fruit weight ranged between 112.3 (Jersey Mac) and 173.9 g (Starkrimson Delicious); the fruit width changed between 64.83 (Golden Delicious) and 74.27 mm (Granny Smith); the fruit length changed between 54.55 (Jersey Mac) and 63.74 mm (Red Chief); the fruit flesh firmness changed between 10.90 lb (Jersey Mac) and 17.60 lb (Granny Smith); soluble solids content (SSC) changed between 10.46% (Starkrimson Delicious) and 13.45% (Cooper 7 SB2 and Golden Delicious); juice pH changed between 3.43 (Jersey Mac) and 4.34 (Cooper 7 SB2), and titratable acidity changed between 0.39% (Super Chief) and 0.90% (Granny Smith) (Ozturk and Ozturk, 2016). In the same study, it was stated that the Jersey Mac variety had a fruit weight of 112.3 g, a width of 67.07 mm, a height of 54.55 mm, a fruit flesh firmness of 10.90 lb, a soluble solids content of 12.80%, a pH of 3.43, and a titratable acidity of 0.74% (Ozturk and Ozturk, 2016).

In studies conducted in different regions of Turkey and abroad, fruit quality shows differences. It is expected that the changes in the harvest season, as well as climate and soil characteristics affect the differences in literature findings regarding the values from pomological analysis results obtained during the study and the differences in varieties, cultural procedures and fruit set percentages.

Conclusions

Regarding apple, variety of which has been consistently increasing due to an increasingly broadrange introduced to the market, adaptation studies should be conducted in cultivation regions that have different ecological characteristics, and varieties suitable for these regions should be recommended based on the result of these studies. This would be beneficial for successful and profitable cultivation before new apple varieties are produced. Besides adaptation studies that should be conducted in different ecologies for new varieties, clonal rootstocks which have been recently cultivated in different countries, and tests conducted in the climate and on the soil of these countries should be immediately tried in Turkey. Thus, the rootstocks on which new apple varieties perform better will be determined using future studies on apple varieties and rootstocks.

This study examined the phenological, pomological and yield features of some apple varieties grafted on M9 and MM 106 in Sanliurfa's ecological conditions. Late frost in spring, which harmed other fruit kinds significantly in some years in Sanliurfa, caused comparatively less damage to apple trees.

It has been concluded that summer varieties, which ripen especially in July can be successfully cultivated under Sanliurfa conditions and the varieties which ripen in August can be cultivated in regions with altitude of over 650 m.

The effects of rootstocks on the yield and some fruit quality characteristics differed based on apple varieties. According to the yield values gathered for many years, the Anna variety grafted on M9 and MM 106 had a higher performance compared to other varieties.

In fruit growing, good agricultural practices should be implemented province-wide in Sanliurfa and modern cold storage, especially controlled atmosphere storage, should be installed within sufficient capacity.

Abstract

Bentonite is a form of clay consisting mostly montmorillonite. It is mainly used as drilling mud in geological studies. Hydration, swelling, water absorption, viscosity and thixotropic properties of bentonite make it a valuable material for a wide range of industrial uses and applications. Bentonite is used in foundry, cosmetic, medical, agriculture, food and construction industries. It is a natural, abundant, low cost and sterile material which can be used as a graft wax. Bentonite was experimented in top working of walnut trees to determine its disponibility and performance in grafting. Study was performed on 10-12 years old walnut trees in two orchards that are located at 750 and 1240 m altitudes. Experiment was designed with two replicates at two locations. Graftings were made using bentonite and water holder paint by bark modified grafting method at the beginning of May in 2015. Graft-take rates, length and thickness of shoots from grafted scions were measured, and total shoot lengths were calculated. During the growing season, disponibility of bentonite were evaluated by observations of top worked trees. The differences between graft-take rates and total shoot lengths were found statistically important according to wax type. Anti-bleeding effect of bentonite were observed that might overcome bleeding problem that is frequently seen in top working of walnut trees.

Keywords: *Walnut, top working, graft-take success, graft wax, bentonite*

Introduction

There is an urgent need to top working of walnut (*Juglans regia* L.) trees in Turkey. Insufficient fruit quality and low yield of seedling trees and damaging of national cultivars due to frosts that frequently occur in springs are main reasons (Akça, 2009). Top working can be applicable to fruit trees at different ages from a few years old thin saplings to several years old big trunks. In grafting of big trees generally scion grafting techniques are used. Cleft and bark grafting techniques are the most widely used techniques (Hartman et al., 1997). In walnut trees, it is being reported that the best graft-take rates could be obtained from bark grafting after a long time experiences (Akça, 2009; Rezaee and Vahdati, 2008; Reil et al., 1998)

Graft waxes of various types are used in fruit tree graftings to seal of cutting surfaces. Waxes help protection and remediation of tree wounds. Using of graft wax is important for graft success and also healing of cutting surfaces (Lewis and Alexander, 2008; Hartman et al., 1997). Tar (pitch), raw resin (rosin), bees wax, tallow, paraffin and similar substances can be used as graft waxes by itself and also mix with other substances like linseed oil (flaxseed oil), alcohol, vaseline, coal dust, chalk, polyvinyl acetate at different rates (Soylu, 2010; Anonymous, 2009; Charles, 1930). For ages, mud of clay soil has been used as sealing agent in grafting process. Still today, clay soil is being used for graft wax due to hardiness of graft wax preparation, difficulty of

finding graft wax whenever you need and its cost. It is reported that 90-97 % graft-take success was obtained by using clay soil mud at walnut tree top working (Kömür, 2011).
Currently, there are approximately 13 million walnut trees all along the Turkey. Nearly four and half million of these trees are older than ten years and at bearing ages (Turkstat, 2016). Most of these trees are from seedling origin and give low quality nuts at low quantities. Also, a considerable part of these trees are undesired early leafing national cultivars that give irregular yield. Top working seems the best choice for the tree owners to convert walnut trees fruitful. Nowadays, there is a big trend of top working of walnut trees in Turkey.
Bentonite has special properties such as hydration, swelling, water absorption, viscosity, thixotropy make it a valuable material for a wide range of industrial uses and applications (Hosterman and Patterson, 1992). Raw bentonite can be treated to produce different forms (Anonymous, 2016a; Anonymous, 2016b). Different forms of bentonite are used in foundry, food and pharmaceutical industries for various purposes (Anonymous, 2016c; Anonymous, 2016d).
Bentonite is accepted an important raw material by the EU. Turkey is the fourth producer of the world with 718.260 tons amount and EU is the main importer of bentonite produced in Turkey with 211.982 tons (EU Commission, 2014). A necessity of affordable, easy accessible and applicable, abundant graft wax materials that have positive effect on graft success is essential. Right here, bentonite may be a good alternative to other waxes in walnut tree top working because of its abundance, naturalness, sterility and affordability. We did not find any research on usage of bentonite in grafting.
The aim of this research is to investigate disponibility of bentonite as graft wax and determine the performance. Results and observations of a practical study were presented in this paper.

Material and Methods

Experiment was designed and performed in spring 2015 with two replicates at two orchards in different locations in Turkey. Orchard 1 is located in Kaman county of Kırşehir province at 1240 meters altitude while orchard 2 is located in Yerköy district of Yozgat province at 750 meters altitude. Graftings were made on 10-12 years old seedling walnut trees at 1 and 2 May 2015. Healthy walnut trees near same trunk diameter were chosen for graftings. One year old shoots of "Kaman 1" cultivar were used as scion. Improved bark grafting method was used for top working of walnut trees according to Reil et al. (Reil et al., 1998). Five walnut trees were used for each treatment and each tree were grafted by inserting two or three scions.
Water holder paint (WHP) and bentonite mud were used as graft waxes on cutting surfaces and graft union. WHP was applied with a little brush directly from commercial pot. Distilled water was added to dust form of bentonite to prepare mud in gel form. Bentonite mud was applied with the help of spatula by hand at 6-10 mm thickness. Cutting surfaces and graft union were wrapped with stretch film to prevent drying.

Properties of Wax Materials

WHP is water based paint with one component consists of acrylic copolymer resin. WHP is very practical water isolation material that can be applicable to all surfaces by brushing. In commercial form, it is ready to use, elastic, paintable. It is in white colour but can be coloured. WHP can be applied whether horizontal or vertical surfaces on interior and exterior surfaces even on rough surfaces. It can cover very hard surfaces and has low labour and material cost (Anonymous, 2015a). Water based plastic paints are advised to use in grafting application for exposed graft areas (Lewis and Alexander, 2008). Usability of WHP in grafting applications comes from its

affordability, durability, elasticity, and breathability to allow callus formation. Detailed technical properties of WHP are given Table 1.

Bentonite is a special form of clay containing 60 % montmorillonite at least. It is generated from the alteration and chemical deterioration of volcanic ash or lavas containing rich aluminium and magnesium. It is soft, porous, ductile and often in colloidal silica structure. It has high ion exchange capacity. It can be various in colours including white, yellow, green and grey at first. It has large surface area (750 m^2/g) and superior ability of swelling volumetrically as much as 15-20 fold. It can sustain the shape deformations that occurred under mechanical tension even after the tension is disposed. It becomes gel when contacted with water and may transform to liquid form when it is shaken (Anonymous, 2015b). In this study, bentonite in API 13 A standard was used. Bentonite has been supplied from one of the world's high-grade natural sodium bentonite source found in Reşadiye district of Tokat, Turkey (Anonymous, 2015c). Important physical and chemical properties of bentonite used in this study were given at Table 2.

Table 1. Technical properties of WHP used in graftings

Form	Semi liquid fluid
Colour	Produced at white colour, but also colorable or paintable with a water based paint having the same elasticity structure
Density	1,29 ± 0,05kg/lt.
Elasticity	Performs % 600 expansion after 24 hours at 1-1.5 mm. thickness and 23℃. Maintains its elasticity at temperature differences; 476% at 70°C, 397% at -17°C
Dry time	12 hours at 20 °C and 65% humidity
Durability	Durable against weak chemicals
Tensile strength	24.5 kgf /cm^2 at 23°C after 24 hours and 55 kgf/cm^2 after 72 hours
Adherence resistance	12 kgf/cm2 , mineral based surfaces: 7.15 kgf / cm
Water vapor permeability	27.6 g/m^2.day at 23°C and 65 % humidity after 24 hour
Consumption	Approximately 1-1,5 kg/m^2 on horizontal surfaces depending on the surface structure, smoothness, porousness and gaps

Table 2. Physical and chemical properties of bentonite used in graftings

Physical properties	**Chemical properties**
Colour: Yellow	SiO2: 61.28 %, Al2O3: % 17.79
Form: Dust	Fe_2O_3: 3,01 %, CaO: 4,54 %
Density: 0.8 – 1.0 gr/cm^3	Na_2O: 2.70 %, MgO: 2.10%
Amount of filtration: 12.5 cc maximum	K_2O: 1.24%
Yield Point, Plastic Viscosity ratio (YP/PV): 1.5 maximum	
Disperse Plastic Viscosity: 10 cp min.	

Graft-take results were recorded at June 2015 and calculated with two way as scion graft-take success rate (SGSR) and tree graft success rate (TGSR). At the end of growing season, number of shoots from scions was determined, thicknesses and lengths of each shoot were measured. Total shoot lengths (TSL) obtained from each grafting were calculated. During the growing season, behaviour of wax materials and events such as durability, diseases, browning, decay at grafting areas and callus formation capabilities were noted. Data were analysed according to Completely

Randomized Design (CRD), One Way ANOVA at $P<0.05$ confidence level with Tukey's test for multiple pairwise comparisons by using Minitab statistical program (MINITAB, 2000).

Results and Discussion

Graft-Take Success

A mean of 57.40 % scion graft- take success rate (SGSR) and 67.50 % tree graft-take success rate (TGSR) were obtained in general. In orchard 1 (Kaman location) 58.50 %, in orchard 2 (Yerköy location) 56.25 % SGSR, 70.00 % and 65.00 % TGSR were obtained respectively. Difference at graft-take success rates between two orchards was not found statistically important. However, graft-take success rates were found significantly different between WHP and bentonite used graftings. Mean value of 40.30 % SGSR and 45.00 % TGSR were obtained from WHP used graftings while 74.50 % and 90.00 % were obtained respectively from bentonite used graftings (Table 3). SGSR and TGSR were considerably higher in bentonite used graftings. This results shows us that bentonite have positive effect on grafting success. Kömür has reported graft-take success rates between 90 % and 97 % in walnut trees by using clay soil mud (Kömür, 2011). Rezaee and Vahdati reported the graft take results of a long term study of top working of walnut trees. They obtained graft take success rates between 30 % and 100 % and survival rates between 0 % and 100 % depending on bark grafting methods, year and cultivar (Rezaee and Vahdati, 2008). Graft-take success over 50 % is accepted normal for top working of walnut trees in Turkey.

Number of Shoots, Shoot Thicknesses-Lengths and Total Shoot Lengths

The number of shoots (NS) originated from successful scions has changed between 1 and 5 depending of the joining degree of graft union and results are not discussed here. Mean shoot thickness (MST) of 28.83 mm, mean shoot lengths (MSL) of 137.58 mm were determined from all graftings. Mean of TSL of two orchards was found 1920.00 cm. MST values were determined 20.60 mm and 25.06 mm, MSL values 122.20 cm and 152.94 cm for orchard 1 and orchard 2 respectively. While the difference in MST was not important, the difference of MSL values between two orchards were found statistically important (Table 3). This can be originated from little differences of trunk diameters and scion thickness, soil conditions and health degree of trees. Total shoot lengths (TSL) values of 2223.00 cm in orchard 1 and 1616.00 cm in orchard 2 were obtained. Although, TSL value of orchard 1 is bigger than orchard 2, the difference was not statistically important. The effect of wax type on TSL was found significantly important while the effect on MST and MSL was not important. A higher value of TSL (2871.90 cm) was obtained from bentonite than WHP (967.15 cm) (Table 3). Also, vigorous development of shoots was distinctive in bentonite used graftings in orchard 1 by visual assessment. According to the measurements and visual assessments, it can be distinctly said that bentonite have promoted shoot elongation from buds of scions more than WHP.

Other observations

It is determined that WHP was found highly durable against to external conditions (daily and seasonal temperature fluctuations, sun, wind etc.) both in summer and winter seasons except of some deformations. Flowing and erupting of WHP from graft union due to bleeding of trees and darkening in paint colour were observed on some trees during the growing season. Cracking on upper surface of bentonite layer has been detected in some trees but that didn’t cause disintegration. Bleeding from cutting surfaces is the result of excessive sap flow in some trees

and especially in walnuts (Shearman and Ellenwood, 1944; Soylu, 2010). Bleeding is reported to prevent graft success. An advantageous of bentonite was observed against to bleeding during the study. Bentonite has absorbed leaked water to itself and prevented bleeding, stayed longer in gel form without cracking. This situation has ensured suitable conditions for callus formation by providing moist environments and also gas exchange in graft union. Walnut is one of the most difficult trees to bud or graft due to its rather slow rate of callus formation (Lewis and Alexander, 2008). Juglone in sap flow is another factor that prevents graft success in walnuts (Karadeniz et al., 1997). Binding of juglone by compounds in bentonites after absorption may eliminate this negative effect. In visual assessments of callus formation, thicker layer of callus was observed in graftings made with bentonite. The durability of bentonite in cutted surfaces and graft union was found sufficient in every cases both in two seasons.

No disease were detected in WHP applied graftings but darkening under the paint layer was observed. Darkening may be caused by oxidation of juglone in sap flow of walnut trees. Apparent darkening was also observed in bentonite layer but no decay was observed in woods or barks of trees. Darkening in bentonite layer also may be caused by absorbed juglone from sap flow. In orchard 2, scale insects were detected over the bentonite applied surfaces on some trees. This may be the result of suitable humid conditions for insect development provided by bentonite layer.

Table 3. NS, SGSR, TGSR, MST, MSL and TSL values of successful graftings according to locations and wax types.

Locations	Wax types	NS	SGSR (%) ***	TGSR (%) ***	MST (mm) ***	MSL (cm) ***	TSL (cm) ***
Orchard 1	**WHP**	17	36.50	40.00	18.74	103.64	872.05
	Bentonite	50	80.50	100.00	22.46	140.82	3574.35
	Mean (Orchard 1)		**58.50a**	**70.00a**	**20.60b**	**122.20b**	**2223.00a**
Orchard 2	**WHP**	14	44.00	50.00	24.58	150.34	1062.25
	Bentonite	28	68.50	80.00	25.56	155.54	2169.45
	Mean (Orchard 2)		**56.25a**	**65.00a**	**25.06a**	**152.94a**	**1616.00a**
	Mean (All)		**57.38**	**67.50**	**22.83**	**137.58**	**1920.00**
	Mean (WHP)		**40.30B**	**45.00B**	**21.66A**	**127.00A**	**967.15B**
	Mean (Bentonite)		**74.50A**	**90.00A**	**24.01A**	**148.18A**	**2871.90A**

Means with the same letter are not significantly different. Comparisons significant at the 0.05 level are indicated by ***
NS: Number of Shoots from Scions **SGSR:** Rates of Scion Graft-Take Success **TGSR:** Rates of Tree Graft-Take Success
MST: Mean of Shoot Thicknesses **MSL:** Mean of Shoot Lengths **TSL:** Total Shoot Length

Conclusion

This study was performed over the walnut trees found in two orchards at two different locations. By comparison of wax materials it is aimed to reveal the disponibility and performance of bentonite as graft wax. Results indicates that bentonite provides distinctly better graft-take success rates and total shoot lengths more than WHP that is commonly used in top working of walnut trees. Bentonite is presently a valuable and multipurpose material and with this study a

new use of bentonite is revealed. Bentonite mud in gel form can be used successively and safely as graft wax if there is no better or low cost alternative absent. Further researches are needed on bentonite usage in tree grafting applications. Although, bentonite mud provides sufficient graft wax performance, other investigations should be done such as using it as an additive to existing graft wax formulas, making new formulas with other substances, and using with plant growth regulators.

Acknowledgments

This work was supported by the Ahi Evran University Scientific Research Projects Coordination Unit. Project Number: ZRT.E2.16.028. Special thanks to the owners of walnut orchards at two locations for the permission of using their trees to graft for this study.

LONG-TERM EFFECTS OF STRAW INCORPORATION AND INCREASING DOSES OF NITROGEN ON THE WHEAT YIELD

Goran JAĆIMOVIĆ[1]*, Vladimir AĆIN[2], Milan MIROSAVLJEVIĆ[2], Jovan CRNOBARAC[1], Branko MARINKOVIĆ[1], Dragana LATKOVIĆ[1]

[1] University of Novi Sad, Faculty of Agriculture, Trg D. Obradovića 8, 21000 Novi Sad, Serbia

Abstract

Investigation of the effects of straw incorporation and fertilization with increasing amounts of nitrogen on the yield of three winter wheat cultivars was carried out at long-term stationary field trial, established in 1971 on the experimental field of Institute of Field and Vegetable Crops, Novi Sad (Serbia). It included the following variants: a) treatments with straw incorporation (SI) and application of increasing doses of nitrogen: 0 (Ø; control treatment), 60, 90, 120, 150 and 180 kg of nitrogen per hectare and b) treatments without SI and with application of increasing doses of nitrogen: 0, 90 and 150 kg N ha^{-1}. On average for all fertilization treatments with nitrogen application, grain yield obtained in the treatment with SI (6.49 t ha^{-1}), was for 540 kg ha^{-1} higher in comparison to the average of fertilization treatments without SI. The highest yield on average of all three wheat cultivars (7.15 t ha^{-1}) was obtained with 120 kg N ha^{-1} and with the SI. It was significantly higher in comparison to all treatments without straw incorporation. The positive effect of long-term SI on wheat grain yield (at comparable variants of experiment: 0, 90 and 150 kg N ha^{-1}) ranged from 100 to 840 kg ha^{-1}, depending on cultivar and amount of nitrogen applied. On average, long-term SI increased yield for 350 kg ha^{-1} (about 6%) of grain (for all three cultivars and the doses of nitrogen applied). Yield increasement by individual cultivars was 350, 390 and 320 kg ha^{-1}, for NS Ilina, Pobeda and Simonida, respectively.

Key words: *wheat, straw incorporation, nitrogen, grain yield*

Introduction

Crop residues represent the mass of organic matter left on the field after harvest or picking of the main products. It can be used for different purposes: as animal feed, litter in livestock production, ploughed (incorporated) into the soil, for mulching, composting and preparation of artificial manure, as a material for energy production etc. *(Kastori and Tešić, 2006; Latković et al., 2015)*. Lack of livestock on farm implies that crop residues cannot be used as animal feed or litter, and returned back to the soil as manure. In that case incorporation of crop residues has advantages in comparison to the other ways of use *(Malešević et al., 2009)*. It represents significant quantity of bio-mass of great importance in cycling of matter in agricultural ecosystem, especially under condition of insufficient use of organic fertilizers *(Kastori and Tešić, 2006)*.

Fertilization with organic and mineral fertilizers has positive effect on humus content. Incorporation of organic matter and mineral fertilizers into the soil increases plant aerial and root mass. It does not only improve nutritional land potential, but also water capacity, aerial and thermal soil properties as well as microbiological activity necessary for mobility of biogenic elements *(Manojlović and Jaćimović, 2014; Jaćimović et al., 2014)*.

On our fields, crop residues are often burned, causing partial or complete loss of biogenic elements. Burning of crop residues is prohibited by our legislation. Crop residues are characterized by a relatively high content of biogenic elements essential for plant nutrition. Long term, permanent removal of plant residues from fields or their burning leads to nitrogen and humus loss, and destruction of living organisms in soil *(Jaćimović et al., 2009)*. In order to increase organic matter in soil, it is necessary to increase incorporation of biomass and crop residues by ploughing, or to apply organic fertilizers. Fate of crop residues (ploughed, burned or removed) has significant effect to the amount of nutrients that are need to be applied.

Incorporation of plant crop residues has positive effect to soil quality, primarily on organic matter content *(Manojlović and Jaćimović, 2014)*. Incorporation of straw or maize stalks into the soil cannot fast increase the amount of humus. It is slow and a time consuming process, but it can improve soil structure, which is especially important for heavy soils. This enables better moisture preservation and uptake, forming of the favourable structure and "biological maturity" of soil, which allows easier and better late soil cultivation, with lower fuel consumption.

In plant production mass of crop residues (hay, stems, leaves, and roots) can be rather large. For instance, in maize it is even up to 10 t ha^{-1}, in wheat 4-6, in sunflower 4-5, in soybean about 4 t ha^{-1}, and in sugar beet even 40-60 t ha^{-1} *(Jaćimović et al., 2009)*. Ploughing, but not removal or burning of this mass, with combined use of organic and mineral fertilizers has effect on significant increase in nutrient content and availability, increase humus content in soil, and thus its general fertility. Application of mineral fertilizers only can partially and in short term amortize harmful effect of organic matter removal and burning of crop residues. According to *Bogdanović et al. (1993)*, in last decades humus content in Vojvodina province soil decreased for 0.2 to 0.81% (0.38% on average). In numerous trials in our country and in the world, positive effect of incorporation of crop residues to yield and its quality has been proved. Moreover, increase of total nitrogen and carbon, improved soil fertility or reduction in nitrogen leaching *(Nicholson et al., 1997; Powlson et al., 1987)*, and on grain yield increase *(Pracházková et al, 2002; Silgram et al., 2002; Latković et al., 2012)* have been noted.

The aim of this research was to examine impact of effect of crop residues – wheat straw incorporation in combination with different nitrogen doses on grain yield of three winter wheat cultivars. It was expected that the obtained results show positive effects of long-term ploughing of crop residues on wheat grain yield.

Materials and methods

Two years study of the effect of crop residues – wheat straw incorporation (SI) with applying increasing nitrogen fertilization doses on the yield of three winter wheat cultivars was performed on international long-term stationary field trial (called ISDV - *Internationale Stickstoff Dauer Versuche*). The experiment was founded in 1971, within the series of trials of the International Commission for the study of soil fertility, at the experimental field of the Institute for Field and Vegetable crops in Rimski Šančevi (N 45° 19`, E 19° 50`), Novi Sad (Serbia). The soil type of this site is the calcareous chernozem on loess, with slightly alkaline reaction, about 3% of humus in the upper layer, medium supplied with easily available phosphorus and well supplied with potassium. Winter wheat is grown in three-crop rotation system (maize-soybean-wheat).

Preceding crop was soybean. The sowing of wheat is performed machined, at row spacing of 10 cm and with sowing density of 550 grains per m^2. Wheat sowing was performed in optimal sowing time for conditions in Vojvodina province - mid-October in 2013/14 and 2014/15. This study presents the average results of these two years of the experiment. The trial was laid out in a two factorial in randomized block design (split plot pattern), in 4 replications. The trial had nine

variants, of which six were with SI, and three without it. The experiment included the following variants of nitrogen fertilization (Factor A):

a) Treatments with SI and application of increasing nitrogen doses: 0 (Ø; control variant), 60, 90, 120, 150 and 180 kg of N ha^{-1} (each year under maize about 5 t ha^{-1} of wheat crop residues were ploughed, with addition of mineral fertilizer (10 kg N per 1t of straw) for more efficient decomposition),
b) Treatments without SI and with application of increasing nitrogen doses of 0, 90 and 150 kg of N ha^{-1}.

As objects of investigation three winter wheat cultivars were selected (Factor B): NS Ilina, Pobeda and Simonida. Application of nitrogen doses was conducted in two occasions: ½ in autumn, before ploughing and ½ in early spring (in topdressing). In all variants the same amount of phosphorus and potassium were applied: 80 kg of P_2O_5 and K_2O ha^{-1} in autumn before ploughing.
The obtained results of wheat grain yield were subjected to ANOVA for two factorial *split-plot* design (statistical software GenStat Release 9.1; *Rothamsted Experimental Station*). Mean comparison was implemented using a LSD test at $p \leq 0.05$ and $p \leq 0.01$.

Results and discussion

Analysis of variance (Table 1) showed highly significant effects of fertilization system and cultivars (F_{pr}<0.001**) while interaction of fertilization x cultivars did not have significant impact to grain yield (Fpr=0.089^{ns}). Observation of the percentage share of individual sources of variation in the sum of total squares indicates that fertilization variants had the largest share in the total of yield variation (60%), followed by cultivars (17%) while interaction AxB participated in yield variation with only 5%.

Table 1. Analysis of variance of wheat grain yield

Sources of variation	Degrees of freedom	Sum of squares	Sum of squares (%)	Mean of squares	F-test	Probability of F-test (F_{pr})
Replications	3	4.012	5	1.337	9.65	/
Fertilization variants (A)	8	51.081	60	6.385	46.08	<0.001**
Residual	24	3.326	4	0.139	0.90	/
Cultivars (B)	2	13.998	17	6.999	45.38	<0.001**
AxB	16	4.052	5	0.253	1.64	0.089^{ns}
Residual	54	8.328	10	0.154	/	/
Total	107	84.796	100	/	/	/

Average grain yield in the trial was 6.31 t ha^{-1} (Table 2). However, grain yield obtained by the treatment with SI (average for all variants of nitrogen fertilization) was 6.49 t ha^{-1}, and it was for 540 kg ha^{-1} (i.e. for 9.13%) higher in comparison to the average for fertilization variants without incorporation of crop residues (5.95 t ha^{-1}).
On average for the all cultivars, the highest average yield of 7.15 t ha^{-1} was obtained by fertilization with 120 kg ha^{-1} of N with SI. Yield obtained in this variant was significantly higher in relation to all other variants with or without SI except at variant 150 kg N ha^{-1} with SI.
In the treatment without SI, the highest grain yield of 6.48 t ha^{-1} was achieved with the highest dose of fertilizer - 150 kg of N ha^{-1}, and was significantly higher in relation to treatment with no nitrogen added.

Results of *Malešević et al. (2009)* indicate statistical and economic justification of wheat fertilization by nitrogen in doses up to 120 kg ha^{-1}. Our results are in agreement with this investigation.

Table 2. Wheat grain yield (t ha^{-1}) at different N doses in treatments with and without straw incorporation

Fertilization variant (A)				Cultivars (B):			
Treatments:		**No.**	**Doses of N (kg ha^{-1})**	**NS Ilina**	**Pobeda**	**Simonida**	**Average (A):**
a) With straw incorporation		1	**0**	5.19	5.19	5.13	**5.17**
		2	**60**	6.52	6.88	5.68	**6.36**
		3	**90**	7.09	7.10	6.24	**6.81**
		4	**120**	7.49	7.42	6.54	**7.15**
		5	**150**	7.25	7.49	6.01	**6.92**
		6	**180**	6.65	6.75	6.17	**6.52**
			Average:	**6.70**	**6.81**	**5.96**	**6.49**
b) Without straw incorporation		7	**0**	5.09	5.26	4.89	**5.08**
		8	**90**	6.50	6.70	5.62	**6.27**
		9	**150**	6.89	6.65	5.91	**6.48**
			Average:	**6.16**	**6.20**	**5.47**	**5.95**
Average (B):				**6.52**	**6.60**	**5.80**	**6.31**

		A	B	BxA	AxB
LSD	**5%**	0.31	0.19	0.54	0.56
	1%	0.42	0.24	0.72	0.74

On average for all fertilization variants, cultivars Pobeda (6.60 t ha^{-1}) and NS Ilina (6.52 t ha^{-1}) achieved statistically significantly higher yield (for 800 and 720 kg ha^{-1}) in comparison to cultivar Simonida (5.80 t ha^{-1}). On the treatments with and without SI, difference between mentioned cultivars was slightly higher and also statistically significant.

Positive effects of long-term straw incorporation on wheat grain yield at comparable variants of trial (treatments with and without SI and with application of increasing nitrogen doses of 0, 90 and 150 kg of pure N ha^{-1}) are presented in Table 3. Depending on studied cultivars and doses of the applied nitrogen, it was within limits of only 100 kg of grains for cultivars NS Ilina in variant without nitrogen fertilization and Simonida in variant 150 kg N ha^{-1}, up to 840 kg ha^{-1} for cultivars Pobeda fertilized with 150 kg N ha^{-1}.

Table 3. Effect of straw incorporation at comparable variants of experiment to wheat grain yield (t ha^{-1})

Nitrogen rate	**Straw incorporation (SI)**	**Cultivars (B)**			**Average**
		NS Ilina	**Pobeda**	**Simonida**	
0 kg N ha^{-1}	With SI	5.19	5.19	5.13	**5.17**
	Without SI	5.09	5.26	4.89	**5.08**
	Difference:	**0.10**	**-0.07**	**0.24**	**0.09**
90 kg N ha^{-1}	With SI	7.09	7.10	6.24	**6.81**
	Without SI	6.50	6.70	5.62	**6.27**
	Difference:	**0.59**	**0.40**	**0.62**	**0.54**
150 kg N ha^{-1}	With SI	7.25	7.49	6.01	**6.92**
	Without SI	6.89	6.65	5.91	**6.48**
	Difference:	**0.36**	**0.84**	**0.10**	**0.43**
Average for all three N doses:	**With SI**	**6.51**	**6.59**	**5.79**	**6.30**
	Without SI	**6.16**	**6.20**	**5.47**	**5.95**
	Difference:	**0.35**	**0.39**	**0.32**	**0.35**

On average for three cultivars, on control variant without nitrogen use, SI increased grain yield for only 90 kg ha^{-1}; in variant with 90 kg N for 540 kg ha^{-1}, while the most intensive fertilized variant with 150 kg N ha^{-1} and SI provided the medium effect on grain yield increase - 430 kg ha^{-1}.
On average for cultivars and all three N doses, SI increased yield for 350 kg ha^{-1}. Cultivar NS Ilina had increase of 350 kg, Pobeda for 390 kg and Simonida 320 kg ha^{-1}.
Table 3 shows that Simonida had significantly better reaction on SI on control and treatment with 90 kg N ha^{-1}, while the Pobeda gave a higher yield increase on the highest nitrogen dose.
In literature there many examples in which SI provides identical results as well as manure application on improvement of soil properties and grain yield. Use of N fertilizers also significantly increases quantity of plant residues which incorporation increases humus content and efficiency of carbon retention in the soil *(Halvorson et al., 1999)*. In trials carried out in our country and in the world, beneficial effect of SI on yield and its quality has been proved *(Limon–Ortega et al., 2008; Jaćimović et al., 2009; Latković et al., 2011; 2012)*.

Conclusion

Based upon results of the study, the following conclusions can be made:
On average for all fertilization variants with nitrogen application, grain yield obtained in the treatment with straw incorporation (6.49 t ha^{-1}), was for 540 kg ha^{-1} higher in comparison to the average of fertilization treatments without SI. The highest yield on average of all three wheat cultivars (7.15 t ha^{-1}) was obtained with 120 kg N ha^{-1} with the SI. It was significantly higher in comparison to all treatments without straw incorporation.
The positive effect of long-term SI on wheat grain yield (at comparable variants of experiment: 0, 90 and 150 kg N ha^{-1}) ranged from 100 to 840 kg ha^{-1}, depending on cultivar and amount of nitrogen applied. On average, long-term SI increased yield for 350 kg ha^{-1} (about 6%) of grain (for all three cultivars and doses of nitrogen applied). Yield increasement by individual cultivars was 350, 390 and 320 kg ha^{-1}, for NS Ilina, Pobeda and Simonida, respectively.

Abstract

β-glucan as a secondary metabolite of barley kernels is a biologically active component with a positive impact on human health. β -glucan from cereal grains is a soluble fibre that reduces the amount of cholesterol in blood, decreases glucose levels after meals, as well as insulin levels. From technological aspect, it negativelyaffects rheological properties of dough. Natural grain coat (chaff) and difficulties in its grinding as well as the lack of gluten narrows the applicability of barley in the fabrication of food. The content of β-glucan in barley kernels varies depending on genotype and agro-ecological conditions. Barley has multifunctional - medicinal role in human diet, which has led to an increase in market demand. The studying of β-glucan contents showed genotypic variations, ranging from 3% to 6.5%. Besides the genotype factors, the authors also detected some significant differences that came as a result of agro-ecological conditions and diseases. The tested samples were three genotypes of barley: *Rekord*, *Zlatnik* and *Nonius*. The content of β-glucan ranged from 3.91 to 4.21%. A higher content of β-glucan in barley kernels, a very important metabolite, is expected in increased demand and promotion of functional characteristics of food and food products. The aim of barley growers should be to increase the production of varieties with higher content of β-glucan. The use of modern technologies of cultivation, selection and breeding, and creation of mutagenic barley populations could pave the way for such development.

Keywords: *barley, β-glucan, fibres*

Introduction

(1-3), (1-4) β-D-glucan is a polysaccharide located in the structure of endospermcell walls of barley kernels (Fincher, 1975). Compared to other types of cereals, β-glucan is most represented in oat and barley kernels. In recent years, fibres from different types of cereals, their functional properties and positive impact on human health have attracted considerable attention within scientific circles (Ronda *et al*., 2015; Sarteshnizi *et al*., 2015). β-glucan from cereal kernels is a soluble fibre that reduces cholesterol in blood, decreases postprandial glucose and insulin levels (EFSA, 2011), and affects the technological properties of dough (Ahmed, 2015; Ahmed & Thomas, 2015). The presence of this fibre in barley kernels can produce a number of problems in malt production during the fabrication of beer (McCleary & Glennie-Homes, 1985). Natural grain coat (chaff) and difficulties in its grinding as well as the lack of gluten narrows the applicability of barley in the fabrication of food. The content of β-glucan in barley kernels varies depending on the genotype and agro-ecological conditions; barley itself has a multi-functional, medicinal, role in human nutrition, and hence there is the trend of increased demand for barley in the market (Dickin *et al*., 2011; Hetherington *et al*., 2013; Pentikäinen *et al*., 2014). According to the FDA,

products having 0.75 g of β-glucan per serving size may be characterized as functional (FDA, 1997; 2008). Due to their high content of β-glucan and a beneficial effect on the human organism, barley kernels are of great importance and quite desirable as a food component. In addition to the traditional and a rather favoured use of this type of cereal in the malt industry, there are also some other possibilities for using barley as a feed component. Given that β-glucan is acomponent of the endosperm cell wall, there are a number of studies that recommend using bare grain genotypes in the food industry, which would significantly reduce problems associated with barley kernel fabrication. Development of new varieties, as a result of genetics and breeding, can encourage a greater use of barley. Moreover, although direct consumption of barley in the human diet is lower than the direct consumption of other types of cereals, such as wheat, maize and rice, adding barley flour in the fabrication of bread and pasta has proved to be successful (Cavallero *et al*., 2004). Breeding of barley for malt production has resulted in genotypes with reduced β-glucan content. Variations in the content are genotypic properties. By the (in)solubility of barley kernels in water, one can find two forms of β-glucan in barley kernels. The total content increases when plants are grown in warmer and dry conditions (Swanston *et al*., 1997). This implies that genetic factors can be expressed in different ways and that the factor of the environment is an important condition in the production of barley kernels with increased genotypic expression requirements for β-glucan content. Although many studies have indicated health benefits of the inclusion of barley in diet, the selection of barley for yield and yield components is still the main goal of barley breeding. Knowing the relation between morphological and biological characteristics and quality would result in considerable saving of resources and at the same time it would increase the yields and improve the quality of barley.

Material and Methods

The experiment was carried out at the experimental field Rimski Sancevi of the Institute of Field and Vegetable Crops, Novi Sad in Serbia (19°51E, 45°20N, altitude 84 m) during the 2012/13 growing season. The soil type where the experiment took place was a non-carbonate chernozem with 2.89% of humus, 54.72 kg ha^{-1} of NO_3, 20.5 kg ha^{-1} of P, and 21.8 kg ha^{-1} of exchangeable K before planting and had a pH of 7.74 (1:2 water). Weather records (daily maximum and minimum temperature and daily rainfall) were obtained from a meteorological station located 1 km away from the experimental site field.

Before sowing, fertilizer was top-dressed as mono-ammonium phosphate (12-48) and then harrowed providing 18 kg ha^{-1} of nitrogen (N) and 72 kg ha^{-1} of phosphorus (P_2O_5). According to N-min analysis, additional nitrogen fertilizer as ammonium-nitrate was applied in spring as a top-dressing at rate 33 kg nitrogen ha^{-1}. Pests and diseases were prevented or controlled by spraying recommended fungicides and insecticides, and weeds were periodically removed by hand. No artificial irrigation was applied throughout the growing season.

The experiment was conducted in a randomized complete block design with three replications. The plots were 1.0 m wide and 5 m long, with 0.1 m spacing between rows. Barley cultivars were sown on 8th of October 2012 with a plot seeder at planting density of 300 germinable grains per m^2 for six-rowed barley and 350 germinable grains per m^2 for two-rowed barley according to common practice in field scale production.

The subject of the research were thekernel samples of three winter barley varieties – *Rekord*, *Zlatnik* and *Nonius*, selected at the Institute of Field and Vegetable Crops in Novi Sad. The chemical analysis consisted of determining moisture (at 105°C to constant weight) and protein content according to Kjeldahl by applying a semi-micro procedure using the "Tecator-Kjeltec

System 1002" apparatus. The crude lipids were analysed according to Sohslet (Kaluđerski and Filipović, 1998).

Determination of β-gluten

After the harvest, samples from the tested plots were selected and finely ground at a laboratory mill (0.5 mm sieve). Thus prepared samples of barley flour were used for the determination of total β-glucan. The total β-glucan concentration was analysed by the spectroscopic method 32-23.01 (AACC, 2003), using the Megazyme mixed linkage β-glucan assay kit (Megazyme International Ireland Ltd., Wicklow, Ireland).

Results and Discussion

The tests were performed on the samples of the three barley genotypes: *Rekord*, *Zlatnik* and *Nonius*. The basic characteristics of the samples are given in Table 1. The samples were crushed in the laboratory mill, the particle size was 0.5 mm, and then they were dried at the temperature of 105°C to constant weight.

Table 1. Characteristics of the analysed samples

Sample	Genotype	Appearance
1	*Rekord*	Dried and milled powder
2	*Zlatnik*	Dried and milled powder
3	*Nonius*	Dried and milled powder

The research also included the chemical analysis of the basic quality parameters of the barley kernels. Results are presented in Table 2.

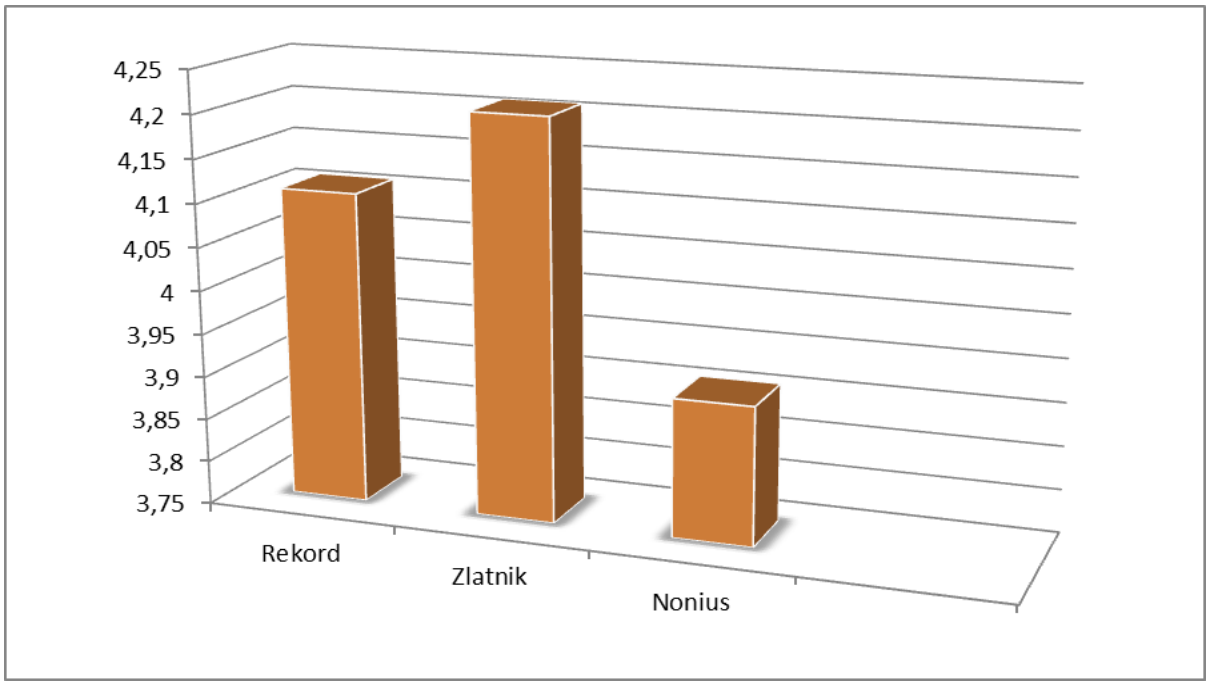
Table 2. Chemical characteristics of the barley kernels

Genotype	Moisture (%)	Protein (%)	Lipids (%)	NFE (%)
Rekord	5.81	10.5	1.94	81.76
Zlatnik	5.91	10.0	1.71	82.38
Nonius	6.22	7.8	1.91	84.07

Legend: NFE. - Nitrogen free extract

Uniform values of water content were recorded in all tested samples. The content of protein was genotype-inherent and varied from 10 to 7.8%. The content of crude lipids ranged from 1.94 to 1.71%. The content of nitrogen free extracts (NFE) was in accordance with the other analysed chemical parameters.

The content of β-glucan in the tested barley samples ranged from 4.21 to 3.91%. The results are presented in Figure 1. A previous study (Gangopadhyay *et al*., 2015) dealing with similar investigations states that the content of β-glucan in barley kernels range from 2.64 to 3.33% for some other genotypes in the region of North Europe. In terms of technology, an unfavourable role of β-glucan in barley bread production is well known (Ahmed, 2015) as well as the impact of β-glucan on flour rheological properties during the formation of dough (Ryua *et al*., 2012).



Graph 1. Content of β-glucan (%) in the tested barley samples

Conclusion

A higher content of β-glucan in barley kernels, a very important metabolite, is expected in increased demand and promotion of functional characteristics of food and food products. The aim of barley growers should be to increase the production of varieties with higher content of β-glucan. The use of modern technologies of cultivation, selection and breeding, and creation of mutagenic barley populations could pave the way for such development.

Abstract

The aim of this study is determined to yield and fruit characteristics of the 'Red Chief' and 'Mondial Gala' cultivars (*Malus domestica* Borkh.) grafted on M9 and MM106 rootstocks under subtropical conditions of Turkey. The experiment was conducted on a private sector orchard in the Eastern Mediterranean Region of Turkey (Yayladağı/Hatay) in 2011. In this study, harvesting date, yield parameters and pomological characteristics of 'Mondial Gala' and 'Red Chief' apple cultivars were evaluated. The fruit characteristics such as fruit weight, fruit width, fruit length, seed number per fruit, pH, TSS, acidity were investigated based on the cultivars and rootstocks. The results showed that, fruit harvesting was 18 August for the 'Mondial Gala' and 29 August for the 'Red Chief'. Average fruit weight was 129.86 g for the Mondial Gala/MM106, 99.13 g for Mondial Gala/M9, 189.86 g for the Red Chief/MM106, and 178.10 g for Red Chief/M9. Yield produced was 0.60 kg/cm^2 for Red Chief/MM106, 0.89 kg/cm^2 for Red Chief/M9, 0.45 kg/cm^2 for Mondial Gala/MM106, and 0.27 kg/cm^2 for Mondial Gala/M9. In conclusion, according to pomological and yield properties, Mondial Gala/MM106 for summer apple and Red Chief/M9 for winter apple cultivations can be promising for the subtropical conditions in the region.

Keywords: *apple varieties, yield, pomological properties, subtropical conditions*.

Introduction

Anatolia, Caucasia, Turkistan, and Europe were centers of origin for the domestic apple (*Malus domestica* Borkh.), now grown in continental climates in the Northern and Southern Hemispheres. Apple cultivation has occurred since ancient times and is one of the most important fruit for human consumption. One reason is great variety in colours, flavours, flesh textures, and other features (Way et al.1990). The most important producer countries are China, United States, Turkey, France, Iran, and Italy. Annual apple production in Turkey is 3.128.000 t, is one of the important producers of the word **(**Anonymous, 2013). More than 500 cultivars of apple are known in Turkey. This abundance has resulted from natural hybridization and selection over thousands of years (Özbek, 1978)**.** Until recent years, local cultivars, Starking Delicious and Golden Delicious are commonly produced in Hatay.

Generally, trade value of these cultivars in international market is very low due to the having subtropical climates of Hatay city. Nowly, summer apple cultivars are planted for early apple cultivation and their fruits are harvested from June to September. In addition to the summer apple varieties, by increasing production of mid-season apple cultivars, Mondial Gala and Red Chief would be supply more gains and also prevent to accumulate of crop in the late season. With become widespread orchards on cloned rootstocks, early fruiting and cultural treatments such as pruning, harvest, thinning and pest management can be easily and cheap. Until today orchard numbers with new cultivars and on dwarfing rootstocks were also very low in the region. It should be increased the number of orchard with early cultivars and on dwarf and semi-dwarf

rootstocks in order to increase yield and quality. Therefore, it is necessary to determine to suitable cultivars in terms of high quality and yield for the region. In the present study, yield and pomological features of Red Chief and Mondial Gala apple cultivars were evaluated in Hatay (Turkey) conditions.

Material and Methods

The experiment was conducted at Yayladağı/Hatay (Latitute 35 58 04 N; 36 00 55 E; Elevation 766 m) in the orchard of private owners during 2011. Regular agricultural practices were used as usual. Hatay province has a typical Mediterranean climate; yearly mean temperatures are ranged between 8.2 and 27.7°C. The summer temperatures between June and September during fruit ripening period are 29.2 and 31.9°C. Total precipitation is 1144 mm which primarily falls in winter and spring seasons (Anonymous, 2015).

The experiment was carried out on eight year old apple cultivars consist of 'Mondial Gala' and 'Red Chief' grafted on dwarf (M9) and semi-dwarf (MM106) rootstock. The trees were planted in 2002 in four replications at a distance 3×1.25 m for M9 and 3×2.50 m for MM106 rootstock. All of the fruits samples were taken at the full maturity stage, which was visually determined. Harvesting date of the cultivars were determined. On the experimental trees the number of fruits were counted, yield (harvested and weighted per tree in kilograms) weighted. Trunk diameter measured at a hight of 20 cm and converted to trunk cross - sectional area (TCSA, cm^2). Average yield per tree and yield efficiency of each scion-stock combination were computed from the harvest data.

Three trees from each variety were used. A total of thirty fruits were taken randomly from four directions of trees (north-south-east-west). The used pomological methods were given elsewhere by Seferoglu et al. (2006). Fruit weight (g) was measured with a scale sensitive to 0.01 g (Precisa XB 2200 C). Fruit length (mm) and diameter (mm), were measured by a digital caliper (Mitutoyo, 0–150 mm).

Firmness was measured using hand penetrometer with 11 mm probe. The firmness measurements were done through two different areas of the equatorial part of the fruits in a way that forms an angle of 180° between them. The mean of the two measurements was taken as the mean of a fruit. Total soluble solids (TSS) content were determined with a hand-held refractometer (NOW, 0–32% Brix) and pH (WTW InoLab pH meter) measurements were performed using a pH meter. Acidity (expressed as malic acid %) was determined by titrating with 0.1 N NaOH upto pH 8.10. Seed number was counted per fruit.

All data were subjected to analysis of variance (ANOVA) using SAS (SAS, 2005). ANOVA tables were constructed using Least Significant Difference (LSD) method at $p< 0.05$.

Result and Discussion

Fruit ripening time is changed according to the apple cultivars, whereas rootstocks had no effects on fruit ripening times. Fruits of Mondial Gala cultivar have matured on 18th of August, while fruits of Red Chief cultivars matured on the 29th of August in subtropical climatial conditions (Table 1).

The beneficial effects of dwarfing rootstock on the precocity and efficiency of tree yields have often been attributed to a change in the partitioning of the dwarfed trees assimilate from shoot growth to fruit production. However, semi-invigorating clonal rootstocks, such as MM106, induce improved yield precocity and efficiency in comparison with seedling rootstocks inducing the same level of scion vigor (Wertheim and Callesen, 2000). Results showed that Red Chief cultivar grafted on M9 had a more yield per tree (4.6 kg $tree^{-1}$) than MM106. Contrary to th result, Mondial Gala cultivar grafted on M9 had a less yield per tree (2.76 kg tree-1) and yield efficiency (0.33 kg cm^2)

less than MM106 (Table 1). Haak (2003) reported that trees on the dwarfing rootstocks yielded one third lesser than the trees on the medium rootstock MM106. In this study, higher yield was obtained for the scions grafted on MM106 rootstock but the ratio in yield increase was not as high as reported by Haak (2003). Further, in this study, the parameters of the number of fruits on the tree, the amount of yield from the tree (kg/tree), and kg-yield/ cm^2 per tree of Red Chief varieties grafted on the M9 rootstock had higher values than the ones from the Red Chief grafted on the MM106 rootstock obtained. Similarly, Dodangeh et al. (2012) reported the cultivars grafted on the M9 had yielded for yield per tree (13.23 kg $tree^{-1}$), yield in hectar, and yield efficiency (kg cm^2) than the Red Chief grafted on the MM106 for the same parameters.

Increased photosynthesis and yield efficiency in grafted cultivars on dwarfing rootstock deriving from reduction of shoot growth vegetative, competition between vegetative and productive growth, more light penetration in canopy and intensity in area unit (Webster, 2001) and then increase setting (Seleznyova et al., 2008). Although it is assumed that tree on dwarf rootstocks have limited vegetative growth resulting higher yield (Robinson, 2007). Rootstock influenced apple yield productivity. One hypothesis is that trees on dwarfing rootstocks terminate shoot growth earlier in the summer than trees on more invigorating rootstocks and thereafter partition more of their available assimilates towards the sites of floral primordia and less towards further shoot growth (Ferree and Warrington, 2003).

Mondial Gala scions on MM106 rootstocks showed good vigor and growth performance with larger trunk diameter. However, as expected, the average trunk circumfrence of scions (52.17 mm) grafted on MM106 rootstock was larger than that obtained for M6 rootstock (32.47 mm). Number of fruits per tree or yield of Mondial Gala scion for MM106 rootstocks was higher than obtained from M9 rootstock-scion combinations. Unlike the Mondial Gala cultivar, number of fruits per tree or yield of Red Chief scion for M9 rootstock was higher than obtained from MM106-scion combinations (Table 1).

Our results indicated that maximum yield per cm^2 trunk (0.89 kg cm^{-2}) was obtained from Red Chief cultivar budded on M9 rootstock whereas it was Mondial Gala for M9 rootstock (0.33 kg cm^{-2}). Soylu et al. (2003) reported that Granny smith grafted on MM106 rootstock produced 7 yearly average yields of 26.4 kg per tree and 0.39 kg per cm^2 trunk under Görükle, Bursa, Turkey, ecological conditions. Seferoglu et al. (2006) reported a cumulative yield of 12.7 kg per tree for 2001 and 2002 years and a yield of 0.33 kg per cm^2 trunk in Aydın ecological conditions. The average yield obtained from a tree was smaller than those of aforementioned studies, but yield per cm^2 trunk was as high as two fold or more. Özongun et al. (2016) reported the M9 rootstocks produced higher yield per square centimeter than the rest of their rootstocks in their study.

Table 1. Havest date and yield parameters of Red Chief and Mondial Gala cultivars grown on the M9 and MM106 rootstocks

Cultivars	Rootstocks	Harvest date	Number of fruit/tree	Yield (kg/tree)	Trunk circum. (cm)	TCSA (cm^2)	Yield (kg/cm^2)
Red Chief	MM106	29 August	24.22 b	4.60 b	31.65 a	7.90 a	0.60 b
	M9	29 August	34.30 a	6.02 a	29.30 a	6.75 a	0.89 a
	LSD (5%)		0.44	1.17	4.78	2.37	0.25
Mondial Gala	MM106	18 August	83.67 a	9.67 a	52.17 a	21.07 a	0.46 a
	M9	18 August	22.66 b	2.76 b	32.47 b	8.33 b	0.33 b
	LSD (5%)		23.95	1.58	5.99	3.27	0.14

In this study, the average number of fruits per tree was 83.67 for MM106-Mondial Gala combinations and 24.22 for MM106-Red Chief combinations. Number of fruits per tree was 34.30 for M9- Red Chief combinations and 22.66 for M9- Mondial Gala combinations. Racsco et al. (2004) tested the performance of 4 years old cultivars budded on M9, MM106, and a wild type rootstock in Nagykutas, western Hungary. They obtained the maximum yield from M9 and the minimum yield from wild type rootstock. The number of fruits per tree was 15.3 and 63.9 fruits per tree in 2002 and 2003, respectively, for Granny smith cultivar budded on M9 and those fruit numbers for Vista Bella were 6.1 and 48.2 per tree. For the MM106 rootstock the reported fruit numbers were 10.4 and 46.4 per tree for Granny smith and 10.4 and 51.9 per tree for Vista Bella. Fruits numbers under subtropics climatical condition, in our study, were higher than those reported by Racsco et al. (2004). Ozongun et al. (2016) tested the performance of different apple variety (Mondial Gala, Skyline Supreme, Lutz Golden, Granny Smith) grafted to clonal apple rootstocks (M9, M26, MM106, MM111) which have different vigour capacity were evaluated for yield development quality characterics in Eğirdir Fruit Research Institute in the study. Rootstocks had a significant effect on yield but they had no significant stable effect on fruit quality. M9 rootstock was determined for highest yield.

The rootstocks did not statistically impact on the average fruit weight, width and length and the number of seeds for the Mondial Gala cultivar. However, the average fruit weight, width and length of grafted plants on MM106 rootstock were higher than the ones from the grafted plants on the M9. The number of seeds in the fruits was found to be higher in the grafted plants on the M9 rootstock compared to the the other rootstock (Table 2).

In Red Chief variety, the rootstock was found statistically effective on the average fruit weight and number of seeds in the fruits, whereas no statistical difference was found for the effect of rootstocks on the fruit width and hight. The average fruit weight, width, height, and the number of seeds have been found to be 189.86 g, 73.26 mm, 67 mm, and 6.89, respectively for MM106 rootstocks in comparison to the respective values 178.10 g, 72.11 mm, 66.49 mm, and 7.62 for the grafted plants on the M9 rootstocks. In both apple cultivars, the average fruit weight and size have been increased for the grafted on the MM106 rootstocks (Table 2). Hampson and Kemp (2003) observed fruits of the Mondial gala cultivar are small-medium size, and fruit weight is not affected by rootstock Ozongun et al.(2016) reported that uniformity of fruit size has decreased despite the increase in fruit weight/size on M26, MM106, and MM111 rootstocks which are stronger than the M9 rootstocks. Baytekin and Akça (2006), Turhal/Tokat ecological conditions, found fruit weights, width, and hight as 235.5 g, 8.21 cm, and 7.11 cm in Red Chief grafted on the MM106 rootstocks, respectively. In the current study, the Red Chief apple varieties have attracted attention in terms of fruit weight and fruit size. The average fruit weight of the Red Chief apple varieties in Eğirdir ecological conditions was found to be 198.82 g **(**Özongun ve ark.2011). Burak et al. (2003) determined average fruit width as 6.27 cm for Galaxy Gala/MM106, 7.60 cm for Red Chief/MM106, and 6.36 cm for Breaburn/MM106 under the ecological conditions of Yalova. Our results are in line with some references but, partly different from others. The difference may be resulted due to cultivar, rootstock, cultural practices as well as variations in fruit formation.

Table 2. Some fruit characteristics of Red Chief and Mondial Gala apple cultivars on M9 and MM 106 rootstocks

Cultivars	Rootstocks	Fruit weight (g)	Fruit width (mm)	Fruit length (mm)	Seed number per fruit
Red Chief	MM106	189.86 a	73.26 a	67.00 a	6.89 b
	M9	178.10 b	72.11 a	66.49 a	7.62 a
	LSD (5%)	7.84	4.03	4.85	0.36
Mondial Gala	MM106	129.86 a	62.87 a	53.91 a	6.33 a
	M9	99.13 a	59.28 a	51.25 a	7.00 a
	LSD (5%)	33.93	5.13	3.27	1.85

Fruit quality attributes such as weight, titrable acidity, and soluble solid concentration are some times measured in junction with fruit colour in 'Gala' apple evaluation. Fallahi et al. (2007) studied quality attributes of Pacific Gala' and reported that irrigation methods and rootstocks type can have a majör impact on fruit size, colour and SSC.

The rootstocks significantly impacted pH, TSS, and acidity values, while no significant effects were observed on the flesh firmness. The highest pH and TSS values were recorded from the Modial Gala and Red Chief grafted on the M9 rootstocks, whereas the highest acidity was obtained from the Red Cheief grafted on the M9 rootstocks and from the Modial Gala grafted on the MM106 rootstocks (Table 3).

Baytekin and Akça (2011) observed TSS, pH, and total acidity for the Red Chief grafted on the MM106 rootstocks as 10.66%, 3.85, and 0.39 cm, respectively in the ecological conditions of Turhal, Tokat, Turkey. Özdemir et al. (1999) reported the Red Chief cultivars gafted on the MM106 rootstocks had an average TSS of 11.8%. This study, subtropical climatological conditions of Hatay province, Turkey, fruit properties of Red Chief and Mondial Gala cultivars, except average fruit weight, have been found similar to the values given for the above mentioned properties of the fruits.

Table 3. Chemical characteristics of Red Chief and Mondial Gala apple cultivars on M9 and MM 106 rootstocks

Cultivars	Rootstocks	pH	TSS (%)	Acidity (%)	Firmness (kg/cm²)
Red Chief	MM106	3.45 b	10.80 b	2.41 b	3.30 a
	M9	3.78 a	14.27 a	2.67 a	3.48 a
	LSD (5%)	0.84	0.44	0.58	0.52
Mondial Gala	MM106	3.28 b	12.53 b	3.96 a	4.37 a
	M9	3.53 a	14.20 a	3.70 b	4.27 a
	LSD (5%)	0.13	0.59	0.17	0.13

Conclusion

Turkey being the original source of apple has sites suitable for apple production; however, studies in Subtropical conditions of Turkey, particularly in the Hatay city, is not sufficient. Our preliminary study showed that 'Red Chief ' and 'Mondial Gala' cultivars, when grafted onto M9 and MM106 rootstocks, respectively, have high economic potential in the Subtropical conditions. Mid-season maturation of these cultivars fruits increases the economic value of the fruit in the market. Despite subtropical climatical conditions of Hatay district, 'Red Chief' and 'Mondial Gala' can be treated as high yield producing species. Since these cultivars are "mid-season maturing cultivars", high temperature induced-disorders such as sun-burn can be common quality problems in the region.

DETERMINATION OF YIELD AND YIELD CHARACTERISTICS OF SOME SMALL SIZED RED LENTIL LINES (*Lens culinaris* Medik.) IN F5 AND F6 LEVEL

Ayşe Gülgün ÖKTEM*, Abdullah ÖKTEM

Harran University, Agriculture Faculty, Field Crops Department, Şanlıurfa, Turkey
*Corresponding author; gulgunoktem@harran.edu.tr

Abstract

Lentil (*Lens culinaris* Medik.) is a source of high quality protein, mineral and vitamins and generally used for human food. The leaves, stems and threshed pods of lentil are used for animal feeding. Lentil plants fix nitrogen in the soil and increase nitrogen level of soil. Sanliurfa province which is located in the Southeastern Anatolia Region has the most sowing area and production in Turkey. This study was aimed to develop the high yield red lentil varieties to Southeastern Anatolia Region of Turkey. Study was conducted in 2009-2010 and 2010-2011 growing seasons under Şanlıurfa conditions. Experiment was established to randomize complete block design with 4 replicates. In the study 20 small sized red lentil lines in F5 and F6 level which are obtained from Icarda (International Center for Agricultural Research in the Dry Areas) collection and 2 standard varieties were used as a crop material. Genotypes were significant about days to flowering, plant height, first pod height, thousand kernel weight, biological yield and grain yield. According to average of years; the highest grain yield obtained from line 1 (2280 kg/ha), whereas the lowest grain yield was found at Yerli Kırmızı standard variety (1389 kg/ha). Some better lines than others were selected in considering plant height, first pod height days to flowering, thousand kernel weight and grain yield values. Line 1, line 4, line 5, line 6, line 9, line 12, line 13, line 15, line 16, line 17, line 18 and line 19 were found better than others and were selected for next generation.

Keywords: *Red lentil, Small sized, Southeastern Anatolia, Grain yield*

Introduction

Lentils were among the earliest of humankind's plant domesticates and associated with the start of the 'agricultural revolution' about 10 000 years ago in the Near East (Cubero et al. 2009). Lentil is a source of high quality protein and generally used for human food. Whole, split, or ground into flour, it is used in soups, stews, salads, casseroles, snacks and vegetarian dishes. In southern Asia, split red lentils are used in curries. Lentil flour, added to cereal flour, is used to make bread. Lentils need less cooking time than other pulses and do not need to be pre-soaked. Dried lentils can be sprouted. Lentil contents high protein in their seed. Lentil grain is a vital source of protein, with a mean of 28.3% ranging from 15.9 to 31.4% over (Grusak, 2009), especially for the poor, who cannot afford animal products. Additionally lentil seed contains high amounts of macro and micronutrients (Ca, P, K, Fe and Zn), vitamins (Niacin, Vitamin A, Ascorbic Acid) and Inositol), fiber and carbohydrates for balanced nutrition (Bhatty, 1988; Savage, 1988). The leaves, stems and threshed pods of lentil are important for feeding sheep and goats in the Middle East. Lentil plants fix nitrogen in the soil, helping reduce the use of nitrogen fertilizer. The crop is grown in rotation with cereals in the winter in Mediterranean and sub-tropical regions and as a summer crop in temperate and high elevation areas. Red lentil has 207 469 ha sowing area, 340 000 tons production and 1640 kg/ha average yield in Turkey. Red lentil

is mostly grown in southeast Anatolia region in Turkey. Southeastern Anatolia Region has 200 995 ha sowing area and 331 574 tons production. Sanliurfa province which is located in the Southeastern Anatolia Region has the most sowing area and production in Turkey. Sowing area and red lentil production amount of Sanliurfa is 99 328 ha and 129 732 tons, respectively (Anonymous, 2015 a). Lentil breeding is important for developing new varieties to highly efficient and earlier in Southeastern Anatolia Region. This study was aimed to develop the high yieldly red lentil varieties to Southeastern Anatolia Region of Turkey. Some research results which made in red lentil are given below; Biçer and Sakar (2008) reported that red lentil grain yield ranged from 776.8 kg/ha (FLIP 96-47L) to 3242.3 kg/ha (FLIP 2004-49L) in Diyarbakır conditions. Shrestha et al. (2005) were reported that the seed yield of red lentil was 330-1270 kg/ha. Younis et. al. (2008) explained that days to flowering, plant height, biological yield and hundred seed weight are very important parameters in seed yield of lentil plant. Biçer and Sakar (2011) investigated nineteen lentil lines and two cultivars in Diyarbakır conduction. Differences among cultivars/lines were found significantly for days to flowering, plant height, first pod height, 1000 seed weight, grain yield and biological yield. Çölkesen et al. (2005) reported that the lowest grain yield was obtained from Emre variety while the highest grain yield was found at line of F90.41 L in Kahramanmaras and Sanliurfa Conditions.

Material and methods

This study was conducted in 2009-2010 and 2010-2011 growing seasons under Sanliurfa conditions in Turkey. Soil samples representing the 0 to 20 cm layer were taken a day prior to seedling; air dried, passed through a 2.00 mm sieve, and analyzed (Jones 1984). The soil of research field was clay, slightly alkaline, high in lime content, and very low in salt content. Climatic data and soil properties were given in Table 1 and Table 2, respectively.

Table 1. Some meteorological parameters belong to the growth period of lentil[†].

In the study 20 small sized red lentil lines in F5 and F6 level which are obtained from Icarda (International Center for Agricultural Research in the Dry Areas) collection and 2 standard varieties, which were Yerli Kırmızı (YK) and Fırat-87 (F-87), were used as a crop material.

Experiment was established to randomize complete block design with 4 replicates. Each parcel was arranged in 6 rows X 5 m X 0.2 m. The testing area firstly was ploughed (18-20 cm depth) and cultivated (10-12 cm depth) then prepared for planting with a single pass of a disk-harrow. Seeding was made by trial drill and 350 kernel/m^2 seed was used. At sowing, 60 kg ha^{-1} of pure N and P, as a 20-20-0 composed fertilizer was applied to each plot. All tested characteristics were measured on randomly selected 10 plants in the center of each plot. An analysis of variance was performed to evaluate statistically differences between results. Means of the data obtained from research were compared using Duncan test at $P \leq 0.05$.

Results and discussion

Variance analyses were performed separately for each year and combined of years for all traits. Plant height, pod height, biological yield, thousand kernel number and grain yield were highly statistically significant (Table 3).

Tablo 3. Variance analyses of plant height, first pod height, days to flowering, biological yield and grain yield in 2009-2010, 2010-2011 and combined analyses.

* ,** indicates statically significant at 0.05 and 0.01 respectively

According to results of variance analysis; plant height was found statistically significant ($P<0.01$ in both trait years (Table 3). In combined analyses, year was statistically significant ($P<0.01$). Plant height values ranged from 32.0 to 42.0 cm in first year and 40.0 to 33.50 cm in second growing season (Table 3). The highest plant height values were obtained from Fırat-87 and Yerli Kırmızı standard varieties in both years. More lodging was seen in Fırat-87 and Yerli Kırmızı standard varieties than others. Hanlan et al. (2006) explain that tall lentil plants have more lodging tendency. Plant height values of lines were smaller than standard verities in both years. Similar results reported by some researchers. L´azaro et al. (2001) stated that landraces of plant

height were higher than Icarda lines in Spain. Also Bicer and Sakar (2007) reported that local verities had higher plant height than Icarda lines in Diyarbakır.

As can be seen from Table 3, first pod height values were statically significant in both years (P<0.01). In combined analysis year, variety and year x variety were statiscally significant (P <0.01). First pod height ranged from 27.6 cm to 14.5 cm in average of years. The highest value was obtained from Fırat-87 variety in first growing season while the highest value was obtained from Yerli Kırmızı variety (Table 4). According to year combined analyses; first pod height of Fırat-87 and Yerli Kırmızı varieties were higher than Icarda lines. Similar finding were reported by Toğay ve Engin (2000). Researchers stated that the highest plant height and pod height obtained from yerli kırmızı standart variety. Our results are in agreement with the findings of some researchers. Biçer and Sakar (2007) reported that some pod height of Icarda lines were between 9.67 and 14.67 cm. Karadavut et al. (1999) emphasized that Icarda lines had lower pod height than standard varieties.

According to variance analyses day to flowering was significant in first (P<0.05) year and second (P<0.01) year. In combined analyses, year, variety and year x variety were significant at P<0.01 level (Table 3). Days to flowering were between 104 (F.87) and 87.67 (line 18 and 19) days in first year, 70 (line 19) and 80 (F.87) days in second year. According to average of years days to flowering changed from 90.8 (Yerli Kırmızı) to 78.8 (Line 19) days (Table 4). The latest days to flowering were obtained from Yerli kırmızı and F.87 standard varieties. Icarda lines had early flowering period. Days to flowering period of number 11, 18 and 19 lines were earlier than other lines and varieties. Some researchers' findings were good agreement with our findings about days to flowering period. Turk and Atikyılmaz (1999) reported that the lines from Icarda were earlier than Yerli Kırmızı and Fırat-87. Aydoğan et al. (2005) reported that Fırat-87 variety had late maturation and late flowering period. Early flowering is warranty product as dry and hot climatic condition like as Southeastern Anatolia.

†: There is no statistical difference among values annotated with the same letter at P<0.05 according to the Duncan test.

*, ** : indicates statistical significant at 0.05 and 0.01 level, respectively.

İn terms of biological yield, varieties were significant in first year (P<0.05) and second year (P<0.01). In combined analyses, year, varieties and year X varieties were significant at P<0.01 level (Table 3). Biological yield ranged from 530.8 to 382.7 g/m^2 in first trait year while it was between 770.2 g and 418.3 g/m^2 in second year (Table 5). Average of both years biological yield values were varied from 649.6 g/m^2 (line 1) to 412.9 g/m^2 (line 8). These results were supported by some studies. Bicer and Sakar (2011) were reported that biological yield changed between 6200 kg/ha and 3820 kg/ha for some lentil lines and varieties.

According to result of variance analyses; 1000 kernel weight value was found statistically significant (P<0.01). In combined analyses, year, varieties and year x varieties were significant (P<0.01). Thousand kernel weight values varied between 30.61 and 44.28 g in first year while 31.20 and 46.33 g in second trait year (Table 5). The highest values were obtained from line 21 in first year and line 24 in second year. According to both years average, the highest 1000 kernel weight value found at line 21. 1000 kernel weight value of second year was higher than first year value due to rainfall of 2010-2011 growing period was higher than 2009-2010 growing period. It is stated that the environment have a significant impact on thousand grain weight (Erksine and Ashkar 1993).

†: There is no statistical difference among values annotated with the same letter at P<0.05 according to the Duncan test.
*, ** : indicates statistical significances at 0.05 and 0.01 level, respectively.

According to variance analysis results, grain yield was statistically significant in both years (P<0.01). In combined analyses; year, varieties and year x varieties were found statistically significant at 0.01 level (Table 3). Grain yield values ranged from 1389 kg/ha to 2281 kg/ha in mean of years. The highest value was obtained from line 19 and line 1 in first and second year, respectively (Table 5). The lowest value was found at Yerli Kırmızı (940 kg/ha) in first year and line 10 (1690 kg/ha) in second year. According to years of average, the highest grain yield was obtained from line 1 (2281 kg/ha) whereas the lowest grain yield was found at Yerli Kırmızı variety (1389 kg/ha). First year grain yield values were lower than second year. The low yields in

the 2010-2011 seasons can be explained insufficient rainfall during reproductive growth (Table 1). However grain yield values of second trait year were higher due to regular raining in pod binding period. Erksine and Ashkar (1993) reported that variation about 80% on grain yield stemed from seasonal raining. Silim et al. (1993) emphasized that rainfall effects grain yield especially in pod binding period. If raining is regular in pod binding period, grain yield will be high.

Conclusion

According to two years research results; considering to flowering period, plant height, thousand kernel weight and grain yield; line 1, line 4, line 5, line 6, line 9, line 12, line 13, line 15, line 16, line 17, line 18 and line 19 were found better than others and were selected for next generation.

DETERMINING THE PRODUCTION AMOUNT OF LEAF TOBACCO USING GOAL PROGRAMMING

Altay Uğur GÜL*, Funda GENCLER

[1]School of Tobacco Expertise, Celal Bayar University, Manisa, Turkey
*Corresponding Author: ugurgul1@hotmail.com

Abstract

Tobacco farming is being done in Aegean, Marmara, Black Sea, East Anatolia, Southeast Anatolia and Mediterranean regions in Turkey. With the introduction of the new law (No: 4733) the marketing system of tobacco has totally changed and has been replaced with the auction system and contract production. The new Law abolished the Monopoly Status of TEKEL and this was the beginning of the withdrawal of the Government from all aspects of tobacco in Turkey. Private firms were allowed to produce cigarettes in Turkey. Leaf tobacco companies buy tobacco due to the contracts between them and the tobacco farmers every year. Tobacco farms vary considerably in size, location, yields and different characteristics in every region thus cause disparity in prices. For this reason this study aims to set the contracted tobacco production planning by using goal programming. This hypothetical study contributes some data for tobacco leaf purchaser companies in Turkey. Goal programming (GP) allows the decision maker to include multiple goals or objectives in the problem formulation. GP applies the linear programming model to situations which contain multiple goals or objectives. The GP approach involves the decision maker in a process that attempts to achieve a satisfactory level of achievement for several objectives, rather than an optimal outcome for a single objective. The goal programming consists of 6 variables and 8 goal functions. As a result, the solution of goal programming; it has been predicted that 61,450 ha. including Aegean Region, totally 90,000 ha contracted farming should be done, the amount of tobacco leaf is 78,708,650 kg and the purchase cost is $ 337,365,060.00.

Keywords; *Turkish Tobacco Production, Contracting Farming, Goal Programming*

Introduction

Tobacco has been brought to Ottoman Empire in the beginning of 1700's from English and Italian sailors. It has been cultivated in Macedonia in 1687 initially in the Empire boundary. Afterwards, the production has become widespread. By the reason of attentive cultivation, accurate agricultural methods and proper ecologic conditions, Turkish tobacco has gained a good reputation with its high quality in the world markets (SPO, 2000). In 2002 as a result of a change in the privatization policies; the support of the state in tobacco (production) is abrogated. With the introduction of the new law (No: 4733) the marketing system of tobacco has totally changed and has been replaced with the auction system and contract production (Kocturk and Cebeci, 2005). The new Law abolished the Monopoly Status of TEKEL and this was the beginning of the withdrawal of the Government from all aspects of tobacco in Turkey. Private firms were allowed to produce cigarettes in Turkey. Once the government sold TEKEL it also ended tobacco production. Turkish tobacco production went from a totally supported subsidized producer base to a free market system based on contract farming under regulation of the TAPDK. The number of cigarette producers increased in the Turkish market and the number of leaf tobacco farmers

dramatically reduced. As the whole market went through a transformation several world class establishments and systems were applied to the Turkish production base. In the old system, tobacco had been produced all over the country based more on political whims than supply and demand.

Turkey is the biggest producer of aromatic Oriental tobacco and together with its product production base is becoming a sizable regional production hub. The tobacco business contributes over a billion dollars in exports and over 11 billion dollars is contributed to the inland revenue the Turkish farmer base is about 80,000 (TAPDK, 2015).

In Turkey tobacco farming is mainly done in following regions; Egean Region (Akhisar, Söke, Manisa, Denizli, Kütahya, Eşme), Black Sea Region (Erbaa, Vezirköprü, Bafra, Samsun, Bolu, Amasya, Trabzon), Marmara Region (Erbaa, Vezirköprü, Bafra, Samsun, Bolu, Amasya, Trabzon), Southeastern Anatolia Region (Malatya, Bitlis, Muş, Hakkari), Mediterranean (İskenderun, Yayladağı, Samandağ). The distribution of tobacco farming area is almost every region of Turkey, except Central Anatolia. Leaf tobacco purchasers use their own method in the market. This method depends on the variables from the other purchasers' demands and the previous experiences. Without any doubt, leaf tobacco market has different factors that affect itself such as quality, quantity, sustainability of production etc.

Goal programming (GP) allows the decision maker to include multiple goals or objectives in the problem formulation. GP applies the linear programming model to situations which contain multiple goals or objectives. The GP approach involves the decision maker in a process that attempts to achieve a satisfactory level of achievement for several objectives, rather than an optimal outcome for a single objective (Markland and Sweigart, 1987; Levin and Kirkpatrick, 1978). GP attempts to find the point which satisfies best the goal or goals in the problem (Budnick, 1988).

The aim of this study is to determine the amount of raw tobacco leaf which is conducted as a contract farming by using goal programming. This hypothetical study contributes some data for tobacco leaf purchaser companies in Turkey.

Material and methods

The data are gathered due to the aim of the study. These are; contracted tobacco farming regions in Turkey and their land size, tobacco production amount and the price of the raw leaf tobacco in these regions (Table 1, TAPDK and Tobacco Experts Association web site)

Table 1. Summary information for the contracted leaf tobacco production in Turkey* (2015).

Regions	The level of production (kg/ha)	Production costs ($/ha)
Aegean	799.2	3499.35
Marmara	857.6	3718.31
Blacksea	1133.9	5576.36
East Anatolia	1806.1	3379.99
Southeastern Anatolia	918.3	2689.31
Mediterranean	1075.5	1993.52

Source: TAPDK* and Tobacco Experts Association, 2016.

* The Tobacco and Alcohol Market Regulatory Authority

Based on these data, the target values in Table 2 are determined to set out the leaf tobacco purchase.

Table 2. Target values of the objective function.

The Goal Function	Target Value (b_i)	The Goal Function	Target Value (b_i)
1	≤350,000,000 $	6	15,000 ha
2	≤90,000 ha	7	50 ha
3	≥75,000,000 kg	8	8,000 ha
4	60,000 ha	9	2,000 ha
5	3,500 ha		

GP minimizes deviations from multiple goals or objectives subject to some constraints that are goal statements (Dykstra,1984). The model is stated with the following set of the objective functions:

$$G_1 \rightarrow \sum_{j=1}^{6} c_j x_j + d_1^- - d_1^+ = b_1$$

$$G_2 \rightarrow \sum_{j=1}^{6} x_j + d_2^- - d_2^+ = b_2$$

$$G_3 \rightarrow \sum_{j=1}^{6} a_j x_j + d_3^- - d_3^+ = b_3$$

$$G_i \rightarrow x_j + + d_i^- - d_i^+ = b_i \qquad (i = 4,5,....9;\ j = 1,2,...,6)$$

where

x_j, decision variable, the contracted leaf tobacco production area in *j*th region,

c_j, the cost of leaf tobacco production in *j*th region ($/ha),

b_i, target value of the *i*th function,

a_j, the leaf tobacco production in *j*th region (kg/ha),

In addition to the constraints, variables and constants described above, the following priorities (P_k) and achievement function ($\bar{a}$) are to be defined.

$$\bar{a} = \min\left\{ \underbrace{d_1^+}_{P_1}; \underbrace{d_2^+}_{P_2}; \underbrace{d_3^-}_{P_3}; \underbrace{\sum_{i=4}^{9} d_i^- + d_i^+}_{P_4} \right\}$$

where

d_i^-, negative deviational variable of the *i*th goal,

d_i^+, positive deviational variable of the *i*th goal,

P_k, priority level

Results and Discussion

The model is solved using the Decision Support Software for Windows and the results are summarized in Table 3 and 4.

According to the solution; 90,000 ha area is determined for contracted leaf tobacco. Total production amount is 78.7 million kilograms and the total cost is $ 337,365,262.71 calculated.

Table 3. Summary of the solution to the GP model

Regions	Area (ha)	Production (kg)	Cost ($)
Aegean	61,450	49,110,840	215,035,320.86
Marmara	3,500	3,001,600	13,014,080.00
Black Sea	15,000	17,005,500	83,645,373.21
East Anatolia	50	90,305	168,999.36
Southeastern Anatolia	8,000	7,346,400	21,514,457.14
Mediterranean	2,000	2,151,000	3,987,032.14
Total	90,000	78,708,650	337,365,262.71

According to the Table 4, the first three priority are assured. However, the cost of contract in the first priority is at most 350 million US dollars (G_1) leads 12.6 million US dollars negative deviation from the target. Also, in the third priority at least 75 million kilograms of tobacco leaf production realization (G3) is actualized and approximately 3.71 million kilograms positive deviation from the target. The fourth priority was not achieved and in the Aegean region the production of 60,000 hectares of contracted tobacco leaf leads 1,450 hectares positive deviation from the (G4) target.

Table 4. Priority and constraint analysis

Priority (P_k)	Non achievement	Goal (G_i)	d_i^+	d_i^-
1	0	1	0	12,634,940,000
2	0	2	0	0
3	0	3	3,708,650	0
4	1450	4	1,450	0
		5	0	0
		6	0	0
		7	0	0
		8	0	0
		9	0	0

Figure 1 shows the distribution of the area where the contracted leaf tobacco production is going to be done. The model shows that, the contracted tobacco farming can be done in the target levels of all regions except Aegean Region.

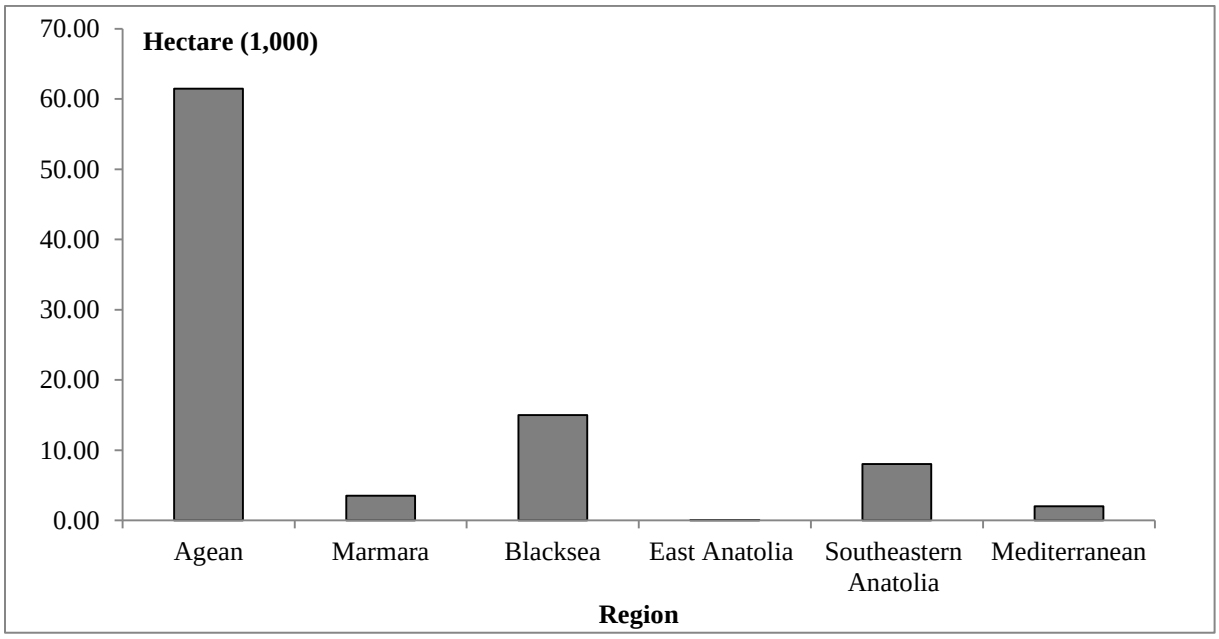

Figure 1. The distribution of the field of tobacco production.

In Figure 2, the distribution of the amount of contracted tobacco leaf production is shown. The Model shows that, the demand of tobacco production can be supplied from Aegean, the Black Sea and Southeastern Anatolia (93,34%) and Aegean Region (62,40%) solely.

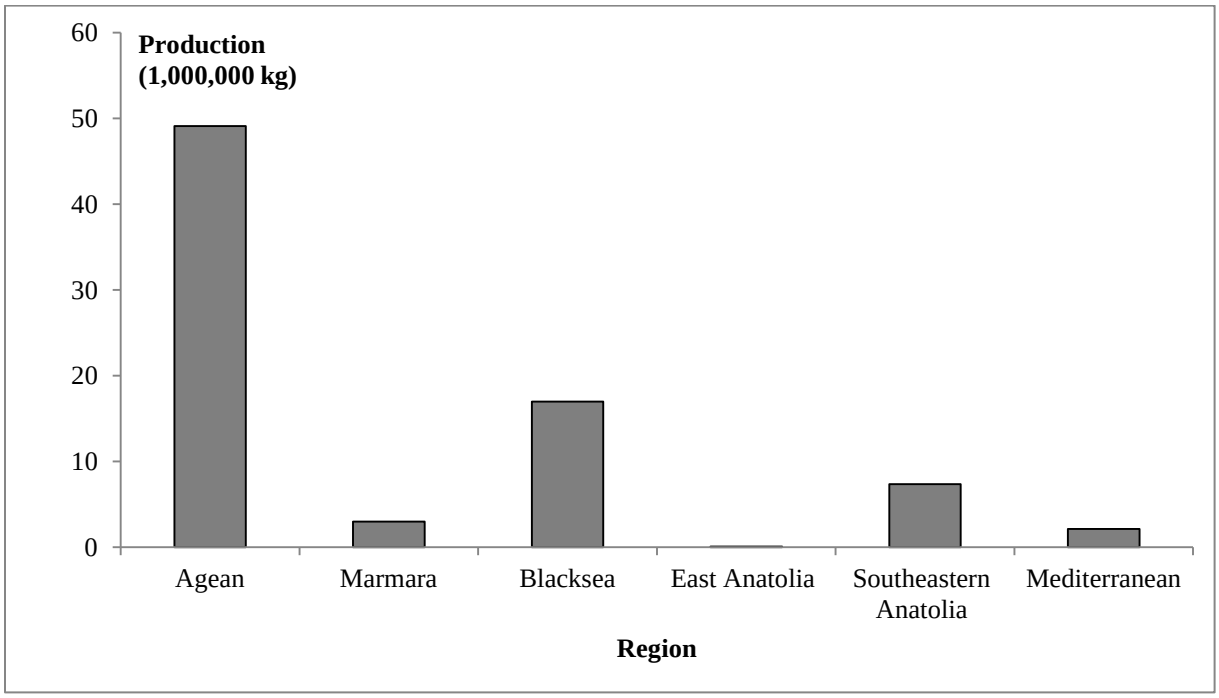

Figure 2. The distribution of tobacco production.

In Figure 3, the distribution of contracted tobacco leaf production cost is shown. The outcomes of the model indicate that the 94,91% of the production costs will be occurred in Aegean, the Black

Sea and the Southeastern Anatolia Regions and 63.74% of the production cost will be occurred in Aegean region.

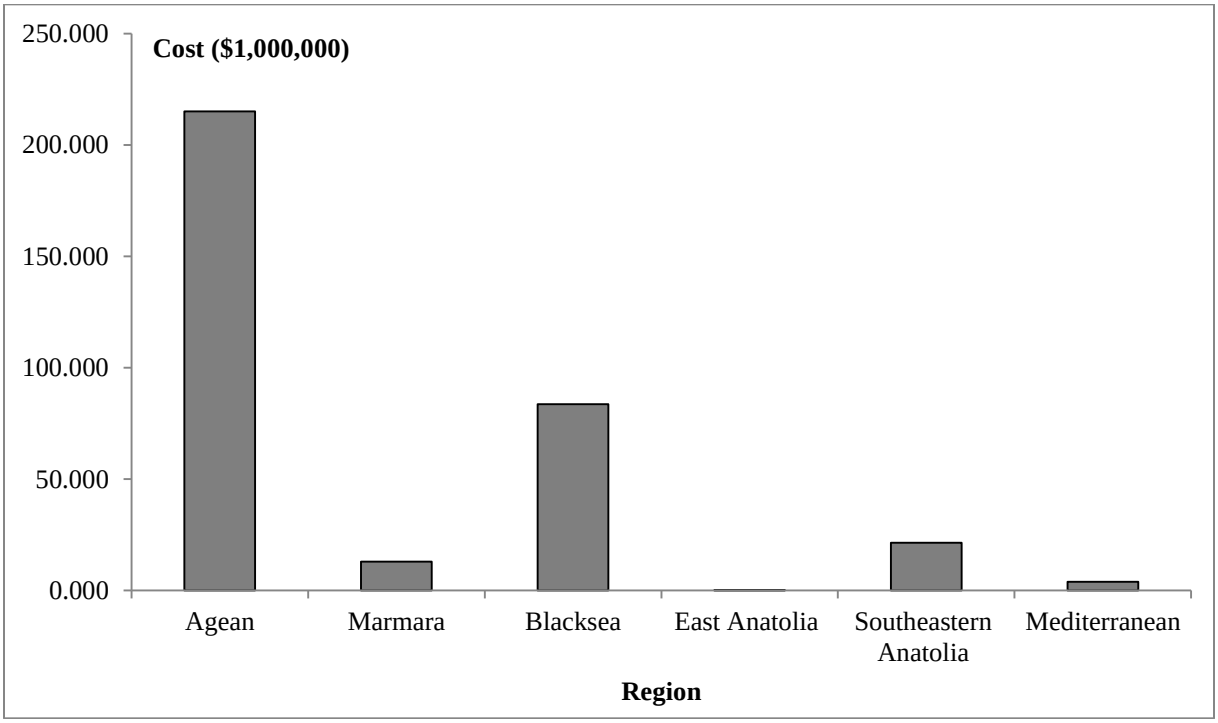

Figure 3. The distribution of the cost of tobacco production.

Priority GP models minimize firstly access function of the deviation variable which is located on the first priority, and then minimize the second, third and other deviation variables in priority areas respectively. In the above model, the first priority of leaf tobacco production is set not exceed 350 million dollars of the total cost, that means it is required to be minimized of the positive deviation. The negative direction deviation is released. The solution also ensured that priority, there is no positive deviation. In the negative direction, approximately 12.6 million US dollars deviation assures less cost in leaf tobacco production which is positive in this aspect. In the last priority, both negative and positive deviations have been asked to minimize the target values for leaf tobacco production areas in six districts. However, there has been a positive deviation 1450 hectares from Aegean Region land target, thus this priority has not been achieved. Because of obtaining a $ 12.6 million less than the production cost in the first priority, the deviation should not be considered significant.

Conclusions

In Turkey, tobacco farming is generally carried out in the form of contracted tobacco production applications. The tobacco yield, tobacco production costs vary in each region. In this case, the tobacco companies are faced with the problem of controlling the amount of production, total tobacco purchasing costs and production areas. Goal programming is widely used as a mathematical method for this purpose. By using 2015 data, it is shown that how this model can be utilized in the determination of contracted tobacco purchases in Turkey.

As a result, the model solution, both production areas, production quantity and production costs aspects, the Aegean Region by 62-68% has an important role; Black Sea Region 16-25% and Southeastern Anatolia Region 6-9% are followed respectively.

THE EFFECTS OF SEED PRIMING AND NITROGEN DOSES ON SEEDLING GROWTH TRAITS OF BREAD WHEAT (T*RITICUM AESTIVUM* L.) VARIETIES

Bekir ATAR[1*], Zekeriya AKMAN[2]

[1]University of Süleyman Demirel, Agricultural Research and Training Center, 32260 Isparta, Turkey

Abstract

This study was conducted to investigate the effects of seed pre-treatments (control, pure water, 100 and 200 ppm GA_3) and nitrogen doses (0, 25, 50 and 75 kg ha^{-1}) on seedling growth of bread wheat (*Triticum aestivum* L.). The field experiments were conducted at Süleyman Demirel University (Turkey), Agricultural Research and Experiment Station throughout the growing season of 2007-08 and 2008-09. The winter wheat cultivars, Dagdas-94, Bagci-2002, and Karahan-99 were used in these experiments. The seeds which had been soaked up for 3 hours before sowing had been air dried at room temperature and then planted. Nitrogen dosages were applied with planting. The effects of seed priming on seedling growth traits were found to be significant. Gibberellic acid treatment (200 ppm) reduced the mean time for 50% germination and increased the length of seedling nearly 33%. Due to increase in the length of seedling, its stems turned out to be yellow and white and lodged. The number of plants per square meter was not affected by nitrogen doses or seed priming. Compared to control and pure water treatments, GA_3 treatments led to an increase in seedling root lengths in both years. Nitrogen doses on the seedling growth traits were not found to be significant.

Key words: *Seed priming, Wheat seedling, Gibberellic acid, Nitrogen doses*

Introduction

Homogeneous and strong seedling emergence is one of the most important factors that affect quality and high yield in direct field planting. Priming treatments are widely used especially in emergence period for the purpose of minimizing the effects of negative environmental factors and improving yield and yield elements. The method is useful in promoting seedling growth and increasing seedling resistance in saline soil and minimizing the adverse effect of late sowing and water deficiency on yield (Mahmood et al. 2009). In addition, it affects germination speed, germination rate, homogenous seedling emergence (Parera and Cantliffe 1994), water use efficiency, harvest index and early blooming and harvest (Harris et al. 2001), protein rate and yield (Bhat et al 1990) positively. The purpose of the study is to determine the effects of seed priming that contains Gibberellic acid (GA_3) and different nitrogen doses on emergence and seedling traits in wheat.

Material and methods

The experiment field has silty, clayed, loamy soil and high lime rate and pH (8.1). Table 1 shows the climatological data obtained during the experiment. The bread wheat varieties Karahan-99, Dağdaş-94 and Bağcı-2002 were used in the experiment, which was designed in a split-split plot with three replications. 0, 25, 50 and 75 kg/ha^{-1} N doses, varieties, and seed priming were placed to main plots, upper subplots, and lower subplots, respectively. Four treatments were used:

control, pure water and gibberellic acid (GA_3) (100 and 200 ppm). The seeds were soaked in solutions and pure water for 3 hours, drained, and then surface-dried using blotting paper. They were dried at room temperature in the shade approximately up to their pre-treatment weights and put inside cloth bags to keep until sowing.

Table 1. Climatological data of province Isparta

	Mean temp. (°C)			Soil temp. at 5 cm. (°C)			Precipitation (mm)		
Years/ Mont.	**October**	**November**	**December**	**October**	**November**	**December**	**October**	**November**	**December**
2007-2008	14.4	7.5	2.7	16.2	8.3	4.0	30.7	91.8	97.2
2008-2009	12.8	9.0	3.7	14.4	10.1	5.0	32.0	60.0	5.4
Long term	12.8	6.9	3.0	13.9	7.6	3.4	38.0	51.5	70.9

Seedling emergence was followed up and counted on a daily basis. About 5 weeks after sowing, five plants were uprooted from each plot to determine seedling length and seedling root length.

Results and discussion

Mean time for 50% germination (E_{50}); E_{50} was not affected by varieties, nitrogen doses or interactions. GA_3 treatments, however, were highly effective in shortening emergence time in both experiment years (Table 2). This difference lasted approximately 2 days in the first year of experiment and 3 days in the second year of experiment. The difference between GA_3 doses seem to be insignificant.

Table 2. Effects of seed priming and nitrogen doses interaction on E_{50} (Day)

Emergence time was shortened as the first and second stages of germination had been completed by allowing the seeds to absorb water through pre-sowing seed treatments (Heydecker and Coolbear, 1977). Besides, it is reported that GA promotes germination (Leubner-Metzger, 2006) and GA_1 synthesis rapidly increases 24 hours after the first water intake by the seed (Woodger et al., 2004). Emergence time was 14.5 days on the average in the first year but decreased to 11.3 days in the second. Higher amount of precipitation was observed in the first year compared to the post-sowing long-term average (Table 1). It is thought that high soil moisture gave rise to a decrease in oxygen rate, slowing germination down (Corbineau and Come, 1995), and further that the temperature of 5cm-deep soil in November, which was 1.8^{o}C higher in the second year, accelerated emergence, resulting in differences between years in terms of emergence time.

The number of plants per square meter; The number of plants per square meter was not affected by nitrogen doses or seed priming (Table 3). In the first year, no difference was found between the varieties. However, in the second year, the highest value was encountered in Bağcı-2002 variety (385.3 plants).

Table 3. Effects of seed priming and nitrogen doses interaction on number plants per square (number)

During germination, environmental stress factors affected the varieties at different levels, which is thought to be a reason of the difference between the varieties. Variety x nitrogen dose interaction affected the number of plants per square meter in both years. In terms of the number of plants per square meter, the effect of nitrogen was not found to be significant. In both years, however, the highest values were obtained from 25 kg ha^{-1} N dose. It has been suggested also by other researchers (Geçit and Çakır, 2006) that nitrogen doses and varieties affect the number of plants per square meter. The average number of plants per square meter was found to be 316.3 in the first year but 366.4 in the second. The reason of the difference between years is thought to be environmental factors. Although different seed treatments have been reported to increase germination and emergence in laboratory and field experiments (Iqbal, 2004; Salehzade et al., 2009), no such results were obtained in our study. It is proposed that seed priming promotes early and homogenous germination, rather than increasing seed viability (Basra et al, 2005). Moreover, considering that not only seed priming but also soil structure and temperature affect final

emergence in field experiments (Hardegree and Vactor, 2000), pre-sowing seed treatments can have limited effect on the number of emerging seedlings as in our study results.

Seedling length; The effects of varieties and nitrogen doses on seedling length were not found to be significant individually. However, seed priming and years had an apparent effect on seedling length (Table 4). In both vegetation periods, the longest seedlings were obtained from 200ppm GA_3 treatments (9.9 and 17.7cm) and the shortest seedlings were encountered in control plots (8.8 and 14.0cm). GA_3 affects seedling length as elongated tissue cells and accelerated cell division (Sun, 2004). There are a great number of researches demonstrating that GA_3 leads to longer seedlings (Salehzade et al., 2009). As a result of our study, it was found that GA_3 treatments caused whitening in seedling stems and inclination in seedlings, which are presumed to arise from the high doses used. The difference in wheat seedling lengths between the two production years was considerably significant. The average seedling length was found to be 8.5cm in the first year of the experiment and 15.5cm in the second year. In the first year,

seedlings got shorter as the delay in emergence times and lower soil and air temperatures in November (Table 1) slowed down plant growth to a large extent. In fact, Tosun et al. (1975) stated that temperature difference could affect seedling length.

*, **: significant at P < 0.05 and P < 0.01 probability levels, respectively.

Seedling root length; Compared to control and pure water treatments, GA_3 treatments led to an increase in seedling root lengths in both years. However, the first year was found to be statistically significant (Table 5). No difference was detected between the pure water treatment and the control treatment in terms of seedling root lengths. Researchers suggest that seed priming has different effects on root length depending on the method employed (Basra et al., 2005) but mostly affects it positively (Afzal et al., 2005). These findings are in parallel with the result we achieved. Kujira et al. (1994), in the study they conducted on different nitrogen dose levels,

concluded that variety-based genotypic traits affected total root length. Differences were observed between the years in terms of average seedling root lengths. The average seedling root length was 20.3cm in the first year of experiment but seen to be 16.2cm in the second year.

Conclusion

GA_3 treatments on seeds significantly shortened 50% seedling emergence time. This trait can be recommended as a method to employ in the completion of emergence before soil moisture is lost in case of lack of rain, which has been encountered in recent years in sowing period due to climatic irregularities. Increased seedling length is useful in bringing deep-set seeds to the soil surface. In addition, trials of GA_3 treatments with lower doses are required so as to determine suitable doses.

DETERMINATION OF MYROBOLAN 29C ROOTSTOCKS REACTIONS AGAINST DROUGHT STRESS *IN VITRO* CONDITIONS

Muzaffer İPEK*, Lütfi PIRLAK

Department of Horticulture, Faculty of Agriculture, University of Selçuk, Konya/Turkey
*Corresponding author: mipek@selcuk.edu.tr

Abstract

In this study, it was investigated morphological response of Myrobolan 29C rootstock against drought stress establishing on culture media including different PEG (Polyethylene Glycol) levels. Three PEG levels (-0.5MPa, -1.0MPa, -1.5MPa) was used in order to make drought stress condition. Plants were measured at 0, 3, 5, 7, 9, 11, 13 and 15 days for morphological parameters (plant height, relative plant weight, leaf area, chlorophyll content) and collected leaves for proline and protein analysis. There were also measured the permeability of membranes and leaf relative water content (LRWC). The highest growth of plant height was obtained by control (4,04%), the lowest growth was obtained by -1,5MPa drought stress level (1,98%). Under all drought stress, plants died on 15 days of culture. The lowest drop rate of relative plant weight was measured from -1,5MPa drought stress level (18.22%). The lowest leaf area was determined to 1cm^2 in -1,5MPa while the highest leaf area was determined to control (2.77cm^2). According to the leaf membrane permeability, -1,5MPa (97.92%) was the highest. LRWC was the lowest in -1,5MPa drought stress level (2.44%). Total protein level increased from initial day to 3 days and after this time its level decreased under all drought application to end of study. The proline content decreased in -0,5MPa and -1,0MPa until end of 13. Days while proline content decreased after 9 days in 1,5MPa.

Keywords: *Drought Stress, Myrobolan 29C, Plant Tissue Culture*

Introduction

Water scarcity is an important environmental limitation to plant productivity (Farooq *et al.*, 2009). It was the catalyst of the great famines of the past. Because of the world's water supply is limiting, future food demand for rapidly increasing population pressures is likely to further aggravate the effects of drought (Somerville and Briscoe, 2001). The severity of drought is unpredictable as it depends on many factors such as occurrence and distribution of rainfall, evaporative demands and moisture storing capacity of soils. While drought stress increase respiration in plants under drought stress, it causes to decrease of plant growth, yield, photosynthesis and disrupts water and nutrient content (Farooq *et al.*, 2009).

Plants respond and adapt to survive under drought stress by the induction of various morphological, biochemical and physiological responses. As a morphological response, plants shortens life cycle or growing season to attain adaptation before the environment becomes dry. Flowering time is an important trait related to drought adaptation, where a short life cycle can lead to drought escape (Araus *et al.*, 2002). As a drought period persists and soil drying becomes more severe, the plant closes stomates but it becomes unable to maintain hydration even with the stomates closed (Verslues *et al.*, 2014). . In terms of physiological response, the low water availability in the soil decreases photosynthesis and carbohydrate accumulation (M. Chaves and Oliveira, 2004; M. M. Chaves *et al.*, 2003; Flexas *et al.*, 2004).

The plant tissue culture techniques are increasingly used for abiotic stress tolerance in numerous plants. *In vitro* culture conditions, stress treatments can be easily controlled so tissue culture techniques are useful for abiotic stress studies (Errabii *et al.*, 2006). Moreover, in vitro cultures provide uniform clonal propagated and synchronously developed plants without genetic instability (Tal, 1983). In addition, *in vitro* culture techniques limit environmental variations via defined plant growth media, controlled atmosphere conditions and homogeneous of stress treatments. Also, tissue culture techniques obtain large plant population in a small area and less period for stress treatments (Sakthivelu *et al.*, 2008).

Material and Methods

This study was carried out in laboratory for horticultural biotechnology at Selçuk University (Turkey) between 2012 and 2014. Plantlets of plum rootstock 'Myrobolan 29C' was propagated through *in vitro* nodal explant cultures.

Establishing Drought Stress Conditions

The drought stress conditions were established according to do Michel (1983) formulation at different osmotic potentials (OP) (0,0, -0,5MPa, -1,0MPa and -1,5MPa). The liquid MS basal media without plant growth regulators was prepared and then PEG was added into liquid media according to the Michel's formula (1983). The OP was calculated using the following formula:

OP= 1,29 x C^2 x T−140 x C^2−4 x C

OP= Osmotic potential

C = PEG quantity

T = Temperature

Measurements of Morphological Parameters

In this study, plants were measured at 0, 3, 5, 7, 9, 11, 13 and 15days for morphological parameters (plant height, relative plant weight, leaf area, chlorophyll content) and collected leaves for proline and protein analysis. There were also measured the permeability of membranes and leaf relative water content (LRWC).

Relative Water Content of Leaves

In order to determine RWC, leaves collected from control and drought stress treated plants were measured for the fresh weight first. Then samples were put into culture tube filled double distilled water for 4h at room temperature for turgid weight (hydration). The turgid weight was measured and leaves were dried in an oven 65°C for 48h. The RWC percentage was calculated using the following formula:

RWC (%) = (FW – DW) / (TW – DW) × 100

where FW is fresh weight, DW dry weight, and TW turgid weight.

Permeability of Membranes

Leaves of three plants per treatment were harvested 0, 3, 5, 7, 9, 11, 13 and 15 days and cut 1cm^2 leaf disks. Leaf disks were washed with three changes of double distilled water to remove surface-adhered electrolytes. Leaf disks were placed in culture tubes containing 10 ml of double distilled water and incubated at 25°C on a rotary shaker. Electrical conductivity of the bathing solution (EC_1) was determined by EC-meter after 24h. Samples were then autoclaved at 121°C for 15min. and a last electrical conductivity reading (EC_2) was obtained upon equilibration at 25°C. The electrolyte leakage was calculated as EC_1/ EC_2 and expressed as percent (Lutts *et al.*, 1996).

Chlorophyll Content

Leaves were harvested for Chlorophyll Content. Chlorophyll content of leaves was determined using portable chlorophyll reader SPAD-502 (Konica Minolta), measuring absorbance at 650 nm, as a non-destructive method. Three readings were made on each leaf. The results were expressed in SPAD units.

Proline and Protein Content Determination

Assessment of proline content was performed with acid-ninhydrin method according to Bates *et al.* (1973). The protein amounts in leaf extracts were determined by the Bradford method (1976) using bovine serum albumin as a standard.

Data analysis

All analyses were done using a completely randomized design with 3 replicates. All data were subjected to one-way analyses of variance (ANOVA). Duncan's multiple range test was used to separate statistically different means at $P < 0.05$ via SPSS 23.0 version.

Results and Discussion

Drought is a meteorological term and is commonly defined as a period without significant rainfall. Generally drought stress occurs when the available water in the soil is reduced and atmospheric conditions cause continuous loss of water by transpiration or evaporation (Jaleel *et al.*, 2009). Drought stress, which effect yield and plant growth, is one of environmental stress factors and triggers some physiological, biochemical and molecular mechanism (Ozfidan *et al.*, 2013). The studies of drought stress help to improve species and cultivars with determination of physiological and biochemical responses to drought stress.

We found that plants which were under drought stress, grew little during study. Plants were not surviving until 15.day and they dropped leaves. Because of leaves drooped, there is not data for plant weight, leaf area, membran permeability, LRWC, chlorophyll content, protein content and proline content without plant height in 15^{th} of drought stress. When OP level was increased, plants height of Myrobolan 29C slightly increased (Table-1). Sustainable plant growth and development depend on protection of plant water content. In case of deficit of water, cell division and development is limited so plants grow slowly (Bertamini *et al.*, 2006). Furthermore, photosynthesis rate is slowed due to lack of water and plant growth rate is decreased. Many studies result (Alizadeh *et al.*, 2011; Karimi *et al.*, 2012; Rostami and Rahemi, 2013) supported our study. Cell growth is considered one of the most drought-sensitive physiological processes due to loss of turgor pressure (Karimi *et al.*, 2012). Rostami and Rahemi (2013) reported that cell growth is limited due to loss of leaf turgor pressure.

In terms of dry plant weight, when OP levels were increased, dry plant weight markedly decreased compared to control. The most of losses of dry plant weight was calculated in -1.5MPa after 3^{rd} day of stress (Table-1). Our results are in agreement with the earlier reports (Abbaspour *et al.*, 2012; Bolat *et al.*, 2014). Decreased dry matter accumulation of leaves as a result of stress may be attributed to the altered carbon and nitrogen metabolisms (Kluge, 1976).

Karimi *et al.* (2012) reported that leaves under drought conditions shows that leaf area development is more sensitive than dry weight accumulation in the leaves. Leaf growth is more sensitive than root against drought stress. Decreasing of leaf area helps to plants under water deficit. The excess of carbon in leaves was transferred to root and it improves root and increases root mass. Furthermore, small leaf area has low transpiration rate and loss less water (Taiz and Zeiger, 2002). In our study, leaf area was decreased when drought levels were risen. The smallest

leaf was obtained from -1.5MPa treatment (Table-1). The results of our leaf area agreed with Nogues and Baker (2000) in olive and Klamkowski & Treder (2008) in strawberry.

Under stress conditions, membrans are damaged by reactive oxygen species (ROS). The membrans which are damaged, cause to leaking of ions into intracellular space. Ions damage cells which are responsible for regulators of osmotic potential and enzyme activity. We found that when drought levels and time were increased, membran damages were heavily observed. Membran permeability rates were range from 86,55% to 97,92 in 13.day. Our data were agreed with Chai *et al.*(2005) in banana, Karimi *et al.* (2012) in 5 almond cultivars and GF 677 rootstock and Zonouri *et al.* (2014) in grape.

Typically, as the water content of the plant decreases, its cells shrink and the cell walls relax. This decrease in cell volume results in lower turgor pressure. Water stress limits not only leaf size, but also leaf number (Taiz and Zeiger, 2002). Under drought stress, Myrobolan 29C plantlets had lower LRWC rates than control. During stress study, the highest average of LRWC rate were observed in control plants with 45%, while the lowest average of LRWC rate was obtained from -1.5MPa drought stress level with approximately 8%. The study results of Boutra *et al.*(2010), Keyvan (2010), Ghaderi and Siosemardeh (2011) are similar to our LRWC result.

Water is important for chlorophyll synthesis. Following a heavy rain, the chlorophyll content of plant leaves will often increase, but during a drought, the chlorophyll content will decrease. On the other hand, if the soil is saturated with water, this results in a decrease in the chlorophyll content of the leaves. The water content of the leaf must be high for maximum chlorophyll content. In our study, chlorophyll content decreased due to drought levels and time of stress treatment. When the control plants had about average of 30ppm throughout 13 days, chlorophyll content in -1.5MPa drought level markedly decreased (26,5 to 9,19ppm). Some researcher reported that plants has lower chlorophyll content under drought condition (Alizadeh *et al.*, 2011; Ghaderi and Siosemardeh, 2011; Rad *et al.*, 2012; Zanjani *et al.*, 2012).

Drought stress causes to changing of protein metabolism and protein synthesis is decreased (Kutlu, 2010). Protein content increased until 10^{th} day in all stress treatments aftermath it's level slightly decreased. This would indicate that the protein buildup occurred up to 10^{th} day of drought stress. Increases in protein content suggest that under water stress conditions synthetic activity is enhanced to accommodate increased metabolic activity for maintaining the osmotic balance (Ali-Ahmad and Basha, 1998). Similar results were found some researcher such as Brito *et al.* (2003) in olive, Bertamini *et al.* (2006) in grape, Behnamnia *et al.* (2009) in tomato.

Stresses such as cold, heat, salt, drought, UV and heavy metal cause significant increase in the proline concentration in a variety of plants. This increase occurs over several hours or days. Interpretations of proline accumulation vary from its role as a useful adaptive response, helping organisms to withstand the effect of stress, to merely a consequence of stress induced damage to the cells. Therefore, proline may not be just a by-product of stress defense, but a chemically active compound, crucially involved in the physiology of stress protection (Ashraf and Iram, 2005). Similar results were reported Abbaspour *et al.* (2012), Rostami and Rahemi (2013) and Bolat *et al.* (2014).

Conclusion

In this study, performance of Myrobolan 29C, which was used extensively for plum and apricot, were determined in drought condition. The obtained data showed that Myrobolan 29C is susceptible drought stress. There was no survived plant in all stress level on 15.day of study except for control plants. The maximum plant height was obtained from control plants (3,09cm). Dry plant weight was higher in control (47.87%) than stress conditions. The largest leaf area was measured in control plant (2,77cm^2). The highest membran permeability was calculated in -1,50MPa stress level (97,92%). The highest rate of LRWC was in control plants (42,58%) while the lowest rate of LRWC was obtain from -1,5MPa treatment (2,44%). The chlorophyll content in control plant (28,66ppm) was higher than other treatments. The highest protein content was calculated in -1,5MPa (667,73µg g^{-1} FW). The -1,0MPa treatments had the highest proline content (29,52 µg g^{-1} FW).

Abstract

Cover crops are specific system of growing and mainly cover the surface of the soil during the winter, improve the physical and mechanical properties of the soil, water regime, increase the content of nutrients, reduce weed control and contribute to the achievement of higher yields of the main crops. The experiments were performed in 2014 and 2015 on experimental field of the Maize Research Institute in Zemun Polje. We have included individual winter cover crops: common vetch, oat, fodder kale and field pea, mixtures common vetch and field pea with oats and two control treatments: dead organic mulch and conventional (traditional) variant. Sowing cover crops is carried out in the autumn, the elementary plots of 35 m^{-2}. Mowing and soil incorporation of cover crops was carried out in late April. Sowing popcorn was done manually in mid-May at a density of 65 000 plants ha^{-1}. In the phase of intensive growth of the popcorn, is determined total number of weed species, total number of plants per species and fresh biomass per m^{-2}. In a year that was rich precipitation (2014), the smallest number of plants per species and fresh biomass of weeds per square meter have been established on the variant with common vetch as a cover crop. The fresh biomass of weeds in the two control treatments (dead organic mulch and conventional variant) was the highest (694.5 and 524.2 g m^{-2}). In 2015, data about weed infestation differed in relation to the previous year, both in terms of total number of weed species and total number of plants per species, but also in terms of fresh biomass per unit area. We can be concluded that perennial weeds could be controlled effectively by sowing cover crops.

Key words: *cover crops, dead organic mulch, popcorn, weed infestation.*

Introduction

Popcorn (*Zea mays* L. ssp *everta* Sturt.) is a specific type of flint maize, and popcorn that are formed from grains of popcorn are the favorite "snack" of people around the world (Srdić and Pajić, 2008). Growing popcorn without irrigation in the conditions of global climate change is a major challenge. As with other subspecies of maize, the yield is a very important feature, but the specificity of popcorn is that it is susceptible to infestation, especially in the beginning of the growing season. In addition to the quantity of the yield, is also important qualitative component, especially popping volume. That is why in recent years the most important goal of the breeding program popcorn correction quality yield but not at the expense of quantity. Aggravating factor in this process is that there is generally a negative dependence on these two yield components (Sakin et al., 2005), while increasing the popping volume causes a decrease in yield.

Popcorn is a direct human food crop, and the current public apprehension to genetically modified foods has prevented the use of genetic engineering to add genetic resistance to herbicides in

popcorn hybrids. Grosbach (2008) cited that narrow popcorn rows may canopy more quickly, some weed control should be expected that might normally be controlled by herbicides or mechanical cultivation.

Agriculture is an ever-changing industry. Producers are always looking to improve their production practices to make the most efficient use of inputs and resources in order to increase production and maximize profit. Correct choice of the growing system is particularly important for crops that are less represented in crop structure, and interesting for an early appearance on the market in such large quantities. The introduction of cover crops in cultivation systems popcorn has full justification, particularly in terms of increasing grain yield through reduction of weed infestation, soil protection and reduced application of fertilizers. Cover crops are a fundamental tool for weed control, especially in organic and low input farming. Species with different functional traits can be combined in mixtures to enhance weed suppression (Ranaldo et al., 2016). They identified 8 species belonging to 4 functional groups: large seeded legumes, characterized by higher height (*Pisum sativum* L., *Vicia sativa* L.), small seeded legumes, able to cover quickly the soil (*Trifolium incarnatum* L., *T. squarrosum* L.), highly competitive grasses (*Hordeum vulgare* L., *Avena sativa* L.) and allelopathic brassicas (*Raphanus sativus* L., *Brassica nigra* L.). Weed establishment and growth can be constrained by cover crops through different physical and chemical mechanisms, so they can be considered as potential biological filters in weed community. The seedbank determination can provide useful information of the longterm effect of management practices in weed control (Alonso-Ayuso et al., 2016) and after 8-years of cover crops rotation, differences in weed composition were found. The seedbank was dominated by *Amaranthus* sp. and *Setaria* sp. (>80%). Cover crops reduced the density of *Datura stramonium* L., *Polygonum* sp, and *Portulaca oleracea* L. However, it was remarkable that both of them enhanced the population of *Setaria* sp., and *Chenopodium album* L. density was higher in barley treatment. Hairy vetch, is widely utilized as winter cover crop in Mediterranean areas, but besides its soil fertility building capacity, the weed control potential of vetch is acknowledged by different species of vegetable (tomato-Testani et al., 2016 or sweet maize- Dolijanović et al., 2013). After vetch termination, allelopathic compounds of residues (i.e. cyanamide) can play a role in weed growth inhibition.

Cover crops are commonly used to suppress weeds prior to establishment of a main crop, along with other benefits (Reiss et al., 2016). Based on natural ecosystem characteristic, which has a positive relationship between diversity and productivity, we expect that more diverse cover crop mixtures would produce more biomass and consequently reduce weed biomass. The objective of this study was to determine the effect of different winter (dead mulch) cover crops and their mixtures with oats on weed infestation of popcorn.

Material and methods

The experiment included four kinds of winter cover crops (common vetch, oat, fodder kale and field pea as well mixtures of legume crops with oats), another variant in which the land was covered with dead organic mulch, and traditional variant, classical plowing in the fall and keeping bare land uncovered during the winter. All of the varieties being used as a cover crops belongs to Novi Sad Field Crops Institute. Crops were grown under rainfed conditions.

Field experiments were conducted in 2013/14 and 2014/15 at Maize Research Institute, Zemun Polje, in the vicinity of Belgrade (44°52'N 20°20'E). The soil was slightly calcareous chernozem with 47% clay and silt, and 53% of sand. The soil properties in layer 0-30-cm of depth were fallow: 3.22% organic matter, 0.19% total N, 1.9% organic C, 16.2 and 22.4 mg per 100 g soil of available P_2O_5 and extractable K_2O, respectively, 1.38% total $CaCO_3$ and pH 7.3. The experiments were located

in different plots in each year and winter wheat was the previous crop. Fallowing nitrogen fixation rates in legume crops, as well recommended fertilization, we came up to the required amount of macronutrients for popcorn (120 kg ha^{-1} N, 90 kg ha^{-1} P_2O_5 and 60 kg ha^{-1} K_2O). In the fall period, before planting of cover crops we have entered the entire amount of P and K in the forms of monopotassium phosphate plus additional quantity of nitrogen 50 kg/ha by ammonium nitrate, and on the two control variants, also all of P_2O_5 i K_2O and 40 kg ha^{-1} N in the form AN.

In the next spring (May 20, 2014 and May 21, 2015) leguminous cover crops had received another 30 kg ha^{-1} N in the form of AN (remaining 40 kg ha^{-1} considered to be provided by nitrogen fixation), oats an fodder kale 70 kg ha^{-1} N, and control plots another 80 kg ha^{-1} N, also in the form of AN. The experimental plots being ploughed in the autumn, have followed one pass of a disk harrow and a field cultivator prior to sowing. Sowing of cover crops were done manually in October 30, 2013 and November 13, 2014. Mowing the above-ground biomass of winter cover crops were performed 7-10 days before planting of popcorn. Planting of popcorn seedlings were done on May 20, 2014 and May 21, 2015. Crops were harvested on October 07, 2014 and September 30, 2015. The meteorological conditions during the growing season are presented in Table 1.

Table 1. Average air temperatures and precipitation sums from April to September at Zemun Polje

Months	Temperature (°C)		Precipitation (mm)	
	2014	2015	2014	2015
April	13.7	12.9	84.8	19.7
May	17.4	19.1	192.5	97.8
June	21.1	22.1	71.2	31.1
July	23.2	26.4	187.4	7.2
August	22.6	25.7	41.0	56.0
September	18.0	20.2	75.6	73.6
Average/Sum	19.3	21.1	652.5	285.4

More favourable conditions in term of quantity and distribution of precipitation were in the first year of the investigation. Popcorn needs for precipitations depend on its development phase and they were lower at the beginning of growing period (about 100 mm), the highest (150–200 mm) in the period of flowering and ears formation. The first year examination also characterized by optimal air temperatures, which has had an effect on the studied parameters weed infestation of popcorn. Precipitation in June and July 2015 was the lowest and air temperatures were the highest and it caused a greater the appearance of weeds that are resistant to drought.

Experimental design

The experiment was in factorial setting with two factors in RCBD with four replications. Popcorn was sown in density of 65.000 plants ha^{-1}. The inter-row distance was 70 cm, while within-row plant distance was 22 cm. The new Zemun Polje (ZP) popcorn hybrids ZP 611k (FAO maturity group 600) was sown. The basic plot size was 16.8 m^2 (2.8 m by 6.0 m).

Measurements and statistical analysis

The fresh and air dried weed biomass in popcorn were analysed in this study. All stated parameters in weeds were determined from samples taken from $1m^2$. The weed infestation analysis was performed on June 27, 2014 and June 22, 2015. Following weed sampling, manual hoeing was done in order to suppress weeds pressure in sweet maize. The yield data were underwent to ANOVA for the factorial trials set up according to the plan for two years, eight variants, where means differences were tested by the least significant difference (LSD) test.

Results and discussion

Generally, the greater weed infestation can be observed in the second year of the investigation and the reason for the worse weather conditions, especially high air temperatures and unfavourable distribution of precipitation which corresponds to more resistant weed species. Different effects in the soil-plant system by cover crop species (i.e. temperature and soil moisture, light interception) are very important to explain differences between investigation treatments. Differences in measured parameters of weediness depending on the year investigation were statistically significant, except for the aboveground fresh weight of weeds (Table 3). The dead organic mulch (straw) is justified in sustainable systems of cultivation of popcorn, primarily in terms of grain yield (Dolijanović et al., 2012). However, from an infestation, especially perennial species, the advantage is on the side of growing cover crops. The number of plants per species in mulch variant usually was higher than in treatment with cover crops, but fresh weight mass shows us a strong presence of perennial weeds (Table 2).

If you look at the impact of investigation kinds of cover crop on the infestation of the main crops we notice that in average the best result given fodder kale, oat and mixture of common vetch and oat in terms of number of species. Common vetch gave the best result in term of the number of plants per species (6.75 m^{-2}). After vetch termination, allelopathic compounds of residues (i.e. cyanamide) can play a role in weed growth inhibition (Testani et al., 2016). However, in terms of number of plants per species and especially in respect of fresh weed biomass per unit area advantages had cover crops which gave highest aboveground biomass (common vetch, field pea, mixtures and fodder kale). Reiss et al (2016) and Ranaldo et al (2016) cited that mixtures of multiple cultivars of a single species tend to suppress weeds better (as biomass) than the average of the same cultivars planted alone. The improved weed suppression in cultivar and species mixtures suggests alternative mechanisms for reduced weed success in these diverse cover crop mixtures.

In all tested parameters, weeds in both investigation year significantly highest values are obtained in conventional treatment, especially in term of aboveground fresh weight of weeds. Winter oat showed the strong effect, especially in terms of the number of weed species and the number of plants per species. In earlier paper, it was emphasized that in terms of reducing the infestation of the main crops, oats gives the poorest results and generally it should be grown in mixtures with legumes (Dolijanović et al., 2013). Liebert et al (2016) investigated effect of mixture barley and cereal rye on the weed suppressive ability of each cover crop in monoculture (barley:cereal rye, 0:100 and 100:00) and in mixture (25:75, 50:50, and 75:25). Weed biomass tended to decrease as the proportion of cereal rye increased; however, they observed disproportionately lower weed biomass than expected in some mixtures given the relatively low cover crop biomass produced.

The differences investigated parameters of weeds, except the number of weed species, in popcorn cultivated after cover crops compared to traditional cropping system are generally statistically significant (Table 3). On the investigated locality, alternative farming systems (intercrops and

cover crops) showed efficacy in reducing weed infestation, particularly the number of plants per species and weed fresh weight per unit area (Dolijanović et al., 2007; 2015).

Observing the two control variants (dead organic mulch and conventional treatment) in both years, based on data in Table 2, we see higher values in the fresh weight of weeds in the conventional system in relation to the dead organic mulch variant. Increasing the biodiversity and number of crops in year per unit area, as in cover cropping, leads to a reduction in the biomass of weeds, more diverse cover crop mixtures would produce more biomass and consequently reduce weed biomass (Reiss et al., 2016). This is consistent with previous research showing that narrow-row corn canopies more quickly, reducing weed emergence (Staggenborg et al., 2001). Because popcorn is not genetically modified for herbicide resistance, narrow rows may be an effective cultural weed control option. Even with fewer weeds, harvest conditions were not ideal and the narrow-row corn header did not handle the weeds very well.

Conclusion

The weed community was composed of a relatively small number of weed species and number of plants per species–3.47 and 11.81 (2014) and 5.81 and 8.22 (2015). Differences in the number of weed plants per species, as well as in air dried weed biomass obtained among observed investigation years were statistically significant. Favorable weather conditions during the first year of trials have resulted in an decreasing number of weed species and fresh weight of weeds, but no number of plants per species of main crop. In dry 2015 oat as an individual cover crop and in mixtures with legumes and dead organic mulch, in terms of fresh weight of weeds measured in main crops were the advantages compared to 2014. The cover crop with common vetch expressed greater efficiency in weed control in comparison to different cropping systems.

Growing cover crops before popcorn expressed a significant advantage in weed control particularly in troublesome perennial species in relation to traditional cropping system. In addition, cost inputs were reduced, but no other common benefits in the long term were found on winter cover crops (increase of organic matter, increase of biodiversity, etc.). The obtained results can help to understand the complexity of plant communities interactions but more research is needed in order to achieve effective weed control strategies.

Acknowlegdement

This study was supported by the Ministry of Education, Science and Technological Development of the Republic of Serbia.

Abstract

The spread of silage maize production in Turkey caused significant increase at population level of corn borer, Sesamia cretica Led. (Lepidoptera: Noctuidae) In the management of this pest general insecticides, such as organic phosphates and synthetic pyrethroids are used. Its damage still occurs in corn fields, in spite of the use of biological control agents, such as entomopathogenic fungi, nematodes or bacteria and egg-larval-pupa parasitoids, as well as Bt-maize, as a popular application for management of S. cretica. In order to detect more effective microbial control agents against this pest and contribute to the integrated pest management studies of corn borer, a study of insecticidal effect of 18 different isolates of entomopathogenic fungi *Beauvaria bassiana* obtained from soil collected from different fields crop production areas in Tokat Province in 2015. The isolates consist of *B. bassiana* isolates (GOPT-19(2)-1, GOPT-41-1, GOPT-64, GOPT-107, GOPT-114, GOPT-122, GOPT-127, GOPT-144, GOPT-167, GOPT- 221, GOPT-284, GOPT-294, GOPT-302, GOPT-355, GOPT-440, GOPT-453, GOPT-458, GOPT-465). Pathogenicity of tested isolates to *S. cretica* was evaluated by dipping larvae (fourth instar) to spore suspension from each isolate. Within 9 days, all fungal isolates caused significant mortality against larva of *S. cretica*. *B. brassiana* isolates GOPT-144 was found to be the most virulent with 90.83% mortality among investigated fungal isolates, followed by GOPT-64 (75.42% mortality) and GOPT-107 (63.75% mortality) against the *S. cretica*. These results indicated that isolates with high virulence could be used for biological control and integrated management of *S. cretica*.

Key Words: *Sesamia cretica*, Corn borer, entomopathogen, *Beauvaria*

Introduction

Maize (*Zea mays* L.) is economically important cereal crop all over the world. Green maize plants as well as maize grains (corn seeds) are a significant source of nutrients for live stock fodder worldwide. In terms of world area and production, maize occupies the 3rd place after wheat and rice (Anonymous, 2015). Moreover, several food industries stand on processing maize grain and their by products, e.g. corn oil, corn flakes, starch, fructose etc. In Turkey, corn is produced on approximately 550 thousand hectares with annual production of 3.5 million tons. Production rate of corn as a second crop in most parts of the Turkey is very high (Özcan, 2009). Under field conditions, *Sesamia cretica* begins to attack maize seedlings within 1-2 weeks after seed germination, and continues invading until they become about 6 weeks old. Occasionally, *S. cretica* infestations may also occur on the mature plants where its full-grown larvae excavate into the stems creating relatively longitudinal tunnels full of larval feces. Similar tunnels may also be seen inside the basal secondary roots, ears and cobs. Infested young seedlings often die and show the characteristic dead-heart symptoms while older plants suffer severe yield-losses (Mostafa,

1981; Semeada, 1988; El-Naggar, 1997). General insecticides, such as organic phosphates and synthetic pyrethroids are used for the management of this pest. Even though the most popular measures like application of biological agents (entomopathogenic fungi, nematodes, bacteria and egg-larval-pupa parasitoids) and planting Bt-maize are regular, damages from *S. cretica* still occur in corn fields. In order to detect more effective microbial control agents against the pest and contribute to the integrated pest management studies of corn borer, we studied the insecticidal effects of 18 different *Beauvaria bassiana* entomopathogenic fungi isolates obtained from field soil collected from different parts of Tokat Province in 2015.

Materials and Methods

Insect

Sesamia cretica larvae were initially collected from crop fields in Şanlıurfa. The larvae used in our experiment were in fourth instar.

Preparing of Inoculum

The entomopathogenic fungal isolates were transferred on PDA (Potato Dextrose Agar) from stock cultures for spore production. The fungus cultures were incubated at 25±2 °C for 17 days. Ten ml of sterilized water with 0.02% Tween 80 was added to each plate and spore harvesting was done by gently rubbing the culture surface using a sterilized glass hokey. Spore suspension from each isolate was adjusted to 10^7 spores mL^{-1}.

In-vitro Efficacy of the Isolates

In this efficacy study, all 18 *B. bassiana* isolates (Table 1) were screened against larvae of *S. cretica*. Fourth instar *S. cretica* larvae were treated in a Petri dish by dipping into the spore suspension for 5 sn. Five larvae were introduced in each Petri dish with filter paper and young fresh corn ear inside. Sterile distilled water with 0.02% Tween 80 was used as negative control. Treated larvae were incubated at 27 °C and 70 ± 5% of relative humidity and maintained for 9 days. The experiment was set up in a Complete Randomized Design with three replications. In the course of the experiment, data on mortality was recorded at the end of 9th day after inoculation. The dead larvae were collected and held in conditions of high humidity in Petri dishes containing damp filter paper to provide sufficient humidity to promote fungal outgrowth. Petri dishes were incubated in the dark at 95% relative humidity and 27°C. Larvae were considered damaged by mycosis when growth of the fungus was visible on the external surface at the end of 14 day incubation period (Figure 1).

The effect of entomopathogenic fungi (EPF) isolates on the larval mortality was analyzed using one-way analysis of variance using SPSS 17.0 (SPSS, 2008) and means were compared using Tukey multiple comparison test ($p \leq 0.05$).

Results and Discussion

There is an increasing demand for finding more effective and safer methods to control plant pests. One way to achieve this is finding effective biocontrol agent against insect pests in agricultural areas and hence decrease the hazardous effects of chemical insecticides to the environment and other living organisms. Among the biocontrol agents entomopathogenic fungi are of greater interest since they are host specific and almost no hazard to the environment and

untargeted organisms. The entomopathogenic fungus *B. bassiana* is a well-known, naturally occurring and widely distributed pathogen of various lepidopteran pests and registered biopesticides based on this fungus are available for use against wide variety of insect pests (Zurek and Keddie, 2000; Sevim *et al*., 2010; Wraight *et al*., 2010). In the current study, fungal pathogens of *S. creatica were* tested as a possible biocontrol agent that can be used in the corn fields. In the present study, 18 *B. bassiana* isolates were tested against *S. creatica* in *in vitro*. Within 9 days of incubation period, some of the isolates caused significant mortality against larva of *S. cretica*.

Beauvaria bassiana isolates GOPT-144 was found to be the most virulent with 90.83% mortality among investigated isolates, followed by GOPT-64 (75,42% mortality) and GOPT-107 (63,75% mortality) (Table 1). Based on the cumulative mortality over the first 9 days it can be seen that some of the isolates of *B. bassiana* controlled more than 60% of the larval population of *S. cretica* (Table 1). The highest virulence was recorded from the isolate GOPT-144. The lowest mortality rate (35%) was obtained with isolate GOPT-302. Similarly, *Beauveria* (M7A and F11A) isolates caused high rate of mortality on *Sesamia calamistis* larvae within 4 days of incubation periods (Terefe *et al*., 2012).

Table 1. Efficacy of local *Beauveria bassiana* isolates ($1x10^7$) spore/ml on *Sesamia cretica* at the end of 9th day incubation period.

*Values in the same column followed by the different letters were significant different at the $p<0.05$ level according to Tukey multiple range test tests

The highest mycelial development rates also were observed in treatments with isolates GOPT-144 (53.85 %), GOPT-355 (33.33 %) and GOPT-284 (28.27 %). This is followed by GOPT-294 (20 %), GOPT-167 (16.7 %) and GOPT-19(2)-1 (8.25 %). On the other hand, some of the isolates did not developed mycelial development on dead insects (Figure 1).

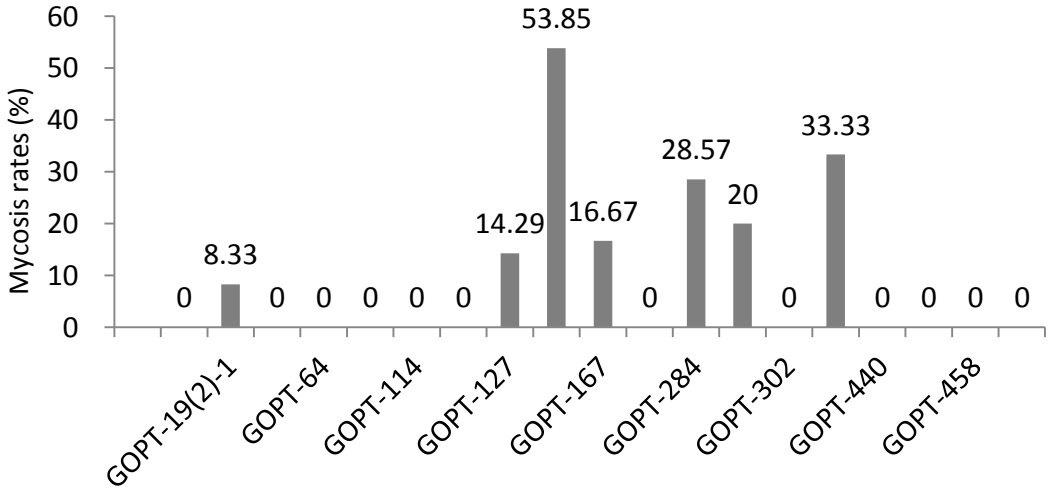

Figure 1. Rates of mycelial development of *Beauveria bassiana* isolates ($1x10^7$) spores mL^{-1} on *Sesamia cretica* 14 days post infection

Conclusion

Beauvaria bassiana GOPT-144 isolate caused 90.83 % mortality and 53.85 % of mycelial development rate. This isolate is very promising one among the tested isolates. This one is followed by GOPT-284 (66.25 % mortality and 28.57 % mycosis) and GOPT-355 (60 % mortality and 33.33 % mycosis). Beside the mortality rates mycosis rates are also important for continuity of fungal infection. Addiss (2008), grouped the entomopathogen fungi as most virulent (84.8-98.32), moderately virulent (40-73) and weak virulent (<40) based on percent mortality. When we done the similar type of grouping GOPT-144 isolate was highly virulent, GOPT-19(2)-1 GOPT-64 GOPT-107 GOPT-122 GOPT-167 GOPT-221 GOPT-284 GOPT-355 GOPT-453 were moderately virulent and rest of them were of weak virulence. These results indicated that isolates with high virulence could be used for microbial and integrated management of *S. cretica.*

Abstract

Plant growth and nutrient uptake and yield can be supported by the use of biostimulants. The study aimed to assess NPK and S accumulation by winter oilseed rape after biostimulant application at varied NPK and S fertilization levels. The field experiment was located in Poland (53°13'N; 17°51'E), conducted in 2011-2013, on a typical Alfisol (USDA). In this experiment the applied levels of NPK were as follows: high (180 N, 70 P, 132 K kg ha^{-1}) or low (144 N, 35 P, 66 K kg ha^{-1}), elementary S fertilization (36 or 0 kg ha^{-1}) and the application of biostimulant Kelpak (2 l ha^{-1} in autumn + 2 l ha^{-1} in spring) or without the preparation. Kelpak is obtained from marine alga (*Ecklonia maxima* Osbeck) and contains auxins and cytokinins (11 and 0.031 mg l^{-1}). This study indicated that the higher NPK rates or S fertilization as well as the use of the biostimulant increased NPK and S accumulation in the plants of oilseed rape during generative development stages. Biostimulant application in rapeseed with lower NPK or without S increased N and P accumulation to the level obtained at higher NPK and with S, without biostimulant. At the fruit development stage S fertilization increased the accumulation of N, P and K in oilseed rape, but only in the case of high doses of NPK. At flowering and maturing, S accumulation was by 10% higher after the application of biostimulant and without S fertilization as compared with that found in rapeseed fertilized with this element but without the preparation.

Introduction

Oilseed rape is one of the most important oil crops in Europe. In recent years (2012-2014) it has been grown in an area of 9 M ha, and the mean seed yield amounted to 2.7 t ha^{-1} (FAOSTAT, 2016). One of methods for increasing the yield of this species may be application of biostimulants. Among them, preparations produced from marine algae are an important group (Craigie 2011; Sharma et al. 2014). Favourable effects of extracts from algae indicate the usefulness of their use in horticultural and agricultural crops (Craigie, 2011; Khan et al., 2009). It was also proved that they improve the uptake of macro and microelements (Billard et al., 2014; Jannin et al., 2012), which may have a favourable impact on the quantity of yield. For winter oilseed rape the important nutrients are K and P. Despite the high soil abundance in P and K, plants may be malnourished (Gaj, 2011). Potassium is taken up by rapeseed in greatest amounts (Szczepaniak, 2014). Insufficient availability of this nutrient limits the plant growth and yield quantity (Govahi and Saffari, 2006). P deficiency in turn restricts both shoot and root growth (Wang et al., 2015). Sulphur is an essential element for plant growth that increasingly limits crops production in several regions of the world. In comparison with cereals, oilseed rape requires a large amount of mineral S (Zhao et al., 1997). A deficiency in S can reduce the amount

and the quality of seed yield (McGrath and Zhao, 1996). According to Wang et al. (2015), balanced application of nutrients should be considered with aim to build an appropriate population structure with balanced plant density and individual growth of rapeseed. The aim of this study was to assess NPK and S accumulation by the winter oilseed rape (roots and shoots) at successive stages of generative development: flowering, fruit development and ripening, after the application of a biostimulant in condition of varied NPK fertilization levels as well as after and without fertilization with S.

Materials and Methods

The study was based on the field experiment located in Poland, in Kuyavian-Pomeranian region (53°13´N.17°51´E), conducted in 2011-2013, on a typical Alfisol (USDA). The topsoil was characterized by a medium content of available P (64.0 mg kg^{-1}) and high of K (126.0 mg kg^{-1}) and a slightly acidic reaction (pH in 1M KCL 5.7-6.1). The content of organic carbon (7.55-7.80 g kg^{-1}) and total nitrogen (0.69-0.75 g kg^{-1}) in the soil was relatively low. The subject of this study was winter oilseed rape of the population variety Chagall. The factors were: NPK fertilization rates high (180 N, 70 P, 132 K kg ha^{-1}) or low (144 N, 35 P, 66 K kg ha^{-1}), elementary S fertilization (36 or 0 kg ha^{-1}), and the biostimulant Kelpak application (2 l ha^{-1} in autumn, after formation of 4-5 leaves + 2 l ha^{-1} in spring, 10-15 days after starting growth) or without the preparation. Kelpak is obtained from marine alga (*Ecklonia maxima* Osbeck) belonging to the division of brown algae, collected on the coast of Africa. It contains phytohormones: auxins and cytokinins (11 and 0.031 mg l^{-1}, respectively), alginians, amino acids, as well as macro and microelements. Rates commonly used in the farm were assumed to be a low fertilization rates. High fertilization level was determined taking into consideration soil abundance, unit uptake and the expected yield. Mineral fertilization into soil with P (triple superphosphate), K (potash salt) and S (Wigor S) was applied presowing in autumn, whereas nitrogen (ammonium nitrate) in spring, at starting growth (100 kg ha^{-1}), and the other part after 3 weeks. The experiment was established in the randomized split-block design, in four replications, and the plot area amounted to 13 m^2. Plant samples were collected three times every 30 days at the following developmental stages: flowering, development of fruit and ripening, from the area of 0.5 m^2. Accumulation of elements was expressed as a product of their content and the amount of the dry matter of the aboveground part and the roots. P content was determined with the vanadium-molybdenum method and K with the flame photometry. The content of nitrogen was determined with the Kieldahl method and sulphate turbidimetric method. The obtained results were statistically worked out in the software Statistica, with the method of the analysis of variance ANOVA, and the differences were estimated with Tukey's test at $\alpha = 0.05$.

Results and Discussion

The study indicated a significant effect of fertilization with NPK and S as well as the biostimulant Kelpak on accumulation of P and K in oilseed rape plants (Table 1.) During flowering, development of fruit and ripening, the accumulation of P and K in the oilseed rape plants increased after the application of higher rates of NPK as compared with the effect of lower rates. Similar results are presented by Szczepaniak (2014). In his study, K accumulation in oilseed rape at flowering and ripening was higher if the plants were fertilized with NPK as compared with control (without fertilization). Zou et al. (2011) in turn proved an increase in K uptake after the use of fertilization with this element. The present study showed that the application of the biostimulant increased P and K accumulation in plants almost in each analyzed developmental stage (Table 1). Moreover, irrespective of fertilization with S, P and K

accumulation in rape fertilized with higher NPK rates without the biostimulant was similar to that found after the application of lower rates and foliar application of Kelpak. Increase in P and K uptake after the application of biostimulants from algae was also shown in the studies of other crops (Shah et al., 2013). The effect of these preparations results from the stimulation of physiological processes responsible for the plant growth (Kurepin et al., 2014). The study

by Jannin et al. (2012) proved an increase in the expression of genes responsible for nutrient uptake of oilseed rape after the application of algae preparations. In the present study also fertilization with S had a favorable effect on P and K accumulation (Table 1). At the fruit development stage S fertilization increased the accumulation of P in the biomass of oilseed rape, but only in the case of high doses of NPK. Identical relationship was indicated for K accumulation at the fruit development stage and at the ripening. The literature data shows that the accumulation of the given element by oilseed rape depends on the availability of the other ones. Wang et al. (2015) claim that P uptake reduces N and K deficiency and K uptake is lower both at the lesser availability of this element but also at deficiency of N and P. Application of some nutrients (e.g. N) has a strong effect on dry matter increase, which results in increased demand for the other elements. Giovahi and Saffari (2006) indicated K and S interaction in dry matter production. Brenan and Bolland (2009) proved that for obtaining high yields of oilseed rape at a growing level of fertilization with N it is necessary to increase P and K rates.

Increasing the NPK rates resulted in an increase in N uptake by oilseed rape plants at flowering, fruit formation and ripening (Table 2). Nitrogen uptake at these developmental stages on average for the other factors also increased after the application of sulfur.

At the fruit formation stage nitrogen accumulation in plants was higher after presowing sulfur fertilization only in the case of increased rates of NPK fertilization. Also other authors point the relationship between the uptake of N and other macroelements. According to Gaj (2011), K deficiency limits N accumulation and transport, which leads to reduction in growth and assimilation area. Szczepaniak (2014) proved that N accumulation at the beginning of flowering of rapeseed depended on K accumulation in the aboveground part.

A favorable effect of the biostimulant on N uptake was found At each of analyzed developmental stages (Table 2). Moreover, it was proved that irrespective of S fertilization, N accumulation in oilseed rape treated with the biostimulant after the application of lower NPK rates was similar to that found at a higher NPK fertilization level without the biostimulant. In the study of oilseed rape it was stated that the extract from algae increased accumulation of N as well as of P and Ca (Billard et al., 2014). Those increases were explained by plant growth stimulation.

It is known from the literature data that similarly to nitrogen (N) uptake (Rossato et al., 2001), the S requirement of oilseed rape depends on the plant development stage (McGrath and Zhao, 1996). In the present study presowing application of sulfur caused an increase in the accumulation of this element in oilseed rape plants only at the ripening stage (Table 2). According McGrath and Zhao (1996) and Postma et al. (1999) the S requirement is not stable during the growth cycle of oilseed rape: S uptake increased from stem extension to the start of flowering, whereas little S uptake was generally (but not exclusively) observed during pod filling. In the present study the increased NPK fertilization had a favorable effect on sulfur accumulation in plants both at the flowering and ripening stages. Also the biostimulant Kelpak, on average for fertilization with NPK and S, increased the uptake of S at the flowering and ripening period. At these developmental stages the accumulation of S in plants, on average for NPK fertilization, was even lower (by 10.9 and 9.8%, respectively) after presowing application of S without the biostimulant than on the treatment without S fertilization but with the biostimulant.

Conclusion

This study indicated that the higher NPK rates or S fertilization as well as the use of the biostimulant Kelpak increased N, P and K accumulation in the plants (roots and shoots) of oilseed rape at the flowering, development of fruit and ripening. Presowing fertilization with S had a similar effect on the accumulation of these elements. Biostimulant application in oilseed rape with lower rates of NPK increased N, P and K accumulation in oilseed rape during generative development stages to the level obtained at higher NPK, without biostimulant. At the fruit development stage S fertilization increased the accumulation of N, P and K in the biomass of oilseed rape, but only in the case of high doses of NPK. Increasing NPK rates stimulated the accumulation of S in oilseed rape at the flowering and ripening stages. Presowing fertilization with S increased the accumulation of this element in plants only at the ripening stage. The use of the biostimulant increased S uptake during flowering and ripening of oilseed rape. At these developmental stages the accumulation of S was even higher after the application of the biostimulant and without S fertilization, as compared with the accumulation of this element in oilseed rape fertilized with S, but without the preparation.

Abstract

The effect of different osmotic potential levels (0,-0.3 MPa, -0.6 MPa, -0.9 MPa, -1.2 MPa, -1.5 MPa) induced by NaCl on germination and early seedling growth in two divergent winter field pea cultivars (‘Kosmaj’ and ‘Letin’) was investigated. Germination was tested in sterile plastic vessels on filter paper moistened with 10ml of distilled water or salt test solutions, in the dark at 20 ± 1°C. Cultivars ‘Kosmaj’ and ‘Letin’ had a high percentage of germination under high osmotic potentials because germination was more than 75% (minimum germination standards is ≥75%). However, the tested cultivars showed different NaCl tolerance at the seedling stage. Cultivar ‘Kosmaj’ had better shoot growth, while cultivar ‘Letin’ root growth. Cultivar ‘Kosmaj’ had significantly higher germination energy (GE) (55.38%), shoot length (ShL) (5.58 cm), shoot fresh weight (ShFW) (79.28 mg), shoot dry weight (ShDW) (7.86 mg), relative seedling water content (RSWC) (87.81%) and phytotoxicity of root (PhR) (44.58%) than cultivar ‘Letin’ (27.83%, 2.23 cm, 57.54 mg, 6.71 mg, 86.10%, 15.32%, respectively). Contrary, cultivar ‘Letin’ had significantly higher germination (G) (98.58%), root length (RL) (10.28 cm), root fresh weight (RFW) (90.16 mg), root dry weight (RDW) (13.22 mg) and seedling vigor index (SVI) (1237.97) than cultivar ‘Kosmaj’ (92.13%, 5.62 cm, 49.62 mg, 6.26 mg, 1068.10, respectively). GE, G, RL, ShL, RFW, ShFW, RDW, ShDW, SVI, RSWC and dry matter stress tolerance index (DMSI) significantly decreased, while PhR and phytotoxicity of shoot (PhSh) significantly increased with the increase in osmotic stress.

Introduction

Plantings of field pea in the Republic of Serbia were estimated at about 5000 ha of forage pea, and 10000 ha of feed pea (Mihailović et al., 2005). It is very small, given that the favorable growing conditions. We distinguish in the agronomic sense, term forage pea which includes genotypes which should be harvested in full bloom at the beginning of the first pod and can be used as green forage, forage dry matter, forage meal, silage and haylage (Mikić et al., 2003), and term protein pea designating the genotypes for grain production and straw (Mikić et al., 2006). Field pea production in Serbia is traditionally based on domestic cultivars, about 95% of the harvested area (Mihailović and Mikić, 2010). Soil salinity adversely affects germination, resulting in poor plant stand. Estimates are that in Serbia about 4.6% of total of agricultural land is affected by salt (Ličina et al., 2011). Many researches showed that cultivars of pea significantly differ in respect to the salt stress. Jovičić et al. (2010) reported that Serbian cultivar ‘Jantar’ expressed a high level of tolerance to increased salt content than cultivars ‘Javor’, ‘Partner’, ‘Kristal’, ‘Pionir’, ‘Junior’, ‘Trezor’ and ‘Dukat’. Petrović et al. (2016) reported that two pea Serbian cultivars ‘Dukat’ and ‘Partner’ are tolerant to salt stress during germination and early embryo growth, but showed greater susceptibility when it comes to growth parameters compared to seed germination. Shahid et al. (2012) classified thirty pea genotypes in terms of salt tolerance

as less salt tolerant, intermediate and high salt tolerant groups at seedling stage. Okçu et al. (2005) concluded that Turkish pea cultivar 'Bolero' was more resistant to salinity during seedling emergence, cultivar 'Sprinter' appeared tolerant and 'Utrillo' is very sensitive. Many researches showed that germination and growth of seedlings of pea significantly decreased with increasing NaCl osmotic potential (Okçu et al., 2005; Jovičić et al., 2010; Jovičić et al., 2013; Cokkizgin and Colkesen, 2012; Naz et al., 2014; Petrović et al., 2016). Munns (2005) indicated that salt inhibits plant growth because it reduces the plant's ability to absorb water, and may enter the transpiration stream and eventually injure cells in the transpiring leaves and these result in slower growth. The aim of this research was to estimate the effects of NaCl osmotic potentials (0, -0.3 MPa, -0.6 MPa, -0.9 MPa, -1.2 MPa, -1.5 MPa) on germination and early seedling growth in two field pea cultivars 'Kosmaj' and 'Letin' under laboratory conditions.

Materials and methods

The effects of NaCl osmotic potentials (0, -0.3 MPa, -0.6 MPa, -0.9 MPa, -1.2 MPa, -1.5 MPa) on germination and early seedling growth of winter field pea cultivars ('Kosmaj' and 'Letin') tested in laboratory conditions of the Institute for Animal Husbandry in Belgrade, in March 2016. Cultivar 'Kosmaj' is local cultivar produced by the Institute of Field and Vegetables Crops in Serbia. Cultivar 'Letin' is foreign cultivar produced by the Agricultural Institute Osijek in Croatia. The cultivars are intended for combined use (green forage and grain). Seeds of cultivars are produced in 2015. Hundred seeds were placed in sterile plastic vessels of dimensions 15cm×21cm×4cm on filter paper soaked with 10 ml of distilled water or NaCl osmotic solutions (-0.3 MPa, -0.6 MPa, -0.9 MPa, -1.2 MPa, -1.5 MPa) prepared according to Coons et al. (1990), and incubated at 20 ± 1°C in the dark for 14 days, in four replications (Mandić et al., 2012). The filter paper substrates in all vessels were changed every other day. Seeds were surface sterilized by soaking in 1% NaOCl for 5 min and washed three times by sterilized distilled water. Randomized Complete Block Design (RCBD) design was applied to an experiment. Germination energy (GE) and germination (G) were determined after 4 and 7 day after sowing (ISTA, 2008). Quantitative seedlings traits (root length (RL), shoot length (ShL), root fresh weight (RFW), shoot fresh weight (ShFW), root dry weight (RDW) and shoot dry weight (ShDW)) were measured after 14 days. RDW and ShDW were measured after drying at 80°C for 24 hours (Mandić et al., 2012). Seedling vigor index (SVI), relative seedling water content (RSWC), phytotoxicity of shoot (PhSh) and root (PhR) and dry matter stress tolerance index (DMSI) were calculated as described in the paper Mandić et al. (2014). The data were processed by ANOVA using program Statistica version 10. Duncan's test was used to compare the treatment means at 5% level.

Results and Discussion

Results of ANOVA showed that cultivar had highly significant effect on GE, G and all quantitative seedling traits (RL, ShL, RFW, ShFW, RDW and ShDW) (Table 1). The tested cultivars showed different NaCl tolerance at the seedling stage. Cultivar 'Kosmaj' had better shoot growth, while cultivar 'Letin' root growth in early seedling phase under osmotic stress conditions. Cultivar 'Kosmaj' had significantly higher GE (55.38%), ShL (5.58 cm), ShFW (79.28 mg), ShDW (7.86 mg) than cultivar 'Letin' (27.83%, 2.23 cm, 57.54 mg, 6.71 mg, respectively). Contrary, cultivar 'Letin' had significantly higher G (98.58%), RL (10.28 cm), RFW (90.16 mg) and RDW (13.22 mg) than cultivar 'Kosmaj' (92.13%, 5.62 cm, 49.62 mg, 6.26 mg, respectively). However, cultivars have a considerably high percent of germinated seeds under high osmotic potentials (the minimum germination standards is ≥75%) although root and

shoot growth was slowed down. Tested cultivars showed greater susceptibility to osmotic stress in early seedling growth compared to seed germination. Petrović et al. (2016) found that pea cultivars 'Dukat' and 'Partner' have a good germination even at 150mM salinity level. Jovičić et al. (2010) found genetic variability between cultivars for tolerance and phytotoxicity effect of NaCl.

Table 1. The effects of cultivar and different osmotic stress on germination energy (GE), germination (G), root length (RL), shoot length (ShL), root fresh weight (RFW), shoot fresh weight (ShFW), root dry weight (RDW) and shoot dry weight (ShDW) of field pea

Means followed by the same letter within a column are not significantly different by Duncan's Multiple Range Test at the 5% level; ** - significant at 1% level of probability, * - significant at 5% level of probability and ns - not significant

GE, G, RL, ShL, RFW, ShFW, RDW and ShDW were significantly decreased with increasing osmotic stress. The maximum GE (89.25%), G (98.88%), RL (11.18 cm), ShL (9.00 cm), RFW (100.25 mg), ShFW (136.88 mg), RDW (13.55 mg) and ShDW (13.56 mg) were recorded at 0 MPa and the minimum at -1.5 MPa (1.25%, 87.50%, 5.02 cm, 0.66 cm, 42.06 mg, 10.92 mg, 6.80

mg and 1.57 mg, respectively). Higher osmotic stress is leading to reduced emergence of seedlings and finally reduced germination. RL and ShL lengths provide important indications of a plant's response to salt stress because roots absorb water due to direct contact with soil and then shoots enable its supply in whole plant. Osmotic stress induced by NaCl slows down water uptake by seeds, inhibited the translocation efficiency and assimilation of stored materials due to this it's caused a reduction in root and shoot growth. The result is in agreement with Okçu et al. (2005), Jovičić et al. (2010), Jovičić et al. (2013), Naz et al. (2014) and Petrović et al. (2016) who observed that germination, seedling length and seedling fresh and dry weight of pea were significantly reduced by increasing osmotic stress. Reducing the weight of fresh seedlings with increasing concentrations of NaCl result is the accumulation of large quantities of sodium ions who negatively affect cell division, metabolism and imbalance of other nutrients (Mer et al., 2000). The interaction of cultivars and osmotic stress had significant effect on GE, G, RL, ShL, RFW, RDW and ShDW.

The cultivar had highly significant effect on SVI, RSWC and PhR (Table 2).

AB	**	*	**	*	**			

Means followed by the same letter within a column are not significantly different by Duncan's Multiple Range Test at the 5% level; ** - significant at 1% level of probability, * - significant at 5% level of probability and ns - not significant

Cultivar 'Letin' had significantly higher SVI (1237.97) than cultivar 'Kosmaj' (1068.10). Contrary, cultivar 'Kosmaj' had significantly higher RSWC (87.81%) and PhR (44.58%) than

cultivar ‘Letin’ (86.10% and 15.32%). PhR of cultivar ‘Letin’ is lower because had better growth of the roots.

The osmotic stress had highly significant effect on SVI, RSWC, PhR, PhSh and DMSI. SVI, RSWC and DMSI significantly decreased, while PhR and PhSh significantly increased with the increase in osmotic stress. Mandić et al. (2014) reported similar results for maize. Cokkizgin et al. (2012) stated that increased NaCl concentration caused a harmful effect in the pea seed because increased SVI. The interaction of cultivars and osmotic stress had significant effect on SVI, RSWC, PhR, PhSh and DMSI.

Conclusions

The tested cultivars ‘Kosmaj’ and ‘Letin’ showed different NaCl tolerance at the seedling stage. Cultivar ‘Kosmaj’ had better shoot growth in all osmotic stress treatments, while cultivar ‘Letin’ root growth. Cultivar ‘Letin’ had better tolerance to osmotic stress than cultivar ‘Kosmaj’ because had higher values for G and SVI and lower values for PhR. Cultivar ‘Letin’ (foreign cultivar) can be recommended for cultivation in salt-affected areas. Increasing osmotic stress induced by NaCl caused reduction in germination and early seedling growth. GE, G, RL, ShL, RFW, ShFW, RDW, ShDW, SVI, RSWC and DMSI significantly decreased, while PhR and PhSh significantly increased with the increase in osmotic stress.

Abstract

There is an increasing global demand to dried of bay laurel leaf, Many bay laurel areas, primarily in the Aegean region of Turkey, have been destroyed because of several factors: Therefore, new bay laurel areas should be established: New plantations should be formed by genotype(s) with superior characteristics. The present study was undertaken to examine leaf characteristics of natural laurel genotypes in Karaburun Peninsula, İzmir/Turkey. Two years old leaves samples were taken in the middle of March, June, September and December from 23 different trees. Leaf size and thickness, leaf area and leaf color were determined. As a result of study, average leaf length was found that ranged between 4,02 and 6,83 cm and average leaf width between 1,90 and 3,58 cm. Thickness of leaves changed between 0,250 and 0,306 cm and leaf areas ranged between 6,64 and 19,27 cm^2. Some values differed by season. As a result of study there were found differences among bay laurel genotypes grown in the Karaburun peninsula.

Keywords: *Laurus nobilis L,, Karaburun peninsula, leaf characteristics, Leaf color, Turkey*

Introduction

Bay laurel (*Laurus nobilis* L.) belongs to the family *Lauraceae*, which included numerous aromatic and medicinal species. Laurel is an evergreen tree or large shrub up to 20 m height. It is also known as sweet bay, bay laurel, Grecian laurel, true bay, and bay. Bay laurel is grown commercially for aromatic constitutes of leaves and fruits (Gökmen, 1973; Acar, 1987),

Bay laurel is native to Asia Minor and Balkans. It is also reported that these trees were seen in the Mediterranean coasts in ancient times. It spread to the many Mediterranean countries (Spain, south France, Corsica Island in Italy, North Africa, Israel and Cyprus) and where the Mediterranean climate is dominant Black Sea coasts of Russia and India (Acar, 1987, Leung and Foster, 1999).

In Turkey, bay laurel grows in the West and Central Black Sea, Marmara, Aegean and Mediterranean regions. In these regions it growing up to 600-800 m, altitude above sea (Davis, 1982) may grow as tall as 5-10 m. Its dried leaves and essential oils are used in Italy, France, Turkey, Algeria, Morocco, Spain, Portugal and Mexico as a valuable spice in the culinary and food industry (Santoyo et al., 2006). Leaves and fruits of bay laurel are utilized in perfumery, soap, food, medicine and varnish / chemical industries. Bay laurel is not only an aromatic and medical plant but also used as an ornamental plant. Due to the perennial and evergreen plant, are used in park and garden landscaping and roadside. Bay laurel are propagated by seeds or stools and cutting as vegetative (Anonymous, 2005).

Bay laurel has an important place in world trade and Turkey has a leading position in the market in terms of quality, price and quantity by holding 90% of the market. It has 10% share in the natural plant product export of our country. Bay laurel is exported as a dried leaves to approximately 60 countries. It was being exported to Britain, Switzerland, Romania, United

States of America, Russia, Canada, Western Germany, Netherlands, Syria, Austria, and laurel oil was exported to Syria during 1960's (Ateş, 1963). According to data of Aegean Exporters' Association (AEA), between 1997-2003 year the most important export countries were Hong Kong, USA, Germany, Brazil, Japan, Poland, Netherlands and France, respectively (Anonymous, 2003). Export amount of Turkey was 35.930.316 kg as dried leaf in 2015 and major importing countries were Vietnam (socialist), Brazil, USA, Poland and Singapore, respectively (Anonymous, 2015).

In Turkey, bay laurel grows naturally. But excessive destruction occurs in natural bay laurel areas due to severe and untimely harvest of leaves. For this reason, establishment of new bay laurel areas required. A large number nursery trees are necessary for planting new bay laurel groves for leaf production besides for to be used in landscaping. However, nursery trees propagated from unknown properties of mother plants. In this case may lead to low the quality of new bay laurel groves.

Therefore in this study leaf characteristics of natural laurel genotypes determined in Karaburun Peninsula, İzmir where one of the most important area in Turkey.

Material and methods

This study was conducted in Karaburun Peninsula, Izmir, Turkey. Leaf characteristic of 23 genotypes were determined. Two years old leaves samples were taken in the mid March, June, September and December in 2006.

Leaf width and length were measured by using a ruler. Leaf thickness measurements were conducted with a micrometer (Mitutoyo, Germany) having an accuracy of 0,001 mm. Leaf areas was firstly scanned in a Hewlett Packard Scanjet 3200 C scanner and then calculated with FLAECHE computer program (Odabaş and Gülümser, 2005).

Leaf color was measured on the both sides of 30 leaf using a colorimeter (CR-300, Minolta Co, Osaka, Japan), which provided CIE **L***, **a***, and **b*** values. Color values were displayed as **L***, **a***, and **b***, which represent a light-dark spectrum from 0 (black) to 100 (white), a green-red spectrum from -60 (green) to +60 (red), and a blue–yellow spectrum from -60 (blue) to +60 (yellow), respectively. These values were then used to calculate Chroma ($\mathbf{C^*} = [\mathbf{a}^{*2} + \mathbf{b}^{*2}]^{1/2}$), which indicates the intensity or color saturation, and hue angle ($h° = \tan^{-1}[\mathbf{b}^*/\mathbf{a}^*]$), which is expressed in degrees: 0° (red–purple), 90° (yellow), 180° (bluish–green), and 270° (blue) (McGuire, 1992).

Statistical analyses of all data were performed with SPSS Version 16,. (SPSS Inc., Chicago, IL, USA), Differences between the means were compared by Duncan test at a significance level of $P<0,05$.

Results and Discussion

It was found that there were differences significant ($p\leq0.05$) among leaf length, width, thickness and area of bay laurel genotypes. As could be seen in Table 1 the seasons' average leaf length ranged between 4,02 and 6,83 cm while leaf widths ranged between 1,90 and 3,58 cm. Based on average leaf length of genotypes 6, 14, 21 and 22 were statistically similar and they had the longest leaves than other genotypes. Genotypes 4, 8 and 23 had the shortened leaves and theirs length of leaves were 4,02 cm, 4,05 cm and 4,28 cm, respectively. Based on average leaf width of genotype 20 had the largest leaves than other genotypes. In terms of seasons both length and width of leaves differences were not significant. Boza and Hepaksoy (2011) found that the average length and width of leaves ranged between 5,77-9,05 cm and 2,37-4,14 cm, respectively, in the Dilek peninsula where the other important area for bay laurel.

Table 1. Leaf characteristics of bay laurel genotypes

Genotype No	Ave, Length (cm)		Ave, Width (cm)		Ave, Thickness (mm)		Ave, Area (cm^2)

22	6,78	a	2,85	c-f	0,250	d-f	15,73	bc
23	4,28	i	2,25	ij	0,258	c-f	8,38	hı

The genotype # 15, 16 and 8 had the thickest leaves (respectively 0,306-0,304-0,288 mm) while # 5, 2 and 22 had the thinnest leaves (respectively 0,242-0,243-0,250 mm). The thickest leaves were found in September while the thinnest leaves were found in March month in terms of periods. Leaf widths range between 2 and 3 cm in 66,7% of the genotypes, while the leaf thickness were ranged between 0,25 and 0,30 mm in approximately 80% of the genotypes.

Tree # 6 had the largest leaf area with 19,27 cm^2 and the tree # 4 had the smallest leaf area with 6,64 cm^2. Any difference did not occur in leaf area of the trees among sampling months.

It general, leaf sizes of the genotypes were found to be small. Leaf sizes were ranged between 5 and 6 cm in the 50% genotypes, while ranged between 6 and 7 cm in the other half. Boza and Hepaksoy (2011) found that the average leaf areas between 11,05 cm^2 and 24,04 cm^2 in the Dilek peninsula of Aydın/Turkey.

Leaf length, width and area of trees grown in Karaburun peninsula were found to be smaller than trees grown in the Dilek peninsula. These differences may be caused by genetic structure or climatic and soil type.

Color values of upper and lower surface of leaves were determined as L, C*, Hue°, Hue° values of both surfaces were not found statistically significant among genotypes. Leaves color were darker green during summer and autumn seasons while a lighter green during winter and spring seasons. The most vivid color of upper surface was found in the genotype 2 (23,85); the lowest

value (17,08) was found in the genotype 10. Leaf lower surface of genotype 19 was determined to be the most vivid color (125,10) while the lowest chroma value were found at genotypes 22 (20,31) and 20 (20,29). It was observed that upper and lower surface of leaves had lower chroma values in winter and spring seasons, respectively. L values of trees' leaves ranged between 53,38 and 39,80 on the upper surface and 55,23 and 45,45 in the lower surface. It was seen that the lightest color leaves grow during spring time in terms of upper surface as period based, while the period has no effect in the lower surface (Table 2). In general leaf formation of bay laurel ends in April. Most probably for this reason, leaves have a darker green, saturated and more vivid color in June. Similarly, the leaves grow beginning again in September and they have more green and shiny at this time. Summer drought conditions stress trees. They may thus lose their leaves prematurely or start color production prematurely. The result is a reduction of color during the peak of the season. But air humidity is high in this region. For this reason lead color may higher during summer and autumn seasons.

Conclusions

The study conducted in Karaburun peninsula where significant bay laurel area exist in the Aegean Region located at the west part of Turkey. This study is very important because of that older studies held on bay laurel are mostly related with volatile oil content of leaves and fruits (Hafızoğlu and Reunanen, 1993: Pino *et al*,, 1993; Ozek *et al*,, 1998; Caredda *et al*,, 2002; Sangun *et al*,, 2007; Sellami *et al*,, 2011; Cherrat *et al*,, 2014). There was not study on leaf properties of trees. It is found that leaf characteristics of genotypes differ to each other.

Average leaf length and width changed between 4,02 to 6,83 cm and 1,90 and 3,58 cm, respectively. As Turkish Standard Institution, laurel leaves are to be 25-100 mm length and 20-45 mm width for drying and trading. Base on research results, many genotypes may use for dried leaf. But it is determined all genotypes which grow at the other regions before decide to use as mother plant for nursery tree propagation.

RELATIONS BETWEEN FRUIT BEARING HABIT, AND CARBOHYDRATE / NITROGEN LEVELS IN 'HACIHALILOGLU' APRICOT CULTIVAR

Ibrahim BOLAT[1*], Mustafa SAHIN[2]

1Department of Horticulture, Faculty of Agriculture, Harran University, Sanlıurfa, Turkey
2Olive Resarch Instititue, Bornova, Izmir, Turkey

Abstract

Turkey is the biggest apricot producer in the world. Most of the apricots are produced in the Malatya region of Turkey. The 'Hacihaliloglu' cultivar is the main apricot cultivar in Malatya. It has an exceptional dried fruit quality, but there are problems in pruning application with respect to fruit bearing habit. In this study, fruit set and carbohydrate–nitrogen level changes were investigated in relation to branch age in 'Hacihaliloglu' apricot. The minimum and maximum fruit set were observed in 1- and 3-year-old branches in two consecutive experimental years, respectively. The flower bud ratios on 2- and 3-year-old branches were higher than those of 1-year-old branches. The carbohydrate contents measured in bark of 2- and 3-year-old branches were higher when compared to 1-year-old branches. On the other hand, the maximum nitrogen contents of shoot barks were obtained in 1-year-old branches. Total carbohydrate / nitrogen ratio was higher on 2- and 3-year-old branches than those of 1-year-old branches. In adjusting the crop load of 'Hacihaliloglu' apricots, there is a need to better recognition of the 1-, 2- and 3-year-old branches on the trees. In years with higher crop load, a thinning on 2- and 3-year-old branches of mature trees in winter pruning would be helpful as well as preserving those branches in the young trees.

Keywords: *Apricot, Fruit bearing, Branch age, Carbohydrate / nitrogen ratio*

Introduction

Apricot is one of the most important stone fruits that can be used fresh, dry and in various processed forms. Turkey takes the first place among apricot producing countries with 812 thousand tons, which is approximately 20% of the world apricot production. In addition Turkey meets 77% of dry apricot production which is 162 thousand tons (FAOSTAT, 2013). Most of the apricots are produced in Malatya province of Turkey. The 'Hacihalilolglu' is a leading apricot cultivar produced in Malatya. It is an exceptional cultivar in terms of dry fruit quality among other cultivars (Ercisli, 2014).

It is important to use all modern techniques in apricot production for high crop potential and quality of the fruit. Pruning is one of the most important cultural practices applied to temperate zone fruit trees. Pruning is made at different forms and periods, affects carbohydrate and nitrogen content in tissues and organs in fruit trees. In temperate zone trees and other woody plants, carbohydrates play an important role as a source of reserve energy. Nitrogen is known to be indispensable element for growth, development and productivity of plant. Carbohydrates and nitrogen are used in metabolism and transferred to other parts of plants. In order to achieve optimal condition for shoot growth, photosynthesis, leaf area, annual building of storage reserves and ultimate realization of good yield with high quality fruit, precise pruning is an essential factor (Lang, 2001; 2005; Demirtas et al., 2010). The pruning of trees results in changes in partitioning

of the reserves in the tree. For a successful pruning branch habit and fruiting behavior should be identified.

The aim of this study, therefore, was to determine the types of branches occurred in 'Hacihaliloglu' apricot variety, where flower buds and fruit sets are intensified. The second aim was to find the accumulation level of carbohydrate and nitrogen in branches of different ages.

Material and Methods

This study was conducted in Malatya Province with 24 years old 'Hacihaliloglu' apricot trees in an orchard with distance 10 x 10 m.

All the shoots on 3 marked skeleton branches of different 'Hacihaliloglu' apricot cultivar trees were measured and counted. All the data were calculated by using 1 linear meter of skeleton wood. The following classification was made for defining the shoots: dwarf shoots - up to 3 cm, spurs - 4-10 cm, floral shoots - 11-30 cm, mixed shoots - 31-60 cm, vegetative shoots – over 60 cm (Tsonev and Tsoneva, 1995).

The numbers of total buds and flower buds on branches in each age group before the period of buds swell at 1-, 2- and 3-year-old branches on the marked skeleton branches were determined. Then flower buds rates were found according to age of branch with the calculation (Askin, 1989). Similarly, branches were labeled by counting 350-600 flower buds at the period of pink buds in selected 1-, 2- and 3-year-old branches on marked skeleton branches. Fruit set levels were established by dividing the number of fruits at harvest time with the number of flower buds (Bolat and Guleryuz, 1994).

Barks of middle parts of the shoots selected at 1-, 2- and 3-year-old branches on skeleton branches in June and October were peeled and the samples of barks were dried at 65°C then in these samples, carbohydrate and nitrogen analysis were made by using methods of Antron (Kaplankiran, 1984)and Kjheldal (Bremmner, 1965) respectively.

The study was designed according to randomized block design with 3 replications. Significance of differences between averages was utilized using the test of "Least Significant Difference" (LSD) at 1% level.

Results and Discussion

In the 'Hacihaliloglu' apricot cultivar, the highest number of shoot with the levels of 52.24% and 56.08% and the lowest number of shoot with levels of 2.42 and 1.07% were found in dwarf shoots (0.00-3.99 cm) and mixed shoots (31.00-60.99 cm) respectively in both years (Table 1). Vegetative shoots could not be determined in both years. On the other hand, the highest rate in shoot length in the first year was occurred in floral shoots (53.65%) followed by spurs (20.02%) and the lowest rate was in mixed shots (11.81 %). Similarly, while also spur and floral shoots took the highest part in the total shoot length, in second year, mixed shots had the lowest value (Table 1). In the study of Tsonev and Tsoneva (1995) made on Kishinevskij rannij, Candelo, Pepitos, Radinskij, Carrascal, Ungarska kaisiya and Modesto apricot cultivars, they determined that spurs and floral shoots were dense and the level of mixed and vegetative shoots was at very low ratio on linear meter of skeleton branches. Moreover, they found that the shoot density in the 11-30 and 31-60 cm length in years of low yield increased and the level of dwarf shoot was high in years of high yield. Researchers pointed out that Candelo and Pepitos cultivars mostly generated spur type shoots, while Kishinevskij Rannij had mostly floral shoots and differences established in shoot types in cultivars must be taken into account in pruning applications.

Table 1. Percentage of shoot categories, with regard to shoot number and length of linear meter of skeleton branch

Categories of shoots	First year		Second year	
	Shoot number (%)	Shoot length (%)	Shoot number (%)	Shoot length (%)
Dwarf	52.24	14.52	56.08	22.82
Spur	24.56	20.02	32.86	37.62
Floral	20.78	53.65	9.99	31.92
Mixed	2.42	11.81	1.07	7.64
Vegetative	0	0	0	0

In 'Hacihaliloglu' variety, the flower bud ratios on 1-, 2- and 3-year-old branches were found to be 64.99-65.86%, 70.95-70.85% and 73.31-70.31% (Table 2). In both experimental years, flower buds in 2- and 3-year-old shoots was found in similar and higher ratios than those in 1-year-old shoots. In many of the temperate fruit species, the levels of flower buds are accepted to be a significant indicator for yield, and were observed to differ with respect to the age of branch. In the study Askın (1989), made on Tokaloglu, Turfanda Izmir, Sam and Malatya apricot cultivar, flower bud ratio in varieties was determined to change between levels of 54.35-79.43%.

The level of fruit set in 1-, 2- and 3-year-old branches in both years were found to be 11.41-10.89 %, 16.80-14.95 % and 20.62-15.98, respectively in 'Hacihaliloglu' variety (Table 2). The fruit set in 2- and 3-year-old branches had higher values than those in 1-year-old branches.

Table 2. Percentage of flower bud ratio and fruit setting at various age of branches

Branch age	First year		Second year	
	Flower bud ratio (%)	Fruit setting (%)	Flower bud ratio (%)	Fruit setting (%)
1-year-old	64.99 b	11.41 c	65.86 b	10.89 b
2-year-old	70.95 a	16.80 b	70.85 a	14.95 a
3-year old	73.31 a	20.61 a	70.70 a	15.98 a
Lsd 1%	2.07	1.77	2.38	1.60

(**):The means followed by the same letter in each column are not significantly different according to LSD test at 1% level.

Some researchers assigned that the level of fruit set could vary according to different portions and shoot types of tree. Therefore, Ozbek (1989), emphasized that yield was mostly formed in 2-year-old and older branches and they need to be saved during the pruning. On the other hand, Pugliano and Forlani (1985) conducted a study to investigate the productivity of shoots in 10 different apricot varieties and they established a difference between fruit set ratios and the level of flower among varieties. The level of fruit set in the terminal part of long shoots in 8 varieties was higher than fruit set ratio of the basal parts of the same shoots (in terminal part 46.90%, in basal part 31.60%).

Also Szujko-Lacza (1985), reported that in apricot trees, flower buds are larger than the vegetative buds and they are formed on the oldest side branches, twigs and on the basal part of the one-year old terminal shoots. Neri et al. (2010) also suggested that apricot varieties have different architectures in their tree habit and fruiting branches. He stated that there are 3 most common architecture groups (1) with a spreading habit and very vigorous, and a tendency to fruit

on spurs, brindles and sylleptic shoots; (2) with a semi-spreading habit and generally less vigorous, and with the capacity to fruit on spurs and more vigorous shoots; and (3) with a very vigorous, mixed spreading habit, and ability to fruit on all kinds of shoots.

When the carbohydrate contents in dry barks were compared, those in shoot bark of 2- and 3-year-old shoots were usually higher than in 1-year-old shoots in both years. The total carbohydrate contents were found to be 13.95 - 13.96 - 14.00 % in June and 13.33, 14.66, 15.36% in October (Table 3). The highest nitrogen contents in shoot barks were found in 1-year-old shoots and the nitrogen levels in 2- and 3-year-old shoots were determined to be same. The nitrogen contents in barks had values of 1.02 – 0.93 – 0.89 % in June and 1.11-1.02-0.99 % in October (Table 3). When total carbohydrate / nitrogen ratio was evaluated, in 2- and 3-year-old branches it was established to be higher than in 1-year-old branches. These ratios showed values of 14.06-15.76-16.57 in June and 12.00-13.95-15.51 in October (Table 3).

Table 3. Total carbohydrate (CH) and nitrogen (N) contents, carbohydrate/nitrogen ratio at various age of branches in average of two years

Branch age	June			October		
	CH (%)	N (%)	CH / N	CH (%)	N (%)	CH / N
1 year-old	13.95	1.02 a	14.06 b	13.33 b	1.11 a	12.00 c
2 year-old	13.96	0.93 b	15.76 a	14.66 a	1.02 b	13.95 b
3 year old	14.00	0.89 b	16.57 a	15.36 a	0.99 b	15.51 a
LSD(**)	---	0.03	1.02	0.85	0.05	1.20

(**):The means followed by the same letter in each column are not significantly different according to LSD test at 1% level.

In the temperate zone trees, total perennial parts have maximum carbohydrate contents in the autumn, that start to decrease in late winter, and rapidly decrease in early spring (Clair-Maczulajtys *et al.,* 1994 , Moing et al., 1994). In temperate zone trees and other woody plants, carbohydrates have a role as an essential source of reserve energy. In metabolism they can become mobile and be transferred to other plant organs. Many factors, such as temperature, moisture, light, pruning, and time of planting affect the concentration and localization of carbohydrates, such as sugars and starches, within tissues (Daie, 1985).

In ‘Hacihaliloglu’ variety in the trial, carbohydrate contents of 3-year-old branches generally were established highest, followed by 2- and 1-year-old branches. Total carbohydrate / nitrogen ratios were revealed to have the same results. The results related to carbohydrate contents achieved from ‘Hacihaliloglu’ apricot variety are compatible with the findings of Stutte et al. (1994), Clair-Maczulajtys et al. (1994), Tamdogan (2006), Demirtas et al. (2010) and İkinci (2014) who conducted studies on apple, cherry, apricot, and peach varieties.

Conclusion

In fruit trees, it is suggested that total carbohydrate / nitrogen ratio known as an indicator of balance of vegetative and generative development is higher in older parts of tree than that in young parts. While in young trees, higher ratio is demanded for producing earlier yield as soon as possible, in old trees, this ratio is tried to be lowered. High total carbohydrate / nitrogen ratios in

'Hacihaliloglu' could be reduced by pruning. The fact that crop load of 'Hacihaliloglu' apricot variety is adjusted is a fundamental need for better recognizing of the 1-, 2- and 3-year-old branches on the trees. In years with high crop load, in winter pruning a thinning on 2- and 3-year-old branches of mature trees would be a good choice. Also, those branches should be saved in the young trees.

MINIMIZATION OF THE COST OF CONTRACTED TOBACCO PRODUCTION USING LINEAR PROGRAMMING

Funda GENCLER[1]*, Altay Ugur GUL[2]

[1]School of Tobacco Expertise, Celal Bayar University, Manisa, Turkey
*Corresponding author: funda.gencler@cbu.edu.tr

Abstract

Turkey has a key role in oriental tobacco farming all over the World. There has been a significant change in tobacco production due to Governmental policies since 2001. The overall marketing system has been transferred to private companies where they are solely determining the tobacco leaf prices. Currently contracted farming system is in charge in tobacco production in Turkey. Under contracted farming, tobacco growers would agree to sell their tobacco at a predetermined price negotiated with buyers before the planting season. The contracts, signed over a one year period with farmers, include details about the production such as the responsibilities of farmers and companies. The contract goes beyond being an explanatory text about the details of tobacco production and works as a tool reformatting the entire tobacco market. The scope of this study is to summarize the tobacco production and marketing policies for last two decades in Turkey and to find out different approaches minimizing purchase costs for private companies. The data that is used in the study were collected from different literature sources: contracted tobacco farming regions in Turkey and their land size, tobacco production amount and producing cost of raw leaf tobacco in these regions. This hypothetical application is done linear programming model with 6 variables and 15 constrains. As a result of the linear programming solution; it has been predicted that 65,556 ha. including Aegean Region, of total 93,117 ha. contracted farming should be done. The amount of tobacco leaf is 80,000 tons and the purchase cost is $ 335,840,770.78.

Keywords; *Turkish Tobacco Policy, Minimizing Purchase Costs, Linear Programming*

Introduction

Tobacco is one of the most talked about and debated agricultural products not only in Turkey but in the whole world (Koçturk and Cebeci, 2005). Oriental tobacco is mainly cultivated in Turkey, Greece, Bulgaria, Macedonia, Moldavia and Kyrgyzstan, however quarter of total oriental tobacco production is performed in Turkey Tobacco is one of the most important export goods which symbolizes Turkey's agricultural export product and it has a vital importance for tobacco farmers. Turkey exports tobacco approximately to 50 countries. Mainly buyers of Turkish tobaccos are European Union countries and USA. The annually export value is just about 430 million dollars (Ersan, 2005).

Rapid increases in tobacco production beginning in 1987, and the expansion of tobacco farms in less than optimal areas resulted in increased stock costs and decreased leaf quality. As a result, the Turkish government developed policies to more effectively control tobacco farming. Quota applications and the development of alternative crops are among those policies. A quota system, introduced in 1995, was instituted each year (except 1997) with quotas set at varying levels (Ren & Alemdar, 2006).

Given that tobacco and its production have been of strategic importance in Turkey, legislation concerning the tobacco sector has all along been specially organized and regulated via institutions

under different statutes. Under Law No. 4733 of 2002, the state tobacco monopol Tekel (which had regulated the tobacco and alcoholic beverages sector since 1923) was transformed into an incorporated company and its market regulation responsibilities were transferred to TAPDK (The Tobacco and Alcohol Market Regulatory Authority).

It is important to note that tobacco production policy has been considerably modified since 2002, with the liberalization of the tobacco market, elimination of the subsidy system and adoption of a contract production model. Many producers could not adapt to the changing conditions, and the 478 000 producers in 2001 had fallen to 207 000 by 2007.

Until recently, tobacco leaf agriculture yielded substantial revenues. The production of leaf tobacco was, however, negatively affected by the arrival of the multinational tobacco industry in 1986 and consequent loss of market share in both the country and the region, combined with regulation of the tobacco sector by the IMF and World Bank in 2000. Turkey is still, however, the fifth largest cigarette producer in the world with approximately 142.9 billion cigarettes produced in 2015 (TAPDK, 2016).

Currently contracted farming system is in charge in tobacco production in Turkey. Under contracted farming, tobacco growers would agree to sell their tobacco at a predetermined price negotiated with buyers before the planting season. The contracts, signed over a one year period with farmers, include details about the production such as the responsibilities of farmers and companies. The contract goes beyond being an explanatory text about the details of tobacco production and works as a tool reformatting the entire tobacco market.

Linear programming (LP) is one of the best developed and most used branches of management science. It concerns the optimum allocation of limited resources among competing activities, under a set of constraints. These constraints could reflect financial, technological, marketing, organizational (Bradley et. al., 1976; Bunday, 1984). The basic problem of LP is one of either maximizing or minimizing a function of several variables, with the variables being subject to a number of constraints (Swanson, 1987). The three basic assumptions of all LP models are: linearity, divisibility and determinism (Markland and Sweigart, 1987).

The aim of this study was to actualize minimizing production costs of raw leaf tobacco by using linear programming in the scope of contracted tobacco farming practice in Turkey.

Materials and methods

The following data were collected from different literature sources: contracted tobacco farming regions in Turkey and their land size, tobacco production amount and producing cost of raw leaf tobacco in these regions (Table 1, TAPDK and Tobacco Experts Association web site).

Table 1. Summary information for the contracted leaf tobacco production in Turkey* (2015).

Regions	The level of production (kg/ha)	Production costs ($/ha)
Aegean	799.2	3499.35
Marmara	857.6	3718.31
Black sea	1133.9	5576.36
East Anatolia	1806.1	3379.99
Southeastern Anatolia	918.3	2689.31
Mediterranean	1075.5	1993.52

Source: TAPDK* and Tobacco Experts Association, 2016

For minimizing the cost of leaf tobacco production was determined target values in Table 2 based on these data.

* The Tobacco and Alcohol Market Regulatory Authority

Table 2. Right hand side (RHS) values of the constraints

The constraints	RHS (b_i)
Area (1,000 ha)	70-100
Leaf tobacco production (1,000,000 kg)	≥80
Aegean (1,000 ha)	50-80
Marmara (1,000 ha)	3-5
Black sea (1,000 ha)	10-15
East Anatolia (ha)	30-60
Southeastern Anatolia (1,000 ha)	7-10
Mediterranean (1,000 ha)	1.5-2.5

The model is stated with the following set of equations:

$$Z_{\min} = \sum_{j=1}^{6} c_j x_j$$

Subject to

$$\sum_{j=1}^{6} x_j \le b_1$$

$$\sum_{j=1}^{6} x_j \ge b_2$$

$$\sum_{j=1}^{6} a_j x_j \ge b_3$$

$$x_j \ge b_i \qquad (i = 4,5,....9;\ j = 1,2,...,6)$$

$$x_j \le b_i \qquad (i = 4,5,....9;\ j = 1,2,...,6)$$

where

x_j , decision variable, the contracted leaf tobacco production area in *j*th region,

c_j , the cost of leaf tobacco production in *j*th region ($/ha),

b_i , the righthand side of *i*th constraint (RHS),

a_j , the leaf tobacco production in *j*th region (kg/ha),

Results and Discussion

According to the solutions of the model; 6.883 hectares (6.88%) is under the upper limit value, and total 93.115 hectares of contracted tobacco leaf production area is determined. Total production quantity is 80 million kilograms and the total cost is $ 335,840,770.78.

Table 3. Summary of the solution to the LP model

Regions	Area (ha)	Production (kg)	Cost ($)
Aegean	65,557	52,392,884	229,405,984.94
Marmara	5,000	4,288,000	18,591,542.86
Blacksea	10,000	11,339,000	55,763,582.14
East Anatolia	60	108,366	202,799.23
Southeastern Anatolia	10,000	9,183,000	26,893,071.43
Mediterranean	2,500	2,688,750	4,983,790.18
Total	93,117	80,000,000	335,840,770.78

The distribution of the area for contracted leaf tobacco production is shown in Figure 1. The Model gives the results that the contracted tobacco farming can be done as follows; in Marmara, East Anatolia, Southeastern Anatolia and Mediterranean region, is within the upper limit level, in Black Sea in the lower limit level for Aegean Region is above 15.557 hectares (31.11 %) in the lower limit level.
Also; 91.88% of all tobacco production is in Aegean, Black Sea and Southeastern Anatolia Regions. This ratio is 70.40 % solely in Aegean Region.

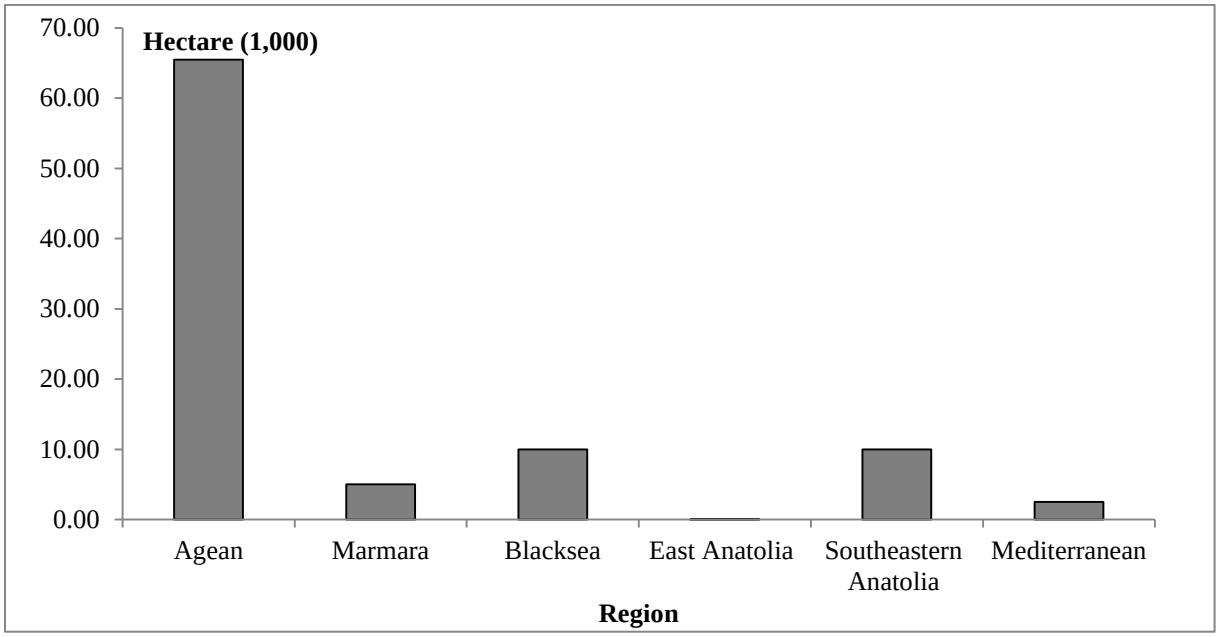

Figure 1. The distribution of tobacco production areas

Figure 1 shows the distribution of the area where the contracted leaf tobacco production is going to be done. The model shows that, 91.14 % of the contracted tobacco farming demand can be provided from the Aegean, the Black Sea and Southeastern Anatolia Regions. Also the ratio is 65.49 % in Aegean Region.

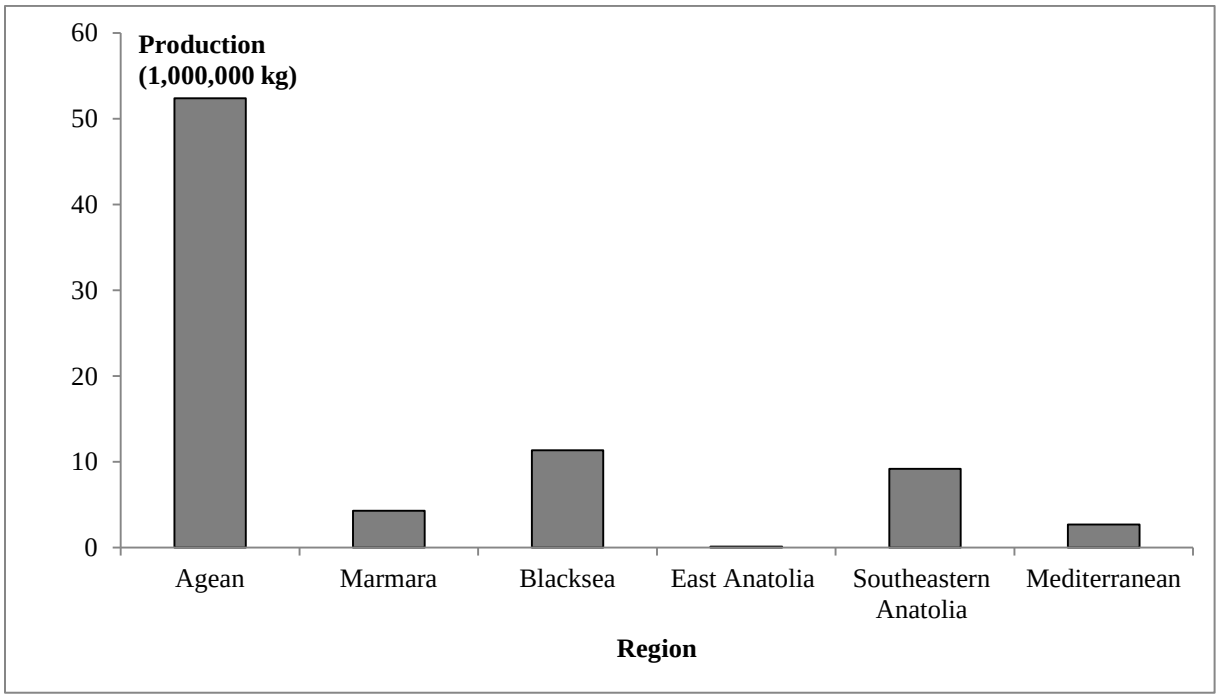

Figure 2. The distribution of tobacco production.

In Figure 3, the distribution of contracted tobacco leaf production cost is shown. The outcomes of the model indicate that the 92,92 % of the production costs will be occurred in Aegean, the Black Sea and the Southeastern Anatolia Regions and 68.31 % of the production cost will be occurred in Aegean region.

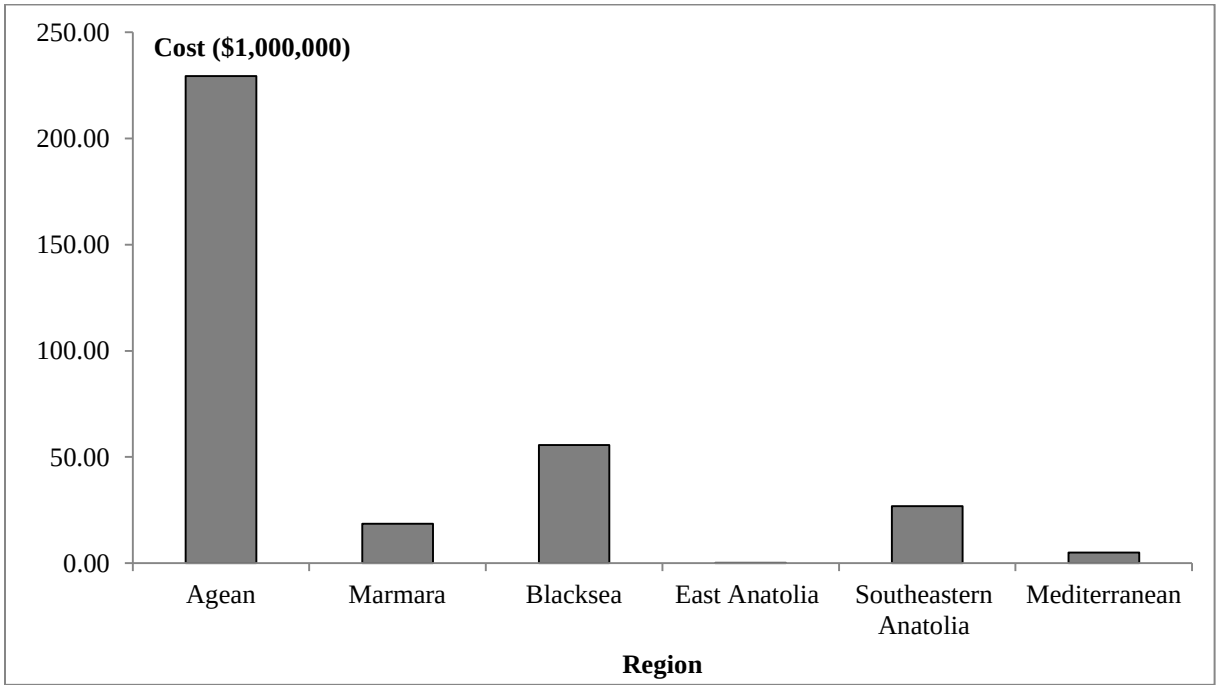

Figure 3. The distribution of the cost of tobacco production.

According to Table 1, the highest yield is in Eastern Anatolia Region and the lowest yield is in Aegean Region.

In the model, in order to minimize production costs, highest production costs in the Black Sea region is limited at the lower level, the limits are set at a maximum level in other regions except Aegean Region. According to Table 1; Black Sea region, is more productive than Aegean region but production costs are high. Therefore the model provides at least 80 million kilograms of tobacco leaf production constraints; Aegean region is selected 15,557 hectares more production area at the lower limit value instead of Black Sea region.

Conclusion

In Turkey, tobacco cultivation is generally carried out in the form of contracted tobacco production. In each region, the tobacco yields and tobacco production costs varies. In this case, the tobacco companies are faced with the problem of minimizing the total cost of tobacco production. Linear programming is widely used as a mathematical method for this purpose. By using 2015 data, it is showed that how this model can be used to minimize the costs of contracted tobacco purchase in Turkey.

As a result, the model solution, both production areas, production quantity and production costs aspects, the Aegean Region by 65-70 % has an important role; Black Sea Region and Southeastern Anatolia Region (10-15%) are followed.

VITAMIN PROFILES OF MAIZE LANDRACES FROM A MINI CORE COLLECTION FOR GRAIN QUALITY

Jelena VANČETOVIĆ, Jelena MESAROVIĆ, Dragana IGNJATOVIĆ-MICIĆ, Sofija BOŽINOVIĆ, Ana NIKOLIĆ, Dragana MRĐEN, Milan STEVANOVIĆ

Maize Research Institute Zemun Polje

Abstract

Profiles of vitamins A and E were analysed in 16 maize landraces from mini core collection for grain quality using HPLC technique. Contents of γ+ß and δ tocopherols (vitamin E fractions) were moderate on the average, and neither landrace showed exquisite values of these compounds, while α-tocopherol content was high in two landraces (13.330µg g^{-1} and 9.138µg g^{-1}). Since these 16 landraces are not high-oil ones, lack of high concentrations of some vitamin E fractions would not be reflected on quality and stability of oil potentially extracted from them. The tested landraces are white to orange flints or semi flints, and vitamin A fractions ranged from the trace values (white landraces) to 11.37µg g^{-1} lutein, 40.91µg g^{-1} zeaxanthin and 5.248µg g^{-1} ß-carotene. Maximum lutein value was not very high, but maximum values for zeaxanthin and ß-carotene were high in comparison with the literature data. One landrace, named L 161, had high value~~s~~ of α-tocopherol (second in range) and both the highest values of zeaxanthin and ß-carotene and it could be used for maize biofortification.

Keywords: *antioxidants, landraces, maize, vitamins*

Introduction

Humans and animals are incapable of carotenoid and tocopherol biosynthesis ~~so~~ and they depend on dietary carotenoid and tocopherol sources. Carotenoids (provitamin A) and tocopherols (vitamin E) are lipid soluble antioxidants associated with decreased risk of several degenerative diseases. Increased zeaxanthin is important for improved eye-sight, while α-tocopherol and ß-carotene are strong antioxidants. The increase of bioavailability of carotenoids, especially β-carotene, has been reported with high amount of protein and fat, a component of oil (Failla and Chitchumronchokchai, 2005). Starch and carotenoids are primarily located in the endosperm of maize grain, whereas oil and tocopherols, consisting mainly of α-, δ-, and γ-tocopherol, are located in the embryo (Sandman, 2001).

Two classes of carotenoid pigments comprise carotenes and xanthophylls, which are responsible for the yellow and orange colours of corn endosperm. Among the major food grains, only yellow maize contains significant levels of ß-carotene (Buckner et al., 1990). Carotenoids are a complex class of isoprenoid pigments providing nutritional value as provitamin A (α-carotene, β-carotene, β-cryptoxanthin) and nonprovitamin A (lutein and zeaxanthin); their varied colours give additional commercial value as colorants in foods and nutrient supplementation (Matthews and Wurtzel, 2007). Yellow maize is also the main source of provitamin A in feed rations for swine and other animals (Brunson and Quackenbush, 1962). In broiler production, skin and shank pigmentation of birds are important quality factors that are supplied by yellow maize in the ration. Egg-laying poultry require high pigment levels in their feed for the production of eggs with dark yellow yolks that are desirable for baking products. Usually, flint maize has high content of proteins and β-carotene. Yellow maize kernels contain carotenoids (0.25µg g^{-1} dry weight) with

provitamin A activity (β-cryptoxanthin, α- and β-carotene) but its content is typically small (15% to 18% of the total carotenoids fraction) compared to lutein (~ 45%) or zeaxanthin (35%), (Kurilich and Juvik, 1999; Brenna and Berardo, 2004). Thus, there is considerable attention for breeding maize with an enhance provitamin A concentrations by shifting carotenoid biosynthesis to favour provitamin A versus other types of carotenoids and thereby increasing nutritional value of the grain.

Among food crops, maize is the only principal source of non-provitamin A carotenoids, especially lutein and zeaxanthin. Zeaxanthin is a rare carotenoid in nature and together with lutein is an essential component of the macular pigment in the eye (Sandman, 2001). The presence of natural antioxidants, especially tocopherols in lipids improves their stability and delays oil rancidity (Weber, 1987a), gives maize oil flavour stability during storage and cooking and enhance shelf life of corn oil (Weber, 1987b; Watson, 1988; White and Pollak, 1995). There is evidence indicating that tocopherols, in particular γ-tocopherol, the predominant form of vitamin E in plant seeds, are indispensable for protection of the polyunsaturated fatty acids and have benefits in meat industry (Rocheford et al., 2002).

Substantial variation in the levels of specific forms and total levels of carotenoids has been shown (Weber, 1987a). High heritability estimates for carotenoid (84-96%) and tocopherol (79-87%) fractions were found (Singh and Chaudary, 1985; Chander et al., 2008b), whereas medium to high levels of heritability for fractions of carotenoids (48-87%) and tocopherols (62-68%) were found by Galliher et al. (1985) and Wong et al. (2004). Moderate to high heritability estimates indicate that breeding for increased levels of both carotenes and tocopherols should be feasible.

Biofortirication aims to develop micronutrient-enhanced crop varieties through conventional plant breeding (Ortiz-Monasterio et al., 2007). It should create micronutrient enhanced maize genotypes without compromising tolerance to abiotic and biotic stresses, grain yield, and acceptable end-use quality, thereby increasing the likelihood that farmers will adopt these cultivars and consumers will accept foods made from them. Since success in crop breeding depends on the existence of genetic variation for the target traits in the gene pool available. The goal of this research was to estimate A and E vitamin profiles of 16 maize landraces as potential sources for maize biofortification.

Material and Methods

Sixteen maize landraces comprising mini core collection for grain quality (Vančetović et al. 2015a, 2015b) and the check hybrid ZP 341 were used in this research. Landraces and the check hybrid were sawn in two years (2014 and 2015) in Zemun Polje in two replications, according to the randomized complete block design (RCBD). Each landrace was multiplied by pair-crossing (full sibling), while the hybrid was selfed. At least 30 pollinated ears from each genotype were harvested, dried and shelled separately. One kernel from each ear was collected and gathered to form a sample for further analysis.

Maize kernels were milled (Perten 120, Sweden) into flour (particle size < 500μm) and stored at -20˚C prior to analysis. Analysis was done on HPLC, for carotenoids by slightly modified method of Rivera and Canela (2012) and for tocopherols by modified procedure of Gliszczyńska-Świgłoet et al. (2007). HPLC grade solvents were: acetonitrile, 2-propanol and ethyl acetate purchased from Sigma Aldrich (Germany), and whilst methanol from J.T. Baker (Netherlands). Standards for tested carotenoids (lutein, zeaxanthin and β-carotene) and tocopherols (α-, γ- and δ) were purchased from Sigma Aldrich (Germany). All derived values are given in μg g^{-1} of dry weight (DW).

Two-way analysis of variance (ANOVA) was done for derived data and mutual comparisons between genotypes were done using the least significance difference (LSD) test at 0.05 level. The MSTAT-C software package (MSTAT Development Team, 1989) was used for statistical analyses.

Results and Discussion

Mean squares from two-way ANOVA for genotypes were significant at 0.001 level for all traits (Tab. 1). Differences between years were significant at 0.001 level for four traits, but not for vitamin δE (significant at 0.01 level) and ß-carotene (non-significant; data not shown). Population × year interaction was significant (at 0.001 level) only for the three components of vitamin A. Average values of vitamin E and A compounds for the analysed genotypes are given in Tab. 1, as well as the results of LSD tests among them.

On the average, ß-carotene comprised 11.95% of all the analysed vitamin A compounds, while lutein and zeaxanthin comprised the rest of 88.05%. This is in accordance with previous findings of Kurilich and Juvik (1999), Brenna and Berardo (2004), Howe and Tanumihardjo (2006) and Kuhnen et al. (2011). Zeaxanthin was the major carotenoid, the same as in the research of Egesel et al. (2003). However, data presented by Weber (1987b) indicated lutein to be the major

component of total carotenoids. These differences in the results are possibly due to different genetic materials analyzed. ß-carotene in our research was the least abundant of the three carotenoid compounds and breeding for its higher concentrations are needed because of its high antioxidant activity. The efforts to breed maize for provitamin A have resulted in varieties with 9-17nmolg^{-1} DW of total provitamin A carotenoids, primarily β-carotene (Kurilich and Juvik, 1999). In the mentioned research lutein content varied from 0 to 20mg kg^{-1}, and ß-carotene from 0.07 to 7.64mg kg^{-1}.

Many studies have shown significant differences among maize genotypes in carotenoid and tocopherol levels. Wyatt et al. (1998) reported the value for total tocopherol content in Mexican corn to be 80.6µg g^{-1}, with relatively high content for γ-tocopherol of 58.0µg g^{-1} and 22.6µg g^{-1} for α-tocopherol. According to Tadmor et al. (2000) total tocopherol content in maize grain of inbred lines ranged between 65 and 90mg g^{-1} DW, while the amount of α-tocopherol varied from less than 10 to more than 50%. Moros et al. (2002) have found a total xanthophyll content of 21.97mg g^{-1}, with lutein 15.7mg g^{-1}, zeaxahthin 5.7mg g^{-1}, and ß-cryptoxanthin 0.57mg g^{-1} among maize yellow dent genotypes. Analyses of CIMMYT accessions with yellow to dark orange kernels have identified large variation in the number of provitamin A molecules (Egesel et al., 2003) and their carotenoid profiles. Among more than 1000 tropical genotypes, promising materials with provitamin A concentrations (8µg g^{-1}) and/or carotenoid profiles were identified that can be used in breeding programs. Variability in the content of β-carotene of analyzed maize varieties by Howe and Tanumihardjo (2006) ranged from undetectable in the white maize to 0.77nmol g^{-1} DW in the yellow, 5.6nmol g^{-1} DW in the orange, and 13.9nmol g^{-1} DW in the dark orange maize. The observed genetic variability in their research suggested profound differences in potential health promotion among genotypes. Eighty-seven elite maize inbreds representing major heterotic groups in China were evaluated for carotenoid and tocopherol fractions by HPLC (Chander et al., 2008a). β-carotene, β-cryptoxanthin, α-carotene, lutein, zeaxanthin, and total carotenoids ranged 0.016-1.726; 0.012-3.666; 0.004-0.852; 0.040-17.504; 0.022-6.728, and 0.096-22.495µg g^{-1} with the joint mean values of 0.449, 0.876, 0.121, 5.803, 3.048, and 10.298µg g^{-1}, respectively. The pooled mean values of α-tocopherol, γ-tocopherol, δ-tocopherol, and total tocopherols were observed as 23.98; 32.90; 2.189; and 59.55µg g^{-1}, with ranges of 3.98-74.81; 2.81-78.16; 0.236-5.338 and 19.60-120.69µg g^{-1}, respectively. A total of 93 landraces belonging to the European Union Maize Landraces Core Collection (EUMLCC) were analysed for the content of lutein, zeaxanthin, and total carotenoids (Berardo et al., 2009). The range of these micronutrients was very large, namely for lutein 1.03 to 21.00mg kg^{-1} DW, for zeaxanthin 0.01 to 35.00mg kg^{-1} DW, and for total carotenoids 1.09 to 61.10mg kg^{-1} DW. A single cross was developed from the population in this research with increased carotenoids content that has been used in Italian food industry. Kuhen et al. (2011) have evaluated 26 maize landraces from southern Brazil for their potential as natural colorants or as functional food ingredients. The highest value of total carotenoids was 11.72mg kg^{-1}, followed by 10.86mg kg^{-1}. Mugode et al. (2014) have found a content of 7.5 to 10.3µg g^{-1} DW β-carotene in the biofortified maize hybrids.

In our research, content of γ+ß and δ-tocopherols (vitamin E fractions) on the average was moderate, and none of the landraces showed high values. For α-tocopherol two landraces had high values (13.330µg g^{-1} and 9.138µg g^{-1}, respectively). Since these 16 landraces are not among the high-oil ones (data not shown), lack of high concentrations of some vitamin E fractions would not be reflected on the quality and stability of oil possibly extracted from them. On the other hand, these landraces are white, yellow and orange flints or semi flints, and vitamin A fractions ranged from the trace values (white landraces) to 11.37µg g^{-1} lutein, 40.91µg g^{-1} zeaxanthin and 5.248µg g^{-1} ß-carotene. Maximum lutein value in our research was not very high, but maximum

values for zeaxanthin and ß-carotene were high in comparison with literature data. One landrace, named L 161, had high values of α-tocopherol (second in the range) and both the highest values of zeaxanthin and ß-carotene. It can be used for the biofortification programs in maize, although its grain yield seemed to be very low (data not shown). This means that alongside with improvement of vitamin contents an attention during selection should be paid to grain yield and other important agronomic characters.

Appart from conventional breeding, marker assisted selection (MAS) can be applied in elevating vitamin content in maize grain. For instance, two inbreds (C1.7 and Deexp3) with high amount of β-carotene (13.6μg g^{-1}) have been identified in temperate germplasm and the molecular marker for β-carotene content in these inbreds has been developed (Ortiz-Monasterio et al., 2007; Harjes et al., 2008). Also, Wong et al. (2004) and Chander et al. (2008b) showed potential of MAS for carotenoids, and Chander et al. (2008c) for tocopherols.

Conclusion

A total of 16 maize landraces were analysed for their vitamin A and E profiles. The content of γ+ß and δ-tocopherols was moderate, while two landraces showed high values of α-tocopherol. Maximum lutein value in our research was not very high, but maximum values for zeaxanthin and ß-carotene were high in comparison with literature data. One landrace showed a high potential for breeding programs for improvement of vitamins contents (biofortification) alongside with agronomic traits.

Acknowledgments

This research was supported by the Project TR 31028 "Exploitation of maize diversity to improve grain quality and drought tolerance" of the Serbian Ministry of education, science and technological development.
