Abstract

Pomegranate (*Punica granatum*) is an important horticultural crop for both domestic and export markets in Turkey. It adapts to all kinds of climate and soil. It is well adapted to the growth conditions in Turkey and Mediterranean countries is frequently found growing in wild or semi wild conditions. Pomegranates can tolerate long periods of drought once the plant is established but regular irrigation is mandatory in commercial production. We investigated the effect of different irrigation water amounts on nutrient uptake and content of leaf pigments of 10-year old pomegranate cv İzmir 1 trees two consecutive years (2009-2010). Three different irrigation water quantities (control, deficit and full irrigation) were applied by drip irrigation system. First leaf samples were taken a week before starting the irrigation treatments and continued until the end of the harvest season with four weeks interval. Results showed that leaf content of phosphorus, potassium, calcium, iron, and zinc was affected with quantity of irrigation water in the first year. But in the second year, only phosphorus content changed by the irrigation levels. In both years of the experiment chlorophyll a, b and total were not affected by the irrigation treatments but they differed during growth periods. Chlorophyll a and chlorophyll b contents increased in the first year, and decreased in the second year during vegetation periods. Total chlorophyll contents of leaves showed same behaviour as chlorophyll a and b. In the first year, all chlorophyll components contents in leaves were found to be higher compared to second year.

Key words: *Pomegranate, İzmir 1, drought stress, deficit irrigation, leaf content*

Introduction

Pomegranate (*Punica granatum* L.), belongs to the family *Punicaceae* which is believed to be native to the southern Iran and Northeast Turkey (Janick, 2007). The medicinal properties of pomegranate, especially in traditional systems, are known from time immemorial (Roy and Waskar, 1997). Commercial pomegranate orchards are grown in many regions of the world, including the Mediterranean Basin countries. It adapts to all kinds of climate and soil. It is well adapted to the growth conditions in Turkey and Mediterranean countries is frequently found growing in wild or semi wild conditions. Favourable growth takes place where winters are cool and summers are hot. It is tolerant to drought, salinity, iron chlorosis and active limestone (Hepaksoy et al., 2013). In Turkey the pomegranate is commercially significant specie due to adaptation is well and beneficial effects on health. Turkey is one of the main pomegranate producer countries in the world. It is possible grow pomegranates in all parts of Turkey except some regions (Onur, 1988). Turkeys' pomegranate production has reached 445.750 tons in 2015 (Anonymous, 2015). The most important growing area of Turkey is the Mediterranean region. Aegean and Southeast Anatolia are other important regions of the country. Although pomegranate is known as a drought tolerant crop, regular irrigation is mandatory to commercial

production. Fruit culture in arid and semiarid areas must be directed towards the use of less water-demanding and more stress-resistant plant materials which, together with deficit irrigation, will allow significant water savings and the profitable production of high quality fruits (Rodríguez et al., 2012). Irrigation scheduling is very important to optimise the use of water resources (Hepaksoy et al., 2009). Water scarcity in arid and semi-arid areas has led to development of new water saving techniques, such as sustained deficit irrigation (Peña et al., 2013).

This study investigated the effects of different irrigation amounts on plant nutrients and leaf chlorophyll contents of pomegranate trees.

Materials and methods

This study was conducted with 'İzmir 1' pomegranate in Bornova County of Izmir province, Turkey (38°27'10" N and 27°13'19" E) during two consecutive years (2009-2010). The dominant climate is a mild Mediterranean. Fertilizers were not applied during the experiment. The experiment was designed in a randomized complete block design with four replications. In each replication one tree was used for sampling. Evaporation was measured in class A-pan placed near the research area. Three different irrigation water quantities (S_0 = no irrigation, S_1 = 50% and S_2 = 100% of the water quantity evaporating from class A pan) were applied by drip irrigation system. Emitters of system have taken place in the crown of the tree, and whole area per tree was not wetted. The crop pan coefficients (Kcp) for I_1 and I_2 irrigation treatment was taken 0.50 and 1.00, respectively. Irrigations were applied with 7-day interval. The applied quantity of irrigation water was calculated as given below formula:

$$I = Epan \times Kcp \times A \times P$$

where:
I: The quantity of irrigation water (liters);
Epan: The quantity of evaporation in class A pan (mm);
Kcp: Crop pan coefficient (0.50 for S_1 and 1.00 for S_2);
A: Tree area (18 m^2 per tree);
P: Wetted area percentage (30%).

The soil moisture to the field capacity within 60 cm soil depth at each treatment was provided a week before starting the irrigation treatments. Irrigation was started 16th June and 6th July; finished 8th and 14th September in first and second years, respectively. Applied water quantities are given in Tables 1 and 2. First leaf samples were taken a week before starting the irrigation treatments and continued until the end of the harvest season with four weeks interval. The leaf samples were taken totally five times. Analysis of Chl a, Chl b, and total Chl in plant tissue was performed by Arnon (1949). Nutrients content, except N, was measured with inductively coupled plasma atomic emission spectroscopy-ICP OES (SpectroGenesis EOP II, Spectro Analytical Instruments GmbH, Kleve, Germany). N analysis was made by the Kjehdahl method (Kacar, 1984).

Table 1. Quantities of irrigation water in first year (L/tree)

Irrigation No	Water quantity[1]		Irrigation No	Water quantity	
	S_1	S_2		S_1	S_2
1	140	281	8	173	346
2	105	210	9	174	348
3	165	329	10	158	317
4	140	280	11.	188	377
5	153	306	12	127	254
6	169	337	13	115	230
7	176	352	Total	1984	3968

[1]S_1 and S_2:= 50 and 100% of the water quantity evaporating from class A pan, respectively.

Table 2. Quantities of irrigation water in second year (L/tree)

Irrigation No.	Water quantity[1]		Irrigation No.	Water quantity	
	S_1	S_2		S_1	S_2
1	124	248	7	144	289
2	137	273	8	160	319
3	154	308	9	133	267
4	165	330	10	87	174
5	127	255	11	80	161
6	129	258	Total	1441	2881

[1]S_1 and S_2:= 50 and 100% of the water quantity evaporating from class A pan, respectively.

Statistical analyses of all data were performed with SPSS Version 16.0 (SPSS Inc., Chicago, IL, USA). Differences between the means were compared by Duncan test at a significance level of $P<0.05$.

Results and Discussion

Leaf mineral nutrient content

Leaf content of the most important plant macro nutrient which is nitrogen was not affected both irrigation and vegetation period as a statistically. Average N contents were found to be 1,516%, 1,622% and 1,591% at the 0%, 50% and 100% irrigation treatments, respectively in the first year (Table 3). In the second year N contents were lower than first year. Average N contents in leaves were 1,282%, 1.450% and 1,428% at the 0%, 50% and 100% irrigation treatments, respectively (Table 4).

Phosphorus (P) content was significantly influenced by irrigation levels and throughout development periods were changed significantly in both seasons of study. Leaf P concentration was highest non-irrigated treatment at both year. The highest values were at the beginning of the season and the lowest values were at the end of season in both years. Average P contents were found to be 0,247%, 0,163% and 0,153% in first; 0,210%, 0,135% and 0,116% in second year non-irrigated, full irrigation and deficit irrigation treatments, respectively (Table 3 and 4).

Leaf potassium concentration was differed by the irrigation in the first year. Average K contents of leaves decreased with the irrigation in the first year. They were 1,156%, 0,922% and 0,878% I_0, I_1 and I_2 treatments, respectively (Table 3). K content throughout development periods was changed significantly at the both years. In the first year, K amount decreased towards fruit ripening and reached the lowest level after harvest time in the deficit and full irrigation

treatments. K content of non-irrigated trees increased till July 31, and then started to decrease and fall down the lowest content at the harvest time. In the second year, K content increased till mid-season and then started to decrease in the 0% and 50% irrigation treatments.

The leaf N percentage was increased slightly (not significant statistically) while P and K concentrations were decreased by the increasing irrigation amounts in the present study. This result for N is in agreement by Khattab et al. (2011) on pomegranate. Low leaf nitrogen concentration in spring was associated with a period of intense vegetative growth (Cabrita and Martins-Loução 1990). Leaf P content is expected to decrease with vegetation because plants uptake a large portion of phosphorus and potassium they need during the first periods of development (Kacar et al., 1979).

Calcium (Ca) contents were statistically affected by irrigation water quantities, between the sampling dates in the first season while the statistically significant differences were observed between the sampling dates in the second season. In the first year Ca content increased by irrigation water quantities. The lowest (1,485%) and the highest (2,474) leaf Ca contents were encountered in the trees non-irrigated and in the trees full irrigated, respectively. They were increased continuously during vegetation and reached the highest level after harvest time in all irrigation treatments (Table 3). In the second year, Ca contents were lower at the beginning of vegetation and after harvest, whereas higher content was observed in the middle of vegetation in all irrigation treatments. Old leaves generally contain a higher level of calcium compared to young leaves (Kacar et al., 1979). For this reason, as leaves got older with vegetation, the level of Ca was found to be higher. Calcium is considered to be an immobile element and the leaf concentration of this element generally increases throughout the growing season (Grigal et al., 1976; Worley, 1977).

-No data

The leaf contents of magnesium (Mg) were not affected significantly by irrigation quantities whereas they changed significantly during the season in both years. In general, Mg content was found to be higher in the middle of the development season compared to the beginning. The lowest values were found at the beginning of season in all treatments at the both seasons. The rate of bonding of total magnesium in plant leaves to chlorophyll molecule is closely associated with magnesium (Kacar and Katkat, 2009).

There were no significant changes in the micro nutrients copper and manganese in the first year and all of them in the second year by the irrigated. Data were given in tables 3 and 4. All micro nutrient elements, except Cu in the first year and Fe in the second year, contents were changed statistically during growth period. The highest and the lowest both iron and zinc contents were encountered in the trees non-irrigated and in the trees deficit irrigated, respectively. Leaf iron contents differed during vegetation period in the first year and it decreased in the non-irrigated trees while increased slightly in the other treatments. Manganese contents were increased during growth period whereas zinc contents were decreased in the first year. The leaf contents of copper continuously decrease until the end of development season and the lowest contents were found after harvest time at the all treatments in the second year. Manganese and zinc contents of leaves increased in full irrigation (100%) treatments but decreased in non-irrigation (0%) and deficit irrigation (50%) treatments. According to Khattab et al. (2011) nutrient uptake retarded under water stress condition where a substantial decrease in transpiration rates and impaired active transport and membrane permeability and resulting in a reduced root absorbing power plant.

Leaf chlorophyll concentration

In both years of the experiment chlorophyll a, b and total were not affected by the irrigation treatments but they differed during growth periods. In the first year, all chlorophyll components contents in leaves were found to be higher compared to second year. Chlorophyll a content increased in the first year, and decreased in the second year during vegetation periods. In the first year it increased from 4,252 mg/L to 5,090 mg/L in non-irrigation, from 3,672 mg/L to 7,270 mg/L in deficit irrigation and from 5,049 mg/L to 6,037 mg/L in full irrigation treatments. In second year it fall down from 3,390 mg/L to 2,375 mg/L in 0% irrigation, from 5,046 mg/L to 2,857 mg/L in 50% irrigation and from 5,981 mg/L to 2,262 mg/L in 100% irrigation (Table 5). As in the case of leaf chlorophyll a, chlorophyll b contents were higher in the first year and they increased in the first year, and decreased in the second year during vegetation periods. Chlorophyll b contents of leaves increased from 1,809 mg/L to 2,138 mg/L in S_0, from 1,554 mg/L to 3,104 mg/L in S_1 and from 1,356 mg/L to 2,548 mg/L in S_2 treatments in the first year. In second year it decreased from 1,732 mg/L to 1,120 mg/L in S_0 treatment, from 2,450 mg/L to 1,384 mg/L in S_1 treatment and from 2,857 mg/L to 1,139 mg/L in S_2 treatment (Table 5). Total chlorophyll contents of leaves showed same behaviour as chlorophyll a and b. Chlorophyll a, b and total contents were not significantly influenced by irrigation treatments but slight reductions were observed by decreasing irrigation amounts in both seasons. These results are in agreement by Khattab et al. (2011) on pomegranate. This increment in leaf pigment concentration could be attributed to increasing of macro element uptake, especially N and Mg as a consequence of improved soil moisture under irrigation. In fact, N and Mg contents of leaves increased a slight in present study.

Conclusion

Experiment results showed that leaf content of phosphorus, potassium, calcium, iron, and zinc was affected with quantity of irrigation water in the first year. But in the second year, only phosphorus content changed by the irrigation levels. In general higher concentrations were obtained from non and full irrigated trees. Also leaf chlorophyll pigments (a, b and total) were not affected by the irrigation statistically. Both leaf nutrient elements and chlorophyll pigments changed during the vegetation periods. Data showed differences between years. Annual climatic changes may affect the growth or yield of tree. So deficit irrigation should be considered in commercial pomegranate orchard as a practice to be long years regularly applied to enhance fruit composition and reduction fruit splitting and cracking.

Abstract

Basil (*Ocimum basilicum* L.) is used as a medicinal. The effects of salt stress were studied on three varieties of basil ("Grand Vert" (GV), "Fin Vert" (FV) and "Grand Vert Sweet" (GVS)). Seeds were germinated in petri dishes and plants were cultivated under plastic house in plastic pots felled of black peat. Under salt stress (NaCl: 1-18g/l), seeds are able to germinate even at 15 g/l but germination period were delayed of 2 days. Plants grew up to 12g/ l, flowered and fruited up to 6 g/l. NaCl affected all organs of the plant (stem length, number of leaves, fresh and dry weight of stems and roots). Photosynthesis parameters (chlorophylls, photosynthetic active radiation, net photosynthesis, conductance, and CO_2) were also affected. Faced to salt stress (NaCl), variety "fin vert" (FV) was more tolerant thanks to large amounts of proline, synthesized and accumulated in stressed plants which had 13 times more than control plants which allowed probably their osmotic adjustment with culture medium.

Keywords: *Basil (Ocimum basilicum L.), NaCl, Germination, Photosynthesis Parameters, Proline.*

Introduction

Ocimum basilicum L. is an aromatic herb belonging to the Lamiaceae family which is characterized by a great variability of morphology. This medicinal plant has several functional characteristics including treatment of headaches, coughs, diarrhea, dyspepsia, flatulence, gastritis, constipation, warts, worms and kidney malfunctions (Simon et *al*., 1999). It is known as culinary herb which has a distinctive flavor for many foods and it is a source of aroma compounds and essential oils containing biologically active constituents. Many researches have reported that this plant has insecticidal, nematicidal fungistatic (Reuveni, et *al*., 1984). Basil extracts are also used in the manufacturing of cosmetic and pharmaceutical products. Medicinal and aromatic plants are cultivated especially for drugs. Owing to their high curing value and wild occurrence in diverse environments, they have been considered to be promising plants for marginal lands, new reclaimed-soils and semi-arid regions (Said-Alahl and Omer, 2011). However, one of the most important factors affecting plant growth and the production of secondary metabolites is salt stress. In fact, salinity is one of the important environmental stresses limiting soil fertility that adversely effects on growth and productivity of plants around the world (Hosni, 2009; Zahedi et *al*., (2010). One of the most important changes in plant response to increasing soil salinity is stopping or reducing vegetative growth and leaf development. This reduction in growth is a consequence of several physiological responses including modifications of ion balance, water status, mineral nutrition, stomatal behavior, photosynthetic efficiency. The rate of photosynthetic CO_2 assimilation is generally reduced by salinity. This reduction is a result of a reduced stomatal

conductance and consequent restriction of the availability of CO_2 for carboxylation (Brugnoli and Lauteri., 1991). Also, Photosynthesis may decrease by direct effect of salt on the photosynthetic apparatus. However, conflicting results concerning the role of stomatal limitation of photosynthesis were reported. For instance, in bean (*Phaseolus vulgaris* L.), a salt-sensitive species, and cotton (*Gossypium hirsutum* L.), a salt-tolerant species, the reduction in assimilation was described as a result of a stomatal limitation (Brugnoli and Lauteri, 1991), but other works attributed the reduction in photosynthesis to non-stomatal limitation (Dunn and Neales, 1993). Compared with other salt tolerant plants, basil would be classified as a plant moderately tolerant to salt during seed germination and seedling emergence (Ramin, 2005).
That's why the objective of this work is to study the effect of salinity on germination, Photosynthesis parameters, and proline accumulation.

Material and methods

Germination in petri dishes:

The seeds were disinfected by sodium hypochlorite (1%) for 10 min, and then rinsed with distilled water. Afterwards, seeds were placed on petri dishes. Eight NaCl concentrations (0 (distilled water), 1, 3, 6, 9, 12, 15, 18 g/l) were used to determine the salt tolerance of seeds. NaCl was dissolved in distilled water. Seeds were germinated on two layers of filter paper in petri dishes (9 cm in diameter). The seeds were allowed to germinate at 25°C in the dark and they were considered as germinated when the emerging radicle was elongated to 2mm. The number of seeds germinated was counted daily for 7 days. Final germination rate was determined using this formula: Final germination rate (%) = n/N x 100 with n: number of germinated seeds on the nth day and N: total number of seeds.

Growth in greenhouse:

The seeds were germinated in plastic pots (25cm of diameter) containing 2kg of soil, in a greenhouse under 27 ± 3ºC day temperature, 85 ± 5% relative humidity and 12h of photoperiod. When fourth leaf was completely expanded, plants were irrigated permanently (every 5 days) with five salinity levels (0, 1, 3, and 6 g/l). Before flowering, chlorophyll a and b content in milligrams (mg) were calculated after estimating the absorbance of the chlorophyll solution, which was measured with a spectrophotometer (T60 Uv /vis) at 645 and 663 nm using the formula of Arnon (1949). Proline content (µ mol /g FW) was estimated based on proline's reaction with ninhydrin and the absorbance of the solution was read at 520 nm using toluene as blank by UV-visible spectrophotometer (Bates et *al*., 1973).After 45 days of salt treatment, growth performances of the plants in terms of shoot height, free proline contents, net photosynthetic rate and transpiration rate of *Ocimum basilicum* leaves were determined prior to the harvest. Net photosynthetic rate, transpiration rate and CO_2 in the first fully expanded leaf after exposure to salt stress (0, 1, 3, 6, and 9 g/l) were measured at 11.00 am using a portable photosynthesis system (CI-301PS de CID Inc).
The experimental designs were Completely Randomized Design for germination experience and Randomized Complete Block for pot experiment. The treatments were arranged in factorial ones with four replications. All data were analyzed by SPSS software and Duncan's Multiple Range Test was used to determine significance of differences between variables ($p<0.05$).

Results and discussions

Germination in petri dishes

The results (Table 1) showed that different levels of salinity have significant effect on basil seed germination. Many researchers have reported similar results (Mousavi et al., (2011) and Zahedi et al., (2010). In all of cultivars, there was a decrease in germination percentage when the concentration of salt increase. While, in this experiment, cultivars had different response to the salinity. In control, seed germination percentage varied between 50% ("Grand Vert Sweet") and 70% ("Fin Vert"). At the highest salt concentration (18 g/l), germination was not possible.

Chlorophyll content

Data regarding chlorophyll content is presented in Table 2. Statistical analysis of the data revealed that different salinity levels and the interaction between salinity and various genotypes had a significantly effect on chlorophyll a and b. By increasing salinity levels from 0 to 6 g/l, these photosynthesis pigments reduced. This decrease is consequence to the reduction of chlorophyll a for the varieties "Grand Vert" and "Fin Vert" and simultaneous the chlorophyll a and chlorophyll b for the variety "Grand Vert Sweet". Maximum reduction was observed when plants were exposed to high salinity level (that is 6 g/l).

Photosynthetic parameters

Photosynthetic active radiation (PAR)

The photosynthetic active radiation, wish can fixes the CO_2 under the chlorophyll pigments a and b, can be lost as heat and fluorescence when the plant is under biotic or abiotic stress. Results showed that in absence of salt stress, the varieties "Fin Vert" and "Grand Vert Sweet" absorbent more than variety "Grand Vert". Under salt stress, the absorbed photons content increases slightly when the concentration of NaCl increase for all the varieties. For exemple at 6 g/l of NaCl, this increasing varies from 2 (variety "Grand Vert") to 12% (variety "Grand Vert Sweet").

Internal CO2 concentration

In control plants (0 g/l NaCl), internal concentration of CO_2 ranges from 100 of the variety "Grand Vert Sweet" to 300 ppm of the variety "Grand Vert"). In stressed plants (1-6 g/l NaCl), the concentration of CO_2 decrease by the increasing of the concentration of NaCl. At the highest concentration (6 g/l), the CO_2 content is only 1/3 comparing to control plants for the variety "Grand Vert". The variety "Grand Vert" has the highest concentration of CO_2.

Net photosynthesis assimilation (Pn)

In control medium, the net photosynthetic assimilation (Pn) ranges from 4.45 (variety "Fin Vert) to 9.5 $\mu mol.m^{-2}.s^{-1}$ (variety "Grand Vert). With the increasing of NaCl, the photosynthetic assimilation decreases. Indeed, for 6 g/l, the Pn decreased by 48% compared to the control for the variety "Grand Vert".

Transpiration

Transpiration varied from 0.5 (variety "Grand Vert Sweet") to 0.9 $mmol^{-1}.m^{-2}\cdot s^{-1}$ (variety "Grand Vert") in control plants. When the concentration of salt increases, the transpiration increases. Indeed, under 6 g /l NaCl, the intensity of transpiration is 7.5 times higher than in the control for the variety "Grand Vert Sweet".

Proline accumulation

Significant differences were observed between the genotypes of basil plants for proline in leaves (Table 2). In this study, the proline content varied among the basil genotypes whether the plants were grown with or without salinity stress. The control plants (grown in absence of NaCl) synthesize and accumulate proline which varied from 5 (variety "Fin Vert") to 30 mg/l (variety "Grand Vert Sweet"). In the presence of the highest concentration 6 g/l, proline content increased from 30 (0g /l) to 40 g/l (variety "Grand Vert Sweet") and from 5 (0 g /l) to 55 g/l (variety "Fin Vert") which means an increase of 11 times comparing to control.

For most plants, the increase of salt (NaCl) causes a decrease in germination percentage; this can be the results of toxic effects of Na^+ and Cl^-. This toxicity changes the activity of some enzymes included in germination process, changes protein metabolism and interrupts hormonal balance (Gomes-Filho et *al*., 2002). This reduction due to the accumulation of ions in the embryo and the mineral disequilibrium (Guerrier, 1980), and the invasion of tissues by Na^+ et Cl^- depends on the useful ion (K^+, NO^{3-} et PO_4^{2-}) (Hannachi, 1997). In fact, those ions reduce the germinative capacity of basil (Al-Karaki., 2001) and they induce metabolic alteration of the germination process and in extreme cases they cause the death of the embryo by excess of ions (Bliss et *al.*, 1986).

Salt stress didn't affect only the germination stage but also the growth stage. So in this stage, there is an alteration of photosynthetic process. There is a reduction of photosynthesis which made the alimentation of all organs by the Carbone Hydrate. The decrease of photosynthetic capacity under salinity might be due to the stomatal closure, which limits stomatal conductance and photosynthetic CO_2 assimilation (Downton et *al*., 1990; Yang and Lu, 2005). In a manner consistent with our results, stomatal closure in leaves of chickpea (Garg and Singla, 2004), sorghum (Netondo et *al*., 2004) and Jatropha curcas L (Oliveria Campos et *al*., 2012) is a prime constraint to photosynthesis by limiting CO_2 flux into the leaves of salt- stressed plants. However, these results are in contrast with those of Praxedes et *al* (2010), who proposed no significant effects of salt stress Pn in cowpea plants. It is well known that salt stress may induce a decline in the Pn (Lu et *al*., 2009; Qin et *al*., 2010). Sensitivity of Pn is an ideal indicator under saline stress. Decline in Pn was correlated with depressed plant growth. The decline in photosynthesis observed in case of salinity could be attributed to stomata factors. During salt stress the concentration of CO2 in chloroplasts decreased because of the reduction in stomata conductance, inspite of the apparent stability of CO_2 concentration in intercellular spaces (Tourneux and Peltier, 1995). Brougnoly and Lauteri (1991) also indicated that reduced photosynthetic carbon assimilation was attributed to reduced stomata conductance. Generally, transpiration rate tended to decline with increasing salinity. This may be due to the fact that lowered water potentials in the root can trigger a signal from root to shoot (such as abscisic acid, which has been suggested to be the operating mechanism (Zhang and Davies, 1991). It was also observed that the stomata conductance of young bean plants declined with salinity. In order to reduce the effect of salt stress, plants produce proline. Proline accumulation in salt stressed plants is a primary defense response to maintain the osmotic pressure in a cell, which is reported in salt tolerant and salt sensitive cultivars of many crops (De Lacerda et *al*., 2003; Kumar et *al*., 2003; de Lacerda, et *al*., 2005; Demiral and Türkan, 2005; Mansour et *al*., 2005; Desingh & Kanagaraj, 2007; Koca et *al*., 2007;). Many plants accumulate proline as a protective osmolyte under stress conditions. In fact, a positive correlation between proline accumulation and salt tolerance can be used like an index for salt tolerance between plants (Misra et *al*., 2004).

Conclusion

In conclusion, this study demonstrated that seed germination of basil varied according to the change in NaCl levels. The increase of salt stress decreased the germination rate. All studied parameters on seedling growth were also affected by salt stress. We found that "Fin Vert" variety is the most resistant to salt stress. In order to improve the tolerance of basil to salt stress in arid and semi-arid region, biotechnological techniques may be useful to regenerate tolerant plants.

CROP YIELD AND SELECTED SOIL PHYSICAL PROPERTIES UNDER DIFFERENT TILLAGE

Rastislav BUŠO[1], Roman HAŠANA[1], Ivana KAŠIČKOVÁ[1], Soňa GAVURNÍKOVÁ[1]

[1]National Agricultural and Food Centre, – Research Institute of Plant Production Piešťany, Slovakia

Abstract

The aim of the study was to investigate an influence of different soil tillage technologies on selected physical properties of soil and yield of winter wheat and spring barley grain. Field experiment was established in growing seasons 2013 – 2015 in Research Station Borovce (NAFC – RIPP Piešťany), Slovakia. Experiment was conducted in four different soil tillage technologies: conventional, minimization, mulch and no-till technology. The highest soil bulk density in the depth of 0.0 to 0.1 m was in conventional technology, 0.10 – 0.20 m in no-till, 0.20 – 0.30 m was in minimization technology (1.46 $t.m^{-3}$, 1.50 $t.m^{-3}$ and 1.54 $t.m^{-3}$ respectively). The highest porosity during the experimental period was observed in depth of 0 – 0.10 m in no-till technology (51.69 %). This was the highest value from the point of view of technology and sampling depth. The highest average value of soil moisture was in depth of 0 to 0.10 m, the most favorable value was reached in no-till technology (18.15 %) in this sampling depth. It was also the highest value throughout the whole soil profile (0 to 0.80 m). The highest grain yield of winter wheat and spring barley has reached in minimization technologies during growing season 2013 – 2015.

Keywords*: soil tillage technologies, physical properties of soil, yield of grain*

Introduction

In the last years, not only in our country but in all countries with intensive agriculture, are beginning to show the negative effects of mechanization in some technologies applied in agricultural production. Significantly, these negative tendencies speech to changes in the form of physical, chemical and biological soil properties, which affect on the crops stability. Soil cultivated significant influenced on its physical properties. The soil should be adjusted to the condition that the cultivation of crops to provide good conditions for growth and development, at the same time is required to minimize the negative impact on the habitats and the environment. Different farming systems and machining technologies have different effects on soil properties. Improper use of tillage can increase soil compaction, reducing the structural stability of the aggregates, disrupt the surface pores and thus the air exchange, reducing the retention and transfer of water and dissolved substances into the soil and increase its losses by surface runoff and erosion. Intensive tillage may also reduce the content of soil organic matter due to increased of mineralization as well as contributing to erosion and reduce of sediment delivery cycle of organic matter from crop residues (Žák et al., 2011). Minimization and land protection technology have a beneficial effect on the soil structural stat, better management of soil moisture, reducing water and wind erosion, reduce leaching of mobile forms of nitrogen and others (Vach and Javůrek, 2011). On the other side, a number of negative consequences, especially the accumulation of soil and stubble-borne plant diseases, the costs of purchasing equipment, residues of herbicides that restrict the choice of crops, accumulation of resistant weeds, concerns about the effects of herbicides on the environment and human health, limit a greather using of no-

tillage technology (Thomas et al., 2007). The goal of work was to compare the relationship between the physical soil properties and harvest of selected field crops under different tillage systems (conventional, minimization, mulch and no-till).

Material and Methods

Field experiment with different technologies of soil cultivation was observed on research institutes NAFC - RIPP in Borovce in 2013 – 2015 years. The area has a continental climate with long-term nature with annual average of rainfall 593 mm (358 mm during vegetation). Long-term average in temperature of 9.2 ° C (15.5 ° C during vegetation). Altitude is 167 m n. m. The area is included in the corn-barley production type. Land on an experimental station is loamy black-brown soil, loess humus with depth from 400 to 500 mm, with a mean supply of P and K, neutral to slightly acidic soil reaction. Topsoil and subsoil horizons are slightly compacted. Humus content in the topsoil profile is moderate (2.43%), in the subsoil horizons is low (0.87 to 1.84%).
Selected crop rotation (winter wheat - grain corn - spring barley - soybean) partly reflects the current proportion of arable land of cereals in Slovakia (over 50%), represented by one legume crops and one cereal which is treated as root crops - grain corn. In experiment we found only two crops – winter wheat and spring barley. Within the problem-solving process are tested four technology tillage: conventional, minimization, mulch and no-till. Size of experimental plots was 35 x 9 m, it was founded in three repetitions. The results were processed by analysis of variance in the programming package Statgraphics and MS Office programs.

Results and Discusion

When we evaluating the growing years 2013 -2015, it should be noted that during the three years of the cases occurred to extreme differences in temperature and precipitation in each month, resulting also significant differences in the average of growing years.
Higher values of soil bulk density and lower porosity values in conventional soil cultivation compared with no-till systems also states Sidiras et al. (2001). On the other side, many authors report a higher specific weight and the lower total porosity variation, the no-till compared to conventional farming techniques with tillage (Hussain et al., 1999; Tebrūgge, During, 1999).
In different years due to high rainfall in the spring we can a sawing of spring crops with a high content of soil moisture and consequently the compaction of soil agricultural machinery, causing a significant increase in specific weight in conventional agrotechnics compared to direct sowing without tillage (Kotorová, 2007) .The average of soil bulk density (Table 1) was from 1.32 $t.m^{-3}$ at a depth of from 0.0 to 0.1 meters in minimization over 1.54 $t.m^{-3}$ also in minimization. The highest value of bulk density in profile 0.0 to 0.3 m were observed in the conventional technology (1.49 $t.m^{-3}$), the lowest 1.43 $t.m^{-3}$ in minimization.

Table 1. The average of soil bulk density ($t.m^{-3}$), Borovce 2013 - 2015

Technology	Depth (m)			
	0.0 – 0.10	0.10 – 0.20	0.20 – 0.30	Average
Conventional	1.46	1.49	1,51	1.49
Minimization	1.32	1.42	1.54	1.43
Mulch	1.36	1.48	1.52	1.45
No-till	1.35	1.50	1.53	1.46

In average of years 2013-2015 we observed the greatest porosity (Table 2) in depth of 0 to 0.10 meters in no-till technology (51.69%). This was the highest value regardless of the technology

and sampling depth. Also, in depth of 0.10 to 0.20 meters was the highest porosity in no-till technology too (48.13%). In a depth of 0.20 to 0.30 meters we observed the largest porosity in conventional technology (43.94%) and the lowest in no-till (41.49%). In average, irrespective of the sampling depth, the highest porosity was in the no-till technology (47.10%). The critical value of the soil porosity is clayey P <45%, and the clay-loamy is P <47% (Fulajtár, 2006).
Increase of soil bulk density and decrease of total porosity with depth, in parallel with the tillage and direct sowing in the soil also included Neudert (2007) and Badalíková - Gross (2004). In our experiments confirmed the relationship between density and porosity.

Table 2. The average of porosity (%), Borovce 2013 - 2015

Technology	Depth (m)			
	0.0 – 0.10	0.10 – 0.20	0.20 – 0.30	Average
Conventional	45.93	44.54	43.94	44.81
Minimization	50.61	47.66	42.59	46.95
Mulch	49.29	44.55	42.86	45.57
No-till	51.69	48.13	41.49	47.10

Average of soil moisture (Table 3) was the highest in depth of 0 to 0.10 m in no-till technology (18.15%). It was also the highest value in the whole profile donations (from 0 to 0.80 meters). In the depth of 0.50 to 0.60 m there was a return to the level of moisture like in the profile from 0.0 to 0.1 meters. On average, regardless of depth, we found the highest soil moisture in mulch technology (17.18%) but not in the conventional technology, we have found the value of 16.82%, which was subject to excessive moisture profile of 0.3 to 0.6 meters.

Table 3. Influence of technology and depth on average of soil moisture (%), Borovce 2013 - 2015

Technology	Depth (m)								
	0.0 – 0.10	0.10 – 0.20	0.20 – 0.30	0.30 – 0.40	0.40 – 0.50	0.50 – 0.60	0.60 – 0.70	0.70 – 0.80	Average
Conventional	16.73	17.17	16.95	17.20	17.44	17.24	16.41	15.42	16.82
Minimization	17.29	16.01	16.28	16.49	16.67	16.20	15.94	15.68	16.32
Mulch	17.23	16.42	16.47	16.92	17.41	17.32	16.58	15.87	16.78
No-till	18.15	17.36	16.95	17.04	17.39	17.45	16.99	16.16	17.18

In the growing years 2013 - 2015 we had the greatest grain yield of winter wheat in minimization technology (6.62 $t.ha^{-1}$) it was overcome of planned harvested by 0.62 $t.ha^{-1}$. In spring barley crop was the highest grain yield on minimization technology (4.87 $t.ha^{-1}$), but not overcome the planned yield 5 $t.ha^{-1}$ (Table 4). Lower grain yield of wheat in the no-till technology state Miština - Maple (2000), Kováč et al. (2010), Ball (2002), however, reported a higher yields for wheat in the cultivation of no tillage than with tillage.

Table 4. Grain yield (t.ha^{-1}), Borovce 2013 - 2015

Technology	Winter wheat	Spring barley
Conventional	6.55	4.42
Minimization	6.62	4.87
Mulch	5.88	3.35
No-till	6.22	4.37
Average	6.32	4.25

Winter wheat Hdd $_{0,05}$ year = 0.25875 ++; technology = 0.3171 ++; Winter wheat Hdd $_{0,01}$ year = 0.38321 ++; technology = 0.40209 ++; Spring barley Hdd $_{0,05}$ technology = 41284 ++; Spring barley Hdd $_{0,01}$ technology = 0,64495 ++

Conclusion

The average of soil bulk density in 2013 - 2015 was from 1.32 t.m^{-3} in a depth 0.0 - 0.1 meters in minimization technology to 1.54 t.m^{-3} also in minimization. The highest value of bulk density in profile 0.0 to 0.3 m were observed in the conventional technology (1.49 t.m^{-3}), the lowest 1.43 t.m^{-3} in minimization.

The largest average of porosity in years 2013 - 2015, regardless of the sampling depth, we observed in no-till technology (47.10%).

On average, regardless of depth, we found the highest soil moisture in mulch technology (17.18%) but not in the conventional technology, we have found the value of 16.82%, due to higher humidity in profile from 0.3 to 0.6 meters.

In the years 2013 - 2015 winter wheat and spring barley grain yield reached the highest in minimization technology.

Abstract

Low soil pH and a high mobile Al content of the soil pose a significant threat to wheat production on over 60% of arable land in Serbia. Wheat is very sensitive to soil acidity and high levels of mobile Al in the soil. However, genotypes show different sensitivity to these stress factors and external factors. Some wheat genotypes exhibit significantly higher tolerance than other wheat genotypes, or other cereal crops. This paper presents the results of testing conducted over three years to evaluate 10 genotypes of winter wheat for their tolerance to low soil pH and high levels of mobile aluminum in the soil. The analysis of productive traits and grain Al content of plants showed that the highest tolerance to low pH and high levels of mobile Al in the soil was exhibited by the genotypes 'Roane', 'Rapsodija', 'Ornil', 'Nora' and 'Nevesinjka', as opposed to the low adaptability to these stress factors in 'Sana', 'Kalyan sona', and 'Zarrin'. Tolerant genotypes had grain yields higher on average by 105%, number of grains per spike by 61%, grain weight per spike by 38% and 1000-grain weight by about 27% in comparison to sensitive genotypes. Also, grain Al concentrations in tolerant winter wheat genotypes were significantly lower (0.18-0.39 mg g^{-1}) than in sensitive genotypes (0.95-1.30 mg g^{-1}).

Key words: *adaptation, aluminum, genotype, wheat, soil*

Introduction

Acid soils cover substantial areas of Central Serbia. The total land area of Central Serbia and Kosovo is 4.7 million ha, of which more than 60 percent or 2.8 million ha are acid in reaction, with 30% of them being extremely acid (Stevanović et al., 1995). As most crops require slightly acid, neutral to slightly alkaline soils, few plants can tolerate conditions existing in these soils. Pseudogleys (epigleys) in Central Serbia have extremely unfavorable physical and chemical characteristics. As found by Narro et al. (2001) and Sumner (2004), the low fertility of acid soils is due to reduced solubility of some biogenic elements (P, Mo, B) and increased presence of some toxic elements and compounds, primarily Al. Also, their reduced productive capacity is mainly the result of increased levels of mobile aluminum which is toxic to most crops (Jelić et al., 2004; Jelić and Đalović, 2008).

Response to low soil pH and high mobile Al levels in the soil differs across species and cultivars. When grown on acid soils, sensitive genotypes produce significantly lower yields, whereas tolerant ones achieve the same or slightly reduced yields compared to non-acid soils. Tolerant plant species and genotypes show different degrees of tolerance. Some of them are essentially more tolerant than others, even within a single species, and the difference in tolerance among genotypes within species may be higher than among species. Rye is among the most tolerant species within the family *Triticeae.* Previous studies on tolerance in cereals have shown that rye

is the most tolerant species among cereals, followed by triticale (*X Triticosecale* Wittmack), wheat (*Triticum aestivum* L.), and barley (*Hordeum vulgare* L.) as the least tolerant (Aniol and Madej, 1996).

Therefore, there has been an increasing need in the cultivation of wheat and other cereal crops on acid soils to formulate fertilization systems and choose genotypes to be adapted to soil and climatic conditions in all cereal producing regions. Therefore, the objective of this study was to conduct biotesting of some winter wheat genotypes to identify genotypes tolerant of low soil pH and high mobile Al content in the soil, which would help increase grain yield and quality of winter wheat on these soils.

Material and methods

Research was conducted at the experimental field of the Dr Đorđe Radić Secondary School of Agriculture and Chemistry in Kraljevo over a period of three years (2012-2014). The soil used in the trial is classified as acid Al-toxic pseudogley. A two-field (wheat-maize) rotation was used.

The experiment was laid out in a randomized block design with three replications. Plot size was 100 m^2. Thirty winter wheat genotypes of different geographic origins and exhibiting great divergence were tested. Results for 10 wheat genotypes ('Pobeda', 'Evropa 90', 'Ornil', 'Roane', 'Rapsodija', 'Nora', 'Nevesinjka', 'Sana', 'Kalyan sona', 'Zarrin') are presented. The genotypes were evaluated for their adaptability based on parameters regarding productivity (grain yield, number of grains per spike, grain weight per spike) and grain quality (test weight, thousand grain weight and grain Al concentration).

Fertilization was based on the soil fertility status and included the following rates of pure nutrients: 120 kg N ha^{-1}, 100 kg P_2O_5 ha^{-1} and 80 kg K_2O ha^{-1}, applied as complex NPK fertilizer (8:24:16), superphosphate (17% P_2O_5) and ammonium nitrate (AN=17% N). Total amounts of phosphorus and potassium fertilizers along with one-third of nitrogen fertilizer were used during seedbed preparation, whereas the rest of the nitrogen was applied as a single treatment at the beginning of spring. The other crop management practices used during the winter wheat growing season were standard.

Seeding was performed at the end of October by a cereal seed drill at 650 germinating seeds per m^2. At full tillering, 1.2 Lha^{-1} Maton was applied for weed control. The crops were harvested at full maturity. Wheat grain properties were determined as follows: grain yield (t ha^{-1}, calculated at 14% grain moisture), number of grains per spike, grain weight per spike (g), 1000 grain weight (g) and test weight (kg hl^{-1}). Thousand grain weight was determined by an automatic seed counter. Test weight was determined by weighing a measured volume of grain expressed in kilograms per hectoliter.

Soil profiles were opened at the experimental plot, and the soil was sampled for analysis. Samples were taken after wheat harvest, at the end of July 2012, from the humus horizon (Ah= 0-15 cm), subhumus eluvial-pseudogley horizon (Eg= 15-40 cm) and from one part of the transitional B_1tg horizon (60-80 cm). The soil was analyzed by standard physical methods (soil texture by the pipette method, a variant of the pyrophosphate method (Živković, 1966)); and chemical methods (soil pH was determined in a 1:2.5 soil - 1 M KCl suspension after a half-hour equilibration period; hydrolytic acidity by Ca acetate extraction using Kappen's method; total adsorbed base cations by Kappen's method; humus content by the Kotzmann method; total nitrogen by the Kjeldahl method, and available P_2O_5 and K_2O levels by the Egner- Riehm Al method). Results were averaged and subjected to statistical analysis - ANOVA (Mead et al., 1996).

Soil characteristics

The soil used in the experiment is classified as pseudogley. Pseudogleys are not suitable for wheat, as this crop is not tolerant of extremely acid environments. The tested soil was heavy loam in the 0-40 cm layer, and light clay in layers deeper than 40 cm (Table 2). The proportion of silt and clay combined i.e. physical clay in the arable horizon (0-20 cm) was relatively high (46.29%), whereas that of total sand was low (11.68%). In deeper layers of the soil, the proportion of physical clay in general and silt in particular increased (over 55%), and that of total sand decreased (5.33%). This indicates a heavy texture (heavy loam soil to light clay soil) and very unfavorable physical properties of the soil.

Table 1. *Texture of Pseudogley*

Depth (cm)	Percentage of soil particles (mm)							Textural class
	2-0.2	0.2-0.05	0.05-0.01	0.01-0.005	0.005-0.001	< 0.001	< 0.01	
0-20	5.47	6.21	42.03	9.28	14.25	22.76	46.29	Heavy loam
20-40	4.23	5.82	42.26	10.60	14.46	22.63	47.69	
40-60	1.03	4.43	34.05	7.78	12.34	40.37	60.49	Light clay
60-80	0.70	4.84	36.31	5.75	15.60	36.80	58.15	
80-100	0.63	4.70	39.30	7.79	13.94	33.64	55.37	

The chemical characteristics of the tested pseudogley are very unfavorable (Table 3). Namely, this soil exhibits high acidity, with relatively low active acidity (pH in H_2O 5.24) in the arable horizon (0-20 cm) and considerably reduced acidity (pH in H_2O 6.04) in the deepest layers. Exchangeable acidity (pH in KCl) of this type of soil across profile depth ranges from 4.48 to 4.80. Hydrolytic acidity (Y^1) is relatively high (15.47 ccm) in the arable layer (0-20 cm), and considerably lower (7.35 ccm) in deeper layers.

Table 2. *Agrochemical properties of Pseudogley*

Depth (cm)	Humus (%)	Y^1 (ccm)	N (%)	T	S	T-S	pH		P_2O_5	K_2O
				(meq 100^{-1} g)			H_2O	KCl	(mg 100^{-1})	
0-20	2.18	15.47	0.14	16.71	8.08	8.63	5.24	4.48	8.0	13.8
20-40	1.84	13.98	0.13	16.69	9.79	6.90	5.55	4.58	7.0	13.6
40-60	0.66	12.45	0.09	26.24	20.02	6.22	5.46	4.42	1.3	8.5
60-80	0.71	9.97	0.07	26.29	21.31	4.98	5.64	4.52	1.0	7.6
80-100	0.63	7.35	0.02	25.62	22.02	3.60	6.04	4.80	0.8	4.3

The composition of the soil adsorption complex was very unfavorable (Table 3), showing very low values for adsorption capacity, total adsorbed base cations, and base saturation percentage. The humus content in the topsoil (0-20 cm) was low (2.18%) and decreases considerably with increasing depth. The pseudogley profile analyzed was moderately supplied with total nitrogen in the humus-accumulating horizon. Total nitrogen in the arable soil layer was 0.14% on average, and decreased significantly with increasing depth (0.02%). In the 0-40 cm soil layer, the soil was poorly supplied with readily available phosphorus (7.0-8.0 mg 100 g^{-1} soil) and moderately supplied with readily available potassium (13.8 mg 100 g^{-1}).

Results and discussion

Results on the testing of winter wheat genotypes for their tolerance to low soil pH and high mobile Al content in the soil are presented in Table 3. Low tolerance was observed in most wheat genotypes. The average grain yield in the tested genotypes was very low (1.53-3.73 dt ha^{-1}), and only 'Roane' achieved an average grain yield of 4.16 dt ha^{-1}. Very low grain yields were obtained by 'Kalyan sona' and 'Sana' (1.53 and 1.87 dt ha^{-1}, respectively), and 'Zarrin' and 'Evropa 90' (2.30 and 2.83 dt ha^{-1}, respectively). As shown in Table 3 parameters, tolerance to extreme soil acidity and high mobile Al content was highest in 'Roane', followed by 'Rapsodija', 'Nevesinjka', 'Ornil' and 'Nora', which gave an average grain yield of 3.30 to 3.73 dt ha^{-1}. The low performance of plants in terms of the number of grains per spike and grain weight per spike were the main reasons for the low yields of the tested genotypes. The significantly higher grain yield in tolerant genotypes ('Roane' and 'Rapspodija') is associated with the formation of more grains per spike and their thousand grain weight.

Table. 3. *Grain yield and quality of ten winter wheat genotypes (averaged over three years)*

Genotype	Tested parameters					
	Grain yield	Number of grains per spike	Grain weight per spike	Test weight	Thousand grain weight	Grain Al concentration
	(dt ha^{-1})		(g)	(kg hl^{-1})	(g)	(mg g^{-1})
'Roane'	4.16	26.1	0.66	74.85	31.0	0.18
'Rapsodija'	3.73	24.7	0.61	73.65	33.0	0.35

Number of grains per spike and grain weight per spike are important indicators of winter wheat productivity. The highest values of the two traits were recorded in 'Roane' (26.1 and 0.66 g, respectively), and the lowest in 'Kalyan sona' and 'Sana' (6.9-9.8 g and 0.25-0.32 g, respectively). Test weight was highest in 'Roane' and 'Zarrin' (75.65kg hl^{-1}), the former genotype being the most productive and the latter exhibiting significantly lower productivity. Therefore, this parameter is not a reliable indicator in evaluating genotype tolerance on acid soils.

Thousand grain weight is an important indicator of grain physical quality. This trait is directly dependent on grain filling percentage, hectoliter weight and some chemical properties (protein level, moisture, starch content, etc.). The highest 1000-grain weight was obtained by 'Kalyanscna' (35.5 g) and the other lower-yielding genotypes ('Pobeda'- 33.5 g, 'Sana'- 33.0 g), which may result from the significant decrease in the number of grains per spike and increase in grain filling. Moreover, grain yield in wheat on unstructured soils is positively affected by organic fertilizers (manure), but the effect of manure was not studied in the present experiment. Manure improves

the development of the root system, enhances the uptake of nutrients, prevents the loss of nutrients from fertilizers, and improves the nutrient binding capacity of the soil and subsequent nutrient release during continuous plant nutrition throughout the growing season (Arshad et al., 2004).

Significant genotypic variations were observed in grain Al concentrations (Table 3). Grain Al contents were high in 'Kalyan sona' and 'Sana' (1.30 and 0.95 mg g^{-1}), but were significantly lower in 'Roane', 'Rapsodija' and 'Nevesinjka' (0.18, 0.35 and 0.39 mg g^{-1}, respectively) compared to the other tested genotypes. The genotypes showing low grain Al concentrations achieved significantly higher grain yields, number of grains per spike and grain weight per spike, which is indicative of their better adaptability to low soil pH. Furthermore, tolerant wheat cultivars normally accumulate lower Al amounts and produce higher grain yields (Darko et al., 2004).

The coefficients of correlation between grain yield and productivity and grain quality parameters are given in Table 4.

Table 4. *Coefficients of correlation between grain yield and the tested productivity and grain quality parameters*

Parameters	GY	NGS	GWS	TW	TGW	CAl
GY	-	-	-	-	-	-
NGS	0.50^{*}	-	-	-	-	-
GWS	0.88^{**}	ns	-	-	-	-
TW	ns	ns	ns	-	-	-
TGW	ns	ns	ns	ns	-	
CAl	-0.71^{**}	-0.50^{*}	-0.80^{**}	ns	ns	-

GY- grain yield, NGS- number of grains per spike, GWS- grain weight per spike, TW- test weight, TGW- thousand grain weight, CAl- Al concentration in the grain

Grain yield showed a weak positive correlation ($r=0.50^{*}$) with grain number per spike and a strong positive correlation ($r= -0.88^{**}$) with grain weight per spike. However, grain Al concentration in the tested genotypes exhibited a much stronger negative correlation with grain yield and grain weight per spike ($r= -0.80^{**}$). Moreover, a negative correlation was observed between number of grains per spike and grain weight per spike and grain Al concentration. Similar results were reported previously elsewhere (Darko et al., 2004).

Conclusion

The results of testing winter wheat genotypes for tolerance to low soil pH and high mobile Al content in the soil showed the following:

Genotypes exhibiting lower than average grain Al concentrations achieved a significant increase in grain yield, number of grains per spike and grain weight per spike, which is indicative of their better adaptability to low soil pH.

The genotypes 'Roane', 'Rapsodija', 'Ornil', 'Nora' and 'Nevesinjka' showed better adaptation to local agroenvironmental and soil conditions, and are recommended as suitable for wheat production on acid soils.

EFFECT OF DIFFERENT HARVESTING TIMES TO YIELD AND EAR CHARACTERISTICS OF BABY CORN OBTAINED FROM SWEET CORN

Abdullah ÖKTEM*, Ayşe Gülgün ÖKTEM

Harran University, Agriculture Faculty, Field Crops Department, Şanlıurfa, Turkey
*Corresponding author: aoktem@harran.edu.tr

Abstract

Baby corn is also known as young corn, mini corn, finger corn, or candle corn. Baby corn is a type of vegetable and consumed as a fresh or canned. It is eaten whole and cob included both raw and cooked. Its cob is too fresh and crisp for human consumption. Baby corn ears are hand-picked as soon as the corn silks emerge or few days after. The harvest of baby corn must be timed to avoid matured corn ears. This study was aimed to determine effect of different harvesting times to yield and ear characteristics of baby corn obtained from sweet corn. Study was conducted in 2014 and 2015 under Harran Plain, Şanlıurfa, Turkey. Experiment was established to randomize complete block design with 3 replicates. In the study 12 harvest times were used. Ears were harvested from 1 to 12 days after ear silk emergence. According to variance analysis, all tested characteristics were significant ($P \leq 0.01$). With husk and without husk ear length, ear diameter, ear weight and baby corn yield values increased with delaying harvest times but ear crisply decreased after 6 days. Considering to ear diameter, ear length and yield; harvest for baby corn can be done within 2-6 day, but considering crisply of ear and custom pleasure; the best harvest time was within 2-4 day after ear silk emergence.

Keywords: *Baby corn, Harvest times, Şanlıurfa.*

Introduction

Corn (*Zea mays* L.) has become the important food grain with wheat and rice in the world. Different consumption type of corn is baby corn. Baby-corn is a very promising product for the internal and external markets (Pereira et al., 1998a). Baby corn is imported mainly from Asia countries in Turkey. It is a relatively new crop in Turkey and has acquired the interest of farmers due to its high premium price in market. But, there are no statistical data about the cultivated area and production of baby corn in Turkey. Baby corn is also known as young corn, mini corn, finger corn, or candle corn. Baby corn is grown for vegetable purpose. Baby corn is a 6-7 cm long, unfertilized, yellow colored, dehusked cob young ear of corn plant harvested within 2-3 days of silking. Baby corn ears are hand-picked as soon as the corn silks emerge or few days after. The harvest of baby corn must be timed to avoid matured corn ears (Galinat, 1985). Production of baby corn has been open-pollinated, of composites, hybrids, sweet corn, and popcorn. The sweet corn and popcorn provided best results due to the major acceptance by consumers (Pereira et al., 1998b). Baby corn is a diversified product composed of baby or young ears consumed as a fresh or canned vegetable (Kumar and Kallo, 2000). Its cob is too fresh and crisp texture and a subtle for human consumption. It is eaten whole and cob included both raw and cooked. Fresh baby corn has slightly sweet corn flavor and produces delicious treat in many recipes for the preparation of special soups, jams, cream, pickles and other delicious eatables. Baby corn is prepared in the form of salads, soups, pickles and meals (Gosavi and Bhagat, 2009). Fresh or frozen baby corn is also used in sandwiches, pizzas, salads, fried food and making pickle (Najeeb

et al. 2011). It is rich in vitamins B and C, potassium, fibers and carotenoids, which helps in the prevention of coronary diseases. Some traits, such as weight, length and diameter of the ears should be considered for the standard baby corn production. Also population density, use of fertilization and harvest time should be investigated in baby corn production (Takur and Sharma, 1999). The present investigation was undertaken to study effect of different harvesting times to yield and ear characteristics of baby corn obtained from sweet corn.

Materials and methods

This study was conducted in Sanliurfa, Turkey during 2014 and 2015. The experimental field is located in Harran Plain (altitude: 465 m; $37^{0}08^{'}$ N and $38^{0}46^{'}$ E) where the climate varies from arid to semi-arid. Table 1. provides the climatic data obtained at the Sanliurfa City Meteorological Station. As can be seen from Table 1. the weather is hot and dry in the months of June, July and August where temperatures were all above 40 ^{o}C while the relative humidity was below 50%. Rainfall was not observed from June to August at the treatment years except June 2014.

Table 1. Monthly climatic data during the baby corn growth period in 2014 and 2015 in Sanliurfa[†].

[†]Data collected from the Sanliurfa Meteorological Station (Anonymous, 2014 and 2015).

The soil of the research field was clay, slightly alkaline, high in lime and very low in salt contents. Field capacity of the soil was 33.8% on dry basis, permanent wilting point was 22.6% and bulk density was 1.41 g cm^{-3}. Merit hybrid single cross sweet corn genotypes (*Zea mays* L. *saccharata*) were used as crop material. Land was ploughed and cultivated then prepared for planting with a single pass of a disk-harrow. The experiment was laid out in a randomize block design with three replications. Each plot area was 14 m^{2} (5 m x 2.8 m) and consisted of four rows of 5 m in length. The plants were grown 70 cm apart between the rows with 18 cm spacing in each row. The seeds were sown in second part of June at a 50-60 mm depth in both years. At sowing, 80 kg ha^{-1} of pure N, P and K, as a 15-15-15 composed fertilizer, was applied to each plot; this was followed by 160 kg ha^{-1} of N as urea when the plants reached 30-40 cm in height. Irrigation water was first applied to all the plots using a sprinkler irrigation system. After the emergence of plants, plots were irrigated equally by the furrow irrigation system. All tested characteristics were measured on randomly selected 20 plants in the center of each plot. In the study 12 harvest times were used. Baby corns were harvested from 1 to 12 days after ear silk emergence. An analysis-of-variance (ANOVA) was performed to evaluate statistically differences between results. Means of the data obtained from research were compared using least significant difference (LSD) at $P \leq 0.05$.

Results and discussion

Baby corn yield without husk and ear characteristics

According to variance analyses, ear weight without husk, ear length without husk, ear diameter without husk and baby corn yield without husk were significant (P<0.01). Ear weight without husk values were ranged from 9.52 to 128.85 g in 2014 whereas from 10.23 to 132.33 g in 2015 (Table 2). Kumar and Bohra (2014) reported that ear weight without husk values were 5.6-7.3 g when the baby corns were harvested within 2-3 days of silk emergence.

The highest ear weight without husk values obtained from harvest time of 12 day after ear silk emergence whereas the lowest values were seen at harvest time of 1 day after ear silk emergence in both years. Ear weight without husk increased with delaying harvest time.

Ear length without husk values were varied from 8.47 to 20.59 cm in 2014 whereas from 7.93 to 21.9 cm in 2015. Similar results were obtained by some researches when the baby corns were harvested within 2-3 days of silk emergence. Studies conducted on maize have shown that ear length without husk ranged from 6.40 to 10.53 cm (Rodrigues et al., 2003), 4.97-7.0 cm (Saha et al., 2007) and 8.1-10.6 cm (Kumar and Bohra, 2014). The highest ear length without husk values was seen at harvest time of 12 day after ear silk emergence whereas the lowest values were seen at harvest time of 1 day after ear silk emergence in both years (Table 2). Ear length without husk values increased with delaying harvest time.

Table 2. Ear weight without husk and ear length without husk values and LSD groups.

**Denotes significant difference among harvest times P<0.01

Ear diameter without husk values ranged from 14.48 to 21.86 mm in 2014 whereas from 15.29 to 32.97 mm in 2015 (Table 3). Our results were supported by Rodrigues et al. (2003). These authors observed that ear diameter without husk values were 10.2-18.3 mm. The highest ear diameter without husk value was found at harvest time of 12 day after ear silk emergence in both years. The lowest ear diameter without husk value was seen at harvest time of 1 day after ear silk

emergence in both years. Values of average of years also were similar. Ear diameter without husk values increased with delaying harvest time.

Baby corn yield without husk values varied between 75.53 and 1022.71 kg/da in 2014 whereas between 81.22 and 1050.33 kg/da in 2015 (Table 3). The highest baby corn yields without husk values were found at harvest time of 12 day after ear silk emergence in both years. The lowest baby corn yields without husk values were seen at harvest time of 1 day after ear silk emergence in both years.

Some researchers stated that baby corn yield was 4.66-7.5 ton/ha at open pollination varieties and 9.38-15.0 ton/ha in hybrids (Anonymous, 2016a). Najeeb et al. (2011) emphasis that baby corn yield was 11.5-12.0 ton/ha. In other study baby corn yield was reported as 7214.4 kg/ha (Anonymous, 2016b). Kasikranan et al. (2001) stated that baby corn ears without husk values found between 1244.6 and 2164.9 kg/ha in six cultivars. Baby corn yields without husk values increased with delaying harvest time. But ear crisply decreased after 6 days after ear silk emergence. Ear diameter and ear length increased with delaying harvest time. Delaying harvest decreased crisply of ears from 6 day after ear silk emergence. Considering to ear diameter, ear length and yield; harvest for baby corn can be done within 2-6 day, but considering crisply of ear and custom pleasure; the best harvest time was within 2-4 day after ear silk emergence. Earlier studies stated that the best harvest time was 1-2 day (Anonymous, 2016c), 3 day (Bar-Zur and Saadi, 1990), 2-4 day (Anonymous, 2016a) and 6 day (Kasikranan, 2011) after ear silk emergence.

Baby corn yield with husk and ear characteristics

According to variance analyses, ear weight with husk, ear length with husk, ear diameter with husk and baby corn yield with husk were significant (P<0.01). Ear weight with husk value ranged from 26.33 to 183.33 g in 2014 and from 27 to 178.33. These results are supported by the findings of Kumar and Bohra (2014), where ear weight with husk values were 26.8-35.9 g when

the baby corns were harvested within 2-3 days of silk emergence. The highest ear weight with husk value was seen at harvest time of 12 day after ear silk emergence whereas the lowest value was found at harvest time of 1 day after ear silk emergence in both years. Ear weight with husk values increased with delaying harvest time.

Ear length with husk values ranged from 13.83 to 21.8 cm in 2014 and from 15.10 to 22.4 cm in 2015 (Table 4). These findings agree with the findings of Rodrigues et al. (2003) in baby corn where ear length with husk ranged from 16.93 to 26.63 cm. The highest ear length with husk value was seen at harvest time of 12 day after ear silk emergence whereas the lowest value was found at harvest time of 1 day after ear silk emergence in both years. Ear length with husk values increased with delaying harvest time.

The lowest ear diameter with husk value was 19.17 mm at harvest time of 1 day after ear silk emergence whereas the highest value (38.97 mm) was obtained from harvest time of 12 day after ear silk emergence at the average of years (Table 5). Similar results were obtained by Rodrigues et al. (2003) and Kumar and Bohra (2014). These authors observed that ear diameter with husk values varied from 20.1 to 24.6 mm, respectively.

*There is no statistical difference among values annotated with the same letter at 0.05 according to the LSD test

** Denotes significant difference among harvest times P<0.01

Baby corn yield with husk values varied between 209.0 kg/da and 1455.1 kg/da in 2014 whereas between 214.3 and 1415.4 kg/da in 2015 (Table 5). Harvest time of 12 day after ear silk emergence gave the highest baby corn yield but the lowest weight of baby corn yield with husk value was seen at harvest time of 1 day after ear silk emergence. Values of average of years also were similar. Baby corn yields with husk values increased with delaying harvest time. Similar results were obtained by some researchers. Rodrigues et al. (2003) reported that baby corn yield with husk values were 324-1190 kg/da. Kumar and Bohra (2014) observed that baby corn yield with husk values ranged between 760 and 980 kg/da. Kasikranan et al. (2001) stated that baby corn ears with husk values were between 4853.1 and 7186.7 kg/ha.

Conclusion

Based on the two years results it may be concluded; baby corn yield and ear characteristics with husk and without husk values increased with delaying harvest time. But delaying harvest decreased crisply of ears from 6 day after ear silk emergence. Considering to ear diameter, ear length and yield; harvest for baby corn can be done within 2-6 day, but considering crisply of ear and custom pleasure; the best harvest time was within 2-4 day after ear silk emergence.

Abstract

An experiment carried out for grass pea (*Lathyrus sativus* L.) crop in Kahramanmaras conditions Turkey in 2012/2013 planting season in order to identify the agricultural characteristics of M1-7, M1-15, M1-16, FLS-225 lines and registered Gürbüz cultivar of grass pea. The lines and species used in experiment were planted in November 2012 and harvested in June 2013. Cultivation was made with the existing precipitation and no additional irrigation was made. The experiment was established as a completely randomized block with three replications. At the end of the experiment, no differences were observed in terms of some agronomic characteristics, yield and yield components such as plant height, number of florescence days, grain yield and thousand seed weight among lines and varieties tested. The highest grain yield and thousand seed weight was observed in M1-15 line as 390 kg da^{-1} and 152.607 g respectively. The differences among species have been significantly important in terms of number of pods per plant, biological yield and harvest index and the highest value was obtained in M1-15 line as 27.67 pods, 1391.7 kg da^{-1} and 37.8% respectively.

Keywords: *Grass pea, grain yield, biological yield, herbage yield, harvesting index*

Introduction

The biggest expense of livestock enterprises is fodder. Doing feed correctly has important role on taking efficiency from livestock. The use of high quality container and mixed livestock feed resources efficiently is one of the most important requirements. In Turkey, qualified forage pastures and forage crops are derived from two major sources. The efficiency of our natural meadows and pastures declined because of early and excessive grazing for a long time. The ecological structure of Turkey is suitable to breed successfully many kind of fodder crops, and it has enough meadows and pastures to close the gap of quality roughage. The problem of qualified roughage which is longing of our livestock sector can be solved with providing to increase production areas of forage crops with scientific, technical, economic and social measures (Alçiçek *et al*, 2010).

Forage crops have also effects on increasing the efficiency of soil, preventing erosion and the protection of the ecological balance. Because of wrong tillage farming methods and one-way products, the salinity and environmental pollution problems have emerged on our country lands. For this reason, it is necessary to increase the share of forage crops in cropping systems (Alay, 2008).

In Turkey, vetch, alfalfa, sainfoin and grass pea are extensively grown as forage crops. Approximately, 6.620 ha of alfalfa (green feed), 1.914 ha sainfoin (green feed), 868 ha of vetch, 6.881 ha of maize (grain), 195 ha grass pea (green feed), 24 ha of fodder beet and other forage

crops are grown according to 2015 data of TUIK (Turkish Statistical Institute). The total area of forage cropping is 24.830 ha (TUIK, 2016).

In Turkey, one of the annual forage crops that can be grown in arid areas is grass pea (*Lathyrus sativus* L.). Kahramanmaras is located in south of Anatolia. Grass pea which is popular as Cılban in the southeast of Anatolia. It is an annual plant belonging to the family of legumes (*Fabaceae*) which can be self-pollination (Gedik, 2007).

There are many features of grass pea. Some of these are; resistance to environmental stress conditions and diseases, high yield potential in terms of peas, appropriates of the nutritional content of seeds. Also, it is strong and resistant to drought thanks to a strong root system of it. Grass pea can be grown in a variety of soil types, including very poor soils (Rybinski, 2003).

Four grass pea lines and one registered cultivar was used in this experimental study. The study was conducted in order to identify the yield potential and agricultural characteristics of certain four grass pea lines and one registered grass pea cultivar in early spring in Kahramanmaras conditions. Also in this study was aimed recognition of grass pea lines and cultivar by producers.

Materials and Methods

Grass pea lines and variety used in this experiment were provided from Adana East Mediterranean Agricultural Research Instıtute. In this study, M1-7, M1-15, M1-16 and FLS-225 lines and registered Gürbüz cultivar were used.

This study was conducted at the lands of Kahramanmaraş Transitional Zone Research of Institute in southern Turkey as a main crop between November 2012 and July 2013 in order to identify the agricultural characteristics of M1-7, M1-15, M1-16, FLS-225 lines and registered Gürbüz cultivar of grass pea. Kahramanmaraş coasted in east Mediterranean region in south of Turkey, has a typical Mediterranean climate conditions. The Mediterranean climate is characterized by dry summers and mild, moist winters. The field trials were designed as completely randomized blocks with three replicates. After five months following wheat harvesting grass peas were sown. Primarily soil cultivation was made deeply with plow and then was used stalk chopper and rolling cylinder. Trial consists of three blocks and five parcels in each block. The trial has totally fifteen parcels. The distance between the blocks is 2,5 m and the distance between the parcels is 25 cm. Each parcel size is 10 m x 1 m and each plot contained five rows. Interrow distances are 20 cm. Parcel size is 10 m^2. Sowing was made by manually at November 21th 2012. Calculation was performed hundred kilograms of seed per hectare. 100 g seed was sown for each plot. Fertilizers and pesticides were not used in the experiment and plots were not irrigated. Harvest was made by hand, seeds are cleaned manually.

Investigated Characteristics

In this study following characteristics were examined;

Plant height (cm), heights of randomly selected 10 plants from each trial spot were measured manually 1-2 days before harvest. Number of florescence days (day) was designated as a number of days between sowing date with 50% florescence period in the parcels. Green forage yield (kg da^{-1}) was obtained by mowing and weighing 1 m^2 area in the middle of each parcel. Then the obtained data was converted to decare yield. Number of pods per plant (number), when bottom pods of selected same ten plants from each parcel turn yellow the number of pods is counted. Physiological maturity days (day), was designated as a number of days between sowing date with fully yellowing period of 3-4 pods on the bottom of plant. Thousand seed weight (g), primarily mean weight of four parallel received 100 seeds weight from each replications was calculated

then it was multiplied by 10. Grain yield (kg da^{-1}), was designated 0.5 m mowed from top and bottom of each parcel and removed, then when seeds mature and harvest time comes the plants mowed and separate from their seeds then obtained seeds were weighted. After then data provided convert to yield/decare. Biological yield (kg da^{-1}), after the plant reach harvest maturity stage, 0.5 m mowed as marginal affect and removed from two sides of each parcel, remaining plant harvested and performed values convert to yield/decare. Harvest index (%) was calculated by the method of biological yield/grain yield.

Data Analysis

Data were analyzed using MSTATC software. Means were separated using LSD test at $P \leq 0.01$ and $P \leq 0.05$ levels (Steel and Torrie, 1980).

Results and Discussion

Some agronomic characteristics, yield and yield components of five grass pea lines and cultivar are shown in Table 1. As shown in Table 1, statistically significant differences were observed between number of blooming days, number of pods per plant, physiological maturity days and harvest index, although no statistical difference was observed between plant height, number of blooming days, green forage yield, thousand seed weight, grain yield and biological yield of the species used in the experiment.

Table 1. Some agronomic characteristics, yield and yield component of grass pea lines and species.

	Investigated Characteristics								
	PH	NFD	HY	NPP	PMD	TSW	GY	BY	HI
M1-7	38.33	146.0 B	2823.3	24.67 AB	189.3 A	141.980	316.7	1351.7	23.0 B

PH: Plant height (cm), NFD: Number of florescence days (day), GFY: Herbage yield (kg da^{-1}), NPP: Number of pods per plant (number $plant^{-1}$), PMD: Physiological maturity days (day), TSW: Thousand seed weight (g), GY: Grain yield (kg da^{-1}), BY: Biological yield (kg da^{-1}), HI: Harvest index (%)

The average values for plant height are shown in Table 1. While the highest plant height was observed in M1-15 line (38.67 cm), the lowest plant height was observed in Gürbüz and FLS-225 varieties (37.67 cm). In studies on plant height; it was found between 34.9 cm - 38.7 cm by Andiç *et al.* (1996), between 47.83 cm - 53.73 cm by Kökten *et al.* (2011). The obtained values are similar to the findings of Andiç *et al.* (1996).

Numbers of florescence day values are shown in Table 1. As shown in table the differences between varieties are important significantly. While the highest value in number of florescence days was obtained in FLS-225 line (148.7 days), the highest value in number of florescence days was obtained in M1-7, M1-16 and Gürbüz (146 days). In studies on number of florescence days; it was found the lowest 128 days and the highest 150.7 days by Gedik (2007), the lowest 54.6 days and the highest 56 days by Gündüz (2012), Also it was report as 177.27 days for first year and 180.58 days for second year by Başaran (2010). Our findings showed same results with Gedik (2007).

Herbage yield values are shown in Table 1. According to table the differences between varieties are not significantly important. While the highest value in herbage yield was obtained in M1-16 line (3106.0 kg da^{-1}), the lowest value in herbage yield was obtained in registered Gürbüz cultivar (2659.3 kg da^{-1}). In studies on herbage yield; it was found the lowest 961.1 kg da^{-1} and the highest 1038.2 kg da^{-1} by Alay (2008), between 2345.73-6180.55 kg da^{-1} by Bucak (1999). Also it was report as 2175.2-2582.5 kg da^{-1} by Karadağ *et al.* (2012). The obtained values are close to Bucak (1999) and Karadağ *et al*. (2012)'s findings.

The average numbers of pods per plant are shown in Table 1. As shown in table the differences between varieties are important significantly. While the highest value in number of pods per plant was obtained in M1-15 line (27.67 pods $plant^{-1}$), the lowest value in number of pods per plant was obtained in M1-16 and Gürbüz (16.17 pods $plant^{-1}$). In some studies on number of pods per plant; it was report between 21.89 pods $plant^{-1}$ and 27.89 pods $plant^{-1}$ by Gül et al. (2004). Also it was report as 14.97-32.87 pods $plant^{-1}$ by Bucak (1999). Otherwise it was narrated the lowest 14.7 pods $plant^{-1}$ and the highest 30.6 pods $plant^{-1}$ by Uzun (2000), between 36.18-78.37 pods $plant^{-1}$ by Bayram *et al.* (2004).

The average values of physiological maturity days are shown in Table 1. As shown in table the differences between varieties are important significantly. While the highest value in physiological maturity days was obtained in M1-7, M1-15 and FLS-225 lines (average 188.4 days), the lowest value in number of pods per plant was obtained in M1-16 and Gürbüz (185.0 and 183.0 days respectively). In studies on number of physiological maturity days; it was observed as 270-272 days by Uzun (2000). Also it was reported the lowest 157.2 days and the highest 160.5 days by Al-Doss *et al.* (1988). Otherwise it was report between 230 days - 244 days by Başaran (2010). Çakmaklı *et al.* (1999) calculated as 191 days maturity days of grass pea. Çakmaklı *et al.* (1999)'s result is close to our findings.

The average values of thousand seed weight are shown in Table 1. As shown in table the differences between varieties are not important significantly. The highest value in thousand seed weight was obtained in M1-15 lines (152.607 g) and then FLS-225, M1-16 and M1-7 lines followed (150.617 g, 145.273 g, 141.980 g respectively). The lowest value in number of pods per plant was obtained in registered Gürbüz cultivar (140.773 g). In studies on number of physiological maturity days; it was observed as 247 g by Milczak *et al.* (2001). It was reported as 270 g by Rybiñski *et al.* (2003). Otherwise it was report between 58.2 g - 68.7 g for first year and 63.4 g- 76.3 g for second year by Sabancı and Özpınar (2000). Gül *et al.* (2004) calculated three years average values as 124.44 g-144.89 g. The obtained values are similar to the findings of Gül *et al.* (2004).

The average values of grain yield are shown in Table 1. As shown in table the differences between varieties are not important significantly. According to this the highest value in grain yield was obtained in M1-15 lines (390.0 kg da^{-1}) and the lowest value in grain yield was obtained in Gürbüz (256.7 kg da^{-1}). In some studies on grain yield; it was report between 70 and 83.9 kg da^{-1} by Al-Doss *et al.* (1998). Also it was report as 71.0-150.23 kg da^{-1} by Karadağ *et al.* (2008). Otherwise it was narrated the lowest 159.16 and the highest 205.37 by Gül *et al.* (2004), between 67.30-202.88 kg da^{-1} by Bayram (2004).

Biological yield values are shown in Table 1. According to table the differences between varieties are not significantly important. According to this the highest value in biological yield was obtained in M1-15 line (1391.7 kg da^{-1}), the lowest value in biological yield was obtained in registered Gürbüz cultivar (1235.0 kg da^{-1}). In some studies on biological yield; it was report as 468.1 kg da^{-1} by Al-Doss *et al.* (1998) and also was found first year between 781-1188 kg da^{-1} and second year between 823-1115 kg da^{-1} by Sabancı and Özpınar (2000). It was also report as

356.47-638.90 kg da^{-1} by Karadağ *et al.* (2008). Otherwise it was narrated the lowest 511.33 kg da^{-1} and the highest 636.89 kg da^{-1} by Gül *et al.* (2004), between 622.2-666.7 kg da^{-1} by Gündüz (2012). The obtained values are different from researchers above due to different cultivar and climate conditions.

The average values of harvest index are shown in Table 1. As shown in table the differences between varieties are important significantly. Mean values composed three groups. According to this the highest value in harvest index was obtained in M1-15 lines (37.8%) in group A, then FLS-225 line followed (29.7%) and the lowest value in harvest index were obtained in M1-7, M1-16 and registered Gürbüz cultivar respectively (23.0%, 22.1% and 19.3%). In some studies on harvest index; it was report as 17%-25% by Al-Doss *et al.* (1998). Also it was report as 27.66%-31.70% by Karadağ *et al.* (2012). Otherwise it was narrated the lowest 18.69% and the highest 19.10% by Uzun (2000), between 39.76%-53.95% by Başaran (2010). The obtained values are close to the findings of Karadağ *et al.* (2012).

Conclusions

At the end of the study, the highest values in grain yield, biological yield, thousand seed weight, number of pods per plant, plant height and harvest index were obtained in M1-15 line. According to all of results we recommend M1-15 which generally has superior characteristics between investigated lines and species, for the farmers who want to grow grass pea in Kahramanmaraş condition.

Abstract

In Turkey, product-price relation in dry onion production is analyzed. Almon model is one of the distributed lag models employed in this study. There are several external factors that affect the production of dry onion. In this study, the secondary data belonging to Turkish Statistical Institute (TURKSTAT) will be used between 1991-2014. In this model, the amount of dry onion production is used as a dependent variable, price series of dry onion and the distributed lag values of the dry onion prices as an independent variables. In the light of these data, the yield of dry onion in Turkey for its predictions various econometric models through inspection will attempt to demonstrate the best fit model. Due to an Almon model obtained from the study, dry onion yield estimation can be made for the future years. Moreover, Whether cobweb effect for dry onion will be analyzed in free market conditions or not. The cobweb theory is an economic model. This model explains why prices might be subject to periodic fluctuations in certain types of market conditions.

Keywords: *Almon model, Dry onion, Cobweb, Distributed lag values, Turkey.*

Introduction

The onion plant has been grown and selectively bred in cultivation for at least 7.000 years. The onion plant is a traditionally crucial plant in Turkish meals. This plant is always used for preparing the Turkish meals. It is a biennial plant, but is usually grown as an annual. For that reason, its storage has only one production year. Nearly, all of this plant's production is used in domestic and the remains is exported to other countries. In Turkey, dry onions is grown up by small scale farmers especially below 50 decares land. This production is very commercially produced not only in own using.

(Şahinli and Özçelik, 2016) in their studies that emphasized there are several external factors that affect the production of hazelnuts. In this study, the secondary data belonging to various institutions will be used between 2000-2014. In the light of these data, the yield of nuts in Turkey for its predictions various econometric models through inspection will attempt to demonstrate the best fit model. Due to an Almon model obtained from the study, nuts yield estimation can be made for future years.

Dry onions statistics about production and price are given in Table 1. According to the Table 1, two different statistics are calculated belong to these variables and 1991=100 is taken as a base year. In 2014 compared to 1991 year, production value increased 11.88 per cent and price value for the same year increased 6.12 per cent. And then, by using the production and price values were calculated for which was used the previous year. In 2014 compared to the 2013 year

production values decreased 6.03 per cent and price values decreased 1.89 per cent (Turkstat, 2016).

Table 1. Production and Price for Dry Onion in Turkey, 1991-2014

	Production		Price	
Yıl	1991=100	According to the previous year is calculated	1991=100	According to the previous year is calculated
1991	-	-	-	-
1992	6.25	6.25	13.27	13.27
1993	3.13	-2.94	50.46	32.84
1994	12.50	9.09	20.17	-20.13
1995	78.13	58.33	29.69	7.92
1996	18.75	-33.33	58.22	22.00
1997	31.25	10.53	4.76	-33.79
1998	41.88	8.10	16.45	11.16
1999	56.25	10.13	7.56	-7.64
2000	37.50	-12.00	20.48	12.02
2001	34.38	-2.27	82.29	51.30
2002	28.13	-4.65	33.54	-26.74
2003	9.38	-14.63	17.48	-12.03
2004	27.50	16.57	3.81	-11.63
2005	29.38	1.47	-26.53	-29.23
2006	10.34	-14.72	-14.29	16.67
2007	16.22	5.33	-2.04	14.29
2008	25.44	7.94	-12.24	-10.42
2009	15.60	-7.85	10.20	25.58
2010	18.75	2.73	81.63	64.81
2011	33.84	12.70	55.10	-14.61
2012	8.49	-18.94	0.00	-35.53
2013	19.05	9.74	8.16	8.16
2014	11.88	-6.03	6.12	-1.89

In this study, we examine the relationship between the dry onion's products and price. During this examination, Almon model is used in this study. At first, the frame of this work is given as follows: Introduction is given in the first section, material and methods is given in the second section and third section is belong to empirical results and conclusion.

2. Material and Methods

A secondary data on dry onion obtained from the Turkish Statistical Institute for the period of 1991-2014 was used for this study. The data is made up of yearly production quantities of dry onion and the corresponding agricultural prices gathering by agricultural farmers (CEF). The CEF has been deflated by inflation values for taking to real values (Turkstat, 2016).

Unit root test is very important to test for stationary for dependent and independent variables. The need for adequate information of the data generation process necessitates the unit root test. As typical of time series data it is imperative to understand the nature of the variable whether is stationary or otherwise. This would avoid estimates which cannot be relied upon as spurious regression might result from the estimation of stationary data which would inevitably produce type one error (Gbetnkom & Khan, 2002).

Augmented Dickey Fuller (ADF) test was used to determine whether the production quantity variable has a unit root. This is to ensure that it has the properties of a time series variable (Dickey and Fuller, 1979).

$$\Delta Q_t = \alpha_0 + \delta Q_{t-1} + \sum_{i=1}^{k} \beta_i \Delta Q_{t-1} + u_t \qquad (1)$$

The hypothesis testing follows that;

$H_0: \delta = 0$ (Y_t has a unit root)

$H_1: \delta < 0$ (Y_t has no unit root/stationary)

Lag length Selection is so crucial that Almon model will be tested after that. The process of lag length selection remains a very important aspect in the estimation of Distributed Lag Model (DLM). The selection of longer lags could result in the inclusion of irrelevant variables either way the selection models with fewer variables has the tendency of leaving out relevant variable that could otherwise contribute to the proper explanation of the dependent variable. The convention according to Davidson and Mackinnon is that lags should be examined starting from higher lags to lower ones (Davidson & Mackinnon, 1993).

A generalised polynomial lag model with k parameters has the form stated below;

$$Y_t = \propto + \beta_0 X_t + \beta_1 X_{t-1} + \beta_2 X_{t-2} + \ldots + \beta_k X_{t-k} + u_t \qquad (2)$$

Using the notation operator, the generalised model stated above can be simplified as follows;

$$Y_t = \propto + \sum_{i=0}^{k} \beta_i X_{t-i} + u_t \qquad (3)$$

During the creation of Almon model, Weierstrass theorem was used (Almon, 1965).

For instance According to array of lagged,

As an illustration suppose we postulate a second-degree polynomial, that is,

$$\beta_i = a_0 + a_1 i + a_2 i^2, \quad (4)$$

We can write a general approximation to the mth-degree plynomial as follows;

$$\beta_i = a_0 + a_1 i + a_2 i^2 + \ldots + a_m i^m \quad (5)$$

If β fits to the second-degree polynomial under an assumption, We can explain the Almon arrays as indicated below;

$$Y_t = \propto + \sum_{i=0}^{k} (a_0 + a_1 i + a_2 i^2) X_{t-i} + u_t \quad (6)$$

As we distrubute X_{t-i} to inside of parantheses;

$$Y_t = \propto + a_0 \sum_{i=0}^{k} X_{t-i} + a_1 \sum_{i=0}^{k} i X_{t-i} + a_2 \sum_{i=0}^{k} i^2 X_{t-i} + u_t \quad (7)$$

Let us define the expressions as follows;

$$Z_{0t} = \sum_{i=0}^{k} X_{t-i} \quad (8)$$

$$Z_{1t} = \sum_{i=0}^{k} i X_{t-i} \quad (9)$$

$$Z_{2t} = \sum_{i=0}^{k} i^2 X_{t-i} \quad (10)$$

We can make an arrange the Almon array;

$$Y_t = \propto + a_0 Z_{0t} + a_1 Z_{1t} + a_2 Z_{2t} + u_t \quad (11)$$

After making an arrange the Almon array, we can solve the regression for Z variables. Ordinary Least Squares (OLS) are used for estimating this model. The lag distributed model is estimated by OLS but anyone must be careful to evaluate these statistical numbers (Tinbergen, 1949).
At this time, gathered estimations of α and a_i provide for OLS assumptions. After estimating for a, β of the distributed lag model will be estimated as follows;

$$\widehat{\beta_0} = \hat{a}_0 \quad (12)$$

$$\widehat{\beta_1} = \hat{a}_0 + \hat{a}_1 + \hat{a}_2 \quad (13)$$

$$\widehat{\beta_2} = \hat{a}_0 + 2\hat{a}_1 + 4\hat{a}_2 \quad (14)$$

……

$$\widehat{\beta_k} = \hat{a}_0 + k\hat{a}_1 + k^2\hat{a}_2 \quad (15)$$

We can summarize the application phase of Almon model;

1. k lag number is determined before. At the process, Davidson and MacKinnon suggestions are used (Davidson and MacKinnon, 1993).

   Akaike Information Criterion (AIC) or Schwartz Bayesian Criterion (SBC) are used for determining the lag number (k) (Schwartz, 1978).

2. After detemining the lag number (k), polynomial degree (m) is determined (Gujarati, 1999).

3. Later, Z is easily determined after gathering m and k.

3. Empirical Results

In order to explain the Almon model in this study, we used the production value and price of dry onion from 1991 to 2014. During this phase, price is deflated by consumer price index (CPI). As to scrutinize the price values in the long term, prices would bring the real situation.
At the frame of these explanations, production (tonnes) depends on in year and the before years for that reason distribution lag model is established as follows;

$$Y_t = \propto + \beta_0 X_t + \beta_1 X_{t-1} + \beta_2 X_{t-2} + \ldots + \beta_k X_{t-k} + u_t \quad (16)$$

In this model;

Y_t : Production (tonnes)

X_t: Attained price by the farmers (Turkish Liras (TL) / Kg)

In this study, this price variable is examined under the its effects to production and AIC values were calculated and then this result is given by Table 2 as follows;

Table 2. According to the Akaike Information Criterion (AIC), lagged numbers (k)

Variables	k	AIC
Price (TL/Kg)	3	-3.50 (1st difference)
Production (tonnes)	1	-3.94 (Level)

According to the polynomial degree, we make an assumptions like this $\beta_i = a_0 + a_1 i + a_2 i^2$. In this situation, we can make an arrange as a Almon model.

$$Y_t = \propto + a_0 Z_{0t} + a_1 Z_{1t} + a_2 Z_{2t} + u_t \quad (17)$$

After using above the equation, parameter estimations of model are given Table 3.

Table 3. Parameter Estimations belong to the Dry Onion

Değişkenler	Values
Sabit terim	2028169
Std.error	(65260.68)
$\boldsymbol{P_t}$	1185.56
Std.error	(417288.2)
$\boldsymbol{P_{t-1}}$	21334.72
Std.error	(641615.5)
$\boldsymbol{P_{t-2}}$	996.22
Std.error	(216893.1)

According to the Z values, we can reach at the regression model below by using Y and Z values:

$$\hat{Y} = 2028169 + 1185.56Z_{0t} + 21334.72Z_{1t} + 996.22Z_{2t} \quad (18)$$

By estimated a coefficients, $\widehat{\beta_0} = \hat{a}_0$ relations will be calculated then approximately as follows;

$$\beta_0 = a_0 = 1185.56 \quad (19)$$

$$\beta_1 = a_0 + a_1 + a_2 = 1185.56 + 21334.72 + 996.22 = 23516.5 \quad (20)$$

$$\beta_2 = a_0 + 2a_1 + 4a_2 = 1185.56 + 2 * 21334.72 + 4 * 996.22 = 47839.88 \quad (21)$$

After re-arranging and trasformations by using β_0 , β_1 and β_2, the new Almon model is given as follows;

$$\hat{Y} = 2028169 + 1185.56P_t + 23516.5P_{t-1} + 47839.88P_{t-2} \quad (22)$$

Conclusions

In Turkey, dry onion has the lowest production rate 3.13 per cent in 1993 and the highest production value 78.13 per cent in 1995. After examining these statistical indicators, we can decide these values of production and price for dry onion that producers follow the prices for growing the dry onion.

In this study, Almon model is examined and implemented for the dry onion and cobweb theorem relations are looked for the previous year of the dry onion. During this phase, production and price are searched for depend on the unit root. And then, according to the unit root test, production value has level stationary and price value has the first level stationary.

After determining these lagged numbers, we started to implement the Almon model in the dry onion's values. Later, we made different transformations into this model and decided to the fit model belong to the dry onion.

The cobweb theory is an important economic theory that explains the relations with the price and lagged dry onion prices. Supply and demand in a market are used for explain to relations with quantity and price of dry onion. It describes cyclical supply and demand in a market where the amount produced must be chosen before prices are observed. Producers especially in agricultural products expect for the current prices and the previous prices of dry onion and later if the previous prices of dry onion belong to any products are tend to increase, producers will be grown up the plants in their fields.

As a result, we found the relations between the production and price of the dry onion using by Almon model. According to the obtained results from our model, the dry onion productions t-1 and t-2 were effected. In the study, increases in the prices for t, t-i period effects the production in upward process compatible with the economics theory.

Abstract

Phenological traits, yield and fruit characteristics of ten plum cultivars bred at the Fruit Research Institute in Čačak were studied in the region of Belgrade in the period of four years (2012-2015). Average time of flowering of tested cultivars was in the first half of April. The earliest flowering was recorded in 'Čačanska Rana' and 'Valerija', at the latest in 'Zlatka'. The range of fruit maturity was about 2.5 months, from June 24 ('Boranka') to September 6 ('Pozna Plava'). The average yield per tree was the lowest in 'Boranka' (7.8 kg) and the highest in 'Čačanska Najbolja' (23.6 kg). The cultivars 'Čačanska Rodna', 'Nada' and 'Valerija' stand out for high cumulative yield efficiency (0.34 to 0.36 kg/cm^2). Fruit weight was the lowest in the cultivar 'Mildora' (23.9 g), and the highest in the cultivar 'Čačanska Rana' (51.3 g). The cultivar 'Zlatka' is distinguished by a small stone (weight of 0.83 g and the share in a fruit weight of 3.1%). The cultivars 'Mildora', 'Pozna Plava' and 'Čačanska Rodna' are characterized by high soluble solids content (19.8-21.0%), while the cultivars 'Mildora' and 'Nada' are characterized by low acid content (0.47-0.48%) and a very sweet taste. The highest scores for fruit appearance obtained the cultivars 'Čačanska Najbolja', 'Čačanska Rana' and 'Nada', and for taste the cultivars 'Nada', 'Mildora' and 'Čačanska Rodna'.

Key words: *Prunus domestica, flowering, maturation, yield, fruit characteristics*

Introduction

Plum is the most important fruit species in Serbia. The average production of 466.735 t in the period of 2010-2012 ranks Serbia on the third place in the world, behind China and Romania (FAO, 2016). However, plum production in Serbia has some negative characteristics. The average yield is very low, only 3 t/ha. This is because the production is mainly extensive and cultural practices are often at a low level. The use of fruits is very unfavorable. The largest amount of produced fruits is processed into brandy (more than 60%). Much smaller amounts of plums are dried, frozen, and processed into other products, while fresh consumption is quite small. In recent years, there is a tendency to increase export of fresh fruits, mostly in Russia (Milatović, 2013).

Plum breeding has been developed in continuity at the Fruit Research Institute in Čačak since its establishment in 1946. The result of this programme are 15 released cultivars (Glišić et al., 2015). The main breeding objectives are high fruit quality, self-fertility, regular and high yield and resistance or tolerance to Sharka (Plum Pox Virus).

New plum cultivars bred at the Fruit Research Institute in Čačak were studied by many researchers in Serbia (Ogašanović et al., 2005; Mitrović et al., 2006; Glišić et al., 2011; Milatović et al., 2011; Milošević and Milošević, 2011) and abroad (Hodun et al., 1998; Blažek et al., 2004; Dragoyski et al., 2005; Dinkova et al., 2007).

The aim of this study was to evaluate phenological traits, yield and fruit characteristics of ten plum cultivars bred at the Fruit Research Institute in Čačak. The best performing cultivars will be recommended for growing in the region of Belgrade, as well as in other regions with similar environmental conditions.

Material and methods

The study was conducted in the plum collection orchard at the Experimental Station "Radmilovac" of the Faculty of Agriculture in Belgrade during the period of four years (2012–2015). The orchard was planted in 2009. The rootstock is Myrobalan (*Prunus cerasifera* Ehrh.) seedling, training system is central leader, and planting distance is 4.5 x 3 m. All cultivars are represented by five trees.

The study included ten plum cultivars bred at the Fruit Research Institute in Čačak: 'Boranka', 'Čačanska Lepotica', 'Čačanska Najbolja', 'Čačanska Rana', 'Čačanska Rodna', 'Mildora', 'Nada', 'Pozna Plava', 'Valerija' and 'Zlatka'.

Flowering was recorded by recommendations of the International Working Group for pollination: start of flowering – 10% open flowers, full bloom – 80% open flowers, end of flowering – 90% of the petal fall (Wertheim, 1996). Trunk cross-sectional area (TCSA) was calculated on the basis of trunk circumference measured at the height of 30 cm above the ground level. Cumulative yield efficiency was calculated by dividing the cumulative yield over three years by TCSA in the last year (2015). Fruit characteristics were measured on a sample of 25 fruits per cultivar. Fruit shape index was calculated using the formula: length × length / width × thickness. Soluble solids were determined by refractometer and total acids (expressed as malic acid) by titration with 0.1 N NaOH. Sensory characteristics of the fruit (appearance and taste) were evaluated by a five-member jury, scoring the cultivars using the scale from 1 to 5 points.

The obtained data were statistically analyzed using analysis of variance. The significance of differences between mean values was determined using Duncan's multiple range test at 0.05 level of probability.

Results and discussion

Average time of flowering of tested cultivars was in the first half of April (Table 1). The earliest flowering was recorded in 'Čačanska Rana' and 'Valerija', at the latest in 'Zlatka'. The average difference between cultivars with earliest and latest flowering was 4 days, and by years it varied from 2 to 8 days.

Table 1. Phenological characteristics of plum cultivars (average, 2012–2015).

Cultivar	Flowering dates			Duration of flowering (days)	Harvest date	No. of days from full flowering to harvest
	Start	Full	End			
Boranka	7 April	8 April	14 April	7.8	24 June	77
Čačanska Lepotica	6 April	8 April	15 April	9.0	22 July	107
Čačanska Najbolja	6 April	8 April	14 April	8.5	9 August	125
Čačanska Rana	5 April	7 April	14 April	8.5	4 July	90
Čačanska Rodna	6 April	8 April	14 April	7.8	13 August	129
Mildora	7 April	9 April	14 April	7.5	15 August	130
Nada	7 April	9 April	16 April	8.8	16 August	131
Pozna Plava	8 April	10 April	15 April	7.8	6 September	151
Valerija	5 April	7 April	15 April	9.5	18 July	104
Zlatka	9 April	10 April	16 April	7.0	12 August	125

Among years, the earliest flowering was in 2014, when the average date of the flowering onset for all cultivars was March, 24. The latest flowering was in 2013 when the average date of the flowering onset was April, 17. The difference between years with earliest and latest flowering was 24 days and it was much bigger than difference between cultivars with earliest and latest flowering.

Flowering of plum cultivars in the region of Belgrade was earlier comparing to Central Bulgaria (Dragoyski et al., 2010), Western Serbia (Glišić et al., 2011) and Northern Montenegro (Božović and Jaćimović, 2012). Differences in flowering time can be explained by differences in environmental conditions between the study regions.

The average duration of flowering ranged from 7.0 days (‘Zlatka’) to 9.5 days (‘Valerija’). Among years, the average duration of flowering for all cultivars ranged from 7.4 days in 2015 to 9.6 days in 2014.

The range of fruit maturity was about 2.5 months, from June 24 (‘Boranka’) to September 6 (‘Pozna Plava’). Similarly, the number of of days from full flowering to harvest ranged from 77 to 151. For most cultivars the earliest fruit maturation was in 2014, and the latest in 2012. Difference between years with earliest and latest fruit maturation varied from 2 to 15 days. Similar to flowering time, harvest dates in conditions of Belgrade were earlier than in Czeck Republik (Blažek et al., 2004), Central Bulgaria (Dragoyski et al., 2010), Western Serbia (Glišić et al., 2011) and Northern Montenegro (Božović and Jaćimović, 2012).

The average yield per tree was the lowest in ‘Boranka’ (7.8 kg) and the highest in ‘Čačanska Najbolja’ (23.6 kg)(Table 2). Although in some previous studies cultivar ‘Čačanska Najbolja’ showed medium productivity (Blagojević et al., 2006; Milatović et al., 2011) in this study it was the most productive cultivar. High yield in this cultivar was also reported by Faber et al. (2002) in Poland and Blažek et al. (2004) in Czeck Republik. Since ‘Čačanska Najbolja’ is self-incompatible cultivar (Nikolić and Milatović, 2010), its cropping highly depends on pollen transfer from polliniser cultivars and on weather conditions during flowering. High yield of this cultivar can be explained by favourable weather conditions during the period of study.

Table 2. Yield, trunk cross-sectional area, and yield efficiency of plum cultivars.

Cultivar	Yield (kg per tree)				Trunk cross-sectinal area (cm^2)	Cumul. yield efficiency (kg/cm^2)
	2013	2014	2015	Average		
Boranka	3.9	7.7	11.9	7.8 d	72.6 ab	0.11 d
Čačanska Lepotica	10.3	36.7	7.5	18.2 ab	63.9 abc	0.28 b

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at $P \leq 0.05$.

Among studied cultivars, the lowest vigour was found in 'Čačanska Rodna', and the highest in 'Čačanska Najbolja'. Cumulative yield efficiency ranged from 0.11 to 0.36 kg/cm^2. The cultivars 'Čačanska Rodna', 'Nada' and 'Valerija' stand out for high cumulative yield efficiency. The results for yield efficiency correspond well to results obtained by other authors (Blažek et al. 2004; Dinkova et al., 2007; Milošević and Milošević, 2011).

Fruit weight ranged from 23.9 g in the cultivar 'Mildora' to 51.3 g in the cultivar 'Čačanska Rana' (Table 3). Most of the studied cultivars are characterized by large fruit (more than 30 g). Exceptions are only cultivars: 'Mildora', 'Čačanska Rodna', 'Zlatka' and 'Pozna Plava' that had medium large fruit.

The cultivar 'Zlatka' is distinguished by a small stone (weight of 0.83 g and the share in a fruit weight of 3.1%). On the other hand, 'Čačanska Rana' had the largest stone (2.67 g).

Table 3. Fruit characteristics of plum cultivars (average, 2012–2015).

Zlatka	26.6 cd	0.83 f	3.1	44.4 b	31.0 c	33.2 bc	1.92	17.5 c

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at $P \leq 0.05$.

Significant differences were found between cultivars for fruit dimensions. Based on the fruit dimensions the shape index was calculated, whose values ranged from 1.02 in 'Valerija' (round shape) to 1.92 in 'Zlatka' (elliptic shape). Stalk length was the shortest in 'Boranka' (10.2 mm), and the longest in 'Čačanska Rodna' (24.6 mm).

Results of fruit characteristics are in accordance with the previous findings for some cultivars (Hodun et al., 1998; Blažek et al. 2004; Ogašanović et al., 2005; Dragoyski et al., 2010; Glišić et al., 2011; Milatović et al., 2011).

The cultivars 'Mildora', 'Pozna Plava' and 'Čačanska Rodna' are characterized by high soluble solids content (19.8-21.0%), while the cultivars 'Mildora' and 'Nada' are characterized by low acid content (0.47 to 0.48%) and a very sweet taste (Table 4).

Table 4. Indices of fruit quality of plum cultivars (average, 2012–2015).

Cultivar	Soluble solids (%)	Total acids (%)	Soluble solids /Total acids	Sensory evaluation (1-5)	
				Appearance	Taste
Boranka	12.3 e	1.13 ab	11.0	3.1 d	3.1 c
Čačanska Lepotica	15.5 cd	1.30 a	13.1	4.3 abc	4.1 a

Valerija	14.2 de	0.98 bc	14.7	4.2 bc	3.4 bc
Zlatka	18.0 bc	0.78 cd	23.8	3.3 d	4.0 ab

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at $P \leq 0.05$.

The results of the soluble solids content in the fruits of the cultivars examined in this study confirm the existence of a positive correlation between the soluble solids content and the ripening time of the fruit (Neumüller, 2010). Late ripening cultivars had soluble solids content over 17% which is in accordance to high quality requirements (Neumüller, 2010). Very high soluble solids content and low acid content of cultivar 'Mildora' confirms its suitability for drying (Ogašanović et al., 2005).

It is a well-known that the ratio between the soluble solids content and total acids (SSC/TA), rather than the very content of soluble solids, represents a reliable indicator of a cultivar's suitability for acceptance by consumers (Crisosto et al., 2004). Early ripening cultivars had lower values of SSC/TA ratio (11,1-19,1) while late ripening cultivars had much higher values (24.8-46.9).

The data on the chemical composition of fruits are in good agreement with most of the previous findings (Mitrović et al., 2006; Dragoyski et al., 2010; Glišić et al., 2011; Milatović et al., 2011). Significantly higher soluble solids content for some cultivars was obtained in this study comparing with the results of Fajt and Usenik (2010) in Slovenia.

The highest scores for fruit appearance obtained the cultivars 'Čačanska Rana' and 'Nada', and for taste the cultivars 'Nada', 'Mildora' and 'Čačanska Rodna'.

Conclusion

Based on the four-year evaluation of ten plum cultivars bred at the Fruit Research Institute in Čačak, for growing in Belgrade area can be recommended the cultivars 'Čačanska Lepotica' and 'Čačanska Najbolja' for fresh fruit consumption and 'Čačanska Rodna' and 'Mildora' for fruit processing. Besides them, the cultivar 'Nada' seems to be very promising as a cultivar of combine traits, suitable both for fresh consumption and processing.

Abstract

Coriander (*Coriandrum sativum* L.) is an aromatic plant grown for seed (*Coriandri fructus*) which contains essential oil (*Coriandri aetheroleum*) with a specific fragrance originating from the main component, limonene. Essential oil is obtained by steam distillation from the dried ripe seed. However, the content of essential oil in seed is low, between 0.1 and 1.8%, depending on variety, geographical origin, agroecological conditions, growing technology, etc. Still, the majority of the produced plant material remained unused. The aim of our investigation was to determine the total polyphenols content in postdistillation waste material which remains after coriander essential oil distillation. Evaluation of its antioxidative capacity was the other purpose of this study. Six coriander accessions of different origins were grown on an experimental field in Mošorin, Serbia, during 2014. According to the obtained results, postdistillation coriander seed waste material, as estimated by the Folin–Ciocalteu method, contained between 40.9 and 57.2 mg GAE/g dry extract of total polyphenols. However, according to DPPH method the antioxidative potential of coriander postdistillation seed waste was poor and it is ranged between 0.03 and 0.04 TE. Further research will be focused on agro-food implementation of postdistillation waste material of coriander and other plants which are used for essential oil production.

Keywords: *Coriandrum sativum*, postdistillation waste material, total polyphenols, DPPH, antioxidative capacity

Introduction

Coriander (*Coriandrum sativum* L.) is annual aromatic plant from the Apiaceae family. It is grown for seed (*Coriandri fructus*) which can be used as spice or for essential oil distillation (*Coriandri aetheroleum*). The dry, ripe fruit and oil have a specific fragrance, sweet, hot and pungent. The scent originates from the main components in the essential oil: limonene, α-pinene and geranyl-acetate. However, the content of essential oil in seed is low, between 0.1 and 1.8% (Diederichsen 1996). The amount of the essential oil and its quality can vary depending on: varieties and cultivars, the geographical position of the region of production, the climate and weather conditions, soil type, agro technology, the stage in which the harvest is performed, drying, storage and applied extraction techniques (Aćimović 2014).

Material efficiency is nowadays an essential topic to promote the sustainable use of natural resources, waste materials and industrial by-products, in agreement with the principle of sustainable development and life cycle assessment (Prokkola et al., 2012). Because of this, the

biological potential of various plant waste materials is in focus of numerous studies. These studies are important, both in terms of economy and ecology, in order to elucidate the way to exploit post-distillation waste material of aromatic plants and other plant waste materials more efficiently (Gavarić et al., 2015).

The aim of our investigation was to determine the total polyphenols content in postdistillation waste material which remains after coriander essential oil distillation. Thestudy of antioxidant activity of postdistillation waste material was the other purpose of this paper.

Material and methods

Plant material. Six different ecotypes of coriander plants were grown for the trial purposes. The local ecotype of coriander seed, widely grown in province of Vojvodina was obtained from medicinal plants grower from Kulpin (plants used for extraction of the oil marked as Coriander 1), while other five types of seed were bought at the local market. The seed producers were: Institute for Medicinal Plant Research "drJosifPančić" Serbia, "Semenarnacoop" Serbia, "Master seeds" Serbia, "Sgaravatti" Italy and "Blumen" Italy (plants used for extraction of the oils marked as Coriander 2, 3, 4, 5 and 6, respectively). Coriander was sown in the first decade of April, by hand at row spacing 35 cm, and around 70 seeds per meter in a row (density of 200 plants per m^2). The size of the experimental plots was5m^2. Weeds were controlled by hoeing and weeding when needed. Disease and insect control measures were not applied. Harvest was carried out by hand in the phase of full maturity, at the end of July. After harvest, the seed waskept in paper bags at room temperature until required for further analysis.

Experiment location and growing conditions. The experimental field was set in a village called Mošorin (45°18' N, 20°09' E) in 2014. Mošorin is located in the north part of the Republic of Serbia. This area has moderate continental climate with some tendencies towards continental. The whole region is located in a semi-arid area where variations in the amount of precipitation, air temperature and other important climatic elements are substantial over the years. The soil at experimental field had a neutral reaction to soil solution (pH 7.3 in KCl) and was moderately supplied with humus (2.7%). The soil is classified as highly calcareous loamy chernozem (with 8.4% $CaCO_3$). The content of readily available phosphorus and potassium was high (81.6 and 75.1 mg/100gof soil, respectively).

Essential oil isolation. The dried samples of coriander were subjected to hydro-distillation using an all glass Clevenger−type apparatus to extract essential oils according to the method outlined by the European Pharmacopoeia.

Determination of the total polyphenolics.The amount of total phenolics in water soluble extracts which remains after essential oil distillation (postdistillation waste material) wasdetermined using the Folin-Ciocalteu reagent with gallic acid as astandard. The reagent was prepared by diluting a stock solutionwith distilled water (1:10, v/v). Samples (1 ml, three replicates)were placed into test cuvettes, and 5 ml of Folin-Ciocalteuphenol reagent and 4 ml of Na_2CO_3 (7.5 %) were added. Theabsorbance of the samples was measured at 765 nm using aUV/VIS spectrophotometer Cintra 40 after incubation at 20 °C for 1 h. The resultswere expressed as milligrams of gallic acid equivalent per 1 g of fresh weight, (mg GAE/g).

Characterisation of phenolics compounds. The water soluble extracts of coriander seed which remains after essential oil distillation were dissolved in methanol to an approximate concentration of 5 mg/ml. The LC/DAD/MS analyses were carried out by an Agilent 1200 HPLC instrument (Agilent Technologies, Waldbronn, Germany) with a binary pump, an autosampler, a column

compartment equipped with a Zorbax Eclipse Plus C18 column (1.8 μm, 4.6 mm × 150 mm, Agilent Technologies) and a diode-array detector coupled with a 6210 time-of-flight LC/MS system (Agilent Technologies). The mobile phase consisted of water containing 0.2% formic acid (A) and acetonitrile (B). A combination of isocratic and gradient modes of elution was used as follows: 0–1.5 min 5% B, 1.5–26 min, 5–95% B, 26–35 min, 95% B. The mobile phase flow rate was 1.4 mL/min, the column temperature was 40 °C and the injection volume was 5 μl. Spectral data from all the peaks were accumulated in the range of 190–450 nm and chromatograms were recorded at 260, 280, 290 and 320 nm. MS-data were collected by applying the following parameters: ionization negative ESI, capillary voltage 4000 V, gas temperature 350 °C, drying gas 12 L/min, nebulizer pressure 45 psi, fragmentor voltage 140 V, mass range 100–2000 **m/z**. A personal computer system running MassHunter Workstation software was used for data acquisition and processing. Phenolic compounds were detected as $[M-H]^-$ or $[2M-H]^-$ signals using these parameters. Compounds were characterized by their retention times ($\mathbf{t}_r$), mass spectra and UV spectra, and were tentatively identified based on previous data published by other authors. Their complete identification was not possible since the full scan mass spectra of the chromatographically separated compounds gave only deprotonated $[M-H]^-$ ions, and MS/MS experiments were not possible with the instrumentation used.

Antioxidant activity. The antioxidant activity of the samples was evaluated by means of the 2,2-diphenyl-1-picrylhydrazil (DPPH) radical scavenging method. This spectrophotometric assay uses stable DPPH radical as reagent. The methanolic solution of the investigated sample (200 μl) (with starting concentrations of 200, 300, 400, 500 μl/ml of solution) was added to a 1800 μlmethanolic solution of DPPH radical (concentration of 0.04 mg/ml) and after shaking, the reaction mixture was left to react in the dark for 30 min at room temperature. Then absorbance of the remaining DPPH radical was measured at 517 nm (A_1) on Cintra 40 UV–Visible spectrophotometer. Every concentration was done in triplicate and the same experiment was done with Trolox standard, a well known synthetic antioxidant. The resultswere expressed as mM of trolox equivalent per 1 g of fresh weight, (mM TE/g). Blank probes were used in the same way, with methanol instead of the investigated solution (A_0). The decrease in the absorption of DPPH solution at 517 nm is calculated by the following equation:

$$I = \frac{A_0 - A_1}{A_0} * 100\%$$

Concentrations of the extracts which reduce the absorption of DPPH solution by 50% (EC_{50}) were obtained from the curve dependence of absorption of DPPH solution at 517 nm from the concentration for each extract and standard antioxidant. Origin 8.0 software was used to calculate these values. Tests were carried out in triplicate.

Statistical Analysis. Data was subject to statistical analysis using the program package Statistica 10 (StatSoft Inc., 2011, University of Novi Sad license) and were expressed as mean value.

Results and discussion

The average content of essential oil in different accessions of coriander seed grown in Serbiawas 0.57%, and varied between 0.42 and 0.95%(Table 1). The highest content of essential oil wasdetermined in local ecotype (Coriander 1). It is well known that essential oil content depends on many factors, among whichthe genotype is a major determinant for the synthesis of secondary metabolites(Gil et al., 2002).

Still, the majority of the produced plant material remained unused (more than 99%). However, the total polyphenole content in coriander postdistillation seeds waste material as estimated by

the Folin–Ciocalteu method in average was 53.78 mg GAE/g dry extract (Table 1). The lowest amount of total phenolic compounds was determined in Coriander 3 (40.9 mg GAE/g dry extract), and highest in Coriander 4 (57.2 mg GAE/g dry extract). However, data about total polyphenole content in methanolic coriander seed extract is very different, and ranged between 18.70 GAE/g dry weight (Dua et al., 2014), up to 65.58 mg GAE/g dry weight (Sriti et al., 2012). According to DPPH method, the antioxidative potential of coriander postdistillation seed waste was poor and it is ranged between 0.03 and 0.04 mMTrolox Equivalents/g sample(Table 1). However, in the study with fruit methanolic extract of three coriander varieties (Tunisian, Syrian and Egyptian) EC_{50}values of reducing power activity varied significantly from 54.20 to 122.01 μg/mL (Msaada et al., 2014).

Table 1. Essential oil content (%) in coriander seed, total polyphenole content (mg Gallic Acid Equivalent/g sample) and antioxidative capacity (mMTrolox Equivalent/g sample) of methanolic extract of coriander postdistillation waste material.

	Essential oil content (%)	**Total polyphenole content (mg GAE/g sample)**	**Antioxidative capacity (mM TE/g sample)**
Coriander 1	0.95	55.7	0.04
Coriander 2	0.56	55.9	0.03
Coriander 3	0.45	40.9	0.03
Coriander 4	0.42	57.2	0.04
Coriander 5	0.49	56.2	0.04
Coriander 6	0.56	56.8	0.04
Average	**0.57**	**53.78**	**0.037**

by applying the lc/dad/ms analysis,43 phenolic compounds were detected in the postdistillation waste material of coriander seed. there are a couple of groups: hydroxybenzoic and hydroxycinnamc acids, as well as glycosides flavanones and flavanols. the most abundant are different hydroxycinnamic acids and their derivates, and glycosides flavanols. esculin, glycosides coumarines,is found in methanolic extract of coriander seed.

Conclusion

Our findings suggest that coriander postdistillation waste material represents a source of polyphenoles, but has low antioxidative capacity according to DPPH method. However, further research needs to be focused on its implementation in agro-food industry, in order to provide high exploitation of plant material.

DETERMINATION OF YIELD AND SOME PLANT CHARACTERISTICS IN SOME SILAGE CORN VARIETIES

Bilal KESKİN*, Hakkı YILMAZ, Süleyman TEMEL, Barış EREN

Igdir University, Faculty of Agriculture, Department of Agronomy, Igdir, Turkey
*Corresponding author: bilalkeskin66@yahoo.com

Abstract

The study was conducted to determine the yield and some plant characteristics of some silage corn varieties which are grown as the main product in Igdir province. The study was applied to randomized complete block design pattern with three replications in irrigate conditions. In this research, plant height (cm), forage yield (t ha^{-1}), dry matter ratio (%), dry matter yield (t ha^{-1}), leaf ratio (%), stem ratio (%), cob ratio (%), the number of leaf (number/ plant), plant weight (g) were determined in 10 silage corn varieties. According to the results; plant height was determined between 204.2 cm (OSSK-602) and 313.9 cm (OSSK-644), forage yield 60.5 t ha^{-1} (OSSK-602) and 110.5 t ha^{-1} (TK-6063), dry matter ratio 30.3% (OSSK-644) and 38.6% (TK-6063), dry matter yield 20.3 t ha^{-1} (OSSK-602) and 41.5 t ha^{-1} (TK-6063),), leaf ratio 14.3% (OSSK- 596) and 18.3% (RX-9292), stem ratio 42.3% (Hido) and 51.0% (OSSK-644), cob ratio 36% (OSSK-644) and 45.6% (OSSK-602), the number of leaf 11.0 (OSSK-602) and 13.3 (TC-6063) plant weight 635.9 g (OSSK-602) and 1160.6 g (TK-6063). As a result, TK-6063, HİDO and SHEMALL varieties has been determined as suitable for the region's ecology.

Key Words: *Silage corn varieties, yield components, plant characteristics*

Introduction

In recent years, the production of silage fodder crops has been increased because of inadequate increase fodder crops depending on rising animal number and especially malnutrition of animals in winter season, Turkey. In this sense, corn (Zea mays L.) is a fodder sustain the animals' fodder need and generally used as silage both in homeland and in the world (Basbag et al., 1997). Corn is a plant which its production is increased throughout the world in silage fodder crop side as it is tasty and high nutrition value in the last half century. At the same time, high green weed profit unit area and its being appropriate to make silage without the additive are among most important features of corn. Because of its peculiarities that are mentioned above, the importance of corn plant's production increases to serve the need of fodder those animals require (Acıkgoz, 1995; Kilic, 1986; Sade, 2002). There are a wide variety of plants used in the production of silage in our country. It can be said that corn and sorghum are the most used kinds in these plants (Saglamtimur et al., 1998). The important thing in silage corn production is highness of green weed production. The highness of green weed profit depends on long vegetation duration. Because of the increase in the vegetation period the plant has provided high yield increases (Temel and Tan, 2002). Stub development in corn plants affects in 50% green weed profit. Because of this, vegetation duration is important in stub development of corn production (Ayaz et al., 2013). It is known that not being able to produce roughage in enough quantities, has very disadvantages in farming and animal products. Especially in Igdir province that is suitable for agriculture, silage corn kinds should be used as fodder to serve the roughage need. In this regard, it can be said that silage corn production in irrigated land will add important effects to the

region's silage corn production capacity. In this study, appropriate and high profit kinds are aimed to determine for silage corn production in Igdir province.

Materials and methods

This research was carried out in aqueous trial areas of the Agricultural Research and Application Center of the Igdir University in 2015. In this study, ten corn varieties (respectively, 72 MAY 80, OSSK-644, TK-6063, OSSK-596, TK-6060, HİDO, RX- 9292, 71 MAY 69, SHEMALL, OSSK-602) were used. Climate values occurred in 2015 in Igdir province are given in Table 1.

Table 1: Average Climate Properties Values of Igdir Province in 2015.

	March	April	May	June	July	August	Sum/Avg.
Average Temperature (°C)	11,0	16,4	21,3	28,5	31,8	30,2	23,2
Monthly Total Precipitation (mm)	52.0	44.1	41.5	27.8	0.3	14.3	30
Monthly Avg. relative Humidity (%)	50,8	47,7	52,9	40	33,6	40,7	44.2

The characteristics of the soil of trial area is as follows: clay-loamy texture, severe alkaline (pH: 8.6, lightly salted (EC 1.37 dS/m), low organic matter content, (1.20%) and rich lime content (CaCO3: 22.27%). Moreover, suitable phosphorus and potassium contents in the soil was determined as 51.7 ppm and 852.4 ppm, respectively (Erdogan, 2013). Studies were designed as 3 replications according to randomized block pattern. Planting process has been made in a manner that row spacing, row top, parcel length and parcel width will be respectively 70 cm, 15 cm, 5 m and 3.5 m by means of marker on 04.04.2015 date. Each plot area was 17.5 m^2. In this research, total 160 kg/ha nitrogen, 80 kg/ha phosphorus fertilization of maize plants were carried out. Half of nitrogen fertilizer was given during planting, but the other half is provided from after plants is 50 cm long raised. Cultural practices such as weed control and tractors anchors which is necessary from sowing to harvest process have been made. At the same time, watering process was regularly made until the harvest by opening furrow after plants is 15-20 cm long. Harvest process is applied in 7.9.2015 date. And then, yield and plant characteristics were determined by measuring over 30 varieties corn randomly selected in each plot. Data obtained from the results of research that we were carried out in Igdir conditions were analyzed with IBM SPSS 17.0 packet program and Duncan's multiple comparison test that was used to reveal the differences between each other's varieties (Anonymous, 2008).

Results and discussion

Plant height (cm):

Plant height of corn varieties used in the study is range from 204.2 to 313.9 cm. In this study, the highest plant height and the lowest height are OSSK 644 and OSSK 602 varieties, respectively. According to result of study carried out in conditions of Van province, the highest plant height and the lowest plant height was 242.6 cm and 143.7 cm (Akdeniz et al., 2004). The average plant height in maize has been reported to range from 1.5 to 3 m (Kun, 1997). The effect of genetic structure is an important factor affected plant height (Hallauer et al., 1988). When studies related to plant height in maize plant considering, we can say that varieties used in the experiment have adequate plant height. It supposes that these differences in results are caused from regional

climate and soil characteristics. Because of hereditary properties of quantitative characters are very low, plants are significantly affected by environmental conditions.

Forage yield (t ha^{-1}), dry matter yield (t ha^{-1}), dry matter ratio (%)

Forage yield is an important factor affecting silage yield (Ayaz et al., 2013). Forage yield in corn varieties used in the study were show statistically significant differences and yields ranged from 60.5-110.5 t ha^{-1}. While the highest value of forage yield was TK6063, the lowest yield value was obtained from OSSK 602 variety. Iptas et al., (2004) have obtained values between 87.9 and 67.2 t ha^{-1} in forage yield as result of studies carried out in Tokat- Kozova conditions. Akdeniz et al., (2004) showed that the highest value in forage yield was 78.4, and the lowest values were 27.2 t ha^{-1} in their study. Dry matter ratio of 10 corn varieties used in the study ranged from 30.3 to 38.6%. While the highest value of dry matter ratio was TK 6063, the lowest dry matter ratio was obtained from OSSK 644 variety. Dry matter yields of varieties are ranged from 20.3 and 41.5 t ha^{-1}. While the highest value of dry matter yield among corn varieties used in this study was 41.5 t ha^{-1} (TK 6063), the lowest dry matter yield value was 20.3 t ha^{-1} (OSSK 602). Iptas et al., (2004) have obtained that the highest value was 23.6 t ha^{-1} and the lowest value was 18.5 t ha^{-1} in dry matter yield as result of studies carried out in Tokat- Kozova conditions. In a study carried out in Van conditions, dry matter yield obtained between 14.6 and 7.4 t ha^{-1} (Akdeniz et al., 2004).

In result of our study carried out Igdir province conditions, we found that forage and dry matter yields obtained from maize varieties was to be higher than the findings of other researchers. It is assume that these differences will be result from different varieties used in study and environmental conditions.

Leaf ratio, stem ratio and cob ratio

While leaf ratio between corn varieties used in the research that we conduct in Igdir conditions is insignificant, stem and cob rate was significant. The stem and cob rate of varieties are range from between 42.3-51.0%, and 36.0-45.6% respectively. While OSSK 644 variety has higher stem ratio, HİDO variety has lowest stem ratio. The highest value and the lowest value in terms of cob ratio among corn varieties was belong to OSSK 602 and OSSK 644 varieties, respectively. Akdeniz et al., (2004) obtained values of cob ratio with 38.2-49.0% and stem ratio with 28.1-43.6% in study carried out in Van conditions.

Leaf number (pieces)

Multiple comparison results belong to leaf number in maize varieties are given in Table 3. Values of between 11.0 and 13.3 in the number of leaves of the corn variety used in this study were obtained. According to our results, while TK 6063 variety has highest leaf number (13.3), OSSK 602 variety has lowest leaf number (11.0). Gunes and Acar, (2006) was found that highest and lowest value in leaf number among maize varieties grown as second production in study carried out in Karaman is 15.8 and 13.8 number/plant, respectively.

Plant weight (g)

Plant weights obtained in this study were significant among maize varieties. Multiple comparison results belong to plant weight in maize varieties are given in Table 3. The highest plant and the lowest plant weight in study were measured as 1160.6 g and 635.9 g. The highest and lowest value of plant weight of maize varieties grown as second production in study carried out in Karaman was determined among 1198.0 g and 913.6 g, respectively (Gunes and Acar, 2006)

Table 2: Plant height, forage yield, dry matter ratio and dry matter yield of maize varieties

* There were not significant differences in 0.05 level among averages shown with same letter. (P<0.05)

Conclusion

In silage maize production, while forage yield, leaf number, leaf ratio, plant weight, dry matter yield and cop ratio of maize crops is desirable to be high, high stem ratio is not desirable. According to data obtained from study, the most suitable varieties to these criteria are TK6063, HİDO and SHEMALL. In result of study, moreover, we found that these varieties were advisable to grow in Igdir conditions.

Abstract

In terms of economic significance, blackberry ranks 3rd in the Serbian production of berry fruits, following immediately after raspberry and strawberry. New systems for blackberry cultivation in enclosed and semi-enclosed areas which have gained global popularity over the past several years offer certain advantages – primarily in terms of protection of fruits from adverse weather conditions, but also by indirectly reducing the threat of infection with economically significant pathogens, thus yielding an overall advantage over open-field production methods. Considering that the Serbian blackberry yield suffers an annual loss of around 30% due to gray mold caused by the phytopathogenic fungi *Botrytis cinerea* Pers., introduction of more intensive blackberry cultivation systems is imperative in order to prevent adverse action of rain and other abiotic components, thus securing continuous harvest and supply of improved-quality fruits. The paper presents results of a three-year study (2011−2013) of rain-shield cultivation system on morphometric and chemical properties of blackberries Čačanska Bestrna. The results showed that most of the tested parameters were affected by production system and environmental conditions during the research, as well as by their interaction. The rain-shield system did not cause any deviation of morphometric properties compared to open-field cultivation. In terms of the chemical properties, soluble solids content (10.26%), total and invert sugar content (6.77%; 6.06%), and sucrose content (0.68%) were higher in blackberries under rain shields.

Keywords: *Blackberry*, *Rain shields*, *Fruit quality*, Serbia.

Introduction

Blackberries are popular fruits widely distributed throughout nature, except the polar regions, and grown worldwide. Berries of this species had pleasant flavor and high nutritive and health value (Milošević et al., 2012).

The economic significance of the European blackberry (*Rubus* subg. *Rubus* Watson) makes it an important berry fruit in Serbia, where it is positioned immediately after raspberry and strawberry (Nikolić and Milivojević, 2015). The blackberry production constitutes 69% of the European and 17.82% of the world's production (Strik et al., 2007), which places Serbia among the four leading global producers of this fruit. The blackberry orchards in Serbia are dominated by the 'Čačanska Bestrna' and 'Thornfree' cultivars, with more than a 95% share, followed by the 'Black Saten', 'Dirksen Thornless' and some more recent cultivars, such as 'Loch Ness', 'Chester Thornless', 'Triple Crown' (Nikolić et al., 2012; Nikolić and Milivojević, 2015). Considering the fact that over the past several years the difficulties in marketing blackberry have been partly due to a relatively weaker fruit quality of the most widely grown cultivars ('Čačanska Bestrna' and 'Thornfree'), it is necessary to introduce new technologies and changes to the cultivars.

Regarding this, intensifying the technology of blackberry cultivation is mostly focused on reducing the adverse impact of inclement weather (low and high temperatures, rain and light). The system of blackberry cultivation in enclosed areas (tunnels) is widely favoured, mostly owing to the protection of the fruits from adverse weather conditions it provides, thereby gaining advantage over open-filed production (Thompson et al., 2009). Depending on the construction type, cultivation of blackberry in enclosed and semi-enclosed areas may take different forms. Double-row rain shields (semi-tunnels) represent simple and highly cost-effective cultivation techniques, conducive to improved fruit quality and increased yields. Gaskell (2004) reported that high tunnels and rain shields cultivation improve fruit quality by moderating the environment and excluding rain and extending the harvest seasons.

The objective of the research is to indirectly examine the impact of the rain-shield cultivation on morphometric and chemical properties of blackberry 'Čačanska Bestrna'.

Material and methods

Experimental design

The investigation was conducted over a three-year period (2011–2013) in the experimental trial of blackberry cultivar 'Čačanska Bestrna', which was established in 2006 and is located at Gornja Gorevnica (43° 53'N latitude, 20° 20' E longitude, 290 m altitude) near Čačak city, Western Serbia. This is mainly an upland area, with an average altitude of about 290 m, characterised by the temperate continental climate. The blackberries were planted in rows spaced 3.0 m apart with plants set at 1.5 m apart in the row, and trained as a three-wire trellis. Plastic arches were placed on the existing trellis structure in the blackberry orchard. The arches were covered using 150 μ thick foil, forming the shape of an umbrella (rain-shield cultivation). The trial was conducted using a randomised block design and it included four replications of each treatment. Fertilization and irrigation practices standard for the region were provided during the period of investigation.

Plant material

Blackberry 'Čačanska Bestrna' was created in 1984 by crossing 'Dirksen Thornless' × 'Black Satin' at the Fruit Research Institute, Čačak. It is a highly vigorous cultivar, producing 4−5 strong canes bent in mid-section, having short internodes. The flowering season is mid-late. It is a self-fertile, abundant cropper. Resistant to low winter temperatures, it is medium resistant to yellow rust (*Kuehneola uredinis* (Link)) and susceptible to purple blotch of blackberry (*Septocyta ruborum* (Lib.) Petrark). Ripening season is mid-early, at the beginning of the third decade of July. The fruit is large, with an average fruit weight of around 9.3 g. It is elongated-cylindrical, glossy black, with a sweet-subacidic taste and pronounced aroma. 'Čačanska Bestrna' is suitable for both fresh use and freezing and for various forms of processing as well. In different agro-ecological conditions, this cultivar has displayed excellent performance in respect of cropping and resistance to diseases and low winter temperatures.

Determination of fruit quality traits

Twenty-five fruits in each replication were randomly selected to determine average fruit weight using the METLER balance (±0.01gaccuracy) and the data were expressed in g per fruit. The fruit dimensions (mm)(length, breadth, and fruit shape index) were also determined in the selected samples using the 'Inox' vernier scales (±0.05 mm accuracy). Chemical parameters viz. soluble solids (SS), total sugars (TS), reducing sugars (RS), titratable acidity (TA), pH, sucrose (SC) and ripening index were measured at the commercial maturity stage. SS (^{o}Brix) was determined using a hand refractometer (ATC, Belgium). TS (%) and RS (%) were determined as

fresh weight basis, using the Luff-Schoorl method. TA was measured by neutralization to pH 7.0 with 0.1N NaOH, the data being presented as percentage of malic acid. Juice pH was measured using a pH meter (Cyber scan 510, Mettler Toledo, USA). SC was calculated by multiplying the difference of the total and reducing sugars contents by the 0.95 coefficient. RI was calculated as soluble solids/titratable acidity ratio.

Statistical analysis

The results are presented as mean ± standard error of mean (SE). Differences between mean values were compared by LSD test in two-way analysis of variance (ANOVA) using MSTAT-C statistical computer package (Michigan State University, East Lansing, MI, USA). Differences with *p* values of ≤ 0.05 were considered insignificant.

Results and discussion

Within the morphometric characteristic of the fruits of the studied blackberry cultivar, the results of examining fruit weight and dimensions (length and width) are shown (Table 1), as well as the fruit shape index (Table 1) in the function of the cultivation system over the three-year period of trial.

Table 1. Effect of cultivation techniques on morphometric properties of blackberry fruits 'Čačanska Bestrna'

The variance analysis showed that the training system and the year made a statistically significant impact on the length and width of the blackberry fruit, whereas their interaction made a significant impact on the length and the fruit shape index. The only impact made on the blackberry fruit weight was that of the year of study. Fruit weight, length, breadth and shape

index ranged from 5.70±0.05 to 7.92±0.11g, 22.16±0.28 to 25.66±0.63mm, 16.45±0.25 to 19.60±0.18mm, and 1.21±0.01 to 1.42±0.01, respectively. The comparison of the different cultivation techniques showed that the morphometric traits (fruit weight, length, and breadth) and shape index were higher in the rain-shield treatment. The weight and length were the highest in second growing year, whereas the breadth was the highest in the third growing year and fruit-shape index reached its peak in the first growing year. In general, the morphometric traits were found to be worse in first growing year, except the shape index.

The obtained results of the morphometric properties of the blackberry cultivar examined in this paper indicate that the application of the rain-shield system made a positive impact on the fruit weight and dimensions, with significant differences occurring in the length and width. Compared to the results obtained by Stanisavljević (1998), a lower fruit weight of the blackberry 'Čačanska bestrna' was obtained by Milivojević (2008) in the Central Serbia conditions and Miletić et al. (2006) in the Eastern Serbia condition. Similarly to these results, Thompson et al. (2009) did not detect major fluctuations in the fruit weight of the primocane blackberry 'Prime Jan' grown in the rain-shield system. On the other side, Miller and Tworkovski (2003) reported that the optimum distribution of light in the shielded and semi-shielded space have a positive impact on differentiation of generative buds in annual plants, as well as on the fruit quality of biennial canes, especially the fruit size and colour, but also the soluble solids content in the fruit. Observed by the year of study, the obtained results for the cultivar under consideration reveal significant fluctuations in the values of the fruit weight and dimensions, which can be explained by the different environmental conditions in the respective years of study. Based on the values obtained in the investigation, it can be observed that the shape index in all treatments was higher than 1, which corresponds to the conic shape of the fruits of the examined blackberry cultivar.

Chemical parameters analysed so far showed a significant effect of cultivation techniques, except SC and TA. On other hand, growing years significantly affected the number of TS, RS, SC, TA, and pH (Table 2a and b). Interaction effect of cultivation techniques and the growing year significantly affected all the chemical parameters, except TS and RS. SS, TS, RS, SC, TA, pH, ripening index in fruit ranged from 9.53±0.04 to 10.35±0.07^{O} Brix, 5.92±0.06 to 7.04±0.21%, 5.16±0.03 to 6.35±0.19%, 0.45±0.04 to 0.84±0.06%, 1.12±0.03 to 1.31±0.07% of malic acid, 2.97±0.03 to 3.47±0.02, and 7.80±0.28 to 9.31±0.20, respectively. Higher chemical parameters, except TA were recorded in the rain shield cultivation. Thompson et al. (2009) reported that it is as yet unkown whether plastic foil used in tunnel system off cultivation makes an impact on the synthesis of primary and secondary metabolites in plants. The average values of the soluble solids content in all the treatments were higher than the values obtained Miletić et al. (2006) for the same cultivar, while at the same time lower in comparison with the values obtained by Stanisavljević (1999).

The analysis of interaction effect of cultivation techniques and growing year (Table 2a and b) inferred that SS, SC, pH, and ripening index were the highest in the rain shield cultivation during the third year, and TS, RS, and TA were the highest under the same cultivation techniques in the first year.

Values within each column followed by the same small letter are insignificantly different at the $p \leq 0.05$ by LSD test;
ns - non significant differences.

Based on the obtained results, it can be concluded that the structure of total sugars is dominated by invert sugars (glucose and fructose), with the fluctuation of the values reflecting the same tendency as the total sugars. The average values of the total sugars obtained in all of the treatments were higher than the values obtained by Miletić et al. (2006) and Veberic et al. (2014).

The sucrose share in the fruits of the studied cultivar was lower, with significant fluctuations in the respective years of study, which is in accordance with the findings of Kaume et al. (2012). In the conditions of the applied cultivation systems, the recorded values of the sucrose content were at a similar level, though slightly higher in the rain-shield system off cultivation. Observed by the year of study, the obtained results indicate that the values of the sucrose content in the blackberry cultivar under consideration recorded significant fluctuations demonstrating a different tendency compared to the total sugars content.

According to Talcott (2007), the organic acids play a key role in the formation of the colour and extension of the storage capacity of fresh and processed fruits. Reyes-Carmona et al. (2005) state that the values of the total acids contents in blackberry fruits vary within the range from 1.02% to 4.22%, whereas Nikolić and Milivojević (2015) and Veberic et al. (2014) conclude that citric and malic acids are the most dominant. The values of the total acids obtained in this study for the different cultivation systems were relatively levelled and showed no significant differences among the respective variants. Each cultivation system was characterised by an identical variation in the levels of the total acids content in the fruit, in each year, meaning that the interaction between the cultivation system and the year made a significant impact on this parameter. Based on the study into the content of sugar and organic acids in the fruit of wild blackberry and economically most important blackberry cultivars conducted over a period of three years, Milivojević (2008) established that the total acids content in the fruits of the 'Čačanska Bestrna' amounts to 0.20 mg g^{-1}. Similar values of the total acids contents in the fruits (17.7 g kg^{-1}) are stated by Veberic et al. (2014) and Miletić et al. (2006).

Conclusion

During the three years of study, the rain-shield cultivation system made a positive impact on the morphometric characteristics of blackberry fruits and the content of the studied parameters of biochemical composition. Regarding this, the preliminary results of studies into the more recent cultivation system, i.e. implementation of the rain-shield system in blackberry production, growers can be advised and given guidelines in the blackberry growing technology with a potential to advance the fruit quality.

Abstract

Even though soil mulching is a common practice in vegetable crop production, there is only scarce information about effect of this technique on the yield of potato (*Solanum tuberosum* L.). Field experiments were conducted to investigate the effects of different mulch materials on productive characteristics of three potato cultivars: Marabel (medium early), Desiree (medium late) and Jelly (medium late) under agro-ecological conditions of Southern Srem, Serbia. Treatments were arranged in a randomized complete block design with four replications with irrigation drip system at the site of Zemun Polje (44°88'N, 20°35'E, 79 m a.s.l.) in years 2011 and 2012. The variants with silver plastic mulch, red plastic mulch and straw mulch were compared to a control plot with bare soil. The highest average number of tubers per plant was determined in cv. Marabel subjected to the straw mulch treatment (11.85), while the lowest average number of tubers was determined in the cv. Desiree's control variant (8.65). Mulching combined with irrigation caused 2-3-fold increase in tuber yield compared to the average yield of potato in commercial production in Serbia. In a two-year study, treatment with red plastic mulch resulted in the highest average total yield in cv. Marabel and cv. Jelly, 55.9 t ha^{-1} and 46.7 t ha^{-1}, respectively, while combination of irrigation and straw mulch resulted in the highest average total yield of cv. Desiree (45.2 t ha^{-1}). The study showed that two investigated factors, type of mulch and cultivar, significantly affected the number of tubers per plant and total yield of potato.

Key words*: mulching, potato, potato yield, number of tubers*

Introduction

Potato yield depends on the chosen variety and its genetic potential, agro-ecological conditions, applied cropping practices, tuber viability, seed tuber size, the number of stems per plant and the number of tubers per plant (Momirović et al., 2010; Poštić et al., 2012). Potatoes are grown on around 78,000 ha in Serbia, with average yield of 11.4 t ha^{-1} (Statistical Yearbook of Serbia, 2014). This yield is significantly lower than average yield of potato in EU and the world (Belgium 44 t ha^{-1}, Netherlands 43 t ha^{-1}, USA 45 t ha^{-1}). In Serbia, the intensive crop management is not extensively used in potato production, especially in the small and economically weak farms. Increase in potato yield can be achieved by adherence to good agricultural practices, adoption of optimal agro-technical deadlines and well-adjusted assortment to agro-technical conditions of production (Broćić and Stefanović, 2012).

Soil mulching with organic or synthetic materials aims to: prevent the development of weeds, improve water and air regime, change the thermal regime of the soil, reduce erosion, increase the level of CO_2 in the zone of the plants. This procedure has been widely used in the production of vegetable crops since, due to a smaller contact with the soil, it contributes to earlier-maturing, cleaner and high-quality fruits and reduces the occurrence of rot. A favourable effect of mulching

type on the growth and development of plants and increased yield was found in maize (Awal and Khan, 2000) and melon (Ibarra et al., 2001). Mulching is increasingly applied in crop production because it also positively affects the structure, as well as the chemical, physical and biological properties of the soil.

Soil mulching with organic material is one method of soil water protection and also helps maintain a constant soil temperature within the root system of crops (Awal and Khan 2000, Kar and Kumar, 2007 Sinkevičienė et al. 2009, Samaila et al. 2011). Straw is most commonly used material for ground covering in crop and vegetable production because of its good thermal insulation properties. The temperature of the soil under the straw can be 5-8 ^{o}C lower than the temperature of bare soil which is especially important in the summer. Reduction of soil temperature has a great importance in countries with hot climate conditions, but now, as the climate is warming, temperature conditions for crops are becoming more unfavourable (Sinkevičiene et al., 2009). Also, the straw decomposition can enrich the soil with organic matter. On the other hand, the use of silver polyethylene films reduces aphids-, white flies- and red spider-attack since reflecting tungsten has a repellent effect on insects (disorientation and change the direction of flight). Red polyethylene film is commonly used in the production of tomatoes and lettuce since it well regulates the temperature, while light diffusion accelerates ripening for 10-14 days (Momirović et al., 2010).

Mulching reduces water evaporation, stabilizes soil temperature and improves soil conditions for plant growth and development. For all these reasons, soil mulching becomes more important also in moderate climate conditions, but there is scarce information about influence of this technique on the yield of potato. The aim of this paper was to evaluate the effect of different mulch materials (organic and plastic mulch) on the number of tubers per plant and potato yield in the lowland regions of Serbia.

Materials and methods

Investigation of the effect of mulching on productive characteristics of three potato cultivars: Marabel (medium early), Desiree (medium late) and Jelly (medium late) was conducted in Zemun Polje, Serbia (44°88'N, 20°35'E, 79 m a.s.l.) during 2011 and 2012. Treatments were arranged in a randomized complete block design with four replications and with irrigation drip system, on the slightly calcareous chernozem soil type. Standard tillage treatment for potato crop was used. Pre-sowing soil treatment included fertilization with Multi-Comp base and BitterMag, as well as organic fertilizer Stallatiko. Plants were foliarly fertilized with Haifa Bonus (N:P:K = 13:2:44, 6 kg ha-1), Haifa Chemicals, Israel. The crop was regularly treated with preparations against downy mildew and Colorado potato beetle. Irrigation tapes were placed in the middle of a shallow bank and incorporated into the soil (sub-irrigation) and soil moisture maintained at about 75% of FWC.

Mulching was conducted in order to preserve moisture, reduce weed infestation, change thermal conditions and improve soil microbial activity. The variants with silver plastic mulch, red plastic mulch and straw mulch were compared to a control plot with bare soil. In plots with plastic mulch, ridges were formed firstly and then covered by the silver and red polyethylene film. Tubers were hand-planted in previously prepared holes in the plastic mulch. In the variant with organic mulch, straw was layered to 25 mm thickness directly after planting and the formation of ridges. Plots without mulch (control) were maintained free of weeds by hand-weeding, especially early in the season.

In both years the planting of tubers (planting density: 80 x 30 cm) was carried out in the first decade of April. Potato harvesting was carried out at the stage of technological maturity in the

second ten days of September; number of tubers per plant was determined, as well as tuber mass and total yield.

Meteorological conditions in the period of investigations

Table 1. The average monthly air temperatures and monthly precipitation sums during the growing season 2011. i 2012. and multi-year average at Zemun Polje

Months	2011		2012		1980-2010	
	^{o}C	mm	^{o}C	mm	^{o}C	mm
April	14.7	14.1	14.6	66.9	12.3	54.6
May	18.3	66.8	18.0	127.9	17.7	56.0
June	21.9	41.1	24.6	16.0	20.9	101.0
July	24.3	95.0	27.0	39.0	22.6	69.2
August	24.6	14.0	26.0	4.5	22.4	55.4
September	23.0	47.7	22.0	30.7	17.5	64.7
Average/Sum	**21.1**	**278.7**	**22.0**	**285.0**	**18.9**	**400.9**

The average air temperatures during potato vegetation period in 2011 and 2012 were 2.2 ^{o}C and 3.1 ^{o}C higher, respectively, than 1980-2010 multi-year average; this was mostly result of average temperature increase in June, July and August. Temperature increase in June was especially significant, considering that this month is important for stolon formation and tuber initiation. Precipitations in summers 2011 and 2012 were below limits of multiple-year average with an uneven distribution during vegetative period in both years. Precipitations in summers 2011 and 2012 were below limits of multiple-year average with an uneven distribution during vegetative period in both years.

Statistical analysis was performed using STATISTICA 10 (StatSoft, Inc. 1984-2011, USA). The data concerning tuber number, tuber mass or yield were subjected to two-factor analysis of variance ANOVA with Cultivar and Mulch Type as factors. If significant interaction between factors was determined, Fisher's-LSD multiple range test was used for analysisat all Cultivar x Mulch combinations. The meteorological conditions during the potato growing season were presented in the Table 1.

Results and discussion

Analysis of number of tubers per plant and total yield (Table 2) showed highly significant differences influenced by potato genotype (G), mulch type (M) and interaction of these two factors (G × M).

Table 2. F-values for observed factors

Factors	Number of tubers per plant	Total yield
Genotype (G)	**	**
Mulch (M)	**	**
G × M	**	**

** - significant at p<0.01; * - significant at p<0.05; ns - not significant

The highest average number of tubers per plant (all three cultivars/genotypes) was recorded in the variant with red plastic mulch (11.0), somewhat smaller number of tubers was determined on variants with organic mulch (10.7) and the variant with a silver plastic mulch (10.3), while the lowest number of tubers per plant (9.6) was determined in control (Table 3).
Considering factor cultivar (Table 3), the lowest number of tubers per plant was found in cv. Desiree (10.1), moderate number in cv. Jelly (10.4), while the highest number of tubers per plant was established in cv. Marabel (10.7).
The smallest number of tubers were formed by cv. Desiree control plants (8.65), while the largest number of tubers per plant was determined in cv. Marabel on the variant with organic mulch (11.85).

Table 3. Average number tubers per plant in 2011. and 2012. year

Mulch	Genotype			Average
	Marabel	Desiree	Jelly	
Silver plastic	9.65	10.70	10.55	10.3
Red plastic	11.50	10.10	11.50	11.0
Straw	11.85	10.85	9.50	10.7
Bare soil	9.95	8.65	10.10	9.6
Average	**10.7**	**10.1**	**10.4**	**10.4**

LSD $_{0.05}$ 0.57
$_{0.01}$ 0.97

The highest average yield of three cultivars/genotypes (Table 4) was determined on variant with organic mulch (48.5 t ha^{-1}), followed by yield of potato plants treated with red plastic mulch (46.8 t ha^{-1}), while the lowest yield compared to control was determined in variant with silver plastic mulch (39,5 t ha^{-1}). With exception of treatment with silver plastic mulch, these results are in accordance with previous findings that mulching of soil significantly increases number of tubers per plant and yield of potato (Momirović et al., 1997; Singh and Ahmed, 2008; Zhao et al., 2012).
Considering factor cultivar (Table 4), the lowest yield was determined for cv. Desiree (39,3 t ha^{-1}), moderate yield for cv. Jelly (43,8 t ha^{-1}), while the highest yield was found in cv. Marabel (51,7 t ha^{-1}).

Table 4. Average total yield (t ha^{-1}) in 2011. and 2012. year

Mulch	Genotype			Average
	Marabel	Desiree	Jelly	
Silver plastic	46.2	34.3	37.9	39.5
Red plastic	55.9	37.9	46.7	46.8
Straw	55.0	45.2	45.2	48.5
Bare soil	49.5	39.7	45.3	44.8
Average	**51.7**	**39.3**	**43.8**	**44.9**

LSD $_{0.05}$ 2.43
$_{0.01}$ 4.15

Considering yield of particular cultivars in different mulching treatments, the highest yields of cv. Marabel i Jelly were determined in variants with organic or red plastic mulch, while cv. Desiree

was showing the highest yield in variant with organic mulch. The lowest yield of each particular cultivar was determined in treatment with silver plastic mulch (Table 4).

Conclusions

In general, soil mulching significantly increased number of tubers per potato plant. Compared to control (bare soil; 9.6), the highest number of tubers per plant was determined in treatment with red plastic mulch (11.0). The highest potato yield was determined in treatment with organic mulch (48.5 t ha^{-1}), while treatment with silver plastic mulch reduced yield (39.5 t ha^{-1}) compared to control (44.8 t ha^{-1}).

Considering production potential of particular cultivars/genotypes, the highest yields of cvs. Marabel i Jelly were achieved in treatments with organic or red plastic mulch. Cv. Desiree was showing the highest yield and percent of mercantile tubers on variant with organic mulch. Conversely, the lowest yield of each particular cultivar was determined in treatment with silver plastic mulch indicating that this mulch type is not appropriate for potato growing under agro-ecological conditions of Southern Srem, Serbia.

Abstract

In this research, 16 genotypes of winter wheat (*Triticum aestivum* L.) were analyzed where 15 genotypes represent perspective lines created in Center for Small Grains in Kragujevac and one standard cultivar. Field experiment was conducted in three growing seasons (2012/13, 2013/14 and 2014/15) on the experimental field of Center for Small Grains in Kragujevac (Serbia). Some grain quality parameters (hectoliter weight and 1000 grain weight) were analyzed in this paper. In average for three years, values of hectoliter weight varied from 76.65 kg hl^{-1} (KG-60-3/3) to 80.05 kg hl^{-1} (KG-1/6). The analyses of variance showed highly significant differences in hectoliter weight between genotypes (F=4.554**) and investigated years (F=150.082 **), but interaction genotype x year was significant (F=1.629*). The highest values of 1000 grains weight expressed line KG- 52/23 (46.75 g) and the lowest line KG-28/6 (39.90 g). Compared to the standard cultivar Pobeda, 10 genotypes had higher values of 1000 grains weight. There were highly significant differences in the weight of 1000 grains among genotypes (F=25.011**), investigated years (F=117.267**), as well as their interaction (F=8.684**).

Key words*: wheat, growing seasons, hectoliter weight, 1000 grain weight.*

Introduction

Genetic potential for yield and quality of specific cultivar has a huge influence in its production. However, the true value of cultivar as well as its impact on wheat production depends not only of its productivity, but of its stability in different environmental conditions (Hristov *et al.*, 2007).

The way genotype reacts to different environmental conditions shows stability and it is very useful in selection and agricultural production. The lower the value of the genotype x environment interaction (GE), the more stable the genotype is. Intensive genotypes, such as high-yield cultivars of wheat which require intensive agricultural technology, are very sensitive to agricultural environment and show greater GE interaction (Dimitrijević *et al*., 2006).

When breeding bread wheat, there is always a tendency appropriate breeding terms high-yield and stable genotypes. Wheat yield is very complex and depends on quantitative traits as its compontents. Yield depends on number of spikes per surface area, number of grains per spike and mass of grains per spike (Kraljević-Balalić *et al*., 2001). However, these quanitative traits affect genes with minor effect whose expression depends on enviromental conditions. Research of behavior of genotypes in different agricultural conditions and their interactions with enviroment in which they grow, helps to choose an ideal genotypes for specific areas of growth. It is preferable that new cultivars of wheat, besides high yield potential and quality of grain, has a lower variability of these traits in different agroecological conditions (Zečević *et al*., 2013).

In Centre of Small Grains in Kragujevac, high yield cultivars were always a tendency as well as lower stem and earlier maturity and higher resistance to main biotic and abiotic factors of enviroment (Milovanović *et al*., 2003; Milovanović *et al*., 2012). Besides high yield, maturity and other traits, KG cultivars possess an excellent technological quality for production of bread and pastry (Milovanović *et al*., 2008).

The goal of this research is investigation of influence of ecological factors, genotypes and their interactions on some wheat quality traits.

Material and Methods

In this research, 16 genotypes of winter wheat (*Triticum aestivum* L.) were analyzed where 15 genotypes represent perspective lines created in Center for Small Grains in Kragujevac (KG – 27/6, KG- 244/4, KG – 199/4, KG – 307/4,KG – 331/4, KG – 28/6, KG – 162/7, KG – 40-12/1, KG – 40-39/3,KG – 52/23, KG – 60-3/3,KG – 52/3, KG – 47/21, KG – 191/5-13 and KG – 1/6) and one standard cultivar (Pobeda). The experiment was done in field conditions, on the experimental field of the Center for Small Grains in Kragujevac, during three growing seasons (2012/13, 2013/14 and 2014/15).

The experiment was a randomized complete block design with three replicates on a plot of $5m^{-2}$. It was carried out by the standard technology of scientific farming production of wheat.

Wheat quality characteristics (hectoliter weight and weight of 1000 grains) were analyzed.

Hectoliter weight was determined according to the JUS E.B1.200 method, and the weight of 1000 grains according to JUS E.B1.200 method. The results of the research were studied by Analysis of Variance (ANOVA) according to completely randomized block design with two main factors (genotype and year) and using MSTAT-C statistical program. Evaluation of the importance of difference between average values of studied characteristics was tested by separate LSD test (Hadživuković, 1991). Components of variance (genetic, interaction and environment) were calculated by Falconer (1981).

Results and Discussion

The obtained results are shown in the table 1. The highest average value of 1000 grains weight was achieved by the line KG -52/23 (46.75 g), and the lowest by the line KG – 28/6 (39.91 g).

According to the growing season of research, in all three growing seasons the highest average 1000 grains weight was achieved by the line KG-52/23 (49.06 g, 44.39 g and 46.82 g). In the years 2012/13 and 2013/14 the lowest average 1000 grains weight had the line KG-28/6 (39.6 g and 37.41 g, respectively), while in the third year of the research (2014/2015) the lowest average value of 1000 grains weight had the line KG-27/6 (38.60 g), table 1. The highest average value of 1000 grains weight for all researched lines of wheat was achieved during the year 2012/2013 (45.58 g), and the lowest (41.90 g) during the year 2013/14.

* Significant at P = 0.05 level; ** significant at P = 0.01 level

Through the analasys of variance high significant differences were detemined among 1000 grains weight of different genotypes (F=25.011**), then among years of research (F=117,267**), and their interactions as well (F=8.684**). Results of this research are in accordance with the previous research (Hristov *et al*., 2007). Analysis of variance's components has shown that the biggest share in it have the interaction genotype x environment (33.53%), and the year (29.62%), table 2.

Average	80.02a	75.36b	79.39a	-

Distinct letters in the row indicate significant differences according to LSD test ($P \leq 0.05$).

The achieved results for the hectoliter weight are shown in the table 3. In period of growing seasons average values of hectoliter weight varied from 76.66 kg hl^{-1} (KG-60-3/3) to 79.73 kg hl^{-1} (KG-1/6). In the first year of the research, the highest average value of the hectoliter weight had the line KG-162/7 (81.73 kg hl^{-1}), and in the second year the line KG-331/4 (77.20 kg hl^{-1}). In the year 2014/2015 the line KG-1/6 had achieved the highest average value of the hectoliter weight (82.17 kg hl^{-1}). The highest average value of hectoliter weight of all researched wheat lines was determined in the 2012/13 growing season (80.02 kg hl^{-1}), and the lowest (75.08 kg hl^{-1}) in the 2013/14 growing season. In comparison to the standard cultivar (Pobeda), 11 lines had higher value of hectoliter weight.

Analysis of variance (Table 4) has shown highly significant differences in hectoliter weight among genotypes (F=4.554**), researched years (F=150.082**), as well as the differences in interaction genotype x year (F=1.629*). The results are in accordance with the previously

obtained results (Kaya and Akcura, 2014; Ayalew *et al*., 2014; Zečević *et al*., 2012). Through the analysis of the variance's components it was determined that the biggest share of the variance has year (66.59 %).

Table 4. Analysis of variance for hectoliter mass

Total	143	-	-	-	-	9.382	100

* Significant at P = 0.05 level; ** significant at P = 0.01 level

Hectoliter weight and the 1000 grains weight are genetically controled traits, which can vary a under the influence of the environment. Lines examined in these researches had different values of hectoliter and 1000 grains weight in the years of examination what indicates to the reaction of a genotype to different conditions during its development. Moreover, it was determined that among the examined lines of wheat the analyzed traits were also different, what indicates that these genotypes are specific.

Conclusion

Values of the examined traits of wheat's quality were different in different years of research, what indicates variabilty of results for the influence of genetical and ecological factors, and their interaction. It is also detemined that the values of hectoliter weight varied from 76.66 kg hl^{-1} (KG-60-3/3) to 79.73 kg hl^{-1} (KG-1/6). Analysis of variances established highly significant differences among the 1000 grains weight between genotypes, years of research and their interaction.

The line KG- 52/23 (46.75 g) had the highest average value of 1000 grains weight, but the lowest value was achivedby KG-28/6 (39.91 g). In this research, highly significant differences were established in the weight of 1000 grains between genotype x year and their interactions.

Hectoliter weight and 1000 grains weight can be used as preliminary indicators for evaluation of productivity and quality of wheat cultivars. For the expression of these characteristics, enviromental factors as well as genetic factors are very important.

Abstract

In the present study, the effect of ammonium fertilizer rate on plant growth and quality of *Cichorium spinosum* L. was examined. Five fertilizer treatments were applied regarding the ammonium nitrogen percentage of total nitrogen, namely (1) 14%, (2) 24%, (3) 34%, (4) 43%, and (5) 53% of total nitrogen applied in the form of ammonium nitrogen. All the treatments received the same total nitrogen rate. Seeds of *C. spinosum* were sown in seed trays containing peat, and young seedlings were transplanted in 2L pots containing peat and perlite in a ratio 1:1. Plants were harvested twice during growing period and when rosettes reached the marketable size. On the harvest days, plant features regarding plant development (the number of leaves, the fresh and dry weight of leaves, and rosette diameter), as well as quality mineral composition, SPAD index of leaves) were recorded. From the results it is suggested that fertilizer composition had a significant effect on plant growth and quality. In particular, fresh weight for both harvests, as well total fresh weight were higher in treatments 4 and 5, where 43 and 53% of the total nitrogen was applied as ammonium nitrogen. Dry weight did not differ significantly in the first harvest, while in the second harvest treatment 1 had the lowest dry weight. Diameter and number of leaves were the lowest in treatments 2 and 3, respectively, while significant differences were also observed between treatments regarding the quality features.

Keywords: *ammonium nitrogen, Cichorium spinosum L., nitrogen, stamnagathi.*

Introduction

Cichorium spinosum L., also known as "stamnagathi", is a native plant of the Mediterranean basin, which abounds in the coastal areas of the mainland as well as in many Greek islands, especially in Crete where it is well known for centuries and used as a vital component of the so-called Mediterranean diet (Melliou et al., 2003).

The fact that the species usually grows in coastal areas suggests a tolerance potential to high salinity and harsh conditions due to sea water intrusion in groundwater deposits (Chartzoulakis & Klapaki, 2000). Despite the fact that during the last few years farmers in Greece as well as in other Mediterranean countries have started to commercially cultivate the species with very promising results, scarce literature is available regarding the cultivation practices of *C. spinosum*, especially regarding the nutrient requirements and the effect of fertilizers on yield and quality of the final product.

Nitrogen is an essential macronutrient for plant growth, since it is a structural compound of chlorophyll, various enzymes, amino acids and proteins (Barker et al., 1974). As a fertilizer, it is one of the most used agrochemicals throughout the world, and is available in various forms, such as nitrate, ammonium and ureic nitrogen. Although the use of fertilizers has rapidly increased yield and farmers' income during the last decades, the irrational use of nitrogen fertilizers has many negative implications for the environment and the consumers' health. Excessive rates of nitrogen fertilizers can be a serious threat for human health, especially in the case of leafy vegetables that tend to accumulate nitrates (Hord et al., 2009). Nitrate accumulation in vegetables is dependent on various factors such genotype, growth conditions, and nitrogen form and application rate (Santamaria, 2006; Petropoulos et al., 2008). However, apart from nitrate content, nitrogen form may affect quality of the final product through the content of various phytonutrients such as organic and fatty acids (Fontana et al., 2006; Szalai et al., 2010).

The aim of the present study was to evaluate the effect of the ammonium nitrogen percentage of total applied nitrogen on both plant growth and quality of *C. spinosum*. For this purpose, five fertilizer treatments were applied, namely (1) 10%, (2) 20%, (3) 30%, (4) 40%, and (5) 50% of total nitrogen applied in the form of ammonium nitrogen.

Materials and Methods

Seeds of *Cichorium spinosum* L. (Asteraceae) were put in seed trays on October 10th 2015 containing peat and transplanted at the stage of 3 leaves (56 days after sowing) on December 5th, 2014 in 2 L pots containing peat (Klassman-Deilmann KTS2, 1.0 L) and perlite (1.0 L). After transplantation plants were fertilized with the same amount of nitrogen (300 mg L^{-1}) through the irrigation water with five fertilizer treatments which differed in their ammonium nitrogen content, namely (1) 14%, (2) 24%, (3) 34%, (4) 43%, and (5) 53% of total nitrogen applied in the form of ammonium nitrogen. In order to prepare the various solutions, the following fertilizers were used: a) 20-20-20 (N-P-K) with nitrogen consisting of urea (10%), NO_3-N (5.6%) and NH_4-N (4.4%), b) ammonium nitrate (34.5% total nitrogen, with a ratio of 1:1 for NO_3-N: NH_4-N), c) calcium nitrate (15.5% nitrogen, [NO_3-N (14.4%) and NH_4-N (1.1%)], and 26.5% CaO), d) urea (46% nitrogen in urea form), e) ammonium sulphate (21% of nitrogen in NH_4-N form, and 24% sulfur. Nutrient solution composition is presented in Table 1.

Plants were harvested twice during growing period and when rosettes reached the marketable size, while extra plants were harvested only once at the same day when the second harvest took place (uncut plants). The day of harvest, SPAD index of leaves was recorded, while after harvest, rosette diameter, number of leaves, and fresh and dry weight of were measured.

For dry weight evaluation, samples of fresh leaves were oven dried at 72 °C to a constant weight (approximately for 48 hours). Water content was estimated as % percentage by subtracting dry weight from the initial fresh weight. Dried samples were analysed for mineral composition. For mineral composition dried samples of leaves tissues were ground to powder, subjected to dry ashing and extracted with 1 N HCl to determine the mineral. Ca, Mg, Fe, Mn, and Zn content were determined by atomic absorption spectrophotometry (Perkin Elmer 1100B, Waltham, MA) and Na and K content by flame photometry (Sherwood Model 410, Cambridge, UK).

For plant growth, statistical analysis was conducted with the aid of JMP v 4.0.2 (SAS Institute Inc.) and Statgraphics 5.1.plus (Statistical Graphics Corporation). Data were evaluated by analysis of variance for the main effects, whereas the means of values were compared by the LSD test and DMRT ($p = 0.05$). For chemical composition analyses, three samples were analysed for each treatment, whereas all of the assays were carried out in triplicate. The results were expressed as mean values and standard deviations (SD), and analysed using one-way analysis of variance

(ANOVA) followed by Tukey's HSD Test with $\alpha = 0.05$. This analysis was carried out using SPSS v. 22.0 program (IBM Corp., Armonk, NY, USA).

Results and Discussion

From the results it is suggested that fertilizer composition had a significant effect on plant growth and quality features of *Cichorium spinosum* aerial parts. In particular, fresh weight for both harvests, as well total fresh weight for cut plants were higher in treatments 4 and 5, where 43 and 53% of the total nitrogen was applied as ammonium nitrogen, indicating that slow release of nitrogen is essential for higher yields. However, for uncut plants although total fresh weight was higher for treatment 4, it did not differ significantly from treatments 1 and 3 (Table 2). In addition, in any case total fresh weight was higher when plant were harvested twice comparing to plants that were harvested one time, while fresh weight for second harvest was significantly lower than that of the first harvest (Table 2). Similar results have been reported for other leafy vegetables, where multiple harvests increased significantly total yield comparing to single harvest (Kmiecik and Lisiewska, 1999; Csizinszky, 1999). This could be attributed to the fact that leafy vegetables that form rosettes are able to continue vegetative growth after harvest, as soon as the apex is not destroyed and growth conditions do not induce transition to flowering stage. In contrast, Szalai et al. (2010) have reported a negative effect of high ammonium nitrate concentration in nutrient solution on fresh weight of purslane plants, which could be due to the shorter growth cycle of purslane comparing to *C. spinosum* plants that does not allow nitrification of ammonium nitrate to take place.

Table 1. Nutrient solution composition expressed in ppm.

	Treatments

LSD	8.5	4.7		11.8	11.4	

*Means in rows followed by different letters without parenthesis, and means in columns followed by different letters in parenthesis are significantly different at $p<0.05$ by LSD test.

Dry weight did not differ significantly in the first harvest, while treatment 1 and treatments 1 and 4 had the lowest dry weight in the second harvest and for uncut plants, respectively (Table 3).

Similar results have been reported by Wang et al. (2009) who also observed an increase in dry weight of spinach plants when nitrogen: ammonium nitrogen changed from 1:0 to 0:1. Additionally, uncut plants had higher dry weight than cut plants in almost every treatment (apart from treatment 4), which could be attributed to the consumption of more carbohydrate reserves for the regrowth of cut plants, comparing to the uncut plants which accumulated carbohydrates in larger amounts (Erice et al., 2011; Table 3).

Table 3. Dry weight (%) of aerial parts of *Cichorium spinosum* in relation to fertilizer treatments and harvest stage.

LSD	1.63	1.06		1.63	0.85	

*Means in rows followed by different letters without parenthesis, and means in columns followed by different letters in parenthesis are significantly different at $p<0.05$ by LSD test.

Diameter and number of leaves were the lowest in treatments 2 and 3 for both harvests, respectively, while for uncut plants treatment 4 resulted in higher rosette diameter, comparing to treatments 2 and 5 (Tables 4 and 5). Differences in rosette diameter were also observed between cut and uncut plants, only for treatments 4 and 5, indicating that higher amounts of ammonium nitrate have no beneficial effect on plant size when multiple harvests are applied (Table 4). In addition, ammonium nitrate has a positive effect on total number of leaves only when multiple harvests are applied, since slow release of nitrogen through nitrification process allows for better regrowth and leaf formation, comparing to plants where a single harvest is applied (Table 5).

LSD	7.1	6.8		11.2	8.1	

*Means in rows followed by different letters without parenthesis, and means in columns followed by different letters in parenthesis are significantly different at $p<0.05$ by LSD test.

Significant differences were also observed between treatments regarding the quality features. SPAD index was the highest when ammonium nitrogen constitutes 24%, 34% and 53% of total nitrogen in the first harvest, and 24% and 53% in the second harvest (Table 6). Moreover, SPAD index was higher in the second harvest and for treatments 2, 4 and 5, whereas the comparison of cut and uncut plants showed no specific trend being decreased, increased or unaffected by multiple harvests.

Table 6. SPAD index of *Cichorium spinosum* leaves in relation to fertilizer treatments and harvest stage.

	SPAD index					
Treatment	1st cut	2nd cut	LSD	Cut	Uncut	LSD
1	60.5 b(a)	51.4 c(b)	8.8	51.4 c(b)	100.7 a(a)	10.7
2	75.9 a(b)	84.6 a(a)	7.6	84.6 a(b)	94.9 a(a)	9.2

LSD	8.0	7.6		7.6	13.4	

*Means in rows followed by different letters without parenthesis, and means in columns followed by different letters in parenthesis are significantly different at $p<0.05$ by LSD test.

Mineral composition of the aerial parts was affected by fertilization treatments (ammonium: nitrate ratio) for most of the minerals evaluated in the present study (data not shown). Differences were also observed between the two harvests but only for specific minerals and fertilization treatments, while significant differences were detected in uncut plants (one harvest at the end of the growing season). In particular, K and Zn content was higher in the first harvest and for (3) and (4) fertilizer treatments, respectively, while Na, Mn and Fe content was higher in the second harvest and for (5), (3) and (1) fertilizer treatments, respectively (data not shown). In addition, cut and uncut plants differed in their mineral content, where in most cases cut plants had a higher content than uncut plants, especially in Fe content and for (3), (4) and (5) fertilizer treatments (data not shown). To our knowledge this is the first time that mineral composition of C. spinosum in relation to fertilization rates is studied; however mineral composition of wild or cultivated ecotypes has been already reported by (Petropoulos et al., 2016; Zeghichi et al., 2003; Zeghichi et al., 2003).

Conclusion

The application of high ammonium: nitrate rates (43% and 53% of total nitrogen) increases significantly total yield of C. spinosum only when multiple harvests are applied, mainly through the formation of more leaves that consequently result in higher total fresh comparing to a single harvest practice. The application of multiple harvests could increase the growing period and therefore allow for higher rates of ammonium transformation into nitrate nitrogen which is more readily available for plants, comparing to ammonium nitrogen. In addition, quality was not negatively affected by high ammonium: nitrate rates regarding SPAD index and mineral composition, indicating that multiple harvests combined with high ammonium: nitrate nitrogen could have a beneficial effect in terms of both quality and yield.

Abstract

The experiment evaluated the effect of climatic factors (air temperature and rainfall) on the content of primary metabolites (soluble solids, total sugars, invert sugars, proteins, titratable acidity and pH) and vitamin C in the fruit of seven black currant cultivars, including 'Ben Lomond', 'Ben Sarek', 'Tsema', 'Titania', 'Čačanska Crna', 'Tisel' and 'Tiben'. During the three-year experimental period, significant differences in the parameters tested were observed among the cultivars. Soluble solids content was highest in 'Tisel' (15.8%) and 'Tiben' (15.6%). High value of total sugars (14.1%) was found in 'Titania', and those for invert sugars (8.92%), proteins (1.28%) and vitamin C (227.5 mg 100 g^{-1} FW) were recorded in 'Čačanska Crna'. The highest content of titratable acidity (2.76%) and the highest pH value (3.21) of the fruit were determined in 'Tisel'. Climatic factors (air temperature and rainfall) had a significant effect on fruit chemical properties. High air temperatures and low rainfall amounts during berry formation and ripening promoted the synthesis and accumulation of soluble solids (15.4%), total sugars (11.2%), invert sugars (8.97%) and proteins (1.36%). Conversely, low air temperatures and high rainfall amounts had a positive effect on the synthesis of titratable acidity (3.00%) and pH value (3.06) of the fruit, whereas vitamin C content (210.0 mg 100 g^{-1} FW) was highest at moderate air temperatures and moderate rainfall levels.

Keywords: *black currant, climatic factors, chemical fruit traits*

Introduction

The black currant abounds with chemical components beneficial for human health. Its fruit is a rich source of sugars and organic acids as important primary metabolites which play a key role in cell metabolism and reproduction (Hartmann, 2007; WCRF/AICR, 2008). The chemical composition of the fruit is governed by the genetic predisposition of cultivar (Bordonaba and Tery, 2008) and maturity stage, but also to a large extent by climatic factors (Zheng et al., 2009; Walker et al., 2010; Vagiri et al., 2013). Internal fruit quality is determined by the content of primary metabolites (sugars, organic acids, etc.) and secondary metabolites (mostly phenols and carotenoids) which contribute to the flavor, aroma and appearance of the fruit (Veberič et al., 2012). An important goal in black currant breeding is to improve the chemical composition of the fruit i.e. its content of sugars, acids, vitamin C and colorants (Mišić and Nikolić, 2003). Black currants thrive in humid mountainous areas characterized by cool summers, high rainfall amounts and high humidity levels. Climatic conditions in a particular environment affect the planting longevity, productivity, fruit quality and the overall profitability of black currant production (Nikolić and Milivojević, 2010).

With this in mind, the objective of this study was to evaluate the effect of climatic factors on fruit quality i.e. the content of primary metabolites and vitamin C in the tested black currant cultivars.

Materials and methods

The research was conducted at the Fruit Research Institute, Čačak, Western Serbia, during 2012-2014. A black currant planting was established in the spring of 2011 using two-year-old plants. Black currants were grown as bushes at a spacing of 3 m between rows and 1 m in the row. Seven cultivars were involved: 'Ben Lomond', 'Ben Sarek', 'Tsema' 'Titania', 'Čačanska Crna', 'Tisel' and 'Tiben'.

The chemical analysis of the fruit included the following: 1. Soluble solids content was determined by a digital refractometer (Kruss, Germany); 2. Total sugars and invert sugars were analyzed by the Loof-Schoorl method (Egan et al., 1981); 3. Titratable acidity was assessed by the 0.1 N NaOH titration method using phenolphthalein as indicator; 4. Protein content was determined by Kjeldahl's method (Helrich, 1990); 5) Actual acidity (pH value) was measured by a pH Meter Iskra MA 5707, Slovenia; 6) Vitamin C was quantified using a Perkin Elmer UV/VIS spectrometer (Lombda 25) and expressed as mg of vitamin C per 100 g of fresh weight (FW).

The experimental data obtained during the three-year research period were subjected to statistical analysis using Fisher's two-factor analysis of variance - ANOVA. Significant differences between the mean values of the tested factors and the interaction means were determined by LSD test at $P \leq 0.01$ and $P \leq 0.05$ significance levels. The results are presented in tabular form.

The average mean monthly and annual air temperatures for the experimental period 2012-2014 are given in Table 1, while the average monthly and annual rainfall totals are presented in Table 2.

Results and discussion

The analysis of variance (F-test) showed highly significant differences in the content of primary metabolites and vitamin C among the cultivars and years. Cultivar x year interactions were observed. The results on the levels of primary metabolites and vitamin C in the tested black currant cultivars are presented in Tables 3 and 4.

Table 3. Content of soluble solids, sugars and proteins in the fruit of tested black currant cultivars

Cultivar/Year		Soluble solids (%)	Total sugars (%)	Invert sugars (%)	Proteins (%)
Cultivar (A)	'Ben Lomond'	14.5±0.13 c	9.30±0.21 d	8.50±0.14 bc	1.19±0.04 c
	'Ben Sarek'	14.5±0.14 c	10.2±0.17 c	8.07±.,27 e	1.19±0.05 c
	'Tsema'	15.0±0.12 b	9.12±0.19 de	8.57±0.16 bc	1.23±0.04 b
	'Titania'	15.0±0.13 b	14.1±0.28 a	8.42±0.10 cd	1.23±0.04 b
	'Čačanska Crna'	14.6±0.12 c	12.7±0.64 b	8.92±0.18 a	1.28±0.05 a
	'Tisel'	15.8±0.17 a	8.94±0.11 e	8.61±0.16 b	1.20±0.03 bc
	'Tiben'	15.6±0.15 a	8.94±0.19 e	8.29±0.06 d	1.20±0.04 bc
Year (B)	2012	15.4±0.08 a	11.2±0.50 a	8.97±0.08 a	1.36±0.01 a

ANOVA					
Cultivar (A)		**	**	**	**
Year (B)		**	**	**	**
A x B		**	**	**	**

Means followed by different letters within the cultivar and year columns are significantly different at $P \leq 0.01$ and $P \leq 0.05$ according to LSD test and ANOVA (F-test) results.

During the three-year experimental period, the highest content of soluble solids was determined in 'Tiben' (15.6%) and 'Tisel' (15.8%), and the lowest in 'Ben Lomond' (14.5%), 'Ben Sarek' (14.5%) and 'Čačanska Crna' (14.6%). 'Titania' had the highest content of total sugars (14.1%), as opposed to 'Tisel' and 'Tiben' (8.94%), which exhibited the lowest values. Invert sugars and proteins were highest in 'Čačanska Crna' (8.92% and 1.29%, respectively), and lowest in 'Ben Sarek' (invert sugars – 8.07% and proteins – 1.19%) and 'Ben Lomond' (proteins – 1.19%).

Table 4. Titratable acidity, pH and vitamin C content in the fruit of tested black currant cultivars

Cultivar/Year		Titratable acidity (%)	pH	Vitamin C (mg 100 g^{-1} FW)
Cultivar (A)	'Ben Lomond'	2.46±0.23 c	3.19±0.03 ab	206.1±3.11 c
	'Ben Sarek'	2.56±0.11 b	3.17±0.03 bc	207.3±5.03 bc
	'Tsema'	2.57±0.17 b	3.15±0.04 c	209.0±3.41 b
	'Titania'	2.38±0.27 d	3.19±0.03 ab	207.3±6.19 bc

	2014	3.00±0.02 a	3.27±0.02 a	227.4±1.09 a
ANOVA				
Cultivar (A)		**	**	**
Year (B)		**	**	**
A x B		**	**	**

Means followed by different letters within the cultivar and year columns are significantly different at $P \leq 0.01$ and $P \leq 0.05$ according to LSD test and ANOVA (F-test) results.

In contrast, as regards acids, the highest values for titratable acidity (2.76%) and fruit pH (3.21) were obtained in 'Tisel', whereas the lowest levels of titratable acidity and fruit pH were recorded in 'Titania' (2.38%) and 'Čačanska Crna' (3.08), respectively. The fruit of 'Čačanska Crna' (227.5 mg 100 g^{-1} FW)

outperformed the other cultivars in terms of vitamin C content, which was the lowest in 'Tiben' (201.8 mg 100 g^{-1} FW) and 'Tisel' (200.7 mg 100 g^{-1} FW) fruit.

Across years, the highest levels of soluble solids, total sugars, invert sugars and proteins were determined in 2012 and the lowest in 2014. The values for titratable acidity, fruit pH and vitamin C content were highest in 2014 and lowest in 2012.

Over the experimental years, during berry formation and ripening, air temperature was 2.1^{o}C higher and rainfall totals were 122.5 mm m^{-2} lower in 2012 than in 2014, which had a stimulating effect on the synthesis of soluble solids, sugars and proteins. In contrast, the synthesis of total acids, fruit pH and vitamin C content were higher in 2014, which had more moderate air temperatures and rainfall amounts compared to the other two experimental years. These results can be supported by the findings of Rubinskiene et al. (2006) who observed a positive correlation between air temperature and the content of soluble solids and sugars, and a negative correlation between rainfall and these parameters. Also, Rubinskiene et al. (2006) found that high amounts of rainfall and low air temperatures during the growing season favor the synthesis of larger amounts of acids in the fruit. Similarly, as determined by Kaldmae et al. (2013), temperature is positively correlated with the contents of soluble solids and sugars, and negatively with vitamin C content, as opposed to rainfall. The conclusions drawn by these authors provide a full explanation of the results of the present experiment. Under the environmental conditions of Čačak, higher levels of sugars and vitamin C, but lower levels of acids were determined in the tested cultivars compared to the findings of numerous authors (Kampuss and Strautina, 2004; Siksnianas et al., 2006; Mladin et al., 2009; Raudsepp et al., 2010), who conducted their research in northern and northeastern Europe at high altitudes. The difference in the measured contents can be explained by strong variations in the synthesis and accumulation of chemical compounds under different climates. Zheng et al. (2009) recorded higher values for invert sugars, and lower levels of vitamin C in black currants grown in southern Finland compared to black currants grown in the north of Finland. The authors found that temperature was positively correlated with the content of sugars and acids, and negatively with vitamin C content. In Walker et al. (2010), black currants grown on south facing slopes that received more warmth and solar radiation contained up to 20% more vitamin C than those grown on north facing slopes. Vagiri et al. (2013) reported higher soluble solids content but lower acids and vitamin C levels in currants grown in the south of Sweden compared to currants grown in the north of Sweden. As explained by the authors, the values obtained were the result of higher air temperatures during harvest season, which was not confirmed in the present study.

Conclusion

The cultivars had high levels of primary metabolites and vitamin C, which directly contributed to fruit quality. 'Čačanska Crna' had a high content of most of the chemical properties tested.

Climatic factors (air temperature and rainfall) have an important effect on plant metabolism and promote the synthesis of different chemical compounds in the fruit, thus positively affecting the quality and commercial value of the fruit.

Abstract

The paper presents the results of research on the influence of three clonal rootstocks ('Pixy', 'Fereley' and 'St. Julien A') and one seedling rootstock (Myrobalan as a control) on the properties of fruiting twigs of three table plums cultivars ('Čačanska Rana', 'Čačanska Lepotica' and 'Čačanska Najbolja') for a period of three years (2013-2015). Morphological properties of fruiting twigs (long and short): length, thickness, number of flower buds and vegetative buds were examined. The average length of long fruiting twigs was from 51.4 cm to 73.4 cm. The results of the study showed that clonal rootstocks 'Pixy' had a statistically significant influence on the lowest length and thickness of long fruiting twigs. The medium vigorous clonal rootstock 'Fereley' had a statistically significant influence on the formation of the highest number of the flower buds per twig. Myrobalan seedling rootstock had the highest number of the vegetative buds per twig. Cultivar 'Čačanska Rana' had lower number of the flower buds per twig in relation to 'Čačanska Lepotica' and 'Čačanska Najbolja' cultivars. The average length of short fruiting twigs was from 2.8 cm to 7.1 cm. Number of flower buds per short fruiting twig ranged from 2.3 to 4.8, while the number of vegetative buds ranged from 2.4 to 4.1. Myrobalan seedling rootstock had influence on the formation of lower number of flower buds per short fruiting twigs in relation to clonal rootstocks.

Key words: *Prunus domestica, rootstock, short fruiting twigs, long fruiting twigs, buds.*

Introduction

Plum is the most important fruit species in Serbia. The average production of 466,735 t in the period 2010-2012 ranks Serbia on the 3rd place in the world behind China and Romania (FAO, 2016). Despite of the high production, there are some negative characteristics: big share of old orchards, out-of-date cultivars, and inadequate application of cultural practices.

Intensification of plum production is necessary for the achievement of a high and regular yields and good quality of fruits. It is necessary to plant new orchards with virus-free nursery trees, to introduce new quality cultivars, and to apply regularly cultural practices, with special emphasis on soil management, fertilization, irrigation, pruning and plant protection. The pruning is one of the most complex practices in fruit production. For the proper pruning performance it is necessary to know the basic physiological properties of species and cultivar and the morphology of bearing wood, e.g. properties of fruiting twigs.

Veličković et al. (1997) analyzed the fruiting twigs of plum in function of cultivars and combinations cultivar/rootstock. They found significant differences between plum cultivars in the share of different types of fruiting twigs. Significant differences were found in the flower buds density in different species and cultivars of stone fruits, which are directly related to yield (*Alburquerque et al*., 2004; *Thurzó et al.*, 2006; *Nenadović-Mratinić et al.,* 2007; *Milatovic et al*.,

2010). Cultivars which are characterized with higher flower bud density are adapted to the conditions of continental climate, considering that this increases the probability of survival of generative organs due to the frost appearance, thereby provides the higher yield (*Okie* and *Werner*, 1996).
The number of flower buds per fruiting twig is primarily caused by genetic factors and it is correlated with the yield (*Milatović et al*., 2010). The intensity of the flower bud formation on the short fruiting twigs is significantly reduced with increasing of the bearing woodage. The density of flower buds is important for determination of the intensity of pruning, because the cultivars with higher number of flower buds require heavy pruning, while the cultivars with less number of flower buds require light pruning (*Milatović* and *Đurović*, 2010).
The aim of this study was to examine the influence of rootstocks on the morphological properties of long and short fruiting twigs on table plums cultivars. On the basis of the results obtained, the recommendations will be done for pruning performance, which is the most important cultural practice for yield regulation.

Materials and methods

The study was conducted in the plum orchard at the Experimental Station "Radmilovac" of the Faculty of Agriculture in Belgrade (Serbia). During the three-year period (2013-2015) the influence of a seedling rootstock (Myrobalan as a control) and three clonal rootstocks ('Pixy', 'Fereley' and 'St. Julien A') was studied on the properties of fruiting twigs of three table plum cultivars ('Čačanska Rana', 'Čačanska Lepotica' and 'Čačanska Najbolja').
The orchard was planted in spring of 2010. Planting distance is 4 m between rows, and in the row different distances were applied depending on the rootstock vigor: 2.3 m for Myrobalan seedling, 2.0 m for 'Fereley' and 'St. Julien A' and 1.7 m for 'Pixy'. Training system is Spindle. Standard cultural practices were applied, including drip irrigation. Every combination cultivar/rootstock was represented by six trees (two replications with three trees).
The fruiting twigs were taken in the spring, before flowering. From each combination cultivar/rootstock were taken 20 long fruiting twigs (shoots) and five two-year old twigs, where all short fruiting twigs (spurs) where analyzed. Length of twigs was measured with a meter, and thickness with a caliper. Number of flower and vegetative buds was registered on every node. The density of flower buds was calculated as the number of flower buds per 1 m length of fruiting twig (*Lombard et al*., 1988).
The results were processed statistically using the analysis of variance. The significance of differences between mean values was evaluated using Duncan's multiple range test for significance level of 0.05. Data analysis was performed using the statistical software package IBM SPSS Statistics 20 (SPSS Inc., Chicago, IL, USA).

Results and discussion

The properties of long fruiting twigs of table plums cultivars are show in table 1.
The largest values of length of long fruiting twigs were found in combination 'Čačanska Lepotica'/Myrobalan (73.4 cm), while the lowest values were found in combination 'Čačanska Lepotica'/'Pixy' (51.4 cm). Among rootstocks, a dwarf rootstock 'Pixy' had a statistically significant lower value of the length of long fruiting twigs then other rootstocks. Between other three rootstocks there were no statistically significant differences.
Among cultivars the average length of long fruiting twigs, varied from 66.1 cm ('Čačanska Rana') to 69.4 cm ('Čačanska Lepotica'). Differences in the length of long fruiting twigs between cultivars were not statistically significant.

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at P≤0.05; FB-Flowering buds; VB-Vegetative buds.

Differences in the length of long fruiting twigs were statistically significant between years. In the second year of the study (2014), the length of long fruiting twigs was the largest (80.8 cm), while it was the lowest (48.1 cm) in the third year of study (2015).

Our results of length of long fruiting twigs were slightly lower than in the report of *Milatović et al.* (2015), who studied 11 European plum cultivars grafted on the seedling rootstock Myrobalan in conditions of Belgrade. However, in our study the length of long fruiting twigs of cultivars 'Čačanska Najbolja' and 'Čačanska Rana' was larger, while in cultivar 'Čačanska Lepotica' was lower than in results of *Nenadović-Mratinić et al.* (2007). The differences can be explained by the influence of different factors such as environmental conditions, rootstocks, age of trees, yield, and cultural practices.

Among rootstocks, the average thickness of the long fruiting twigs varied from 6.9 mm ('Pixy') to 7.9 ('St. Julien A'). Among cultivars, these values were from 7.3 mm ('Čačanska Rana') to 7.8 mm (Čačanska Lepotica'). Significant differences in thickness of the long fruiting twigs were also found between years. The largest value of thickness of the long fruiting twigs was in 2015 (8.9 mm), while the lowest value was in 2014 (6.5 mm). Results of thickness of the long fruiting twigs in our research were in accordance with the previous findings (*Nenadović-Mratinić et al*., 2007; *Milatović et al.,* 2015).

The medium vigorous clonal rootstock 'Fereley' had a statistically significant influence on the formation of higher number of the flower buds per twig (19.0 on average) then other rootstocks. Among cultivars, 'Čačanska Rana' had a significantly lower number of the flower buds per twig in relation to 'Čačanska Lepotica' and 'Čačanska Najbolja' cultivars. Significant differences in

number of the flower buds per twig were also found between years. The highest number of the flower buds per twig was in the first year of study (2013), compared to two other years.
Myrobalan seedling rootstock had the highest number of vegetative buds per twig (27.4 on average) compared to three other rootstocks. Among cultivars, 'Čačanska Rana' had lower number of the vegetative buds per twig in relation to 'Čačanska Lepotica' and 'Čačanska Najbolja' cultivars. Significant differences were also found between years. The highest number of the flower buds per twig was in the second year of study (2014).
According to many authors (*Nenadović-Mratinić et al*., 2007; *Thurzó et al*., 2008; *Milatović et al*., 2014), the density of flower buds is an important parameter which indicates the potential yield of cultivars. The highest density of flower buds on one-year old twigs (27.9 per 1 m) was on the medium vigorous clonal rootstock 'Fereley', while this value was lowest in the control rootstock - Myrobalan (17.9 per 1 m). Results of density of flower buds in our research were lower than in the study of *Milatović et al.* (2015), and higher than in the study of *Nenadović-Mratinić et al*. (2007).
Very important parameter for the yield and quality of fruit is a balanced relationship between flower buds and vegetative buds. Specifically, a certain number of leaves per fruit was necessary to achieve optimal quality of fruit. The lowest ratio of flower to vegetative buds per long fruiting twig was in the combination 'Čačanska Rana'/Myrobalan (0.3) while the highest ratio was in the combination 'Čačanska Najbolja'/'Fereley' (0.9). The lower value of the ratio of flower to vegetative buds points to lower yield, while the higher ratio indicates a potentially higher yield, but can have negative characteristics in terms of lower fruit quality because in that case a smaller number of leaves per fruit could be expected.
The short fruiting twigs were analyzed on the two-year old twigs and their characteristics are shown in table 2.

Table 2. The properties of short fruiting twigs in plum cultivars on different rootstock (2013-2015).

	Čačanska Najbolja	3.7 b	4.4 a	2.6 b	1.1	88.2

Mean values followed by the same letter within a column do not differ significantly according to Duncan's multiple range test at P≤0.05; FB-Flowering buds; VB-Vegetative buds.

Among rootstocks, the average length of short fruiting twigs varied from 3.7 cm (Myrobalan) to 4.8 cm ('Pixy'). Cultivar 'Čačanska Rana' had statistically significant higher length of short fruiting twigs compared to cultivars 'Čačanska Lepotica' and 'Čačanska Najbolja'. Among years, the differences in the length of short fruiting twigs were statistically significant. In the third year of the study (2015), the length of short fruiting twigs was the largest compared to other two years. Compared to results of *Milatovic et al*. (2015) in our study the lower length of short fruiting twigs was found.

Number of flower buds per short fruiting twig ranged from 2.3 to 4.8. Myrobalan seedling rootstock had influence on the formation a less number of flower buds per short fruiting twig compared to clonal rootstocks. Cultivar 'Čačanka Najbolja' had a statistically significant influence on the formation of higher number of the flower buds per twig then other cultivars.

The number of vegetative buds ranged from 2.4 to 4.1, and there were no statistically significant differences between the rootstocks. Among cultivars, 'Čačanska Rana' had the higher number of the vegetative buds per twig then cultivars 'Čačanska Lepotica' and 'Čačanska Najbolja'.

The average ratio of flower to vegetative buds was from 0.8 ('Čačanska Rana' /Myrobalan) to 1.9 ('Čačanka Najbolja'/'Fereley'). Too high ratio can indicate lower fruit quality and also greater tendency to bare wood formation.

The number of flower buds per 1 m of 2-year old twig was lowest in the combination 'Čačanska Rana'/Myrobalan (37.8), while the highest value was in cultivar 'Čačanska Najbolja' grafted on 'St. Julien A' (102.2). Among rootstocks, the lowest value was on the control - Myrobalan (51.6), and the highest was on the clonal rootstock 'St. Julien A' (78.2). Among cultivars, the lowest value was on cultivar 'Čačanska Rana' (58.1), and the highest in cultivar 'Čačanska Najbolja' (88.2). This parameter indicates the potential yield of the cultivar, as the low density of flower buds points to a lower yield potential. Results of flower bud density on 2-years old twig in our research were lower in cultivars 'Čačanska Najbolja' and 'Čačanska Lepotica' and higher in cultivar 'Čačanska Rana' compared with the previous findings (*Milatović et al.,* 2015; *Nenadović-Mratinić et al*., 2007).

Conclusions

Based on the three-year trial in the region of Belgrade, it can be concluded that the rootstocks had significant influence on the properties of long and short fruiting twigs on table plums cultivars. The clonal rootstocks 'Pixy' had a statistically significant influence on the lowest length and thickness of long fruiting twigs. The medium vigorous clonal rootstock 'Fereley' had a statistically significant influence on the formation of the highest number of the flower buds per twig. Myrobalan seedling rootstock induced the highest number of the vegetative buds per twig. Myrobalan seedling rootstock had influence on the formation a less number of flower buds per short fruiting twigs in relation to clonal rootstocks.

Based on the number of flower buds per 1 m, it can be concluded that in studied table plums cultivars flower bud density was higher on short fruiting twigs than on long fruiting twigs. Therefore, the short fruiting twigs are the main holders of the yield.

Based on these results, we can make recommendations for pruning performance. Cultivars and rootstocks, which are characterized with higher density of flowers buds on short and long fruiting twigs, require more severe pruning for the better quality of fruit and preventing the bare wood formation. The cultivar/rootstock combinations that have lower density of flower buds require pruning of lower intensity. Among cultivars, 'Čačanska Lepotica' and 'Čačanska Najbolja' had

higher flower bud density than ‘Čačanska Rana’. Also, flower bud density was higher on clonal rootstocks compared to Myrobalan seedling rootstock.

EFFECT OF SOME PLANT GROWTH PROMOTING RHIZOBACTERIA ON GROWTH, LEAF WATER CONTENT AND MEMBRANE PERMEABILITY OF TWO CITRUS ROOTSTOCK UNDER SALT STRESS CONDITION

Şeyma ARIKAN*, Muzaffer İPEK, Lütfi PIRLAK

Department of Horticulture, Faculty of Agriculture, University of Selçuk, Konya, Turkey
*Corresponding author: arikan@selcuk.edu.tr

Abstract

Some plant growth promoting rhizobacteria (PGPR) (*Bacillus subtilis* EY2, *Bacillus atrophaeus* EY6, *Bacillus spharicus GC subgroup B* EY30, *Staphylococcus kloosii* EY37 and *Kocuria erythromyxa* EY43) were investigated under salt stress conditions in two citrus rootstocks (*Citrus aurantium* L., *Poncirus trifoliate* L. Raf.). Effects of EY2, EY6, EY30, EY37 and EY43 were tested on plant growth (plant height, plant and root fresh weight, root length), leaf relative water content (LRWC), and membrane permeability in citrus rootstock. The plants were grown in pots and irrigated with a NaCl solution (100 mM). Irrigation was applied once a week during growing period which continued for ten weeks. All bacteria treatments significantly increased plant height and root length in both citrus rootstocks. The LRWC range from 58.62% (100 mM NaCl treatment) to 87.08% (EY43 bacteria strain) in trifoliate. On the other hand, in sour orange, LWRC ranged from 23.20% (100 mM NaCl treatment) to 75.49% (Control). The highest membrane permeability rate was determined in NaCl treatment in sour orange and trifoliate orange.

Keywords: *PGPR, NaCl, citrus rootstock, plant growth*

Introduction

Because of saline soil occurs in the arid and semi-arid zones of the world, the most of soils in the world has saline structure In such areas, long periods of drought coincide with high temperatures (Alizadeh *et al.*, 2011). However, salinity occurs quickly in these regions with irrigation. Salt in the upper layers of soil transported to by capillary during the irrigation and evaporation and accumulates in the rhizosphere. The wrong applications of irrigation, presence of high soluble salts level in water, lack of drainage and salinity are among other causes. Salinity is one of the major problems in the agricultural area of Turkey. Agricultural fields, about 1.500.000 ha, are faced with salinity problem in Turkey (Anonymous, 2008). Salinity is one of the most effective factors which limited yield and soil fertility in production areas. Salt stress cause increasing of respiration rate, ion toxicity, changes of plant growth, mineral disorders, damaging of membrane permeability, decreasing of photosynthetic activity. On the other hand, soil salinity has negative impacts on nitrogen and carbon metabolism. The salinity tolerances of different species or cultivars and their sensitivity at different stages of growth, different soil and environmental conditions show differences. The reactions of fruit species to salinity were examined (Maas and Hoffman, 1977) and it was observed that many fruit species are very sensitive to salinity. (Table1).

Table. Response of fruit species against Salinity (Maas and Hoffman, 1977)

Tolerant	**Moderately Sensitive**	**Too Sensitive**
Pheoneix dactylifera	*Ficus carica*	*Citrus paradisi*
	Punica granatum	*Citrus limon*
	Olea europea	*Citrus reticulata*
		Citrus sinensis
		Prunus amgydalus
		Prunus armeniaca
		Prunus avium
		Pyrus communis

In order to breeding of soil salinity, it needs lots of time and more money. Therefore, these methods cannot be applied prevalently countries. Many studies focused on chemical treatments and suitable rootstocks against for saline soil but nowadays, biological treatments with plant growth promoting rhizobacteria (PGPR) have been started to use for solve this problem (Ashraf *et al.*, 2004; Karlidag *et al.*, 2010).

PGPR are free-living microorganisms as colonizing in the rhizosphere of plants (Karlidag *et al.*, 2010). These bacteria have a great importance in sustainable agriculture which increased root growth and plant pathogens kept under the control. Such as bio-control of plant disease, plant growth promoting, bio-fertilizers and growth regulator substances production have been functions (Antoun and Prévost, 2005). PGPR effects on plants a-symbiotically notwithstanding plant species. In naturally, bacteria which stay in low concentration, is applied to plant roots, it effects on plant growth and development. PGPR can have beneficial effects on plant growth and yield by two main mechanisms. These is direct and indirect mechanisms. There are different ways in the direct effect mechanism. Direct mechanisms may act on the plant itself and auxins, cytokinins, and gibberellins or lowering of the ethylene in plant, solubilization of inorganic phosphate and mineralization of organic phosphate, asymbiotic fixation of atmospheric nitrogen, and stimulation of disease-resistance mechanisms (Antoun and Prévost, 2005; Zahir *et al.*, 2003). In the indirect mechanism, PGPR act like biocontrol agents reducing disease or stimulate other beneficial symbioses or protect the plant (Jacobsen, 1997). Additionally, PGPR improve plant's tolerance to stresses, such as drought, high salinity, metal toxicity, and pesticide load (Bashan and de Bashan, 2005).

In the present study, we aimed to determine effect of PGPR strains (*Bacillus subtilis* EY2, *Bacillus atrophaeus* EY6, *Bacillus spharicus* GC subgroup B EY30, *Staphylococcus kloosii* EY37, *Kocuria erythromyxa* EY43, *Rhodococcus* 9/4, *Pseudomonas* 53/6) which were identified positive effects on vegetables, apple, cherry and crops on plant growth, leaf relative water content and membran permeability of sour orange and trifoliate orange.

Material and Methods

This study was carried out under controlled greenhouse conditions at Selçuk University Department of Horticulture in 2014-2015 in Turkey. Sour and Trifoliate Orange was used as plant materials and seedlings were planted to 2 liter pots in March, 2014. The pots contained 2:1 peat: perlite mixture.

Strains of bacteria, EY2, EY6, EY30, EY37, EY43 were obtained from University of Iğdır in Turkey. A single bacteria colony was transferred to 500 ml flasks containing Nutrient Broth (NB), and grown aerobically in flasks on a rotating shaker (150 rpm) for 48 h at 27°C. The

bacterial suspension was then diluted in sterile distilled water to a final concentration of 10^9 CFU ml^{-1} (Karlidag *et al.*, 2010).

The all bacteria strain inoculation roots before planting to pots. Roots were hold in bacteria suspension for 30 minutes. After planting seedling was watered two times with bacteria suspension once in a month. Seedlings of bacterial inoculation was made after one-month planting with irrigation twice a week 100 mM NaCl application in pots and have continued during the growth period. Growth promoting effects of bacterial treatments were evaluated by determining plant height, root length, stem and root fresh weight, leaf relative water content (LRWC) and membrane permeability in seedling.

Experiment divided into seven application groups including seven seedlings with three replicates in a completely randomized design. The collected data were analysed statistically using the SPSS 17. All data in the present study were subjected by analysis of variance (ANOVA) and means were separated by Duncan's Multiple Range Tests at 5% level of significance.

Results and Discussion

In both sour orange and trifoliate orange, plant height range from 20.22cm to 38.94cm. The highest plant height was obtained from EY43 bacteria strain in both sour (24.83cm) and trifoliate orange (38.94cm). The EY43 strain increased plant height 16.40% in sour orange and 14.93% in trifoliate orange in comparison to control plants (Table2). These results were explained that soil salinity reduces the soil water potential and the ability of plants to take up water. These reduces the rate of cell expansion in growing tissues (Munns, 2011). However, Jha and Subramanian (2013) reported that PGPR under saline conditions increase 31% plant height in paddy rice. Similarly, *Pseudomonas* strain treatment was significantly increased plant height compared with any treatment under salt stress in rice plants (Sen and Chandrasekhar, 2014).

The root length of rootstocks was measured between 18.61cm and 27.47cm. While EY43 bacteria strain had the longest root length in trifoliate orange (22.72cm), EY37 strain had the longest root length in sour orange (27.47cm) (Table2). The higher concentrations of NaCl caused a significant reduction in root length. The reduction in root length might be due to the inhibitory effects of salt on the metabolic activities which associated with cell division, differentiation and elongation (Abdel-Hussein, 2006; Heszky *et al.*, 1992). Some author reported that PGPR treatments increase root growth. Sen and Chandrasekhar (2014), in ADT43 rice genotype, decreasing of root length was measured in treatment of *Pseudomonas* strain TDK1 under salinity. Like-wise, Yildirim *et al*. (2008) were found that PGPR treatment had greater root length than the control treatment in radish under salt stress conditions.

In terms of fresh root weight, two bacteria strain appeared with good result. The EY43 and EY6 bacteria strain had the best result for fresh root in both sour and trifoliate orange. In sour orange, EY6 strain obtained 8.63g, when EY43 obtained 8.55g for fresh root weight. In trifoliate orange, EY43 had the best result with 12.87g. Bacteria strains increased fresh root weight of both rootstocks. The fresh root weight was increased by EY6 (25.07%) and EY43 (23.90%) strain in comparison to control in sour orange (Table2). The four bacteria strain appeared in fresh plant weight in both citrus rootstocks. The EY6 and EY30 had the highest fresh plant weight in sour orange, when the EY2 and EY43 had the highest fresh plant weight. EY6 and EY30 increased fresh plant weight approximately 50% in sour orange. On the other hand, EY2 and EY43 strain increased fresh plant weight about 70% and 60% respectively. Yildirim *et al*. (2008) identified under salt stress EY2 strain that gave the highest value for shoot and root fresh weight in radish plants.

The leaf relative water content results were difference in both rootstocks. The control group led with 75.49% in sour orange while EY43 led with 87.08% in trifoliate orange. The all bacteria strain treatments were behind the control group in sour orange. In trifoliate orange, EY43 and EY37 were in front of the control group with 87.08 and 87.60% respectively (Table2). The highest damage in membrane was obtained from NaCl treatment in both rootstocks. The membrane damages of sour orange were the higher than trifoliate orange's. EY30 reduced damage of membrane with 11.21% in trifoliate orange, when EY37 (18.70%) bacteria strain reduced damage of membrane in comparison to NaCl treatment in sour orange. The LRWC result of our study is supposed by Karlidag *et al*. (2010) in strawberry. They determined LRWC decreased by salt treatment but all bacteria inoculations were increased LRWC. EY2 bacteria treatment having the best result was found to increased LRWC rate 88.4%. Cell membrane stability can be conserved by bacterial inoculation. They also found that all bacterial strains significantly decreased membrane permeability compared with 35 mM NaCl treatment.

As a result of, trifoliate orange has more tolerant than sour orange with EY43 bacteria treatments. In terms of LRWC, membrane permeability and other parameters, EY43 bacteria strain showed more effective and protective role in both rootstocks. Because of this positive effect, EY43 bacteria strain can be recommended to use for salinity problems in land.

Conclusions

The results of the present study showed that used bacteria strains had been ameliorative of the deleterious effects under salt stress in citrus rootstocks. This study was observed to improved plant growth and reduced membrane injury with bacterial applications. EY43 bacteria strain had the best effect on plant height in both Sour Orange (24,83cm) and Trifoliate Orange (38,94cm). In root length, E37 bacteria strain (24.47cm) was found the best result in Sour Orange, while EY43 bacteria strain (22,72cm) was found the best result in Trifoliate Orange. In Sour Orange, maximum fresh root weight was obtained from EY43 (6,83g) and EY6 (6,55g). EY43 significantly increased fresh root weight in Trifoliate Orange. EY6 (10,48g) and EY30 (10,25g) dramatically increased fresh plant weight in Sour Orange, while EY2 (13,66g) and EY43 (12,40g) bacteria strain significantly increased fresh plant weight in Trifoliate Orange

The maximum LRWC was obtained from control plants (75,49%) in Sour Orange. In Trifoliate Orange, the highest LRWC was found in EY30 bacteria strain (87,60%). The NaCl treatments increased membrane permeability in both Sour Orange (88,58 %) and Trifoliate Orange (32,63%).

Abstract

As a result of the intensive tillage, application of various agrotechnical measures, the use of large amounts of fertilizers and pesticides, during the production of horticultural crops with relatively high yields, including the cauliflower, disrupts natural processes in the soil. The microbiological activity and fertility of the soil can be improved by using pure cultures of the microorganisms used for the production of microbiological fertilizers – bio -fertilizers, that create or improve conditions for microbiological activity in the rhizosphere, without disrupting the natural processes in the environments. This research was aimed at determining the impact of microbiological fertilizer Slavol, applied in two ways, foliar with dorsal sprinkler and through the drip irrigation system, on the yield and chemical composition (water, dry matter, fiber, protein and calcium) of cauliflower produced outdoors during 2011, 2012 and 2013. The results of this study showed that the application of Slavol significantly affected the yield of the cauliflower, especially when applying through the drip irrigation system. Chemical analyzes showed increased content of water, fiber, protein and calcium in the curds of the cauliflower treated with the microbiological fertilizer.

Keywords: *cauliflower, microbiological fertilizer, yield, chemical composition*

Introduction

Cauliflower is one of the popular winter season vegetable grown throughout the world. The edible curd is a rich source of protein, minerals and vitamins which protects human from certain cancers and heart diseases (Keck, 2004).

Intensification of the vegetable production in order to achieve high yield at the expense of the quality of the vegetables and environmental conditions, impose new trends in the agricultural production. These trends are including limitation of the application of fertilizers and pesticides whose uncontrolled use affects the microbiological and physical-chemical properties of the soil (Najdenovska and Ćolo, 2012) and their replacement with microbial fertilizers, which because of the ability of microorganisms to provide necessary food for plants, occupy a significant place in the vegetable production.

Soil is an essential precondition for the crop production and it is favorable environment for the development of various biochemical and microbiological processes. The soil contains a number of different groups of bacteria. Their number and activity in the soil is an important indicator for the fertility, for the growth and development of the plants, for the degradation of some inorganic

substances and more. Their representation is conditioned by: climate characteristics, soil type, water-air regime, temperature, mechanical composition, the presence of organic matter, and more.

Knowing the role and the flow of the microbiological processes in the soil can be directed towards increasing the intensity of microbial activity and soil fertility, using the effective strains of azotobacter and phosphorus soluble bacteria that can replace or reduce the use of mineral fertilizers. The effect of use of bio-inoculants in cauliflower and its agronomic efficiency is not well known (Sharma et al., 2009). Further, the integrated use of different organic materials not only increase the nutrient status of agricultural soil but also help to improve various physical, chemical and biological properties of soil leading to improved soil fertility and also to increased fertilizer use efficiency (Dick and Greegorich, 2004).

The positive impact of the microbiological fertilizers is visible in the early stages of plant development through the improved process of germination, growth, increased activity of roots and activity of photosynthesis, improved plant nutrition with nitrogen, phosphorus, potassium and trace elements, increased yield for 10 to 25%, increased microbial biomass in the soil, improved water-air regime and reduced or eliminated negative impact of pesticides and mineral fertilizers. According to Bashyal L.N. (2011), biofertilizers increased the efficiency of nitrogen fertilizer, and subsequently increases the yield and quality of cauliflower.

The main objective of this research was aimed at determining the impact of microbiological fertilizer Slavol, applied in two ways, foliar with dorsal sprinkler and through the drip irrigation system, on the yield and chemical composition (water, dry matter, fiber, protein and calcium) of cauliflower produced outdoors during 2011, 2012 and 2013.

Material and method

The experiment was set near Skopje (Capital of Macedonia), in the village of Jurumleri, with coordinates 41°58'20,84" north and 21°33'24,44" east,276 m above sea level, on alluvium soil type, during the seasons in 2011, 2012 and 2013.

As research material was used cauliflower (*Brassica oleracea* L. var. *botrytis*), hybrid Barcelona F1.

The cauliflower was cultivated from seedlings produced in cold beds, transplanted on open field.

During 2011 and 2012, the sowing of the cauliflower was performed on May 20th, while in 2013 sowing was on May 25th. The germination of 50% of the seeds was observed for 5 to 7 days after sowing.

The transplantation of the seedlings was on open field in experimental plots with size of 3,2 m^2, distributed according to a random block system (method of Fisher) in three variants, with four repetitions. The seedlings ware planted at a distance of 0,5 m in the row, and 0,8 m between the rows, which means that in each experimental plot has 8 plants.

The variants ware set according to the time and way of treatment with the microbiological fertilizer Slavol, which is a combination of 6 bacteria: *Azotobacter chrococcum* (10^8 cfu/mL), *Azotobacter vinelandii* (10^8 cfu/mL), *Derxia sp*. (10^8 cfu/mL), *Bacillus licheniformis* (10^9 cfu/mL), *Bacillus suptilis* (10^9 cfu/mL) and *Bacillus megaterium* (10^9 cfu/mL). It also contains natural vitamins, enzymes and biostimulants.

The variants were set in the following order:

1. Ø control - without application of microbial fertilizer;
2. Variant 1 (V-1) - treatment of the seedlings by dipping in a solution of 5 L of water and 50 mL Slavol for 5 minutes and treatment of the plants during the vegetation through the leaves with dorsal sprinkler every seven days with a solution of 2 mL Slavol dissolved in 2 L of water, and
3. Variant 2 (V-2) - treatment of seedlings by dipping in a solution of 5 L of water and 50 mL Slavol for 5 minutes and then treatment of the plants during the vegetation through the drip irrigation system with a solution of 150 mL Slavol, dissolved in 150 L of water, with floodplain rate of drop per rate of 2 L per hour, every two days.

The time of the treatment with dorsal sprinkler in the three years of research is given in Table 1, while treatment by drip irrigation system is given in Table 2.

Table 1. Time of treatment with dorsal sprinkler by year

After harvesting the curds of the cauliflower was measured the weight of each curd by using a scale, while the total yield per hectare was calculated by multiplying the average yield of the plant with the number of plants per hectare (25 000 plants).

The analysis for the chemical composition of the curds are made by the following methods:

- Total content of water and dry matter in the curds is determined by drying the fresh plant material at a temperature of 105°C to constant weight (Sarić, 1990);
- Proteins are determined by the method of Kjeldahl (Sarić, 1990);
- The content of fiber is determined gravimetric;
- The total protein content is determined accrual % of total nitrogen x 6.25 (Jekic, 1988);
- Calcium is determined by atomic absorption spectrophotometry (Sarić, 1990).

Statistical analysis were made with a computer program SPSS, v19.0.

Results and discussion

Harvesting cauliflower can be done by uprooting the whole plant, then cut the leaf stalks, outer leaves are cut at the base, leaving 3 to 5 leaves for protection of the curd. Harvesting is successive, and the yield ranges from 20 to 50 t/ha (Đurovka, 2008). The average yield in the three years of testing in our research showed highly statistically significant differences between all variants. The average yield of the curds of the cauliflower in the three years of testing ranged from 34 161,46kg/ha for the control, 40 824,22 kg/ha for V-1 and the B-2 average yield was 46 548 18 kg / ha.

Table 3. Average values and standard error for the average yield in cauliflower in kg/ha

Variants	Mean	Standard deviation	Error of the mean (± SE)
Control	34 161,46	5920,83	604,29
V-1	40 824,22	5961,40	608,43
V-2	46 548,18	9195,66	938,53

Analysis of the values for the yield of the cauliflower per hectare between the variants made by the method of analysis of variance showed highly statistically significant differences ($p < 0.01$) between all of the factors of variation.

Table 4. Results of the analysis of variance for the average yield in cauliflower with different ways of applying the microbiological fertilizer

Total	22 118 494574,653	287			

Table 5. LSD - test for the average yield in cauliflower

Dependent variable			Difference between means	Standard error	Sig.	Confidence interval 95%	
						Lower bound	**Upper bound**
Yield	Control	V-1	-6662,76*	1038,01	0.000	-8705,90	- 4619,62
		V-2	-12386,71*	1038,01	0.000	-14429,86	-10343,58
	V- 1	Control	6662,76*	1038,01	0.000	4619,62	8705,90
		V-2	-5723,95*	1038,01	0.000	-7767,10	-3680,82

The data in Table 5 show a statistically significant difference ($p < 0.001$) between all tested variants.

Bambal et al. (1998) has studied the effect of bio fertilizers (by dipping of seedlings) and nitrogen on the growth and yield of cauliflower. Different treatments were applied using *Azotobacter* and *Azospirillum* individually and in combination with different doses of nitrogen, 0, 50, 75 and 100% of the recommended doses of 125: 75: 60 kg/ha N: P_2O_5 and K_2O. In addition, treatment

with *Azospirillum* and *Azotobacter* and 100% of nitrogen, has resulted with obtaining the highest yield (29,64 t/ha) and the shortest vegetation period.
Islam et al. (2014), in their research for the effect of the bioinoculantson the characteristics of the cauliflower found that dipping of the root seedlings in bio-fertilizer significantly impacts on the growth and yield of the cauliflower. They assume that increased growth and yield is due to increased availability, solubility and mobility of nutrients,because of the made bioinoculation of the the seedlings.
Cauliflower features a slightly higher nutritional value than the cabbage. The water content in the cauliflower curds is around 92%, carbohydrates around 5.3%, 1.98% protein and contains very little fat around 0,10% (Červenski and Gvozdenović, 2007). In addition, cauliflower contain quite minerals and vitamins. From the minerals highestcontainedare potassium, sulfur, phosphorus and calcium, while from the vitamins the vitamin C is present with the highest content.
The results of the analyses for the percentage of water in curds of the cauliflower during the three years of research are presented in Table 6.

Table 6. Average values for the water content in % in the curds of the cauliflower for the three variants in 2011, 2012 and 2013

Year	Control	V-1	V-2
2011	92,37	93,63	93,14
2012	92,04	90,49	92,34
2013	91,73	90,28	91,41
Average	92,04	91,46	92,29

During the three years of research lowest percentage of water content was obtained in the curds of theV-1 from 90.28% in 2013, while the highest percentage of water from 93.63% was also obtained in the curds of V-1 in 2011. The highest average water content for the three years of research was obtained in the curds of V-2 from 92.29%, and the lowest from 91.46% in V-1. According to Lešič et al. (2002), the cauliflower contains a relatively high percentage of water from 90.9 to 94.5%.
From technological aspect, the content of dry matter in plant products is a major factor in determining the quality characteristics of the products themselves.

Table 7. Average values for the dry matter content in % in the curds of the cauliflower, for the three variants in 2011, 2012 and 2013

Year	Control	V-1	V-2
2011	7,63	6,37	6,86
2012	7,96	9,59	7,66
2013	8,27	9,72	8,59
Average	7,95	8,56	7,70

From the data in Table 7 for the content of dry matter in the curds of the cauliflower, can be seen that the lowest content was 6.37% in V-1 in the year 2011, and the highest was 9.72% also in V-1 in 2013. The average content of dry matter in the three years of testing was highest in V-1 where it was 8.56%, while the lowest it was in the V-2 from 7.70%.
From the scientific research for the application of bio-fertilizers combined with mineral fertilizers, Khurana et al. (2009), determined the effect on the increase of the dry matter in the curds of the cauliflower. The highest content was determined in the curds where it was applied *Azotobacter* with a recommended dose of a mineral fertilizer (N: P: K 120 60 60 kg/ha), where the percentage of dry matter was 8.33% in 2007 to 9.30% in 2008.
Fiber found in fruits, vegetables, grains and legumes are characterized as a kind of carbohydrates that are not absorbed by the body. There are two types of fiber, soluble and insoluble.
Table 8 shows the average values for the content of fiber in the curds of the cauliflower in the three years of research for the three variants.

Table 8. Average values for the fiber content in % in the curds of the cauliflower, for the three variants in 2011, 2012 and 2013

Year	Control	V-1	V-2
2011	20,60	26,15	26,69
2012	31,37	26,98	31,07
2013	27,30	28,22	29,08
Average	26,42	27,12	28,95

The content of fiber in the curds of the cauliflower has the lowest with the control in 2011 from 20.6% of, and the highest was also in the control in 2012 from 31.37%. According to the average values for the three years of research, the percentage of fiber was highest in V-2 with 28.95%, while lowest it was in the control with an average value of 26.42%.
Plant proteins are containing many amino acids, but not a single plant product contains all of the essential amino acids. The average protein content in curds of the cauliflower according to Tudzarov (2011), is around 3.3%, while according to Lešič et al. (2002) the proteins are present from 1.5 to 2.72%.
Table 9 shows the percentages of protein per year and the average protein content in the three years of research.

Table 9. Average values for the proteins content in % in the curds of the cauliflower, for the three variants in 2011, 2012 and 2013

Year	Control	V-1	V-2
2011	1,92	2,03	2,20
2012	1,98	2,08	2,28
2013	2,30	2,34	2,72
Average	2,07	2,15	2,40

The lowest percentage of protein from 1.92% was observed in the control in 2011, while the highest from 2.72% was in V-2 in 2013. According to the average values for the three years of testing, protein content was the lowest in the control from 2.07%, then in V-1 from 2.15% and inV-2 it was highest with 2.4%.
The calcium content in the curds of cauliflower, according to Lešič et al. (2002), ranges from 17 to 31 mg/100 g, and according to Tudzarov (2011) the content of calcium in the cauliflower is 53 mg/100 g.

Table 10. Average values for the calcium content in mg/100 g in the curds of the cauliflower, for the three variants in 2011, 2012 and 2013

Year	Control	V-1	V-2
2011	50,00	70,00	112,00
2012	87,00	69,00	113,00
2013	96,00	99,00	150,00
Average	87,60	79,30	125,00

From Table 10 may be noted that the content of calcium in the cauliflower's curds was highest in V-2 with 150 mg/100 g in 2013, while the lowest calcium content was noted in the control from 50 mg/100 g in 2011. From the data it can be seen that in 2013 the three variants have significantly higher calcium content than previous two years. The average values for the three years showed that V-1 has the lowest calcium content of 79,3 mg/100 g, while V-2 has the highest content of calcium of 125 mg/100 g.

Conclusions

From the results obtained in the three years research for the impact of the microbiological fertilizer Slavol on the important economic properties of the cauliflower (*Brassica oleracea* L.var. *botrytis*), we can make the following conclusions:
- The average yield of the curds for the three years of testing ranged from 34 161,46 kg/ha for the control, 40 824,22 kg/ha for V-1 and 46 548,18 kg/ha forV-2. Statistical analysis of the data showed highly statistically significant differences among the three studied variants.
- The average content of water, fiber, calcium and protein was highest in the curds of V-2;
- The average dry matter content was highest in the curds of V-1.

Abstract

Nowadays, climate change is a serious problem in the world. The water management has become increasingly important because of the temperature increasing and the precipitation decreasing. The water holding capacity of the growing media have major role in the ornamental plant production. During our work, two moisture controlling agents, such as Finnish BRT® Evergreen in 10 v/w% and German Aqua +3 in 8 g/l and 16 g/l were applied in *Aquilegia flabellata* var. *pumila* and *Pelargonium peltatum* 'Rainbow Rose' production. Plant diameter, plant height, fresh weight, root parameters, chlorophyll content, phosphorous and potassium content of media were measured. BRT® had significant effects on plant diameter and plant height of *Aquilegia* and also doubled the chlorophyll content. BRT® had 50% increase in plant height of *Pelargonium*. The fresh weight was doubled and tripled by Aqua+3 (16 g/l) and BRT® as well. Aqua+3 (8 g/l) doubled and Aqua+3 (16 g/l) and BRT® tripled the number of roots. Aqua+3 (8 g/l) had 50% increase in root length and root weight. Chlorophyll content had 50% increase by Aqua+3 (16 g/l) and was doubled by BRT®. In the soil mixture of BRT®-containing group 50% of potassium and 150% phosphorous was measured comparing to the control. The results proved that the use of BRT® Evergreen and Aqua +3 have economic benefit for plant growers. With these products, the plants have more fresh weight without more irrigation water. Stress tolerance of plants is getting better using of these agents.

Keywords: *moisture controlling agents, chlorophyll, fresh weight, plant height*

Introduction

Nowadays, climate change is a serious problem in the world. The water management has become increasingly important because of the temperature increasing and the precipitation decreasing. The water holding capacity of the growing media have major role in the ornamental plant production. The decreasing of water consumption, the moisture controlling agents such as the Finnish BRT® EverGreen and German Aqua+3 (Geohumus®) have important role in the cultivation.

In the last decades, soil amendments and moisture controlling agents were tested in the horticultural production. Superabsorbents (hydrogels or superabsorbent polymers) are synthetic substances and water-insoluble polymers (PORA *ET AL.*, 2015). It has got the ability to swelling in water and retaining of water within their structure (ZOHURIAAN-MEHR AND KABIRI, 2008). Zeba® increased moisture conservation and nutrient use efficiency of cotton (NGOBEN *ET AL.*, 2007) and Zeba® particles hold moisture in the soil of oat, onion and watermelon (VIZTIU *ET AL.*, 2014). Stockosorb® reduced the required water of the soils (ABEDI-KOUPAI AND ASADKAZEMI, 2006), had a positive effect on turfgrass (ZHENG *ET AL.*, 2005) and had better water holding capacity on *Salvia officinalis* (SAVI ET AL., 2014). The mineral-polyacrylate water absorbent Geohumus®, helped to improve soil water content, reduce plant stress, and extend plant survival period of

Dianthus chinensis, *Mukdenia rossii* and *Pachysandra terminalis* (LI *ET AL.*, 2016), decreased irrigation application rate of *Hydrangea macrophylla* (KAPSIMALIS *ET AL.*, 2011) and responded stronger drought stress on *Zea mays* (DUONG AND ASCH, 2012). Hydrogel enhanced the efficiency of water uptake and utilization of photosynthetic products of *Eucalyptus* species grown in soil (ORIKIRIZA *ET AL.*, 2009), increased salt stress tolerance of turfgrass (HADAM *ET AL.*, 2011), improved nutrients uptake efficiency of *Solanum tuberosum* (FARIED *ET AL.*, 2014) and also increased root and shoot biomass of *Fagus sylvatica, Picea abies* and *Pinus sylvestris* (ORIKIRIZA *ET AL.*, 2013).

Material and Methods

Aquilegia flabellata var. *pumila* seeds were sawn and *Pelargonium peltatum* cuttings were grown in the greenhouse of the Department of Floriculture and Dendrology, Szent István University, Budapest in 2013. The processing of samples was performed in the labour of the Department of Floriculture and Dendrology and Department of Soil Science and Water Management, Szent István University, Budapest.

Aqulegia flabellata var. *pumila* (Huth) Kudo (syn. *A. japonica* Dwarf.) is a 10-15 cm high perennial. Native in Japan, Kurilen, Sachalin and Korea. The flower stems reach up to 20 cm. Leaves are lacy and often coloured red. Species can be planted in rock garden (JELITTO AND SCHACHT, 1990, RICE, 2006).

Pelargonium peltatum is one of the most popular potted balcony ornamental plant. Rainbow series are a big and simple flower geranium with compact habit and does not require to deadhead. 'Rainbow Rose' is pink flower geranium (FELTWELL, 2001).

The moisture controlling agent Aqua+3 is composed polymerization of various substances and volcanic rocks is added. It containes bentonite, sand, magnesium oxide, calcium oxide and water-insoluble polyacrylate. This product is able to store up to 130% of its volume. Aqua+3 is reduced the leakage of water and evaporation. Mineral elements of Aqua+3 help the growth of seedlings and the biomass. It provides several years of intense growth, soil ventilation, nutrients and minerals better use and a 30% reduced rate of irrigation (DUONG, 2012).

The Finnish developed BRT® EverGreen is a moisture control and soil amendment product. It is composed of methylene-urea resin. During the manufacturing, phosphorous acid is added and after the foaming, wetting agent is added. It is a slow releasing nitrogen and phosphorous fertilizer as well. The product is hydrophilic, able to store up to 90% of its volume and release it slowly to plant root systems and also provides roots with extra oxygen needed for growth. Using of this product, the number of irrigations and the amount of water used for irrigation will be reduced. The recommended concentration is between 10% and 30% (REMES, 2014).

Three treatment groups (control (C), 8 g/l Aqua+3 and 10 g/l BRT® EverGreen) were set up for *Aquilegia flabellata* and four treatment groups (control (C), 8 g/l and 16 g/l Aqua+3 and 10 g/l BRT® EverGreen) were set up for *Pelargonium peltatum*. Plant height (cm), diameter (cm) and chlorophyll content were examined on *Aquilegia flabellata*. Plant height (cm), fresh weight (g), root weight (cm), root number, root length (cm) and chlorophyll content were examined on *Pelargonium peltatum*. During soil testing the available phosphorous and potassium were examined.

To determine chlorophyll content, 300 mg leaf samples were collected. With quartz sand the samples were homogenized and completed with 80 % Acetone solution to 10 ml. After 24 hour rest the light absorbance of the solution was measured on 663, 644 and 480 nm wave length (ARNON, 1949).

Available phosphorous and potassium content were determined with acid ammonium lactate extraction (EGNÉR *ET AL*., 1960).
Statistical analysis was performed by IBM® SPSS STATISTICS (Version 22) by 95% significance level. One-way ANOVA model was used to compare the varieties. The assumptions of homogeneity of variance were hold. Normality of residuals was proved by Kolmogorov-Smirnov test. Pairwise comparisons were run by Tukey's Post Hoc test (TABACHNICK AND FIELDS, 2013).

Results and Discussion

Aquilega flabellata var. *pumila*

Plant height, plant diameter and chlorophyll content were examined on *Aquilegia flabellata* var. *pumila* (Table 1.).
We detected significant differences between treatments groups for plant diameter [$F(3;57)=304.148$; $p<0.001$]. BRT® group was significantly wider than the Aqua+3 and control groups. The product approx. 1 cm increased the diameter of plant.
Significant differences were detected for plant height [$F(2;57)=776.269$; $p<0.001$]. BRT® group and Aqua+3 were significantly higher than the control group. The differences were 1.2-fold. The height of plant is one of the most important quality properties.
The chlorophyll content was detected by laboratory measurements, on average samples. All of the treatment groups significantly differed from the control [$F(2;12)=587.398$; $p<0.001$]. BRT® doubled the chlorophyll content. Aqua+3 1.5-fold increased the chlorophyll content. Higher concentration of chlorophyll increases photosynthetic activity which makes better "fitness" of plants.

Table 1. The results of morphological characteristics and chlorophyll content of *Aquilegia flabellata* var. *pumila.*

	Plant diameter		Plant height		Chlorophyll content	
C (control)	13.84	**a**	4.32	**a**	558.7	**a**
Aqua+3 8 g/l	14.27	**b**	5.18	**b**	833.9	**b**
BRT® EverGreen 10 g/l	15.12	**c**	5.58	**b**	1315.6	**c**

Pelargonium peltatum 'Rainbow Rose'

Plant height, fresh weight, root weight, root number, root length and chlorophyll content were examined on *Pelargonium peltatum* (Table 2.).
We detected significant differences between treatments groups for plant height [$F(3;56)=7.308$; $p<0.001$]. BRT® group was significantly higher than the other treatment groups. The product 1.5-fold increased the height of plant. This result may be remarkable in ornamental plant production. Soil amendments, Hydrogel doubled the height of potato seedlings (FARIED *ET AL*., 2014). The height of plant is one of the most important quality properties. The results (7 cm higher) may be remarkable in the ornamental plant production, it could result more marketable seedlings.
Significant differences were detected for fresh weight [$F(3;56)=40.624$; $p<0.001$]. All of the treated groups differed from the control. 8 g/l Aqua+3 was approx. 1.5-fold increased the fresh weight. 16 g/l Aqua+3 doubled and BRT® 2.5-fold increased the fresh weight. It is an important

result. The bigger fresh weight means greater leaf area with greater photosynthetic surface which increases plant productivity.

We detected significant differences for weight of roots [F(3;56)=4.831; p=0.008]. Plants of 8 g/l Aqua+3 treatment group became significantly heavier than the control. The difference was 1.5-fold. The same trend was observed for number of roots and the fresh weight. Significant differences were between the treatments groups [F(3;99)=106.217; p<0.001]. All of the treatments groups differed from the control. 8 g/l Aqua+3 doubled, 16 g/l Aqua+3 and BRT® 2.5-fold increased the number of roots. Length of roots had the same trend as the weight of roots. 8 g/l Aqua+3 had significantly longer roots than the control [F(3;56)=3.823; p=0.015]. The difference was 1.5-fold. At first we thought that the reason for the marked difference of root length was phosphorus deficiency, but the soil examination did not substantiated it. More roots could have better nutrient uptake which makes better "fitness" for plants. The result of the roots may be important for the growers.

Physiological conditions were examined by chlorophyll content. The chlorophyll content was detected by two laboratory measurements, on average samples. At the first time BRT® group significantly differed from the control [F(3;16)=4.371; p=0.020]. BRT® approx. doubled the chlorophyll content. At the second measurement we did not able to detect significant differences between the treatments group [F(3;16)=0.969; p=0.431]. Some medium additives such as biochar or humic acid increased the chlorophyll content of *Calathea insignis* (ZHANG *ET AL.*, 2014). Higher concentration of chlorophyll increases photosynthetic activity which makes better "fitness" of plants.

Table 2. The results of morphological characteristics and chlorophyll content of *Pelargonium peltatum* 'Rainbow Rose'.

	plant height		fresh weight		root weight		root number		root length		chlorophyll content (2013)		chlorophyll content (2014)	
C (control)	10.13	**a**	2.32	**a**	1.67	**a**	10	**a**	20.33	**a**	337.0	**a**	365.4	**a**
Aqua+3 8 g/l	10.46	**a**	3.14	**b**	2.67	**b**	19	**b**	30.83	**b**	389.1	**ab**	399.4	**a**
Aqua+3 16 g/l	12.43	**a**	5.06	**c**	2.04	**ab**	26	**c**	25.83	**ab**	584.1	**ab**	456.9	**a**
BRT®	17.20	**b**	6.35	**c**	1.85	**a**	26	**c**	21.50	**a**	640.1	**b**	454.6	**a**

We detected significant differences between treatment groups for the potassium and phosphorous content of medium (Table 3.). All of the treated groups differed from the control [F(3;16)=1061.448; p<0.001]. BRT® reduced by half the potassium content. All of the treated groups also differed from control for phosphor content [F(3;16)= 452.560; p<0.001]. BRT 1.5-fold increased the phosphorous content. Several measurements were taken with the nutrient uptake of geraniums. The added phosphor had positive effect on foliar magnesium and potassium content (SEDIBE AND ALLEMANN, 2012). Phosphorous stress reduced the number of shoots and flowers (BAAS ET AL, 1995). In peat grown geranium, higher nitrogen content and lower potassium content was measured than in cork oak bark (AGUADO *ET AL.*, 1993). Foliar Ca, P and

K content significantly differed from control for the phosphorus concentration in the nutrient solution (SEDIBE AND ALLEMANN, 2013). Potassium application had positive effect on plant height, potassium tissue content and oil composition (KHETSHA AND SEDIBE, 2015). In the case of our results, all of the treatment groups contained appropriate amount phosphorous for growing of geranium but BRT® had negative effect for potassium content. Nevertheless, there were no deficiency symptoms in plants, because of the short examination time.

Table 3. The potassium and phosphorous content of medium.

	Potassium content (mg/100 g)		Phosphorous content (mg/100 g)	
C (control)	285	**a**	135	**a**
Aqua+3 8 g/l	256	**b**	155	**b**
Aqua+3 16 g/l	263	**b**	150	**b**
BRT® 10 g/l	149	**c**	220	**c**

Conclusions

Aquilegia flabellata var. *pumila* and *Pelargonium peltatum* 'Rainbow Rose' treated with two moisture control agents.

BRT® EverGreen and also Aqua+3 increased the plant height, plant diameter and chlorophyll content of *Aquilegia flabellata* var. *pumila.* BRT® doubled the chlorophyll content and 1.5-fold increased the height of plants. BRT® EverGreen increased the plant height and fresh weight of *Pelargonium peltatum*. Both characteristics were 1.5-fold higher than the control. 8 g/l Aqua+3 increased the root length and root weight. It is excluded that 1.5-fold longer roots was caused by phosphorus deficiency. BRT® EverGreen doubled the chlorophyll content. These are remarkable in practical aspect as well. These results may be important for growers to improve the most important morphological characteristics during ornamental plant production. All of the treatment groups contained appropriate amount phosphorous for growing of geranium but BRT® had negative effect for potassium content.

Summarizing, further experiments are suggested. Using of these agents is recommended on *Aquilegia flabellata* var. *pumila* and *Pelargonium peltatum* 'Rainbow Rose'.

THE EFFECT OF N-FERTILIZATION ON *ROSMARINUS OFFICINALIS L.* (AN UPRIGHT VARIETY) YIELD IN CENTRAL GREECE

Eleni WOGIATZI-KAMWOUKOU, Nickolaos GOUGOULIAS, Zoi PAPADOULI, Baia THEODOSIOU, Kyriakos D GIANNOULIS

Abstract

The effect of three different N-fertilization levels (N1: 625, N2: 385 and N3: 770 kg ha^{-1}; where in case of N1 was used the 3-6-10+3MgO+30% OM and in cases of N2-N3 the 26-0-0 fertilizers) on fresh and dry weight of the perennial *Rosmarinus officinalis* (upright cultivar) was investigated during the 2nd year after establishment at the Experimental Farm of the Technological Educational Institute of Thessaly in Greece (TEI; Larissa plain) in 2015. It is well documented that the crop reaches its potential yield on the third year of cultivation and continues producing biomass for as long as eight years. Complete weather data (air temperature, radiation, air humidity, precipitation) were recorded hourly in an automatic meteorological station, which was installed to the experimental farm of TEI. Upon harvest (November 3rd 2015), the crop reached a maximum fresh yield of 11.67 tons per hectare and dry yield of 4.3, respectively. The average fresh weight was 8.2, 8.4 and 8.9 t ha^{-1} and the dry weight were 2.6, 3.1 and 3.2 t ha^{-1} for the N1, N2 and N3 levels, respectively. Furthermore the higher moisture content was observed in the case of N1 level (68%). Therefore, the above data show that rosemary cultivation could be a promising alternative crop, especially in case of the consideration that average selling price of dry rosemary in Greece is 3.5 € kg^{-1} and the average gross income exceeds the amount of 10.000 € ha^{-1}.

Keywords: *Rosmarinus officinalis L.*, fertilization, upright variety, fresh yield, dry yield.

Introduction

Rosemary is an evergreen perennial shrub, which belongs to the class Magnoliopsida, subclass Lamiales, family of Lamiaceae or Labiate (Labiatae) which comprises up to 200 genera and about 3500 species, and it is naturally found in all of the coastal regions of the Mediterranean Sea (do Amaral Franco and daRocha Afonsa, 1972) and the genus *Rosmarinus, officinalis* species. The plant botanically characterized from its square stems, while leaves are opposite in pairs and arranged crosswise. Most important of all is the fragrant smell.

Generally rosemary is a plant which grows in areas where there is mild hot and cold climate. A feature of the plant is that it can be grown in lowland areas with an elevation of up to 600 meters (Dordas, 2012). *Rosmarinus officinalis* L., has been widely cultivated since antiquity as herb and garden plant, and also for its essential oil (Porte et al., 2000).

The red light affects the morphology of rosemary, the phenology as well as the essential oil. More specifically, the quantity and quality of the essential oil of rosemary which was grown in greenhouse conditions, affected by the wavelength of red light (660 nm) and dark-red (730 nm) which was applied (Mulas et al., 2006). Photoperiod is a very important factor, who irrelevant to the formation of the plant metabolic mechanism, from the production of photosynthetic carbon to determine the path that leads either to the class selection (terpenoids, phenylpropanoids) or in group selection (monoterpenes, sesquiterpenes, etc.) (Sangwan et al., 2001).

The temperature seems to be an important factor determining both the composition of the essential oil and the content of plant essential oil. The effects of temperature and moisture in growth, development and morphology of plants cannot easily be studied separately as it is closely related and interdependent environmental factors. The sum of the amount of the four main components represents the phenolic path and appears to be affected by how hot the climate is (Vokou et al., 1993). The number of flowers and their total weight was greatest at low than at high temperatures (Putievsky et al., 1997). Plants adapted to hot and dry climates environments develop small leaves, wrapped and covered with a dense coat to resist the water loss from the surface (Fitter and Hay, 1987).

Irrigation must be done depending on the precipitation of the selected region. Thus, in areas with low rainfall where plants get strong root system is necessary supplemental irrigation. In contrast, in areas with rainfall (over 500 mm) and in case that the plants have fully installed, the crop can continue to develop with minimal irrigation at critical points. Specifically, the lack of water and the water stress in rosemary reduces plant growth in contrast to the proportion of the essential oil which is increased (Leithy et al., 2006).

Rosemary is cultivated for green and dry drug and essential oil. The harvest period is determined by the desired product. Because the crop is perennial, harvest takes place from the second year of crop establishment and the plant goes into full production in the third year. The aroma of flowers diffused in the environment so attracted insects and as a result have better pollination and crossing of not self-pollinating plants (Mahmoud & Croteau, 2002).

This study was conducted in the main agricultural plain (Thessaly) to evaluate the effect of Nitrogen fertilization on the fresh and dry yield of Rosemary repens and upright (R*osmarinus officinalis*) in Greece.

Materials and Methods

Rosemary upright was cultivated in the Farm TEI of Thessaly. The planting took place on 09.04.2014 and the harvest during its second year after establishment at the start of the flowering period when the concentration of essential oils maximized (Marquard et al., 2001). The effect of three different N-fertilization levels (N1: 625, N2: 385 and N3: 770 kg ha^{-1}; where in case of N1 was used the 3-6-10+3MgO+30% OM and in cases of N2-N3 the 26-0-0 fertilizers) on fresh and dry weight of the perennial *Rosmarinus officinalis* (upright cultivar) was investigated during the 2^{nd} year after establishment at the Experimental Farm of the Technological Educational Institute of Thessaly (TEI; Larissa plain) in 2015. The experiment had a randomized block design and each experimental piece had an area of 16 m^2 with 28 plants. The leaves and shoots after harvesting were dried in a dark place at room temperature. The fresh and dry weight data were analyzed using the GenStat 7^{th} Edition statistical package.

Results and Discussion

Soil Analysis

The soil used for the rosemary cultivation was of low organic matter content and low salinity as it is presented in the following Table 1.

Table 1. Chemical properties of the Rosemary field experiment.

Property	Soil depth (0-25) cm	Soil depth (25-50) cm
	Before transplanting	After harvest
Texture	Loam	Loam
pH (1part soil:5parts H_2O)	7.81 ± 0.16	7.82 ± 0.16
Electrical conductivity, extract(dSm^{-1}) (1part soil:5parts H_2O)	0.11 ± 0.01	0.10 ± 0.01
Organic matter (%)	0.93 ± 0.05	0.77 ± 0.04
N-inorganic (mg kg^{-1})	44.8 ± 4.07	41.3 ± 3.44
K-exchangeable (mg kg^{-1})	373.3 ± 7.45	314.5 ± 7.86
P –Olsen (mg kg^{-1})	13.1 ± 1.87	10.2 ± 1.46
$CaCO_3$ (%)	0.63 ± 0.07	1.04 ± 0.12

Data represent average means and SE deviation. (n)=4

Fresh Yield

In Figure 1 is illustrated the average fresh weight of rosemary as it is affected from the three different used nitrogen levels and fertilizer types. There was not found any statistical significant difference (Table 2) between the used nitrogen levels. It was found that the use of the N1 type and level of fertilizer (625 kg ha^{-1} from 3-6-10+3MgO+30% OM) which was almost the double quantity of N2 (385 kg ha^{-1} from 26-0-0) produced an average yield of 8.19 t ha^{-1}, yield almost the same with the produced in case of N2 level (8.36 t ha^{-1}). Moreover by increasing the quantity of the 26-0-0 to the double dose the average yield increased only by 0.54 t ha^{-1}.

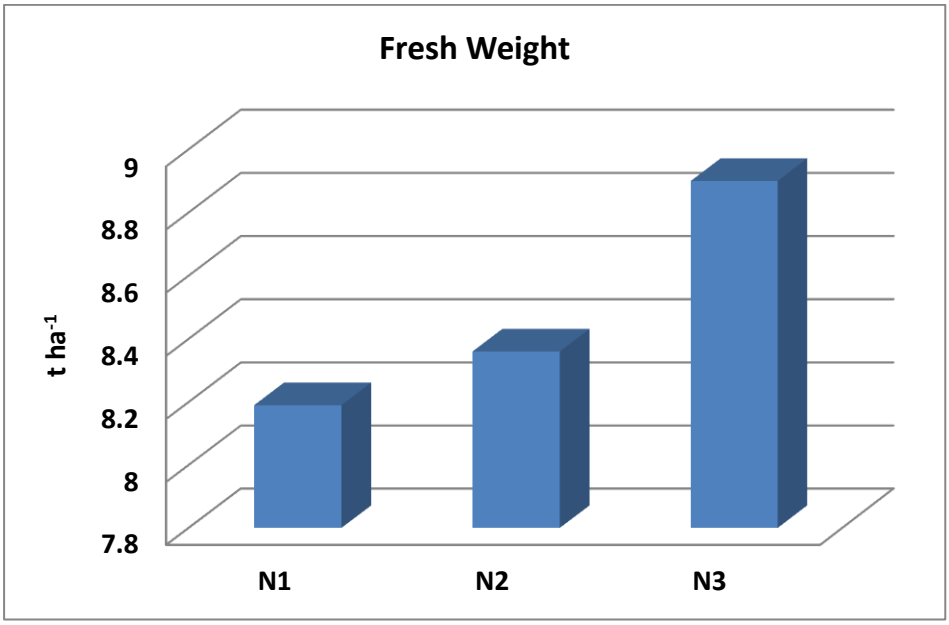

Figure 1. Fresh weight of *Rosmarinus officinalis* as affected of the three different nitrogen levels and fertilizer types.

Dry yield

Figure 2 illustrates the average dry weight of rosemary as it is affected from the three different nitrogen levels and fertilizer types. There was found no statistical difference (Table 2) for the examined factor. Verified the results of fresh weight, it was found that by increasing the quantity of the 26-0-0 to the double dose (N2 vs. N3) the average dry yield increased only by 0.15 t ha^{-1}. In case of the N1 the average dry yield was 2.64 t ha^{-1}.

Therefore, it could be assumed that N1 type is not delivering the expected results, and rosemary is a plant of low nitrogen requirements, since by increasing the dose in double, the yield of the plant does not perform statistical significant differences.

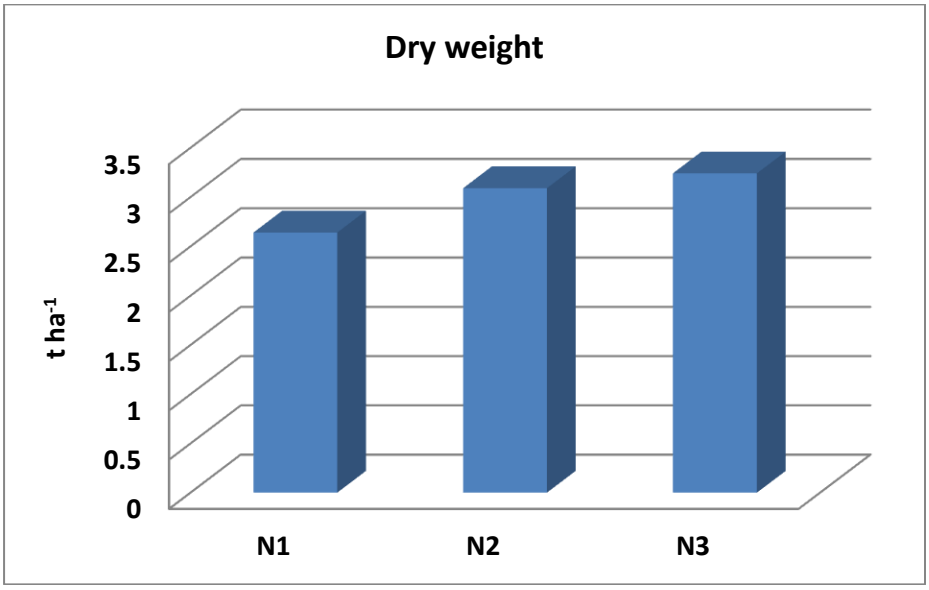

Figure 2. Dry weight of *Rosmarinus officinalis* as affected of the three different nitrogen levels and fertilizer types.

In comparison with previous studies in six different locations (Gurbuz et al., 2015) ranged between 0.55 to 0.82 t ha^{-1}, yield which is lower than the half of the produced in this study. In contrary, it was reported (Kirpik, 2005) a yield 7.82 t ha^{-1} during the first year after establishment and reached up to 22.12 t ha^{-1} for the year after. This high difference may best be explained by ecological conditions and different crop age. In a two year trial Sonmez (2007) yielded 1.23–2.18 t ha^{-1} for two continuous years, which results are in agreement with those that were found. Furthermore the higher moisture content was observed in the case of N1 level and fertilizer type (68%).

Table 2. Fresh and dry weight of *Rosmarinus officinalis* under different nitrogen levels and fertilizer types.

Rosmarinus officinalis	**Fresh Weight (t ha^{-1})**	**Dry Weight (t ha^{-1})**
Nitrogen Levels		
N1 (625 kg ha^{-1}; 3-6-10+3MgO+30% OM)	8,19	2,64
N2 (26-0-0; 385 kg ha^{-1})	8,36	3,09
N3 (26-0-0; 770 kg ha^{-1})	8,90	3,24
$LSD_{0.05}$	ns*	ns*
CV %	17,6	15,0

ns: non significant difference

Conclusions

The general conclusion that was found from this study is that *Rosmarinus officinalis* is a low nitrogen requirement crop, where by doubling the fertilization dose there was only observed constant voltage supremacy. The N-fertilization level of 385 kg ha^{-1} using the 26-0-0 fertilizer type produced an average dry yield of 3.09 t ha^{-1} setting this level as the best choice for farmers if someone will take in mind the fertilization costs. Therefore, the above data show that rosemary cultivation could be a promising alternative crop, especially in case of the consideration that average selling price of dry rosemary in Greece is 3.5 € kg^{-1} and the average gross income exceeds the amount of 10.000 € ha^{-1}, but further investigation is necessary to be conducted as to be able to lead to safer conclusions.

BREEDING LOW LINOLENIC ACID CONTENTED LINSEED VARIETIES FOR SAMSUN ECOLOGICAL CONTIDITONS

M. Safa HACIKAMİLOĞLU, Merve GÖRE*, Orhan KURT

University of Ondokuz Mayıs, Faculty of Agriculture, Department of Field Crops, Samsun, Turkey
*Corresponding author: merve.gore@omu.edu.tr

Abstract

Research results indicate that stem weight found 1.2-5.1 g per plant, seed weight 0.07-1.02 g per plant, biological weight 1.7-6.8 g per plant, plant height 40.4-57.8 cm per plant, number of branches per plant 2.6-6.5, number of capsules per plant 4.6-37, capsule weight per plant 0.14-1.7 g/plant, palmitic acid rate 5.5-6.0%, stearic acid rate 3.7-6.8%, oleic acid rate 17.6-31.0%, linoleic acid rate 10.3-55.0%, linolenic acid rate 10.1-6.1%. There were positive and significant correlation found between palmitic acid and stearic acid; positive and significant correlations found between palmitic-linoleic acid and stearic-oleic acid; significant and negative correlations found between linoleic-linolenic acid and linolenic-palmitic acid. Agricultural characters and fatty acid composition is not significantly correlated. According to our results, BxW combination has the lowest linolenic acid content and it is considerable most suitable for edible oil.

Keywords: *linseed, linolenic acid, gene pool*

Introduction

Oil is an organic substance that composes one of the essential nutrients in human and animal diets. Plant based oil is preferred by people because it is known as a good source of unsaturated fatty acids. Plant-oil composition differs with genotype and environment and these factors limit the quantity and quality of oil (Uysal and Kurt, 2014). The most common plant-oil quality factors are palmitic (C_{16}:0), stearic (C_{18}:0), oleic (C_{18}:1), linoleic (C_{18}:2) and linolenic (C_{18}:3) acid rates (Baydar and Turgut, 1999). Turkey has been importing a vast quantity of plant oil to compensate for its oil deficit. Turkey needs to develop better quality varieties, expand the cultivation areas for oil crop to increase the yield, and also find some alternative oil seed crops (Kurt, 2002; Uysal and Kurt, 2014). Linseed is one of the multi-purpose oil seed crops, which can be cultivated in any season. Linseed belongs to the *Linum* genus. The *Linaceae* family consist of 11 sub-families and 200 species but only *Linum usitatissimum* L. can be cultivated for oil and fibre production. This variety is widely cultivated in Europe, America and Asia. Some species are located naturally in Anatolia and about half of them are endemic. Varieties that have height and less branches are used for only fibre production and varieties which are shorter and with more branches are used for both seed and oil production. Linum seeds contain 35-45% oil content. Varieties with 45-65% linolenic acid are used for industrial purposes and varieties with low linolenic acid (< 2 %) are used for edible oils (Kurt, 1996; Kurt et al., 2005).

Linseed oil has positive effect on health due to the presence of high omega-3 fatty acid contents (especially α-linolenic acid). Several studies demonstrated that linseed oil inhibits blood clotting and prevents cardiovascular diseases and embolism. α-linolenic acid (ALA) reduces the LDL (low density lipoprotein) and inhibits arthrosis, which is known as vessel wall thickening. Linseed contains excess amounts of dietary fibre. Fibre contents are good for preventing constipation. The seed also contains SDG lignans (secoisolariciresinal diglucoside). Lignan

component improves the antioxidant properties of seeds and also good for cancer prevention. The phytoestrogens and lignans in seed composition enhance and balance the hormones especially progesterone levels in women to meliorate post-menopause problems. Researchers recommend that the daily use of 10g of linseed helps prevent cancers, constipation and forgetfulness. Recent studies indicate that linseed acts as an antioxidant and protects against diseases if the patient consumes 10g of seeds per day for a long period of time. Short-period usage is not effective. Scientist decided to blend linseed flour into bread and some other daily foods to provide a long term intake. Several studies indicate that the flavour of linseed oil is bitter when cooked and also it reduces the shelf-life. Poly-unsaturated fatty acids cause this effect more prominently.

There is no low-linolenic content linseed in the *Linum* gene pool. For this reason, different studies are ongoing in this topic. In this study, high quality linseed varieties and local lines were crossbred and agronomic and biochemical analyses were done in order to evaluate linseed genotypes.

Materials and methods

This study was conducted in the research area of the Faculty of Agriculture, Ondokuz Mayıs University-Samsun (Turkey). According to the soil analysis report, it was medium in organic matter having clay-loam structure. The experiment was conducted 120 meters above sea level. Ecological conditions in 2013 were stable but a little drier than the long term annual average.

Plant materials were Windermere (W), Nareum (N), Bionda (B), Antares (A), Mureş (M), local (Ay) and their some combinations [WxAys, BxWs, WxA, (WxA)xWk, WxN, (WxA)xWs, WxNs, WxAk, WxMu, (WxN)xWs, (AxW)xAs, WxWs].

The experiment was arranged according to augmented experimental design. Each experimental unit was 2m in length and contained 5 rows. The distance between the rows was 20cm. All experimental units were fertilised at the time of stem formation with ammonium nitrate. Plants were harvested when mature. Agricultural characters were analysed in 10 randomly selected plants from each line, and the rest of the plants were used for oil analysis according to Kurt et al. (2005) protocol. Statistical analysis was done with SPSS 21 and the graphs were created with Microsoft Excel.

Result and discussion

Agronomic parameters and fatty acid contents are given in Table 1&2 respectively. According to Table 1, stem weight varies between 1.2 (12) -5.1 (5) with mean value 2.6 g; seed weight 0.07 (15) -1.02 (5) g, mean 0.3 g, biological weight per plant 1.7 (16) -6.8 (5) g mean 3.2 g; plant height changed between 40.4 (4) -57.8 (13) cm, and mean 50.0 cm, number of branches changed between 2.6 (16) -6.5 (13) and mean 4.1; number of capsules 4.6 (12) -37.7 (5) and mean 14.3; capsule weight per plant 0.14 (11,12) -1.7 (5) g, mean 0.47 gr.

Fatty acid parameters are given in Table 2. According to Table 2; palmitic acid rates of all lines varied between 5.5 %(5)- 6% (2) and the mean 5.8%; stearic acid rate varied between 3.7 %(10)-6.8 %(15), mean 4.7%. Poly-unsaturated fatty acid oleic varied between 17.6 %(4)-31.0 %(15) and mean 21.6 %; linoleic acid rate varied between 10.3 %(15)-55 %(2) and mean 43.7%; linolenic acid rate varied between 10.1 %(2)-16.1 %(9)and mean 43.7 %.

Kurt (2012) found that palmitic acid rate 6.41%, stearic acid rate 2.84%, oleic acid rate 16,47%, linoleic acid rate 37,77% and linolenic acid rate 36,49% in their hybrid plants. Literature findings are compatible with this study. Kurt (2012) has found lowest linolenic rate in WxN combination with 9.44%, but the lowest rate in this study in BxW combination with 10.07 %.

Table 1. Agronomic parameters of hybrid combinations

Combination		Plant Height (cm)	Number of Branches	Number of Capsule	Capsule Weight (g)	Biological Weight (g)	Stem Weight (g)	Seed Weight (g)

16	WxWs	52.10	2.65	8.55	0.31	1.74	1.43	0.16

Linum bienne populations from different locations showed variations in fatty acid compositions. The palmitic acid rate changed between 5.47% - 8.58%, stearic acid rate 0.00% -6.51%, oleic acid rate 12.72%-37.13%, linoleic acid rate 5.22%-13.25% and linolenic acid rate 42.47%-70.85% (Uysal and Kurt, 2014). In this study, linolenic acid content is relatively lower and oleic acid rate is higher than the findings above.

Table 2. Oil compositions of hybrid combinations

Combination		Fatty Acid Contents (%)				
No	**Name**	**Palmitic**	**Stearic**	**Oleic**	**Linoleic**	**Linolenic**

14	WxMu	5.65	4.59	18.84	26.74	44.17
15	WxN(4)	5.74	6.78	31.00	10.31	46.17
16	WxWs	5.58	4.17	20.50	19.61	50.14

Statistical correlations on fatty acids are given in Table 3. As seen in the chart; a significant positive correlation is found between palmitic and stearic acid (r= 0.558) and a significant negative correlation is found between linolenic acid and linoleic acid (r= -0.932).

Linseed oil quality is commonly affected by oleic and linolenic acid levels. Studies have shown that linoleic acid level increases by the linolenic acid decrease because of the reduction enzyme absence. This mechanism causes a negative correlation between linoleic and linolenic acid rates (Green, 1986). The findings of this study are compatible with this literature.

There is an association between linoleic and linolenic acid being broken in this generation and prospective relations can be estimated that this relation will not be seen in future generations. Other fatty acids are not related to linolenic content and will not affect future generations. This explains linoleic-linolenic and linolenic-palmitic correlations.

Table 3. Correlations between fatty acids

	Palmitic	**Stearic**	**Oleic**	**Linoleic**	**Linolenic**
Palmitic	1	0.558*	0.320	0.624**	-0.759**
Stearic		1	0.801**	0.065	-0.384
Oleic			1	-0.154	-0.210
Linoleic				1	-0.932**
Linolenic					1

*Correlation is significant at the 0.05 level (2-tailed); **Correlation is significant at the 0.01 level (2-tailed).

Conclusion

The aim of creating a gene pool is to develop a high quality edible linseed oil. In order to achieve this aim, several lines were crossed to obtain low-linolenic linseed lines. According to the results, BxWs combination produced the lowest linolenic content (10.07%). Phenotypic parameters are not associated with oil parameters. On the other hand, the negative correlations found between linoleic and linolenic acid seem promising for developing better quality linseed varieties, however, further studies are required. New linseed genotypes with low linolenic and high oleic acid content would be beneficial for the Turkish market.

Abstract

The aim of this study was to determine the performance of yield and some quality features of sole sowing and different mixture ratios of Hungarian Vetch and annual ryegrass. The experiment was conducted in a randomized complete block design with Altınova-2002 Hungarian vetch and Trinova annual ryegrass varieties in Kırşehir (39°08'32"N, 34°06'48" E), Turkey. Fresh herbage, dry matter and crude protein yields were determined between 683.5 and 963.3 kg da^{-1}, 205.3 and 315.9 kg da^{-1}, 23.70 and 50.18 kg da^{-1}, respectively. Crude protein, ADF, and NDF ratios ranged between 11.58 and 17.86%, 28.69 and 39.66%, 37.12 and 59.67%, respectively. Dry matter yields of mixtures were higher than those of pure sown Hungarian vetch and annual ryegrass. The highest value of this yield component was obtained from the Hungarian vetch 80% + annual ryegrass 20% mixture. Because of the increasing rate of Hungarian vetch in the mixtures, NDF and ADF ratios of mixtures decreased. Reductions in ratios of NDF and ADF caused increases in the crude protein content and yield. Consequently, Hungarian vetch 80% + annual ryegrass 20% mixture was found superior than the other pure sown species and mixtures in terms of yield and quality features. It is concluded that this mixture can be grown successfully for the production of high quality roughage in Kırşehir or similar ecological conditions.

Key words: *Hungarian vetch, annual ryegrass, yield, ADF, NDF*

Introduction

The first culture forms of Hungarian vetch were found in Hungary. It is a resistant forage and can grow under extreme climatic conditions where many forages cannot (Balabanlı, 2009; Aksoy and Nursoy, 2010). However, lodging problem frequently seen in vetch species decrease the herbage and seed yields (Açıkgöz, 2001). Therefore, mixed seeding with cereals was recommended (Bakoğlu and Memiş, 2002). In vetch + cereal mixtures, annual ryegrass can be used as an alternative to cereals including barley, oat and triticale. Ryegrass is an annual grass forage and can form intensive tillering at higher altitudes. Also, it can be cultivated as a mixture with some legume forages and contributes to the yield and quality of the mixtures and improves the production of roughage (Baytekin *et al*., 2009).

In Central Anatolia, the share of forage agriculture in field crop agriculture is very low. Forage cultivation conducted in Central Anatolia comprises only 13.7% of the forage cultivation carried out in Turkey. Agricultural areas in Kırşehir comprise 6% of the total cultivation area in Central Anatolia Region, and only 2.9% of this area for forage cultivation (Anonymous, 2014).

Intensive wheat and barley farming carried out in Central Anatolia leads to an intensive use of cereal straw as roughage. In this case, not quantitatively but qualitatively, a serious amount of

*This paper is a part of MSc thesis of Süleyman ŞİMŞEK.

roughage shortage arises. Therefore, annual legumes and their mixtures are of paramount importance in order to meet the coarse feed needs. Because, cultivation of annual forages which can also be sown in fallow lands as sole crops or mixtures will contribute to the reduction of fallow lands in Kırşehir which has 1.2 million ha of fallow lands (Anonymous, 2014).
The aim of this study was to determine the mixture ratios of Hungarian vetch and annual ryegrass that can be cultivated in the region in terms of yield and quality performance as an alternative to the classic annual legumes and cereal mixtures.

Materials and methods

The study was conducted at 2013-2014 vegetation period at the experimental field located at Ahi Evran University Bağbaşı Campus (39°08'32"N, 34°06'48" E) using Altınova-2002 Hungarian vetch (*Vicia pannonnica* Crantz) and Trinova (*Lolium multiflorum* Lam.) annual ryegrass varieties. The characteristics of the soil in the experimental field were poor in organic matter, rich in phosphorus, potassium and calcium, moderate alkaline with clay and loam content. The average temperature (7.3 °C) of the vegetation period for 2013-2014 in which the study was conducted was higher than the average long-term temperatures (6.9 °C) for the same period. The average temperature values of all months, except December, was higher than the average monthly long-term temperature values. The total precipitation (259.3 mm) was lower than the average long-term total precipitation (315.8 mm) for the same months. Particularly, total precipitation values for January and April were significantly lower than the average long-term total precipitation values.
The study was designed in randomized complete block design in three replications. In the study, two sole species (100% Hungarian vetch- HV, 100% annual ryegrass- AR) and four mixtures (20% HV + 80% AR; 40% HV + 60% AR; 60% HV + 40% AR; 80% HV + 20% AR), a total of six subjects were examined. In sole plantings, 10 kg da^{-1} seed was used for Hungarian vetch while 2 kg da^{-1} seed was used for annual ryegrass. Sole species and mixtures were sown manually on 25 October 2013 with 30 cm row spacing on 8 rows with a length of 6 m. The size of the plot in the study was 14.4 m^2. Weed control was applied in the spring manually or using a hoe. In the study, mowing schedule was determined according to Hungarian vetch species. All species and mixtures were harvested during the full flowering period of Hungarian vetch (on 30th May 2014). Two end-rows of eight rows of each plot and 50 cm distances from the starting point of each plot was removed as the edge impact. The remaining 9 m^2 area was mowed and herbage yield was determined. The weight of each herbage sample were 500 g and dried at drying oven at 60 ºC until the consecutive weights were fixed (Sleugh *et al*., 2000). The dried samples were weighed using a precision scale to calculate dry matter yield. Nitrogen contents of the samples in the study were determined by the Kjeldahl method. Total nitrogen values were multiplied by 6.25 coefficient value to calculate crude protein contents of species and mixtures (Helrich, 1990). Then, crude protein ratios were multiplied by dry matter yield value, and crude protein yield of the species and mixtures were calculated. Acid Detergent Fiber (ADF) and Neutral Detergent Fiber (NDF) contents of the species and mixtures were determined using ANKOM 200 Fiber Analyzer (ANKOM Technology Corp. Fairport, NY, USA) (Anonymous, 2005). Analysis of variance of the data obtained in the study was performed according to the randomized complete block design using the MSTAT-C statistical software. The significant differences between the mean values were compared by Duncan multiple comparison method.

Results and discussion

Fresh herbage yields of the species and mixtures were between 683.5 kg da^{-1} and 963.3 kg da^{-1} while the dry matter yield values were between 205.3 kg da^{-1} and 315.9 kg da^{-1}. The lowest yield values in species and mixtures were determined in sole annual ryegrass whereas the highest yield was obtained in 80% HV + 20% AR (Tabe 1). The differences between dry matter yields were statistically not significant, however dry matter yield values of all mixtures were higher than those of sole Hungarian vetch and annual ryegrass.

Sabancı and Ürem (1993) reported that 90%-10% or 80%-20% mixtures of Persian clover + annual ryegrass were suitable in terms of both fresh herbage and dry matter yields. Luginbuhl (1998) reported that the fresh herbage yield of annual ryegrass as 3581 kg da^{-1} while Kuşvuran (2011) found that 470 kg ha^{-1}and 550 kg ha^{-1} nitrogen treatments produced 54834 kg ha^{-1} and 54976 kg ha^{-1} herbage yield, respectively. Kuşvuran and Tansı (2011) determined 80754 kg ha^{-1} herbage and 14932 kg ha^{-1} hay using 30 cm inter row spacing. Kuşvuran *et al*. (2014), in their study on different mixture and row spacing applications, determined the highest herbage yield (33.4 t ha^{-1}) and hay yield (7.5 t ha^{-1}) values in the 60% HV + 40% AR mixture and 30 cm row spacing application. Fresh herbage and dry matter values obtained in the present study were lower than those reported in the studies mentioned and summarized above. These results can be associated with different applications such as fertilization as well as the positive effects of ecological factors including precipitation and temperature on yield.

Table 1. Yields of fresh herbage, dry matter, crude protein and the ratios of crude protein, ADF and NDF of species and mixtures

Species and Mixtures	Fresh herbage yield (kg da^{-1})	Dry matter yield (kg da^{-1})	Crude protein ratio (%)		Crude protein yield (kg da^{-1})		ADF (%)		NDF (%)	
HV	840.5	244.5	17.86	a**	43.78	ab**	28.69	f**	37.12	f**
AR	683.5	205.3	11.58	f	23.70	c	39.66	a	59.67	a
20% HV+80% AR	749.2	261.1	13.42	e	35.17	b	38.83	b	53.04	b
40% HV+60% AR	801.4	271.4	14.22	d	38.80	b	34.95	c	50.18	c

80% HV+20% AR	963.3	315.9	15.83	b	50.18	a	32.17	e	44.35	e
Mean	816.5	263.5	14.67		39.07		34.16		48.51	

**: Means followed by the same letter in the same column are statistically not significant (p<0.01).

Crude protein ratios varied between 11.58% and 7.86%, in average as 14.67% (Table 1). The lowest crude protein ratio was found in sole annual ryegrass planting whereas the highest was obtained from sole Hungarian vetch planting. It can be said that when Hungarian vetch ratios increased in mixtures, ADF and NDF ratios of mixtures were decreased, allowing increases in crude protein ratios of the mixtures. Caddel and Allen (1997) reported that the crude protein ratio of legume roughage was higher 19% before flowering than after flowering and the crude protein ratios in the mixtures varied between 11% and 19%, depending on the ratio of grass. Geren *et al*. (2003) found out that the crude protein ratio of hairy vetch + annual ryegrass mixtures in the hay as 21.37%. Kuşvuran *et al*. (2014) reported that the crude protein ratios of Hungarian vetch, annual ryegrass and their mixtures were 18.6% and 11.4%, respectively, while the crude protein ratios of their mixtures varied between 12.6% and 15.8%.

In the present study, crude protein yields of species and mixtures varied between 23.70 kg da^{-1} and 50.18 kg da^{-1}. The highest crude protein yields group was determined in 80% HV + 20% AR mixture, sole Hungarian vetch planting and 60% HV + 40% AR mixture whereas the lowest

crude protein yield was determined in sole annual ryegrass planting (Table 1). Crude protein yield is associated with crude protein ratio and dry matter yield. Indeed, crude protein yields of the species and mixtures were in line with their dry matter yields and crude protein ratios and the samples with the highest dry matter yield and crude protein ratio values were the ones with the highest crude protein yield values. Kuşvuran *et al*. (2014), in line with the findings of the present study, determined the highest crude protein yield in 80% HV + 20% AR mixture.

The lowest ADF ratio in the species and mixtures were obtained in sole Hungarian vetch planting (28.69%) whereas the highest ADF ratio was obtained in sole annual ryegrass planting (39.66%). The average ADF ratios of species and mixtures was 34.16%. ADF ratios of the mixtures decreased as the ratio of Hungarian vetch in the mixture increased (Table 1). In the study of Caddel and Allen (1997), the ADF ratio of dry legume before flowering was 31%. Bingöl *et al*. (2007) determined it in Hungarian vetch as between 30.35% and 31.80%, while Yolcu *et al*. (2009) found out it between 29.59% and 31.10%, and Canbolat *et al*. (2013) as 27.57%. Kuşvuran *et al*. (2014) concluded that the ADF ratios as 35.8% for Hungarian vetch, as 39.7% for annual ryegrass and between 36.7% and 38.5% for Hungarian vetch + annual ryegrass mixtures. According to Bingöl *et al*. (2007), Vetch varieties had different ADF ratios. Yılmaz *et al*. (2015) reported that the ADF ratios decreased by inclusion of Hungarian vetch in the mixture.

NDF ratio values of species and mixtures were in line with the ADF ratios. The lowest NDF ratio was determined in sole Hungarian vetch planting (37.12%) whereas the highest NDF ratio was in sole annual ryegrass planting (59.67%) (Table 1). NDF ratios of the mixtures, similar to the ADF ratios, decreased by Hungarian vetch inclusion. NDF ratios of the mixtures varied between 53.04% (20% HV + 80% AR) and 44.35% (80% HV + 20% AR). The average NDF ratio values of the samples was 48.51% (Table 1). In the study of Yılmaz *et al*. (2015), the increase inclusion of Hungarian vetch in the mixture reduced the NDF ratio. Bingöl *et al*. (2007) indicated that, as in ADF ratio values, NDF ratio values of vetch varieties varied.

Conclusion

Crude protein ratios of the mixtures increased as the Hungarian vetch ratio in the mixture increased. ADF and NDF values of species and mixtures decreased as the crude protein ratios increased. The crude protein yields were also high in species and mixtures with high dry matter yield and crude protein ratio values. NDF and ADF ratios of the mixtures decreased by increased inclusion of Hungarian vetch in the mixture. The decrease in the NDF and ADF values of the mixtures increased the crude protein ratios. To conclude, 80% Hungarian vetch + 20% annual ryegrass mixture demonstrated superior properties in terms of yield and, especially, quality to get a good quality roughage production for Kirşehir or areas with similar ecological conditions.

Abstract

Seedlings of Demre sharp pepper varieties, in the hydroponic system containing Hoagland nutrient solution were grown in climate – controlled plant growth room. In the study, 100 mM NaCl was applied to three week old seedlings in stages and salt applications were continued in the same concentrations at the stage of refreshment of solutions that were renewed on a weekly basis. In order to to reduce the negative effect of salt on plant development, GA_3 (gibberellic acid) with 5 ppm, 7.5 ppm and 10 ppm dose together with salt were added to pepper seedlings. In the samples taken on 10 th and 20 th day of this application were investigated physiological changes that occurred as a result of salt stress. Also, plant root,stem, leaves wet weight, number of leaves, plant height and node intermediate distance were investigated. Furthermore, a scale of stress resistance was created based on the symptoms on leaves. In GA_3 applications made along with salt during the study, the best plant growth was observed in plants which had been applied the 10 ppm dosage of GA3. Furthermore, it was observed that the NaCl+10 ppm GA_3 application caused the least morphological damage and the lowest scale value among NaCl applications.

Keywords: *Pepper (Capsicum annuum L.), gibberellic acid, hormone, plant growth, salt stress*

Introduction

Salinity is a significant source of stress which cam emerge in arid and semi-arid areas where incorrect fertilization and incorrect irrigation are practiced, and areas and greenhouses where the salinity of irrigation water is a problem, and can have a negative influence on plant production or in some cases render it impossible. Since the pepper plant has a significant share in open and greenhouse cultivation, it is negatively influenced by salt stress. Crop losses due to these negative conditions can reach significant amounts. However the most significant and surest way of eliminating these negative influences is to develop plant types and varieties that are tolerant to salinity, and to conduct applications that eliminate the detrimental effects of salinity. In order to develop such species and varieties with high tolerance, the stress mechanism of the plant must be illuminated very well.

The administration of growth regulators such as GA3 and cytokinin to plants is beneficial in altering the negative effect of salt stress (Xiong *et al.* 2002). Indeed, in a study conducted by Lin and Kao (1995), the authors have claimed that GA reduces the hindrance to development of offshoots in saplings in rice seedlings to which salt had been applied. In the study conducted by Rodriguez *et. al.* (2006) the authors have reported that GA_3 applications played a role in reducing the promotion of the hindrance to plant development in some plants including rice. In the same study, the application of salt had a negative influence on all measured parameters except chlorophyll. It was also stated that the application of GA_3 prevented the influence of salt on chlorophyll b, caretenoid content, the dry weight of shoot, and the length of shoots.

In this study whose results we have provided, giberallic acid (GA_3) was applied to pepper plants that had been subjected to salt stress with the purpose of determining the reaction of plants to stress.

Material and Methods

Seedlings of Demre sharp pepper varieties, in the hydroponic system containing Hoagland nutrient solution were grown in climate – controlled plant growth room. For this purpose pepper seeds were planted into 45 cm plastic germination containers that had been filled with pumice, with 100 seeds to each container, and watered with tap water. Germination containers were placed in a climate controlled room with 25°C temperature and 70% humidity, the containers that had been covered with moist paper were regularly checked and continued to be watered in small quantities with tap water to prevent the drying out of the pumice. Papers were removed when germination began to be observed. Seedlings that had grown their 2nd real leaves in the pumice environment were transferred to a water culture in 18 cm plastic tubs filled with Hoagland nutrient solution. Pepper seedlings were wrapped in small pieces of sponge and placed on plastic trays that had been specially prepared with perforations for each seedling. The trays were placed over the tubs making sure to immerse plant roots in the nutrient solution. Aeration was conducted by immersing thin plastic pipes connected to aquarium pumps into the nutrient solution.

Application of salt was begun on seedlings with 4-5 real leaves that had been cultivated in a water culture for two weeks. The trial was set up with three repetitions with 10 plants to each repetition, according to the pattern of random based trial pattern. NaCl was added to provide a salt concentration of 100 mM in the nutrient solution for seedlings that would be administered salt. Salt applications were continued in the same concentrations at the stage of refreshment of solutions that were renewed on a weekly basis. Gibberellic acid was added in doses of 5.0 ppm, 7.5 ppm, and 10 ppm to pepper seedlings along with salt in the study.

Sampling was conducted twice on the 10th and 20th days of salt application. In these samples the wet weights of green parts of bodies, the number of leaves, the height of plant, and node intermediate distance were measured and a scale of stress resistance was formed according to the symptoms on leaves.

Plants were assigned scores between 1 and 5 according to the symptoms listed below on the 10th and 20th days of salt application (Uzal, 2009).

1: No effect on plant from salt stress
2: Slowing down in growth, local yellowing and curling on leaves
3: Yellowing on leaves and necrotic spotting in 25%
4: Necrotic spotting and shedding, and death in 20%-75% on leaves
5: Severe necrosis in 75%-100% in leaves or complete plant death

Results and Discussion

Some plant development parameters pertaining to pepper plants that had been in the control and test groups are provided in Table 1. Significant variation occurred as compared to the control in terms of leaf weight and count on samples taken on the 20th day. A statistically significant difference compared to the control group was also observed on samples taken on the 10th and 20th days with respect to plant height and node intermediate distance. In applications of GA_3 along with NaCl, statistically significant differences were observed with respect to root weight on the 20th day, and in terms of leaf weight and count in NaCl +7.5 ppm GA_3 application on the 20th day, and in all NaCl + GA_3 applications. While a statistically significant difference existed

as compared to the control group on the 10th day in all NaCl+GA_3 applications, no differences as compared to the control group were found in the NaCl+10 ppm GA_3 application on the 20th day. No statistically significant differences as compared to the control group were observed in the node intermediate distance on the 10th and 20th days in the NaCl+10 ppm GA_3 application. In comparing NaCl+GA_3 applications with plants to which only salt had been administered no statistically significant differences were determined with respect to root, stem, leaf weight and count, statistically significant differences were observed on the 10th and 20th days in the NaCl+10 ppm GA_3 application with respect to plant height and spacing between nodes. The spacing between nodes were also found to be different to a statistically significant extent in both periods of NaCl + GA_3 applications as compared to plants to which only salt had been administered. As expected, the plant height and node intermediate distance of NaCl+GA_3 applications as compared to plants to which only salt had been administered were found to be significantly increased in the NaCl+10 ppm GA_3 application. These values were found to be almost identical to the values of control plants. As expected, in plants that had only been applied GA_3, the leaf count, plant height, and spacing between nodes had increased as compared to the control in samples taken on the 20th day on all plants that had been applied GA_3.

Table 1. Plant growth parameters ın the samples taken on 10 $^{-th}$ and 20 $^{-th}$ day of applications (plant root weight (g), stem weight (g), leaves weight (g), number of leaves (number), plant height (cm), node intermediate distance (cm))

Application	Root W. (g)		Stem W. (g)		Leaves w. (g)		Number of Leaves (number)		Plant height (cm)		Node intermediate distance (cm)	
	10 th day	20 th day	10 th day	20 th Day	10 th Day	20 th day	10 th day	20 th Day	10 th day	20 th day	10 th Day	20 th day

Mean values indicated by the same latter are not significant different ($p<0.05$).

Table 2. The scale resistance according to the symptoms of stress in leaves (point)

Application	10 th day	20 th day
Control	1	1
NaCl	3	4.5
NaCl+5 ppm GA_3	3	4
NaCl+7,5 ppm GA_3	3	4
NaCl+ 10 ppm GA_3	2	3.5
5 GA_3	1	1.5
7,5 GA_3	1	1.5
10 GA_3	1	1

As had been stated in the method of creating a scale for the purpose of expressing the degree of the morphological damage in plants, the seedlings were assigned scores from 1 to 5 (Table 2). Thus, the application with the highest score was found to be NaCl, NaCl +5 ppm GA_3, NaCl +7,5 ppm GA3 with the assessment conducted on the 10th day. The application with the highest score was found to be NaCl, NaCl +5 ppm GA_3, NaCl +7,5 ppm GA3 according to the assessment conducted on the 20th day. According to these values these were found to the the applications that suffered the highest effects from salt, had the highest score in the salt resistance scale, and suffered the highest morphological damage as of the 10th and 20th days. It was observed that the NaCl+10 ppm GA_3 application caused the least morphological damage and the lowest scale value among NaCl applications.

Examining data obtained with respect to some plant development parameters, no statistically significant differences were observed as compared to the control grup in groups that had been administered only salt or administered NaCl+GA3, as well as a significant decrease in these groups as compared to the control with respect to leaf weight and count, but no difference was observed among NaCl+GA3 applications. As expected, in plants that had only been applied GA3, the leaf count, plant height, and spacing between nodes had increased as compared to the control in samples taken on the 20th day on all plants that had been applied GA3. On the 20th day, the plant height and spacing between nodes were found to be within the same statistical group with the control plants in the NaCl+10 ppm GA3 application. This proves the expected effect of GA3 on plant height and spacing between nodes. Parallel findings were made in comparing these values with scale values.

Karanlık (2001) has expressed that the necrosis and clorosis observed in plants as a result of salt stress exhibited a close correlation with the decreases in yield of wheat genotypes, and that a scale that would be created by assessing the symptoms which emerge on leaves as a result of salt stress could provide information on the sensitivity of genotypes to salt stress. Dasgan *et. al.*(2002) have reported that, in the 1-5 scale which they had used in their salinity study on tomato, genotypes that exhibites less damage as a result of salt stress had lower sca evalues, and in contrast the degree of damage increased as a function of Na accumulation with genotypes taking high scale values. In the study they conducted on the level of genotypes with respect to tolerance to salt in melons, Kuşvuran *et.al.*(2007b) have determined that scale values could be used as an effective parameter in determining tolerance to salt. In an aridity trial conducted on okra, it was reported that genotypes exhibited variations with respect to scale values, and had different scores (Kuşvuran *et.al.*, 2007a).

Ashraf *et. al.*(2001) have determined decreases in the wet and dry weights of offshoots and roots, plant height, and leaf with increases in salt, but applications of GA have caused significant

improvement in both varieties with respect to these development parameters. In general GA applications have promoted vegetative development of both varieties of wheat under salt stress but GA has caused an insignificant decrease in grain yield. In the same study a significant increase was observed in the concentration of Na and Cl in the shoots and roots of two lines of wheat in a saline development environment, but the accumulation of Na and Cl was reported to increase in both roots and shoots with the application of GA_3.Xiong *et. al.,* 2002 have reported benefits in altering the negative influence of salt stress with application to plants of growth regulators such as GA_3 and cytokinin while a study conducted by Lin and Kao (1995), GA_3 was reported to decrease the hindrance to development of shoots of rice seedlings to which salt had been applied, and a study conducted by Rodriguez *et. al.,* 2006 has reported that applications of GA_3 played a role in reducing the promotion of the hindrance to plant development in some plants including rice. Giberellins promote growth by stimulating cell division and increasing plastides in cell walls, convert carbohydrates to sugar, and reduce pressure on the cell wall. Thus since water is taken into the cell, cell lengthening occurs (Arteca, 1995). Furthermore, while GA_3 increases the height of short plants it reduces stem thickness, reduces the area of leaves, and causes a lightening in the green color of leaves (Cecconi *et. al.,*2002; Bibi *et. al.,* 2003).
The results we have obtained in the study conform to the studies mentioned, in these aspects.

Conclusions

In this study whose results we have provided, giberallic acid was applied to pepper plants that had been subjected to salt stress with the purpose of determining the reaction of plants to stress. In GA_3 applications made along with salt during the study, the best plant growth was observed in plants which had been applied the 10 ppm dosage of GA_3. Furthermore, it was observed that the NaCl+10 ppm GA_3 application caused the least morphological damage and the lowest scale value among NaCl applications.

Abstract

This study was carried out to determine the possibility of propagation of seeds in 5 different Rhododendron species of Turkey. The seed materials of the worked species were collected from the flora of East Black Sea Region in the period of August and October 2010. Study was carried out in randomized block design with 5 species and 4 replications each including 100 seeds. Results showed that the weight of thousand seed were between 0.067 and 0.142 g and their emergences were between 21 and 45 days. The longest emergence time was seen in *R. caucasicum* species having the *s*mallest seed while the shortest emergence time was seen in *R. luteum* having the heaviest seed weight. There was a positive correlation between the particular size of seed and emergence rate. The emergence rate was determined as between 55.50-78.50 %. To conclude, the emergence results evidenced the possibility of propagate Rhododendron species from their seeds.

Keywords: *Rhododendron*, seed sowing, seed weight, seed emergence

Introduction

Being rich in diversity of plants, Turkey flora includes rhododendrons. Rhododendrons belonging to Ericaceae family, with having 1.000 natural species, are defined as evergreen or deciduous shrub and rarely in the form of small tree (Küçük, 2005). In many countries, Rhododendrons have been popularly used as outdoor arrangements and potted plants because of their ornamental traits. These plants have become important ornamental plant due to their flower colors, plant forms and leaf structure (Nelson, 2000). Rhododendrons have never lost their actuality since the date of firstly diagnosing, and the attentions of researchers have been still on them. Their distribution in our country and in the world has been studied by many researchers and still ongoing (Stewens, 1978; Oh et al., 2000; Choo and Kim 2005; Cullen, 2005; Boratyn's et al., 2006; Mao and Gogoi, 2007; Veteas et al., 2007; Sigdel, 2008; Gao et al., 2008; Ashish et al., 2010; Altun, 2011). Although the most of the species of rhododendron have distributed in the northern hemisphere, some species have grown in South hemisphere, especially in Mountain Carstensz, Papua New Guinea and Bellenden Ker Mountain in Australia (Avcı, 2004). In Turkey, rhododendrons are seen along the whole Black Sea coast, starting from the east of Artvin province, spreading overlooking site of mountain to the Black Sea, to Istıranca Mountains. Eastern Black Sea contains the intensive species diversity of rhododendrons.

Two species (R. ponticum L. and R. luteum Sweet.) of rhododendron are present outside of the Black Sea region. These species were determined intensively in Marmara region, Sakarya and Kocaeli provinces and in small populations found in Bursa (Iznik), Yalova, Istanbul and Kırklareli provinces. Also, two small populations of R. luteum Sweet species, being away from

each other, were found in the southern slopes of the Kaz Dagı in Canakkale (Stewens, 1978; Altun et al., 2016).

Aesthetic beauty of rhododendrons has let them to use in landscape design for "aesthetic" and "functional" purposes rather than other goals. Many rhododendrons cultivars which improved by breeding have been recently used in Urban landscape planning, beside of natural cultivated rhododendrons species (Harrison and Jenny, 1997; Pulatkan, 2001). Nowadays, the use of natural species has become more popular than the standard commercial ornamental plants. In this context, most of the natural plants could not been transferred from originated locations to city center because of limited knowledge of production and propagation methods. Therefore, in this preliminary study, the emergence rates of seeds in rhododendrons species were investigated to determine whether it will be a candidate ornamental plant in Turkey, as intensively used in many other countries.

Materials and methods

The seeds were collected from 5 rhododendrons species (*R. ponticum* L., *R. luteum* Sweet, *R. caucasicum* Pallas, *R. smirnovi* Trautv. and *R. ungerni* Trautv.) in Turkey flora, as experimental material. Capsules were harvested before scattering and fully opening capsules when they become brown color. Then, samples were placed to clean and dry cloth labelled bags and transferred to experimental area in Black Sea Agricultural Research Institute (Samsun, Turkey). Seed capsules were placed in large plates in a dry place at room conditions until when the capsules are fully opened. Seeds from opened capsules were extracted and ready for sowing. In order to determine the weight of 1.000 seeds, three series of 1000 the seeds were counted and weighed with precision glass scales. Also photographed on graph paper and binoculars in the seed and created an archive.

Seeds were sowed in acidic filled with foam containers peat on the surface (Güngör et al., 2002) in randomized plot trial with 4 replications each contained 100 seeds in mist propagation conditioned room. After sowing, the emergence of seeds were counted by using a magnifying glass for 7-d intervals until the reaching of the same seedlings number for consecutive counting. Then, emergence values were calculated as percentage based on the number of seeds at the beginning of sowing. The Randomized Complete Block Design were used with 4 replications and 100 seeds in each replication. The percent data transformed using $\arcsin\sqrt{x}$ transformation and statistical analyses applied to these data.

Results and Discussion

In the present study, it was aimed to determine 1000-seed weight and emergence rate of rhododendrons in Turkey. The results are given in Table 1 and Figure 1. The determined 1000-seed weight was found out between 0.142 g and 0.067 g (Table 1).

Table 1. Rhododendrons 1000 seeds weight

Species	Mean (g)
Rhododendron ponticum L.	0.073
Rhododendron luteum Sweet	0.142
Rhododendron smirnovii Trautv.	0.076
Rhododendron ungernii Trautv.	0.071
Rhododendron caucasicum Pallas	0.067

The means of 1000-seed weights were determined as 0.073 g, 0.142 g, 0.076 g, 0.071 g and 0.067 g in *R. ponticum*, *R. luteum*, *R. smirnovi*, *R. ungerni* and *R. caucasicum*, respectively. Czekalski (1998) determined 1000-seed weights of rhododendron species grown in Riga Botonik Garden (Latvia) and found out that these weights were 0.078 g for *R. caucasicum* and 0.105 g for white-flowered *R. ponticum*. These findings are not in line our findings on 1000-seeed weights. This is, more likely, due to the condition of the seed is taken from the botanical gardens. On the literature, it can be come across the least 1000-seed weight as evidenced by Var and Dinçer (2006)'s finding 0.0081 g for *R. ponticum*.

Emerging rates (%) were subjected to arcsin$\sqrt{x}$ transformation before statistically analyzed (Table 2). Analyses showed that there was significant difference between species with respect to emerging rate (Table 3, $P<0.01$). The means were compared with Duncan Multiple Range Test (JUMP, 7.00). The earliest emergence incidence was obtained on 21st day after sowing for R.luteum seeds while the latest emergence was obtained 45th day after sowing for *R. ungerni* and *R caucasicum* seeds. The highest emergence rate was found as 78.50%, in *R. ponticum* scenes while with the lowest rate was 55.50% in *R. caucasicum* species (Figure 1).

Table 2. Analysis of Variance

Source	DF	Mean Square

Table 3.Rhododendrons seed emergence values (%)

Species	*R. poticum*	*R. luteum*	*R. smirnovii*	*R. ungernii*	*R. caucasicum*
Means (%)	78.50 a	76.00 a	64.75 ab	57.25 b	55.50 b

LSD Value (P<0.05) 13,98

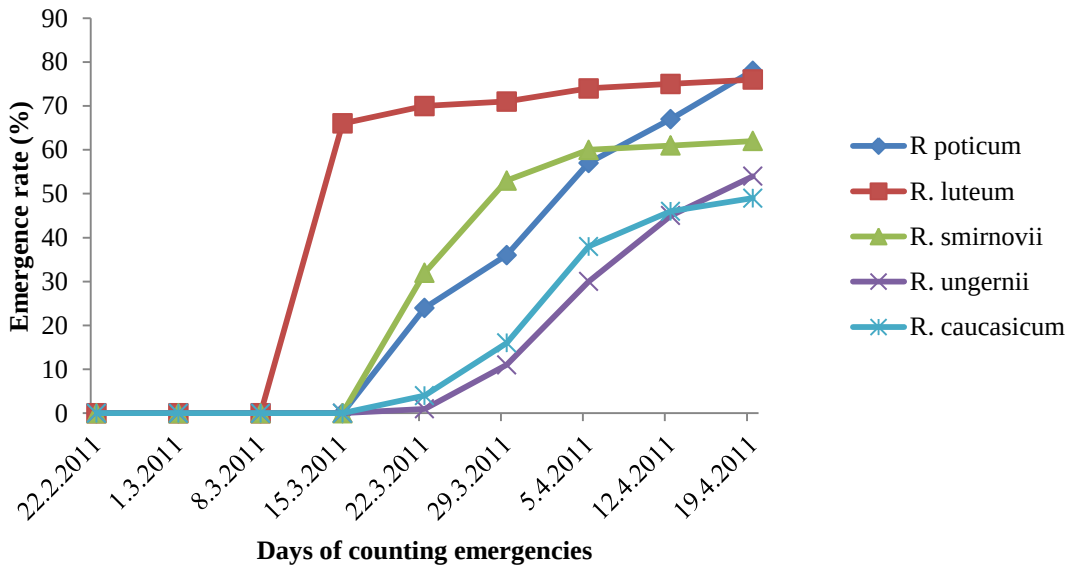

Figure 1.Weekly emerging rates of seeds of Rhododendron species

In the present experiment, it was determined the emergence time as 30 days after sowing of *R. ponticum* ve *R. smirnovii* seeds. Similarly, in the study of Sekergider (2002), this emergence time was 28 days in *R. ponticum* and *R. luteum*, agreeing with the current finding *for R. ponticum* ve *R. smirnovii* seeds. Zhang et al. (2006) sowed 5 rhododendron subgenus seeds in early May and found out Pentanthera seeds from these subgenus gave the highest seed germination rate. When *R. luteum* Sweet's thought to be involved in these subgenera, their finding is in line with our finding. In the present study, the highest emergence rate was determined in the seeds of *R. ponticum* L. (78.5%), followed by *R. luteum* Sweet (76.00%), *R. smirnov*i Trautv. (64.75%), *R. Urgerni* Trautv. (57.25%), and *R. caucasicum* Pallas, which gave the lowest emergence rate (55.50%). Sakharova (1993) obtained 71.00% emergence in *R. luteum* Sweet. This result was supported by our finding on *R. luteum* Sweet. Czekalski (1998) collected *R. smirnovi* Trautv seeds from nature and obtained 80.00-85.00% emergence rate 12-15 days after sowing. He, also, obtained germination in *R. ungerni* Trautv seeds 19-22 days after sowing. The present findings were lower than his results. This difference may be attributed to the difference between rootstock plants, sowing times, ambient temperature.

According to the study carried out by Cherevko and Sapozhenkov (1975), freshly sowed *R. kotschyi* Simonka seeds gave lower emergence rates 6.00-12.00%. When these seeds were sowed after 8-11 months waiting, emergence was found as between 30.00-43.00%. However, these higher rates were reduced when 4-5 years old seed used, because of losing its liability. Rhododendrons seeds require light for germination. Because of this, seed are sowed on the surface of medium to be emerged easily. However, only light is not sufficient for germination. The success in seed germination in Rhododendrons are dependent upon year (air), seed collection time, ambient temperature and pH (Sakharova, 1993). Blazich et al. (1991) investigated the effect of photoperiod on germination of *R. catawbiense* Michaux and *R. maximum* L. seeds in different temperatures. They found out 64% germination rate on 30th day after sowing in control, and 95 % germination rate on 15th day after sowing in 0.5-12 hours photoperiod treatment. Jin et al. (2007) reported that media is very important factor on seed germination. The optimum temperature for the germination of Rhododendrons seed was 16 - 20 ° C according to the study of

Zhang et al. (2006). Also they stated that the ideal environment was topsoil seed + seaweed mixture for germination. Vologdina (2006) collected seeds from natural populations of *R. dauricum* L., *R. mucronulatum* Turcz. ve *R. sichotense* Pojark found out that their seeds were sensitive to lighting and germinated about 73.00-90% in 20-23 °C ambient temperature.

In conclusion, Rhododendron species can be propagate by their seed although these species were different in each other with respect to seed weight, germination time and rate. For ornamental design, *Rhododendron ponticum* L. *and Rhododendron luteum* Sweet species will be suggested because of their higher emergence rates.

Abstract

Maize grains contain a high level of *β*-carotene and tocopherols. This research was performed to estimate differences in tocopherols (*α-, β + γ-, δ-*), *β*-carotene, zeaxantin and lutein content in thirty maize populations from the MRI gene bank by using high-performance liquid chromatography (HPLC). Among the genotypes, variation was observed in the traits of interest: *α*-tocopherol content was higher in the introduced than in the local populations. The local populations showed a higher concentration of lutein (1.50-15.94µgg^{-1}) than the introduced populations (1.24-6.79µgg^{-1}). The content of *β*-carotene ranged from 0.55 to 4.80 µg g^{-1}in the local populations and from 0.26 to 7.95 µgg-1 in the introduced populations. The zeaxantin content was higher in the introduced (0.48 to 40.86µgg^{-1}) than in the local populations (1.51 to 30.05µgg^{-1}). The population 25 with orange kernels had a high level of zeaxantin, *β*-carotene and tocopherols. That population is used for improvement of tocopherol and carotene content in inbred lines. The population was crossed with 5 inbred lines during 2015. *β*-carotene content in the inbreds ranged from 0.47 to 2.98µgg^{-1}, and in the crosses from 3.22 to 16.48µgg^{-1}. Furthermore, the content of tocopherols was higher in the crosses than in the inbred lines per se. This population could be used in future breeding programs for improving the nutritive value of commercial inbred lines.

Keywords: *maize, population, tocopherols, carotene*

Introduction

In addition to protein, oil and carotenoid, tocopherol content has been a focus of modern agriculture. Pigmented maize has received increased attention from a nutraceutical perspective because it contains several bioactive phytochemicals such as carotenoids, tocopherols, phytic acid and phenolic compounds (Bacchetti *et al.*, 2013). Carotenoids (provitamin A) and tocopherols (vitamin E) are lipid soluble antioxidants occur naturally in maize. Maize kernel is a major component in diets of humans and animals, and may have added value with increased content of carotenoids and tocopherols. Two classes of carotenoid pigments are carotenes and xanthophylls, which are responsible for the yellow and orange color of maize endosperm. Yellow maize kernels contain several carotenoid isoforms, including two carotenes-α and *β*-carotene and three xanthophylls—β cryptoxanthin, zeaxanthin, and lutein. *β*-carotene is present in the highest concentration, while either lutein or zeaxanthin is the most prevalent form of the xanthophylls. Daood *et al*. (2003) estimate genetic variation among the different types of maize on the basis of carotenoid content and found that lutein and zeaxanthin were the dominant carotenoids. Harjes *et al*. (2008) and Hulsof *et al*. (2007) reported a range of 55.5-66mg g^{-1} and 9.90-39.96mg g^{-1} respectively for carotenoids in maize kernel. According to Safawo *et al.* (2010) grain color and

carotenoid content showed the low correlation between visual grain colour and total carotenoids R2= 0.184, β -carotene R2=0.033 , in diverse inbreds.
Tocopherols are the major lipid-soluble antioxidants in maize grain. Vitamin E antioxidant activity order is as follow: α –Tocopherol > β – Tocopherol > γ – Tocopherol > δ – Tocopherol . α-tocopherol is the major vitamin E in nearly all green plants, in non-green plant parts, such as seeds and fruits, where γ-tocopherol is preferentially found (Matea *et al*., 2008).
Maize kernels have low α -tocopherol content, the compound with the highest vitamin E activity, thus, raising the risk of vitamin E deficiency in human populations relying on maize as their primary vitamin E source. Several studies have shown significant differences among maize inbreds for carotenoid and tocopherol levels (Egesel, 2001).
The study was conducted to identify carotenoids and tocopherol content in maize grain in localy adapted and introduced populations.

Material and methods

Carotenoids and tochopherol content in maize grains were studied on thirty accessions from MRIZP gene bank, 15 local and 15 introduced populations (Table 1).

Table 1. Color and type of kernal for local and introduced populations

15	yellow	semi flint	30	orange	flint

Maize grains were milled (Perten 120, Sweden) into flour (particle size < 500μm) to obtain greater surface contact, and stored at -20˚C prior to analysis.
Carotenoids were extracted according to the slightly modificated method proposed by Rivera *et al.* (2012). Briefly, 0.15 g of the grain maize sample was extracted twice with 5 mL of mixture methanol-ethyl actetate (6:4, v/v) for 30 min at ambient room conditions. Collected extracts after centrifugation (3000 rpm, for 5 min) were evaporated under the stream of nitrogen to the dryness, and redissolved in 1mL of the mobile phase. Afterwards, extracts were filtered through syringe filter and analyzed by Dionex UltiMate 3000 liquid chromatography system (Thermo Scientific,Germany) fitted with photodiode array detector (DAD–3000) analytical column, Acclaim Polar Advantage II, C18 (150 × 4.6mm, 3μm). Mixture of methanol-acetonitrile, (90:10,

v/v) was used as mobile phase. The flow rate was 1.0mL/min, temperature of column was set at 25 ºC and the injection volume was 50µL. Chromatograms were generated at 450nm and 470nm. Carotenoids were identified and quantified by comparing characteristic retention time of appropriate standards, and expressed as micrograms per gram of dry matter.

Tocopherols (α-, γ+ *β*- and δ) were extracted by method proposed by Gliszczyńska-Świgło *et al*. (2007) with minor modification. Approximately 0.2g of sample was mixed with 2-propanol (4mL) and homogenised for 30 min at room temperature. The extracts were then centrifuged at 3000 rpm for 5min, filtered through a 0.45µm membrane filter and a aliquot of clear supernatant was directly injected into the Dionex UltiMate 3000 liquid chromatography system (Thermo Scientific, Germany) equipped with fluorescence detector (FLD–3100). Chromatographic separation of tocopherols was accomplished on analytical column, Acclaim Polar Advantage II, C18 (150 × 4.6mm, 3µm) operated at 30ºC. Mixture of acetonitrile and methanol (1:1, v/v) was used as a mobile phase at flow rate of 1 mL/min. Injection volume was 5µL, while the wavelengths for excitation and emission were maintained at 290 nm and 325 nm, respectively. Tocopherols were identified, and quantified comparing characteristic retention time of corresponding standards. The tocopherols content is expressed as micrograms per gram dry matter.

Carotenoids standards (lutein, zeaxanthin and *β*-carotene) and tocopherols standards (α-, γ- and δ), were from Sigma Aldrich (Germany).

Results and disscussion

Maize displays considerable natural variation for carotenoid and tocopherols content. The carotenoid in population with white kernel (sample 22), was not detected. White kernel maize lacks carotenoids due to the presence of recessive *y1* (non-functional *phytoene synthase1*) in homozygous state, which are involved in biosynthetic pathways of carotenoids. In addition, yellow kernel maize exhibits tremendous natural variation for both provitamin A (α-carotene, β-carotene and β-cryptoxanthin) and non-provitamin A (lutein and zeaxanthin) carotenoids. The local populations showed a higher concentration of lutein (1.50-15.94µgg^{-1}, average 7.64µgg^{-1}) than the introduced population (1.24-6.79µgg^{-1}, average 2.99µgg^{-1}). The zeaxantin content was higher in the introduced (0.48 to 40.86µgg^{-1}, average 11,79µgg^{-1}) than in the local populations (1.51 to 30.05µgg^{-1}, average 8.95µgg^{-1}). Population 18 has the highest zeaxantin content (40,86µgg^{-1}) among introduced and population 5 (30.05µgg^{-1}) among local populations. Local populations have average content of β carotene 2,39µgg^{-1} and introduced populations 3.39µg g^{-1}. Population 25 has the highest β carotene content (7.95µg g^{-1}) and population 30 the lowest one (0.265µgg^{-1}). In breeding program for high carotenes maze lines, Safawo *et a*l.(2010) have also determined high variation in β-carotene in maize grains. Vignesh *et al*. (2015) found wide genetic variation for lutein (0.36–15.75µgg^{-1}), zeaxanthin (0.25–22.76µgg^{-1}), and β-carotene (0.07–17.41µgg^{-1}) in 48 diverse maize inbreds. Allelic variations and dosage effects may be responsible for the wide range of variability for carotenoids in yellow maize (Chander *et al.*, 2008) . High level of β - carotene was observed in populations 25, 24, and 27 and they would be used in the breeding programs to enhance the β – carotene contents.

Table 2. Content of carotenoids in thirty maize populations

Local populations				Introduced populations

11	7,0309	3,1291	1,3083	26	1,7367	10,4042	5,0878
12	7,3521	1,8726	4,0707	27	2,9967	4,4766	5,5234
13	15,4930	10,3772	4,7908	28	2,1937	7,1380	1,4940
14	3,7678	2,2809	0,7387	29	2,1976	9,2825	1,1428
15	14,4811	7,8641	2,0403	30	3,7987	3,8602	0,2646
Average	7,6377	8,9514	2,3875	Average	2,9095	11,1678	3,0617

Average content of α tocopherol was higher in introducted (5.78μgg^{-1}) than in local populations (4.59μgg^{-1}) but local populations have higher content of γ tocopherol (25.23μg g^{-1}) than introduced populations (20.66μgg^{-1}). Content of α tocopherol varied from 1.043 to 7.93 μgg^{-1} for local, and from 1.99μgg^{-1} to 27.20μgg^{-1} in introduced populations. γ tocopherol content range from 13.25μgg^{-1} to 37.27μgg^{-1} for local, and from 14.22μgg^{-1} to 37.56μgg^{-1} for introduced populations (Table 3). The local population 12 have high α and γ tocopherol content as well as introduced population 25. Tocopherol levels in maize kernels vary widely, however, α-tocopherols constitutes less than 20% of total in maize kernels (Rocheford, 2002).

The population 25 with orange kernels had a high level of zeaxantin, *β*-carotene and tocopherols. That population is used for improvement of tocopherol and carotene content in inbred lines. The population was crossed with 5 inbred lines during 2015. *β*-carotene content in the inbreds ranged from 0.47 to 2.98μgg^{-1}, and in the crosses from 3.22 to 16.48μgg^{-1}. Furthermore, the content of tocopherols was higher in the crosses than in the inbred lines *per se* (Anđelković *et al*., 2016).

Conclusions

Variability for carotenoides and tocopherols in grain of 15 local and 15 introduced maize populations was determined. The population 18 had the highest concentration of zeaxanthin and local population 9 of lutein. The β – carotene and zeaxantin content were higher in introduced populations with orange kernal. The local population 12 and introduced population 25 with high α and γ tocopherol content could be used in further breeding program for improving the nutritive value of commercial inbred lines.

MEDİCİNAL AND AROMATİC PLANT POTENTİAL OF RİZE/TURKEY

Fatih SEYİS*, Yusuf ŞAVŞATLI, Emine YURTERİ, Aysel ÖZCAN

Field Crops Department, Faculty of Agriculture and Natural Sciences, Recep Tayyip Erdogan University, Rize, Turkey
*corresponding author: fatih.seyis@erdogan.edu.tr

Abstract

Rize has a different and special flora because of its geographical position, climate, and topography. The natural plants of Rize have a very big usage potential and value in some sort of industrial branches. In particular, the different activity traits of natural plant oils and extracts have formed the basis of many applications, including raw and processed food preservation, pharmaceuticals, alternative medicine and natural therapies. Rize is located in the northeast Anatolia to the east of coastline of Eastern Black Sea between 40^{o} 22' and 41 ^{o} 28' meridians east and 40 ^{o} 20' and 41 ^{o} 20' parallels of latitude north. Rize is surrounded by District of Trabzon in the west, İspir District of Erzurum in the south, Yusufeli District and Arhavi District of Artvin in the east and Black Sea in the north. It covers an area of 3,920 km2 except lakes. It has a mountainous and rugged terrain. Rize region is highly rich in terms of forested land and plant species diversity. This study gives brief information about medicinal and aromatic plant species in Rize. Our statement is that plants, which are grown naturally in our province represent a potential source of abundance, should be utilized for medical and economic purposes, and also researched for more potential uses in medicine and pharmacy.

Keywords: *medicinal and aromatic plants, Rize*

.

Introduction

Turkey is one of the countries with richest plant diversity in the Mediterranean (Davis 1965-1986; Davis *et al*., 1988; Guner *et al*., 2001). A number of human races and tribes have settled here during different periods bringing in different cultures and customs. As a result of this we
come across a great accumulation of knowledge of traditional medicine in the country. A recent survey of traditional and folk medicine in Turkey has revealed that most of these plants are still in use by the local inhabitants (Yesilada and Sezik, 2003).

Turkey is located in three biogeographical regions: Anatolian, Mediterranean, the Black Sea region, and their transition zones. Its climatic and geographical features change within short intervals of space due to the country's position – a bridge between two continents. Thanks to its location, Turkey's biological diversity can be compared to that of a small continent: the country's territory consists of forests, mountains, steppe, wetlands, coastal and marine ecosystems and different forms and combinations of these systems. This extraordinary ecosystem and habitat diversity has produced considerable species diversity (Kahraman *et al*., 2011; Kahraman *et al*., 2012). Regarding biodiversity the Black Sea region belongs to one of the richest regions of Turkey. Totally 2239 species are present in the East Black Sea region, 514 of them are endemic and the endemism ratio is ca. 23 %. More than half of the plants distributed at the East Black Sea region are present in the Rize province. 70 % of the plants are of medicinal and aromatic value.

Plant diversity in Rize

Floristic studies carried out in Rize revealed that 2239 species diversity and 222 endemic plant taxons are presnet in this province (Anşin, 1980). Regarding species diversity Rize is one of the

richest provinces inTurkey. İn an TUBİTAK founded project 1430 different plant species and 110 endemic plant species were detected in Rize. 15 of this species were new records for the Turkish flora, 4 were new records were new for the world fauna (Güner *et al*., 1987). Therefore this region displays rich biological diversity.

Medicinal and Aromatic Plants in Rize

Because Turkey is located in a region of three crossing floristic regions it displays a rich plant diversity. One of this locations is the Rize province at the East Black Sea region. There are citations that about medicinal and aromatic plants are present in this region but the correct number is still unknown (Gül, 2014). Birinci (2008) stated that 117 plants are used for medicinal and aromatic purposes. Yaldız et al. (2010) pointed out that farmers in Rize have knowledge only about the production of lime tree, black sesame, chili pepper, cumin, cinnamon, hibiscus, mint, pepper, green tea and ginger; the study revealed that the same farmers had no knowledge about other medicinal and aromatic plants.

Studies investigating the province rize grouped the present plant species. Akbulut (2013) seperated the species according tp their ethnobotanical features: plants fopr medicinal uses, plants used as food, plants used in animal healig and fodder, plants used as spice and tea, plants used for firing nad plnats used for different purposes. Further, Yaldız (2010) grouped traded and natural plants in Rize as natural tea used plants, plants saled for its flowers, plants used as spice, plants used for food, gum and resin obtained plants, plants used in animal healing, plants used as insectisides, plants for paint production and plants used for medicine raw material abroad.

Table 1 illustrates plant species in Rize used for medicinal purposes.

Tabel 1. Plants used for medicinal purposes

Plant name	**Used for**	**Plant name**	**Used for**
Achillea millefolium subsp. *millefolium*	Breath clearing, wounds, haemorrhoid	*Castanea sativa* Mill.	Rough, dropping blood pressure
Alchemilla crinita Buser	Tranquilizer, wound healing,	*Centaurium erythraea* Koth. subsp. *turcicum*	Haemorrhoid
Alnus glutinosa (l.) Gaertn subsp. *barbata* (C.A. Mey.) Yalt	Haemorrhoid, wound cleaning, tummy ache, astringent	*Chelidonium majus* L.	Eczama, acne
Anthemis cotula L.	Gynaecological diseases	*Circium arvense* (L.) Scop. subsp. *vestitum* (Wimmer&Grab.) Petrak	Diabetes
Anthemis tinctoria L. var. pallida DC.	Gynaecological diseases, Difficulty in breathing	*Convolvulus arvensis* L.	Arthralgia
Anthemis vulgaris	Appetising, antifebrile	*Coryllus avellana* subps. *avellana*	Cough
Atropa bella-donna		*Crataegus monnogyna* Jacq. subsp. *monnogyna*	Roborant
Asplenium trichomanes L.	Tummy ache, haemorrhoid	*Cyclamen coum* Miller	Sinusitis
Ballota nigra	Sleeplesness, cough	D*actylorhiza urvilleana* (Steudel) Baumann & Künkele	Roborant
Bellis perennis L.	Cold, diuretic	*Datura stramonium*	Difficulty in breathing, painkiller
Calluna vulgaris (L.) Hull	Cold, cough	*Digitalis ferruginea* L. subsp. *schischkinii* (Ivan) Werner	Urologic problems
Camellia sinensis	Cancer, diarrhea precluison	*Dioscorea communis* (L.) Caddick& Wilkin	Body pain
Carduus acanthoides subps. *sintenisii* Kazmi in Mitt.	Antifebrile, increase in urine	*Diospyros lotus* L.	Gastritis, prevention of diarrhea

Developed using Akbulut (2013), Güner et al. (1987) and Yaldız (2010)

Tabel 1. Plants used for medicinal purposes (continued)

Plant name	**Used for**	**Plant name**	**Used for**
Dryopteris filix-mas (L.) Schott	Tummy ache	*Polygonum persicaria* L.	Haemorrhoid, mouthwash of gingival bleeding
Equisetum arvense L.	Blood purification, urological problems, quinsy	*Rhododendron caucasicum* Pall.	Difficulty in brathing, cancer
Euphorbia L.	Wound, wart	*Rhododendron ponticum* L. *subsp. ponticum*	Headache, eczema
Fagus orientalis Lipsky.	Tummy ache, dropping worms	Rosa canina L.	Diabetes, cold
Ficus carica L. subsp. *carica*	Wart, tootache, chilblain	*Rubinia pseudoacacia* L.	Tranquilizer, stoppage,
Frangula alnus Miller. subsp. *alnus*	Haemorrhoid	*Rubus idaeus* L.	Cancer, eczema
Hedera helix L:	Tummy ache	*Rumex acetosella* L.	İgestive disorders, gingivitis, tummy ache, sinusitis
Helichrysum plicatum DC. subsp. *plicatum*	Dropping kidney sand	*Salvia glutinosa* L.	Wound, burnt
Helleborus orientalis L.	Dropping worms	*Sambucus ebulus* L.	Haemorrhoid, rheumatic pain
Hypericum perforatum L.	Regulating blood pressure, tranquilizer, haemorrhoid	*Sambucus nigra* L.	Haemorrhoid
Hypericum xylosteifolium (Spach) Robson	burnt	*Sanicula europaea* L.	Difficulty in breathing, tummy ache in babys
Juglans regia L.	Diabetes, reducing cholesterol, asthma	*Sedum spurium* M. Bieb.	callosity
Lamium pupureum L. var. *purpureum*	Balancing cholesterol, roborant	*Smilax excelsa* L.	Renewal of brain cells
Laurocerasusofficinalis Roem.	Diabetes, ulcer, kidney diseases, cough	*Solidago virgaurea* L. subsp. *virgaurea*	Body immaflation
Laurus nobilis L.	Reducing cholesterol, flu, cold, tootache, rheumatism	*Stachys arvensis*	Haemorrhoid
Lycopodium clavatum L.	Body irritants	*Stachys macrantha* (C. Koch.) Stearn.	Relief od stomache
Malva sylvestris	Breathing difficulty, antifebrile	*Symphytum asperum* Lepech.	cough
Mentha aquatica L.	Nauseation, gastritis, bad breath	*Panacetum partenium* (L.) Schultz Bip.	Body immaflation
Morus nigra L.	Cancer, reducing blood sugarici	*Taraxacum officinale*	costiveness
Nasturtium officinale R. Br.	Haemorrhoid, prostat diseases, tummy ache	*Thymus pseudopulegioides* Klokov Des.-Shost	Cold, stomache diseases
Origanum vulgare L. subsp. *viride*	Cold	*Tilia rubra* DC. subsp. *caucasica* (Rups.) V. Eng	Diaphoretic, cough, asthma
Oxalis corniculata	costiveness	*Trachystemon orientalis*	İntestine disorders
Picea orientalis (L.) Link	İnflammated wounds	*Tussilago farfara*	Cough, expectorant
Phylitis scolopendrium (L.) Newn.	Haemorrhoid, tummy ache, arteriosclerosis, burnt	*Verbascum thapsus*	cold
Physalis alkekengii L.	Blood pressure, diabetes	*Viscum album*L.	Heart diseases, Haemorrhoid
Phytolocacca americana L.	Painkiller	*Urtica dioica* L.	Cancer,haemorrhoid, rheumatic pain

Developed using Akbulut (2013), Güner et al. (1987) and Yaldız (2010)

İn Table 1 not only herbaceous medicinal plants are listed, also shrubs and trees are present. As can be seen from the Table different plants fromdifferent specieshave widely use in the treatment of different diseases and other aims.
İn Table 2 we can see the plants used as natural tea and spice in the Rize province. Of course, we have to mention black tea (*Camellia sinensis* L.) which is of big economic value fort he local farmers. Plants usage as tea and spice known by local people are listed in this table.

Tabel 2. Plants used as tea and spice

Plant name	**Used for**	**Plant name**	**Used for**
Achillea millefolium	Tea	*Mespilus germanica*	Fruit stew
Angelica sylvestris	Tea	*Origanum vulgare* L.subsp. *viride*	Spice
Buxus sempervirens	Tea	*Physalis alkekengi*	Tea
Calamintha grandiflora	Spice, tea	*Plantago major*	Tea
Camellia sinensis	Tea	*Plantago lanseolata*	Tea
Castanea sativa	Tea	*Primula vulgaris* Huds.	Tea
Daphne glomerata	Spice	*Rhus coriaria*	Spice
Fragaria vesca	Syrup	*Rosa canina*	Tea
Fragaria viridis	Syrup	*Rubus idaeus*	Tea
Galium aperine	Tea	*Salvia glutinosa*	Tea
Hippophae rhamnoides	Tea	*Tanacetum parthenium*	Spice
Humulus lupulus	Tea	*Thymus pseudopulegioides*	Tea, spice
Hypericum perforatum	Tea	*Tilia rubra* subsp. *caucasica*	Tea
Laurocerasus officinalis	Tea	Urtica dioica	Tea
Matricaria camomilla	Tea	Vaccinium myrtillus	Tea
Mentha aquatica	Spice	Vaccinium vitisidea	Tea
Mentha longifolia	Tea, spice	Verbadcum thapsus	Tea
Mentah piperita	Tea, spice		

Developed using Akbulut (2013), Güner et al. (1987) and Yaldız (2010)

Of course the number of medicinal and aromatic palnst are not restricted with the listed plant species. More research is necessary to cover all potential plants in a whole survey. Furthermore chemical analysis is needed to determine the compounds in investigated species
İn areas where agricultural land are limited is it necessary to detect medicinal and aromatic plants for employment increase. The nexty step has to be the introduction of plants with high economical value to local farmers, to develop an sustainable plant collection strategy and the education of farmers regarding medicinal and aromatic plants.
İf these steps are handled accurately and with correct marketing strategies based on market demand local farmers will get higher economical income and many socail benefits.

Conclusion

Almost all people living in rural areas are engaged in agriculture which plays a key role in rural development. For this reason, arrangements in crop planning and marketing and sales are extremely important. While making arrangements, the regional priorities and the climatic data should be considered and alternative agricultural crops must be recommended. Additionally, agricultural production and quality should be ameliorated and the living standards of people living in rural areas should be improved by using new agricultural production techniques (Samet and Cikilli, 2015).
Medicinal and aromatic plants are of big importance for additive plant production Rize. Rize contains very rich natural resources. Therefore detailed ethno pharmacological and botanical

research is necessary to find out the other herb families and species of economic value beside determined ones.

Many endemic and endangered species are still collecting and selling by local people. These activities could bring some profits to the local people but also dangers many endemic species and prevents the sustainability (Toksoyet al., 2008).

Current political and economical practices could not obstruct the incorrect usage of the natural resources. Some suggestions from determined results are given below, to provide the sustainability and manageability of the natural herb resources (Toksoy, 2010).

i. The herb collecting from the nature, (used domestically or for exportation) must be regularly and sustainable. Institutional and educational studies must be increased.

ii. Production and marketing activities have to be coordinated with the global markets and needs

iii. Blacksea region has very rich natural herb resources, but the people don't have enough information about these resources. This deficiency must be eliminated with right methods, like education activities.

iv. The need of scientific researches is very high. It is highly recommendable to making botanical and pharmacological researches.

THE DETERMINATION OF SOME MEDICINAL PROPERTIES OF BERMUDAGRASS, WHITE CLOVER AND BUCKWHEAT USING AS FORAGE CROPS

Nur KOC, Sadiye Ayse CELIK, Ramazan ACAR, Yuksel KAN

Department of Field Crops, Selcuk University, Selcuklu, Konya, Turkey
Corresponding author: nurkoc@selcuk.edu.tr

Abstract

The plants of *Cynodon dactylon* (L) Pers, *Trifolium repens* L, and *Fagopyrum esculentum* Moench, which have vegetable properties such as their being able to use erosion control plant and soil improving plant, due to pollution in resources, which increases in the recent years in the world, are considered as forage plants not only for breeding but also in terms of sustainability. In addition, bermudagrass, white clover, and buckwheat, due to important effective substances (respectively, vitexin, quercetin, myricetin and rutin) they have, are used in the traditional medicine in the different places of the world. Therefore, in our study carried out as three repeated pot trial in greenhouse conditions, these three species of plants were grown in such a way that there will be five plants in each pot. In our study, bermudagrass and white clover, were mowed in 130 days after seeding; buckwheat, in 50th days when flowering of 10 % occurred. After the heights and wet weights of plants are determined, the plants mowed were dried at shadow and their wet weights, and ash, moisture, antioxidant activity, total phenol, and total flavonoid contents were identified. It was detected antioxidant activity, total phenols and total flavonoids using by spectrometer as a method DPPH free radical scavenging activity. As a result of trial we carried out, in buckwheat and bermudagrass, while antioxidant activity and total flavonoids are high, in white clover, total phenol was found high. In this study, the similarities and differences of three plants in terms of medical use were tried to be interpreted.

Keywords: Bermudagrass (*Cynodon dactylon* L. Pers.), Buckwheat (*Fagopyrum esculentum* Moench), Forage crops, Medicinal plant, White clover (*Trifolium repens* L.)

Introduction

In the today's world, when a high quality fodder plant is mentioned about, the features such as becoming preferable by animal i.e. flavor, chemical composition and digestibility of plant firstly come into mind. In short, that a fodder plant gives a rise to increase in yield values of animals such as live weight, and amount of milk and wool shows that it is high quality fodder (Yavuz et al., 2009). However, the values such as raw protein, raw oil, raw fiber, carbohydrate are metabolites used in plants, it should not be forgotten that secondary metabolites are also synthesized in every plant.

Although the amount of secondary metabolites synthesized by plants is less, the importance of defense mechanism of plants in pollination is considerably high. In addition, they are relatively important substances for human health in terms of features of providing flavor, odor, and color in human food and of being a medical raw material (Verpoorte and Memelink, 2002). Besides that they are important to human health, in addition to the features such as odor and flavor provided by plant about the preferences of animals as fodder, with their features such

as development of rumen ecosystem of extracts of plants, its increasing the affectivity of rumen mechanism, and promoting or inhibiting the secretion of some hormones in animals, it should not be forgotten that they are important to animal health (Greathead, 2003). Therefore, while the issue of being preferred of a fodder plant by animals are dealt with, it is also necessary to deal with the importance of secondary metabolites. Especially this issue, for the reasons such as the increasingly pollution and decrease of resources in the world, as a result of gradually limitations of agriculture, is considerably important about knowing the effects of fodder plants, which we can use to eliminate the needs of animals for fodder, on animal health.
We used in the study the fodder plants of bermudagrass, white clover, and buckwheat, have botanical features such as their being able to be used as erosion control plant and soil improving plant. And these plants are used in the traditional medicine in the different regions of the world with the secondary metabolites (vitexin, quercetin, myricetin, and rutin, respectively) (Babu et al., 2009; Schittko et al 1999, Kreft et al 2006). It is known buckwheat is a good fodder plant and a good medical plant with its rutin content it has. White clover is used in the traditional medicine for treatment of diseases such as rheumatic disorder, deworming remedy, sore throat, fever, pneumonia, meningitis, etc. (Kolodziejczyk-Czepas, 2012). Bermudagrass can be used in traditional medicine as anti-inflammatory, diuretic, antiemetic, antidiabetic and blood-purifying agent (Rai et al 2010). Therefore, in order to identify the medical features of these three fodder plants, in the study, their activities of total phenol, total flavonoids, and antioxidant activities were determined.

Materials and methods

This research was carried out during February and June 2016 in Breeding Greenhouse of the Department of Field Plants, Faculty of Agriculture, Selcuk University. The populations of bermudagrass, white clover and buckwheat were used as a material for this research. In this study, designed as three repeated according to Test Design of Random Parcels, the plants were grown in the pots in the dimensions of 16x16 cm. Seeding was made in such a way that there will be five plants in each pot. In the trial, the cutting was made when each plant was flowered by 10%. While buckwheat was cut after 50 days from seeding, bermudagrass and white clover were cut after 130 days from seeding in such a way that it will be from root collar.
Also, plant height (cm), fresh weight (g), and dry weight (g) were identified. It was determined dry matter (%), moisture content (%) of these plants by using moisture analyzers. After moisture content (%) had been found in moisture analyzers, dry matter (%) was calculated. For finding the ash %, these plant samples were weighted, firstly. Then, these samples were burned at 8 hours in temperature 600˚C in ash oven. The samples taken out from ash oven were weighted, and ash content % was calculated by the following formulas.

$$Ash\ \% = \frac{[(Crucible\ Weigh + Ash) - Crucible\ Tare]}{[(Crucible\ Weigh + Sample\ Weigh) - Kroze\ Tare\ ]} * 100$$

Determination of Antioxidant Activity in Extracts

2,2-Diphenil -1-picrihydrasile (DPPH) Determination of free radical scavenger

The stable 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activity was determined by the method of Blois (1958). DPPH free radical scavenger activity of extracts was determined by spectrophotometrically measuring transformation from dark violet color into light yellow color in UV visible region in wave length of 517 nm against the radical of 2.2 –diphenyle, 1,2-

picrilhydrasile (DPPH) (Sigma-Aldrich Chemie, Steinheim, Germany). Of the extracts we have prepared, the necessary amounts of DPPH stock solutions of 250 µg/ml, 500 µg/ml and 1000 µg/ml were weighed in such a way that there would be in the concentration of $6x10^{-5}$mol/l solved in ethanol (75%). Taking 300 µl of each sample by means of micropipette into test tubes, 2700 µl of DPPH solution was added onto them. Then, tubes were kept for 20 minutes at dark at room temperature. At the end of the time, absorbance of samples was read on spectrophotometer (Agilent Technologies UV-Visible spectrophotometer, Germany) against ethanol used as blind at the wave length of 517 nm. % inhibitions of samples against DPPH free radical of samples were calculated according to the formulas given below. Each sample was treated in three parallel works and % scavenger effects of the results were statistically examined.

$$\text{Inhibition \%} = [(A1 - A2) / A1] \times 100$$

A1 = Absorbance of DPPH stock solution at the wave length of 517 nm.
A2 = Absorbance of DPPH sample solution at the wave length of 517 nm.

Determination of total phenolic and flavonoid contents in the extracts

For determining total content of phenol, method of Folin-Ciocalteau, modified by Singleton and Rossi (1965), was used. In brief, some dilutions of gallic acid (50– 500µgmL−1) were obtained to prepare a calibration curve. The extracts and gallic acid dilutions diluted in ethanol (75%) were mixed with 750µL of Folin –Ciocalteau's reagent and 600µL of sodium carbonate in test tubes. The tubes were then vortexed and incubated at 40°C for 30min. Afterward, absorption was measured at 760 nm at a Unico 4802 UV–visible double beam spectrophotometer (Dayton, NJ, USA). The total flavonoid content of the extracts was established by aluminum chloride colorimetric method (Woisky and Salatino, 1998). To sum up, some dilutions of quercetin (50–500µgmL−1) were obtained to prepare a calibration curve. Then, the extracts and quercetin dilutions were mixed with ethanol (75%), aluminum chloride reagent, 0.1mL of sodium acetate as well as distilled water. Following incubation for 30 min at room temperature, the absorbance of the reaction mixtures was measured at a wavelength of 415 nm with a Unico 4802 UV–visible double beam spectrophotometer (Dayton, NJ, USA). The total phenol and flavonoid contents of the extracts were expressed as Gallic acid and quercetin equivalents (mgg−1 extract), respectively.

Results and discussion

In this study we have carried out to determine the medical features of three sorts of fodder plant, while the values obtained related to the height, wet weight, dry weight, rate of wet weight/dry matter, ash content, and moisture of the plant are presented in Table 1, the results of antioxidant activity, total phenol, and total flavonoids were given in Table 2.

Table 1. Average values of the plant height, fresh weight, dry weight, dry matter, ash content, and moisture content of the plant obtained from three sorts of plant

Plants	Plant Height (cm)	Fresh Weight (g)	Dry Weight (g)	Dry Matter (%)	Ash (%)	Moisture Content (%)
White Clover	13,78	0,98	0,50	91,41	12,87	8,59
Buckwheat	45,11	2,36	0,64	92,20	14,59	7,80
Bermudagrass	38,44	2,27	0,81	91,04	6,86	8,96

Table 2. Antioxidant activity, total phenols and total flavonoids of white clover, buckwheat, and bermudagrass

Plants	DPPH (% free radical scavenging activity)	Total Phenols (mg/g GAE)	Total Flavonoids (mg/g KE)
White Clover	22,949	14,91	1,026
	23,029	14,92	1,024
	23,016	14,96	1,024
Buckwheat	79,343	9,515	2,032
	79,397	9,514	2,033
	79,330	9,513	2,000
Bermudagrass	71,957	8.251	1,318
	71,971	8,305	1,320
	72,131	8,257	1,319

As a result of the trial we have carried out, while in terms of plant height, buckwheat was found as the longest plant, it was followed by bermudagrass, and white clover, respectively. While the plant height of white clover, and bermudagrass, obtained in the trial, showed the similar results to Vahdati et al (2012), FAO (2012) and Anonymous (2016), the plant height of buckwheat showed difference with Guzelsarı (2016). When fresh weight was examined, while the plant of buckwheat was the heaviest, it was followed by the plants of and bermudagrass, and white clover. When regarded to fresh weight examined in the trial, while buckwheat showed similarity to Park (1995), in the studies carried out, it was found that Nazarı et al 2014 and Vahdati et al 2012) showed difference. In terms of rate of dry matter, the rate of dry matter of buckwheat is high and the other two of them is the same. The rate of dry matter, obtained in the study we have carried out, it was identified that the other two, except for white clover (Anonymous 2016), were the same as the other studies carried out (Anonymous 2016, Campell 1997). When ash % they contain was examined, while buckwheat had the highest ash content, bermudagrass, had the least ash content. It was identified that ash content %, other than white clover. (Anonymous 2016), in the studies carried out was different from the other two plants (Anonymous 2016, Guzelsarı 2016). In terms of moisture content %, bermudagrass, and white clover is the same, moisture content buckwheat is the lowest. While the average values we have taken related to moisture content % is the same as the studies on bermudagrass (Anonymous 2016), it was identified that those of buckwheat and white clover were different from the other studies (Guzelsarı 2016,Anonymous 2016) carried out. The difference occurring in the results we obtained in the trial may be due to completion of the trail at the beginning of flowering or the material used.

It was found that buckwheat was a plant species, whose antioxidant activity and total flavonoids, and whose medical value is the most, are the highest. Following buckwheat, it was identified that bermudagrass, had the highest antioxidant activity and total flavonoids. When compared to white clover and equivalence of gallic acid, it has considerably higher phenol content than the other two. The results obtained in our study was compared with those of the other studies carried out (Kahrören et al 1999,Oleszek and Stochmal 2002, Auddy et al 2003, Sun and Ho 2005, Francini et al 2007,Severino et al 2007, Mangathayaru et al 2009, Krishanti et al 2010) and it was identified that they showed similarity.

Conclusion

According to the results of the study we have carried out, while antioxidant activity and total flavonoids of buckwheat and bermudagrass are high, total phenol of white clover is high. According to this study, carried out to identify the medical properties of these three plants, these species of three plants are medically important, and we have an opinion that from medical point of view, more studies should be carried out on especially the plants of bermudagrass and white clover.

Abstract

Opium poppy (*Papaver somniferum* L.) is an important industry plant whose capsule yields alkaloids and seeds yield oil. This study was carried out to determine oil and alkaloid contents (such as morphine, codeine, oripavine, thebaine, noscapine, and papaverine) of some opium poppy (*Papaver somniferum* L.) varieties and lines. In the research, registered by different organizations 5 standard opium poppy varieties (Ofis 95, TMO3, Kemerkaya, Seyitgazi, Tınaztepe) and 97 advanced line material were used. The experiment was carried out with a randomized complete block design, under the field conditions in 2015 year at experiment plots of the Central Black Sea Gateway Zone Agricultural Research Institute, Tokat, Turkey. Oil analyses were done in soxhlet device using extraction method in Central Black Sea Gateway Zone Agricultural Research Institute. On the other hand, alkaloid analyses were done in HPLC device in the laboratory of Bolvadin Alkaloid Factory. As a result, varieties and lines; morphine, codeine, oripavine, thebaine, noscapine and papaverine ration values ranged between (0.26 - 1.46%, 0.045 - 0.33%, 0.006 -0.11%, 0.011-1.75%, 0,01 - 0.49 %, 0.02 - 0.40 %) respectively, and oil ration values ranged between 32.5-51.7%.

Key words: *Poppy , Papaver somniferum L., alkaloid , oil, seeds*

Introduction

One of the medicinal plants, opium poppy (*Papaver somniferum* L.) is an important pharmaceutical industry plant whose capsule yields alkaloids and seeds yield oil. It is grown in Turkey, India, Australia, Spain, France and Hungary as legal main producer countries under the supervision of the United Nations to obtain opium and opium alkaloids for medicinal purposes in World. India produces opium gum, whereas other countries produce dried opium capsules. The average legal opium poppy cultivation area in 2011-2016 is 103.893 ha on the basis of main producers in the world. The average cultivation area in Turkey in 2011-2016 is 43.151 ha, which accounts for 41.5 % share of total legal opium poppy cultivation areas in the world. The average capsule production of the main producer countries of the world in 2010-2014 was 63.856 tons. Turkey had a 35 % share among legal capsule producers with 22.699 tons of average capsule production in 2010-2014 (Anonymous, 2016).

Opium poppy farming in Turkey is implemented within the 70 thousand hectares limit allocated by the United Nations Organization for our country in areas permitted by the Council of Ministers and within the planning framework of General Directorate of Turkish Grain Board. The production is subject to licensing and control in the form of dried opium poppy capsules without incision. The cultivation in 2015/2016 winter and summer farming season took place in

Afyonkarahisar, Denizli, Konya, Burdur, Uşak, Isparta, Eskişehir, Kütahya, Manisa, Balıkesir, Çorum, Amasya and Tokat provinces.

Today, opium poppy makes a significant contribution to the country economy in terms of making up both morphine and derivatives export and grain export of Turkey. In Afyon Alkaloids Factory with its 25.000 tons/year dried un-incised poppy capsule processing capacity, which was established to commercialize opium poppy and meet the legal alkaloid requirement of the market, approximately 80-100 tons of morphine is produced based on the proportion of morphine content of capsules. 10 % of the morphine and derivatives produced is used in domestic pharmaceutical industry and the rest 90 % is exported for medical purposes. 85 % of the export goes to the USA and the rest goes to Asian, European and African countries. The opium based drug consumption in the world for medicinal and scientific purposes is about 450-500 tons. Turkey holds around 20 % of this market share (Anonymous, 2015).

In addition to the main alkaloids of poppy capsule having medical significance such as morphine, codeine, thebaine, noscapine, and papaverine, it contains 30 various alkaloids and has been found to contain around 40 alkaloids by recent studies (Valizadeh, 2015). They are used to produce semi-synthetic active pharmaceutical raw materials with derivatives and high added value. Of these alkaloids, morphine and codeine have drug properties, whereas noscapine and papaverine do not. Poppy capsule contains morphine at most. In addition to its drug properties, this alkaloid is used as a pain killer. Several semi-synthetic materials such as heroin, pentazocine and oxycodone can be obtained from morphine. Noscapine is used as a medicine due to its antitussive (cough suppressant) properties. It is not addictive and it is not a drug or pain killer. Thebaine is the most poisonous opium alkaloid, and it has been used in the production of semi-synthetic medicines with analgesic, antitussive (cough suppressant) and depressant properties. Codaine is found in the form of colorless white crystals or powder, it has little analgesic effect, and it is a good antitussive (cough suppressant) since it eliminates cough reflex. Papaverine loosens smooth muscles. It treats muscle spasm. Duodenum is used in the composition of drugs used in intestinal spasm and gallbladder obstruction (Arslan et al., 2008).

In Turkey, opium poppy seeds are traded in free market conditions. Compared to its 25 thousand tons of poppy seeds production, Turkey has an annual export potential of about 40 thousand tons. The most significant property of opium poppy seeds is that it has 45-55 % oil and 20-30 % protein content. The seeds are traditionally used in bread and pastries. The oil obtained by pressing the seeds is used in cooking and food industry. In addition, it is also known to be used in cosmetic and dye industry (Kahraman, 2011).

Several varieties of opium poppy have been registered so far through breeding programs within the collaboration framework of the General Directorate of Turkish Grain Board (TMO), Research Institutes of Ministry of Food Agriculture and Livestock and universities in Turkey. However, it is necessary to determine the genotypes found in the current gene pool to improve alkaloids and oil rates higher varieties through opium poppy breeding. This study was carried out to determine oil and alkaloid contents (such as morphine, codeine, oripavine, thebaine, noscapine, and papaverine) of some opium poppy (*Papaver somniferum* L.) cultivars and lines.

Material and Method

This experimental study was conducted in the trial field of Central Black Sea Gateway Zone Agricultural Research Institute (Turkey) in 2015. In the study, 5 standard opium poppy varieties (Ofis 95, TMO3, Kemerkaya, Seyitgazi, Tınaztepe) registered by different organizations and 97 advanced line material obtained from Ankara University, Agricultural Faculty, Agronomy Department genetic stock were used. Each variety/line was planted in two rows 3 m in length

according to randomized blocks experimental design. Row spacing was set to 40 cm and plant spacing was set to 10 cm later by thinning. The summer planting was implemented on 27 February, 2015. Oil analyses were done as two replicates in soxhlet device using extraction method in Central Black Sea Gateway Zone Agricultural Research Institute. On the other hand, alkaloid analyses were done in HPLC device in the laboratory of Bolvadin Alkaloid Factory. Plant care such as fertilization, thinning, irrigation, and hoeing works was conducted and diseases and pests were fought when necessary during the vegetal development of opium poppy plant. 20-20-0 Compound NP fertilizer was applied as 5 kg/da N during sowing and AN (ammonium nitrate) fertilizer was administered as 5 kg/da N before the first hoeing. Upon the maturation of all capsules in the trial field, they were harvested by picking up by hand on 30 July, 2015.

Results and Discussion

Table 1 presents the mean and T-test values for alkaloid (morphine, codeine, oripavine, thebaine, noscapine, and papaverine) and oil proportions of 5 varieties and 97 advanced lines used in the trial.

Table 1. T-test and mean values concerning alkaloids and oil proportions of varieties and lines.

Variety/Line	Morphine rations (%)	Codeine rations (%)	Oripavine rations (%)	Thebaine rations (%)	Noscapine rations (%)	Papaverine rations (%)	Oil rations (%)
Seyitgazi	0,71	0,15	0,02	0,10	0,19	0,07	41,7

**p<0,05 level is important.*

As is seen in Table 1, a statistically significant difference was found when the mean morphine proportion values of the varieties and lines were compared. The morphine proportion value of the varieties varied between 0.36 - 0.71 %, whereas it ranged between 0.26 – 1.03 % for lines. The highest morphine proportion value among lines belonged to AUAF – line 20 with 1.03 %. Values of 6 advanced lines (20, 54, 31, 5, 100, and 11) in research appeared over (0,58 %) mean morphine proportion of varieties. In previous studies, morphine proportions were found as follows: Erdurmuş (1989), 0.32 – 0.82 %; Novak and Strakova (1989), 0.66 – 0.75 % in 20 opium poppy varieties; and Arslan (2000), 0.25 – 0.89 % in 353 samples collected from various regions. The results obtained from our study exhibit great similarities to the findings from these studies.

Significant difference was not found when the mean codeine proportion values of the varieties and lines were compared. The codeine proportion value of the varieties varied between 0.04 - 0.33 %, whereas it ranged between 0,05-0,36 % for lines. The highest codeine proportion value among lines belonged to AUAF – line 2 with 0,36 %. Values of 17 advanced lines (2, 31, 54, 24, 5,55, 23, 16, 88, 73, 85, 10, 65, 76, 79, 35 and 51) in research appeared over (0,18 %) mean codeine proportion value of varieties. Subrtova et al. (1989) found the lowest codeine content as 0 % and the highest as 0.39 % in 25 opium poppy varieties of selected poppy populations. The findings of this study are also similar to those of ours.

Significant difference was found when the mean oripavine proportion values of the varieties and lines were compared. The oripavine proportion value of the varieties varied between 0,01-0,03 %, whereas it ranged between 0,01-0,07 % for lines. The highest oripavine proportion value among

lines belonged to AUAF – line 10 with 0,07 %. Values of 70 advanced lines in research appeared over (0,02 %) mean oripavine proportion value of varieties.

Significant difference was not found when the mean thebaine proportion values of the varieties and lines were compared. The thebaine proportion value of the varieties varied between 0,06-0,16 %, whereas it ranged between 0,00-0,38 % for lines. The highest thebaine proportion value among lines belonged to AUAF – line 20 with 0,38 %. Values of 17 advanced lines (20, 81, 78, 67, 80, 85, 70, 35, 52, 19, 26, 30, 38, 54, 87, 61 and 63) in research appeared over (0,10 %) mean thebaine proportion value of varieties. Subrtova et al. (1989) found the lowest thebaine content as 0 % and the highest as 0.35 % in 25 opium poppy varieties of selected poppy populations. The findings of this study are also similar to those of ours.

Significant difference was found when the mean noscapine proportion values of the varieties and lines were compared. The noscapine proportion value of the varieties varied between 0,02-0,19 %, whereas it ranged between 0,01-0,27 % for lines. The highest noscapine proportion value among lines belonged to AUAF – line 1 with 0,27 %. Values of 46 advanced lines in research appeared over (0,09 %) mean noscapine proportion value of varieties.

Significant difference was found when the mean papaverine proportion values of the varieties and lines were compared. The papaverine proportion value of the varieties varied between 0,02-0,11 %, whereas it ranged between 0,02-0,40 % for lines. The highest papaverine proportion value among lines belonged to AUAF – line 1 with 0,40 %. Values of 93 advanced lines in research appeared over (0,06 %) mean papaverine proportion value of varieties. Subrtova et al. (1989) found and the highest as 0.30 % in 25 opium poppy varieties of selected poppy populations. The results obtained from our study exhibit higher than the findings from these studies.

Statistically significant difference was found when the mean oil proportions values of the varieties and lines were compared. The oil proportion proportion value of the varieties varied between 41,7-50,7 %, whereas it ranged between 32,8-51,7 % for lines. The highest oil proportion proportion value among lines belonged to AUAF – line 1 with 51,7 %. Values of 39 advanced lines in research appeared over (46,28 %) mean oil proportion proportion value of varieties. Arslan (2000), oil proportions values was found between 38.86-53.39 % in 325 samples collected from various regions. The findings of this study are also similar to those of ours.

Conclusion

As a result, the outstanding genotypes of 5 opium poppy varieties and 97 opium poppy lines in terms of alkaloid proportions were found to be AUAF-line 20 in terms of morphine and thebaine proportion, AUAF-line 2 with respect to codeine, AUAF-line 10 in terms of oripavine, and AUAF-line 1 in terms of noscapine, papaverine and oil proportion. Varieties with higher alkaloids (morphine, codeine, oripavine, thebaine, noscapine, and papaverine) and oil rates can be grown by carrying out breeding programs on these identified lines.

Abstract

Turkey is the, center for many plant species, where is one of the world's richest countries in terms of the diversity of plants. In our country opium poppy cultivation is traditional, *Papaver somniferum* L., which is a one-year crops. The aim of study was to determine some botanical and agricultural characteristics of opium poppy (*Papaver somniferum* L.) varieties and lines. The research was carried out under the field conditions year at experiment plots of the Middle Black Sea Transition Zone Agricultural Research Institute in 2015. In this study were used the 5 varieties of opium poppy with 97 ahead of opium poppy as standard. The lines were planted in a randomized block design. Capsules and seed yield have been investigated with some phonological and morphological signs of value. According to the research results, the output was observed within 15-20 days, while the output time did not show a significant difference. Flowering time 80-100 days, plant height from 46.22 to 79.77 cm, the number of branches per plant from 2.4 to 5.4, the number of capsules per plant from 2.4 to 5.4, the capsule length 26.2 - 40.44 mm, the capsule width from 21.88 to 40.2 mm, the number of stigmatic rays from 7.00 to 11.83, capsule yield per decare from 28.78 to 181.57 kg, seed yield per decare from 43.9 to 205,32 kg, were found.

Keywords: *Opium poppy, Papaver somniferum L., capsule yield, seed yield.*

Introduction

Papaver somniferum L. the opium poppy, is a traditionally cultivated annual cultivar. It is from *papaveraceae* family of *Rhoedales* group. It is classified in *Papaver* genus of this family. There are 28 genera and nearly 250 species in *papaveraceae* family. (Davis *et al*.1988).

It is grown in Turkey, India, Australia, Spain, France and Hungary as legal main producer countries under the supervision of the United Nations to obtain opium and opium alkaloids for medicinal purposes in World. India produces opium gum, whereas other countries produce dried opium capsules. The average legal opium poppy cultivation area in 2011-2016 is 103.893 ha on the basis of main producers in the world. The average cultivation area in Turkey in 2011-2016 is 43.151 ha, which accounts for 41.5 % share of total legal opium poppy cultivation areas in the world. The average capsule production of the main producer countries of the world in 2010-2014 was 63.856 tons. Turkey had a 35 % share among legal capsule producers with 22.699 tons of average capsule production in 2010-2014 (Anonymous, 2016).

Opium poppy farming in Turkey is implemented within the 70 thousand hectares limit allocated by the United Nations Organization for our country in areas permitted by the Council of Ministers and within the planning framework of General Directorate of Turkish Grain Board. The production is subject to licensing and control in the form of dried opium poppy capsules without

incision. The cultivation in 2015/2016 winter and summer farming season took place in Afyonkarahisar, Denizli, Konya, Burdur, Uşak, Isparta, Eskişehir, Kütahya, Manisa, Balıkesir, Çorum, Amasya and Tokat provinces.

Opium poppy of *Papaver somniferum* L. species, an annual herbaceous plant, can grow to 60-200 cm depending on climate and growing conditions. The leaves of opium poppy are hairy lobed and hairy fragmented. The flower bud and flowers in opium poppy plant are found at the end of the stem. The bud is egg and pear-shaped. The poppy flowers are quite large and up to 8-10 cm in diameter. There are two sepals surrounding the flower and they fall when it blossoms. It has 4 petals inside. The petals are large and have flashy colors in a range of pink, purple and white. Inside the flower are the male parts around 80-150 in number. There is one female part in the middle of the flower topped with around 4-20 stigmas. The closed capsule (cocoon) is the fruit of the plant and it may have oval, conical and cylindrical shapes. Opium poppy is a 90 % self-fertilized species. Depending on the variety and environmental factors, foreign fertilization is also observed in varying rates. Opium poppy attracts insects and particularly bees with its numerous stamens, large and colorful flowers and abundant pollen. These insects and bees increase the rate of foreign fertilization by carrying the pollen from a flower to another (Valizadeh and Arslan, 2013).

Several varieties of opium poppy have been registered so far through breeding programs within the collaboration framework of the General Directorate of Turkısh Grain Board (TMO), Research Institutes of Ministry of Food Agriculture and Livestock and universities in Turkey. However, it is necessary to determine the genotypes found in the current gene pool to improve more quality and efficient varieties through opium poppy breeding. This study was to determine some botanical and agricultural characteristics of poppy (*Papaver somniferum* L.) varieties and lines.

Material and Method

This experimental study was conducted in the trial field of Central Black Sea Gateway Zone Agricultural Research Institute in 2015. In the study, 5 standard opium poppy varieties (Ofis 95, TMO3, Kemerkaya, Seyitgazi, Tınaztepe) registered by different organizations and 97 advanced line material obtained from Ankara University, Agricultural Faculty, Agronomy Department genetic stock were used. Each variety/line was planted in two rows 3 m in length according to randomized blocks experimental design. Row spacing was set to 40 cm and plant spacing was set to 10 cm later by thinning. The summer planting was implemented on 27 February, 2015. Plant care such as fertilization, thinning, irrigation, and hoeing works was conducted and diseases and pests were fought when necessary during the vegetal development of opium poppy plant. 20-20-0 Compound NP fertilizer was applied as 5 kg/da N during sowing and AN (ammonium nitrate) fertilizer was administered as 5 kg/da N before the first hoeing. Upon the maturation of all capsules in the trial field, they were harvested by picking up by hand on 30 July, 2015.

Results and Discussion

When we examined the emergence durations of 5 varieties and 97 lines used in the trial, emergences were observed within 15-20 days and no difference was found in terms of emergence durations of varieties and lines. The flowering durations in materials used in the trial took between 80-100 days. The earliest flowering duration was observed in TMO 3 (varieties), and Ankara University Agricultural Faculty (AUAF) –line 30 (lines). On the other hand, the latest flowering was observed in Kemerkaya and Ofis 95 (varieties) and AUAF –line 46 (lines). White, violet tones (light medium and dark tones) and red flower colors were observed in the population. Gümüşçü and Arslan (1999) reported 192-211 days of flowering durations in winter poppies, and

81-96 days of flowering in summer poppies. The findings of our study are similar with the results of this study.

Table 1 presents the mean and t-test values for plant height (cm), number of capsule/plant, number of baranches/plant, stigmatic rays/plant, capsule length (mm), capsule width (mm), seed yield (kg/da) and capsules yield (kg/da) of 5 varieties and 97 advanced lines used in the research.

Table 1. T-test and mean values concerning morphological observations, seed and capsules yield of varieties and lines.

Variety/Line	Plant height (cm)	Capsules /plant	Branches /plant	Stigmatic rays/plant	Capsule length (mm)	Capsule widht (mm)	Seed yield (kg/da)	Capsule yield (kg/da)

**p<0,05 level is important.*

As is seen in Table 1, a statistically significant difference was not found when the mean plant height (cm) values of the varieties and lines were compared. The plant height (cm) value of the varieties varied between 56,8-62,6 cm, whereas it ranged between 46,2-79,7 cm for lines. The highest plant height (cm) value among lines belonged to AUAF – line 26 with 79,7 cm. The highest plant height (cm) value among varieties belonged to TMO 3 variety with 62,6 cm. Values of 44 advanced lines in research appeared over (64.84 cm) mean plant height of varieties.

Significant difference was not found when the mean number of capsules per plant values of the varieties and lines were compared. The number of mean capsules per plant value of the varieties varied between 3,3-3,9, whereas it ranged between 2,4-5,4 for lines. The highest number of capsules value among lines belonged to AUAF – line 98 with 5,4. The highest number of capsules value among varieties belonged to Seyitgazi variety with 3,9. Values of 65 advanced lines in research appeared over (3,60) mean number of capsules per plant of varieties. Büyükgöçmen (1993), a study on opium poppy it reported that the number of capsules per plant ranged from 1,30 to 4,39. This study showed similar results with our work.

Significant difference was found when the mean number of branches per plant values of the varieties and lines were compared. The mean number of branches per plant value of the varieties varied between 3,4-3,9 whereas it ranged between 2,4-5,4 for lines. The highest number of branches value among lines belonged to AUAF – line 98 with 5,4. The highest number of branches value among varieties belonged to Ofis 95 variety with 3,9. Values of 68 advanced lines in research appeared over (3,62) mean number of branches per plant of varieties.

Significant difference was not found when the mean number of stigmatic rays per plant of the varieties and lines were compared. The mean number of stigmatic rays per plant value of the varieties varied between 8,2-11,8 whereas it ranged between 7,0-11,8 for lines. The highest number of stigmatic rays value among lines belonged to AUAF – line 74 with 11,8, The highest number of stigmatic rays value among varieties belonged to Kemerkaya variety with 11,8. Values of advanced lines (1, 30, 53, 71, 74 and 100) in research appeared over (10,8) mean number of stigmatic rays per plant of varieties.

Significant difference was not found when the mean capsule lenght (mm) values of the varieties and lines were compared. The mean capsule lenght (mm) value of the varieties varied between

28,5-35,9 mm, whereas it ranged between 26,55-40,44 mm for lines. The highest capsule lenght (mm) value among lines belonged to AUAF – line 93 with 40,44 mm, The highest capsule lenght (mm) value among varieties belonged to TMO 3 variety with 35,9 mm. Values of 58 advanced lines in research appeared over (32,66 mm) mean capsule lenght of varieties.

Significant difference was not found when the mean capsule widht (mm) values of the varieties and lines were compared. The capsule widht (mm) value of the varieties varied between 29,1-40,2 mm, whereas it ranged between 21,88-36,88 mm for lines. The highest capsule widht (mm) value among lines belonged to AUAF – line 54 with 36,88 mm, The highest capsule widht (mm) among varieties belonged to Seyitgazi variety with 40,2 mm. Values of advanced lines (24, 54, 98 and 100) in research appeared over (33,22 mm) mean capsule widht value of varieties.

Significant difference was not found when the mean seed yield (kg/da) values of the varieties and lines were compared. The mean seed yield (kg/da) value of the varieties varied between 117-177 kg/da, whereas it ranged between 43-205 kg/da for lines. The highest seed yield (kg/da) value among lines belonged to AUAF – line 61 with 205 kg/da, The highest seed yield (kg/da) among varieties belonged to Ofis 95 variety with 177 kg/da. Values of 32 advanced lines in research appeared over (145 kg/da) mean seed yield of varieties. Valizadeh (2015), raported that seed yield (kg/da) varied between 88.62-188.2 kg/da in study to determine effect of heterosis on yield and yield components of hybrids from alkaloid types opium poppy cultivars and lines. The findings of this study are also similar to those of ours.

Significant difference was not found when the mean capsule yield (kg/da) values of the varieties and lines were compared. The mean seed yield (kg/da) value of the varieties varied between 90-126 kg/da whereas it ranged between 28-181 kg/da for lines. The highest seed yield (kg/da) value among lines belonged to AUAF – line 100 with 181 kg/da, The highest seed yield (kg/da) among varieties belonged to Seyitgazi and Tınaztepe variety with 126 kg/da. Values of 31 advanced lines in research appeared over (117 kg/da) mean capsule yield of varieties. Valizadeh (2015), raported that capsule yield (kg/da) varied between 68.44-160.40 kg/da, in study to determine effect of heterosis on yield and yield components of hybrids from alkaloid types poppy cultivars and lines. The. The findings of this study are also similar to those of ours.

Conclusion

As a result, In this study seen come to the fore of AUAF (26, 98, 74, 93, 54, 61 and 100) advanced lines. On the other hand, 24 advanced lines value were found more higher than mean seed and capsule yield of varieties used as standard. Varieties with higher seed and capsule yield can be grown by carrying out breeding programs on all these identified lines in Turkey.

Abstract

Apples are one of the most frequently consumed fruits in the world. From 2003 to 2005, the average per capita apple consumption in Europe was 61 g per day, which is twice as high as the per capita consumption worldwide and represents one quarter of the total European fruit consumption. Apple fruits are an important source of secondary plant metabolites and one of the major sources of dietary phenolic compounds. The apple cultivars evaluated in this study were: Braeburn, Fuji, Granny Smith and Red Delicious, grown in Sarajevo region, Bosnia and Herzegovina. The total phenols contents (TPC) in the apple samples were measured by using a modified colorimetric Folin-Ciocalteu method. Total polyphenol content was calculated by means of an external standard calibration with methanolic catechin standards and expressed as mg catechin equivalents/100 g fresh matter (FM). The mineral contents (N, P, K Ca and Fe) of samples were analysed by Inductively Coupled Plasma Atomic Emission Spectrometry (ICP-AES). The cultivar, Fuji contained the lowest amount of polyphenols (expressed as mg catechin equivalents/100 g), 98 mg per 100 g of edible FM), followed by Granny Smith and Red Delicious (117 and 125 mg per 100 g of edible FM), while Braeburn contained the highest concentrations (143 mg per 100 g of edible FM). These results suggest that variability accounted for fruit quality was due to either genotypes or environmental conditions prevailing in the growing areas or interaction of both the factors.

Key words: *Apple, Phenolic Content, Mineral Composition, Cultivars*.

Introduction

Apple (*Malus* × *domestica* Borkh.) is one of leading fruits which is being grown in temperate region of the world. According to the FAO database (2013), global fruit production in 2013 was 610.15 million tons, of which apple production comprised 80.82 million tons, accounting for 13% of total fruit production. From 2003 to 2005, the average per capita apple consumption in Europe was 61 g per day, which is twice as high as the per capita consumption worldwide and represents one quarter of the total European fruit consumption (Ceymann et. al., 2012).

Chemical composition of apple fruit is very complex. It consists of numerous organic and inorganic compounds and macro- and micro biogenic elements. Organic and inorganic compounds content in fruit depends on fruit cultivar, ripeness, physiological condition of a tree as well as soil and weather conditions (Wu et al., 2006). Apple fruits are an important source of secondary plant metabolites and one of the major sources of dietary phenolic compounds. Polyphenols are secondary plant metabolites and contain one or more aromatic rings and at least two hydroxyl groups. Several thousand different polyphenols are known (Sies, 2010). The two main classes of polyphenols in foods are phenolic acids and flavonoids. Flavonoids are further divided into flavones, flavonols, flavan-3-ols, flavanones, isoflavones and anthocyanidins. Generally, five major polyphenolic groups are found in apple cultivars: hydroxycinnamic acids,

flavan-3-ols/ procyanidins, anthocyanins, flavonols, and dihydrochalcones (van der Sluis et al., 2001). Sun et al. (2002) found that apples had the highest soluble free phenolics when compared to 10 other commonly consumed fruits. The distribution of phenolic compounds in fruits varies considerably among different cultivars and also within different tissues (Khanizadeh et al., 2008). The objective of this study was to evaluate phenolic content of different apple cultivars, grown in Sarajevo region, Bosnia and Herzegovina.

Material and Methods

The apple cultivars evaluated in this study were: Braeburn, Fuji, Granny Smith and Red Delicious, grown in Sarajevo region, Bosnia and Herzegovina, during 2014 year. The apple samples were collected at their commercial maturity. Each sample is composed of 20 fruits. The fruits were grown on trees with normal crop load and, with an integrated plant protection strategy. The chemical characteristics of the soil were moderate acid pH (5.9 in 1M KCl), medium humus content (2.7%), slightly assuring of nitrogen, phosphorus and potassium in the top soil layer (0–40 cm). The total phenols contents (TPC) in the apple samples were measured by using a modified colorimetric Folin-Ciocalteu method. The total polyphenol content method described by Singleton et al. (1999). Ten µL of Folin-Ciocalteu reagent and 100 µL of distilled water were automatically pipetted to 10 µL of methanolic extract in a 200 µL cuvette. After 1 min, 40 µL sodium carbonate solution (200 g/L) and 40 µL distilled water were added, thoroughly mixed and incubated for 30 min at 37^0C. Absorption was measured automatically at 700 µm. Total polyphenol content was calculated by means of an external calibration with methanolic catechin standards and expressed as mg catechin equivalents/100 g fresh matter (FM). Statistical analyses were conducted using analysis of variance (ANOVA) to evaluate significant differences ($P < 0.05$).

Results and Discussion

Apples constitute an important part of the human diet, as they are a source of monosaccharides, minerals, dietary fibre, and various biologically active compounds, such as vitamin C, and certain phenolic compounds which are known to act as natural antioxidants (Wu et al., 2006). Phenols are secondary plant products that can be found in the peel and pulp of apples. The polyphenol content of apples depends on their biosynthesis, which can be influenced by light, mineral nutrition, rootstock, production method, growing season, growing region, cultivar and mutant variety (Treutter, 2010).

Total phenolics contents (TFC) of different cultivars of apple fruit is given in tab. 1.

Tab. 1. Total phenolics contents (TFC) of different cultivars of apple fruit

Cultivar	Total phenolics contents (TFC) (mg catechin equivalent/100 g of edible fresh matter)
Fuji	$98 \pm 3.21^{\mathbf{c}}$
Granny Smith	$117 \pm 2.25^{\mathbf{b}}$
Red Delicious	$125 \pm 2.11^{\mathbf{b}}$
Braeburn	$143 \pm 4.90^{\mathbf{a}}$

The cultivar, Fuji contained the lowest amount of polyphenols (expressed as mg catechin equivalents/100 g), 98 mg per 100 g of edible FM), followed by Granny Smith and Red Delicious

(117 and 125 mg per 100 g of edible FM), while Braeburn contained the highest concentrations (143 mg per 100 g of edible FM) (tab. 1).

The differences between varieties were significant. This could be caused by different amounts of individual phenolics constituting apple phenolic complexes of varieties with different antioxidant and antiradical efficiency. Vanzani et. al. (2005) estimated that polyphenols contributed from 47% (Granny Smith) to 78% (Braeburn), with an average value of 54% to the total antioxidant efficiency experimentally measured in the apple extracts.

Recent studies have shown that the content of phenolic compounds in apples varies considerably among different cultivars (Alonso–Salces et al. 2004; Hecke et al., 2006; Renard et al., 2007; Wojdylo et al., 2008). The chemical composition and concentrations of polyphenolic compounds have been found to be affected mainly by genetic variation, although they can also be influenced to some degree by growing conditions (Tsao, 2003). The results of our present investigation are in agreement with those reported by Vieira et al. (2009), who found that peel extract of different varieties of apple fruit contained greater amount of phenolics, anthocyanins and flavonoids than pulp extract. A previous study has demonstrated that the concentration of polyphenolic compounds in apple fruit can vary considerably between different apple cultivars in Sweden (Ahmadi–Afzadi, 2015). Lata (2007) measured phenolics spectrophotometrically in 19 different cultivars over two growing years. They detected either no variation in individual polyphenol classes for cvs. Gala and Red Rome or up to three-fold differences for cv. Granny Smith. Comparable experiments have been carried out in New Zealand (McGhie et al. 2005), Italy (Lamperi et al. 2008) and Chile (Yuri et al. 2009) for one or more cultivars and in these studies growing environment more consistently influenced the polyphenol content of the apples. McGhie et al. (2005) found significant differences between three growing environments in New Zealand for 10 different apple cultivars. They concluded that the growing environment influenced the polyphenol content, but the level of change was highly cultivar-dependent. However, a comparison of the studies remains difficult due to the different methods used. For example, some authors investigated apple skin and apple flesh separately and other reported data of freeze dried samples. Additionally, the cultivars investigated were common dessert apple cultivars or regionally cultivated ones. Clearly, many studies concerning polyphenol contents in apples have already been made, however more investigations are needed which compare the different cultivars with the same analytical technique.

Conclusion

This study demonstrated that total phenolic content vary among apple cultivars. These results suggest that variability accounted for fruit quality was due to either genotypes or environmental conditions prevailing in the growing areas or interaction of both the factors. The fruits with high contents of phenolic substances may impart health benefits when consumed and should be regarded as a valuable source of antioxidants.

Abstract

The aim of this study was to determine the dependence on the two most important indicators of the quality of peppers seeds, germination energy and total germination of the test methods. Rating seed germination was performed on two different substrates (filter paper and sand). For the study two hybrids (SK-5 F1 and Atris F1) and one local variety (Elephant's ear) were used. Results of germination energy and total germination studied hybrids and cultivars show significantly ($p=0.01$) higher values on the surface filter paper, compared to the values obtained in the surface sand. The highest average germination energy 82% and total germination 95%, was found in the hybrid SK-5 F1, while the lowest average values of 68% and 77% recorded in the variety Elephant ear. Statistical analysis of the total germination showed significant ($p = 0.01$) difference under the influence of varieties and substrate tests. Between the two test methods for vigor, a significant correlation was established ($r = 0.889$, $p = 0.01$), while for the total germination determined highly significant correlation ($r = 0.987$, $p = 0.001$) was observed. It is very important that the seeds of peppers have a high germination energy and total germination, because uniform germination of seeds depends on them.

Keywords: *Germination energy, total germination, pepper*.

Introduction

Seeds are one of the basic preconditions of successful agricultural production, ie stable, high yields of good quality, and the identification and testing of seed quality is of great importance. Quality of pepper seeds is varietal characteristics and at the same time depends on the biological and agroecological conditions (Gvozdenović et al., 1995). The most important indicator of the quality of seed germination certainly, which is also an indicator of the viability of which depends on the use value of seed (Poštić et al., 2010b). If soil conditions are almost ideal (temperature and soil moisture) seed germination obtained in laboratory conditions is a good indicator of seed vigor on the basis of which can be predicted seeds sprouting in the field (Durrant and Gummerson, 1990). However, germination of seed is not a sufficient indicator of seed quality. In addition to meeting the standards that are prescribed in the rules on the quality of seeds, it is important that the seeds have a high germination energy, especially if you are sowing seeds performs in the open field (mainly in the production of industrial processing) Postic et al., 2010a. In practice, it is very important quick and uniform emergence of plants. Germination energy is an important indicator of quality seeds, which precisely speaks of the ability of seeds for rapid and uniform germination (Veselinov, 1984; Gvozdenović et al., 1995; Poštić et al., 2010a).

If the germination and sprouting of plants slowly, all the greater percentage of seeds and seedlings die because of the attacks of pests and diseases, formation crusts of soil, or the deviation from the optimum conditions for germination. The aim was to carry out assessment of

the two most important indicators of the quality of seeds depending on the different testing methods.

Material and methods

As a material used in the research is the local variety of pepper (Elephant ear) and two hybrids of red peppers in type, strokes, which are grown by us (SK - 5 F1 and Atris F1). Assessment of quality indicators (germination energy and total germination) pepper seeds carried in 2011 and 2012 in the laboratory for testing the quality of seeds of agricultural plants, the Institute for Plant Protection and Environment, Belgrade (Serbia). Used two test methods for determining seed germination: 1) standard laboratory filter paper moistened between 0.2% aqueous solution of KNO_3 and 2) in sterile sand. The seed was incubated for 14 days at a temperature of 20-30 ° C and a relative humidity of 95%. Seventh-day incubation period is estimated germination energy, and 14 total germination, and the number of typical seedlings (ISTA Rules, 2009).

According to the Regulations on the quality of the seed (Gazette SFRJ no. 47/87), the minimum permitted germination of seeds is 65% for release seed on the market, while the Regulations on the medical examination of crops and facilities for the production of seeds, seedlings and planting materials (Gazette RS no. 119/2007) was examined by the health of seed (table 1):

Table 1. Allowed (%) presence pests in the seeds of peppers

Pests	Allowed (%) in the plant material in trade
Fusarium solani	5
Alternaria solani	5
Colletotrichum dematium	5
Rhizoctonia solani	1
Sclerotinia sclerotiorum	1
Phytophtora capsici	0

Obtained results were analysed by the analysis of variance (ANOVA, F-test; $P \leq 0.05$ and $P \leq 0.01$) and effect of factors (year, genotype, method and their interaction). Correlation between observed parameters were determined by Pearson correlation coefficients (r). Data were processed by program STATISTICA, version 8 (StatSoft Inc, Tulsa, OK, USA).

Results and discussion

Analysis of germination energy and total germination of seeds (table 2) showed highly significant differences influenced by the variety factor (G). The impact test methods factor (M) on the germination energy was not statistically significant, while the total germination very significant impact. Very significant interactions studied factors in terms of total germination seed of peppers were obtained with the mutual influence of factors G × M. Significant interactions studied factors in terms of germination energy and total germination were obtained with the cumulative impact factor Y × G × M (table 2).

In hybrids was found higher germination energy and total germination on both substrates, as compared to the variety Elephant ear (table 3). These results are consistent with the results (Poštić et al., 2010a).

Table 2. F-values for observed factors

Factors	Germination energy	Total germination
Year (Y)	ns	ns
Genotype (G)	**	**
Method (M)	ns	**
Y × G	ns	ns
Y × M	ns	ns
G × M	*	**
Y × G × M	*	*

** - significant at 0.01; * - significant at 0.05; ns - not significant

By applying the method to the filter paper was influenced by that germination energy of the tested genotypes increased by an average of 3.5 to 6.0%, compared to the determined germination energy on the medium sands (table 3).
The genotypes showed an average increasing total germination for 7.5 to 12.5% on the medium filter paper, compared to the other tested surface sand.

Table 3. Germination energy and total germination pepper seeds

Method	SK 5 F1		Atris F1		Elephant's ear	
	GE	TG	GE	TG	GE	TG
Sadn	79,75	93,25	74,50	85,50	64,75	71,75
Filter paper	83,25	95,75	80,50	93,00	70,50	81,25
Average	81,50	94,50	77,50	89,25	67,63	76,50

Legend: GE - germination energy, TG - total germination.

The lowest average germination energy 67.6% and total germination 76.5 % was found in the variety Elephant's ear, while the highest germination energy 81.5% and 94.5% total germination founded in hybrids F1 SK 5 (table 3). Germination energy is an important biological properties of the seeds of which depends on the speed and uniformity of germination and emergence (Poštić et al., 2010a). Considering that the largest percentage of pepper seedlings produced in greenhouses without additional heating of the amount of energy depends directly on the seed germination and percentage of emerged plants.

Table 4. The correlation coefficients between the observed traits (n=6)

Germination energy	Total germination
0,889**	0,987***

Pearson correlation coefficient: *** P≤ 0.001, ** P≤ 0.01, * P ≤ 0.05, respectively

Germination is the percentage of seed capable of producing a typical seedlings, that emerge in a field under optimal environmental conditions (Postic et al., 2010a). For predicting field emergence seed total germination is a very reliable indicator. Durrant and Gummerson (1990) found a high correlation (r = 0.75 to 0.97) germination energy and total germination, but only under ideal field conditions.

Statistical analysis of the total germination showed significant ($p = 0.01$) difference under the influence of varieties and substrate tests. Between the two test methods for vigor, a significant correlation was established ($r = 0.889$, $p = 0.01$), while for the total germination determined highly significant correlation ($r = 0.987$, $p = 0.001$) was observed (table 4).

Conclusion

Based on the presented results of testing the quality of seeds studied cultivars and two hybrids of pepper, we can conclude the following:

By applying the filter paper method resulted in higher germination energy of the tested genotypes by an average of 3.5 to 6.0% and an increase in the total germination for 7.5 to 12.5%, compared to the established germination energy and total germination on surface sand.

The higher the value of in hybrids germination energy and total germination will affect faster and more even emergence of seed that will especially be important in the production of pepper seedlings in greenhouses without additional heating.

Estimated indicators of the quality of pepper seeds were above the legally prescribed standards and meet the requirements of putting seeds in the market. Very high quality hybrid seeds of peppers is a good basis to need additional production conditions (soil management, fertilization, irrigation and protection) can be achieved high yields of good quality. It is very important that the seeds of peppers have a high germination energy and total germination, because uniform germination of seeds depends on them.

Abstract

Standard seed germination rate (GR) and cold test germination rate (CTGR) were scored for 10 maize singlecrosses, their reciprocals and inbred line components, where five hybrids belong to FAO 300-400 and five to FAO 500-600 maturity group. A total of 12 inbreds was included, since the hybrids comprising the same maturity group have one inbred in common. The aim was to estimate influence of the reciprocal crosses on GR and CTGR. Analysis of variance showed statistically significant effect of genotypes on both parameters, while reciprocal crosses significantly influenced only GR. Average GR for hybrids was from 94,0% (ZP 335) to 99,25% (ZP 388), while among inbreds it ranged from 93,0% (ZPL12) to 99,5% (ZPL9). Average CTGR for hybrids was from 91,5% (ZP 335) to 99,5% (ZP 366), while for inbreds it was from 94,0% (ZPL6) to 99,0% (ZPL10). Among original hybrids with ZPL1 as the male parent average GR i.e. CTGR was 96,0% i.e. 95,8%, while among their reciprocals it was 98,6% i.e. 95,8%. The average GR i.e. CTGR for original later maturity hybrids (ZPL7 as the male parent) was 95,9% i.e. 97,4% and for their reciprocals it was 96,8% i.e. 97,2%. The highest difference in GR between original and reciprocal cross for a single hybrid was estimated for ZP 335, where original version had 89,5% and reciprocal 98,5% germination rate. Regarding this parameter both ZPL1 and ZPL7 performed better as a female parent.

Key words*: cold test, maize, germination rate, reciprocal cross*.

Introduction

Seed germination rate (GR) and cold test germination rate (CTGR) represent one of the most important physiological seed quality parameters. Standard (warm) seed germination rate is an indicator of the ability of the seed to emerge from the soil to produce a plant in the field under normal conditions, while CTGR represents ability of the seed to emerge under cold, wet conditions of planting season and is an indicator of seed vigor. Seed germination under low temperature is of great importance not only in northern-growing maize regions, but in southern as well. Namely, farmers in Serbia and neighbouring countries were faced with cold and humid springs in the last couple of years, followed by extremely hot summers. Under these conditions, both GR and CTGR become highly important parameters influencing final grain yield.

Reciprocal effect in maize reffers to phenotypic difference between reciprocal F1 hybrids. This effect has been reported by several researchers for various agronomic traits in different types of maize for diverse use (Egesel et al., 2003; Lunsford et al., 1974; Mann and Pollmer, 1981; Mann et al., 1981; Melchinger et al., 1985; Seitz et al., 1995). Several factors attribute to differences between reciprocal crosses such as genomic imprinting (parent-of-origin effect), xenia (the effect of pollen on the endosperm phenotype in the same generation), dosage effects (in case of triploid tissue such as endosperm), and cytoplasmic effects (so-called maternal effects). Reciprocal effect

on variuos kernel and germination traits has also been detected. In particular, studies reported the effect on whole-kernel growth rate (Groszmann and Sprague, 1948), embryo and endosperm dry weight (Bagnara and Daynard, 1983), embryo oil and protein (Miller and Brimhall, 1951), zein synthesis (Chaudhuri and Messing, 1994), seed germination at low temperatures (Pinnell, 1949) and tolerance to drying injury (Bdliya and Burris, 1988).

The aim of this study was to examine the influence of reciprocal effects on standard and cold germination rate for ten maize single cross hybrids belonging to different maturity group. We also wanted to determine if the two shared inbred lines perform better as female or male parent regarding studied parameters. The results could serve as a recommendation for a seed production of the tested hybrids.

Materials and methods

Plant material

Ten single-cross hybrids, their reciprocal crosses and their parental inbred lines were selected for this study. Five hybrids belong to medium early (FAO 300-400), while five belong to late (FAO 500-600) maturity group. Twelve inbred lines in total were included, since the hybrids comprising the same maturity group had one parental component in common. ZPL1 inbred line was a common parent for medium early maturing hybrids, while ZPL7 was a common parent for late maturing hybrids. Hybrids and their corresponding parental components are listed in the Table 1. All the examined genotypes were multiplied in 2015. year.

Seed quality parameters analysis

Standard seed germination rate and cold seed germination rate for all the genotypes were scored at the ISTA accredited Seed Testing Laboratory of the Maize Research Institute Zemun Polje. Method between the filter paper was used for standard warm germination test. Two hundred seeds per each genotype were placed between the two wet filter papers in four replicates (50 seeds per replicate) and wraped in a roll. After seven days at 20°C genotypes were scored. The percentage germination is calculated from the number of normal seedlings out of the total number of seeds evaluated. Cold test was performed using a method in a rolled filter paper. Two hundred seeds per each genotype were tested in a four replications. Fifty seeds per replicate were placed on a wet filter paper covered with a thin layer of soil, and than covered with another wet filter

paper and wraped in a roll. The rolls were first placed in a germinator for seven days at 10°C, and then for another seven days at 20°C. After this the emerged seedlings were counted and the cold germination percentage is calculated.

Statistical analsyis

Three factorial nested ANOVA has been done, with common parental component and reciprocal effect as the main factors and hybrid as the nested factor. A t-tests have been performed for testing the significance of differences between the normal hybrids and their reciprocal versions. All the analysis have been done using SPSS 16.0 software.

Results and discussion

Average GR for inbred lines ranged from 93.0% (ZPL12) to 99.5% (ZPL9) (Table 2), while average values (AVG) for hybrids were from 94.0% (ZP 335) to 99.25% (ZP 388) (Table 3). Average CTGR for inbreds was from 94.0% (ZPL6) to 99.0% (ZPL10) and for hybrids it ranged from 91.5% (ZP 335) to 99.5% (ZP 366). Although GR and CTGR values among the inbred lines significantly differed all of them showed good germination ability in both tests. It can be noticed that several inbreds showed better CTGR than GR values, and that the later maturing inbred lines had slightly better performance regarding tested parameters.

AVG	95.90	96.80	96.35	97.40	97.20	97.3
AVG	95.95	97.70	96.80	96.60	96.50	96.55

ANOVA showed significant effect of hybrids on both parameters, while reciprocal effect significantly influenced only GR (Table 4). Common parental inbred line significantly influenced only CTGR, while there was no statistical difference for GR. Finally, interaction between reciprocal effect and shared parents was highly significant for both traits.

Five out of ten hybrids showed significant reciprocal effect for GR (Table 5). Three out of five early maturing hybrids had higher GR in reciprocal crosses, but the difference was significant only for ZP 333 and ZP 335. Hybrid which showed the worst result regarding this parameter was ZP 335, where reciprocal version had 9% higher GR than the normal one. On the other hand two late maturing hybrids had significantly negative reciprocal effect on GR. Namely, ZP 606 and ZP 685 normal versions had significantly higher GR score than their reciprocal versions. Nevertheless, ZPL1 and ZPL7 on average performed better when used as female parents. The obtained differences could be explained by the strong maternal influence on seed size and weight (Zheng et al., 2016). Namely, seed size affects germination rate in maize, where larger seeds have higher GR than the smaller (Yusuf et al., 2014).

Table 4. ANOVA of standard germination rate (GR) and cold test germination rate (CTGR) for hybrids

ZP 648	ns	ns
ZP 684	*	ns
ZP 685	*	ns
ZP 749	ns	ns

*, ** Significant at 0.05 and 0.01 probability levels, respectively; ns – statistically not significant.

Practically no difference between normal and reciprocal versions was detected for CTGR in both groups (Table 5). This was not in accordance with the results of Pinell (1949) who determined significant reciprocal effect on cold germination rate. The discrepency could easily be explained by the different genotypes used in the two experiments. Novel modern elite inbred lines are now being selected for resistance to main abiotic stresses, as well as for good specific and general combining ability. This allows them to be used succesfully both as female and male component in hybrids. Although ANOVA didn't show significant reciprocal effect on CTGR, ZP 335 reciprocal had 11% higher CTGR score than ZP 335 normal.

Normal and reciprocal versions of early maturing hybrids had significantly lower CTGR score than late maturing ones - average CTGR for early hybrids was 95.8%, while for late it was 97.3%. It can be concluded that ZPL7 line positively influenced this parameter, whether it was used as female or male component.

Finally, diallel analysis should be done to more deeply explore combining abilities and reciprocal effect on these two parameters (Cockerham, 1963). Also, according to Mann et al. (1981) the differences between reciprocal crosses were not stable over environments. Considering this and the fact that year of multiplication significantly influences seed quality, the same analsys will be done for genotypes multiplied in 2016.

Conclusion

Reciprocal effect has been reported for many important agronomic trais of maize. Influence of this effect on kernel traits, especialy seed quality parameters is of special interest for plant breeding. We showed high significant reciprocal effect on standard germination rate of ten maize hybrids belonging to different maturity groups. The effect was both positive and negative depending on the genotype itself. On the contrary, we did not detect reciprocal effect on cold germination test rate, although one of the hybrids reacted positively regarding this parameter. Diallel analysis will be done in order to explore the analysed effect more detailed.

Abstract

Water scarcity is the main constraint in crop production within arid and sami-arid regions. In recent decades, the subject of partial root-zone drying irrigation (PRD) gained a lot of attention for increasing water use efficiency (WUE) in many plant species. The effect of water shortage stress on corn (Zea mays L.), single cross (SC704) yield was evaluated on a silt-sandy soil during 2012 farming season in Mahmoudabad, 5 km south of the Caspian Sea shore, Mazandaran province, Iran. A RCB design with 4 treatments of 1) Full irrigation (FI) plants receiving 100% of field capacity (FC); 2) PRD_{80} plants receiving 80% of FC; 3) PRD_{50}, which plants received 50% of FC and 4) Deficit irrigation (DI_{50}), which plants received 50% of FC. The effect of water treatments on corn yield and yield components were highly significant ($p<0.001$). The PRD_{80} treatment consumed 18% less water relative to FI treatment during its growing season, while its yield was not significantly different from FI. The high water stressed treatments of PRD_{50} and DI_{50} yields were significantly lower than that of FI and PRD_{80} treatments. The substantial compensatory effect of PRD irrigation on yield and yield components indicates that ABA and stomatal regulation in favouring of photosynthesis to transpiration could be the key. During calm, clear sky nights dew deposited on corn leaves, which finally dropped to soil close to the corn stem. No difference was found between water treatments regarding dew deposition. In conclusion, the PRD irrigation strategy in comparison with conventional DI irrigation could benefit corn growth and development.

Keyword: *Corn, deficit irrigation, water stress, ABA, PRD*

Introduction

Water scarcity in arid and semi-arid regions is a major constraint in crop production. Iran major areas are in arid and semi-arid regions, where water availability is vital for livelihood and crop production. In these regions drought occurrence, as one of the most common environmental stresses in crop production, is a regular feature of the nature. Thus, a great deal of emphasis is on crop physiology and crop water management to use water efficiently (Stikic et al., 2003). In sub-humid and humid regions of northern Iran, south of Caspian Sea, crop production during the late spring and early summer encounter water scarcity and drought conditions.

Partial root-zone drying (PRD) irrigation, as a further development in deficit irrigation (DI) method nowadays, based on crop physiology and crop water management, is gaining a lot of attention for reducing crop water consumption and increasing water use efficiency. The partial root-zone drying irrigation (PRD) relative to conventional deficit irrigation (DI) is more beneficial, where plant root system gets alternate irrigation on both sides. Water stress mainly reduces stomatal conductance, where transpiration rate reduction is more inhibited relative CO_2 gain, therefore, in general WUE increases by water stress (Raeini-Sarjaz et al., 1998).

Meanwhile, in PRD strategy the dry part of the plant root system in response to water deficit generates abscisic acid hormone (ABA), which regulates stomatal pores to control transpiration (Liu et al., 2003; Liu et al., 2005), by which plant WUE enhances. The PRD is commonly consider as a DI method, because it does not receive more than 50-70 percent of water relative to full irrigation (Marsal et al., 2008).

Corn (Zea mays L.) is a C_4 plant and relative to C_3 plants has a higher WUE. The PRD irrigation strategy may further enhances its WUE. Based on Yazar et al. (2009) this water management strategy relative to full irrigation (FI) and DI method increased maize WUE significantly, while Sepaskhah and Khajehabdollahi (2005) reported a reduction in WUE for semi-arid regions.

In coastal areas one source of plant water availability is dew deposition on the plant leaves. Dew formation occurs when the water vapor pressure of the air is higher than the saturation water vapor pressure at leaf surface temperature.

The objective of this study was to evaluate the effect of partial root-zone drying irrigation strategy on corn grain yield relative to deficit and full irrigation strategies in a humid climate with low rain during late spring and early summer period.

Materials and Methods

Experiment layout

The experiment was conducted in a silt- sandy soil during farming season of 2012 in the Haraz Extension and Development Technology Center, Mahmoudabad (Iran) 10 km south of Caspian Sea shore with a humid climate based on de Martin classification, to investigate the effects of water stress on corn yield (Zea mays L., single cross SC704) and yield components. To conduct the experiment a complete randomized block design with four treatments and four replications were employed. The treatments were: 1) full irrigation (FI), as control, which plants received 100 percent of field capacity (FC); 2) Partial root-zone drying irrigation (PRD), which plants received 80 percent of FC (PRD_{80}); 3) Partial root-zone drying irrigation, which plants received 50 percent of FC (PRD_{50}) and 4) Conventional deficit irrigation, which plants received 50 percent of FC (DI_{50}). Plants were grown on late May 2012 on rows spaced 75 cm apart with 25 cm between plants on rows. Soil water content for each water treatment was monitored using TDR (time domain reflectometry) soil moisture meter and plants received corresponding water level using drip irrigation system. During the corn growth and development crop yield components and finally grain yield were measured.

To investigate dew deposition on corn leaves, as source of water, during some clear and cool nighttime stable weather conditions, dew deposition on flag leaves was measured. Deposited dew amount on specified leaf area was collected using paper towels. Each moist paper towel was then inserted in a zip-lock plastic bag and dew amount was measured using a precise balance (0.001 g).

Corn yield and yield components data were analyzed using ANOVA of SAS software (SAS 9.1), and the SNK post hoc test was employed to compare treatment means.

Results and Discussion

All treatments received 130 mm of water for crop establishment before to implement water stress strategies, therefore, for the whole corn growth and development stages the control treatment (FI) received 750 mm of water. During this period no precipitation was registered. The water-stressed treatments of PRD80, PRD50 and DI50 received 635, 445 and 445 mm of water, respectively.

The effect of water treatment on corn yield and yield components was highly significant ($p < 0.05$). The mean yield across different water treatments is presented on Table 1. Soil water

content significantly affected corn yield. The highest grain yield achieved with full irrigated treatment, although not significantly different from PRD80 treatment. In this case mean FI grain production was 13.5 percent higher than that of PRD80, while FI plants on average consumed 18 percent more water. On the other hand, the mean yield of both severe stressed treatments of PRD50 and DI50 was significantly less than those of FI and PRD80, while no difference was registered between PRD50 and DI50, but when considering the percentage declines PRD50 produced 21 percent more seed in compared to DI50, although both received the same amount of water. It seems behavior of corn in response to same amount of soil water content, but with different water strategies, is slightly different, as could be seen for FI and PRD80 treatments. Hakeem et al. (2016) had four treatments of FI, alternate PRD (APRD), fixed PRD (FPRD) and deficit irrigation (DI), all three deficit irrigation strategies received 50% of FI water quantity. The FI significantly produced the highest corn grain yield, while APRD grain yield was significantly more than that of FPRD and DI, almost by 15%. Yazar et al. (2009) with a 7-day scheduling irrigation cycle also reported higher grain production with FI relative to deficit irrigations of PRD and DI which received 50% of FI water amount.

It is an obvious knowledge that water stress makes plants more conservative, through stomatal conductance, to reduce transpiration rate (Raeini-Sarjaz 1997), which is ultimately translated to growth reduction. The response of plants to similar water-stress seems depends on water strategy managements. The response of plants to partial root-zone drying system is better than conventional deficit irrigation. This response has been assigned to ABA generation on dry-zone of the root system, which receives water alternately (Stoll et al., 2000), and signals stomata to regulate the pore to conserve water, while the moist zone of the root receives adequate water to continue photosynthesis (Liu et al., 2003). Therefore, better achievements of PRD treatments relative to DI could be due to better stomatal response to water shortage at root zone. The fixed PRD data in Hakeem et al. (2016) showed that this method is not helping the ABA generation strategy of PRD procedure.

Table 1) Mean corn yield and yield components across different water treatment.*

Treatments	Yield (tone hc^{-1})	100 seed weight (g)	Ear length (cm)	Ear diameter (cm)	Seeds per row	Seeds per column
FI	8.4 ± 0.9^{a}	34.6^{a}	25.2^{a}	4.81^{a}	15^{a}	51^{a}
PRD80	7.4 ± 0.5^{a}	35.8^{a}	24.6^{a}	4.75^{a}	14^{b}	49^{a}
PRD50	5.7 ± 1.0^{b}	35.2^{a}	21.6^{b}	4.35^{b}	13^{c}	41.3^{b}
DI50	4.7 ± 0.9^{b}	32.6^{a}	20.5^{b}	4.22^{b}	13^{c}	37.8^{c}

* On each column means that carrying the same letters are not significantly different (5% level).

Yield components which could be an indicator of final grain yield, such as mean ear length, ear diameter, seeds per row and per column also copied the same trend as did grain yields. Means of ear length and ear diameter and seeds per column were similar in both FI and PRD80, while both treatments were significantly different from PRD50 and DI50 treatments (Table 1). The mean 100 seeds weight across different water treatments was not significantly different between the treatments (Table 1). Mean plant heights of FI and PRD80 significantly were more than those of severe stress treatments of PRD50 and DI50 along the time (Table 2). Results of yield components of this experiment are in agreement with those of Hakeem et al. (2016) except 100 grains weight. In current trial other factors might have compensated for water shortage, such as dew deposition on corn leaves during clear and cool nights.

Table 2) Mean corn height (cm) during corn growth across different water treatment.*

Treatments	Corn height (cm) days after seed emergence				Mean dew deposition on leaf (g m^{-2})
	44	58	68	91	
FI	82.5[a]	185[a]	268.3[a]	290.5[a]	116.9
PRD80	74.7[b]	171.7[a]	240.7[a]	270[ab]	118.6
PRD50	51.7[c]	138.3[b]	204.3[b]	242.3[bc]	117.3
DI50	51.5[c]	137.5[b]	200.5[b]	230.3[c]	121.3

* On each column means that carrying the same letters are not significantly different (5% level).

Mean dew deposition on leaf across different water treatments was not significantly different (Table 2). Dew deposition onto surfaces, due to air and soil water vapor condensations, is a natural phenomenon. Dew is a vital source of moisture for ecosystems in arid and semi-arid climates (Jacobs et al., 1998), although it promotes diseases in susceptible plants, but in some plants it could be considered as a source of water requirements. Visual observation showed that in corn because of leaf structure and leaf angle relative to stem, the deposited dew finally drops to stem base on the soil. In light soils, such as sandy loams it could be absorbed by root system. The location of the present study was 10 km south of the Caspian Sea, therefore the chance of dew formation on light soils during calm, clear, cool nights is high. Mean of 118 gm^{-2} of water deposition on corn leaf (Table 2) could compensate for water shortage in stress treatments. Similar 100 grains weight in different water treatments, or not significantly different grain yield in FI and PRD80 might be due to this source of water.

Conclusion

The irrigation strategies that keeps root-zone water content close to field capacity produce higher grain. In the case of PRD strategy in our experiment, grain yield was comparable to full irrigation with almost 13% yield reduction and 18% water saving. It looks water management and climate has a major influence on this success. The region where the experiment was held has a humid climate with late spring and early summer free-rain period, but humid air. It is speculated that leaf dew deposition compensate for part of deficit irrigation. Others reported higher water-use efficiency for alternate PRD relative to the FI strategy (Hakeem et al., 2016), while Yazar et al. (2009) found no benefit in corn yield compared to conventional deficit irrigation under water scarcity conditions in the Mediterranean region of Turkey.

Abstract

The seed treatment with insecticides in certain cases causes lower values of seed germination due to phytotoxicity, which is manifested as a truncated and thickened main root. In the Seed Testing Laboratory, the method most suitable for seed germination was sought out in order to reduce effects of phytotoxicity of treated seeds to the minimum. This study encompassed germination tests of 10 seed lots of maize hybrids of different maturity groups stored in the controlled-environment chamber for a year. One part of seeds was treated with the fungicide Maxim XL, while the remaining part was treated with the fungicide Maxim XL + insecticide Sonido. The seed germination tests were carried out in the Seed Testing Laboratory, Maize Research Institute, Zemun Polje, by the between paper method (4x100 and 8x50 seeds) and the sand method (4x100 seeds). Seeds were germinated in the room germinator at the alternating temperature of 20<=>30^{o}C and 16:8 (light : dark) photoperiod. The first counting was done on the fourth day and the final one on the seventh day when the BP method was used. In cases when the S method was applied, the final counting was done on the seventh day. When seeds were germinated, the control sample was also placed for germination. Considering results of the last year germination, it was determined that seed germination was not significantly changed after a year of storing in the controlled-environment chamber. The comparison of results on germination of seeds treated only with the fungicide with seeds treated with fungicide+insecticide, shows lower values in seed germination in all three treatments in fungicide+insecticide-treated seeds. The lowest germination values were recorded in seeds treated with fungicide+insecticide in sand, while the highest values were obtained by the BP method (8x50 seeds).

Key words: *germination, insecticide*

Introduction

Seed germination is the most important parameter of seed quality and it is represented by the total germination, i.e. by the number of seedlings that will be developed into a normal plant. The reduction in seed germination occurs due to unfavourable environmental factors, untimely technological procedures, as well as by treatments of seeds with insecticides prior to sowing. (Bača *et al.*, 2008) concluded that insecticides on seeds did not essentially affect either the increase or the decrease of the plant stand and even resulted in higher average grain yields. Although seed treatments with insecticides result in the lowest consumption of insecticides, attention should be paid to their phytoxic effects on seed that will lead to the reduction of the total seed germination.

The presence of pesticides and insecticides on seeds under conditions of high humidity and temperatures during the process of seed germination reduces the total seed germination by the occurrence of abnormal seedlings. On this occasion, due to the phytotoxic effect on seeds, the root system thickens and shortens or the above-ground seedling parts elongate. (Vujaković *et al.*,

2003) reported that certain dressing agents adversely affected the growth of above-ground parts of wheat seedlings. During the process of seed germination, it is important to apply the adequate seed germination method that will mitigate the adverse effect of insecticides and thereby show an actual value of the total germination. (Stanković *et al.*, 1995) determined that prolonged storage of insecticide-treated seeds resulted in higher toxicity and therefore in the significant reduction of germination.

According to ISTA Rules, (ISTA Rules 2016), maize seed germination is tested by the following methods: between paper (BP), in sand (S) and on top of crepe paper and sand (TPS). Germination tests of maize seeds are mainly performed using the between paper method, because it is easiest to apply, while sand is used and recommended when testing of infected samples is impractical because of infection spread among seeds and seedlings, for research purposes and when seedlings express phytotoxic symptoms.

Material and Methods

This paper presents results on germination first count and total germination of 10 lots of maize hybrids of different maturity groups, stored in the controlled-environment chamber (18^{o}C, 60% RH) for a year. One portion of seeds was treated with fungicide Maxim XL 035FS, while the remaining portion was treated with fungicide Maxim XL 035FS and insecticide Sonido.

Seed germination testing was carried out 2016 year in the Seed Testing Laboratory of the Maize Research Institute, Zemun Polje, using the between paper method (4x100 and 8x50 seeds) and in sand (4x100 seeds). Tests were performed under controlled conditions at alternating temperatures 20<=>30^{o}C and the light regime 16 h : 8 h (light : dark). When the between paper method had been used, the first count was made at four days, while the total germination was determined on the seventh day, (ISTA Rules 2016). Obtained values were expressed in percentage of normal seedlings.

Gained results were statistically processed by the computer program MSTAT. The two factorial analysis of variance and the least significant difference (LSD) test were applied, (Hadživuković 1991).

Results and Discussion

The analysis of variance shows statistically significant differences in the total germainion over tested seed lots, as well as between the applied seed treamtnet and germination method. Interactions among observed factors were also statistically signifianct (Table 1).

There were no statistically signifianct differences between replications and interactions of all three observed factors.

Table 1. Statistical significance of effects of observed facrots on total germination of seeds

Factor	Degree of freedom (DF)	Mean squares (MS)	F value
Replication	3	3.494	0.7264^{ns}
Factor A	9	341.178	70.9187**
Factor B	1	653.400	135.8186**
AB	9	23.150	4.8121**
Factor C	2	56.963	11.8405**
AC	18	16.435	3.4162**
BC	2	7.238	1.5044**
ABC	18	9.960	2.0703^{ns}
Error	177	4.811	

ns – not significant; ** - significant at the level of 0,01%; df – degree of freedom

The average total germination over seed lots ranged from 84.71% to 97.38% for observed methods and the applied treatment. The analysis of results based on the LSD test for the interaction between methods and the seed treatment shows the lowest value of the total germination for the lot 10 (F), which is a statistically significant difference, while differences determined in lots 2 and 4 (A) were not statistically significant.
Table 2 shows that the total germination was reduced for all test methods after seeds had been treated with insecticides. (Tamidžić *et al.,* 2013) revealed that all insecticides, regardless of the type of active ingredients, affected the reduction in seed germination of maize inbred lines.

Table 2. Average values of germination expressed in % of seeds over methods and lots

	Method	Tested lots										Average over methods
		1	2	3	4	5	6	7	8	9	10	
Maxim XL	S	98	98	95	98	89	97	97	95	98	89	95.35 B
	BP 4x100	98	99	98	99	96	96	97	97	98	90	96.70 A

Maxim XL + Sonido	S	94	97	90	95	87	93	91	91	95	81	91.43 D
	BP 4x100	96	95	89	99	95	97	97	90	95	83	93.45 C
	BP 8x50	97	97	95	94	91	93	94	93	97	78	92.85 C
Average over lots		96.58 ABC	97.38 A	93.92 D	96.83 A	91.88 E	95.38 C	95.54 BC	93.42 D	96.63 AB	84.71 F	

S - sand, BP – between paper

Values of the total germination of seeds treated with fungicide + insecticide were on the average equal regardless of applied methods (BP with 4x100 and 8x50 seeds). These two testing methods are the most reliable for insecticide-treated seeds. The lowest value of the total germination was recorded when the S-method was applied, pointing out that this seed germination method was not reliable for insecticide-treated seeds (Table 2).
The highest total germination of fungicide-treated seeds was obtained by the BP method (4x100 seeds), while values of the total germination obtained by methods BP (8x50) and S were equal (Table 2).
In recent times the use of soil, as a substrate, has been increasingly mentioned and recommend for seedlings manifesting phytotoxic symptoms, not as a primary substrate but as alternative one. It has been observed that the total germination of seeds germinated in soil under laboratory conditions was the highest in inbred line seeds treated with insecticides.

Conclusion

According to obtained results, it can be confirmed that the total seed germination reduces after seeds were treated with insecticides. The BP method (4x100 and 8x50 seeds) is the most reliable germination method. The sand method did not prove reliable in tests of insecticide-treated seeds. The standard germination method (BP 4x 10 seeds) proved to be the best for fungicide-treated seeds. Furthermore, the BP method (8x50 seeds) that is used in our laboratory for testing germination of insecticide-treated seeds proved to be the best. Based on achieved results it is observable that the BP method (4x100 seeds) was equally reliable and therefore it will be more applied in the future work. Future objectives of laboratory studies should be aimed at testing soil

as a germination substrate for testing insecticide-treated seeds in order to obtain results on the total germination as reliable as possible and to reduce phytotoxic effects.

THE EFFECT OF CULTIVAR AND HARVESTING DATES ON ROOT YIELD AND SUGAR CONTENT OF WINTER SOWN SUGAR BEET

Süreyya Gülfem ALTUNBAY

Sugar Institute, Plant Breeding Department, T.ŞF.A.Ş. Ankara, Turkey
*Corresponding author: : sureyyagulfem@hotmail.com

Abstract

Sugar beet is cultivated on irrigated areas in summer; sugar beet cultivation, root yield and sugar content are dependent on irrigation significantly. In addition, summer sown sugar beet harvest begins in October at the earliest, until this month the sugar factories waiting for work. This condition is caused by the rising costs of production and sugar factories remain idle. Using less water in the production of sugar beet, sugar beet factories to process early and in order to grow a second crop after sugar beet harvest, wintery sugar beets were sown. The aim of this study was to determine root yield and sugar content of two winter sugar beet species (Eudora and Sculta) in three harvesting dates (June 11, 27 and July 19). This study was conducted in 2011-2012 growing season of Kahramanmaraş, established as a split plot design with 3 replicates. Species in main plots and harvesting dates in the sub-plots were placed. In the study, the head and leaf yield, root yield and sugar content were examined. As a result of analysis of variance, it was determined that there were no significant differences between species in terms of investigated features, the effect on the head and leaf yield and root yield of harvesting times were significant. At the end of the study, 14.43% sugar content, 2.63 ton/da head and leaf yield and 6.83 ton/da root yield from Eudora; 14.34% sugar content, 2.84 ton/da head and leaf yield and 6.80 ton/da root yield from Sculta species were obtained. The effect of harvesting dates on head + leaf and root yields except sugar content were significant. The highest head and leaf yield (3.13 ton/da) in the second harvest (June 27), the highest root yield (8:42 ton/da) in the third harvest (July 19) was obtained. Delayed harvest date increased root yield, the head and leaf yield decreased after the second harvest. Drying of leaves and leaf losses resulted in the head and leaf yield reduction in the time of final harvest.

Keywords: *Sugar beet, Beta vulgaris L., winter beet, root yield, sugar content*

Introductıon

Sugar beet is the most important plant that sugar is obtained after the sugar cane. 30 % of the sugar production of the world is obtained from sugar beet. Compared to the average of the last 3 years (2009-10-11). Turkey cultivates sugar beet in the field of 315 487 ha and 17 million tons of sugar beet is produced (Anonim, 2011). Economic sugar production is realized only in planting high technological quality of sugar beet. The climatic conditions of the region and cultivation techniques are important in generating satisfactory income by cultivating a product. Ensuring the necessary conditions in cultivating sugar beet is important with respect to product yield and quality. Provided that sugar beet is early cultivated in favorable climatic and soil conditions, the root yield and quality become higher (Durr and Boiffin, 1995). The productivity and sugar content are influenced by kinds and harvest season as well as environmental factors (Takada, 1998). The sugar beet is a cultivated plant which is planted in summer time normally. However, the matter that sugar beet is planted winterly in fall is quite old. The reclamation of a kind of

winter resistant sugar beet is handled in Kleinwanzleben city of Eastern Germany in 1930 by the researchers and the durability characteristic to run to seed is more given the top importance in the selections made. It was proved in the tests made with the species obtained that those species were not appropriate to fall planting but they are superior to other types with respect to durability to run to seed. The studies regarding wintery sugar beet after the Second World War more velocity are accelerated. First reclaimed species; are the kinds AA (German), Cesena NSA (Italian), US15 and US75 (American). New kinds have been placed on the market in recent years and these are; Kaweinterpoly, Kawe Tr, 861 (Germany), Semerave, H 5612 (The Netherlands), Alba Autopoly Alba Polka, Mezzano Au Poly, Mezzano Poly A (Italian), Autopoly (Denmark), Aupoly, Monatonna (Sweden), Aj. Poly 1 (Poland) and USH 10, SP 9B, S 45H (America). These species can be planted in fall in the regions that sugar beet could maintain its vegetative growth in which the winter is pretty hot and not subject to danger of frost especially, and they are planted in the beginning of summer. In this way, the agriculture of sugar beet in California, Spain and in southern regions of Italy is being applied successfully today.

In the test of wintery sugar beet that was carried out in England, it was stated that the rate of running to seed reduced due to the fact that wintery sugar beet planting changed from the end of september to the middle of october, and this resulted from the shortening of the growth period of the plant which is sensitive to cold (Wood and Scott, 1975). Because the matter of wintery sugar beet has become actual in our country recently, some studies were conducted on this matter in southern regions of our country between the years of 1976 - 1981. The sugar beet has been cultivated every summer preferably since 1926 that is the first production year of Turkey. The opinion that the investigation of the possibilities of planting the sugar beet both in winter and summer period in southern regions of the country came up with GAP project firstly in the mid of 70's. The possibilities of cultivating sugar beet in winter in southern regions of Turkey was investigated by using wintery Kaweinterpoly kind between the years 1976-77 and 1981-82 (Özgür and Erdal, 1982). The researchers tested 7 harvesting time in one month intervals each between February 1 and August 1, and in 20 days intervals between July 1 and November 20. It was pointed out that the optimum harvesting time of wintery planting is june and july, it causes a major frost damage in young plantsin Aegean region and exclusively in Southeastern Anatolia Region with the delay of harvesting time and the slow down of development, on the other side, taking forward the planting time (taking to the beginning of october or mid-september) encourages the run to seed for all wintery sugar beet species, that the species like Kaweinterpoly, Aupoly, Autopoly, Monatunno are highly durable against running to seed (Castilo and Garcia, 1986). It was pointed out that early planting provides higher quality dry matter accumulation, encourages the growth of leaves and this increases the root and sugar yield in the study where the productivity of sugar and root in wintery sugar beet is investigated by using 3 different planting periods (october, november, december) of 3 years, 2 different plant population (100 000 and 80 000 plant/ha) and 3 kinds (Monauta, Monatonno and Kaweinterpoly). The researchers stated that the wintery sugar beet starts the active development by the end of the winter season after 160 days upon the plantation and it has mostly in this period the dry matter accumulation and leaf area index; furthermore, wintery sugar beet planting is possible in Mediterranean region where winter season is temperate, that harvesting of wintery sugar beet runs into hot periods of summer season, and so the precipitation of winter and spring seasons are better benefited (Lopez and Bellido, 1986). In another research [8], 3 planting periods (September 1, September 20 and November 10) and 3 harvest seasons (April 15, May 15 and June 15) were researched and it was pointed out that the first planting period had the highest rate of running to seed, while the third plantin period had the lowest rate of running to seed and harvest season of September 1 and May

15 are better for root yield. This researchers stated in the planting time attempt carried out in Kermanshah region that (Basati and Neamati, 2003) the most appropriate planting time for the region is till September 20, while the most appropriate harvesting time is until May 15. In a research [9] conducted by using two sugar beet species (DEZ and BRI), 3 planting periods (August 22, September 10, October 2) and 3 harvest seasons (April 3, May 4 and June 4), it was reported that DEZ kind has more root and sugar yield than BRI kind, the rate of running to seed and substances apart from sugar are less in DEZ kind, the best planting period is August 22 with sugar yield of 9.64 ton/ha, root yield of 85.09 ton/ha and sugar content of % 11.44, while the best harvest season is July 4 with sugar yield of 9.38 ton/ha. In a study (Rinaldi and Vonella (2006) conducted in Apulia region of Italy by using the planting of fall (October, December) and spring (May), it was stated that fall planting had higher root yield, dry substance amount and sugar content than spring period. In another study (Reinsdorf and Koch, 2010), it was pointed out that the dry substance amount of wintery sugar beet that is planted lately decreases considerably, sugar beet has high yield in early planting, resistance to cold winter conditions depended on climate conditions (low temperature and snow cover) and morphological features of sugar beet (root diameter), furthermore, snow cover increases the tolerance of wintery sugar beet against frosts. It can be seen from the conducted studies that in planting the wintery sugar beet, the rate of sugar is lower than the planting in summer time. However, when taking into consideration some advantages, it is possible to plant sugar beet in winter season too in areas where winter is moderate. The campaign period of sugar beet could be up to six months in case wintery sugar beet is planted. Thanks to planting wintery sugar beet, sugar plants will be ensured to operate for longer periods. The costs will be lower in terms of farmers in wintery sugar beet planting and so the costs like irrigation and disinfection will decrease. Furthermore, the possibility that our farmers could plant the second product corn and other products that are appropriate for the second product will come out because the farm is harvested in may. It will be possible to obtain two products in a year through the wintery sugar beet application.

Materıal and Method

The study was established as 3 repetitions according to experimental design of split plot in growing season of 2011–2012 in Kahramanmaraş conditions (Turkey) with wintery sugar beet species. The species (Eudora and Sculta) were placed into main parcels, while harvest seasons (June 11, June 27 and July 19) were placed into sub-plots. Seed sowing was applied in October 10 by beet seeder of 5-rows, 120 kg N and 60 kg P2O5 for each hectar and the plants were grown without irrigation. Irrigation was performed once before harvest season in order to simplify harvesting process only. The productivity of top and leaves, body yield and sugar content were investigated in the study. Data regarding investigated features was analysed by using MSTATC statistical program package.

Result and Dıscussıon

The values regarding investigated features in the study and the formed groups are given in Chart 1.

Chart 1. The Values Regarding Investigated Features in Wintery Sugar Beet and the Formed Groups

Variety	The yield of top+leaves	Root Yield (ton/da)	Sugar Content (%)
Eudora	2,63	6,83	14,13
Sculta	2,84	6,80	14,34
Average	2,74	6,81	14,38
11 Haziran	2,61 b	5,94	14,33
27 Haziran	3,13 a	6,08 b	14,47
19 Temmuz	2,47 c	8,42 a	14,35
LSD (% 5)	0,05	0,27	NS
Çeşitler (A)	NS	NS	NS
Hasat Zamanları (B)	**	**	NS
AXB	**	NS	NS

It can be seen in Chart 1 that there is no important differences among species in terms of investigated characteristics, while harvest season is effective on the productivity of top and leaves and body yield, moreover it can be understood that the kind-harvest season interaction is important. It was obtained %14.43 of sugar content, 2.63 ton/da of productivity of top and leaves and 6.83 ton/da of body yield from Eudora kind; while %14.34 of sugar content, 2.84 ton/da of productivity of top and leaves and 6.80 ton/da body yield was obtained from Sculta kind. The sugar content has not changed importantly according to harvest season, the highest productivity of top and leaves (3.13 ton/da) was obtained from second harvest season (June 27), while the highest body yield (8.42 ton/da) was obtained from the third harvest season (19 July). It was pointed out by many researchers that harvest season is effective on body yield [4, 5, 6, 7, 8, 9, 10, 11]. As harvest season was delayed, the body yield increased; while the productivity of top and leaves reduced after the second harvest season. Reduction of productivity of top and leaves in the last harvest season is supposed to cause by first drying of the leaves and increase in leaf loss.

Conclusıon

As a result of the conducted study, it was pointed out that the planting of wintery sugar beet could be realized in mild winter climate conditions like the climate of Kahramanmaraş in case there is appropriate kind, and that sugar content of 14 %, body yield about 6 ton and productivity of top and leaves about 2.7 ton could be obtained.

Abstract

The decline and dieback of raspberry plantings observed in western Serbia not only lead to a decrease in yield in the current growing season, but also reduce productivity in future years. In order to determine possible causes of raspberry dieback, soil samples were taken in the 2012 growing season at Leušići (Municipality of Gornji Milanovac). Sampling results provided information on soil acidity, the content of available forms of macroelements (N, P, K, Ca, Mg) and microelements (Fe, Mn), the level of mobile aluminum and the total content of heavy metals (Ni, Pb, Cd, Cr). Samples of plant material (leaf and fruit) were also collected and analyzed for the concentrations of the above mentioned elements. To reduce acidity, two lime treatments, each at a rate of 500 kg/ha CaO, were applied, i.e. broadcasting treatment and row application. The soil exhibited an acid reaction (pH/H_2O 5.70; pH/KCl 4.45), a moderate humus supply (4.56%), good availability of nitrogen and potassium, and phosphorous deficiency. Regardless of the good soil Ca and Mg availability, the ratio between the two elements was unfavorable. The content of microelements was within the allowable concentrations, with no aluminum detected. The total levels of Ni and Cr were above the maximum allowable concentrations and the content of Pb was within the allowable range, whereas no Cd was found. Lime-induced changes in the chemical properties of the soil were likely to match the implemented soil neutralization, with the broadcast application of CaO being more effective.

Keywords: *Raspberry, soil acidity, macro- and microelements, heavy metals*

Introduction

Raspberries have highly specific requirements for good growing conditions, including the proper choice of soil and favorable climatic conditions. They grow best and produce the highest yields on deep, loose, fertile soils having a favorable nutrient ratio. Also, good results are achieved in upland and mountainous areas if a proper cultivar choice is made. However, the soil can act as a limiting factor in raspberry production under these agroenvironmental conditions, especially if it has an acid reaction due to intensive fertilizer use. On such soils, raspberry yields are lower, fruit quality is poorer and the risk of partial or complete decay of raspberry orchards is higher.

In western Serbia, acids soils account for more than 50% of the total land area (Stevanovic et al., 1987). Therefore, raspberry growing technology should necessarily involve the use of physiologically alkaline fertilizers, especially during supplemental fertilization, to reduce the risk of blocked nutrient uptake while creating favorable conditions to establish nutrient balance and obtain good quality fruit. The content of almost all macro- and microelements in the leaf is correlated with their content in the soil (Güleryüz et al., 1995; Yu-Yen, 2006).

While analyzing the soil situation and changes in soil properties in raspberry orchards in the Arilje region, Stevanovic et al. (2004) found that the agrochemical properties and nutrient content

of the soil under “healthy” raspberry canes were significantly different from those of the soil under "sick" raspberry canes. The soil taken from the root zone of diseased raspberry canes showed an increase in acidity by an average of 0.9 pH units and an increase in the level of available forms of phosphorus, potassium and aluminum by 6 mg/100 g soil, 3 mg/100 g soil and as much as 17 mg/100 g soil, respectively, while the magnesium content was decreased by 7 mg/100 g soil, when compared to soil samples collected from the root zone of healthy canes. Similarly, in their analysis of causes of root and cane base rot of raspberries in the Arilje raspberry growing region, Gajic et al. (2004) suggested that, in addition to the acid soil reaction, this problem is largely caused by the presence of Al-ions in the adsorption complex which lead to poor root and cane development, resulting in inferior plant appearance and low disease resistance. Based on the above, the aim of this research was to examine the initial status regarding agrochemical soil properties, determine changes in the soil as induced by different liming treatments, and evaluate the leaf nutrient content of raspberries.

Material and Methods

The experiment was carried out at Leušići, Municipality of Gornji Milanovac (Serbia), on ranker soil in a ‘Willamette’ raspberry orchard, where the average soil sample was taken before trial establishment. The sample was taken from the 0-30 cm soil layer and tested for the following parameters: active acidity (pH/H2O), exchangeable acidity (pH/KCl), humus content, available forms of macro- and microelements (N, P, K, Ca, Mg, Fe, Mn), and the content of harmful elements (Al, the total contents of Ni, Pb, Cd, Cr, available contents of Ni and Cr).

Based on the initial results on soil acidity, the need for liming was established, and CaO was applied in the following treatments:

1. CaO - 500 kg / ha (row application)
2. CaO - 500 kg / ha (broadcast treatment – over the entire surface).

Liming was performed in autumn 2012. Following the 2013 growing season, 20 soil samples were taken for agrochemical tests and 50 raspberry leaf samples were collected. Soil tests were the same as those performed before the experiment. Leaf samples were analyzed for the content of biogenic elements (N, P, K, Ca, Mg, Fe, Mn) and heavy metals (Ni, Pb, Cd, Cr).

During the 2013 growing season, 600 kg/ha NPK 15:15:15 was applied through basal fertilization and 350 kg/ha CAN as supplemental fertilization.

The soil pH was measured at a 1: 2.5 soil:distilled water ratio and soil:KCl ratio, using the pH meter. The humus content was determined by Kotzman’s method, the nitrogen content by Kjeldahl’s method, available phosphorus and potassium by the Egner-Riehm AL-method (phosphorus - colorimetrically, potassium - flame photometrically). The content of available Ca, Mg and microelements was determined by atomic absorption spectrophotometry. Total heavy metal concentrations in the soil samples were measured using the aqua-regia (HCl/HNO3, 3/1) extraction method by an atomic absorption spectrophotometer. Available Ni and Cr content was determined by extraction with 0.005M DTPA + 0.01M $CaCl_2$ + 0.1M TEA solution, pH=7.3.

In leaves, total N was determined by Kjeldahl analysis; P was analyzed spectrophotometrically by the phospho-vanadate colorimetric method; K was determined by flame photometry; Ca, Mg, Fe and Mn by atomic absorption spectroscopy (AAS1N, Carl Zeiss, Jena). Total heavy metal concentrations were digested with HNO_3 and $HClO_4$ at a 5:1 ratio and determined by an atomic absorption spectrophotometer.

Results and Discussion

Before the experiment, the raspberry orchard soil was found to be of very acidic reaction (pH/KCl 4.45), well supplied with humus, total nitrogen and available potassium, and poorly supplied with available phosphorus (Tab. 1). The content of available forms of Ca and Mg was satisfactory, but their ratio was unfavorable (about 2: 1).

Table 1. Chemical properties of the soil before the experiment

Depth (cm)	pH		Humus (%)	N (%)	P_2O_5	K_2O	Ca	Mg
	H_2O	KCl			mg/100 g soil			
0-30	5.70	4.45	4.56	0.215	3.09	21.1	156.91	77.23

The content of available forms of microelements (Fe, Mn) was within the permissible concentration range (Tab. 2). As for harmful elements, no presence of Al and Cd was detected, while total Pb was within the maximum allowable concentration (MAC). Total Ni was 278.0 mg/kg and total Cr 159.2 mg/kg i.e. above the MAC (Kabata-Pendias and Pendias, 2001). The increased content of Ni and Cr is most likely of natural origin, because the soil is formed on serpentines, although it may be due to human influence associated with the use of fertilizers and pesticides (Bogdanović, 2007). The absence of mobile aluminum ensures successful cultivation of raspberries in the soil having a strongly acid reaction (pH/KCl 4.45). However, this acidity comes from H-ions, and not from Al-ions which at levels above 10 mg/100 g soil block the uptake of certain nutrients (particularly phosphorus), thus adversely affecting the growth and development of raspberry (Stevanovic et al, 2004).

Table 2. Available concentrations of biogenic elements and total content of harmful elements before the experiment

Depth (cm)	Fe	Mn	Al	Ni	Pb	Cd	Cr
	mg/kg		mg/100 g	mg/kg			
0-30	27.35	103.0	0.0	278.0	28.0	0.0	159.2

Liming induced changes in the chemical properties of the soil, primarily including decreased acidity and increased levels of phosphorus, calcium and magnesium (Tab. 3). A better effect was achieved by the broadcast application of CaO, with the soil classified as slightly acid to neutral based on the pH/H_2O of 7.16 and pH/KCl of 6.30 pH units. The content of P_2O_5 was increased to 6.6 mg/100 g of soil, but the level of this nutrient is still insufficient and, therefore, NPK-fertilizer with a high content of phosphorus should be used because raspberries require 8-10 mg P_2O_5/100 g of soil for their growth (Petrovic and Milosevic, 2002). The content of available Mn and Fe was reduced by liming, with the decrease being more pronounced after the broadcast application of CaO.

Table 3. Chemical properties of the soil after liming

Treatment	pH		P_2O_5	K_2O	Ca	Mg	Fe	Mn	Pb	Cd
	H_2O	KCl	mg/100 g of soil				mg/kg			
Before the experiment	5.70	4.45	3.09	21.1	156.91	77.23	27.35	103.0	28.0	0.0
CaO (row application)	5.72	5.36	3.60	22.3	375.0	150.0	21.0	90.0	26.2	0.0
CaO (broadcast application)	7.16	6.30	6.60	22.4	375.0	225.0	15.0	74.23	25.8	0.0

Given the increased content of total Ni and Cr in the soil before the experiment, their available levels were also determined, indicating that they account for a small percentage of the total content of less than 5% (Tab. 4). These values suggest that the content of Ni and Cr comes from the parent material on which the soil is formed, which is in compliance with the previous research of Ninkov et al. (2016). The tested soil contains increased amounts of both Ni and Cr, which is also evidence of their natural origin, given their coexistence in nature. The increase in soil pH after liming is an important factor in reducing the mobility and availability of Ni and Cr in soil, which is associated with an increase in the adsorptive properties of the solid phase of soil (Uren, 1992; Bogdanović et al., 1994).

Table 4. Total and available contents of nickel and chromium in soil (mg/kg)

Treatment	Ni		Cr	
	Total	DTPA-Ni	Total	DTPA-Cr
Before the experiment	278.0	12.10	159.2	1.3
CaO (row application)	58.0	8.95	42.1	1.0
CaO (broadcast application)	40.0	7.05	36.5	0.9

The content of all biogenic elements in the raspberry leaf (Tab. 5) was within the allowable limits (Tab. 6, Bergmann, 1983), indicating normal plant development and nutrient uptake from the soil, which is associated with the optimum soil pH after liming.

Table 5. The content of biogenic elements and heavy metals in the raspberry leaf

Treatment	(% d.m.)					mg/kg of dry matter					
	N	P	K	Ca	Mg	Mn	Fe	Ni	Pb	Cd	Cr
CaO (row application)	2.86	0.38	1.92	1.27	0.45	104.0	75.5	1.04	2.14	-	0.21
CaO (broadcast application)	2.90	0.41	2.15	1.35	0.40	86.0	68.7	0.95	2.43	-	0.34

The content of the tested heavy metals in the raspberry leaf (Tab. 5) was within the normal range (Tab. 6, Radojevic and Baskhin, 2006). This result was expected given the soil reaction (pH/KCl 6.30) which led to reduced mobility of heavy metals in the soil and, hence, possibly to reduced translocation of these elements from the root to the leaf of the plant. Heavy metals are uptaken from the soil through root cells; then, they pass through the plasma membrane and enter the cell via plant transporters. Their mobility from roots to leaves and further on to fruits is restricted by the internal detoxification system (Cieśliński et al., 1996) which is able to reduce the translocation of these elements, thus causing a decrease in their levels in the above-ground parts and, hence, reducing their toxicity to plants. The major mechanism in tolerant species of plants appears to be compartmentalization of metal ions, i.e. sequestration in the vacuolar compartment, which excludes them from cellular sites where processes such as cell division and respiration occur, thus proving to be an effective protective mechanism (Chaney et al., 1997; Hall, 2002).

Table 6. Allowable limits of biogenic elements and heavy metals in the raspberry leaf

Element	(%)					mg/kg dry matter					
	N*	P*	K*	Ca*	Mg*	Mn*	Fe*	Ni#	Pb#	Cd#	Cr#
	2.8-3.5	0.25-0.50	1.8-2.5	0.8-1.5	0.3-0.6	25-150	61-200	0.02-5.0	0.2-20	0.1-2.4	0.03-14

*Bergmann (1983); #Radojevic and Baskhin (2006)

It is especially important to note that there was no uptake of excess Ni and Cr, which is related to their deposition in the soil and the fact that their uptake and accumulation by plants was primarily caused by the soil reaction rather than by their total amount in the soil (Jakšić et al., 2013).

Conclusion

Based on the objective and results of this study, the following conclusions were drawn:

• Liming caused changes in the chemical properties of the soil, primarily including reduced soil acidity and increased contents of phosphorus, calcium and magnesium. A better effect was achieved by the broadcast application of CaO;

• The content of all biogenic elements in the raspberry leaf was within the allowable limits, indicating normal plant development and nutrient uptake from the soil;

• The contents of the examined heavy metals in the raspberry leaf were within the normal range, as was to be expected considering the soil reaction (pH/KCl 6.30) which led to reduced mobility of heavy metals in the soil.

Abstract

Climatic conditions prevailing during crop growth, the period to which crops are planted and varying population densities are great determinants of yield of crops. Turmeric growers are faced with a lot of barriers affecting the production and the yield in Nigeria ranging from appropriate sowing date, inadequate plant population, and insufficient information about the emergence and growth and yield patterns. In an attempt to assess appropriate sowing date and spacing for turmeric, an experiment was carried out in the rainy season of 2010 at the National Horticultural Research Institute, Ibadan, Nigeria. Planting dates and spacing had a significant effect on the plant height, number of leaves and rhizome yield of turmeric. Early planting in May produced significantly higher plants, number of leaves and number of tillers while planting in June produced the highest rhizome yield. Wider spacing of 45cm x 40cm had significantly highest plant height, number of leaves and number of tillers while close spacing of 45cm x 10cm gave the highest rhizome yield. The appropriate planting date and spacing for optimum production of turmeric is recommended for the month of June and 45cm x 10cm spacing respectively.

Keywords: *Population density, planting dates, Curcuma longa, yield*

Introduction

Turmeric (*Curcuma longa* L.) is one of the most important spices with diversified uses in Nigeria that belongs to the family Zingiberaceae. The tuberous rhizomes or underground stems of turmeric have been used from antiquity as condiments, dye and as an aromatic stimulant in several medicines (Islam, 2002).Turmeric is very important spice in India, which produces nearly entire whole world's crop and consumes 80% of it. India is by far the largest producer and exporter of turmeric in the world (82%), followed by China (8%), Myanmar (4%), Nigeria (3%) and Bangladesh (3%) though figures about area and production are not available (Singh *et al*.1997)

Demand for turmeric is increasing year by year in Nigeria because of the larger industrial request for dye making in textile and local mat manufacturing. However, development of suitable production technology to boost the crop yield is essential as the yield potential alone is not sufficient for increasing the yield. Proper planting period is an important non-monetary input in crop production. Too early or delayed planting will affect the growth, yield and performance of the crop. Another important factor is the plant spacing which determines the optimum plant population, the degree of competition between plants and consequently the yield.

Turmeric growers are faced with a lot of difficulties ranging from weed management, fertilizer application, and inadequate plant population because of insufficient information about the emergence, growth patterns and yield of turmeric plants, weed growth in relation to the planting

date. Turmeric production per unit land area is very low because of poor knowledge on proper cultivation technology of the farmers (Ishimine*et al*., 2003; Kiran *et al*., 2013).Improvement of crop cultivation technology for local climatic and edaphic factors is important for successful production (Ishimine*et al*., 2003; Kiran *et al*., 2013). The yield of the turmeric can be increased by adapting improve production technology like proper plant spacing. Spacing is being one of the most important factors which actively influence the inter plant competition, growth and ultimate yield of turmeric (Kiran*et al*., 2013). Plant spacing is an important agronomic attribute since it is believed to have effects on light interception during which photosynthesis takes place which is the energy manufacturing medium using green parts of the plant. The climatic condition prevailing during crop growth is also a great determinant of yield of crop. In Nigeria, the erratic nature of rainfall and high temperature makes determination of sowing date crucial. Also population density determines the size and geometry of crop which indirectly influences photosynthetic activity which has direct influence on yield. This is because if the plant is small, the leaves will be small and the surface area for absorbing the energy for photosynthesis will be reduced resulting in low yield. The importance of this factor necessitated the determination of turmeric under varying environmental conditions and population density to improve its productivity. Therefore the objective of this trial was to determine the appropriate sowing date and spacing for optimum production of turmeric.

Materials and methods

The experiment was carried out between May and December 2010 at the National Horticultural Research Institute, Ibadan, Nigeria (07^0 24'N, 03^0 35'E, and 213m above sea level).Ibadan lies in the derived savannah of South Western Nigeria. The trial was laid out in a 4 x 4 factorial in randomized complete block design in three replications. Treatments compared were four spacing viz 45 x 10cm, 45 x 20cm, 45 x 30cm and 45 x 40cm and four sowing dates May 26^{th}, June 9^{th}, June 23^{rd} and July 7^{th}. The plot size was 3m x 3m.Data on morphological characters which includes plant height, number of leaves, and number of tillers were taken fortnightly while the yield components were recorded at harvesting.

Results and discussion

Plant spacing and planting dates had a significant effect on the plant height, number of leaves and yield of turmeric (Table 1).

Table 1: Effect of planting date and spacing on the growth and yield of Turmeric

	Plant Height(cm)			Number of Leaves			Number of Tillers			Yield(t/ha)
Date	6	10	14WAP	6	10	14WAP	6	10	14WAP	
May 26	17.2	21.7	27.9	8.0	9.7	10.5	1.62	3.3	5.75	23.39
June 9	14.2	20.6	27.2	7.3	9.5	9.5	0.42	3.0	5.34	27.06
June 23	12.5	20.1	26.3	6.0	9.0	9.0	0.85	2.7	5.25	27.36
July 7	9.0	18.7	24.4	4.9	8.7	8.7	-	1.7	5.05	24.61
LSD(0.05)	1.00	1.60	1.60	0.40	0.52	0.60	0.20	0.33	0.40	11.6
Spacing(cm)										
45 x 10	13.2	18.2	23.1	6.52	7.25	8.75	0.44	1.95	4.30	42.0
45 x 20	13.2	19.7	25.3	6.45	7.50	9.14	0.55	2.50	4.90	22.44

P.D x S		NS			NS			NS		NS

WAP= Weeks after Planting, P.D-Planting dates, S- Spacing and NS-Non significant

This in agreement with Islam *et al.*, (2002) who reported that plant spacing, had significant effect on number of leaves and the yield. Early planting in May produced significantly higher plants, number of leaves and number of tillers (Table 1). This is in agreement with the findings of Yadav *et al*. (2013) who showed significant effect on plant height, number of tillers and yield of ginger with different planting dates and early planting. Enhanced vegetative growth was also observed as the spacing widens. Wider spacing of 45 x 40cm had significantly highest plant height, number of leaves and number of tillers. This is also in agreement of the findings of Islam *et al.,(*2002) who reported a significantly highest plant height and number of leaves with a wider spacing and Gopichand *et al*.,(2006) who reported the same for the number of tillers. However planting turmeric in June generally resulted in highest rhizome yield, while close spacing at 40 x 10cm gave the highest rhizome yield (Table 1). These results are also in agreement with the findings of Chaudhury*et al*. (2000) who described that closer spacing (50 x 15cm) gave the higher yield of turmeric when conducted an experiment with three spacing viz 50 x 15cm, 50 x 20cm and 50 x 25cm. Islam *et al*.,(2002) also gave similar results with closer spacing of(45 x 10cm) when conducted an experiment with four spacing viz 45 x 10cm, 45 x 20cm, 45 x 30cm and 60 x 30 cm. Planting date and spacing interaction was not significant(Table 1).

Conclusion

It can be concluded from the experiment that planting of turmeric in May produced good vegetative growth even as spacing widens, planting in June produced the highest rhizome yield. Spacing of 40 x 10cm also produced the highest rhizome yield.

Abstract

Biological (symbiotic) nitrogen fixation plays an important role in sustainable crop production. It is a safe, productive and cost-effective form of land management which provides a significant input of biologically-fixed nitrogen in soil. In sustainable crop production, inoculation of pea seeds (*Pisum sativum* L.) with effective strains of *Rhizobium leguminosarum* becomes more and more exploited. Selection of *R. legumiosarum* strains that are effective and adapted to specific environmental condition is essential prerequisite for successful inoculation. The experiment was set up with two most common pea cultivars in Herzegovina in randomized block design with three replications. Influence of referent and indigenous strains on pea cultivars characteristics was assessed. The results confirm that higher values of nitrogen content in grain of peas are significantly affected by cultivars, while the nitrogen content in the aboveground plant parts were significantly affected by the interaction between the elected indigenous and referent strains and pea cultivars. The highest yield (3.83 t ha^{-1}) was obtained by application of referent strain of *R. leguminosarum* 1001 (inoculated) but without statistical significant differences to indigenous strains and control. The number of root nodules and their dry weight were significant affected by the indigenous strain S1 but the number of nodules was also influenced by the cultivars. Besides observing the effect of seed inoculation on some important characteristics in two pea cultivars (yield, number of nodules, dray weight of nodules, nitrogen content in the aboveground plant and grain) the paper also shows their correlations relationships.

Keywords: *Rhisobium leguminosarum, pea, nitrogen, yield, nodulations*

Introduction

Legume inoculation is a way of assuring of *Rhizobium* strain appropriate for the cultivar being planted was present in the soil at the proper time and in sufficient number assuring a quick and effective infection (nodulation) and subsequent nitrogen fixation (Bejandi et al., 2012) Burns and Hardy (1975) reported that nodulation bacteria fixed about 175 × 106 tons of nitrogen per year. It is a much higher amount of nitrogen in comparison with the world annual production of nitrogen fertilizers being 30 × 106 tons (Postgate, 1982). Many authors stated that yields could be increased by legume seed inoculation compared to nitrogen fertilizer variants (Kálalová and Šimon, 1993; Dobereiner et al., 1995). The inoculation of seeds with *Rhizobium* increase nodulation, nitrogen uptake and seed protein (Bejandi et al., 2011; Tahir et al., 2009). Selection of appropriate inoculation strains in nitrogen deficient soils may offer an excellent opportunity for improving legume growth and development as an alternative to commercial nitrogen fertilizers. Bacterial inoculation of legumes seed presents an important ecological and economic measure. This is one of the preliminary researches conducted in Herzegovina region relating to the study of the composition and characteristics of indigenous strains of *Rhizobia* on pea

cultivars. Yet it can be assumed that there is a natural population of these bacteria and that the indigenous strains significantly differ in their symbiotic impact on plant. The study aimed also to encourage use of symbiotic nitrogen fixation as natural process for sustainable pea cultivation in the area of Herzegovina region.

Material and methods

A field trial with two pea cultivars Čudo Amerike and Mali Provansalac inoculated with bacterial strains was located in Mostar city area (Donja Jasenica) in 2014. Seeds were inoculated with two isolated indigenous strains (S1 and S13) and one reference strain of *R. leguminosarum* bv. *viciae* (S 1001) and results were compared to the uninoculated–control plants (K). The trial was set up in three repetitions on the area of 294 m^2, with 28 m^2 per experimental plot. Peas are sown by hand in second half of March 2014. Selected indigenous and reference strains were amplified and prepared for the soil inoculation of pea seeds at the Department of Microbiology, Faculty of Agriculture University of Zagreb. In the harvest period five whole plants were selected from each central plot part for analysis. Number of nodules per plant, dry weight of nodules per plant (g), total nitrogen content (%) in the aboveground part of the plant, grain and grain yield of peas (t ha^{-1}) were measured to evaluate symbiotic effectiveness. Determination of nitrogen in aboveground plant part and grain was carried out by a standard Kjeldahl method. All collected data were analyzed with statistical package Genstat 7.2 (Rothamsted Experimental Station, 2004). The trial site was extensively used in the vegetable productions; however, the soil nutrients state before peas sowing was performed. The chemical analysis of soil included the determination of soil reaction in water and 1M KCl humus (%) basis by Kozmann-in, total nitrogen (%) by Kjeldahl method, physiologically active phosphorus (P_2O_5 mg 100 g^{-1} of soil) and potassium (mgK_2O 100 g^{-1} of soil) by AL-method. The weather data were taken from Federal Hydro-meteorological Institute stations in Mostar.

Results and discussion

Standard chemical analyzes were conducted on soil samples collected from experimental locations in Herzegovina (Table 1). Soil samples were taken from the surface layer (0-30 cm depth) before setting up the trial.

Table 1. Chemical soil characteristics

Soil sampling depth	pH H_20	pH KCl	Total $CaCO_3$ %	Humus (%)	Total nitrogen (% N)	Potassium mg K_2O/100 g soil	Phosphorus mg P_2O_5/100 g soil
0-30	8,26	7,51	25,94	4,32	0,15	21,76	35,36

According to chemical analyzes of the soil at the location Donja Jasenica soil pH reaction was alkali. The soil has high humus rate due to its intensive use for the vegetable cultivation and manure fertilization. The nitrogen content in the soil was good. Soil supply with physiological active phosphorus and potassium was very good.

Mean annual air temperatures in 2014 were significantly higher than normal values for the period 1961-1990 in the entire observed area of Bosnia and Herzegovina. Air average humidity for March till May was 64% and precipitation average for these three months was 96.66 mm. After the pea sowing the first period was very dry while the April was very pluvial and at the end of vegetation season again dries time. This had reflected on development phase of pea plants. It has been known influence of plant and environmental factors on native and introduced Rhizobia in

the soil. Rhizobia prefer a soil temperature of 25° to 30°C, a pH value of 6.0 to 6.8 and sufficient soil moisture. The soil moisture was not satisfying factor in our trial regarding the dry period on the beginning and the end of pea vegetation. Based on the analysis of variance results of trials showed a strain S1 (LSD 5% = 0.32) significantly influence on nitrogen content (3.78%) in the aboveground mass of the pea relative to the other strains applied and the control. There were no significant differences for other strains on nitrogen content. Plants grown whit strains S1001 and S13 had 8.5-9.5% lower value of nitrogen in the aboveground mass and the control strain (K-uninoculated) up to 15% lower content than strain S1 (Figure 1). Nitrogen content in aboveground mass of pea cultivars Mali Provansalac and Čudo Amerike statistically were not differed.

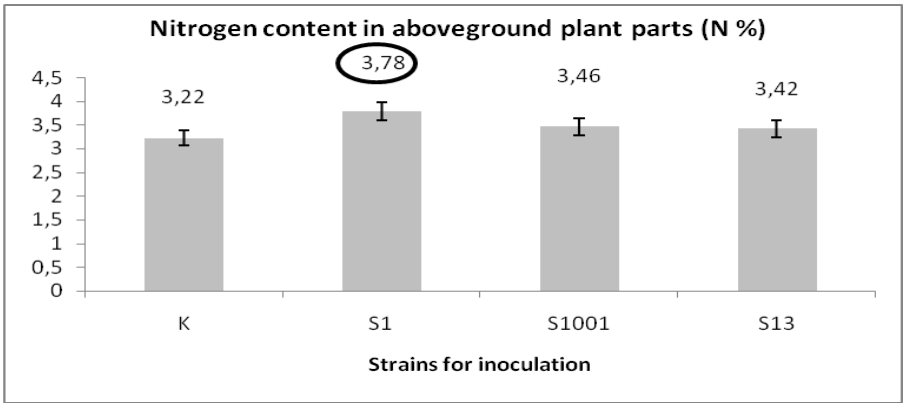

Figure 6. Average nitrogen content in aboveground plant parts (N %) regarding applied different strains

Results of statistical analysis indicated that there was significant interaction between applied strains and cultivars of pea. Nitrogen content for cultivar Mali Provansalac in the aboveground part of pea shows significant differences ($LSD_{1\%}$ = 0.46%) in the applied strain S1 (about 22% higher) comparing to the control (K) and other applied strains (S1001 and S13) (Figure 2). According to the research of Hadi and Elsheikh (1999) protein content of cultivars could be improved by selecting a good cultivar and a competitive, infective and effective Rhizobium strain.

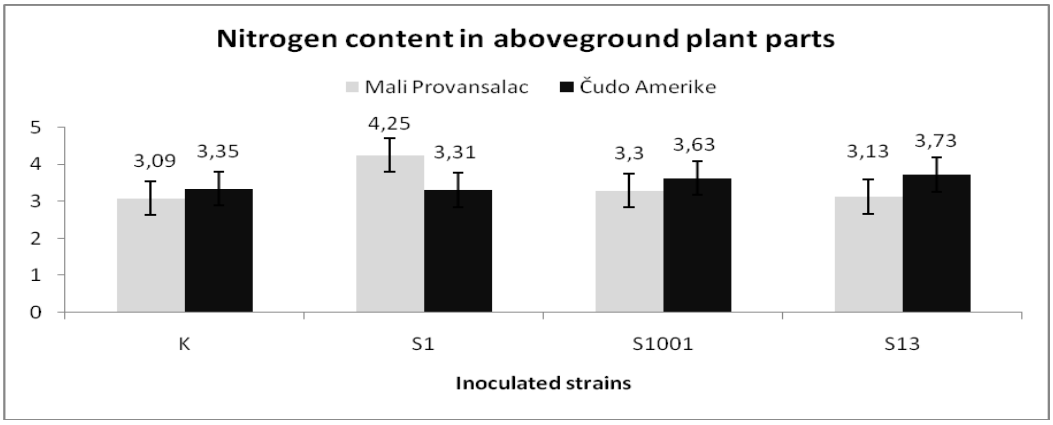

Figure 7. Average nitrogen content in aboveground plant parts (N %)

The results of the ANOVA indicated that the nitrogen content of the pea grain regarding to control and applied strains did not statistically differed. But results showed that the nitrogen

content in the pea grain significantly differed between used cultivars. Cultivar Čudo Amerike has had significantly higher nitrogen content in the grain (4.94 % N to 4.33; $LSD_{1\%}$ = 0.23). Interaction between these two factor is absent for recorded character.

Results of analysis of ANOVA showed that the cultivars as well as selected strains have no significant effect on the yield. The lowest yield was achieved by using strain S1 (2.76 t ha^{-1}), which showed 33% lower yield than control treatment and 38% to 19% lower than strains S1001 and S13. Although there were no significant differences between used cultivars in the experiment Čudo Amerike had 6.5% higher yield (3.51 t ha^{-1}) (Figure 3). There were no significant interaction between cultivar and strain for the yield. According to the Jordan (1984) infectivity and effectiveness of inoculation representing individual characteristics and they may vary within a wide range depending on the bacterial strain and genetic factors of the host plant. The capacity of modulation is more stable property than the fixation ability. Also important factor for effectiveness of strains on most of pea cultivar characteristic were environmental conditions which may be inconvenient not only for cultivar development progress but also for bacterial activity in the soil.

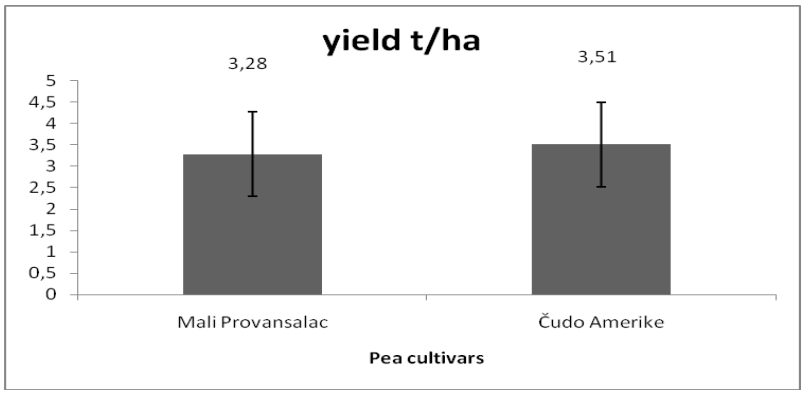

Figure 8. Average yield values of different peas cultivar

Comparing the results of indigenous strains to reference strain 1001 there is no significant differences in yield even the referent strain should have limited genetic potential in relation to the indigenous which should be well adapted to the certain environmental conditions and easier adopt to the environmental changes.

Statistical analysis showed significant differences in dry matter of nodules identified on pea root at the level of $LSD_{1\%}$ = 0.16. The differences in dry matter of nodules were showed between pea plants inoculated with S1 strain compared to the control and the other two applied strain. The difference in the dry matter of nodules in plants inoculated with the strains S1001 and S 13 were not significant and also dry matter of nodules was much higher with these two strains compared to the uninoculated variant-control (Figure 4).

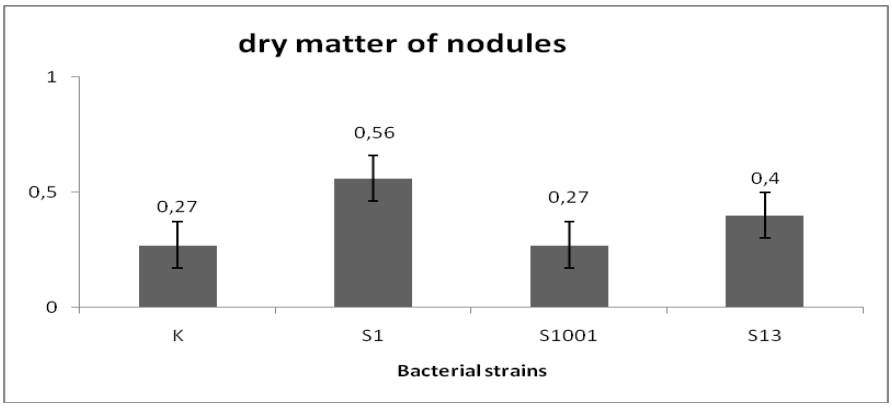

Figure 9. Dry matter of nodules regarding inoculated and uninoculated plants

Cultivars did not show differences in dry matter of nodules.

Salih (1984) recorded significant differences in dry matter of nodules with inoculants treatment and cultivar.

Statistical analysis for the characteristic number of nodules on roots indicate highly significant influence of the strains on the level of LSD 1% = 13.47%. The differences between the numbers of nodules per plant inoculated with variant strain S1 showed a statistically significant difference compared to the other two strains, as well as in relation to the variant without inoculation. S1 strain showed 70% higher number of nodules compared to the control and the 57% higher number of nodules in relation to S1001 and S13 strains (Figure 5). Differences in the number of nodules between control and those plants inoculated with strains S1001 and S 13 were not significant. According to the authors Elsheikh (1992), Mahdi (1992) inoculation with a selected *Rhizobium* strain can result in a significant increment of nodule number per plant, its dry matter and yield.

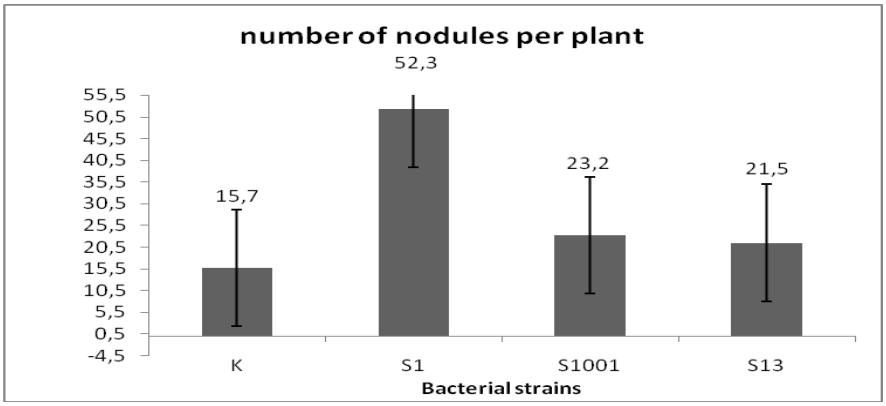

Figure 10. Number of nodules regarding inoculated and uninoculated plants

Cultivar has had significant impact on number of nodules per plant with $LSD_{1\%}$ = 9.52. Cultivar Čudo Amerike showed a higher nodulation on the roots of peas for even 39% compared to cultivar Mali Provansalac.

Between the number of nodules identified on pea root and its dry matter it was established a positive moderate correlation with Pearson's correlation coefficient of r = 0.31. Meaning that with the increase of root nodules number the dry matter was slightly increased. Correlation between yield and the number of nodules, as well as between yield and dry matter of nodules is very weak

or absent. Nitrogen content in the pea grains and the number of nodules, as well as nitrogen content in aboveground mass of plants and the number of nodules were not in strong correlation. Negative and mild correlation showed between the dry matter of root nodules and nitrogen content in the pea grains with Pearson coefficient of r = -0.23. Positive and mild correlation was found between the dry matter of root nodules and nitrogen content in the aboveground mass of plants with Pearson coefficient of r = -0.33 meaning that with increasing nitrogen content in the aboveground mass the dry matter content in the root nodules grow. Among other correlative relationship mildly positive correlation was found between the yield of pea and nitrogen content in aboveground mass of peas with a Pearson correlation coefficient of r = 0.21, while a correlation between nitrogen content in the pea grain and yield was absent. The *Rhizobium*-legume symbiosis, which is a N_2-fixing system, the process of N_2 fixation is strongly related to the physiological state of the host plant. Therefore, a competitive and persistent rhizobial strain is not expected to express its full capacity for nitrogen fixation if limiting factors (e.g., salinity, unfavorable soil pH, nutrient deficiency, mineral toxicity, temperature extremes, insufficient or excessive soil moisture, inadequate photosynthesis, plant diseases, and grazing) impose limitations on the vigor of the host legume (Peoples et al., 1995). The very low or absent correlation between evaluated characteristic were probably result of some limiting environmental factor so the research should be repeated again in same or similar condition for making same strong conclusion.

Conclusion

Studied indigenous and referent strains have different nodulation and symbiotic ability with selected pea cultivars and environmental condition of location. The best results of adaptation in environment of selected location regarding the nodulation, dry matter of nodules and aboveground nitrogen content have sowed indigenous S1 strain. Cultivar Čudo Amerike has shown statistically higher nitrogen grain content without significant difference in selected strains and control. The same cultivar showed also higher, but not statistically significant, yield (3.51 t ha^{-1}) to the other cultivar. The most positive correlation effect was that increase of nitrogen content in the aboveground mass increase the dry matter content in the root nodules. In the future it should be more agronomic studies on legume seed inoculation with miscellany of strains to provide more information on its effectiveness in different terms of the growth.

Abstract

Application of fertilizers in the production of aromatic herbs and other crops depends on several factors, whereby the soil fertility and requirements for individual nutrients culture are the most important. The principle of application of mineral fertilizers should ensure optimal conditions for maximum nutrition grown culture, whereas the contamination of the environment is not questionable. Since the Chamomile is characteristic plant of poor soil, it requires very little nutrients. However, intensive farming and carefully balanced fertilization helps achieving better. The present study was carried out to determine the effects of different nitrogen doses on yield and exuberance of Chamomile flower.The experiment was set in randomized block design with four replications which included four different types of fertilizers.Fertilization consisted of applying increasing nitrogen unit in quantities of: a1-control, A2-15 kg / ha, a3-27 kg / ha, a4-41kg / ha. Larger amounts of nitrogen resulted in the increased share of green mass (herb). The most vigorous plants have been registered with the highest nitrogen concentration variant a4 (57,51cm; 25,13g).On the other hand increased nitrogen rates had a negative impact on the formation and development of the flower.The least number of flowers was registered in the variant with the highest nitrogen concentrations a4 (11.68), while the highest number of flowers was registered in the variant a2 (21.68).

Keywords: *chamomile, fertilization, exuberance, yield*.

Introduction

Herbal medicineis the oldest method of treatment. Many nations throughout its history have learned to use medicinal herbs which succeeded in their climate (Turudija Živanović, 2010). In addition to the pharmaceutic industry, the medical and aromatic plants are used by cosmetic industry (bakery industry, industry of alcoholic and non-alcoholic beverages, confectionery industry) and others (Turudija Zivanovic, 2010). Some ingredients of the herbs are used as flavorings of the aroma, taste and color and flavour enhancers as the product performance itselfis improved by their active ingredients. It is significant to mention the use of herbs in cooking (Turudija Živanović, 2010).The very purpose of the production of medicinal plants is their useful ingredients, essential substances and essential oils notably used in today's medicine and pharmaceutical industry.They were used in ancient Greece, India, China (Janick and Hummer, 2010)

Chamomile (Matricaria chamomilla L.) is a hardy, wild medicinal plant widespread throughout the world. It contains a large number of active substances, and the main ingredients are easily withdrawable essential oil (0.3 to 1.3%), which has a bactericidal action, it normalizes function of the stomach and intestines, and promotes sweating. Important components of the chamomile oil

are alpha bisabolol, farnesene and bisabolol oxides. Thanks to its ingredients, Chamomile has anti-inflammatory, antioxidant, antimicrobial, spasmolytic, carminative effect. It accelerates the processes of wound healing and regulates the metabolism of the skin while Chamomile polysaccharides show immune stimulating effect. It is used in local therapy with acute and chronic inflammation of the skin (dermatitis, eczema), neurodermatitis (atopic eczema), wound treatment, solar skin damage, babies eczemaand treatment of hemorrhoids. (Arsic, 2005)

Chamomile is one of the oldest remedies of traditional medicine. As early as 1570 Hieronymus Bock wrote about its curative effect: „Nothing can be achieved without this flower, quite ordinary flower of Chamomile since there is no medicinal herb more useful than this one used for all diseases".

Because of medicinal properties, its production and consumption is of high interest in most countries. The growth indices, flower yield and active substance of chamomile plants are affected by genetic background and environmental conditions (Hadi et al., 2015). These attributes are strongly modified by many other factors and management skills such as using the different kinds of fertilizers.

Among the macro- elements, nitrogen has the most significant effect on growth characteristics of chamomile. Increasing concerns about the negative effects of chemical fertilizers have generated substantial interest in the use of other nitrogen sources [11- 13]. Despite the importance of nitrogen in production of field crops andmedicinal plants, application of this nutrient element from chemical sources has resulted in environmental problems and pollution of the global ecosystem (Hadi et al., 2015).

Conventional agriculture with focus on chemical fertilizers has caused rapid reduction in organic matter and fertility of soils. Therefore, it is essential to apply proper production management in order to improve physical, chemical and biological characteristics of soils (Hadi et al., 2015).

As practice shows, thehighest Chamomile yield and growth is achieved with the use of combined mineral and organic fertilizers (Shams et al., 2012.). The present study was carried out to determine the effects of different nitrogen doses on yield of chamomile flower.

Materials and methods

Field experiment was conducted in the research field of the Faculty of Agriculture, University East Sarajevo (entity of Republic of Srpska, Bosnia and Herzegovina). The experiment was set in a randomized block design with four replications at the end of the second week in May 2014 and 2015. Seeds were sown on the rows with 0.30 cm spacing. The standard measures of care as hoeing, watering, fertilization and weed control have been carried out during the experiment.

Fertilization consisted of applying increasing nitrogen unit in quantities of: a1-control; A2 200kg / ha of NPK (7:20:30); a3-200kg / ha NPK (7:20:30) +100 kg / ha KAN (27%); 100 a 4 kg / ha KAN (27%)

Vegetative and generative increase has been analyzed on a sample of 5 plants with all variants of fertilization. Vegetative increase is analyzed through the following components:average weight of above-ground portion of plants and plant height. Generative increase is analyzed through the number of flowers per plant.The studyresults wereprocessed by the analyses of variance, and the difference between the variants was tested by LSD-test and presented in tables.

Results and discussion

Soil and climatic conditions

Based on the mechanical composition analysis of the samples taken from the alluvial soil conducted on the experimental field of the Faculty of Agriculture (University of East Sarajevo) it was found that the soil is light texturedbecause the content of the total sand fraction (<0,02 mm) is 56,30 to 58,50%.

Powder composition (0.02 to 0.002 mm) is 22.40 to 24.90%, while the percentage of clay particles (<0,002 mm) 18.80-19.10% (Tab. 1).

Tab.1 The results of chemical analyses of soil

Soil sampling depth (cm)	Coarse sand 2-0.2 mm(%)	Fine sand 0.2-0,02 mm(%)	Powder 0.02-0.002 mm(%)	Clay 0.002 mm(%)
0-25	11.09	47.41	22.40	19.10
25-50	10.79	45.51	24.90	18.80

Based on analysis of texture, ie. texture of soil type such asfluvisol, it was found that it belongs to the class of sandy clay(Tab. 1).

Tab.2 The results of chemical analyzes of soil types, alluvium (fluvisol)

Soil sampling depth (cm)	pH/H_2O	pH/KCl	$CaCO_3$ (%)	Humus (%)	N	P_2O_5 (mg/100 g)	K_2O (mg/100 g)
0-25	7.38	6.13	<1	2.3	0.151	> 40	34.6
25-50	7.49	6.75	1.5	2.4	0.158	> 40	36.8

Chemical analysis of samples taken from soil type fluvisol with depth of 0-25 cm, indicates that the soil has slightly acid to neutral reaction with minorcarbonate content,intermediary secured with humus and with an increased amount of available phosphorus and potassium (Tab. 2).Chemical analysis of soil samples taken from a depth of 25-50 cm showed similar values of the analyzed soil samples taken from the depth 0-25 cm, except that the carbonate content and humus was increased at the depth of 25-50 cm, while the content of available phosphorus was decreased compared to values obtained from a depth of 0-25 cm (Tab. 2)

Graf.1 Average daytime temperature and relative humidity at the time of experimental performance

Tab.3 Analysis of variance for measured properties of chamomile (Matricariachamomilla L.)

Fertilization		The average weight of the fresh stem (g)		The average height of the fresh stem (cm)		Number of flowers per plant	
		2014.g	2015.g	2014.g	2015.g	2014.g	2015.g
a_1		15.69	19.94	49.40	47.03	14.35	8.53
a_2		14.17	24.37	55.82	46.28	19.40	13.96
a_3		29.29	27.47	58.83	56.20	13.01	10.35
a_4		22.80	18.66	43.03	36.10	18.73	13.78
LSD	5%	1.89	4.61	3.94	6.18	5.90	3.26
	1%	2.53	6.17	5.28	8.29	7.91	4.37

The average weight of the fresh stem

Variants applied to nitrogen had a statistically significant impact on the fresh plant's weight. Maximum weight of plants (29,29g; 27,47g) was achieved in the variant with the highest nitrogen rate (200 kg / ha NPK (7:20:30) +100 kg / ha KAN (27%)

The average height of the fresh stem

Variants applied to nitrogen had a statistically significant impact on the height of fresh plant. Maximum height of plants (58.83cm; 56,20cm) was achieved in the variant with the highest nitrogen rate (200kg/ha NPK (7:20:30) +100 kg/ha KAN (27%) parallel with the results of Kariminejad and Pazoki (2015).

Number of flowers per plant

The research results clearly indicate that the minimum flower productionhas been achieved through the variant fertilized with the highest rate of nitrogen units.Increased amounts of nitrogen in the soil affected larger share of green mass and number of flowers reduced per Chamomile plant. Many scientific studies show similar results (Zeinali et al.,2014; Dadkhahet al., 2012).

Conclusion

The results of this research indicate that the use of increased nitrogen fertilizers led to the expansive growth of green mass reducing the number of chamomile flower. The research results indicate that the maximum amount of nitrogen needed to achieve high yield is 200kg / ha of NPK using 7:20:30fertilizer formulation. Exceeding the maximum dose leads to increasing the share of green mass and plants lodging which significantly hampers or prevents the harvest.Primarily, increased plant height can be attributed to the effect of nitrogen on the vegetative growth and division of cells in the plant, stalk particularly.

Abstract

Breeding of grain crops (wheat, barley, triticale, rye and oats) in our institution lasts about 50 years, but the completion of the breeding program of these plant species has been occurred in the last ten years. Realistically, there is a need and the possibility of breeding work on triticale, which resulted in the creation of multiple varieties and excellent lines of great genetic potential. The created lines have the weight of spike over 4 g and over 65 grains per spike in terms of less seeding. Significantly, our new lines, as well as recognized varieties, confirmed its production values in the experiments as well as in production. Besides varieties Oskar and Viktor, it is important to emphasize the excellent line of triticale, which was reported to the Directorate of Plant Protection, Ministry of Agriculture and Environment of Republic of Serbia under the code BL T – 55 at the end of 2011. In the trials conducted at 6 locations, this line achieved higher yield, 350 kg/ha^{-1} more than standard variety Odisej, and proved to be a significant carrier of genetic yield potential with a maximum yield of 12.141 kg/ha^{-1} at the location of Sombor city (Serbia). High-yield, early to mid-early variety of winter triticale Oskar was developed by crossing genetically divergent parents, variety Presto and one of the local lines of winter triticale. Variety Oskar is characterized with a high fertility potential, good technological quality, very good resistance to lodging, excellent resistance to low temperatures, as well as the causal agents of major diseases of grain crops. According to the two-year results of the Commission for the registration of varieties, variety Oskar achieved excellent grain yield of 8952 kg/ha^{-1}. The highest yield was achieved in conditions of intensive production in Serbia, in particular in municipality of Sremska Mitrovica (9509 kg/ha^{-1}), and cities of Novi Sad (9077 kg/ha^{-1}) and Kragujevac (8452 kg / ha^{-1}). In three-year comparative trials at the production part of the Public Institution (PI) Agricultural Institute of Republic of Srpska - Banja Luka, this variety achieved a yield of 8805 kg/ha^{-1}. This variety is characterized by extremely coarse grain, absolute mass of about 44 g, excellent gravity about 72 kg and the protein content of about 15%.

Keywords: *Breeding, Potential, Variety, Line, Yield, Quality.*

Introduction

The paper analyzes the genetic and production potential for yields of new lines and varieties of triticale, which will represent a new generation that are creating at the PI Agricultural Institute in Republic of Srpska. Our analysis are based on the results achieved by these lines and varieties, both in our conditions and on a number of sites and for several years, in comparison with standard varieties and our lines. In the Institute, it is recognized the fact that triticale can be very rational plant species in terms of food sources, primarily in the field of animal husbandry.

Breeding program in our Institution lasts about 15 years and this work has resulted with the creation of several varieties and several important lines of this plant species. Certainly, this is an important species for growing in our conditions, sowing area of 10000 ha, so considerable attention is devoted here which is quite modest in comparison to more developed breeding centers.

Triticale grain quality depends on the efficiency of breeding and production conditions. 1000 grain weight is a reliable parameter in assessing the quality and technological characteristics of grain and positively correlated with grain protein content. Varieties with higher test weight also have a higher content of the extract.

A large number of varieties from our collection, as well as the newly created lines have very good to excellent resistance to low temperatures. Winter without snow cover and a longer frost can lead to significant degradation of certain materials. Here is a common problem how to find a combination whose progeny have good or excellent agronomic and technological characteristics as well as good resistance to low temperature. The results are different in the earlier and later generations, but during the process of breeding and monitoring of material it is possible to reach the right target.

The aim of work

This paper aims to present the principle activity of breeding work on triticale, the essential characteristics of the new varieties and lines with values that show a significant genetic potential as well as the characteristics of a variety in production with its main agronomic and technological characteristics. Variety "Oskar" represents a material worthy of attention with economical and stable production potential as well as the good results achieved in the production in favorable growing conditions with adequate production technology.

Material and methods

Our gene collection of different varieties of winter triticale is about 150 genotypes, which are grouped into appropriate groups that are needed in order to facilitate and to make easier the formation of breeding programs, as well as the realization of the same. 100 crossing combinations are made annually. All material is grown in combination of pedigree and bulk method depending on the generation of separation. Selected lines are sown in the preliminary and comparative trials, tested to the required characteristics and then applying to the Variety Commission. The basic material for this program were the following varieties: Almo, Bogo, Alda, Ticino, Agrano, Bc Goran, Amarilo, Corn Mah, Corn winter, Presto, KG-20, Jugo TS -11, Jugo TS 16 and the domestic lines of hexaploid wheat and the lines of triticale.

The hybrid material was bred using pedigree method. Phenotypically uniform lines were selected over the past few years. All the important and necessary characteristics were monitored during the preliminary and comparative trials on the experimental field of the Agricultural Institute, in comparison with about thirty varieties (foreign, domestic, old and new ones) as well as the leading varieties in production in our region. Lines are submitted for testing to Variety Commission in Belgrade, for testing sites (Novi Sad, Pančevo, Sremska Mitrovica, Zaječar, Sombor, Kragujevac, Banja Luka), and based on the two-year results are recognized and permitted to be introduced into production at the area of Republic of Serbia, as well as the territory of BiH.

Results and discussion

Top seven triticale lines were analyzed and observed the characteristics of the number of grains per spike, weight of grains per spike and spike length (Tab. 1). From the above values, which are shown in the table, it can be concluded that triticale has great genetic potential, judging by the number of grains per spike and weight of these grains. Those lines were grown under the conditions of less sowing and show the possible values for the realization of genetic yield potential.

Tab. 1 Analyzed lines of BL triticale

Line	Average number of grains/spike	Grain weight/spike (g)	Spike length (cm)
Bl T - 1	65	3,42	12,5
BL T – 2	54	2,63	10,5
Bl T - 3	55	2,62	12,0
BL T - 4	70	3,04	11,3
BL T - 5	52	2,59	11,5
BL T - 7	60	3,55	11,7
BL T -12	69	3,91	12,4

Yield increase according to our research at the above lines was accompanied by an increase in length and number of grains per spike, and ultimately the weight of spike. Plant height at the mentioned lines is around 110 cm, and we have an increase in harvest index, thereby increasing the yield which is in accordance with the results of Austin (1982). Increased productivity per spike can be attributed to the impact of gene for number and grain weight, not only the redistribution of organic matter.

Testing in Serbia lasts two years at six locations. At the end of 2011, one line of winter triticale was reported for recognition in Serbia (Belgrade) under the code BL T-55, which filled the necessary requirements to enter in the recognition process. Seed and spike were delivered for VCU and DUS test. Variety achieved a higher yield or 350 kg from standard variety Odisej, but not statistically significant and it was not recognized by the Commission. Although deviations in terms of grain yield were not highly significant, line T-55, in most years and in most locations showed higher yields compared to the standard, which is a significant success as a result of several years of work.

Tab. 2. Grain yield of winter triticale line on six locations in comparison with a standard

Site	Year	Grain yield (kg/ha)	
		T-55	Odisej
Kikinda	10/11.	7408	8786
	12/13.	8218	7931
		7813	8358
Kruševac	12/13.	7333	6758
Novi Sad	10/11.	11524	10594
	12/13.	10320	10070
		10922	10332
Pančevo	12/13.	10557	8463
S. Mitrovica	10/11.	10196	8878

	12/13.	10043	11093
		11092	11315
□	10/11.	10317	9963
	12/13.	9294	8969
□ (2010/11 i 2012/13.)		9749	9399
h	0,05	365	
	0,01	486	
Cv		7,61	

Line T-55 achieved a maximum yield of 12141 kg^{-1} at the site of Sombor, as well as the significant values of the yield on locations of Novi Sad and Pančevo. The average two-year yield for all locations, a total of 6, was 9749 kg^{-1}. These values (tab. 4) show that it is a line with great genetic potential.

In terms of physical-chemical or technological properties of grain of which depends the quality of flour, the results obtained by the line T-55 were in the level of standard. It is known that the standard variety Odisej, one of the best varieties that are grown in our region, and also the variety that occupies the largest area in our country and in the production achieves yields of over 4.5 t/ha^{-1}.

Tab. 3. Heading date, plant height and lodging

Site	Year	Heading		Plant height (cm)		Lodging (mark 1-9)	
		T-55 (date)	+/-days from standard	Line 3	Odisej	Line 3	Odisej
Novi Sad	2011/12.	07.05.	6	124,5	120,3	1	1
	2012/13.	05.05.	4	122,5	111,5	1	1

Pančevo	2011/12.	07.05.	5	117	111	1	1
	2012/13.	02.05.	2	109	95	1	1
	□		3,5	113	103	1	1
Sremska Mitrovica	2011/12.	11.05.	3	103	108	1	1
	2012/13.	18.05.	1	105	107	1	1
	□		2	104	107,5	1	1
Sombor	2011/12.	03.05.	0	118	116	1	1
	2012/13.	05.05.	6	126	128	1	1
	□		3	122	122	1	1
□	2011/12.	-	4,8	118,7	115,06	1	1
	2012/13.		3,0	115,1	109,5	1	1
□ 2011/12.-2012/13.			3,8	116,7	112,1	1	1

Note: Heading: .+ later than standard Lodging: 1= no lodging
.- earlier than standard 9= 100% of lodged plants

The table shows that the line of triticale, in terms of the heading date is slightly later than the standard variety Odisej. The differences in the heading date stand out depending on the year and the site at which the line is tested. Thus, at the site of Kikinda, line 3 headed on 14 May or 10 days later in relation to the standard. Due to this difference manifested in 2011/12. and that was not so expressive in the coming year, we can conclude that a large impact on this feature had year. At the site of Sombor, line 3 headed on 3 May and remained at the level of standard. According to the final average line 3 is later by 3.8 days compared to the standard variety Odisej.
In terms of plant height, line 3 is slightly higher than the standard, while in terms of resistance to lodging maintained at the level of the standard variety.
According to Variety Commission, line BL T-21 or a variety Oskar achieved an average yield of 8952 kg/ha^{-1}, which is 350 kg more than the standard. The highest yield this line achieved in terms of the intensive production of Sremska Mitrovica 9509 kg/ha^{-1}, Novi Sad 9077 kg/ha^{-1}, Kragujevac 8452 kg/ha^{-1} and Zaječar 9516 kg/ha^{-1}. In extremely dry 2002, this line achieved the highest yield of 7546 kg/ha^{-1} at Banja Luka. In the three-year trials, at the site of the production part of the Agricultural Institute, this line achieved a yield of 8805 kg/ha^{-1}.

Tab. 4. Grain yield of the line BL T-21 and standard in 2005. (kg/ha^{-1})

Variety	Localities						x
	Kragujevac	N. Sad	Pančevo	S Mitro.	Sombor	Zaječar	
BLT 21	8452	9077	7960	9509	8700	9516	8869
KG-20	8088	8046	7680	6850	5800	8740	7534

By the time of heading variety Oskar is very early variety. In our agroecological conditions tillering stage is at the beginning of May. It has excellent resistance to low temperatures. Plant height is about 115 cm, with a very long (about 15 cm) semi loose spike. This line is characterized by extremely coarse grain, absolute mass of about 44 g and excellent gravity about 72 kg. Flag leaf is semi erect and as such is held by the end of milk ripeness, when lightly falls in a horizontal position. Basic and essential characteristics of other several lines we can briefly show through agronomically important features shown in the following table. In addition to these properties, essential characteristic is the protein content around 15%.

Tab. 5. The yield of triticale varieties at the site of the Agricultural Institute in 2013

No.	Variety	Date of heading	Plant height	kg/ha
1.	ODISEJ	16.V	108	6896
2.	OSKAR	23.V	118	7199
3.	AGRANO	23.V	109	7520
4.	KG 20	20.V	95	4640
5.	BL T 8	24.V	115	6880
6.	BL T 17	1.VI	100	6670
7.	TRIMERAN	26.V	110	6540
8.	BL T 10	18.V	117	7161

It is significant to note that our new lines and recognized varieties confirm their production values, both here and in the production trials with farmers.

Conclusion

With the introduction of varieties Oskar and Viktor in the production assortment, of our region, our assortment is richer and more diverse. The new lines of winter triticale show a positive trend in terms of increasing the genetic potential that is the main component of yield. It is very likely that some of these lines will be recognized in the near future as new varieties and will be involved in the production in our region.

In addition to the excellent agronomic characteristics, these varieties or lines have excellent technological properties. The protein content is from 12 to 15%, and is followed by a very good values of other agronomic and technological characteristics.

Due to breeding, the average annual increase of genetic yield potential in our broader terms as estimated per year or 0.61%.

BIOLOGICAL AND POMOLOGICAL CHARACTERISTICS OF INTRODUCED PLUM VARIETIES (Prunus domestica L.)

Nada ZAVIŠIĆ*, Željko ROSIĆ

Agricultural Institute of Republic of Srpska, Banja Luka, Bosnia and Herzegovina
*Corresponding author: nada.z@blic.net

Abstract

In the area of Balkans, plum was the most common fruit species based on the number of trees and quantity of the production. The biggest problem in growing of plum trees is plum pox virus (PPV), which endangers growing of the most important plum variety (Požegača) in our areas. One of the solutions to the problem of PPV is to grow resistant and tolerant varieties. To date, the series of plum varieties, which are tolerant to PPV, are selected. In addition to some well-known selections from Čačak (Serbia), there are also varieties selected in other selection centres. Trials with resistant varieties are the basis for the introduction of new varieties in commercial production. Research was carried out during 2013 and 2015 in the collection orchard of the introduced plum varieties: Katinka, Haroma, Topper, Topfive, Jojo, Topfirst, Elena and Presenta. Čačanska ljepotica and Čačanska rodna were used as standards. In 2009, the orchard was set up in Banja Luka (Bosnia and Herzegovina). All varieties were grafted onto Myrobalan (*Prunus cerasifera*) and set up at planting distance of 4 x 2 meters, and growth form was the spindle bush. Each variety was represented with 5 trees. Protection against diseases and pests was carried out according to the principles of integrated production. The orchard was without irrigation. The biological (flowering and ripening) and pomological (fruit and stone weight, height and width of the fruit, the fruit yield) were analysed, as well as the content of soluble dry matter in the fruit. According to the research results, the varieties Jojo and Presenta showed the best characteristics of the fruit. Time of ripening cannot be determined on the basis of skin colour. Analysis and monitoring of soluble solids content (SSC) in the fruit during ripening could give more reliable information on the determination of harvest time.

Keywords: *Plum, variety, flowering, fruit quality*

Introduction

In the area of Balkans, plum was the most common fruit species based on the number of trees and volume of the production. Variety Požegača was once the leading variety of plum but due to high susceptibility to plum pox virus (PPV), its cultivation in question.

The biggest problem in the cultivation of the plum is PPV. One of the solutions to the PPV problem on plum is growing of resistant and tolerant varieties. To date, a series of plum varieties that are tolerant to the PPV were selected. Apart from some, to us well-known selections from Čačak (Čačanska rana, Čačanska najbolja and Čačanska lepotica), there are varieties selected at other selection centres.

The aim of breeding work within the species *Prunus domestica* L. was conducted to adapt to characteristics of moderate continental climate, size and fruit quality, yield, spreading of ripening time, less vigour, and resistance to the most economically important diseases and pests with special emphasis on resistance to PPV (Mišić, 1987). In last two decades there have been

recognized a number of varieties of plums, of which the most interesting varieties was that which are resistant to PPV (Nikolić and Radović, 2010).

The largest number of new high-quality varieties, tolerant to PPV was created in breeding centres in Germany and to the selection of Hohenheim and Geisenheim (Jacob, 2002; Hartmann, 1994). The use of the German varieties led to extending the harvesting period and offers of plum on the market even to mid-October (Agnes, *et al*., 2016).

New varieties tolerant to plum pox virus, which are suitable for growing in our agro-ecological conditions, have not been significantly represented in nursery production. Those same varieties, because of size and fruit quality, maturation time, deserve their place in the orchards of plums. Introductory experimental orchards are the basis for the introduction of new varieties in commercial production. That is because without verification of biological and production characteristics of the variety in concrete conditions are not recommendable to expand production significantly.

The aim of this study was to examine biological and pomological characteristics of some new plum selection in comparative monitoring with the known varieties in agro-ecological conditions in Banja Luka.

Materials and Methods

The study of biological and pomological characteristics of plum varieties carried out in the collection orchard of the Department of Fruit growing and Viticulture, Public Institution Agricultural Institute of Republic of Srpska, Banja Luka (PI AIRS) (Figure 1).

Seedlings for orchard were obtained from "Rasadnik" doo Nevesinje which imported buds of new varieties of plums from Germany for their own needs. Orchard was planted in 2009 in Banja Luka (Bosnia and Herzegovina). All varieties are grafted on cherry plum (*Prunus cerasifera*). The distance between trees were 4 x 2 meters, a growth form was the spindle bush. In the test plantation is located five of each variety of plum trees: Katinka, Haroma, Topper, Topfive, Jojo, Topfirst, Elena and Presenta. As the standards varieties were used Čačanska lepotica and Čačanska rodna. Plant protection against diseases and pests is carried out in accordance with the principles of integrated pest management. Orchard hasn't been irrigated.

In period after planting growth stages of flowering and maturation were regularly monitored. In 2013 and 2015, on average sample of 25 fruits of all varieties, were carried out following pomological measurements: fruit and stone weight (g) measured with precision automatic scales, width and height of the fruit (mm) measured with calliper with automatic micrometre. Also it was determined flesh ratio of fruit and the soluble solids content (SSC) is determined by refractometer. The exception was the variety Katinka, which were without fruits due to human factors, so we could not do pomological measurements in 2015. The significance of differences was determined on the basis of an analysis of variance with the use of F-test for two-factorial trial. For individual comparisons LSD test was used. Statistical analysis did not include the variety Katinka because it was without fruits in 2015.

Figure 1. The experimental orchard of new varieties of plums at Economy PI AIRS, Banja Luka

Results and Discussion

In the studies of the varieties resistant and tolerant to the PPV, (Malinowski *et al*., 2013) sensitivity to the PPV was monitored during the period of eight years. Varieties Katinka and Presenta showed high sensitivity to PPV. For variety Jojo tree analysis shown no presence of the virus, but on the fruits changes were recorded in the flesh of the fruit in the form of stone structures.

Pomological and chemical characteristics of the newer varieties of plums in Croatia (Gadze *et al*., 2011) according to the characteristics of the studied time and maturation, among others, the variety Jojo stands out as interesting for our production orchards. Our trial results regarding the variety Jojo were similar to the results of trails in Croatia.

Table 1 shows the average values of pomological and technological characteristics of the fruit varieties of plums during the two-year test.

Fruit size is varietal characteristics, but also depends on climatic conditions and technological process of production, as well as the number and position of the fruit on the tree. Size of the fruit can be expressed by mass or dimensions of the foetus.

The results of measuring the size of the fruit and soluble solids contents (SSC) in our research for some varieties of plums (Čačanska Lepotica, Jojo, Elena and Čačanska rodna) were similar to the results from Bulgaria (Minev and Stoyanova, 2012).

Table 1. Pomological and technological characteristics of the tested varieties of plums in 2013 and 2015, in Banja Luka

Variety	Year	Date of picking	Fruit weigh (g)	Fruit width (mm)	Fruit eight (mm)	Stone weigh (g)	Flesh stone ratio (%)	Soluble solids (%)

	Average		21,84	29,70	40,90	1,19	94,47	21,48

Variety Jojo, which resulted from crossing Stanley and Ortenauer varieties, is similar to Stanley according to the characteristics of the fruit, and is suitable for drying due to good and uniform fruit size (Mitrović *et al.*, 2009). Results of analysing fruit weight (32.21 g), stone weight (1.73 g) and the contents of SSC (21.9%) of Jojo variety are similar to results from Ćačak (Mitrović *et al.*, 2009).

Results of statistical data analysis for pomological characteristics of the fruit in a two-year research are shown in Table 2.

The average fruit weight was 29.63 g, and found differences between varieties were statistically significant, while differences occurred under the influence of the year as factors were not significant.

Table 2. Pomological characteristics of fruit for the analyzed plum varieties, Banja Luka locality (averag of 2013 and 2015)

Variety	Fruit weight (g)	Fruit width (cm)	Fruit height (cm)
Topfirst	38.45	3.49	4.54
Topper	31.55	3.58	4.07
Topfive	27.84	3.29	3.82
Jojo	33.88	3.63	4.77
Haroma	32.84	3.72	4.63
Elena	24.04	3.67	3.67
Prezenta	22.14	3.61	3.61
Čačanska ljepotica	32.57	3.58	4.14
Čačanska rodna	23.40	3.12	4.17
Average varieties	29.63	3.52	4.16
Average year			
2013	29.05	3.62	4.04
2015	30.21	3.41	4.27
LSD (A ,variety)			
0,05	3.84	0.20	0.21
0,01	5.11	0.26	0.28
LSD (B ,year)			
0,05	1.81	0.09	0.10
0,01	2.41	0.12	0.13
LSD (AxB)			
0,05	6.08	0.32	0.33
0,01	8.07	0.42	0.44

There are significant differences between varieties in terms of the fruit dimensions, the height and width, respectively. The interaction factor between the year and the varieties significantly affects the resulting fruit dimensions of the analyzed plum varieties.

The variety Elena according to characteristics of the fruit is similar to Čačanska rodna. Because of late ripening the variety Elena offers the possibility to extend the season of fresh plums for nearly a month and therefore deserves to be expanding (Dinkoca *et al*., 2009). The results of the size of the fruit and the content of the SSC indicate that this variety is suitable for consumption both as fresh, but also for drying and processing.

Soluble solids content increases with ripening fruit and is a good indicator of quality and ripeness in fruits. SSC in fruits in variety Elena in our research is similar to the results in Zagreb (Družić *et al.*, 2007).

The content of SSC in the fruit varies from year to year, which is caused by rainfall and weather conditions during the period of maturation. In 2013 and 2015, there were large variations in the content of SSC with the same variety. The differences in the content of SSC exist between varieties with earlier period of ripening (Katinka and Top First) and are characterized by the values for the lower SSC content related to later varieties.

Conclusion

The varieties of plums in the test plantation in Banja Luka, Bosnia and Herzegovina have covered a wide period for market of fresh plums from the earliest such as Katinka and Topfirst (second half of June), to the late, Elena and Presente (end of September). Fruit skin colour is not a sure indication for determining of ripeness and the moment of picking. Analysis and monitoring of

SSC in the fruit during maturation is the best indicator for determining the picking time. Picking time depends on the usage of the fruits, whether it is for consumption or for processing.

Based on the results of pomological and technological characteristics of the fruit varieties of plums can be recommended for different purposes. The varieties Katinka and Topfirst ripen earlier and because of that they are recommended for consumption as fresh. Variety Jojo, because of size and quality of the fruit is suitable for various kinds of processing and drying. Varieties Elena and Presenta, due to late ripening time extend season of fresh plums on market, and can be used in different ways.

Abstract

Drought stress is one of the major abiotic factors affecting seed germination and plant growth especially in arid and semi-arid regions. In current study, we investigated the effects of drought stress on seed germination and seedling growth of five varieties of rapeseed. Seven drought stress levels of zero (control), -3, -5, -7, -9, -11 and -13 bars were considered using polyethylene glycol-6000 (PEG-6000). Complete randomized design with three replications was used for this experiment. Germination percentage (GP), germination rate (GR), mean germination time (MGT), root length (RL) and shoot length (SL) were used to evaluate the varieties response to PEG-induced drought stress. Drought stress, variety and interaction of both had a significant effect on all studied parameters. GP and GR decreased with the increase in stress level while MGT increased. Rapeseed varieties 'INRA-CZH2' and 'INRA-CZH3' performed better in germination and early seedling growth. There was no seed germination for all varieties at the -11 bars and -13 bars. Shoot length decreased with increasing drought stress but varieties showed different performance under this stress. Root length decreased with increasing levels of severe drought stress. However, the presence of moderate drought stress could improve the root growth of the investigated varieties. The varieties 'INRA-CZH2' and 'INRA-CZH3' exhibiting the highest germination percentage could be recommended for environments with early cropping cycle drought.

Keywords*: Rapeseed; Drought stress; Germination; Seedling growth; varieties.*

Introduction

Rapeseed (*Brassica napus* L.) is one of the most important sources of vegetable oils and protein rich meals worldwide. Rapeseed ranks fifth among economically important crops following wheat, rice, maize, and cotton (FAOSTAT, 2011). Rapeseed is the world's third most important source of vegetable oil after palm and soybean (Beckman, 2005).

Drought was always present in Morocco's history, but during this last decade, drought has become more frequent, with a net reduction in precipitation and an increasing temperature trend. Climatic data during the period 1961-2004 showed an increase in drought frequency, severity and spatial distribution (Stour and Agoumi, 2008). In Morocco with an arid and semi-arid climate, rapeseed is more often planted in late autumn and harvested in early summer. Accordingly, this stress is also considered as an essential limiting factor for rapeseed growth and production due to poorly distributed rainfall over the crop growing season. Drought is a severe limitation of plant growth, development and productivity, particularly in arid and semi-arid regions (Galle et *al.*,

2007), where the rainfall varies from year to year. However, depending upon plant species, certain stages such as germination, seedling or flowering could be the most critical stages for drought stress.

The objective of this study was to evaluate the effect of drought stress on rapeseed germination and early seedling growth, and to determine whether there was intraspecific variation in drought tolerance between different rapeseed varieties.

Materials and methods

The plant material used in this study consists of five varieties of rapeseed (*B. napus*) from the collection of the National Institute for Agricultural Research (INRA), namely 'INRA-CZH2', 'INRA-CZH3', 'INRA-CZSyn1', 'Moufida' and 'Narjisse'.

The experiment was conducted in a double factorial completely randomized design, with three replications. The first factor was the variety, with five levels, and the second was the drought stress, with seven levels. Drought stress was induced by polyethylene glycol (PEG-6000) solutions. Application of six levels of drought stress, with osmotic potentials of -3, -5, -7, -9,-11 and -13 Bars, was used and prepared as described by Michel and Kaufmann (1973). Distilled water was used as control. For each treatment, 100 seeds were allowed to germinate in a Petri dish double lined with filter paper moistened with 15 ml of the appropriate level of PEG-6000 at 25 ± 1 °C for 8 days. Germination counts were made after 2, 4, 6 and 8 days after planting. Seeds were considered germinated when the radicle was at least 3 mm long. For germination percentage, the number of seeds germinated on day 8 was considered. The germination rate index was determined by GR = $\sum$ (Ni/Di) as described by Carlton et *al.* (1968), where Ni is the number of seeds germinated between two counting's and Di represents the day of counting. Mean Germination Time (MGT) expressed in d, is the inverse of GR (MGT = 1/GR). Root length and shoot length were measured on the eighth day after germination (end of experiment).

The statistical analysis was conducted with the software package SPSS for Windows (Version 22). Data were subjected to an analysis of variance (ANOVA) at 5% probability level. Differences between rapeseed varieties and treatments means were compared by Duncan's Multiple Range Test (DMRT).

Results and discussion

Drought stress effect on germination

Results of analysis of variance indicated that drought stress (PEG-6000) significantly influenced rapeseed seed germination percentage (GP), germination rate index (GR) and mean germination time (MGT) (Table 1). There were also significant effects of variety and variety × drought on these parameters (Table 1). All seed germination parameters measured, GP, GR and MGT, were affected by drought stress. One could observe that GP (Figure 1) and GR (Figure 2) decreased with the increase in stress levels, while MGT (Figure 3) increased. These findings agree with those of Zraibi et *al* (2011) in safflower and El Harfi et *al* (2016) in sesame. However, the varieties 'INRA-CZH2' and 'INRA-CZH3' were less affected than 'INRA-CZSyn1', 'Moufida' and 'Narjisse', indicating that, during seed germination, 'INRA-CZH2' and 'INRA-CZH3' were more tolerant to drought stress than 'INRA-CZSyn1', 'Moufida' and 'Narjisse'. To germinate, all varieties of rapeseed could tolerate until -9 bars, and from -11 bars, no seed germination was recorded. Kaya et *al*., 2006 reported that none of sunflower seeds could germinate at -12 bars and in a recent study on sesame, it was shown that seeds ceased to germinate already from -12 bars (El Harfi et *al*., 2016), indicating that sunflower and sesame should be more tolerant than

rapeseed to drought stress during germination stage. However, for safflower, seeds ceased to germinate already from -2.5 bars (Zraibi et *al*., 2011).

Table 1. Analysis of variance (mean squares) for seed germination and seedling related traits of five rapeseed varieties evaluated under drought stresses.

Source of Variation	Degree of freedom	Germination	Germination rate	Mean germination time	Root length	Shoot length

V × D	24	200.20***	62.16***	0.0005***	3.35***	9.26***

*, **, *** Significant at 0.05; 0.01 and 0.001 of probability levels, respectively.

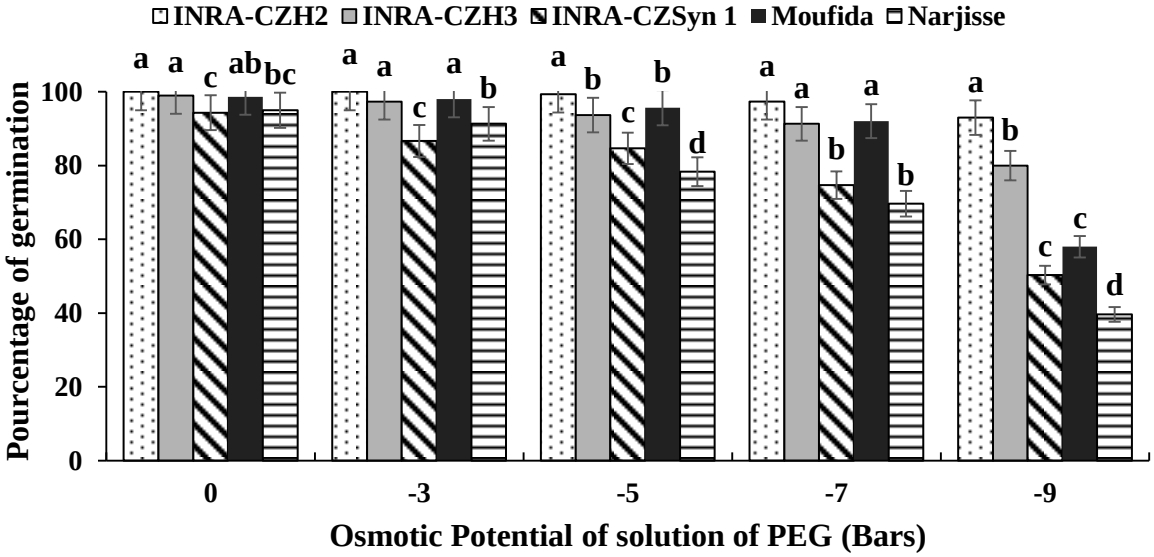

Figure 1. Effect of PEG induced drought (bars) on seeds germination percentage of five rapeseed varieties. Values with different alphabetical superscripts are significantly different ($p \leq 0.05$) according to DMRT.

Drought effect on seedling growth

The effect of drought stress (PEG) on shoot length (SL) and root length (RL) was statistically highly significant in all varieties (Table 1). Shoot length decreased with increase of osmotic potential of PEG treatment (Figure 4) but different varieties showed different performance under stress environment. Our findings agree with other studies on different species including Zraibi et *al*. (2011) in safflower and El Harfi et *al*. (2016) in sesame. There are many reports which are in agreement with the present findings, indicating that drought stress severely reduce the shoot length. Root length also decreased with increasing levels of severe drought stress. However, the presence of moderate drought stress could even improve root growth of investigated varieties (Figure 5).

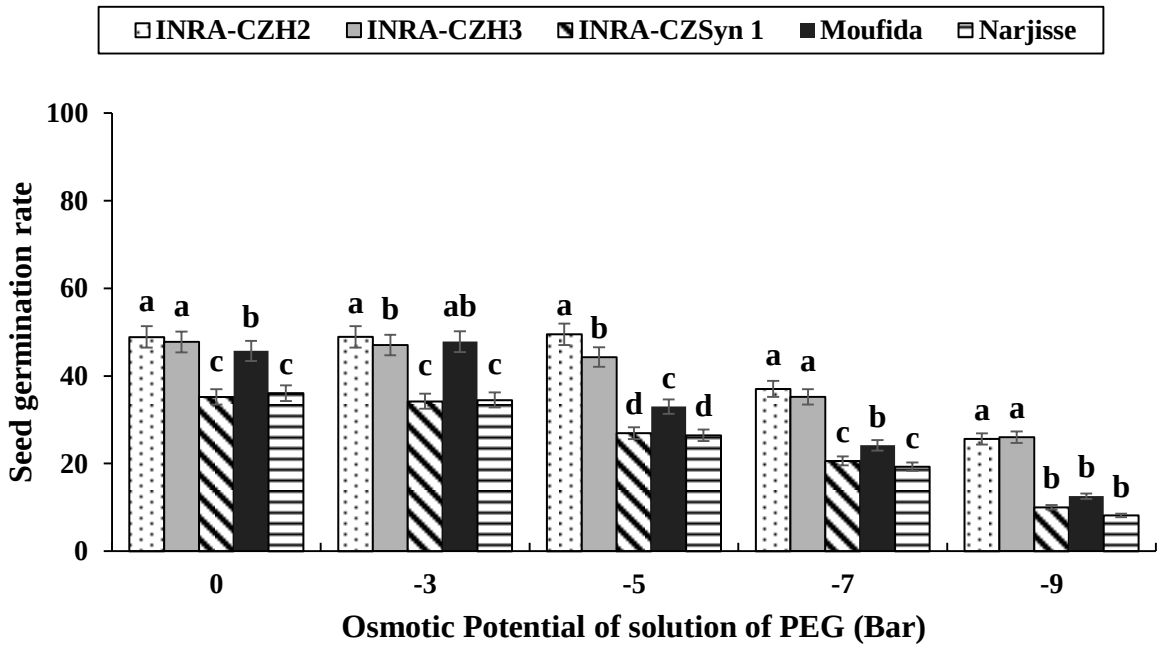

Figure 2. Effect of PEG induced drought (bars) on seeds germination rate (GR) of five rapeseed varieties. Values with different alphabetical superscripts are significantly different ($p \leq 0.05$) according to DMRT.

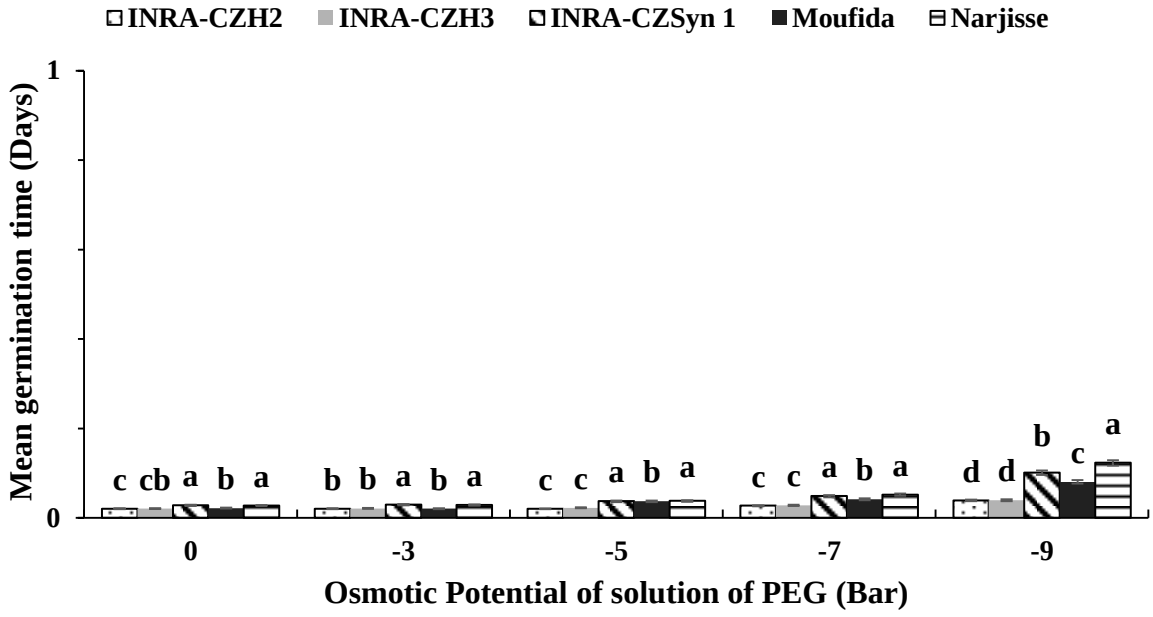

Figure 3. Effect of PEG induced drought (bars) on mean germination time (MGT) of five rapeseed varieties. Values with different alphabetical superscripts are significantly different ($p \leq 0.05$) according to DMRT.

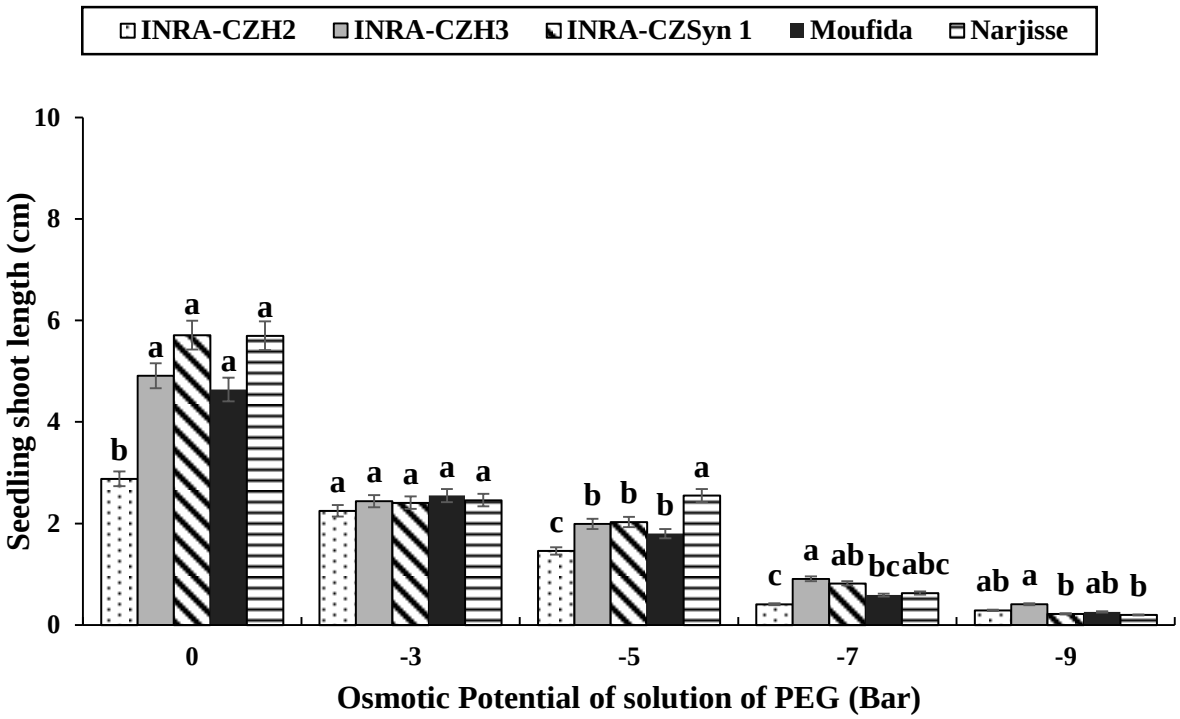

Figure 4. Effect of PEG induced drought (bars) on seedling shoot length of five rapeseed varieties. Values with different alphabetical superscripts are significantly different ($p \leq 0.05$) according to DMRT.

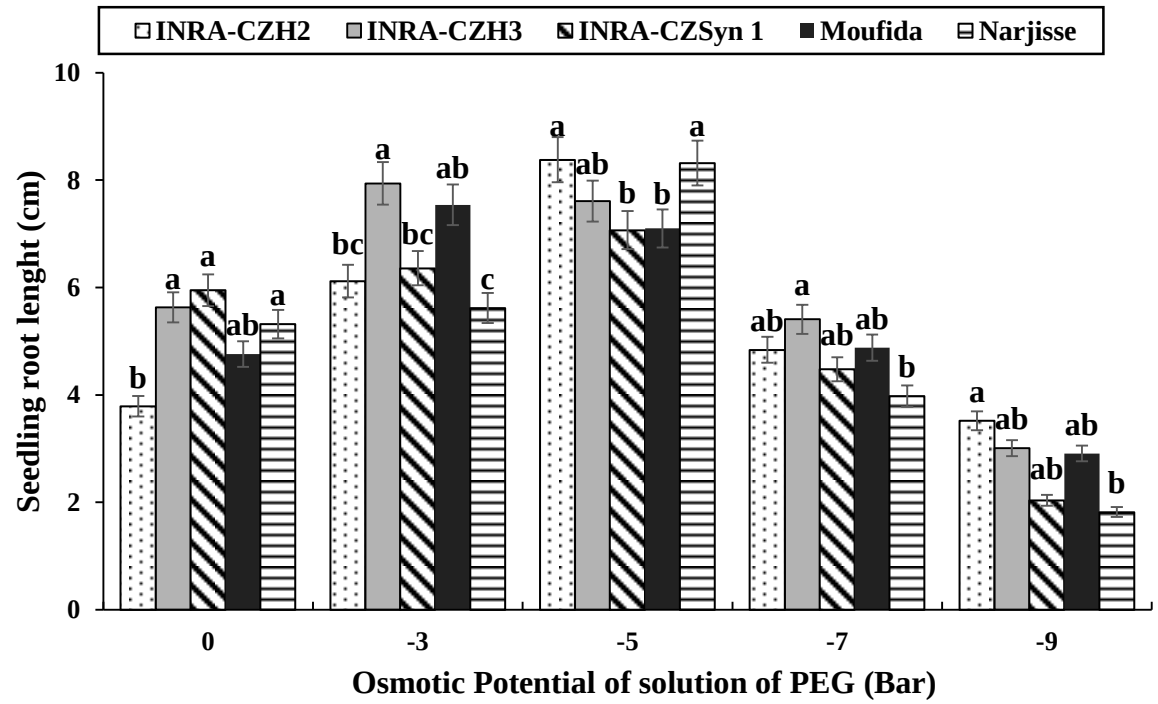

Figure 5. Effect of PEG induced drought (bars) on seedling root length of five rapeseed varieties. Values with different alphabetical superscripts are significantly different ($p \leq 0.05$) according to DMRT.

Conclusion

Based on the results of this study, the varieties 'INRA-CZH2' and 'INRA-CZH3' showed better seed germination and early seedling growth, under drought conditions, than 'INRA-CZSyn1', 'Moufida' and 'Narjisse'. It is also concluded that variation among varieties was found to be a reliable indicator of drought tolerance in rapeseed. This suggests that the choice of the rapeseed variety to be planted in a given environment should depend upon the presence and the degree of the stress observed in such environment. In a non-stressed environment, 'INRA-CZSyn1' and 'Narjisse', even with an intermediate germination percentage, should be selected because they had the best seedling growth (root and shoot length). In drought stressed environments, 'INRA-CZH2' and 'INRA-CZH3', exhibiting the highest germination percentage, should be recommended.

Abstract

The paper presents the results of three years research (2011-2012) on productivity of the alternative cereal– spelt, grown on degraded land in two localities: the mine Stanari (ST) (Bosnia and Herzegovina) and the"Nikola Tesla"thermalpower plant - "TENT 2" in Obrenovac (OB) (Serbia). Spelt was examined by using standard agricultural practices for growing this alternative cereal.Harvest was carried out manually at full maturity and the yield was determined by measuring biomass yield. The average yield of spelt biomass, when observed all the factors, both localities and all three years of research, was 1,509 kg ha^{-1}. When observed by locality, the average biomass yields ranged from 1,792 kg ha^{-1} (OB-Serbia) to 1,225 kg ha^{-1} (ST-B&H). There was a statistically significant difference in biomass yields between the localities. The locality by year interaction had a statistically significant impact on biomass yield. Fluctuations in biomass yields were due to different soil conditions – different nutrient contents and distribution of precipitation at early stages of crop growth.

Key words: *alternative cereal, spelt, deposole-type soil, biomass yield, locality*

Introduction

Harmonising a sustainable development strategy with the environment, having more strict regulations on protection of living/working environments and adjusting environmental management to be in line with a series of international standards, are the matter of extreme importance that should be addressed with special attention. Given that global demand for alternative cerealsincreases continuously, with qualitative changes in human dietthese cerealsare given back the importance they once had (*Glamočlija et al.,* 2010, 2015). This is mostly due to their nutritional specificity (use-value). Over a long history,alternative cerealshave been cultivated in less favourable agro-ecological and soil conditions, hence developing natural resistance and tolerance to abiotic stress, increasingly present nowadays as an effect of global climate change.Plant species that are most successful in meeting nutrition requirements with their productive parts, regardless of their origin, will soon occupy the world's largest agricultural areas. Hence, the largest areas under wheat and other small cereals are situated in China, North America and South America, although wheat originated in the Fertile Crescent.

There is a bad trend of increasing the areas with degraded soil (*Allen*, 2000) as a consequence of multiplication of degradation factors that comes from nature itself and from people (*Dragićević et al.*, 2008). On certain soil, crops cannot be cultivated at all (very saline soil, marsh soil, soil

affected by erosion, chemical agents, etc.).One should point out that alternative cereals, like some other cultivated plants, give higher yields of good quality if grown on better soil (*Jankovićet al.*, 2015).

Many research papers that cover this topic can be found in literature. There is much evidence that alternative cerealsgrow well on different types of soil and on soil with poorer productive characteristics as well. Especially important is that they can also grow on degraded soil. It is estimated that there are about 1.5 billion hectares of such soil worldwide (*Rodríguez-Quijano et al.*, 2010).In the last forty years, about 30% of agricultural land has suffered from degradation processes, especially in developed countries. In Serbia there is about 30,000 hectares of corrupted (degraded) soil. Yet these areas have beenslightly exploited, which seriously affects national agriculture. Degradation dynamics is such that about 4,000 hectares of agricultural land is "destroyed" each year (*Đorđević et al*., 2010).Soil is mostly affected by mining activities, open pits, industry, traffic routs, water supply reservoirs, landfills and tailings (*Zhelceva-Bogdanova*, 1995).

There have been some attempts to restore/re-cultivate degraded soil, but such results in our country and in the world are mostly symbolic. A lot of researchers imply that such soil can be restored (*Lukač and Knežević*, 2010). In Serbia, there is a rising awareness of the importance of soil, including degraded soil, for food production (*Dražić*, 2010). The same author point out that more and more research has been done lately to restore and exploit degraded soil. Therefore, some appropriate experiments have been conducted and their results published. It is concluded that certain cultivated crops, including alternative cereals, achieve satisfactory results on degraded soil. Some tangible results have been already obtained regarding alternative cereals, such as spelt wheat, buckwheat, miscanthus, and some others.

On the territory of Republika Srpska recultivation of soil is done in the coal mine Stanari. The Stanari is the first open pit mine that has received a new ecological permission from the Ministry of Environmental Protection of Republika Srpska and achieved international standards by getting ISO 14001 certification on environmental protection management.

Reviving of spelt production has started in hilly and mountainous areas of Switzerland, Germany and Austria, and later in other countries in mid- and west Europe and North America. In the late 20^{th} century this cereal started to raise interest in our country, too, being grown until recently in hilly and mountainous areas (*Hristov et al., 2008*). The nutritive value of spelt kernels implies that they could be used to produce quality and healthy food, particularly suitable for those who are allergic to gluten from common wheat.

*Triticum aestivum spp. spelt*is hexaploid wheat with 21 chromosomes. It is a spring form originated in 5,000-6,000 BC in the Middle East (present-day Turkey) by spontaneous cross-breeding of grass species (*Pavićevic*1988,*Jankovićet al.*, 2015, 2016). Spelt is more tolerant to adverse agro-ecological conditions and pathogens and it does not require intensive cropping practices used for soft (common) wheat. Hard, leathery chaffs are good at protecting kernels from air contaminants and pests, whereas waxy layers on stalks and leaves prevent the occurrence of pathogen fungi that are disease agents.Spelt is more adapted to adverse abiotic conditions than common wheat and therefore suitable for growing in the system of organic farming (*Glamočlija et al.*, 2010, 2015, Popović, 2010).

The goal of this paper was to determine the biomass yield of spelt wheat grown on degraded soil in two localities: Stanari (B&H) and "TENT 2" (Serbia).

Material and method

The experiments were conducted during 2010, 2011 and 2012on degraded deposole-type soilin two localities. Locality 1 is in the vicinity of the Stanari mine (ST-B&H), and locality 2 is next to the "Nikola Tesla"thermalpower plant –"TENT 2" (OB-Serbia). The experiments were set up in a randomised block design with four repetitions. The subject-matter was alternative cereal – spelt.

Prior to setting-up the experiments, agro-chemical properties of these soils were determined at accredited laboratories in Bosnia and Herzegovina and in Serbia (Table 1).

The conducted agro-chemical analyses showed that the soil in both localities had a pronouncedly acidic pH reaction.pH in KClvaries from 4.1 ("TENT 2") to 4.6 (Stanari). *Resulovićet al*. (2008) and*Veselinović et al*. (2010) point out that Stanari deposoles are more acidic than Kolubara deposoles but less acidic than deposoles in the area of the "Nikola Tesla" thermal power plant in Obrenovac.Picture.1. Biomass of Triticum spelt

Janković et al. (2016) state that the soils had a low percentage of organic matter and humus, and the level of nitrate salts in the surface layer ranged from 0% to 0.4%. These soils were also classified as very poor in easily approachable phosphorus and potassium.

Table1. Agro-chemical properties of soil fertility, deposole-type soil

Values	pH		Organic matter (%)	Humus (%)	N (%)	Easily approachable forms	
	H_2O	KCl				P_2O_5 mg/100g	K_2O mg/100g
Stanari	5.8	4.6	1.6	0.01	0.0	0.38	1.94
TENT 2	5.2	4.1	1.8	0.01	0.4	1.82	3.25

*Jankovic et al. 2016.

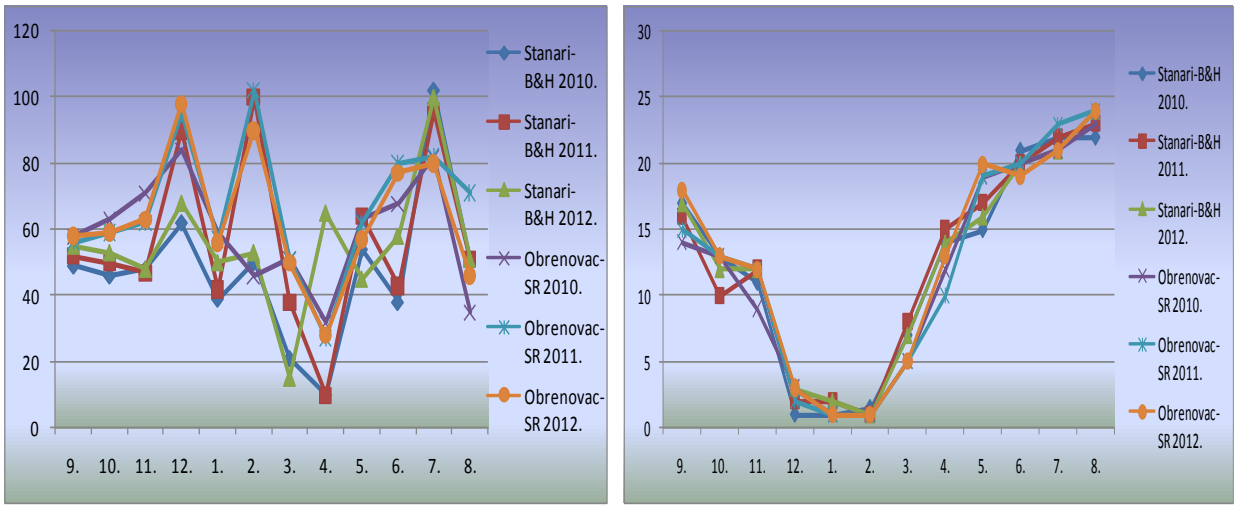
The standard cropping technology was in both localities - conventional basic tillage, soil preparation with harrows and manual sowing.Spelt was sown in mid-March. Manual weeding and hoeing were crop tending measures used for keeping the inter-row space clear. Once the crops reached technological maturity (Pic.1), manual harvest was done and the yields were calculated by measuring the yield of above-ground biomass from each basic plot.

The data were then analysed by using analytical statistics and statistical analysis software *STATISTICA 12 for Windows (StatSoft*).

Meteorological conditions

In this research, the key meteorological indicators, such as precipitation distribution and sums and temperature conditions during the period of vegetation, were monitored and analysed. Data on monthly precipitation sums and average temperatures of air in 2010/2012 were retrieved from the Hydro-meteorological Office of the Republic of Serbia and the Hydro-meteorological Centre of Bosnia and Herzegovina.

Precipitation.Regarding precipitation sums and distribution by month and by year, water regime during the period of spelt vegetation was relatively favourable in both localities,Graph 1.



Graph 1. Precipitation (mm), and temperature, Obrenovac-Serbia andStanari B&H, 2010-2012

Monthly distribution of precipitation in both localities showed that the crops were well supplied with water during the period of vegetation despite the fact there was very little rainfall in April. A lack of precipitation was more pronounced in the locality of Obrenovac, yet this did not have a significant impact on winter crops since abundant rainfall provided enough water for early spring growth of crops in all three years of research. On the other hand, although less precipitation in both localities in April had an adverse impact on the early growth of spelt, tillering was satisfactory, especially in 2011.

Temperature conditions. During the years of research, monthly temperature distribution favoured spelt growth and development, especially in 2011. In both localities, the pre-winter period (October, November and the first half of December) with the average temperatures of air above 10^0C enabled the optimal autumn growth for the crops to tiller and such enter the winter, Graph. 1b.

Temperature distribution in the springtime and gradually increased temperatures until the summer enabled the crops to pass from the vegetative stage to the generative stage of growth, having the optimal temperature regime. There were no big variations between the localities in average monthly temperatures, although the temperatures in Obrenovac were 1-2^0C lower in the autumn/winter and higher in the spring/summer.

The temperature regime favoured the early stages of plant growth, resulting in emergence, early growth and tillering of spelt. The summertime was characteristic for high temperatures of air, especially in the locality of Stanari. However, due to increased precipitation, it did not have negative effect on the generative growth of the crops.

Results and discussion

Yield of the above-ground biomass in the investigated localities

The results of this three-year research on above-ground biomass yield conducted in two localities clearly show that growing crops on degraded soil results in satisfactory yields.

The average yield of spelt biomass when observed all the factors, both localities and all three years of research, was1,509 kg ha^{-1}. The average yields of the biomass ranged from 1,792 kg ha^{-1} (OB-TENT, Serbia) do 1,225 kg ha^{-1} (ST-Mine, B&H). A statistically significant difference in yields between the localities was recorded, Tables 2 and 3, Graphs 3 and 4.

Table 2.Biomass yield of spelt on degraded soil, localities ST and OB*

Locality	Year	Grain biomass, kg ha^{-1} Mean	Std.Err.	-95.00%	+95.00%	Std. Dev

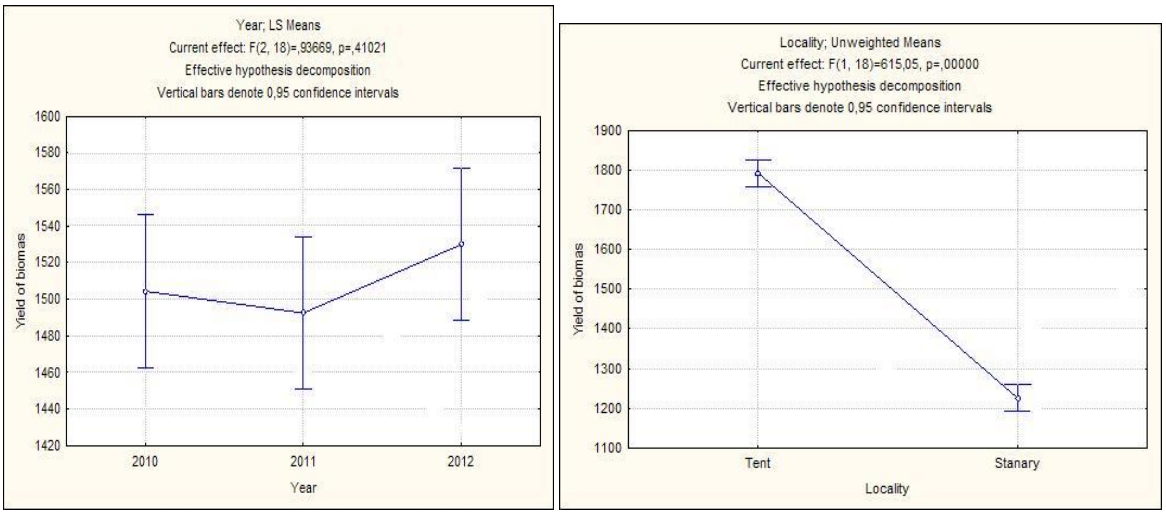
Error	18	56469	3137		
Total	23	3299499			

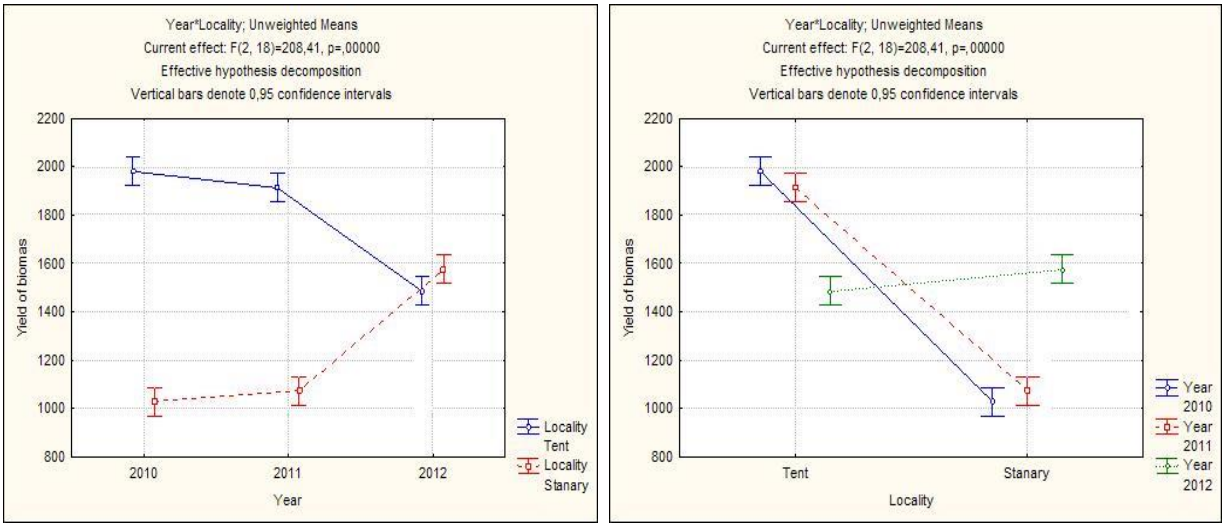
The locality byyear interaction had a statistically significant importance on spelt biomass yield, Table 3.



Graph 3. Average biomass yield of spelt,by year and locality, ST and OB*

Between the years,there was no statistically significant difference in yields in the locality of Obrenovac or in the locality of Stanari.

In the locality of Obrenovac, the highest biomass yield was obtained in 2010 (1,980 kg ha^{-1}) and the lowest biomass yield in 2012 (1,485 kg ha^{-1}), Table 2, Graphs 4. In this locality, standard deviation for all years averaged 234.65, Table 2.Soil conditions had a great impact on biomass yield, given that deposoles have less favourable chemical and physical properties so water quickly leaves the surface layer of soil.



Graph 4. Spelt biomass yield, given by year (2010-2012) and locality (ST and OB*)

In the locality of Stanari, the highest yield was obtained in 2012 (1,575 kg ha^{-1}), and the lowest in 2010 (1,028 kg ha^{-1}), Table 2, Graphs 4 In this locality, standard deviation for all years averaged 263.67, Table 2.

Discrepancies in the yields came as a result of different soil compositions and different distribution of precipitation in early stages of growth. The average biomass yield was lower than yields obtained on agricultural soil. However, it should be pointed out that such a low yield was generally satisfactory, bearing in mind the average values from both localities.

Biomass, i.e. harvest residues in fields, represents a significant amount of organic matter suitable for ploughing down into the soil. Ploughing of harvest residues into deposoles is very important since decomposing of harvest residues activates microbiological processes, increases the number of useful micro-organisms and humus content in the soil.

Having studied the ways to re-cultivate deposoles in the areas of open-pit coal mines and to start agricultural production, *Krümmelbein et al*. (2010) conclude that productive properties of cultivated crops depend on their ability to adopt plant assimilates but also on amounts of these nutrients in degraded soil.

In terms of finding the most suitable crops for deposole recultivation, *Ikanović et al*. (2010), *Glamoclija et al.* (2011) and *Jankovic et al.* (2015) favour plants with strong roots that better utilise assimilates from deeper layers of soil.

Conclusion

Based on the results of the research on the impact of agro-ecological conditions and locality on yield of the alternative cereal – spelt grown on degraded soil, one can make the following conclusion:

- The average yield of spelt biomass for all the investigated factors, both localities and all three years was 1,509 kg ha^{-1}.
- The obtained average biomass yields ranged from 1,792 kg ha^{-1} (OB-TENT, Serbia) to 1,225 kg ha^{-1} (ST-Rudnik, B&H).
- Observed by year, there was no statistically significant difference in yields between the locality of Obrenovac and the locality of Stanari.
- A statistically significant difference in biomass yields was recorded between the localities.
- The locality by year interaction had a statistically significant impact on biomass yield.
- Pronounced variation in grain yields by locality depended on soil conditions and precipitation distribution in early stages of growth of this alternative grain.
- Soil conditions had a great impact on biomass yield. Deposoles are characteristic for having less favourable chemical and physical properties, thus making water leave the surface layers of soil faster.
- The most appropriate crops for deposoles re-cultivation are plants with strong root that are better at using plant assimilates from deeper layers of soil.

Abstract

Tunisia is a major producer of pomegranate fruit; many varieties are cultivated such as Jbeli, Gabsi, Khalledi, Tounsi, Zaghouani, and Zehri. Gabsi is the important commercial variety. The valorisation of this type of fruit as fresh cut produce could be an important alternative for many pomegranate varieties. The objective of the present work is to study the aptitude of *Gabsi* variety to be commercialized as fresh cut fruit and to determine the postharvest shelf life. Fresh arils were hand extracted; chlorine disinfected, rinsed and dried then packed in polyethylene bags. Treatments were passive modified atmosphere packaging (MAP), enriched CO_2 MAP and control, each one had three replicates. Quality evaluation was assessed on days 5 and 10. Weight loss, luminosity (L*), redness (a*), Chroma (C), Hue angle (H), firmness, titratable acidity (TA), Total soluble solids (TSS), pH and anthocyanins content were determined and a sensorial evaluation was done. MAP treatment reduced significantly arils weight loss, increased C, a* and hue angle (H) parameters compared to control. Arils firmness was not significantly affected by MAP and enriched CO_2-MAP. MAP Treatments had not significant decrease in TSS and pH, an increase of TA and total anthocyanins in MAP. No significant changes were observed for all treatments in sensory analysis and did not affect the eating quality. For an acceptable quality attributes of ready to eat *Gabsi* pomegranate arils a storage conditions with MAP or CO_2-MAP at 4°C and a postharvest shelf life for 10 days were achieved.

Keywords: *Pomegranate arils, MAP, quality, postharvest shelf life*

Introduction

Pomegranate (*Punica granatum* L.) fruit consumption is growing due to its unique sensory and nutritional properties coupled with medicinal benefits attributed to high content of antioxidant.

Pomegranates constitute a typical product of many Mediterranean countries such as Tunisia, which present huge variety diversification for this fruit. Gabès is the major governorate of variety cultivation and production under the oasis system. The important commercial variety is Gabsi which is fully mature from October.

Minimally processed pomegranate arils have high economic importance due to their benefits and their desirable sensory characteristics as compared to whole produce, which poses difficulties in extracting arils (Artès *et al*., 2007).

Modified atmosphere packaging (MAP) is a postharvest tool used to preserve quality of several whole and minimally processed fruit and vegetables. MAP combined with low temperature storage has been successfully used to extend the shelf life of many fresh fruits and vegetables. Thereby maintaining packaged produce freshness, quality attributes and microbial safety (Banda *et al*., 2015). Ready to eat pomegranate arils have become many interested due to their convenience, sensory attributes and health benefits. However maintaining pomegranate arils is a major challenge, since it loose quality attribute easily such as texture and colour together with an

increase in microbial spoilage (Caleb *et al*. 2012). Otherwise shelf life of pomegranate arils is shorter than whole fruit. While the latter can be stored for 3 to 4 months at temperatures below 10 °C, pomegranate arils have a shelf life of 1 to 2 weeks when stored under 5 °C. Modified atmosphere and cold storage could extend the shelf life of minimally processed pomegranate arils.

The aim of the present study is to determine the effect of two different packaging atmospheres on the quality attributes of minimally processed pomegranate arils (cv. Gabsi).

Materials and methods

Sample preparation and packaging

Pomegranate fruits (cv. *Gabsi*) were harvested at commercially ripened stage in October 2015. They were purchased from a farm in Tastour-Tunisia. Fruit free from visible physical defects and with healthy outer skins and uniform in size and appearance were selected. Husks were carefully cut with shrap knives and arils were manually extracted.

Arils were collected in a tray, washed in chlorine solution (100µL L^{-1}) for 3 minutes and further rinsed in tap water, drained and excess water removed from arils with paper towels. Approximately 200 g of fresh arils were filled in trays and packaged with polyethylen platstic film 'ZOEPAC' supplied by 'Deccoiberica postcoscha, Valencia, Spain'.

Arils were divided in 3 lots for the following treatments: Control, Modified atmosphere packaging (MAP), CO_2 enriched MAP (CO_2-MAP). Each treatment was tri-replicated.

A total of 18 samples were stored at 4°C using the cold facilities of the postharvest laboratory of the Higher Agricultural Institute of Chott-Mariem. Quality evaluation was carried out after 5 and 10 days.

Aril quality determination

Weight loss

To evaluate arils weight loss, three 200g samples of arils per treatment were weighed at the beginning and the end of storage. Weight loss % (WL) was calculated according to the following equation:

$$\mathrm{WL}\ (\%) = \frac{\text{Initial weighted according t}}{\text{Initial weight}} * 100$$

Firmness

Firmness of individual arils was measured using fruit texture analyser model GS by compression. Averages of 20 arils were tested for each treatment. Firmness was expressed as maximum compression to reputure arils force in Kg/cm^2.

Colour

Colour of arils was determined on basis of CIE L*a*b* colour system by Commission International de l' Eclairage (CIE) measured using a digital colour meter (Minolta Chroma Meter, CR-400, Japan). Calibration of the colour meter was performed against a white tile background prior to each measurement. Arils were spread to cover a petri dish and colour measurements were taken from different points of the dish. Colour parameters, lightness (L*), redness/greenness (a*) and yellowness/blueness (b*) were measured. Chroma (C) values, which indicate the quantitative attribute of colour intensity and hue angle (H) which is considered as the qualitative attribute of samples colour were calculated using equations (1) and (2) (Pathare et al. 2013).

$$(1)\ C = \sqrt{a^{*2} + b^{*2}}$$

$$(2)\mathrm{H} = \mathrm{Arctg}\left(\frac{\mathrm{b}}{\mathrm{a}}\right)$$

Total soluble solids, titratable acidity and pH

Arils were juiced using a Molinex centrifuge. TSS was measured by a digital refractometer (Model PAL-1, ATAGO) expressed in °Brix. Each treatment was done in three replicates with three values for each replicate.

Titratable acidity (TA) measured by titration with 0.1 mol L^{-1} NaOH to an end-point of pH 8.2 using a digital burette, TA was expressed as g per 100mL of pomegranate juice of citric acid. Each treatment had three replicates with two values for each replicate.

pH was measured by a pHmeter (Crison model). Each treatment had three replicates.

Total anthocyanins concentration

Total anthocyanin concentration (TAC) was quantified using the pH differential method with two buffer systems comprising of potassium chloride (pH 1, 0.025 mol L^{-1}) and sodium acetate (pH 4.5, 0.4 mol L^{-1}) (Banda *et al*., 2015; Fawole *et al*., 2013).

0.4 mL of juice sample was mixed with 3.6 mL of pH 1 and pH 4.5 buffers, separately. The absorbance of the mixtures was measured at 520 and 700 nm using a UV–vis spectrophotometer (ZUZI spectrophotometer Model 4201/50), after 30 min incubation. All analyses were carried out in triplicates. Results were expressed g Cyd-3-glucoside equivalent per litre of pomegranate juice (g L^{-1}). TAC was expressed as cyanidin-3-glucoside using the following equations:

$$\mathrm{TAC} = \frac{\mathrm{A}*\mathrm{MW}*\mathrm{DF}*100}{\epsilon * \mathrm{l}} \qquad \mathrm{A} = (\mathrm{A510}-\mathrm{A700})_{\mathrm{pH\ 1.0}} - (\mathrm{A510}-\mathrm{A700})_{\mathrm{pH\ 4.5}}$$

Where A = absorbance (nm), ϵ = 26,900 molar extinction coefficient, MW = molecular weight of Cyd-3-glucoside (449.2 g mol^{-1}), DF = dilution factor and L = cell path length (1 cm).

Sensory evaluation

Sensory evaluation of pomegranate arils was performed during storage (5 and 10 days) by a sensory panel of 10 untrained panelists. Panelists were asked to evaluate colour, taste, aroma, richness in sugars, acidity, and product acceptability using a 9-point scale. Scores of 5 and above were considered as acceptable for commercial purposes. Overall product acceptability was scored on a 9-point hedonic scale where 9 corresponded to extremely liked and 1 corresponded to extremely disliked.

Statistical analysis

Data were analysed using the General Linear Model of SPSS (version 18.0) statistical package. Multifactor analysis of variance was conducted. Tukey test was used to perform post-hoc evaluations, when F-values were significant at the $p < 0.05$, mean differences were separated by the least significant difference procedure.

Results and discussion

Weight loss

The effect of MAP treatments was significant on the weight loss. Arils weight had lower loss with MAP and CO_2-MAP (weight loss did not exceed 1.2%) compared to the control (approximately 12%) (Table 1). Arils packed with MAP or with CO_2-MAP at 4°C had no significant difference after 5 and 10 days of storage**.**

Caleb *et al* (2013) studied the effect of modified atmosphere packaging and storage temperature on volatile composition and postharvest life of minimally processed pomegranate arils (cvs. 'Acco' and 'Herskawitz', under 5°C storage conditions MA-packaged 'Acco' and 'Herskawitz pomegranate arils were best kept than at 10 and 15°C.

The observed increase in weight could be associated with the evaporation of moisture from the aril surface and initial condensation inside the package.

The use of polymeric films in MAP serves as a mechanical barrier to the movement of water vapour and helps to maintain a high level of relative humidity within package, and reduce produce weight loss (Caleb *et al*., 2013).

Table1. Effect of MAP treatments on weight loss (WL)

Days	**5**			**10**		
	Control	**MAP**	**CO_2-MAP**	**Control**	**MAP**	**CO_2-MAP**
WL (%)	5.93^{b}	$0,88^{c}$	0.91^{c}	$12,66^{a}$	1.23^{c}	1.00^{c}

Firmness of arils

Firmness of arils decreased during storage. MAP treatments had no significant difference on arils firmness. Compared to control arils firmness was best kept under MAP; high arils firmness was observed for MAP on day 5 and for CO_2-MAP on day10 of storage (Table 2).

This observation is similar to that reported by Ayhan and Esturk (2009) who observed slight or no significant change in firmness for 'Hicaznar' pomegranate arils stored in passive-MAP or active-MAP until day 15 at 5°C. Gimenez *et al* (2003) stated that high O_2 concentration may also contribute to loss of texture in arils packaged in MAP.

Table 2. Effect of MAP treatments on aril firmness

Days	**0**	**5**			**10**		
	Initial	**Control**	**MAP**	**CO_2-MAP**	**Control**	**MAP**	**CO_2-MAP**
Aril Firmness (Kg/cm^2)	0,80	$0,67^{b}$	$0,75^{a}$	$0,68^{a}$	$0,66^{b}$	$0,76^{a}$	$0,71^{a}$

Colour

MAP and CO_2-MAP had no significant influence on the changes in chromatic parameters (Table 3). Minimal change in chroma colour intensity (C), redness (a*) and hue angle (H) values were observed across packaging treatments over storage days. An increase in chroma was observed in arils packed under MAP followed by CO_2-MAP compared to control at days 5 and 10 of storage. Arils kept its redness with MAP treatments without significant difference. Hue angle had a little decrease for MAP treatments compared to control. There was no significant difference between MAP treatments for all colour parameters.

Gil *et al* (1996) reported a relatively small change in L* values for '*Mollar*' arils packed in oriented polypropylene (OPP) bags stored at 8, 4 and 1°C for 7 day. Sepulveda *et al* (2000) observed no colour change in minimally processed '*Wonderful*' arils stored at 4°C ± 0.5 in semi-permeable films for 14 day.

Ayhan and Esturk (2009) reported that MAP application or storage time had no significant effect on redness a* and yellowness of b*, but observed small fluctuations throughout the 18 days of storage at 5°C.

Table 3. Effect of MAP treatments on aril colour

Days	**0**	**5**			**10**		
	Initial	**Control**	**MAP**	**CO_2MAP**	**Control**	**MAP**	**CO_2-MAP**
C	9.02	9.19[a]	9. 78[a]	9.53[a]	8.67[b]	9.12[a]	9.34[a]
H	20.39	24.78 [a]	24.57 [a]	24.77 [a]	22.94[a]	22.24[a]	23.63 [a]
a*	19.05	20.61[a]	23.41[a]	24.15[a]	14.0[b]	19.49[a]	20.19[a]

Total soluble solids, titratable acidity and pH

MAP had no significant effects on chemical attributes of minimally processed arils for both packaging atmospheres, except for pH on day 5 (Table 4). TSS values of arils ranged from 15.3% to 13.2% across treatments. TSS decreased by the end of the storage day. Titratable acidity (TA) ranged from 0.21 to 0.29 g 100 mL^{-1}. CO_2-MAP had lower TA on days 5 and 10 than MAP (Table 4).

Grady *et al* (2014) showed a non significant effect of packaging and storage on TA, TSS and pH of pomegranate arils juice.

Variability in pH, TA and TSS values in the studies could be attributed to the effect of increased CO_2 solubility inside the packages (Caleb *et al*., 2013).

Table 4. Effect of MAP treatments on TSS, TA and pH of arils

Days	**0**	**5**			**10**		
	Initial	**Control**	**MAP**	**CO_2-MAP**	**Control**	**MAP**	**CO_2-MAP**
TSS(°Brix)	15.34	15.00[a]	14.36[b]	14.27[b]	14.82[a]	13.26[b]	13.95[ab]
TA (g 100 mL^{-1})	0. 30	0.24[a]	0.24[a]	0.21[a]	0.28[a]	0.29[a]	0.24[a]
pH	3.75	3.06[a]	2.80[b]	3.02[a]	2.77[a]	2.87[a]	2.90[a]

Total anthocyanin

Anthocyanins are water soluble polyphenolic compounds responsible for the red colour in pomegranate fruit peel and arils (Banda *et al*., 2015). Total anthocyanin concentration (TAC) fluctuated with storage day in MAP. Generally MAP maintained the levels of TAC compared

CO_2-MAP. In addition, higher TAC was observed in arils packaged under MAP compared to CO_2-MAP with significant difference only on day 5 of storage.

Bhatia *et al* (2013) showed that arils packed in PP bags had highest average anthocyanins content. Anthocyanins are unstable and susceptible to degradation, during processing and storage. Various factors such as processing temperature, storage conditions, application postharvest treatments, chemical nature of anthocyanins, pH, sugars, exposure to light and metals can affect the stability of anthocyanins (Maghoumi *et al*., 2013)Table 5. Effect of MAP treatments on total anthocyanins

Days	**0**	**5**			**10**		
	Initial	**Control**	**MAP**	**CO_2-MAP**	**Control**	**MAP**	**CO_2-MAP**
TAC (g L^{-1})	0.95	0.66^{ab}	0.82^{a}	0.58^{b}	0.74^{ab}	0.82^{a}	0.69^{ab}

Sensory evaluations

The shelf life based on overall acceptability scores was limited to 10 days for arils packaged with MAP treatments. Panelists evaluated all arils treatments with a score of 6 out of 9 which present moderate intensity for arils colour, aroma, taste, acidity and richness in sugars in day 5 of storage. However by the end of storage period (10), panelists evaluated arils below the level of acceptability due to loss in texture, colour and aroma.

Conclusion

According to the results, the use of MAP for minimally processed pomegranate arils (cv. Gabsi) had a relevant effect to maintain arils weight loss, firmness and colour. TA, TSS and pH, were not significantly affected by packaging.

Total anthocyanin content was best kept in MAP. Otherwise, in this study, using a passive MAP only or with enriched CO_2-MAP was found to have similar characteristics to maintain arils quality, product shelf life (5 days) and overall acceptability. This study provides a useful guide towards improved postharvest handling, packaging and storage of minimally processed Tunisian pomegranate arils.

Acknowledgment

The authors want to thank the Institution of Research and Higher Agricultural Education- IRESA Tunisia for the financial support.

Abstract

This study was conducted to determine some soil traits under legume (*Vicia pannonica* Crantz) x cereals mixtures (*Hordeum vulgare* L., *Triticum aestivum* L. and *Triticosecale* Wittmack) and silage corn rotation during 2013-2014 and 2014-2015 growing seasons. The experiment was conducted in the experimental field of Bozok University in Yerkoy-Yozgat (Middle Anatolia, Turkey). The firstly of Hungarian vetch (*Vicia pannonica* Crantz) and cereals (*Hordeum vulgare* L. *Triticum aestivum* L. and *Triticosecale* Wittmack) were sown as binary mixtures with different seed rates (100:0 70:30, 60:40, 50:50 and 40:60) and harvested at different stage (flowering and milk dough stages) as forage. Then silage corn was sown. The experiment was planned in split plot-design with four replications, main plots were cutting time and sub plots were mixture ratio. Soil samples were taken 30 cm deep and by three different points of each treatment analyzed to fallow traits; nitrogen, organic matter, phosphorus, potassium, salt and lime content. According to results, soil samples that beginning of experiment was more different than at the end of study. Nitrogen and organic matter of soil did not change after Hungarian vetch+cereals mixtures, while they decreased after silage corn. Phosphorus content of the soil decreased continuously during the trial.

Key words: *Hungarian vetch, cereals, silage corn, rotation, soil.*

Introduction

The mixed cropping of legumes with cereals may affect the growth rate of individual species in mixtures as well as forage yield and quality. Incorporation of legume with cereal could be of importance for nutritive value forage mixture and also to subsequent soil health. Inclusion of legumes into crop rotation increases organic matter and nitrogen content in the soil. Increased levels of soil organic matter enhance water and nutrient retention, and decreases synthetic fertilizer requirements. Therefore, smaller amounts of nitrogen fertilizers are necessary in legumes cultivation.

In legume-cereal intercropping systems, the amount of nitrogen by fixed legumes depends on legume species, morphology, type of growing and competition with cereals (Ofori and Stern, 1987). The fixed Nitrogen by legumes are used by cereals during the growing season and it's may be meet the potential demand of following crop. According to Heichel (1978) and Pimentel et al. (1978), continuous rotation of corn and soybean cannot be sustained without substantial additions of fertilizers. Also, N over application results in environmental contamination through nitrate, N runoff or leaching that making nitrate the most common contaminant of the soil and ground water.

Crop rotation is a key principle of agricultural sustainability and has many benefits in improves soil structure, prevent erosion, reduces soil degradation, reduces risks of water-logging, water

supply to soil during droughts. Organic matter, total N, pH, salinity, lime content and soil aggregation are important indicators of dynamic soil quality because they are responsive to changes in soil management (Wander, 2004).
So, these traits should be determined and well known. The objective of the study was to determine the changing of some traits in soil under legume x cereals mixtures and silage corn rotation.

Material and methods

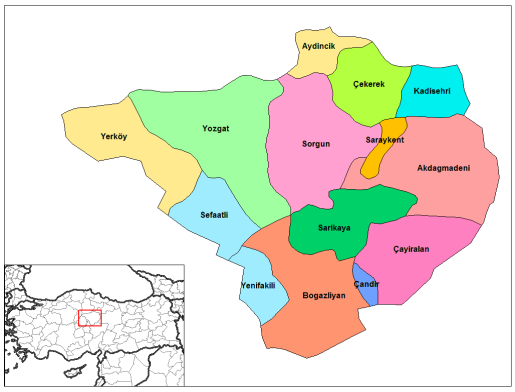

Fig. 1. Map of Yerkoy District (Turkey)

This study was conducted to determine the effects of legume x cereals mixtures and silage corn rotation on some soil traits under during 2013-2014 and 2014-2015 growing seasons. The experiment was conducted in the experimental field of Bozok University in Yerkoy-Yozgat (Turkey) (34° 28′ 0″ E, 39° 37′ 0″ N) with the altitude of 774 m above sea-level. The annual precipitation and mean temperature are 574.4 mm and the 9 ^{0}C respectively (Table 1).

Firstly, Hungarian vetch (*Vicia pannonica* Crantz) and cereal (*Hordeum vulgare* L., *Triticum aestivum* L. and *Triticosecale* Wittmack) were sown as binary mixtures with different seed rates (100:0 70:30, 60:40, 50:50 and 40:60) and harvested at different stage (flowering and milk dough stages) as forage. Then silage corn was sown. The experiment was planned in split plot-design with four replications, main plots were cutting times and sub plots were seed ratio. Soil samples taken 30 cm deep and by three different points of each treatment were analyzed in Turkish chamber of agriculture cooperation for organic matter, nitrogen, phosphorus, potassium, salt and lime content.

Results and discussion

According to results, organic matter of soil samples that beginning (1.91%) of experiment was higher than at the end of study (1.53%) (Table 3). These results can be attributed to intensive tillage during the experiment. Oxygen entering into soil with tillage promotes the organic material consumption by the microorganism and results its reduction (Doran and Smith, 1987).

The effect of Hungarian vetch+cereals mixtures on soil organic matter content was not high; however, it significantly reduced after silage corn (Table 3 and Fig. 2). Degradation of the Hungarian vetch + cereals residue in soil is slow (Saglam, 1997). However, silage corn is a hoe plant irrigated during vegetation and these treatments accelerates degradation and organic matter content (Kavut and Geren, 2015).

As seen in table 3, initial nitrogen content of soil, is 0.095% was 0.0763% by decreasing at the end of study (Fig. 3). The nitrogen content of the soil decreased after corn is an expected result. But the reduction in nitrogen after legume-cereal mixtures is quite interesting. This might be attributed to the high organic matter in soils at the beginning. It is highly possible. Because the experiment area was fallowed previous three years with no cultivation. In fact, the second year data explained this situation with the increase in soil N content after Legume x cereal mixtures and also with the decrease after corn. The variation of organic matter and N content in soil was in line between first and second cutting time.

Hungarian vetch + cereals mixture of organic matter and nitrogen ratio that second cutting time was higher than at the first cutting time. It may be due to vegetation period. Vegetation period is long especially legumes give more organic matter and nitrogen to the soil (Kara *et al*, 2011).

Table 3. Traits of experimental soil.

Soil traits	Means	Beginning	2013-2014		2014-2015

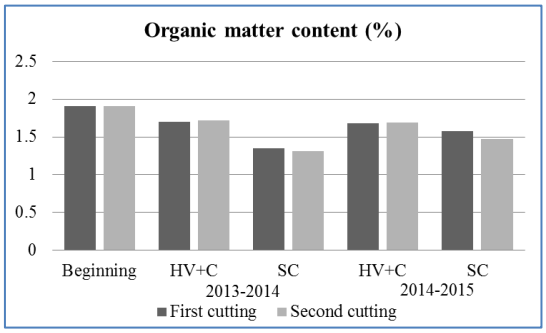

Fig. 2. Change of organic matter content in experiment soil during the trail.

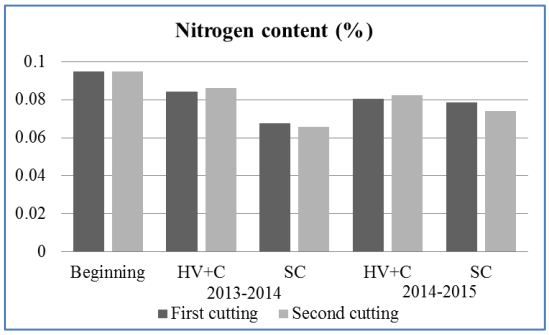

Fig.3. Change of nitrogen content in experiment soil during the trail

Phosphorus is known to be second limited mineral in the cultivated soils of the arid and semi-arid regions after nitrogen. If phosphorus not sufficient in soil, absorption of other minerals were adversely affected. Phosphorus content of experiment soil is middle degree (Table 2) and it was 8.62 kg/da at beginning of the experiment. Phosphorus content of the soil decreased continuously during the trial (Table 3). This result can be explained with substantially Phosphorus consumption of plant and also with fixed Phosphorus by soil. Contract to Phosphorus, Potassium content of experiment soil was high and it did not changed during the trial (Table 3 and Fig. 5). Salt content of the experiment soil was decreased after Hungarian vetch+cereals mixtures, while it increases after silage corn (Table 3 and Fig. 7) it can be connected with irrigation or the salt reached to surface by dissolving due to irrigation and high evaporation (Dolarslan and Gul, 2012.

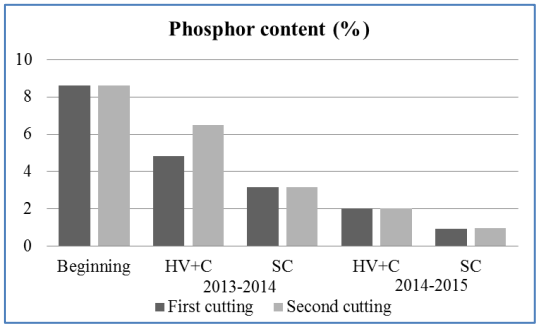

Fig. 4. Change of phosphorus content in experiment soil during the trail.

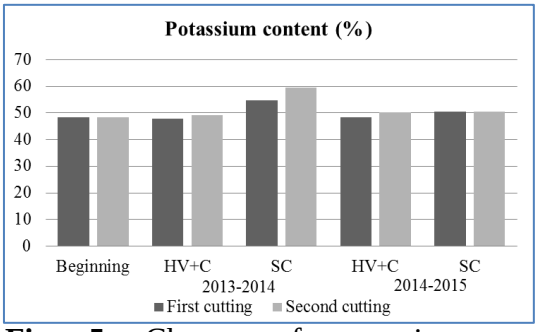

Fig. 5. Change of potassium content in experiment soil during the trail.

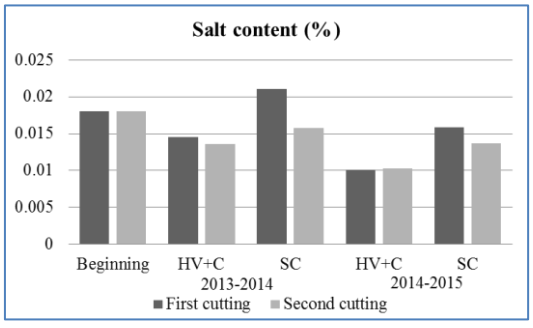

Fig. 6. Change of salt content in experiment soil during the trail.

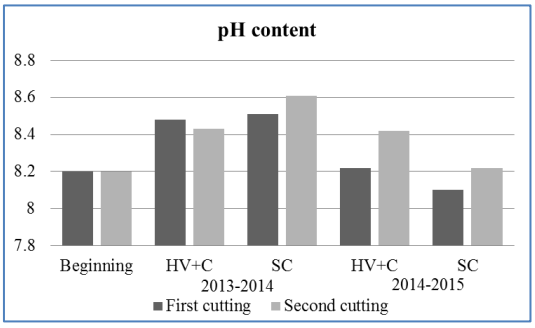

Fig. 7. Change of salt content in experiment soil during the trail.

The pH content of experiment soil is light alkali (Table 2). Arid and semi-arid soils exhibits generally alkaline characters, which are mostly result of insufficient precipitation for leaching the soluble salt in the present experiment pH did not change significantly among treatments and years.

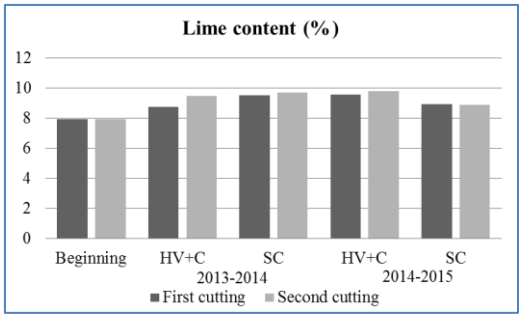

Fig. 8. Change of lime content in experiment soil during the trail.

The lime content of experiment soil is middle degree in both years (Table 2). Final lime content of soil was higher than that was at the beginning (7.93%) (Table 3 and Fig. 8). Saglam, (1997) reported that high root residue in intense agricultural regions can be results to increase in lime content of soil. So, the increase in lime content in the present study may be connected with increase root biomass after Hungarian vetch + cereals and silage corn rotation.

Conclusion

Crop Rotation helps maintain the agriculture and soil healthy for a long time. Crop rotation, especially legume-cereal rotation is crucial for sustainability. When legumes are part of the rotation, they fixes nitrogen, therefore, supply the nitrogen for fallowing crop and decrease chemical fertilizer uses. In addition crop rotation ameliorates soil physical traits, organic matter content and aggregation. This study showed that Hungarian vetch + cereals and silage corn rotation resulted significant changes and also present study indicated that the effect of crop rotation on soil highly depend on general characters of climate and soil.

TOTAL PHENOLIC CONTENT AND ANTIOXYDANT ACTIVITY OF RHODODENDRON SPECIES COLLECTED FROM THE RİZE PROVINCE (TURKEY)

Aysel ÖZCAN, Emine YURTERI, Fatih SEYİS*

Field Crops Department, Faculty of Agriculture and Natural Sciences, Recep Tayyip Erdogan University, Rize, Turkey
*Corresponding author: fatih.seyis@erdogan.edu.tr

Abstract

Rhododendron species (mountain laurel) are deciduous or evergreen shrubs commonly used as garden plants worldwide. Six Rhododendron species, one of which (*R. smirnovii*) is endemic, grow naturally in Turkey, especially in the northeastern Anatolia (Black Sea region). Turkish Rhododendron species grow naturally from sea level to altitudes of 2500 (3100) m. They take the form of shrubs (R. luteum Sweet), dwarf shrubs (*R. caucasicum* Pallas) and large shrubs (*R. ponticum* L., *R. ungernii* Trautv., *R. smirnovii* Trautv.). Rhododendron samples obtained from Rize province (Turkey) were screened for total phenolic content by the modified Folin–Ciocalteu method, for potential antioxidant activity using phospho-molybdenum assay and by the 1,1-diphenyl-2-picryl hydrazyl (DPPH) and FRAP method for antiradical activity. Total phenolic content and antioxidant activity plant parts (flower, leaf) of two Rhododenron sepecies, namely *Rhododendron luteum* L. and *Rhododendron ponticum* L. were determined. The total phenolic content of leaves of *Rhododendron luteum* L. collected from different altitudes ranged between 112,363 and 219,071 mg GAE/gr DW. Total phenolic content of flower parts of the same species ranged between 82,275 and 201,642 mg GAE/gr DW. The total phenolic content of different parts of *Rhododendron ponticum* L. were higher compared with *Rhododendron luteum* L. On the other side, the antioxidant activity values of leaf parts of *Rhododendron luteum* L. were lower compared with flower parts and like the phenolic content the antioxidant activity values of *Rhododendron ponticum* L. parts were higher compared with *Rhododendron lutem* L.

Keywords: Rhododendron, *phenols, antioxidant activity*

Introduction

According to Metcalfe and Chalk (1950) Ericaceae, particularly Rhododendron L. is widely distributed, but species are numerous especially in China and South Africa. Rhododendron species are distributed in China, Tibet, Burma, Nepal, New Guinea, Tropical Asia, Europe and North America. There are about 700 species in these regions (Heywood, 1978; Davidian, 1989). Suzuki and Ohba (1988) stated that habitats of Rhododendron species show a wide range, from low montane forests to alpine regions more than 4000 m high. These species are usually shrubs and tall trees about 30 m high and 100 cm in diameter in Nepal. In Turkey, the ones distributed from sea level to about 3200 m, are usually large shrubs (R. ponticum L**.,** R. ungernii Trautv.), shrubs (R. smirnovii Trautv., R. luteum Sweet.) or dwarf shrubs (R. caucasicum Pallas). *R. luteum* is deciduous, and the others are evergreen shrubs. R**.** caucasicum is alpine type, and the others are forest type. Rhododendrons (Rhododendron ponticum L. and Rhododendron luteum Sweet) dominate the understories of the mesic forests of the Black Sea Region (BSR) of Turkey (Eşen *et al*., 2006). They are deciduous short trees with green leaves and have flowers of different colours and an aesthetically important role in landscape.

Many species of the genus Rhododendron contain a large number of phenolic compounds and antioxidant activities that could be developed into pharmaceutical products (Qiang *et al*., 2011). In addition, some members of the genus are already used in traditional medicine for several ailments, especially arthritis, acute and chronic bronchitis, asthma, pain, inflammation, rheumatism, hypertension, and muscle and metabolic diseases (Popescu and Kopp, 2013; Iwata *et al.*, 2004; *Li et al.*, 2011; Wu and Li, 2011; Fu *et al.*, 2012). The total phenolic content and antioxidant activity of flower and leaf parts of Rhododendron luteum and Rhododendron ponticum collected from different altitudes were investigated in this study.

Materials and methods

The research material was collected during 2016 in the Çat district of the Rize province (Turkey). The information of investigated material is given in Table 1.

Table 1: Collection site of Rhododendron species

Species	Definition	Altitude	Analysed part
Rhododendron luteum	SK- 1 (L)	749 m	Leaf (L)
Rhododendron luteum	SK-1 (F)	749 m	Flower (F)
Rhododendron luteum	SK-2 (L)	968 m	Leaf (L)
Rhododendron luteum	SK-2 (F)	968 m	Flower (F)
Rhododendron luteum	SK-3 (L)	980 m	Leaf (L)
Rhododendron luteum	SK-3(F)	980 m	Flower (F)
Rhododendron luteum	SK-4 (L)	1062 m	Leaf (L)
Rhododendron luteum	SK-4 (F)	1062 m	Flower (F)
Rhododendron ponticum	MK-1 (L)	740 m	Leaf (L)
Rhododendron ponticum	MK-1 (F)	740 m	Flower (F)
Rhododendron ponticum	MK-2 (L)	980 m	Leaf (L)
Rhododendron ponticum	MK-2 (F)	980 m	Flower (F)
Rhododendron ponticum	MK-3 (L)	1107 m	Leaf (L)
Rhododendron ponticum	MK-3 (F)	1107 m	Flower (F)

- All samples were collected from Çat district, Rize/Turkey

Chemical Analysis

Total Phenolic content

The total phenolic content of collected samples were determined using UV-Vis spectrophotometer as mg GAE/gr DW.

Antioxidant activity

The FRAP assay was sued to determine the antioxidant activity of collected samples as mg FSO4/gr DW.

Statistical analysis:

Principal component and Bipplot analysis was used to distinguish the collected samples regarding analysedcharacteristics (Backhaus et al., 1989). Principal component and Biplot analysis was

performed using XLSTAT2016 Trial Version. The calculated first two Principal Components are corresponding in % to the present variation regarding the investigated traits.

Results and discussion

The obtained total phenolic contents and antioxidant activity values of collected samples are given in Table 2 and Fig. 1. As can be seen in Table 2. the total phenolic content of leaves of Rhododendron luteum increased generally with increasing altitudes. The same can be remarked for the flower parts of the same species with increasing altitude. İn case of antioxidant activity the determined levels were lower in leaf parts of this species compared with the flower parts.

İn Rhododendron ponticum also the total phenolic content and antioxidant activity increased up to 980 m altitude, then both values decreased at 1107 m altitude in leaf and flower parts of this species. The determined values for both traits were inleaf parts higher compared with flower partsof this species. İf we compare both species, the total phenolic contents and antioxidant activities of leaf and flower parts of *Rhododendron ponticum* was higher compared with *Rhododendron luteum* /Table 2 and Fig. 1).

Table 2: Total phenolic contents and antioxidant activity values of collected samples

Species	Definition	Altitude	Total phenolic content (mg GAE/gr DW)	Antioxidant activity (mg FSO4/gr DW)
Rhododendron luteum	SK- 1 (L)	749 m	188,228	22,191
Rhododendron luteum	SK-1 (F)	749 m	98,223	505,628
Rhododendron luteum	SK-2 (L)	968 m	196,874	42,400
Rhododendron luteum	SK-2 (F)	968 m	82,275	561,896
Rhododendron luteum	SK-3 (L)	980 m	112,363	106,990
Rhododendron luteum	SK-3(F)	980 m	146,398	201,300
Rhododendron luteum	SK-4 (L)	1062 m	219,071	463,624
Rhododendron luteum	SK-4 (F)	1062 m	201,642	768,744
Rhododendron ponticum	MK-1 (L)	740 m	230,580	933,192
Rhododendron ponticum	MK-1 (F)	740 m	213,974	1062,769

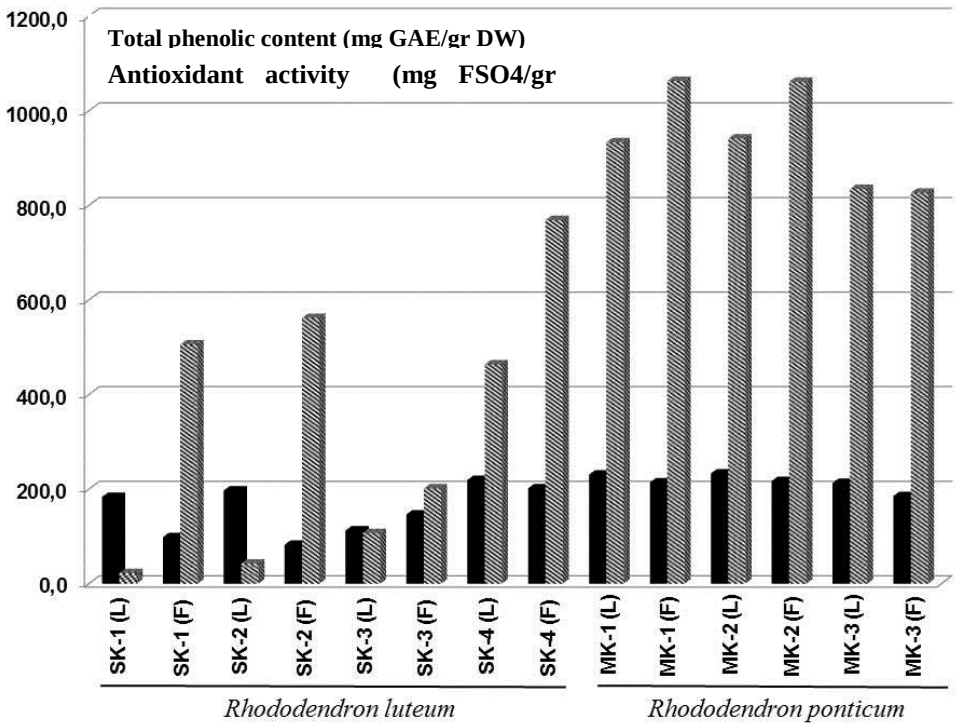

Fig. 1. Comparison of total phenolic contents and antioxidant activity values of collected samples

As can be seen in Fig. 2 the investigated samples of *Rhododendron luteum* could be clearly seperated from the leave and flower samples of *Rhododendron ponticum*. Especially the higher total phenolic contents and higher antioxidant values of *Rhododendron ponticum* samples led to this clear diversification.

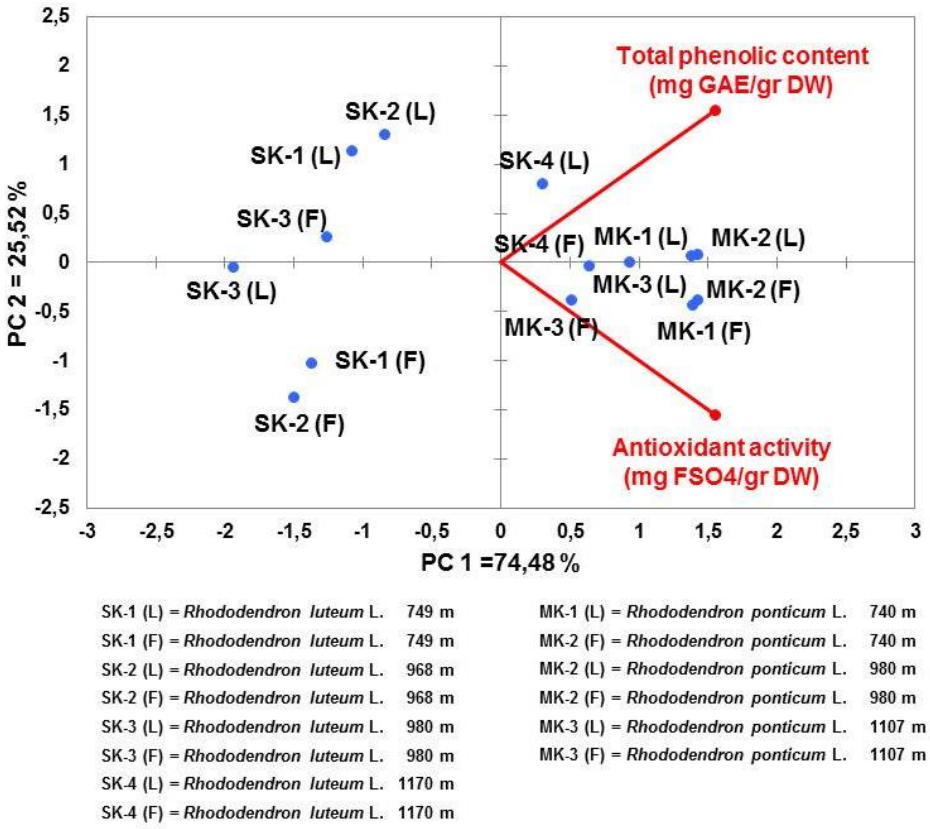

Fig. 2: Biplot analysis of different parts of Rhododendron species based on their phenolic contents and antioxidant activity values

Environmental factors, such as soil composition, temperature, rainfall and ultraviolet radiation incidence can affect the concentrations of phenolic compounds (Kouki and Manetas, 2002; Monteiro *et al*., 2006). Among phenolic compounds, the tannins can be influenced by development of the plant and by environmental changes (Hatano *et al*., 1986; Salminen *et al*., 2001). Thus, phenolic compounds and others secondary metabolites represent a chemical interface between plants and environment (Gobbo-Neto and Lopes, 2007). Changes in phenols amounts influence directly the quality of the plant for medicinal application (Santos *et al*., 2006). Therefore it is not surprising that the collected samples differed in their total phenolic content and antioxidant activity.

Conclusion

In folk medicine, the tincture prepared from Rhododendron plant leaves are use to treat gout, epilepsy, headaches, insomnia, intimate and diuretic conditions, rheumatism, dysentery, sharp and chronic colic. Broth prepared from rhododendron is recommended by fork medicine as a cure against syndrome of oxygen insufficiency.

Also in general and in the study area present Rhododendron plants are present as deciduous short trees with green leaves and have flowers of different colours and an aesthetically important role in landscape.

İn the present study only two sepcies and two traits were analysed. Further studies should involve different species from different locations and determimation of compounds which coulşd be helpful in future studies.

Abstract

This research was carried out in order to determine the suitable sowing time for peanut in the condition of GAP region (is located in Turkey's Southeast) at the GAP Agricultural Research Institute Talat Demirören Research Station in 2013-2014. Two peanut cultivars (NC-7, Halisbey) and eight different sowing dates (April 15, April 25, May 5, May 15, May 25, June 5, June 15 and June 25) were studied. Trial was conducted as split plots design with three replications. The main plots were consisted of planting dates; the sub-plots were consisted of cultivars. In the result of combined analysis of two year, the differences between sowing dates were found significant at the level of 1% in terms of capsules number per plant, seed number per plant, seed yield, protein ratio, and oil yield except 100-seed weight. As a result of two-year interaction of this research, the seed yield ranged between 489.1 kg/da and 325.4 kg/da in terms of sowing times. While the highest seed yield was obtained either from the sowing date of April 25 with 489.1 kg/da or from the sowing date of May 15 with 488.7 kg/da, the lowest capsule yield was obtained from the sowing date of June 25 with 325.4 kg/da. While the highest oil yield was obtained from the variety of NC-7 with 144.3 kg/da in the sowing date of May 5, the lowest oil yield was from the variety of Halisbey with 84.6 kg/da in the sowing date of June 25, and the highest protein ratio received from the variety of NC-7 with the 20.75 % in the sowing date of June 25.

Keywords: *GAP region, peanut, sowing date, variety, yield and yield components*

Introduction

The world's peanut production made in many countries (*Arachis heypogaea L.*) for both human nutrition or although finding large proportion of usage in livestock and various branches of industry, in our country is consumed only for as an appetizer.

Peanut seeds is a valuable source of food for humans and animals with contains oil, protein, carbohydrates, vitamins, and mineral substances. Peanut seeds contains, varies according to the variety, the rate of 44-56% oil, the rate of 22-30% protein, and 18% carbohydrate (Rowell et al., 1999). Because of easily digestible of amino acids which constituting the protein in peanut increases the nutritional value. Therefore, peanut seeds are consumed in large quantities in fresh or dry roasted snack (Arıoğlu, 1999).

Tocopherol is an abundant antioxidant in Peanut oil and prevents oil from degradation by oxidation. Especially, peanut oil is mixed as proportion of 30% with diesel fuel (biodiesel) are used as fuel in the operation of diesel engines (Woodroof, 1983).

In 2013, 45.2 million tons of peanut were produced from the 25.5 million hectares of cultivation area in the world, and 141.263 tonnes were produced from the 39 943 ha in Turkey (FAO, 2013).

With the completion of Southeastern Anatolia Project, 1.7 million hectares of agricultural land will open to irrigation gradually, and the planting area and production of oil crops will also increase substantially. As envisaged in the GAP Master Plan; the share of soy bean was 10%, peanut, sunflower and sesame were 5% in crop pattern (Kolsaracı et al., 2005).

Our country is divided into natural geographical regions, each of these regions has a different climate. As a result of this, the plant species grown in the region reveals differences even in the same species plants show different reactions in different ecologies. Therefore, in our country, crop planting techniques and times constitute an important part of the researches.

The research has contributed to expand the range of cultivated crops in our region and also with providing optimal planting time for peanut in the conditions of GAP region tried to ensure value added to the region and the country's economy.

Materials and methods

Trials was carried out in the experimental field of GAP Agricultural Research Institute Talat Demirören Research Station in 2013 and 2014 years. Talat Demirören Research Station is 34 km away from downtown and located between the town of Akçakale and Şanlıurfa province. Geographical location, 36º 42' North and 38º 58' East and 410 m above sea level.

NC-7 and Halisbey peanut varieties were used. The study established in randomized complete block design split plots with with three replications. Eight different planting time (April 15, April 25, May 5, May 15, May 25, June 5, June 15 and June 25) were placed as main plots and varieties (NC-7 and Halisbey) in sub plots in the trial. The parcels; row spacing of 70 cm, intra row spacing of 20 cm and parcel row organized length of 6 m (4x0.70x6=16.8 m^2) with 4 rows.

Results and discussion

Number of Pods and Seeds Per Plant

Table 1 examined; according to the average of two-year, the number of pods and seeds per plant in terms of sowing date x cultivar interaction was found significant ($p<0.01$). While the highest number of pods per plant obtained from the variety of Halisbey with 73.9 pieces/plant on April 15, the lowest number of pods per plant obtained from the variety of Halisbey with 26.3 pieces/plant on June 25. The highest number of seeds per plant obtained from the variety of NC-7 with 86.0 pieces/plant on May 5, the lowest number of seeds per plant obtained from the variety of Halisbey with 32.6 pieces/plant on June 25

Protein Ratio and Oil Yield

Table 3 examined; according to the average of two-year, the protein ratio and oil yield in terms of sowing date x cultivar interaction was found significant ($p<0.01$).
While the highest protein ratio (%) was obtained from the variety of NC-7 with 20.75 % on April 25, the lowest protein ratio (%) was obtained from the variety of Halisbey with 18.61 % on May 5 and from the variety of NC-7 with 18.61 % on May 25. The highest oil yield (kg/da) was obtained from the variety of NC-7 with 144.3 kg/da on May 5, the lowest oil yield (kg/da) obtained from the variety of Halisbey with 84.6 pieces/plant on June 25

Conclusion

According to the results of two years of sowing date x cultivar interaction; it has been identified the most appropriate planting time for peanut in the GAP region were late April and first half of May, and varieties of Halisbey and NC-7 can be easily cultivated in the conditions of GAP region. Also; in order to prevent seed decay and growth disorders it would be useful to avoid quite possible from early sowing. And with a sudden rise in the temperature in the event of sowing late may passes plant to generative period early. It has been identified that these negativeness may be caused to the decline in yields.

As a result; with this study as determined the appropriate sowing time offered to farmers in the region were helped to establish the supply-demand balance in production, contributed the producers to get higher income by created alternative products.

Abstract

An experiment was set up to evaluate techniques of multiplication of plantlets through stumps was laid in a Randomized complete Block Design (RCBD) with 10 treatments in two replications. The treatments were of different sizes of 5,7,10 and 20cm split and unsplit with a whole stump as control. Data were days to 50% emergence, number of plantlets and weight of sucker. The evaluation of sources and rate of Nitrogen influence on rapid early growth of plantlets was in a completely randomised design (CRD) with 10 treatments replicated 3 times. The treatments: control, brewery waste + poultry dung 200, 150 and 100 kg N/ha, brewery waste + cattle dung 200, 150 and 100 kg N/ha, N.P.K 20:10:10 200, 150 and 100 kg N/ha. Parameters were; area of the D leaf (cm^2), Plant height (cm) Number of leaves and weight of suckers (g). Data were analysed using descriptive (ANOVA). Significant means were separated with DMRT at $\alpha 0.05$. Apical, middle and basal portions gave100%, 87.5% and 75% emergence respectively. The number of plantlets was significant on control (2.5) and split 5cm (7.0) weight of plantlets on split cut 20cm (66.25) and control (70.15). All fertilizer sources at 150 kg N/ha rate gave a significant difference in size (450-500g), area of the D leaf (47.87) and number of leaves (25.33). Therefore, 20cm cut is recommended for high quality plantlet on weight basis while 5cm cut gave highest number of plantlets and fertilizer rate of 150 kg N/ ha is also recommended.

Keywords: *plantlets, pineapple sucker, compost, macro-propagation.*

Introduction

Ananas comosus is an herbaceous perennial with narrow leaves that may or may not posses spines and a characteristic peculiar fruits fragrance, (Jonathan, 2013). It is an important fruit crop with high demand at the international market (Fawole, 2008) and cherished by large population in Nigeria, it is of higher economic value since the demand from local fruit juice industries and fresh fruits consumers are more than the supply, hence it is necessary to improve pineapple production techniques in other to increase yield per hectare as well as increase farmers gain. One of the major challenges militating against pineapple production is scarcity of adequate planting materials that is usually obtain from the old pineapple field 5-8 months after fruit harvest under rainfed condition, this materials will be produced at different intervals hence the have different sizes resulting in unsynchronized fruiting. Within the period farmers wait for suckers from old orchard to plant a new field, some stands may not produce sucker, some cases maximum of two undersize suckers might be produced. Planting period that will favour rainfed crop becomes late resulting in small fruiting in the drought. However, in this study, stumps that are regarded as waste which should have been thrown away as a thrash during re-cropping or eradication of old

orchard will be use for sucker production. A sucker in pineapple is a type of vegetative propagules which eventually grows up to become a pineapple plant (Morton, 1987). The technique of pineapple sucker generation was described by (Macluskie, 1939) and (Py, 1957) how an old pineapple stumps could be use to produce pineapple plantlets to solve the farmers challenges of insufficient planting materials.

Materials and Methods

The experiment was sited at the university of Ibadan teaching and research farm at these coordinates Latitude 7.45176N and Longitude 3.896E within 4 meters location beginning from 30th April 2014 followed by plantlet growth performance in the screen house of the department of Agronomy, University of Ibadan (Nigeria) with the following coordinates Latitude 7.45176N and Longitude 3.896E within 4 meters location. An experiment was set up to evaluate techniques of multiplication of plantlets through stumps was laid in a Randomized complete Block Design (RCBD) with 10 treatments in two replications. The treatments were of different sizes of 5,7,10 and 20 cm split. and unsplit with a whole stump as control. Data were days to 50% emergence, number of plantlets and weight of plantlets. Followed by the evaluation of different sources and rates of Nitrogen influence on rapid early growth of plantlets was in a completely randomised design (CRD) with 10 treatments replicated 3 times. The treatments: control, brewery waste + poultry dung compost (BPD) 200, 150 and 100 kg N/ha, brewery waste + cattle dung compost (BPC) 200, 150 and 100 kg N/ha, N.P.K 20:10:10 200, 150 and 100 kg N/ha. Parameters measured were; area of the D leaf (cm^2), Plant height (cm) Number of leaves and weight of suckers (g). Matured pineapple plants of the same age were selected from University of Ibadan orchard after fruit harvest. They were uprooted, defoliated exposing axial buds on the stumps (Ucheagwu and Obiefuna, 1991) and (Olaniyi and Kelani 2010) and the stumps were cut into 5 cm, 7 cm, 10 cm and 20 cm having both cuts unsliced and sliced sizes (Olaniyi and Kelani 2010) the control 20 cm was not cut nor sliced. Top soil was used for planting of cut stumps at 2 cm depth and at a spacing of 10 cm apart. Each stump pieces (split) and whole bears at least two axial buds. (Ucheagu and Obiefuna, 1982). The cut stumps were air dried for two hours to ensure drying and healing of the wound to harden the materials against pest and disease invasion. The stumps (split or whole) were planted randomly with each having its label. Adequate moisture was maintained by wetting when necessary. Suckers were observer for emergence at 4 weeks after planting and suckers were milked at 8 weeks after planting. For the second experiment, top soil was sampled using soil auger from 0-15 cm to know physicochemical properties of the soils sites used for the experiment, when the soil was analysed, nitrogen was deficient and3 kg soil was potted into polyethylene bags. There were perforated to enhance drainage. The actual quantity of fertilizer types were applied using a hand trowel to scoop soil from the polyethylene bag creating a hollow, the fertilizer materials was placed and a little quantity of soil was placed on the fertilizer before the plantlets of uniform seizes were planted on the fertilized polyethylene bags after which it was wetted forth night. Before, application of treatment a test was carried out to ascertain the quantity of water that will wet the soil at field capacity.

Results and Discussion

The apical, middle and basal portions gave100%, 87.5% and 75% emergence respectively, (Py, 1957) apical portions seems to emerge suckers earlier than the basal portions. The number of plantlets was significant on control (2.5) and split 5 cm (7.0) weight of plantlets on split cut 20 cm (66.25) and control (70.15). In site B, (table 1.) the soil nitrogen, phosphorus, potassium were low, low and very high respectively, the pH was slightly acidic to neutral. However the textural

class was loamy sand (USDA) which is suitable growing pineapple, though nitrogen application was necessary for adequate growth. (Morton, 1987).

Table 1. Pre-planting soil analysis for site B (Nursery)

Parameters	Value
pH (H_20 1:1)	6.7
Total Nitrogen (g/kg)	0.67
Organic Carbon (g/kg)	1.32
Available Phosphorus (mg/kg)	6.23
Exchangeable Bases (cmol/kg)	
K	1.97
Ca	0.71
Na	0.61
Mg	0.64
Micro nutrients (mg/kg)	
Fe	43.1
Cu	13.3
Mn	664
Particle Size Distribution (g/kg)	
Sand	880
Silt	20
Clay	100
Textural Class (USDA)	Loamy sand

Table 2. N. P. K content of the compost fertilizers materials (%)

Fertilizer	N	P	K
BPD Compost	2.27	0.92	0.73
BCD Compost	2.23	0.81	0.40
N.P.K Inorganic	20	10	10

Key: Brewery waste +poultry dropping (BPD) and Brewery waste and cattle dropping (BCD) Nitrogen, phosphorus and potassium (N. P.K)

Nitrogen sources an rates applied have significant influence on area of D leaf of pineapple, at 20 weeks after planting, IBCD 200 kg/ha gave (48.57 m^2) significantly ($p \leq 0.05$) larger area of D leaf than control (33.73 m^2), (IBPD 150 kgN/ha, IBPD 100 kg N/ha and IBCD 100 kg N/ha but not

significantly different from other treatments owning to the fact that pineapple perform well on sandy to sandy loam soils (Collins 1960; Morton 1987). This result corroborate with that of (Omotoso and Akinrinde, 2007) that N-rates have significant influence on area of D leaf in pineapple.

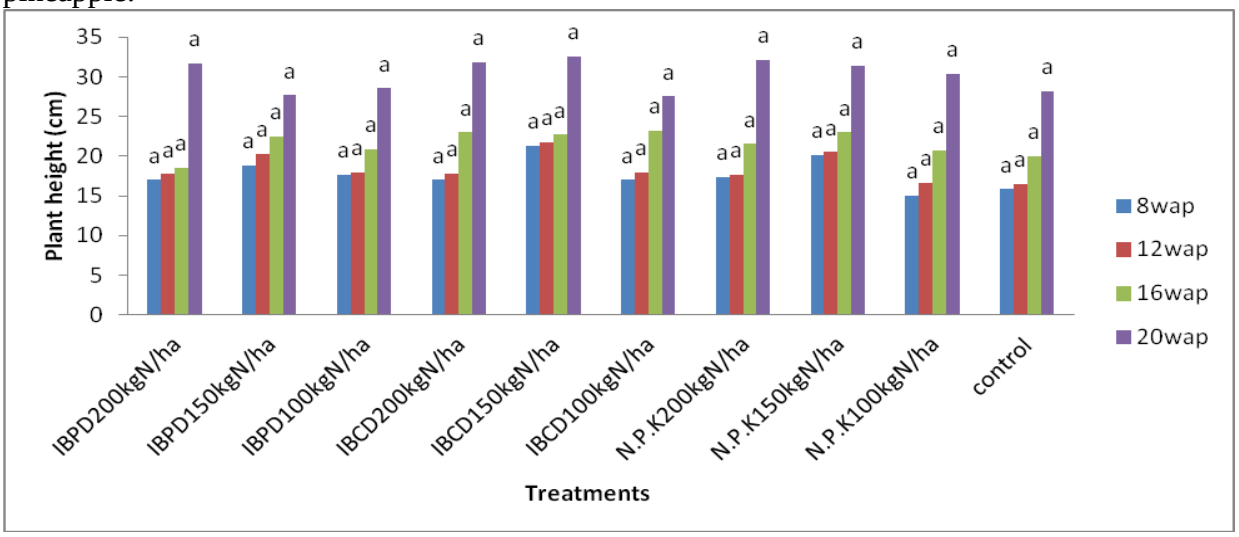

Figure 1. Effect of fertilizer types and rates on height of pineapple plantlets in the nursery

There was a significant difference ($p \leq 0.05$) in height and number of leaves at 20 weeks after planting, 200,150 and 100 kg N/ha from all the sources have significantly ($p \leq 0.05$) higher number of leaves than other treatment but not significantly different from other treatments (figure 1). However, at the end of the observation, 200 and 150 kg N/ha rates from all the sources gave the highest size (weight) of pineapple sucker, (Najafvand *et. al*, 2008) also found out that nitrogen rates increased number of leaves and plant height of tomato. This result is also in line with (Omotoso and Akinrinde, 2007) that N-rates have significant influence on number of leaves in pineapple.

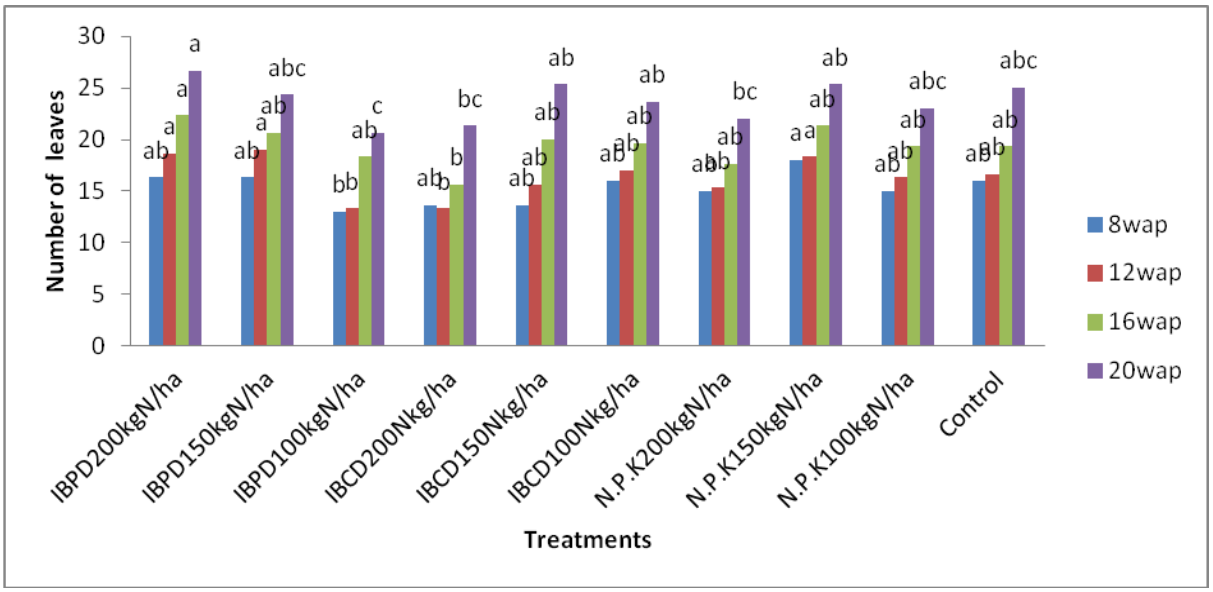

Figure 2. Effect of fertilizer types and rates on number of leaves of pineapple plantlets in the nursery

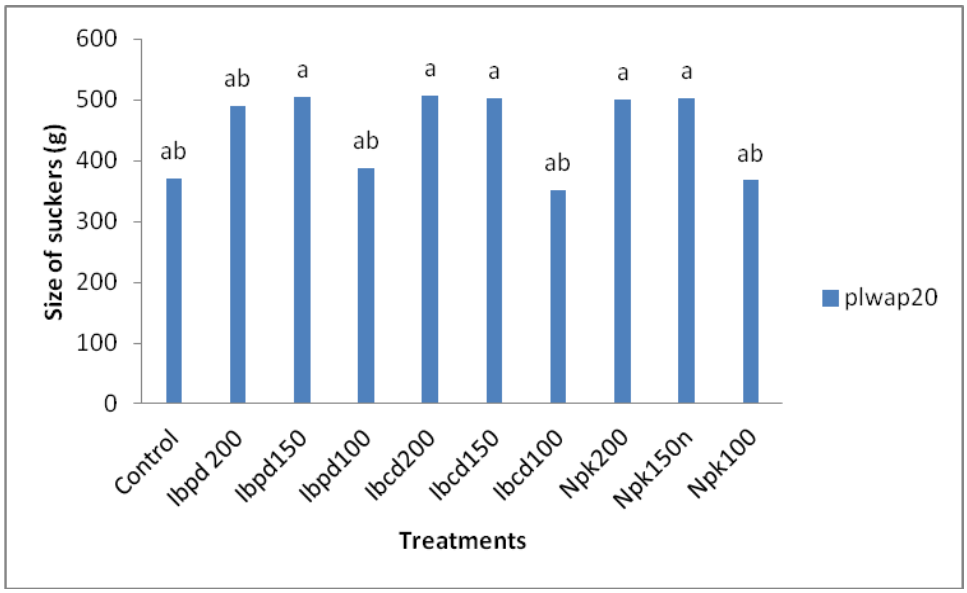

Figure 3. Effects of fertilizer sources and rates on the size of pineapple suckers for field planting

Conclusion

The apical portion gave the highest percentage emergence (100%). The control gave the least number of plantlets whereas highest significant plantlet weight at milking; the bigger the weight of pineapple stump, the bigger the plantlets produce and the higher the quality of propagules. The split 5cm cut gave the least weight and highest number of plantlets and highly significant from other treatment, it also shows that it can give 8 times more number of suckers than the control (whole 20cm stump length). Nitrogen has significant influence on area of D leaf, Numbers of leaves, plant height and weight of suckers by all fertilizer sources used and at 150 kg N per hectare rate. Therefore, I recommend apical portion for early and 100% emergence, 5-7cm cut for higher plantlets production, control or 20cm for plantlet that will meet field size (500g) early and 150 kgN/ha rate for all the sources used based on soil analysis report. More work need to be done on pineapple plantlet multiplication using plastic mulch technique on the nursery field.

AIRJECTION® INTO SUB-SURFACE DRIP IRRIGATION SYSTEMS AS A TOOL FOR CLIMATE-SMART IRRIGATION

Michael DAVIDSON

Davidson Consultants, USA
*Corresponding author: michael.davidson@climatesmartirrigation.com

Abstract

Climate-smart Agriculture (CSA) has been developed as a model to address socio-ecological systems. CSA consists of a suite of tools and methods that, when implemented in a sustainable manner and locally supported, leads to the achievement of three basic objectives; mitigation of environmental damage caused by traditional agricultural practices; adaptation of farming methods and regimes that cope with the uncertainty and variability of climate change; and food security or improved agricultural production and profitability for the grower. Organic agriculture is a framework that integrates the triple goals of CSA but not all tools are appropriate for organic agriculture. Among the recent innovations of CSA that is particular appropriate for organic agriculture is the development of air injection This paper summarizes the work of Goorahoo, et al and presents the results of an 8-year study that satisfies the objectives of CSA and can serve as an important tool for cost-effective agricultural improvement in organic landscapes. The Goorahoo case study provides evidence that injecting air into a sub-surface drip irrigation system creates an aerobic oxygen/nitrogen root environment with no added chemicals or additives, which significantly and positively improves production with no increases in fertilizers, water or fuel. This study evaluates the carbon and nitrogen cycling implications, and cost benefit analysis benefits of the AirJection® System on cantaloupes, corn, honeydew and bell peppers in central California.

Keywords: Climate-smart agriculture, sub-surface irrigation, air injection, root zones

Introduction

The primary components of soils are: solids (mineral and organic fractions); water; and air (Hutmacher, 2016). The "pore volume" is the aggregate of water and air, which is a characteristic of soils, but can be modified by managing compaction (Hutmacher, 2016). All crops require water, oxygen and proper nutrition. Roots trapped in anaerobic environments are deprived of sufficient oxygen and stressed to the extent that crop yields and quality are significantly and negatively impacted. Photosynthesis is weakened and roots cannot absorb naturally occurring and applied nutrients. Hypoxia stress is the mechanism that explains how "air is squeezed out of the soil in the process of traditional irrigation" (Yuan, et al., 2016). In addition to irrigation applications, all tractor work and, in particular, deep plowing, increase hypoxia stress in the root zone. There are many methods for alleviating this stress and creating a more aerobic environment for the root zone. This paper examines the process of injecting oxygen into a sub-surface drip irrigation (SDI) system for the purpose of reducing hypoxia stress. AirJection has been successfully applied to improve yields, water use efficiency and crop health in pineapple (Dhungel, Bhattard, & Midmore, 2012). This paper reviews an eight-year study on cantaloupes in the San Joaquin Valley of California that compared changes in crop yield, energy costs and investment costs over one year and over an eight-year period. This study significantly

contributes to the efficacy of the CSA model and has significant and positive implications for organic agriculture.

Materials and Methods

This original, controlled, experiment was installed at Stamoules Farms in Mendota, California. The AirJection® system was installed by the farm operation with the oversight of technicians from the Mazzei Company in Bakersfield, California who is the manufacturer of the AirJection® system. This experiment used venturi-type injectors on each drip lateral. The injection rate was calibrated to achieve 15% by volume (California Council on Science and Technology, 2014). The AirJection® system operated simultaneously and always with the irrigation system.

The cantaloupe crop was grown on 5 feet (1.5 meters) (Goorahoo, Decker, S, Zoldoske, & Mazzei, 2014). "The experimental plot consisted of four alternating replications of AirJection® and no air injection (control). Each replicate was made up of seven beds to accommodate the width of the tractor-drawn trailers during harvesting" (Goorahoo, Decker, S, Zoldoske, & Mazzei, 2014). A diesel pump was supplied to increase line pressure from 15 psi (1 bar) to 25 psi (1.7 bar).

Figure 1 schematically illustrates the buried water supply line and buried injectors with snorkels for air suction that were utilized in this experiment. Figure 2 is a photo of the AirJection® system.

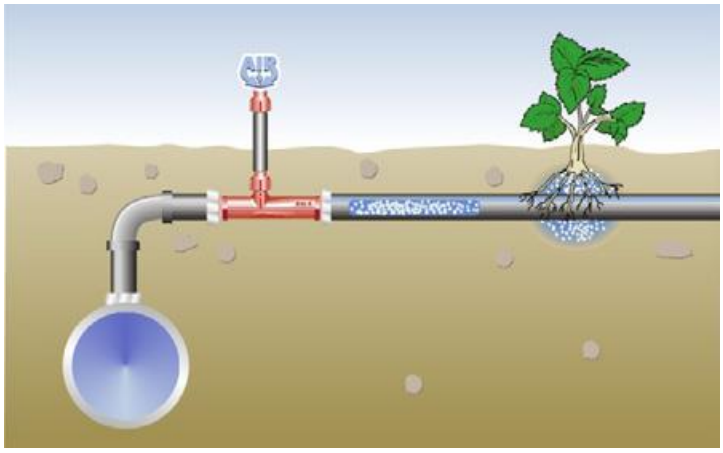

Figure 11 Buried water supply line with buried injector with snorkels for air suction (Mazzei)

Figure 12 photo of AirJection® system (Mazzei)

Results

The experimental results were positive to the extent that the Stamoules company decided to expand the AirJection® system to a commercial scale.

First Year

The first-year results of the AirJection® application showed an ROI of about $1 million on 1500 acres (600 hectare) of cantaloupes. Table 1 is a summary of installation costs and production outputs for year 1. Table 2 illustrates the energy costs and ROI for year 1.

Table 3 Summary of installation costs and production outputs for year 1

Acreage	Number of AirJection® units/acre (ha)	Installation cost/acre (ha)	Total installation cost for field	Total of produce boxes with AirJection®	Total box for control
1497	5.5 (13.75)	$140 ($350)	$209,580	1,597,664	1,190,362

Table 4 Energy costs and ROI for year 1

Total additional energy cost	Additional energy cost per acre (ha)	Average per acre increase in cantaloupe boxes (ha)	Total box increase over farm average	Conservative net price per box	ROI	1st year Net ROI
$15,554	$10.35 ($25.88)	272 (680)	407,302	$3.00	$1,221,906	$996.772

Eight Year Average

The eight-year average for the cantaloupe crop consists of 6,480 acres (2,622 ha) and showed an average increase of 1.3 million boxes. Table 3 illustrates the average (mean) of production and increase from 2005-2012. Table 4 illustrates the average production over eight years and the energy costs of AirJection® compared to the control.

Table 5 Average (mean) of production and increase, 2005-2012

Crop	Total AirJection® acreage (ha)	Total of AirJection® boxes	Total boxes for controlled acreage	Average per acre increases in boxes (ha)	Total box increase over control
Cantaloupe	6,480 (2,622)	6,891,383	5,590,794	201 (502)	1,300,590

Table 6 Average summary of energy costs for AirJection® and control, 2005-2012

Crop	Total AirJection® acreage (ha)	Total AirJection® boxes	AirJection® energy cost per box	Total boxes for control	Non-AirJection® equivalent energy per box
Cantaloupe	6,480 (2,622)	6,891,383	$0.02	5,590,794	$0.012

Overall yields over the eight-year period were 12%-34% greater than in prior years. Figure 1 illustrates the increases in yield per year from 2005-2012

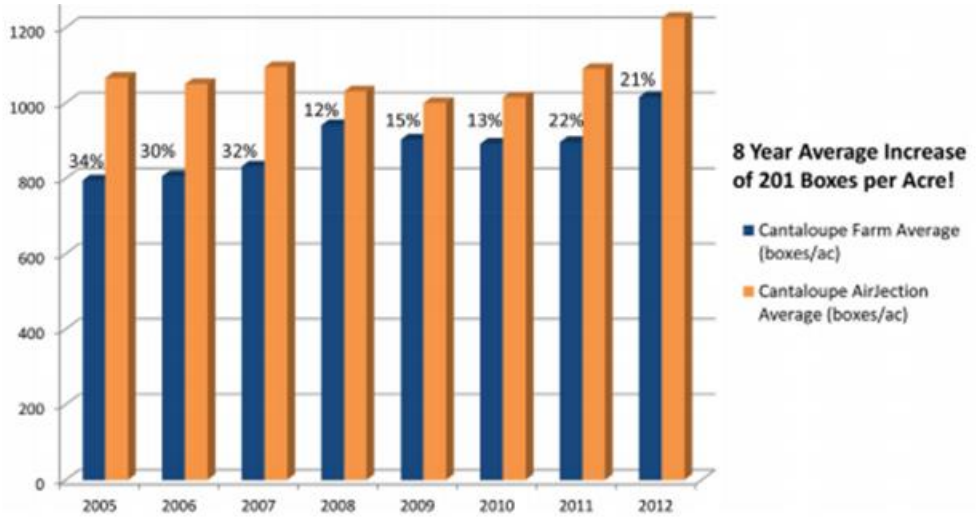

Figure 13 Increases in yield per year ,2005-2012

Discussion

The grower experimented with AirJection in the first year on 600 hectares of cantaloupes and realized a net return on his investment of almost $1,000,000 or $1667/hectare. The installation of the AirJection system was the only intervention in the first year. After the first season, the grower expanded the scope of his investment and installed the AirJection system on 2,622 hectares and realized a significant and positive return on investment in each of the subsequent seven years. The average increase in yield over the eight-year period was just over 200 boxes per acre (500 boxes/hectare), which is equivalent to $600/acre or $1,500/hectare.

The grower had experience in sub-surface drip technology and had already achieved a high degree of water-use efficiency.

Conclusions

The conclusions for this experiment are of significant value for all SDI systems. No additional fertilizers or irrigation water were applied. The ROI was positive in the first year and the associated energy costs per box in the subsequent eight years were insignificant. The AirJection® system was calibrated and adjusted during the first year and maintained its operation efficiency

over the following eight years with no additional calibration. The increase in yield was significant and positive.

The implications for organic agriculture are also significant and positive. There are no associated material costs to absorb when using the AirJection® system and the only elements that are injected are oxygen and nitrogen. No chemicals are used.

A second significant implication is the added value AirJection® brings to SDI in general. SDI reduced evaporation, improves transpiration losses and has the highest water-use efficiency values of any irrigation system. Increasing yields and achieving higher water and nutrient -use efficiency by incorporating AirJection® with SDI is very promising.

Acknowledgements

This research is a summary of the experiments conducted by Goorahoo, et al (Goorahoo, Decker, S, Zoldoske, & Mazzei, 2014). Goorahoo is the lead author of the original study on the AirJection® study.

Abstract

This study was carried out to examine the variation of some traits of *Digitalis ferrugineae* L. at Pazar/Rize/Turkey conditions. The experiment was conducted in 2014/2015 in the field trials belonging to the Faculty of Agriculture and Natural Science, Recep Tayyip Erdoğan University. *Digitalis ferrugineae* L. seeds were sown firstly into viols in greenhouse. The seedlings were planted into the field at 5-6 leave stage in 2014. All measurements were done using selected twenty plants in 2015. There were great variation between the plants investigated in the study. The change interval was 68,5-148,5 cm for plant height; 28,0-95,5 cm for spike length; 3,92-10,08 mm for spike diameter just below the first capsule; 5,92-13,5 mm for root collar diameter; 0-14 for number of branches per plant; 0,3-9,4 g for seed yield per plant and 0,31-0,69 g for 1000 seeds weight. The positive corelations were found significant ($P<0.05$) between seed yield per plant and three characters which were spike length (r=0,4890), spike diameter (r=0,5181) and root collar diameter (r=0,5799). In addition, relationship between plant height and spike length was found significant. As a result the plants of *Digitalis ferrugineae* L. multiplicated with seed displayed great variation and could be advantageous for further breeding studies.

Keywords: *Digitalis ferrugineae, spike, seed, variation*

Introduction

Digitalis ferruginea (=*D. aurea* Lindley) is a widespread member of the eight *Digitalis* species from the family *Plantaginaceae* (=*Scrophulariaceae*) in Turkey (Davis, 1978). The genus *Digitalis* composed of more than 20 species, and is commonly known as the "foxglove". The name *Digitalis* means "finger of a glove" as Latin which refers to the shape of the flowers (Clemente et al., 2011). Members of the genus *Digitalis* L. are medicinally and economically important plants as they comprise the main source of cardiac glycosides, which are therapeutically used for the healing of congestive heart failure and regulate heart rhythm (Baytop, 1999).

It is known that only two species have been grown as a source of glycosides for pharmaceutical industry, especially *Digitalis lanata* Ehrh. and *Digitalis purpurea* L. (Bown 1995). These species successfully grown at farms with excellent biomass and seed production capacity in recent years (Negi et al., 2012). Moreover it is known that *D. lanata* were cultivated in 230 hectares of Netherlands by 1984s (Mastenbroek, 1985).

Apart from cardiotonic therapeutic efficacy, it is also used as diureticand in the reduction of oedema due to its ability to improve cardiovascular circulation (Perez-Bermudez et al., 1990). In addition, preliminary studies have revealed that digoxin and digitoxin obtained from *Digitalis* species are also effective agents in cancer, in particular for prostate and breast cancer treatments (Yeh et al., 2001; Lopez-Lazaro, 2007; Newman et al., 2008).

In fact, the Digitalis species which also have ornamental value have been the subject of studies for the improvement the cultivars with high content in cardiotonic glycosides to be used for medicinal purposes (Ardelean et al., 2006).

All parts of *D. ferruginea* are poisonous (Chiej, 1984) and this species is known as "rusty foxglove" all over the world and "pas renkli yüksük otu" in Turkey (Ozturk et al., 2008) It is a biannual or perannual plant. As with other *Digitalis* species, *D. ferruginea* also comprises cardiac glycosides and is the most abundant of *Digitalis* members in Turkey flora.

There is no research on agricultural traits of *D. ferruginea* before. Cultivation with sowing of seeds in medicinal plants in particular can lead to a new variation in the plants which are available to cross pollination. That variation is great in terms of breeders is a great opportunity to improve new cultivars. In this study, the plants of *D. ferrugineae* L. multiplicated by seed were compared regarding the stem, spike and seed traits.

Materials and methods

This research was conducted in 2014/2015 in the field trials belonging to the Faculty of Agriculture and Natural Science in Recep Tayyip Erdoğan University in Pazar district of Rize Province in the Black Sea Region of Turkey. Expermental field is located at 41°10.668′ N latitude, 40°54.018′E longitude with an average altitude of 65 m above mean sea level.

The district Pazar has a climate displaying warm summer, moderate winter and rainfall in every season. According to the records of the Turkish State Meteorological Service, the District's Long-term average precipitation is 1978.1 mm; long-term average of growing season (April-October) is 1100.1 mm (TSMS, 2013).

The seeds of *Digitalis ferrugineae* L. populations (foxglove) from flora were firstly sown into viols in greenhouse on 21th of february in 2014. When the seedlings reached the stage with 5-6 leaves, they were planted into the field. The distances between the plants were 40x30 cm. Twenty plants were selected and some traits of these plants were determined in the next year (2015) of the experiment.

In this study, examined agricultural traits of foxglove were plant height, spike length, spike diameter (just below the first capsule), root collar diameter, seed yield per plant and 1000 seeds weight.

Results and discussion

Stem characteristics

Plant height is one of the most important agricultural traits to enable harvest in almost all crops. Moreover, plant height may also influence to prevent yield loss at harvest. The plant with high height generally are under risk to yield loss because of laying. In addition, there are possible correlations in between the plant height with other traits of plants.

In the present study, plant height varried from 68,5 cm to 148,5 cm (Table 1). Plant height was positively correlated with spike length and **s**pike diameter. The highest value (10,08 mm) regarding to spike diameter were obtained from the plant number 2 which plant heigth was 100 cm. Similarly, the plant number 2 had also the highest value regarding to root collar diameter.

Positive correlation was found between root collar diameter and spike diameter. These two characters assure a stronger stem structure in plant against adverse environmental conditions such as heavy rainfall and wind. In this study, firstly, the plant number 2 with number 15 had more advantageous of stem structure than others. On the other hand, an unusual branching on the bottom part of the stem was determined in only a plant.

The plant number 15 had been the only plant showing branching on the bottom of the stem. The stem traits of twenty plants examined showed a wide variation and it is clear that among these plants regarding to stem stiffness, in particular number 2 had a strong stem.

Gntyp: plant, B: brown, DB: dark brown, LB: light brown

Spike characteristics

Spike length is one of the important characteristics that affect the seed yield. The positive corelations were found significant ($P<0.05$) between spike length and four characters which were plant height (r=0,6980), spike diameter (r=0,8698), root collar diameter (r= 0,6648) and seed yield per plant (r= 0,4890) (Table-2). Among the plants examined in the study, spike length showed a large variation between 28,0 cm and 95.5 cm. The highest spike length was obtained from the plant number 14 and followed it plant number 2 with 93.7 cm, plant number 15 with 93.0, plant number 9 with 79.5 cm, plant number 3 with 66.5 cm and others respectively.

A total of four plants occurred branching in their spikes. Numbers of branch ranged from 0 to 14 in the plants. The highest values regarding to spike lengths were obtained from same four plants. In addition, these four plants took place within the first eight for seed yield per plant and seed yield per plant ranged from 0,27 g to 9.42 g for all the plants. This research showed that the seed yield per plant correlated with three characters, spike length, spike diameter and root collar diameter. In terms of seed yield per plant, the highest values as 9.42 g, 6.20 g and 6.06 g obtained from plants number 3, 20 and 2 respectively. The only negative relationship which was not statistically significant occured between seed yield per plant and 1000 seeds weight. Although some plants (such as plant number 2) had higher both spike length and 1000 seeds weight, their seed yield per plant was lower. This decrease in the seed yield per plant could probably arise from differences in the number of capsules per spike and number of seeds per capsule.

Table 2. The relationships (corelations) between characters

	Characters	Plant height	Spike length	Spike diameter	Root collar diameter	Seed yield per plant	1000 seeds weight
1	Plant height	1,0000					
2	Spike length	0,6980*	1,0000				
3	Spike diameter	0,4772*	0,8698*	1,0000			
4	Root collar diameter	0,3596	0,6648*	0,8896*	1,0000		
5	Seed yield per plant	0,4141	0,4890*	0,5181*	0,5799*	1,0000	
6	1000 seeds weight	0,1855	0,1676	0,1501	0,1299	-0,0192	1,0000

*P<0.05 (the relationships between characters was determined acording to 5 % of significant level)

Seed characteristics

The plants forming leaf rosette in the first year comprised spike in the second year. After the planned measurements were carried out, the harvest was performed in complete dry period of the spikes. All the plants harvested on 10th of August in 2015 except the plants number 19 and 13 which harvested on 20th of August and 25th of August respectively.

Great differences were determined in the plants regarding to seed color, seed length, seed width and 1000 seeds weight. Seed colors were in eleven plants was brown, light brown in seven and dark brown in two. 1000 seeds weight in the examined plants ranged from 0.308 g to 0.686 g. The longest seeds obtained from the plant number 15 while the largest seeds observed in the plants number 1, 13 and 19. The highest 1000 seeds weight was determined from the plants with large seeds except number 13. A great part of the seeds of the late maturing plant number 13 were undersized and did not have the ability to germinate. This immature seeds caused to decrease 1000 seed weight of the plant number 13. On the other hand, in terms of germination ability, the strong seeds of the same plant were combined and measured for 1000 seeds weight. Its seeds were even larger than the plants number 1 and 19, and reached to 1 g regarding to 1000 seeds weight.

Twenty plants were compared with Cluster Analysis for total of 6 characters (from stem, spike and seed characteristics) to determine the relationships between each other. The dendrogram obtained from cluster analysis showed in Figure-1. It was seen that the plants number 1, 2, 3, 4, 6, 7, 9, 14, 15, 19 and 20 with other plants number 5, 8, 10, 11, 12, 13, 16, 17 and 18 constituted two distinct groups in the dendrogram. As seen in the cluster, the closer pairs of plants were number 10-17, 5-8, 6-7 and 10-12 respectively. Plants which the most distant to each other were between number 1 and 3 plants including number 3, 2 and 5 respectively.

Conclusion

The data obtained from this study are important for creating resources in future researches. A wide variation was determined in a limited number of plants in *Digitalis ferruginea* L. multiplicated with seed regarding to stem, spike and seed characteristics. In addition, it may be possible to obtain a wider variation by increasing the number of plants grown in present conditions. A great variation can create an advantage for breeders in terms of their studies and also provides ease of superior material selection.

PROLONGING STORAGE LIFE OF '0900 ZIRAAT' CHERRIES BY USE OF MODIFIED ATMOSPHERE PACKAGING (MAP)

Mehmet Seckin KURUBAS, Mustafa ERKAN*

Akdeniz University, Faculty of Agriculture, Department of Horticulture, Antalya, Turkey
*Corresponding author: erkan@akdeniz.edu.tr

Abstract

In this research, the effects of modified atmosphere packaging on postharvest life and fruit quality of '0900 Ziraat' cherries (*Prunus avium* L.) were investigated. For this purpose cherries were harvested at optimal maturity and stored at 0°C temperature with 90-95% relative humidity for 50 days in three different modified atmosphere packaging (MAP). The first group of cherries was packed into ordinary non-perforated polyethylene bags (MAP-1). The second group of cherries was packed into ZOEpack (MAP-2) and the third group of cherries was packed into ordinary perforated polyethylene bags (MAP-3-control). Fruit samples were taken at 10 days intervals from different storage conditions and various physical and chemical analyses such as weight loss, flesh firmness, fruit removal force, soluble solids content, titratable acidity, skin color (*L**, *C** and *h*°), percentage of pitting and stem browning and taste were conducted. Furthermore, the changes in O_2 and CO_2 concentrations in MA bags during long term storage were recorded. Experimental results showed that the lowest weight loss was on the cherries stored in MAP-2. The fruit stored in MAP-2 had the highest flesh firmness, fruit removal force, soluble solids, titratable acidity, *L**, *C**, and taste scores at the end of storage. The most effective MAP for controlling pitting and stem browning was MAP-2. It can be concluded that '0900 Ziraat' cherries were successfully stored at 0°C temperature and 90-95% RH in MAP-2 for 50 days with minimal quality loss.

Keywords: *Cherry, 0900 Ziraat, modified atmosphere packaging, postharvest, quality*

Introduction

The leading cherry producer and exporter country in the world is Turkey. The total world production of cherries is about 2.333.155 tons (Anonymous, 2013a). The total production of cherries in Turkey is about 494.325 tons and export value of Turkey is approximately 155 million dollars (Anonymous, 2013b). '0900 Ziraat' is the most prominent cherry cultivar grown in Turkey and almost all of Turkey's cherry export comprises with this cultivar.

Sweet cherry (*Prunus avium* L.) is highly perishable non-climacteric fruit. Their shelf life is very short, manifested by browning and drying of the stems, darkening of fruit color, shrivel, and development of decay (Alique et al., 2003). The main parameters for cherry quality are fruit and stem color, sweetness, sourness and firmness (Kim *et al*., 2005). Fruit quality is determined by visual appearance, stem color, firmness and flavor. Loss of firmness, discoloration of the stem, shriveled fruit surface, darkening of fruit color, and development of decay are the major problems in shortening the shelf life of cherries (Esturk et al., 2012).

Modified atmosphere packaging (MAP) is a useful technique to maintain postharvest quality and extend storage life of different horticultural crops as well as cherries. MAP can be defined as an alteration in the composition of gases in and around fresh produce by respiration and transpiration when such commodities are sealed in plastic films. The use of MAP in postharvest

preservation of cherries is the most important technique to reduce weight losses as well. High relative humidity in the atmosphere surrounding the product, low O_2, and high CO_2 concentrations in the package can potentially reduce respiration rate, ethylene sensitivity, and production, as well as decay and physiological changes such as oxidation, with the resulting benefit of extending product life (Thompson, 2010).
The objective of this study was to determine the effects of different MAPs during long term storage on postharvest fruit quality of '0900 Ziraat' cherries.

Materials and methods

0900 Ziraat, which is the leading cherry cultivar in Turkey, was used as fruit material in the experiment. Cherries were harvested at the optimum harvest maturity and pre-cooled by cold water just after harvest and fruit were immediately transported to the storage unit of Department of Horticulture, Akdeniz University. Cherries were carefully selected for uniform size, free from visual symptoms of any disease, decay or blemishes. Superior quality fruit 26-30 mm in size were selected for the experiment.
The packaging applications were as given below: (1) MAP-1, these group of fruit was packed into non-perforated ordinary polyethylene bags (83x85 cm), (2) MAP-2, these group of cherries was packed into ZOEpack (Patent no: 203563, Serpak Co., Antalya, Turkey) and the third group of cherries was packed into perforated ordinary polyethylene bags (with 128 holes of 5.5 mm diameter, and total perforated area of 0.43%) (83x85cm), MAP-3 and this group of cherries was considered as control. After packaging, all groups of fruit samples were placed in cold storage room and stored for 50 days at 0°C with 90-95% relative humidity (RH). Fruit samples were taken at 10 days intervals and various physical and chemical changes on the fruit were determined.
For weight loss, at harvest 100 individually numbered fruit were weighed, and at the end of each storage period these fruit were re-weighed again and cumulative weight loss was determined and expressed as percent loss from their initial weight.
Flesh firmness was measured by Chatillon Digital Force Gauge equipped with an 8 mm tip. One hundred fruit, in each replication, were penetrated at three different sides of their equatorial axes and the firmness was recorded and expressed as N.
Fruit removal force was measured by Chatillon Digital Force Gauge equipped with notch adapters. One hundred fruit, in each replication, were picked off fruit stem and the fruit removal force was recorded and expressed as N.
External skin color was measured using a Minolta Chromameter (CR 200, MINOLTA Camera Co., LTD Ramsey, NJ, USA) and CIE $L^*a^*b^*$ color space values were recorded. According to CIELAB system, which express color in three parameters: L^*, that corresponds to lightness. Depending on a^* and b^* values, hue angles [$h° = \tan^{-1}(b^*/a^*)$] and chroma values [$C=(a^{*2}+b^{*2})^{1/2}$] were calculated. h° is the angle formed by a line from the origin to the intercept of a* (x axis) and b* (y axis) co-ordinates, where 0°= red, 90°= yellow, 180°= green, 270°= blue. Chroma is the perpendicular distance from the lightness axis, indicating the color intensity (Mozetic et al., 2004). Measurements were taken on opposite sides of each fruit along their equatorial axes and the mean values were determined.
Stem browning and pitting were visually evaluated during the experiment. Any cherries with visible stem browning and pitting were considered browned and pitted. Stem browning and pitting were expressed as percentage of fruit showing symptoms.

Cherries were evaluated by 5 trained panelists at day 10, 20, 30, 40, and 50 of storage. Each treatment group was coded, presented in random order and evaluated based on general visual appearance using this scale: 5 = excellent; 4 = very good; 3 = good; 2 = poor; 1 = very poor.
The O_2 and CO_2 concentrations of the headspace inside the packages were measured using O2 and CO2 analyzer (Servomex Oxygen Analyzer 570 A Inj. and Bühler CO_2 Analyzer IR Analysator Typ-3000). Three replicates and three bags for each replication were used to measure O_2 and CO_2 concentrations in the bags. The results were expressed as kPa O_2 and kPa CO_2 inside the package.
For soluble solids contend (SSC) fruit juices were extracted using a hand blender and SSC were determined using a digital refractometer and means were expressed as percentage (%).
Titratable acidity was determined by titrating 2 mL of fruit juice in 38 mL of distilled water with 0.1 N NaOH to the end point of pH 8.1 and expressed as percent of malic acid equivalents.
The experimental design was completely randomized. Groups of three replicates of 100 fruit per treatment for the cold storage were established. Statistical differences with P-values under 0.05 were considered significant. The Duncan test was used for comparing the averages of the sources of variation.

Results and Discussion

Weight losses of '0900 Ziraat' cherries were given in Table 1. The effects of both storage period and MAP on weight losses were found statistically significant ($p<0.05$). As it is seen from Table 1, the weight loss of cherries increased by the storage time prolonged. The weight loss of cherries stored in MAP-1, MAP-2 and MAP-3 were 2.73%, 1.29%, and 3.81% respectively. During the storage period while the lowest weight loss was obtained from the cherries stored at MAP-2 (1.29%), the highest weight loss was obtained from the cherries stored at MAP-3 (3.81%). Weight loss of cherries increased in all treatments during the storage period. MAP-2 significantly reduced weight loss during cold storage. In our study, while the lowest weight loss was obtained from the cherries stored at MAP-2 the highest weight loss was obtained from the cherries stored at MAP-3. Esturk et al. (2012) reported that the weight loss of control fruit was 28% after 42 days of storage, it was below 1% in the fruit stored at micro perforated MAP.
Flesh firmness is an important quality attribute in cherries that affects consumer acceptance, fruit storage potential, and resistance to mechanical damage (Brown and Bourne, 1988). The effects of storage period on flesh firmness were found statistically significant but the effects of MAPs on flesh firmness were found similar ($p<0.05$). Flesh firmness of cherries at harvest was 17.95 N and decreased to 7.15 N at the end of storage (Table 1). The highest flesh firmness was obtained from the cherries stored at MAP-2 (13.04 N) and the lowest flesh firmness was obtained from the fruit stored in MAP-3 (11.90 N). Flesh firmness was affected by MAPs and MAP-2 was more suitable than the other MAPs in maintaining of flesh firmness of cherries. Our results were similar to the findings of Remon et al. (2000) indicated that micro perforated MAPs were maintained the flesh firmness of 'Burlat' cherries.
The values of fruit removal force of cherries were given in Table 1. While the effects of storage period on fruit removal force were found statistically significant the effects of MAPs on fruit removal force weren't found statistically significant ($p<0.05$). As it is seen from Table 1, the fruit removal force of cherries decreased by the storage time prolonged. Fruit removal force of cherries at harvest was 8.30 N and decreased to 4.37 N at the end of storage. The highest fruit removal force was obtained from the cherries stored at MAP-3 (6.13 N) and the lowest fruit removal force was obtained from the fruit stored in MAP-1 (5.71 N). The fruit removal force

values of cherries decreased by the storage time increased. Our results showed that fruit removal force values of MAP-2 and MAP-3 were higher than that of stored at MAP-1.

Skin color is the most important visual indicator of quality and maturity of fresh cherries (Gao and Mazza, 1995). *L** values of cherries were given in Table 1. The effects of both storage period and MAPs on *L** values were found statistically significant ($p<0.05$). *L** value of cherries at harvest was 28.67 and it was determined as 25.94 after 50 days of storage. At the end of storage, the highest *L** value was obtained from the cherries stored at MAP-2 (28.10) and the lowest was obtained from the fruit stored in MAP-3 (26.92). The L* values decreased in all treatments but the highest values obtained from MAP-2. These results were similar to the findings of Giacalone and Chiabrando (2013) observed that L* values were higher in cherry fruit packaged with micro perforated MAP.

Hue angles *(h°)* of cherries were given in Table 1. The effects of storage period on *h°* were found statistically significant but the effects of MAPs on *h°* weren't found statistically significant ($p<0.05$). *h°* value of cherries at harvest was 7.31 and it was determined as 7.68 after 50 days of storage. At the end of storage, the highest *h°* value was obtained from the cherries stored at MAP-3 (7.27) and the lowest was obtained from the fruit stored in MAP-2 (6.74).

*C** values of cherries were given in Table 1. The effects of both storage period and MAPs on *C** values weren't found statistically significant ($p<0.05$). *C** values of cherries at harvest was 15.52 and decreased to 13.54 at the end of storage (Table 1). While the lowest C* value (13.69) was obtained from the cherries stored at MAP-3, the highest (15.19) was obtained from MAP-2. Our results showed that the C* values of cherry fruit packaged with MAP-2 was higher than that of MAP-1 and MAP-3. Similar results were obtained by Padilla-Zakour et al. (2004) on 'Lapins' cherries. These researchers indicated that cherries packaged with micro perforated MAP had significantly higher chroma values than that of control group.

The effects of both storage period and MAPs on pitting development were found statistically significant ($p<0.05$). Longer storage periods resulted in higher amount of pitting during storage. The mean amount of pitting was 0% at harvest (day 0) and increased to 70% on the 50^{th} day of storage. The highest pitting was obtained from the cherries stored at MAP-1 (52%) and the lowest was obtained from the MAP-2 (28%) (Table 1). Surface pitting of cherries increased by the storage time increased but the lowest surface pitting was obtained from the MAP-2. Our results were similar to the findings of Kappel et al. (2002) on cherry fruit. These researchers observed that cherry fruit stored in micro perforated MAP had lower surface pitting than that of control group.

Table 1. Weight loss, flesh firmness, fruit removal force, skin color (*L**,*C**,*h*°), pitting, stem browning, taste, soluble solids and, titratable acidity of '0900 Ziraat' cherry cultivar during storage at 0°C.

Stem browning of cherries was given in Table 1. The effects of both storage period and MAPs on stem browning was found statistically significant ($p<0.05$). Stem browning dramatically increased especially in MAP-1 and MAP-3 with prolonging storage duration. The mean amount of stem browning was 0% at harvest (day 0) and increased to 51% on the 50th day of storage. The

highest stem browning was obtained from the cherries stored at MAP-1 (34%) and the lowest was obtained from the MAP-2 (20%) (Table 1). Our results are supported by the findings of Kappel et al. (2002) on different cherry cultivars.

The effects of both storage period and MAPs on taste were found statistically significant ($p<0.05$). Taste scores of cherries were given in Table 1. The taste score was 4.07 on the 10^{th} day, 3.80 on the 20^{th} day, 2.97 on the 30^{th} day, 3.13 on the 40^{th} day and 2.93 on the 50^{th} day of storage. The highest taste value was obtained from the cherries stored at MAP-2 (3.80) and the lowest was obtained from the MAP-3 which was 2.74 (Table 1). Our results were similar to the findings of Padilla-Zakour et al. (2004) remarked that micro perforated MAP had better eating quality compared to control cherries.

Soluble solids content of cherries were given in Table 1. The effects of storage period on soluble solid content were found statistically significant but the effects of MAPs on soluble solid content weren't found statistically significant ($p<0.05$). Soluble solids content of cherries increased by the storage time prolonged. Soluble solids content of cherries at harvest was 16.60% and increased to 17.02% at the end of the 50 days storage period. During the all storage period while the highest soluble solids content was obtained from the cherries stored at MAP-2 which was 17.31%, the lowest soluble solids content was obtained from the cherries stored at MAP-3 which was 16.78%.

Titratable acidity of cherries was given in Table 1. The effects of both storage period and MAP on titratable acidity were found statistically significant ($p<0.05$). Titratable acidity at harvest was 2.94% and decreased to 1.88% at the end of the storage period. The highest titratable acidity was obtained from the cherries stored at MAP-2 (3.02%) and the lowest was obtained from the MAP-3 (2.71). In our study, titratable acidity increased at day 10 then decreased in all treatment groups and the highest titratable acidity was obtained from the cherries stored at MAP-2. Similar results were obtained by Giacalone and Chiabrando (2013) on 'Sweetheart' cherry fruit. These researchers indicated that cherry fruit stored in micro perforated MAP had higher titratable acidity than that of control group.

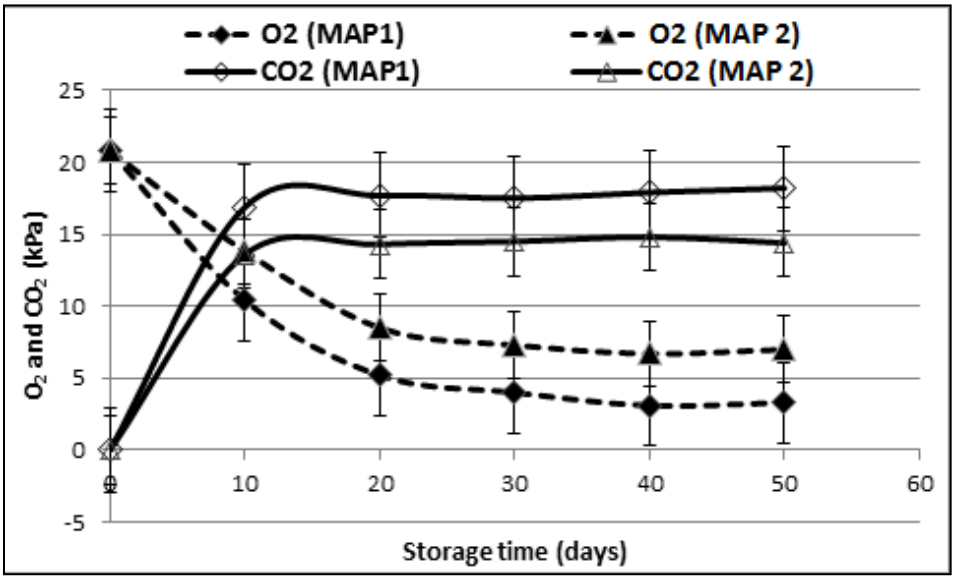

Figure 1. The changes O_2 and CO_2 levels in MAPs during storage

The variations in O_2 and CO_2 concentrations in different MAPs during storage were presented in Fig. 1. The initial O_2 concentration was approximately 21% in MAPs and the level of O_2

decreased from 20.8% to 3.3% in MAP-1 and to 7.0% in MAP-2 after 50 days of storage. The level of CO_2 increased from 0.03% to 18.2% in MAP-1 and to 14.4% in MAP-2, during the 50 days of storage. During storage, a decrease in O_2 and an increase CO_2 levels occurred inside MAP-1 and MAP-2 but the O_2 and CO_2 levels in the MAP-2 remained constant throughout the 50 days of storage. Similar trends of decreases in O_2 and increases in CO_2 levels during storage of MAP cherries were detected by in previous studies. Similar results were obtained by Padilla-Zakour et al. (2004) on 'Hedelfingen' and 'Lapins' cherries.

Conclusion

Micro perforated MAP (MAP-2) extended the postharvest life of '0900 Ziraat' cherry fruit by decreasing weight loss, maintaining firmness and visual appearance (*L**, *C**), reducing the rate of acidity loss and surface pitting, preserving taste quality and by retaining stem freshness. As a conclusion, the most effective MAP was MAP-2 for maintaining quality of the '0900 Ziraat' cherry fruit.

Abstract

Timely and high-quality application of pesticides contributes to environmental protection, economical production and production of healthy food. The efficacy of pesticide application depends not only on the quality of pesticides but also the quality of the application. One of the factor that most influences on the applications quality, from the standpoint of mechanization, are nozzles. They applied liquid on the surface of the plant which resulting that same volume of pesticide is applied to the entire surface of the plants. To achieve this goal, nozzles must performed uniform application of liquid per unit area, or working width. The variable factor in the application of pesticides may be nozzle and operating pressure. With increasing working pressure it was obtained smaller droplets. The paper presents test of three different nozzles. Each nozzle is characterized by a flat jet with an angle of 110^{o} and a flow rate of 1.6 l / min at a pressure of 3 bar. Differences between each other is the way of jet disintegration. Exactly this characteristic causes that with pressure change coming to changes in the uniformity of nozzles transverse distribution. The best distribution has nozzle with a flat jet. The coefficient of variation is between roughly from 4 to 6% at the pressure application of 2 to 4 bar. Obtained mathematical model that describes changes in the coefficient of variation depending on pressure applications can be a good basis for easy harmonization parameters in the pesticide application.

Keywords: *nozzle, coefficient of variation, uniformity of distribution, pressure, sprayer, disintegration.*

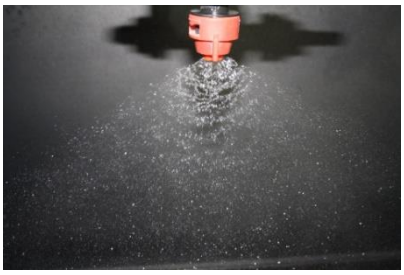
Introduction

Today's way of plants protecting require a modern technique for pesticide application. The technique as sprayer must be well chosen, functional, calibrated and maintained. Nozzles are important because of their impact on biological efficiency, environmental protection and weed control efficiency. Their quality is reflected at the work in altered weather conditions, in that they have wide range of operating pressure, flexibility in terms of flow with movement speed change. For efficient application of pesticides, nozzles must be uniformly distributed over the entire surface of boom working width. In this effect is influenced by two components. One of them is a horizontal-enabled application that depends on the boom, the distance between nozzles, nozzles type and exploitation factors. Leung et al. (1990) adds that pressure and height of boom as the operational parameters and that they are the most important for the pesticides uniform application. Nowakowski (2007) states that the pressure plays a major role in the quality of the transverse distribution in terms of variation coefficient. Douzals (2012) in the examination of flat jet nozzles at a pressure of 1.5 bar to 3.5 bar and boom height from 0.3 to 0.9 m comes to the entire data spectrum of variation coefficient. On that basis he concluded if pressure increases it result to reduction variation coefficient. Rising up to a value of 1.08% at a pressure of 3.5 bar and

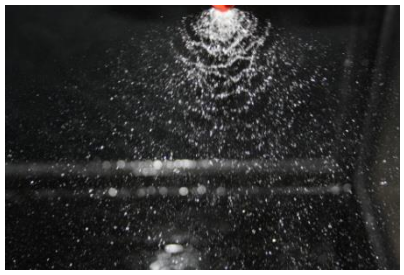
the boom height 0.9 m. Similarly, Sawa et al. (2012) confirms indicated by recommending that one of the most important factors just a good selection of nozzles. Nozzles precisely characterized by transverse distribution as the most important factor. This characterizes them and to their most important feature according to Bahadir and Saim (2011). Application in rows is even better technique pesticide application because the treatment is done predefined part (Nigar et al. 2011). Worn or damaged nozzles will not only have a bad transverse distribution of fluids, but also larger droplets Subra et al (2015). The task was to carry out a measurement of the transverse distribution of three different nozzles in the laboratory. The aim is to show the impact of different types of anti-drift nozzles on the transverse distribution. The resulting mathematical models describing the change at the coefficient of variation of other parameters tested applications for nozzles.

Materials and methods

In the laboratory control techniques for the application of pesticides is done measuring the transverse distribution of three different nozzles. All nozzles are flow rate of 1.6 l / min, red in color and are set to triple rack nozzles on the wing length of 6 m for every 0.5 m. All nozzles were tested at pressures recommended by the manufacturer. These are pressures from 2 to 4 bar or 2 to 6 bar examination every 0.5 bar. Identification of the nozzles AD, AD / D and ADIA. The first noozzle was labeled with AD is anti drift nozzle with a flat jet angle of 110^{o}. The second is the same as the first but it has only long nozzles body and rotated jet by 30 ° in the negative direction. The last tested nozzle was injector nozzle with a spray angle of 110 ^{o}. Nozzles are shown in the following photos.



AD



AD/D

ADIA

Applications height was 0.5 m. The temperature was about 25 ° C and the relative humidity exceeded 65%. Everything was done in accordance with ISO 16122-2: 2015 Agricultural and forestry machinery - Inspection of sprayers in use - Part 2: Horizontal boom sprayers. Given that the said standard relates to crop sprayers, all measurements were done on crop sprayer. It is a field sprayer, which is used for laboratory purposes, where drive of piston diaphragm pump of 85 l / min is performed by electric motor. The tank holds 300 liters and measuring and control device is a mechanical pressure gauge with a measuring range up to 8 bar. Booms are 6 m width and divided into two sections , every 3 m.

For measuring the transverse distribution was used Spray scanner company AAMS Salvarani. The dimension is 1.2 m x 0.8 m in width which was divided into 8 funnels. All the liquid collected in funnels flowing in tubes of a known volume. The tubes have upper and lower contacts, which measures the time required for filling the tube. In this way, the total flow rate is calculated. On the computer among other parameters, shows the coefficient of variation as a measure of the transverse distribution uniformity. If this ratio is less than 10%, the average

distribution nozzles is acceptable. For a coefficient of variation greater than 10%, the horizontal distribution of the working fluid is unacceptable.

Results and discussion

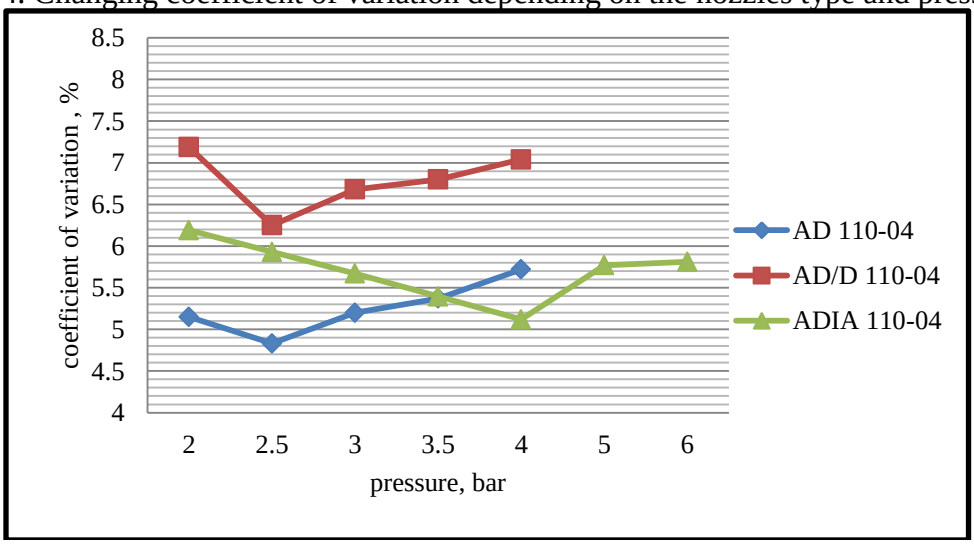
By measuring the transverse distribution are obtained coefficient of variation indicated in the following table. In all nozzles were recorded mainly coefficient of variation of less than 7%, which is an excellent horizontal distribution at all tested pressures. Thus, at lower pressures the best lateral distribution has nozzle as AD at a pressure of 2.5 bar coefficient of variation of only 4.83%. This is less than 7.19%, which has rotated the nozzle spray to 30 ° at a pressure of 2 bar.

Tab. 1. Coefficients of variation of tested nozzles

Nozzle/ Pressure, bar	AD 110-04	AD/D 110-04	ADIA 110-04
2	5,15	7,19	6,19
2,5	4,83	6,25	5,93
3	5,2	6,68	5,67
3,5	5,37	6,8	5,395
4	5,72	7,04	5,12
5	/	/	5,77
6	/	/	5,81

At higher pressure applications deteriorates transverse distribution of fluids. In this regard, the dispenser AD / D has a higher coefficient of variation of 7% at a pressure of 4 bar. This is still an acceptable value or distribution is not perfect. At the same pressure distribution has the best horizontal injector nozzle with a spray 5.12%. It is interesting that at higher pressures the coefficient of variation does not increase dramatically with this nozzles and amounts 5,77% at 5 bar person respectively 5.81% at 6 bar. This is very important at the application of pesticides. Generally, anti drift nozzle with a fan-shaped jet has the best distribution with a note that statistics do not differ much uniformity from one another.

Fig. 4. Changing coefficient of variation depending on the nozzles type and pressure.



On the previous picture is shown a graph which represent changes variation coefficient with the change of pressure and nozzles type. For all the notes that as the pressure increases, the quality of the transverse distribution improves and then with further increasing pressure it start to be worse. However, the changes are not so drastic and have a great impact on the quality of distribution. The equations that describe the change in the coefficient of variation of the following:

AD: $y = -0{,}042x^3 + 0{,}463x^2 - 1{,}323x + 6{,}034 R^2 = 0{,}945$

ADIA: $y = -0{,}010x^4 + 0{,}175x^3 - 0{,}935x^2 + 1{,}590x + 5{,}345$, $R^2 = 0{,}873$

AD/D: $y = -0{,}104x^3 + 1{,}083x^2 - 3{,}311x + 9{,}492$, $R^2 = 0{,}879$

Given equation can be used to obtain the coefficient of variation for pressures and tested nozzles. They have an important role at application chooses the parameters of crop sprayers and given nozzles.

Conclusion

In examining three different anti drift nozzles at the recommended pressure can conclude the following:

- Best horizontal transverse distribution of the working fluid has a nozzle with AD coefficient of variation of 4.83% to 5.72%;
- It is expected that the injector nozzle has the worst distribution but this is not the case, because AD / D jet nozzle has rotated by 30 °, which leads to lower transverse distribution with a range of 6.25% to 7.19%;
- Injector nozzle maintains uniform distribution of working liquid despite the high pressures of between 5 and 6 bar.

The obtained equations can be very useful when selecting operational parameters pesticide application. It is necessary to ddatno perform tests at different altitudes because the applications boom is not a course are not always parallel, at a distance of 0.5 m.

Note: The paper is the result of research on the project TR 31073, Improving the production of maize and sorghum in the conditions of stress, which is funded by the Ministry of Education and Science of the Republic of Serbia.

BIOETHANOL PRODUCTION FROM SUGAR BEET

Süreyya Gülfem ALTUNBAY

Department of Plant Breeding, Sugar Institute, T.Ş.F.A.Ş. Ankara, Turkey
*Corresponding author: sureyyagulfem@hotmail.com

Abstract

Today, gradually running out of fossil fuels, the destruction of ecosystems, efforts to avoid depending on foreign countries for energy and to increase energy diversity have increased the importance of fuels such as bioethanol. Biomass production of bioethanol from sugar beet molasses will lead to open a new market for beet producers, to widespread the crop rotation, to create an energy farming culture and lead to an increase in sugar beet growing areas. Bioethanol also contributes favorable support to the ecology by providing diversity in agricultural production and it is important for creating sustainable agricultural structure and supporting rural development. Bioethanol in general is obtained by fermentation of plants containing sugar and starch. Sugar beet molasses is used for the production of bioethanol from sugar beet. Production of bioethanol from molasses is carried out at three stages such as yeast reproduction, fermentation and distillation. The alcohol obtained in 96% purity during ethanol production process is not used as biofuel. In order to be used as biofuel it should be in 99.5% purity. Therefore, in alcohol plants the purification and distillation units are needed in addition to fermentation unit. Attention should be paid to alternative energy sources such as bioethanol since the oil reserves are decreasing and environment problems are increasing.

Keywords: *Sugar Beet, bioethanol, energy, biomass*

Introduction

The conbination of volatility in the oil market and finitive oil resources and effect on global climate change from the addition of CO_2 to atmosphere as a result of burning fossil fuels has increased the interest in sustainable energy generation from renewable biofuels. At present, approximately 10% of the primary global energy demand is met using biomass (Antoni et. al. 2007). Secondary biofuels often are divided into 1 st generation (with a feedstock of seeds, grains, or sugars), 2 nd generation (from lignocellulosic biomass) and sometimes 3rd generation (from algae and seaweed) (Nigam and Singh 2010; Larson 2006). Most 1 st generation biofuels in current production are liquid (either bioethanol or biodiesel) with the bioethanol the product of fermentation (Antoni et al. 2007; de Vries et al. 2010; FAO 2008).

Sugar crops due to cultivating a wide area has some many advantages according to grain. Sugar beet provides an abundance of sucrose, which is easily fermented by many microbes. The amount of sucrose extracted per hectare is dependent on three factors, the weight of the beets harvested, the percentage sucrose in those beets, and the amount of the sucrose that is extractable. The root of the sugar beet may contain 20% sucrose by fresh weight. However the amount extracted is less (15,3 % average from the U.S. crop 200-2009) (USDA-ERS 2010) because some cations (e.g., Na^+ and K^+) or amino nitrogen compounds (e.g., betaine and glutamine) interfere with the extraction of sucrose (McGinnis 1982).

After the sucrose has been extracted, the remaining juice is molasses. The molasses from one tonne (t=Mkg) of sugar beet (fw) weights about 20 kg and is approximately 50% sucrose

(Shapouri et al. 2006). Pulp or marc remains after the sucrose and molasses have been extracted from the crop. The pulp represents the 22-28% of the dry mass of the sugar beet root that is not solubilized during the sugar beet extraction process (Scott and Jaggard 1993) and is fermentable. The conversion of sucrose to ethanol is a simple process requiring only yeast fermentation, whereas producing ethanol from maize, wheat or other cereal grains e.g., requires enzymes to convert starch to sugars (Antoni et al. 2007;Jacobs 2006).

Sugar beet as a Feedstock for Ethanol Production

Sugar beets are defined at a factories and unlike sugarcane, are produced directly into white, refined sugar (Eggleston, 2008). This makes the processing of sugar beet ethanol more economical than for sugarcane (Anon, 2009c). The major products from sugar beet processing are pulp, which is the fibrous root material left over after the extraction process, and molasses which consist of the soluble impurities left after sucrose extraction (Harland et. al., 2006). Both are used as animal feed.

The sucrose content of sugarbeets ranges from 16-18% (wet weight), whereas sucrose in sugarcane varies from 10-15%. In a recent study, it was calculated that the yield of ethanol from the sucrose in a sugarbeet was 118 l/t of root (we weight) (Shapouri et. al., 2006). This calculation was based on a refined sucrose recovery of 15.5% (of wet weight) and a yield of 20 kg of sucrose from 1 t of beet molasses. The pulp represents the 22-28% of the dry mass of the sugarbeet root that is not solubilized during the sugar beet extraction process. A large portion of the pulp might provide additional feedstock for the production of cellulosic biofuels if the sugars can be released from the biomass. Theoretically available sugars could be solubilized using enzyme digestion (Kozak and Laufer, 2009).

Sugar Beet and Ethanol

The yield of sugarbeet is dependent on many factors, including whether it is irrigated or rainfed, disease or other abiotic stresses present. All things being equal, the amount of sucrose in the beet is directly proportional to the amount of solar radiation intercepted by a full canopy (Millford,2006). Sucrose content also varies by location and would play an important part in ethanol yield if the ethanol were to be produced from the fermantation of sucrose. For ethanol produced solely from pulp and molasses, the yield would range between 7 and 11 l/t wet weight of sugarbeet assuming a 30 and 50% conversion of pulp to feedstock (Eggleston et al. 2008).

The conversion of sucrose to ethanol is a simple process requiring only yeast fermentation, whereas producing ethanol from maize, wheat or other cereal grains e.g., requires enzymes to convert starch to sugars (Antoni et .al. 2007; Jacobs 2006).

On a per hectare basis, sugar beet is one of the most efficient sources of ethanol. It has been calculated that sugar beet produces between 100 and 120 l/t (fw) of ethanol through the fermentation process (110 l/t (FAO 2008), 103,5 l/t (Shapouri et al. 2006), 117 l/t (Panella and Kafka 2010). The dry weight equivalent of one tonne of sugar beet (fw) has been calculated to contain about 3.89 GJ of energy (Tzilivakis et al. 2005). Ethanol has an energy content of 21.2 MJ/I (Schmer et al, 2008), which would be give an energy value of 2.44 GJ/t sugar beet (fw), assuming production of 115 l/t when converted to ethanol. FAO (2008) calculates 5,060 l/ha yield for sugar beet compared with a 1,960 l/ha yield for maize or 952 l/ha for wheat, using a global estimate of average yield (46 t/ha for beet, 4.9 t/ha for maize, 2.8 t/ha for wheat). Von Felde (2008) has estimated that anaerobic digestion methods for whole beets to produce bio-methane would produce 137% more energy than would fermentation of sugar beet to ethanol.

It is relatively easy to exract sugar from sugar beets. The beets are chopped into thin chips called cossettes and washed in a counter current flow with water. The washed cossettes are pressed to remove remaining water and sugar. The sucrose rich water is then cleaned of impurities with lime and filtration and separated by drying and crystallization (Process description, 2000). If the sugar from beets was used to create ethanol instead of sugar, the cleaned sucrose rich water could be put through a fermentation step instead of drying and crystallization. The current sugar extraction process could be duplicated exactly up until this point. The sucrose water mixture might have to be diluted or concentrated to be a recover ethanol, most likely by distillation, would finish the process of creating ethanol from sugar beets.

Sugar Beet Breeding for Bioethanol Production

For energy beets, breeding progress, and as with sugar beet variety development. Well adapted, high sucrose content sugar beet will be best choise for founder populations of energy beets. High biomass, defined as the yield of dry matter, is desirable for an energy crop. Relationships between water and dry matter, dry matter and sucrose content have a genetic and physiological basis (Carter, 1987). In most regions over the next few years economic conditions will require a sugar beet may be grown as a sugar crop as well as an energy crop. However, in those areas were sugar beet is used only as biofuel feedstock, different criteria will become import. Earlier studies have shown that if biomass yield is the most important parameter, crossing fodder beet and sugar beet in hybrid combination will yield more biomass (Doney and Theurer 1984; Theurer et al. 1987).

Situation of Turkey's Bioethanol Production

In Turkey, production of bioethanol has just begun. First generation bioethanol production is still carried out by eight factories, most of them are sugar factories and use molasses to produce bioethanol. Only in Amasya, Çumra and Eskişehir do the sugar factories perform dehydration and vinasse enriching (Bayrakçı, 2009). The Çumra sugar and ethanol factory is still producing bioethanol, while the others are closed because of policy and budget problems. The Turkish Energy Regulatory Agency (EMRA) issued a new regulation for bioefuel blending which will be mandatory starting from 2013 and 2014 respectively for bioethanol (2%) and biodiesel (1%). The blending ratio will be increased up to 3% respectively for bioethanol in 2014 and biodiesel in 2016 (EMRA,2011).

Conclusions

Increasing number of motor vehicle, too high fuel consumption, the destruction of ecosystems, increasing energy demand by the years bring the new approach about bioethanol. Fossil fuels will not be able to respond to all energy requirements after approximately 150 years. Only by adding a dehydration unit in the premises of sugar factories, alcohol production facilities will be able to make the production of bioethanol. Sugar beet production should be increased. When using gasoline with bioethanol content, the performance of vehicle will increase, the agricultural sector will be supported. Bioethanol should have been seen as one part of a portfolio of technological and policy solutions. The research and development must be envisioned.

Abstract

Climate change requires the conscious use of water for agricultural production, both in Turkey and in the world. The most important factor in getting nutrient for a plant is water. Water is the most important factor in the plant's nutrient intake. Therefore, the farmers always irrigate corn field until the harvest. The forming of corn grain start with fertilization that pollens falling over their stigma of ear. Corn grain formation begins after fertilization of the ear tassel by ear tuft. If plants are exposed to water stress during this period their physiological activities will stop. Therefore, fertilization will not occur and desired grain yield would not be provided. In the study, irrigation termination process was started after tassel emergence 7th day, water cut-off operations continued in 7 days interval. The total of irrigation termination consisted of 6 application. The last time of water cut-off was 42nd day after tassel emergence. In this study, P. T83 hybrid corn was planted in GAP Agricultural Research Institute in Sanlıurfa on 20,June, 2015. The trial was conducted as randomized block experimental design with 3 replications. In the study, the effect of irrigation termination at seven-day intervals in six different stage after tasseling on plant height, ear diameter, grain yield, grain protein, starch and oil content of P. 32T83 hybrid corn grown in the first cropping season were investigated. Research results showed statistically significant differences according to the last irrigation on examining all the features of corn. Research results were showed statistically significant differences according to the last irrigation time in terms of plant height, ear diameter, grain yield, protein, starch and fat rate. The values of these parameters have been changed between 213.33 - 226.33 cm, 25.00 - 30.33 mm, 4910.93 - 9140.36 kg ha^{-1}, 9.33% - 10.80%, 74.16% – 75.06%, 3.06% - 3.30% respectively.

Keywords: *Corn, irrigation, grain yield*.

Introduction

Corn (*Zea mays* L.) located in grains group is one of the plants versatile research, due to the use of very intensive industries in recent years. Corn (Zea mays L.) is one of the plant in grain groups investigated as versatile plant due to its very intensive usage in industry recently. Corn plant needs a certain temperature because of the C4 plant. It can be grown either first or second crop, if the temperature required by the corn plant are fully met. The production of forage, silage and fresh ear are made in places where the temperature is insufficient, so maize farming is spread over a wide area. The corn plant take nutrients from the soil as fast, because of growing in a very short time and creating a lot of above-ground biomass (Kırtok, 1998). The greatest contribution to the nutrient intake of maize is provided by water. The amount of water corn needed is greater in total due to its total transpiration surface, the amount of dry matter, and high evaporation in the growing period. The most sensitive period of water stress on corn have reported previous two and

the next two to three weeks of ear silk emergence (Singh and Singh 1995). Formation of corn grains begin after fertilization of ear tuft by tassel if plants are exposed to water stress during this period, due to the cessation of physiological activities fertilization will not occur and grain formation will not take place. The lack of water will decrease yield of corn (Kaya et al., 2006).
The reduction in the amount of available water in the world and Turkey especially affects the agricultural sector significantly, It makes mandatory controlled usage of irrigation water resources Therefore, in this study, the effect of irrigation termination at seven-day intervals in six different stage after tasseling on plant height, ear diameter, grain yield, grain protein, starch and oil content of P. 32T83 hybrid corn grown in the first cropping season will be investigated.

Materials and Methods

The field trial area, plowed with plow and no action was taken in the field until spring after the harvest of the previous year sesame plant. The trial area was tillaged with a second class tillage tools and flattened with rollers before planting. Seed sowing was made by sowing machine in 20 May 2015. 5 meters in length each parcel consisted of 70x20 cm plant density with four rows. During cultivation 8 kg/da phosphorus and 8 kg/da nitrogen fertilizer was applied. Then as top fertilizer 170 kg $ha^{-1}$of nitrogen fertilizer is given. Hoeing and earthing up is done twice 2,4-D and florasulam active ingredient of herbicides for weed control, thiacloprid active ingredient of insecticides for the pest were used. 473 mm total irrigation water was used until tassel emergence considering field capacity. The irrigation termination process was started after tassel emergence 7th day, water cut-off operations continued in 7 days interval.
The first application of irrigation water was applied as 58 mm 7 days after tassel emergence (W1). The second application of irrigation was 110 mm in two times application in total 14 days after tassel emergence (W2). The third application was applied 21 days after tassel emergence with 3 times using 155 mm of irrigation water (W3). The fourth application was performed 28 days after tassel emergence with four-times irrigation using 200 mm water (W4). In the fifth applications 247 mm water was used in five times irrigation 35 days after tassel emergence (W5). The sixth application was done by applying 290 mm water in six times after 42 days of tassel emergence (W6). Plants were harvested in the second week of October. The climatic data of the field trial are shown in Table 1. The effect of last irrigation times in the generative stage of corn on plant height, ear diameter, grain yield, grain protein, starch and oil content were investigated.
The amount of irrigation water after tassel emergence was calculated multiplying the crop-pan coefficient (Kcp) by total of seven days evaporation from Class A pan. The volume of irrigation water was calculated by the following equation.

$V=Kcp \times Eo \times A$,
Where;
V: The irrigation water amount (lt), Kcp= coefficient of irrigation water, (Kcp=1.00), Eo= Seven day Class A-pan evaporation (mm), A= Plot area (m^2).
EC, lime, pH, phosphorus, potassium, organic matter and saturation of the 0-30 cm depth in the soil were reported 83 dS/m, 24.7%, 7.7, 4.2 kg/da, 193.2 kg/da, 2.19 and 70% respectively (Anonymous, 2015a).

Table 1. Climatic data in the study arae

2015	May	June	July	August	September	October
Max. tem. (°C)	36.9	38.4	42.8	43.1	40.4	33.0
Min. tem.(°C)	11.8	16.7	21.4	22.1	18.7	12.7
Ave. tem. °C)	22.8	27.7	33.2	31.5	29.8	21.6
Relative hum.(%)	38.0	35.3	26.5	37.4	30.5	50.5
Total rainfall (mm)	10.3	0.7	0.2	0.0	0.0	58.8

(Anonim 2015b)

The months in trial conducted had any rainfall and low humidity (Table 1.). Therefore, the plants water requirement was met by irrigation.

Results and Discussion

Table 2. The average and groups of the examined characteristics concerning to irrigation termination of six different times after tassel emergence of the corn plant.

Applications	The amount of water (mm)	plant height (cm)	ear diameter (mm)	grain yield (kg ha^{-1})	% protein rate	% starch rate	% oil rate
W1	58	218.00 b	25.00 d	4910.33 c	9.93 c	74.16 c	3.06 c
W2	110	217.00 b	25.66 d	6190.90 bc	10.20 b	74.40 bc	3.13 bc
W3	155	220.00 ab	27.00 c	6550.46 b	10.30 b	74.53 b	3.13 bc
W4	200	213.33 b	27.33 c	7180.46 b	10.40 b	74.60 b	3.16 bc
W5	247	226.03 a	28.66 b	8660.53 a	10.76 a	74.96 a	3.23 ab
W6	290	216.00 b	30.33 a	9140.36 a	10.80 a	75.06 a	3.30 a

Plant height (cm)

The statistically significant in plant height of P. 32T83 corn variety is achieved differences according to termination of irrigation. Plants height of the first, second, fourth and sixth application that watering termination made on the seventh, fourteenth, twenty-eighth and forty second day after tassel emergence were 218.00, 217.00, 213.33 and 216 cm respectively. The differences amongst once, twice, four and six times irrigation after tassel emergence in terms of plant height was statistically insignificant and located in the same group. Plants height of the fifth application that watering termination made on the thirty-fifth day after tassel emergence were 226.03 cm and consisted statistically different group from other applications except for three times irrigation. Bassou et al. (2012) were reported that plant height was highest under the full watering applications compared to other limited watering ones. Their findings are in agreement with our findings (Table 2).

Ear diameter (mm)

The statistically significant in ear diameter of P. 32T83 corn varieties is achieved differences according to the watering termination. The lowest value of ear diameter was obtained from the first irrigation which is applied on the seventh day after tassel emergence is 25.00 mm. After this the second value in the second practice that watering cut- off on the fourteenth day after tassel emergence with an ear diameter of 25.66 mm was measured. . There are no statistically differences in terms of ear diameter between two and three times irrigation after tassel emergence. Both are located in the same group and statistically different from other applications. The third highest value belongs to the third application that watering cut- off on the twenty-first day after tassel emergence is 27.00 mm. In fourth, ear diameter was measured as 27.33 mm for the fourth application that water cut-off made on the twenty-eighth day after tassel emergence. There isn't significant statistically differences in terms of ear diameter between three and four times irrigation after tassel emergence. They are located in the same group and consist of as statistically different group from other applications. The maximum ear diameter is measured as 30.33 mm in the sixth application in which last irrigation made on the forty-second day after tassel emergence statistically significant different from other applications Second maximum ear diameter is 28.66 mm for fifth application that is irrigation termination on the thirty-fifth day after tassel emergence. It was determined that showed statistically significant differences from other applications. (Table 2). Ertek and Kara (2013) findings support our findings.

Grain yield (kg ha^{-1})

The irrigation practices of corn plant were terminated in different periods after tassel emergence. Grain yield obtained according to the irrigation termination periods had significant statistical difference. The lowest grain yield for the P. 32T83 corn variety obtained from the first application (481.33 kg) that was irrigation termination on the seventh day after tassel emergence. It was determined to be statistically significant differences from the others except for the second applications and included in the different groups. Grain yield for the third (three times) and the fourth (four times) applications that were finished irrigation on the twenty-first and twenty-eighth day after tassel emergence were 655.46 kg/da and 718.46 kg/da respectively. They do not constitute any statistical difference between them and located in the same group, but they had statistically significant differences from the others. The second application in term of lowest grain yield was the second with 619.90 kg/da yield and consists a transition between the first application and the third, the fourth applications. The grain yield of the fifth and the sixth application was 866.53 kg/da and 914.36 kg/da, respectively. They weren't any statistical difference between each other. It was determined that they take place in the same group and showed significant differences from the other applications (Table 2). Our findings are in agreement with Abou-El-Kheir and Mekki (2007), Castiglioni et al (2008), Ertek and Kara (2013), Ghamarni et al. (2013), and Kuşcu et al (2013) findings. They were reported that grain yield reduction may vary according to the varieties irrigated with limited watering. Durmus et al (2015) determined that total grain yield decline slightly as a result of limited water application.

Protein Rate (%)

Protein rate (%) in grain for P. T83 corn variety according to the termination time of irrigation in different times were collected under three groups that different from each other. The lowest value

of protein rate was obtained with 9.33 % from the first application that made irrigation on the seventh day after tassel emergence. The statistically significant differences were noted compared to other applications. The protein rates of the second, the third and the fourth application were 10.20, 10.30, 10.40 % respectively. They observed in the same group and there was not statistically significant difference between each other. The highest protein ratio obtained from the sixth application as 10.76 %, it were followed by the fifth application as 10.76 %. There weren't statistically differences between each other and they were consisted statistically different group from other applications (Table 2). The findings of Karasu et al (2015) are not consistent with our findings in terms of the effect of irrigation levels on protein rate. Ertek and Kara (2013) findings support our findings that protein rate of corn can be decreased due to low or high amount of irrigation levels. Khan (2016) reported that grain protein could be altered to 8.1% from 10.8% depending on the genotype or the N supply. In other words, corn protein content is stated to vary according to application.

Starch rate (%)

After tasselling hybrid P.32T83 corn plant according to the termination time of irrigation in different periods the starch content differences in the grains was observed among the three groups and it has been shown to be a transition group. The lowest value of starch was obtained with 74.16 % in the first application that made irrigation on the seventh day after tassel emergence. It was consisted statistically different group from other applications except for the second application. The starch rates of the third and the fourth application were 74.53% and 74.60 % respectively and they took place in the same group. They made statistically significant difference from the others, except for the second application. The starch rate (%) of the second application was reported as 74.40 %. It took place between the first and the third, fourth application. The second application was a transition group. The highest starch rate obtained as 75.06 % from the sixth application, it was followed by the second row as 74.96 % with the fifth application. There weren't statistically differences between each other and they were consisted statistically different group from the other applications (Table 2). Ertek ve Kara (2013) reported that if the level of irrigation water was applied more or less than certain amount for corn, it caused reduced content of starch. These findings support our findings. Khan (2016) revealed that starch rates were varied from 67.7% to 69.6% and oil rate from 4.8% to 5.1%. These findings not support our findings. Because the starch content of oilseed varieties are low and oil rates are high.

Oil rate (%)

The % amount of oil rates in corn grain according to the termination time of irrigation in different periods after tasselling of the hybrid P.32T83 corn plant were significant and noted that there were two different groups and two transition group. The lowest value of oil was obtained from the first application as 3.06 % that made irrigation on the seventh day after tassel emergence. It were consisted statistically different group from other applications except for the second, the third and the fourth applications. The oil rates of the the second, the third and the fourth application were 3.13%, 3.13%, and 3.16% respectively. They took part in the same transition group and were statistically significantly different from the other applications. The oil rate of the fifth application that made irrigation on the thirty-fifth day after tassel emergence was 3.23% and consisted statistically different group from the first applications. In addition to this, it is noted that it formed a second transition group in the other groups. The highest oil ratio

obtained from the sixth application as 3.3 %, It was consisted statistically different group from other applications except for the fifth application that had one transition group. Karasu et al (2015) were said that oil values ranged between 3.0-3.6%. These findings are in agreement with our findings. Khan (2016) was declared that increased grain yield resulted in greater oil production per unit of land area and the amount of nitrogen was ineffective on the oil content. It is an evidence of the characteristic of this variety.

Conclusion

The negative effect about lack of water before the tassel emergence for maize is known. Therefore, when considering the irrigation termination after tassel emergence, it was determined that irrigation should be done at least twice. The number of irrigation should be increased according to the climatic conditions, soil type, variety, and purpose of consumption.

Abstract

This study was conducted to determine the yield and plant characteristic of 10 (ten) grain corn varieties in Igdir (Turkey) University Agricultural Research and Application Centre field trial in 2015. The study was established in randomized complete blocks experimental design with three replications. The difference between yield and plant characteristic of corn varieties were statistically found. It was found between plant height of varieties 217.0 with 181.0 cm, grain yield 2780.3 with 1589.2 kg/da, the first cob height 125.8 with 77.6 cm, the length of the cob 24.3 with 18.6 cm, cob weight 313.1 with 214.6 g, grain weight in cob 288.4 with 156.3 g, diameter of cob 50.1 with 45.0 cm and 1000-grain weight 475.1 with 339.2 g. According to research results it was found RX 9292 and TK 6060 varieties of grain yield was higher. It can be recommended for these types of ecology. At the same time, grain yield which is taken from the unit of area will increase the plant height and cob of the grain weight held in breeding studies.

Keywords: *Grain corn, yield, variety, plant characteristic.*

Introduction

Corn plant (*Zea mays* L.) is a forage plant belonging to the *Poaceae* (Gramineae) family, the use of which has been increasing day by day, and has agricultural importance for both our country and the world. Corn plant is the subsequent plant after wheat among the grains in the world in terms of planting and production. Being produced as main crop and after crop, corn (*Zea mays* L.) is also a successful alternative plant (Başbağ et al., 1997; İdikut and Kara, 2013). Corn plant is highly demanded in the world due to its rich variability among grains and its capability of high yield and adaptation (Petrovici, 1977; Hill, 1993; Yaşak et al., 2003; Kırtok, 1998; Alan et al., 2005). Upon evaluation of the corn production data, it was reported that the production in the year 2014 was 1.02 billion tons in 183 million hectare of cultivation area with the yield of 577 kg/da. Corn plant is mainly planted for the purpose of grain production in our country (İptaş et al., 2002). Upon evaluation of the grain corn production data, it was reported that the cultivation area was 688.170 hectare, the harvested area was 6.861.686 da, the production was 6.400.000 tons, and the yield was 933 kg/da (TÜİK−The Statistical Institute of the Republic of Turkey, 2015). The grain corn production in the province of Igdir according to the data of the year 2015 was as 37.091 da of harvested area, 31.323 tons of production, and 844 kg/da of yield. It can be mentioned that the production amount and the yield of corn across the province of Igdir is less than the other provinces. Nevertheless, Igdir is a region with high potential in terms of corn production. Especially, a wide variety certificated corn seeds are used for grain production. It becomes more of an issue to determine the most appropriate kinds for the region. In this study, it is aimed to determine the kinds with high yield in the ecological conditions of Igdir.

Materials and Methods

The study was carried out under irrigating conditions in the test fields belonging to the Agricultural Practice and Research Centre of Igdir University from March to August in the year 2015. Commonly used 10 kinds of corn (72 MAY 80, OSSK-644, TK-6063, OSSK-596, TK-6060, HIDO, RX- 9292, 71 MAY 69, SHEMALL, OSSK-602) were used in the test. The climate values belonging to the months within the year the study was carried out are shown in the Table 1. It was found out for the province of Igdir from March to August in the year 2015 as 30 mm of the amount of precipitation in average, 23.2 ^{o}C of mean temperature and 44.2 of mean relative humidity. The type of the soil in the test field was clayey-loamy, the values of which was as follows; pH: 8.6, EC: 1.37 ds/m, organic matter: 1.20%, lime ($CaCO_3$): 22.27%, nitrogen: 0.06%, phosphor: 51.7 ppm, potassium: 852.4 ppm.

Table 1. Average climate values of the province of Igdir in the year 2015

Months	Mean Temperature (°C)	Total Monthly Amount of Precipitation (mm)	Monthly Mean Relative Humidity (%)
March	11.0	52.0	50.8
April	16,4	44.1	47.7
May	21,3	41.5	52.9
June	28,5	27,8	40
July	31,8	0.3	33.6
August	30.2	14,3	40.7
Average	**23,2**	**30**	**44.2**

The test was designed in 3 repetition according to random blocks test pattern. Planting was applied manually after row spacing had been specified as 70 cm and intrarow spacing had been specified as 15 cm. Each parcel area was designed as 17.5 m^2 by 5 m length and 3.5 cm width. Planting was executed on 04/04/2015 after the parcelling procedures. Nitrogen and phosphor fertilizers were sprinkled during planting. After specifying nitrogen (N) as 16 kg/da and phosphor (P_2O_5) as 8 kg/da, the half of the amount was applied during planting while the other half was applied after the plants grew for 50 cm. Irrigation was made in the cases when available soil moister capacity was below 50% upon measurements of the soil by moisture meter during the test. The irrigation system of sprinkling was used until the plants grew for 50 cm. Then, the row irrigation system was applied after the plants grew for 50 cm. Hoeing and necessary weeding were also applied the plants grew for 20 cm. The process of earthing up was executed after the plants grew for 40-50 cm and the nitrogen application. The grain harvests of corn kinds were made on 25/09/2015 and the yield and the vegetal characteristics of corn kinds were specified. The data were exposed to GLM (General Linear Models) with SPSS (version 20) on the basis of main effects. Mean separating were performed using Duncan test.

Results and Discussion

Plant Length (cm)

In our study, the values from 190.6 cm up to 217.0 cm were obtained for plant lengths. The highest value for plant length in the study was obtained for RX 9292 (217.0 cm) while the lowest value was for HIDO (190.6 cm). Plant lengths obtained in the study of Ayaz et al. (2013) varied

between 258.7 cm and 266.6 cm, while the highest value for plant length was 203.2 cm and the lowest value for plant length was 199.1 cm in the study of Avcıoğlu et al (2003). In their two year study, Özata and Kapar (2013) obtained values for plant length that varied between 255.8 cm and 335.8 cm. It is also known that the highest difference for the plant length of corn plant varies 2 m up to 3 m (Kün, 1997). When compared to the studies carried out, the data we obtained reveals close values to the literature values.

Grain Yield (kg/da)

In the study, the average grain yield was 21.6 t ha^{-1}, the highest grain yield was 27.8 with RX 9292 kind and the lowest grain yield was 15.8 t ha^{-1} with OSSK 644 kind. In the study of Kuşvuran et al (2014), the average grain yield was 16.0 t ha^{-}, while the lowest and the highest values varied between 14.0 t ha^{-1} and 18.6 t ha^{-1}. In the study carried out in different provinces of Öz and Kapar (2006), the lowest and the highest values were found as 8.4 t ha^{-1} and 11.9 t ha^{-1} respectively. Karaşahin and Sade (2011) reported that the average grain yield was 17.3 t ha^{-} in their two year study which row irrigation system was applied. The results we obtained in this study were higher than those obtained in the studies of Öz and Kapar (2006), Karaşahin et al. (2011) and Kuşvuran et al. (2014). It is possible to observe differences in the values obtained due to the variables such as diversity in genetic structures and environmental compliance. The results obtained in this study that was carried out under Igdir conditions reveal that higher grain yield was achieved than it was in a great deal of studies carried out in other regions.

Table 2. Plant length, grain yield, first cob height and cob length of corn kinds grown for the purpose of grain production

Kinds	Plant Length (cm)	Grain Yield (t ha^{-1})	First Cob Height (cm)	Cob Length (cm)
72 MAY 80	214.0 ab	21.7 bc	108.4 abc	20.4 bc

* There is no significant difference at the level of 0.05 between the averages indicated by the same letter ($P<0.05$)

First Cob Height (cm) and Cob Length (cm)

The average first cob height of 10 corn kinds used in the study was found as 105.5 cm. The highest value for the first cob height was for OSSK 596 (125.8 cm) and the lowest value for the first cob height was for OSSK 602 (77.6 cm). The results we obtained in this study were higher than those obtained in the studies of Öktem and Öktem (2006) and İdikut and Kara (2013) but lower than those obtained in the studies of Özata and Kapar (2013) and Kuşvuran et al. (2014). The average cob length was found as 21.4 cm, the highest value for cob length was found as 24.3 cm and the lowest value for cob length was found as 18.6 upon evaluation of the Table 2. The

results of the study showed parallelism with those of Kuşvuran et al. (2014) and İdikut and Kara (2013), while they were higher than those obtained in the study of Tuncay et al. (2005).

Cob Diameter (mm)

The average cob diameter of 10 corn kinds analysed in the study was found as 47.5 mm. The highest value for cob diameter was for TK 6060 (50.1 mm) and RX 9292 (49.5 mm), while the lowest value for cob diameter was SHEMALL (45.0 mm). Karaşahin and Sade (2011) reported that cob diameter was 52.6 mm in their two year study which row irrigation system was applied. Kuşvuran et al. (2014) found the average cob diameter as 49.0 mm, the highest value for cob diameter as 51.8 mm and the lowest value for cob diameter as 46.6 mm.

Cob Weight and Grain Weight on Cob (g/pcs)

There were significant differences in terms of cob weight among the kinds. The average cob weight among the kinds were found as 268.9 g/pcs, while the highest value for cob weight was for TK 6060 (313.1) and for RX 9292 (310.5), and the lowest value for cob weight was for OSSK 644 (214.6 g/pcs). In their study in Cankiri, Kuşvuran et al. (2014) reported that cob weight varied between 233 g/pcs and 308 g/pcs, and the average cob weight was 277 g/pcs. In their two year study, Öktem and Öktem (2006) obtained the data of values for cob weight between 167.8 g/ pcs and 251.7 g/pcs. Turgut (2000) reported the average cob weight as 302.9 g/pcs in his study carried out under Bursa conditions. On the other hand, the highest value for grain weight on cob was for RX 9292 (288.4 g/pcs) and the lowest value for grain weight on cob was for OSSK 644 (156.3 g/pcs), while the average grain weight on cob was 223.5 g/pcs. In their study, Kuşvuran et al. (2014) reported that grain weight on cob varied between 159 g/pcs and 211 g/pcs, while the average grain weight on cob was 180 g/pcs.

Table 3. Cob weight, grain weight, cob diameter and weight of one thousand grains of corn kinds grown for the purpose of grain production

Kinds	**Cob Weight (g/pcs)**	**Grain Weight on Cob (g/pcs)**	**Cob Diameter (mm)**	**Weight of One Thousand Grains (g)**
72 MAY 80	255.5 abc	228.5 ab	45.1 b	414.0 abc
OSSK 644	214.6 c	156.3 b	45.4 b	339.2 c
TK 6063	276.2 abc	231.6 ab	49.2 ab	398.3 abc
OSSK 596	232.7 bc	208.4 ab	45.2 b	421.1 ab
TK 6060	313.1 a	264.4 a	50.1 a	397.9 abc

71 MAY 69	259.7 abc	227.3 ab	47.9 ab	407.9 abc
SHEMALL	250.2 abc	212.8 ab	45.0 b	345.7 ab
OSSK 602	280.8 abc	209.8 ab	49.1 ab	462.3 a
Average	**268.9**	**223.5**	**47.5**	**408.4**

* There is no significant difference at the level of 0.05 between the averages indicated by the same letter ($P<0.05$)

Thousand Grain Weight (g)

The average weight of one thousand grains was found as 408.4 upon evaluation of the Table 3. The highest value for weight of one thousand grains was for RX 9292 (475.1 g), OSSK 602 (462.3 g) and HIDO (422.5 g). Among the corn kinds, the lowest value for weight of one thousand grains was for OSSK 644 (339.2 g). In their test in Konya which row irrigation system was applied, Karaşahin and Sade (2011) reported the average weight of one thousand grains as 375.0 g. In their study carried out in Konya, Ayrancı ve Sade (2004) reported weight of one thousand grains between 203 g and 341 g.

Conclusion

Increasing in importance day by day for both human and animal nutrition, corn kinds with high grain yield has been of vital importance. Igdir is known for its ecological suitability for corn production. Under ecological conditions of Igdir, the kinds RX 9292 and TK 6060 have the highest values in terms of agronomic characteristics, especially grain yield.

Abstract

In this research were examined three different grape varieties Tempranillo, Sangiovese, Petit Verdot a period of 2010-2012 at the locality Lepovo, near Negotino an altitude of 250 m. The main parameters in these research are yield (kg/ha) and chemical characteristics of the must, sugar (g/L) and total acids (g/L) from this three grape varieties.

The climatic factors, the vegetative sum of precipitation and the vegetative temperature sum measured at the meteorological station on Winery Bovin, at the locality Lepovo. We made a comparison between the correlation coefficient among the climatic factors and yields for each variety individually and correlation coefficient between climatic factors and chemical characteristics of each grape variety.

The obtained results from this work were statistically processed using the SPSS statistical software package 19, from where it can be measure the frequency, the percentage share of data, measures of central tendency (median, standard deviation, dispersion, arithmetic mean), such as graphic representation of data (a histogram). The analysis indicates that there is a high correlation value between yield and climatic factors, chemical characteristics and climatic factors. Although the correlation between yield, sugar and total acids in the must with the vegetative sum of precipitation is a negative value, still shows a high correlation coefficient.

Key words: *Yield, chemical characteristics, climatic condition, correlation coefficient*

Introduction

Vitis vinifera L, includes many varieties of grapevines that are grown in different viticultural areas. Considering the ecological conditions, almost every country has its own grape wine assortment formed over a long time *(Božinovic, 2010).*

Sangiovese is the most planted variety in Italy (about 10 percent of total acreage), especially in Tuscany. Sangiovese has been cultivated in Italy for well over a thousand years, and is presently the most widely planted grape cultivar there, covering some 2,350 hectare or approximately 10% of total vineyard acreage. Although considered indigenous to Tuscany, Sangiovese is grown throughout Italy, indicating its adaptability to different environmental conditions. *(Molon, 1906; Calo et. al., 2001, Giavedoni and Gily, 2005).*

The Tempranillo grape variety, known as Tinto Fino, originated from Spain, the area Rioja. The core of almost every red wine from this area is Tempranillo *(Bettiga, 2003).* The wines are characterized by a good balance of alcohol content, color and acidity, and aging receive smooth structure, specific fruity taste that lasts long. In Spain produce 28 different types of wines with a protected designation of origin *(Dimovska et al. 2015).*

Petit Verdot is a variety used for red wine production. It originates from Bordeaux, France. The highest concentration of vineyards is being in the St. Emilion district. Later, it appears in many

vine-growing regions of southern Europe, America and Australia. The name Petit Verdot derives from the berries characteristics, and indicates the small (petit) size of the grape berries, and it is roughly translated as "green one" and reflects the variety's propensity to under-ripeness, and it looks like the bunch of grapes is speckled with green. *(Dimovska et al. 2014).* Introduction of varieties is a method that is widely used in the global grape wine science and practice. These three newly introduced varieties Sangiovese, Tempranillo, Petit Verdot, are included in R. Macedonia recently. They are located on collection plantations or on small production areas *(Božinovic, 2010).*

The main purpose of this research is to make a comparison between the correlation coefficient among the climatic factors and yields for each variety individually and correlation coefficient between climatic factors and chemical characteristics of each grape variety.

Material and Methods

In this research as a material for testing were used three different grape varieties Tempranillo, Sangiovese, Petit Verdot a period of 2010-2012 at the locality Lepovo, near Negotino an altitude of 250 m. The grapevines were grown by applying appropriate agro-technical and ampelo-technical measures. The plantations were planted in 2006 with certified planting material at the distance of 2.4 m between the rows and 1 m between the grapevines in a row. The applied farming system is the two legged Guyot system by leaving 7 buds per vine. The plantations are under a drop-by-drop irrigation system (drip irrigation system).

The main parameters in these research are yield (kg/ha) and chemical characteristics of the must, sugar (g/L) and total acids (g/L) from this three grape varieties.

The climatic factors, the vegetative sum of precipitation and the vegetative temperature sum measured at the meteorological station on Winery Bovin, at the locality Lepovo. We made a comparison between the correlation coefficient among the climatic factors and yields for each variety individually and correlation coefficient between climatic factors and chemical characteristics of each grape variety.

The obtained results from this work were statistically processed using the SPSS statistical software package 19 (*Badioze Zaman H. et al. 2013*), from where it can be measure the frequency, the percentage share of data, measures of central tendency (median, standard deviation, dispersion, arithmetic mean), such as graphic representation of data .

For the analyzed properties is calculated the Pearsons's correlation coefficient. Dependent variables critical in our work are the yield (kg/ha) and chemical characteristics of the must, sugar (g/L) and total acids (g/L) from this three grape varieties. These parameters are dependent variables from climatic factors.

Using the software package SPPS 19 is made table display of correlation between yield and climatic factors, chemical characteristics and climatic factors.

Results and discussion

Beside the characteristics of the variety and their biological potential, yield depends on agroecological conditions where the variety is grown.*(Karoglan J et al. 2000).* In Table 1. is detailed overview of the main climatic parameters measured a period of 2010-2012 at the meteorological station on Winery Bovin, at the locality Lepovo, vegetative temperature sum (° C) and vegetative sum of precipitation (l/m^2). The vegetation period lasts on average from 206 to 209 days, enough for the grapes to reach technological and full maturity.

The average vegetative temperature sum a period of 2010-2012 amount 4179 °C, where the highest was recorded in 2012 and amount 4528 °C. The average vegetative sum of precipitation a period of 2010-2012 amount 232 l/m ^{2} , where the highest was recorded in 2010 and amount 268 l/m ^{2} .

Table 1. Climatic factors at the locality Lepovo, vegetative temperature sum (°C) and vegetative sum of precipitation (l/m ^{2})

Climatic factors		
Year	Vegetative temperature sum (°C)	Vegetative sum of precipitation (l/m ^{2})
2010	4339	268
2011	4424	238
2012	4528	190
2010/2012	4179	232

The yield of this three different grape varieties Sangiovese, Petit Verdot and Tempranillo by 1ha was mathematically calculated.
In table 2. are presents the results of the main parameter yield (kg/ha), calculated a period of 2010-2012. The average yield, a period of 2010-2012 amount 12.090 kg/ha of the variety Sangiovese, 12.926 kg/ha of the variety Petit Verdot, and the highest value 14.233 kg/ha of the variety Tempranillo. This indicates that the variety Tempranillo has achieved the highest yield in terms of these ecological and climatic factors, any year from research.

Table 2. Yield of the grape (kg/ha), a period of 2010/2012

Yield (kg/ha)			
Year	Sangiovese	Petit Verdot	Tempranillo
2010	8.190	11.401	13.039
2011	12.120	12.600	13.747
2012	15.960	14.777	15.914
2010/2012	12.090	12.926	14.233

The content of sugar in the must was determined by Oechsle Scale, and the composition of total acids was determined by titration method using solution of N/4 NaOH with factor 1.0000.
In table 3. is detailed overview of the main chemical characteristics of the must, from this three different grape varieties Sangiovese, Petit Verdot and Tempranillo sugar (g/L) and total acids (g/L) from this three grape varieties a period of 2010/2012.
The results explained that the variety Petit Verdot and Tempranillo have approximately the same values for measured sugar (g/L) and total acids (g/L) in the must, where Petit Verdot has the average value of sugar 238 g/L, Tempranillo 237 g/L and the average value of total acids in the must are 5.53 g/L for the variety Petit Verdot, 5.6 g/L for variety Tempranillo. The variety Sangiovese has a difference from the two previous varieties, with 226 g/L sugar and 6.8 g/L total acids in the must.

Table 3. Chemical characteristics of the must, sugar (g/L) and total acids (g/L) from this three grape varieties a period of 2010/2012.

Year	Chemical characteristics					
	Sangiovese		Petit Verdot		Tempranillo	
	Sugar (g/L)	Total acids(g/L)	Sugar (g/L)	Total acids(g/L)	Sugar (g/L)	Total acids(g/L)
2010	220	6.8	228	5.5	215	5.4
2011	228	6.7	232	5.0	225	5.5
2012	230	7.1	254	6.1	270	5.8
2010/2012	226	6.8	238	5.53	237	5.6

Using the software package SPPS 19 is made table display of correlation between yield and climatic factors, chemical characteristics and climatic factors. Comparing by the Pearson's coefficient of correlation we can see which parameters have a higher connectivity. If $\rho = 1$, it means that there is a perfect linear dependence and the growth of the one variable well the other variable is growing.

Display of Pearson's coefficient of correlation (ρ) received from correlation between yield, sugar and total acids with climatic factors (vegetative sum of precipitation and the vegetative temperature sum), from this three grape varieties a period of 2010/2012 is given in Table 4.

The analysis indicates that there is a high correlation value between yield and climatic factors, chemical characteristics and climatic factors. Although the correlation between yield, sugar and total acids in the must with the vegetative sum of precipitation is a negative value, still shows a high correlation coefficient.

Table 4. Display of Pearson's coefficient of correlation (ρ) received from correlation between yield, sugar and total acids with climatic factors (vegetative sum of precipitation and the vegetative temperature sum), from this three grape varieties a period of 2010/2012

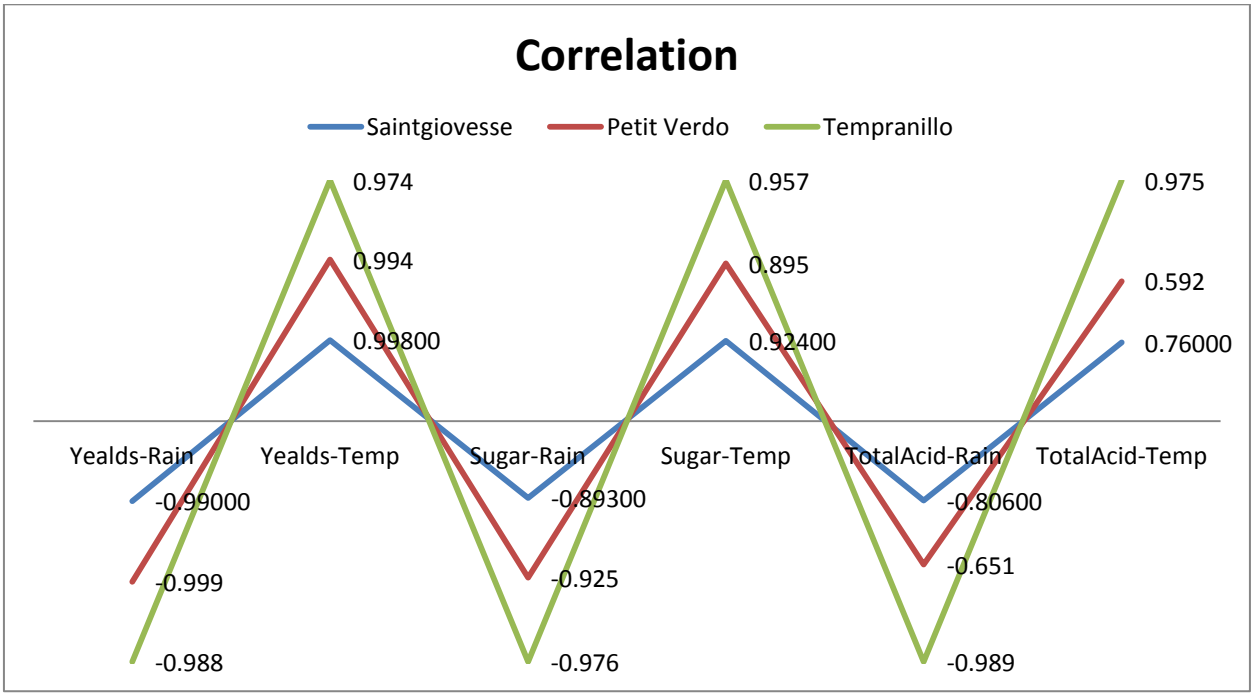
	Pearson's coefficient of correlation (ρ)					
Variety	Yield-Rain	Yield-Temp.	Sugar-Rain	Sugar-Temp.	Total acids-Rain	Total acids-Temp.
Sangiovese	-0,99000	0,99800	-0,89300	0,92400	-0,80600	0,76000
Petit Verdot	-0,999	0,994	-0,925	0,895	-0,651	0,592
Tempranillo	-0,988	0,974	-0,976	0,957	-0,989	0,975

On the graph 1. is displyed correlation coefficient between the yield, sugar and total acids with climatic factors for this three grape varieties a period of 2010/2012.

The variety Tempranillo has a highest connectivity, and the variety Sangiovese lowest connectivity for all parametars, although the correlation between yield, sugar and total acids in the must with the vegetative sum of precipitation is a negative value (-).

As indicated above that correlation coefficient ranging between 0.9 and 1 means a very high connectivity, we can conclude that this three varieties Sangiovese, Tempranillo and Petit Verdot, showed high correlation between climatic factors (vegetative sum of precipitation and the

vegetative temperature sum) with yield (kg/ha), and chemical characteristics of the must, sugar (g/L) and total acids (g/L).
The climate conditions has a direct effect on the quantity and quality of the grapes and on the wine production (*Angelov L, Stalev B.,2011*).
This research explain that climatic factors have a significant impact on the yield and quality of grape must and wine from this three newly introduced varieties Sangiovese, Tempranillo and Petit Verdot.



Graph 1.The graph shows correlation coefficient between the yield, sugar and total acids with climatic factors for this three grape varieties

Conclusion

1. This research explain that climatic factors have a significant impact on the yield and quality of grape must and wine from three introduced varieties.
2. We made a comparison between the correlation coefficient among the climatic factors and yields for each variety individually and correlation coefficient between climatic factors and chemical characteristics of each grape variety. The variety Tempranillo has a highest connectivity, and the variety Sangiovese lowest connectivity for all parametars, although the correlation between yield, sugar and total acids in the must with the vegetative sum of precipitation is a negative value (-).
3. The analysis indicates that there is a high correlation value between yield and climatic factors, chemical characteristics and climatic factors. Although the correlation between yield, sugar and total acids in the must with the vegetative sum of precipitation is a negative value, still shows a high correlation coefficient, which is approximately the value 1, and indicating a very high connectivity.

Abstract

The trials conducted during 2014 and 2015 on plots and at the seed laboratory at the Institute of Medicinal Plant Research ″Dr Josif Pančić″ from Belgrade, located in Pančevo, (Vojvodina, Serbia) investigated the impact of pre-planting application and foliar application (pre-planting soil treatment and foliar treatment) of the product called EM-AKTIV on morphological, productive and qualitative properties of the basil (*Ocimum basilicum* L.) cultivar *″Sitnolisni aromatični″*, which is grown and propagated at the Institute. The plots on which the product was not applied were used as a control variant. The trail was set up in a complete randomised block design with four replications and the size of basic plots was 3.25 m^2 (5.0 m x 0.65 m). The research investigated the impact of the EM-AKTIV on plant height, root length, plant width, the number of inflorescences, above-ground fresh biomass yield, dry biomass yield, essential oil content and essential oil yield per hectare. The highest yield of dry biomass was obtained in the first year in the soil treatment variant (3,134 kg ha^{-1}). The same variant in the second year of research gave the highest content of essential oil (25.9 kg ha^{-1}). These years were quite different in terms of climatic conditions, and precipitation sums, distribution and average daily temperatures in the first year favoured the formation of higher values for most of the investigated parameters.

Key words: *basil, above-ground biomass, plant height, yield, essential oil content, EM-AKTIV product*

Introduction

Due to its aroma, basil (*Ocimum basilicum* L.) has long been used in this region as a medicinal, sacred herb and a spice. Basil is grown for its above-ground parts (*Basilici herba*), from which essential oil is extracted (*Basilici aetheroleum*). Dry matter of basil biomass contains 0.5-1.5% of essential oil, characteristic for its pleasant and pungent smell (Stepanović and Radanović, 2011).
In our country, the most commonly grown basil cultivar is "*Sitnolisni aromatični*", good as a culinary herb and as an ornamental plant. According to its general characteristics, "*Sitnolisni aromatični"* yields about 3,000 kg ha^{-1} of dry biomass (Anonymous, 2016). Moreover, it contains significant amounts of good-quality essential oil suitable for use in the pharmaceutical industry. Biomass productivity/yields depend on a series of factors. In order to achieve desired results for a certain plant cultivar, it is necessary to meet all agro-ecological, agro-technical, edaphic,

genotypic, seeding and other factors that affect chances of obtaining expected quantities of raw material of satisfactory quality (Glamočlija et al., 2015).

By using effective micro-organisms in basil fields, one can achieve intensive proliferation of micro-organisms, especially in early stages of plant growth, which in some cases leads to an increased intake of mineral nitrogen (N) and inhibits growth of plants (Frąszczak et al., 2012).

Over the last twenty years the use of effective micro-organisms (EM) has been intensified. Higa (2003) claims that EMs are capable of producing anti-oxidants and preventing the emergence and growth of free radicals with oxygen. Free radicals contribute to the development of certain diseases, whereas anti-oxidants produced by EM eliminate those diseases, combat them or enhance the effects of oxygen activity. Microbiological products with active PGM micro-organisms diminish negative effects of water deficit; especially in combined inoculation where many useful micro-organisms can affect the direction and dynamics of micro-organisms and hence maintain and improve fertility in the soil (Heidari and Golpayegani, 2011).

Aside from getting vigorous plants with high quality biomass, the role of basil reflects in the fact that soil remains clear after harvest, with no weed but with good physical properties, which makes basil a great preceding crop for most crop species, especially if it is included in crop rotation on fields with organic production (Glamočlija et al., 2015).

The use of EM-based products is one more way to produce organic herbs. Hence the goal of this paper was to determine the possible impact of the product EM-AKTIV on morphological, productive and qualitative properties of basil biomass.

Material and methods

This research investigated the basil (*Ocimum basilicum* L.) cultivar *"Sitnolisni aromatični"* grown and propagated at the Institute for Medicinal Plant Research "Dr Josif Pančić" in Belgrade. The trials were carried out during 2014 and 2015 on plots and in the seed laboratory at the Institute in Pančevo (44°52'20"N; 20°42'06"E; 74 m altitude). The trial was set up in a complete randomised block design with four repetitions, and the size of basic plots was 3.25 m^2 (5.0 m x 0.65 m). The researchers investigated the impact of the EM-AKTIV (Effective Micro-organisms) on morphological parameters, productivity and the quality of basil biomass and essential oil content. The EM-AKTIV is a product containing a mix of lacto-acid bacteria (*Lactobacillus casei*, *L. plantarum* and *Streptococcus lactis*), photosynthetic bacteria (*Rhodopseudomonas palastrus* and *Rhodobacter spaeroides*), yeasts (*Saccharomyces carevisiae* and *Candida utilis*), actinomycetes (*Streptomyces albus* and *S. griseus*) and moulds (*Aspergillus aryzae* and *Mucor hiemalis*). In this research it was used twofold. In the first variant, the soil was treated with the EM-AKTIV three days before harvest, when the product was raked directly into the soil. In four repetitions, 0.4 dl of the EM-AKTIV with 7 l water was applied into the soil. In the second variant, the EM-AKTIV was used foliarly – three weeks after transplanting, when 0.13 dl of the EM-AKTIV with 7 l water was applied. A plot without the EM-AKTIV was used as a control variant.

Meteorological data for the vegetation period of basil were retrieved from the Meteorological station of the "Tamiš" Institute, Pančevo (Table 1).

Table 1. Meteorological data for the vegetation period of basil, 2014 and 2015

Parameters	V	VI	VII	VIII	IX	X	Sum	Aver. T
Precipitation 2014	220.2	52.1	87.1	113.7	140.6	39.9	653.6	-
Precipitation 2015	88.2	20.1	4.8	69.1	86.4	68.3	336.9	-
Temperatures 2014	16.4	21.5	22.7	22.4	18.1	13.6	-	19.1
Temperatures 2015	18.5	23.3	27.5	25.5	20.9	10.7	-	21.1
Precipitation 1994-2013	61.4	81.7	61.8	49.6	65.2	49.7	369.4	-
Temperatures 1994-2013	18.6	21.9	23.8	23.5	18.0	12.6	-	19.7

Basil seedlings were produced in a plastic greenhouse. The production was standard, like production of vegetable seedlings. Seeds for future seedlings were sawn in late February. Three months later, in mid-May, the seedlings were transplanted. At that time the seedlings had 3-4 pairs of leaves and were 10-12 cm high, being at the stage when seedlings have the best chances to grow after transplantation. The marigold (*Calendula officinalis* L.), a medicinal plant species, was a preceding crop on the trial plots. Planting was done manually, on May 8 in the first year, and on May 18 in the second year. Row spacing was 50 cm, and crop spacing 30 cm. The first watering was carried out the day before planting, and the second watering right after planting, whereas other watering was done when needed. A watering norm in each of four watering was 25 mm/m^2.

Standard crop tending measures were applied during the period of vegetation. Weeds were eliminated mechanically, without using pesticides. During vegetation, no disease or pest infestations were recorded, and therefore there was no need for protective measures.

The first harvest of green biomass was conducted at full bloom, in late July. In that stage, basil contains most of essential oil and green biomass yields are highest. The second harvest was conducted in early October. Prior to harvest, a sample of five plants from each plot was taken to measure plant height, root length, plant width and the number of inflorescences. Harvest was carried out manually, with a sickle, at the cut height of 8 cm, in nice and sunny weather. After harvest, weight of fresh biomass was measured, and yield per hectare was calculated and expressed in kilograms. The green biomass was air-dried in a draught place, after which dry biomass yield was measured and samples were taken for determining the content of essential oil. Essential oil was extracted in the process of hydro distillation of dry material by using a Clevenger apparatus, following the procedure described in Ph. Jug. IV (Ph. Jug. IV, 1984). 20 g of the fragmented plant material was hydro distilled in a balloon of 1000 ml with 400 ml of water. The mass was then heated to the point of boiling and such distilled for two and a half hours. After distillation, the volume (ml) of the essential oil was detected and the content of the essential oil (in %) in 100g of dry biomass (v/w) was calculated according to the following formula:

$$C = (b : a) \times 100$$

Where: a – measured biomass quantity (in g); b – essential oil content (in ml); C – content (in %) of essential oil in 100 g of biomass. Results of determining the content of essential oil in basil biomass are the mean value of three continuous determinations. The yield of essential oil per hectare was determined by calculating the percentage of oil in biomass weight per hectare and expressing it in kilograms.

Testing the significance of differences between the mean values of the investigated factor (use of the EM-AKTIV) was conducted by using the model of the analysis of variance, in the following mathematical form:

(i=1,2,3;...,r; j=1,2,...s; k=1,2,3,4)

All the assessments of significance were based on the F-test and LSD-test at the level of 5% and 1%. The analysis of variance (*ANOVA, in Randomized Blocks*) was done with Statistica for Windows 10 (STATISTICA, 2010). The same software was used to calculate the coefficient of variation (C_v).

Results and discussion

High variation in morphological and productive parameters of the basil cultivar "Sitnolisni aromatični" is the result of a long dry period recorded in the second year (Table 1, 2 and 3).

Table 2. Morphological parameters of the basil cultivar ″Sitnolisni aromatični″

Years	Treatment	Plant height (cm)	Root length (cm)	Plant width (cm)	Number of inflorescences
2014	Control (no product used)	47.3	36.7	26.1	92.3
	Soil treatment	54.2	40.2	33.2	106.7
	Foliar treatment	52.9	41.3	31.0	102.0
2015	Control (no product used)	37.7	28.9	23.7	76.7
	Soil treatment	44.4	31.5	24.6	85.6
	Foliar treatment	43.8	32.4	23.9	79.7
2014	Average	51.5	39.4	30.1	100.3
2015	Average	42.0	30.9	24.1	80.7
	Total average	46.7	35.2	27.1	90.5
	The coefficient of variation	13.2	14.3	14.9	13.6
LSD	0.05	22.2	11.7	15.4	30.5
	0.01	29.7	16.4	20.6	40.2

Plant height is an important property both from the agro-technical and the production aspect. Knowing this parameter allows us to define and assess more precisely the habitus of basil. In this research, the highest values for plant height, in both years of research, were obtained in the variant treated with the EM-AKTIV, 54.2 cm on average (in 2014), which was statistically much higher than values obtained in the control variant, i.e. the variant with lowest height (37.7 cm, in 2015). In the research of Labra et al. (2004), the height of tiny-leaf forms of basil ranged from 30 cm to 35 cm, and the height of large-leaf forms ranged from 40 cm to 45 cm. Analysing the results obtained for root length, one can see that the use of the EM-AKTIV (in both variants) increases root length, whereby the recorded differences were not statistically significant. Plant width and plant height together define plant habitus. In other words, by comparing plant height and plant width one can determine plant habitus. Plant width in this research ranged from 23.7 cm (control in 2014) 33.2 cm (soil treatment variant in 2015). Eckelmann (2002) claims that basil height and width mostly depends on environmental conditions, whereas its shape, leaf area and tips are genetically determined and represent identifying properties of cultivars. This opinion is backed by Polish researchers (Nurzyńska-Wierdak and Borowski, 2011), who treated basil with foliar fertilisers. Basil develops dichasial inflorescences of different length. The number of inflorescences in this research ranged from 106.7 (recorded in the soil treatment variant in 2014),

to 76.7 (in the control variant in 2015). Basil is morphologically diverse in terms of size, shape, colour, leaves and inflorescence (Szabó et al., 1996). Statistically significant discrepancies in certain properties of basil were recorded in the research of Rahimi et al. (Rahimi et al., 2013), when different types of bio-stimulators and bio-fertilisers were used.

In the second year of the research more dry weight was recorded, which can be seen from the fresh-dry matter ratio that averaged 4.1 : 1. Unfortunately, low humidity in 2015 resulted in 31.5% lower dry biomass yield (Table 1 and 3).

Table 3. Yield, content and yield of essential oil from dry biomass of the basil cultivar ″Sitnolisni aromatični″

Years	Treatment	Yield of fresh biomass (kg ha^{-1})	Yield of dry weight biomass (kg ha^{-1})	Essential oil content (%)	Essential oil yield (kg ha^{-1})
2014	Control (no product used)	13,728.0	2,965	0.74	21.8
	Soil treatment	12,880.7	3,134	0.75	23.6
	Foliar treatment	12,831.0	2,820	0.66	18.5
2015	Control (no product used)	6,896.1	1,810	1.05	19.0
	Soil treatment	9,635.3	2,333	1.11	25.9
	Foliar treatment	8,560.8	1,968	1.13	22.2
2014	Average	13,146.6	2,973	0.71	21.3
2015	Average	8,364.1	2,037	1.10	22.4
	Total average	10,755.3	2,505	0.91	21.8
	The coefficient of variation	25.8	21.9	23.6	12.8
LSD	0.05	4,638.3	1,374.5	0.089	4.21
	0.01	6,388.8	1,687.2	0.128	5.72

The highest yield of fresh biomass (13,728.0 kg ha^{-1}) was recorded for the control variant (the variant without the EM-AKTIV) achieved in the first year of research. It was twice as higher value than the minimum value recorded for the same variant but a year later (6,896.1 kg ha^{-1}). Previous experience has shown that the maximum weight of biomass is achieved in the period from the end of bloom to the beginning of seed maturity. Depending of agro-ecological conditions, that period can last from 150 to 180 days after planting (Putievsky and Galambosi, 1999). After drying, the highest biomass yield was recorded in the soil treatment variant (3,134 kg ha^{-1}) in the first year of research, and the lowest yield in the control variant in the second year of research (1,810 kg ha^{-1}). The average yield of dry biomass in this research was 34.0% lower than in the research of Adamović (Adamović, 2012), where it was 3,800 kg ha^{-1} in early harvest, and 2,500 kg ha^{-1} in late harvest – what was in line with our research. The content of essential oil in dry biomass averaged 0.91%, whereby the coefficient of variation was 23.6%. The highest content of essential oil was achieved in the second year in the variant with the foliar EM-AKTIV treatment (1.13%). The same variant in the first year of research gave the lowest content of essential oil (0.66%). In general, the content of essential oil in dry biomass was significantly higher than in some of the latest national research (Bulut, 2012; Filip, 2014). Essential oil yield had the most uneven values of all investigated parameters. For that situation a reason can be found in climatic factors, which are in correlation between yield and essential oil content. The highest content of essential oil was obtained in the soil treatment variant in the second year (25.9 kg ha^{-1}), and the lowest in the foliar treatment variant in the first year of research (18.5 kg ha^{-1}). Plant development stages affect the yield of oil to a great extent. A study conducted in the late

20th century showed that the maximum concentration of oil was achieved at full bloom (Putievsky and Galambosi, 1999), which was also conducted in this research.

Conclusions

The goal of this research was to determine whether there is an impact of the EM-AKTIV product on morphological and yield parameters, and on the content of essential oil of the basil cultivar "*Sitnolisni aromatični*". When compared the years and all morphological parameters, yield of fresh biomass and yield of dry biomass, one can see a statistically significant differences in 2014 and 2015. Precipitation sums and average daily temperatures during the first year were favourable for having higher values for the investigated parameters. Agro-ecological indicators in the second year were more favourable for the content of essential oil and its higher yields. When observed both years of the research, the soil treatment variant with the EM-AKTIV obtained the highest values for plant height, root length, plant width, the number of inflorescences, yield of green biomass and yield of dry biomass. However, the highest values for root length (in 2014 and 2015) and the content of essential oil in 2015 were recorded in the foliar variant.

Abstract

Fruit quality characteristics of Şalak (Apricose) apricot cultivar, which is grown under climatic conditions of regions located in Aras Basin (Turkey) at different altitudes, were studied for two consecutive years. Physical attributes (width, length, height, fruit shape index, fruit weight, kernel weight, fresh/kernel ratio), chemical parameters (total soluble solids content, pH and acidity) and textural parameters (hardness, adhesiveness, springiness, cohesiveness, gumminess, chewiness and resilience) were evaluated in the study. These properties are important in the design of equipment for harvesting, separating, packing, processing and transportation. Fruit width, fruit length, fruit height, fruit weight, seed weight and kernel weight of Şalak (Apricose) apricot cultivar collected from four different locations varied between 41.06-48.83 mm, 49.47-56.80 mm, 40.53-47.27 mm, 53.42-73.82 g, 2.24-2.72 g and 0.75-0.85 g, respectively. Based on the chemical properties of Şalak (Apricose) apricot cultivar, it was determined that total soluble solids, pH and acidity contents changed from 13.72 to 16.40 %, from 4.46 to 4.96 and 1.01-1.69 %, respectively. In terms of textural properties the average hardness, adhesiveness, springiness, cohesiveness, gumminess, chewiness and resilience were detected as 9.13 N, -27.48 g.s, 0.57, 0.24, 195.88 g, 142.11 g and 0.08, respectively.

Keywords: *Apricot, Physical Properties, Textural Properties.*

Introduction

Apricot belongs to the family Rosaceae and this fruit is botanically known as *Prunus armeniaca*. (Özbek, 1978). Turkey is the leading apricot producer in the world with 795 768 tons produced annually (FAO, 2012). About 78% of total apricot production is provided from Malatya, Erzincan, Mersin and Iğdır provinces in Turkey. Iğdır, located in Aras Valley, produces 2/3 of total Turkish apricot production. In this region, the most widely used apricot cultivar is Şalak and it is grown on traditionally generative rootstocks. As an attractive cultivar, Şalak has rather large, delicious and medium hardness fruits and it is suitable for fresh consumption. It has vigorous growth and large canopy size and it is grown on altitudes from 830 m to 1400 m in Aras Valley. Şalak tree may produce about 150-200 kg of yield depending on cultural practices and maintenance conditions (Ozyoruk and Guleryuz, 1992; Ercisli, 2009).

Apricot is a very sensitive and easily perishable stone fruit and very exposed to some physical damage and disease. Therefore, it softens very quickly and this situation limits its marketing duration (Antunes et al, 2003) Apricot is generally consumed fresh, as well as being processed into some food commodities such as dried, frozen or canned, jam, jelly, marmalade, pulp, juice, etc. (Bruhn et al., 1991; Botondi et al., 2000; Missang et al., 2011).

Apricot has a short shelf life and is also a perishable species. Thus its texture and physical properties are essential quality parameters.

The fruit texture is a very important trait for maintaining good taste and shelf life of the fruit. As a significant quality parameter, fruit hardness affects postharvest physiology as well as the consumer preferences (Vicente et al., 2007).

Both fresh and processed fruit and vegetables are considered as to their sensory quality parameters, such as texture, colour, flavour and taste (sweet, sour, salt and bitter sensations) and physical properties such as size and shape (Stow, 1995; Karlsen, et al., 1999).

Texture, color, antioxidant and other biochemical properties are important for fruit acceptability. Appearance of the fruit is particularly affected by texture and color (Takahashi, et al., 2009).

Various important studies have been carried out concerning the physical and textural properties of fruits and vegetables such as sweet and sour cherry (Blahovec et al., 1995), apple (Karslen et al., 1999;Guine et al., 2011), cherry laurel (Calisir and Aydin, 2004), pear (Huang and Hsıeh, 2005), wild plum (Haciseferogullari et al., 2005), mango, (Jha et al., 2006), apricot (Haciseferogullari et al., 2007), kiwi fruit (Razavi and Parvar, 2007), pinapple (Montero-Calderon et al., 2010), tomato (Sirisomboon et al., 2012)

According to our knowledge, there are limited studies on the textural properties of apricot as a sensory analysis. Therefore, this study was aimed to determine some physical, chemical and textural properties of Şalak (Apricose) apricot cultivar grown in Aras Valley.

Materials and Methods

Material

In this study, Şalak apricot cultivar was used as a fruit material grown at four different altitudes of the Aras Valley during 2012 and 2013. For this purpose, fruit samples were collected from trees that are at commercially mature stage in Iğdır (800 m), Tuzluca (1100 m), Kağızman (1200 m) and Üçkaya (1400 m) provinces (Turkey).

Some Physical and Chemical Characteristics

Fruit, kernel and seed weight of sampled apricots were measured using precision scales with an accuracy of 0.01 g. In addition, fruit width, fruit length and fruit height were measured using a digital caliper with an accuracy of 0.05 mm. Soluble solids content (SSC) was determined using hand refractometer. Reaction of fruit juice was determined using digital pH meter. TA, expressed as a percentage of malic acid was determined with well mixed juice by titration against NaOH (0.1 M), using a pH meter(El-Motty et al., 2007; Lara et al., 2004).

Texture Profile Analyses

The fruits were peeled and cut into 10*5mm (D * H) pieces. Texture profile analysis (TPA) was performed with the fruit pieces by a TA-XT plus texture analyzer (Stable Micro Systems Ltd., Godalming, Surrey, UK). The operating parameters were as follows: load cell = 30 kg, probe = 35 mm diameter aluminum cylinder, pre-test speed = 5 mm/s, test-speed = 0.5 mm/s, post-test speed = 0.5 mm/ s, compression degree = 30%, time = 3 s, and trigger force = 3.0 g (Shao, Tu, Zhao, Chen, & Zhao, 2006). Hardness is defined as the peak force of the first compression of the sample. Ten apricots were measured individually for each treatment group.

Texture parameters used in TPA analyses consist of hardness, adhesiveness, springiness, cohesiveness, gumminess, chewiness and resilience. Definitions of these parameters are given in Table 1.

Table 1. Definition of texture characteristics evaluated in conventional profiling in apricot fruit (Bourne, 2002)

Characteristic name	Definition
Hardness	the force required to compress a substance between the molar teeth (in the case of solids) or between the tongue and palate (in the case of semisolids)
Adhesiveness	Force required to remove material that adheres to the mouth (generally the palate) during the normal eating process
Springiness	Force with which sample returns to its original size/shape, after partial compression.
Cohesiveness	Amount of deformation undergone by the material before rupture, when biting completely through the sample.
Gumminess	Energy required to disintegrate a semisolid food to a state ready for swallowing.
Chewiness	The length of time required to masticate a sample at a constant rate of force application to reduce it to a consistency suitable for swallowing.
Resilience	Degree to which the sample returns to the original shape (elasticity)

Statistical analyses

The experimental design was randomized with three replications. Data were subjected to variance analysis using SPSS statistical software. Differences between means were tested using the LSD test.

Results and discussion

Physicochemical Properties

Fruit samples were taken from the orchards at different altitudes ranged from 800 m (Iğdır) to 1400 m (Üçkaya). It was determined that there were statistically significant ($P \leq 0.05$) differences between some fruit quality properties of Şalak apricot variety cultivated at different altitudes (Table 2). Table 2 shows multiple comparison test of the values obtained from the study. As the results were examined, the difference between regions in terms of fruit width, length, height, and weight, seed weight, and kernel weight of Şalak variety was found to be differences according to two-year mean data. While the highest fruit width (48.83 mm), length(56.80 mm), height (47.27 mm), and fruit weight (73.82 g) were obtained from Iğdır region, the lowest fruit width (41.06 mm), length(49.47 mm), height (40.53 mm), and fruit weight (53.42 g) were obtained from Kağızman region. In the study, it was found that seed weight was 2.24 - 2.72g and kernel weight was 0.75 - 0.85 g. Özyörük and Güleryüz, (1992) determined fruit weight and seed weight of Şalak apricot variety in Iğdır region as 62.1 g and 2.4 g, respectively. Batmaz (2005) reported that fruit weight varied between 16.60 and 72.33 g and seed weight varied between 2.43 and 7.33g in 16 apricot genotypes. Hacıseferoğulları et al., (2007) determined that fruit length, width, thickness, and seed weight in 6 different apricot varieties were 29.26-46.98 mm, 30.16-40.43 mm, 27.64-36.76 mm, and 1.44-2.94 g, respectively. Muradoğlu et al., (2011) found that mean weights of fruit, seed, and kernel in Şalak variety among 6 apricot varieties cultivated in Iğdır region were 51.79g, 2.05g, and 0.75g, respectively.

When different regions were examined in terms of SSC (Soluble Solid Content) levels; SSC in fruit samples from Iğdır, Tuzluca, Üçkaya, and Kağızman regions were found to be statistically different. While the highest SSC was found in samples (16.40%) from Üçkaya region, the lowest SSC was determined in samples (13.72%) from Kağızman region. The pH values in Şalak variety samples obtained from Iğdır, Tuzluca, Üçkaya, and Kağızman regions were statistically different. Whilst the highest pH value was obtained in samples of Iğdır region (4.96), the lowest pH value was determined in samples of Tuzluca region (4.46). There were statistical differences between acidity levels of samples from Şalak variety. Among apricot samples, the highest acidity amount was found in apricots from Tuzluca region whereas the lowest acidity level was observed in apricots from Üçkaya region.

Batmaz (2005) determined that pH value varied between 3.19 and 3.71, acidity varied between 0.93% and 2.47%, and SSC varied between 12.6% and 18.4% for 16 apricot genotypes. In their study, Hacıseferoğulları et al., (2007) reported that pH value ranged between 4.16-5.23, acidity level ranged between 0.17-0.79%, and SSC ranged between 17.69-23.63% for 6 apricot varieties. Muradoğlu et al., (2011), found that pH was 5.27 on average, while acidity was 0.2%, and SSC was 14.67%.

Table 2. Some pomological and chemical properties of Şalak apricot cultivar grown in different regions

Regions	Fruit width (mm)	Fruit length (mm)	Fruit height (mm)	Fruit weight (g)	Seed weight (g)	Kernel weight (g)	TSSC	pH	Acidity (%)
Iğdır	48.83^{a*}	56.80^{a}	47.27^{a}	73.82^{a}	2.69^{a}	0.85^{a}	14.22^{b}	4.96^{a}	1.25^{b}
Üçkaya	45.89^{ab}	54.91^{a}	44.95^{ab}	68.20^{ab}	2.72^{a}	0.82^{ab}	16.40^{a}	4.88^{a}	1.01^{b}
Tuzluca	42.64^{bc}	49.81^{b}	42.30^{bc}	59.17^{bc}	2.24^{c}	0.75^{b}	15.66^{ab}	4.46^{b}	1.69^{a}
Kağızman	41.06^{c}	49.47^{b}	40.53^{c}	53.42^{c}	2.42^{b}	0.77^{b}	13.72^{b}	4.50^{b}	1.29^{b}

P≤0.05 least significant difference at 0.05 level. * Means within treatment variables not followed by the same letter are different at 5% levels.

.

Textural Properties

Table 3 shows values of hardness, adhesiveness, springiness, cohesiveness, gumminess, chewiness, and resilience examined as textural properties of Şalak apricot variety. A significant difference was not found between regions in terms of textural properties of Şalak apricot variety. Accordingly, textural properties of Şalak fruits showed no changes in terms of different altitudes and climatic characteristics and preserved its quality.

According to the obtained results, values of hardness, adhesiveness, springiness, cohesiveness, gumminess, chewiness, and resilience in apricot fruits were measured as 12.13 N,-24.42 g.sec, 0.56, 0.24, 336.76, 198.37, and 0.08 in Tuzluca region; 8.40 N, -36.88 g.sec., 0.57, 0.26, 243.17, 138.93, and 0.09 in Iğdır region; 8.39 N, -22.31 g.sec., 0.57, 0.24, 22.84, 130.81, and 0.08 in Kağızman region; 7.58 N, -26.32 g.sec., 0.56, 0.22, 180.75, 100.33, and 0.08 in Üçkaya region, respectively.

Among regions, the highest values of hardness, gumminess, and chewiness were obtained from Tuzluca region (12.13 N, 336.76, 198.37) and the highest value of adhesiveness was obtained from Iğdır region (-36.88 g.sec.) while similar results were obtained in terms of springiness, cohesiveness and resilience values. Hacıseferoğulları et al., (2007) determined average hardness value in Zerdali, Çataloğlu, Hacıhaliloğlu, Hasanbey, Soğancı, and Kabaaşı varieties as 5.64,

8.20, 7.18, 7.63, 6.16, and 8.48 N, respectively. As for different fruit species, average hardness value were determined as 7.85 N for wild plum, 4.3 N for wild medlar, and 8.83 N for strawberry (Calisir et al., 2005; Hacıseferogullari et al., 2005; Ozcan et al., 2007).
Guiné et al., (2011) found that adhesiveness, cohesiveness, springiness, and chewiness values in different apple varieties were between –0.06 and – 0.27, 0.43 and 0.75, 0.70 and 0.92, 5.28 and 15.19; respectively. Compared to the results of this study, adhesiveness and chewiness values of Şalak fruits were observed to be higher.

Table 3. Textural properties of Şalak apricot cultivar grown in different regions

Regions	Hardness (N)	Adhesiveness (g.sec)	Springiness	Cohesiveness	Gumminess	Chewiness	Resilience
Tuzluca	1237.20	-24.42	0.56	0.24	336.76	198.37[a]	0.08[a]
Iğdır	856.76	-36.88	0.57	0.26	243.17	138.93[a]	0.09[a]
Kağızman	855.62	-22.31	0.57	0.24	22.84	130.81[a]	0.08[a]
Üçkaya	772.53	-26.32	0.56	0.22	180.75	100.33[a]	0.07[a]
Average	930.53	-27.48	0.57	0.24	195.88	142.11	0.08

Conclusion

Apricot is generally consumed as fresh, dried, frozen or as processed such as jam, marmalade, and fruit juice. It is important to know textural properties of apricot in order to enrich these different usage areas and to facilitate product processing processes. There is a limited number of studies in the literature on textural properties of apricot. Textural properties of Şalak variety, an important table fruit which has been cultivated significantly in Aras Basin, were determined in this study. As a result, it was concluded that textural properties of Şalak fruits does not change according to regions and preserves its fruit quality. The results obtained from this study would be useful for further studies such as harvesting, packaging, elongation, storing and processing for various purposes.

Abstract

This study aimed to determine cowpea seed varieties that may be suitable for the production efficiency and affecting yield factors in Turkey's located Middle Anatolia ecological conditions. The study was conducted for 2 years in 2014-2015. In research, 4 cowpea varieties (Amazon, Sırma, Karagoz, Akkız) and control Nevsehir / Hacıbektas, obtained from the district domestic genotype 1, were used. Research was conducted in a randomized complete block experimental design with three replications. Sowing was performed on 10 May 2014 and on 8 May 2015. The local cowpea cultivars and genotypes according to the two-year average 50% flowering number of days 68-80 days, 50% pod connecting number of days 93-102 days, plant height 41-83 cm, pod number in plant 2-10 pieces, pod length of 5-15 cm, 100 seed weight and seed yield 11.46-18.75 g per plant between 1:21 to 6:19 g/plant ranged. As a result, number of pods per plant and seed per plant, plant and yield per plant and the number of days between the number of pods per pod connect with biological yield was found to be very important relationship. At the same time the first pod height, plant height and number of pods with one seed per plant were among the important relationships that were identified in both years. In cowpea breeding programs, in the number of pods per plant, yield per plant, number of pods per plant and has laid the biological traits could be used as selection criteria.

Key words: *Kırsehir, cowpea, local genotypes, yield, yield components*

Introduction

Cowpea is an important food legume as fresh and dry seed in human diet and as animal feed and green fertilizer for the improvement of soil fertility (Akcin, 1988). Depending on the cultivar and environment conditions, it contains 18-31.6% protein, 50-67% carbohydrates, 1.3% oil, 3.9% cellulose and 3.6% ash. Fresh pods and dry seeds of cowpea are used as edible legumes. Due to eating habits in human diet, priority is given to the consumption of animal-derived proteins. However, for a healthy diet, plant-derived proteins, as well as animal-derived proteins, should be consumed. Because, cowpea plant is rich in amino acids, lysine, tryptophan, carotene and B1 vitamin (Ozturk, 2010). Cowpea which is an edible legume is the third in legume production in the world following beans and chickpeas with 11.926.786 ha cultivation area, 6.224.698 tons of production and 52 kg da^{-1} yield. In Turkey, it is fifth in legume production following chickpeas, beans, lentils and broad beans with 1.941 ha cultivation area, 2.006 tons of production and 103 kg da^{-1} yield (FAO, 2013). Cowpea cultivation in Turkey is unsatisfactory. Cowpea cultivation should be developed and a cultivator culture should be established on this subject. As in other culture plants, it is of great importance, as well as other cultural applications, to use cultivars suitable to the ecological conditions for increasing the yield per unit area (Sertve Ceyhan, 2012).

Ozturan and Gulumser (2004), in their study on Akkız and Karagoz cultivars, determined some yield properties including plant height, pod number in plant, yield per plant, seed yield, 1000-seed weight and crude protein have reported the highest seed yield as 273.1 kg da^{-1}. The researchers obtained the highest seed yield per plant in Karagoz cultivar (69.0 g). Oztokat and Demir (2010), in their study on 31 different cowpea genotypes in Aegean region, determined the highest yield as 84.20 kg da^{-1}. Vural et al. (2000), in their study, stated that growing condition is the most important factor that affects the yield. The researchers have reported that ecological conditions seriously affect the fertility. Tomer and Verma (1989) have reported that seed weight had a sufficient effect on the growth and development in cowpea. Gul (1996) has reported that the humidity should be high for the germination of cowpea. The researchers determined that cowpea may not germinate in soils where most of the legume types easily can.

Kırsehir is ecologically suitable for cowpea cultivation. However, the production level is not satisfactory due to the consumption habits of the producers. The aim of this study is to determine the genotypes of cowpea (line/variety) in terms of yield suitable for Kırsehir/Turkey ecological conditions which features all the characteristics of Central Anatolian ecological conditions.

Material and Methods

The present study aims to determine the yield and some agronomic properties of cowpea (*Vignasinensis*L.) genotypes under Kırsehir/Turkey ecological conditions. The study was conducted for 2 years in 2014-2015 at trial farmlands in Kırsehir. The altitude of Mucur country in which the study was carried out is about 80 m and it is located at 39°3'48.00"K latitude and 34°22'19.71"D longitude (Figure 1).

Figure 1.Locations where the conduct of the trials

Examining the analysis results for the soil used in the study, it was seen that the soil had a clayey-loamy structure with mild alkaline characteristics, saltless, calcareous, moderate in phosphorus, rich in potassium and moderate in organic substance for the every both years.

The average monthly temperatures and relative humidity ratios for both years were highly similar to those of long-term temperature and relative humidity values. However, examining the monthly total precipitation values, the total precipitation values for all months for both 2014 and 2015 were considerably higher compared to the long-term average values. Particularly, 161.4 mm precipitation value for June 2015 was 11 times higher than the long-term average values (Table 1).

The study was established according to the randomized complete block experimental design in three replications. Four cowpea standard cultivars (Akkız, Amazon, Karagoz, Sırma) and one domestic population, a total of five cowpea genotypes were included in the study. The seeds were sown in plots consisting of 4 rows which were prepared using a 5 m marker with 60 row spacings (5 x 2.40 m= 12 m^2) and 10 cm intra-row spacings manually between10 May 2014 and 8 May 2015. In addition to planting, the necessary fertilization (15 kg diamonium phosphateper decare)

was distributed among the plots homogeneously and herbicide application was carried out before planting and sprouting. Additionally, plants were irrigated our during the required period for the plants. Harvest was carried out manually between 14 September 2014 and 11 September 2015. In each plot consisting of 4 rows, the 1st and the 4th rows of the plots and 50 cm distances from the starting point of each plot was removed as the edge impact and total harvesting was performed in the remaining area.

Flowering and pod setting values of all cowpea genotypes in all plots for the two years and phonological and agronomic properties including plant height (cm), first pod height (cm), the number of pods per plant (piece/plant), the number of seed per pod (piece/pod), the number of seed per plant (piece/plant), seed yield per plant (g), 100 seed weight (g), pod height (cm) and biological yield (g) for 10 plants randomly selected from each plot were determined according to Akcin (1974) and Gulumser (1981).

Table 1.Climate data for the Kırsehir.

Climatic Factors	Years	Months				
		May	June	July	August	September
Total Rainfall (mm)	2014	46.6	36	13	17	30.4
	2015	39.2	161.4	20.6	11.8	1
	ALY*	10.7	13.9	2.9	1	2.6
Average temperature (^{0}C)	2014	16.9	20.8	27.6	28.2	20.1
	2015	16.4	18.9	24.9	25.9	23.8
	ALY*	16.2	20.6	24.8	24.9	19.6
Average Relative Humidity (%)	2014	59.5	51.6	33.6	33.6	50.8
	2015	57.5	65.6	41.5	45.4	41.1
	ALY*	56.2	50.9	38.4	37.6	43.3

*ALY: Average Long Years

The combined data of the two years were subjected to the ANOVA using JUMP5.0 statistical software. The "LSD Multiple Comparison Test" was used for the comparison between the significant differences between the average values. The study comprised combined data of the each property examined for the both years.

Results and Discussion

50% The Number of Flowering and Pod Connecting Days

In terms of the average 50% number of flowering days for the both years, the differences between the cowpea genotypes were very significant ($P<0.01$). The genotypes with the longest 50% flowering periods were sırma and akkız genotypes with 75.9 days and 75.5 days, respectively (Table 2). The shortest 50% flowering period was determined in the domestic genotype with 69.5 days. The average 50% flowering period for all genotypes were 73.2 days. These results were in line with the results reported by Gulumser et al. (1989) who have reported that the flowering period for native cowpea genotypes varied between 66 and 73 days. Similarly, Buyukkılıç (1995), in their study conducted under Sanlıurfa conditions have reported that flowering period varied between 56 and 57 days. This was associated with the different ecological conditions in terms of humidity and temperature of the area that the study was conducted. Pod connecting and flowering periods are directly related to each other 50% pod connecting period is described as the number of days for the plant until the date of 50% pod connecting. The average pod setting for

the two years in the study was determined as 96.7 days and the differences between the genotypes were statistically not significant (Table 2). The genotype with the longest pod connecting period was sirma with 99 days whereas the shortest pod setting period was determined in the native population with 94.5 days.

Plant Height

Analysis of variance revealed that the differences between the average plant heights of cowpea genotypes for the two years were very significant (P<0.01). The average values of plant height for cowpea genotypes for the two years and the LSD groups are shown in Table 2.The genotypes with the highest plant heights were sırma, amazon and native cowpea genotypes with 61.5 cm, 59.9 cm and 57.7 cm, respectively. The lowest plant heights were determined in akkız and karagoz genotypes with 45.8 cm and 47.6 cm, respectively. The average plant height was determined as 54.5 cm. The difference between the plant heights of the highest genotype and the lowest genotype was 15.7 cm. In a study on the determination of the effects of different intra-row spacings and via on seed yield and some agronomic properties of cowpea (*Vignasinensis (*L.) *Savi*) cultivars under Hatay province ecological conditions, the plant height values varied between 33.22 cm and 60.37 cm (Sert, 2011). In another study on the determination of plant properties and ability of cowpea cultivars under Hatay ecological conditions, the differences between the plant height values of ecotypes were statistically significant (Atıs ve Yılmaz, 2005). The results obtained by the researchers were in line with the results obtained in the present study.

First Pod Height

Results for the analysis of variance for first pod height values of the cowpea genotypes and the LSD groups in the study are shown in Table 2. As seen in Table 2, the differences between the first pod height values of the genotypes were statistically significant (P<0.05). Examining the average values for the two years, first pod height varied between 21.3 cm and 25.4 cm. The highest first pod height values were determined in amazon and akkız genotypes with 25.4 cm and 25.1 cm, respectively.

These two genotypes were statistically located in the same group (a). The lowest first pod height was determined in domestic cowpea genotype with 21.3 cm. The average first pod height for the cowpea genotypes was 23.9 cm (Table 2). The higher first pod height values obtained in the present study was associated with high plant height values. Karasu (1999), in their study on the determination of the agronomic characteristics of some cowpea ecotypes under Isparta ecological conditions 1996-1997, have reported the first height between 17.8 cm and 22.7 cm. Although the variation was high, our results were within this variation.

Table 2. Two-year average of the investigated properties for cowpea genotypes

Genotypes	50% flowering number of days	50% pod connecting number of days	plant height (cm)	first pod height (cm)
Sırma	75,9 a	99	61.5 a	24.5 ab
Akkız	75,5 a	95.5	45.8 b	25.1 a
Karagoz	74,5 b	96.5	47.6 b	23.4 ab
Amazon	70,5 c	98	59.9 a	25.4 a
Domestic	69,5 d	94.5	57.7 a	21.3 b
means	73.2	96.7	54.5	23.9
level of significance	**	ns	**	*

ns, *, **=not significant and significant effect at 5 and 1 % respectively

The Number of Pods in the Plant

One of the most important components that affect the yield is the number of pods in the plant. As a result of the analysis of variance for the combined data of the two years, the differences between the genotypes in terms of the number of pods in the plant were significant (P<0.01). The groups formed in terms of the number of pods in the plant and LSD values are shown in Table 3.
Examining Table 3, it was seen that the number of pods in the genotypes varied between 3.7 and 6.5 pieces. Genotypes with the highest number of pods were akkız, amazon, sırma and native genotype with 6.5, 5.5, 5.5 and 5.5 pieces respectively. The genotypes were statistically located in the same group (a). The lowest number of pods were determined in karagoz genotype with 3.7 pods. The difference between the lowest and the highest number of pods (between sırma and akkız genotypes) was 2.8.
Ceylan and Sepetoglu (1983), in their study, have reported that the number of pods in cowpea genotypes varied between 2.1 and 26.5. On the other hand, Karasu (1999) have determined the number of pods in the plant between 29.4 and 40.6. In a study on the determination of the effects of different row spacings and via on seed yield and some agronomic characteristics conducted under Hatay ecological conditions in 2009, have reported the number of pods in the plant between 12.19 and 14.59 (Sert, 2011).
The numberof pod obtained in the present study was lower than those obtained by other researchers. This was mainly associated with the decrease in plant growth in pod connecting period as well as the increase in high temperatures.

The Number of Seeds per Pod

The average number of seeds per pod values of cowpea genotypes and the groupings are shown in Table 3. Examining Table 3, the differences between the genotypes in terms of the number of seeds per pod were significant (P<0.01).
The number of seeds per pod varied between 4.1 and 5.6. The highest number of seeds per pod was determined in amazon genotype with 5.6 seeds. This genotype was statistically located in (a) group. This genotype was followed by akkız, sırma and karagoz genotypes with 5.3, 4.6 and 4.4 seeds, respectively. These three genotypes were located in the same group (ab). The lowest numbers of pods were determined in native genotype with 4.1 pods.
Clarke and Skeete (1982), in their study on arauca cowpea cultivars, have reported that, in five different plant spacing applications, planting spacing frequency had no effects on the number of seeds per pod and 100-seed weight. Bahceci (1987), in their study conducted under Cukurova ecological conditions, have reported that the number of seeds per pod increased as the intra row space increased.
In a study on the effects of different row spacings and nitrogen fertilization on the yield and yield components of akkıiz and karagoz cowpea cultivars under Samsun ecological conditions, the number of seeds per pod varied between 10.4 and 11 (Ozturan, 2003).

Pod Length

The average pod length values of cowpea genotypes for the two years are shown in Table 3. The differences between the genotypes in terms of pod lengths were found to be statistically not significant. Pod lengths of the genotypes in the study varied between 8.7 and 9.6 cm and other genotypes varied between these two genotypes.

The average pod length of the genotypes was 9.12 cm. The highest pod length value was determined in Amazon genotype with 9.6 cm whereas the lowest pod length values was in karagoz genotype with 8.7 cm. In a study on the determination of physiological and morphological properties and yield and yield components of cowpea (*VignaSinensis L.*) ecotypes cultivated under Ordu ecological conditions, it has been reported that pod length values varied between 15.1 and 19.8 cm (Ozturk, 2010).

In another study on the determination of the most suitable variety and seed planting period for cowpea (*Vignaunguiculata*L.Walp) under dry and aqueous ecological conditions of Isparta, the highest pod length value was determined in akkız cultivar with 16.19 cm whereas the lowest pod length values was determined in sarıgobek cultivar with 12.34 cm (Unlu, 2004). Pod length values obtained by the researchers were substantially higher than those obtained in the present study. This was associated with the increase in temperature and the decrease in humidity in the area that the study was conducted during pod setting period and the decrease in plant growth.

Table 3. Two-year average of the investigated properties for cowpea genotypes

Genotypes	the number of pods per plant	the number of seed per pod	pod length
Akkız	6,5 a	5.3 ab	9.0
Amazon	5,5 a	5.6 a	9.6
Sırma	5,5 a	4.6 ab	9.0
Domestic	5,5 a	4.1 b	9.3
Karagoz	3,7 b	4.4 ab	8.7
means	5.34	4.8	9.12
level of significance	**	**	ns

ns, *, **=not significant and significant effect at 5 and 1 % respectively

100 Seed Weight

The average 100 seed weight values of cowpea genotypes and statistical groupings are shown in Table 4. The effect of genotypes on 100 seed weight was statistically very significant ($P<0.01$). 100 seed weight values of the genotypes varied between 13.56 g and 16.94 g and the highest 100 seed weight value was determined in sırma genotype with 16.94 g. On the other hand, the lowest 100seed weight values were determined in native genotype and akkız genotype with 13.56 g and 14.24 g, respectively. These two genotypes were statistically located in the same group. The difference between the highest and the lowest 100 seed weight values was 3.38 g and the average 100 seed weight was 15.36 g. In a study on the determination of plant characteristics and adaptation capabilities in different cowpea ecotypes obtained from different parts of Turkey under Hatay ecological conditions, 100 seed weight value varied between 12.93 and 21.94 g (Atış, 2000). In a study on the determination of the most suitable cowpea cultivar (akkız, karnıkara and sarıgobek) and seed planting period under dry ecological conditions in Isparta, 100seed weight was reported between 12.55 and 21.53 g (Unlu, 2004).

Seed Yield per Plant

The average seed yield per plant values and statistical groupings are shown in Table 4 and the differences between the genotypes in terms of seed yield per plant values were very significant at 1% level. Examining Table 4, seed yield per plant values varied between 1.916 and 3.003 g. The two genotypes with the highest seed yield per plant values were akkız and amazon cowpea

genotypes with 3.003 g and 2.998 g, respectively. These two genotypes were statistically located in the same group (a). This was followed by sırma and native genotypes with 2.684 g and 2.382 g and these two genotypes were statistically located in the same group (ab). The lowest seed yield per plant was determined in karagoz genotype with 1.916 g.

The difference between the highest and the lowest seed yield per plant values was 1.087 g. In a study conducted under Cukurova conditions, Bahceci and Engin (1989) have reported that the highest seed yield per plant values were determined in karagobek cultivar in 30 cm (44.03 g) and 25 cm (35.53 g) planting spacings, respectively, and in kırmızı cultivar in 25 cm (32.35 g) and 30 cm (28.30 g) planting spacings, respectively.

In another study conducted under Samsun ecological conditions, seed yield per plant values varied between 48.4 and 69 g (Ozturan, 2003). The seed yield per plant values obtained in the present study were lower than those obtained by other researchers. This associated with the effect of temperatures much above 30 °C in maturation period on seed maturation.

Table 4. Two-year average of the investigated propertiesfor cowpea genotypes

Genotypes	seed yield per plant	100 seed weight
Akkız	3,003 a	14.24 c
Amazon	2,988 a	15.81 b
Sırma	2,684 ab	16.94 a
Domestic	2,382 ab	13.56 c
Karagoz	1,916 b	16.22 ab
means	2.594	15.36
level of significance	**	**

ns, *, **=not significant and significant effect at 5 and 1 % respectively

Conclusion

The aim of the present study was to determine the yield properties and the factors that affect the yield in cowpea under Kırsehir/Turkey ecological conditions 50% flowering number of days, 50% pod connecting number of days, plant height (cm), first pod height (cm), the number of pods per plant (piece/plant), the number of seed per pod (piece/pod), seed yield per plant(g/plant), 100 seed weight (g) and pod length (cm) values were examined and compared with other studies.

In conclusion, the results obtained for the two years were not satisfactory to make a clear conclusion. However, the result obtained in terms of yield components in particular, the number of seeds, 100 seed weight and the yield per plant were promising for some cultivars. Indeed, high yields were obtained from akkız, sırma and amazon cultivars. In order to acquire better results on cowpea cultivation, it was concluded that the study should be conducted for a couple more years in Kırsehir and neighboring locations.

Considering the importance of edible legumes in human diet, there is need for research and development on the breeding and cultivation techniques for cowpea. These research studies will contribute to the development of agricultural production and hence the elevation of socio-economic structure.

Abstract

Wheat is considered the most important cereal as a staple food for humans. For normal grow anddevelopment plants need at least 14 minerals elements such as micronutrients nitrogen, phosphorus, potassium, calcium, magnesium and sulfur and macronutrients chlorine, brown, iron, manganese, copper, zinc, nickel, and molybdenum. Deficit on any kind of these mineral elements in the soil reduced plant growth, yields and nutritional quality of products.Nowadays, the causes and consequences of zinc deficiency and iron in the soils are well documented and there are well-established effective methods to overcome the deficiencies in agriculture.Bio-fortification is a process with help on which increase concentration on micronutrientssuch as zinc, iron, manganese and etc. in the agriculture products–especially in the wheat cultures.The aim of this research is to examine the influence of Fe-EDTA and Zn-EDTA fertilizers through soil, foliar and soil+foliar application on qualitative and productive characteristics of soft wheat variety Radika. The analysis of variance for comparing on average values has shown existing of important differences between variants in morphologic characteristics only in the place of the number of little earsthehectoliter mass of wheat obtained with foliar application on Zn-EDTA showed value of 76.05(kg/hl), which is 1.33 % more than value of the control 75.05(kg/hl).During the investigation we determined that the largest weight of 1000 grains showed wheat obtained by application of Fe EDTA soil + foliar for 8.21%, compared to the control variant. It might be concludedthat the agronomic bio-fortification which nowadays is emphases alternative economic justified solution leads to improvement of the qualitative and productive features.

Keywords: *bio-fortification, Fe-EDTA u Zn-EDTA,*

Introduction

Bio-fortification is a process with it is help increases concentration on micro-nutrients like Zn, Fe, Mg, and etc. in agriculture products –especially in wheat cultures. There are two kinds:
-Agronomic bio-fortification, includes using of fertilities with higher concentrations of Zn and other micro-nutrients.
- Genetic bio-fortification uses special raised cultures that will be capable to accumulate more Zn and other micronutrients from the soil in nutritional parts of the grains (Ryan, 2010)
There are more evidence showing that the combination of foliar or soil+foliar fertilization with Zn/Fe under field conditions is very practical and efficient way to increase the uptake and accumulation of Zn in wheat grain. With the increase of the percentage of Zn in the seeds being improved yield, resistance to abiotic factors, resistance to diseases and germination of the seed. Agronomy bio-fortification is essential to maintain the enough and the available amount of Zn in soil and providing adequate transportation to seed during the reproductive stages of plant growth.

Also it is necessary for optimizing and providing conditions for the success of genetic bio-fortification. Better plant nutrition in terms of micronutrients depends on many factors in the soil (Abbas 2012). The amount of nutrients which accumulate in plants, fruits or seeds mainly depends on the availability of each element in the soil and the ability of plants to accumulate those one and trans-locate nutrients to the appropriate parts.

One of the ways to increase the content of micronutrients in a plant grains to provide the micronutrients in highly soluble efficient form throw the soil or throw foliar application. According to (Wiedemuth et al., 2005) Fe fertilizer can be applied to inorganic form (such $FeSO_4$) or chelated form (such as Fe-EDTA, Fe-EDDHA or Fe-citrate).

This research was conducted to investigate the impact of the use of chelating Fe and Zn fertilizers on the quality of qualitative and productive qualities of soft wheat variety Radika

Material and methods

Plant material

The variety of the type "Radika" soft wheat (Triticum aestivum), was used as a plant material in this research.

Location and setting experiment

On the lands belonging to the Agricultural Institute in Skopje (Macedonia), in the testing economy "Dolno Lisiche", during the production year 2012/2013, a test was placed according to the method of accidental bloc system, with 7 variants, three time repeated, while the testing parcel being of 30 m² size. The distance between the variants and the repeating procedures was 50 cm. The procession of the parcel was a standard one by bringing the plowed layer in condition of normal sowing. The sowing was conducted manually with 600-650 life-able grain/m².

Application of fertilizer

The following variants are included in the test of this research:

- Fe application in soil (variant 1)
- Fe application in soil and foliar (variant 2)
- Fe foliar application (variant 3)
- Control – without fertilizing (variant 4)
- Zn application in soil (variant 5)
- Zn application in soil and foliar (variant 6)
- Zn foliar application (variant 7)

Basic characteristics of the fertilizers

Yara Vera™ Amidas is a highly qualitative granular fertilizer which contains nitrogen and sulfur. The nitrogen is mostly available in the form of urea. The sulfur is available in the form of sulfate and is totally water-soluble. The ratio between the nitrogen and sulfur is from 7 towards 1.Nutrichem folifer-Fe EDTA chelate product, which is used for a foliar nutrition of the plants.Yara Vita Rexolin is a product for prevention of a shortage of zinc formulated in the form of EDTA chelate. Containing 15% and 148 grams of zinc per kilogram a product can be used for soil or foliar application.

Period of application of fertilizer

The nutrition of the wheat is conducted in the following stages of development:

1. Germination stage-fertilizing with NPK(9:15:15) 200 (kg/h) soil at the variants 1,2,3,4,5,6 and 7. Fe EDTA 10 (kg/h) soil apllication with the variants 1 and 2. Zn EDTA 20 (kg/h) soil apllication with the variants 5 and 6.

2.Tillering stage- applied Yara Vera Amidas 160 (kg/h) soil at the variants 1,2,3,4,5,6 and7.

3. Booting stage- Yara Vera Amidas 100 (kg/h) soil at the variants 1,2,3,4,5,6 and 7.
4. Booting stage- Fe EDTA 1 (kg/h) foliar at the variants 2 and 3. Zn EDTA 1kg/h(0.1%) foliar at the variants 6 and 7
5. Heading and flowering- Fe EDTA 1(kg/h) foliar at the variants 2 and 3.Zn EDTA 1kg/h(0,1%) foliar at the variants 6 and 7
6. Flowering Fe EDTA 1 (kg/h) foliar at the variants 2 and 3. Zn EDTA 1kg/h(0,1%) foliar at the variants 6 and 7
The foliar fertilizing was conducted by a dorsal sprinkler, with 3 liters of solution (mixture) with the variants 2 and 3 at the early morning hours.
Biometric methods for analysis of the morphologic and producing characteristics
The examinations of the morphologic and producing characteristics were conducted by biometric measuring at the end of the vegetation, following the collection of material in the laboratory.
From morphological characteristics analyzed: stem height, ear`s length. Measuring the height of the main stem to class (n=20). Before the sowing, a material of 1m² is taken from each parcel for laboratory analyses. The laboratory analyzed the following product characteristics: number of little ears, grains number, grains weight, ear`s weight, weight of 1000 grain and hectoliter mass.
Methods of soil analysis
Before placing the test, soil tests were taken with a view to precisely determining the soil`s fertility. The tests were made (i.e. udertaken) from several places in the depth from 0 up to 30 cm, according to chess method for small parcels (Menkinoska M. 2014).
Statistical analysis of data
The statistical procession of the data was conducted by means of the statistic-analytical program SPSS and Statistika 8.0. The statistical analysis includes ANOVA for testing the equality of average values of the examined parameters, LDS post hoc analysis for the significance of the obtained differences, as well as modeling of generalized linear models (GLM). As a level of significance is taken 0,05, that is, the values of the test-statistics are considered as significant of $p<0,05$.

Results and discussion

Characteristics of the Experimental Fields

Weather characteristics and soil conditions

During the tested year, while the period from the sowing to sprouting, there was a sufficient quantity of rainfalls and an optimal temperature for the wheat`s sprouting (Menkinoska M. 2014). The contents of the soluble iron in the examined soil test is 13.54 ppm and belongs to the soils with a low level of Fe (Menkinoska M. 2014). The content of soluble zinc in the examined soil test is 1.62 ppm and belongs to soil with low level of Zn.

Morphologic and producing characteristics of wheat

The analysis of variance for comparing the average values (Tab.1) showed the existence of significant differences between variants in the morphological characteristics only in number of little ears. According Post hoc analysis (Tab.2) is supplied that the significance of the test due to significant differences in number of little ears between variant 1 and 3 (LSD 0.8 $p = 0.00$), variant 1 and 5 (LSD = 1.3 $p = 0.00$) and variant 1 and 7 (LSD 0.7 $p = 0.00$). The addition of Fe soil fertilizer showed better results in number of little ears compared to the control, soil Zn and Zn soil + foliar. LSD showed difference between variants 2 and 5 (LSD = -0.8 $p = 0.01$), 4 and 5 (LSD = -0.7 $p = 0.02$) and 5 and 6 (LSD = -0.9 $p = 0.00$), which means that application of soil+foliar Fe, control and Zn soil + foliar fertilizer has a better effect on the

number of little ears compared with the addition of Zn soil. According to (Manasievska, S. 2002) the number of little ears depends on the length of class spindle, also from the number of fertile on the class spindle , in which in our research we found that of all varieties to increase the of number of little ears leads application of Fe EDTA in the soil, while the addition of Zn soil did not show the effect over the tested perimeter.

Mass of 100 grains and hector-liter weight

The test parameter is especially important because according to (Ilieva V. et al., 2011) mass of 1000 grains depends on the size of the grain, it is fullness and healthy condition.

Therefore often mass of 1000 grains also an indicator of the size of the seed. The seed with greater mass usually has better developed stub and gives better developed and more resistant plants in the early stages of development. If the seed is larger, that has more expressed life ability-capacity. The larger seed more uniformly raises, the plants more uniformly grow and developed, that brings to better yield of surface area. During the research we found un-significant higher values for the mass on 1000 grains to the variance 1 for 3.45%, variance 2 for 8.21%, variance 6 for 2.5 % and variance 7 for 0.99 %, while the variance 3 for 3.13% and 5 for 0.04% lower values in comparison with the variance 4. The largest absolute mass of the grain of wheat dependable of the application of fertilizer showed variance 2 for 8.21% compared to the variance 4. The mass of 1000 grains it is important perameter in the bakery industry, because it is found that the larger grain, with more compact endosperm , with higher percentage of clearness and thinner wrapper gives more amount of flour by unit weight on the seed (Manasievska S., 2002). Also according Draganavic S., Maksimovic, L. (2000) the biggest difference in absolute mass shows up between varieties of soft wheat, which presents genetic characteristic. From the literature reviewed we found the data from the research of G. Abbas et al., 2009, which are not in accordance with our results, conducted by the application of N, P and K in doses of 150: 100: 60 kg N: P_2O_5: K_2O ha-1 and the usage of $FeSO_4$ with doses of 0, 4, 8, 12 and 16 kg/h, the time of sowing. The results showed that the implementation on NPK fertilizer brings to significant increase of the height of the plants, length of the class, number of grains in main class, yield and mass on 1000 grains in comparison with the control, (within NPK). The best results are obtained when applied $FeSO_4$ a dose of 12 kg/h with the recommended dose of NPK.

Similar results have been presented and the authors Pahlavan-Rad, M. R .; Pessarakli, M.2009 which found the biggest mass 1000 grains with usage of 80kg/h ZnSO4 and foliar application of Fe. Usage of 80kg/h $ZnSO_4$, combined with foliar application of Mn significantly increases the yield. From our results and from reviewed literature we concluded that, the mass of 1000 grains though it represents a genetic characteristic depends also from the kind of usage fertilizer from it is form, dose and the time of application.

Table3. Physical features of the seed of the varieties Radika

Variance	Hectoliter mass		Weight of 1000 grains	
	(kg/hl)	Index of the control	(g)	Index of the control
1	75,85	101,06	48,80	103,45
2	75,45	100,53	51,03	108,21
3	75,25	100,27	45,68	96,87
4	75,05	100,00	47,16	100,00
5	75,85	101,06	47,14	99,96
6	75,86	101,07	48,32	102,50
7	76,05	101,33	47,63	100,99

As for the hectoliter mass of variance 1 for 1.06 % , variance 2 for 0.53 %, variance3 for 0.27 %, variance 5 for 1.06 %, variance 6 for 1.07 and variance 7 for 1.33% all of them have non-significant higher values that are approximately close in relation of the variance 4. According the data in the Table3 the largest volume on the grain of the tested variance depends of the application of the fertilizer, has the variance 4. The most suitable variance for getting of the grains with large hectoliter mass are the variance 1, 5, 6 and 7.

The high hectoliter mass point on minor and round grains with cuddly surface area, compact endosperm and small content of moisture, also low hectoliter mass give the large and oblong grains with smooth surface and larger content of moisture. Our results are close to the results with Ivanoski, M. and Stanoev, V (2006), which found that the foliar fertilizer Kristalon ™ Special with (N:P:K:Mg 18:18:18:3) and micro elements Br (0.025%), Cu (0.01%), Fe (0.07%), Mn (0.04%), Mo (0.004%) and Zn (0.025%) applied at the time with the vegetation on five yields of soft wheat leads to biggest increasing of the mass of 100 grains of the yields Radika in comparison with the control, while the biggest increasing of hectoliter mass showed the yield Treska in the two variance in relation with the control.

Conclusion

Based on the results obtained may be adopted the following conclusions:

With agronomic bio-fortification throw soil, foliar and soil-foliar application with Zinc and Fe chelating fertilizers it is found that:

- Existence on significant differences between variance in morphologic characteristics depends of the kind of application of the fertilizer it is concluded only in Number of little ears.
- It was found the highest value of the mass of 1000 grains for wheat gained with the application of Fe soil-foliar.
- The largest volume of the grain from the tested variance dependable has the variance 7 in relation to the variance 4.

In this case of study, it is concluded that , the agronomic bio-fortification with Zinc and Iron leads to improvement of the qualitative and productive features on soft yield radika.

Abstract

The objective of this study was to evaluate stability of the flower head yield in different chamomile varieties (Banatska, Bona, Novbona and Mina) using the model which provides not only regression coefficient *bi*, but also a second stability parameter - standard deviation from regression S^2di. Significant differences for the yield were determined among studied genotypes. Variety Mina expressed notably higher yield in comparison to the others. Significant differences in F-test were obtained on experimental locations. On locality in StaraPazova all experimental varieties achieved significantly higher yields.Analysis of stability parameters *bi* and S^2di showed that varieties have different levels of stability. According to the method applied, stabile genotype is achieved with $bi = 1$, and it is desirable that S^2di tends towards zero. In relation to the parameter *bi*, Banatska is the most while. Bona is the least stable variety. Variety Bona grows better in favorable cultivating conditions, while Mina variety is better adapted to unfavorable growing conditions. This implies that appropriate environmental conditions are crucial for growing these varieties in large extent.

Key words: *chamomile, flower head yield, stability, variety*

Introduction

Productive traits of chamomile depend on the genetic potential of the variety, while stability depends on the variety response to environmental conditions which is highly dependent on its genetic composition. As the response of a variety varies over different growing conditions there is an interaction between the variety and the environment. It is believed that the genotype with the stable yield has a minimal interaction with the environment and respond esfavourably to the improvement of the environmental conditions (Dražić et al.,2007). Several procedures for the determination of stability parameters and their application in the analysis of breeding material of different cultivated plants have been developed. One of the first studies based on the application of the regression analysis was performed by Yates and Cochran (1938), and then by Finlay and Wilkinson (1963). Plaisted and Peterson (1959) developed a procedure that provided the evaluation of the proportion of the each genotype x environment interaction in the total variance of the genotype x environment interaction.The model coined by Yates and Cochran was modified by Eberhart and Russell (1966). Their model is based on the calculation of the linear regression (*bi*) for each genotype in relation to the environmental conditions, as well as, the deviation from regression S^2di. Afterwards, similar other developed methods were also based on the regression analysis (Perkins and Jinks, 1968, Freeman and Perkins, 1971).

The objective of this study was to evaluate stabilities of the flower head yield of different varieties, with the application of the model, which provides not only regression coefficient *bi*, but also a second parameter of stability, standard deviation from regression S^2di (Eberhart and Russell, 1966).

Material and methods

Two local varieties, Banatska and Mina, as well as two varieties, Bona and Novbona, introduced from Slovakia were used in the trial (Oravec, 1996., Salamon, 1998., Dražić and Dražić, 2011). The previous studies carried out with these varieties showed the differences between means and their variations (Dražić, 2000).The experiments were conducted in 3 locations in Serbia: Nova Pazova (location 1), Pančevo (location 2) and Kučevo (location 3). According to the morphological and genetic characteristic, the soil at the experiment plot in Nova Pazova municipality belongs to chernozem, Kučevo to cambisols, while the one in Pančevo belongs to marsh soil. Average annual temperatures of these locations were approximately 12^{o}C. Due precipitation in Nova Pazova (620-800 mm) was higher when compared to locations in Pančevo (500-550 mm) and Kučevo (550-600 mm). Based on the analysis of the agroecological conditions, we can state that the conditions in Nova Pazova were the most favourable.The four-replication trial was set up according to the randomized block design. The elementary plot size was 4m^2. Sowing was done in September, while harvest was performed in the succeeding year.Based on the following mathematical model developed by Eberhart and Russell (1966), the values of stability parameters (*bi*) for each genotype and the deviation from the regression line (S^2di) were used to estimate stability of yields:

$Yij = \mu i + biIj + \delta ij$, where:

Yij - mean of genotypes *i* at the location *j*

μi - grand mean of genotypes *i* at all locations

bi - regression coefficient of genotypes *i* over locations

Ij - environmental index (ecological index)

δij - deviation from regression

The first stability parameter is a standardised regression coefficient (*bi*), which is standardised in relation to 1: $bi = \Sigma YijIj : \Sigma I^2j$

Statistical significance of the regression coefficient (*bi*) is estimated by the group F-test or the individual t-test.Another stability parameter is the standard deviation from regression that is estimated by the definition: $S^2di = (\Sigma \delta ij : (n-2)) - Se : r$, where:*Se* - error mean squares from the analysis of variance, *n* - number of locations and, *r* - number of replications.

Results and discussion

Varieties responded differently to the conditions of production, so the mean value of the yield varied over locations. The average yield ranged from 595 kg/ha (variety Bona) to 839 kg/ha (variety Mina). The varieties Banatska and Novbona had almost equal yields that were considerably lower than the variety Mina but higher than the yield recorded for the variety Bona. The coefficient of variation indicates different responses of genotypes to the environmental conditions (CV=4.8%-Mina and 16.7%-Bona). A relatively higher coefficient of variation in the variety Bona implies a significant effect of the environment. This effect was reflected upon the variation of yields over locations (489-700 kg/ha), Table 1. This points out that adequate ecological conditions for large scale production of these varieties have to be provided.

Table 1. Flower head yield (kg ha^{-1})

N°	Variety	Locations			Average	Rank	CV (%)
		1	2	3			
1.	Banatska	789	751	670	737	2	6.7
2.	Bona	700	595	489	595	4	16.7
3.	Novbona	793	735	676	735	3	6.5
4.	Mina	887	839	790	839	1	4.8
	Average	793	730	656	727	-	-
	$LSD_{0.05}$	78					
	$LSD_{0.01}$	118					

It is quite common that better yielding genotypes also respond better to environmental conditions and vice versa (Eberhart and Russell, 1969; Lamky and Hallauer, 1984; Živanović, 1993), which was also confirmed by these studies (variety Mina, Table 1). Petrović et al. (1988) determined that the yield dependence and the values of regression coefficient could be positive and negative, as was also established in these studies (Table 3). These authors emphasise that genotypes, improved by selection, have not only better combining abilities for the yield, but also respond better to favourable growing conditions than the initial populations.

Table 2. Analysis of variance

Source of variation	d.f.	MS
		Flower head yield
Genotype (G)	3	30.206**
Location (L)	2	20.192**
G x L	6	0.152
Total	11	-

**, significant at 0.01 probability level

Considerable differences among locations were established with the F-test (Table 2).The most and the least favourable location for cultivation were Nova Pazova (location 1) and Kučevo(location 3), respectively. The highest average yield of flower heads for all varieties was recorded in Nova Pazova(793 kg/ha). It is important to emphasise that the variety Mina had the highest yield in all three locations (Table 1).

Table 3. Stability parameters

Variety	Flower head yield			
	bi	Rank	S^2di	Rank
Banatska	0.8800	1	0.0897	3
Bona	1.5453	4	-0.0489	1
Novbona	0.8570	2	-0.0817	2
Mina	0.7176	3	0.1172	4
Se_{bi}	0.8912			

The analysis of stability parameters, *bi* and S^2di, indicated that different varieties showed different stability levels in yield of flower head (Table 3.). According to this method, a stable genotype has *bi*=1 and it is desirable that S^2di does not deviate from zero. Based on the parameter

bi the most stable yield was detected in the variety Banatska (*bi*=0.8800). This was expected because the variety Banatska is an autochthonous variety that has been produced for more than a decade. It is highly adaptable to different environmental conditions. The least stable was Bona (*bi*=1.5453). It better responded to various environmental conditions, while the variety Mina better responded to unfavourable environmental conditions (*bi*=0.7176). To support this it may be added that the highest yields were recorded in the variety Mina (Table 1.). According to the other stability parameter S^2di, the most stable was the variety Bona while the least stable was the variety Mina (0.1172). Values of *bi* stability parameter were insignificant, probably because of a small number of tested genotypes, so the valueof Se_{bi} was high (0.8912), Table 3.

Conclusion

Significant differences in yields were observed in studied genotypes. A significantly higher yield was recorded in the variety Mina than in remaining varieties. Significant differences for locations were established by the F-test. Significantly higher yields for all varieties observed in the trial were recorded in Nova Pazova. The analysis of stability parameters, *bi* and S^2di,indicate that these varieties were characterised with different stability. Based on the parameter *bi* the moststable variety was Banatska. On the other hand the least stable was the variety Bona, which better responded to more favourable conditions. The variety Mina better responded to unfavourable production conditions. The obtained results indicate that is a need for further studies of the relationship between genotypes and environmental conditions, for the purpose of determining the most favorable region for cultivating chamomile.

Abstract

During the two-year period the studies were carried out on the effect of increasing doses of nitrogen on the productive elements of the ears with different varieties of spring malting barley. The experiment was set on a farm in the vicinity of Krusevac (village Globoder). The experiment involved the following factors: fertilizing with increasing nitrogen application rates N_0, N_{60}, N_{80}, N_{100}. On the variants with nitrogen rate also used were 90 kg ha^{-1} P_2O_5 and K_2O and varieties Kraguj, Dunavac, Uros and Slavko. The experiment was set up in four replications according to a split-plot method with random assignment of treatments. The basic plot size was 5.0 m^2. The aim of this research was to determine the role of mineral nitrogen nutrition on productive elements of ears with different varieties of spring malting barley depending on the amount of nitrogen. All in order to contribute to increased yield with varieties of spring malting barley based on better understanding of importance of nitrogen in the production process. The obtained results showed that the use of nitrogen had a positive effect on the productive elements of the ears in all variants and in all varieties. By applying increasing doses of nitrogen the maximum weight of grains per ear and the number of grains per spike at the variant of fertilisation with 80 kg ha^{-1} N were determined. The ear length was achieved at the highest dose of nitrogen of 100 kg ha^{-1}. The different reaction of the tested varieties to the use of mineral fertilizers is the result of their varietal characteristics.

Keywords: *spring malting barley, nitrogen, fertilization, variety, productive characteristics*.

Introduction

The quality of malting barley to a significant degree also depends on the applied agrotechnics. However, of all the agricultural measures, the most significant impact has fertilizing using mineral fertilizers, both from the standpoint of quantity and from the standpoint of ratios of assimilatives. Nitrogen has a special impact on the quality of barley (Knežević, 2005). The optimum amount of nitrogen that is applied in barley nutrition should be uniform (Veigh and Rajkai, 2006; Paunović et al., 2009). In Novi Sad program of malting barley refining the increased number of grains per ear is one of the important ways to increase yield (Pržulj and Momčilović, 1995). After the formation of the number of ears and number of grains per ear during the vegetative phase, the yield becomes largely dependent on grain weight, which is the function of the intensity and duration of grain filling. Grain filling rate represents an average increase of grain weight during the filling period, while grain filling period is the period from flowering to physiological maturity. Physiological maturity represents the moment at the end of the period of grain filling, after which there is no significant increase in dry weight of grains

(Wiegand and Culler, 1981). It is preferable that the malting barley varieties have a low and firm stem with the coefficient of the tillering productivity of 2 to 3. It is known that barley tilters the most of all the right grains and has an average of 4 to 5 stems and the number of stems may vary up to a few tens. Malešević and Starčević (1992) and Paunović et al. (2007a) state that in barley of the sparse structure prolonged tillering is observed, with the coefficient of tillering that can be extended from 4 to 6. By specifying the appropriate sowing density and mineral nutrition plants are enabled to establish the optimal number of ears, which will provide high yield (Paunović et al. 2007b). In addition to the direct effect of nitrogen nutrition on productive characteristics of spring malting barley, nitrogen often acts indirectly through the sinking of plants, which results in a reduction in yield. The aim of this study was to determine the optimum amounts of nitrogen that provide high yield and good quality of productive traits of spring malting barley in agroecological conditions of Krusevac (Serbia).

Material and methods

Preceding crop to barley in the experiment was potato, in the first year, and corn in the second year. The main soil cultivation was carried out during the autumn of last year, at 25 cm depth. Pre-sowing soil preparation was performed directly before sowing. Thereat applied was the standard acgrotechnics. The following fertilizers were used: triple superphosphate (45% P_2O_5) and potassium salt (40% K_2O). Of nitrogen fertilizers calcium ammonium nitrate (27%) was applied. The total amount of phosphorus and potassium fertilizers and ½ of nitrogen fertilizer was applied in pre-sowing soil preparation. The rest of the nitrogen fertilizer was used as the top dressing. There were two top dressings (each with half of the remainder of nitrogen fertilizer), first in the tillering stage, and the second in the beginning of plants growing into a stem. In the first year of the trial the sowing was done in the second half of February, manually in rows with 400 germinating seeds/m^2, while in the second year of the trial the sowing was carried out also manually, in early March in the same seeding density. During the growing season all the changes in crop were tracked and all observations were recorded at the very experimental plot. For the analysis of ear length, number of grains per ear and grain weight in the ear, samples were taken from each plot by plucking the plants. The obtained data were processed using the method of variance analysis and correlation analysis.

Results and discussion

Ear length

The results in the first year of the trial showed that the average maximum ear length had the variety Uroš 11.7 cm, which was also the longest average ear length in the period studied, and the shortest average ear length had variety Kraguj 9.7 cm. Under the influence of fertilization the largest increase in the ear length showed the variety Uroš. Considering the effect of nitrogen on the ear length it was found that there were highly significant differences in the ear length in the first year of testing, between control and fertilization variants with 60, 80 and 100 kg ha^{-1} (Table 1). The differences in the ear length between increasing doses of nitrogen were very significant.

The results in the second year of the study showed that there was a significant difference in the ear length between the varieties both by years of testing and by the applied dosages of fertilizer. The average maximum ear length had the variety Uroš 9.5 cm, and the average minimum ear length had the variety Kraguj 7.8 cm (Table 2).

A two-year study showed that with increasing nitrogen rate the barley ear length increased. The maximum ear length was in the variety Uroš (10.5 cm), and the minimum in variety Kraguj (8.9 cm), where we can see a clear difference in ear length between the selected varieties of spring

barley tested. Based on these data, we can conclude that the average ear length in the two-year period for the tested varieties was 9.75 cm. The ear length in all tested varieties was significantly dependent on increasing nitrogen rates.

The number of grain per ear

The final number of grains per ear depends on the maximum number of spikelets that are germed in the ear and the percentage of survival of these spikelets. Spikelets develop in the period from developing flowers to awns emergence, and surviving of spikelets is in the period from emergence of primordia awns to flowering, which actually corresponds to the period of tillering (Pržulj et al., 2010). In the first year of the trial the results show that fertilization influences the increase in the number of grains per ear up to increasing nitrogen rates of 80 $kgha^{-1}$ and then with increasing doses of nitrogen up to 100 $kgha^{-1}$ the number of grains in the ear drops, but only slightly. The varieties statistically differ significantly and the increasing dose of nitrogen has a statistically significant effect. The average number of grains per ear in this year amounted to 33.05 (Table 2).

During the second year of study we conclude that the variety Uroš, which had the highest average number of grains per ear significantly differed from all other varieties. The number of grains per ear in the variety Dunavac was on average higher than in the variety Kraguj and Slavko, and at the level of variety Uroš. Based on the obtained results (Table 2) we note that the average number of grains per ear for all tested varieties and all variants of fertilizing in the two-year study period was 30.93. In Novi Sad malting barley refining programs, the increased number of grains per ear is one of the important ways of increasing yield (Pržulj and Momčilović, 1995). On average for the two-year period the variety Uroš (32.62) had a significantly higher number of grains per ear in relation to all the other, the variety Dunavac higher than the variety Kraguj and Slavko. The number of grain in the ear depends on the nitrogen, conditions in the embryonic period, ear differentiation and flowering. The number of grains per ear, as well as numerous other elements of the ear structure, is the varietal characteristics, but it also depends on other factors, including nitrogen nutrition (Lazović et al., 1997).

The weight of grains in ear

The results in 2013 show that the tested varieties differed statistically significantly and that the increasing dose of nitrogen had a statistically significant effect on grain weight per ear. Also, the

effect of mineral nutrition increased to the increasing nitrogen dose of 80 kgha^{-1} and then decreases with increasing nitrogen dose of 100 kgha^{-1}. In the studies by Pecio and Bichonski (2006) a significant reduction in grain weight with increasing doses of nitrogen was determined. Compared to the control variant the increasing nitrogen dose showed a larger mass of grains per ear. Analyzing the average mass of grain per ear among the tested varieties, we conclude that the variety Uroš had a larger grain weight per ear (1.56 g) compared to all other varieties; the variety Kraguj had a lower grain weight per ear (1.35 g) in relation to other varieties.

A - cultivar; B - rate of fertilizer; C - year of study.

In the second year of the study phenotypic differences among the cultivars significantly affect this property, while the influence of fertilization is manifested to a lesser extent. The increase of grain weight at variants of fertilization with increasing nitrogen rate up to 80 kgha^{-1} was observed, and then it decreased and the grain weight was the smallest on the variants with the highest nitrogen rate of 100 kgha^{-1}. Our results are consistent with previous findings (Campbell et al., 1993; Cantero-Martinez et al., 2003; Malecka and Blecharczyk, 2008). The two-year study showed that on average for all varieties and fertilization variants, the mass of grains in ear in the second year of the trial (1.18 g) was significantly lower than in the first year of the trial (1.46 g). When examining the mass of grains per ear in barley during the two-year period, we noticed that there were statistical differences and that there was the statistical significance of the effect of increased doses of nitrogen on this property, including the control. The average weight of grain in the ear for all the tested varieties was 1.33 g (Table 3). Nitrogen topdressing affected the increase in grain weight per ear. Absolute variation in grain weight per ear was 0.92 g (of the variety Kraguj in 2014) to 1.68g (the variety Uroš in 2013). Lalić and Rakočević (1978) point out that analogously to the number of grains per ear, the grain weight per ear behaves according to the same laws. On average weight of grains per ear ranged depending on variant nutrition from 0.82 to 0.96 g. Grain weight per ear was the lowest in the unfertilized plots, and by using NPK and especially by increasing the quantity of the fertilizer, the grain weight per ear increased, and the differences were statistically highly significant.

Conclusion

The results show that the use of nitrogen had a positive effect on the productive elements of the spring malting barley ears in all variants of fertilization and in all varieties. By applying increasing doses of nitrogen the maximum weight of grains per ear and number of grains per ear at nitrogen rate of 80 kg ha^{-1} were determined. The maximum ear length was achieved using the highest nitrogen rate of 100 kg ha^{-1}. The different reaction of tested varieties to the use of mineral fertilizers is the result of their varietal characteristics.

Abstract

Adequate and balanced nutrition is important key for a healthy life. Needs for food and protein increase due to drastic increases in the world population and decreased resources. The world protein needs are supplied from plant sources, about 70%. Peas (*Pisum sativum* L.) are one of the important sources of protein. This study was conducted to evaluate changing of crude protein contents in different part of pea during various growth stages at the experimental area of Faculty of Agriculture, Ondokuz Mayis University, Samsun (Turkey). We monitor crude protein contents at vegetative stage, 50% flowering stage, full bloom stage, seed filling stage and at seed maturity period in different parts of the plants such as leaves, stem, flowers, and in matured seeds. Crude protein contents of different plant parts showed **broad range** of **variation due to growth stages**. Crude protein contents of leaves, stem flowers and seeds were ranged between 8.78-24.72%, 3.27-11.13%, 38.97-40.80% and 21.99-25.76%, respectively. In conclusion, the highest crude protein contents were found in flowers, According to study results, overall protein content has gradually decreased with the growing stages. Leaves had the largest range for crude protein content among the plant parts. Also different parts are harvested according to their usage during the production, and consumption regarding appropriate development can be determined.

Key Words: *Crude protein, Pea, Growth stages*

Introduction

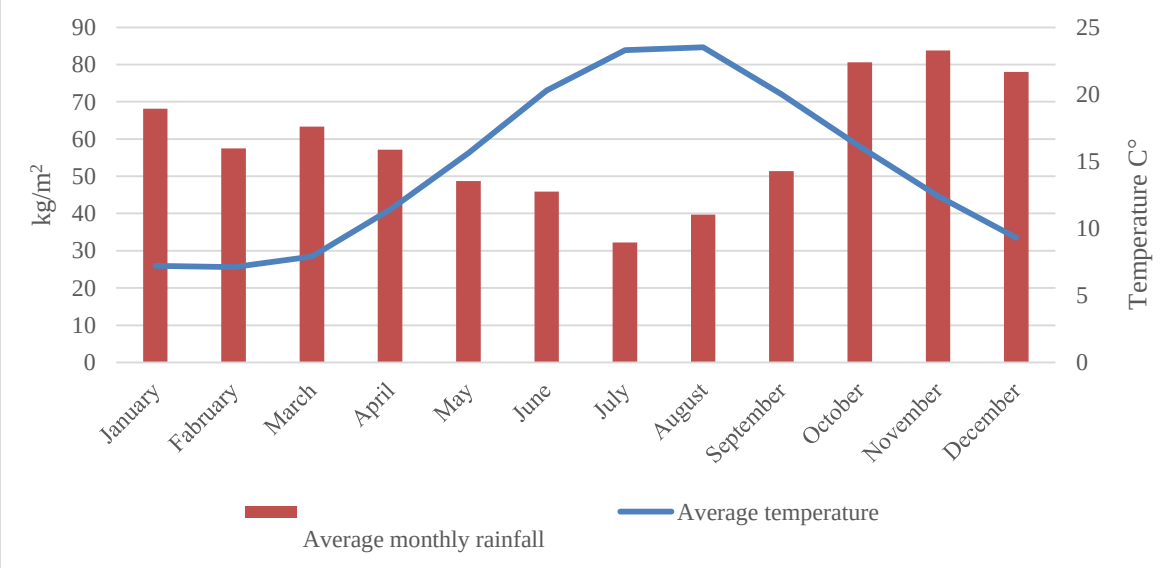
Legumes are cultivated throughout the world. Species are used that are adapted to climates ranging from temperate to tropical, humid to arid. Edible legumes, with the high amount and quality vegetable protein source thereof, differ from other groups of plants. Edible legumes are quite rich in B vitamins and contain a large amount of dietary fiber (18% in peas, lentils and chickpeas, and 28% in beans) (Pekşen and Artık, 2005). Legumes are rich sources of protein and the essential amino acid. The proteins contained in legumes are similar to proteins of animal origin in terms of essential amino acids (leucine, isoleucine, lycine, methionine, threonine, tryptophane, valine) (Çiftçi, 2004). Provision of adequate proteins of animal origin is difficult and expensive. An alternative for improving nutritional status of the people is to supplement the diet with plant proteins. Attention, therefore, has to be directed to the nutritional evaluation of proteins from plant species. Legumes (poor man's meat) play an important role in human nutrition since they are rich sources of protein, calories, certain minerals and vitamins (Deshpande, 1992). Adequate and balanced nutrition are essential for people in order that they can continue their lives in a healthy way. There is a big problem of insufficient and unbalanced nutrition in addition to the hunger problem in the world. Production has to be increased to reduce the number of malnourished population while production of vegetable and animal proteins with high protein content has also to be increased in order to reduce the number of populations having

unbalanced nutrition. This study aims to detect the protein changes at different developmental periods of peas and determine the most appropriate parts and development period of the plant.

Material and Methods

Soil samples received from trial fields of the Faculty of Agriculture, Ondokuz Mayıs University (Turkey), from a depth of 0-20 cm to determine physical and chemical properties thereof showed that the soil had an argillaceous structure, its salt content was in medium level (0.359 %), slightly acidic (pH: 5.88) and less calcareous (0.38 %). Phosphorus and potassium contents and organic substance of the soil of the trial field were determined as 4 kg/ha, 45 kg/da and 2.88 %, respectively. Samsun province located in the coastal region of Central Black Sea is mild and rainy in winters and hot and humid in summer seasons. The temperature and precipitation value of the year (2013), in which the experiment was conducted, is provided in Table 1.

Table 1. Temperature and rainfall monthly



Rondo, which is registered pea (*Pisum sativum* L.) variety obtained from the Field Crops Central Research Institute, was cultivated as genetic material in this study. It has large adaptation and so can be grown almost anywhere in Turkey. It also has strong development and its pods are big and suitable for fresh consumption with high yield. The study was conducted in randomized plot experimental design in 2013. The design had 4 parcels contained 12 rows in each parcel. Inter-row and intra-row spacing were 40 cm and 10 cm, respectively. Plants were harvested in 5 different development periods as vegetative period (I), 50 % flowering period (II), full blooming period(III), grain filling period (IV) and maturity period (V). 40 individual plants were harvested for each period. Harvested plant samples were firstly dried and then these samples were grinded for analysis of crude protein. Amount of crude protein was measured in grinded samples. Crude protein content was determined by Dumas method. Principle of Dumas Method is measurement of nitrogen which passes to gas phase after combustion. The samples were flared with pure oxygen by combusting in 800 to 950°C. The residual gases as a result of combustion are kept in the filters and then eliminated and when oxygen is removed on hot copper, NOx is converted into N_2. In this way, quantitative analysis is performed by measuring nitrogen in

helium with thermal conductivity. Protein amount of the samples was determined by multiplying obtained nitrogen amount with protein conversion factor (6.25).

Results and Discussion

While protein contents of leaves and stem were analyzed in vegetative period (I) sampling, protein contents of leaves, flowers and the stem were determined in 50 % flowering period (II) and full blooming period (III). During the grain filling period (IV), protein content of the grains were also determined in addition to leaves, stem and flowers. Finally, protein contents of all plant parts were determined in maturity period (V). The results of protein contents were given in Figure 1., Figure 2. and Figure 3.

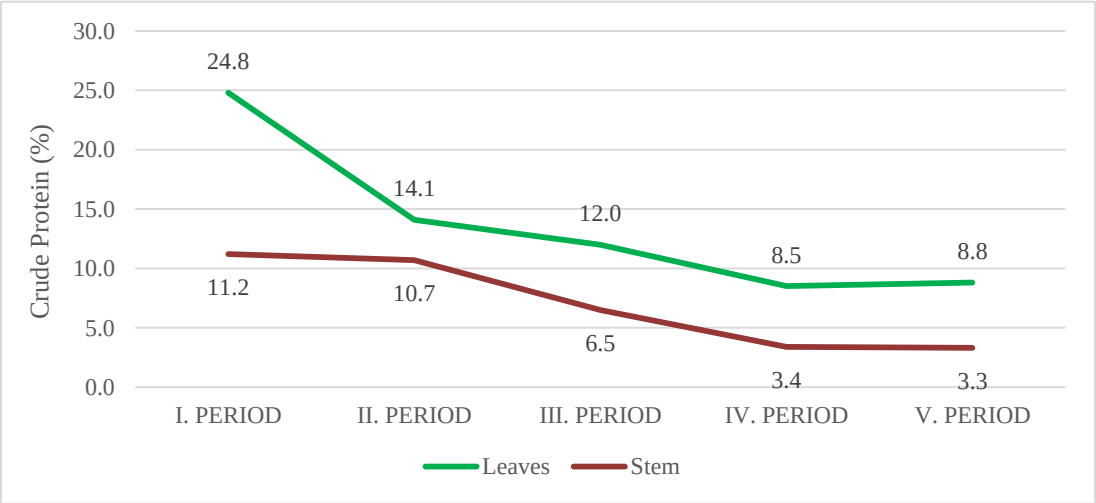


Figure 1. According to different development periods in the leaves and stem of peas (*Pisum sativum* L.) crude protein (%)

Crude protein ratio shows decrease from vegetative period (24.8 %) to maturity period (8.8 %) (Figure 1.). These results also show similarity with the results of protein ratio of the stem. While crude protein ratio was found as 11.2 % in vegetative period, this ratio was 3.3 % in maturity period (Figure 1.). This decrease in protein content among periods is caused by transferring protein from leaves and stem to flowers and grains.

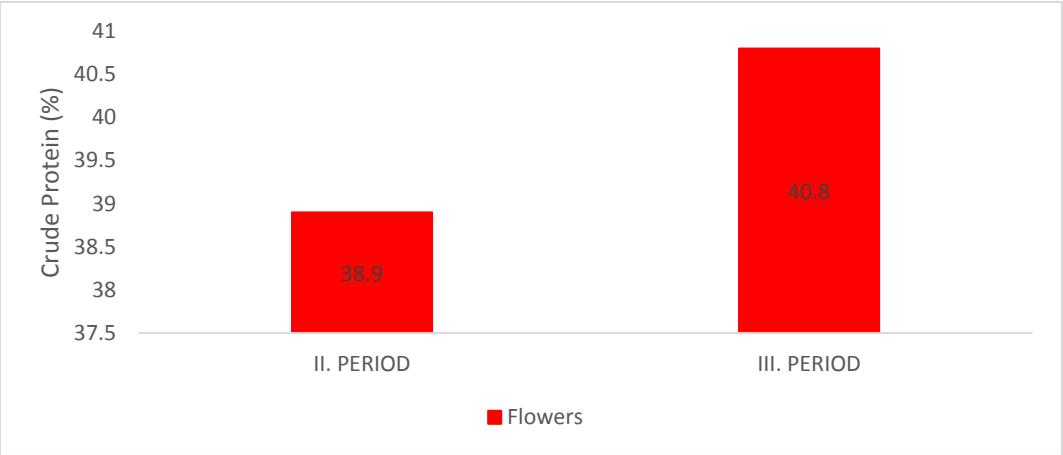

Figure 2. According to different development periods in flowers of peas (*Pisum sativum* L.) crude protein (%)

When we examine Figure 3.2 we see that the pea flowers contain high protein. Crude protein ratio of 50% at blooming period (II) was found to be 38.9%, while it was found to be 40.8%. at fullblooming period (III)

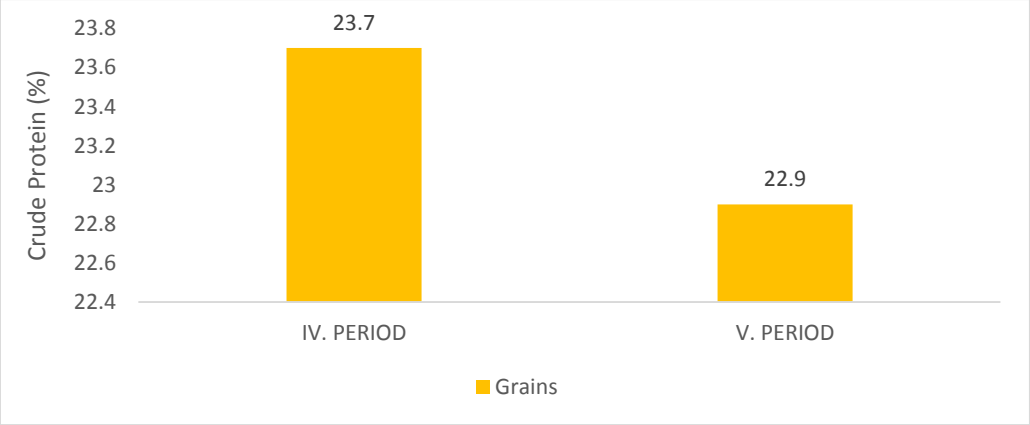

Figure 3. According to different development periods in grains of peas (*Pisum sativum* L.) crude protein (%)

When we examine Figure 3.3 we see that the crude protein in the grains harvested in development periods IV and V was determined as 23.7% and 22.9% respectively considering their development periods. Crude protein content in plants is reduced in the development periods depending on the development of plant growth periods.
Gülümser (1981) has investigated effects of nitrogen fertilization and irrigation on yield and yield components and the protein ratio of the grain on Valor and WR-195 type of peas in ecological conditions of Erzurum. The researcher has been reported that crude protein contents of the grain vary between 32.92% and 28.75% by making some applications on seed varieties. Gülümser et al. (1994), in the study they have carried out to determine the effect of different seeding time of peas on grain yield in ecological conditions of Samsun have found that, protein ratio of different

types seeded in winter vary between 19.75% and 24.01%. Results obtained from the research Gülümser et al. is in parallel with the results of this study.

Pekşen et al., (2002), in the study they have carried out to determine the effect of different inter row spacings on fresh grain yield of pea varieties (Carina, Sprinter and Utrillo) and some other features in conditions of Samsun (20, 30 and 40 cm) they have found the grain protein content as 27.24%, 26.40% and 28.10% at 20, 30 and 40 cm inter row spacings respectively, Protein contents determined in Pekşen's work is seen higher than the ones detected this study. Karayel (2012) has reported in the study he has carried out for identification of local pea genotypes and some agronomic characteristics thereof that protein content of genotypes ranged between 16.3 to 23.6% as a result of the examinations carried thereby.

Seyis (1994), has found in the study he has carried out to determine seed yield of pea varieties and some major features planted in summer in ecological conditions of Samsun that the crude protein content in grain is between 18.72% and 24.37%. The results of the studies are found to be close to the reported results. Ceyhan and Önder (1999) have studied the effects of different seeding times and edible pea varieties on yield and yield quality. Protein content was determined as 22.80% considering the average of different seeding times and edible pea varieties.

Cousin et al., (1985) have reported that dry pea seeds contain 23-33% protein in the study conducted thereby. Grain protein content obtained in studies onducted on peas is consistent with the study results. In studies conducted in regions with different climatic conditions on different genotypes it was reported that content of crude protein in feed peas ranged between 16.9% and 26.3 (Kearl et al., 1979; Açıkgöz and Çelik, 1986; Tekeli and Ateş, 2007; Uzun and Aşık, 2009). Manga et al., (1995) have reported as a result of the study they have made on feed peas that the grains contain crude protein of 20-30%. Soya et al. (1989) have researched the effects of different seeding time and the distance of inter row spacing on grain yield and certain features of the feed peas. In the application made in the studies crude protein content of the grain was 24.22% and 24.05%. in 40 cm and 60 cm inter row spacing respectively. The results of studies on protein content in feed peas are similar to the content of protein content of the edible peas investigated in this study.

Conclusions

Crude protein content of the leaves of peas grown in the study conducted was 34,720%, 14,139 %, 11,996 % 8,496% and 8,776% in Period I, Period II, Period III, Period IV, Period V respectively while crude protein values of the stem, as a result of analyzes performed, was found to be % 11.125 - 10.629 - 6.452 - 3.393 - 3.274 during the same growth periods. The crude protein content found in flower was 38.965% during50% blooming period and 40,798% during fullblooming period. As a result of the examination on grains crude protein content was found as 23,685% in Period IV and 22,978% in Period V.

The highest crude protein content was found as 40.8% in fullblooming period. When outcomes obtained from this study is observed a decrease in general was found in crude protein content of the leaves stems and grains as the growth period continued. Crude protein content of different organs of peas grown in ecological conditions of Samsun in different development periods was determined. Although it varies according to the purpose of usage ,plant selection can be done in terms of crude protein content. Soil structure can be developed by growing in soils which are not rich in organic substances by mixing stems and leaves with high protein content remaining after harvest with soil. If it is desired to consume higher amounts of protein; it is in harvested grain filling period (filling seeds) and made ready for consumption as tins. Production and

consumption of edible legumes which are similar to and cheaper than animal protein sources can be increased in order to eliminate the protein deficiency of developing countries by harvesting different organs during appropriate development periods in line with their usage purpose. The stem and pods of edible legumes remaining from the harvest and post-harvest can be used in animal nutrition since they contain high protein.

HERITABILITY OF YIELD AND YIELD COMPONENTS OF ZAER LENTIL LANDRACE

Nadia BENBRAHIM*, Fatima GABOUN, Mona TAGHOUTI

National Institute of Agricultural Research (INRA), Morocco
*Corresponding author: nadiabenbrahim@gmail.com

Abstract

Lentil (*Lens culinaris* Medik.) is one of the most important food legumes grown in Morocco under rainfall conditions. Zaer is the second lentil production region which is characterized by annual rainfall variability with a high incident of drought and heat mainly during flowering and pod filling season. Lentil is produced from both a landrace and L56 variety on farm conserved. They are distinguishing according to some agro-phenotypic characters. The landrace is threatened by both climate change and L56 variety. Thus, the aim of this study is to evaluate landrace yield variability and to estimate the contribution of ten agronomic traits related to yield for 24 accessions of the landrace. The analysis of recorded agronomic data of both 230 lines collected from farmers' field and 108 lines regenerated in experimental field, showed a high significant effect of genotype, year and genotype x year interaction on yield and yield components. In addition, the path analysis multiple regression methods provide us with the effective components of yield determination. Indeed, the result revealed that plant height, number of pods per peduncle, number of pods per plant, number of seeds per plant and thousands seed weight are the most effective components of the yield which account 50% of yield variation. Number of pods per plant (13%) and thousands seed weight (24%) are among the major components of yield according to their contribution to yield variability. Moreover, their broad sense heritability was high with 0.67 and 0.92 respectively. This information is useful to improve landrace yielding.

Keywords: *Lentil, landrace, yield components, path analysis, heritability*

Introduction

Lentil (*Lens culinaris* Medik.) as a legume plays a significant role in supporting sustainable agriculture worldwide. Legumes provide numerous ecosystem services in soil fertility and functionality and body requirements of dietary protein and essential minerals. Moreover, legumes are also valuable as fodder for livestock, and play an important role in pulse-based cropping systems within the improvement of soil fertility especially nitrogen availability, the enhancement of organic carbon in the soil because of the input of high quality biomass. Thus improve soil structure and increase efficiency of water and storage of nutrients in the soil. The biological nitrogen fixation can supply 50-80% of nitrogen uptake by legumes (Rattan Lal, 2016). The residual of fixed nitrogen contribute to the following cereal crop. In Morocco, lentils are mainly produced by small farmers in rainfall traditional agro-system with low input from landraces (98%). Lentils contribute to food security of vulnerable people and farmers' incomes depending on growing season climate. Landraces are often preferred because of their specific and dynamic adaptation to environment adversity; add to their high food quality (Frankel et al., 1970, Altieri et al., 1987; Almekinders et al., 1994). However, at Zaer region which provides 28% of national lentil production, the increase of drought incidence at the end of growing season led farmer's to

adopt in addition of their landrace an improved variety for its earliness. The landrace is identified by its seed diversity, agronomic potential, nutritional and tasty quality. Farmers identify their landrace as a genetic and a cultural heritage.

The main objective of this study is to strengthen the on-farm conservation of the local base genetic diversity which is threatened by both climate change and the improved variety. This could be achieved through improving yield in Zaer environment constraints. In this context, current study undertakes the evaluation of yield potential and the yield components contribution to yield for 24 accessions of Zaer landrace collected from three locations. Moreover, Path analysis of yield components and the estimation of broad-sense heritability are useful for identifying the main agronomic selected criteria of promising lines within the meta-population of the landrace towards improving seed yield and yield stability.

Materials and Methods

The current study was carried on lentil landrace of Zaer. 230 lines of the landrace have been collected during 2012/13 from 24 farmers' field across three locations of Zaer region according to the standards referenced in the practice guide of Marchal et al. (1994). Fields were randomly selected. At field level, fifteen plants were randomly collected at physiological seed maturity stage along field diagonal at regular intervals. After harvest, a sample of seeds were collected from correspondents' farmers to be sown during the next growing season (2013/14) at the experimental field station of the National Institute of Agronomic Research at Marchouch (6.71°W, 33.60°N, 410 m altitude). The trial was set in randomized complete blocks design with three replications. Each experimental plot consisted of four rows of 2m long spaced from 30 cm (2.4 m²). Fertilizers were applied during seed bed preparation at the rate of 30 kg P_2O_5, 15 kg K_2O and 15 kg N/ha.

The days to flowering, days to maturity and seed yield were recorded on a whole plot. The agro-morphological traits related to yield components such as plant height, primary and secondary branches, number of vegetative and fertile knots, number of pods/peduncle, number of pods/plant, number of fertile pods/plant, number of seed/pod, number of seed/plant, and thousand seeds weight were recorded from a random sample of ten plants in each experimental plot.

Data analysis of variance with Duncan's multiple comparison tests was used for the determination of the means of accessions over years and by sites was determined for all characters. Variance components were estimated from expected mean squares of genotype variance, genotype x year variance, and phenotype variance. The value of broad-sense heritability of the quantitative characters was estimated by the ratio of genotypic variance to phenotypic variance (σ^2g / σ^2p). The Path coefficient analysis was conducted to determine direct and indirect contribution of various yield components to seed yield using forward selection analysis.

Results and Discussion

Variance analysis over two growing season for all agro-morphologic characters indicated that year, genotype and genotype x year were highly significant. The effect of year was larger for almost all recorded characters (Table 1). Yield components vary across years according to climate (Figures 1-2) and across locations (Figures 3) related to the accession diversity size in accordance with Muehlbauer et al. study (1985).Variability within the landrace was greatest for number of secondary branches (57.5%), number of fertile knots (61.6%), number of pods per plant (58.8%), number of fertile pods per plant (66.9%) and number of seeds per plant (65.2%). This result suggests that there is a large possibility for yield improvement through selection of

productive lines. Maximum of inter-annual variability was recorded for number of secondary branches (58.3%), number of vegetative knots (51.6%), number of fertile knots (42.7%), number of pods per plant (46.2%), number of fertile pods per plant (49.4%) and number of seeds per plant (50.0%) (Figure 1, Table 1). The coefficients of genotypic inter-annual variation exhibit the environment effect on yield formation from many components contribution. The estimation of broad sense heritability of yield components might be useful for selecting the most determining traits of grain yield towards improving and stabilizing yield in changing climate (Ortiz et al., 2000).

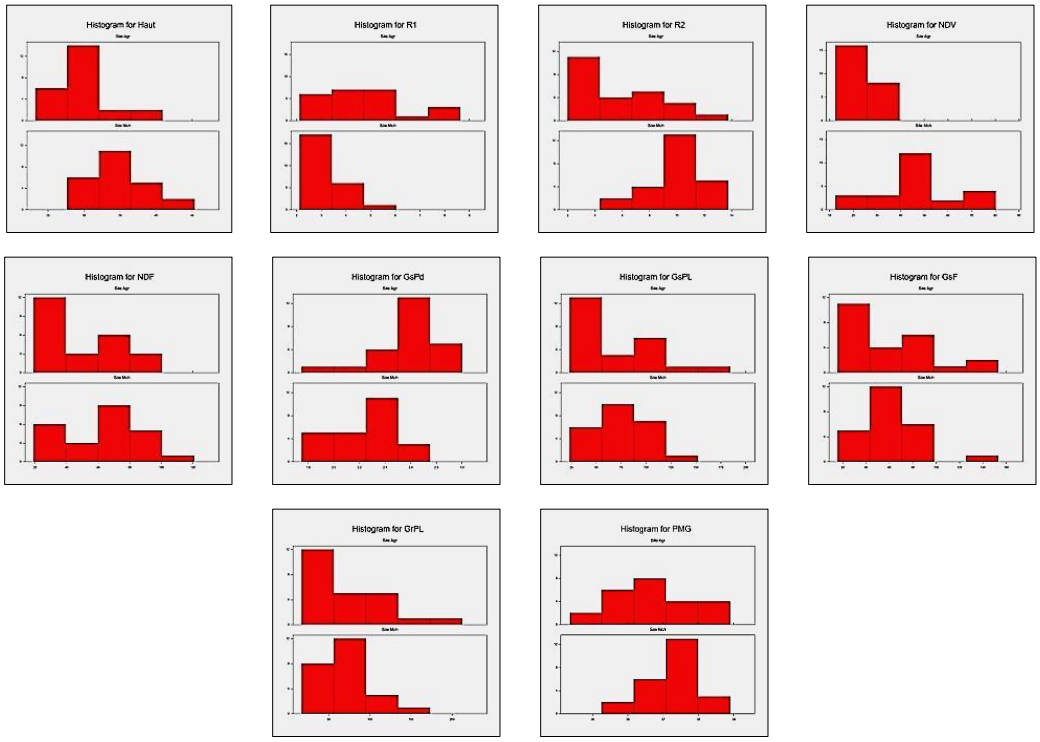

Figures 1: Inter-annual variation on yield components of Zaer landrace

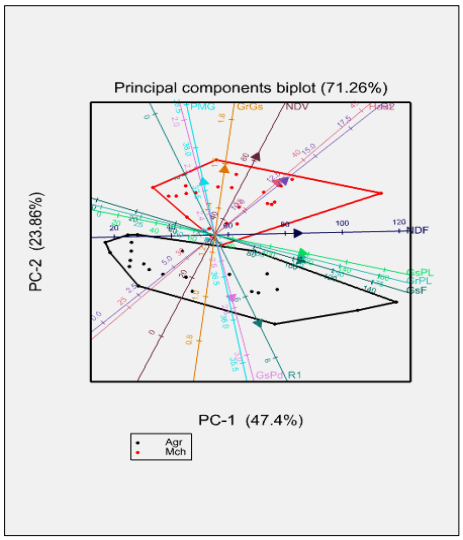

Figure 2: Effect of climate and agriculture practices on yield components

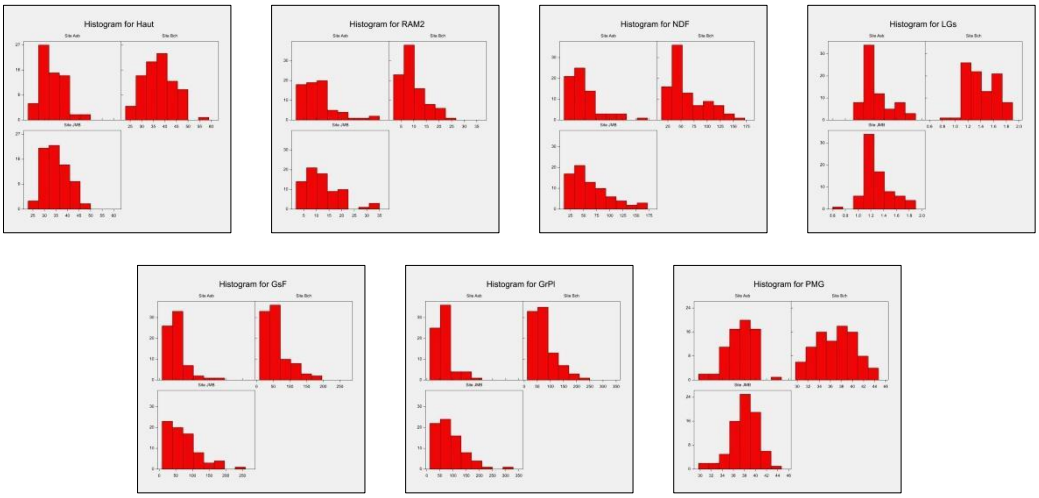

Figures 3: Inter-locations variation on mean yield components of Zaer landrace

Plant height varied from 21.0 to 49.0 cm (Table 1). This characteristic exhibited moderate heritability (0.42) reported also by Dixit et al. (1985) and Chauhan et al. (1998). First branches, and vegetative knots had also moderate heritability with respectively (0.40) and (0.39) (Table 2). The principal component analysis showed that the effect of environment such as agriculture practices and climate from first to second year, on the most of agronomic characters seemed high (Figure 2). The correlation between plant height and seed yield was negative and no significant (-0.141^{ns}). The direct effect of this character on seed yield was small and no significant (0.044^{ns}) according to path analysis of forwards selection. However, plant height has an indirect effect on seeds yield through the number of fertile knots (0.624***), number of pods (0.581***) and seeds per plant (0.565***) which are positively and highly correlated. Number of fertile knots (0.64), number of pods per plant (0.67) and number of seeds per plant (0.66) had high value of broad sense heritability indicating that a great genetic gain could be achieved for these traits by using Zaer landrace in lentil breeding programs. The difference between number of fertile pods heritability (0.62) and total number of pods per plant heritability (0.67) is related to climate effect on yield formation. The rainfall condition had also a significant effect on secondary branches and number of pods per peduncle that had low estimates broad sense heritability (0.28 and 0.37 respectively). Sharma, (2011) had reported that pods per peduncle is highly influenced by environment conditions.

Table 2: Variance components estimated from expected mean squares and broad sense heritability

Sources of variation	Plant height	R1	R2	NDV	NDF	Pods/ Peduncle	Seeds /pods	Pods /plant	Filled pods /plant	Seeds /plant	1000 seed weight
Genotype	8.265	0.844	2.927	105.732	415.753	0.026	0.047	765.884	628.031	1089.2	0.805
Gen. x Year	11.265	1.248	7.411	162.043	232.306	0.044	0.043	379.689	376.307	551.724	0.066
Error	10.34	2.03	21.23	318.90	557.96	0.213	0.145	1070.0	879.2	1278.2	0.970
Phenotype	19.530	2.092	10.337	267.776	648.059	0.071	0.090	1145.57	1004.339	1640.92	0.872
Heritability	0.423	0.403	0.283	0.395	0.641	0.371	0.526	0.668	0.625	0.664	0.923

Seed weight varied from 33.3 to 40.5 g/1000 seeds (Table 1). The variability of seeds weight over year was lower (2.66%) and the broad sense heritability value was the highest with (0.92) compared to others yield components (Table 2). That's suggested that seeds weight character was not affected by the growing environment. High heritability of seed weight was also reported by Rajput et al. (1989), and Chauhan and Singh (1998). Sharma, (2011) investigation showed that seed weight is under polygenic control and the alleles for low seed weight have partially dominant effects.

Seed weight was positively and significantly correlated to earliness (0.583***) and pods length (0.159*). While it was negatively and significantly correlated with almost yield components such as plant height (-0.481***), primary branches (-0.243**), secondary branches (-0.172*), number of fertile knots (-0.332***), number of pods per peduncle (-0.457***), pods per plant (-0.319***), fertile pods per plant (-0.292***) and seeds per plant (-0.278***).

Days to 10% flowering of accessions varied between 91 and 96 days (Table 3). Flowering initiation is under control of a single recessive gene "sn" (Sarker et al., 1999). Chauhan et al. (1998) reported low broad sense heritability for day to flowering, where Muehlbauer et al., (1995) reported moderate a large heritability and Biçer et al. (2004), Biçer et al. (2008) and Biçer et al. (2010) reported high heritability for days to flowering respectively (0.82), (0.94) and (0.71). The earliness was positively correlated with plant height (0.375*), number of pods per peduncle (0.300*), number of pods per plant (0.323*) and number of seeds per plant (0.323*) and negatively

and highly correlated with 1000 seed weight (-0.583***) and with yield (-0.054^{ns}). Days to maturity varied between 152 – 160 days. Broad sense heritability value was high for days to maturity (0.80) according to Bicer et al. (2010) and Chauhan et al. (1998) studies. Days of maturity was negatively and highly correlated with 1000 seed weight (-0.410***).
The mean of seed yield varied from 8.9 to 19.4 quintal/ha with large effect of the environment (Table 3). Muelbauer et al. (1995), Bicer et al. (2004) had reported high variability and low heritability of seed yield per plant (0.26) and Bicer et al. (2004) had reported moderate heritability for grains yield (0.41). Seed yield is negatively and significantly correlated to primary branches (-0.299*), number of fertile knots (-0.398**) and number of pods per plant (-0.345*). Correlation coefficients implied that number of primary branches, number of fertile knots and number of pod/plant could be considered as the mean selected traits for yield improvement.

Table 3: Analysis of variance of some agronomic characters on landrace accessions at Marchouch

Sources of variation	Days to 10% flowering	Days to maturity	1000 seed weight	Seeds yield
Genotype	3.37^{ns}	9.04^{ns}	2.31^{ns}	16.8^{ns}
Error	2.26	3.41	7.84	27.9
Means	93.96	156.1	37.66	17.08

The variation in yielding ability of the landrace under two different growing year condition, leads us to evaluate the relationship of seed yield with divers yield components. The path analysis multiple regression Forward selection methods may provide us with the effective components of yield determination to be used as selection criteria for landrace genetic improvement of yield (Yadav et al., 2003; Karadavut, 2009).
The result revealed that plant height, number of pods per peduncle, number of pods per plant, number of seeds per plant and thousands seed weight are the most effective components of the yield which account 50% of yield variation. Number of pods per plant and thousands seed weight are among the major components of yield with significant and direct effect on the yield according to their contribution to yield variability with 13% and 24% respectively (Table 4). Dixit et al. (2005) study showed that number of pods per plant, weight of 100 seeds and number of seeds per pods had the most positive and direct effect on yield which was reported also by Barghi et al. (2012). Muehlbauer (1974) have reported that the number of pods per plant is one of the major components of yield while, Bitaraf et al. (2010) has reported that 100 seed weight is the most component of yield in lentil.

Table 4: Path coefficient of forwards selection to identify direct and indirect contribution of agro-morphologic traits to seeds yield

Zaer Landrace	R^2 partial	R^2 model	C(p)	F value
Weight of 1000 seeds	0.24	0.24	1.9624	7.98***
Number of pods per plant	0.13	0.37	-0.2166	4.83*
Number of pods per peduncle	0.05	0.42	0.0219	2.13^{ns}
Plant height	0.04	0.47	0.5834	1.80^{ns}
Number of seeds per plant	0.03	0.50	1.4383	1.46^{ns}
Significant at 0.05 (*), 0.01 (**) and at 0.001 (***) probability level respectively				

Correlation analysis showed that the weight of thousands seed was positively correlated to plant height (0.187*), number of total pods per plant (0.276**), number of filled pods per plant (0.309 ***) and to number of seeds per plant (0.299**). Whereas, number of pods per plant was positively correlated to plant height (0.422***), secondary branches (0.569***), number of fertile knots per plant (0.735***), number of pods per peduncle (0.387***), number of filled pods per plant (0.974***), number of seeds per plant (0.958***) and to thousands seeds weight (0.276***). Based on these results, we deduce that plant height; number of secondary branches; number of fertile knots per plant; number of filled pods per plant; number of seeds per plant and seeds weight are the main agronomic selected traits of promoted lines within the landrace for improving yield. Add to earliness as key factor for adaptation to Zaer climate change.

Conclusion

The main objective of this study was to strengthen the on-farm conservation of lentil landrace through improving yielding in changing climatic condition. Grain yield is the result of many yield components contribution. The study was therefore based on the assessment of genetic variability of yield components and their heritability in order to determine the direct and effective selection component on yield. Heritability of agronomic characters could be useful to guide selection for improving yield across generations.

Indeed, this study has described a high phenotypic diversity for the main agro-morphological traits of Zaer landrace of lentil. Variation between lines within the meta-population for the majority of measured traits implies great genetic diversity and potential for breeding program through selection of high yielding lines with early flowering and maturing, high plant vigor (plant height, primary and secondary branches) and high ability for seed production (number of pods and seeds/plant, and high seed weight) in accordance with Al-Ghzawi (2011) study. Plant height, pods per peduncle, pods per plant, seeds per plant and 1000 seeds weight are the most effectives seed yield components. Moreover, number of pods per plant, seeds per plant and thousand seed weight are the primary components that have direct effect on yield. Their broad sense heritability was high (67%, 66% and 92% respectively) indicating low environmental effects. Thus, selected criteria of promoted lines among the meta-population should be based on those characters in order to improve and stabilize yielding in changing climate. Otherwise, this study has demonstrated that Zaer landrace has a rich genetic potential to be advanced for breeding program of lentil.

Abstract

Thyme (*Thymus vulgaris* L.) is a medicinal and aromatic plant intensively used in pharmaceutical, food, and cosmetic industries. The first-year of a thyme (*Thymus vulgaris* L.) crop's growth and productivity as affected by nitrogen fertilization was investigated under field conditions in central Greece. In April 2015, winter cuttings of a native thyme cultivar were transplanted to an experimental field set up in Nea Aghialos, Magnesia, central Greece. The experimental design was a completely randomized design with three nitrogen dressings (0, 50, 100, kg N ha^{-1}) in four replications. The growth and final productivity of the crop was measured in three destructive samplings of the crop during the summer of 2015. The results demonstrated that nitrogen fertilization had a significant effect on thyme productivity and final yield in the first year of the crop.

Introduction

Thyme (*Thymus vulgaris* L.) is a member of the Lamiaceae family, which is met in different areas of the Mediterranean and Asia. Thyme has been used medicinally since ancient times (Hornok, 1992). It is used as a raw material in the production of plant medicine having a series of bactericidal and fungicidal effects. Thyme crops are of increasing economic importance for North America, Europe and North Africa (Letchamo and Gosselin, 1996) as thyme is commercially cultivated in large scale in many countries due to the fact that it has shown great economical potential (Bernath, 1990; Youdim et al., 2002; Badi et al., 2004). Thyme is a perennial shrub which grows up to 40-50 cm in height, forming many branches (Bernáth, 1993a). The sessile leaves vary in shape from elliptic to linear or diamond-shaped towards the apex. The flowers, varying in color from white to purple, are found in clusters at the top of the branches. The fruits consist of a smooth, dark-colored 4 - sectioned nutlet found in the remains of the calyx (Bernáth, 1993b). Since garden thyme is cultivated commercially (Bernáth, 1990), the optimum amount of nitrogen fertilization has been the subject of many investigations (Hornok et al., 1975, Shalaby and Razin, 1992, Ceylan et al., 1994). The main purpose of this trial was to determine, whether N supply could have a significant effect on the growth parameters of thyme under Greek conditions, even in the first year which is considered an establishment year for the crop.

Materials and methods

Crop establishment

The experiment was set up in the rural area of Nea Aghialos in Central Greece (39°16'02.3"N 22°47'47.5"E) on May 5, 2015. The soil of the experimental plots was a sandy loam one with a pH of 6.8 and an organic carbon (C) of 2.5 g kg^{-1}. Thyme cuttings (40 days old) were obtained from a local nursery. The soil was prepared and divided into plots; each of them was 4,2 m χ 2,4 m and contained three drip rows. The cuttings were transplanted on May 5. Distance between plants and distance between rows were both 60 cm. Twelve plots containing a total of 216 plants were arranged in a completely randomized design with irrigation being the main factor and nitrogen fertilization the factor split into sub-plots. Each experimental unit consisted of three rows of plants, 0.6 m apart, with the two outer rows serving as buffers. There were 17 plants per row, spaced 60 cm apart.

Fertilization

Nitrogen dressings were manually applied in three levels: N0, N50 and N100 (0, 50 and 100 kg ha^{-1} respectively) in the form of a urea fertilizer on June 9 of 2015.

Irrigation

The amount of irrigation water was equal to 100% (562 mm) of the recorded evaporation values of a class-A pan. Another 110mm of rain fell during the months of the experiment. Irrigation water was applied by drip irrigation system and the irrigation interval was seven days. Surface drip irrigation system consists of an irrigation pump connected to sand and screen filter and a hydraulic fertilizer injection pump was used. The actual water discharge rate was 8 L h^{-1} along the drip lines. Weed control was carried out via application of a polyethylene transpiring mulch as this material has demonstrated a 100% efficiency in weed control among other tested mulches in other medicinal species according to Hoeberechts et al (2004).

Harvesting and Drying

Harvests (destructive samplings) were carried on transplant – May 5, June 29, July 29 and finally August 28. Two plants per plot were harvested and all aerial parts of the plants were cut 5 cm above ground and the following growth parameters were determined: plant height, fresh weight of leaves/plant and fresh weight of stem/plant. The same parameters were determined after drying plant material in dark storage rooms on specially designed shelves. This method of drying was chosen as it is the method most commercial growers in Greece actually use. The results of the three final harvests are demonstrated in this paper.

Statistical analysis

All recorded values of this experiment were statistically analyzed using analysis of variance through the Genstat Program. Means were compared using revised L.S.D. test at 0.05 levels. The first harvest was not subjected to analysis of variance due to extensive rainfall during June.

Results and discussion

During the third and final harvest (28/08/2015) dry leaf yield (t ha-1) and dry stem yield (t ha-1) were significantly affected by nitrogen fertilization level. Dry stem yield means were 0.28, 0.20 and 0.32 t ha-1 for treatments N0, N50 and N100 (Figure 2) respectively while dry leaf yield means were 0.24, 0.23 and 0.35 t ha-1 for treatments N0, N50 and N100 respectively (Figure 1). During the second harvest (29/07/2015) nitrogen fertilization had no significant effect on the crop's growth parameters (Figure 1, 2). Dry leaf yields were 0.30, 0.23 and 0.36 t ha-1 and dry stem yields were 0.29, 0.20 and 0.31 for treatments N0, N50 and N100 respectively. Plant height remained unaffected by nitrogen fertilization during the experiment. The LSD test showed that dry leaf yields of treatment N100 differed greatly than the rest during the final harvest (Table 1) while dry stem yields of treatments N0, N50, N100 all differed greatly when compared to each other.

Figure 14. Dry leaf yield (t ha^{-1}) means grouped by nitrogen fertilization level during the experiment.

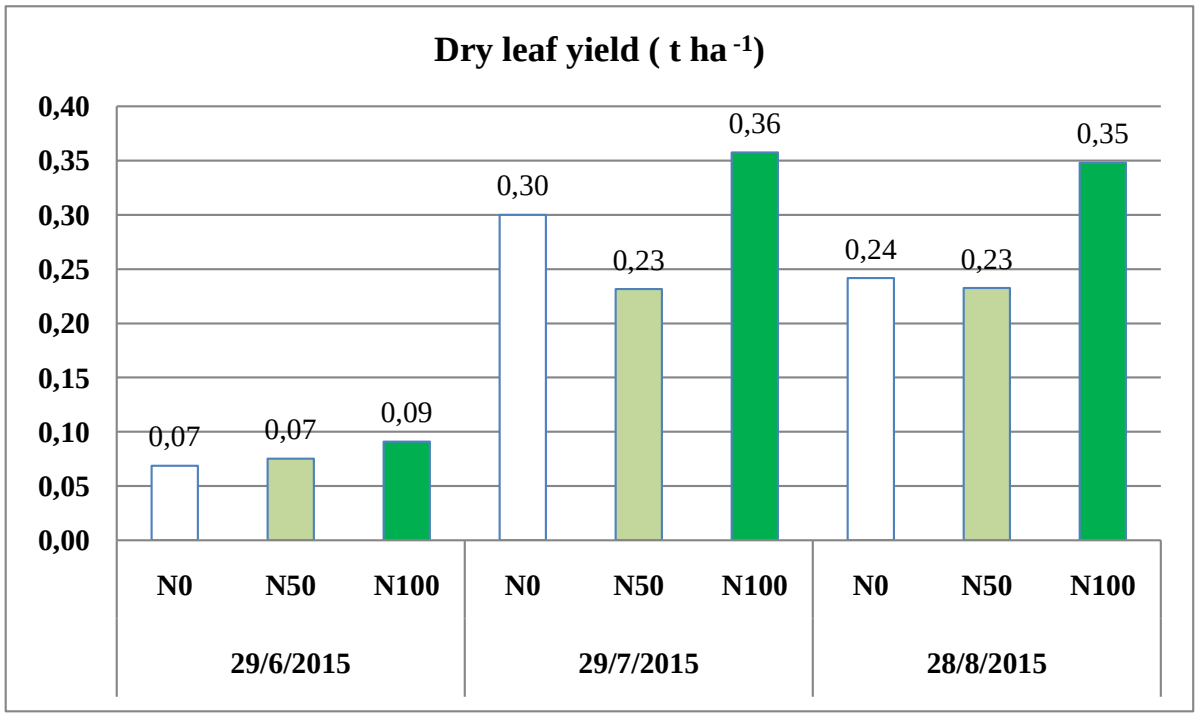

Figure 15. Dry stem yield (t ha^{-1}) means grouped by nitrogen fertilization level during the experiment.

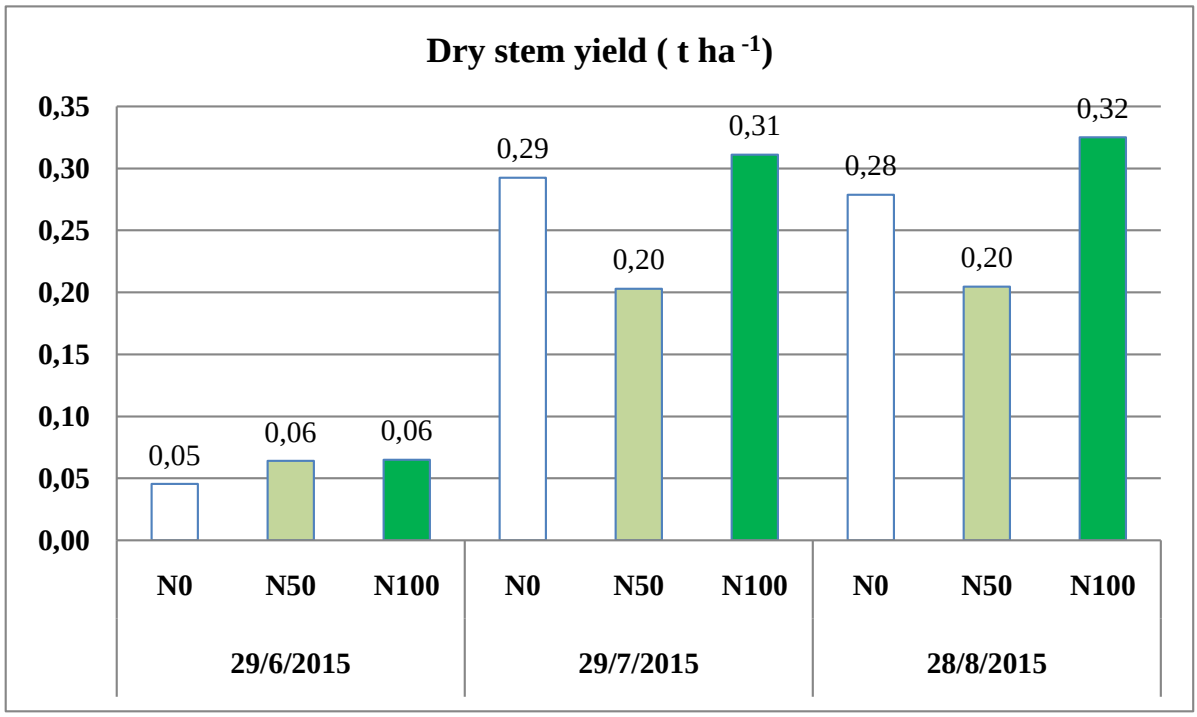

Figure 16. Plant height (cm) means grouped by nitrogen fertilization level during the experiment.

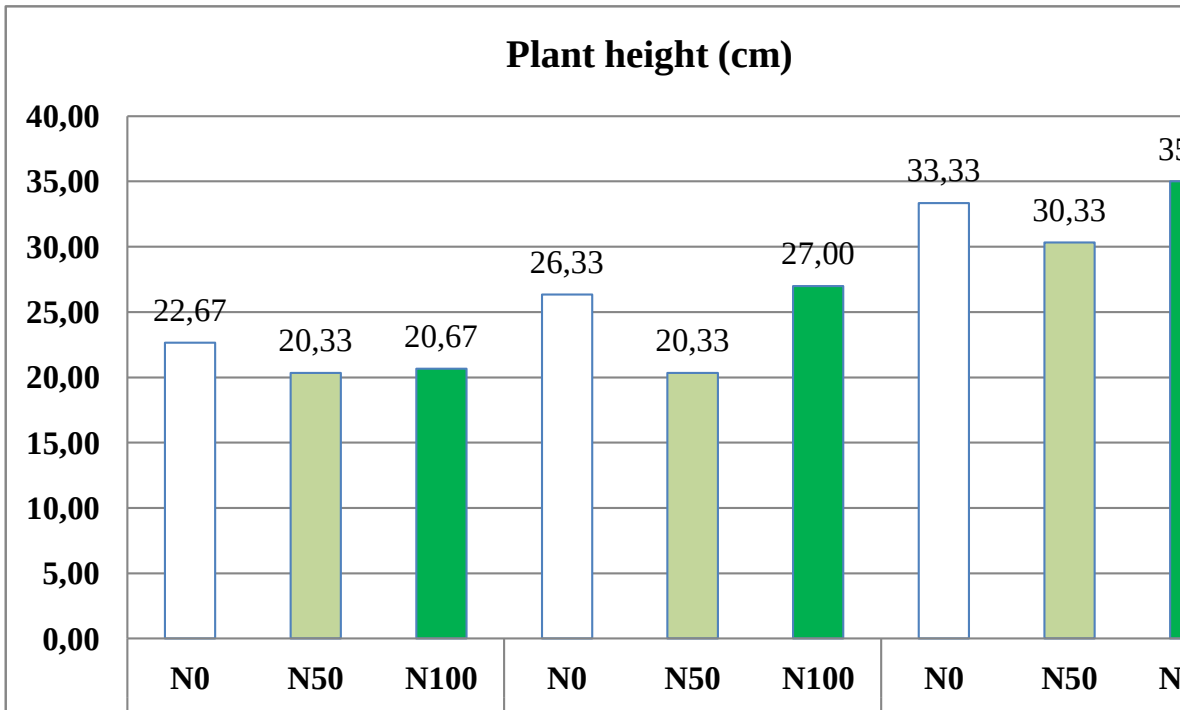

Table 7. Means of vegetative growth data of thyme as affected by different nitrogen fertilization regimes and nitrogen during the experimental season.

Harvest date	Nitrogen treatment	Plant height (cm)	Dry stem yield (t ha^{-1})	Dry leaf yield (t ha^{-1})
29/06/2015	N0	22,67a	0,05a	0,07a
	N50	20,33a	0,06a	0,07a
	N100	20,67a	0,06a	0,09a
29/07/2015	N0	26,33a	0,29a	0,30a
	N50	20,33a	0,20a	0,23a
	N100	27,00a	0,31a	0,36a
28/08/2015	N0	33,33a	0,28a	0,24a
	N50	30,33a	0,20b	0,23a
	N100	35,00a	0,32c	0,35b

Means followed by different letters were significantly different according to revised L.S.D. test at 0.05 level.

Conclusion

During the first year of the crop's establishment nitrogen's paramount effects were demonstrated. Future experiments for consecutive growing seasons and in different soil types are recommended in order to assess the prospects of thyme cultivation in Greece and the possible financial interest of the crop. As nitrogen pollution of underground water reserves has been prominent in the past years in Greece, this aromatic and medicinal crop shows potential as it can prove lucrative with little nitrogen inputs when compared to other traditional crops of central Greece. Finally, soil

erosion continues to be a problem in Greece (Kosmas et al, 2001), making perennial crops like thyme a suitable candidate for the eradication of the problem.

Abstract

Thyme, a native plant of the Mediterranean, is a crop which holds an increasing importance for the essential oil production in the industry of cosmetics and food additives. The first-year of a thyme (*Thymus vulgaris* L.) crop's growth and productivity as affected by irrigation volume was investigated under field conditions in central Greece. In April 2015, winter cuttings of a native thyme cultivar were transplanted to an experimental field set up in Nea Aghialos, Magnesia, central Greece. The experimental design was a completely randomized design with three irrigation levels (0, 50, and 100% of potential evapotranspiration) in four replications. Irrigation was carried out via a drip system. The growth and final productivity of the crop in dry yield was measured in three destructive samplings of the crop during the summer of 2015. The results demonstrated the important effects of irrigation on thyme productivity and final yield in the crop's first year.

Keywords: *thyme, fertilization, growth, nitrogen, evapotranspiration.*

Introduction

Thyme (*Thymus vulgaris* L.) is a member of the Lamiaceae family, which is met in different areas of the Mediterranean and Asia. Thyme has been used medicinally since ancient times (Hornok, 1992). It is used as a raw material in the production of plant medicine having a series of bactericidal and fungicidal effects. Thyme crops are of increasing economic importance for North America, Europe and North Africa (Letchamo and Gosselin, 1996) as thyme is commercially cultivated in large scale in many countries due to the fact that it has shown great economical potential (Bernath, 1990; Youdim et al., 2002; Badi et al., 2004). Thyme is a perennial shrub which grows up to 40-50 cm in height, forming many branches (Bernáth, 1993a). The sessile leaves vary in shape from elliptic to linear or diamond-shaped towards the apex. The flowers, varying in color from white to purple, are found in clusters at the top of the branches. The fruits consist of a smooth, dark-colored 4 - sectioned nutlet found in the remains of the calyx (Bernáth, 1993b). Since garden thyme is cultivated commercially (Bernáth, 1990), the crop's growth parameters have been the subject of many investigations (Hornok et al., 1975, Shalaby and Razin, 1992, Ceylan et al., 1994). The main purpose of this trial was to determine, whether irrigation could have a significant effect on the growth parameters of thyme under Greek conditions, even in the first year which is considered an establishment year for the crop.

Materials and methods

Crop establishment

The experiment was set up in the rural area of Nea Aghialos in Central Greece (39°16'02.3"N 22°47'47.5"E) on May 5, 2015. The soil of the experimental plots was a sandy loam one with a pH of 6.8 and an organic carbon (C) of 2.5 g kg^{-1}. Thyme cuttings (40 days old) were obtained

from a local nursery. The soil was prepared and divided into plots; each of them was 4,2 m χ 2,4 m and contained three drip rows. The cuttings were transplanted on May 5. Distance between plants and distance between rows were both 60 cm. Twelve plots containing a total of 216 plants were arranged in a completely randomized design with irrigation being the main factor and nitrogen fertilization the factor split into sub-plots. Each experimental unit consisted of three rows of plants, 0.6 m apart, with the two outer rows serving as buffers. There were 17 plants per row, spaced 60 cm apart.

Fertilization

A nitrogen dressing was manually applied (50 kg ha $^{-1}$) in the form of a urea fertilizer on June 9 of 2015.

Irrigation

The amount of irrigation water was equal to 0% (rainfed – 110 mm), 50% (281 mm) and 100% (562 mm) of the recorded evaporation values of a class-A pan. Irrigation water was applied by drip irrigation system and the irrigation interval was seven days. Surface drip irrigation system consists of an irrigation pump connected to sand and screen filter and a hydraulic fertilizer injection pump was used. The actual water discharge rate was 8 L h^{-1} along the drip lines. Weed control was carried out via application of a polyethylene transpiring mulch as this material has demonstrated a 100% efficiency in weed control among other tested mulches in other medicinal species according to Hoeberechts et al (2004).

Harvesting and Drying

Harvests (destructive samplings) were carried on transplant – May 5, June 29, July 29 and finally August 28. Two plants per plot were harvested and all aerial parts of the plants were cut 5 cm above ground and the following growth parameters were determined: plant height, fresh weight of leaves/plant and fresh weight of stem/plant. The same parameters were determined after drying plant material in dark storage rooms on specially designed shelves. This method of drying was chosen as it is the method most commercial growers in Greece actually use. The results of the three final harvests are demonstrated in this paper.

Statistical analysis

All recorded values of this experiment were statistically analyzed using analysis of variance through the Genstat Program. Means were compared using revised L.S.D. test at 0.05 levels. The first harvest was not subjected to analysis of variance due to extensive rainfall during June.

Results and discussion

During the second harvest (29/07/2015) dry leaf yield and dry stem yield were significantly affected by irrigation volume. During the second harvest dry stem yield means were 0.25, 0.24, 0.36 t ha^{-1} (Figure 2) and dry leaf yield means were 0.22, 0.26 and 0.41 t ha^{-1} (Figure 1) for treatments I1, I2 and I3 respectively. These values were the highest recorded during the experiment. During the third and final harvest (28/08/2015) irrigation volume, all recorded growth parameters were unaffected (Figure 1, 2, 3). Plant height remained unaffected by irrigation volume throughout the experiment (Figure 3). The LSD test showed that dry stem and dry leaf yields of treatment I3 differed greatly than the rest during the second harvest (Table 1).

Figure 17. Dry leaf yield (t ha^{-1}) means grouped by irrigation volume during the experiment.

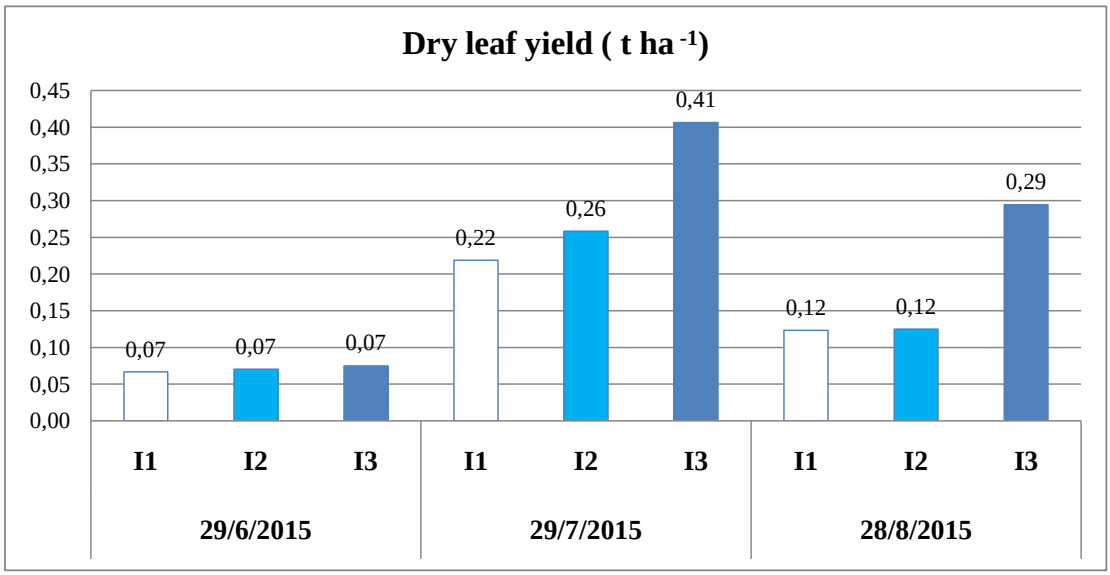

Figure 18. Dry stem yield (t ha^{-1}) means grouped by irrigation volume during the experiment.

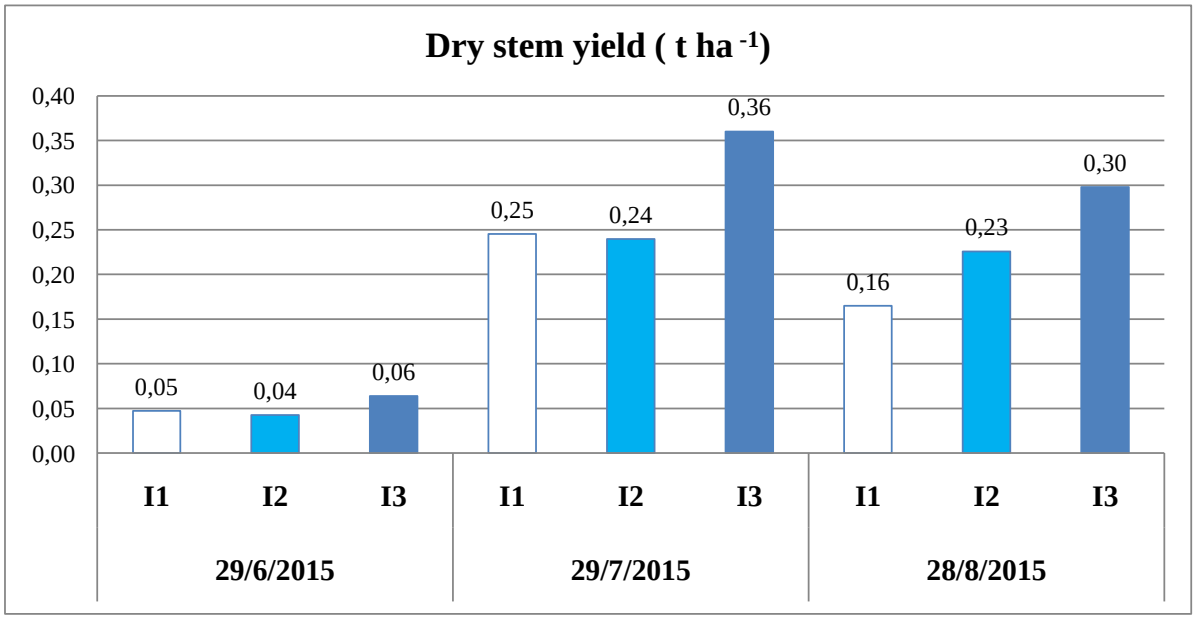

Figure 19. Plant height (cm) means grouped by irrigation volume during the experiment.

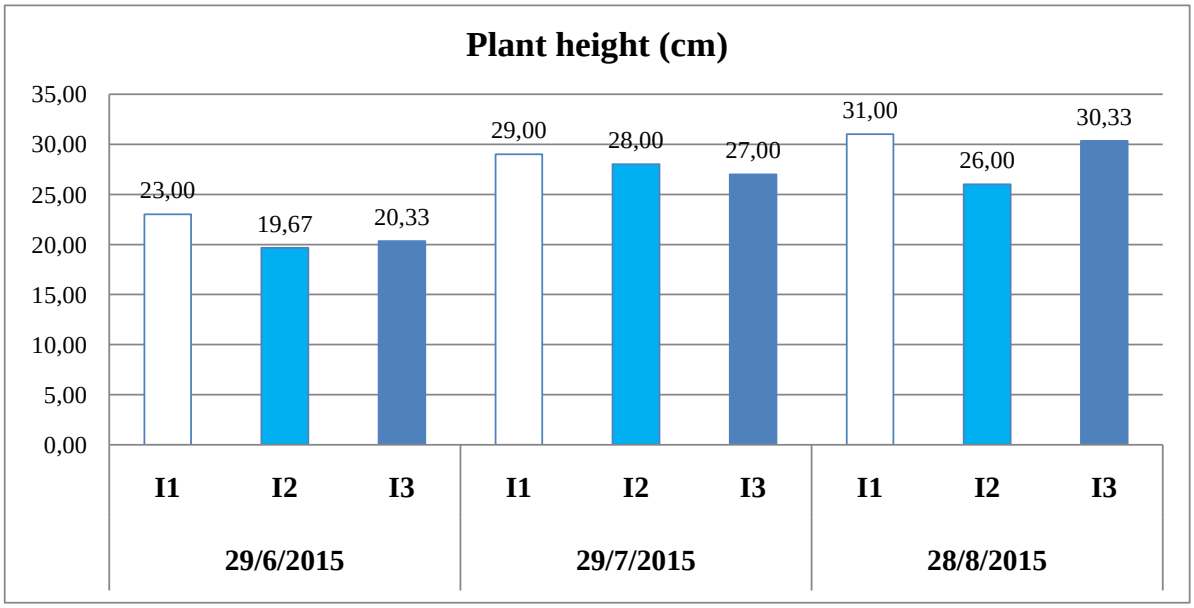

Table 8. Means of vegetative growth data of thyme as affected by different irrigation volumes during the experimental season.

Harvest date	Irrigation treatment	Plant height (m)	Dry stem yield (t ha^{-1})	Dry leaf yield (t ha^{-1})
29/06/2015	I1	23,00a	0,05a	0,07a
	I2	19,67a	0,04a	0,07a
	I3	20,33a	0,06a	0,07a
29/07/2015	I1	29,00a	0,25a	0,22a
	I2	28,00a	0,24a	0,26a
	I3	27,00a	0,36b	0,41b
28/08/2015	I1	31,00a	0,16a	0,12a
	I2	26,00a	0,23a	0,12a
	I3	30,33a	0,30a	0,29a

Means followed by different letters were significantly different according to revised L.S.D. test at 0.05 level.

Conclusion

During the first growing season year of the crop, irrigation had a significant effect on plant growth. Future experiments for consecutive growing seasons featuring different cultivation strategies (spacing, harvest times etc.) and different soil types are recommended in order to assess organized thyme cultivation in Greece. It seems that water is an important input for thyme crops in central Greece as its supply leads to higher herbage yields. Finally, soil erosion continues to be a problem in Greece (Kosmas et al, 2001), making perennial crops like thyme a suitable candidate for the eradication of the problem.

Abstract

Natural zeolites can perform adsorption of ammonium ions of manure and in the mixture the manure can be used as organic-nitrogen fertilizer. There are about 50 different types of natural zeolites (Analcime (analcite), clinoptilolite, chabazite, faujasite, phillipsite, mordenite, etc.). Clinoptilolite and chabazite are the most commonly used natural zeolites, which are increasingly used in agriculture. Clinoptilolite added to the soil improves its physical and chemical characteristics. Zeolite may retain the N, K, Ca, Mg and micronutrients in many plants and the root zone to allow their use when needed, thus allowing efficient use of N and K fertilizer. The application of zeolite, because of these qualities, applies small amounts of fertilizer, which reduces production costs and allows increased yields. The aim was to determine the effect of zeolite on the morphologic and productivecharacteristics of soybean produced in the organic farming system. In this research three varieties*Glycine Max.*: NS Kaća, (000 MG), NS Pantera (00 MG) and Galina (0 MG) in two types of cultivation: the first control and the second variant with zeolite - Clinoptilolite. The average weight of plants, plant height, first pod height and weight of pods of soybean plants was higher in variants with zeolite compared to the control. Plant height was significantly higher in the variant with zeolite compared to the control. The maximum mass of plants, the first pod height and weight of the pods had a variety Galina compared to the cultivars. Significantly higher average plant height had NS Pantera in relation to the variety tested. Variety Pantera had higher plants in variants with zeolite for 11.8 cm respectively for 9.27%, while the variety Galina had higher plants in the 2nd variant for 16.76 cm respectively for 19.20% compared to the first variant- control. Application of zeolite prevents the leaching of nutrients, is of great importance both from the economic as well as the ecological aspect and also for achieve bigger productivity of soybeans.

Keywords: *Soybean, variety, zeolite, morpho-productive characteristics,organic farming system*

Introduction

Glycine Max. L. Merr is a legume that from year to year recorded a significant increase in area and production. Soybean yields recorded fluctuations and in large dependence on meteorological conditions during the vegetation growing period. Areas under soybean in the World in 2013 amounted to 111.27 million hectares, with the total production of 276.40 million tonnes. America is the world's largest producer of soybean, with an area of 85.63 million ha, or with total world share of 76.95%, followed by Asia with an area of 20.69 million hectares and Europe with an

area of 3.18 million hectares and total production of 5.94 million tonnes. (Zivanović&Popović, 2016).The seeds of soybean contain 40% good quality protein, 17-24% highly palatable oil containing zero cholesterol level, 6% ash, 29% sugars (Essa and AlAni, 2001; Agarwal, 2007; Shi and Cai, 2010, Popović, 2010,Popovic et al. 2012a, 2012b, 2013). Except above all benefits, it is also a good source of polyunsaturated fat, fibers, vitamins and contains a small amount of minerals and energy (Krishnan, 2001). It contains about 85% of the world oil seed and placed in group of the oil seed crop. Soybean seed is processed into soybean meal and vegetable oil. Soybean may be a significant source for biofuel production (Anonymous, 2009).

In the organic farming system, fertilization of plants is possible only with means that are allowed for use in organic farming system. Natural zeolites can perform adsorption of ammonium ions of manure and in the mixture the manure can be used as organic-nitrogen fertilizers and in organic cropping system. Its implementation is desirable because it improves the physical and chemical characteristics of the soil.Zeolites are natural microporous crystals which consist of the elements of the Earth's crust: silicon, aluminum and oxygen. Natural zeolite deposits were created millions of years ago by volcanic ash. There are about 50 types of natural zeolites. Zeolites are used for various applications in industry, agriculture and environmental protection. Clinoptilolite features, such as such as the selectivity to certain ions and the ion exchange capacity, motivate research on the possibilities of its application in agriculture; particularly in the areas of crop production, where there is expressed need for carriers of nutrients and micro-elements.Application of natural zeolites in agriculture is based on their ability to binding other substances and their mechanism of ion exchange or adsorption.

The zeolites exhibit affinity for the binding (removal) of ammonia from aqueous solutions. The way that they can carry out the adsorption of ammonium ions from manure zeolites in a mixture with manure can be used as organic-nitrogen fertilizer. This allows their use in agriculture and horticulture. Application of zeolites is also possible in the processing of waste water which be used than in agriculture. As soil additives land, can reduce acceptance of mercury and other heavy metals by plants, and so prevent their entry into the food chain. Clinoptilolite isthe most commonly used natural zeolite clinoptilolite, because of its high adsorption capacity, the possibilities of ion exchange and applications of ion exchange catalyst, , as well as of its high dehydrating capacity. The application of zeolites in agriculture and especially in the field of nutrition of livestock is largely based on their ability to bind the various chemicals species, either by ion exchange or adsorption mechanisms. Zeolites showing exceptional selectivity for the adsorption of ammonia from aqueous solutions. This allows their use in agriculture and horticulture (natural zeolites are used as organic-nitrogen fertilizer - ammonium ion adsorption from manure is one of the main applications of natural zeolite clinoptilolite). This characteristic also allows the use for purification of industrial and agricultural waste water, fisheries and livestock feed. As soil additives, natural zeolites reduce the adoption of mercury and other heavy metals by plants and prevents their entry into the food chain (Armbruster, 2001, Polat et al., 2004).

There is nearly 50 different types of natural zeolites (Analcime (analcite), clinoptilolite, chabazite, faujasite, phillipsitemordenite, etc.). Deposits of natural zeolites were created millions of years ago of volcanic ash aluminosilicate which were reacted with water in which the dissolved inorganic salts. The synthetic zeolites are more numerous in the database of the International Zeolite Association (International Zeolite Association - IZA; www.iza-structure.org). In 1970 was stated 27; 2001 133 and 2009 180 different structural types of zeolite.

Clinoptilolite and chabazite are commonly used natural zeolites and their application are increasing continuously. The structure of clinoptilolite is layered. Openings the door of the channels are elliptical in shape (Armbruster, 2001).

Clinoptilolite is very prevalent in nature, usually located in open pits, and is readily available and inexpensive. Its properties, such as high adsorption capacity, ion exchange capacity, catalytic activity, dehydration activity, make this mineral can be important for plant production. Clinoptilolite added to the soil improves its physical and chemical characteristics. Zeolites may retain N, K,Ca, Mg and many microelements in the plants root zone and to allow their use when needed, thereby enabling more efficient utilization N and K fertilizers. The application of zeolites, because of these qualities, applied small amounts of fertilizer, which reduces production costs and to increase the yield (Rakic et al., 2015).

Prevention of nutrient leaching is very significant economically as well as it is ecologically. Namely, it is particularly important avoid loss of nutrients of fertilizers that often occurs in some of the types of land, most often in the sandy (Mumpton, 1999).

The aim of the study was to determine the effect of zeolite on morpho-productive characteristics soybean produced in the organic farming system.

Materials and methods

Experiment with three soybean varieties (*Glycine max* L.): NS Kaća (000 MG), NS Pantera (00 MG) and Galina (0 MG) was carried out on experimental field of Institute of Field and Vegetable Crops at certified plots in BackiPetrovac, Serbia, 2015, in two growing variants: 1.variant - Control – withoutzeolite and 2.variant- the application with zeolite - Clinoptilolite.

The standard technology for growing early soybean varieties was applied during the experiment. Sowing was carried out at the optimum time. Crop cultivation were applied during the vegetation period. Plants were irrigated three times each with 35 l of water in the flowering stage, the formation of pods and grain filling. The harvest is carried out manually in technological maturity. Samples were taken with each plot and morphological analysis of plant have been done.

Statistical Analysis: All information presented here were results of three replication experiment.Results were interpreted by using a statistical package, statistic 12.

Results and discussion

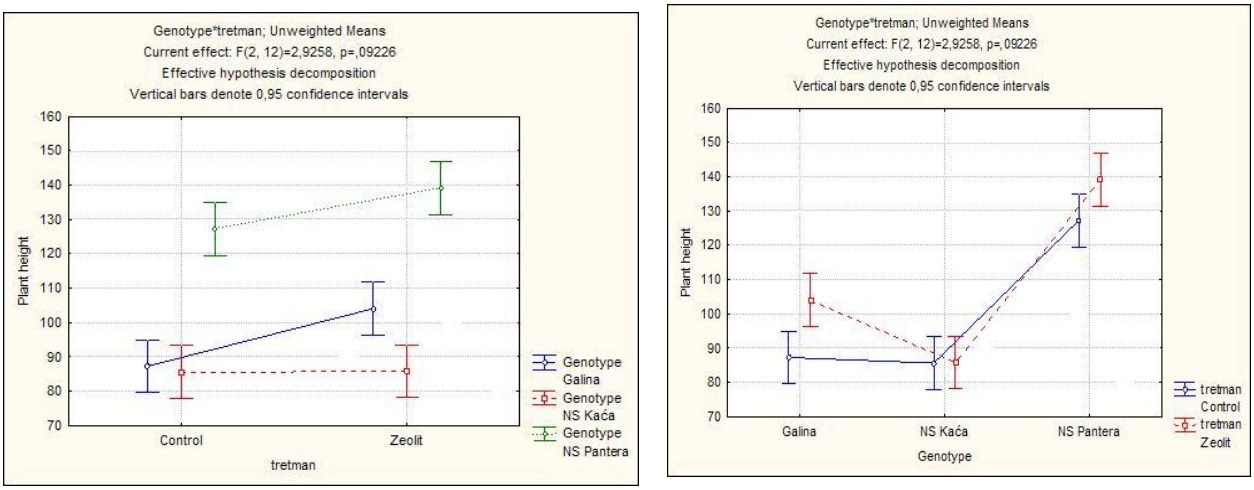
Genetic differences in plants provide a valued tool in assortment of genotypes with required traits (Misra and Dwivedi, 2004, Popovic, 2015). Genotype variant had a statistically significant effect on plant height. Plants height of by an average of all tested varieties was significantly higher in variants with zeolite compared to the control. The average plant weight, plant height, first pod height and weight of pods of soybean plants was higher in variants with zeolite compared to the control, table 1.

Significantly higher average plant height had variety NS Pantera in relation to the variety tested. Variety Pantera had higher plants in variants with Zeolite for 11.80 cm (9.27%), while the variety Galina had more plants in other variants of 16.76 cm (19.20%) compared to the control, table 1 graph. 2.Largest mass of plants (19.82 g), height of first pod (10.10 cm), and the mass of pods (13.05 g),had avariety Galina compared to the tested varieties under table 1.

Table 1.Morpho-productive characteristics of soybean plants

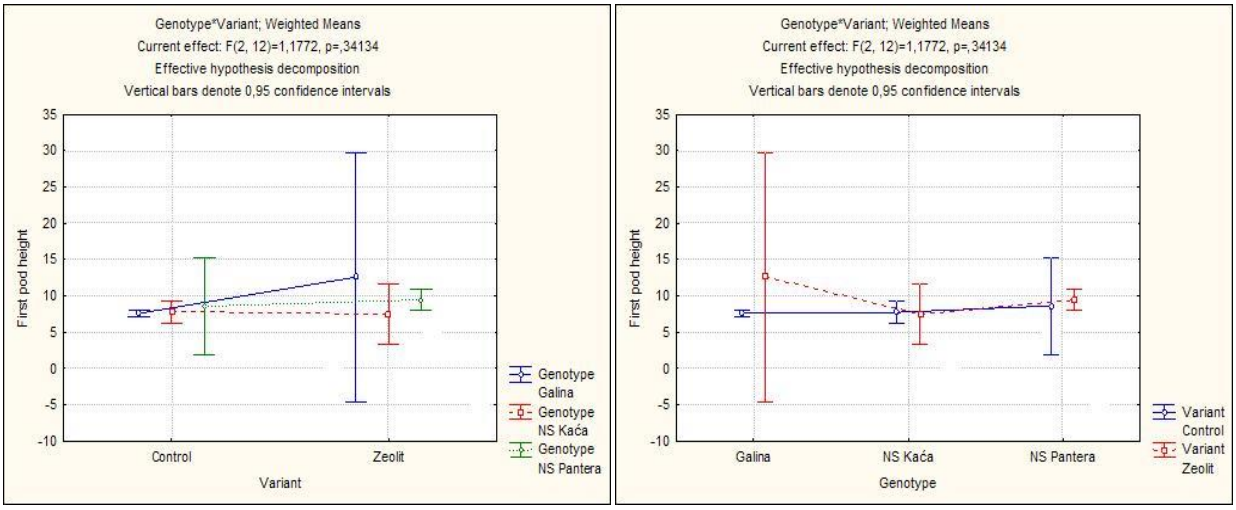
Parameter	Genotype	NS Kaća	NS Pantera	Galina	Average
Plant mass, g					
Variant	Control	16.43	19.75	17.33	17.84
	Zeolite	17.90	19.03	22.30	19.74
	Average	17.17	19.39	19.82	18.79
Plant height, cm					
Variant	Control	85.63	127.27*	87.27	100.05
	Zeolite*	85.76	139.07*	104.03*	109.62*
	Average	85.70	133.17*	95.65*	104.62
First pod height, cm					
Variant	Control	7.73	8.63	7.60	7.99
	Zeolite	7.50	9.47	12.60	9.85
	Average	7.62	9.05	10.10	8.92
Pod mass, g					
Variant	Control	11.26	13.30	11.70	12.09
	Zeolite	12.87	12.57	14.40	13.28
	Average	12.07	12.93	13.05	12.68

LSD	Plant mass			Plant height			First pod height			Pod mass		
	G	V	G x V	G*	V*	G x V*	G	V	G x V	G	V	G x V
0.5	2.55	3.71	6.43	7.72	6.31	10.92	3.94	3.22	5.57	3.45	2.82	4.88
0.1	6.04	4.93	8.54	10.26	8.38	14.52	5.24	4.28	7.41	4.58	3.74	6.48



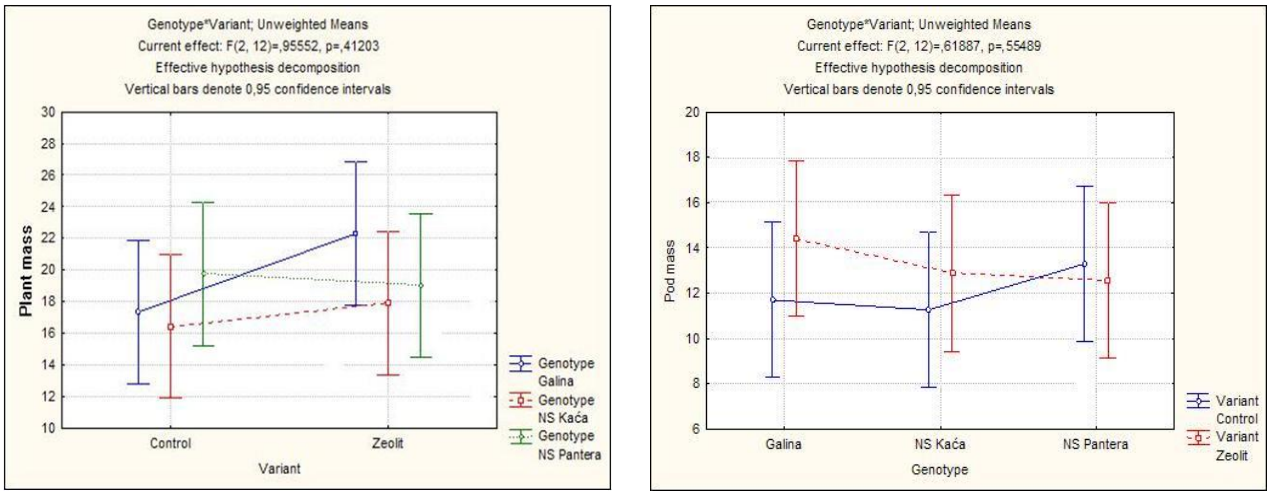
Graph 1. The effect of genotype and nutrient at the height of the soybean plants

Variety Galina had a largest mass of plants (19.82 g), followed by variety NS Pantera (19.39 g), and variety NS Kaća (17.17 g), table1, graph 1.



Graph 2. The effect of genotype and nutrient at the height of the first pod of soybean

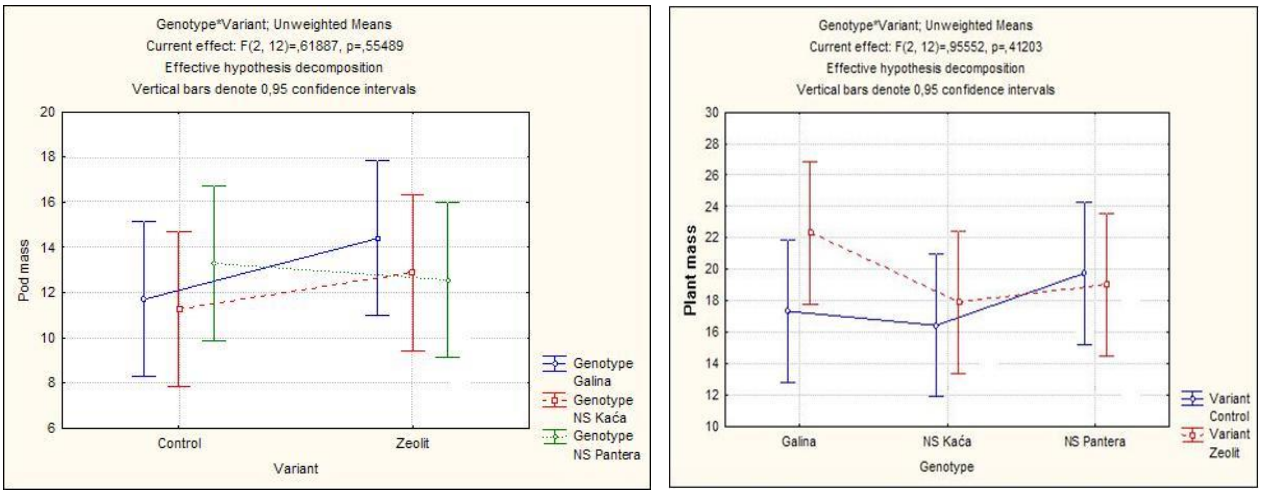
The average of the first pod heightof all tested cultivars was higher in variants with zeolite up to 23.28% compared to the control, table 1, graph 3.



Graph 3. The effect of genotype and nutrient on the mass soybean plants

The average of pods weight for all tested cultivars was higher in variants with zeolite up to 9.84% compared to the control, table 1, graph 4.

The application of Zeolite prevents rinsing of nutrients and by that better morpho-productive characteristics of soybeans which is of great importance from the economic as well as ecological aspect.



Graph 4. The effect of genotype and nutrient on the mass pods

With adequate potassium nutrition, yield, oil percentage and protein contents increased per unit area. Cost of production decreased and yield and profit increased (Epstein and Bloom, 2005, Khan et al., 2010, Djekic et al, 2013).

Correlations investigated traits

Correlations represent the interconnectedness between different occurrences presented values of two variables. Genotypic correlation coefficient enables an insight into correlation of properties and indicates the properties that may be useful as indicators of the behavior of some important properties (Johnson et al., 1955). Authors report that the correlation may help to identify characteristics that have little importance in the breeding program and provide important information for plant breeding. The link between the two parameters - variables means that the value of one variable can be predicted with a certain probability based on the knowledge of the value of other variables.

Strong, highly significant positive (direct) correlation was achieved between the weight of the plants and mass of pods. The correlation coefficient between these two parameters was 0.93, Table 2.

Table 2. Correlations investigated traits

Variable	Plant mass	Plant height	First pod height	Pod mass	Variant
Plant mass	1.00	0.30^{ns}	-0.01^{ns}	0.93**	0.27^{ns}
Plant height	0.30^{ns}	1.00	0.26^{ns}	0.19^{ns}	0.22^{ns}
First pod height	-0.01^{ns}	0.26^{ns}	1.00	-0.08^{ns}	0.30^{ns}
Pod mass	0.93**	0.19^{ns}	-0.08^{ns}	1.00	0.24^{ns}
^{ns} – nonsignificant; significant at 0.1					

Among others tested parameters achieved positive insignificant correlations, except for the mass of plants and first pod height where he was recorded poor negative correlation, Table 2.

Positive genotypic correlations between the two properties means that the selection of one can automatically achieve the progress in breeding for other (Johnson et al., 1955).

Conclusions

Based on the research of zeolite applications in soybean crops, we can conclude the following:

- ✓ The genotype and nutrition had a statistically significant effect on plant height.
- ✓ The height of plants by an average of all tested varieties was significantly higher in variants with Zeolite compared to the control.
- ✓ Average plant weight, plant height, first pod height and weight of pods of soybean plants was higher in variants with zeolite compared to the control.
- ✓ A significantly higher average plant height had variety NS Pantera of all tested varieties. Variety Pantera had higher plants in variants with Zeolite for 11.80 cm (9.27%), while the variety Galina had more plants in other variants of 16.76 cm (19.20%) for compared to the control.
- ✓ The largest plant mass (19.82 g), height of first pod (10.10 c), and the mass of pods (13.05 g), had a variety Galina compared to the tested varieties.
- ✓ Variety Galina had the greatest plant mass (19.82 g), followed by NS Pantera (19.39 g), and NS Kaća (17.17 g).
- ✓ First pod height by an average of all tested cultivars was higher in variants with zeolite up to 23.28% compared to the control.
- ✓ The weight of pods on average for all tested cultivars was higher in variants with zeolite of 9.84% compared to the control.
- ✓ A strong, highly significant positive (direct) correlation was achieved between the weight of the plants and the mass of pods. The correlation coefficient between these two parameters was 0.93.
- ✓ Application of Zeolite inhibits rinsing of nutrients. It is of great importance both from the economic as well as the ecological aspect and also for achieves bigger productivity soybeans.

Abstract

A two year (Y) field plot was conducted on experimental fields of Institute of field and vegetable crops in Novi Sad (Serbia). The effect of stand density on the most important quality criteria in commercial production of confectionary sunflower: oil content (OC) the protein content (PC) and 1000 seed mass (TM) was researched. Three hybrids (H) of NS Seed Company were used (NS-goliat, NS-slatki, NS-gricko). There were six stand densities (D), from 20000-70000 plants per hectare with increasing step of 10000. According to F-test all factors (Y, H, D) and some their interaction had highly significant influence on all quality traits of confectionary sunflower. According to partitioning in total of sum squares off all treatments the most important factor for oil content is hybrid, for protein content is year and for 1000 seed mass is stand density. There were high significant correlations between stand density and OC, PC and TM, +0,99, -0,90 and -0,98, respectively. By increasing stand density by each 10000 plants OC regularly increase by +1,06%, while PP and TM contrary regularly decreases by -0,37% and -8,29g, respectively. Concerning hybrids in average for two years and all stand densities, significantly the lowest OC of 28,03% had hybrid NS-goliat, the highest PC of 16,79% hybrid NS-gricko and the highest TM of 126,03g again hybrid NS-goliat.

Keywords: *confectionary sunflower, plant density, oil and protein content, 1000 seed mass.*

Introduction

Although sunflower is the main oil crop in Serbia, unfortunately production of confectionary sunflower is very low. Non-oil type or confectionary sunflower is distinguished from standard oil type by bigger size of plants and seed, higher protein and lower oil content, better seed hull ability because of thicker hull which is loosely connected to the kernel, as well as by different shell colour and seed shape. Larger size of seeds is especially desirable, because they have higher market value (Crnobarac et al. 2014). There are only a few research about confectionary sunflower. Zubriski and Zimmerman (1974) found that seed yield of nonoil sunflower increased with increase in plant density from 28200 to 47800 plants ha-1. Robinson et al. (1980) found that the minimum plant density required for maximum yield of nonoil sunflower ranged from 25 000 to 62 000 plants ha-1, depending on location. They attributed the differing effects of plant density on yield among the six locations to soil, temperature and rainfall. Also optimum plant density is influenced by sunflower ability to compensate different plant densities through the number of seeds per head and seed weight. Robinson et al. (1980) found that nonoil and oilseed sunflower generally required the same plant densities for maximum yield, while Zubriski and Zimmerman (1974) found that plant density for maximum yield of oilseed sunflower was greater than for nonoil sunflower. In deciding on an optimum plant density for nonoil sunflower, both seed yield and size must be considered. Since

seed size decreases as plant density increases, it is desirable to aim for the plant density that will produce enough large seed without severely reducing overall yield (Gubbels and Dedio, 1986).
The aim of this study was to research hybrid specificity of confectionery sunflower to plant density and it influence on quality criteria oil content (OC) the protein content (PC) and 1000 seed mass (TM)

Materials and Methods

Field plots were conducted in 2011-2012 on experimental field of the Institute of Field and Vegetable Crops, Novi Sad, Serbia. The soil type was the chernozem. The effect of plant density on next quality criteria was researched: oil content (OC), protein content (PC) and 1000 seed mass (TM). Three hybrids (H) of NS Seed Company were used (NS-goliat, NS-slatki, NS-gricko). The hybrids were sown on six plant densities (D), from 20000-70000 plants per hectare with increasing step of 10000. Design of trial was a split plot, where hybrids were on whole plot and density on subplot level. Individual experimental plots were 10 by 4,2 m, with six rows in every plot. Planting was done manually with 2-3 seed per hill; at 70 cm between rows. At stage of 2-3 pair of leaves the plots were thinned at one plant per hill. Harvesting was done manually at maturity by harvesting the two inner rows in each plot. Even there we did not harvest first and last plant in those rows, because of edge effects. Sunflower seeds were threshed on a stationary thresher and further cleaned by hand to remove any broken seed or impurities. Seed oil content (%) was determined from absolutely clean and air dried seed on the NMR-analyzer and seed protein content was determined by Kjeldahl method. Mass of 1000 seeds (g) was measured on a random sample of an absolutely clean and air dried seed. Data was processed by ANOVA and regression analysis. The ANOVA was completed using the Mstat C software and model 'Two Factor Randomized Complete Block Design with Split Plot Combined over Locations'.

Results and Discussion

The influence of year on all traits was high significant ($p<0.01$) and accounted from 10-69% of total of sum squares of all treatments variability (Tab.1). The lowest part of variability was on oil content and the highest on protein content. The influence of genotype on all traits also was highly significant and accounted from 8-51% of variability. The lowest influence of genotype was on 1000 seed mass and the highest on oil content. The influence of plant density also was highly significant for all traits. The lowest influence of density was on protein content (11%) and the highest on 1000 seed mass (69%). Partition of each double interaction in variability for all traits were low and the highest were H x D interaction, 7% and 5% for OC and PC respectively. Triple interactions were also low and significant in oil and protein content, while in 1000 seed mass triple interaction was nonsignificant.

Table 1. Partitioning of treatments sum of square and significances, derived from ANOVA

Source of variation	df	Oil content	Protein content	Mass of 1000 seed
Year (Y)	1	10 **	69 **	20 **
Hybrid (H)	2	51 **	11 **	8 **
Y x H	2	0 ^{ns}	1 *	1 ^{ns}
Plant density (D)	5	24 **	11 **	69 **
Y x D	5	4 **	0 ^{ns}	1 *
H x D	10	7 **	5 **	1 ^{ns}
Y x H x D	10	4 **	3 **	1 ^{ns}

****** Indicates significance at $p < 0,01$, ***** at $p < 0,05$, ^{ns} – non significant.

Level of oil content in seed was pretty low, what is appropriate for confectionery type of sunflower (Tab. 2). Between two research years there is significant difference in oil content, in 2012 was higher for 2,38%. On average for two years and six plant densities, hybrid NS-gricko had significantly the highest (34,16%) and NS-goliat the lowest oil content (28,05%). On average for two years and three hybrids the oil content regularly increased with higher density, and those differences were significant between each step of plant density. There were strong linear regression (r = +0,99) and oil content regularly increase 1,06% for each increasing density for 10000 plants (Graph. 1). Similar influence of plant density was in both researched year and same rule was at each hybrid. In both research year and in each plant density hybrid NS-goliat had significantly lower oil content then another two hybrids. (Tab. 2).

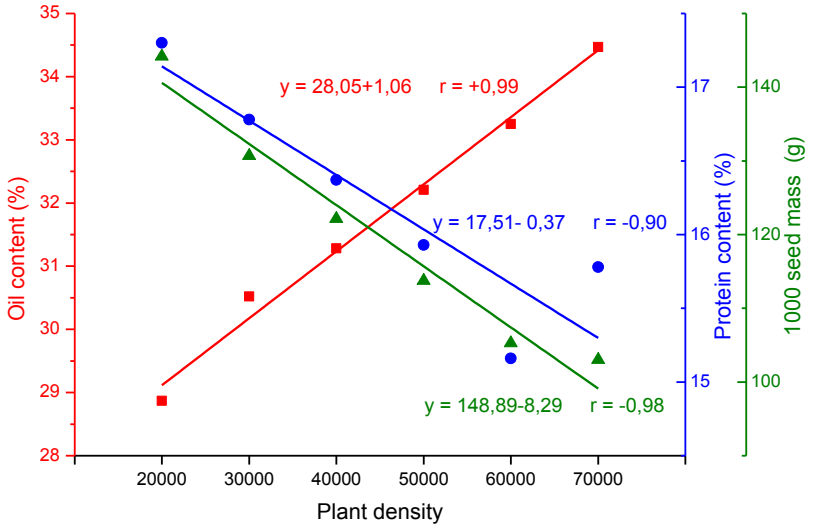

Graph. 1. Regression of confectionary sunflower plant density with of oil and protein content and 1000 seed mass

Like oil content for common oil type of sunflower, for confectionery sunflower protein content is main quality indicator. In average for all other treatments if we look only year, in 2011 was significantly higher protein content than in 2012, difference was 3,29% (Tab.3) and it was opposite to oil content. In average for all others treatments if we look only hybrid, the significantly lowest content of 15,25% had hybrid NS-goliat, after are hybrids NS-slatki and NS-gricko which are similar to each other. In both investigated year order of hybrids was the same like on average. In average for all others treatments if we look only plant density protein content significantly decrease with increasing plant density till to 60000 plants per hectare. At 20000 plants per hectare was 17,30% and at 60000 plants only 15,16%. There were strong linear regression (r = -0,90) and protein content regularly decrease 0,37% for each increasing density for 10000 plants (Graph. 1). Similar influence of plant density was in both researched year. In two way interactions of density and hybrid, there were similar influence of plant density in each hybrid.

$LSD_{0,01}$	0,28	0,34	0,41	0,48	0,58	0,71	1,00
$LSD_{0,05}$	0,20	0,24	0,31	0,34	0,44	0,53	0,76

In average for all others treatments if we look only year, in 2011 was significantly higher 1000 seed mass than in 2012, difference was 15,5 g (Tab. 4) and it was opposite to oil content. In average for all others treatments if we look only hybrid, all hybrids had average 1000 seed mass higher than 100g and even hybrid NS-goliat had 126,4 g. It was significantly higher values than hybrids NS-slatki and NS-gricko which are similar to each other. In both years the were similar relation between hybrids.

In average for all others treatments if we look only plant density seed mass significantly and regularly decrease with increasing plant density till to 60000 plants per hectare. The biggest seed of 144,2g was at 20000 plants per hectare and the lowest of 103,0 was at the highest plant density of 70000 plants. There were strong linear regression (r = -0,98) and regression coefficient was 8,29, it means that seed mass regularly decrease 8,29g for each increasing density for 10000 plants (Graph. 1). Similar trend was in both researched year. Because of non significant influence of interactions hybrid x density all hybrids had significant decreasing of seed mass with increasing plant density were till to 60000. It means that confectionary sunflower hybrids are more sensitive to higher plant density, but hybrids NS-goliat and NS-gricko had market requested seed mass over 100g even at the highest plant density of 70000 plants per hectare.

Table 4. The effect of plant density and hybrids on 1000 seed mass of confectionery sunflower

Year: Y	Hybrid: H	Plant density: D						Av.: YH	Av.:Y
		20	30	40	50	60	70

$LSD_{0,05}$	2,9	3,6	2,8	5,1	4,5	5,5	7,7

Conclusions

According to the quality criteria of domestic confectionery sunflower hybrid we find out that:
Oil content like qualitative traits in confectionery hybrids were pretty low, in all average around 32 % and all investigated factors had significant influence on it, but the highest had hybrid.

- In 2012 oil content was higher, in average for 2,38%
- In both year the lowest oil content achieved with hybrid NS-goliat (28,05%)
- Oil content regularly increased with increasing plant density.

Protein content like main quality traits of confectionery sunflower was influenced by all investigated factors , bat the highest influence had year.

- In 2011 protein content was higher, in average for 3,29%
- In both year the highest protein content achieved with hybrid NS-gricko (16,79%)
- Protein content regularly decreased with increasing plant density.

Seed size or 1000 seed mass was significantly influenced by all investigated factors , but the highest influence had plant density

- In 2011 seed size was higher for 15,5 g.
- In both year hybrid NS Goliat (126,4 g) had the highest 1000 seed mass.
- Seed size regularly decreased with increasing plant density.

Generally, with increasing plant density protein content and 1000 seed mass linearly decrease while oil content increase, for each 10000 plant they changes were -0,37% -8,29g and +1,06%, respectively. The highest influences on and protein content had year, while genotype had on 1000 seed mass. Plant density had the highest influence on 1000 seed mass. According to quality criteria optimal density for confectionary hybrids is around 40000-50000 plants per hectare.

Abstract

Garden sage *(Salvia officinalis* L.) which grows naturally in Albania,is also one of the most economically important aromatic plants cultivated in some areas of the country. In the last decades, molecular markers have been successfully used to assess genetic relationships and genotype identification with great impact on plant breeding programs, germplasm management, and biodiversity preservation. In this study, in order to evaluate the natural biodiversity of populations of northern Albania, eight populations were analyzed based on RAPDs. Genomic DNA was isolated based on a modified CTAB protocol and PCR amplification was completed, using five decameric random primers from Operon Technologies, performed in a volume of 25µl. Amplified profiles were visualized in agarose gels and genetic polymorphic distances were analyzed based on PCoA and R-software. A dendrogram of similarity for the eight populations was produced as well. RAPDs markers proved to be an efficient marker system in detecting polymorphisms among *Salvia officinalis* populations and work will continue with more populations and decameric primers, in order to have these preliminary data enriched and reliable.

Key words:*common sage, molecular markers, genetic variability, RAPDs*

Introduction

Salvia officinalis L.*i*sone of the most important representatives of *Lamiaceae*family. It has been known for its medicinal and culinary uses since ancient times. These species have been investigated mainly for the content and composition of the essential oil, since this has proved to be responsible for most of the pharmacological effects attributed to the plant (Penso, 1983). Sage is valued because of its antiseptic, anti-inflammatory, antioxidant, carminative, cholagogue and diaphoretic properties. Common sage is widespread in the Mediterranean, South-East Africa, as well as in Central and South America, where it is largely cultivated both for culinary and medicinal purposes (Farkas, 2008; Echeverrigaray, 2006; Edris, 2007; Vera *et al.*, 1999). Sage is also used as spice and flavoring agent in perfumery and cosmetics (Delamare *et al*., 2007; Skoula, 1999; Karousou, 2000).Meanwhile, Sage (*Salvia officinalis*), which is grown naturally in Albania, is studied and used extensively for trade. Also it is cultivated in a number of private companies for the high quality of the essential oils.Previous works have demonstrated that,based on morphological and chemical content of their essential oils, Albania is rich in natural populations of sage.

Molecular markers provide another powerful tool for proper characterization of plant germoplasm and their management. Among developed genetic markers, RAPDs, AFLPs and SSR have beenwidely used for diversity analyses (Thimmappaiah*et al*., 2009;Adhikari S. 2013;Grepts, 1993; Khali,l 2005).RAPDs markers have been used widely because they don't require DNA

probes and no sequence information for the design of specific primers. RAPD analysis can be used to identify genetic variation (Bered 2001; Taghian 2003), genetic diversity analysis (Zheng, 2001; Maric, 2004) and phylogenetic relationships (Tsuji, 2000; Goriunova, 2004).
A number of studies have addressed the diversity of the sage populations of Central and Southern Albania (Bacu*et al*., 2005; Bacu*et al*., 2009; Kongjika*et al*., 2014; etc). However, the populations of north of the country are less exploited. Considering that they are grown in geographically isolated areas, with specific climatic and pedological conditions, we expectpolymorphismsnot only in botanical characteristics but in DNA level as well.The aim of the study is to evaluate the natural biodiversity of eight populations of northern Albaniabased on RAPDs.

Material and Methods

Plant material: Fresh young leaves from eight natural populations of *Salvia officinalis*of Northern Albania,10 plants from each population, were used to extract total genomic DNA (Table 1).

Table 1. Sage germplasm used in this study, their source and origin.

Natural populations	Source	Origin
Salvia officinalis	Ulza 1	Albania
Salvia officinalis	Ulza 2	Albania
Salvia officinalis	Kruje	Albania
Salvia officinalis	Lezhe	Albania
Salvia officinalis	Valbona 1	Albania
Salvia officinalis	Shengjini 1	Albania
Salvia officinalis	Shengjini 7	Albania
Salvia officinalis	Shiroke mix	Albania

Isolation of genomic DNA: Equal amounts (0.1 g) of leaf tissue were placed in a mortar chilled with liquid nitrogen and were ground to fine powder. Total genomic DNA was extracted as described by Doyle and Doyle (1987). Quality and quantity of DNA was measured according to Sambrook*et al*., 1989.

PCR amplification:
Five arbitrary RAPD primers were used, OPA06, OPA 14, S2134, OPA02, OPB06 (Cinnagen, Tehran, Iran). Primers were chosen from Scoula*et al*., 1999(Table 2).
The PCR amplifications were carried out in Veriti 96-Well Thermal Cycles (Applied Biosystem) in a total volume of 25 µl containing Master mix (Cinnagen, Tehran, Iran), genomic DNA (30 ng), 50 pmoles of decameric primer and ddH2O. The PCR program started with an initial phase of 1 minute at 95^{o}C, followed by 45 cycles of 30 s at 95^{o}C, 30 s at 39^{o}C, 2 min at 72^{o}C and 10 min final elongation at 72^{o}C.

Table 2. RAPD primers sequences according to Scoula*et al*., 1999.

Primer	Primer sequence (5'-3')
OPA02	TGATCCCTGG
OPA06	GGTCCCTGAC
OPA14	TCTGTGCTGG
OPB06	TGCTCTGCCC
S2134	GACCAGCCCA

The amplified products were separated by electrophoresis in horizontal 1.2% agarose gels in 10X TBE. Gels were stained with 2 µl ethidium bromide, and visualized under UV light.
Fragments were scored as a binary variable, (1) for the presence, and (0) for the absence of each band. The most distinct well-resolved stable bands were considered for statistical analysis.

Statistical analysis: RAPDs gels were analysed by Principle Correspondance Analysis (PCoA) to infer the phylogeographic pattern of polymorphism distribution using R-software and "adgenet" library.

Results and Discussions

The RAPDs based analysis of eight populations of sage of northern Albania displayed a variable level of similarity for different primers used to amplify arbitrary primed regions. Three, random primers out of five gave best stable polymorphic profiles, which were further processed, respectively OPA14, OPA02 and S2134(Fig 1).

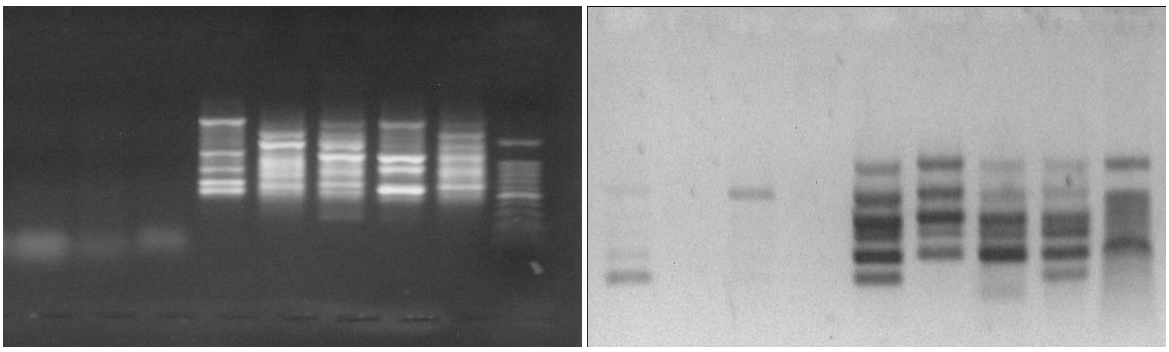

Fig 1.RAPDs profiles fromeight sage populations generated from amplification with primers S2134 (right) and OPA02 (left). From left to right populations of Ulza 1; Ulza 2; Kruje; Lezhe; Valbona 1; Shengjin 1; Shengjin 7; Shiroke mix; 100bp marker.

Primer S2134 gave 12 bands from which 10 polymorphic, and primer OPA02 gave 13 bands from which 12 polymorphic. Reproducibility of banding patterns was good, and these bands were used for further processing in order to build clusters of similarity among the populations (Fig 2, 3, 4).

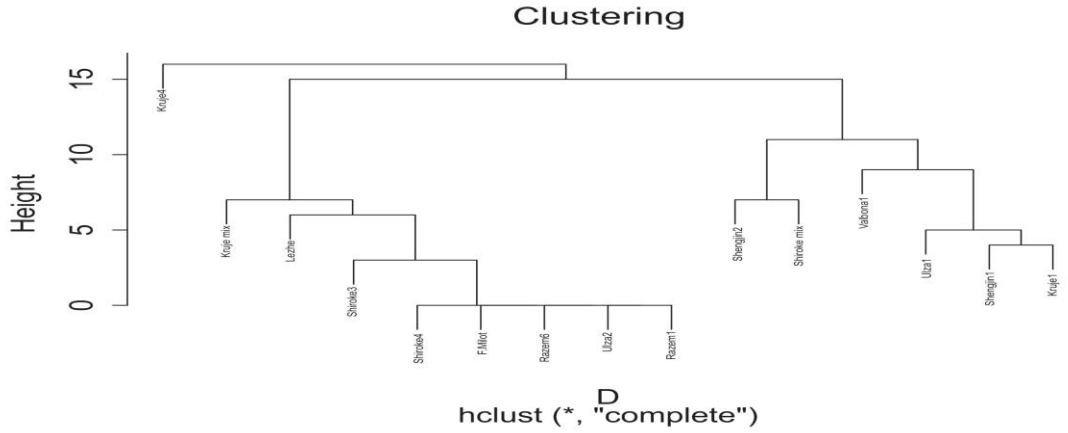

Fig 2. Dendrogram of polymorphic distances between analyzed samples, constructed by a complete linkage method.

The complete linkage method showed that populations are clustered in two main groups made of four populations each, with population of Kruja as a distinct one.

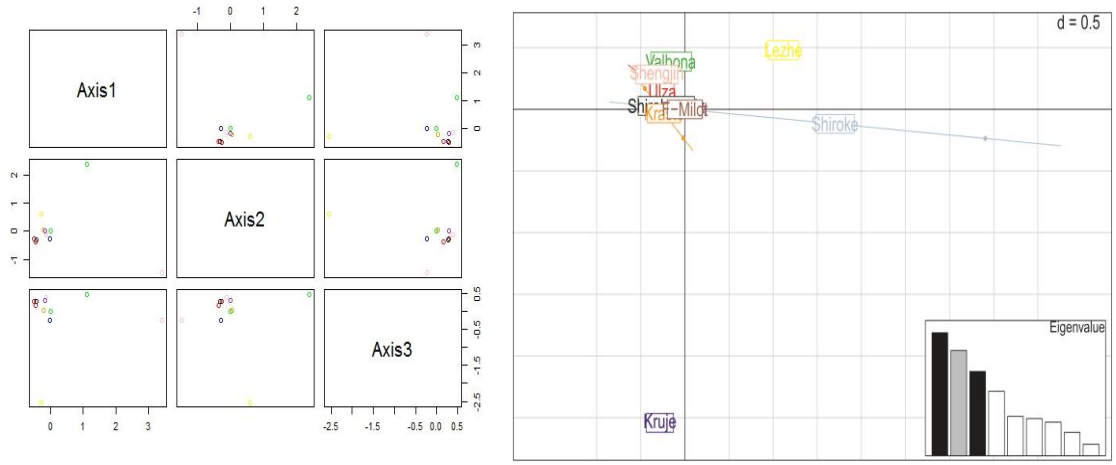

Fig 3/4. Clustering of populations of *Salvia officinalis* based on three principal components (PC).

Principle Correspondence Analysis (PCoA) of eight *Salvia officinalis* populations from the Northern Albania, which is plot by PC weight, shows that the most distant populations are Kruja, Shiroka, and Lezhe.

Conclusions

1. The RAPDs reactions showed that three out of five random primers (OPA14, OPA02 and S2134) are able to distinguish polymorphism between *Salvia officinalis* populations.
2. The PCoA suggests a highergenetic distance among Lezha, Shiroka and Kruja populations with the rest, based on polymorphism of randomly amplified bands.
3. RAPDs analysis is a valuable tool to distinguish diversity at population level for Salvia *officinalis* populations, and can be implemented successfully to assess even the diversity among genotypes within populations.

COMPARATIVE EXTRACTION PROTOCOLS FOR AN EFFICIENT GENOMIC DNA FROM S*alvia officinalis* L.

Stela PAPA*, Ariola BACU

Department of Biotechnology, Faculty of Natural Sciences, University of Tirana, Albania. Blv "Zogu I", Tirana, Albania
*Corresponding author: stelapapa@yahoo.com

Abstract

Studies on plants genetics generally and those on aromatic-medicinal species, including sage, particularly start with establishing of protocols for high quality DNA extractions. Different protocols have been reported, including CTAB based and commercially available kits. DNA from medicinal and aromatic plants such as common sage (*Salvia officinalis*, L.), as a result of the high content of secondary metabolites, which interfere with DNA isolation, need to be extracted with protocols modified in order to produce a DNA of good quality. In this study, two protocols were compared. DNA was isolated from fresh and dried leaf materials of 6 populations of *Salvia officinalis* of Northern Albania and quantity and quality in each case were determined based on spectrophotometry. Results show that for a good quality and quantity of genomic DNA the samples should be fresh young leaves and that both CTAB modified protocol and Plant Genomic DNA Kit (SIGMA) protocol avoid contaminants as carbohydrates and phenolics.

Key words:*genomic DNA, CTAB, Salvia officinalis*L.

Introduction

Medicinal plants have been used as natural remedies for thousands of years and in our days they are attracting more attention for researchers. Medicinal plants have a great diversity of bioactive components, which have been studied from many aspects (Leone *et al*. 2007; Ramawat and Merillon, 2008; Arora, 2011).These plants contain exceptionally high amounts of polysaccharides, polyphenols, and other secondary metabolites, which are often responsible for their therapeutic and pharmacological properties (Abu-Romman, 2010).

Garden sage (*Salvia officinalis* L.) has a very long tradition as a medicinal and aromatic herb with a broad range of applications. Sage is an important member of the mint family (*Lamiaceae*) used in medicine for treating many diseases (Lu and Foo, 2000).Common sage is characterized by a high content of polysaccharides, polyphenols, flavonoids, alkaloids, carbohydrates and diterpenoids (Kintzios, 2000), and so may be a recalcitrant target for isolation of large quantities of pure genomic DNA. Several studies have shown sage to be one of the sources of some potent antioxidants and antimicrobial agents (Cuvelier *et al*., 1996). The application of molecular technology would increase and will as well facilitate the production of these substances (Stöckigt *et al*., 1995) and help save natural resources (Pirttilä *et al*., 2001).

These same substances that make the aromatic plants worthy of different studies may also be an impediment for isolation of large quantities and efficient genomic DNA. Phenols and polysaccharides bind firmly to nucleic acids during DNA isolation and interfere with subsequent reactions. Polyphenols released from vacuole during the cell lysis process are oxidized by cellular oxidases and undergo irreversible interactions with nucleic acids causing browning of the DNA

thus making the DNA resistant to restriction enzymes and polymerases (Abu-Romman, 2010; Aleksic, 2012).

The aim of this study was to establish an efficient DNA isolation protocol to obtain large amount of high quality DNA. The procedure of Doyle and Doyle (1987) and Plant Genomic DNA Kit (SIGMA) protocolwere tested forten sage plants of natural populations; Additional modifications were used to simplify the isolation procedure and to improve both DNA yield and purity. DNA isolates were used for specific PCR amplification of one nuclear region (26S rDNA), and one MTPs specific region, which can be potentially informative for future studies in common sage.

Material and Methods

Plant materials

Fresh young leaves were obtained from six populations of *S. officinalis* grown naturally in northern Albania region (populations of Rubik, Balldren, Lohe, Kruje, Fushe-Milot, Razem). Before proceeding with DNA extraction, leaves were placed in a mortar pre chilled with liquid nitrogen. Frozen sample was ground with a pestle andliquid nitrogen was added to prevent thawing, and two protocols were followed.

A) Modified Doyle & Doyle DNA extraction

All reagents and chemical used for optimization of DNA extraction has been manipulated in different combination for obtaining pure DNA from the leave sample.

- Doyle and Doyle(1987) protocol were followed up to the dilution of the DNA pellet in TE;
- Than were added 50mg of PVPP and 5µl of Proteinase K in order to rapidly inactivate nucleases that might otherwise degrade the DNA or RNA during purification.
- RNAse treatment were followed in order to definitely degrade the RNA traces possibly present at samples.

B) GenElute TM Plant Genomic DNA Kit (SIGMA) protocolG2N-70; LOT 094K6032

After the extraction procedure described according to the manufacturer of Plant Genomic DNA Kit (SIGMA), a second purification procedure was followed using phenol-chlorophorm-isoamylalcohol according to Sambrook *et al*. (1989).

Measurement of quality and quantity of DNA was completed following Sambrook *et al*., (1989) using the spectrophotometer ACTGene ASP-3700. Results are given at table1.

PCR Analysis: In order to verify the quality of the genomic DNA extracted with both methods, two specific PCR amplification reactions were prepared: One for the direct amplification of the approximately 300bp region, a control DNA fragment, with Phire Plant Direct PCR Kit F-130, according to Demesure *et al*. (1995), and the second for the amplification of a central region of MTPs coding genes;

***Amplification of the control DNA fragmentaccording to* Demesure *et al*. (1995):**

50ng of genomic DNA were used as a template for PCR amplification.

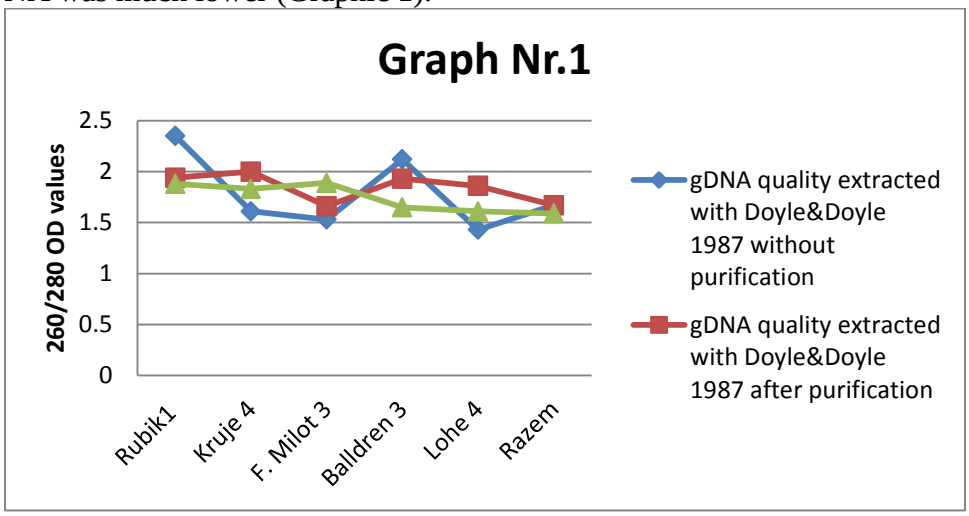
The amplification was carried out in a 20 µl reaction mixture containing 2X Phire Plant PCR buffer (includes dNTPs and $MgCl_2$) 10µl, 25 µM Control Primer mix (Forward Primer 5'-AGTTCGAGCCTGATTATCCC-3' and Reverse primer 5'-GCATGCCGCCAGCGTCATC-3'), 0.4 µl Phire Hot start II DNA Polymerase and 7,2 µl ddH_2O. Cycling conditions consisted of an initial 5 min at 98°C followed by 5 sec denaturing at 98°C, 5 sec annealingat 62°C and 20 sec elongation at 72°C repeated for 40 cycles andwith 1 min extension at 72°C.

Amplification of the central region of MTPs coding genes:

To test the suitability of the extracted DNA for enzymatic reactions, PCR was carried out using specific primers, Forward primer Sbs350 (5' TTCAACAGTTGGAGTTGATTGATGA 3') and reverse primer Sbs1010 (5' ATTCCACAATCCTATCTCTCACAAA 3'), designed to amplify a 720 bp amplicon for *S. officinalis* gene. The amplification was carried out in a 25 µl reaction mixture containing 1x PCR reaction buffer, 0.2 mM dNTPs, 100 pmol forward and reverse primers, 3 µM $MgCl_2$, and 0.5 U of *Taq* DNA polymerase. Cycling conditions consisted of an initial 3 min at 94°C followed by 0.5 min denaturing at 94°C, 1 min annealing at 66°C and 30 sec elongation at 72°C repeated for 35 cycles and with 5 min extension at 72°C.
Genomic DNA extracted using the two protocols was used as template for PCR amplification.

Results and discussions

This research was focused on comparing two types of DNA extraction protocols in order to establish the most suitable one for the isolation of nucleic acids from *Salvia officinalis* leaf tissue. The establishment of suitable nucleic acid isolation protocols that can produce high yield of genetic material with minimal contaminant from this plant is an important starting point forsubsequent molecular genetic studies. A good quality and quantity of isolated DNA is crucial for molecular techniques such as polymerase chain reaction (PCR), Southern blotting and other genomic analysis. The modified CTAB protocol was efficient and so did the CTAB based method, however both were modified with additional steps. The first DNA extraction protocol was based on Doyle and Doyle (1987). CTAB, a strong ionic detergent, has been used to facilitate the separation of proteins from nucleic acids in extractions of biological materials. There were made some modifications to the original protocol such as the additional steps of PVPP and Proteinase K as well as the treatment with RNase in order to improve the extracted of DNA. Based on Krizman *et al*., (2006)this modification works well with aromatic plants, and our results prove this as well. The second protocol was the GenElute TM Plant Genomic DNA Kit (SIGMA). Without a second purification based of phenol:chlorophorm:isoamylalcohol, the quality of DNA was much lower (Graphic 1).



Graphic1. Comparative data of gDNA quality extracted with Doyle and Doyle (1987) without the second purification (blue line) with phenol:chlorophorm:isoamylalcohol and the data of purified gDNA quality extracted with Doyle and Doyle (1987) (red line) and with GenElute TM Plant Genomic DNA Kit (SIGMA) protocol (green line), both after purification steps with phenol:chlorophorm:isoamylalcohol.

Table 1 shows the yield and quality of sage DNA isolated using both methods and suggests that the first based on Doyle and Doyle(1987) modified, gives better results on the quality of the DNA.

Table 1. Quality and Quantity results measured spectrophotometrically.

The DNA yield obtained via the modified protocol varied from 6-100 ng/µl DNA of leaf tissue (Table 1).

Specific PCR results

Figure 1 (left) illustrates the amplification of the 297 bp control DNA fragment from the gDNA of two populations of sage.Figure 2 (right) illustrates the amplification of the MTP coding region from six populations of sage. Population of Razem in MTPs primers (Fig 2) amplification did not give an amplicon (first line after the marker). These results indicate that the two protocols of DNA extraction were able to produce a relatively good quality DNA suitable for PCR amplification, however, there are differences in the quantity.

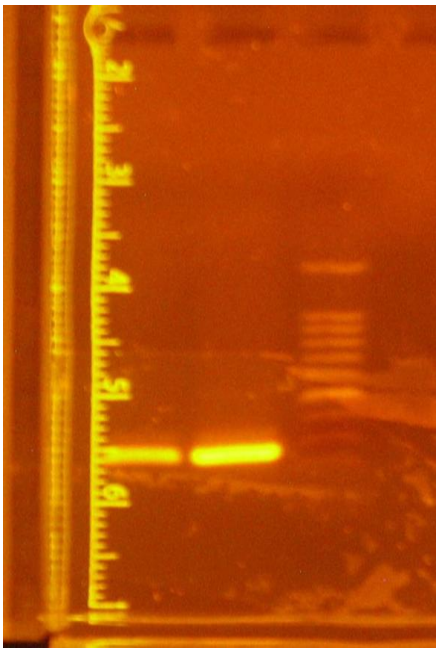

Fig 1. Two populations of sage Rubik 1, Kruje 4, 100bp marker (from left to right), amplified of the 297bp control DNA fragment with FINNzymes protocol.

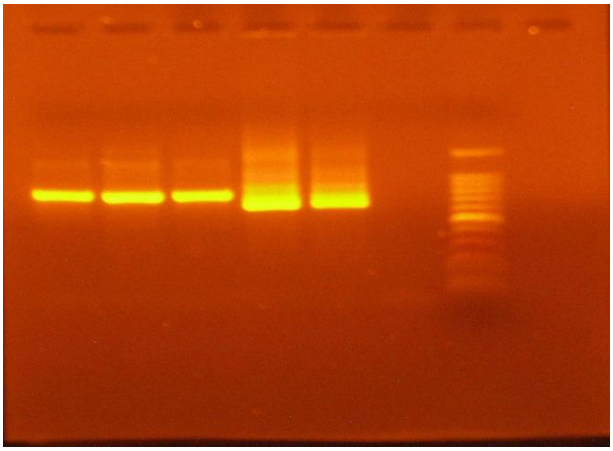

Fig 2. Six populations of sage, Rubik1, Kruje4, F.Milot 3, Balldren 3, Lohe4, Razem 100bp marker(from left to right), amplified with specific primers for MTPs.

Conclusions

Summing up, the two methodologies tested in this study were shown to be adequate for molecular studies in common sage. However, the modified CTAB methodology is recommended due to lesser costs especially and SIGMA kit is recommended due to the practicability of the method, especially considering DNA extraction from freshplant leaves.

Abstract

Some allelochemical compounds secreted by variety plants parts may cause allelopathic effects on other organism. The aim of this study was to investigate the effect of *Origanum onites* L. (*Ori*) and *Rosmarinus officinalis* L. (*Ros*) essential oils on durum wheat germination and seedling growth. Doses of 0, 2, 4, 8 and 16 µL per petri dishes were applied, and five durum wheat cultivar seeds were allowed to germinate at 20 ± 2 °C in the dark for 10 days. Germination percentage (GP), germination index (GI), mean germination time (MGT), seedling shoot length (SL), seedling root length (RL), and seedling fresh weight (SFW) of cultivars were measured. Results showed that the significant allelopathic effect of essential oils was depended on cultivars, oil types and oil practiced doses. Both *Ori* and *Ros* essential oil caused a generally reducing effect on GR, GI, SL, RL, and SFW of the tested genotypes. Inhibition rates related to tested traits was increased with the increasing doses. When control and lowest oil doses and control and highest oil doses were compared, *Ori* oil caused 46.2 to 98.3 % GP inhibition, 60.3 to 94.6 % GI inhibition, 25.1 to 90.8 % SL inhibition, 47.8 to 95.6 % RL inhibition, 21 to 84 % SFW inhibition, respectively. When *Ros* oil was concerned inhibition rate range of GP was from 15.1 to 91.5 %, GI from 31.8 to 96.6 %, SL from 22.1 to 88.2 %, RL from 24.2 to 91.9 %, and SFW from 14.4 to 68.5 %. There was a delay on MGT of cultivars as the oil dose was increased. *Ori* oil had higher allelopathic effect than did *Ros* oil on seed germination and seedling growth of durum wheat. The result of the study also demonstrated that essential oil of *Ori* and *Ros* had allelopathic potential and should be evaluated as allelopathic agents if it will be used for control of weeds and volunteer wheat species.

Key words: *Durum wheat, oregano, rosemary essential oils, germination and seedling growth*

Introduction

Being a leading crop, bread wheat (*Triticum aestivum* L.), durum wheat (*Triticum durum* Desf.), and soft wheat (*Triticum compactum* Host.) cultivars or landraces are grown varying geographical conditions of Turkey; such that 15 - 12% of the wheat produced in Turkey belongs to durum wheat (Anonymous, 2013). When wheat species are grown there are varied environmental constraints that affect wheat yield and yield components. Weeds are one of the main constraints that negatively affect wheat yield loss across the wheat growing areas of the world as well as Turkey since they deprive the plants from limited available nutrients, light and moisture. More specifically, weeds are responsible for 23% wheat yield reduction in the worldwide (Oerke, 2006). Some weeds are also shown for their allelopathic or toxic effect on the wheat germination and seedling growth (Faragasso et al., 2013). Accurate weed control is needed for wheat based food security for every country of the world. To achieve weed control, increased amount of herbicides have been used. In long run chemical weed control will be facing some

challenges such as herbicide resistance in weeds, negative impact of herbicides on environment, human and animal health and increasing management cost for herbicide. This has resulted in increased consideration to alternative strategies for development of new environmental friendly biodegradable compounds especially in organic farming (Jabran et al., 2015).

Some allelochemical compounds secreted by variety plants parts may cause allelopathic effects on other organism or plants (Angelini et al., 2003; Bonanomi et al., 2006; Jabran et al., 2015). Allelopathic effect of some essential oil crops has been investigated in various oil or ornamental plants or crops by varying different parts. Different chemical components of essential oils have varying effect on crop plants. Germination inhibition caused by essential oils, as applied to the germinated seed of various crops and weeds has been reported by the previous works (Azirak and Karaman, 2008; Mutlu and Atıcı, 2009; Uremis et al., 2009; Gitsopoulus et al., 2013)

In Turkey, durum wheat cultivars' products frequently are used as a homemade food such as bulgur, macaroni, eriste (noodle), cakes, breads etc. For making healthy homemade food products, organic durum wheat is highly preferred by the consumers. By using plant biodegradable agents in weed and insect control is an indispensable component of organic durum wheat farming. For these aims different essential oils, doses and different durum wheat cultivars should be tested and investigated for potential weed control agents or volunteer wheat.

To the best of our knowledge, there were not much previous reports on cultivar based allelopathic effects of essential oil. The aim of this study was to evaluate essential oils of *Origanum onites* L. (*Ori*) and *Rosmarinus officinalis* L. (*Ros*) as an allelopathic agent on five durum wheat cultivars germination and seedling growth.

Materials and Methods

This study was conducted at the Faculty of Agriculture, Mustafa Kemal University, Hatay (Turkey) in 2015. Registered durum wheat cultivars seeds of Turkey namely 'Ankara-98 (A), Ç-1252 (Ç), İmren (İ), Kızıltan-91 (K), and Yelken-2000 (Y)' were provided by the Field Crops Central Research Institute (Ankara, Turkey). Germination and early seedling growth (10 days) of the cultivars were studied using distilled water (control) and essential oil doses of 2, 4, 8, 16 µL / petri dish containing *Ori* or *Ros.*

The essential oil was extracted from shade dried shoots and leaves of *Ori* and *Ros* samples. The GC-MS analysis were also performed by using a gas chromatograph HP 6890 (Agilent Technologies, Palo, Atla, USA) with electron impact ionization (70 eV) to determine yield of oils. Detailed information and procedure about used plant material, oil extraction and yield of essential oil can be seen in our previous work (Atak et al., 2016).

For each wheat cultivar surface sterilized seeds, 0, 2, 4, 8 and 16 µL essential oil per petri dishes (9 cm) were tested for seed germination and seedling growth with four replicates. To test the effect of the essential oils, 25 seeds were put on two layered filter paper (Whatman no 1.) in a petri dishes moistened with 6 mL distilled water. Aforementioned amount of essential oils was applied on the small piece of filter paper attached inside the petri dishes caps. Petri dishes were closed immediately and tightly sealed with parafilm to prevent loss of moisture, essential oil and avoid contamination and then incubated in a germination cabinet (SANYO FOC 225 İ, Refrigerated-Incubator, JAPAN). The wheat seeds were allowed to germinate at 20 ± 2 °C in the dark for 10 days (ISTA, 1996). A seed was considered as germinated when the emerging radicle elongated to 2 mm. Germination percentages were recorded every 24 h for 8 days.

Mean germination time (MGT) was calculated to assess the rate of germination (Ellis and Roberts, 1980). Germination index (GI) was calculated by using Maguire's (1962) procedure. The seedlings were thinned to 10 plantlets per petri dish after the eighth day. Fresh root and shoot

length and seedling fresh weights were measured on the tenth day of the experiment (Atak et al., 2016). A completely randomized design was used with a factorial arrangement of treatments (Oil (O), cultivar (G) and essential oil concentration (D)) with 4 replications and 25 seeds in each replicate. Data were analyzed by 2-way analysis of variance using statistical package MSTAT-C, and differences among the means were compared using Duncan's multiple range test ($P < 0.05$).

Result and Discussion

Analyses of variance (ANOVA) showed that tree ways interactions of tested treatments were highly significant except SL and SFW. All main effects of G were significant for all the treatments. Main effects of O were significant for all the tested treatments but not for the SL. Main effects of D were significant for all the tested treatments.

Performed ANOVA indicated that GP was significantly affected by O x G x D interaction (Figure 1). The essential oil of *Ori* and *Ros* significantly inhibited GP of wheat genotypes compared to respective control. The GP inhibition was higher for the essential oil of *Ori* and it was more pronounced at increasing dose of the respective oil (Figure 1). When 16µL and 2µL *Ori* was used 98.3% and 46.2% GP, respectively, inhibition was noted in durum wheat cultivars. The wheat cultivars' germination inhibition rate of *Ros* was ranged 91.3% (16µL) to 15.1% (2µL). The GP inhibition effect of *Ori* essential oil was more apparent as the dose increased. More specifically, at the highest dose of *Ori* there was no germination in other cultivars but cv. İmren showed 8% GP. On the other hand, all cultivars GP were not totally inhibited at 16 µLof *Ros* (Figure 1). GP of cultivars was ranged 5 to 12% at the highest dose of *Ros*. These results showed that essential oil dose of *Ori* and *Ros* had inhibition effect on seed GP of the durum wheat cultivars, but inhibition effect of *Ori* oil was more remarkable (Figure 1). It was reported that terponoids, in particular monoterpenes and sesquiterpenes were the main components of essential oils responsible for inhibitory effects on weeds and crops (Gitsopoulus et al., 2003; Uremis et al., 2009). Dudai et al. (2004) informed that monoterpenes such as Carvacrol had very powerful seed germination inhibitors for wheat. Our experiment result also reveals that carvacrol had negative effect on the germination of durum wheat cultivars in varying proportions since *Ori* oil had more carvacrol rate than *Ros*. Our previous experiment results showed that *Ori* oil had more inhibition effect than the *Ros* oil had on bread wheat and some weed species germinating and seedling growth (Atak et al., 2016).

Mean germination time (MGT) was delayed as the dose of essential oil increased (Figure 1). When the genotypes exposed to *Ori* oil MGT ranged 2.79 to 6.29 days. But the MGT for the genotypes exposed to *Ros* oil ranged 1.97 to 6.93 days (Figure 1). There are no previous experimental results representing essential oil effect on MGT in durum wheat. Our results showed that interested essential oils affected MGT in durum wheat cultivars variably depending on concentration of type of essential oil and cultivars.

Germination index (GI) was decreased as the dose of oil increased. GI for the genotypes exposed to *Ori* oil ranged 14.6 to 0.78. But the GI for the genotypes exposed to *Ros* oil ranged 15.5 to 0.52 (Figure 1). There were no previous experimental results representing essential oil effect on GI in durum wheat. Our results showed that respective essential oils affected GI in durum wheat cultivars variably depending on dose, type of essential oil and cultivars. Higher GI represents the higher seed vigor of crops. Our results showed that when used *Ori* seed vigor of the genotypes were more affected as compared to *Ros* oil.

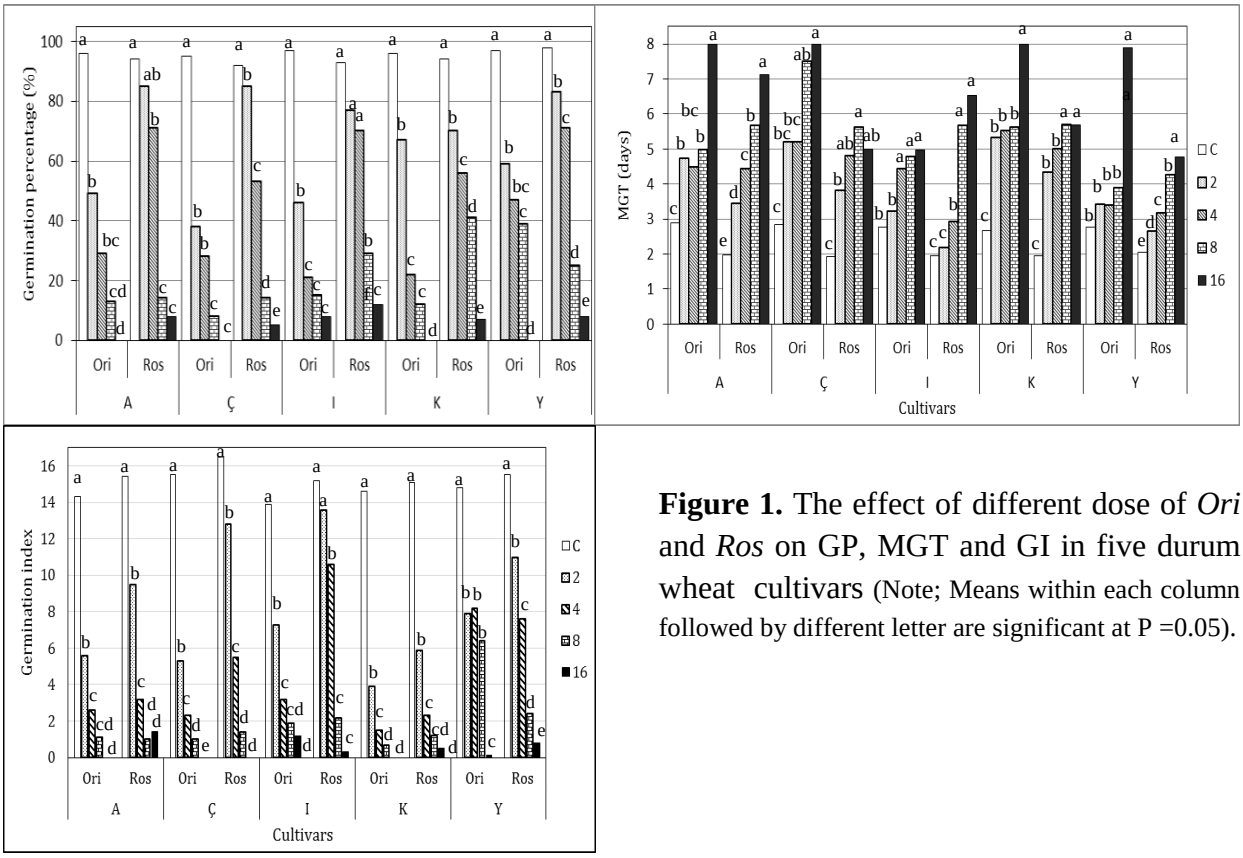

Figure 1. The effect of different dose of *Ori* and *Ros* on GP, MGT and GI in five durum wheat cultivars (Note; Means within each column followed by different letter are significant at P =0.05).

Essential oil of *Ori* and *Ros* not-significantly reduced seedling shoot length (SL) of durum wheat cultivars compared to respective control treatments (Table 1). But, the reduction rate of SL was relatively increased with the increasing dose of both essential oil types. The essential oil of *Ori* proved more powerful allelopathic effect compared to the essential oil of *Ros.* Both oil dose of 2µL and 16µL when compared, shoot length of genotypes ranged 72.5 to 9mm and 79.6 to 12.0mm using *Ori* and *Ros,* respectively. Cultivars showed the varying inhibitory effect with increasing oil doses of essential oil type (Table 1).

Essential oil of *Ori* and *Ros* significantly reduced the seedling root length (RL) of durum wheat genotypes compared to respective controls (Table 1). The inhibition rates were relatively increased with the increasing dose of both essential oils. But RL inhibition rate caused by *Ori* was higher than the inhibition rate of *Ros*. Previous experiments reported that essential oil effect on various cereal crops (Dudai et al., 1999; 2004) including bread wheat germination inhibition (Atak et al., 2016).

Essential oil of *Ori* and *Ros* significantly decreased the seedling fresh weight (SFW) of durum wheat genotypes compared to respective controls (Table 3). The inhibition rate was relatively increased with the increasing dose of both essential oils. The SFW of durum wheat genotypes were inhibited by 84% and 68.5%, by application of highest dose of *Ori* and *Ros* oil, respectively (Table 1). This study results confirmed allelopathic activity (inhibition) of essential oils extracted from *Ros* and *Ori* on the investigated durum wheat cultivars. The essential oil of *Ori* exhibited the more powerful allelopathic effect compared to *Ros* essential oil on the tested durum wheat cultivars in terms of germination and seedling growth.

*) Means within each line followed by different letter are significant at P =(0.05).

The results also revealed significant difference in the inhibitory effect of the two essential oil types and doses against durum wheat genotypes. This different response can be attributed to different rates of allelochemical metabolism (Gitsopoulus et al., 2013). The higher phytotoxicity of *Ori* may be attributed to Carvacrol as the main constitute that had a negative effect on germination of wheat genotypes (Dudai et al., 2004; Azirak ve Karaman, 2008; Atak et al., 2016). The amount of metabolize certain monoterpenes responsible for inhibition effect on germinated seed (Dudai et al., 1999). The essential oils are believed to be secure since they breakdown quickly in the natural environment and show low toxicity (Mutlu ve Atıcı 2009; Uremis et al., 2009; Gitsopoulus et al., 2013). In this regard they differ from synthetic herbicides. They can be used as an environment friendly tool for weed or pest control in field crops; however, they must act selectively, giving no damage to crops that are intended to grow (Azirak ve Karaman, 2008).

For this intention, the herbicidal effect of the essential oil should be evaluated both at field level by using various cultivars and relevant harmful weed species.

Our previous work results showed that bread wheat genotypes were affected less compared to weed species showing proper dose of these essential oils could be used as a bio- herbicide for weed control. Dudai et al. (1999) and Gitsopoulus et al. (2013) revealed variable essential oil responses among cereal crops. In present study, the essential oil of *Ori* exhibited the higher phytotoxic effect compared to *Ros* oil on durum wheat germination and seedling characters.

Conclusion

More knowledge about bio-degradable herbicides or pesticides would help to decrease man made environmental damages. The present study results showed that the essential oil of *Ori* and *Ros* could be considered as potential allelopathic agents in durum wheat cultivars. Using dose of 16µL / petri or more will also be useful to suppress or control the volunteer durum wheat species in organic crop areas.

Abstract

In this study, the effects of 1% Disper Cu Max and 5% sodium hypochlorite treatments on postharvest quality and decay control of baby cucumbers were evaluated. After Disper Cu Max and sodium hypochlorite applications, cucumbers were packaged in modified atmosphere packaging (MAP). Packed baby cucumbers were stored at 8°C temperature with 90-95% relative humidity (RH) for 28 days. Samples were taken at 7 day intervals from different storage conditions and various physical and chemical analyses such as weight loss, flesh firmness, titratable acidity, pH, soluble solids, skin color (L*, C*, h°), percentage of physiological disorders and decays were determined. Furthermore, the changes in O_2 and CO_2 levels in the MA bags were recorded. Experimental results showed that the lowest weight loss, decay and disorder development were determined on the baby cucumbers treated with sodium hypochlorite + MAP combination. Dipping the cucumbers in Disper Cu Max solution had the highest titratable acidity and soluble solids content at the end of the storage. The highest L*, C* and pH values were obtained from Disper Cu Max + MAP treated cucumbers. It can be concluded that baby cucumbers were successfully stored at 8°C temperature and 90-95% RH in Disper Cu Max + MAP combination for 28 days with minimal quality losses.

Keywords: *Baby cucumber, storage, MAP, fruit quality*.

Introduction

The production of vegetables in Turkey is on the fourth place in the world after China, India and the USA. Turkey produced 28 million tons of vegetables in 2013 (FAO, 2013).

Cucumber is one of the most economically important vegetables belonging to the Cucurbitaceae family (Jeffery, 1980). Total world production of cucumber in 2012 was 65.1 million tons, of which over 73.7% was produced in China (FAO, 2012). However, the quality of cucumbers rapidly decline after harvest and the fruit have very limited shelf-life as well. The main factors limiting shelf-life of cucumbers are fruit yellowing, disease development and excessive water loss (Zhang et al., 2014).

New techniques for reducing undesired microbial contamination, spoilage and decay, as well as maintaining the product's visual quality, textural and nutritional quality are required at all steps of the production and distribution chain (Marcin et al., 2014). Chlorine has been widely used primarily to wash agricultural produce due to its low cost and proven efficacy against bacterial pathogens (Adams et all., 1989). The frequently used forms of free-chlorine are liquid chlorine and hypochlorites (Parish et al., 2003). It is typically used in the range of 50 – 200 ppm free chlorine, usually having contact time of 5 min (Rico et al., 2007).

MAP is used to prolonged the storage duration and shelf-life of different fruits and vegetables (Sandhya, 2010). By creating higher CO_2 and lower O_2 concentrations in the surrounding atmosphere of the commodities decay development, respiration rate, ethylene production, and enzymatic activity can be controlled, resulting in an increase in postharvest quality of different commodities (Kader and Watkins, 2000; Caleb et al., 2012). MAP may also prevent weight loss and fruit shriveling by creating a higher relative humidity in the surrounding environment of the products (Zagory et al., 1989).

The objective of this research was to find out the effects of MAP, 1% Disper Cu Max and 5% sodium hypochlorite treatments on postharvest quality and decay control of baby cucumbers.

Materials and methods

Fruit material

Freshly harvested baby cucumbers (cv. Silor) at commercial harvest maturity were obtained from a local farm in Antalya (Turkey), and transported to the Postharvest laboratory of Department of Horticulture, Akdeniz University within 3 h after harvest. On the same day, samples were selected for uniformity in size, shape and color. Fruit with signs of mechanical damage, sunburn, blemishes, disease and pest damage were discarded.

Postharvest treatments and storage

After sizing and selecting, baby cucumbers were randomly divided into five groups of 120 fruits from each group. The first group of cucumbers was dipped in 1% Disper Cu Max solution for 60 sec. The second group of cucumbers was first dipped in 1% Disper Cu Max solution for 60 sec. then packed in MAP. The third group of cucumbers was treated in 5% sodium hypochlorite solution for 60 sec. The fourth group of cucumbers was first dipped in 5% sodium hypochlorite solution for 60 sec. then packaged in MAP. The fifth group of cucumbers was not treated and considered as control. Treated baby cucumbers were stored at 8°C with 90-95% RH for 28 days.

Weight loss

For weight losses, at harvest, individually numbered fruit were weighed, and at the end of each storage period the cucumbers were re-weighed again and weight losses was determined and expressed as percent loss from initial weight.

Fruit firmness

Fruit firmness was measured by a manual penetrometer (Model FT 011) with a 3 mm diameter flat probe. The flat probe was inserted to a depth of 5 mm. While measuring the firmness, peel of the cucumbers was not removed. The results were expressed as kg/cm^2.

Titratable acidity and pH

For titratable acidity (TA) and pH, juice from baby cucumbers is squeezed by using a blender. TA was determined by titrating 5 mL of fruit juice in 35 mL of distilled water with 0.1 N NaOH to an end point of pH 8.1 and expressed as percent of citric acid equivalents. pH measurements of the cucumbers were carried out by using a digital pH meter.

Total soluble solids content

For total soluble solids (TSS) content, fruit samples taken from fresh baby cucumbers and the juice obtained by using a blender.TSS content of the cucumbers was determined by using a digital refractometers and expressed as % Brix.

Skin color (L, C*, h°)*

The skin color of the cucumbers was assessed by using a MINOLTA CR-200 Chromameter, (MINOLTA Camera Co, LTD Ramsey, NJ). Skin color of the cucumbers were presented as lightness (L*), hue angle (h°), and chroma (C*) by conversion from a* and b* values. The h° indicates how green or yellow a fruit is, and C* describes the vividness to dullness of the color (Selcuk and Erkan, 2015).

Changes in oxygen (O_2) and carbon dioxide (CO_2) levels in the MA bags

O_2 and CO_2 levels inside the MA bags were monitored during the storage by using an O_2 and CO_2 gas analyzer (Dansensor CheckPoint 2014, Denmark). Measurements were taken at 2 different sides of the each MAP. Total of 6 measurements were made at 3 packages for each treatment. The results were represented as O_2 and CO_2 kPa.

Statistical analysis

The experimental design of the research was completely randomized. Groups of three replicates of 24 fruit per treatment for the cold storage period were established. The data were analyzed using the Statistical Analysis System software program, version 9.0 (SAS Inst., Cary, N.C. U.S.A.) and treatments means were statistically compared using the Duncan's multiple range test ($P \leq 0.05$).

Results and discussion

Skin color (L, C*, h°)*

One of the most important quality parameters for marketing of fruit and vegetables is fruit colour. The effect of sodium hypochlorite, Disper Cu Max and MAP on the fruit color of baby cucumbers was determined by monitoring the changes in L*, C* and h^o color values. In terms of skin color there were no statistical differences among treatments. The L* values of the cucumbers progressively increased with prolonging the storage duration. Reduction in $h°$ was also observed during the storage (Table 1). The degradation of chlorophyll causes yellowing phenomenon, shortens shelf life and affects quality of horticultural crops as well as cucumbers (Fukasawa et al., 2010). Roji and Uday (2015) also reported that a combination of sodium hypochlorite dipping and MAP treatment was the most effective and promising treatment for colour retention of fresh-cut cilantros during storage.

Total soluble solids, Titratable acidity and pH

Total soluble solids (TSS) content, titratable acidity (TA) and pH are the most important factors that give the taste and flavor to the fruits and vegetables (Selcuk and Erkan, 2016).

TSS content of the cucumbers slightly declined with prolonging the storage duration. At the end of the storage, the highest TSS content was in Disper Cu Max treated cucumbers and the lowest was in Disper Cu Max + MAP treated cucumbers (Table 2).

TA content of the cucumbers increased significantly with prolonging the storage duration in all treatments during storage. The initial value of TA at harvest was 0.088% and it increased to 0.115% at the end of the storage. The highest TA content was in the treated with Disper Cu Max and the lowest was in group Disper Cu Max + MAP (Table 2) .

Changes in the pH values of baby cucumbers along the storage period were determined to be statistically significant (P≤0.05). At harvest the initial pH was 5.96 and it decreased to 5.70 at the end of the 28 days of storage period. In terms of pH minimal changes occurred in Sodium hypochlorite + MAP and Sodium hypochlorite + MAP treated groups (Table 2).

Contrary to our findings Jose-Neptali et al. (2012), reported that there were no effect of Sodium hypochlorite on TA, TSS and pH of tomatoes.

Table 2. The effects of different postharvest treatments and storage duration on total soluble solids, titratable acidity and pH of baby cucumbers during storage at 8°C.

Weight loss (%)

Weight loss of fresh produce contains the dry matter and moisture which is related to respiration and transpiration rates (Roy et al.,1995; Varoquaux et al.,1999). Similar to most of the vegetables water loss is a common storage problem occurred during long term storage of cucumber as well.

Weight losses of cucumbers in all groups increased with prolonging the storage duration. As expected, the weight loss of baby cucumbers was the highest in Disper Cu Max (13.01%), Sodium hypochlorite (11.79%) and control group (10.48%). MAP lowered the weight loss of the cucumbers and Disper Cu Max + MAP (2.21%) and Sodium hypochlorite + MAP (1.19%) treatments was the least weight losses occurred group in the experiment (Table 3).

Similar to our results Roji and Uday (2015) reported that Sodium hypochlorite + MAP combination was the most effective treatment in reducing weight loss of fresh-cut cilantros.

Fruit firmness

Firmness is the key factor in determining postharvest deterioration of fruit and vegetables. It is the rate of softening, which influences shelf life and is infected by postharvest pathogens. Generally speaking, the most obvious sign of it is firmness (Brummell and Harpster, 2001).

In this study, firmness of baby cucumber slowly increased. The biggest change was recorded in control group, from 22.24 to 26.06 kg/cm^2. In Disper Cu Max + MAP combination occurred the smallest changes, to the 23.61 kg/cm^2, (Table 3). However, no obvious differences existed among treatments or controls. Ji Heun and Kenneth (1997) reported the similar results and Sodium hypochlorite had no effect on firmness of tomatoes.

Table 3. The effects of different postharvest treatments and storage duration on weight losses and fruit firmness of baby cucumbers during storage at 8°C.

Changes in O_2 and CO_2 concentrations in the MA bags

The levels of O_2 inside the packages decreased and CO_2 levels increased during storage due to the continuous process of respiration after harvest. Our results showed that the concentration of O_2 in the Sodium hypochlorite + MAP combination decreased slightly, from 20,05 kPa to 18.2 kPa, and CO_2 levels increased from 0.05 kPa to 2.3 kPa until the end of the 14th day of the storage. On the 28th day of storage the O_2 levels in MA bags increased slightly, 19.2 kPa, and CO_2 is decreased to 16.6 kPa, and CO_2 levels in MA bags increased to 4.6 kPa. The concentration of O_2 levels in Disper Cu Max + MAP combination decreased until the end of the third week from 20.01 kPa to the 16.2 kPa, then increased to the 17.6 kPa on the 28th day of storage. The levels of CO_2 increased to during the 21st day of storage then there were a decline (Fig. 1).

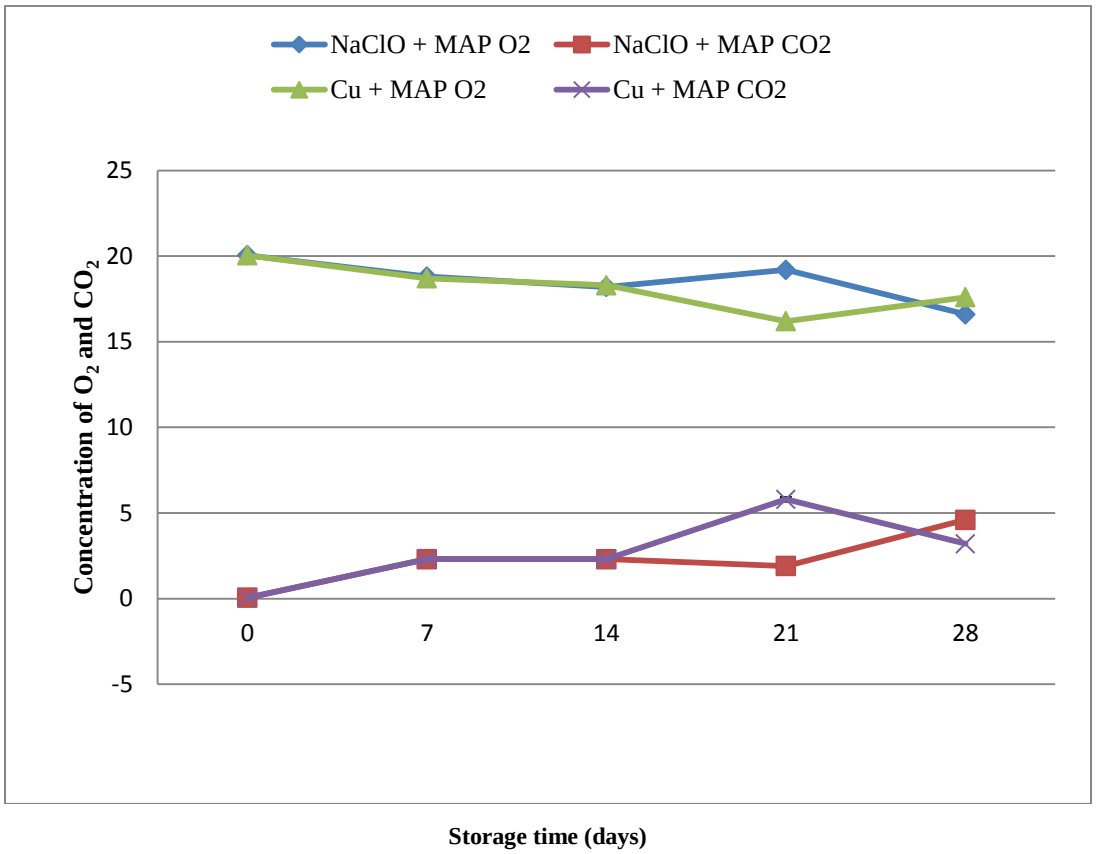

Fig. 1. Changes in CO_2 and O_2 levels inside MAPs during storage at 8 °C.

Conclusions

This study is one of the first reports about quality and postharvest life of baby cucumbers. Results showed that the lowest weight loss, disease and disorder development were determined on the baby cucumbers treated with Sodium hypochlorite + MAP combination. Dipping of cucumbers in Disper Cu Max solution had the highest titratable acidity and soluble solids content at the end of storage. The highest L*, C* and pH values were obtained from Disper Cu Max + MAP treated baby cucumbers. It can be concluded that baby cucumbers were successfully stored at 8°C temperature and 90-95% RH in Disper Cu Max + MAP for 28 days with minimal quality losses.

Abstract

Three winter-type cultivars of wheat (Jelena, Bosanka and Nova bosanka), selected in the Agricultural Institute of the Republic of Srpska in Banja Luka, were examined for resistance to osmotic and salt stress in the period of early germination. The trial was set up in the laboratory of the Faculty of Agriculture in East Sarajevo. The seeds were sterilized in 96 % alcohol and 50 uniform and healthy seeds for each type and treatment were put into Petri dishes. Filter papers soaked in the solution of a certain concentration (of mannitol and salt) and water potential of 0, -0.3 and -0.6 MPa, were put into the dishes. The seedlings were incubated for 7 days at a temperature of 20°C, or until the first leaves appeared. On the seventh day of the trial, or when the first leaves appeared, the measurement of a fresh coleoptile and root mass was conducted by an analytical balance (Adventurer). By drying the samples in a drying oven (Memmert) for 24 hours at 80°C and by weighing them, dry root and shoot weight was specified as well. The calculated dry root/shoot weight ratio is a significant indicator for the screening of genotypes for the resistance to drought-stress in the germination stage. Examination of germination in different conditions (concentrations of salt and mannitol) showed that the type Nova Bosanka is the most resistant to stress conditions. Stress conditions affect coleoptile forming in type Bosanka, and root forming in type Jelena. The usual border line of mannitol and salt concentration for germination is at -0.3 MPa.

Key words: *type, resistance, mannitol, salt, root, coleoptile*

Introduction

In their lifetime in nature, plants are exposed to various environmental factors which affect their growth, metabolism and crop. Temperature extremes, salinity, water supply changes, high light intensity and different kinds of pollutants are stress factors which limit plant productivity (*Lawlor*, 2002). The prolonged water deficit is called the drought. The drought is one of the most important abiotic stress factors for plants and it represents a complex form of stress which affects different metabolical processes (physiological, biochemical and molecular) of the whole plant, in almost all plant organs and cell parts (*Yordanov et al*., 2000). Saline soils are a common limiting factor for agricultural productivity in semi-arid and dry areas of the world. Seed vigour and shoot length are the most sensitive to drought stress, followed by root and coleoptile length (*Dhanda et al*., 2004). Wheat coleoptile is a specialised protective tissue for first leaves until they reach a certain length, or appear above the ground. Water access affects coleoptile growth and germinating. The distinction between the coleoptile length and drought tolerance index in stress-exposed wheat is significant, which is why it is recommended that the coleoptile length can be used as a drought tolerance indicator for screening the tolerant genotypes in wheat. Barley, maize and wheat are more sensitive to salinity during the germination, so crops get more harmed by salinity in earlier stages of growth (*Anonymous*, 2005).

Materials and methods

The tests included examination of three winter-type cultivars of wheat (Jelena, Bosanka and Nova bosanka) under controlled conditions. The seeds were selected at the Agricultural Institute of the Republic of Srpska. The experiment was set up in the laboratory of the Faculty of Agriculture in East Sarajevo. Only completely healthy and clean seeds were picked out for testing. The seeds were sterilized in 96 % alcohol for 30 seconds, then washed using distilled water several times, and 50 uniform and healthy seeds were put into sterile Petri dishes. Doubled filter papers soaked in the solution of a certain concentration (of mannitol and salt), were put into the dishes and dissolved with water potential close to 0, which was a control state, then with -0.3 and -0.6 MPa (*Braccini et al.*, 1996). Each Petri dish was filled with 15 ml of solution. Alcohol mannitol is used to induce water stress and sodium chloride to induce salt stress. Every treatment and type was replicated four times. The seedlings were incubated in an incubator (Binder) for 7 days at a temperature of 20°C, or until the first leaves appeared. On the seventh day of the trial, or when the first leaves appeared, the measurement of fresh and dry root mass (g) and fresh and dry coleoptile mass (g) was conducted.

The root and coleoptile were carefully split apart by fingernails and weighed separately. Fresh coleoptile and root mass was measured by an analytical balance (Adventurer). Dry root and shoot weight was also specified in the trial by drying the samples in a drying oven (Memmert) for 24 hours at 80°C and then by weighing them. Dry root/shoot weight ratio was established as well, which is a significant indicator for the screening of genotypes for the resistance to drought-stress in the germ stage.

All data were statistically processed using Analysis of variance (ANOVA). Differences between treatments in each type and differences between types within
treatments were tested with the test of Least significant difference (LSD).

Results and discussion

Germination and early seedling growth are affected by genetic and environmental factors. Different types have developed distinctive mechanisms for adjusting to unfavorable conditions. Sodium chloride is a strong osmotic agent and it affects the growth when there is an increased concentration of it in a medium. Salt stress affects many physiological aspects of plant growth. Increased salt concentration in a medium increases the breathing of the root and shoot. When winter-type crops are concerned, including the winter-type wheat, sowing soil can contain more salt in the sowing period because of the evapotranspiration during the previous summer, in which case the salt migrates upwards to the surface, so the sowing layer is the richest in salt. In order for a seed to germinate under these conditions, it has to have a strong vigour, so it can break through the layer of salt to the surface and to survive in general (*Huang et al*., 1995). The effects of different salt concentration to the fresh and dry root and coleoptile mass of three types, created at the Agricultural Institute of the Republic of Srpska, are shown in the table 1 and figure 1, 2, 3 and 4.

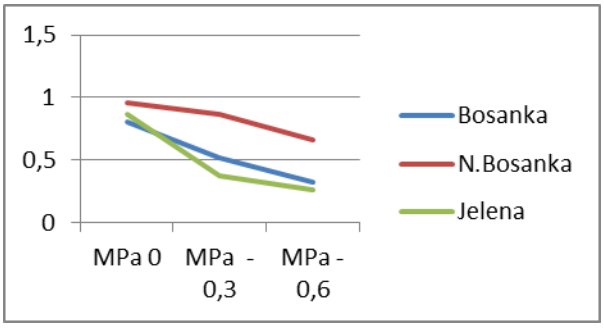

Figure 1. Effects of type and salt to the fresh root mass

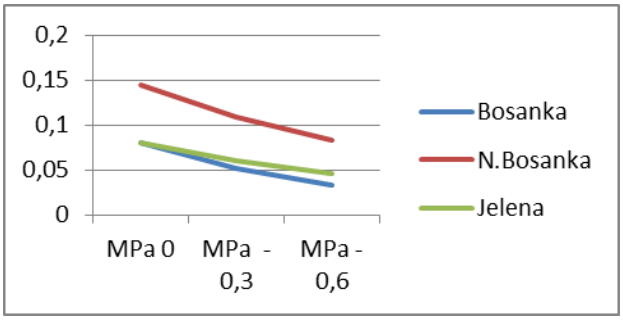

Figure 2. Effects of type and salt to the dry root mass

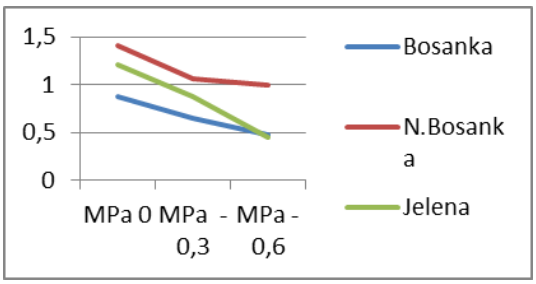

Figure 3. Effects of type and salt to the fresh coleoptile mass

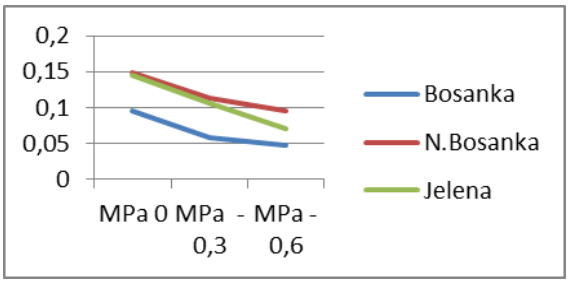

Figure 4. Effects of type and salt to the dry coleoptile mass

Placed statistically high, type Nova Bosanka had a significantly greater fresh and dry root mass, compared to the types Bosanka and Jelena, while the distinction between the latter two types was not established. Increased salt concentration led to a significant reduction of fresh and dry root mass, which is in accordance with the results of *Begum et al*. (1992). Type Jelena turned out to be the most sensitive because with the increased salt concentration, fresh root mass was significantly reduced, while in dry root measurement, type Bosanka displayed the lowest results. This is in accordance with the results of *Wang et al*., (2011), which reported that the fresh root and coleoptile mass of two types of lucerne were inhibited by 200 mM NaCl and that with the further salt increase, the germination was stopped. Capability of a seed to germinate in salinity conditions does not depend only on the salt concentration, but also on the other biological factors, seed age, dormancy, seed coat thickness, seed vitality.

Placed statistically high, types Nova Bosanka and Jelena had a significantly greater fresh and dry coleoptile mass, compared to the type Bosanka. Increased salt concentration led to a significant reduction of fresh and dry coleoptile mass. Type Bosanka turned out to be the most sensitive because with the increased salt concentration, fresh and dry root mass was significantly reduced.

Measurement results of a dry root/shoot ratio in different types of wheat under different water deficit conditions, were maximized in controlled state and minimized at the water potential of -0.6 MPa. Type Bosanka was the most sensitive at water potential of -0.3 MPa, while type Jelena of -0.6 MPa.

The effects of different mannitol concentration to the fresh and dry root and coleoptile mass of three types, created at the Agricultural Institute of the Republic of Srpska, are shown in the table 2 and figure 5, 6, 7 and 8. Alcohol mannitol is used to induce water stress (*Chen et al*., 2010), as an osmoticum in the germination test and it is an impenetrable solution, i.e. it leaves the embryo intact (*Almansouri et al*., 2001), which induces germination inhibition by affecting water absorption.

Placed statistically high, types Nova Bosanka and Bosanka had a significantly greater fresh and dry root mass, compared to the type Jelena, while the type Nova Bosanka also had a significantly greater dry root mass than type Bosanka, but both types Bosanka and Jelena significantly differed in dry root mass as well. Increased mannitol concentration led to a significant reduction of fresh and dry root mass. Type Jelena turned out to be the most sensitive because with the increased mannitol concentration, fresh and dry root mass was significantly reduced.

Placed statistically high, types Nova Bosanka and Jelena had a significantly greater fresh and dry coleoptile mass, compared to the type Bosanka. Fresh and dry coleoptile mass in type Nova Bosanka was significantly greater compared to the fresh and dry coleoptile mass in type Jelena. Increased mannitol concentration resulted in significant fresh and dry coleoptile mass reduction.

Reduction of dry root and coleoptile mass was greater in type Bosanka, while in types Nova Bosanka and Jelena, it was lower. In type Jelena, increased osmotic stress with water potential of -0.6 MPa, led to increased values of the examined parameter, in type Nova Bosanka with water potential of -0.3 MPa compared to -0.6 MPa and controlled state, and in type Bosanka with the controlled state compared to water potentials of -0.3 MPa and -0.6 MPa, as well as with comparing water potentials of -0.3 MPa and -0.6 MPa. Determined differences in type Bosanka were of statistical importance, while in types Nova Bosanka and Jelena were not. Our results are in accordance with the trials conducted by *Pratap i Sharma* (2010). High root/shoot ratio during germination in a number of winter-type wheat examined, is a reliable indicator for wheat drought resistance (*Baalabaki et al*., 1999).

Conclusion

The results show that the osmotic and toxic effects of salt had an impact on germination at early stages of development in all examined types of wheat. Based on the examination of stress condition effects, of different osmotic potential and salinity intensity, it can be concluded that in all types there was a reduction of examined germination parameters starting with water potential of -0.3MPa, and that could be one of the indicators of their sensitivity to stress conditions. Germination was reduced less with water potential of -0.3MPa, more with -0.6 MPa. Osmotic stress and specific ions equally affected both fresh and dry root and coleoptile mass, although it is considered that mannitol and sodium chloride work through different mechanisms in a seed and in a plant. Based on the trial results, conclusion is that the border line of water potential, under the effects of mannitol and sodium chloride, with the possibility for all types to germinate successfully, is -0.3 MPa, i.e. under lower intensity stress.

THE EFFECT OF VARIETY AND WATER DEFICIENCY ON PRODUCTIVE QUALITIES OF POTATO

Branka GOVEDARICA*, Tanja JAKIŠIĆ, Igor ĐURĐIĆ

University of East Sarajevo, Faculty of Agriculture, Vuka Karadzica 30, Bosnia and Herzegovina
*Corresponding author: brankacg89@gmail.com

Abstract

As a result of global climate changes, in the past years, during summer months, more or less expressed rainfall deficit is occurring, which has negative effects on potato production. Some varieties, thanks to their ability of fast growth, good land coverage and early tuber seeding, endure some of the stressful situations easier than others. The goal of this paper was to examine, in controlled environment, the reaction of five varieties on moisture deficit, and also to determine if the productivity of potato will be affected by application of biostimulators. Three factorial experiments were set on 02.04.2016. in the greenhouse of the Faculty of Agriculture in East Sarajevo (Entity of Republic of Srpska, Bosnia and Herzegovina). The research included variety reaction (factor A – five varieties: A_1 - Agria, A_2 - Faluka, A_3 - Kenebek, A_4 - Kurada and A_5 - Dezire) and biostimulators (factor B: B_0 – without foliar top dressing and B_1 – foliar top dressing – three treatments with Isabion) on moisture deficit in the soil (factor C water deficit –C_0 – draught was created by stopping the substrate irrigation in the phase of tuber seeding and C_1 – optimal irrigation during the vegetation – substrate was watered every day until optimal water capacity, until water content in substrate was in field water capacity of 36%) on potato plant productivity. Faluka variety had the largest percentage of small and the smallest percentage of large tubers, while the Kenebek variety had the largest percentage of large and the smallest percentage of small tubers. The application of Isabion positively affected on yield increase at varieties: Agria, Kenebek and Dezire, as well as its application in varieties where there was a brake in irrigation during the phase of tuber seeding. The drought effect influenced the process of organic compounds synthesis and their translocation, which was notable for understanding the effect of drought on potato yield.

Key words: *variety, foliar top dressing, irrigation, yield, tuber.*

Introduction

Due to its importance as a food source and for existance of a large number of population, the potato is, on a global level, increasingly considered to be the food of the future and an ideal cultivar for crysis situations (*Jovović et al*., 2013). In the times where a large global food shortage is expected, many scientists believe that potato is the cultivar that can ease the hunger. The potato is a worldwide plant, beeing grown troughout the world because of its great polymorphism, that is existance of a large number of varieties that can adapt to different ecological conditions. Modern approach in research of grown plants production is primarily based on studies of photosynthesis, growth and watering regime as the basic physiological processes which determine the plants productivity. Knowledge about theese processes can contribute to overcoming the effects of stress factors, particularly drought, and to achieving the fertility potential of agricultural cultivars in certain agroecological conditions (*Passioura,* 2007). At the beggining of the vegetation period, potato plants ussually have suficient amounts of water

(significant amounts are accumulated through rainfall during the winter), so the drought is very rear in that period. As a result of global climate changes, in the past years, during summer months, more or less expressed rainfall deficit is occurring, which has negative effects on potato production. Soil water deficit in the periods of stolons formation and tuber seeding plays a crucial role in yield forming. (*Tomasiewicz et al*., 2003).

Larger genetic variability enables wider spread area and better ability of adaptation to different environmental changes, including new diseases, vermins and climate changes (*Hamer and Teklu*, 2008). Larger variability also provides better basis for production of new genotypes with noumerous desirable properties. With correct choice of assortments, unfavorable effects of environment would be significantly reduced (*Jovović*, 2010; *Bugarčić et al*.,2000). Some varieties, due to their fast growth abilities and early tuber seeding, can endure stressful situations easier. The goal of this paper was to examine, in controled conditions, reaction of five varieties on moisture deficit, and also to determine will the productivity of potato be affected by application of biostimulators.

Materials and methods

Three factorial experiments with six repetitions were set on 02.04.2016 in the greenhouse of the Faculty of Agriculture in East Sarajevo (Entity of Republic of Srpska, Bosnia and Herzegovina). The research included variety reaction (factor A – five varieties: A_1 - Agria, A_2 - Faluka, A_3 - Kenebek, A_4 - Kurada and A_5 - Dezire) and biostimulators (factor B: B_0 – without foliar top dressing and B_1 – foliar top dressing – three treatments with Isabion) on moisture deficit in the soil (factor C water deficit –C_0 – draught was created by stopping the substrate irrigation in the phase of tuber seeding and C_1 – optimal irrigation during the vegetation – substrate was watered every day until optimal water capacity, until water content in substrate was in field water capacity of 36%) on potato plant productivity (tubers number, tubers mass, yield by dish and percentage participation of individual fractions – calibrating <35 mm, 35-55 mm and >55 mm). Germinating tubers were planted in dishes (30x35 cm) which were filled with Pot ground H substrate (Klasmann-Deilmann, Germany). Removing of the potato tubers was done by hand in their full physiological maturity.

Research results were processed by variation-statistical analysis and the evaluation of differences significance in LSD test is depicted in tables. During the experiment, temperature and relative air humidity were measured by electronic thermo-hygrometer (model THG312, Oregon Scientific). Potato has moderate requirements regarding temperature, relative air humidity and slightly increased requirements regarding rainfall during tuber bulking phase, full inflorescence and later after flowering in the phase of yield formation and bulking.

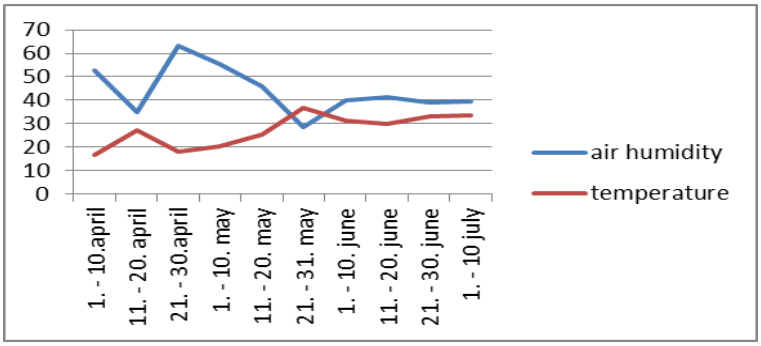

Chart 1. Temperature and air humidity in the greenhouse during the experiment

Ecological conditions during the experiment (temperature and air humidity) are depicted in chart 1. The formation of root system occurred in soil temperatures above 7ºC. Above – ground vegetation part was formed on temperatures between 15-20ºC. These temperatures are biological optimum for above – ground assimilative part (trunk and leaves) and below –ground vegetative organs (stolons and tubers) formation. Higher air (>25ºC) and soil (>20ºC) temperatures slow down tubers formation. Largest yield was achieved in average daily temperatures of around 21ºC. Potato has also moderate requirements regarding air humidity, with optimum being 75-80% (*Bašović, et al*., 1980).

Results and discussion

The number of newly formed tubers per plant is a variety feature, but it greatly depends on the number of above-ground sprouts per plant, size of tubers used as seed, agroecological conditions and technology in potato production (*Barkley*, 2005). It is considered that for most varieties optimal number of tubers per plant is 12-14, which enables achieving high potato yield. In our research (table 1) it's determined that Faluka variety formed the biggest number of tubers compared to other varieties. Determined differences were highly significant, as were the differences between varieties Kurada and Kenebek. In our research variety Faluka confirmed tolerance to high temperatures and moisture deficiency which had no effect on number of tubers formed per plant. The number of tubers formed per plant was not significantly affected by application of biostimulators and watering interruption.

Table 1. Average number of tubers per plant

0,01	2,777	1,755	1,755	3,937	3,937	2,489	8,805

Average tuber mass is property of a certain variety, but it depends a lot on influence of agroecological factors, applied agrotechnics, way of garden bed forming, size of seed tuber, number of above-ground sprouts per plant, number of tubers per plant, and length of stolons (*Tadesse et al*., 2001; *Bussan et al.*, 2007). Kenebek variety, compared to other varieties, had the largest average tuber mass and that difference was highly significant, compared to average tuber mass in varieties Faluka, Kurada and Dezire, as well as the difference in tuber mass between Faluka variety and other varieties, because Faluka variety had the smallest tuber mass. Average tuber mass per plant decreases when the number of tubers per plant increases. *Mišović and Šušić* (1985) came to similar conclusions. Treatments with biostimulator (Isabion) had positive effect on tuber mass. In the part of the experiment where the treatment with Isabion was conducted, average tuber mass was 65, 13 g, which is significantly higher compared to average tuber mass (56,21g) in the part of the experiment where the treatments were not conducted. The application of the biostimulator proved to be especially effective when applied to Kenebek variety because the average tuber mass of this variety ranged from 64,14 g (without biostimulator application) to 80,06 g (treated with biostimulator). Biostimulator also had positive effects on tuber mass on the part where watering was interrupted because tuber mass ranged from 53, 89 grams (without Isabion application) to 65, 09 grams (with Isabion application).

Yield of every plant species is the most important quantitative property, which is very variable and dependent on strong influences of agroecological and agrotechnical factors. Yield increase is one of the most important tasks to which the modern intensive agriculture strives. Those varieties which have high and sustainable yield potential in different agroecological conditions are favored. When choosing the assortment, yield is considered to be one of the most important features. Average yield of tubers per dish (table 3) ranged between 696, 67 grams in Dezire variety and 903, 95 grams in Faluka variety. Dezire variety compared to other varieties had the smallest yield which was very statistically significant, while the differences between other tested varieties did not have statistical significance. Highly significant differences were determined in variety B, where, with foliar top dressing, average yield was 861, 98 grams, while in varieties without foliar top dressing with Isabion, yield was 783, 81 grams. Watering interruption affected the yield with high significance, which ranged from 786, 18 grams (watering interruption) to 865, 98 grams (watering). The application of Isabion positively affected the yield increase in varieties: Agria, Kenebek and Dezire, as well as its application in varieties with watering interruption in tubers forming phase. Water deficit in the tubers initiation phase and phase of their early development increased the number of rough and deformed tubers which significantly decreases potato yield, while the water deficit in the period of tuber bulking, negatively affected not only the quantity, but also the quality. (*King and Stark*, 2011). *Steyn et al*. (1998) established that there was significant reduction in potato yield and tubers size, caused by water reduction, but they also pointed out the influence of the genotype as a response to water stress. Water deficit in the early phase of growth led to yield reductions and development of small tubers (*Hasasan et al*., 2002), which is in accordance with our results.

Total watering		11,20	10,65	31,15	32,11	57,68	57,33

The achievement of high number of certain sized tubers in total yield is imperative for every potato grower. Physiological processes which determine the number and size of the tubers are numerous and there are a lot of agronomic and physiological factors which are included in those processes (*Bus and Dustman*, 2007). Size of the potato tubers, especially its percentage in the total yield is feature of a variety, which also depends on level of agrotechnics, climate conditions, soil type and its structure, the way the garden bed was formed, number of tubers per plant, and stolons length. Early and mid-early sorts usually have short stolons with small number of big tubers, while the mid-late and late sorts form longer stolons with larger number of small tubers. *Mackerron et al.* (1988), *Dwyer and Boisvert* (1990) and *Walwort and Carling* (2002) concluded that the water deficit in the soil caused increase in number of smaller faction tubers.

Largest percentage of small faction (20,03%) had the variety Faluka, where the foliar top dressing was not applied and watering was interrupted in the phase of tuber initiation, and the smallest percentage of the small faction had the variety Kenebek (5,39%) in the variety without the foliar top dressing and with watering interrupted in the phase of tuber initiation. Faluka variety had also the largest percentage of middle tubers faction (56, 25%) and that was in the variety with foliar top dressing and with regular watering. The largest percentage of big tubers (74, 51%) had the Kenebek sort in the variety without foliar top dressing and with regular watering. The most desirable faction structure had the Kenebek sort, because in the production of market tubers, it is desirable to produce as few as possible of small tubers, and as many as possible of big tubers.

Conclusion

Based on the gathered results, these conclusions can be derived:

- The Faluka variety formed the biggest number of tubers, while the Kenebek variety had the smallest number of tubers. Number of formed tubers affected the average mass, as well as faction structure, so the Faluka variety had the smallest tuber mass, while the Kenebek variety had the largest. Faluka variety had the largest percentage of small and the smallest percentage of large tubers, while the Kenebek variety had the largest percentage of large and smallest percentage of small tubers.
- Foliar application of Isabion had significant influence on average tuber mass and potato yield. Application of Isobion positively affected yield increase in following varieties: Agria, Kenebek and Dezire, as well as its application in the parts of the experiment where the watering was interrupted in the phase of tubers formation.
- The drought effect influenced the process of organic compounds synthesis and their translocation, which is significant for understanding the effects of drought on potato yield.

EFFECT OF GROWTH REGULATORS AND THEIR MIXTURES ON WINTER WHEAT GROWTH, COLD RESISTANCE AND PRODUCTIVITY

Virgilija GAVELIENĖ, Lina PAKALNIŠKYTĖ, Leonida NOVICKIENĖ

Institute of Botany, Nature Research Centre, Akademijos 2, Vilnius, Lithuania
E-mail: virgilija.gaveliene@botanika.lt

Abstract

This study was aimed to investigate the effect of growth regulators containing free amino acids, macro- and micro-elements on winter wheat freezing resistance, growth and productivity formation; and to test mixtures of regulators retardant and herbicide activity on wheat growth and productivity. Effect of regulators was established in controled cold conditions and natural field experiments in 2012–2015. The tested regulators applied to wheat ′Skagen′ at BBCH 13–14 stage in controlled cold stress conditions actively restored wheat seedlings growth after freezing at −5°C and −7°C temperature. Under the impact of Ruter AA (1 ml/100 ml), Terra Sorb (1 ml/100 ml) and Razormin (0.1/100 ml) seedlings survival, compared with control, increased by 28, 17 and 11%, respectively. In natural field experiments tested regulators produced stimulating effect on wheat plants growth in autumn, plants overwintering,vegetation renewal and productivity elements formation. At full maturity stage, it was revealed that Ruter AA (2 l ha^{-1}), Terra Sorb (2 l ha^{-1}) and Razormin (200 ml ha^{-1}) increased the number of productive stems and grain number per ear as well as grain weight per plant. 1000 seed weight differed among the test variants and was significantly highest after treatment with Terra Sorb (2 l ha^{-1}). Investigation of Razormin, Terra Sorb in mixture with herbicide Sekator (200 ml ha^{-1}) and retardant Cykocel (1.5 l ha^{-1}) applied at BBCH 31-32 stage on wheat showed that herbicide and more retardant did not damage the activity of the tested regulators on plants growth and productivity.

Keywords: *amino acids, Triticum aestivum L., overwintering*

Introduction

At present the world population constantly increases and therefore the global food productivity shows a decreasing trend due to the accumulating negative effects of abiotic-biotic stresses. For all that the agriculture production in the world is rapidly increasing; it strongly depends on the use of modern agrochemistry agrotechniques, as well as the use of suitable growth regulators, their mixtures and combinations. European agrometeorological conditions, particularly in periods of winter crops hardening-preparation for wintering, overwintering and vegetation renewal, are unfavourable and varying. So the search for tools regulating plant growth, development and productivity is important. In the above-mentioned regulation process synthetic plant growth regulators of various chemical structures participate: physiological analogues of phytohormones, compounds of contrary action – retardants, herbicides regulating weed management, and amino acids products (Auškalnienė, 2005; Rademacher, 2000). Latter are established growth regulators or so-called special fertilizers, containing free amino acids, macro and micro elements (Velini *et al*., 2010). Free amino acids have a lower molecular weight, so they are quickly absorbed by plants, especially through leaves, and only small amount through roots. Several different amino acids: lysine, glutamine, glicine have been tested for their effects on nitrate and ammonium

influx, transcription, and for these process glutamine was most effective (Miller *et al.,* 2007). As well as exogenously applied amino acids, glutamine and especially proline increased free proline content and is involved in the response to cold stress. So proline level may be an indicator of plants cold hardening and freezing tolerance (Haya *et.al.,* 2012). (Gaveliene *et al.,* 2014). Glutamic and aspartic acids are very important acids for synthesis of other amino acids. The absence of one amino acid, which participates in individual protein structure, hindered protein synthesis (Nikiforova *et al*., 2006). Plants themselves synthesize amino acids from inorganic nitrogen (N). During this process nitrate is assimilated via convesion to nitrite, then ammonium ions into amino acids (Miller *et al.,* 2007). So the scientific investigation and employment of the products – growth regulators with optimal ratio of amino acids is perspective. Even the practices of using multi-component mixtures (growth regulators, herbicides) of various combinations are spreading (Auškalnienė, 2005). Many plants can deactivate or metabolize plant growth regulators, including herbicides. Wheat and barley tolerate 2.4-D and MCPA, because they can metabolize these chemicals faster than broad-leaved plants. Some cultivars of wheat are tolerant while others are susceptible to the herbicide difenzoquat. This difference is due to specific genes within the plants (Gunsolus, 2013 (http://www.extension.umn.edu/)). From the practical point of view the multi-component mixtures of growth regulators save money and time, fields are less damaged by vehicles, but the knowledge of what products can be mixed in order to regulate plant growth, development and productivity formation processes in the desired direction and be efficient against weeds, are insufficient.

Therefore the main task of this research was to investigate the effect of growth regulators containing free amino acids, macro- and micro-elements on winter wheat freezing resistance, crops autumnal growth, vegetation renewal, productivity formation in laboratory and field conditions; to test some regulator mixtures with compounds of retardant and herbicide activity on winter wheat in natural field conditions.

Material and Methods

The investigation of the action of different growth regulators and their mixtures on winter wheat (*Triticum aestivum* L.) growth and development was carried out in controlled conditions at the Laboratory of Plant Physiology and in natural field conditions at the Field Experimental Station of the Institute of Botany of Nature Research Centre (Lithuania) in 2012-2015. The tested products were: Ruter AA containing (%) total free amino acids 8.4, N - 6.6, P_2O_5 - 6.0, K_2O – 4.2, Fe-0.04, Mn-0.06, Mo-0.12, Zn-0.08 and 18 % organic matter; Terra Sorb containing (%) free amino acids 9.3, total N 2.1, organic N 2.1, B-0.02, Mn-0.04, Zn-0.07 and organic matter 14.8; Razormin containing (%) free amino acids 7, N – 4, P_2O_5 – 4 , K_2O – 3, Fe-0.4, Mn-0.1, Zn-0.085, B-0.1, Cu-0.02, Mo-0.01 and organic matter-25.0; For experiments we used winter wheat genotype ′Skagen′ tolerant to cold, produced in Germany by the Nordic A/S seed growing company. *In laboratory conditions* wheat seedlings were germinated for 20 days in soil (6 growing dishes 16 seedlings in each) in the Climacell plant growing chamber at 18±2°C temperature, under illumination of 60 μmol m^2s^{-1} and photoperiod 16/8 h. At BBCH-13-14 stage (Meier, 2001) plants were treated with water solutions of tested growth regulators. After 24 hours seedlings were acclimated at 4^oC for 96 h in the Friocell chamber. After hardening the seedlings were held at temperature −1°C, −3°C, −5°C and −7°C for 24 h. After freezing the seedlings were transferred into a plant growing chamber, at a temperature of 18±2°C for 7 days and after that the survived seedlings were noted and estimated.

The growth regulators with amino acids investigated in controlled laboratory conditions, were further studied in *natural field conditions.* Field experiments were performed in sixfold repetition on light loamy Endocalcari-Epihypogleic Combisol. The main agrochemical parameters of the arable soil layer: pH - 7.0-7.3; P_2O_5 – 769.8-770 mg kg^{-1}, K_2O – 214-214.6 mg kg^{-1}. Plants were cultivated using standard agrochemical and agrotechnical technology for these crops (Liakas *et al.,* 2000). Experiments were set in the 2nd week of September. Fertilization of wheat ($N_{100}P_{90}K_{60}$) plants was performed as follows: P, K and N_{30} were used before soil autumn ploughing, whereas in spring N_{90} kg ha^{-1} were used before the renewal of plant vegetation period. The test products were applied on plants foliar spread of water solutions, 100 ml for each plot at BBCH- 22-25 stage (tillering phase). In order to assess the success of plants overwintering, the number of plants was calculated in autumn and in spring in six plots (1 m^{-2} each) of test products and of control. The morphometrical parameters of plant growth (the stem height, leaf number, plant fresh and dry weight) were estimated in autumn at BBCH 30-32 stage and in spring, at the vegetation renewal period, from 30 plants for each investigated product (regulator) and control. From each plot 5 plants were randomly rooted out and sampled in all – 30 plants. For investigation of growth regulators Ruter AA (2 l ha-1), Terra Sorb (2 l ha-1) and Razormin (200 ml ha-1) in mixture with herbicide Sekator (200 ml ha-1) and retardant Cykocel (1.5 l ha-1) on winter wheat growth and productivity, plants was applied in spring at BBCH-31-32 stage. At full maturity stage the wheat yield structural elements: number of productive stems, number of grain per ear, grain weight per plant, 1000-grain weight and grain weight from each plot (1m-2x6) in all variants were determined.

The data were processed statistically Data was performed using STATISTICA 10.0 for Windows, one-way analysis of variance (ANOVA) at the confidence level $p \leq 0.05$. Data was processed using software MS Excel (version 7.0).

Results and Discussion

At present it is known that free proline and glutamine play a significant role in the cold acclimation and freezing tolerance processes of the wintering plants (Dörffling *et al.,* 2009; Gaveliene *et al.,* 2014). Therefore it becomes interesting to study the effect of growth regulators, containing free amino acid on plants freezing tolerance.

Experiments in controlled laboratory conditions. The evaluation of wheat freezing resistance under the impact of the tested regulators revealed that wheat seedlings are resistant at temperature –1°C. The most significant differences in the effects of growth regulators were determined at –5°C temperature. Under the impact of Ruter AA (1 ml/100 ml), Terra Sorb (1 ml/100 ml), and Razormin (0.1/100 ml) seedlings survival, compared with control, increased by 28%, 15%, and 11%, respectively (Table 1).

Table 1. Effect of growth regulators on winter wheat ′Skagen′ seedlings' resistance to freezing

Test variant	Freezing temperature, °C			
	−1	−3	−5	−7
	Resistant seedlings %			
Control	95.2±6.3	88.0±2.3	35.7±2.3	4.1±0.1
Ruter AA (0.5 ml 100 ml^{-1})	98.0±5.8	95.3±6.3	38.9±2.0	4.5±0.0
*Ruter AA (1 ml 100 ml^{-1})	100.0±7.7	96.7±4.0	45.8±2.4	5.7±0.1
Terra Sorb (0.5 ml 100 ml^{-1})	99.5±6.1	98.5±5.2	37.0±5.2	4.8±0.8
*Terra Sorb (1ml 100 ml^{-1})	97.1±5.0	100.5±4.2	41.2±2.8	6.4±2.1
*Razormin (0.1 ml 100 ml^{-1})	98.1±3.3	97.3±6.0	39.7±3.6	5.7±0.3
Razormin (0.25 ml 100 ml^{-1})	100.3±6.3	90.0±7.1	36.7±2.2	4.8±0.2

Note. Each data represent the mean ± SE of three biological and thirty morphometrical replicates; * – differences are statistically significant based on t test at P≤0.05.

The represented data for the first time showed that products containing free amino acids in cold stress conditions increased seedlings' freezing tolerance. This data supplemented studies about the role of amino acids proline and glicine betaine in response to environmental stresses. There are data on proline being supplied exogenously and at low concentrations enhancing tolerance to cold stress (Gaveliene *et al.,* 2014). But in order to investigate the effect of growth regulators on autumnal growth, vegetation renewal, productivity elements formation of winter crops, the experiments should be carried out in natural field conditions.

Field experiments. The meteorological conditions of winter wheat growing season in Lithuania coincide with growth and development conditions of this plant. But some growth regulators may be able to optimize plants physiological and morphological processes related with wheat growth and productivity formation (Novickienė et al., 2007). Study of the effect of tested growth regulators on wheat growth and development in autumn revealed the most active products and their doses: Ruter AA (2 l ha^{-1}), Terra Sorb (2 l ha^{-1}), Razormin (200 ml ha^{-1}), Terra Sorb (1 l ha^{-1}). After application of these compounds plants formed the optimal number of shoots, plants were on average by 6-21% higher in comparison with control. Positive effect of these growth regulators on fresh and dry weight accumulation was noted too. In spring, after vegetation renewal, in trial plots treated with Ruter AA (2 l ha^{-1}), Terra Sorb (2 l ha^{-1}) and Razormin (200 ml ha) the number of overwintered plants was by 10-20 % higher than control (Fig.).

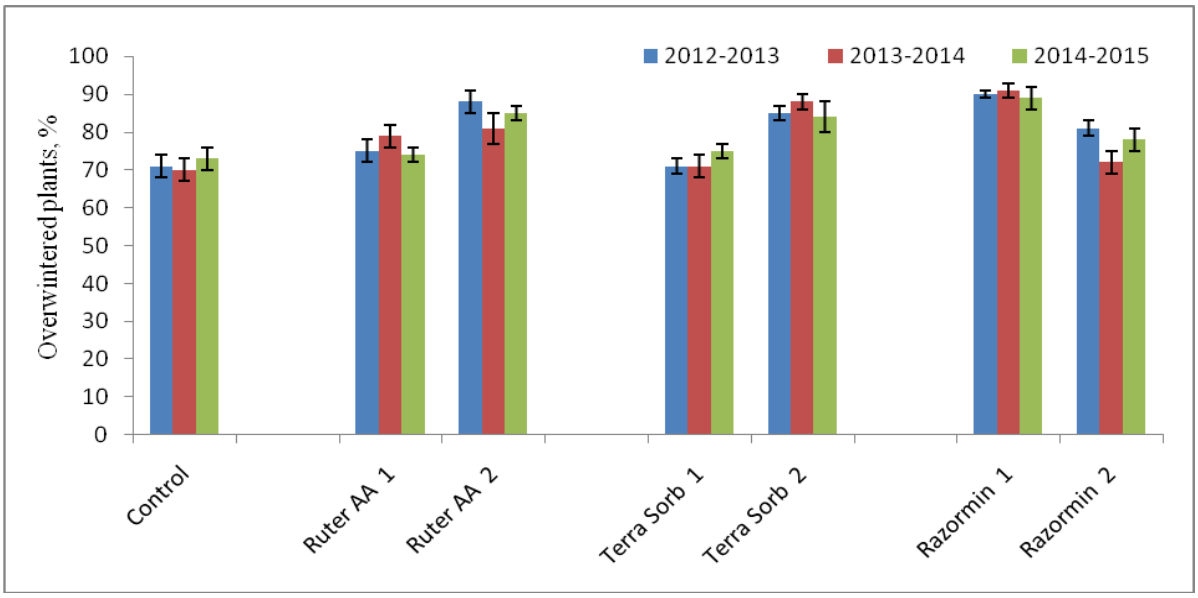

Figure. Effect of growth regulators on winter wheat ′Skagen′ plants overwintering, 2012-2013; 2013-2014 and 2014-2015. Ruter AA 1 – 1 l ha^{-1}; 2 – 2 l ha^{-1}; Terra Sorb 1 – 1 l ha^{-1}; 2 – 2 l ha^{-1}; Razormin 1 – 200 ml ha^{-1}; 2 – 500 ml ha^{-1}. Each data represent the mean ± SE. * – differences are statistically significant at P≤0.05.

At full maturity stage (BBCH 97-99) the effect of tested regulators on wheat linear growth and productivity formation was estimated. It was found that all tested products more or less stimulated stems linear growth. Evaluation of the effect of tested compounds on number of productive stems, number of grain per ear, grain weight per plant and 1000 grain weight of wheat revealed that Ruter AA (1 l ha), Razormin (200 ml ha), increased productive stems formation. Terra Sorb (2 l ha) and Razormin (200 ml ha^{-1}) stimulated 1000 grain weight formation. Employing the data obtained in laboratory and in small-plot field experiments we revealed that products containing amino acids are promising to modify winter wheat growth and productivity elements formation. At present the use of growth regulators and pesticides mixtures is widely spread (Lydy et al., 2004; Auškalnienė, 2005). Bearing that in mind, we investigated the impact of the mixture of Razormin (200 ml ha^{-1}), Terra Sorb (2 l ha^{-1}), Ruter AA (2 l ha^{-1}) with herbicide Sekator and retardant Cykocel on winter wheat ′Skagen′ stem growth and productivity formation.The morphometrical measurement at full maturity stage BBCH 96-97 showed that under the effect of Sekator stem height was close to control, but under effect of Sekator and Cykocel mixture stem growth significantly decreased, about 30% in comparison with control. Analysis of the impact of the tested herbicide Sekator on productivity elements formation showed that under the impact of Terra Sorb (2 l ha^{-1}**)** in mixture with Sekator O and Cykocel significantly increased the number of productive stems per plant. Cykocel and Ruter AA in mixture with Sekator O increased the number of productive stems only by 5%. Grain number per ear increased under all tested regulators, even Sekator O. Statistically reliable data on 1000 grain weight have been obtained under the effect of Terra Sorb (2 l ha^{-1}**)** , Razormin (200 ml ha) in mixture with Cykocel (1.5 l ha^{-1}) (Table 2).

Table 2. Effect of growth regulators mixture on winter wheat ′Skagen′ productivity elements formation at full maturity stage (BBCH96-97), 2014-2015.

Test variant	Number of productive stem	Grain number per ear	Grain weight per plant	1000 grain weight
	n		g	
Control	5.7±0.26	38.6±0.85	6.90±1.01	77±0.25
Sekator O (200 ml ha^{-1})	5.6±0.25	40.7±1.04	6.90±1.00	77±0.16
Sekator O (200 ml ha^{-1})+Cykocel (1.5 l ha^{-1})	5.8±0.37	41.0±1.24	6.98±1.33	72±0.08
Sekator O (200 ml ha^{-1}) +Cykocel (1.5 l ha^{-1})+Ruter AA (2 l ha^{-1})	6.0±0.27	41.9±1.39	7.02±1.52	75±0.42
Sekator O (200 ml ha^{-1})+Cykocel (1.5 l ha^{-1})+Terra Sorb (2 l ha^{-1})	6.5±0.31	40.8±1.56	7.08±1.50	78±0.65
Sekator O (200 ml ha^{-1})+Cykocel (1.5 l ha^{-1})+Razormin (200 ml ha^{-1})	6.2±0.29	41.7±1.28	7.12±1.52	79±0.33

Note. Each data represent the mean ± SE of forty replicates, for 1000 grain weight of four replicates.

It is important that tested herbicide Sekator did not damage regulators with amino acids activity. Some authors indicated that herbicides act on pathways or processes, crucial to plants, in an inhibitory or stimulatory way, low doses of any herbicide might be used to beneficially modulate plant growth and development (Velini et al., 2010). But in general pesticides are chemical stressors in that they are designed to have biological activity, but are intentionally placed into the environment in large quantities (Lydy *et al.*, 2004).

Conclusion

In conclusion, we can state that growth regulators, containing free amino acids, micro-and macro-elements, applied to wheat cv. ′Skagen′ at BBCH 14-15 stage in controlled cold stress conditions significantly increased seedlings' freezing tolerance. Ruter AA (1 ml/100 ml), Terra Sorb (1 ml/100 ml), Razormin (0.1 ml/100 ml) more actively restored wheat seedlings growth at -5°C temperature. In natural field conditions the tested growth regulators produced significant stimulating effect on wheat growth in autumn, acclimation to the cold, over wintering, vegetation renewal in spring and productivity elements. Growth regulators Ruter (2 l ha^{-1}), Terra Sorb (2 l ha^{-1}), Razormin (200 ml ha^{-1}), in mixture with herbicide Sekator and retardant Cykocel showed, that herbicide and more retardant did not damage the activity of tested regulators on winter wheat on growth and productivity formation

Abstract

The main purpose for inducing mutation in rice crops is to increase the mutation rate in a short period of time and to develop new plant varieties with useful agronomical traits in order for sustainable food production to become a possibility. The occurrence of a spontaneous mutation frequency rate is very rare and exceptional, making it difficult for plant breeders to exploit. Mutations are commonly induced by chemical (*e.g*. ethyl methane sulfonate) and physical (*e.g.* gamma radiation) mutagen treatment of both seed and vegetatively propagated crops. Here, more than 10,000 seeds of the rice variety Gohar were initially subjected to mutagenesis using ethyl methane sulfonate (EMS). The EMS-treated seeds were rinsed with deionized water, and then sown in the seedbed. A population of about 5,250 M1 plants was developed. At maturity, a single panicle was picked from each plant. The following year, to achieve 3,510 M2 plants, the seedlings selected from the nursery grown panicles were grown in the field. Then, one panicle was chosen from each mature plant in M2 to get the M3 population. In the M4 population, the selection criteria were early maturity, high fertility rate, dwarf growth habit, and plant type. Eventually, six plants possessing early maturing traits were selected for commercial release.

Keywords: *Chemical mutagen, early maturity, rice, mutation, ethyl methane sulfonate*

Introduction

The rice cultivation system in Iran is completely irrigated, and the production level in 2015 was quite impressive, with 3.5 million tons from approximately 0.550 million hectares of harvested rice area (Karbalaei Aghamolki *et al.,* 2015). Increasing Iranian rice production within limits in available land, water resources and challenges of climate change is a difficult task (Dorosti *et al.,* 2016). Hence, it is important to maintain rice diversity in the production areas for improved varieties as well as traditional landraces in equitable proportions. Induced genetic variation is a basic requirement for crop improvement to gain a long term sustainable food production (Jain, 2010). Plant breeders have successfully recombined the desired genes from the existing available gene pool with the related plant species through crossing (hybridization). Hybridization successfully obtained new varieties of a crop with desirable characteristics, such as high yield, biotic and abiotic stress tolerant.

The foremost goal of induced mutations is to enhance the mutation frequency rate in order to select appropriate variants for the purpose of breeding crops efficiently (Jain, 2010; El-Degwy, 2013). Induced mutations have played a pivotal role in the development of superior crop varieties over the past 50 years (Jain, 2005; Kharkwal and Shu, 2010), and are effective in enhancing world food security. Mutation breeding tools are the best method through which mutants with multiple traits can be identified (Till *et al*., 2007; Jain, 2010; Kharkwal and Shu, 2010). Although

mutation is a random event (or sudden heritable change) in the genotype of an organism, some specific traits which are found in mutated plants are very desirable. In order to obtain new property /character, we need to have a large population for screening for the most desired mutants. The mutation frequency rate of spontaneous mutations is rather low and is therefore difficult to exploit by plant breeders (Jain, 2010). Mutagenesis is used by physical (*e.g*. gamma radiation) and chemical (*e.g*. ethyl methane sulfonate) mutagen treatment of seed crops (Chopra, 2005; Till *et al*., 2007; Jain, 2010; Kharkwal and Shu, 2010). Short growing seasons and late season heavy rains are the main challenges to rice cultivation in the Northern part of Iran. Thus, the isolation of novel mutants with a higher yield, shorter growing period (earlier maturation date), and higher grain quality is necessary. Chemical agents can be beneficial since they provide high mutation rates to produce variants for tolerance to biotic/abiotic stress conditions (Jain, 2010). The dose assessment for chemicals is characterized by altering the duration and concentration of treatment; the solvent used (*e.g*. dimethyl sulfoxide); or the pH of the solution (Jain, 2005). Gohar is a high yielding variety with slender grains and good cooking quality. The variety is *late in matur*ing, requiring a growing period of 135 to 140 days (seed to seed) under local conditions. Therefore, it is of particular importance to improve the variety in order to have early maturing varieties with a growing period of less than 115 days (seed to seed). The aim of *this work has been to select* new lines of rice (Gohar variety) that are high yielding, early maturing and with good grain cooking quality.

Materials and Methods

Mutation breeding on rice (Gohar variety) was conducted with ethyl methane sulfonate (EMS) targeting higher yield, early maturity and dwarf morphology. Initially, the best dose of EMS was calibrated for LD50% (data not shown). Indeed, one of the first steps in mutagenic treatment is the estimation of the most appropriate dose to apply. Almost, 10,000 seeds of Gohar variety were rinsed with deionized water and then treated with EMS concentrations 0.5%, 1%, 1.5% and 2% (V/V), pre soaked and kept on shaker for 18 hours at room temperature. All treated seeds were eluted and sown on the seedbed to grow. After 25 days, seedlings were transplanted in to the paddy field with spacing 25 × 25cm. Plants were followed from M1 to M4 populations following a strict selection criteria. The M2 population was around 3,510 plants selected for agronomic traits like early flowering and plant type. Only a few plants with visible good agronomic/ stable phenotypic characters were selected in M3 generation. In the M4 population, selection was made only on plants with stable characteristics like early flowering, good plant type, high panicle fertility and semi dwarf nature. Following EMS treatment on M0 seeds, 5,250 numbers of seeds germinated and the seedlings were investigated under field condition (M_1 population). One panicle from each plant was chosen at the ripening stage. Those panicles were grown under field condition and 3,510 plants were selected in M2. One seedling per hill was exploited in all generations from M1 to M4. Five seeds from each plant were selected and grown in seedbed; and were later transplanted to the paddy field. These plants were marked based on early flowering, and 34 plants were selected (M3). For the next year, five plants were transplanted from these materials (M4). In this generation only plants with early flowering and some other agronomic traits in comparison to the base population (Gohar) were selected and harvested. The total number of plants was 16, which flowered earlier by around 1-3 weeks than the maternal parent-Gohar. Six plants were chosen based on early maturity, leaf structure, grain quality, panicle fertility and high grain yield and were named Mutants 1 to 6.

Results and Discussion

Mutant1: Early flowering was the major character for selection. The characteristics of amylose content and fertility percent in mutant 1 were both better than the maternal parent. This mutant had long and slender grain, brick color paddy and at least flowered one week earlier than its maternal parent and was susceptible to lodging.

Table 1. Comparative performance of Mutant 1 with its maternal variety-Gohar

Characteristics	Mutant 1	Gohar (mother variety)	Percent increase or decrease related to Gohar (%)
Days to flowering*	114	121	-6.1
Plant height* (cm)	112	114	-1.8
Average productive tillers	18	18	0
Filled grain per panicle	123	126	-2.4
Fertile percent*	70.8	65	8.2
1000-grain weight (g)	23.4	23.6	0
Head rice yield (%)	58.1	57.8	1.5
Amylose*content (%)	22.8	24	-5.3
Standard heterosis for fertility (%)	6.63	-	-

*= Characters that were important for selecting mutants

Mutant 2: High yielding, early flowering (by 10 days), filled grain per panicle (19.7%) and good architecture were major criteria for selection. Fertility percent (13.9%) was also better than the maternal parent.

Table 2. Comparative performance of Mutant 2 with its maternal variety-Gohar

Characteristics	Mutant 2	Gohar (mother variety)	Percent increase or decrease related to maternal variety (%)
Days to flowering *	112	121	-8
Plant height (cm)	114	114	0
Average productive tillers	18	18	0
Filled grain per panicle	157	126	19.7
Fertile percent*	75.6	65	13.9
1000-grain weight (g)	23.7	23.6	0
Head rice yield (%)	54.9	57.8	-5.2
Amylose content (%)	24.3	24	-1.2
Standard heterosis for fertility (%)	12.36	-	-

*= Characters that were important for selecting mutants

Mutant 3: It was the best selected line. The selection was made on the basis of early flowering (by nearly 3 weeks), filled grain per panicle (171), high fertility rate (91.2%), long panicle length

(28.5cm) as well as medium amylose content (22.3%). Mutant 3 had tall and erect flag leaves and the standard heterosis for this mutant was also high (34.2 %) as compared to the mother variety.

Table 3. Comparative performance of Mutant 3 with its maternal variety-Gohar

Characteristics	Mutant 3	Gohar (mother variety)	Percent increase or decrease related to maternal variety (%)
Days to flowering*	104	121	-17.3
Plant height (cm)	115	114	0.8
Panicle length(cm)*	28.5	25.5	10.5
Average productive tillers*	12	18	-50
Filled grain per panicle*	171	126	26.3
1000-grain weight (g)	23.5	23.6	0
Fertile percent*	91.2	65	29.4
Head rice yield (%)	59	57.8	2
Amylose* content (%)	22.3	24	-7.6
Standard heterosis for fertility (%)	34.2	-	-

*= Characters that were important for selecting mutants

Mutant 4: This mutant had characteristics such as early flowering (at least 10 days earlier than the maternal parent), semi-dwarf plant height (104.5cm), panicle length (28.6cm), filled grain per panicle (155) and high fertility rate (91.2%). This mutant also had good taste/ aroma and cooking quality.

Table 4. Comparative performance of Mutant 4 with its maternal variety-Gohar

Characteristics	Mutant 4	Gohar (mother variety)	Percent increase or decrease related to maternal variety (%)
Days to flowering*	111	121	-9
Plant height* (cm)	104.5	114	-9
Panicle length* (cm)	28.6	25.5	10.9
Average productive tillers	16	18	-12.5
Filled grain per panicle*	155	126	18.7
1000-grain weight	23.5	23.6	0
Fertile percent*	91.2	65	40.7
Head rice yield (%)	59.2	57.8	-
Amylose*content (%)	23.6	24	-1.7
Standard heterosis for fertility (%)	34.8	-	-

*=Characters that were important for selecting mutants

Mutant 5: It had long slender grains and was early flowering (107 days to flowering) with higher number of productive tillers (18.7) than the maternal parent. In spite of low head rice yield (48.8%), this mutant had good cooking quality. This variety can grow well in saline condition, which is above the threshold range for rice (EC 0.3–3.6 mmhos/cm) and could be suitable for growing in regions affected by salinity (Baloch *et al.*, 2006; Deepa Sankar *et al.*, 2011).

Table 5. Comparative performance of Mutant 5 with its maternal variety-Gohar

Characteristics	Mutant 5	Gohar (mother variety)	Percent increase or decrease related to maternal variety (%)
Days to flowering*	107	121	-13
Plant height (cm)	93	114	-22.6
Panicle length (cm)	27.3	25.5	6.6
Average productive tillers	18.7	18	3.4
Filled grain per panicle	112	126	-12.5
1000-grain weight (g)	23.7	23.6	0
Fertile percent*	78.3	65	17
Head rice yield (%)	48.8	57.8	-18.4
Amylose content (%)	25.8	24	6.9
Standard heterosis for fertility (%)	2.26	-	-

*= Characters that were important for selecting mutants

Mutant 6: Six characteristics of this mutant were found to be more appropriate for selection. Criteria for selection were days to flowering (108 days), plant height (106.3cm), panicle length (28.4cm), number of fertile tillers (17), grain per panicle (178) and fertile percent (93.7%). The quality characteristic of mutant 6 was better than the maternal parent. The data suggest that mutagenic material did not modify 1000-grain weight. Our findings are in agreement with results of rice researchers using EMS to evolve high yielding mutant rice varieties (Baloch *et al.*, 2001, 2005; Bughio *et al.*, 2007; Jain, 2005, 2010; Talebi *et al.*, 2012).

Table 6. Comparative performance of Mutant 6 with its maternal variety-Gohar

Characteristics	Mutant 6	Gohar (mother variety)	Percent increase or decrease related to maternal variety (%)
Days to flowering*	108	121	-12
Plant height* (cm)	106.3	114	-7.2
Panicle length* (cm)	28.4	25.5	10.2
Average productive tillers*	17	18	-5.8
Filled grain per panicle*	178	126	29.2
Fertile percent*	93.7	65	30.6
1000-grain weight (g)	23.6	23.6	0
Head rice yield (%)	54.6	57.8	-6
Amylose content (%)	24.3	24	-1.2
Standard heterosis for fertility (%)	9.35	-	-

*= Characters that were important for selecting mutants

Conclusion

As mentioned earlier, induced genetic variation is essential for crop improvement for long term food production and securing food security. Hence, we conclude that for maintaining rice diversity and generating improved varieties; our attempts in inducing chemical mutation on rice seeds on the base population of Iranian rice variety Gohar using EMS has been successful. Our mutation breeding efforts in selecting successive mutants by managing populations across M1 to M4; was successful in identifying six desirable mutants with multiple traits suitable for Iranian agronomic conditions. The mutants were selected for traits such as dwarfness, early maturity, high fertility rate and plant type.

Abstract

Salinity of soil has adverse impact on germination, growth and yield of maize. Hybrids show larger or smaller tolerance onto saline stress. Thus tests were conducted in laboratory of the Faculty of Agriculture of the University of East Sarajevo (Entity of Republic of Srpska, Bosnia and Herzegovina), to examine tolerance of four hybrids (BL-43, ZP- 427, Cisco and Maverick) maize (*Zea mays L*.) to different concentration of NaCl (0, -0,3 i -0,6 MPa). The tests included % of germination energy, % of seeds' germination, cotyledon and coleoptile length, fresh mass of cotyledon and coleoptile, dry mass of cotyledon and coleoptile, ratio of dry mass of the root and coleoptile. Based on statistically processed results the significant differences between the hybrids were determined in stress level as well as their interaction for most of the tested characteristics, the most resistant and most sensitive hybrid to saline stress. For the most of tested features, the most resistant hybrid determined is Cisco and the most sensitive is Maverick.

Key words: *maize, hybrid, stress, salt, germination, root, coleoptile.*

Introduction

During the vegetation period plants are exposed to various stress conditions within their environment, which have unavoidable effect on the development, thus significantly reducing the yield and the quality of their products. Stress tolerance indicates the plants' ability to adapt to sudden and unfavorable conditions, should those occur, and not become too damaged in the process. Mechanisms that enable the plant to survive the stress are called resistance or immunity. Salinity of the soil often occurs close to coastline areas but it can also result from irrigation process. There are two types of salinity of the soil: soils with high concentration of NaCl – sodicity, and soils with high concertation of different salts-salinity. High concentration of NaCl not only harms the plants (*Zaki*, 2011), but also impairs favorable soil structure (the base) thus becoming less permeable to water. Soil salinity can produce external, osmotic potential that limits the seeds' absorption of water or sodium ions and chloride ions can uptake into seeds that germinates, which has a toxic effect. Germination is first critical period in a plant production (*Figueiredo-e-Albuquerque and Carvalho 2003; Misra and Dwivedi, 2004*). Ability of seeds to germinate in soils with high concentration of salt is of a key significance for survival of numerous plant species. Although the salt stress mostly reduces the germination ratio and delays the germination start, its effect can be lessened under influence of other environment factors (*Bojović et al*., 2010). Since salt stress affects germination, growth and the crops' yield, it presents one of limiting factors in agriculture production in arid and semiarid regions (*Yohannes and Abraha*, 2013).

It has been determined that, when growing maize in saline soils, it results in slow plants growth and reduced yield (*Ouda et al*., 2008). In comparison to other grains, corn is has higher sensitivity to salt stress (*Maas et al., 1986; Ouda et al*., 2008), thus it is very important to pay

particular attention to development of hybrids that are tolerant to salt and water stress (*Janmohammadi et al*., 2008). Aim of the research was to compare four hybrids grown in the area and select the hybrid most tolerant to salt stress.

Materials and methods

Researches included monitoring of germination in seeds of maize hybrids (BL-43, ZP- 427, Cisco and Maverick) in controlled environment. The experiment was set in laboratory of of the Faculty of Agriculture of the University of East Sarajevo (Entity of Republic of Srpska, Bosnia and Herzegovina). After received in laboratory, the seeds were subjected to manual separation of damaged and unhealthy seeds. Only completely healthy and pure seed were chosen for the test. The seeds were sterilized in 96% alcohol for 30 seconds, then washed several times with distilled water and 25 the same size seed were placed in sterile petri dishes (diameter: 9cm), with cover, to prevent moisture loss. Seeds of each hybrid for each treatment were placed in petri dishes. The dish contained double layer of filter paper soaked in NaCl solution with water potential 0, -0.3 and -0.6 MP (*Braccini i sar*., 1996). Each petri dish contained 15ml of the solution. Controlled petri dish contained distilled water. The experiment was set with four repetitions for each treatment and for each hybrid separately. Sprouting embryo were incubated in the incubator (Binder) for period of 9 days, under temperature of 25 °C. The day when primary root reached length of 2mm marked the germination start. During the experiment, the following parameters were measured: germination energy (4th day of the experiment included counting all seeds germinated up to then and presented the amount in per cent, in relation to total number of seeds). On ninth day of the experiment, when the first leaf appeared, the following measurements were conducted: germination percentage or total seeds germinated in proportion to total number of seeds of one variant of the experiment, then separated 10 germinated seeds and measured length of coleoptile and cotyledon (the longest cotyledon was measured) with elastic meter, measuring the length of sprouts of each seed. Using fingernail the root was separated from coleoptile and their weight measured separately. Fresh mass of coleoptile and the root were measured by analytic scale (Adventurer). Dry mass of the root and the sprout were determined by drying in the dryer (Memmert) on 80°C for period of 24 hours, the weight measured as well as proportion of dry mass of the root/ dry sprout, an important indicator for genotype screening for resistance to drought during the sprouting embryo phase.

All data were statistically processed using Statistics analysis of variance (ANOVA). Differences between treatments within each cultivar and differences between varieties within treatments were tested with the test of least significant difference (LSD).

Results and discussion

Sodium chloride is a strong osmotic agent and affects the growth when increased concentration in medium. Salt stress affects numerous physiological aspects of plant growth. Impact of different salt concentrations on % of germination energy, % of total germination, root and coleoptile length, fresh and dry mass of the root and coleoptile, as well as proportion of dry mass of the root/coleoptile in four hybrids (BL – 43 produced on Institute of Agriculture of Republika Srpska, ZP-427 produced in Institute for Maize Zemun Polje, and two Syngentina hybrids Cisco and Maverick) presented in table 1.

The highest germination energy of 92% was in hybrid BL-43, and the lowest was in Maverick (74%). Hybrids BL-43 and Cisco, in comparison to other tested hybrids, had significantly higher germination energy, speaking in terms of statistics, as well as hybrid ZP-427 in comparison to hybrid Maverick. With increase of water potential, the percentage of germination energy reduced.

With water potential -0,3 MP hybrids ZP-427 and Cisco had higher germination energy in comparison to the control variant, while hybrids BL-43 and Maverick with increased water potential NaCl resulted in decreased percentage of germination energy. That the change of water potential toward more negative results in reduced germination energy was proven by *Pratap and Sharma* (2010) in research of vigna, where germination energy and germination percentage were inhibited with increase in osmotic potential.

Hybrid Cisco had the highest germination in total, and the lowest was in hybrid Maverick. Hybrid Maverick had the lowest germination in comparison to other hybrids examined, and the differences recorded were of high significance. With increased water potential the total seed germination was reduced in all hybrids, except in hybrid ZP-427 where salt and water potential did not impact the reduction of total germination greatly. Similar results were found in sugar beet, where seed germination and growth of the sprouting embryo was inhibited with NaCl (*Wang et al*., 2011). *De Lima and Torres* (2009) published similar results and concluded that salt stress depends on plant species. Our results are in accord with *Moezel and Bell* (1987) where NaCl affected germination as ion effect, when ion reach toxicity level in the cell.

Hybrid BL-43 had the longest roots in comparison to other hybrids, while hybrid Maverick had the shortest root, in comparison. Determined differences were of high significance. Maximum values of the root length in all hybrids were controlled and with -0.3 MP applied the value has declined. Higher salt stress applied (-0.6MP) in hybrid ZP-427 and Maverick resulted in significant reduction of the root length, while in hybrid BL-43 and Cisco it resulted in significant reduction of the root length with lower level of salt stress applied. *Shalhevet et al*., (1995) published that in soybeans and maize, elongation of the root is directly connected to cell elongation. In tests of *Maghsoudi and Maghsoudi* (2008) conducted on winter wheat it was determined that salt stress inhibits coleoptile growth more than of the root. Similar results were found during coleoptile measurements. Hybrid BL-43 had the smallest length in coleoptile, in comparison to other hybrids. With increase in salt concentration the length of coleoptile reduced. Exception was hybrid Cisco with water potential of -0,6 MP, which produced longer coleoptile in comparison to water potential of -0,3 MP. Similar results were found by *Machado Neto et al*., (2004) in tests on soybeans where maximum values were controlled and with increase of water potential the length of coleoptile has reduced. *Katerji et al*., (1994) found the close connection between percentage of germination reduction and that of plant growth under salt stress in sunflower and maize and their yield in controlled environment.

Table 1. Impact of hybrids and salts on growth and development of the sprouting embryo

Hybrid	NaCl (MPa)	Germination energy (%)	% total germination	Root length (cm)	Length of coleoptile (cm)	Fresh mass of root (g)	Fresh mass of coleoptile (g)	Dry mass of root (g)	Dry mass of coleoptile (g)	Dry mass of root/ coleoptile (g)

Results of dry mass of the root and sprout show maximum values controlled and the reduction with negative water potential. Statistics of significant reduction in fresh mass of the root and coleoptile was in hybrid BL-43, Cisco and Maverick. This is in accord with results of *Wang et al*., (2009) which published that fresh mass and length of the root and of coleoptile in 2 alfalfa cultivars were inhibited 200mM of NaCl and with further increase of salt the germination process stopped. Exception was in hybrid ZP-427 where, with mild increase of concentration, there was increase in fresh mass of coleoptile and in comparison to control variant. Significant differences were recorded in fresh mass of the root and of coleoptile among the tested hybrids. The lowest fresh mass of the root was found in hybrid Maverick, while the lowest was in Cisco. Ability of seed to germinate in saline conditions does not exclusively depend on salt concentration but on other biological factors, age of seed, dormination, seed coat thickness, seed viability of seed.
Hybrid Maverick, in comparison to other hybrids, had the lowest dry mass of the root and these differences were of high significance, while differences in dry mass of coleoptile in each hybrid examined were not of statistics' significance. In all hybrids, the increase of salt concentration resulted in significant reduction of dry mass of the root. *Begum et al*., (1992) concluded that increase of salt concentration produces decline of dry mass of the root, which is in accord with our results. When salt concentration increased in hybrid BL-43 and ZP-427 it was recorded that dry mass of coleoptile reduced while in hybrid Cisco with increase of salt concentration the mild increase of dry mass of coleoptile occurred with controlled variant and in hybrid Maverick, the increase of dry mass of coleoptile was significant in mild increase of salt concentration (-0,3MP).
Maximum values of proportion of dry mass of the root/sprout were in controlled variant and in comparison to water potential of -0,3 MP and -0,6 MP was of high statistics' significance. Maximum values of proportion of dry mass of the root/sprout were found in hybrid BL-43 and Cisco and those are highly significant in comparison to hybrids ZP-427 and Maverick, as well as the differences between hybrid ZP-427 and Maverick. In hybrid ZP-427 with increase in salt concentration it came to the increase of proportion the root/sprout, which is in accord with results of *Magsoudi and Maghsoudi* (2008).

Conclusion

For most of characteristics tested, the best results were achieved in controlled variant. Exceptions are recorded only in dry mass of coleoptile because the lowest mass was found in controlled variant. Increased salt concentration had negative impact on germination energy, total

germination, length of the root and coleoptile, fresh mass of the root and coleoptile and the dry mass of the root, while increase of salt concentration resulted in the increase of dry mass of coleoptile but increase of salt concentration from -0,3 MP on -0,6 MP resulted in formulation of longer maize root. Significant variations in tolerance on salt stress were recorded in all hybrids tested. Hybrid BL-43 had the highest germination energy and longest root. Hybrid ZP-427 had the best dry mass of coleoptile and the highest total germination when higher salt concentration applied, which is extremely significant for arid and semiarid soils exposed to salt stress. Hybrid Cisko had the best total germination, fresh mass of the root, fresh mass of coleoptile and maximum value of proportion of dry mass of the root, dry mass of coleoptile and maximum value of proportion of dry mass of the root/coleoptile. Hybrid Maverick had the longest coleoptile.
Hybrid Cisco appeared as the most tolerant on salt stress and the lowest tolerance was recorded in hybrid Maverick.

Abstract

In Mountain Thyme (*Thymus kotschyanus* Boiss. & Hohen.) the mating system is mostly cross pollination which can cause a high level of genetic polymorphism. In terms of uniformity, vegetative propagation as stem cuttings is an accessible and inexpensive method. Stem cuttings have the ability to form adventitious roots, and root cuttings can regenerate a new shoot system. The aim of this trial was to determine the effect of NAA on rooting of mountain thyme cuttings. The trial was established as a randomized block design with 3 replications during 2015, in greenhouse of the Agronomy Department, Faculty of Agriculture of Urmia University, Iran. At first, one stock plant was selected from Baba Hasan Valley, Sulduz region, West Azerbaijan province. Stem cuttings were taken from the stock plant. Before placing in the media the cuttings were treated with NAA (0, 125, 250, 500 and 1000 ppm). According to the results the average of stem height ranged 4.27-6.17 (cm); number of nods ranged 3.27-5.20 (pcs); number of leaves ranged 6.53-10.40 (pcs); number of roots ranged 7.00-9.47 (pcs); the highest root length ranged 2.43-5.70 (cm); root fresh weight ranged 0.007-0.017 (g); shoot fresh weight ranged 0.031-1.106 (g); total fresh weight ranged 0.042-0.088 (g); root dry weight ranged 0.004-0.008 (g); shoot dry weight ranged 0.011-0.033 (g); total dry weight ranged 0.016-0.038 (g); ratio of root fresh weight ⁄ shoot fresh weight ranged 0.119-0.324; ratio of root dry weight ⁄ shoot dry weight ranged 0.154-0.429. In terms of root number, shoot fresh weight, root fresh weight, shoot dry weight and total dry weight, NAA 500 ppm; in terms of leaf number, nod number, stem height and total fresh weight, NAA 125 ppm and in terms of highest root height and root dry weight NAA 125 ppm were the best.

Keywords: *Mountain Thyme, NAA, Propagation, Stem Cutting.*

Introduction

Iranian medical schools are accounted for as one of the oldest and richest in the world. Numerous innovations have been offered in this medicine by Iranian scientists, for instance, in the 9th century (3rd Hegira), spinal cord injuries (SCI) with various treatments on them have been touched in the book entitled al-Hawi, compiled by Razi, an Iranian scientist (Abolghasemi, 2013). Worldwide use of medicinal plants has risen significantly over the past two decades, fueling development of an important agricultural market valued at over US $ 60 billion annually (World Health Organization, 2004). At present, 80 percent of the population in developing countries relies largely on plant-based drugs for their health care needs, and the WHO has estimated that in coming decades a similar percentage of the world population may well rely on plant-based medicines. Thirty percent of the drugs sold worldwide contain compounds derived from plant material. The expanding interest in medicinal and aromatic plants, new income-generating opportunities are opening up for rural populations. This rapid rise in demand,

however, has not been matched by equal increases in cultivation. With many of the medicinal and aromatic plants gathered from the wild, the collection and sale of medicinal and aromatic plants is providing a complementary source of cash for many extremely poor rural households. However, despite the fact that the products collected can have very high value in the final products, the collectors typically receive only a small share of the final value, either because they are unaware of the real value, are unable to market it in the form wanted by buyers or are unable to market to these buyers (Pagliarulo *et al*., 2004; FAO, 2010).

The pharmaceutical industry is largely dependent upon the wild populations for supply of these plant species for the extraction of their intrinsic bioactive component. Because the land sources of wild medicinal plants are limited, attempts to allow the replenishment or cultivation of this important flora is more necessary and there is an urgent need to develop effective propagation methods for cultivation of these important medicinal plants which will ultimately lead to their conservation as well as supply for commercial use. More often, plant species are hard to propagate sexually and they also show complexities and undesirable characters (Tiwari and Das, 2010; Johnston *et al*., 1959).

Sexual reproduction has been responsible for the wide genetic diversity observed in many plants. While vegetative propagation of plants is essentially the reproduction of plant material from vegetative organs so that the offspring will contain the exact characteristics of the parent plant with regards to genotypes and health status. Cuttings are severed uninodal leafy shoot or root fragments that can develop adventitious roots and shoots respectively. Uninodal leafy shoot cuttings are usually placed into a suitable rooting substrate and kept under high humidity in propagators until roots and shoots are formed. Propagation by cuttings is a relatively easy method and can provide a large number of propagules in a very short time. Thus, vegetative propagation as stem cutting is the most vital and sole method to reproduce these plants species (Macdonald, 1996; Nanda, 1970; Tiwari and Das, 2010). In vegetative propagation, the rooted plants by cottage have many advantages, such as faster growth rate (Ooyamma and Toyoshima, 1965), greater stock stand uniformity, better site matching and true– to- type planting material production (Fielding, 1969). Cutting can be categorized into three groups; easy to root, difficult to root and obstinate to root (Nanda, 1970; Mumtaz et al., 2009).

The family Lamiaceae is one of the most important plant families in which *Thymus* with about 215 species, is a significant genus (Zaidi and Crow, 2005). The medicinal properties of the genus *Thymus* have made it one of the most popular medicinal plants (Nickavar *et al*., 2005). The genus Thymus L., is a well-known aromatic perennial herb originated from Mediterranean region. Among 215 species of this genus grown in the world, 18 species are distributed in Iranian flora, and 4 of these species are endemic (Jalas, 1982; Stahl-Biskup & Saez, 2002). Thymus species are well known as medicinal plants because of their biological and pharmacological properties. In traditional medicine, leaves and flowering parts of Thymus species are used. In Iran, *T. daenensis* Celak., *T. kotschyanus* Boiss. and Hohen. Are more widely used as herbal tea, flavoring agents (condiment and spice) and medicinal plants. Infusion and decoction of aerial parts of *Thymus* species are used as tonic, carminative, digestive, antispasmodic, anti-inflammatory, antitussive, expectorant and for the treatment of colds in Iranian traditional medicine ((Amin, 2005; Zargari, 1990). *Thymus kotschyanus* Boiss. & Hohen. Common name: (thyme) belongs to the Lamiaceae family. The plant is an aromatic and medicinal plant that grows wild in Iran (Azerbaijan, Gilan, Mazandaran, Qazvin and Tehran provinces). The essential oil chemical composition of the plant was identified Thymol (38.0%), Carvacrol (14.2%) and 1, 8-Cineole (13.2%) as the main components of the oil of the species collected from Dizin in Iran. In Iraqi folk medicine, the whole plant is anthelmintic, antioxidant, strongly antiseptic, antispasmodic, carminative,

deodorant, diaphoretic, disinfectant, expectorant, sedative and tonic. Internally, it is taken in the treatment of bronchitis, catarrh, laryngitis, flatulent indigestion, painful menstruation, colic and hangovers. Externally, it is applied to minor injuries (wound-healing), mastitis, mouth, throat and gum infections (Rustaiyan, R., 1999; Rechinger, 1982; Al-Rawi and Chakravarty, 1988).

Sato *et al*. (2005) reported that 8.8 μmol BAP and 11.42 μmol IAA caused to increase proliferation rate in shoot tip explants in the plant. The multiplication rate was the highest (3.44 ± 0.25 cm) when BAP was used in combination with NAA (naphtalic acetic acid). Presence of NAA promotes shoot elongation as reported by Barrueto *et al*. (1999). Root formation required the presence of NAA in culture medium (Tavares *et al*., 1996). The rooting ability of the plant was inhibited in medium containing activated charcoal. After 25 days of treating plants with 1 mg/L NAA, 96% rooting was obtained while the same concentration of IBA induced 64% rooting of shoots (Meftahizade *et al*., 2010). In the present study, the effect of NAA (0, 125, 250, 500 and 1000 ppm) on rooting of Mountain Thyme stem cuttings were evaluated.

Materials and Methods

At first, one stock plant was selected from Baba Hasan Valley, Sulduz region (Naghadeh), West Azerbaijan province, Iran. Sulduz region (36:57º E , 45:22º N), is a district of West Azerbaijan province that is located on the north west of Iran. Sulduz takes its name from watery and flat in Azeri language. The region is surrounded by Urmia city and Urmia Lake from the north, Mahabad city from the south, Miyandoab city from the east, Piranshahr from the west, and Oshnaviyeh city (located in the border of Turkey and Iraq) from North West. The altitude is 1000 m at the foot and 2100 m at the summit of the mountain. The annual average temperature of the region is 11.3-13.71°C; the summer average is 22.76°C, and the winter average is 2.45°C. The coldest months are December-January (-0/3°C) and the warmest are July-August (24.21°C). Average precipitation is 326.43 mm (Rahimi *et al*., 2012). Stem cuttings were taken from the stock plant. Vegetative propagation of the plant was carried out in green house at the Department of Field Crops, Faculty of Agriculture, Urmia University, Urmia, Iran during the period from 25. 05. 2015 till 26.06.2015. The stem cuttings were prepared at same size each as 0.2 cm diameter and 8 cm long. Plant cuttings were planted in plastic pots filled with sand substrate as a material to root. Before placing in the media the cuttings were treated with NAA (0, 125, 250, 500 and 1000 ppm). After placing the cuttings were irrigated regularly by hand depending on weather conditions and development stage of plants. Cuttings were harvested 31 days after planting and evaluated for different properties such as stem height, number of nods, number of leaves, number of roots, the longest root length, root fresh weight, shoot fresh weight, total fresh weight, root dry weight, shoot dry weight, total dry weight, the ratio of root fresh weight⁄shoot fresh weight and the ratio of root dry weight⁄shoot dry. Stem height and longest root length were measured. Fresh and dry weight of shoot, roots and total were weighed. The number of leaves and roots were counted. The ratio of root fresh weight ⁄ shoot fresh weight and ratio of root dry weight ⁄ shoot dry weight were calculated.

Results and Discussion

The average of stem height, number of nods, number of leaves, number of roots, the longest root length, root fresh weight, shoot fresh weight, total fresh weight, root dry weight, shoot dry weight, total dry weight, the ratio of root fresh weight⁄shoot fresh weight and the ratio of root dry weight⁄shoot dry in different treatments are shown in Table 1.

Table 1. Some properties of Mountain Thyme rooted cuttings

properties	0 ppm	125 ppm	250 ppm	500 ppm	1000 ppm
stem height (cm)	5.87	4.30	**6.17**	4.73	4.27
number of nods (pcs)	4.73	4.13	**5.20**	4.20	3.27
number of leaves (pcs)	**10.40**	8.13	**10.40**	8.40	6.53
number of roots (pcs)	7.00	8.93	8.13	**9.47**	7.00
the longest root length (cm)	5.47	**5.70**	3.53	2.43	2.57
root fresh weight (g)	0.007	0.013	**0.014**	0.017	0.010
shoot fresh weight (g)	0.056	0.060	**0.074**	0.106	0.031
total fresh weight (g)	0.062	0.073	**0.088**	0.066	0.042
root dry weight (g)	0.004	**0.008**	0.006	0.005	0.005
shoot dry weight (g)	**0.029**	0.024	0.022	0.033	0.011
total dry weight (g)	0.034	0.032	0.028	**0.038**	0.016
root⁄shoot (fresh)	0.119	0.220	0.185	0.162	**0.324**
root⁄shoot (dry)	0.154	0.319	0.265	0.160	**0.429**

According to the results the average of stem height ranged 4.27-6.17 (cm); number of nods ranged 3.27-5.20 (pcs); number of leaves ranged 6.53-10.40 (pcs); number of roots ranged 7.00-9.47 (pcs); the highest root length ranged 2.43-5.70 (cm); root fresh weight ranged 0.007-0.017 (g); shoot fresh weight ranged 0.031-1.106 (g); total fresh weight ranged 0.042-0.088 (g); root dry weight ranged 0.004-0.008 (g); shoot dry weight ranged 0.011-0.033 (g); total dry weight ranged 0.016-0.038 (g); ratio of root fresh weight ⁄ shoot fresh weight ranged 0.119-0.324; ratio of root dry weight ⁄ shoot dry weight ranged 0.154-0.429. In terms of root number, shoot fresh weight, root fresh weight, shoot dry weight and total dry weight, NAA 500 ppm; in terms of leaf number, nod number, stem height and total fresh weight, NAA 125 ppm and in terms of highest root height and root dry weight NAA 125 ppm were the best.

Conclusion

Results show a positive effect of NAA on rooting and vegetative growth of mountain thyme cuttings in terms of stem height, number of nods, number of leaves, number of roots, root length, root fresh weight, shoot fresh weight, total fresh weight, root dry weight, shoot dry weight and total dry weight. However, effect was dependant on NAA concentration. The best results were obtained with NAA 500 ppm in cases of root number, shoot fresh weight, root fresh weight, shoot dry weight and total dry weight while the best positive effect on leaf number, nod number, stem height, total fresh weight, root height and root dry weight was obtained with NAA 125 ppm.

Abstract

Canada goose (*Branta canadensis* L.) is one of the iconic species representing wild America; and is a native of the continent of North America, northern Europe and Far Eastern Asia. The range of the species stretches from Canada, through continental US to some parts of Central America. Within continental North America the species is widely distributed within several ecosystems from the Pacific on the west to the Atlantic in the east. It is a truly pan American avian species for its widespread distribution in the continent of North America stretching from northern Canada across the US to northern parts of Mexico. Canada goose is a grandeur symbol of the North American life, nature and eco-environmental values and is being currently reviewed based on popular voting organized by the famous Canadian Geographic magazine as one of the top five contending species for being considered as the National Bird of Canada. The majestic migratory avian species has several sub species reported across the west to east stretch of the continent of North America. The species usually travel to southern US, northern Mexico and some other parts of Central America during winter and returns to their northern breeding grounds in US and Canada during summer for nesting and breeding purposes Although the exact number of sub species is debated; but researchers consider around 8-10 distinct sub-species. The species is related to the socio-cultural and ethnic history of the continent and the migrating flocks to the south during fall is considered to be an important iconic symbol of continental North America.

Key words: *Canada goose, eco-environmental, eco-sociological, North America, species*

Introduction

Canada goose (*Branta canadensis* L.) is one of the iconic avian species from continental North America, parts of Northern Europe and Far East (Krohn and Bizeau, 1980). Several introduced species are also known from several parts of the planet including New Zealand. The range of distribution for the Canada geese extends from Canada, through the United States to some warmer parts of the Central America; and the species is reported along both the Pacific coast on the west as well as the Atlantic in the east, being a truly pan American iconic avian species (Chapman et al., 1969; Basu, 2015a-d). Canada goose is also a grand symbol of the Canadian life, nature and eco-environmental values and is being currently reviewed based on popular voting organized by the famous Canadian Geographic magazine as one of the top five contending species for being considered as the National Bird of Canada (Basu, 2015a-d). This majestic species has trans-continental distribution (North America) with several sub species reported along a west to east stretch of the continent. Although the exact number of sub species is debatable among researchers; but, generally accepted varying somewhere between eight to ten (Shields and Wilson, 1987; Basu, 2015a, c). New molecular studies are providing further insights into the complex separation of close related sub species or geographic variants or morphological variants.

Sub species diversification

The commonly reported Canada goose sub species across the continental North America are mentioned as follows: Atlantic Canada Goose (*B. canadensis canadensis*) breeding in Labrador & Newfoundland (Eastern Canada), while wintering in Florida (US); Interior Canada Goose (*B. canadensis interior*) breeding in Canada; winters to Florida & Louisiana (US), Vancouver Canada Goose (*B. canadensis fulva*) is a predominantly resident species that breeds from coastal parts of southern Alaska (US) to British Columbia (Canada), Giant Canada Goose (*B. canadensis maxima*) used to be found in great numbers in the Great Plains of North America, but their numbers have fallen considerably and are now restricted to wildlife reserves of both Southern Canada and the Northern US; Lesser Canada Goose (*B. canadensis parvipes*) breeding from Central Alaska (US) to Alberta, Saskatchewan and Manitoba (Canada), while wintering in southern US; Dusky Canada Goose (*B. canadensis occidentalis*) predominantly breeds around South Western Alaska, wintering in mainland US; and Moffitt's Canada Goose (*B. canadensis moffitti*) breeding in areas in and around the Great Northern Plains and the Great Basin (US) and also in southern Canada, while wintering in South and South Western US (Chapman et al., 1969; Krohn and Bizeau, 1980; Shields and Wilson, 1987; Paxinos, et al. 2002; Basu, 2015a-d).

Biological behaviors

The number of sub-species of the Canada goose varies according to various research reports; and there is serious confusion and taxonomic debates around them (Shields and Wilson, 1987; Paxinos et al., 2002; Basu, 2015a-d). The geese are known to lay between 2-12 eggs depending on the seasonal weather patterns, quality of food supply and the levels of predation of eggs and chicks by predators such as coyotes, foxes, badgers and raptors. The Canada geese are devoted parents and dedicated partners raising their chicks together; and are known to be extremely territorial and highly aggressive in defending their nests, eggs, chicks and roosting areas (Krohn and Bizeau, 1980). They are predominantly dependent of aquatic vegetations, crustaceans, insects and also on grains and other available plant parts as their regular or standard diet (Sedinger, 1986; Sedinger and Raveling, 1988). They are gregarious species and usually like assembling or flocking together on the ground in between their long, exhausting flights often following together in close knit family groups as giant flocks (Hanson and Eberhardt, 1971). Canada geese are commonly seen in and around water bodies, marshes, bogs, swamps, lakes, ponds, parks and agricultural fields across the continent of North America. Many sub species of Canada geese prefer laying their eggs and raising their chicks within the safe boundary of agricultural fields throughout the Prairies of North America for easy access to food and nesting materials and protection from predators (Basu, 2015b, c).

Canada goose has become a symbol of environmentalism

Canada goose represents a unique eco-sociological symbol of nature and is very a well known migratory species of geese. The famous “v-shaped” flying pattern of trumpeting and migrating Canada geese flocks are seen as one of the most well known and symbolic signs of the change of season across the range of this beautiful species (Hanson and Eberhardt, 1971). Many aboriginal communities from North America consider this as a sign of good luck and fortune and there are numerous references of this majestic species in different indigenous folklores, legends, songs and indigenous stories and thereby constitute an essential part of the rich Canadian heritage from a sociological and historical perspective (Basu, 2015b). The majestic species is consider to be an important symbol of the majestic wildlife and grandeur wilderness of the continent of North America as well as a dynamic symbol of the socio-ecological heritage of the world’s second

largest country, Canada (MacInnes and Misra, 1972; Basu, 2015a,c,d). The V-shaped flight formations by huge flocks of Canada geese trumpeting across the horizon is a mesmerizing frame of natural beauty marking the change of seasons. The precisely organized and highly disciplined flight pattern of the majestic avian species literally represents the underlying strength, unity and solidarity among the coherent flock members. It is a legendary, socio-cultural and eco-ethnic symbol of numerous aboriginal communities from the continent of North America stretching across the frozen North to the dry Southern reaches of the vast continent. The large water bird with its wide flashy, black wings widely stretched while flying overhead is a poetic representative of the free spirit of eco-environmentalism across the continent of North America (Basu, 2015a, b).

The North American life is intricately interwoven with this natural wild icon. The species has been once inscribed on a one Canadian dollar coin to commemorate the spirit of winter Olympic held in Canada; and has regularly found spots in the circulating postage stamps of both Canada and the US. This commonly visible species is used as an important model in developing eco-environmental education, consciousness and awareness among local kids from the very foundation of formal education to help them grow up as responsible and eco-sensitive citizens of future. All these demonstrate that the environmental eco-sociological engagement with the species has been historical in this continent. It may have played a significant underlying role in the eco-environmental awareness, consciousness and successful eco-sociological conservation of the majestic species across the entire continent. This is a classical example of pan continental eco-environmental engagement, cooperation and conservation initiative that has resulted into a successful protection for this majestic avian species and can easily serve as a global model for successful eco-sociological conservation effort. The species is currently considered as Least Concern by the International Union of Conservation of Nature (IUCN) (Basu, 2015a, d).

Conclusion

Canada goose is grandeur, iconic symbol of wild North America and a native of the continent. The species is distributed from the Pacific to the Atlantic coast across the entire breadth of continental America. The distribution of the species stretches from Canada across the US to northern Mexico. The migratory species has several sub species reported across continental North America. This species migrates to southern US, northern Mexico and other parts of Central America to avoid harsh North American winter and returns to their breeding and nesting grounds in US and Canada during summer. Currently considered as a Not Threatened species with wide distribution reported across the continent in different ecosystems. Canada goose is as a species reflects to the eco-environmental dynamics of North America and is deeply connected to the socio-cultural life and history of several ethnic groups inhabiting the continent of North America and constitutes parts of several folklores, legends, stories and poems of indigenous communities as well as both rural and urban citizens of the continent.

Abstract

Fenugreek (*Trigonellafoenum-graecum* L.sp.) is one of the oldest reported medicinal plant, spice herb and forage crop in the world. The plant is believed to be native to the Mediterranean region. Indigenous species of fenugreek have been reported from Asia, North Africa, Europe and Australia. Over 25 species of fenugreek are reported across the globe. Currently grown widely across the Indian subcontinent, China, some parts of SE Asia and the Far East; in West Asia and North Africa; Mediterranean Europe and Russia; Australia and recently in parts of Western Canada, the United States and Argentina in the Americas. Fenugreek is an annual forage legume with appreciable genetic diversity and is suitable for the low input agricultural regions of Asia, Africa and Latin America as a forage crop, medicinal herb, spice as also an industrial crop for the nutraceutical and functional food industry.

Keywords: *Fenugreek, Trigonella foenum-graecum L., forage, spice, medicinal. Phytochemicals*

Introduction

Fenugreek (*Trigonella* sp.) is one of the oldest reported medicinal plant, spice herb and forage crop in the world (Acharya et al., 2006; Basu & Prasad, 2011; Zandi et al., 2015). The plant is believed to be native to the Mediterranean region. Indigenous species of fenugreek have been reported from Asia, North Africa, Europe and Australia (Acharya et al., 2006). Over 25 species of fenugreek are reported across the globe; however, the most popular species is *Trigonella foenum-graecum* L (Basu et al., 2008a, b; 2009; Zandi et al., 2011a,b). The term "*foenum-graecum*" means 'Greek hay' indicating its use as a forage crop in the past (Basu et al., 2008a, b; 2009; Zandi et al., 2013). Currently grown widely across the Indian subcontinent, China, some parts of SE Asia and the Far East; in West Asia and North Africa; Mediterranean Europe and Russia; Australia and recently in parts of Western Canada, the United States and Argentina in the Americas (Solorio-Sánchez et al., 2014). The plant belongs to the legume family (Fabaceae) like alfalfa (*Medicago sativa* L.); and can be easily identified by its dark green trifoliate leaves with ovate leaflets, cream to white small leguminous flowers and hard textured golden yellow coloured seeds. On an average, 20 seeds are produced in each sickle-shaped, glabrous, slender, greenish to light brown or partly purplish pods varying in length between 12-18 cm (Acharya et al., 2006; Basu et al., 2008a, b; 2009; Zandi et al., 2013). Plants are indeterminate in growth habit; and hence continue to flower until frosting or till any desiccant is applied. Fenugreek being a self-pollinated crop; does not need the use of pollinators (Acharya et al., 2006; Basu et al., 2008a, b; 2009; Zandi et al., 2013).

Fenugreek seed and leaves contain a number of medicinally important phytochemicals including the galactomannans, steroidal sapogenins such as diosgenin, tigogenin, yamogenin;

dihydroxysapogenins like gitogenin; spirostanol saponins such as graecunin; triterpenoids; alkaloids; flavonoids; and amino acids like 4-hydroxy-isoleucine (Zandi et al., 2015). Galactomannan helps in reducing glucose intake thereby providing efficient control of blood glucose levels in diabetic patients (Zandi et al., 2013). The amino acid isoleucine has similar role by regulating the release of insulin from the pancreatic cells (Acharya et al., 2011). The steroidal sapogenins are important sources of synthetic sex steroids and are used in the treatment of hypercholesterolemia. Furthermore, the plant has been reported to have antioxidant, antimicrobial, anti-leukemic and anti-neoplastic properties to mention only a handful (Acharya et al., 2008, 2010). However, the amount and nature of these phytochemicals have been found to vary under different environmental conditions and also with the change in the genotype demonstrating Genotype X Environment interaction (Zandi et al., 2015). Hence, locally adapted cultivars of fenugreek are suggested for optimal production of different agronomic and/or biochemical traits of the crop (Basu & Prasad, 2011). Currently fenugreek is also actively used in the global nutraceutical and functional food industries due to its rich medicinal properties (Basu et al., 2007). India is the largest global producer of fenugreek seeds where the plant is also used as a traditional spice in preparing traditional curries. The seeds are also used in producing artificial maple syrup. Fenugreek seeds are reported as an important galactagogue; and helps in promoting milk flow both in lactating women and animals (Acharya et al., 200, 2010).

Crop benefits

Fenugreek has nitrogen fixing ability thereby restricting the need for application of costly synthetic nitrogenous fertilizers and hence environment friendly by nature; and could be used in Organic Farming for soil nitrogen enrichment (Acharya et al., 2006;Basu et al., 2008a,b; 2009; Basu & Prasad, 2011; Zandi et al., 2011a,b). It is suitable for short term rotations (Acharya et al., 2008; Basu et al., 2008a, b; 2009; Zandi et al., 2013) and also suited to dry land as well as rainfed conditions suitable for semi-arid regions; and hence cuts down irrigation expenses (Acharya et al., 2006; Basu et al, 2007 a,b; Zandi et al., 2010). *In vitro* dry matter disappearance and crude protein level in fenugreek has been found to be higher than that of alfalfa; however, *in vitro* gas production and volatile fatty acid content are almost similar. The forage quality (protein and fibre content) of mature fenugreek is comparable to prime cut alfalfa; and hence can be easily utilized at any growth stage (Acharya et al., 2006;Zandi et al., 2010; Basu & Prasad, 2011). Reasonably high yield of forage fenugreek is reported from semi-arid regions (Acharya et al., 2008). The crop is known to be bloat free unlike alfalfa (Acharya et al., 2011; Basu & Prasad, 2011; Zandi et al., 2010, 2013).

The fenugreek phytochemicals reduces the need for application of synthetic steroids in the cattle (Acharya et al., 2007; Basu et al, 2007 a,b; Basu et al., 2008a, b; 2009; Basu & Prasad, 2011). Fenugreek promotes muscle growth and hence supports higher carcass weight in animals (Acharya et al., 2014). Fenugreek seed is an important galactagogue (Acharya et al., 2011). Being comparable to alfalfa in most forage properties along with additional attributes as mentioned above have led to the potential increase in the global forage, nutraceutical and functional food markets for fenugreek (Zandi et al., 2010). However, due to presence of the phytochemicals fenugreek seed has a characteristic odour and could possibly taint the milk and meat, if fed exclusively to animals. Fenugreek mixed with alfalfa and/or sainfoin (*Onobrychis* sp.) has better end results (Acharya et al., 2010;Basu et al., 2008a, b; 2009; Basu et al, 2007 a,b).

Agronomy

Tristar is an annual forage legume cultivar of fenugreek developed by the Agriculture and Agri-Food Canada Research Centre in Lethbridge, AB. This particular cultivar has the ability to maintain high yield consistently over years and at different locations and is suitable for the semi-arid regions of North America (Basu & Prasad, 2011). The production is consistent at a particular location over years; however, production sometimes varies from one location to another (Basu et al., 2014). Tristar can be used as hay, silage, straight grazing or swath grazing. Addition of phosphate rich fertilizers in optimum amounts to phosphate deficient soil boosts Tristar growth. But, no effect was observed in soils already rich in phosphorus. Well drained loamy soil with a pH of 8-8.5 is preferred for cultivation. Tristar, a dryland crop responds reasonably well to irrigation for both forage and seed production (Basu & Prasad, 2011). The crop is quite easy for establishment establish and can be conveniently harvested using conventional hay cutting or cereal combine equipment. The crop is extremely suitable for agronomic productions in the dry and semi-arid areas of Asia, Africa and Latin America (Zandi et al., 2010; Basu and Agoramoorthy, 2014; Basu et al., 2014; Zandi et al., 2015).

Tristar seedlings like other fenugreek cultivars do not develop canopy to reduce weed growth until several weeks post seeding; and hence yield could be reduced by the annual grasses and broadleaf weeds common in the Prairies (Basu et al., 2008a, b; 2009). However, Tristar has been reported to demonstrate appreciable level of tolerance to herbicides such as trifluralin, ethalfluralin and imazamox/ imazethapyr. Attempts are under way to get minor use registration for some of the herbicides (Acharya et al, 2007). Application of gibberellic acid to the seeds prior to sowing improve seed yield. Application of chemicals like ethyl methane sulphonate or dimethyl sulfoxide or cholchicine on the seeds have resulted in plants with determinate growth habit, bigger seed sizes and higher seed oil contents under experimentation (Basu et al, 2007 a,b; Basu & Prasad, 2011).

Several bacterial, viral, fungal and insect diseases of fenugreek are reported globally impacting forage production (Basu et al., 2008 a,b). However, the two most common fungal diseases are the Leaf Spot caused by *Ascochyta* sp and the Powdery Mildew caused by *Oidopsis sp* in wet years and if the crop is irrigated beyond August in Western Canada (Basu et al., 2014; Chakraborty et al., 2014). Tristar is particularly susceptible to the Powdery Mildew. Conditions favouring Powdery Mildew are relative humidity between 95-97 %, temperature within a range of 23-30 ^{0}C and annual precipitation between 350-400 mm with warm days and cool nights (Acharya et al., 2007). *Pseudomonas syringae* infection is a common bacterial infection. Potential insect pests of fenugreek in southern AB include *Lygus* sp. and *Adelphocoris* sp. However, the plant being new to the North American continent does not have significant insect pest load reported as of now (Basu et al., 2006).

Tristar has been reported to be suitable for intensive silage and hay production in Western Canada particularly for regions having warmer summer (Basu et al., 2008 a,b). Tristar biomass yield is 2 and 11% higher compared to the check cultivar Amber under dryland (rainfed) and irrigated conditions, respectively. Tristar has 26% higher seed yield compared Amber under irrigated condition of southern AB. Field trials demonstrated Tristar having higher forage yield (t DM ha^{-1}) compared to Amber under both irrigation and dryland (rainfed) conditions (6.0 vs 5.4 and 5.8 vs 5.7, respectively); and higher seed yield (t ha^{-1}) than Amber under both irrigation and dryland (rainfed) conditions (1.26 vs 1.0 and 0.78 vs 0.77, respectively) (Acharya et al., 2007). Mature golden brown seeds of Tristar are smaller in size (14.3 g 1000 seed^{-1}) compared to that of check cultivar Amber (15.5 g 1000 seed^{-1}) (Acharya et al., 2007).

Concluding remarks

Fenugreek (*Trigonella foenum-graecum* L.) is an annual forage legume with appreciable genetic diversity and is suitable for the low input agricultural regions of Asia, Africa and Latin America as a forage crop, medicinal herb, spice as also an industrial crop for the nutraceutical and functional food industry. The plant has been known since ancient times for its yellowish brown, angular seeds that are rich in gum, fiber, alkaloids, flavonoids, saponins, volatile substance and other nutritional contents.Possessing high concentration of fiber, fenugreek herb could be effectively considered as a food stabilizing, emulsifying and adhesive agent so as to change the food texture for specific purposes.In regard with nutraceutical properties, fenugreek might also be favored by nations asa means forproviding medicinal or health benefits in many cases involvingcarcinogenic, diabetic, and bacterial illnesses. It can also works as antioxidant, anti-anorexia agent, gastric stimulant and effective cure for hypoglycemia and hypercholesterolemia.

Abstract

Among many fruit trees, apples are the most cultivated trees in Albania, and the region of Korça is the main market supplier with apple fruits. This specie represents around 70% of total fruit trees. The increase of production and the quality of this fruit are related not only with Good Agricultural Practice but even with the use of pesticides. The fruit trees are in the second place regarding to the used amount of pesticides per hectare. In this study we have been focused on the evaluation of penconazole and myclobutanil residues in apple based on QuEChERS method. The experiments are performed with two types of apple cultivars (Golden Delicious and Starking). The apples trees were treated with the minimum and maximum doses of pesticides penconazole and myclobutanil that are required. The number of treatments according to European Union (EU) did not exceed 4 treatments for season. For determination of penconazole and myclobutanil residues from each apple variety 10g homogenated sample were weighted. Then, the sample was placed in a centrifuge tube test 50mL, when 10 ml acetonitrile and 100µl solution of 20ppm TPP was added. The centrifuge tube test was closed and mixed in a vortex. After that, a mixture of magnesium sulfate anhydrous, sodium chloride, trisodium citrate dehydrates and disodium hydrogen citrate sesquihydrate was added. Then, extract was centrifuged for 5 minutes in a centrifuge with speed 3500rpm. A small quantity of supernatant was added in e centrifuge tube that contained 150 PSA and 900 mg magnesium sulfate anhydrous and undergoes the mixture with vortex and centrifugation. The supernatant was placed in a vial and kept in refrigerate to be ready for chromatography analyses.

Keywords: *apples, pesticides residues, penconazole, myclobutanil.*

Introduction

Fruits are an essential component of our diet due to their nutritional value. They serve as supplementary sources of carbohydrates, lipids, vitamins, minerals, antioxidants which play an important role in the metabolic pathways and inhibit the abnormal growth of cells. A high intake of fruit has been encouraged not only to prevent consequences due to vitamin deficiency but also to reduce the incidence of major diseases such as cancer, cardiovascular diseases and obesity (Wattenberg, 1992; WHO, 2002; Latif *et al*., 2012). According to The World Health Report 2002, high fruit and vegetable intake is estimated to reduce about 31% of ischemic heart disease and 11% of stroke worldwide.

Among many fruit trees, apples are the most cultivated trees in Albania, which represents around 70% of total fruit trees, and the region of Korça is the main market supplier with apple fruits.

Unfortunately, not all farmers follow legal practices, and by using tremendous number of pesticide applications they make this agricultural product a subject of contamination, which often leads to the presence of pesticide residues in fruit after harvest (Food and Drug Administration, 1999; Fillion *et al*., 2000; Lehotay, 2000; Abdulrauf et al., 2012)

A number of analytical methods are designed to determine multiple pesticide residues (Lehotay, 1996), but the usual methods for isolating pesticides from fruit samples are: Liquid-Liquid Extraction (LLE), Pressurized Liquid Extraction (PLE), Liquid-Liquid Microextraction (LLME), Microwave-ssisted Extraction (MAE) and Ultrasound-assisted Extraction (UAE). Extract clean-up techniques are the most commonly employed Solid-phase Extraction (SPE), Solid-phase Micro-extraction (SPME), Stir Bar Solvent Extraction (SBSE) and Gel Permeation Chromatography (GPC) (Blasco *et al.*, 2002; Sanusi *et al.*, 2004; Sanchez et al., 2006). Currently, the Solid Phase Extraction (SPE) is the most popular extract clean-up technique (Stajnbaher and Zupancic-Kralj, 2003).

Anastassiades et al. (2003) described the "Quick, Easy, Cheap, Effective, Rugged, low solvent consumption, wide pesticide range (Polar, pH – dependent compounds) and Safe" (QuEChERS) method for pesticide residues analysis, which provides high quality results in a fast, easy, an inexpensive approach. Since that time, the QuEChERS method using MeCN for extraction has been successfully validated in several laboratories and in interlaboratory trials. The method (with minor modification differences) has become an Official Method of Association of Analytical Communities (AOAC) International and the European Standard Organization (CEN) (Lehotay, 2007).

The most common techniques in modern multi-residue target pesticide analysis are gas chromatography, liquid chromatography coupled to mass spectrometry (GC-MS, LC-MS) and/or tandem mass spectrometry (GC-MS/MS, LC-MS/MS). Núñeza *et al*., 2012 have noticed in their study that liquid chromatography coupled with mass spectrometry (LC–MS) or with tandem mass spectrometry (LC–MS–MS) or with time-of-flight (LC-TOF-MS) has lately become a powerful analytical technique for the identification and quantification of pesticides residues in fruits such as apples.

Materials and methods

Experimental Field

In this study we have chosen two species of apple trees; Golden Delicious and Starking Delicious, because these species are the most affected by diseases. The field experiment was performed at the Korça region (Albania). The application of the pesticides on the trees was done through a tractor in which two sprays were mounted. In the Table 1 are listed the commercial name, active substances and some other characteristics of pesticides (fungicides) that are used in this study.

The apple orchard was divided into four plots. Golden Delicious where placed on the first and second plots, while Starking Delicious where placed on the third and fourth plots. During the treatment two doses were used, one with minimum and the other one with maximum of optimum level needed for the decease treatment. The doses (%) for myclobutanil and penconazol are listed on the Table 2.

Table 1 *Some characteristics of fungicides used in experiment*

Commercial name	Active substance	Mode of action	Group Name	Chemical group	FRAC Code
Chorus50 WG	Cyprodinil	Amino acid and protein synthesis	AP - fungicides (Anilino-Pyrimidines)	anilino-pyrimidines	9
Captan 80 WG	Captan	Multi-site contact activity	phthalimides	phthalimides	M4

10	10.09.2015	Pen 10 EC	0.025	0.04

Sampling procedure

The first samples were taken for analysis on 21th August 2015 one day after the treatment of trees with Brik 24 and then into intervals (see the Table 3).

Sampling was performed by hand-picking of the apples (around 1kg of fruit). The apple samples were taken in accordance with European Commission Directive 2002/63/EC. The transportation of apples to the laboratory was done through cooling boxes. The temperature inside the boxes did not exceed 5-6^{0}C.

Table 3. *The last treatments and sampling data*

Data of Treatment	Type of treatment	Sampling Data
20.08.2015	Brik24	21.08.2015
		26.08.2015
		03.09.2015
10.09.2015	PEN10 EC	11.09.2015
		17.09.2015
		22.09.2015
		29.09.2015

Sample preparation

The acetate-buffered QuEChERS sample preparation method for pesticides (UNI EN 15662:2009) was applied to all the samples. After homogenization of 1 kg apples with a domestic blender, a 10 gr portion of homogenized sample was placed in a centrifuge tube test 50mL, when 10 ml acetonitrile and 100µl solution of 20ppm TPP were added. The centrifuge tube test was closed and mixed in a vortex. After that, a mixture of magnesium sulfate anhydrous, sodium chloride, trisodium citrate dehydrates and disodium hydrogen citrate sesquihydrate was added. Then, extract was centrifuged for 5 minutes at 3500rpm. A small quantity of supernatant was added in e centrifuge tube that contained 150mg PSA and 900 mg magnesium sulfate anhydrous and undergoes again the mixture with vortex and centrifugation. The supernatant was placed in a vial and kept in refrigerate to be ready for LC-MS/MS analysis.

Results and Discussion

Chromatography analysis data

Chromatography analysis data of myclobutanil and penconazole residues in apple are presented in the Table 4. These data are taken by using QuEChERS methods and LC-MS/MS apparatus.

Table 4**.** *The parameters of method for residues analysis of myclobutanil and penconazole in apple*

No.	Parameters	Pesticides	
		Myclobutanil	Penconazole
1	Recovery (%)	80,0	86,2
2	Limit of Detection (LOD) (mg/kg)	0,005	0,005
3	Limit of Quantification (LOQ) (mg/kg)	0,01	0,01
4	Reproducibility (%)	≤ 10	≤ 10

The obtained data showed that applied method is suitable for analysis of myclobutanil and penconazole residues in apple as the LOQ are lower than the Maximum Residues Limit (MRL) for myclobutanil and penconazole in apple, which are 0,6 and 0,2 mg/kg, respectively. Furthermore, recoveries and reproducibility parameter of the methods were satisfactory, as they are above required limits. Therefore, this method can be applied for further analysis of myclobutanil and penconazole residues in apple. According to Vladi, 2015 this method can be applied even for other pesticides residues in fruits and vegetables.

Conclusion

The used method in this study is available for the analysis of pesticide residues as myclobutanil and penconazole in apple. The evaluated parameters of method showed good reproducibility and were in required interval for pesticide residues analysis. Thus, QuEChERS methods is simple, fast phase extraction sample, with the largest number of pesticides determined at the same time, higher reliability and simultaneously lower costs.

Abstract

Entomofauna of pears in region of East Sarajevo (entity of Republic of Srpska, Bosnia and Herzegovina) was examined in 2011 and 2012 in intensive orchards in the locations Vojkovići and Kula, in semi-intensive orchards in locations Tilava and Petrovići, and in extensive orchard in the location Kasindo. Using entomological methods, collecting before adult and adult stadium phytophagous and entomophagous-predators species, taking a sample of infested plants organs, cultivation before adult eclosion and determination of collected and newly hatched insects was carried out. Total number of determined insect's species is 44, of which 35 are phytophagous, 8 entomophagous - predators and one with mixed feeding regiment. The largest number of phytophagous insect species trophic related to pear was in semi-intensive orchards, 29 species in the Tilava and 23 species in the Petrovići. In intensive orchards, 13 species was found in Kula, 9 in Vojkovići, while in extensive orchard in the Kasindo, there was 17 species. The most numerous of entomophagous insects - predators was found in intensive orchards in the Vojkovići (8 species) and lowest in extensive orchard in the Kasindo (2 species).

Key words: *Entomofauna, Pear, East Sarajevo region*

Introduction

The total world production of continental fruit, according to the FAO, pear (*Pyrus communis* L.) is in second place, right after the apple, with an average production of 19 million tons. (Mratinić, 2000; Milatović, 2009). In Bosnia and Herzegovina (BiH), pear is on the third place, after the plums and apples, but with a tendency to increase surface area.

During a growing season, the pear is exposed to many pests' attacks, where important place belong to insects from different insects order. Some insect species are present on pears during whole year and hibernate in different stages, but some of them occur only in a certain period of the vegetation, depending on development stages of a plant and bionomy insect species. Feeding by different parts of plants, insects cause physiological weakening of a plant, deformation of plant organs, reduced fruiting or defoliation, while species which damage the fruits, often can cause their prematurely falling, reducing the market value, and sometimes even complete destruction of the plant.

In countries around the world, some species are economically very important, such as psyllid species: *Cacopsylla pyri* L., *Cacopsylla pyrisuga* Foerster and *Cacopsylla pyricola* Foerster (Jerinić – Prodanović, 2010). In addition, important pests of pear are *Cydia pomonella* L. and *Cydia pyrivora* Danilevszkij, which causing damage of fruits, their prematurely falling, and reducing their market and the value in use in many parts of Europe and Asia (Lacey *at al*., 2002).

In addition to harmful species, on pear are present many beneficial insects, particularly pollinators and many entomophagous species or predators and parasitoids, from different insect orders (Heteroptera, Neuroptera, Diptera, Dermaptera and Coleoptera). They are very important in the regulation harmful insects (Maceljski, 2002; Almaši *et al*., 2004; Jerinić-Prodanović, 2010; Tamaš, 2012). In the region of Sarajevo and BiH, there is no enough literature data about harmful and beneficial insects on pear. In the midd 60´s in the XX century, leaf miners were studied in this region (Dimić, 1964). Since then the important examination was not until 2004, when the area of Sarajevo and the other locations in Bosnia and Herzegovina on pear, discovered Phytoplasmatic disease "Pear decline" (Trkulja *et al*., 2004; Delić *et al.*, 2005), transmitted by *C. pyri* and *C. pyricola* (Garcia - Chapa *et al*., 2005). The main objective of this paper was to examine insects' fauna diversity on pear in the area of East Sarajevo, in different rearing systems.

Materials and methods

The examination was realized in 2011 and 2012 in the orchards (locations Vojkovići, Kula, Tilava, Petrovići, Kasindo) and in the laboratory of the Faculty of Agricultural in East Sarajevo.

Method of visual examination of randomly selected trees was determined the presence of insects, their number and symptoms of damage. Visual examination of trees was done during the vegetation season at intervals of 10-15 days, and during the winter. It was done overview of plants for the presence of overwintering form of insects and collecting material by sampling at different insect stages. Winter examination of plants was done by the two samples of the total length of 2 m of two- or three-year branch were survey (from different places was taken of the 10 branches of length 20 cm) and examined in detail in the laboratory under the dissecting microscope. In the locations Petrovići, Tilava and Vojkovići, were examined of 20 trees, while in the Kula and Kasindo examination included of 10 trees. Predators were collected together with the sample plant material.

By method of shaking branches, using entomological meshes and exhauster, all stages of insects which lived freely in the plant organs, were collected. In the locations Vojkovići, Kula, Tilava and Petrovići, one sample was a 100 strokes with 100 branches, of which the two branches of the same trees, at different heights and positions. In the locations Kasindo and Kula, one sample was 100 strokes with 10 of different branches on each of 10 trees.

By method of sampling of 100 different plant organs (leaf and flower buds, leaves, fruits) with a randomly selected tree, the presence of insect pests and their development stage was determined.

All sampled infested plant material was observed in laboratory. All collected eggs, larvae and pupa of phytophagous and entomophagous insects, were reared in the lab to adult stadium. In this purpose was used plastic containers and Petri dishes. In the bottom placed a layer of cellulose wadding occasionally misted in order to maintain the freshness of the leaf. The rearing of psyllid species was by the method Hodkinson & White, 1979, (cit. Jerinić-Prodanović, 2010). Also, the collected and reared insects were fixed in 70% alcohol; some of them were prepared, making microscopic preparations or the entomological collection.

Determination of species was based on morphological characteristics of the adults and before adult stadium, followed by keys and appropriate entomological literature (Balachowsky 1966; Hering, 1957). For determination to psyllid species, were done microscopic preparations of whole insect or body parts essential for determination.

Results and discussions

Two-year research of entomofauna on pears in the area of East Sarajevo, in the intensive, semi-intensive and extensive orchards, resulted in 44 detected species from orders Hemiptera, Neuroptera, Coleoptera, Lepidoptera and Diptera. Obtained results are according to the literature data (Ciglar, 1998; Alston and Murray, 2007). The most numerous species was in semi-intensive orchards, 39 species in the Tilava, and 31 species in the Petrovići. The following intensive orchards with 20 species in the Kula and 17 species in the Vojkovići. In extensive orchard, in the Kasindo, it was found 19 species. Of the total number of detected species, 35 were phytophagous, 8 species were entomophagous-predatory, and one species *Cantharis decipiens* was with mixed feeding regiment (Table 1).

Of the total number of determined species, nine species of insects have been determined in all localities: *Cacopsylla pyri* L., *Cacopsylla pyrisuga* Forster, *Phyllobius oblongus* L., *Anthonomus pomorum* L., *Adalia bipunctata* L., *Harmonia axyridis* Pallas, *Cydia pyrivora* Danilevszkij, *Cydia pomonella* L. and *Stigmela malella* Stainton. Eight species *(Aphis pomi* De Geer, *Lepiodosaphes ulmi* L., *Pulvinaria vitis* L., *Anthocoris nemorum* L., *Ptycholoma lecheana* L., *Leucoptera malifoliella* Costa, *Aporia crataegi* L. and *Contarinia pyrivora* Ribey*)* were present in only one location, usually in semi-intensive pear orchard in the Tilava.

During our research, by method of winter examination woody parts of plants were found: *Q. perniciosus* Comstock, *L. ulmi* L. , *E. leperii* Signoret and *P. vitis* L., according to the literature data (Cean *et al*., 2012).

By methods of review of plant organs, were found three species: *C. pyri, C. pyrisuga* and *C. pyricola*, according to many authors about their distribution and harmulness in all areas where pears are grown (Sestras *et al*., 2009; Maceljski, 2002). Among of them, the most numerous species was *C. pyri*, especially in the intensive orchards in locations Vojkovići and Kula, while *C. pyrisuga* and *C. pyricola* were more present in semi-intensive and extensive orchards, acoording to literature data about their more presence in the less-tended orchards (Jerinić-Prodanović, 2010).

Among of dangerous defoliators, included leaf miners which in the former Yugoslavia, occurred in the late 70´s in XX century, when they became a serious problem. In the area of Sarajevo and the environment on pear, five species were found: *L. corylifoliella* Haworth, *L. mespiliella* Frey, *Lyonetia clerkella* L., *Cemiostoma scitela* Costa and *C. hemerobiella* Scopoli of which the most numerous was *L. corylifoliella* (Dimić, 1964). Our research resulted in six species of leaf miners: *L. malifoliella, L. blancardella, L. corylifoliella, S. malella, C. denticulella* and *Coleophora hemerobiella* (Table 1).

Buds and leaves of pears in this area were damaged by *Hibernia defoliaria* L. and *Cheimatobia brummata* L., but without important damage, according to literature data (Ciglar, 1998; Almaši *et al.*, 2004). In addition to these species, in locations Tilava and Petrovići were found *Pasiphila* (=*Chloroclystis*) *rectangulata* L. which except the pears, damage and the other plants from fam. *Rosaceae* (apple, cherry, etc.), but didn't cause important damage (Maier, 2009). Also, the leaf and flower buds were damaged tortricid moth (*Hedya nubiferana* Haworth, *Archips rosana* L., *Archips podana* Scopoli), especially in the semi-intensive orchards (Tilava and Petrovići). In contrast to literature data about dominance *A. rosana* in Bosnia and Herzegovina (Ciglar, 1988; Maceljski, 2002), during our research both species of the genus *Archips* were found as individual specimens in the semi-intensive orchards. Very important pests of fruit pears are *C. pomonella* and *C. pyrivora* (Aghdam, 2010), but our research showed the presence of individual damaged fruits.

The semicircular damage on the leaves was done by species from the genus *Phyllobius* which didn't consider economically important pest, except in the orchards near to the forest (Almaši *et al*., 2004). In our examination, these species were present in small number and located in the orchards near the forest, in the locations Kula, Tilava and Petrovići, without important damage.

Table 1. The presence of insects in orchards pears in the area of East Sarajevo in 2011 and 2012 year

			Total number of species	**17**	**20**	**39**	**31**	**19**

Harmfull species Entomophagous species Mixed feeding regiment

Except harmful insects, in pear orchards were collected 8 entomophagous species of insects - predators. From order Coleoptera and fam. Coccinelidae three species were found: *Adalia bipunctata* L. and *Coccinella septempunctata* L. as predators psyllid species according to literature data (Jerinić-Prodanović, 2010), and *Harmonia axyridis* Pallas, which with these two species, were reared from the colonies of aphids *Dysaphis pyri* Boyer de Fonscolombe, according to literature data (Vuković, 1990). All these species have already been identified in the area of East Sarajevo as predators of aphids on apple (Tešanović *et al*., 2010). Besides these species, from order Neuroptera and fam. Chrysopidae, two species were found: *Chrysoperla carnea* Stephens and *Chrysopa septempunctata* Westmael as predators of aphids and psyllid species, in all localities except the Kasindo, according to literature data (Vuković, 1986, cit. Tamaš, 2012). The important predatory species were from the order Diptera and fam. Syrphidae (*Episyrphus balteatus* De Geer, *Syrphus ribesii* L., *Metasyrphus colorae* Fabricius, *Sphaeroforia scripta* L., *S. menthastri* L., *Scaeva pyrastri* L., *Syrphus latifasciatus* Macquart (Vuković, 1990). Our examination showed the presence of two species (*E. balteatus* and *S. ribesii),* determined in locations Vojkovići and Tilava, while in the locality Kula identified only *E. balteatus*. Their larvae were feeding of colonies of *D. pyri,* according to literature data (Vuković, 1990; Tamaš, 2012). From the order Hemiptera, *Anthocoris nemorum* L., was determined in the locality Vojkovići. According to many authors, this species was present one of the most important predatory species, which feeds by psyllid species, *C. pyri* and *C. pyrisuga* (Jerinić-Prodanović, 2010).

Conclusion

In the area of East Sarajevo, in intensive, semi-intensive and extensive orchards of pears, in 2011 and 2012 year, 44 species were found. They belong to different orders: Hemiptera, Neuroptera, Coleoptera, Lepidoptera and Diptera. Among of them, 35 species were phytophagous, 8 entomophagous and one with mixed feed regime. From 35 phytophagous species, 31 were related to the trophic pear.

From the order Hemiptera were determined: *Dysaphis pyri*, *Aphis pomi*, *Quadraspidiotus perniciosus*, *Lepidosaphes ulmi*, *Epidiaspis leperii*, *Pulvinaria vitis*, *Cacopsylla pyri*, *Cacopsylla pyrisuga* and *Cacopsylla pyricola*.

Order Coleoptera was represented with species: *Phyllobius oblongus*, *Phyllobius pyri*, *Phyllobius argentatus, Anthonomus pyri, Anthonomus pomorum* and *Epicometis hirta*. From order Lepidoptera was found: *Cydia pyrivora*, *Cydia pomonella, Hedya nubiferana, Archips rosana, Archips podana* and *Ptycholoma lecheana, Lithocoletis blancardella, Lithocoletis corilifoliella, Calisto denticulella, Stigmella malella, Leucoptera malifoliella and Coleophora hemerobiella, Hibernia defoliaria, Cheimatobia brummata and Pasiphila (=Chloroclystis) rectangulata).*

Order Diptera was represented with species: *Dasineura pyri* and *Contarinia pyrivora*. The most numerous species to trophic related to pear was in semi-intensive orchards, in Tilava 29 species, and Petrovići, 23 species. In intensive orchard in the Kula, 13 species were found and 9 species in the Vojkovići, while in extensive orchard in the locality Kasindo, 17 species were found.

From entomofagous – predators species were found: *Anthocoris nemorum, Chrysoperla carnea, Chrysopa septempunctata, Adalia bipunctata, Coccinella septempunctata, Harmonia axyridis, Episirphus balteatus* and *Syrphus ribesii.*

The most numerous entomofagous species was in intensive orchard in the Vojkovići (8), and the least was in extensive orchard in the Kasindo (2).

Abstract

The experimental work was carried out during 2013-2015 in the training and experimental base for implementation of the Agricultural University of Plovdiv. In the trail the maize (*Zea mays L.*) hybrid "Florence" (FAO group 480) was used. The plant density was 6500 plants da^{-1}. In the experiment three herbicide tank mixtures during the vegetation were applied. In each of the herbicide combinations, the product Nishin 4 OD (40 g/l nicosulfuron) at dose of 130 ml da^{-1} was used. Against the broad leaf weeds, the herbicides Flurostar 200 EC (200 g/l fluroxypyr) at dose of 70 ml da^{-1}, Mustang 306.25 SC (florasulam + 2.4 D) at dose of 60 ml da^{-1} and Kalisto 480 SC (480 g/l mezotrione) at dose of 20 ml da^{-1} were applied. All products were studied together with one and two mechanized intercrop soil tillages. On one third of the treated experimental plots the soil tillages were not applied. The three herbicide mixtures were highly effective against the weeds and selective for maize. They effectively protect the crop free of weeds for more than 60 days. The highest efficacy against weeds and maximum yield was obtained after the combined usage of the herbicides Flurostar 200 EC + Nishin 4 OD. In the conditions of highly blended weeding, the mechanized soil tillage complemented the herbicide efficacy in the weed management very well.

Key Words: *maize, herbicides, soil tillages, weeds*

Introduction

Maize (*Zea mays L.*) is main grain-forage crop with adaptive ability to different geographical and climatic conditions. That is the reason for the successful growing of this culture in many regions around the globe. In Bulgaria it is strategical field crop. Maize has the highest energy value in comparison to the others forage crops (Tomov and Yordanov, 1984). The quality of maize grain is the main factor for the wealthy nutrition of the farm animals (Ivanov, 2007). One of the main negative factors for agricultural production is the weeds. They decrease the yields and the quality of maize grain (Spasov, 1995; Masqood *et al.,* 1999; Tonev, 2000; Werner *et al*., 2004; Changsaluk *et al.,* 2007). Weeds are annually emerging all over the fields and are causing great damage of the maize production (Tonev *et al.,* 2007). There are a lot of publications that indisputably prove the harmful effects of the weeds in the crops. There is large number of possibilities to control the weeds by mechanical tilth and chemical applications (Fetvadzieva, 1982; Spasov, 1995; Fetvadzieva *et al.,* 1991). Mezotrione for example is a member of the benzoylcyclohexane-1,3-dione herbicides, which are chemically derived from a natural phytotoxin of *Callistemon citrinus* (Curtis) plants. Mezotrione has been shown to be effective for both pre- and postemergence control of weeds in maize (Sutton *et al.,* 1999; Armel *et al.,* 2003). Nicosulfuron is a postemergence sulfonylurea herbicide that even in low rates can control many difficult to manage monocotyledonous weeds at maize (Green and Hale, 2005). Integrating the intercrop tillage with contemporary herbicides at maize is a perspective way for obtaining high

efficacy of weed control and decreasing the harmful after-effect of the products for plant protection (Ljubenov, 1988; Tonev, 2006).
The objective of the study is to determine the alone and combine effect of systemic leaf herbicides applied together with three different intercrop tillages and their influence on maize grain yields.

Material and Methods

The experimental work was carried out during the period from 2013 to 2015 in the training and experimental base for implementation of the Agricultural University of Plovdiv. The trail was conducted by the split plot method with 12 variants in 4 replications. The size of the experimental plots was 60 m^2.

Table 1. Variants of the trail

X_1 Flurostar 200 EC - 70 ml da^{-1} + Nishin 4 OD - 130 ml da^{-1}	250 g/l fluroxypyr + 40 g/l nicosulfuron
X_2 Mustang 306.25 SC - 60 ml da^{-1} + Nishin 4 OD - 130 ml da^{-1}	6.25 g/l florasulam + 300 g/l 2.4 D ester + 40 g/l nicosulfuron
X_3 Kalisto 480 SC - ml da^{-1} + Nishin 4 OD - 130 ml da^{-1}	480 g/l мezotrione + 40 g/l nicosulfuron
T_1 (a)	Without mechanized tillage
T_2 (b)	With one mechanized tillage
T_3 (c)	With two mechanized tillages

The herbicide efficacy was compared with the untreated controls. Each of the treated 60 m^2 plots was divided into three different 20 m^2 plots. On one of these plots two mechanized tilleges were done - first tillage in phenophase 3^{rd} – 4^{th} leaf and second tillage in 7^{th} – 8^{th} leaf of maize. On the second of these plots only one tillage in phenofase 3^{rd} – 4^{th} leaf of the crop was accomplished. On the third plot the weeds were controlled only with the evaluated herbicides and no tillage was performed. The herbicides were sprayed just before the tillage was done. The expense of spray solution was 25 l da^{-1}.
In the trail the maize (*Zea mays L.*) hybrid "Florence" (FAO group 480) was used. Plants were grown under irrigated conditions and the plant density was 6500 plants da^{-1}. Herbicides were applied with back sack sprayer for plot trails (brand "Solo").
The tillage during the vegetation was done with cultivator for intercrop dredging. The second tillage was combined with earthing up of the maize.
Predecessor of maize in the crop rotation was winter wheat. After the wheat harvest deep plowing at 30-32 cm depth was done. Before this tillage fertilization with 16 kg P_2O_5 and 12 kg K_2O da^{-1} was applied (the fertilizer rates are in active substance). Before maize sowing, fertilization with nitrogen at rate of 22 kg da^{-1} was applied.
The herbicide efficacy was reported on the 14^{th}, 28^{th} and 56^{th} day after treatment. The weed species were observed by the visual scale of EWRS (European Weed Research Society), and the degree of weeding was evaluated by the quantitative method (number of weeds per 1 m^2).
The maize grain yield was recorded on the base of experimental plot for the four replications. The standard grain humidity was 14 %. For disperse statistical analyses of the collected data, the software package of Biostat 5.1 was used (Penchev, 1998).

Results and Discussion

According to Tonev *et al*. (2008) maize is highly sensitive to weeding especially in the early development stages. That is observed especially in the cases when the germination is delayed because of unfavorable conditions. It is proved by a lot of experimental work that at high weed infestation the maize grain yield could be decreased from 77 to 91 % (Tonev *et al*., 2008). For the current study natural background of weeding of the maize field of the experimental base of the Agricultural University of Plovdiv was used. The weed associations that prevailed on the field during the experimental period were 12 annual species: Common amaranth (*Amaranthus retroflexus L.*), Thorn apple (*Datura stramonium L.*), Rough cocklebur (*Xanthium strumarium L.*), Black nightshade (*Solanum nigrum L.*), Fat-hen (*Chenopodium album L.*), Velvetleaf (*Abutilon theophrasti L.*), Purslane (*Portulaca oleraceae L.*), Wild raddish (*Raphanus raphanistrum L.*), Charlock (*Sinapis arvensis L.*), Barnyard grass (*Echinochloa crus gali L.*), Yellow bristle-grass (*Setaria glauca L.*) and Red finger-grass (*Digitaria sanguinalis L.*). From the perennial weed species, with highest density were Johnson grass *(Sorghum halepense L.*), followed by Field bindweed (*Convolvulus arvensis L.*), Bermuda gras (*Cinodon dactilon L.*) and Creeping thistle (*Cirsium arvense L.*). The examined herbicide mixtures were with closer spectrum of action. The studied herbicide combinations controlled mostly the annual broad leaf and grass weeds, as well as the Johnson grass *(Sorghum halepense L.*) developed from seeds and rhizomes and also the root-sprouted species. As leaf herbicides, their efficacy against the weeds was not highly influenced by the soil moisture at the time of the treatment, as well as the net precipitation and its distribution. On table 2 is shown the efficacy against weeds after the alone and combined effect of herbicide application and intercrop tillage at maize 56 days after treatments.

Table 2. Efficacy against weeds after the alone and combined effect of herbicides application and intercrop tillage average for the period of the study (2013-2015)

Var.	Herbicide / tillage	Average weed number per 1 m^2 – 56 days after treatment				Total weed number
		Monocotyledonous	Di-cotyledonous	Annual	Perennial	
X_1 Flurostar 200 EC - 70 ml da^{-1} + Nishin 4 OD - 130 ml da^{-1}						
1.	Without mechanized tillage	5.6	5.2	10.8	11.8	22.6
2.	With one mechanized tillage	3.4	2.6	6.0	8.8	14.8
3.	With two mechanized tillage	1.4	1.4	2.8	5.6	8.4
X_2 Mustang 306.25 SC - 60 ml da^{-1} + Nishin 4 OD - 130 ml da^{-1}						
4.	Without mechanized tillage	4.8	5.0	9.8	16.2	26.0
5.	With one mechanized tillage	1.8	3.2	5.0	10.6	15.6
6.	With two mechanized tillage	1.0	1.8	2.8	6.4	9.2
X_3 Kalisto 480 SC - 20 ml da^{-1} + Nishin 4 OD - 130 ml da^{-1}						
7.	Without mechanized tillage	3.8	7.6	11.4	18.6	30.0
8.	With one mechanized tillage	2.0	4.4	6.4	13.2	19.6
9.	With two mechanized tillage	1.4	3.2	4.6	8.6	13.2
Without herbicide application						
10.	Without mechanized tillage	42.6	65.6	108.2	25.6	133.8
11.	With one mechanized tillage	19.4	38.8	58.2	19.4	77.6
12.	With two mechanized tillage	11.6	21.8	33.4	8.8	42.2

The highest total weed number on the 14th day after the treatments was 141.2 specimens per 1 m^2 at the untreated control (without herbicide application and without tillage). On the same date, after the application of the studied herbicides, at the variants without applied tillage, the total weed number was as follows: At variant X_1 (Flurostar 200 EC - 70 ml da^{-1} + Nishin 4 OD - 130 ml da^{-1}) – 29.5, at variant X_2 (Mustang 306.25 SC - 60 ml da^{-1} + Nishin 4 OD - 130 ml da^{-1}) – 32.8 and at variant X_3 (Kalisto 480 SC - 20 ml da^{-1} + Nishin 4 OD - 130 ml da^{-1}) – 37.0 specimens per 1 m^2. At the second report of the herbicides efficacy (on 28th day after treatments) the total number of unaffected weeds was again for the untreated control - 138.4 specimens per 1 m^2. The number of unaffected weeds at the treated plots was as follows: At variant X_1 – 25.4, at variant X_2 – 29.6 and at variant X_3– 33.2 specimens per 1 m^2.

The highest total weed number on the 56th day after treatments was for the untreated control – 133.8 per 1 m^2 (Table 2). After the usage of the herbicides without application of tillage there were a number of weeds that remained in the field. The number of the existing specimens after the treatments were: At variant X_1 – 22.6 specimens per 1 m^2, at variant X_2 – 26.0 specimens per 1 m^2 and at variant X_3 – 30.0 specimens per 1 m^2. The main part of not influenced or recovered weeds after the treatments were mostly from the perennial species.

Variants		Yields			Average

The highest efficacy of the examined herbicide tank mixtures was recorded at the combination of Flurostar 200 EC - 70 ml da^{-1} + Nishin 4 OD - 130 ml da^{-1} (Table 2). The supremacy of the herbicide compilation with Mustang 306.25 S + Nishin 4 OD - 130 ml da^{-1} was observed at the high density of the weed Fat-hen (*Chenopodium album L.*) in 2014. The superiority of Flurostar 200 EC was strongly revealed at the fields infested with Field bindweed (*Convolvulus arvensis L.*). That could be explained with the fact that the active substance of this herbicide (fluroxypyr) have very high efficacy against this weed.

By the one or especially two intercrop tillages more than the half of the unaffected from the herbicides weed plants, were temporarily cut. That was inhibiting their growth and development. At the conditions of highly blended weeding with different species, the intercrop tillage successfully supplemented the herbicide effect of the used products. The tillage complemented maize to use fully the resources like water, light, soil nutrients and air. The tillages contributed for the statistically proved increase of the maize grain yields when compared with any of the variants with applied herbicides without any performed tillage.

Pandej (1989) conduct field trials in Bihar and recoreded that the earthing up at the 25th or 25th and 45th days after sowing as well as the application of metribuzin at dose of 0.5 kg ha-1 and pendimethalin at 1.0 kg ha-1 (at pre-emergence), and spraying with 2.4-D at 0.8 kg ha-1 after emergence led to increasing of maize yield and suppressed the Wild hemp (Canabis sativa L.) growth. The best results in the study were recorded after usage of metribuzin and pendimethalin + two times earthing up. The highest yield average for the period in our study was achieved after the combined application of Flurostar 200 EC - 70 ml da-1 + Nishin 4 OD - 130 ml/da + two intercrop tillages – 1036 kg da-1 (Table 3). At the variants treated with herbicides plus one intercrop tillage the maize grain yield was increased from 68 to 102 kg da^{-1}. The two intercrop tillages together with herbicide spraying contributed for even higher yield increase – from 124 to 178 kg da^{-1}.

The selectivity of the studied herbicides to maize on the 10^{th} and on the 20^{th} day after the treatment was reported. There were not visually observed symptoms of fitotoxicity on the crop in any of the three years of the trail.

Conclusions

The three examined tank mixtures of the products Nishin 4 OD with Flurostar 200 EC, Mustang 306.25 SC and Kalisto 480 SC were herbicide combinations with strong effect against the broadleaf and grass weeds. The products had also continuous influence on weeds that was observed on the 56th day after treatments.

The studied herbicide mixtures were highly selective for the maize crop.

The highest herbicide efficacy and the highest maize grain yields were obtained after the use of Flurostar 200 EC + Nishin 4 OD. The active substance of the product Flurostar 200 EC (fluroxypyr) had excellent control of the broadleaf weed - Field bindweed (*Convolvulus arvensis L.*).

At the conditions of highly blended weeding with different species the intercrop tillage successfully supplemented the herbicide effect of the used products that lead to increasing of the maize grain yields.

Abstract

Agriculture is a significant user of water resources through irrigation but it also has considerable effect to the quality of water, especially in view of the effects caused by pesticides and fertilizers that end up dissolved in rivers and ground waters. In addition to agricultural production, major pollutants of aquatic ecosystems are: industry, municipal wastewater, waterway traffic, accidents, etc. The analyzed water was taken from two locations of the River Lesa in Portugal. By using biological assay in the laboratory, quality and impact of water were tested regarding the following test plants: barley (*Hordeum vulgare*) and radish (*Raphanus sativus*). Physiological and morphological parameters of the test plants were used for evaluation of water quality by the filter-paper method ISTA (2013) and according to the Regulations on the seed quality for agricultural plants in Serbia. Results for physiological parameters are expressed in percentages. The values of morphological parameters are shown as average values and are processed using the ANOVA and Duncan's multiple comparison tests, with confidence interval of 95%. Physico-chemical analysis of water indicates that nitrates, nitrites and ammonium were detected in values exceeding maximum allowable concentration, according to Portuguese regulations of water quality. Also, in the analyzed water samples cadmium (Cd) and iron (Fe) were found in quantities that exceed the MAC values, as well as some pesticidal substances (MCPA, fonofos). In the tested samples, long list of pharmaceuticals were detected. The obtained results indicate differences in tolerance of test plants towards water quality. The expressed variability of parameters reveal their potential as possible bioindicators.

Key words: *Lesa, water pollutants, phytoindicators, barley, radish.*

Introduction

Agriculture is one of the main sources of diffuse water pollution. Problems occur due to improper use of chemical agents in agricultural production, which is unprofessionally used by farmers. The use of chemical resources is necessary on a large scale production but it is crucial to use them at the right time and in an appropriate concentration. In addition to agriculture the major polluters are: industry, municipal wastewater, waterway traffic, accidents, etc. To prevent and reduce environmental pollution, it is essential to carry out the continuous monitoring of water quality. Quality assessment and detection of pollution of waterways, involves the use of various methods (physical, chemical, biological) in order to include the characterization of pollution, but also the effects on wildlife. For the quality assessment of the environment and detection of contamination, biological methods are increasingly being used. Methods that involve the use of cultivated plants as test organisms are extremely important for assessing the contamination of water used in agricultural production, because its results reflect the benefits of the area for cultivation of plants and the use of water for irrigation.

Material and Methods

In 2014, water sampling was conducted by experts from "Northern Region Water Institute"-IAREN (Instituto da Água da Região do Norte) from Portugal. Water was sampled from two sites along the River Lesa in Portugal.

The sampling sites and coordinates:

- Lesa I - Rio Leça (Ponte do Carro) (N 41°12'52.2"; W 8°40'05.35),
- Lesa II - Rio Leça (Ponte Teófilo) (N 41°12'27.6"; W 8°40'14.10).

Physico-chemical analysis of water was also conducted in Portugal and includes the following parameters: general parameters of water quality, organic compounds, heavy metals, pesticides, pharmaceuticals. For chemical analysis, the following techniques were used: Atomic Adsorption Spectrometry-Flame Technique (EPA Method 7000B), Liquid Chromatography-Tandem Mass Spectrometry (LC-MS-MS), Gas Chromatography Mass Spectrometry (GC-MS) and Inductively Coupled plasma Mass spectrometry (ICP-MS).

For the extraction that preceded detection of the presence of pollutants Solid Phase Extraction (SPE) and Accelerated Solvent Extraction (ASE) were used. The maximum allowable quantities (MAC) used in this experiment are stipulated by Portuguese regulations Decreto-Lei nº 103/2010, D.-Lei nº 236/1998 and the EU Directive 2008/105/EC.

Test plants were barley (*Hordeum vulgare*) and radish (*Raphanus sativus*). Water quality was evaluated using physiological (germination energy and germination /%/) and morphological parameters (length of roots and shoots of seedlings /cm/, fresh and dry weight of roots and shoots of seedlings /g/) of the test plants.

A filter-paper method by ISTA (International rules for seed testing) for 2013 and the Regulations of the seeds quality for agricultural plants („Sl. List SFRJ“, no. 47/87, 60/87, 55/88 and 81/89 and „Sl. List SRJ“, no. 16/92, 8/93, 21/93, 30/94, 43/96, 10/98, 15/2001 and 58/2002, „Sl. List RS“, no. 23/2009, 64/2010, 72/2010 and 34/2013) was used.

Results for physiological parameters are expressed in percentages. The values of morphological parameters are shown as average values and are processed using the Analysis of Variance and Duncan's multiple comparison test, in the statistical software R ver. 3.2.2.

Results and Discussion

According to the results of the physico-chemical analysis (Tab. 1.), in water sample Lesa I a high concentration of ammonia nitrogen (exceeding MAC for 126x) and nitrite (3x) was established, while the other test parameters were in allowable limits. In water sample Lesa II was found that nitrate values exceed the MAC for 2.5x and ammonia nitrogen (184x), so this water sample is also polluted and does not meet the required quality for irrigation.

Water containing a high concentration of nitrogen and nitrogen compounds can adversely affect the yield and quality of barley, sugar beet and some vegetable crops, causing excessive growth of vegetative organs (Bauder et al., 2014). The results indicate that the length and fresh weight of root and shoot of barley was significantly stimulated by water from the sample Lesa I and Lesa II (found to have a high concentration of nitrate, nitrite and ammonia nitrogen) which is consistent with the allegations of Bauder et al. (2014).

Table.1. Physico-chemical analysis of the general parameters in analyzed water samples

Location	Detected values of general parameters							
	pH	EC (mS/cm) at 20˚C	t°C	NO_3^- mgN/l	NO_2^- mgN/l	NH_3 mgN/l	P mgP/l	B mgB/l
Lesa I	7.5	463	21.4	0.6	**3.0**	**6.3**	<0.1	<0.1
Lesa II	7.3	423	22.3	**25.0**	0.7	**9.2**	0.9	<0.1
MAC	**5-9**	**≤1000**	**30.0**	**10.0**	**1.0**	**0.05**	**1.0**	**1.0**

The results from analysis of heavy metals and other elements from the list of priority pollutants indicate an extremely high amount of cadmium (Cd), three times higher than the MAC and also the increased amount of molybdenum (Mo) and magnesium (Mg) in the water sample Lesa I. Iron (Fe) is found in high quantities in a water sample Lesa II (2.5x more than the MAC). In the sample Lesa II a higher concentration of manganese (Mn) was also detected, but values were below the MAC (Tab. 2).

Heavy metals are very harmful because of their non-biodegradable nature, long biological half-lives and their potential to accumulate in different body parts. Most of the heavy metals are extremely toxic due to their solubility in water (Arora et. al., 2008).

Cadmium is toxic to many plant species. High concentrations of cadmium cause the inhibition of plant growth, development and to the occurrence of deformities. The shoots are shortened, the root is reduced and becomes brown, stiff (Rascio & Navarre-Izzo, 2011).

Iron is one of 16 essential elements for plant growth and reproduction. Although required by plants in small amounts, Fe is involved in many important compounds and physiological processes in plants. Toxicity of iron has not been reported under most aerobic plant production systems (Hochmuth, 2011).

Table. 2. The content of heavy metals and elements from the list of priority pollutants in water samples

Location	Detected values of heavy metals and other elements									
	Cd (µg/l)	Se (µg/l)	As (µg/l)	Mo (µg/l)	Cr (µg/l)	Pb (µg/l)	Mn (µg/l)	Fe (µg/l)	Zn (µg/l)	Mg (mg/l)
Lesa I	**16**	<2.5	<1.0	33	<0.5	<0.2	<1.0	<0.1	<10.0	75
Lesa II	<0.5	<2.5	<1.0	<0.01	5	<0.2	72	**250**	24	9,6
MAC	**5**	**10**	**10**	**50**	**50**	**50**	**100**	**100**	**500**	**50**

Chemical analysis of pesticide content in the tested waters showed the presence of pesticide substances MCPA and fonofos. The highest concentration of these substances was found in water sample Lesa I. In the sample Lesa II listed pesticides were below the limit of detection (Tab. 3.).

Fonofos represents a highly toxic organophosphate insecticide. In plant tissues it is rapidly metabolized to non-toxic compounds. It is extremely dangerous and toxic to bees, birds, fish and other aquatic organisms (Wagner, 1983).MCPA is a selective herbicide for control of broadleaf weeds. Applied in small quantities, it stimulate growth like natural hormones. Moderate amounts stimulate cell division and elongation, while large amounts inhibit grow (Konstantinović, 2008). The research results are consistent with this these, as the test plants (barley and radish) had a growth stimulation in the treatment with water from sample Lesa I, where it is detected an increased amount of MCPA.

Table. 3. The content of pesticides and organic compounds in water samples

Location	Parameters (µg /l)						
	Endosulfan	**MCPA**	**Alachlor**	**Simazin**	**Fonofos**	**Aldrin**	**Benzene**
Lesa I	<0.009	**5.9**	<0.01	<0.05	**670.0**	<0.01	<0.28
Lesa II	<0.009	<0.05	<0.01	<0.05	<0.01	<0.01	<0.28
MAC	**0.01**	**0.5**	**0.7**	**4.0**	**10.0**	**30.0**	**50.0**

Chemical analysis of the content of pharmaceuticals in tested water samples showed that the drugs such as paracetamol, naproxen, ibuprofen, hydrochlorothiazide, azithromycin, diclofenac, furosemide and ciprofloxacin were over the limit of detection (Tab. 4). Water sample Lesa II contained the highest concentrations of these drugs, so it can be considered more polluted compared to Lesa I.

The main sources of pollution of surface and ground-waters with these compounds are urban and agricultural waste waters or households, hospitals and agricultural lands (Robinson et al., 2007). Also, the significant source of drugs for the environment are wastewaters from the pharmaceutical industry and the farms, on which they are used extensively for livestock and poultry treatments (Grujić, 2009). On the most farms antibiotics are used as prevention or for infection treatments, as well as a food additive that favors the growth of animals (Hirsch et al. 1999). By using manure, antibiotics can still be transferred to agricultural land and then, due to leaching, reach groundwaters (Heberer, 2002).

Table. 4. The content of detected pharmaceuticals in water samples

Location	Parameters (ng /l)							
	Paracetamol	**Naproxen**	**Ibuprofen**	**Hydrochloro-thiazide**	**Azithro-mycin**	**Furo-semide**	**Cipro-floxacin**	**Diclofenak**
Lesa I	<0.02	<0.04	<0.17	<0.03	<0.01	<0.17	<0.03	<0.01
Lesa II	**550.0**	**100.0**	**400.0**	**180.0**	**150.0**	**150.0**	**150.0**	**100.0**

Bioassay results - test plant barley

Germination energy and germination. Barley seeds were not influenced by the quality of the water and all values are on the same level of significance with each other and with the control ($F=0.46$ ns, $p>0.05$; $F=0.46$ ns, $p>0.05$).

Length of root. Root was significantly stimulated by Lesa I and Lesa II water samples (by 28% and 34%, respectively, compared to control). Differences between the treatments are statistically significant ($F=20.23^*$, $p<0.05$).

Fresh weight of root. The highest average value of fresh weight was recorded in the sample Lesa II (94% higher, compared to the control) and in water from sample Lesa I it was higher for 40%. Differences between the treatments are statistically significant ($F=63.38^*$, $p<0.05$).

Dry weight of root. Dry weight was stimulated by the samples Lesa I and Lesa II (by 31% and 21%, respectively, compared to control). Differences between treatments are statistically significant ($F=11.17^*$, $p<0.05$).

Length of shoot. Shoot was significantly stimulated by Lesa I and Lesa II samples (by 37% and 35%, respectively, compared to control). Differences between the treatments are statistically significant ($F=8.56^*$, $p<0.05$).

Fresh weight of shoot. Fresh weight was stimulated by the samples Lesa I and Lesa II (by 21% and 23%, respectively, compared to control). Differences between the treatments are statistically significant (F=14.09*, p <0.05).
Dry weight of shoot. This parameter has not been affected by water quality and all values are on the same level of significance. (F=2.73 ns, p> 0.05).

Bioassay results - test plant radish

Germination energy and germination. Radish seeds were not influenced by the quality of water and all values are on the same level of significance with each other and with the control (F=2.55 ns, p>0.05; F=1.90 ns, p >0.05).
Length of Root. Root has not been influenced by the water and all values are on the same level of significance with each other and with the control (F=1.55 ns, p>0.05).
Fresh weight of root. Fresh weight has not been influenced by water and all values are on the same level of significance with each other and with the control (F=0.05 ns, p >0.05).
Dry weight of root. Dry weight was not under the influence of water and all values are on the same level of significance with each other and with the control. (F=1.03 ns, p> 0.05).
Length of shoot. Length of shoot was significantly stimulated by water from Lesa I (by 21%) as compared to control, and from Lesa II by 25%. Differences between the treatments are statistically significant (F=11.78*, p <0.05).
Fresh weight of shoot. Fresh weight was stimulated by the samples Lesa I and Lesa II (by 14% and 18%, respectively, compared to control). Differences between the treatments are statistically significant (F=4.57*, p <0.05).
Dry weight of shoot. Dry weight was not under the influence of water and all values are on the same level of significance with each other and with the control. (F=0.72ns, p> 0.05).

The achieved results indicate that physiological parameters of barley and radish are not good indicatiors of water quality, and therefore, some morphological parameters may be considered more reliable (Tab. 5.,6.,7.).

Table. 5. Water quality influence on physiological parameters

Parameters	Water sample	Barley	Radish
Germination energy (%)	Lesa I	94.25 ±1.89 a	97.75 ±0.50 a

Conclusions

Based on the conducted tests and the results achieved on the impact of water quality (Lesa I, Lesa II) on the test plants (barley, radish) the following can be concluded:

• In water sample from Lesa river site I, detected pollutants, in the quantities exceeding MAC according to the Regulations, are: nitrites, ammonia, cadmium, fonofos and MCPA, and none of the tested pharmaceuticals. Based on the biological test of water quality on phyto-indicators, plants reacted in a significant stimulation of the length, fresh/dry weight of root (barley) and length and fresh weight of shoot (barley, radish), which can be attributed to the presence of ammonia, nitrites and MCPA;

• In a sample of water from the site Lesa II in quantities exceeding MAC, nitrates, ammonia and iron were registered. The pharmaceuticals such as: paracetamol, naproxen, ibuprofen, hydrochlorothiazide, azithromycin, diclofenac, furosemide and ciprofloxacin, were also detected. Water significantly stimulated length, fresh/dry weight of root (barley) and length and fresh weight of shoot (barley, radish). These effects can be attributed to the presence of ammonia, nitrates and iron in a greater amount in this water sample;

Bioassay test results indicate the different susceptibility of tested plant species and parameters as well as their validity in assessing water contamination. Different plant species and parameters responded in dissimilar manner to the quality of the sampled water. An expressed variability of parameters indicates their potential as possible bioindicators.

Abstract

Species in the genus Diaporthe and their Phomopsis asexual states are responsible for diseases on a wide range of plant hosts, some of which are economically important worldwide, causing root and fruits rots, stem cankers and leaf spots. In December 2015, quince fruit (cv. Asenica) with symptoms of brown rot were collected from storage in the area of Šabac. The isolates formed white mycelium, with dark pigmentation developing in the centre of the colony grown on a potato dextrose agar (PDA). Alpha conidia were abundant, aseptate, hyaline, ovate to ellipsoidal. Based on the morphological characteristics of the colony, shape of conidia and conidiomata as well as sequences of internal transcribed spacer regions (ITS), the fungus was identified as *Diaporthe eres*. Total DNAs were extracted directly from the fungal mycelium with a DNeasy Plant Mini Kit (Qiagen, Hilden, Germany) and PCR amplification was performed with primers ITS1/ITS4. The sequence analysis of ITS region revealed that representative isolate 7-16 (GenBank Accession No. KX274026) shared 100% identity (100% query coverage) with sequences of 13 *D. eres* isolates deposited in the GenBank. A pathogenicity test was conducted and Koch's postulates were fulfilled by re-isolation of the fungus from the diseased tissues. To our knowledge, this is the first report of *D. eres* causing fruit rot on quince in Serbia.

Keywords: *Quince, Diaporthe eres, ITS region*

Introduction

The genus *Diaporthe* Nitschke (syn. *Phomopsis* (Sacc.) Bubák) represents a cosmopolitan group of fungi occupying diverse ecological niches as saprobes, endophytes and plant pathogens (Rossman et al. 2007; Udayanga et al. 2011). *Diaporthe* species are responsible for some important crop diseases worldwide including root and fruit rots, dieback, cankers, leaf spots, blights, decay and wilt (Mostert et al. 2001; Santos et al. 2011; Thompson et al. 2011).

Diaporthe eres has been regarded as a minor pathogen causing leaf spots, stem cankers and diseases of woody plants in diverse families including the *Ericaceae, Juglandaceae, Rosaceae, Sapindaceae, Ulmaceae, Vitaceae* and others, mostly in temperate regions worldwide (Vrandečić et al. 2010; Anagnostakis 2007; Thomidis and Michailides 2009; Baumgartner et al. 2013). In addition, it is considered a pathogen with plant health inspection and quarantine significance (Cline and Farr, 2006). Post-harvest losses in fruits canbe attributed to several factors, the most important of which is post-harvest disease. *Diaporthe* species has also been reported to be associated with post-harvest rots of fruit. However, post-harvest diseases cause severe losses during storage, transportation, marketing, and in retail stores during shelf-life (Luongo et al. 2011).

Consequently, the objectives of this study were to identify *D. eres* of quince fruits for the first time in Serbia based on morphological and molecular characteristics.

Materials and methods

Sampling and morphology

In December 2015, quince fruits (cv. Asenica) produced on a farm located at Šabac area showing post-harvest symptoms of brown rot were investigated with the aim of identifying the disease agent.

Representative fruit rot samples were brought to the laboratory for isolation of the associated fungal pathogens (Dhingra and Sinclair, 1985). Samples were cut into small pieces (3-5 mm) and surface sterilized with 1% sodium hypochlorite solution for 2-3 min followed by two washes with sterile distilled water. Samples were blotter dried and placed on potato dextrose agar (PDA) medium and incubated for 7 days at 25ºC under a 12 h light/dark cycle. Fungal colonies expressed after 7 days of incubation were identified based on macro and micro-morphology of vegetative structures, pycnidia and conidia.

Pathogenicity test

The Koch's postulates were applied using the basic principles of the methodology described in other investigations (Xiao and Rogers, 2004; Mari et al. 2012). Inoculation was performed on quince fruits (cv. Asenica) sterilized in 70% ethanol. Quince fruits were inoculated with 50 µl of a spore suspension (1 x 10^6 conidia/ml) from the cultures grown 7 days on PDA on 3 mm deep. The control fruit was inoculated with 50 µl of sterile distilled water. After inoculation the quinces were placed in sterile plastic boxes on the wet paper towel and incubated at 25°C up to 10 days. After incubation reisolation of the pathogenic fungi was performed and these were identified according to the morphological characteristics.

DNA extraction, PCR amplification and sequencing

Genomic DNA was isolated from mycelium scraped from the surface of a 7 days old culture with DNeasy Plant Kit(Qiagen, Hilden, Germany), following the manufacturer's instructions. The universal primers ITS1 and ITS4 (White et al. 1990) were used to amplify the ITS region of the ribosome genes. PCR reaction was performed in a total volume of 25 µl with 12.5 µl 2 X PCR Master mix (K071, Fermentas, Lithuania), 9 µl RNase-free water, 1.25 µl each of both forward and reverse primers (100 pmol/µl, Metabion International, Deutschland) and 1 µl template DNA. DNA amplification was performed in a Thermal Cycler PCR system 2720 (Applied Biosystems). Cycling parameters were 94°C for 2 min, followed by 35 cycles of 2 min at 94°C, 30 sec at 57°C, 1 min at 72°C, and a final extension for 10 min at 72°C.

Amplified products were analyzed by 1% agarose gel electrophoresis, stained with Midori Green DNA Stain (Nippon Genetics), and visualized under a UV transilluminator. Sequencing in both directions was performed on an automated sequencer (ABI 3730XL Automatic Sequencer Macrogen, Korea). Sequence generated in this study was subjected to a Megablast search analysis at NCBI's GenBank nucleotide database for sequence similarity. Sequence of Serbian representative isolate (7-16) was aligned by using ClustalW algorithm implemented in MEGA 5 (Tamura et al. 2011).

Results and discussion

Although *D. eres* has been previously reported as causal agent of fruit rots in other plant species, such as *Prunus persicae* (Ko and Sun, 2003), *Malus domestica* (Arsenijevic and Gavrilovic, 2005) and *Actinidia deliciosa* (Luongo et al. 2011), to our knowledge, this is the first report of occurrence of this pathogen on quince in Serbia, causing fruit rot. Necrotic lesions appeared on stylar end and quickly expanded on other parts of the fruit, followed by occurrence of whitish mycelium mass (Fig. 1). A total of 12 samples of fruit rot were collected from one storage in the area of Šabac, three samples were infected by *D. eres*as evident on PDA isolation.

Fig. 1. Symptom of fruit rot of quince caused by *Diaporthe eres*

Colonies of *D. eres* isolates on PDA were white, aerial, reverse centre dark pigmentation developing in centre, producing abundant, black stromata at maturity (Fig. 2a). Pycnidia were globose, embedded in tissue, erumpent at maturity, with a long, black, elongated neck. Conidia were extruded from ostioles in yellowish masses (Fig. 2b). Two types of conidia (alpha and beta) were observed. Alpha conidia were abundant, aseptate, hyaline, ovate to ellipsoidal (6.2-8.7 × 2.5-3.7µm) (Fig. 2c). Beta conidia were filiform, curved, hyaline and aseptate (20-27.5 × 1.2-2.5µm) (Fig. 2d). Colony and conidial morphology were consistent with those of a *D. eres* (Udayanga et al. 2014).

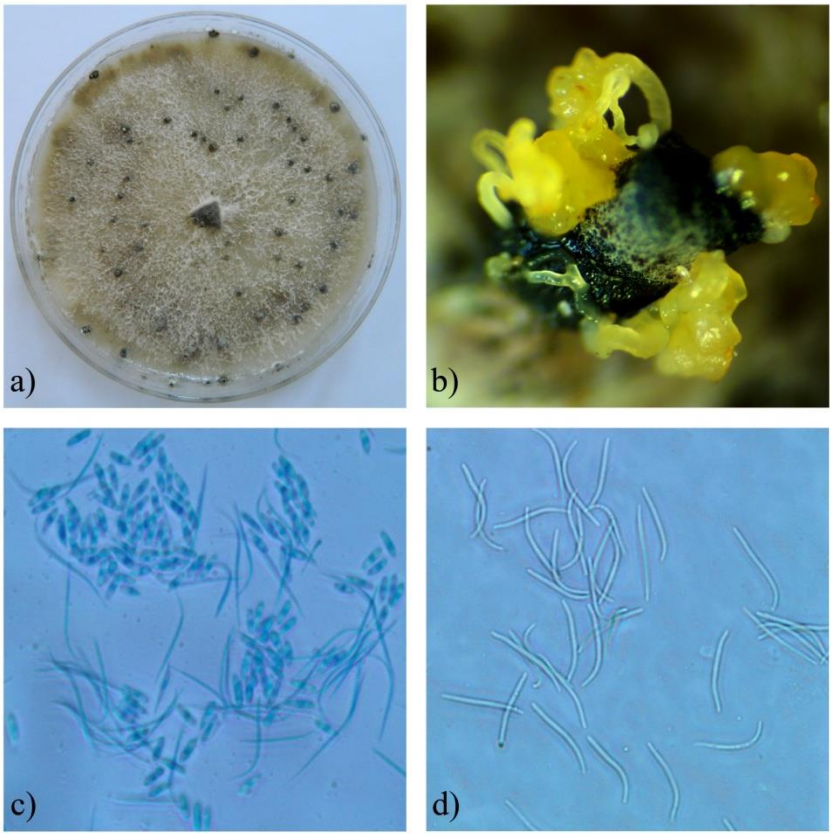

Fig. 2. Morphology of *Diaporthe eres*: **a)** colony cultured on PDA; **b)** sporulating pycnidia with yellowish masses; **c)** aseptate, ellipsoidal alpha conidia and beta conidia; **d)** aseptate, slightly curved beta conidia

A total of three isolates of *D. eres* obtained from naturally infected fruits of quince were tested for pathogenicity. Within 10 days, inoculated fruits developed typical brown rot symtoms. No symptoms were observed on any of the control fruits. Koch'spostulates were fulfilled by re-isolating colonies from fruit rots and by obtaining the same morphological characters as the isolates used for inoculation.

To confirm morphological identification, sequence analysis of 550 bp of the ITS region of nuclear ribosomal DNA was performed. Since all the ITS sequences of the *D. eres* isolates from quince fruit were 100% identical (100% query coverage), the sequence of a single isolate (7-16) was used for comparison and deposited in GenBank (Accession No. KX274026). The representative isolate 7-16 shared the highest identity with sequences of 13 *D. eres* isolates deposited in the GenBank. DNA sequence data were effectively used for identification of *D. eres* in this study. For a majority of groups of fungi, the nuclear ribosomal internal transcribed spacer (ITS) region is the predominantly available sequence in public databases (Nilsson et al. 2008, 2014; Kõljalg et al. 2013). To date, different gene sequences species limits of *D. eres*, actin (ACT), DNA-lyase (Apn2), translation elongation factor 1-α (EF1-α), beta-tubulin (TUB), calmodulin (CAL), 60s ribosomalprotein L37 (FG1093) and histone-3 (HIS), can be used for the detection of *Diaporthe* at species level and have been successfully applied in the characterization of closely related species (Udayanga et al. 2014). Molecular identification of *D. eres* species was conducted for the first time in our country, and represents introduction in molecular

characterization of this important species in Serbia. Results of sequencing of ITS region showed the need for detailed analyses of genetic structure of Serbian population of this pathogen, including sequencing of other informational parts of genom.

Management of storage conditions may delay disease development and retain fruit quality. Cold storage of fruit immediately after harvest may be a method to control the postharvest occurrence of *Phomopsis* fruit rot (Eguchi and Hara, 2005). According to the results of Thomidis and Michailides (2009) that showed that artificially inoculated peach fruit with *D. eres* did not develop any symptoms of rot when they were stored at 10°C or lower temperatures. This is basis may be good starting point for investigation postharvest control measures.

Conclusion

Knowledge of the composition of populations of Diaporthe species of quince fruit in Serbia is of great importance due to their ability to reduce quality, and provides the base for development of effective disease management strategies. This is the first detailed report of D. eres associated with fruit rot on quince diseases in Serbia with morphology, pathogenicity and molecular data. Further characterization and research on diversity of pathogens causing fruit rot on quince in Serbia are needed. Possible emergence of new pathogenic isolates and species could lead to a higher incidence of the disease and economically even more significant yield looses.

Abstract

Dried fruits and nuts production are important agricultural activity in Turkey. From a phytosanitary point of view, storage pests infesting dried fruits and nuts, especially during drying and storage period, may cause significant problems in dried fruits and nuts sector. Objective of this study is to test gaseous ozone for rapid disinfestations of dried fig and hazelnut as an alternative to methyl bromide by evaluating its toxicity against major insect pests of stored dried fruits and nuts. Gaseous ozone at low concentrations (1-2, 5-6 and 10-11 ppm) for short exposure periods (1, 2 and 4 hour) resulted in very low mortalities of against all life stages of *Ephestia cautella* (Walker) and *Plodia intepunctella* (Hubner). Ozone flush treatment at 30 minute intervals for 6 hours resulted in almost complete mortality of adults and pupae of *E. cautella* and *P. interpunctella* placed in top position of 1.3 kg of dried fig and hazelnut whereas eggs and larvae of *E. cautella* and *P. interpunctella* placed in top position of 1.3 kg of dried fig and hazelnut were hard to kill. The results indicated that gaseous ozone cannot be alternative to methyl bromide for rapid disinfestations of dried fruits and nuts (quarantine treatment) since it did not provide the complete mortality of all life stages of *E. cautella* and *P. interpunctella* on dried fig, and hazelnut even at its high concentrations.

Keywords: *Gaseous ozone, Methyl bromide, Alternative, Quarantine, Ephestia cautella, Plodia interpunctella*

Introduction

Dried fruits and nuts production is an important agricultural activity in Turkey. The annual Turkish dried fig production is around 55 to 60 000 tones and comes from a single cultivar, (*Ficus carica* Sarilop (= Calimyrna)), grown in the western part of Turkey, making Turkey the leading country of the world in dried fig and nut production. Nearly 90% of the production goes to the export market, with the main period of marketing being between late September and December (Aksoy *et al.*, 2008). Storage pests infesting dried fruits and nuts especially during drying and storage period may cause significant problems in dried fruit and nut sector. The fig moth (*Ephestia cautella* (Walker) and Indianmeal moth (*Plodia intepunctella* (Hubner) reduce fruit quality by feeding and damaging the fruit and contaminating by leaving its excretions and other residues as silky net weaves (Damarlı *et al.*, 1997). Large populations can develop before being detected and severe damage may occur rapidly (Jarratt, 2001). Moreover, from a phytosanitary point of view, during export, the presence of insects, or their fragments, has cost inestimable losses, due to cargo returns.

Ozone is a triatomic form of oxygen (O_3) and is referred to as activated oxygen, allotropic oxygen or pure air. It is an unstable gas and its life span lasts about 20 minute, depending on the temperature. Electrical generation of ozone eliminates the handling, storage, and disposal

problems of conventionally used post-harvest pesticides. Attractive aspect of ozone is that it decomposes rapidly (half-life of 20-50 min) to molecular oxygen without leaving a residue. These attributes make ozone an attractive candidate for controlling insects and fungi in stored products. Ozone in its gaseous form has been also considered to have potential to kill insect pests in commodities and was subjected of several research studies (Erdman, 1980; Mason *et al.*, 1997; Kells *et al.*, 2001). High mortality was achieved for adults of the maize weevil, *Sitophilus zeamais* (Mostsch.), and the red flour beetle *Tribolium confusum* (Jacqueline de Val), and the larval stage of the Indian meal moth, *P interpunctella* exposed to lower ozone concentrations ranging from to 5 to 45 ppm (Erdman, 1980; Kells *et al.*, 2001).

Methyl bromide has frequently used as a fumigant for disinfestations of other stored agricultural commodities such as nuts, cereals and fruits since it kills the insects rapidly, has a wide spectrum of activity and relatively low-cost (Fields and White, 2002). However it had been banned in developed countries since 2005 and scheduled for worldwide withdrawal from routine use as a fumigant in 2015 under the directive of the Montreal Protocol on Substances that Deplete Ozone Layer (Schneider *et al.*, 2003) except quarantine, laboratory and pre-shipment purposes. As a consequence, There is a critical need to develop new fumigants for quarantine purposes, where rapid insect mortality is required (exposure time less than 1 day). Objective of present study was to test gaseous ozone for rapid disinfestation of dried fruits and nuts as a replacement for methyl bromide by evaluating its toxicity against major insect pests of stored dried fruits and nuts.

Materials and Methods

Test insects:

Tests were carried out on all life stages (adult, larva, pupa and egg) of *E. cautella* and *P. interpunctella.* All life stages of *E. cautella* were obtained from stock cultures reared at 26 ± 1°C and 65 ± 5% r.h. at the incubator on a standard diet of wheat flour mixed with brewer's yeast (17:1, wt:wt) using standard culture techniques. *P.interpunctella* was reared on diet of a 10:2:1 mixture of wheat flour: wheat germ: dried brewer's yeast at the same environmental conditions described for *E. cautella*. Eggs aged 1-2 days in 9 cm Petri dishes were placed in 3 litter jars and then were exposed to ozone treatments. Larvae were removed from culture jars and exposed to the treatments 21 days after oviposition. Two days old pupae were obtained by daily separation from culture jars and were exposed to ozone treatments. Seven day old adults were placed in culture jars and then were exposed to ozone treatments.

Commodity:

In-shell hazelnuts with moisture content (m.c.) of 10.5%±0.5 and dried figs at m.c. of 21%±0.5 were used in the tests. In order to minimize the reaction of microbial loads in the commodity with ozone the hazelnuts and dried figs used in the tests were sterilized under high pressurized stem.

Fumigation chambers:

Test chambers consisted of 3 liter glass jar, each capped with a metal stopper equipped with entry and exit tubing. Two pieces of rubber tubing, 5 cm long, 6.2 mm ID, were attached to the tubing and sealed with pinch-clamps.

Ozone fumigation procedures:

Ozone generator in laboratory scale was provided from the company Ozomax Inc., Ozone gas was generated using a laboratory corona discharge ozone generator (Model OZO-1VTT) from purified extra dry oxygen feed gas. Ozone was introduced as gaseous into the exposure jars using a ozone generator. The 100 mm Hg measure referred to herein is absolute pressure, with 760 mm

Hg considered as atmospheric pressure. Prior to each test, twenty larvae, pupae or adults were placed, separately, inside 3 cm diameter by 8 cm long wire-mesh cages. For eggs, fifty eggs placed in opened Petri dishes were used per fumigation.

For application of low ozone concentrations, ozone concentrations 1-2, 5-6 and 10-11 ppm were exposed to the eggs, pupae, larvae and adults of *E. cautella and P. interpunctella* for short exposure periods (1, 2 and 4 hour). The insects were first placed in exposure jars and then, constant ozone concentrations of 1-2, 5-6 and 10-11 ppm were continuously flushed into exposure jar and were exposed to the insects for 1, 2 and 4 hours. For intermittently repeated ozone treatment in presence of commodity, each desiccators was loaded separately with 1.3 kg of dried fig and in-shell hazelnut, and then 50 eggs, 25 pupae, 25 adults and 25 larvae placed inside the wire-mesh cages were inserted into top and bottom position of the commodity the desiccators were briefly evacuated to 760 mm Hg. Afterwards gaseous ozone at concentrations of 8.35 mg/l (3895 ppm) and 33.33 mg/l (15545 ppm) was flushed into exposure jar until reaching atmospheric pressure and it was repeated every half an hour for 6 hours. Untreated control insects were exposed to atmospheric conditions. Each test was replicated at three times. For all ozone fumigations, r.h. and temperature were maintained at 65±5% at atmospheric pressure and 26±1°C, respectively.

Data processing and analysis:

After each ozone treatment, larvae, pupae, and adults were transferred to 250-mL jars containing standard diets and were held at 26 ± 1°C and 65 ± 5% r.h. until examined for mortality. The eggs were transferred into "pits" drilled into Perspex exposure slides, each slide containing 50 pits. They were held under the same conditions until the oviposition sites were examined for egg hatch. Mortality data was subjected to Arcsine transformation and then, were analyzed using one-way analysis of variance (ANOVA). The means were separated using the LSD method at 5% level.

Results and Discussion

Mortality rates (%) of all life stages of *P. interpunctella* and *E.cautella* exposed to low concentrations of gaseous ozone are given in Table 1 and 2, respectively. Gaseous ozone at low concentrations (1-2, 5-6 and 10-11 ppm) for short exposure periods (1, 2 and 4 hour) resulted in very low mortalities of against all life stages of both tested species. The mortality rate of all life stages of *P. interpunctella* and *E. cautella* exposed to low ozone concentrations for short exposure periods varied from 6.7% to 28.3% and 3.8% to 46%, respectively.

Table 1. Mortality rates of all life stages of *Plodia interpunctella* exposed to low concentrations of gaseous ozone

Ozone concentration	**Exposure period (h)**	**Mortality rate (%) ± S. error**			
		Pupa	**Adult**	**Egg**	**Larva**
1-2 ppm	**1 h**	10±0	15±2.89	28.33±1.67	6.67±1.67
	2 h	11.67±1.67	18.33±3.33	25±2.89	10±0
	4 h	10±0	18.33±3.33	25±2.89	6.67±1.67
5-6 ppm	**1 h**	11.67±1.67	21.67±1.67	26.67±1.67	8.33±1.67

Mortality rates (%) of life stages of *E. cautella* and *P. interpunctella* placed at top and bottom position against 6-h exposure intermittently gaseous ozone treatment in presence of 1.3 kg of hazelnut are given Table 3 and 4, respectively. The results of biological tests indicated that ozone treatment at 33.33 mg/l concentration resulted in % 100 or nearly % 100 mortalities of only adult

and pupa stage of *E. cautella* and *P. interpunctella* placed at top position of the hazelnut. However, ozone treatments at lower concentration (8.35 mg/l) caused nearly % 100 mortalities of only pupa stage of *P. interpunctella* at placed at top position of the hazelnut. It was clear that ozone treatments at low concentration (8.35 mg/l) resulted in significantly lower mortalities of all life stages of *E. cautella* and *P. interpunctella* that those at high concentration (33.33 mg/l). Generally, in all ozone treatments the mortalities of tested insects placed at top position of the hazelnut were higher than those placed at bottom position of the hazelnut. Notably, it was hard to kill the larvae and eggs of *E. cautella* and *P. interpunctella* placed at bottom position of the hazelnut.

Mortality rates (%) of life stages of *E. cautella* and *P. interpunctella* placed at top and bottom position against 6-h exposure intermittently gaseous ozone treatment in presence of 1.3 kg of dried fig are given Table 5 and 6. Ozone treatment at 33.33 mg/l concentration resulted in % 100 or nearly % 100 mortalities of egg, adult and pupa stage of *E. cautella* and only adult and pupa stage of *P. interpunctella* placed at top position of the dried fig. However, ozone treatments at

lower concentration (8.35 mg/l) caused nearly % 100 mortalities of only pupa stage of *E. cautella* and *P. interpunctella* at placed at top position of the dried fig. Thus, ozone flush treatment at 30 minute intervals for 6 hours resulted in almost complete mortality of eggs, adults and pupae of *E. cautella* placed in top position of 1.3 kg of dried fig whereas larvae of *E. cautella* placed in top position of 1.3 kg of dried fig and hazelnut were hard to kill. Similar to the results obtained from ozone treatment on the hazelnut, low ozone concentration (8.35 mg/l) resulted in significantly lower mortalities of all life stages of *E. cautella* and *P. interpunctella* that high ozone concentration (33.33 mg/l). Generally, in all ozone treatments the mortalities of tested insects placed at top position of the hazelnut were higher than those placed at bottom position of the hazelnut.

Conclusion

The results indicated that gaseous ozone cannot be alternative to methyl bromide for rapid disinfestations of dried fruits and nuts (quarantine treatment) since it did not provide the complete mortality of all biological stages of *E. cautella* and *P. interpunctella* on dried fig and hazelnut even at its high concentrations.

Abstract

This study was carried out to determine fumigant toxicity of garlic essential oil, its active compounds (diallyl sulphide and diallyl disulphide) and mixture (diallyl sulphide+diallyl disulphide) against life stages of Tribolium confusum du Val. Garlic essential oil, its active components and mixtures showed different fumigant toxicity against life stages of T. confusum. On the basis of LC90 values, toxicity of vapour of treatments to T. confusum eggs and adults in descending order was: diallyl sulphide > diallyl disulphide > garlic essential oil and diallyl sulphide+diallyl disulphide > diallyl disulphide > garlic essential oil ≥ diallyl sulphide, respectively. Garlic essential oil, their active compounds and mixture required less than µl l-1 to kill 90% of the eggs. Garlic essential oil, diallyl disulphide and mixture diallyl sulphide+diallyl disulphide required less than 6 µl l-1 to kill 90% of the pupae. Garlic essential oil, diallyl disulphide and mixture diallyl sulphide+diallyl disulphide required less than 20 µl l-1 to kill 90% of the adults. On the other hand, garlic essential oil, its active compounds and mixture required the doses ranging from 6.44 to 23.31 µl l-1 to kill 90% of the larvae. Bioassay tests indicated that the adults and larvae were the most tolerant stages while the eggs and pupae were the most susceptible stages to treatments of garlic essential oil, its active compounds and mixtures. Toxicity tests indicate that garlic essential oil and their active components can be used as possible alternative bio-fumigants in controlling stored grain insects.

Keywords: *Garlic, Essential oil, Diallyl sulfide, Diallyl disulfide, Fumigant toxicity, Tribolium confusum*

Introduction

The application of various synthetic insecticides and fumigants to grain storage over the years has led to a number of problems, including the development of insecticide resistance in stored grain insect pests in various parts of the world (Champ and Dyte, 1976). Another concern is the accumulation of pesticides (including fumigant) residues in treated grain (Snelson, 1987). These problems have highlighted the need for the development of natural products derived from plants as an alternative to conventional insecticides. Many types of spices and herbs are known to possess insecticidal activities (Tripathi *et al.*, 1999) especially in the form of essential oils (Shaaya *et al.*, 1991). They do not leave residues toxic to the environment and have medicinal properties for humans with lower toxicity to mammals (Duke, 1985).

Essential oils are among the best-known substances tested against insects. These compounds act as fumigants (Regnault-Roger and Hamraoui, 1995; Shaaya *et al.*, 1997), contact insecticides (Schmidt and Streloke, 1994), repellents (Plarre *et al.*, 1997), antifeedants (Harwood *et al.*, 1990)

and may affect some biological parameters such as growth rate, life span and reproduction (Regnault-Roger and Hamraoui, 1995). Essential oils are potential sources of alternative compounds to currently used fumigants. Various studies have demonstrated fumigant activity of various essential oils against various stored product insects (Shaaya *et al.*, 1997; Tunç *et al.*, 2000; Lee *et al.*, 2003). Karcı (2006) tested toxicity of various essential oils and their volatile constitutes against all life stages of the flour beetle, *Tribolium confusum* (du Val.) (Coleoptera: Curculionidae) and reported that two essential oils, garlic and onion had potent fumigant activities on *T. confusum*. Gözek (2007) reported that the adults and larvae of *T. confusum* were the most tolerant stages and the eggs and pupae were the most susceptible stages to treatments of garlic essential oil, their active compounds and mixture. The present study was carried out to investigate fumigant toxicity of garlic essential oil, its active compounds (diallyl sulphide and diallyl disulphide) and their mixtures (diallyl sulphide+diallyl disulphide) against life stages of *T. confusum*.

Materials and Methods

Insect culture:

Biological tests were carried out on all life stages (egg, larva, pupa and adult) of *T. confusum*. *Tribolium confusum* were obtained from cultures reared in 1 l glass jars at 25 ± 1°C and 65± 5 % relative humidity (RH) on a diet of wheat flour mixed with dry brewer's yeast (17:1, wt:wt) (Donahaye 1990). Eggs were daily separated from oviposition jars by sieving (60 mesh, 250µm sieve). Eggs for exposure to treatments were transferred into the glass vials (2.5 cm diameter and 5 cm long). The 10 ml glass tube (18 cm height × 18 cm width × 12 cm diameter), each containing 50 eggs 1–2 days old, was exposed to each treatment. Larvae were removed from culture jars and exposed to the treatments 25-30 days after oviposition. Two day-old pupae were obtained by daily separation from culture jars and held in wheat flour for 24 h before the exposure. Newly emerged adults were held in pre-exposure jars containing wheat flour, and were exposed to treatment 7-10 days after emergence.

Garlic Essential Oil and Their Main Compounds:

Essential oil from garlic (*Allium sativum* L.) and its main compounds, diallyl disulphide and diallyl sulphide were tested against all life stages of *T. confusum*. Essential oil extracted by stem distillation method was provided commercially from ATL Canada Company. Diallyl disulphide (Sigma-Aldrich, 317691, 80 %) and diallyl sulphide (Sigma-Aldrich, 35801, 97%) were provided commercially by Sigma-Aldrich. After purchase, garlic essential oil and their main compounds were collected in sealed glass containers and refrigerated in the dark at 4 ºC until their use.

Bioassay Tests and Experimental Procedures:

Tested stages of *T. confusum* were collected from the cultures and placed in the glass vials covered with a fine mesh to allow penetration of any volatiles emanating from garlic oil, its main compounds (diallyl sulphide and diallyl disulphide) and mixture (diallyl sulphide + diallyl disulphide). Fifty eggs and twenty five larvae, pupae and adults were used for each replicate. Bioassays were carried out in 3 l glass jars closed with metal screw-on lids, which served as fumigation chambers and were kept at 25 ± 1°C and 65 ± 5 % RH at the incubator. The single-dose biological tests were carried out to determine the effective doses of essential oil and each compound against the all life stages of *T. confusum*. Each tested stages were exposed to a constant concentration of 25 µl l^{-1} air of garlic oil, diallyl sulphide, diallyl disulphide and micture diallyl sulphide + diallyl disulphide (each compound at 12.5 µl l^{-1} air) for 24 h. Garlic oil, diallyl sulphide, diallyl disulphide and diallyl sulphide + diallyl disulphide were applied on

filter paper (2 cm x 5 cm) attached to the under-side of the lids of fumigation chambers by using 50 µl micropipette. After eggs, larvae, pupae and adults were transferred separately into fumigation chambers, they were closed with screw-on lids, which were made air-tight. Each treatment and control was replicated three times. For the control treatment, all life stages of *T. confusum* were exposed to atmospheric conditions and were kept at 25 ± 1°C and 65 ± 5 % RH at the incubator.

Garlic essential oil, diallyl sulphide, diallyl disulphide and diallyl sulphide + diallyl disulphide were subjected to lethal concentration tests to determine their LC_{50} and LC_{90} values. Four to seven dose levels ranging from 0.5 to 25 µl l^{-1} for garlic oil, from 0.5 to 50 µl l^{-1} for diallyl sulphide, from 0.5 to 18 µl l^{-1} for diallyl disulphide and from 5 to 25 µl l^{-1} for diallyl sulphide + diallyl disulphide were used for life stages of *T. confusum*. The dose levels were selected for each stage of *T. confusum* on basis of the single-dose biological tests. Three replicates were set up for each dose and control. Fumigation procedures were the same as in above mentioned bioassay tests.

Data Processing and Analysis:

After each treatment, the eggs in their Perspex slides were held at 26 ± 1°C and 65 ± 5% r.h. until the oviposition sites were examined for egg hatching. It was checked 7 days after treatment for mortality counts. Mortality counts for adults were done 4-5 days after exposure; for larvae they were based on those individuals that had failed to pupate 9 days after exposure; pupal mortality was based on those pupae that failed to develop in adults 9 days after exposure. Mortality data obtained from bioassay tests were corrected by using Abbott's formula (Abbott, 1925). Mortality data obtained from preliminary bioassay tests were normalized using arcsine transformation and then were analyzed using two-way analysis of variance (ANOVA). The means were separated using the Duncan's test at the 5 % level (SAS Ins., 1989). Data obtained from each zero dose control and exposure time-mortality responses were subjected to probit analysis by using maximum likelihood program software (POLO-PC) (LeOra Software, 1987) to determine LC_{50}s (Lethal Concentration$_{50}$), LC_{90}s (Lethal Concentration$_{90}$) and their respective 95% confidence intervals. Differences in toxicity were considered significant when 95% confidence intervals did not overlap.

Results and Discussion

Percent mortalities of *T. confusum* eggs, larvae, pupae and adults exposed to 25 µl l^{-1} dose of garlic essential oil, its main compounds and their mixture for 24 h are given in Table 1. Preliminary bioassay tests indicated that both vapours of tested compounds and the insect stage had a significant effect on mortality of the life stages of *T. confusum* when exposed to a dose of 25 µl l^{-1} for 24 h (for compounds $F_{4, 40} = 513.17$, $P<0.0001$; for insect stages $F_{3, 40} = 34.09$, $P<0.0001$). According to results of single-dose biological tests, garlic essential oil, diallyl disulphide and mixture diallyl sulphide + diallyl disulphide resulted in 100% or almost 100% mortality of all life stages of *T. confusum*. Diallyl sulphide achieved 100% or almost 100% mortality of eggs, larvae and pupae while resulted in low mortality of adults (3.9%). Single-dose tests indicated that all tested compounds (garlic essential oil, diallyl sulphide, diallyl disulphide and diallyl sulphide + diallyl disulphide) at a dose of 25 µl l^{-1} for 24 h had high fumigant activity on all life stages of *T. confusum* except diallyl sulphide for adults (Table 1). Compared with the investigation of Karcı (2006) for garlic essential oil and Gözek (2007) for garlic essential oil and their components our results indicated a similar toxicity of garlic oil and their main compounds against all life stages of *T. confusum.*

Table 1. Percent mortalities of *Tribolium confusum* eggs, larvae, pupae and adults exposed to 25 µl l^{-1} dose of garlic essential oil, its main compounds and their mixture for 24 h

Compounds	Mortality (%) ± S.E.				F and P value

Two-way ANOVA was applied to the data. Means within a row with the same lower-case letter and a column with the same upper-case letter do not differ significantly (Duncan test at 5% level)
The results of probit analysis (LC_{50} and LC_{90} values) for all life stages of *T. confusum* exposed to various doses of garlic essential oil, its main compounds and their mixture for 24-h are given in Table 2. Probit mortality regression data indicated a remarkable difference in toxicity of tested compounds against all life stages. Garlic essential oil, diallyl sulphide, diallyl disulphide and mixture diallyl sulphide + diallyl disulphide against *T. confusum* eggs had 2.47, 1.35, 1.39 and 1.80 µl l^{-1} of LC_{90} value respectively. Therefore, it appears that diallyl sulphide was the most toxic to *T. confusum* eggs, followed by diallyl disulphide, diallyl sulphide + diallyl disulphide and garlic oil, respectively. LC_{90} values for diallyl sulphide and diallyl disulphide against larval stage of were significantly lower than those for garlic oil and diallyl sulphide + diallyl disulphide, since 95 % confidence intervals (CLs) of diallyl sulphide and diallyl disulphide did not overlap those for garlic oil and diallyl sulphide + diallyl disulphide (Table 2). Garlic oil, diallyl disulphide and diallyl sulphide + diallyl disulphide were more toxic to pupae with LC_{90} values of 5.03, 3.96 and 5.25 µl l^{-1} respectively than diallyl sulphide with LC_{90} value of 20.14, 42.26. Diallyl sulphide + diallyl disulphide were more toxic to adults with LC_{90} values of 8.72 µl l^{-1} than garlic oil and diallyl disulphide with LC_{90} value of 19.05 and 16.61, respectively. Considering all results obtained from lethal concentration tests, diallyl disulphide was the most toxic compound to all life stages of *T. confusum* except adults. Likewise, Huang *et al.* (2000) reported that main components of garlic oil, diallyl trisulphide, diallyl disulphide and methyl allyl trissulphide, had high fumigant toxicity against *Tribolium castaneum* (Herbst) and *Sitophilus zeamais* Motschulsky and can be considered as potential alternative fumigant for controlling stored product insects.
Toxicity data for garlic essential oil, its active compounds and mixtures indicated a remarkable difference in susceptibility between life stages of *T. confusum* (Table 2). Bioassay tests indicated that the adults and larvae were the most tolerant stages while the eggs and pupae the most susceptible to treatments of garlic essential oil, its active compounds and mixtures. LC_{50} values for the adult was significantly different from those of the eggs, pupae and larvae, since 95 %

confidence intervals (CLs) of the adult did not overlap those of its egg, pupa and larva. LC_{50} values for the egg was also significantly different from those of the larvae, pupae and adult, since 95 % CLs did not overlap.

Table 2. Probit analysis data of garlic essential oil, its main compounds and their mixture for *Tribolium confusum* eggs, larvae, pupae and adults following 24-h laboratory fumigation

Life stage	Compounds	N[a]	Slope[b] ± S.E.	LC_{50} (µl l^{-1}) (Fiducial limit)[c]	LC_{90} (µl l^{-1}) (Fiducial limit)[c]	χ^2 [d]
Egg	**Garlic oil**	900	3.1±0.29	0.96 (0.84-1.08)	2.47 (2.15-2.96)	7.03
	Diallyl sulphide	750	4.58±0.39	0.71 (0.62-0.79)	1.35 (1.18-1.62)	15.99
	Diallyl disulphide	750	3.58±0.33	0.61 (0.54-0.67)	1.39 (1.24-1.61)	3.05
	Diallyl sulphide+ Diallyl disulphide	900	3.46± 0.32	0.77 (0.65-0.88)	1.80 (1.55-2.23)	18.34
Larva	**Garlic oil**	900	2.87±0.65	7.98 (4.40-10.41)	22.33 (18.15-32.66)	9.86
	Diallyl sulphide	1050	2.27±0.25	1.76 (1.35-2.22)	6.47 (4.95-9.24)	8.27
	Diallyl disulphide	900	2.69±0.32	2.15 (1.68-2.67)	6.44 (5.02-9.04)	11.31
	Diallyl sulphide+ Diallyl disulphide	900	2.49 ± 0.39	6.69 (4.14-8.81)	21.85 (16.89-33.35)	15.57
Pupa	**Garlic oil**	900	2.53±0.35	1.56 (1.11-1.99)	5.03 (3.87-7.13)	2.88
	Diallyl sulphide	1050	2.02±0.19	4.66 (3.55-5.82)	20.14 (16.03-26.81)	12.75
	Diallyl disulphide	900	2.24± 0.26	1.06 (0.803-1.32)	3.96 (3.09-5.53)	3.93
	Diallyl sulphide+ Diallyl disulphide	900	2.36±0.25	1.51 (1.19-1.83)	5.25 (4.16-7.18)	2.05
Adult	**Garlic oil**	900	5.49±0.66	11.13 (9.21-12.69)	19.05 (16.62-23.41)	20.79
	Diallyl sulphide	1200				
	Diallyl disulphide	900	5.65±0.95	9.85 (7.29-11.52)	16.61 (14.18-22.55)	21.76
	Diallyl sulphide+ Diallyl disulphide	1050	4.93±0.82	4.79 (3.49-5.63)	8.72 (7.39-12.09)	26.69

[a]: Number treated, excluding controls, [b]: Slopes are non-parallel and unequal where noted,
[c]: Value in parentheses refers to the 95% confidence range, [d]: Chi-square,
[e]: Calculated LC_{50} ve LC_{90} values were found to be far beyond tested application dose ranges

Conclusion

Toxicity tests in this study indicate that garlic essential oil, its active compounds (diallyl sulphide and diallyl disulphide) and mixtures (diallyl sulphide + diallyl disulphide) provided the complete mortality of all life stages of *T. confusum* at relatively low concentrations and short exposure period. In conclusion, present study showed that garlic essential oil, its active compounds and mixtures would be potential as an alternative to conventional fumigants.

MICROBIAL CONTAMINANTS AT VAROUS STAGES OF BREWING PROCESS

Linda LUARASI[1], Rozana TROJA[2], Luljeta PINGULI[2]

[1]Department of Biotechnology, Faculty of Natural Sciences, University of Tirana, Albania

Abstract

Beer may contain microbial contaminants which originate from different sources such as the raw materials, manufacture equipment, and those introduced during bottling. The raw materials including malt, water and hops contain their own microflora. The brewing yeast should be stored and propagated with maximal hygienic condition in order to avoid contamination. At the bottling process, the contamination can occur in the filling sector as well as in the sealing sector. The airborne microorganisms are a significant problem in all the breweries. The spoilage microorganisms which are mostly encountered in the whole brewing process are molds, wild yeasts and lactic acid and acetic acid bacteria. Species of *Alternaria, Cladosporium* and *Fusarium* are field fungi, while *Aspergillus* and *Penicillium* are grown during barley storage. The non-*Saccharomyces* wild yeasts include *Brettanomyces, Hanseniaspora, Pichia, Torulaspora, Zygosaccharomyces* etc. The contamination of brewing yeast from bacterial strains may be a serious problem to the fermentation process. The most isolated bacterial contaminants are lactic acid and acetic acid bacteria. The paper presented here is an introduction of a study related to the determination of environmental contaminant strains and other spoilage microorganisms of beer in Albania. A number of critical points were identified in the technological process taking into consideration the most probable polluted areas of production. The cultivation methods were performed. Isolated and identified strains detected during the microbiological control belonged mainly to the genera of *Penicillium, Aspergillus* and *Rhodotorula*. Spontaneous strains were very few in number and were not considered problematic for the indigenous microbial population.

Keywords: *contaminants, beer, microorganisms, fermentation*

Introduction

The microbiological stability of beers relies on three basic aspects, including the microbiological quality of the raw materials used for brewing – malt, water, hops and yeast - the nature of the process and product, taking into consideration whether or not the pasteurization is applied and the sanitary condition of the beer-contact surfaces, including the cleaning processes of the brewing equipment and the plant. These three factors serve as indicators of the sanitary and microbiological quality of all beers, whether they may be brewed in industrial scale or in microbreweries (Priest *et al.* 2003).

This paper presents some aspects of the research work on the microbiology of brewing process. Some beers are typically more susceptible to microbial spoilage, especially those which are not pasteurised or sterile filtered. Further, some beer companies usually lack a well-established quality control laboratory, and in some cases the cold storage is not guaranteed throughout the distribution chain (Moretti, 2013). So this research work allowed to determine some critical control points of the process, especially investigating the microbiological control of equipment

used; management of the yeast and the management of cleaning and sanitizing; as well as the microbiological control of beer sampled from different types of packages.

Processing areas. The environment where beer is produced is quite variable, ranging from modern equipment established in well maintained buildings, to outdated equipment and old buildings that are sometimes historic places. Thus testing the airborne microorganisms is recommended in the brewing industry. The impurity of the environmental air surrounding the processing area is high affected by the seasons. Some studies have shown that the different periods of the year have had an effect on total number of aerobic airborne microorganisms with the spring months being five times higher than other months (Miller, 2011). Routine microbiological environmental air testing is a good indicator of overall brewery hygiene.

Bottling. Most microbreweries use new, nonreturnable bottles. These are rinsed and sanitized with specific kinds of detergents. The finished beer in bottles is finally analyzed microbiologically. The canning line in the brewery was found to be contaminated with beer spoiling bacteria on average 75% of the time. Critical areas in the brewery, such as the bottling and canning lines, should be routinely tested for airborne microorganisms as they could lead to final product contamination (Miller, 2011).

Wild yeasts must have been a problem in beverage fermentations throughout history, and have been the subject of numerous reviews since their microbiological nature became understood. It is important to practice testing for the absence of undesirable yeasts at each sensitive stage of the brewing process (Priest *et al.* 2003). The microbiological CCPs of the brewing industry have been identified in the Recommended Methods of the Institute of Brewing and American Society of Brewing Chemists (Vaughan, 2005). Contamination of pitching yeast, even if initially pure, is probably inevitable after a number of fermentations and repitching in traditional open vessels, although the contaminant may stabilize at a relatively low and therefore harmless level.

The focus of this paper work is the detection of spoilage microorganisms at various stages of brewing process during the investigation of the most probable critical areas.

Material and Methods

Samples were selected from a private company of beer production in Tirana, during April and May, 2016. Sampling involved selection of some critical control points in the brewery.

Microbiological quality of filtered beer

The filtered beer in this case means beer without any kind of sterilization. The sampling point was the pressure tank. 50 ml of filtered beer was taken for plating in selective media, wort agar and PCA. The methods are described in EBC Analytica Mibrobiologica 3.3.4.1.

Microbiological quality of beer during fermentation

Samples were taken in a sterile manner 4 days after pitching of the yeast, from the main fermentation unit. Cultivation methods were performed using the pour plate technique in WA and PCA. The methods are described in EBC Analytica Microbiologica 3.3.2.

Microbiological quality of beer in kegs

The same technique was followed for the microbiological testing of beer in kegs. The procedure of sampling was carried out in sterile manner.

As noted previously, there is no selective medium that suppresses brewery or distillery culture yeasts and supports the growth of all contaminants that could be present. However, wild yeast contaminants of the genus *Saccharomyces* will probably form spores and can be selected by their marginal heat resistance in comparison with nonsporing culture yeasts (Campbell, 2003).

Results and Discussion

Microbiological controls, focused on the quality of the final product, demonstrated the presence of some specific microorganisms, most of them non harmful bacteria, yeast and molds. The risk of a microbial contamination was related not only to the microflora of the raw materials but also to the operating conditions in the processing environment.
The microbiological test of different beer samples showed the following results.

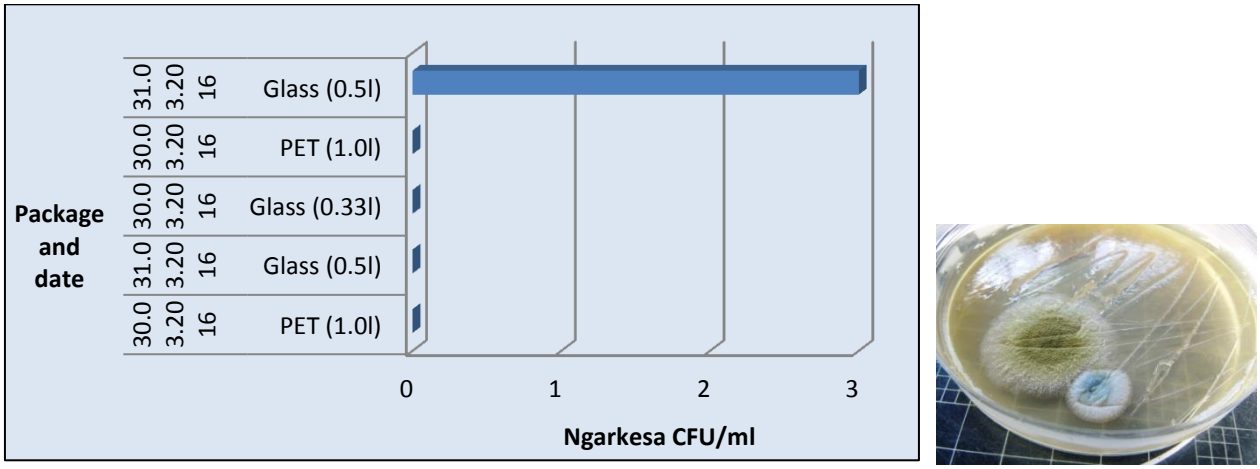

Figure 1. Total count of microorganisms in PET and glass bottles of finished beer (wort agar)
The obtained results showed a few spontaneous strains, which is believed to come from the surrounding environment. The strains belonged to *Penicillium* genera.

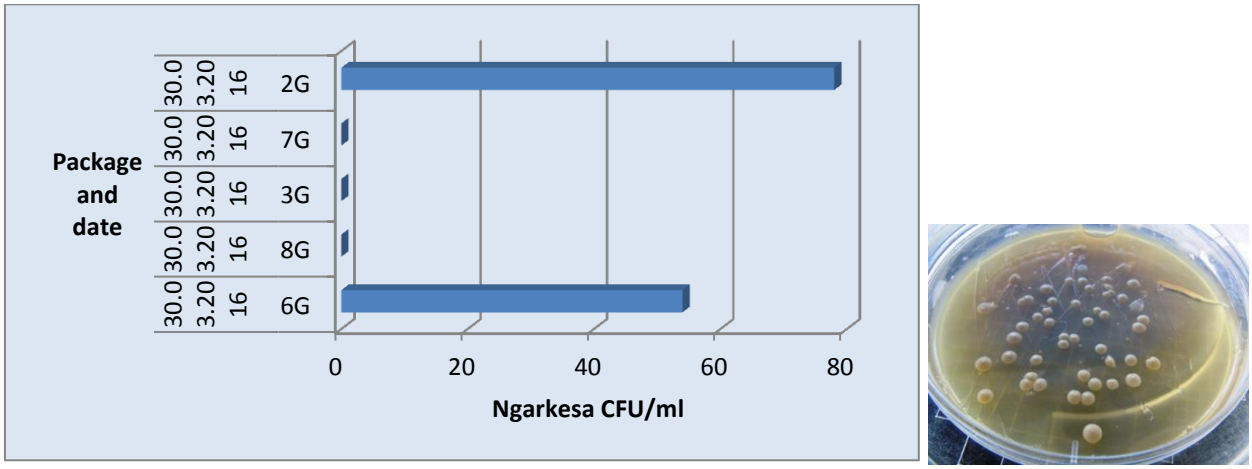

Figure 2. Total count of microorganisms in filtered beer incubated in wort agar

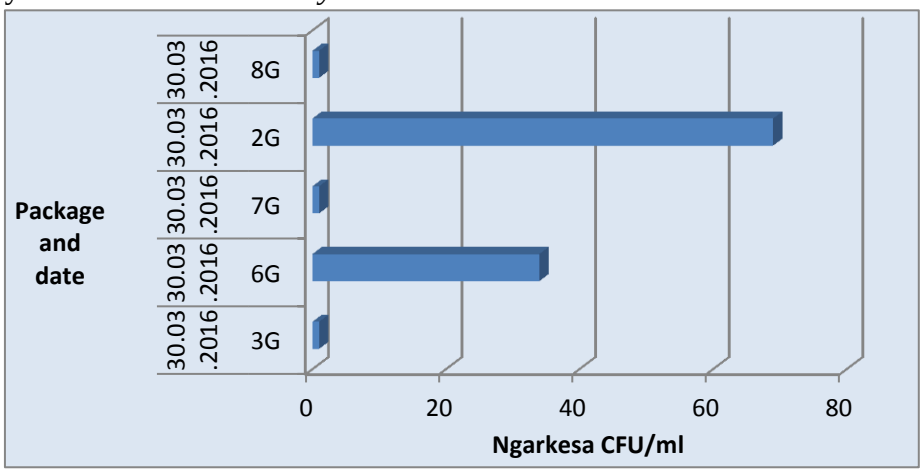
The total count of microorganisms in filtered beer during the growth in wort agar belonged to the yeast culture *Saccharomyces uvarum*.



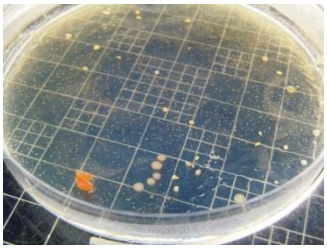


Figure 3. Total count of microorganisms in filtered beer incubated in PCA

Considering the total count in filtered beer in PCA, it is noted the presence of the pink yeasts, *Sporobolomyces* and *Rhodotorula.*

According to the other studies, it is believed that these wild yeasts belonging to the *non-saccharomyces* family originate from the raw materials. Yeast numbers in finished malt have been reported to lie in the range 7.2 x 102-1.1 x 104 /g, with the pink yeasts in the genera *Sporobolomyces* and *Rhodotorula* often being abundant (Wiles, 1953).

Other related studies provided a comprehensive survey of culture media for detection and isolation of wild yeasts, which they defined as 'yeasts not playing a significant part in a normal fermentation.' In the earlier reviews of wild yeasts it is used the definition 'yeasts not deliberately used and under full control' which indicates the accidental nature of wild yeast contamination.

The results obtained in samples of beer during the fermentation showed an uncountable total charge in PCA medium. Meanwhile the microbiological control of beer in keg containers showed no growth of microorganisms.

Conclusions

The general evaluation of the total count of microorganisms in different stages of beer production has shown the presence of some specific strains which are not considered pathogenic or harmful. However, brewing companies apply good hygienic practices, it is inevitable the presence of airborne microorganisms as well as those microorganisms encountered in the storage environment. The mold colonies including *Penicillium* and *Aspergillus* are frequently found in the storage sector of malt grains. The wild yeasts belonging to the *non-sacharomyces* family, *Sporobolomyces* and *Rhodotorula* are common environmental basidiomycetous yeasts, frequently found in brewing processing areas. During the evaluation of total count of microorganisms in the fermentation process, no specific strains were noted. Concerning the control points, the most problematic and of increased importance are beer leavening the filter, pressure tank, beer entering filler, empty bottles, and beer before crowning. The bottles washing process is also considered a delicate process being a potential source of microorganisms' growth.

Abstract

The goal of this paper is to conduct a comparative analysis of physical and chemical characteristics of honey in the area of Gorazde municipality, Bosnia and Herzegovina. Sampling of honey was carried out by random selection of three producers of honey from Gorazde. Physical and chemical analyses were conducted on three types of honey: floral, meadow and forest honey. Physical and chemical analyses have included following parameters: level of water by drying method, level of ashes, conductometric level of reduced sugar according to Luft-Schoorl, level of sucrose according to Luft-Schoorl and level of free acids in terms of volumetry. All parameters were given in percentages and they are compared with the existing Rulebook. The obtained results show that all three analyzed samples of honey have the necessary quality. The conclusion is that, in the period of analysis, the controlled samples have shown the necessary safety and they are in accordance with the regulations of existing Rulebook on honey and other bee products (Official Gazette of Bosnia and Herzegovina, No 37/09).

Keywords: *Honey, physical and chemical analyses, quality.*

Introduction

Since the beginning of man to this day, his diet includes honey as a foodstuff but as well as a medicine. Men have always had great respect for the bee products. With time, scientific achievements have enabled organized honey production based on contemporary processes with permanent presence of development and progress in the quality of final bee product.

Honey is a foodstuff that cannot be produced artificially. Honey is completely natural product what can be used directly from the beehive in its natural form in which it was made from bees.

The main chemical ingredients of honey are: 38.19% fructose, glucose 31.28%, 1.31% sucrose, maltose and disaccharides 7.31%, 17.20% water, acid 0.57%, 0.26% protein, ash 0.17% and the other the different components of 2.21%. (Čondić, 2003)

In many European countries, the average consumption of honey is 7-10 grams per day(Wong, 2001).

Honey is also functional food. These characteristics are based on its antibacterial quality, i.e. it has bactericidal and bacteriostatic effect on the majority gram positive bacteria. Antibacterial quality of honey depends on its botanic origin. High content of sugar in honey and low quality Ph are increasing antibacterial quality in honey.

Gorazde is a suitable area for development of vegetable and fruit growing, animal husbandry, farming and beekeeping based on its geographical position, hydro graphic, relief and other characteristic.

There are significant conditions in the area of Gorazde municipality for development of

beekeeping thanks to its rich flora and honey plants on big meadows and there is a significant number of beehives at this location. The production of honey is very important in Gorazde municipality and 104 tons were produced only in 2013. The placement of honey is difficult and uncertain due to nonexistence of organized purchase and sale. Therefore the placement is reduced to individual attempts and activities. The area of Gorazde municipality had cca 8050 beehives in 2013.

The goal of this paper was to examine physical and chemical characteristics of three different types of honey produced by three different producers from the area of Gorazde and compare the results with parameters given in the existing Rulebook and assess its acceptability for future potential consumers on free market with the presentation of the results of chemical analysis in tables.

Material and Methods

The sampling was carried out by the producers of three different types of honey. Sample no. 1 was floral honey, sample no. 2 meadow honey and sample no. 3 forest honey in 2015 in the area of Gorazde. The physical and chemical analyses included the following parameters:

Water content (%) - the method of drying,
Ash content (%) - conductometric method,
Content of reducing sugars %, -method by Luft-Schoorl,
Content of sucrose in% - the method by Luft-Schoorl and
Content of free acids in millimoles/kg by volumetric method

The analyses were carried out according to the methods in Rulebook on methods for control of honey and other bee products. The content of moisture was determined by gravimetric drying method on $100^{o}C - 105^{o}C$. The measuring was carried out on analytic beam balance Sartorius BP 110S.

Electric conductivity at $20^{o}C$ was determined with conductometre Eutech Instruments Con 110) by using a water solution of honey (the amount of honey was equivalent to 20 grams of dry honey matter dissolved in 100 ml of distilled water).

The content of mineral material was determined in solution, right after measurement of electric conductivity, by transferring in TDS (Total dissolved solids) way of working on Eutech Instruments – Cyberscan con 110 instrument.

Determination of sugar was carried out by using Luff – Schrool method. The method is based on the principle that in a certain conditions reduced sugar (natural invert) transforms Cu2+ ions into Cu+ ions. Unused amount of CU2+ ions retrites with the solution of sodium tiosulfate. From the difference of spent for blind experiment and the real test, we can see the amount of sugar from the table that shows correlation between the reagent spent and the amount of sugar. Non-reduced disaccharide (sucrose) must be previously inverted, i.e. hydrolysed to reduced monosaccharide with acid, after we re-determine the sugars with Luff reagent. In this way, we receive the data regarding the total amount of sugar in the analysed sample.

Method principle to determine reduced sugar is based on reduction of Fehling' solution at the boiling point by titration with solution of reduced honey sugar and by using methylene blue as an indicator.

Determining the sucrose was carried out according to the Rulebook on methods for control of honey and other bee products and it is calculated as a difference in content of reduced sugar before and after hydrolyse, multiplied by factor 0,95.

The free acidity is determined by titration of a standard solution of sodium hydroxide with phenolphthalein as an indicator.

Third year students of Agro Mediterranean faculty in Mostar carried out organoleptic analysis. A commission, that meets the conditions foreseen for analysis of raw material, was formed i.e. they were all introduced to the material they were analysing, theoretically – what conditions honey must meet in terms of foodstuff on the market. They were all in good health and mentally stable. They formed the commission of nine members.

Results and Discussion

Physical and chemical analyses on samples of meadow, floral and forest honey from the area of Gorazde were carried out at federal Institute for agriculture in Sarajevo and Agro Mediterranean faculty of Dzemal Bijedic University of Mostar. The obtained analyses results of content of sugar, ash, sucrose and free acids are compared to the parameters in existing Rulebook on honey and other bee products (Official Gazette of Bosnia and Herzegovina No. 37/09) and in that way we have created the complete image regarding the quality of the very product.

Table 1. Results of the physical and chemical analyses – sample no. 1 (Floral honey)

Parameter	Analysis result	Rulebook value
Water content (%)	13,38	< 20
Ash content (%)	0,420	< 0,6
Reduced sugar content (/%)	73,56	>60
Sucrose content (%)	5,32	< 5
Free acids content (milimol/kg)	20,0	< 50

In Table 1, the obtained results of chemical analysis are compared to allowed parameters according to existing Rulebook. They show that the content of water, ash, reduced sugar and content of free acids within the allowed parameters.
Analysed parameter of sucrose content shows a deviation from the allowed level of sucrose content i.e. the obtained results are somewhat increased (for 0,32%)

Table 2. Results of the physical and chemical analyses – sample no.2 (Meadow honey)

Parameter	Analysis result	Rulebook
Water content (%)	13,93	< 20
Ash content	0,339	< 0,6
Reduced sugar content	72,48	>60
Sucrose content	2,57	< 5
Free acid content	26,0	< 50

Obtained results of physical and chemical analysis carried out on sample no. 2 show that all analysed parameters are in keeping with existing Rulebook on honey and other bee products (Official Gazette of Bosnia and Herzegovina No. 37/09)

Table 3. Results of the physical and chemical analyse – sample no.3(Forest honey)

Parameter	Analysis results	Rulebook
Water content	13,97	< 20
Ash content	0,478	< 0,6
Reduced sugar content	70,86	>60
Sucrose content	5,83	< 5
Free acid content	28,0	< 50

Obtained results of physical and chemical analysis carried out on sample no. 3, similar to sample no. 1 show that analysed parameters of content of water, ash, reduced sugar and free acids are within the allowed concentrations while there is a deviation from the existing Rulebook with content of sucrose that should not be higher than 5 while the obtained result is 5,83%

Organoleptic analysis of all three analysed honey samples we have determined the colour, consistency and taste. We have reached the following conclusions:

- They have thick – liquid consistency
- That it is ripe and it is not in condition of fermentation or mouldiness
- That it has an aroma and taste characteristic to honey without an outside aroma or taste
- That it has no outside ingredients
- That it is not infected by insects or their parts

Conclusions

The results obtained with sample no. 1 and sample no. 3 show a mild deviation in terms of sucrose content what is not in line with the allowed foreseen concentrations stipulated by the Rulebook, while all other analysed parameters (content of water, ash, reduced sugar and free acids) were in line with the existing Rulebook.

Obtained results of physical and chemical analyses of all analysed parameters with sample no. 2 were in line with existing Rulebook and as such it can be placed on the market and made available to consumers as a high quality product in both chemical and organoleptic terms.

All three analysed honeys are a product of self-organized producers in the area of Gorazde. obtained results show that all three analysed samples in the majority of examined parameters are within allowed concentration limits. Sample no. 2 stands out in terms of quality i.e. all technological processes production of honey are in line with existing Rulebook.

Abstract

Triticale is a cereal species created by crossing the wheat and rye species. It is characterized by good quality and high yielding capacity which is specific for wheat and high tolerance to abiotic and biotic stress factors which is specific for rye. The high yield potential of triticale is determined by genetics and influenced by environmental factors. The aim of the paper is to present the results obtained at different triticale varieties under different climatic conditions regarding the grain mass spike^{-1}. Five triticale (*xTriticosecale* Wittm.) cultivars (KG 20, Bolero, Rtanj, Odisej and Bogo) were investigated in field experiment which was conducted as a randomised block design in five replications on 5m^2 size of unit plot, during three years period (2010-2013). In full stage of maturity 100 plants (20 plants per replication) were used for analysis of grain mass spike^{-1}. Obtained results for grain mass spike^{-1} showed significant differences among studied triticale cultivars, years of experiment and interaction genotype/year. The average value of grain mass spike^{-1} for all three years and all five tested cultivar of triticale was 2.28g. The cultivar Bolero had the lowest average value (2.15g) and Odisej the highest value (2.52g) of grain mass spike^{-1} in average for three years period.

Keywords: *grain mass, spike, triticale, cultivars*

Introduction

Triticale is highly productive cereal species which use for planting as alternative to other cereals in region where growing conditions are unfavorable or in low-input systems (Erekul and Köln, 2006; Jelić et al., 2007). Triticale is, in general, more tolerant to environmental stresses than wheat and barley. Breeding for marginal areas (acidic or alkali soils), phosphorus deficiency, micro-elements deficiencies (Cu, Zn, Mg) or toxicity (boron) and drought stress in the arid and semi-arid zones is the important task of breeding programs in the world (Oettler, 2005; Knezevic et al., 2010). By breeding was increased grain yield, improved resistance to disease and optimized morphological traits and grain protein composition (Hernández, 2001). Triticale can be used for different purpose as animal and human food (Zečević et al., 2007; Martinek et al., 2008). Flour of triticale very often use to replace soft wheat flour in mixtures for breads, cakes or cookies (Bagcı, 2005; Zecevic et al. 2005). The grain mass spike^{-1} is important factor for grain yield which have positive association with grain number spike^{-1} and with yield (Yanbeyi et al., 2006). Except, grain mass spike^{-1}, the numerous morphometric components (plant height, tillering, grain number spike^{-1}, thousand grain mass, hectoliter mass, etc.) have contribute to total

grain yield. Response of genotypes on different environmental conditions is a good way for estimation which genotypes is more adaptive to specific area for growing (Kirchev et. al., 2014). The formation of grain yield varied under the influence of environmental factors (temperature, precipitation). Grain yield depends of variations of precipitation in critical months. Triticale breeding programs are focused on increasing grain yield, biomass yield, earliness, grain filling percentage as well nutritional quality (Grabovets and Popova, 2015; Moskalets et al., 2016). The strong interaction between genotype/environment require the creation of varieties with specific adaptability to climatic conditions both favorable and unfavorable (Zečević et al., 2010). For improvement of spike traits, grain yield and yield components depends on the amount of nitrogen nutrition (Kirchev et at., 2006; Madic et al., 2015) and that require study to optimize measure of technology growing (Jelić et al., 2007) in different area of triticale production, considering the climate change. The changes of environmental conditions as well climate in recent years emphasized the extreme variations, with consequences on the agricultural production (Zečević et al., 2010).

The aim of this paper is study of variability of grain mass spike-1, in five genetically divergent winter triticale cultivars influenced by different environmental conditions.

Material and Methods

The five cultivars of triticale (KG 20, Bolero, Rtanj, Odisej and Bogo) were included for investigation variability of grain mass spike^{-1}. Field experiment was set up as a randomised block design in five replications on 5m^{-2} size of unit plot, which carried out in three growing season (2010/11, 2011/2012 and 2012/2013). The experiment conducted on the soil type pseudogley which characterized acidic pH (pH_{H2O} = 4.1) and the following content: humus 2.36%, readily available phosphorus 7.8 mg 100^{-1} g soil and potassium 14.3 mg 100^{-1} g soil. In full stage of maturity of 100 plants (20 plants per replication) were used for analysis of grain mass spike^{-1}. The analysis of variance was computed according to randomize complete block design with two factors: A (cultivars), B (year) and using ANOVA (MSTAT-C program, 1989). The significant differences among the means were estimated by least significant difference (LSD) test (Hadživukovic, 1991). Components of variance (genetic, interaction and environment) were computed by Falconer (1981).

Climatic conditions during growing seasons

In the years of experiment the values of temperature and precipitation were different. Also, those values in comparison with computed average values for 10 previous years were different (tab. 1). In the first year the average temperatures (8.74^{o}C) were similar to average of ten years period (9.08^{o}C) and in second (8.13^{o}C) were in average slightly lower than in first year and ten year period, while in third year of experiment (2012/13) average value of temperature (9.73^{o}C) was higher than in other year of experiment and average temperature for ten years period. In the first year 2010/11 the amount of precipitation (520.5mm) was higher than in second 2011/12 (474.7mm) year, while in the third year 2012/13 was the highest amount of precipitation (611.5mm). The average value of precipitation in the first and second year of experiment was lower, while in the third year was higher than average value of precipitation for ten year period (2000-2010). Amounts of precipitation in the first and third years was higher and suitable up to the June in the stage of ripening plant. The precipitation in the second year in the period of emerging (November) was extremely low, while from December to June distribution of precipitation was suitable at each stage of development, while the low amount of precipitation in June (17.8mm) at the stage of grain filling. This precipitation was suitable for seed maturity

phase, and was lower for 52.9mm than in first year, 136.85mm than in the third year and for 74.4mm lower than in ten years average values.

Results and discussion

The analysis of gran mass spike-1 showed differences among cultivars as well for the same cultivars depends of year. Under specific environmental conditions of experimental season 2010/11 the gran mass spike-1 varied between 2.12g (KG 20) and 2.49g (Odisej) with an average value for five investigated cultivars of 2.29g. The values for grain mass spike-1 in 2011/12 varied between 2.08g (Bolero) and 2.26g (Odisej and KG20) with average value for all five cultivars of 2.20g. In the climatic year conditions of 2012/13 grain mass spike-1 varied between 2.13g (KG20) and 2.81g (Odisej) with an average value for five investigated cultivars of 2.34g. The average value of grain mass spike-1 for all three years and all five tested cultivar of triticale was 2.28g and variation value of grain mass spike-1 was between 2.15g (Bolero) and 2.52g (Odisej) table 2.

The results for grain mass spike-1 in this research were similar to obtained value of grain weight (ranged from 1.94 to 2.58g) for triticale lines, reported by Dogan et al., (2009) and similar to research (Giunta et al., 2004; Kociuba et al., 2010). However, values of grain mass spike-1 in this study is higher to obtained values in investigation (Pochişcanu, et al., 2013; Gerdzikova, 2014). Also, different values of grain mass spike-1 in comparison to our investigation were found in other studies Atak et al. (2006), Yanbeyi et al. (2006) and Akgun et al. (2007). These differences may arise from different ecological conditions in which different researcher were conducted.

The better climatic conditions of 2012/13 compared to 2011/12, especially concerning the much better water supply from precipitation, determined a significant increase in the grain mass spike-1 at analyzed triticale cultivars. Except of genotype specificity, higher amount of precipitation in first (520.5mm) and third (611.5mm) year in relation to second year of experiment (474.7mm) have influence to efficient grain filling as well higher grain mass spike-1.

The investigation (Hernández, 2001) showed that under good rainfed condition (~ 700mm) triticale has 15% higher grain yield than wheat, or approximately three fold higher than under low (~300mm) rainfed condition. This advantage is much larger under dry and marginal conditions. Also, physiological-genetic variable have influence on the variations of yield among crop plant genotypes and has been linked to stomatal conductance and assimilation. Productive genotypes which also sustain growth and yield under variable moisture and temperature conditions express higher stomatal conductance and gas exchange (Horie et al. 2006; Blum 2011; Reynolds et al., 2012; Blum, 2013; Wang et al., 2014).

Table 2. Mean values for grain mass spike^{-1} of triticale cultivars in different growing seasons

Genotype	grains mass spike^{-1} (g)			
	Year			Average
	2010/11	2011/12	2012/13	
KG 20	2.12gh	2.26cde	2.13fgh	2.17c
Bolero	2.19efgh	2.08h	2.20defg	2.15c
Rtanj	2.34c	2.20defg	2.24cdef	2.26b
Odisej	2.49b	2.26cde	2.81a	2.52a
Bogo	2.31cd	2.20defg	2.34c	2.28b
Average	2.29	2.20	2.34	2.28

Distinct letters in the row indicate significant differences according to LSD test ($P \leq 0.05$).

Through the analasys of variance highly significant differences were detemined among grains mass spike^{-1} of different genotypes (F=59.017**), then among years of research (F=23,523**), and their interactions as well (F=16.406**), table 3. Differences among cultivars of triticale according to grin mass spike^{-1} influenced with genetic specificity and different regime of temperature and precipitation during vegetative period in experimental years. It means that grain mass spike^{-1} is highly depended on genetic and interaction genetic/environmental factors.

Table 3. Analysis of variance for grain mass spike^{-1} (g)

Source of variance	*Degree of freedom* (DF)	*Mean square* (MS)	F-test	*LSD*		*Components of variance*	
				0.05	0.01	σ^2	%
Repetitions (R)	4	0.002	0.401^{ns}	-	-	-	-

Error	56	0.006	-	-	-	0.006	14.63
Total	74	-	-	-	-	0.041	100.00

* Significant at P = 0.05 level; ** significant at P = 0.01 level

The investigated genotypes of triticale expressed significant differences for the average values of grain mass spike^{-1} in different year of growing that indicates on diversity of examined genotypes. Variability of grain mass spike^{-1} depended on investigated genotypes and year as well what is in agreement of investigation. These findings are in agreement with previous study (Knezevic et al., 2010; Kondić et al., 2012; Madic et al., 2015). For increasing grain mass spike^{-1} the important role have morphological and anatomical structure of plants and their organs (Kondić et al., 2012).

Conclusion

The analyzed triticale cultivars showed differences in average values of grain mass spike^{-1} what indicates that these genotypes are specific. The cultivars examined in this study had different

values of grain mass spike^{-1} in the years of examination what indicates different reaction of a investigated cultivars to different conditions during its development. The expression of variability of grain mass spike^{-1} were influenced by genetic and environmental factor. The effect of genetic factor and interaction of genetic/environmental was highly significant. The largest impact of environmental factor (annual and monthly average value of temperature, precipitation) with 41.46% and the genotypes with 39.03% of variance. Promising genotypes for use in the breeding process are those that have expressed the stability of mass of spike in different climate with high average values, and among them are the cultivar Odisej and Bogo. The grain mass spike^{-1} was different for the analyzed triticale cultivars and play important role in forming of grain yield. However, increasing of genetic potential of grain yield is achievable through improvement of other quantitative characteristics, as well as increase of the size and capacity of spike as well as improvement of anatomical structure of spike. The phenotypic variability is possible to identify which genotype could be involved in future triticale breeding programs.

Abstract

The main task of modern agriculture is the production of safe food. Testing of plant protection machines began in the late nineties in the European Union (EU). Using correct and adjusted machines for the application of pesticides, in favorable weather conditions, increases the effect of protection, and reduce losses of pesticides and toxic contamination of environment. The adoption of relevant legislation in this field is expected in the future because of the desired entry of Serbia into the EU. Current situation in Serbia is such that the percentage of sprayers in operation over ten years is 82%. Crop protection machines are not tested, and also testing of new machines in operation are mostly not implemented. Mostly operate machinery manufacturers that did not have some sort of the training. Plant Protection Department of the Ministry of Agriculture and Environment of the Republic of Serbia, in accordance with European Parliament Directive 2009/128 / EC and 2006/42 / EC, establishes a framework for the control of sprayers and mistblowers. These directives are becoming significant in Serbia, with joining Serbia to the EU. The introduction of Hazard Analysis Critical Control Points (HACCP) and Global Good Agricultural Practices (Global G.A.P.) standards in agricultural production guarantees the health safety of products, as well as the absence of pesticide residues. This is important especially for fresh fruits and vegetables. This allows farmers to export their health safe products on the EU market, which should fulfill all the conditions set by the "Global G.A.P." standards.

Key words: *measurement techniques, sprayers, mistblowers, plant protection.*

Introduction

In agriculture pests and diseases of agricultural crops, as well as weeds, every year cause significant losses in yield, quality, and sometimes can completely destroy agricultural products. In practice, there are many ways and methods to control harmful organisms, weeds and diseases. One of the most effective ways to fight both for preventive protection against disease, and pest and weed control is chemical way. This method is used by numerous and different chemical compounds, which are called by the general name of pesticides (Urošević, 2001). In modern agriculture the chemical method of protection is now the primary means of plant protection. The quality of treatment machines for pesticides application is closely related to adjustment, technical solution and modernity machines, which affect the accuracy of distribution, dosing accuracy and size of losses (Bugarin et al., 2010;. Srivastava, 2014). The main task of mechanizing protection, which is performed on larger areas with sprayers is to provide a uniform vertical distribution of fluids with precise dosing of individual zones with the least possible losses on land in the air, in

order to preserve the environment (Bugarin et al., 2008). In recent years in Serbia have increased the area under orchards. Particular attention in the care of orchards deserves the protection against diseases and pests. Chemical protection of orchards is usually performed with mistblowers. Class and type of mistblowers affects the quality of work, but also the efficacy of pesticides. If pesticides are not applied appropriately in 60% of cases may be the cause of the inefficiency of the preparation and of the same harmful effects on operator, animals and the environment (Sedlar et al., 2008; Sedlar et al., 2014). On the uniformity of sprayers distribution affect the way the disintegration of the working fluid. Uniformity of distribution describes the coefficient of variation expressed in percentages and it is very important for the quality and efficiency of plant protection from diseases and pests and desiccation (Višacki et al., 2014). The most important factor in machine protection products are nozzles. They perform important functions such as failure to specify the quantity of liquid per unit time, making disperse liquid droplets of appropriate size and form (Tadić et al., 2014; Bajkin et al., 2014). In the Republic of Serbia in the category "attachable unit" there was a total of 138.084 sprayers and 17.281 mistblowers (Radivojević, 2014). In 1999., in the Republic of Serbia adopted the Law on the provision of services in the field of plant protection which provides for mandatory verification sprayer and mistblowers, as well as the Plant Protection Act. The adopted laws are in accordance with EU 91/414 EEC and refer to control sprinklers mandatory and assisted sprayers (Koprivica et al., 2015). The EU introduced regulations, required inspection of technical means of plant protection directive 2009/128 / EC and 2006/42 / EC, which is the basis of the standard EN 13790 (Banaj et al., 2014; Djokic et al., 2015). Three main arguments for periodic inspection testing machine for the application of pesticides in use are: improving the safety of workers who apply pesticides (operators) and other workers (those who enter treated areas to perform certain activities); reducing the potential risk of environmental pollution by pesticides; efficient control of harmful organisms, with minimal application of pesticides. Equipment for pesticide application must meet all the important aspects that have achieved a high level of environmental and human health. Full effectiveness of the application ensured proper handling and operation of equipment.Control sprayer and assisted sprayers that are used in EU member states is required since 2009, with the entry into force of the Directive on the sustainable use of pesticides (2008/128 EC).

In the Republic of Serbia in 2015. and 2016. control is voluntary and free, and in 2017 began regular review. Testing accuracy of machines for plant protection products is carried out in accordance with the norm EN 13790, which prescribes methods and equipment for control. Control stations in Serbia are equipped with the latest technology to control. In Serbia there are two central laboratories in agricultural universities in Belgrade and Novi Sad, as well as 31 other regional laboratories in universities, institutes, agricultural stations and schools. Institute for forage crops in Globoder-Kruševac is responsible for testing the protection of plants in Rasina district.

The aim of this study was to carry out a practical test sprayer and measuring the pressure and flow to multiple types of agricultural sprayer to determine the accuracy and uniformity of flow nozzles.

Experiment was done during the month of June in the Rasina region and a control station in Institute for forage crops in Kruševac-Globoder (Serbia). Testing of sprayer, nozzles, manometers, and the uniformity of flow to nozzles with flow measurement, was carried out. Testing was done in three repetitions, three different types of sprayers (I, II, III), and the two modes of operation. Flow measurement is carried out at a pressure of 3 bar and PTO speeds of 540 min^{-1}. Also, the flow at lower rpm PTO 300 min^{-1}, which corresponding to 840 min^{-1} engines

for tractors IMT 539. Sprayer tip I is mounted sprayer manufacturer "Agromehanika" from Kranj. The capacity of the pump sprayer was 60 l min^{-1}, a tank volume of fluid was 400 l. Sprayer type II is mounted by "Morava" from Požarevac tank volume was 330 l. Sprayer type III is carried crop sprayer with capacity of 400 l from manufacturer "Fischer" from Switzerland. Number of nozzles is different and depends on the type of sprayer. Ranged from 19 (I) 16 (II) 22 and (III). We used measurement equipment manufacturer AAMS Salvarani: examiner individual nozzles S001, control pressure gauge "Wika" and the examiner pumps. AAMS Salvarani Nozzle Flow Rate Tester S001 (Figure 1) is a device that defines the flow of all types of nozzles, accuracy class 1%. It is used as a handheld portable device, and it is designed for fast and precise control characteristics of the nozzles. If measurement determines that the flow nozzles deviate by more than ± 10% of tablet value in a particular operating pressure, according to EU standards, such nozzles should be removed from use.

Figure 1. Nozzle Flow Rate Tester S001- AAMS-SALVARANI

AAMS Salvarani Pumptester and flowmeter (Figure 2) is used to determine the actual capacity of the pump at different pressures. It is equipped with inductive flow sensor and an electronic pressure sensor. Both sensors are connected to the monitor that continuously displays the pressure and flow rate.

Figure 2. Pumptester and flowmeter- AAMS-SALVARANI

Results and discussion

The Table 1 shows the average value of three repetitions and three different types of sprayers (I, II, III). Overall, sprayer type I had the lowest average value of the flow of fluids (at 300 min^{-1} 0.779 l min^{-1} and at 540 min^{-1} 0.846 l min^{-1}) with the smallest variations in both RPM PTO as indicated by the lowest coefficient of variation (CV = 5,662% and in the average value of flow rate of 0.846 l min^{-1} CV = 6.587%). It is evident that the type sprayers III had the highest average value in both RPM PTO rate (at PTO 300 min^{-1} 1,253 l min^{-1} and at 540 min^{-1} 2,437 l min^{-1}). Sprayer type II as measured by these indicators had the biggest variation (CV = 57.16% for speed revolution of 300 min^{-1} and CV = 57.95% for 540 min^{-1}).

For all three types of sprayer by increasing the number of revolutions PTO increases the amount of chemical agent for plant protection (Tab. 1).

Conclusion

By analyzing the work of three different types of sprayers (I, II, III) in two different modes engine, and RPM PTO (300 min^{-1} and 540 min^{-1}) can be concluded that all three sprayers showed different results. The better work quality had sprayer I ("Agromehanika" Kranj), which had the lowest average value of liquid flow and the smallest variation from the average value in both modes. Sprayer II ("Morava", Požarevac) had the greatest variation. Sprayer III ("Fischer", Switzerland) had the highest average value of the flow of fluids in both RPM PTO. Quality of work sprayers depends on the proper setting mode sprayers, as well as the choice of nozzles, and the quality and type of nozzles. Defective nozzles represent the biggest problem for the proper functioning of machines for plant protection. By reducing the quantity of chemical mixture reduces overall costs, and also increases the profit in agricultural production. All this justifies the use of measuring equipment for testing the safety of the device for the application of pesticides, because measuring the exact set up any deviation and irregularity in work.

Acknowledgment

This study was supported by the Ministry of Education, Science and Technological Development of the Republic of Serbia, Project No TR – 31057, as well as Ministry of Agriculture and Environment of the Republic of Serbia and the Ministry of Agriculture, Food and Forestry Policy of the Republic of Italy.

Abstract

Hazelnut (*Corylus avellana* L.) is one of the most important tree nut crops in Turkey. As having the 80% of world production area, it has the leading position in production and export of hazelnuts. Although there are 16 licensed provinces for growing hazelnut in Turkey, the majority of production is carried out in six provinces including Ordu, Giresun and Trabzon. This study was conducted in 2008 in hazelnut growing areas in provinces Ordu, Giresun and Trabzon in Black Sea Region in order to determine hazelnut kernel defects and associated fungi. Survey was carried out on 221 hazelnut orchards in July-August, near harvest time. Total of 5886 nuts derived from 1750 fruit clusters were dried and stored at room temperature in open air and then examined for kernel defects. The main observed defects were blank, blank and moldy, decayed or moldy kernel, brown spot in internal cavity and spotted kernel. Fungi from these defected kernels were isolated, counted and their incidence was calculated as a percent of total isolated fungi. Total of 65 fungal isolates belonging to 9 genera were isolated from defected kernels. The incidence of *Cladosporium* spp. (24.62%) had the highest rate, and was followed by *Penicillium* spp. (20.00 %) and *Trichothecium roseum* (18.46%). The incidence of *Aspergillus* spp. was relatively low with 7.69%.

Keywords: *Hazelnut, Kernel defects, fungi, Black Sea Region*

Introduction

Hazelnut (*Corylus avellana*) is one of the most important tree nut crops in Turkey. As having the 80% of world production area, it has the leading position in production and export of hazelnuts (Anonymous, 2015a). It is not only one of the most important export crops for Turkey, but also the main economical activity for near 400000 households under the form of family farmer in the Black Sea Region (Tanrıvermiş *et al.*, 2006). Hazelnut production in Turkey extends along the Black Sea region, from Georgia border at east, to Istanbul at west. In terms of provinces, although 33 provinces have hazelnut growing areas, 16 of them are licensed for growing hazelnut. Almost all production (90 %) is carried out in six provinces: Ordu, Giresun, Trabzon, Samsun, Sakarya and Düzce (Anonymous, 2015b).

Insect pests, diseases, environmental factors and growing techniques can be major constraints for hazelnut production. Many fungal, bacterial and viral diseases cause crop losses in hazelnut orchards when environmental condition favours disease development and spread. Main fungal hazelnut fruit diseases in the world are brown rot caused by *Monilia fructigena* and *M. laxa*, anthracnose caused by *Gloeosporium coryli*, fruit rot caused by *Botrytis cinerea* (Belisario and Santori, 2009), gray fruit necrosis caused by *Fusarium lateritium* (Santori *et al.*, 2010). In Turkey, *Botrytis cinerea*, *Monilia fructigena* or *M. coryli* were previously determined as hazelnut fruit diseases agents in Bolu, Zonguldak and Bartın provinces (Yürüt *et al.*, 1994). *B. cinerea* was

the most important and the most prevalence disease for hazelnut fruit clusters during 2008-2009 surveys conducted in Ordu, Giresun and Trabzon provinces (Sezer and Dolar, 2012).
There are several types of defects for nut of hazelnut including blank, moldy kernels, black tips, doubles, shrivelled kernels, poorly filled nuts, brown stain, brown stain in kernel cavity, kernel spot. While some of them are considered as physiological disorders, certain are associated with some fungi and some insect pests (Mehlenbacher and Pscheidt, 2002; Doster *et al*., 2002; Romero *et al.,* 2001; Romero *et al*., 2009; Maness, 2005; Tuncer *et al*., 2009). The severity of kernel decay varies from year to year with average 0.5-1% and losses in individual hazelnut orchards. In Oregon (USA) frequently reach 3-10% (Doster *et al*., 2002).
The objective of this research was to determine hazelnut kernel defects and associated fungi in provinces Ordu, Giresun and Trabzon, which are important as hazelnut growing areas in Turkey.

Materials and methods

Survey, sample collection and preparation for examination

Survey was carried out in 221 hazelnut orchards in July-August in 2008, near harvest time, in 19 district in Ordu, 12 district in Giresun and 11 district in Trabzon provinces in Black Sea Regions (Figure 1). Total of 1750 healthy-looking fruit clusters externally were picked up from trees. Nuts (total 5886) were separated from husk by hand and dried at room temperature in open air for several days. Nuts were stored the same condition until examination.

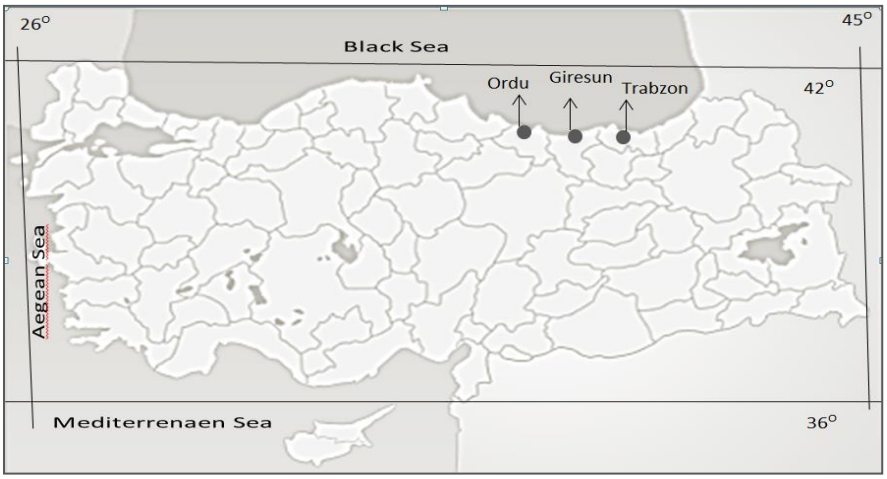

Figure 1. Survey area in Turkey: provinces Ordu, Giresun and Trabzon

Determination of defects

Whole nuts were manually shelled using wooden hammer and kernels aseptically removed and evaluated for defects. After detection of blank, blank and moldy, decayed or moldy kernels, other kernels were cut for internal defects such as brown spot in internal cavity, spotted kernel, black tip etc. Nuts were scored for frequency of observed defects.

Fungal isolation and identification

Nuts with defects were surface-sterilized with 0.5-1% (w/v) sodium hypochlorite for 1-2 min before placed on potato dextrose agar (PDA, Merck) that contained streptomycin. Fungal parts (spores or hyphae) were plated directly to the same medium from kernels with obvious fungal growth on. Single spore isolates from fungal cultures were incubated at 23±1°C with a 12-h photoperiod for 3-5days and stored on PDA slant tubes at 4°C.

For identification at the genus level culture morphology and conidial morphology were observed from 7-10 day-old cultures grown on PDA (Booth, 1971; Ellis, 1976; Sutton, 1980; Nelson *et al*., 1983; Anonymous, 2011c).

Pathogenicity tests

At pathogenicity tests inoculations were performed using both mycelial culture disk and conidial suspension of fungi. After disinfesting their surface with a cotton ball with 70% ethanol (Merck), good looking kernels were divided in half and placed in 9 cm petri dishes containing sterile filter paper moistened. Each kernel part was inoculated by placing a mycelial disc (3 mm) from an actively growing edge of the 10-day-old fungal culture or dropping 10 µl conidial suspension ($1x10^3$-$1x10^6$conidia/ml) on center of each half. PDA discs or sterile distilled water were used as controls. After incubation at 25±2^{o}C, for 7 days and 12 h photoperiod, symptoms were assessed and re-isolations were performed.

Results and discussion

A total of 1750 fruit clusters were picked up from 221 hazelnut orchards in provinces Ordu, Giresun and Trabzon in 2008. In total 5886 nuts derived from these fruit clusters were examined for kernel defects. The main noticed defects were blank means a nut containing no kernel or a kernel filling less than one-fourth the capacity of the shell. Some of these blanks had visible fungal growth on, categorized as blank and moldy while some not and were blank. Decayed or moldy kernel, brown spot in internal cavity and spotted kernel were found as other defects (Figure 2). Rate of blanks and kernel with brown spot in internal cavity were 15.85% and 2.36% respectively. Rate of the others were less than 1% (Table 1).

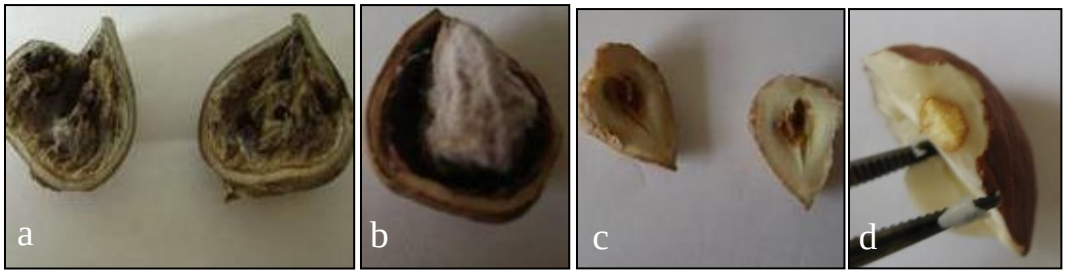

Figure 2. Kernel defects in hazelnut: a. Blank and moldy, b. decayed/moldy kernel, c. brown spot in internal cavity, d. spotted kernel

A total of 65 isolates belong to 9 fungal genera (*Acremonium, Aspergillus, Cladosporium, Fusarium, Penicillium, Pestalotiopsis, Phomopsis, Rhizopus* and *Trichothecium*) were isolated from defective kernels. Identification was made at genus level except *Trichothecium roseum*. *Cladosporium* spp. were the most common isolated fungi from defective kernels with 24.62% frequency. It is isolated from all defect types. According frequency of appearance *Cladosporium* spp. was followed by *Penicillium* spp. (20.00%) and *T. roseum* (18.46%). Fortunately, the incidence of *Aspergillus* spp., (some of them may produce aflatoxin) was relatively low with frequency of 7.69%. The rates for *Fusarium* spp. and *Pestalotiopsis* spp. were the same, 9.23%. The fungi belongs to genera *Phomopsis, Rhizopus* and *Acremonium* were isolated in very low level (6.15% for *Phomopsis*, 3.02% for *Rhizopus* and 1.54% for *Acremonium*, respectively).
Cladosporium spp., *Penicillium* spp. and *T. roseum* were isolated from all defects. Although these three were isolated from kernels with brown spot in internal cavity symptom, this sypmtom

is considered as a physiological disorder and the main cause agent is not known yet. It seems that the disorder could be related to some enzymatic process that could be affected by temperature (Romero *et al*., 2009). Regarding spotted kernel, in this study a total of 22 isolates belong to 6 fungal genera (*Aspergillus*, *Cladosporium*, *Fusarium*, *Penicillium*, *Phomopsis* and *Trichothecium*) were isolated. This symptom is associated generally with bugs mostly belong to Pentatomidae, Coreidae and Acanthosomatidae families of the order Heteroptera (Tuncer *et al*., 2005; Tuncer *et al*., 2009). On the other hand, in Italy and Oregon (USA) it is stated that the same symptom was consistently associated with *Nematospora coryli*, an ascomycetous yeast (Doster *et al*., 2002).

Table 1. Numbers and percentage of kernel with different defects

Provinces	Number of Examined Nut	Number of Blank	Rate (%)	Number of Blank and Moldy	Rate (%)	Number of Decayed or Moldy Kernel	Rate (%)	Number of Brown Spot in Internal Cavity	Rate (%)	Number of Spotted Kernel	Rate (%)
Ordu	2838	366	12.9	6	0.21	13	0.46	91	3.21	27	0.95

Total	12	17	14	22	65	100

In Turkey *T. roseum*, *Dothiorella* sp. and *Cryptostictis* sp. was determined in a past on decaying hazelnut fruits (Bremer 1948). Eke (1984) stated that *T. roseum* is one of the most frequently encountered species inside the shell during harvest, drying and storage of hazelnut. In addition to its mycotoxigenic character, it produces enzyme lipase which hydrolyses fat to produce free fatty acids which causes bitterness and effects badly the quality and taste of hazelnut (Sipahioglu and

Heperkan 2000).While Karahan *et al*., (1978) have found hazelnut kernel contaminated with *Aspergillus* spp. and *Penicillium* sp. at high rate, they determinated *Cladosporium* spp., *Cephalosporium* spp., *Alternaria* spp., *Rhizopus* spp., *Mucor* spp., *Trichothecium roseum*, *Fusarium* spp., *Pestalozzia* spp., *Verticillium* spp., *Oospora* spp., *Macrosporium* sp., *Botryodiplodia* sp., *Glomerella* sp., on kernels also.

Pathogenicity tests were conducted in this study with most isolated fungi: *Cladosporium* sp., *Penicillium* sp. and *T. roseum*. In both methods (either using mycelial culture disk or conidial suspension of fungi) from the second day on, fungal growth was visible. Almost all fruit surface was covered with mycelium on the seventh day and rot in inner tissue was found (Figure 2). However, sypmtoms similar to original symptoms like spotted kernel or brown spot in kernel cavity were not detected in this experiment. It is difficult to decide certainly if these fungi (*Cladosporium* sp., *Penicillium* sp. and *T. roseum*) were causal agents or not for spotted kernel or brown spot in kernel cavity. Regarding hazelnut kernel decay, it is known that *Ramularia* sp., has been associated with necrosis of kernel tips, *Phomopsis* sp., *Septoria ostryae* are associated with internal discoloration and *Nematospora coryli* with kernel spot, but their pathogenicity has not been proved yet (Doster *et al.*, 2002).

Figure 2. Symptoms caused by: *Trichothecium roseum* (a), *Penicillium* sp. (b), *Cladosporium* sp, control (d) at pathogenicity test

Conclusion

In the study conducted in provinces Ordu, Giresun and Trabzon in order to determinate kernel defects and associated fungi, the main detected defect was blank. The others were brown spot in internal cavity, spotted kernel, decayed or moldy kernel, and blank or moldy kernel, respectively. Total of 65 associated fungal isolates belonging to 9 genera were isolated from defected kernels. *Cladosporium* spp., *Penicillium* spp. and *T. roseum* were most common isolated fungi. The incidence of *Aspergillus* spp., was relatively low. Pathogenicity of fungi associated with brown spot in internal cavity and spotted kernel was not proved with pathogenicity test. Therefore, more comprehensive studies started in the orchard are needed in future.

THE COMBINE EFFECTS OF EICOSANOID BIOSYNTHESIS INHIBITORS AND TWO NATIVE ISOLATES OF BEAUVERIA BASSIANA ON MORTALITY OF SPODOPTERA LITTORALIS LARVAE

Hasan TUNAZ*, Ali A. IŞIKBER, Mehmet Kubilay ER

Abstract

In this study, the effect of *B. bassiana* isolate (6646) was expressed in a time dependent manner on mortality of the larvae although the effect of *B. bassiana* (3288) isolate on mortality was lower. When *B. bassiana* (6646) isolate was co-injected with the eicosanoid biosynthesis inhibitors (phenidone dexamethasone, naproxen, indomethacin, esculetin, ibuprofen) with different modes of action it caused an increased and faster mortality of the larvae. Similarly, increasing phenidone (eicosanoid biosynthesis inhibitor) dosages were associated with increasing mortality of the larvae co-injected with *B. bassiana* (6646) isolate. These findings support that virulent effects of entomopathogen, *B. bassiana* (6646) can be increased when *S. littoralis* immune systems were suppressed and that increased effects of microbial control of pest insects.

Keywords: *Nodulation; eicosanoid; Beauveria bassiana; Spodoptera littoralis.*

Indroduction

Two categories of immunity to microbial infections, humoral and hemocytic were expressed by insects (Gillespie *et al*., 1997; Stanley, 2000). Humoral immune reactions involve induced biosynthesis of anti-bacterial proteins (Leulier *et al.,* 2003; Stanley and Miller, 2006). Hemocytic immune reactions involve direct interactions between circulating hemocytes and infecting microbes (Stanley and Miller, 2006). These immune functions are well known and the contemporary research frontiers reveal information on the signal mechanisms responsible for mediating and coordinating insect immunity.

Stanley-Samuelson *et al* (1991) first s suggested that eicosanoids mediate one or more cellular reactions responsible for clearing bacterial infections from hemolymph circulation. This suggestion prompted more detailed research meant to determine which of the several cellular defense reactions depend on eicosanoid biosynthesis. Because nodulation is the predominant cellular immune reaction to bacterial infections, it has been hypothesized that eicosanoids mediate nodulation reactions to bacterial infections (Miller *et al.,* 1994). On the basis of these findings, Stanley and his colleagues developed the hypothesis that eicosanoids mediate nodulation reactions to bacterial infections in most, if not all, insect species, now known as the eicosanoid hypothesis (Stanley, 2000). Several research groups have tested the hypothesis for about 20 insect species, as summarized in reviews (Stanley, 2006; Stanley and Miller, 2006). All experimental work has strongly supported the idea.

Connick *et al* (2001) tested role of eicosanoid biosynthesis inhibitors (EBIs) when co-applied with the pathogenic bacterium, *Serratia marcescens* for insect pest control. They reported increased mortality of the termites; *Coptotermes formosanus* when the bacteria were co-applied with eicosanoid biosynthesis inhibitors. Similarly, Tunaz (2006) tested influence different fungal

species on nodule formation and on mortality of *P. brassicae* larvae and to determine whether injecting *P. brassicae* larvae with EBIs plus fungus would influence larval mortality. Again his result showed that increased and faster mortality of *P. brassicae* larvae was seen when the fungi were co-applied with eicosanoid biosytnhesis inhibitors. To continue developing the idea that EBIs can influence mortality in infected insects, the objectives of this study were to determine the influence two native isolates of *B. bassiana* on mortality of *S. littoralis* larvae and to determine whether injecting *S. littoralis* larvae with EBIs plus *B. bassiana* would influence larval mortality.

Materials and Methods

Organisms

S. littoralis were reared on a culture (38 g agar, 2600 ml distil water, 300 g corn flour, 120 g wheat embryo, 100 g yeast, 20 g casein, 14 g wesson salt, 8 g sorbic acid, 4 g nipagin, 600 mg streptomisin, 18 g ascorbic asid and 80 mg vitamin complex) and maintained in the laboratory at 25±2 °C and 65±5% relatıve humidity (RH). The larvae (5. instars) were tested for each bioassays at 25 ± 2 ^{o}C and 65 ±5 % RH. The entomopathogenic fungus, *B. bassiana* (3288, 6646) isolates were used in this study. The isolates were grown at 25 ^{o}C on potatoe dextrose agar (PDA) for 30 days. Conidia were harvested from these plates in sterile distilled water containing 0.1 % Tween 80 and vortexed vigorously.

Reagents

The phospholipase A_2 (PLA_2) inhibitor dexamethasone {(11β, 16α)-9- fluoro-11,17,21-trihydroxy-16-methylpregna-1,4-dione}, the cyclooxygenase inhibitors naproxen, indomethacin and ibuprofen {O-2-(6-methoxy-naphthyl) propionic acid}, the dual cyclooxygenase and lipoxygenase inhibitor phenidone {1-pheny-3-pryazolidinone}, and the 5- and 12-lipoxygenase inhibitor, esculetin {6,7-dihydroxycoumarin} were all purchased from Sigma Chemical Co. (St. Louis, MO).

Influence of two different isolates of *B. bassiana* on mortality of *S. littoralis* larvae

Larvae were applied with individual isolates($1x10^7$ conidiaspor/ml for each isolates). Control insects were applied with 0.021 % Tween 80 solution. After application, the larvae were kept on room temperature. Mortality was assessed at selected times after injections.

Effects of eicosanoid biosynthesis inhibitors on mortality of *S. littoralis* larvae when co-injected with *B. bassiana* isolate (6646)

S. littoralis larvae were divided into groups and individuals in each group were injected with either the phospholipase A_2 (PLA_2) inhibitor dexamethasone, three of the cyclooxygenase inhibitor, naproxen, ibuprofen and indomethacin, the dual cyclooxygenase and lipoxygenase inhibitor phenidone, or the lipoxygenase inhibitor esculetin, all in standard dosages of 104 µg in 4 µl EtOH. Control insects were injected with 4 µl EtOH. Following injections, the larvae were injected with $1x10^7$ conidiaspor/ml in 5 µl 0.021 % Tween 80 solution. After injection the larvae were kept on room temperature as described. Mortality was assessed at selected times after injections as described above.

Influence of phenidone (eicosanoid biosynthesis inhibitor) dosages on mortality of *S. littoralis* larvae when co-injected with *B. bassiana* isolate (6646)

Individuals in five groups of larvae were injected with 4 µl of ethanol, or 52, 104, 156, 208 µg of phenidone in 4 µl ethanol, then infected with a standard concentration of *B. bassiana* isolate (6646**)**. At 24 hpi, mortality was assessed.

Results and Discussion

Effects of different isolates of *B. bassiana* on mortality of *S. littoralis* larvae

Table 1 indicates that compared to control, two isolates of *B. bassiana* caused higher mortality of *S. littoralis* larvae at each time. At day 9, control caused no mortality of larvae of *S. littoralis* whereas the isolate (6646) of *B. bassiana* caused approximately 67 % mortality of the larvae.

Table 1. The influence of two different isolates of *B. bassiana* on mortality of *S. littoralis* larvae

***B. bassiana* Isolates**	**Time (days)**			
	3	**5**	**7**	**9**
6646	33,33±3,33[a]	60,00±0,00[a]	66,67±3,33 [a]	66,67±3,33[a]
3288	6,67±3,33[b]	26,67±6,67[b]	33,33±8,82[b]	33,33±8,82[b]
Control	0,00±0,00[c]	0,00±0,00[c]	0,00±0,00[c]	0,00±0,00[c]

[a]Mean number in a column followed by different letters are significantly different (P <0.05)

Effects of co-injected *B. bassiana* isolate (6646) and EBIs on mortality of *S. littoralis* larvae

EBIs strongly enhanced absolute mortality and the speed of kill due to *B. bassiana* isolate (6646) challenge (fig. 1). Higher mortality obtained in larvae treated with the all inhibitors except dexamethasone plus the concentration ($1x10^7$ spor/ml) of *B. bassiana* isolate (6646) by 72 h PI. Lower mortality was recorded in the control and the inhibitor, dexamethasone at 72 h PI.

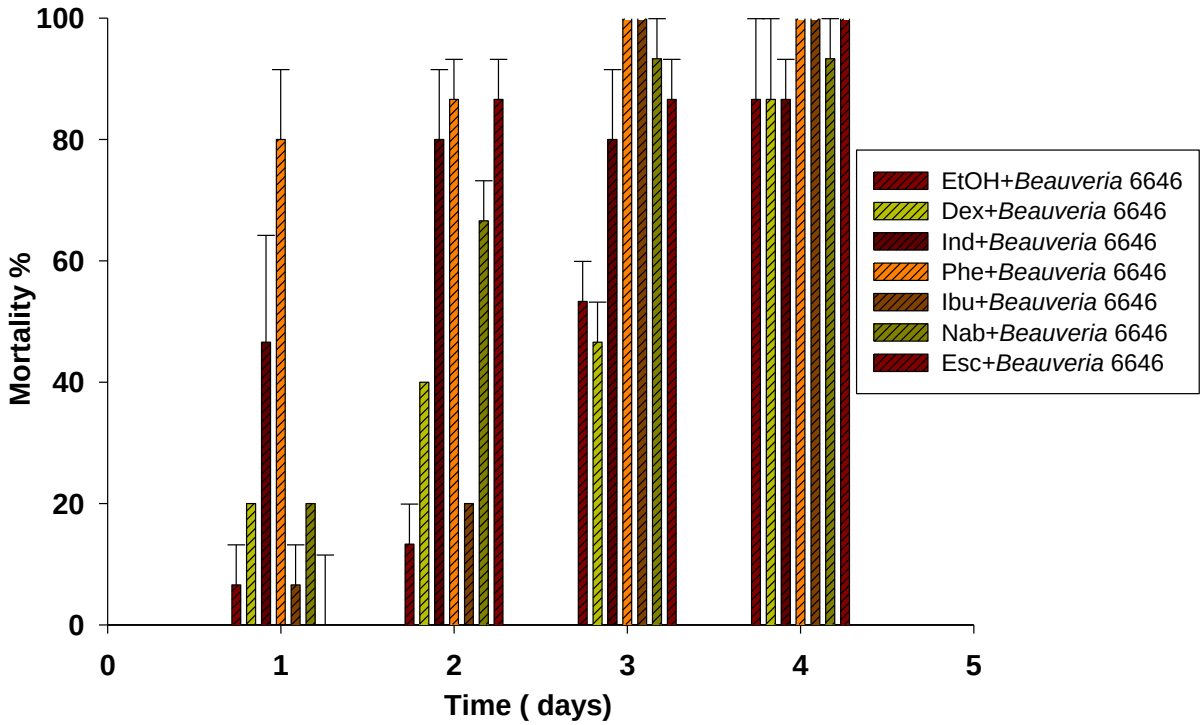

Figure 1. Effect of eicosanoid biosynthesis inhibitors on mortality *S. littoralis* larvae infected with of *B. bassiana* isolate (6646)

Influence of phenidone (eicosanoid biosynthesis inhibitor) dosages on mortality of S. littoralis larvae when co-injected with *B. bassiana* isolate (6646)

Figure 2 indicates that the mortality due to phenidone was express in a dose-dependent manner. Increasing phenidone (eicosanoid biosynthesis inhibitor) dosages were associated with increasing mortality activity of the larvae co-injected with *B. bassiana* (6646) isolate.

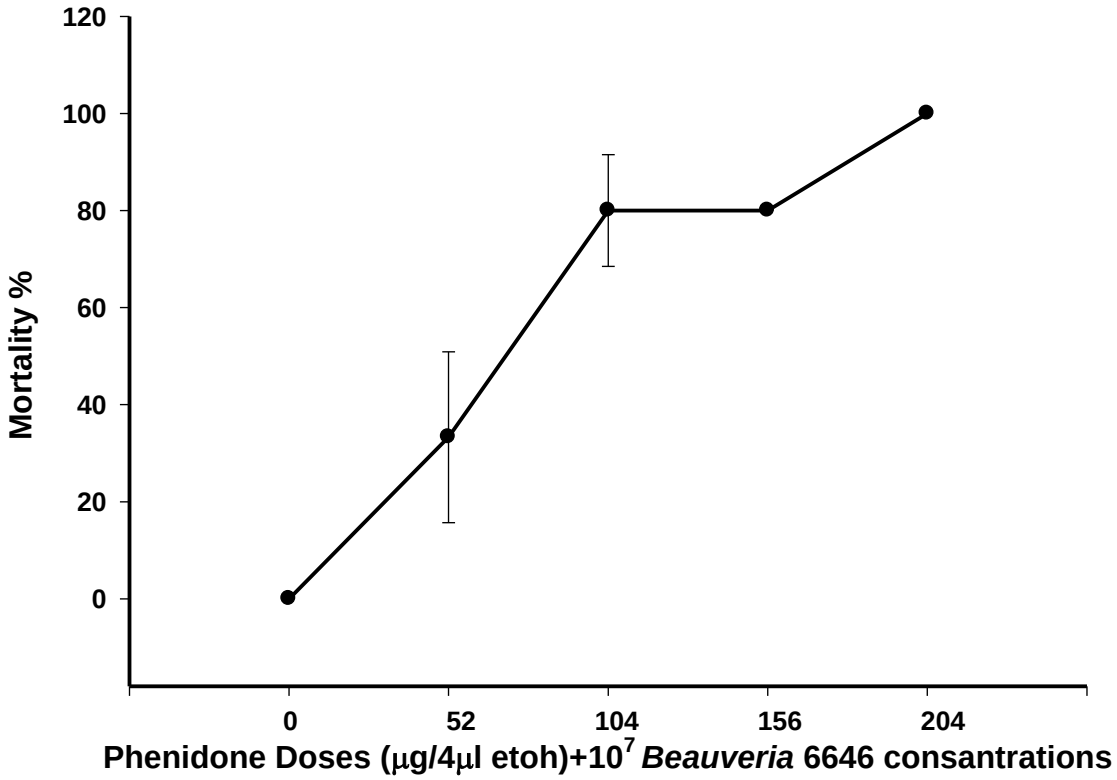

Figure 2. Influence of phenidone dosages on mortality of *S. littoralis* larvae when co-injected with *B. bassiana* isolate (6646)

The data reported in this work support the idea that EBIs significantly increased insect larval mortality due to the pathogenic fungal challenge. First, compared to control, two isolates of *B. bassiana* caused higher mortality of *S. littoralis* larvae at each time. Second, treating the larvae with any of six EBIs except dexamethasone substantially increased mortality due to the fungal challenge. Third, increasing phenidone (eicosanoid biosynthesis inhibitor) dosages were associated with increasing mortality activity of the larvae co-injected with *B. bassiana* (6646) isolate. We infer from these data that disabling immune signaling by inhibiting eicosanoid synthesis renders insects unable to protect themselves from fungal challenge and that the lack of immune protection is lethal. The idea that eicosanoids mediate insect cellular immunity was first suggested by Stanley-Samuelson et al (1991). They showed that when eicosanoid biosynthesis is inhibited by EBIs, *M. sexta* larvae could not clear the pathogenic bacterium, *S. marcescens* from their hemolymph. More important, this situation increased insect mortality. Since this first paper, several laboratory groups have indicated eicosanoids are involved in nodulation formation (Stanley, 2006; Stanley and Miller, 2006). There is now considerable evidence for the involvement of eicosanoids in insect immune reactions to bacteria, fungal, protozoan and parasitoid challenge in a wide range of insects. Tunaz (2006) tested influence of different fungal species on nodule formation and on mortality of *P. brassicae* larvae and tried to determine whether injecting *P. brassicae* larvae with EBIs plus fungus would influence larval mortality. The result showed that increased and faster mortality of *P. brassicae* larvae was seen when the

fungi were co-applied with eicosanoid biosytnhesis inhibitors. Similar to this work, we suggested that there were synergestic effects of EBIs with the fungus, *B. bassiana* (6646) isolate on mortality of *S. littoralis* larvae. The pharmacological chemicals we used inhibit different eicosanoid biosynthetic pathways in mammals. Dexamethasone inhibits phospholipase A_2 which releases arachidonic from membrane phospholipids; naproxen inhibits cyclooxygenase; esculetin inhibits lipoxygenase; and phenidone inhibits both cyclooxygenase and lipoxygenase (Stanley, 2000). Hence, because all the inhibitors we tested enhanced the susceptibility of *B. germanica* to the injected bacteria, it is possible that both cyclooxygenase and lipoxygenase pathways are involved in mediating the immunomodulatory effects of eicosanoids in this insect.

Conclusion

Virulent effects of entomopathogenic fungi, *B. bassiana* (6646) can be increased when *S. littoralis* immune systems were suppressed by EBIs and that increased effects of microbial control of pest insects. From these data, we can conclude that disabling immune signaling by inhibiting eicosanoid synthesis renders insects unable to protect themselves from fungal challenge and that the lack of immune protection is lethal.

Abstract

The aim of this work was to assess the profile of volatile compounds changes during the cold storage in 'Pink Lady' apples. Six-year-old Cripps Pink (Pink Lady) apple trees grafted onto M9 rootstock were used as a plant material for this study. The trees were in a commercial orchard in Çanakkale-Turkey. Fruits were carefully picked up by hand at the commercial harvesting time. The fruits were dipped into calcium oxide solutions (concentrations of 2 and 4%) during three minutes. Control fruits were exposed to distilled water. Fruits were stored at 0 °C and 90% relative humidity for 6 months. The aroma volatile content of apples determined by GC/MS (Gas Chromatography/Mass Spectrometry) analysis followed by liquid-liquid extraction. Stored fruits were analyzed immediately for their volatile contents at the 2nd, 4th and 6th months. Fresh fruits at the initial stage contained 15 aroma volatile content in total. However, higher levels of aroma volatile compounds were detected after 6 months of cold storage. According to the chromatography results, control fruits had 24 volatiles, 2% CaO treated fruits had 25 volatiles and 4% CaO treated fruits had 27 volatiles at the end of 6 months of cold storage. Apples at the initial stage produced an abundance of hexyl acetate (4.56%), butyl acetate (3.83%), and hexanoic acid hexyl ester (1.68%), which confer typical apple aroma characteristics. Mostly, ester production exhibited a fairly broad peak, declining as fruit aged. Propanoic acid 2-methyl-2-propenyl acetate (initial 0.548%) was lower at the beginning of the storage compare to the end of storage (control fruits 0.064%, 2%CaO 0.127%, 4% CaO 0.203%). CaO applications especially 4% concentration had deformation effect on epidermal layer cells on fruit surface. As a result, CaO applications had a significant effect on aroma enhancement in Pink Lady apples.

Key Words: *Pink Lady, Apple, Calcium oxide (CaO), Aroma volatile, GC/MS*

Introduction

Production of aroma volatile compounds is an important factor determining quality of fruit produce and is directly influenced by fruit maturity (Mattheis *et al*., 1991). Flavor is one of the most important criteria of fruit quality. The formation of flavor and aroma compounds in fruits is a dynamic process, volatile substances are continuously synthesised and developed during fruit growth and ripening. Volatile composition changes qualitatively and quantitatively (Amira, 2011). Aroma compound analysis plays an important role in the process of quality apple breeding. The aroma of a fruit is the result of a complex mixture of esters, alcohols, aldehydes, terpenoid compounds, etc. (Nie *et al*., 2006).

Increment in tissue Ca content by postharvest Ca treatment reduces disorders and maintains storage quality of whole fruit including apple (Saftner *et al*., 1998), ethylene production (Conway and Sams, 1987), to inhibit respiration and ethylene production rates and to persistent inhibitory

effect on volatile production (Brackmann, 1993), the factor considered most likely responsible for diminished apple flavor (Knee and Hatfield, 1981). Postharvest injection of $CaNO_3$ solution into the core of apples has been shown to nonsignificantly inhibit quality-associated volatile production (Wills, 1972). Genotype is a major factor accounting for the phenotypic differences in the composition of the volatile fraction emitted by fruit, as significant qualitative and quantitative variation is found among apple and pear cultivars (Young *et al.*, 2004).

'Pink Lady', is very popular, late maturing apple (*Malus* × *domestica* Borkh.) cultivar increasingly grown in many apple-producing areas of the world owing to its excellent flavor and sensory attributes. Commercial interest is thus focused on developing suitable criteria for harvest maturity as well as appropriate storage procedures in order to assure quality of final produce (Villatoro *et al.*, 2008). It is firm, has fine dense flesh, is crisp and juicy, excellent flavor (Corrigan, 1997). Production of aroma volatile compounds is an important factor determining final sensory quality of fruit produce and hence consumer satisfaction and influenced by maturity (Mattheis, 1991). Whereas deficient aroma volatile production in immature fruit, suggested to arise from low rates of precursor synthesis, is gradually overcome as fruit approach the optimal harvest date (Song and Bangerth, 1994),

In this study, 2% and 4% CaO treated fruits are stored at the cold storage during the 6 month. 2^{nd}, 4^{th} and 6^{th} month aroma volatile compounds were detected by GC-MS. It is investigated differences aroma volatile content among treatments and storage period.

Materials and Methods

Fruit source

Six year old Cripps Pink (Pink Lady) apple trees which grown in a commercial orchard (40°24'04" N and 26°24'35" E, just 35 m above sea level) in Çanakkale (Turkey), were used as plant materials for this study. The trees were randomly selected from unblemished trees showing general characteristics of the apple cultivar. The fruits were carefully harvested by hand. Starch content of the harvested apples was determined by standard procedures using a starch index (1 to 8, Generic Starch Iodine Index Chart for Apples). When the average starch index reached 5, the fruits were picked up for the experiment.

Control fruits of Pink Lady apple cultivar were exposed to distilled water. Experiment fruits were dipped into solutions of calcium oxide (both at the concentrations of 2 and 4%). The fruits stored later at 0°C and 90% relative humidity for 6 months. Aroma volatiles contents were analyzed on the fruits taken out of at the 2^{nd}, 4^{th} and 6^{th} months.

Aroma volatile content

The aroma volatile content of the stored apples was determined by GC/MS analysis followed by liquid-liquid extraction. Liquid-liquid extraction was performed by use of diethyl ether solvent. Each extraction included two replications and each replication contained 100 g apple puree obtained by using a liquidizer (homogenizer). 100 mL diethyl ether solvent was added into the Erlenmeyer flask with 100 g apple puree. After solvent treatment, the extract was concentrated to 1 mL with a centrifuge and concentrator. Then the solvent was directly injected into a gas chromatograph for α volatile compound (Solis-Solis *et al.*, 2007).

The amount of the aroma volatile determined with a gas chromatograph-mass spectrometer (Shimadzu QP2010 GC/MS) fitted with a DB-WAX column (30 m x 0.25 mm ID, 0.25 µm film thickness; J & W, USA). Identification of volatile content was carried out by mass spectrometry using a mass spectrometer set at 280 °C of capillary direct interface temperature,

the ionization energy of the mass spectrometer was programmed for 70 eV. Also the ion source temperature was set at 250 $^{\circ}$C and 40-350 amu of mass interval and 666 amu s^{-1} scan rate. WILEY and NIST libraries were used for identification of compounds. One microliter samples were injected in 1:50 split ratio (with 280 ^{o}C injection temperature) by an auto injector. Firstly, the column temperature was set at 40 ºC for 2 min. After the column reached at 280 $^{\circ}$C by 10 $^{\circ}$C min^{-1} and held for 10 min

Results and Discussion

15 volatile compounds were detected at harvest stage of apples (Table 1). The compounds were consisting of 5 alcohols (61.06 %), 6 esters (11.679%), 1 aldehyde compound (0.540%), 1 alkane (0.848%), 2 other compounds (25.869%). The alcohols were ethyl alcohol (0.040%), 1-propanol (0.0687%), 1-hexanol (5.414%), 1,3-Octanediol (2.321%), and 10-nonadecanol (52.602%). The esters were buthyl ester of hydroxyacetic acid (0.677%), buthyl aceate (3.862%), hexyl acetate (4.604%), 2-methyl-2-propenyl ester (0.548%), propanoic acid 1-methyl ester (0.309%), hexanoic acid hexyl ester (1.680%).The aldehyde was trans-4-hexenal (0.541%) andhe other compounds were toluene (1.027%) and alpha farnasene (24.842%).

According to the obtained results of storage periods, volatile compounds were changed in both of qualitative and quantitatively. While initial alcohol content was around 61.06%, its content decreased at the 2nd month of storage. Control fruits were more alcohols levels than CaO treatments (Table 1). Total alcohol content increased at the end of 4th and 6th month storage. However, among the treatments resulted similarly. Ethyl alcohol has increased significantly, during the storage period. Especially, 4th and 6th month resulted higher level of ethyl alcohol. Control fruits were resulted 64.192% while 2% CaO 63.106%, 4% CaO 56.784% showed the lowest content of ethyl alcohol. Initially, nonadecanol was observed at very high amounts. But, according to analysis 2nd month were not detected for nonadecanol. 4th and 6th month increased too slight. Alcohol precursors paralelled that of the corresponding esters for 'Gala' (Fellman, 2000) and Fuji (Lara, 2006).

Ester compounds were largely predominant in the aroma profile. In this research ethyl acetate were not determined at harvest time. 2nd and 4th month increased. But, end of the 6 month haven't observed. The maximum level of ester compounds obtained at 4% CaO (3.790%) end of the 4th month. Control fruits (3.320%) and % CaO (3.106%) were lower. 1-chloroethyl acetate is determined only, end of the storage. 4% CaO, 2% CaO and control (0.117%, 0.104% and 0.089%) fruits were given respectively.

The beta-oxidation pathway provides alcohols and acyl co-enzyme, acyl (CoA), which are the main precursors for volatile ester production. Acyl CoAs are reduced by acyl CoA reductase to produce aldehydes, which in turn are reduced by alcohol dehydrogenase (ADH) to form alcohols that are converted to esters via the action of aspartate amino transferase (AAT) (Song and Bangerth, 1994)

At harvest time, individual straight chain 2-methylbutyl acetate were high (3.862%). During the cold storage, buthyl acetate content slightly decreased. 2nd and 4th month 4% CaO higher than 2% CaO and control fruits. End of the storage, 2% CaO more than, 4% CaO and control fruits (Table 1). CaO treatments have not effective on reducing of buthyl acetate. On the contrary, it caused increasement of ester. 3-methyl-buthyl acetate was not determined at harvest time. 2nd and 4th month was seen in the experiment. 2nd month 4% CaO, 4th month 2% CaO applications were higher compound.

2-methyl-butyl ester was not determined at harvest time. 2nd month only 4% CaO application gave a low level of compound (0.246%). 4th month 4% CaO (0.337%), 2% CaO (0.242%) and control fruits (0.234%) were given 2-methyl-butyl ester respectively.
2-propenyl ester, at harvest time hasnt determined. 2nd month, 2% CaO and 4% CaO 4th month, only 2% CaO treatments gave to 2-propenyl ester.
Hexyl acetate, at harvest time determined 4.604%. 2nd month increased of compound. 4% CaO treatment gave to high percentage (5.817%), control fruits (5.206%), 2% CaO (4.668) treatments respectively. 4th month, ester content decreased, 6th month, hasnt determined to hexyl acetate.
At harvest 2-hexenyl acetate hasn't determined. 2nd month 4% CaO higher compound content. 4th and 6th month, control fruits gave to higher 2-hexenyl acetate.
Propanoic acid hexyl ester was not determined at harvest time. 6th month, 4% CaO the highest compound propanoic acid hexyl ester determined. 2% CaO and control fruits gave to lower content. propanoic acid 1-methyl ester is determined only at initial.
Hexanoic acid buthyl ester was not determined at harvest time and 6th month. Second month 2% CaO, 4th month, 4% CaO treatments determined higher ester.
Butanoic acid hexyl ester was not determined at harvest time and 6th month. 2nd and 4th month control fruits were given higher ester.
Butyric acid 2-methy-hexyl ester was not determined at harvest time and 6th month. 2nd month control fruits, 4th month, 4% CaO treatments gave to higher butyric acid 2-methy-hexyl ester.
At the harvest time, 1.680% hexanoic acid hexyl ester determined. 2nd month 2% CaO (3.053%), 4th month, 4% CaO (4.011%), 6th month, 2% CaO (0.569%) treatments were higher than 4% CaO (0.533%) and control fruits (0.274).
Iso buthyl caprylate determinated end of the 2nd month, only 4% CaO treatments and 4th month, control and 2% CaO treatments.
Octanoic acid hexyl ester, 2nd month, 4% CaO, 4th month, control fruits were higher than 4% CaO and 2% CaO treatments. 6th month only control fruits showed to octanoic acid hexyl ester.
Cyclohexanol, 2-methyl, propionate has determined only end of the cold storage.
Total ester content examined in this research. 2nd month gave the 4% CaO, 4th month, control fruits, 6th month 2% CaO showed to higher content os esters during the cold storage.
Aldehydes examined totally in this research. At the harvest time, 0.541% aldehyde determinated. 2nd month, 4% CaO treatments (2.193%), 2% CaO (0.883), control (0.832) fruits were given respectively. 6th month, 2% Cao (9.902%), control (6.533%), 4% CaO (4.370%) showed respectively. The higher concentration of aldehydes was found to correspond with increased green/grassy odor of apple juice (Komthong *et al*, 2007). (E)-2-hexenal and the increased content of acetate esters which were well corresponded with the green and sweet aroma intensity, respectively (Komthong *et al*., 2006).
Initially alkane content was too low (0.848%). End of the storage, total alkane, 4% CaO (15.051%), 2% CaO (6.260%), control fruits (4.898%).
Other compounds are toluene, xylene and alpha farnesene. Especially, alpha farnesene was determined too high (25.868%). Its concentration was reduced during the storage. 2% CaO (4.484%), control fruits (3.257%), 4% CaO (2.665%) at the end of 6th month.

Conclusions

CaO solutions were not resulted in reduced total volatile levels. 2% CaO and 4% CaO treatments beyond 6 months storage, cause higher total volatile levels as those in the corresponding control fruit. The two concentrations of CaO used in this study had a similar effect on total volatile levels during cold storage. It can be concluded that CaO applications especially 4% concentration had

deformation effect on epidermal layer cells on fruit surface. As a result, CaO applications had a significant effect on aroma enhancement.

Abstract

In present study, residual toxicity of Spinosyn group insecticide, Spinosad solution was evaluated on chickpeas against adult of *Callosobruchus maculatus* (F.) under laboratory condition. In laboratory bioassay, *C. maculatus* adults on chickpeas were exposed to Spinosad at 6, 12, 24, 48, 72 and 108 ppm (mg active substance/l water/ 0.5 kg product) concentrations for 7 days. The concentration of spinosad suspension and the exposure period had a significant effect on paralysis and mortality rate of *C. maculatus* adults on chickpeas. %100 paralyze and mortality rate of *C. maculatus* adults were recorded on surface treated chickpeas at 48 ppm concentration of spinosad for 7 day of exposure. At 72 and 108 ppm of spinosad concentrations no progeny production was observed while at 48 ppm concentration progeny production was only 1 adult. These results indicated that spinosad treatment at 48 ppm and above concentrations achieved complete mortality and completely suppressed the progeny production of *C. maculatus*. In conclusion, surface treatment of spinosad would be potential of controlling major stored legume pest, *C. maculatus* and be an alternative to conventional synthetic insecticides.

Keywords: *Spinosad, Callosobruchus maculatus, chickpeas, residual toxicity*

Introduction

Cowpea weevil, *Callosobruchus maculatus* (Fab.) is the principal pest of stored chickpea (Iturralde-Garcia *et al*., 2016) and major pest for grain legumes in many tropical and subtropical countries (Singh, 1997). *C. maculatus* females lay about 50 eggs on each seed coat. Embryo development takes approximately 6 days, when larvae cross the seed coat and penetrates the cotyledons, where it feeds intensively to complete development. Adults emerge 25-30 days after oviposition (Credland, 1987; Southgate,1979) and rapidly engage in reproduction and egg laying. The larvae of *C. maculatus* feed on the grain, causing considerable damage, which produces qualitative and quantitative losses. Estimated annual losses caused by *C. maculatus* in West Africa alone exceed $ 50 million (Shade *et al*., 1986). At present, control of stored product insects is mainly based on the use of fumigants and residual insecticides, both of which pose serious hazards to mammals and the environment (Shaaya *et al*., 1997; Ren *et al*., 2008). Fumigation is still one of the most effective methods for prevention of storage losses. Phosphine and methyl bromide (MB) are the most common fumigants used for stored-product protection throughout the world. However, MB was phased out at end of the 2015 in all over the world and for phosphine insect resistance problem is a global issue now and control failures have been reported in field conditions in some counties (Taylor, 1989; Collins *et al*., 2002; Opit *et.al*., 2012; Saglam *et al*., 2015). One of the potential alternative insecticides for controlling stored product insects is spinosad which is member of the spinosyn group insecticides. Spinosad is an insecticide

product from Dow AgroSciences (Indianapolis, Indiana, U.S.A.), derived via fermentation from a naturally-occurring soil actinomycete, *Saccharopolyspora spinosa* Mertz and Yao (Bacteria: Actinobacteridae). Spinosad contains two insecticidal factors, spinosyns A and D, present in an approximately 85:15 % ratio in the final product (Mertz and Yao, 1990; Kirst *et al*., 1992; Sparks *et al*., 1999)

Spinosad is highly active by both contact and ingestion to numerous pests in the orders Lepidoptera, Diptera, Thysanoptera, Coleoptera, Orthoptera, Hymenoptera, and others (Sparks *et al*., 1995; Bret *et al*., 1997). It affects nicotinic acetylcholine and gamma amino butyric acid (GABA) receptors sites of the insect nervous system (Salgado and Sparks, 2005). Some of the most important properties of spinosad are low mammalian toxicity and a highly favorable environmental profile (Cleveland *et al*., 2001). Spinosad is also considered as a natural product and thus approved for use in organic agriculture by numerous national and international certification bodies (Racke, 2007). In present study, residual toxicity of spinosad solution was evaluated on chickpeas against *Callosobruchus maculatus* (F.) adults under laboratory condition.

Materials and methods

Insect culture*:* Insects were reared on *Cicer arietinum* L. *var. kocbasi* chickpea seeds in glass jars at 26 ±1 °C temperature, 65±5 % RH at laboratory condition. Insect cultures were maintained in on chickpeas in 1 liter glass jars under continuous darkness. New subcultures were established weekly, by removing approximately 100 beetles from each of the two oldest jars, the oldest then being discarded. In biological tests 2-3-day old adults were used.

Commodity: Uninfested and untreated chickpea (*Cicer arietinum* L. *var. kocbasi*) with 8±0.5 % of moisture content was used for the bioassays and insect rearing. The chickpeas was placed a freezer at -18 °C for one week to destroy any remaining insects before the seed was used for insect rearing and laboratory trials.

Insecticide and insecticide treatment: A suspension concentrate (SC) formulation of Spinosad (Laser 480 SC) that contained 480 g of active ingredient (AI) per liter and was supplied by Dow AgroSciences, UK was used for bioassays. 500 g of chickpea was sprayed with spinosad at seven concentration levels: 0 (control), 6, 12, 24, 48, 72 and 108 ppm (mg active substance/ l water/ 0.5 kg product). The spinosad SC formulation was suspended with distilled water to prepare each concentration and 1 ml of the appropriate suspension was sprayed in each lot. The insecticide application was made by using HSENG Airbrush AS18 model (Ningbo Haosheng Pnömatik Machinery Co., Zhejiong, China). To achieve even distribution of the insecticide, the bean was spread into a plastic tray (48 x 33 x 8 cm) providing a thin mono layer as a spraying surface. Then, the sprayed bean lots in the plastic tray were shaken manually for approx. 1 min to enhance the insecticide distribution. Additional lots of 500 g of chickpeas were sprayed with distilled water as a control treatment. After spinosad treatment, commodities were left one day for drying under laboratory conditions.

Bioassays: Cylindrical glass vials with 330 ml of capacity were used as the experimental units for bioassays. For each spinosad concentration, five samples, each of 100 g, were taken from each jar of treated bean and placed in vials. Then, 20 one to three-day old and mixed-sex adults of *C. maculatus* were introduced into each vial (separate vials for each concentration). All these vials were placed in incubators set at 25±1 °C, 65±5 % RH and continuous darkness. Dead (no motion) and paralysis (only moving antenna and legs) of the exposed individuals were recorded

after 1, 3, 5 and 7 day of exposure in the treated and untreated substrate. After the 7 day of exposure, all adults (dead or alive) were removed and the jars returned to the experiment conditions. Forty-two days later (Rees, 2004), adult progeny emergences (F_1) were counted in treated and untreated vials.

Data analysis: For each exposure time, mortality rate and paralysis rate of *C. maculatus* adults were calculated. Since control mortality was generally low, no correction was considered necessary. Arcsine transformation was applied to mortality and paralysis data and then were subjected by two-way ANOVA (factors: exposure time and concentration) (Proc GLM: Univariate, SPSS, 2009). For progeny production, one-way ANOVA was performed, by using the same software, with number of progeny as the response variable, and concentration as main effect. In this case, the number of progeny in the control vials was also included in the analysis. The means were separated using Duncan test at the 5% level (Proc CM: One-way ANOVA, SPSS Statics 18, 2009).

Results and discussion

Biological tests indicated that concentration and exposure time had significant effect on mortality (for concentration; $F_{6,172}$ =587.1, P<0.0001 and for exposure time; $F_{3,172}$=120.5, P<0.0001) and paralysis rate of *C. maculatus* when exposed to spinosad solution (For concentration; $F_{6,172}$=50.2, P<0.0001 and for exposure time; $F_{3,172}$=85.7, P<0.0001). Generally, mortality of *C. maculatus* adults increased with increasing of concentration at each exposure time. At the highest concentration (108 ppm) 80 % mortality rate was obtained after 1 day of spinosad treatment while at 48 ppm concentration 100 % mortality rate was achieved after 3 days of exposure time. The lowest mortalities were achieved at 0.1 ppm concentration for each exposure time.

High levels of paralysis were observed during 1st day of exposure time and then decreased on following exposure times. Spinosad treatments at 48 and 72 ppm for 1 day of exposure had significantly higher paralysis levels of *C. maculatus* than those at other spinosad concentration. However, very low paralysis levels were obtained at same concentrations after 3 day of exposure (Table 2).

(*Two-way ANOVA was applied to the data. Means within a row with the same lower-case letter and a column with the same upper-case letter do not differ significantly (Duncan test at 5% level).

There were significant differences in progeny production between spinosad concentrations and control treatment. At 72 and 108 ppm, no progeny of *C. maculatus* was produced, whilst progeny production was observed at the lowest concentrations (6, 12 and 24 ppm). These results indicated that spinosad treatment at 72 and 108 ppm would completely suppress the progeny production of *C. maculatus* (Table 3).

*(Means followed by the same upper case letter at each concentration are not significantly different; Duncan test at 0.05).

Conclusion

Based on the results obtained from the biological tests, the concentration of spinosad suspension and the exposure period had a significant effect on paralysis and mortality rate of *C. maculatus* adults on chickpeas. The highest efficacy of dust treatment of spinosad was achieved at 0.7 to 1.44 ppm concentrations against some stored product insects (*R. dominica, S. zeamais* and *P. truncatus*) (Subramanyam 2006; Mutambuki *et al*., 2012). Sadat *et al*. (2006) also reported LC_{50} value as 149 ppm of spinosad against *C. maculatus*. In present study, spinosad treatment at 48 ppm and above concentrations achieved complete mortality and completely suppressed the progeny production of *C. maculatus*. Differences in the results obtained from present study can be attributed to different test methods and insect populations. In conclusion, surface treatment of spinosad would be potential of controlling major stored legume pest, *C. maculatus* and be an alternative to conventional synthetic insecticides

Abstract

The Wild hemp (Cannabis sativa L.) is relatively rare weed in Bulgaria. Its presence in high density in the sunflower fields makes the production difficult and sharply decreases yields. To solve this problem a field trail in sunflower (*Helianthus annuus L.*) field infested with the weed Wild hemp in high density was conducted. The experiment was carried out during the vegetation periods of the sunflower from 2010 to 2014. The trail was stated on the agricultural land of village Krumovo, near Plovdiv, Bulgaria. The sunflower plants were grown by "ExpressSun" technology. The primly used herbicide is Express 50 SG (containing 500 g/kg tribenuron-methyl). For better Wild hemp control as partner products in our study, the adjuvant Trend 90 and the herbicide Pledge 50 WP (containing 500 g/kg flumioxazine) in dose of 7 g/da were used. The trail was conducted in four replications and the size of the plots was 28 m². The evaluated herbicides were applied in three different dates and in different doses. The obtained data for the efficacy of the herbicides were compared with the untreated dredged and not dredged controls. The efficacy of the herbicides against the weeds by the quantitative method (number of weeds per 1 m²) and the percentage of efficacy (%) by the visual scale of EWRS (European Weed Research Society) were reported three times annually. The influences of the examined factors on the sunflower seed yields were also studied. The results from the study showed that the wild hemp control is extremely difficult and for the best way to control this weed, a system of herbicide application in the correct time is required.

Keywards: *wild hemp, sunflower, herbicides, efficacy, yields*

Introduction

The Wild hemp (*Cannabis sativa L.*) is late spring weed and is observed mainly in spring field crops and in orchards (Small *et al.*, 2003). This weed species has aboveground biomass reaching 2 - 3 m of height, as well as powerful and deep root system. The Wild hemp infests a lot of different crops. At the rice fields in the northern part of western Bulgaria it is very aggressive weed that makes great economic damages (Duary and Mukherjee, 2003). The existence of Wild hemp as secondary emerged weed in unevenly topped winter wheat crop is also observed. Reisinger *et al.* (2005) reported that the Wild hemp is significantly more competitive compared to the culture. That leads to ineffective use of the present soil moisture and available nutrients. Ved Prakash *et al.* (2000) recorded that at the onion (*Allium cepa L.*) fields in the North-west Himalia the main weed species are Wild hemp (*Cannnabis sativa L.*), Java grass (*Cyperus rotundus*) and Gallant soldier (Galinsoga parviflora). The weeding is decreasing the yields with 81,2 %. The Wild hemp is relatively rare weed in Bulgaria. Its presence in high density in the sunflower fields makes the production difficult and sharply decreases yields (Osman *et al.*, 2014). For the Wild hemp control different methods are applied. Many authors recommend the biological control by

using mycoherbicides. For this aim several virulent strains of Fusarium oxysporum f. sp. cannabis are studied and evaluated (Noviello et al., 1990; Tiourebaev et al., 2001). Páli *et al.* (2007) established that trough fiercely burning the seeds of the wild hemp (*Cannabis sativa L.*) significantly decreases their viability. The information about the chemical control of the Wild hemp at sunflower as well as at the other crop is still limited. Pandey (1989) established that the infestation with Wild hemp at maize is controlled by usage of metribuzin at dose of 0.5 kg/ha, pendimethalin at dose of 1.0 kg/ha and two times earthing up on the 25th and on the 45th day after sowing. At the conventional technology of sunflower growing, none of the registered herbicide products cannot control the Wild hemp. Weed control at sunflower should be performed at the optimal phases of the crop before the critical period for decreasing the morphological parameters is reached (Simic et al., 2011). The introduction of the "Express sun" technology marks a new stage at weed control at sunflower production (Delchev and Georgiev., 2015).
The aim of the present study was to establish the possibilities for herbicide control of Wild hemp (*Cannabis sativa L.*) at sunflower grown by "ExpressSun" technology.

Materials and Methods

The experiment was carried out during the vegetation periods of the sunflower from 2010 to 2014 (without 2013), on field infested with Wild hemp in high density. The sunflower plants were grown by "ExpressSun" technology. The trail was stated on the agricultural land of village Krumovo, near city of Plovdiv, Bulgaria. The primly used herbicide was Express 50 SG, containing 500 g/kg tribenuron-methyl. For better hemp control as partner products in our study, the adjuvant Trend 90 and the herbicide Pledge 50 WP (active substance - flumioxazine 500 g/kg) in dose of 7 g/da were used. At variant 6 the herbicide Pledge 50 WP was applied immediately after sowing, and Express 50 SG was sprayed at phenofhase from the emergence of 2-4 leaves of the sunflower (at variants 3 to 6) and from the emergence of 6-8 leaves (at variants 5 and 6). In the first three years of the study the sunflower hybrid "PR64 E83" was grown, and in the last experimental year (2014) the hybrid "PR64 LE25" was sowed.
The trail was conducted in four replications with size of the harvesting plot 28 m². The evaluated herbicides were applied in three different dates and in different doses (2 и 4 g/da). The obtained data for the efficacy of the herbicides were compared with untreated dredged two times controls (variant 2), as well as untreated not dredged controls. The efficacy of the herbicides against the weeds by the quantitative method (number of weeds per 1 m²) and the percentage of efficacy (%) by the visual scale of EWRS (European Weed Research Society) were reported three times annually. The influence of the tested factors on the yield of sunflower was also evaluated. In the trail intercrop tillage during the vegetation was not performed. The fields for the experiment were selected so that the prevailing weed infestation to be from the weed Wild hemp. The control of the single specimens from the other existing weeds on the field was accomplished by their removal by hand. The removing of the weeds was done to phenophase 8-10 leaves of the plants. Statistical analysis of collected data was performed by using Duncan's multiple range test (1955) of SPSS program. Statistical differences were considered significant at $p<0.05$.

Results and Discussion

The number of the Wild hemp specimens in the untreated control varied from 17,3 to 50,9 per m^2 in the different years (Table 1). This variant showed the enormous competitive abilities of Wild hemp in its uncontrolled coexistence with sunflower. In comparison to the untreated control, in the twice dredged control (variant 2) the number of the Wild hemp plants was 4 times lower and varied from 3,9 to 9,4 specimens per 1 m^2 (Table 1). The most unsatisfied herbicide effect on the

examined weed was observed at variant 3 (Express 50 SG at dose of 4 g/da). According to Jursik *et al.* (2011), by applying adjuvants together with herbicides, the biological efficacy and crop selectivity of the used product is going to be improved. This statement was proved in our study. The adding of the adjuvant Trend 90 significantly improved the efficacy against the Hemp. In a study performed by Delchev (2013), the herbicide tank mixture of Express + Stratos Ultra by "ExpressSun" technology led to complete control of all annual and perennial grass and broadleave weeds. In our experiment, by the application of Express 50 SG at dose of 2 + 4 g/da in combination with the adjuvant Trend 90 twice during the vegetation, over 90 % efficacy against Wild hemp was achieved. By the system of twice treatment the just emerged specimens of the weed were affected in maximum rate. After the second treatment, the secondary emerged weed plants were significantly affected. The highest herbicide effect against the Wild hemp was recorded at variant 6 (Pledge 50 WP + Express 50 SG + Trend 90, applied tree times) (Table 1). The results were the highest at phenophase cotyledons to 2-4 leaves of the plants. After the treatment of the sunflower plants with Express 50 SG at the time when the Wild hemp was at phenophase "rosette", the efficacy of the studied herbicide was sharply decreased.

The observations and reports for selectivity in the first three years of the study showed that the examined herbicide products had limited signs of fitotoxicity for sunflower. The visible indication of stress at the crop was expressed in meaningful lightening of the leaves that was continuing for 7-10 days. After this period the fitotoxicity signs completely disappeared. Between 2 and 5 % from the heterozygous hybrid "PR64 E83" did not form normal sunflower heads after the treatment with Express 50 SG. With implementation of the new homozygous hybrid "PR64 LE25" in 2014, any visible indications of fitotoxicity were not observed.

The highest yields in the experiment were obtained in 2014 (Table 2). The reasons for this fact were complex. On the first place, the summer of the concrete year was with the highest precipitation (the total precipitation for the period from April to August was 361,7 mm). On the second place was the implementation of the hybrid "PR64 LE25" that have high productivity potential and higher resistance to the applied herbicide in comparison to the hybrid used in the previous three years of the study ("PR64 E83"). The Pants of the new generation of hybrids do not undergo a state of stress after the application of Express 50 SG. At the older generation heterozygous hybrids the stress is expressed in short-term yellowing of the leaves after the treatment, a slight development delay, as well as blocking of the flowering of up to 5 % of sunflower plants.

Yield generally decreased with increased duration of weed interference (Elezovic *et al.,* 2012). In our trail the average yield for the period of investigation from the untreated and undredged controls was with 2,49 to 3,67 times lower in comparison to the variants with applied herbicides. During every experimental year, with statistically proved lowest yields among the treated variants, was the variant with single application of Express 50 SG without the adjuvant Trend 90 (Table 2). The epicuticular wax is the most significant barrier to the penetration of watersoluble herbicides (DiTomaso, 1999). The presence of epicuticular wax on the Wild hemp's leaves should be overwhelmed so the herbicide can get into the plant tissues. Our observations showed that with the aging of the Wild hemp, the weed was becoming more resistant to Express 50 SG and the necessity of the adjuvant application was more obvious. The lowest yield from the untreated control in 2011 corresponds to the highest level of weed infestation with Wild hemp (Table 2). Another important factor was undoubtedly the precipitation in this season. The total precipitation for the period April-August 2011 was 184.1 mm.

Conclusions

The results from the trails showed that the control of the Wild Hemp (*Cannabis sativa L*.) by the "ExpressSun" technology was extremely difficult and for the best way to control this weed, a system of herbicide application in the correct time is required. The Wild Hemp could decrease sunflower seed yields from 2,49 to 3,67 times in comparison to the variants with herbicide application.

When the product Express 50 SG was applied alone the herbicide control of the Wild Hemp was insufficient that had negative effect on sunflower yields.

The adding of the adjuvant Trend 90 to Express 50 SG increased the efficacy of the product during the fourth experimental years. The combined usage of the herbicide and the adjuvant led to increase of the yields over 13 % when compared with the alone herbicide spraying.

The application of Express 50 SG twice during period of 10 - 14 days increased the herbicide efficacy against Wild hemp with 10 - 15 % when compared with the alone application. As a result, there was yield increase on average over 16,5 %.

The highest and stable efficacy against the Wild hemp and the highest yields were achieved after the application of the herbicide combination of Pledge 50 WP + Express 50 SG + the adjuvant Trend 90 applied three times during the vegetation.

THE VALIDATION OF (ALTAIR AGRAR) MODEL AS A DECISIONS TOOL OF IPM PROGRAMES IN COTTON FIELDS

Ahmed ABDU HAMED AMIN

Emeritus Professor Plant Protection Res. Institute, ARC, MOA
7, Nady El-Sayied Street, Dokki, Giza 12311, Egypt
Corresponding:aahakaa@gmail.com

Abstract

A physiologically based model has been developed for use in addressing crop and pest management decisions in processing cotton (ALTAIR AGRAR).Field studies were conducted during 2014-2015 cotton growing seasons in Fayum Governorate (Egypt), to detect the adult population of the pink bollworm (*Pectinophora gossypiella),* cotton leaf worm (*Spodoptera littoralis),* cotton aphis *(Aphis gossypii),* white fly *(Bemisia Tabaci)* and red mite *(Tetranychus Urticae)*. Field generation numbers, life table parameters for field, thermal requirements and heat unit's accumulation were used. Cotton plant phonology was recorded as well as weather factors. The relationships in cotton complex were detected. The interaction of pest (5 pests), plant (phenology) and weather (four Factors) were tested by (ALTAIR AGRAR) Model, on cotton varieties (Giza 90). A comparison was made between the expected and observed data. Most of the validations produced results that were in reasonable agreement with the observed data. The forecasts were more accurate, when the phenology of the population peaks was compared than when actual population densities were compared. In general, no computer model can make perfect forecasts; however, we can use (ALTAIR AGRAR) Model successfully to help to take the decisions in cotton fields.

Keywords: *ALTAIR AGRAR, Model, Plant phenology, cotton, Egypt*.

Introduction

Modelling techniques that applied to agriculture can to be useful to define research priorities and understanding the basic interactions of the plant-atmosphere system. by Using the models could estimate the importance and the effect of certain parameters, that could be most useful. Beginning the mid-1960 through the present, a considerable effort has been directed at development of computer models of agricultural systems.

Cotton in Egypt, is subjected to yield and quality losses by insect pests. The Pink bollworm (PBW), *Pectinophora gossypiella* and Cotton Leafworm, (CLW), *Spodoptera littoralis* are remaining the most destructive pests causing significant losses to the yield. Most economic losses caused by these pests due to larval feeding within boll basis. Since the larvae penetrate the bolls soon after hatching, efficient control by insecticides is hard to achieve. In addition, application of toxic insecticides may result in increased pest resistance to insecticides, interference with the activity of beneficial insects, environmental pollution, and hazards to public health. The reduction of insecticide applications in cotton is, therefore, of great correspondence. Cotton bollworm has a number of difficult problems regarding sampling techniques, i. e. (A)- Larvae feed inside the green bolls causes' special difficult in estimation the population density in the developmental stages of these insect pests. (B)- PBW and CLW have variable numbers of annual generations. Amin et al. (1994) found that PBW showed four generations. CLW found to has seven overlapping generations annually by many authors (Bishara, 1926; Abdel-Badie, 1977; Dahi, 1997). The indiscriminate use of insecticides has caused

a number of problems to various ecological niches around the world including Egypt. Hence there is a growing necessity and interest in the use of Ecological approaches for management these pests.
The rates of development in insects under natural conditions are largely determined by temperature. In most microenvironments, temperature is characterized by daily and seasonal cyclic variations with superimposed irregular fluctuations. However, studies of insect development rate most often involve experiments performed under constant temperatures (Howe, 1967). In the development and application of development-rate models, it is always assumed that development rate at a given temperature is independent of thermal regime, whether the model is linear or nonlinear in relation to temperature. This assumption is also inherent in efforts to derive development-rate models from data obtained under varying temperatures, such as the work by Dallwitz & Higgins (1978) Babasaheb et al (2014), Marc Sporleder et al (2004). According to this assumption, development rate follows a definite function with respect to temperature, when other factors are equal, and the amount of development can be calculated by ac-cumulating the fraction of development per unit time; i.e., rate summation (Kaufmann 1932). The procedure may be expressed as:

$$D = f\, r\, [T\,(t)]\, DT$$

Where development D is a function of temperature, T, which in turn is a function of time, t, and the development rate, r; adjusts instantaneously to temperature. The above assumption is fundamental to the formulation of development-rate functions for phonological models. Life table studies are fundamental to not only demography but also too general biology. In such studies, development tunes and survival rates of each stage, longevity of adults, and the daily fecundity of females are recorded for every individual. Using elementary statistics, means and standard deviations can be calculated. In traditional life-table analysis, these means are used to calculate age-specific survival rates and age-specific fecundity using either the Leslie matrix (Leslie 1945) or Birch's method (Birch 1948). These procedures have been widely used by researchers in many different fields (Laing 1969, Shib et al. 1976, Cave & Gutierrez 1983, Vargas et al. 1984, Carey & Vargas 1985). However, variation in development rate is well known, even when a population is kept under constant laboratory conditions. The range of variation depends on many factors (for example, temperature and food). To assume that all individuals have the same development rate is biologically unrealistic and may be misleading. Therefore, ignorance of such variation when using either the Leslie matrix or Birch's method should be carefully considered. The method of incorporating this variation is the use of distributed delay theory in modelling (for example, Gutierrez et al. 1984, Plant & Wilson 1986). On the other hand, Chi & Liu (1985) developed an age-stage life table theory for both sexes, incorporating variable developmental rates among individuals. In comparison with the distributed de-lay models, Chi & Liu's model is different in that both sexes were included, and variation in development rates was integrated sequentially for all stages and expressed in the form of a stage distribution. The stage structure of a population can also be calculated in Chi & Liu's model. Furthermore, most life-table analyses have been concerned only with the "female" population. Most lepidopteran, coleopterans, and orthopteran pests are not parthenogenesis, however, and both males and females are economically important. Moreover, the development rate may differ between the sexes. Susceptibility to either chemical or biological control agents may be quite variable among stages and sexes. These and many other differences among stages and sexes explicitly point out the inadequacy of the female age-specific life table. In addition, whether to calculate the intrinsic rate of increase of a "female" population or of the population as a whole is a central question in ecology. In the theoretical model of Chi & Liu (1985), the population parameters are calculated with respect to both sexes and incorporating variable developmental rates among individuals. However, the major obstacle in taking the variable developmental rates and tire male population into account is the difficult and tedious work of applying the age-stage, two-sex life table theory to the raw data analysis Jean-Francois(1999).

The number of days between observable events, such as cotton seedling emergence and first squares of the duration of insect generations can characterize the growth and development of plants and insects. The number of days between events, however, may be misleading because growth rates vary with temperatures. The measurement of events can be improved by expressing development units in terms of the temperature and time. The deviation between events is then based on accumulated degrees per unit time above a lower temperature re-presenting a threshold of growth.
The goal of this study is to test the accuracy of pest-plant-weather components of (ALTAIR AGRAR) with cotton variety for short and long predictions to forecast the density and timing of cotton pest's populations.

Material and Methods

(ALTAIR AGRAR) is a temperature driven model with development based on cumulative heat above a lower developmental threshold (Wilson and Barnett, 1983). Unlike simple phenology models, however, biological rates are not strictly linearly proportional to heat above the lower threshold; factors such as solar intensity, water deficit stress, and so on regulate these temperature dependent rates. The linear approximation to physiological time, however, serves as a useful parameter for estimating potential rates of structural production (numbers) and biomass accumulation, which is in turn modified by the feedback mechanisms incorporated into the model.
The crop model consists of four parallel interacting subpopulations of seedlings, leaves, flowers, and bolls. Each subpopulation has its own birth rates, death rates, and growth rates.
The interface for (ALTAIR AGRAR) consists of a series of screens enabling a user to modify any of several default parameters at the start of a simulation. Key parameters for the crop currently include planting date, cotton Varity, planting date, and geographical location of the simulated field.
(ALTAIR AGRAR) validation data were collected from Fayum Governorate cotton fields (90 Km south Cairo) in Middle Egypt. Data were collected throughout two successive cotton-growing seasons (2014-2015). Giza 90 was the variety that cultivated in 2014 and 2015 seasons. Data was collected on: 1-pests numbers 2-injured fruit numbers, 3-cotton fruit numbers, 4- predator numbers, and 5- weather. Protocol was as follows: 1- pheromone traps: Six PBW and CLW pheromone delta traps were placed from February 15th to the end of October. The gossyplure baits were replaced with new one every 2 weeks or less depending on the weather. Adult males from each pheromone trap were checked twice per week.
Yellow sticky traps were used for aphids and white fly. Visual examination for red mite was made on all plants found in 25 m quadrate randomly selected.
2- Cotton fruit: Twenty-five meters of canopy were examined weekly for: a) No. of squares (pinhead to matched, matched to 1/4 inch and 1/4 inch to > 1/4 in diameter).
b) No. of bolls (<3/4 inch, >3/4 inch in diameter), and open bolls. c) No. of plants count (plants in each m^2 multiply by 4.047 to obtain the absolute number per acre). d) Plant height/m. 3-Crop injury. Samples of 100 bolls collected weekly. Small, medium and large bolls were taken randomly from each field and the infestation percentages were estimated in the lab.

Results and Discussion

I - Prediction of cotton phonology

Data were collected from three different planting dates in Fayum Governorate cultivated with cotton Giza 90. The three planting dates are: 15/2/2014, 1/3/2014 and 15/3/2014. The Cultivation Dates for 2015 cotton growing season for Giza 90 variety were: 20/2/2015, 7/3/2015 and 16/3/2015.
Table (1) illustrated the plant phonology; planting date, seedling emergence, Catyledons stage, first true leaf, first fruiting branch, first bud, first flower, first boll and bolls maturation for the nine cultivation dates. The table shows deviation between the observed data that collected from the fields

and the predicted that obtained after applying the (ALTAIR AGRAR) model, by means of heat units.

The careful examination of date in the table reveal that the general average of devotion of DD's for the six cultivation dates for the eight plant stages tested ranged from 4 to -108.9 (first flower) and from -3.6 to 3.8 (first bud) DD's .

Data in Table (2) demonstrate the deviation of means between observed and predicted cotton phenology by days. As it could be seen the average ranged between -1 and -12 (boll maturation) and from 6 to -4 (seedling emergence) days.

As it could be concluded from the obtained results, the growth development curves observed actually did not differ significantly than those obtained by (ALTAIR AGRAR) model as all observed curves demonstrated a similar growth rate curve prior to the (ALTAIR AGRAR) model.

II – Prediction of Cotton key pests

Cotton in Egypt, is subjected to yield and quality losses by insect pests. The Pink bollworm (PBW), *Pectinophora gossypiella* and Cotton Leafworm, (CLW), *Spodoptera littoralis* are remaining the most destructive pests causing significant losses to the yield. Most economic losses caused by these pests due to larval feeding within boll basis. Early season sucking pests; *Aphis gossypii,* white fly, *Bemisia Tabaci* and red mite, *Tetranychus Urticae*. also play an important role in reducing the yield quality and quantity. The proposed model ((ALTAIR AGRAR)) predicate the occurrence of these insect pests, consequently the goals of this work is to make the validation of that model.

Simulated and observed cotton tested insect pests densities are depicted in Table (3). (ALTAIR AGRAR) explained only 69.55 % of the variability in the field data of aphid as an average for the two seasons, 83.45% for red mite, 84.65% for the white fly, 77.95% for the cotton Leafworm and 79.1 % for the pink bollworm. The predicted trend of population peaks is closed to the actual population peaks, the general average for pest component as whole reached to 78.94 %.

However, the (ALTAIR AGRAR) model could be successfully used for cotton insect pest's predictions in Fayum, Middle Egypt.

Table (3): Simple correlation of Log observation and prediction curves of some cotton insect pests during two successive cotton growing seasons (2014-2015) at Fayum Governorate, Middle Egypt

Pest	R^2		% Accuracy

Abstract

The effectiveness of alcoholic extract of Oak gall and Neem seeds on the integrity of eggplant seeds was examined. Five different seed samples were collected from the northern provinces of Iraq and used in this study. The result of our examination showed presence of various fungi including Aspergillus, Aurobasedium, Botrytis, Cladosporium, Fusarium, Phoma and Rhizoctonia in the examined seeds and roots samples. Isolation rate of fungi ranged from 1% to 17%. Fungi that were isolated from studied roots included Alternaria, Botrytis, Chaetomium, Cladosporiu, Drechslera, Fusarium, Geotrichum, Macrophomina, Phytophthora, Pythium, Rhizoctonia, Sclerotium and Stemphyllium. Alcoholic extract of Oak gall showed inhibitory effect of 8% and 10% against F. oxysporum and F. semitectum respectively . Whereas, Alcoholic extract of Neem seeds showed inhibitory effect of 64% and 61.77% against R. solani and F. oxysporum respectively. The soil-borne fungus *Trichoderma harzianum* showed an antagonistic activity, and it had antifungal effect against several pathogenic fungi, especially *F. solani*, with antibiosis level of 1.66. *Bacillus subtillis* also showed high inhibitory activity of 100% against *F. semitectum* and 92.66% against *F. solani*.

Key words: *Eggplant, Biological Control, Fungi, Neem, Oak gall*.

Introduction

Biological control is an effective method against diseases transmitted by seeds. It is well known that, this method positively affect the activity of most microorganisms, and it improves soil conditions and sustainability of agriculture (Papavizas and Lewis, 1989). Biological control method is also proven to cause no harm to environment, and it reduces human health risks.

It is believed that, Eggplant, *Solanum melongena L*., is originated in China and India. It grows as a wild plant (Chen and Li, 1996), and it usually needs a warm climate for growth. Generally, eggplant is economically important vegetable crop, and it ranks third after potatoes and tomatoes in terms of world production.

The plant is cultivated in tropic and subtropics region of Iraq, and the total area of planting is 21,665 ha and production is 24,321.84 kg /ha (anonymous, 2001) .The plant is grown seasonally in open fields in spring, to produce fruit during summer months and autumn. Due to its importance and increased demand in winter and early spring, cultivation of this crop in protected facilities began in 1980s in Iraq to enhance and extend its production capacity (Bozorgi, 2012). The available information on the most producing countries of eggplant in descending order are: China (18 million tons), India (8.4 million tons), Egypt (1.2 million tons), Turkey (813 thousand tons), Indonesia (389 thousand tons), Iraq (380 thousand tons), Japan (371 thousand tons) , Italy (321 thousand tons), and Sudan (230 thousand tons) (FAO, 2008).

However, eggplant is susceptible to many diseases, particularly fungal infections. Seeds play a vital role in transferring and spreading of these diseases. The damaging effect of diseases to crops, and massive economic loss as a result was indicated in a previous study, where the study stated a

substantial economic loss (up to100%) which was related to vascular wilt diseases (Alabouvette et al., 1996).
This study aimed to investigate seeds and roots diseases of eggplants that were collected from three Northern provinces in Iraq, and to determine the efficiency of two different biological methods in controlling of such diseases.

Material and Methods

Isolation and diagnosis of fungi associated with seeds:

Five samples of eggplant seed lots were collected from several local companies and farmers in three provinces Akrae in Dohuk, Erbil, and Koya in Sulaimani (Iraq)..
The samples were kept in polyethylene bags in the refrigerator at 5°C until use. Fungi were isolated from seeds using agar plate method that was described by the International Seed Testing Association (ISTA, 1976). A 200 seeds were surface-sterilized by immersion in 1% sodium hypochlorite (NaOCL) for three minutes. Distilled water was used to wash the seeds thoroughly, and then seeds were dried between two layers of the Whattman filter paper. The treated seeds were distributed in separate dishes. Each ten seeds were placed in a dish containing 15 ml of PDA with streptomycin sulfate (50 mg /L).Plates were kept at 25°C for 12 h under light and 12 h under dark regime for one week. After the incubation period, plates were examined for the presence of fungal growth, and the detected fungal colonies were identified according to (Booth, 1971; Toussaun and Nelson, 1976; Pitt and Hocking, 1997; Leslie and Summerell, 2006). The isolated colonies were purified by using single spore or hyphal tip technique, and preserved on PDA slant at 5°C until used.

Isolation and diagnosis of fungi associated with roots:

Several field-infected plants were transferred to Plant Protection laboratory at the Faculty of Agriculture, University of Salahaldeen. Isolation of fungi from the infected plants was performed according to the method described by Agnihorti, (1971). Following a week of incubation, the colonies were examined and prepared as mentioned in the preceding paragraph and preserved on PDA slant tubes at 5°C.

Pathogenicity of isolated fungi:

Pathogenicity of the isolated fungi from the infected seeds and seedlings was tested. The PDA medium was used for cultivation of fungi, and cultivated plates incubated at 25°C°+2. The grown fungi colonies were used in inoculation of sandy loamy soil. For this experiment 2 kg sandy loamy soil was used. The soil then inoculated with the fungi colonies grown on one half of the PDA plate. The added fungi growth mixed thoroughly with the surface layer of the soil (Saydam et al., 1973). Following mixing, the soil distributed in 1% formalin sterilized 20 cm-diameter pots. The experimental pots were placed in the canopy of wood for three days. Eggplant seeds that had been obtained from Erbil were used for the experiment at rate of 10 seeds per pot. Prior to spreading of seeds on the pots, seeds were sterilized with 1% sodium hypochlorite solution for three minutes. After sterilization, the seeds washed with sterilized distilled water, and spread on contaminated soil.

Biological control:

a) Plant extracts:

Two types of forest tree extracts were tested to assess their effectiveness against pathogenic fungi. Oak gall was obtained from Akrae, and Neem seeds were obtained from Sami Abdul Rahman Park in Erbil. Both Oak gall and Neem seeds washed with distilled water, and then placed on a filter paper at room temperature to dry. Each dried plant was kept in a labeled polyethylene bag until use.

A twenty gram of each oak gall powder and Neem seed powder was separately added to 200 ml of 95% ethanol in 400 ml flasks. The mixtures left in shaking condition in water bath (Karlsruhe Company-Germany) for 1 hour, and then kept in refrigerator at 4ºC for 24 hours. The extract was filtered through two layers of gauze, filtrate placed in a petri dish and left to dry at room temperature. The alcoholic plant extracts then collected in glass bottles and stored at -20ºC in deep freezer until use (Alnoman, 1998).

One gram amount of alcoholic extract was added to 5 ml of dimethyl sulfoxide (DMSO) (BioSolve BV, Netherlands). The mixture then filtered using Millipore filters (0.2 micrometer). A 10 mg /ml of the above substance were added to 500 ml sterile PDA medium, and the medium poured into sterile glass petri dishes. The same procedure was followed in preparation the other concentrations (8, 6, 4, and 2 mg /ml). Freshly prepared disc (0.5 cm diameter) of pathogenic fungal colonies was placed over the prepared plates. Each treatment was repeated three times, control containing medium without alcoholic plant extract was also included in the experiments (Riso et al, 1987).

b) With fungi and bacteria:

Antagonism activity test carried out by using the bio-agent T. harzianum against pathogenic fungi that were grown on PDA plates. The plate was divided into two parts, a disk (0.5 cm diam.) containing colonies of T. harzianum was placed on the first half of the medium. While another disk (0.5 cm diam.) containing colonies of pathogenic fungi was placed on the second half of the medium. The distance between both microorganisms was almost 4 cm. The experiment repeated three times. Control was also included in the experiment, where, T. harzianum was used to inoculate a centre of a medium plate, and a disk containing pathogenic fungi was used to inoculate a different plate. The results obtained after a week of incubation at 25ºC, and evaluated according to Bell et al., (1982).

Antagonism test of Bacillus subtillis against fungal pathogens:

Each PDA plate was inoculated with 0.5ml of *B. subtillis* at rate of 2.5×10^8 cfu/ml. The bacterial culture was grown in a nutrient broth at 37 ºC for 24 hours, and 0.1ml of a fresh culture aseptically spread on the surface of the plate. Inoculated disks with fungal cultures were placed at the center of PDA plates, and plates were incubated at 25 ºC. Experiment for each fungi culture was repeated three times. Results of grown fungal colonies on plates were recorded and the ratios of Qatrin perpendicular and the percentage of inhibition were calculated. Generated data was statistically analyzed using the Statistical Analysis System-SAS (Anon, 2005), and validated by Duncan's multiple range test.

Results and Discussion

Isolation and diagnosing of fungi associated with seeds

The testing result of seeds integrity of five eggplant samples that were obtained from Erbil, Dohuk, and Sulaimani is shown in (Table 1). The table shows that R. solani was found in 7% of examined seeds, with the highest rate (63.6%) of frequency which was recorded in seeds collected from Arbil. This finding is agreed with the findings of (Ismail, 2010), who indicated isolation of fungi from eggplant seeds. In addition to R. solani, Aspergillus sp. was also found, and the later fungus

presence was recorded in all examined samples at a range between 2-5%. The highest debut (100%) was found in seeds obtained from Sulaimani, and the lowest (20%) was found in seeds obtained from Akrae. A similar result was showed in a previous study by (Al-Kassim and Monawar, 2000), who also stated isolation of these fungi from seeds of eggplant. Moreover on fungal isolation from eggplant seeds, F. oxysporum was also isolated from the seeds obtained from Akrae at rate of 10%. A similar result regarding isolation the latter fungi from seeds were also reported by Ismail (2010). However, it is noteworthy to mention that F. oxysporum can cause a significant loss in production through causing diseases such as wilt disease. Symptoms of the disease usually occur on mature plants and unilateral gestures. Yellowing may appear on one side of infected plant then extend to all parts followed by wilt (Siva et al., 2008).

In a recent study, researchers were able to isolate both *F. oxysporum and F. solani* from seed embryos of eggplant (Habib *et.al*., 2007). The occurrence of *F. solani* in soil is common, and contaminated seeds are the main route of transmission. This fungi can cause root rot diseases and stem ulceration in various plants (Gordon, 1960), and it considered one of the most dangerous pathogenic fungi that can cause wilting (Chakraborty and Chatterjee, 2008).

(ISTA, 1976)

Isolation of fungi from roots of eggplant:

Our data in Table 2 shows presence of *Fusarium* sp. in all samples that were collected from all studied sites in the regions of Erbil with repetition rate of 66.66%. However, information of the conducted field survey demonstrated isolation of *F. solani* from several studied sites especially in Shmamk, Khabat, and Ainkawa at rate of 4.76%, 3.57%, and 1.47% respectively. In addition to what we have explained earlier, as these fungi are commonly found in soil and can be transmitted through seeds, they can also penetrate plants through wounds on lateral roots or through the exposure to undesired conditions. Because its parasitic nature, it can cause root-rot diseases to many plants (Gordon, 1960), and subsequently the infected plants develop symptoms such as taproot and lateral roots browning. The later description of fungal root infection was also indicated in another study were the researchers stated that, the infection that had been occurred in the root reflected first on the aerial parts then yellowing and drought without discoloration of the vascular vessel (Ahmad and Al-Moussalli, 1987). In addition to *Fusarium* sp., *R. solani* was also isolated from all of the

surveyed sites with the highest incidence found in Ainkawa 22.05%, Khabat 17.85%,and Shmamk9.52%. However, its occurrence may due to the contamination of soils in these sites with this fungus, which is considered as one of the most causal agent of rot and seedling death to its wide range host that may exceed 230 plant species. Especially when we conclude that, *R. solani* can remain in the case of vegetative growth in the wet soil for the rest of the year (Parameter,1970).However, during infection process; the fungi affect seeds and seedlings in the soil before and after emergence.At the final stage, the disease attacks the roots and aerial parts of affected pots, fruits, leaves and stems (Anne et.al, 2002).

Pathogenicity of fungi isolated from eggplant:

Seed rot and seedling death of eggplant.

Results regarding seed rot and seedling death of eggplant collected from the region of Erbil are shown in Table 3. F. solani and F. oxysporum were the most virulent fungi isolated from seeds at rate of (63.3%) without showing any significant differences between the species of fungi except control treatment. Our result also shows contribution of F. semitectum, F. copactum and R. solani in causing seed rot that reached 53.3% and 43.3 % respectively. However, A. alternata caused pre-emergence damping-off at less extent 26.7%. And, R. solani, F. miscanthi, and F. solani caused the post emergence damping-off at rate of 36.3%, 16.7%, and 13.3% respectively. Meanwhile, F. miscanthi did not cause death of seedlings and the surviving percentage of the infected plants with

F. miscanth was 63.3%, which indicates a weak pathogenicity of these fungi. While, surviving percentage the infected plants with R. solani reached 20.3%, which refers to high pathogenicity.

Biological Control

Effect of alcoholic extract of Oak galls on fungal growth:

The effect of alcoholic extract of Oak gall in inhibition growth of pathogenic fungi is shown in Table 4. The inhibition rate of the extract at 10% concentration against *F. compactum* found to be 61.4% with no significant differences between the treatments and the control plants. On the other hand, testing the impact of alcoholic extract of Oak gall on *F. miscanthi* showed the highest inhibition rate of 10% of the extract was 64.9%, and the

Numbers that bear similar letters do not differ significantly at 0.05 probability level using Duncan multiple range test (vertically) .* Each number represents the average of three replicates .

lowest inhibition rate of 2% of the extract was 35.1%. When the influence of Oak gall extract was tested against F. oxysporum, a significant inhibiting action (100%) of the extract on the fungus was obtained. Although, there were no significant differences among the concentrations used, but a difference was found between control plates and the extract at 2% concentration, where the lowest inhibition rate 76.6% was observed. Moreover, the 10% alcoholic plant extract also had a significant inhibition action (100%) on the growth of F. semitectum. Meanwhile, the 2% extract showed the lowest inhibition rate of 62.5% with no significant differences among tested concentrations. The differences were only found with the control. However, F. solani was found to be the most susceptible to the plant extract treatment. Similar conclusion was also stated by Yamunarani, et.al.,(2005),who indicated inhibition of fungi growth by protein extracted from Oak. Söhreto et al., (2007) also mentioned the impact of alcoholic extract of Oak galls on mycelium growth of these pathogenic fungi.

Table 4: Effect of alcohol extract of oak galls in the growth of Fusarium species pathogenic to eggplants.

* Each number represents the average of three replicates.

Effect of alcoholic extract of Neem seeds on fungal growth:

The effect of alcoholic extract of Neem seeds in inhibiting growth of pathogenic fungi is shown in Table 5. The inhibition level of alcoholic extract of Neem seeds on F. solani was found to be 64.0% with no significant differences between treatments. A similar finding was also indicated by other researchers (Carpinella et al., 2003). Increasingly, F. oxysporum was also negatively impacted by this seed extract; the inhibition level was 61.8%. The highest inhibition level was observed at concentration of 8 and 10%. This particular result was in contrast with the result obtained by Hassanein et al., (2008) who found the inhibition rate of Neem plant extract at 20% concentration on the growth of F. oxysporum and F.solani to be 7%. But the inhibition rate of the same concentration on the growth of F. semitectum was 60.1%. The impact of 8 and 10 % extract concentration was found to be significantly different from the rest of the treatments. On the impact of the extract on the growth of F. miscanthi, the extract's inhibition rate was 58.1% with no significant differences between all treatments. Effectiveness of the alcoholic extract of Neem seeds may be attributed to its content of paraisine, which is one of the alkaline substances that inhibit fungi growth. It may also due to its combination with the dynamic biological processes, including the precipitation of the amino acid in the proteins synthesis (AL-Rawi and Chakravaraty, 1964). Another reason it could be containing materials effective against fungi including Vanillin and 4-hydroxy-3- methoxycinnam aldehyde and Pinoresinol (Carpinella et al., 2003).

Biological control using bacteria and fungi:

Efficiency of Trichoderma harzianum against pathogenic fungi.

The result presented in Table 6 indicates the high antagonism ability of T. harzianum against pathogenic fungi that infected eggplants. The antagonism level against F. solani found to be 1.7 degree, followed by Drechslera spp. Our results were in line with the results observed by other researchers, (Küçük and Merih, 2003) emphasized the ability of different bio- control such as T. harziurum in inhibiting growth of Drechslera sorokiniana, F. oxysporum and R. solani. In regard to F. miscanthi, F. oxysporum and F. semitectum the degree of antagonism level was found to be 2.0, while the degrees of antagonism against A. alternate , F. compactum and R. solani, were 2.3, 2.2, and 2.3 respectively. These results are consistent with the results reported by Wahgunde and Patil, (2009) in relation to the antagonism ability of the fungi T. viride and T. harziurum in inhibiting the growth of A. alternate. The antagonism ability of bio-control T. harzianum can be attributed to the production of B-1-3-glucanase enzyme, which weakens the pathogenic fungi and releasing cellulose enzymes in small quantities. However, this may assist in the penetration process of the bio-controls to pathogenic fungi cells and production of antibiotic, which degrades fungal thread (Benhamon and Chet, 1993).

Table 6: The efficiency of biocontrol Trichoderma harzianum against fungal pathogens of eggplants.

Fusarium solani	1.7
Rhizoctonia solani	2.3

* According to the world peace quintet Bell et.al., (1982).

** Each number represents the average of three replicates.

Proficiency test of bacterial antagonism activity against pathogenic fungi:

The bacterial antagonism activity against pathogenic fungi was tested by using *B. subtillus*. The results in table 7 show that the inhibitory affect of *B. subtillus* was highest (100%) on *F. miscanthi.* On the other hand, it showed no effect on the growth of *Drechslera sp*. However, in a previous study of Korston and de Jager, (1995) the authors found a remarkable antagonism activity of this bacterium on spores growth and mycelia of *Drechslera setariae*. While, the inhibition rate reached up to 92.7% against *F. solani*. In another previous study, Kim, *et.al*., (1994) have also reported a potential antagonism activity of same bacteria on the growth of *F. solani*. Where the authors concluded the following, treated eggplant seedlings with *B. subtillus* prior to planting in contaminated soil reduced seedling infection rate from 68 % to 76 % by *F. solani*, and 90.8% by *F. oxysporum* within 25 to 30 days after treatment. However, this antagonism activity may be due to the ability of these bacteria in secretion group of antibiotics which include Difficidin, Prydifficidin , Bactracin, and Bacillomyin. It may also attribute to their ability in producing volatile organic compounds.

Table 7: Effect of biocontrol (Bacillus subtillis) against fungal pathogens of eggplants

Fungi	% of Inhibition
Alternaria alternata	59.3
Drechslera spp.	0.0
Fusarium compactum	83.3
Fusarium miscanthi	100.0
Fusarium oxysporum	90.8
Fusarium semitectum	66.7
Fusarium solani	92.7
Rhizoctonia solani	63.0

Diameter of colony control (9 cm).

Conclusion

Based on the presented results and discussions can be determined the following results:

1- The result of our examination showed presence of various fungi including *Aspergillus, Aurobasedium, Botrytis, Cladosporium, Fusarium, Phoma* and *Rhizoctonia* in the examined seeds and roots samples.

2- Isolation rate of fungi ranged from 1% to 17%. Fungi that were isolated from studied roots included *Alternaria, Botrytis, Chaetomium, Cladosporiu, Drechslera, Fusarium, Geotrichum, Macrophomina, Phytophthora, Pythium, Rhizoctonia, Sclerotium* and *Stemphyllium*

3- The soil-borne fungus *Trichoderma harzianum* showed an antagonistic activity, and it had antifungal effect against several pathogenic fungi, especially *F. solani*, with antibiosis level of 1.66. *Bacillus subtillis* also showed high inhibitory activity of 100% against *F. semitectum* and 92.66% against *F. solani*.

Abstract

Sclerotinia sclerotiorum is a major pathogen of many economically important vegetable crops worldwide. Plants can be infected at any stage of their development. The pathogen survives in crops as sclerotia in soil or as mycelium in infected plant debris. This study was conducted in order to: a.) reveal trends of the disease occurrence on lettuce in Serbia, and etiological aspects of the causal agent *Sclerotinia* spp., and b.) evaluate the antagonistic effect of *T. harzianum* and *Bacillus* sp. against *Sclerotinia* spp. Lettuce with symptoms of basal rot were collected between 2012 and 2014 in the area of Lazarevac. All *Sclerotinia* isolates obtained from the diseased lettuce were identified as *Sclerotinia sclerotiorum*, based on morphological and cultural characteristics. *Trichoderma harzianum* (DSM 63059) and three bacterial biocontrol agents: *Bacillus* sp. strains SS 12.6, SS 13.1, and SS 51.1, were evaluated *in vitro* for their antagonistic potential against *S. sclerotiorum*, isolated from the lettuce plant. *T. harzianum* and the cell-free culture filtrate of *Bacillus* strains SS 12.6 and SS 13.1 showed the greatest potential for controlling *S. sclerotiorum* and these agents will be further tested in field trials.

Key words: *Sclerotinia sclerotiorum*, *morphology, antagonistic effect, Trichoderma harzianum, Bacillus* sp.

Introduction

The genus *Sclerotinia* contains a number of soil borne plant pathogenic fungi that occurs widely in temperate and subtropical areas of the world. The disease name was recorded as *Sclerotinia* drop rot, drop, decay, or watery soft rot depending on the hosts (Farr et al., 1989). The fungus survives in the soil as sclerotia, which are long-term survival and dissemination structures that can withstand adverse environmental conditions such as extreme temperature, UV light, desiccation, or antagonistic organisms (Ben-Yephet, et al., 1993). Germination of sclerotia can either be myceliogenic (forming mycelium) or carpogenic (forming apothecia). Regardless of the type, both germination methods results in initiation of disease (Clarkson et al., 2004).

It has been reported that *Sclerotinia sclerotiorum* (Lib.) de Bary and *S. minor* Jagger cause sclerotinia rot on some composite vegetable crops (Farr et al., 1989). Lettuce drop, caused by these two pathogens, is one of the most destructive lettuce diseases, causing severe yield losses worldwide (Subbarao, 1998; Kim et al., 2002; Bolton et al., 2006). The third species which also causes lettuce drop symptoms was detected in China is *S. nivalis* (Li et al., 2000).

Controls of *Sclerotinia* spp. are currently limited to the use of cultural and chemical control methods. In search of alternatives, biological control has emerged as a way of managing these pathogens. Numerous antagonistic and mycoparasitic fungi that belong to the genera, *Acrostalagmus, Aspergillus, Fusarium, Gliocladium Hormodendrum, Mucor, Penicillium, Stachybotrys, Trichoderma, Ulocladium* and *Verticillium* have proved to be effective against *S. sclerotiorum* (Bedi, 1961; Adams and Fravel, 1990; Li et al., 2003).

Trichoderma species have been shown to attack both sclerotia and mycelia of *Sclerotinia* species and have been used in the field with varying degrees of success (Chitrampalam, 2008). The mechanisms for the suppression of pathogens by *Trichoderma* include mycoparasitism, competition for space and resources, and antibiosis. The extracellular cell wall degrading enzymes produced by many strains of *Trichoderma* are traditionally included in the concept of mycoparasitism, due to their integral role in direct physical interactions (Howell, 1998; Monte and Llobell, 2003). Also, bacteria particularly those which produce antibiotics, such as *Pseudomonas fluorescences, P. putida,* and *Bacillus* spp., may have a direct or indirect impact on the survival of sclerotia (Tu, 1997). *Bacillus* spp. have special characteristics that make them good candidates as biological control agents (BCAs). The strains of this genus are ubiquitious, posses a resistant spore stage and produce several kinds of antifungal compounds (Yoshida et al., 2001; Leelasuphakul et al., 2008).
This study was conducted in order to: a.) reveal trends of the disease occurrence on lettuce in Serbia, and etiological aspects of the causal *Sclerotinia* spp., and b.) evaluate the antagonistic effect of *T. harzianum* and *Bacillus* sp. against *Sclerotinia* spp.

Material and methods

Fungal isolation

The lettuce plants with symptoms of basal rot were collected between 2012 and 2014 in the area of Lazarevac. Isolation was achieved by cutting the small pieces on the margin of healthy and diseased tissue. The pieces were surface sterilized with 10% sodium hypochlorite solution for 2 min, rinsed several times with sterile distilled water, and plated on potato dextrose agar (PDA). The Petri plates were incubated at 25^{o}C for 7 days.

Morphological and cultural characteristics

Fungi were identified based on morphological and cultural characteristics. The four representative isolates were cultured on PDA at 25^{o}C for two weeks for production of sclerotia. Sclerotia produced on the medium were examined for the morphological characteristics and preserved in a low temperature incubator at 0^{o}C. After one month of incubation, the sclerotia were put in 250 ml flasks with sterile wet sand and incubated at 15^{o}C for five months in alternating cycles of 12 hr fluorescent light and 12 hr darkness. Apothecia produced from the sclerotia during the incubation were collected and examined for the morphological features.

In vitro inhibition of *Sclerotinia* spp.

T. harzianum (DSM 63059), employed for *in vitro* antimicrobial assay was obtained from German Collection of Microorganisms and Cell Cultures (DSMZ). Three strains of antagonistic bacteria: *B. licheniformis* SS-12.6, *B. amyloliquefaciens* SS-13.1, and *Bacillus* sp. SS-51.1 were obtained from cultural collection of Faculty of Biology.
a.) *T. harzianum* was screened for their antagonistic activity against isolates of *Sclerotinia* spp. using dual culture tests based on the percent growth inhibition (PGI). A 5 mm diameter mycelial agar disc was cut from the margin of 7 day old culture of *Sclerotinia* spp. and placed on one side of a 9 cm Petri plate containing PDA medium. Another 5 mm mycelial agar disc from 7-day old culture of *T. harzianum* was placed 6 cm away from the disc of *Sclerotinia* spp. on the same plate. Plates inoculated only with pathogens served as controls. The cultures were incubated at 25°C. Hyphal interaction and morphology were examined under a light microscope.

b.) The mycelial growth inhibitory effects of the extracellular metabolites from culture extract of *Bacillus* sp. SS-12.6, SS-13.1 and SS-51.1 were estimated by using the radial growth inhibition assay. For the production of antimicrobial substances, *Bacillus* sp. strains were grown in 200 ml of Luria-Bertani (LB) broth at 30°C in a shaker at 200 rpm over the night. The cells were harvested by centrifugation at 13,000 x *g* for 15 min, and the culture supernatant was tested. The agar disc of each tested isolates of *Sclerotinia* spp. was transferred to the surface of PDA, previously inoculated with 0.5 ml of bacterial cultures extract. Plates inoculated only with test pathogens served as controls.

In both tests, PGI of isolates of *Sclerotinia* spp. was calculated after 7 days using the formula: KR-R1/KR x 100, where KR is the colony diameter in control plate without antagonist, and R1 is the colony diameter in treated plate.

Results and discussion

Morphological and cultural characteristics

The morphological characteristics of isolates are presented in Table 1. Colonies of *Sclerotinia* spp. on PDA consisted of white mycelia and globose to irregular and black sclerotia. All isolates obtained from the diseased lettuce were identified as *S. sclerotiorum*, based on morphological and cultural characteristics. The morphological characteristics of our isolates of *S. sclerotiorum* are similar to those reported by other researchers (Kohn, 1979, Willetts and Wong, 1980).

Table 1. Morphological characteristics of *S. sclerotiorum* isolated from lettuce.

Morphology		Isolates			
		LS-1	LS-2	LS-3	LS-4
Sclerotium	Color	black	black	black	black
	Shape	irregular	irregular	globose	globose
	Size (mm)	5.0×7.0	4.5×6.5	7.5×8.0	8.0×8.5
Apothecium	Size of disk (mm)	0.5-7.3	0.5-7.5	1.0-8.5	1.0-8.0
	Length of stalk (mm)	2.0-10.5	2.0-8.0	2.5-14.0	2.0-14.0
Ascus	Shape	cylindrical	cylindrical	cylindrical	cylindrical
	Size (μm)	100-180×8-11	100-200×8-11	100-180×8-11	100-200×8-11
Ascospore	Shape	ellipsoid to ovoid	ellipsoid to ovoid	ellipsoid to ovoid	ellipsoid to ovoid
	Size (μm)	10-18×5-8	10-16×5-8	10-18×5-8	9-16×5-8

In vitro inhibition of *Sclerotinia* spp.

a.) *T. harzianum* is a saprophytic fungus which is generally used as a BCA against a wide range of economically important aerial and soil borne plant pathogens (Papavizas, 1985). Results from the dual culture test showed that *T. harzianum* exhibited the strong antagonism against isolates LS-1, LS-2, LS-3 and LS-4 of *S. sclerotiorum* with a high PGI value (71%, 68%, 65%, and 63% respectively). No distinct inhibition zones were observed between antagonistic fungus and pathogens. Microscopic examination of dual culture assay showed alternation of the mycelium of pathogen where it was in contact with antagonist. *T. harzianum* induced abnormal stunted, highly

branched hyphal tips, swollen hyphae and the vacuolar appearance of the mycelium of all tested fungal pathogens (Figure 1). Beside competition for resources and space, the invasive mechanism of *Trichoderma* includes lysis, mycoparasitism, antibiosis and local or systemic induced resistance (Howell, 2003; Harman, 2005). Similarly, in this study it was observed that the mechanisms of antagonism for all tested isolates of *S. sclerotiorum* were through competition, lysis, and mycoparasitism. *In vitro* test showed that *T. harzianum* (DSM 63059) had the capacity to recognize the fungal host by the formation of ‘‘hook-like’’ and ‘‘appressorial’’ structures around the hyphae of *S. sclerotiorum.*

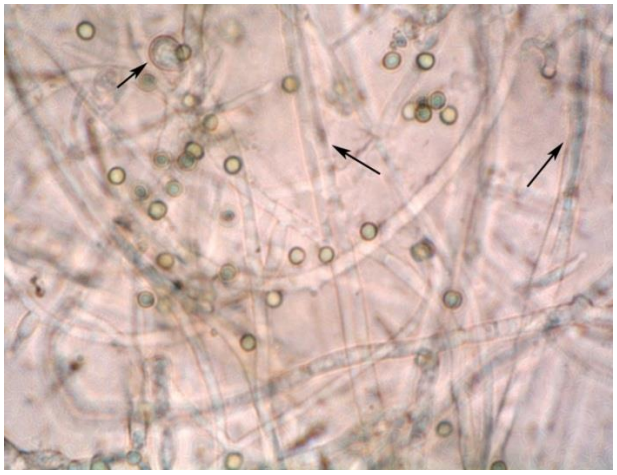

Figure 1. Malformed and swolled hyphae of *S. sclerotiorum* (isolate LS-3) parasitized by *T. harzianum*.

b.) The result of mycelial growth inhibition assay showed that a culture extracts of *Bacillus* sp. SS-12.6 and SS-13.1 inhibited the growth of all tested isolates (LS-1, LS-2, LS-3 and LS-4) of S. *sclerotiorum* by 100% in comparison with control (Figure 2). Bacterial extract of strain SS 51.1 did not showed inhibitory effect on the growth of the tested isolates of S. *sclerotiorum*. *Bacillus* spp. are known to produce antibiotics (iturin, surfactin and fengycin), cell wall-degrading enzymes (chitinase, and β -1,3 glucanase), and antifungal volatiles which are effective against various pathogens (Knox et al., 2000). Ethyl acetate extracts of cell-free supernatants of *Bacillus* sp. SS 12.6 and 13.1, showed the presence of PCR products related to genes involved in synthesis of iturins and surfactins, and exhibit strong antimicrobial activity against a wide spectrum of postharvest fungal pathogens (Dimkić et al., 2013).

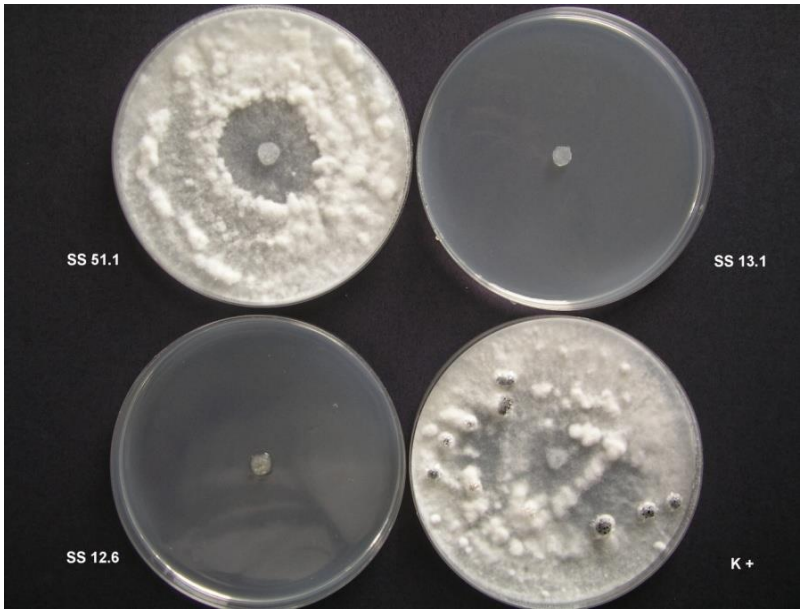

Figure 2. *In vitro* effect of bacterial extract of *Bacillus* strains SS 51.1, SS 13.1 and SS 12.6 on mycelial growth of *S. sclerotiorum*; K+ control without bacterial extract (isolate LS-3).

Conclusion

Biological control of *S. sclerotiorum* has been considered a more natural and environmentally acceptable alternative to the existing chemical treatment methods. The results of the present study suggest the need for further experiments on the antagonistic activity of *T. harzianum* and *Bacillus* strains, SS 12.6 and SS 13.1 against *S. sclerotiorum* using *in vivo* assays with plants under controlled greenhouse conditions.

Abstract

The Elm tree (*Ulmus* spp.), is a tree which grows as both natural and ornamental in warm regions of Europe and Asia. It grows naturally and is also grown as ornamental plant in Iğdır province. This study was conducted to determine egg parasitoids and parasitism rates of Elm Leaf Beetle, *Xanthogaleruca luteola* (Müller 1766) (Coleoptera: Chrysomellidae) feeding on Elm leaf (*Ulmus* spp.) in Central, Aralık, Karakoyunlu ve Tuzluca districts of Iğdır provinces in the Eastern Anatolia region (Turkey) in the years 2013-2014. In each two years, the total 12.697 eggs were collected and cultivated at 25±1◦C and 65±5% RH in glass tube (2x10 cm) in the laboratory. As a result of study, *Oomyzus gallerucae* (Fonsocolombe, 1832) (Hymenoptera, Eulophidae) was obtained. This species was recorded for the first time for the fauna of Iğdır province, East Anatolia, Turkey. The average parasitism rates in elm plantations were 39.9% and 48.3% in Iğdır provinces in 2013-2014 years, respectively.

Keywords: *Elm, Ulmus spp., Xanthogaleruca luteola, Egg parasitoid, Oomyzus gallerucae, Parasitism rates*

Introduction

Elms (*Ulmus* spp) are huge trees that drop their leaves in winter, prevail in warm regions of Europe and Asia (Anonymous, 2016). It belongs to Ulmaceae family *Ulmus* L. genus, it is a forest tree and it is generally used as park, garden and road tree (Dutkuner and Avcı 2000). It is widely grown starting from North and Eastern Europe, Western Asia and all the forested areas in Turkey especially in Black sea. The Elm tree (*Ulmus* spp.), is a tree which grows as both natural and ornamental and has become the symbol of Iğdır province. So far many harmful insects have been determined which harm the Elms. *Xanthogaleruca luteola* (Müller) one of these insects is one of the most harmful ones. *X. luteola* was first discovered in the east of USA, Baltimore (Maryland) in 1830s (Glover, 1871; Riley 1883). This harmful insect exists in almost all the places where the elms are grown in North America (Davidson, 1979). The first record about this harmful insect was kept by Çanakçıoğlu (1993). Luck and Scriven (1976) determined *Tetrastichus brevistigma* Gahan (Hymenoptera, Eulophidae) as the egg parasitoid of *X. luteola* in the research the made in the years between 1973-1974 in South California. Hall and Johnson (1983) first determined *Oomyzus gallerucae* (Fonsc.) as the egg parasitoid of *X. luteola* in USA in 1982. They presented the first time that this parasitoid spent the winter as adult. Graham (1985), determined the *O. gallerucae* and *Tetrastichus suevius* (walker) as the egg parasitoid of *X. luteola*.

This research was carried out the first time to determine the egg parasitoid of X. luteola, the harmful insect of the Elm in Iğdır and parasitism rates in period 2013-2014.

Materials and methods

To determine the egg parasitoid of *X. luteola*, the eggs were collected in the dates between– 08/06/2013 - 08/05/2014 and 02/05/2013-20/06/2014 when the eggs are seen as the first and the last time, in the years between 2013-2014 in the districts Tuzluca (Üçkaya - 39°56'58.0"N, 43°39'49.0"E and Turabi - 40° 04'41.0"N, 43°45'51.0"E), Aralık (Karasu neighborhood - 39°51'52.1"N, 44°32'01.6"E), and Karakoyunlu (39°58'25.4"N, 44°10'43.5"E), the center of Iğdır (the city forest - 40°02'04.2"N, 43°49'53.6"E). The collected eggs were taken in tubes sized 2x8 cm and label information have been added. These eggs were brought to the laboratory in ice container and were taken in the 25±1 °C and 65±5% R.H. culture. The eggs were checked daily and the parasitoid adults that leave have been protected being involved in 70 % alcohol. The identification of these insects was made by Dr. Miktat DOĞANLAR. At the end of research the parasitism rates have been determined by counting the eggs which are parasited and not parasited.

Results and discussion

In the study carried out in 6 locations in Iğdır, 12 597 eggs of *X. luteola* were collected and as egg parasitoid; *Oomyzus gallerucae* (=*Tetrastichus gallerucace*) Fonsolombe, 1832 (Hymenoptera, Eulophidae) were obtained. *O. gallerucae* was added in Iğdır fauna. Luck and Scriven (1976), determined *Tetrastichus brevistigma* (Hymenoptera, Eulophidae) as the egg parasitoid of *X. luteola* in the research they made in the years between 1973-1974. Hall and Johnson (1983) determined *O. gallerucae* as egg parasitoid of *X. luteola* in USA in 1982 the first time. Graham (1985) determined the species *O. gallerucae* (Fonsc) and *Tetrastichus suevius* (Walker). To determine the rates of parasitism, in 6 different locations where Elms are grown widely 6981 eggs of *X. luteola* (Table 1), were collected in 2013 and 5716 eggs were collected in 2014. In the first year, the adult parasitoids obtained 2786 of these eggs and in the second year 2776 of the eggs. The parasitoids obtained parasitism rates have been found as respectively 39.9 %, 48.3 %. On the table 1 and 2 the parasitism was observed mostly in the rate 46,95 % in 2013 in the locations where the researches are made in the City forest, in 2014 73.63 % rate in Sarıçoban. Puttler and Bailey (2003) determined the parasiting rate 26.3–51.7 % in the research they have made in Columbia, Missouri in the period 1999-2000.

Table 1. The number of collected eggs and parasitism rates of *Xanthogaleruca luteola* in Iğdır province in 2013 year

Location		**The number of collected eggs**	**The number of parasitized eggs**	**Parasitism rate (%)**
Central	Sarıçoban	312	56	17,9
	City forest	4440	2085	46,95
Aralık	Central	378	69	18,2
	Ortaköy	693	186	26,83
Tuzluca	Üçkaya	16	0	0.0
	Turabi	1142	390	34,15
Total		**6981**	**2786**	**39,9**

Table 2. The number of collected eggs and parasitism rates of *Xanthogaleruca luteola* in Iğdır province in 2014 year

Location		The number of collected eggs	The number of parasitized eggs	Parasitism rate (%)
Merkez	Sarıçoban	349	257	73,63
	City forest	2037	1293	63,47
Aralık	Central	28	0	0,0
Tuzluca	Turabi	2659	1104	41,51
Karakoyunlu	Central	671	122	18,18
Total		**5744**	**2776**	**48,3**

Conclusion

The studies are made in 2013 and 2014 and Elm Leaf Beetle, *X. luteola* and egg parasitoid *O. gallerucae* was found in all the areas where the elms are grown in Iğdır. Parasitism was recorded as the rate 39.9 % and 48.3 % as a result of two years of studies. The parasitism rates are denser in natural areas away from the settlements and are less densely found in the elms which are grown park and ornamental plants near the settlements. The reasons of this fact are considered to be the pest control efforts of the municipality for other insects on elm, the fumes coming out of the exhaust pipes and the dust appearing by the sides of the road.

WHEN SHOULD THE FRUIT BE CONSUMED IN TERMS OF NUTRITION?

Kazim GUNDUZ*, Safder BAYAZIT, Oguzhan CALISKAN

Abstract

Today, the idea of eating healthy food for a healthy life is becoming worldwide popular. The consumption of fruit rich in bioactive compounds is very important for health as it is known for their characteristics such as anticancer, antimutagenic and antioxidant. Fruit is consumed by people at the fully ripen stage. In some studies, it can be seen that fruit has a few times less bioactive compounds at the fully ripen stage when compared to the previous stages. For example: according to analysis results of the samples of cornelian cherry (*Cornus mas* L.) taken at four different stages (light yellow, blush, light-red and dark red) it is found that at light-red stage, the fruit has about 1.7 times more phenolic, 3.48 times more antioxidant and 2.32 times more tannin when compared with the fully ripen stage (dark red). Similar result was taken for *Ziziphus jujuba* Mill., *Vaccinium macrocarpon* Ait., and *Phoenix dactylifera* L.. In terms of anthocyanin, the values are similar. For this reason, the most important time of consuming fruit in terms of nutrition is not fully ripen stage but the stages before it.

Keywords: *Fruit, time of consuming, nourishment, phytochemicals*.

Introduction

Recent interest in food phenolics has greatly increased on account of the antioxidant and free radical-scavenging abilities associated with some phenolics and their potential effects on human health (Hamid et al., 2011). Agronomic research has set priorities to obtain high yield, better resistance to disease and transportation and longer shelf-life of fruit. Thus, fruit breeding programs have been aimed at improving yield and fruit size, resistance to disease and pests, adaptation to particular growing systems and rate of ripening. Most recently, research has been focused on the quality of fruit (Capocaso et al., 2008). Particularly small fruits constitute a good source of natural antioxidant substances. Fruits are a good source of natural antioxidants, containing many different radical scavenger components that provide protection against harmful-free radicals and consequently are associated with lower incidence of cancer and heart diseases in addition to number of other health benefits (Shui and Leong, 2006; Hamid et al., 2011). Antioxidants reduce oxidative damage to cells that can lead to cancer, heart disease, and other degenerative diseases. Especially the anthocyanin compounds, that give red berry their red color, are powerful antioxidants (Prior, 2003; Zafra-Stone et al., 2007). Among natural compounds phenolics and, in particular, flavonoids have been found to be an important part of human diet and are considered to be the active component in many medicinal plants (Cooper-Driver, 2001). Genotype-variety is the major factor in determining fruit nutritional quality. Nutritional quality is also affected by crop conditions, ripening season, pre-harvest and post-harvest conditions, shelf-life and processing (Connar et al., 2002; Capocaso et al., 2008). Maturity or ripening index is another important factors which can strongly influence the nutritional value as well as physiological properties such as development of colour and texture of fruits (Ali et al., 2004; Schweiggert et al., 2011). According to some researchers, the changes in antioxidant properties were found to be varied among different fruits such as *Olea europaea* L., orange, *Solanum lycopersicum* L., and *Ziziphus jujuba* Mill. (Castrejón et

al., 2008; Huang et al., 2007; Ilahy et al., 2011; Wu et al., 2012). Various factors (climatic, agronomic, genomic, pre- and postharvest conditions, and processing) may affect the chemical composition of plant foods and may have a significant role in determining the phenolic composition and the bioactivity of these compounds (Imeh and Khokhar, 2002). Maturity stage is another important factor that may influence the compositional quality of fruit and vegetables. In fact, during fruit ripening, several biochemical, physiological, and structural modifications happen and these changes determine the fruit quality attributes. Harvesting at the proper maturity stage is essential for optimum quality and often for the preservation of this quality after harvest and storage (Amira et al., 2012).

The aim of this compilation is to pay attention on consumption time of fruit species in respect to nutritional ingredients. Fruit species are generally consumed in their full ripe stages.

Studies on the Changes Made in the Stages of Fruit Ripening

In recent years, a great number of researches are carried out about fruit quality change effect of ripeness stages of fruit and vegetables. The reason of this is phytochemicals which exist with high levels in fruit and vegetable ingredients. Therefore, it is a necessity to determine consumable fruit ripeness of useful bioactive substances which exist with high amounts in fruit and vegetables.

Gündüz et al. (2013) was evaluated at chemical properties and antioxidant characteristics of cornelian cherry fruits at four ripeness stages (Table 1). The stages were light yellow, blush, light red and red. TPC and TEAC averages gave similar patterns: the highest averages were recovered at the light yellow (8033 µg GAE/g fw) and 55.0 µmol TE/g fw) and blush (8206 µg GAE/g fw and 55.3 µmol TE/g fw) stages; and the averages were reduced at the light red (7110 µg GAE/g fw and 27.1 µmol TE/g fw) and red stages (4162 µg GAE/g fw and 7.8 µmol TE/g fw). A reverse pattern was observed for TMA and tannins. TMA was lowest at the light yellow stage and reached to 65.0 and 65.8 µg cy-3-glu/g fw at the red and red light stages. Tannin content was reduced from 4.45% to 1.58% from the light yellow to red stages.

Table 1. Mean and mean separations for total phenolic content (TPC), antioxidant capacity (TEAC), anthocyanin (TMA) and tannins of cornelian cherries fruits sampled from four maturation stages

Stage	Weight (g)	TSS (%)	TPC (µg GAE/g fw)	TEAC (µmol TE/g fw)	TMA (µg cy-3-glu/g fw)	Tannins (%)
Light yellow	3.9 d	11.3 c	8033 a	55.0 a	4.9 c	4.45 a
Blush	4.2 c	12.2 b	8206 a	55.3 a	16.5 b	3.79 b
Light Red	5.0 b	16.0 a	7110 b	27.1 b	65.8 a	3.66 b
Red	6.4 a	16.5 a	4162 c	7.8 c	65.0 a	1.58 c
Mean	4.9	14	6878	36.3	38	3.37
$SD_{5\%}$	0.4	0.6	350	1.9	2.2	24

Some of the chemical properties and antioxidant capacity of cranberry (*Vaccinium macrocarpon* Ait. cv. Pilgrim) fruits were investigated at light green, blush, light red and dark red maturation stages (Celik et al., 2008). The berry size progressively increased during the fruit maturation (Table 2). Similarly, the Brix values increased from 6.0 to 9.3% (Table 2). Total phenolic and total anthocyanin contents of each maturation stages were statistically different (Table 2). During maturation, from green to dark red stage, the total phenolic content was decreased from 7990 to

4745 mg GAE/kg fw, while total monomeric anthocyanin content was increased from 0.8 to 111.0 mg/kg fw from green to dark red stage. The highest antioxidant capacities were recovered from green stage followed by blush. The lowest antioxidant capacities were determined at light red (Fig 1). The results clearly demonstrated that some of the chemical properties and antioxidant capacities of some fruits are affected by maturation stages. Significant variability was found for overall total phenolic, anthocyanin, organic acids and antioxidant capacity of different maturation stages. Total phenolic and anthocyanins content affected the antioxidant capacity. Green stage of some fruits had the highest antioxidant capacity.

Table 2. Mean and significances for several pomological and chemical parameters of cranberry fruits sampled from four maturation stages

Stage	Weight (g/100 berries)	TSS (%)	TPC (µg GAE/g fw)	TMAc (µg cy-3-glu/g fw)	Total Organic Acids (g/100g)
Green	67.3 c	6.0 d	7990 a	0.8 c	1.50 c
Blush	87.6 b	6.8 c	6853 b	6.6 c	1.71 b
Light Red	135.3 a	8.7 b	4901 c	50.2 b	1.81 b
Dark Red	141.8 a	9.3 a	4745 c	111.0	2.04 a
Mean	108	7.7	6122	42.2	1.76
HSD5%	11.8	0.4	218	7.6	0.14

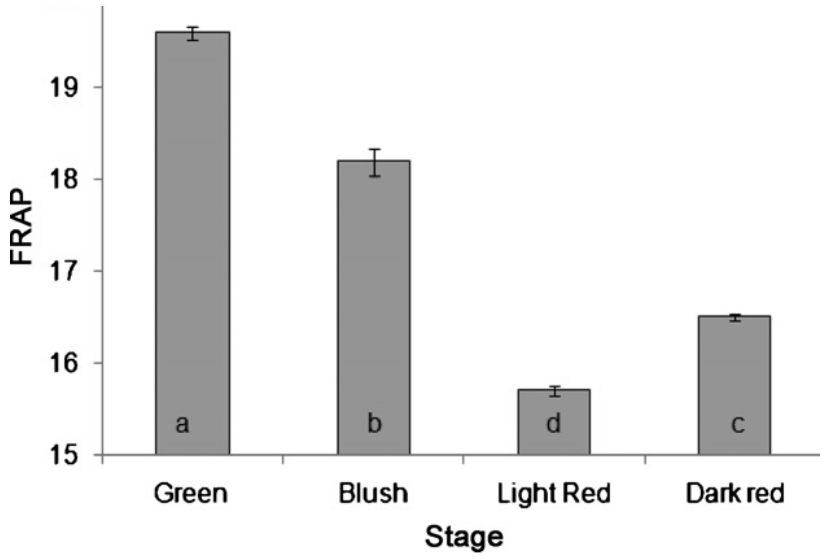

Fig. 1. Total antioxidant capacities of the cranberry fruits sampled from four maturation stages. The values are expressed as mmol of trolox equivalents/kg fw.

In another study some of the chemical properties and antioxidant capacity of jujube (*Ziziphus jujuba* Mill.) fruits were investigated at four maturation stages (Gündüz et al., 2014). The maturation stages were classified by degree (%) of dark color formation on the fruit surface (Stage (S1), 1-10% (S2), 11-50% (S3), 51-100% (S4). According to findings, TSS increased from 12.8% to 18.3% from the S1 to the S4 fruit stage, respectively. S3 had the highest TPC (6518 mg GAE/g fw). The highest AOC were recovered from S2 (TEAC; 74.4 µmol TE/g fw, FRAP; 50.9 µmol TE/g fw), followed by S3 (TEAC; 63.6 µmol TE/g fw, FRAP; 37.6 µmol TE/g fw). The average AOC measured was 59.5 and 37.9 mmol TE/kg fw by TEAC and FRAP methods. The main organic acid was citric acid

determined by the HPLC method. Average glucose and sucrose was similar among stages. Fructose content tended to be more stable than glucose and sucrose. As a result, significant variability was found for overall fruit characteristics tested in the study, phytochemical accumulation, antioxidant activity and types of sugars of jujube at four different maturity stages. S3 stage had highest TPC and AOC. Therefore, to recover the highest anti-oxidant capacity, fruit should be harvested at the S3 stage (Table 3).

Table 3. Means and mean separations for specific and total sugars and acids of jujube fruits sampled from for maturation stages

Stage	Weight (g/)	TSS (%)	TPC (µg GAE/g fw)	TEAC (µmol TE/g fw)	Total Organic Sugar (g/100g)	Total Organic Acids (g/100g)
S1 (O% dark)	6.4 b	12.8 d	5138 b	49.8 b	14.8 b	0.54 a
S2 (1-10% dark)	6.6 b	14.5 c	4742 b	74.4 a	12.7 c	0.38 d
S3 (11-50% dark)	7.3 a	16.7 b	6518 a	63.6 a	21.1 a	0.45 c
S4 (51-100% dark)	6.8 b	18.3 a	5451 b	50.2 b	21.8 a	0.48 b
Mean	6.7	15.6	5462	59.5	17.6	0.46
$LSD_{5\%}$	0.5	1.2	809	10.9	1.26	0.15

In another study changes in total phenolic content (TPC), total flavonoid content (TFC), individual phenolic compound content, DPPH radical scavenging activity and antioxidant capacity were investigated in jujube fruits during three edible maturity stages and measured by FRAP assay of four phenolic fractions (free, esterified, glycosided and insoluble-bound) (Wang et al., 2016). The maturity stages of jujubes were established as white maturity (WM), half-red maturity (HM) and red maturity (RM). The free fraction in jujube at WM stage had the highest TPC, TFC, total phenolic acid contents, and antioxidant capacities. The phenolic contents and their activities greatly decreased with the increasing maturity stage. Caffeic acid was the most predominant in all detected phenolic compounds at WM stage, while rutin dominated at HM and RM stages. Even though most of phenolic compounds with antioxidant activity in jujube existed at the WM stage as the free form, the insoluble-bound fractions also contained a large number of phenolic compounds.

Amira et al. (2012) analyzed four cultivars of Tunisian date palm fruits (*Phoenix dactylifera* L.) (Gondi, Gasbi, Khalt Dhahbi, and Rtob Ahmar) at at three different maturation stages according to the pollination date: besser, rutab, and tamr for their antioxidant activities (AA) using 2,2′-azino-bis (3- ethylbenzothiazoline-6-sulfonic acid) and 2,2-diphenyl-1-picrylhydrazyl radicals cation, and reducing power (RP) methods. The total phenolic (TPC), total flavonoid (TFC), and condensed tannins (CTC) contents were measured. Results showed that all samples have the highest TPC, TFC, CTC, and AA at besser stage. The results presented in this work clearly demonstrate that the amounts of phenolic compounds and the antioxidant capacities of date fruits were affected by maturation stages. Date cultivars have different levels of TPC, TFC, CTC, and AA during ripening most of which were present at besser stage.

Singha et al., (2015) investigated phytochemical changes in aril and pulp of *Momordica subangulata* ssp. Renigera (G. Don) de Wilde fruit during ripening process. Aril had higher lycopene (57.0 µg/g), carotenoids (149.8 µg/g), flavonoids (396.0 mg/100 g), phenolics (297.7 mg/100 g), tannin (495.4 mg/100 g), and xanthophylls (111.8 mg/100 g) than pulp at stage-1. Carotenoids, lycopene and xanthophylls in aril fraction increased from turning yellow to ripe stage by 205.0%, 524.5%, and 303.7%, respectively while in pulp by 633.2%, 557.4%, and 1113.2%,

respectively. Flavonoids (18.3%, 16.5%), tannins (24.4%, 26.8%), phenolic (20.2%, 19.5%), β-carotene (87.4%, 70.6%), and chlorophyll (55.1%, 82.0%) were decreased in aril and pulp. The ABTS and DPPH activities reduced in both fractions with ripening.

Almeida et al. (2013) investigated the chemical composition the bioactive compounds and antioxidant potential of the *Ximenia. Americana* in different stages of maturation. The fruits at green maturity stage showed higher content of yellow flavonoids (22.07 mg/100 g), anthocyanins (1.92 mg/100 g), polyphenols (3051.62 mg/100 g), starch (4.22%), antioxidant activity (489.40 g fruit/g DPPH and 198.77 mmol Trolox/g) and activity of antioxidant enzymes; the antioxidant activity allocated to the fruit was shown to be related to the contents of extractable polyphenols, yellow flavonoids, total anthocyanins and antioxidant enzymes.

Fawole and Opara (2013) was conducted to investigate changes in physico-chemical, elemental and antioxidant capacity of pomegranate fruit cultivar 'Ruby' at different maturity stages were investigated to provide useful information regarding quality changes during fruit development. Results obtained showed that major compositional changes in the fruit are developmentally regulated. Significant increase in total soluble solids (TSS), sugars (glucose and fructose) and anthocyanins, coupled with significant decline in titratable acidity (TA) and organic acids as well as total phenolics was observed along the days after full bloom.

In the study Zainudina et al. (2014) the variations in bioactive compounds and antioxidant activity of carambola (*Averrhoa carambola* L.) fruit (cv. B17) at different ripening stages were investigated. The carambola fruit was harvested from week 9 until week 13. Bioactive compounds such as TPC, TFC, β-carotene, γ-and δ-tocopherol were found to be dominant in unripe fruit while those of sugar (sucrose, glucose and fructose), TCC, α- and β-tocopherol were prominent in the ripe fruit. The findings of this study advocate harvesting of carambola fruit at an appropriate stage to get maximum nutritional benefits.

Wolfberry (*Lycium barbarum* L.) fruits of three cultivars ('Damaye', 'Baihua' and 'Ningqi No.1') were harvested at five different ripening stages and evaluated for sugars and organic acids. Fructose, glucose and total sugar contents increased continually through development and reached their maxima at 34 days after full bloom (DAF). Fructose and glucose were the predominant sugars at maturity, while sucrose content had reduced by maturity (Zhao, et al. 2015). Sugar ingredients are increasing along with ripeness. Therefore it has been stated that fruit sugar is harmful in respect to human health.

Conclusion

People generally consume fruit when they are fully ripened or when their phenolic content drops and when their sugar content rises. In terms of health, it is important to consume fruit when phenolic and antioxidant content is high; but, when they are at edible ripening stage. The conducted compilated studies show that phenolic content (excluding anthocyanin) and antioxidant capacity of fruit drop and sugar content rises at fully ripening stage. It is stated that glucose content is harmful for a healthy diet. It is possible to suggest that people for a healthy diet should eat fruit one stage before fully ripening stage. On the other hand, studies on the changes of food content of fruit types when they are at ripening stage should be carried out.

Abstract

This paper presents the results of study on the resistance of wheat varieties to *Blumeria graminis tritici*. During the 2010-2011 period, in the Small Grains Research Centre in Kragujevac, investigations were performed of resistance at 140 commercial wheat varieties in the field conditions. Sowing was carried out in rows length of 1 m, catch variety in one row, with distance of 20 cm. In the period of maximal development of parasites estimations of reaction of investigated cultivars were carried out by determination of types of infection from 0 to 4 and intensity of infection from 0 to 100%. Majority of them belong to average susceptible category (60.35%), than to susceptible (23.92%) and intermediate (9.64%). Consideration of results demonstrated that mayority of varieties were susceptible to *B. graminis tritici* (84.22%), while limited number of varieties were resistant (5.73%). In season 2010, varieties Jasenica, Fortuna and Nera were very resistant, while in 2011 the most resistant were varieties Fortuna, Pesma and Dina, with coefficient of infection 0. At some varieties (Fortuna, Dina and Pesma) differences in resistance were established depeding of season of investigation. These investigations underlines the importance of work on creation of new wheat cultivates.

Keywords: *Blumeria graminis tritici, resistance, variety, wheat, Serbia*

Introduction

The fungus epiphytous Blumeria graminis tritici is a cosmopolitan species, which appears widespread of world in wheat growing areas (Newton and Cherewick, 1947; Dikson, 1956; Smiljaković, 1996). It is one of the most widespread dis ases of wheat in Serbia. Influence of powdery mildew on grain yield of wheat in Serbia depends of variety, at some varieties this influence was significiant, and in some of the, the decrease of grain yield was small (Bošković et al., 1983). Intensity of powdery mildew infection depends on resistance of cultivars too, which can be different in diverse growing areas. Infection intensity varies in dependence of wheat variety, climate conditions and agricultural practices. Although there have been no epiphytotics in Serbia yet, this disease can play a significant role in yield formation. Successful wheat breeding for resistance to the causal agent of powdery mildew is based on the identification of virulence and changes in the pathogen population (Jevtić et al., 2004).

The most efficient and the most economic suppression of powdery mildew causers in wheat achieves bay creation and growing of resistant cultivars. But, creation of such cultivars is long term and complex activity, because it is very complex relation of two live organisms. The pathogens exchangen continuously in the nature, forming nerw virulent genotypes to which, existing resistant varieties the becomes sensitive. Because of that many of our genes and their introgression in nerw cultivars.

The goal of this paper was to point out the resistance of some important wheat cultivars to causer of powdery mildew, with the aim of introduction in cultural practice the most resistant ones.

Materials and methods

During the 2010-2011 period, in the Small Grains Research Centre in Kragujevac (Serbia), investigations were performed of resistance at 140 comercial wheat varieties in the field conditions. Sowing was carried out in rows length of 1 m, catch variety in one row, with distance of 20 cm. The artificial inoculations were performed by mixture of prevalent pathotypes of parasites, by transplant of previous inoculated plants of susceptible variety Little Club in the rows of procective belt.
In the period of maximal development of parasites, reaction estimations of investigated cultivars were carried out by determination of infection types from 0 to 4 (Mains and Dietz, 1930) and intensity of infection from 0 to 100%. Types of infection have the next meaning: 0-very resistant; 1-resistant; 2-average resistant; 3-average susceptible; 4-very susceptible.
On the basis of type of infection and intensity of infection, coefficients of infection were canculated. According to values of coefficients of infection, investigated varieties were divided in few categories (Levine and Vasile, 1960): 0-5%-immune; 6-10%-very resistant; 11-25%-average resistant; 26-40%intermediate; 41-65%-average susceptible and 66-100%-very susceptible.

Results and discussion

From data presented in the Table 1. in can be noticed that number of cultivars per categories of resistance was different. Majority of them belong to average susceptible category (60.35%), than to susceptible (23.92%) and intermediate (9.64%). Only few varieties belong in category of immune ones (1.08%), very resistant (1.08%) and average resistant (3.57%). Majority of cultivars were in categories of susceptible (84.22%), and small number-resistant (5.73%). Intermediate category was present in 9.64% of varieties. Optained results comply with data of Stojanović and Stojanović (1992) which pointed out that small number of cultivars were in category of resistant, majority in categories of susceptible, while some cultivars were intermediate.

Table 1. *Summary review of varieties and resistant*

Category	Year				Total	
	2010		2011			
	No	%	No	%	No	%
0-5	0	0.00	3	2.14	3	1.08
6-10	3	2.14	0	0.00	3	1.08
11-25	4	2.85	7	5.00	11	3.57
26-40	16	11.42	11	7.85	27	9.64
41-65	85	60.71	84	60.00	169	60.35
66-100	32	22.85	35	25.00	67	23.92
Total	140	100.00	140	100.00	280	100.00

These results demonstrate that the work on vreeding of resistant varieties to causer of powdery mildew in Serbia must be more intensive. In accordance to this, great number of new very resistant lines were lines were created, some of which will recently find place in agricultural practice. Howerer, the fact, hathat resistance of variety can be changed in addition to changes of parasites virulence must be concisered. That is the reason of continuing nature of the work on creation of resistant varieties.
The resistance of some more important commercial varieties was showen in Table 2, as well as those which could be used in breeding programs as donors of genes for resistance.

T.i.-the type of infection; I-the intensity; K-the coefficient of infection

In varieties Jasenica, Fortuna and Nera with the coefficient of infection 8 were very resistant season in 2010. Average resistance expressed varieties Zvezda, Zelengora, Jelica and NS 6902 with coefficients of infection from 16 to 24. Great numbers of varieties were intermediate as Takovčanka (40), Jugoslavija (40), Sremka (40), Pesma (40), Sloga (40) and ZA 16/94 (40). Rest varieties were average o very susceptible.

In 2011 season, immune were varieties Fortuna, Pesma and Dina, with coefficient of infection 0, and varieties Jasenica, Kg 78, Zelengora, Maja and ZA 16/94 wereaverage resistant with coefficients ranking from 16 to 24. Intermediate were varieties Ravanica (40), Jelica (30), Tiha (40) and Sloga (40). Rest varieties expressed high susceptibility.

In season 2010, variety Fortuna was very susceptible, Dina-average susceptible, and Pesma-intermediate, while in season 2011 these theree varieties were immune. This demonstrates, that depending on structure of parasites virulence, variety in one location can express different degree of resistance, pointing out the need of more seasons of investigation of variety resistance.

Results of many studies (Kostić and Ribaković, 1985; Jevtić, 1993), point out the high variability of *Blumeria graminis tritici* population in Serbia. The greatest pressure on structure of virulence and changes in pollution of this fungus make varieties included in agricultural practice (Powers and Sando, 1957).

Obtained results demonstrate that in the voth seasons of examination, the greatest resistance expressed varieties Jasenica and Zelengora. Majority of commercial wheat varieties were very susceptible, which points out the need for future work of creation of resistant varieties to cause of powdery mildew.

Conclusion

On the basis of these investigations it could be concluded that:

-Resistance of some varities of wheat to *Blumeria graminis tritici* was different. Small number of vaieties (5.73%) was in category of resistant, and majority (84.22%) in category of susceptible, while as intermediate appeared 9.64% of varieties.

-In season 2010 varieties Jasenica, Fortuna and Nera were very resistant, and in season 2011-varieties Fortuna, Pesma and Dina.

-At some varieties (Fortuna, Dina and Pesma) differences in resistance were established depeding of season of investigation. Reason for that were specific conditions in ecological factors and virulence of parasites.

-In both seasons of investigations, the greatest resistance and varieties Fortuna, Jasenica and Zelengora.

-Majority of commercial varieties of wheat were very susceptible, which points out the need for intensicve work on breeding of resistance wheat cultivars.

THE VIRULENCE SPECTRUM OF *PUCCINIA GRAMINIS TRITICI* FROM DIFFERENT *BERBERIS* SPECIES

Mirjana STALETIĆ*, Vera ĐEKIĆ, Milivoje MILOVANOVIĆ, Vladimir PERIŠIĆ, Kristina LUKOVIĆ

Small Grains Research Centre, Save Kovacevica 31, Kragujevac, Serbia
*Corresponding author: staleticm@kg.ac.rs

Abstract

The paper presents the virulence spectrum of the *Puccinia graminis tritici* populations from *Berberis* spp. The investigations were carried out at the Small Grains Research Centre in Kragujevac over 2011 and 2012. The aecidiospore samples were collected from 24 species of *Berberis* spp. from the Kragujevac collection. Then most widespread was the pathotypes with virulence's formula (V/A): / 5, 21, 9e, 7b, 11, 6, 8a, 9g, 36, 9b, 30, 17, 13, 22, 24, 25, 26, 27, 29, 31, 32, 33, 37 (50%) that did not contain virulence alleles for the Sr wheat resistance genes studied. The maximum total number of spots with aecidia on the leaf was recorded on May 14, 2011 and on May 18, 2012, being 2053 and 2322, respectively. The aecidia formation rhythm differed between the years. Pathotype BBB was the most widespread (50%) whereas the rest of the pathotypes were present at considerably lower level (4.55-18.19%). Twelve virulence formulas were identified and the highest frequency was recorded with the virulence genes V5, V7b and V6 (45.46%). Resistance genes Sr36, Sr31 and Sr33 were 100% effective. Although *Berberis* spp. Is not a necessary precondition for the rust incidence and spreading, the intensity of the disease is known to be higher in the presence of this intermediate host.

Keywords: *Berberis* spp., *Puccinia graminis tritici, virulence spectrum*

Introduction

Wheat, barley and certain number of the *Poaceae* family species serve as primary and additional posts of the causal agent of wheat stem rust (*P. graminis tritici*). The completion of the parasite´s development cycle requires the presence of and intermediate post *Berberis* spp. (Barberry). As early as 1920. Craige (1981) experimentally proved the parasite hybridization on *Berberis* spp; later to be confirmed by Stakman (1944). Convincing data on the abundance of the physiological races formed on *Berberis* spp. were given by Johnson and Green (1957). They identified seventeen physiologic races from ten samples collected from *Berberis* spp. The population of *P. graminis tritici* on *Berberis* spp. was composed 12 virulence formulae werw established (Staletić et al., 2004).

The subject matter of this investigation as well was the role of *Berberis* spp. in the life cycle of the fungus and the virulence spectrum of the pathotypes produced.

Berberis spp. is important mostly from the point of view of the parasite hybridization taking place on it and resulting in the evolution of new fungus pathotypes that may disturb the existing balance in the parasite-plant system. The goal of these investigations was therefore to study the pathotypes of *P. graminis tritici* derived from *Berberis* spp. and determine their virulence.

Materials and methods

The investigations were carried out at the Small Grains Research Centre in Kragujevac (Serbia) over 2011 and 2012. The aecidiospore samples were collected from 24 species of *Berberis* spp. from the Kragujevac collection (Table 1). The aecidia formation on the shrubs of *Berberis* spp. was observed

and samples were collected at the time of their full development. Every seven days during the months of May and June, the sampling of *Berberis* spp. leaves with aecidia was performed, the collected samples being the average ones considering the highly variable number of aecidia on the leaves. For that reason, the samples were taken from different sided of and heights on the *Berberis* spp. shrubs. One hundred leaf samples were collected from each species of *Berberis* spp. The leaves were dried at room temperature and then kept in refrigerator at +4°C till the beginning of the examination.

During the aecidia sampling, observation was also made on the following morphological traits in different *Berberis* species (*B. ilicifolia, B. gilgiana, B. francisci ferdinandi, B. Fischeri, B. chinensis, B. candidula, B. bidentata, B. atropurpurea, B. aridocalida, B. amurensis, B. angulosa, B. aquifolium, B. purpurea, B. vulgaris* var. *atropurpurea, B. vulgaris, B. virescens, B. vernae, B. thunbergii, B. provincialis* var. *serrata, B. oblonga, B. mutabilis, B. lyceum, B. latiflora* var. *oblanceolata, B. cunawurensis*): the full flowering time, thenumber of inflorescence on the 30-cm-long shott, the number of flowers per inflorescence as well as the number of leaves per nodus. Thed thorn length (mm) was measured and thorn number on the 30-cm-long shoot was identified. The average of then leaves of *Berberis* spp. was taken and the average leaf length and breadth expressed in cm were measured. The shrub development was estimated visually using the following attributes: stunted, moderately vigorous, vigorous and very vigorous.

The artificial wheat inoculation was carried out during winter in the greenhouse using the isogenic wheat line seedlings. The isogenic line multiplication and inoculation method was described in detail by Kostić (1962) and is therefore not presented there. One day prior to the inoculation the leaves with aecidia were placed into Petri dishes contain wet filter paper for the purpose of fructification or releasing as many aecidiospores as possible. The susceptible wheat cultivar Little Club plants were inoculated by the aecidiospores. When the parasite on the susceptible cultivar had been fully developed, individual pustules were taken and multiplied. Pure parasite cultures used for the later inoculation of the isogenic wheat lines were obtained in this way. Twenty grains of each isogenic line were planted in flowerpots. During the first leaf full development stage, their inoculation was performed. 10-12 days later, the plant reaction was estimated by determining the infection types 0-4 (Stakman et al., 1962).

Based upon the results obtained by determining the types of the infection, the pathotypes and virulence spectrum of *P. graminis tritici* were identified.

The pathotype identification was done using Sr lines classified into three groups (Roelfs and Mc Vey, 1974). The lines containing the genes Sr5, Sr9d, Sr9e and Sr7b belong to the first group, those with the genes Sr11, Sr6, Sr8 and Sr9a and Sr36, Sr9b, Sr13 and Sr10 belong to the second and third groups, respectively.

The isogetic wheat lines with known Sr resistance genes (Sr5, Sr6, Sr7b, Sr8a, Sr9b, Sr9e, Sr9g, Sr11, Sr13, Sr17, Sr21, Sr22, Sr24, Sr25, Sr26, Sr27, Sr29, Sr30, Sr31, Sr32, Sr33, Sr36 and Sr37) were used for determining the virulence formulas *P. graminis tritici*.

The isogenic line plants can react in two ways: by resistant (R) types of infection (0-2) and susceptible (S) types of infection (3-4) reactions. Parasite can be virulent (V) or avirulent (A) to the isogenic lines of wheat. Based upon these interactions, the virulence formulas (V/A) as well as virulence groups, being formulas for each isolate studied, were obtained (Green, 1981).

Results and discussion

During then observations, from April 23 to June 24, 2011, a total of 94 aecidiospore samples was collected. In 2012, during seven observations, from April 23 to June 9, 64 samples were collected. Although *Berberis* spp. is not a necessary precondition for the occurrence and spreading of wheat rust, the intensity of the disease incidence is known to be higher in the presence of this intermediate host. The role of *Berberis* spp. in the *P. graminis tritici* epidemiology is primarily connected with the

development and occurrence of new parasite pathotypes, due to which 158 samples were examined during 2011 and 2012.

The onset of the *Berberis* spp. leaving in the conditions of Sumadija is in the first days of April. With this in mind, the observations in both years mentioned started in the second half of April, which is in accordance with the results of Kostić et al. (1970). In this period, the leaf size is such that permits infection by basidiospores. In the course of the first observation (April 23) in 2011, only traces of spermatia were identified, the number of which increased rapidly by the time of the second observation. It was only in the course of the third observation (May 7) that the first aecidiae were identified. It is noteworthy that the first spermatia in the second study year were also identified on April 23. Seven days later, the first aecidia occurred on the leaves. These investigations confirmed the previous findings on the volume and time of aecidia formation in our climatic conditions (Kostić, 1960).

(*A-flowering time; B-the number of inflorescences per shrub on the 30-cm-long shoot; C-number of flowers per inflorescences; D-then number of leaves per nodes; E-then number of thorns on the 30-cm-long shoot; F-thorn length in mm; G-average leaf length in cm; H-average leaf breadth in cm; I-shrub development)

The maximum total number of spots whit aecidia on the leaf was recorded of May 14, 2011 and on May 18, 2012 being 2053 and 2322, respectively. From the mentioned data it could be concluded that the time difference in the aecidia occurrence between the years was not high, being only there days. The termination of aecidia formation takes place at different periods of time. In 2011 it was on June 18 and in 2012 of June 2. Aecidia formation in 2011 and 2012 lasted 61 and 46 days, respectively. The aecidia formation rhythm differed between the years. More intense aecidia formation was registered in 2011 characterized by fluctuating dynamics but in the following year the aecidia formation was somewhat less intense having no sudden rises.

Data on the presence of the pathotypes in 2011 are not shown because no aecidiospores infection of the sensitive wheat cultivar was registered, the primary reason for that being unfavorable climatic conditions during the sampling period. The incessant rain caused washing off and decay of the aecidiospores. Optimal temperature for teleutospore and basidiospore germination ranged from 20-22°C and from 15-20°C, respectively (Vennot-Bourgin, 1949). Humidity necessary for spore germination was positively affected by evenly distributed precipitations as well as by dew.

Although the aecidia were present almost more than two months, the aecidiospores did not exert almost any effect on the occurrence of *P. graminis tritici* on wheat in the observation region. The reason for this should be sought in low virulence of the pathotypes optained from *Berberis* spp. as well as in unfavorable conditions for the development of the infection. Early infection and numerous uredopustules occurred on some *Poaceae* spp. and particularly on *Agropyron repens* growing under or by the shrubs of *Berberis* spp.

All *Berberis* spp. species are charachterized by uniform flowering onset time. In all species it started around April 7 on average. Then number of flowers per shrub on the 30-cm-long shoot highly varied ranging from the absence of inflorescence (*B. aridocalida, B. oblonga* and *B. cunawurensis*) to 23 inflorescences (*B. vernae*). Besides having the highest number of inflorescences, the species *B. vernae* had also the highest number of flowers per inflorescence, being 24 on average. Then number of leaves per nodes was rather uniform ranging from 7 to 11. In the species *B. francisci ferdinandi* leaving was not recorded. The average leaf length was greatest in *B. chinensis* species (4.29 cm) and smallest in *B. aridocalida* (1.65 cm). *B. aridocalida* species had also the smallest average leaf breadth (0.59 cm). The highest being recorded in *B. candidula* species (2.12 cm). The vigor of shrubs of the *Berberis* spp. species ranged from very vigorous (*B. Fischeri, B. amurensis, B. angulosa, B. vulgaris* var. *atropurpurea* and *B. vernae*) to stunted species (*B. francisci ferdinandi, B. atropurpurea, B. aridocalida, B. aquifolium* and *B. purpurea*), (Table 1).

In 2012 by the analysis of 22 isolates of *P. graminis tritici* from *Berberis* spp.; twelve virulence formulas were detected. Then most widespread was the pathotypes with virulence`s formula (V/A): / 5, 21, 9e, 7b, 11, 6, 8a, 9g, 36, 9b, 30, 17, 13, 22, 24, 25, 26, 27, 29, 31, 32, 33, 37 (50%) that did not contain virulence alleles for the Sr wheat resistance genes studied. The rest of the pathotypes were represented by one isolate each or 4.55%. The number of virulence genes in then ranged from 1 to 15 (Table 2).

Table 2. *Virulence formulas of P. graminis tritici from Berberis spp. in 2012*

From the data in Table 3. it could be seen that the highest frequency in the population of parasite *P. graminis tritici* in 2012 was registered with virulence genes V5, V7b and V6 (45.46%) and the lowest one with the genes V36, V31 and V33 (0%). The frequency of other genes ranged from 4.55% to 40.91%.

The Sr gene effectiveness against the isolates of *P. graminis tritici* from *Berberis* spp. in 2012 is shown in Table 3. The most effective genes were the genes Sr36, Sr31 and Sr33 which did not have virulence alleles in the parasite population, followed by genes Sr9e, Sr8a, Sr24, Sr26 and Sr32, their effectiveness being 95.46%. The rest of the genes were more or less ineffective.

Table 3. The effectiveness of Sr genes against isolates of P. graminis tritici from Berberis spp. in 2012

Sr genes	R		S	
	Number of isolates	%	Number of isolates	%
5	12	54.55	10	45.46

37	18	81.82	4	18.19

Although *Berberis* spp. is not unnecessary precondition for the rust incidence and spreading, the intensity of the disease is known to be higher in the presence of this intermediate host. Relatively low variability of *P. graminis tritici* is caused by low presence in nature of the intermediate host *Berberis* spp. where the sexual stage of the life cycle of the fungus takes place. Barberry destruction was performed with the aim of preventing the hybridization of races and therefore the virulence gene recombination. However, the spreading of the disease and incidence of novel pathotyipes have not been stopped.

Conclusion

Based upon the results obtained of the study of the *P. graminis tritici* population structure in accordance with the research goal, the following conclusions may be drawn:

-The maximum total number of spots whit aecidia on the leaf was recorded of May 14, 2011 and on May 18, 2012 being 2053 and 2322, respectively. The aecidia formation rhythm differed between the years. More intense aecidia formation was registered in 2011 characterized by fluctuating dynamics but in the following year the aecidia formation was somewhat less intense having no sudden rises.

-In 2012 bay the analysis of 22 isolates of *P. graminis tritici* from *Berberis* spp.; twelve virulence formulas were detected. The most widespread was the pathotype with the virulence formula (V/A): /5, 21, 9e, 7b, 11, 6, 8a, 9g, 36, 9b, 30, 17, 13, 22, 24, 25, 26, 27, 29, 31, 32, 33, 37 (50%) that did

not contain virulence alleles for the Sr wheat resestance genes studied. The rest of the pathotypes were represent by one isolate each or 4.55%. The number of virulence genes in the ranged from 1 to 15.

-The highest frequency in the population of the parasite in 2012 was registered with virulence genes V5, V7b and V6 (45.46%) and the lowest one with the genes V36, V31 and V33 (0%). The frequency of other genes ranged from 4.55% to 40.91%.

-In the some year, the most effective genes were the genes Sr36, Sr31 and Sr33 which the not have virulence alleles in the parasite population, followed by genes Sr9e, Sr8a, Sr24, Sr26 and Sr32, their effectiveness being 95.46% the rest of the genes were more or less ineffective.

-Although *Berberis* spp. is not unnecessary precondition for the rust incidence and spreading, the intensity of the disease is known to be higher in the present of this intermediate host.

Abstract

Rainfall and humidity is one of the abiotic environmental factors may influence bread wheat quality during grain filling period in Trakya region (Turkey). It was investigated effect of the rainfall and humidity, in April May and June, to quality of the bread wheat cultivars. Rainfall and humidity from shooting up to grain filling period were taken in experimental area. This research was established with 25 genotypes in RCBD with 4 replications in Edirne, between 2005 and 2015 growing seasons. Aldane, Selimiye, Pehlivan and Gelibolu were selected from this experiment. Grain yield, TKW, TW, protein ratio, gluten, hardness and sedimentation and relationship amongst these traits were investigated. There were various relations among investigated parameters. The rainfall in shooting stage positively affected and increased protein ratio, gluten, hardness, sedimentation, and grain yield. Rainfall during heading and grain filling period significantly affected and increased TKW, test weight, while negatively affected and decreased protein ratio, gluten value and sedimentation (r= -0.670). The rainfall in late stage of grain filling negatively affected test weight and grain hardness. Grain yield and sedimentation was positively correlated. Mean humidity from shooting up to grain filling positively and significantly affected and increased gluten index. Also, there was highly significant correlation between protein with gluten (r= 0.976**), hardness (r= 0.589), and sedimentation (r= 0.780). There was negative relation between TKW with protein ratio, gluten, index, hardness and sedimentation, while positive relation between yields. The rainfall in April and June positively affected yield potential of the cultivar. During heading and grain filling period high amount of rainfall and humidity decreased grain quality except TKW and test weight.

Key Words: *Bread wheat, cultivar, rainfall and humidity, yield, quality characters*

Introduction

Trakya region is located in the Northwestern part of Turkey. Mostly bread wheat cultivars are grown and it covers 5-6% of the total wheat area of Turkey. Average wheat yield is almost 5.0 tons/ha and production 3 million tons per year (Anonymous, 2011). Although the average annual rainfall is 560 mm this precipitation ranges between 350 mm to 850 mm. During the growing season (October-June) the distribution of this rainfall is not regular. Due to this fluctuation of rainfall in some growing year causes decrease in grain yield and quality (Anonymous, 2011). Almost all breeding programs in the world aim to improve varieties with stable yields (Pfeiffer and Braun, 1989). Environmental factors play a main role in the expression of genotype characteristics (Peterson et al., 1998). In wheat, grain yield and baking quality are dependent on the environment, genetic factors and the interaction between them (Yan and Holland, 2010; Coventry et al., 2011). Both the quality and content of the wheat protein are affected by the climatic conditions during

wheat maturation (Johnson et al., 1972; Johansson and Svensson, 1998). Increasing yield potential without affecting negatively the quality of the grain is difficult, mainly because increases in grain yield are generally accompanied by a decrease in the grain's protein content, which is strongly associated with bread-making quality (Pena 2002). Grain protein content in the mature grain is largely determined by environmental and farm management factors, with genetics playing a minor role in being either low or high in protein content. By contrast, protein quality is determined by the genetic composition of the wheat variety and also how the environment influences genetic expression (Blakeney et al., 2009). Environmental factors, such as nitrogen fertilization, water and temperature, influence protein content (Sissons et al., 2005). In contrast, protein quality is largely under genetic control (Lerner et al., 2006; Rogers et al., 2006). The physical characteristics of grain are important as they are indicative of potential processing quality. Grain hardness, which is largely genetically determined (Pena, 2008). Also grain hardness is a grain quality trait associated with the milling properties of wheat (Miller et al., 1982). Success of a wheat breeding program depends on the regional adaptability of the cultivars improved and adaptability of such cultivars in the target environments determined by its tolerance to biotic and abiotic stresses. The most important abiotic stress factor is the shortage of rainfall in the region. There are three critical periods of rainfall; fall rains during the early vigor and tillering, early spring rains during the tiller survival and stem elongation, and late spring rains during grain filling period (Altay, 2012). The purpose of the study was to investigate and comparison grain yield with the major quality characteristics of four widely cultivated varieties under varied rainfall and humidity condition in in Trakya region, Turkey.

Materials and Methods

The experiment was conducted in Trakya Agricultural Research Institute experimental area during 2005-2015 growing seasons. Twenty five winter wheat genotypes were examined under field condition with randomized complete block design with four replications. Four cultivars which are Pehlivan, Gelibolu, Aldane and Selimiye were selected from these experiments. All plots were sown into 6 rows, and plot sizes were 6 m^2 at harvesting. It was used 500 seeds/m^2 at planting. Sowings were performed by using a plot drill in October and in November, and nitrogen was applied at tree times, and for weed control chemical was used.

Grain yield, thousand kernel weights and test weight, (Blakeney et al., 2009), protein ratio, grain hardness, gluten, gluten index, and sedimentation (Köksel ve ark., 2000; Perten H. 1990; Anonymous, 2002; Anonymous, 1990) were investigated. The quality analysis of Zeleny sedimentation test and wet gluten content were determined according to ICC standard methods No. 116/1 and 106/2, respectively (Anonymous, 1972; Anonymous, 1984).

The rainfall and mean humidity in April (Z31-Z47), May (Z49-Z75) and June (Z77-Z90) from shooting up to ripening period were taken from 2005 up to 2015 growing years in experimental field (Table 1). The Zadoks Decimal Code (Z) was used to describe plant growth stages of cereals. The described plant development stages are; April: Zadoks Z31 (first node detectable) from up to Z47 (flag leaf sheath opening), May: Z49 (first awns visible) from up to Z75 (medium milk), June: Z77 (late milk) from up to Z90 (ripening). Also, regression graphs are used to predict comparison of characters. The statistical analyses of measurements were performed by using statistics program for and the differences among the means were compared with LSD (Least Significant Differences) at a 5% significant level (Kalaycı 2005).

Table 1. The rainfall (mm) and mean humidity (%) scored in April, May and June

Results and Discussion

According to mean yield and other investigated traits there were significant differences among years. The highest average yield was 863.6 kg in 2008, and in 2014 with 824.4 kg/da. The lowest yield was obtained in 2009 due to environmental condition. Test weight is the weight of a specific volume of grain and is an indication of the bulk density of the grain. It reflects the extent of grain filling and the potential for flour yield (Blakeney et al., 2009). There were significant differences among years, so test weight ranged from 79.9 kg in 2013 to 85.2 kg in 2015. Mean test weight was 82.1 kg. Grain or kernel weight is the mass of a given number of kernels and is a useful measure of grain size (Blakeney et al., 2009). The highest TKW was measured in Pehlivan (46.6 g). TKW ranged from 34.5 g in 2011 to 51.6 g in 2005 among years and mean value was 43.8 g. (Table 2 and 3). There were significant differences among years according to protein ratio and ranged from 9.8% in 2014 up to 14.5%in 2011 year. Mean protein ratio was 12.0%. Wheat hardness is influenced especially by genetic factors, but can be influenced also by environment and factors like moisture and protein content (Turnbull and Rahman 2002). In this study there were significant differences among years according to grain hardness and ranged from 46.0 in 2010 up to 55.0 in 2011 year. Mean of the grain hardness was 49.4 (Table 2 and 3).

Statistically significant differences for wet gluten content were found among genotypes, and years. According to years, the highest wet gluten content was measured in 2011 year (42.3%), while the lowest with 25.9% in 2014 year. Mean gluten content was 33.9%. Also, there was a significant difference for gluten index. Gluten index ranged from 74.9% in 2012 up to 93.0% in 2014 year. Analysis of variance showed highly significant differences among genotypes investigated years for sedimentation value. Average sedimentation value ranged from 33.0 ml (in 2017) to 64.3 ml (in 2011). Genotypes reacted differently on investigated years. The highest sedimentation value achieved in Aldane cultivar (59.1 ml), while the lowest in Pehlivan (41.9 ml). The mean sedimentation value was 48.5 ml (Table 2 and 3).

Analysis of variance showed highly significant differences among genotypes (G) investigated years (Y) for all quality parameters and year 2011was very favourable for protein ratio, gluten value, grain hardness, gluten index and sedimentation value. It was very favourable year of 2012 for 1000-kernel weight and test weight.

The four cultivars, Pehlivan, Gelibolu, Aldane and Selimiye, selected from this study and for the comparison rainfall and mean humidity with their yield, quality parameters. The results of variance analysis showed that there was statistically difference among genotypes according to yield and quality parameters. Selimiye was the highest yielding cultivar with 746.3 kg/da. The highest value of the TW, protein ratio, gluten value and hardness was determined in Selimiye cultivar. Aldane have highest gluten index and sedimentation (Table 3).

In order to find, relationship and effect of the rainfall, from Z31 (first node detectable) up to Z47 (flag leaf sheath opening) plant growth stage on some quality parameters was investigated (Figure 1). Rainfall from Z31 to Z47 plant growth stage affected positively gluten value, grain hardness and

sedimentation value. A positive correlation was found between rainfall and gluten content (R^2=0.136), hardness (R^2=0.344) and slightly relation with sedimentation value (Figure 1). Also, it was investigated, relationship and effect of the mean humidity, from Z31 up to Z47 plant growth stage on some quality parameters (Figure 1). Mean humidity from Z31 to Z47 plant growth stage affected positively gluten index value, grain hardness and sedimentation value and negatively affected 1000-kernel weight. A positive correlation was determined between mean humidity with gluten index (R^2= 0.522), and sedimentation value (R^2=0.261), while a negative correlation existed between the mean humidity and the 1000-kernel weight (R^2= -0.214) (Figure 1).

Relationship rainfall and mean humidity with yield and quality parameters from Z49 (first awns visible) up to Z75 (medium milk) plant growth stage was given in Figure 2. The increasing in rainfall during Z49 up to Z75 (booting, heading and grain filling period (from Z49 to Z75) positively affected and increased TW, TKW and gluten index, also negatively affected and decreased protein ratio, gluten value and sedimentation. A positive correlation was found between rainfall and test weight (R^2= 0.182), 1000-kernel weight (R^2=0.237), while a negative correlation existed between the rainfall and sedimentation value (R^2=0.449), protein ratio (R^2=0.180) and gluten value (R^2=0.113). The mean humidity during Z49 up to Z75 positively affected gluten index (R^2= 0.376) (Figure 2).

Gluten index and mean humidity in April | Sedimentation and mean humidity in April

Figure 1. Relationship rainfall and mean humidity with yield and quality parameters from Z31 (first node detectable) up to Z47 (flag leaf sheath opening) plant growth stage

During Z77 with Z90 relationship among rainfall with yield and quality parameters was investigated. The rainfall positively affected and increased TW, TKW and gluten index, also negatively affected and decreased protein ratio, gluten value and sedimentation. There was negatively relation rainfall with test weight (R^2=0.166), and grain hardness (R^2=0.169), while a positive correlation founded between rainfall and the grain yield (R^2=0.216) and gluten index. The mean humidity during Z77 up to Z90 was positively correlated with gluten index and sedimentation value with R^2 values of 0.536 and 0.191 respectively (Figure 2). Also, mean humidity during Z77 up to Z90 was slightly negatively correlated with test weight.

Note: Significance at **: P<0.01 and * :P<0.05; RAPR: Rain April (Z31-Z47); RMAY: Rain May (Z49-Z75); RJUNE: Rain June (Z77-Z90); MHA: Mean Humidity April (Z31-Z47); MHM: Mean Humidity May (Z49-Z75); MHJ: Mean Humidity June (Z77-Z90); GY: Grain yield (kg/da), TKW: Thousand kernel weight (g), TW: Test weight (kg), PRT: Protein content (%), GLT: Gluten (%), IND: Gluten index (%), HARD: Hardness, SED: Sedimentation (ml)

Correlation coefficients among the tested characters were given in Table 4. It was found various relations among investigated parameters based on rainfall and humidity with yield and quality parameters. The rainfall in April (Z31-47) positively affected and increased protein ratio (r= 0.273), gluten (r= 0.370), hardness (r= 0.587), sedimentation (r= 0.314), and grain yield (r= 0.435). Rainfall in May (Z49-75), during heading and grain filling period, significantly affected and increased TKW (r= 0.487), test weight (r= 0.427), but negatively affected and decreased protein ratio (r= -0.425) gluten value (r= -0.337), and sedimentation (r = -0.670). The rainfall in June (Z77-90) positively affected sedimentation and grain yield, while negatively affected test weight and grain hardness. Mean humidity in April (r= 0.723), May (r= 0.614) and June (r= 0.732) positively and significantly affected and increased gluten index. Also, there was highly significant correlation between protein and gluten (r= 0.976**), hardness (r= 0.589), and sedimentation (r= 0.780). There was negative relation between TKW with protein ratio, gluten, gluten index, hardness and sedimentation, but positive relation between grain yields.

The rainfall in April and June positively affected yield potential of the cultivar. During heading and grain filling period high amount of rainfall and humidity decreased grain quality except 1000-kernel weight and test weight.

Conclusion

Environmental factors over years strongly influenced the grain yield and quality parameters. This large difference in variance between environmental and genotypic influences clearly demonstrates the importance of growing season weather impact on quality for adapted bread wheat genotypes. There were various relations among investigated parameters. The rainfall during shooting stage positively affected and increased protein ratio, gluten, hardness, sedimentation, and grain yield. Rainfall during heading and grain filling period significantly affected and increased TKW, test weight, while negatively affected and decreased protein ratio, gluten value and sedimentation. The rainfall in late stage of grain filling negatively affected test weight and grain hardness, also positively affected gluten index and sedimentation. The mean humidity from shooting up to grain filling period positively affected and increased protein ratio, gluten, gluten index, hardness and sedimentation. During heading and early grain filling period mean humidity increased TKW, hardness and gluten index.

Also, there was highly significant correlation between protein with gluten, grain hardness, and sedimentation value. There was negative relation between TKW with protein ratio, gluten, index, hardness and sedimentation, while positive relation between test weight and yields. During heading and grain filling period high amount of rainfall and humidity decreased grain quality except 1000-kernel weight and test weight.

WEED CONTROL IN SUNFLOWERS WITH *CLEARFIELD PLUS* TECHNOLOGY

Todor MANILOV*, Ivan ZHALNOV

Department of Agronomy, Agricultural University, Plovdiv, Bulgaria
Corresponding author: t.manilov@yahoo.com

Abstract

Field trial experiments were set up in a region close to the town of Pazardzhik (Bulgaria) in the period 2013 - 2015. The object of the experimental work was *Clearfield Plus* technology, which included soil herbicides. The sunflower hybrid that was used during three years of the experiment was *EC Candimis CL Plus*. The main aim of the experiment was to determine the selectivity of imazamox-based herbicides to the sunflower and herbicidal efficacy of the combinations of pre and post emergence herbicides against economically important weeds in the sunflower. Reported herbicide tolerance to crop in three years, which is characterized by slightly lightening the leaves on some of the tretments.The phytotoxicity disappeared within 14 – 21 days after the application of postemergence herbicides. The trial results over the last three years showed that the most significant differences were in the efficacy of *Pulsar 40* against perennial weeds. Solely application of herbicide *Pulsar 40* without *Dash*, significantly reduced its effectiveness against *Sorghum helepense* L., *Cirsium arvense* L. and *Chenopodium album* L. However, against annual broadleaf species – *Amaranthus* spp, *Sinapis arvensis* L, *Raphanus raphanistrum* L, *Solanum nigrum* L. and others – its efficiency was 100%. The pre-emergence herbicides- used immediately after sowing showed great at controlling over some economically important annual weeds in early stages of crop development.

Keywords: *Selectivity, efficacy, herbicides, sunflower*

Introduction

Sunflower is one of the most important oil-bearing crops in the world due to its high adaptation capacity, mechanization and also the fact that it is preferred by customers as a vegetable oil. The areas where sunflower is grown are not very large worldwide owing to the fact that the profits are lower because as a summer crop it is influenced by the conditions of the environment. In order to increase the production, it is important to reduce the effect of factors decreasing the seed yield by using techniques that boost production and also by developing cultivars giving higher yield (Skoric, 2012; Kaya, 2014b).

The fight against weeds in sunflower must be initiated during the earliest phenophases of the crop because when it enters the stage of intensive growing of the stems, the crop itself is capable of successfully coping with the competition of the weeds. The weeds that are most widespread in sunflower are *Amaranthus* spp, *Sinapis arvensis* L., *Echinochloa crus-galli* L., *Setaria* spp, *Chenopodium album* L., *Cirsium arvence* L., *Sorghum helepense* L., *Orobanche cumana* W. and others. During the conventional growing of sunflower, what is crucial for the successful outcome of the fight against weeds is the early deep ploughing after gathering the previously grown plants and the additional summer and autumn cultivation. Thus, we obtain a bed for sowing sunflower which is relatively better cleaned from weed seeds (Tonev, 2000, Jocić , *et al*., 2011).

The most important thing in the pre-sowing spring cultivation is the early initial cultivation by means of harrowing, which eliminates all the weeds that have survived the winter and triggers the

germination of new weed seeds. Sunflower is a crop that can stand both pre-germination and post-germination harrowing using light weed spike-tooth or rotary harrows. The timely harrowing, which has to coincide with the period of mass germination of the weeds, has a substantial anti-weed effect (Mitkov and Stoychev, 2014).

When sunflower plants become overgrown with weeds, two or three inter-row cultivations must be performed, reaching a depth of 6-8 cm. During the last cultivation, it is recommended to earth up the sunflower plants slightly. Thus, a large number of shoots of the late-growing weeds will be covered with soil and will die as a result. The need to conduct vegetation cultivation of sunflower is reduced depending on the level of cleaning of the soil from weeds after the successful application of herbicides (Tonev, *et al*., 2010; Tonev, *et al*., 2015).

Considering the fact that with the conventional sunflower hybrids the selective herbicides do not show effectiveness regarding *Xanthium strumarium* L and *Cirsium arvence* L, whose density over the last years has been too high, a good alternative is offered by the technologies „*Sun"* and „*Clearfield*" in sunflower. In order to fight all types of *Orobanche cumana* W. in sunflower, we use the technology *Clearfield* (Tóth *et al*., 2004; Suresh and Reddy, 2010, Tonev, *et al*, 2009).

The inclusion of sunflower in appropriate and scientifically substantiated crop rotations, in which it is usually alternated with densely sown crops, facilitates the fight against the perennial and the late-spring weeds (Malidža *et al*., 2011; Reis *et al*, 2014).

The purpose of this research is to:

- Conduct comparative testing in order to establish the selectivity of the imazamox-containing herbicides towards the new generation of sunflower hybrids based on the *Clearfield* technology.
- Establish the effectiveness of various doses of imazamox-containing herbicides with added adjuvant *Dash* and also in combination with soil herbicides against the most economically significant weeds in sunflower which is grown based on the technology *Clearfield Plus* considering the conditions in Bulgaria.

Material and Methods

In the period 2013-2015, we conducted a field experiment on areas sown with sunflower in the region of the village of Chernogorovo, district of Pazardzhik. The subject of the experiment was the technology *Clearfield plus* and during the three years of the experiment we used the sunflower hybrid ES *Candimis CL Plus*. The tested soil herbicides *Stomp Aqua* (455g/l pendimethalin) and *Gardoprim Plus Gold* **(**312.5 g/l S-metolahlor + 187.5 g/l Terbutilazin) were applied right after the sunflower was sown and all the other herbicides were applied during the 4^{th}-6^{th} leaf phenophase of the sunflower, the rosette stage of the main broadleaves weeds and the tillering stage of the grass weeds.

Field trial has 6 treatments plots and each plot was with size of 21m2 made in four replications. The untreated area were included in the randomization in each replication. We also included an additional control sample which had undergone mechanical treatment once (Dimova, D., *et al*, 1999).

As a result of the experiments, we determined the selectivity of the herbicides towards sunflower and the effectiveness against weeds on the 14^{th}, 28^{th} and 56^{th} days (in % based on the EWRS scale) upon the application of the vegetation herbicides. The experiments were conducted in accordance with the EPPO standards of the European Union.

Results and Discussion

The manifestations of phytotoxicity on cultivated crops are an important element of the effectiveness of a certain herbicide used to control weeds. We registered the phytotoxicity towards the crop of the herbicides used to fight weeds in sunflower during two stages – on the 14^{th} and 28^{th} days upon the application of herbicides. The results showed that upon the application of vegetation herbicides, there is slight phytotoxicity in variants 4 and 5 which is manifested as slight lightening of the treated sunflower plants. These symptoms of the sunflower plants completely disappear after the 28^{th} day upon the application of the vegetation herbicides.
The effectiveness of the herbicides regarding the main weed types growing among the sunflower plants are shown in Tables 3, 4 and 5. The results from the experiments show that the most significant differences are to be observed in the effectiveness of *Pulsar 40* against perennial weeds. The individual use of *Pulsar 40* without the adjuvant *Dash* significantly reduces its effectiveness against *Sorghum helepense* L., *Cirsium arvense* L., *Xanthium strumarium* L., *Chenopodium album* L. and *Portulaca oleracea* L. Regarding the effectiveness against annual

broadleave types – *Amaranthus retroflexus* L., *Sinapis arvensis* L., *Raphanus raphanistrum* L., *Solanum nigrum* L. and others – it is 100% and there are no differences between the various doses applied – 1.0 and 1.2 l/Ha. The individual application of the herbicide *Pulsar 40* in a dose of 1.2 l/Ha, without the adjuvant *Dash*, makes it as effective against the most resistant weeds as the herbicide applied in a dose of 1.0 l/Ha in combination with 1.0 l/Ha of the adjuvant *Dash*.
The use of the soil herbicides *Stomp Aqua* and *Gardoprim Plus Gold* applied in a dose of 3.5 l/Ha after sowing and before the germination of the crop controls the annual weeds, with the exception of *Xansthium strumarium* L. *Sorghum helepense* L., *Cirsium arvense* L.. At the time of applying the vegetation herbicides during the 4^{th}-6^{th} leaf stage of the crop, the density of the annual grass and broadleave weeds is significantly lower compared to the untreated area.

Conclusion

In order to exercise effective control over the resistant types *Sorghum helepense* L., *Xanthium strumarium* L., *Chenopodium album* L., *Portulaca oleracea* L. and *Orobanche cumana* W., it is necessary to apply *Pulsar 40* in the highest tested dose of 1.2 l/Ha, with the compulsory addition of the adjuvant *Dash*.

In case of weeds that are highly sensitive to the herbicide *Pulsar 40* such as *Sinapis arvensis* L *Solanum nigrum* L., *Myagrum perfoliatum* L. and others, *Pulsar 40* can be applied in the lowest tested dose of 1.0 l/Ha, without adding the adjuvant *Dash*.

In case of areas significantly overgrown with *Sorghum helepense* L from rizoms, the herbicide *Pulsar 40* must be used in a dose of 1.2 l/Ha, in combination with adjuvant Dash in a dose of 1.0 l/Ha.

The use of soil herbicides in combination with *Pulsar 40* is justified in those cases when there are areas significantly overgrown with annual grass and broadleaves weeds and later application of the herbicide *Pulsar 40*.

Abstract

One of the main imperatives of agriculture and processing industry is the production of safe food of high nutritional quality free of biological, physical and chemical contaminants. Cereals are an essential part of human nutrition. Microorganism represents permanent microflora elements of cereals and fruits. The most frequent moulds are *Aspergillus*, *Penicillium*, *Fusarium*, *Claviceps* and *Alternaria*. Some of them biosynthesizes and excrete mycotoxins (aflatoxins, ochratoxins, sterigmatocystin, zearalenone, fumonisin, deoxynivalenol, ergot alkaloids). Data testify that about 25% of the total world production of grain is contaminated with at least one mycotoxin. Among the raw materials that are usually contaminated with mycotoxins are cereals, maize, oilseeds, dry and stone fruits. Mycotoxins in humans and animals cause mycotoxicosis and manifest mutagenic, teratogenic, embryo-toxic, hepatogenic, nephrotoxic, dermatogenic and carcinogenic effect. Stored products are also attacked by storage pests. The most important insect storage pests are *Sytophilus granaries*, *Rhyzopertha dominica*, *Tribolium* sp., *Pyralis farinalis*, *Sitotriga cerealella*, *Plodia interpuctella*, *Ephestia kuehniella* and *Tinea granella*. Contamination by insects, their metabolites and excrements reduces the quality of the food and makes it unsuitable for consumption. Many insect species are hosts and vectors of pathogens of man and/or animals. Carcinogenic and teratogenic substances are produced only by *Tribolium* sp. Professional exposure to the infested dust of grains is associated with changes in the type of allergic conjunctivitis, dermatitis or asthma. From rodents as storage pests and vectors of infectious diseases emphasize *Ratus norvegicus*, *Mus musculus* and *Rattus rattus*. Contaminants of food are global problem, they cause economic damage and have a negative impact on food and feed i.e. human and animal's health.

Keywords: *mycotoxins, insects, health risks.*

Safe food means good health

Imperative of agriculture and processing industry is the production of safe food of high nutritional quality without the biological, physical and chemical contaminants. For secure safe final product is very important production and quality of raw materials i.e. "from farm to fork". Cereals and cereal products are very present in the nutrition of humans and animals (Perši *et al*., 2011). It is necessary to minimize the presence of contaminants in grain weight. Permanent companions of grain and grain mass are microorganisms. Contamination by microorganisms and their metabolites occurs in the fields, during the harvest, then during transport and storage (Coffey *et al.,* 2009). They pose a major problem especially expressed during the rainy weather (Pepeljnjak *et al.,* 2008; Mitak *et al*., 2011).

Fungi and mycotoxins as a serious danger

Fungi are ubiquitous plant pathogens that are major spoilage agents of foods and feedstuffs. The infection of plants by various fungi in the same time having results in reduction in crop yield and quality with significant economic losses. Also the fungi contribute contamination of grains with poisonous fungal secondary metabolites called mycotoxins. The ingestion of such mycotoxin contaminated grains by animals and humans has enormous public health significance. These toxins can cause diseases in human and animals (Makun, 2013). The disease produced by mycotoxins is termed as "mycotoxicosis" (Pal, 2007). Acute mycotoxicoses can cause serious and sometimes fatal diseases. The possibility of mycotoxin intoxication should be considered when an acute disease occurs in several persons when there is no evidence of infection with a known etiological agent, and no improvement in the clinical picture following treatment. Most of the outbreaks of mycotoxicoses described are a consequence of the ingestion of food that is contaminated with mycotoxins. The thorough control of food quality, in both industrialized and developing countries, is therefore necessary to avoid such outbreaks (Pal, 2015). According to Ožegović and Pepeljnjak (1995) - the most common molds are of genus *Aspergillus*, *Penicillium*, *Fusarium*, *Claviceps* and *Alternaria* and they are classified into field molds (*Alternaria*, *Helminthosporium*, *Fusarium* and *Cladosporium*) and storage molds (*Penicillium* and *Aspergillus*). Species of the genus *Penicillium*, *Fusarium* and *Alternaria*, as well as teleomorph class Ascomycetes (*Aspergillus alliaceus*, *Aspergillus nidulans*, etc.) are most often cited as potential producers of mycotoxins (Samson *et al*., 2004). *Aspergillus*, *Penicillium* and the *Eurotium* are "storage" fungi that develop within water activity (aw value) of 0.85 or lower, so that they can be isolated from spices, dried fruits, vegetables, sunflower seeds and similar products. Types from genus *Fusarium* and *Alternaria* are the "field" fungi and their development requires a higher moisture content in the substrate and lower temperature. These types are often found in/on grain cereals and cereal products (Kocić-Tanackov and Dimić, 2013). Mycotoxins are toxic byproducts (secondary metabolites) produced by fungi. Namely, aflatoxins, ochratoxin A, fumonisins, certain trichothecenes, and zearalenone are considered the most serious threat to human and animal health due to their carcinogenic potential of hepatogenic, teratogenic, and mutagenic effects (Pal, 2015).

Alternaria toxins biosynthesize different species of genus *Alternaria*, the frequent causal agents of plant diseases. These types of fungi are the main contaminants of wheat, sorghum, barley, sunflower, canola, tomatoes, apples, citrus fruits, olives (Desphande, 2002).

Zearalenone - zearalenone are like fumonisine derivatives polyketides. They are natural contaminants of harvested and stored grain and their derived products around the world (Kocić-Tanackov, 2004; Zinedine *et al.*, 2007; Weidenbörner, 2008; Rhyn and Zoller, 2003).

Sterigmatocystine (STC) is a secondary metabolite of some species of the genus *Aspergillus* and as the most important producer of this toxic metabolite is cited *A. versicolor* (Veršilovskis and De Saeger, 2010).

Aflatoxins are highly toxic coumarin derivatives mainly biosynthesized by *A. flavus* and *A. parasiticus*. The most important mycotoxins from this group are aflatoxins B1 (AB1), B2 (AB2), G1 (AG1), G2 (AG2), M1 (AM1) and M2 (AM2) (Samson *et al*., 2004; Park *et al*., 2000). These mycotoxins fungi biosynthesize in/on a number of substrates, such as oil seeds, cereals and their products, stone fruits, subtropical fruits, spices (Weidenbörner, 2008). Most often they are found in products that are not sufficiently dried after harvest or during storage at relatively high temperatures. From this group of mycotoxins AB1 is the strongest carcinogen, followed AG1, AM1 and AB2. At mammals aflatoxins cause acute aflatoxicosis, which are manifested primarily

through liver damage, although the kidneys, lungs and spleen may be damaged. AB1 is described as the strongest potential hepatocancerous (Fink-Gremmels, 2008).
The high average temperatures and a long drought cause heat stress in plants, causing a plant contamination with fungi of the genus *Aspergillus*, especially in the period of flowering and tanning corn silk (Marsh *et al.*, 1984; Kocić-Tanackov *et al.*, 2013).
Fusarium growth often implies production of mycotoxins (e.g. trichothecenes, zearalenone, fumonisins, moniliformin, etc) which pose a threat to human or animal health (Krsmanović *et* al., 2005).
One of the first known mycotoxicosis is ergotism. Ergotism was responsible for the deaths of thousands in medieval Europe (Duraković *et al*., 2003; Diaz, 2005).
Ergot alkaloids are compounds produced as a toxic mixture of alkaloids in the sclerotia of species of *Claviceps*, which are common pathogens of various grass species. Modern methods of grain cleaning have significantly reduced ergotism as a human disease. However, it is still an important veterinary problem (Bennett and Klich, 2003).
The most important in the transmission of mycotoxins are grains because they consume humans and animals. It is assumed that even 25 to 40% of the world grains are contaminated with mycotoxins (Pittet, 1998; Peraica and Domijan, 2001, Surai *et al*., 2008). Although there are more than 300 isolated mycotoxins (Betina, 1984), studies mainly refer to those who threaten the health of people, domestic animals and pets. In recent years numerous studies have been conducted on the impact of mycotoxins on human health and the emergence of certain diseases of unclear etiology. Since 1993, "World Health Organization International Agency for Research on Cancer" estimated potential carcinogenic and mutagenic effects of certain mycotoxins on humans (WHO-IARC, and WHOIARC 1993a, 1993b). Comprehensive negative effect on people (Peraica *et a*l., 1999) and animals (D'Mello and MacDonald, 1997) gave in their review articles.
Crop rotation (Jaime Garcia and Cotty, 2010) is one way to reduce the risk of contamination by molds and mycotoxins in the field. Alsao, the storage conditions after harvest are of great importance for the prevention of occurrence of mycotoxins. Sorting and drying kernels are important parameters to prevent subsequent contamination of grain mycotoxins (Jaime Garcia and Cotty, 2007; Birck *et al*., 2006).

Insects as vectors of disease

Stored products of agricultural and animal origin are attacked by more than 600 species of beetle pests, 70 species of moths and about 355 species of mites causing quantitative and qualitative losses (Rajendran, 2002). Insect contamination in food commodities is an important quality control problem of concern for food industries. In industrialized countries like Canada and Australia there is zero tolerance for insects in food grains (White, 1995; Pheloung and Macbeth, 2002). The fact is that a reduction in quality and contamination of food by insects, their metabolites and excrements makes food unsuitable for human consumption. The most common insects as food contaminants negatively affect the quality of the food itself, but also on human health (Orris and Whitehead, 2000). Insects cause physical, chemical and microbiological contamination of products in warehouses. Physical contamination represent occurrence of different parts of the insect body or insect stage (eggs, larvae, exuviae or excrements). Many insect species in warehouses are hosts and vectors of pathogens of man and/or animals. In that way become leading agents in microbial contamination of stored food products (Olsen, 1998). The most common contaminants are the insects with hidden development - within the stored grains such as *Rhyzopertha sp*. and *Sitophilus sp* (Tanasković *et al*). *Sitophilus oryzae* (L.), *S. granaries* (L.) or *Rhyzopertha dominica* (F.) are the main source of physical contamination in

flour (Pedersen, 1992; Perez-Mendoza *et al*., 2003). The major storage pests of milled rice are *Sitophilus spp*. and *Tribolium caslaneum*, with *Corcyra cephalonica*, *Ephestia kuehniella*. *Rhyzopertha dominica* and some other secondary pests causing minor damage (Sidik *et al*., 1985). Carcinogenic and teratogenic substances are produced only by *Tribolium spp*. (El-Mofty *et al*., 1989, 1992). Namely, in secretion of these species (*T. castaneum*) were identified 13 different quinone (Howard, 1987). These ingredients give an unpleasant flavor in storage products and at some small vertebrates can cause cancer of the liver and spleen (El-Mofty *et al*., 1988; 1989; 1992). Although quinones may endanger the health of animals for experiments, the level of contamination *T. castaneum* in warehouses of finished products is low or normal, however cumulation quinone may endanger human health (Hodges *et al*., 1996). Insects of ranks Blattodea, Coleoptera, Lepidoptera and Psocoptera can cause allergenic reactions in humans. Sources of allergies are body parts or secretions of insects and mites. Continuous exposure to insects and mites can cause occupational diseases in farmers, millers and bakers (Revsbech and Dueholm, 1990). Exposure of infested grain dust is associated with a number of allergic reactions to a type of conjunctivitis, rhinitis, dermatitis, and asthma (Jeebhay *et al*., 2001).

Rodents attacks for humans and animals health

Since the Middle Ages is known that rodents can contribute to human disease, as black rats were associated with distribution of plague. However, also in modern times rodents form a threat for public health (Meerburg *et al*, 2009). Rodent-related problems exist in public health due to their role as vectors and reservoirs for bacterial diseases such as leptospirosis, murine typhus and salmonellosis, in addition to plague. As humans and livestock are in regular contact with rodents, the potential for transmission of zoonotic diseases is high (Gratz, 1994; Webster and Macdonald, 1995). Because of their adaptable characteristics, types of commensal rodents, house mouse (*Mus musculus*) and the brown rat (*Rattus norvegicus*) have adapted to the conditions of storage areas, which are easily accessible shelters and food (Vukša, 2010). Except with their nutrition, rodents contaminate up to nine times more food than they need for food with their feces, urine, hair, and many other impurities (Drummond, 2001; Brown et al., 2007).

Detection of contaminants

Mycotoxins in feeds, milk, urine, blood, bile, and faeces can be detected by several techniques such as TLC, GLC, HPCL, ELISA, RIA, and RFLP (Pal, 2015).

To identify a physical contamination by insects may be used flotation fragments, immunochemical methods (ELISA), molecular methods (PCR) and infrared spectroscopy - NIRS (Perez-Mendoza *et al*., 2005).

Abstract

The fruits of strawberry tree (*Arbutus unedo* L.) species contain a higher amount of nutrients and bioactive compounds and a good source of antioxidants compared to many other cultivated species. *Arbutus* fruits are also good sources of beta carotenes and anthocyanines. However, consumption of those fruits is currently not widespread. This research was aimed to determine cold storage conditions for *A. unedo* berries and to prolong its shelf-life in the market and also to increase its use in the pharmaceutical industry. For this purpose, *Arbutus* fruits were collected from Şevketiye village of Lapseki sub-province of Çanakkale province (40°23' N, 26°52' E) at 92 m above sea level, which is located in the Northwestern part of Turkey in December 2010. The fruits were stored for 14 days at 0 °C and 90% relative humidity at modified atmosphere packaging (MAP) and normal atmosphere (NA) conditions. The **β**-carotene and anthocyanine contents of the fruits were determined in 7 days interval. The fruits were kept at 20 °C plus 2 days for shelf life at the end of the storage experiments. In this study, we presented the **β**-carotene content at initial day, 7th day, 14th day and plus 2 days at 20 °C modified atmosphere (MA) (85.00, 83.00, 78.00, 67.00 mg/100 g, respectively), and control fruits, (85.00, 80.10, 67.03, 55.78 mg/100 g, respectively). Anthocyanine contents were as follows; under MA conditions (37.00, 39.08, 29.76, 54.89 mg/100 g, respectively), and control fruits (37.00, 48.71, 44.84, 43.20 mg/100 g, respectively). Storage conditions are very important for fresh *A. unedo* fruits. MA packaging material preserved the physicochemical characteristics and sensory quality of the fruits during the storage period especially at 0 °C. However, unpackaged (control) *Arbutus* fruits were stored for only 7 days under NA conditions, and 14 days under MA conditions due to significant changes in their physical and sensory properties. Keeping fruits further at plus 2 days at 20°C conditions did not yield any positive results, especially with the MA conditions. MAP should only be implemented under cold storage to best keep of the *A- unedo* fruits.

***Key words**:* strawberry tree, *Arbutus unedo, anthocyanins,* **β**-carotene, *MAP- Cold Storage Conditions*

Introduction

In Turkey, important studies have been carried out to select the *Arbutus* genotypes for superior fruit quality from the Northwestern part of Turkey, as well as to prevent extinction and to allow extensive cultivation of the strawberry trees (Celikel *et al*., 2008). Some researchers investigated the nutritional properties of fresh strawberry fruits (Ozcan and Haciesrefogulları 2007; Şeker and Toplu, 2013).

The strawberry tree (*Arbutus unedo* L.) belongs to the family Ericaceae, is an evergreen shrub or small tree, typical of the Mediterranean fringe and climate, and it is widely distributed in the

Mediterranean region and North Africa. In Turkey, *Arbutus* trees grow wildly especially in the Mediterranean region and it is found to grow on dry rocky slopes and hillsides, or in pine forests, particularly in the Taurus Mountains (Papoff *et al*., 1993; Ayaz *et al*., 2000; Barros *et al*., 2010). Strawberry tree fruits are suitable for the production of alcoholic beverages, jams, jellies and marmalades (Alarcao-e-Silva *et al*., 2001; Pallauf *et al*., 2008). The fruits are frequently used in traditional medicine in some countries, such as Spain and Morocco (Tahraoui *et al*., 2007). In several Portuguese regions, the fruits are eaten raw or made into liqueurs, as well as bark or roots decoctions, which are used as anti-inflammatory, laxatives, carminatives, digestives, odontalgics and cardiotonics (Barros *et al*., 2010). Recently, important studies have been carried out to select the *Arbutus* genotypes for superior fruit quality from the Northwestern part of Turkey, and thus to prevent extinction and to allow extensive cultivation of the strawberry trees (Çelikel *et al*., 2008).
Fruits are an important part of human diet. They provide, not only the major dietary fibre component of our food, but also a range of micronutrients, including minerals, vitamins and antioxidant compounds, such as carotenoids and polyphenols. For example, carotenes act as a precursor for vitamin A, which can only be obtained from diet and which as an antioxidant, is known to play a role in the prevention of several diseases. Anthocyanines are the largest group of water-soluble pigments in the plant. Several studies have pointed out the anti-oxidant properties of anthocyanines and their positive role in our diet.
Postharvest practices such as modified atmosphere packaging (MAP) reduces undesirable physiological, chemical/biochemical and physical changes in foods, it controls microbial growth and it prevents product contamination. MAP extends the shelf-life of fresh fruits.
Arbutus fruits are highly perishable, non-climacteric and a short self-life. Loss of firmness, shriveled fruit surface, changing of fruit color, and development of decay are major problems shortening the shelf- life (Floros and Matsos, 2005).
The objective of this study was to determine cold storage conditions of *Arbutus* fruits, the effects of packaging materials (MAP) and during the storage on anthocyanine and **β**-carotene quality of *A. unedo* berries.

Material and Methods

Arbutus fruits were collected from Şevketiye village of Lapseki sub-province of Çanakkale province in Turkey (40°23’ N, 26°52’ E) at 92 m above sea level, which is located in the Northwestern part of Turkey in December 2010. The area has a subtropical climate conditions. The average annual rainfall is around 600 mm. August is the driest month. The mean temperature ranges from a minimum of -11.2 °C in February to a maximum of 39 °C in July according to long years data. Fully matured *Arbutus* fruits were harvested in fully red appearance period in November. The fruits were approximately 2.5 kg of freshly harvested fruits for each replication. The *Arbutus* berries were not selected for size, but reflected the typical size for the species. The experiment was established with four replications. The fruits were stored at normal atmosphere and modified atmosphere packaging (MAP) conditions for 14 days at 0 °C and 90% RH. The fruit anthocyanine and beta carotene content were determined in 7 days interval. The fruits were kept at 20 °C plus 2 days for shelf life at the end of storage experiment.

Quality analysis methods

Determination of total anthocyanine contents

Total anthocyanine content was measured with the pH differential absorbance method, as described by Cheng and Breen (1991), Gallik (2012). The absorbances were read at room temperature, using a Perkin-Elmer Win-Lab 25 UV-Vis spectrophotometer. Absorbance of the extracts were measured at 510 and 700 nm in potassium chloride buffer at pH 1.0 (hydrochloric acid-potassium chloride, 0.2 M) and sodium acetate buffer at pH 4.5 (acetic acid-sodium acetate, 1 M). The following equation was used for calculating the monomeric anthocyanine pigment concentration (C mg/L):

$$C(mg/L) = (\ A \times MW \times Df \times 1000\ ) / (\ \varepsilon \times l\ )$$

where A is absorbance = $[(A_{510} - A_{700})_{pH\ 1.0}\ ] - [(A_{510} - A_{700})_{pH\ 4.5}]$; MW is the molecular weight for compound (cyanidin-3-glucoside = 449.2 g/mol; DF is the dilution factor; ε is the molar absorbance coefficient and *l* is the pathlength (1cm). The total monomeric anthocyanines content was expressed as cyanidin-3-glucoside equivalents (MW = 449.2 g/mol and ε=26900). Results were expressed as mg cyanidin-3-glucoside equivalents per 100 g fresh weight.

Determination of β-carotene

Total carotene content was determined using the modified method of Park (1987). Each analytical sample (Pulp, 30 g) added with %1 potassium hydroxide solution was extracted with a mixture of petroleum ether and ethanol (1:1, 25 mL). Celite was added in extract. The extracts were filtered through a Buchner funnel with Whatman No. 1 filter paper. The residue was re-extracted until it became colorless. The filtrates were combined in a separating funnel and washed with four times distilled water (15 mL). To remove the water in the petroleum ether solution, an amount of $MgSO_4$ (anhydrous) was added as desiccant. The petroleum ether phase was transferred to a volumetric flask. Spectra were collected in the range of 350-550 nm for each sample in petroleum ether as blank using Perkin-Elmer Win-Lab 25 UV-Vis spectrophotometer. The concentration of β-carotene in the solution was determined from the absorbance at 450 nm the standard curve for prepared β-carotene (Lichtenthaler and Buschmann 2001).
The following equation was used for calculating the carotenoid pigment concentration:

$$Total\ carotenoid\ (mg/100g) = (\ A \times Df\ ) / (\ \varepsilon \times 1000\ )$$

A is Absorption of extract, D_f is the dilution factor, ε is the molar absorbance coeffcient and *l* is the pathlength (1 cm). The total content of carotenoids was expressed as β-carotene equivalents at 445 nm , by using ε = 2370.

Statistical Analysis

Data were evaluated in a two-way Anova analysis by using Minitab software (ver. 14).

Results and Discussion

The interest in berry fruits has increased worldwide because of their multiple health promoting phytochemicals. In addition to the usual nutrients, berry fruits are also rich in flavanols, anthocyanidins, proanthocyanidins, catechins, flavones, and glycosides. These components are capable of performing a number of antioxidant activity (Wang *et al*., 2010).

Consumption of anthocyanins has been linked as protective agents against many chronic diseases, since several studies have shown that they provide powerful antioxidant, antiinflammatory and anticarcinogenic activities, and possess very strong antioxidant properties leading to a variety of health benefits (Welch *et al.*, 2008). It has long been known that plants containing colors are usually those that are of great benefit to human health. The absorption spectrum for 14th days is shown in Figure 1. As it can be seen, there are two different absorption peaks in the spectrum at pH 1.0 and 4.5 and all of them are identified as anthocyanins due to a variety of molecular transformations at the anthocyanidin system with pH changes (Fig. 1).

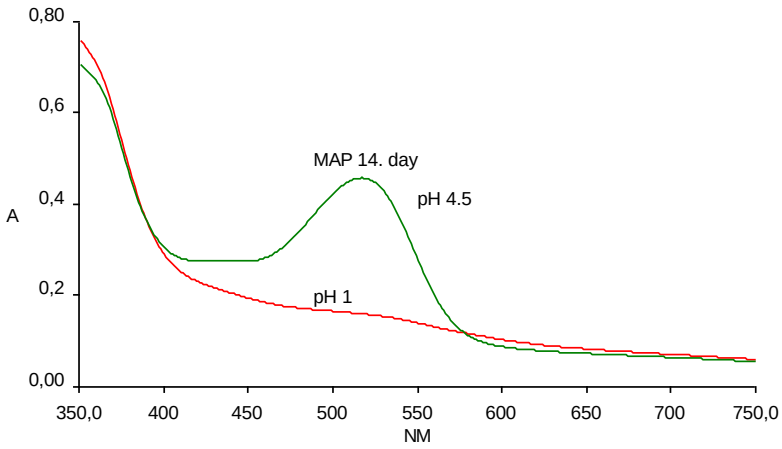

Fig 1. UV-Vis absorption spectrums for the anthocyanine profile of *Arbutus unedo* fruits at pH 1 and 4.5 on 14. days storage conditions.

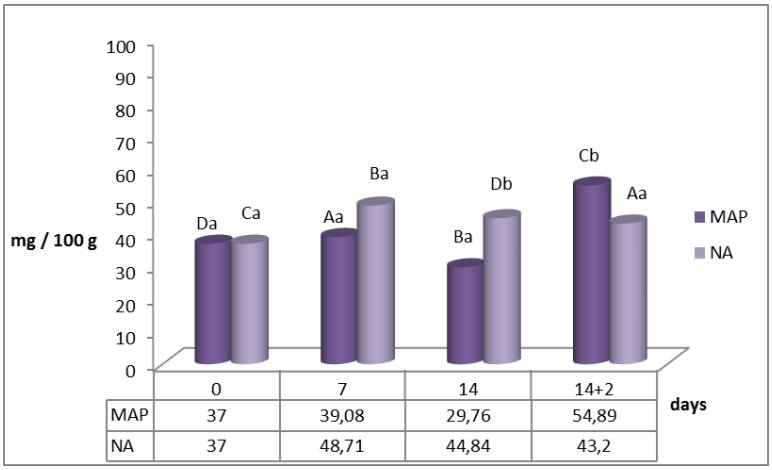
The amount of quantitative of total calculated anthocyanine are found as 37.00, 48.71, 44.84, 43.20 mg/100 g (initial, day 7, day14 and day14+2 at NA) and 37.00, 39.08, 29.76, 54.89 mg/100 g (initial, day 7, day14 and day14+2 at MAP), respectively, at different store conditions (Fig. 2). According to data, It is seen that MAP conditions is observed to be better than NA condition due to humidity (wetness) values (Fig. 2).



** Means within columns not followed by the same small letter are significantly different at the P <0:01 level by of application

Fig 2.Total anthocyanine content of *Arbutus unedo* fruits during the cold storage period

Many factors, such like the pH, temperature, light, presence of other phenolic compounds, enzymes, metal ions, sugars, ascorbic acid, and oxygen have impact on the stability of

anthocyanins. In aqueous solution, carotenoids and anthocyanins to be coumarine derivatives undergo structural transformations that are pH-dependent. Therefore, processing and storage under low temperature can investigate to improve the stability (Rein, 2005).

As it can be seen at Figure 3, absorption of β-carotene in *Arbutus* berries observed as qualitative by UV-Vis spectral analysis. The β-carotene contents were determined from the standard curve for prepared β-carotene and found as 85, 83, 78, 67 mg/100 g (initial, 7th day, 14th day and 14+2nd day in MAP), respectively. 85.00, 80.10, 67.03, 55.78 mg/100 g (initial, 7th day, 14th day and 14+2nd day in NA) (Fig. 4).

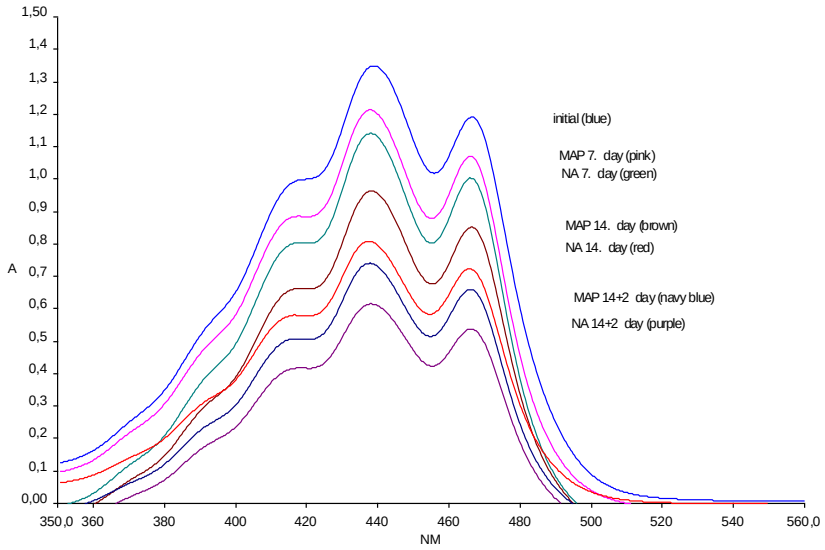


Fig 3. UV-Vis absorption spectrums for the carotene profile of *Arbutus unedo* fruits at initial, 7, 14 and 14+2 days according to MAP and NA storage conditions.

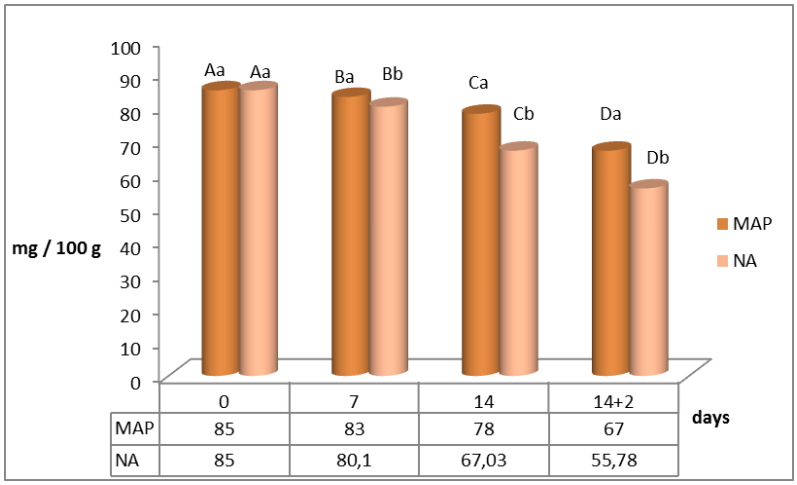

** Means within columns not followed by the same small letter are significantly different at the P <0:01 level by of application

Fig 4. UV-Vis absorption spectrums for the *Arbutus unedo* fruits during the cold storage period (0 ºC)

More research is required to identify those storage conditions that will minimize nutrient and quality losses in these highly perishable products. The objective of our study was to assess a variety of *Arbutus unedo*, postharvest storage treatments including: modified atmosphere

packaging (MAP) and normal atmosphere (NA). Effects of packaging on β-carotene content investigated in *Arbutus* over 14-day storage at 0 °C. Relative to the initial level, total carotenoids were retained fully in MAP samples, but a dramatic loss (34%) in total carotenoid was observed in other NA treatments by 14+2 days. MAP resulted in the best retention of anthocyanin and β-carotene content on *Arbutus unedo* during post-harvest storage.

The data generally show that antioxidants and antioxidant capacity increase after harvest and can be sustained during low temperature storage. However, the rapid decline in fruit quality after cold storage is reflected in a loss in these properties. This suggests that as well as a need to prolong storage life, maintaining shelf-life quality should be a major target in developing this fruit as a commercial crop.

Conclusion

To our knowledge, there is no published article on *Arbutus* storage by using NA and MAP treatments. So, this study is particularly important for obtaining preliminary results of different storage treatments on *Arbutus* berries. MA packaging effectively reduced mass loss during the storage period. MA packaging material preserved the physicochemical characteristic and sensory quality during the storage period especially at 0 °C. However, unpackaged (NA) *Arbutus* fruits can be conserved for only 7 days due to significant changes in physical and sensory properties. However MAP has provided always better performance and extent twice the storage period. Therefore, suggested of *Arbutus* fruits were 7 days for control fruit and 14 days for MA treatments. Plus 2 days 20 °C, so dangerous for MA treatments. Those results could be used for fresh *Arbutus* berry storage especially for food and pharmaceutical drug industries.

THE CITRUS SANITATION PROGRAM IN TUNISIA

Asma NAJAR[1*], Kaouther BEN MAHMOUD[1], Nebiha METOUI[2], Emna JEDIDI[1], Rachida GHEZAL[1], Ahmed JEMMALI[1]

[1]Departmentof Plant Protection, National Institute of Agronomic Research of Tunisia,Ariana,Tunisia

Abstract

The total citrus growing area in Tunisia is about 24,000 ha mainly located in Cap Bon (Northwest region) with an average yield ranging from 15 to 18 tons/ha. This yield decrease is mainly attributed to biotic constraints. From these, viral diseases are known to seriously reduce the potential of the most cultivars. In fact, almost all of citrus trees in Tunisia are infected with one or more virus and virus-like diseases which induce high economic losses. The establishment of Citrus Sanitation Program was needed to solve this problem.

A National Virus Free Citrus Program was initiated in 1992. Selected trees of the commercially important varieties of sweet orange, clementine and lemon were indexed for several viruses, stubborn and viroids and subjected to shoot tip grafting and re-indexed. These virus free mother plants served as a starting foundation block that was enriched in 1996 by other varieties imported from the French Citrus Variety Improvement Program (National Institute of Agricultural Research of Corsica) in order to extend the list of marketed varieties. Actually, there are around 45 varieties in the foundation block. The pre-basic materiel increased from the mother plants was used for the multiplication of the basic materiel in 29 Citrus nurseries.

Keywords: *Citrus, Sanitation program, virus, Tunisia.*

Introduction

Citrus crop is an important agriculture activity in Tunisia. It covers 24 thousands hectares with 6.4 millions trees mainly located in Cap-Bon region (in the Northern east of Tunisia) that is characterized by its favorable climate for citrus cultivation (DGPA, 2014). Unfortunately, the level of citrus production remains low compared with the other citrus-producing countries. This low production is mainly related to viral infections of the nursery plants that were not subjected to any sanitation control. Indeed, these infections affected the source plant material belonging to the INRAT (Tunisian National Institute of Agronomic Research) collection located in Cap-Bon and the national foundation block installed in Sbikha (Central west of Tunisia) since 1974-1976. Propagation by grafting allowed large dissemination of graft-transmissible diseases caused by viruses, viroids or other pathogens. Vectors and farming practices also contributed to the spread of these diseases. Among these, concave gum, blind pocket and *impietratura* were frequently encountered in old citrus orchards and citrus psorosis virus was identified on Clementine (32%), Valentia late (23%), Maltese orange (20%) and lemon (4%) (Khlij*et al*.,2004). Infections with viroids such as *Citrus exocortis viroid,Citrus bent leaf viroid, Hop stunt viroid, Citrus dwarfing viroid* and *Citrus bark cracking viroid*have also been identified with respective infection rates 68%, 33% , 68%, 81% and 3% (Najar and Duran-Vila, 2004). Stubborn disease was identified since 1998 (Najar et al, 1998) but, no infection with citrus tristeza virus has been reported.

Regarding their incurability, virus and virus-like diseases need specific means for their eradication e.g. genetic resistance of rootstock-scion or *in vitro* techniques. These approaches constituted the best way for our national program based on the propagation of healthy and authentic source material. As a result, a national citrus conservatory has been installed since 1996 with virus free clones representing cultivars from the old INRAT collections and the newly introduced ones from INRA Corsica San Giuliano station.
This paper will report the main steps and the realized actions under auspices of the national program of citrus certification.

Material and methods

Practically, the real certification program started in1992 with the aim to obtain virus-free budwood of all the major commercial citrus cultivars. It aimed to eliminate many viral diseases such as Citrus psorosis, Concave gum, blind pocket, *impietratura*, *Citrus exocortis viroid*, *Citrus bent leaf viroid*, *Hop stunt viroid*, *Citrus bark cracking viroid*and *Citrus dwarfing viroid.*
The citrus certification scheme in Tunisia is based on the same concepts as adopted in other citrus-producing countries in the world especially in Spain (Navarro, 1993) and Morocco (Zemzami, 2002).

Program design

Actions sequentially consisted in selecting, indexingcultivars, thermotherapy and *in vitro*shoot-tip grafting.

Initial foundation block

Because they were established in open and uncontrolled conditions, the initial foundation block(located in Sbikha region) and INRAT collections (located in Cap Bon region) are faced to all possible infections. In this field, two operations were made:

1. Selection of the best clones based on agronomic characters.
2. Indexing of these selected specimens for the following pathogens: tristeza, psorosis, concave gum, blind pocket, *impietratura*, citrus exocortis viroid, citrus bent leaf viroid, hop stunt viroid, Citrus bark cracking viroid and Citrus dwarfing viroid.

Indexing tests (biological, serological and molecular) revealed that these plants were infected by viral diseases. Then, they were subjected to sanitation techniques such as thermotherapy combined with shoots tip grafting. The shoot-tip grafted plants underwent re-indexing to verify their sanitary state. Healthy plants constituted a new foundation block.

New foundation block (mother plants)

The new foundation block, which consisted of 4 shoot-tip grafted plants onto sour orange rootstock and maintained under screen cover and indexed for the above mentioned diseases with trueness-to-type assessment.

Prebasic block (prebasic material)

It consisted of 12 potted trees propagated from the mother plants and maintained under screenhouse and indexed systematically for diseases as cited above.

Increase block (basic material)

It consisted of few hundred grafted on 2 types of rootstocks of trees propagated in the registered nurseries from the previous types of material and maintained for production of certified buds.

Certified nursery plants

It consisted in the production of certified plants using certified buds from basic material. They are inspected and tested at random.

Developed techniques

Indexing

Detection of graft-transmissible diseases of citrus is based primarily upon biological indexing, which is accomplished by grafting tissue of the budline onto citrus indicator seedlings. Specific indicator seedlings are used to detect specific diseases. Indicator varieties have been selected for sensitivity to diseases and ability to express symptoms. In each index, adequate positive controls, or disease-infected seedlings along with healthy control seedlings of each indicator variety, are held under the same environmental conditions as test seedlings. Controls are used as a comparison with the test source and also as confirmation that environmental conditions in the greenhouse are optimal for plant growth and symptom expression. Plant material is indexed with cedrat Etrog for viroids, Hamlin for virus-like disease (concave gum, blind pocket and *impietratura*) and Madame vinous for Stubborn disease.

Laboratory tests are also used for the disease diagnosis process. The enzyme linked immunosorbent assay (ELISA) is used for the detection of Tristeza using two types of antibodies: Spain monoclonal antibody 3DF1+3CA5 from Plant Print and a polyclonal antibody from Biroeba (Switzerland) and also for psorosis using monoclonal antibody from Agritest. Sequential polyacrylamide gel electrophoresis (sPAGE) (Iglio, 1983) and hybridization with specific probe (Palacio *et al*.,2000) used for the detection of citrus viroids[(Citrus bent leaf viroid (CBLVd), Citrus exocortis viroid (CEVd), Hop stunt viroid (HSVd), Citrus dwarfing viroid (CDVc), Citrus bark craking viroid (CBCVd)] and polymerase chain reaction (PCR) is used for the detection of stubborn (Bové,1997). Pathogen detection or indexing occurs at different times and steps of the sanitation program. One small scale testing (pre-index) takes place at the time of introduction. The results of the pre-index indicate the need and type of therapy necessary (Navarro, 1993; Vidalakis *et al*., 2010).

Thermotherapy and shoot-tip grafting

Thermotherapy or heat treatment is performed by taking buds from the infected budline and grafting them onto sour orange seedlings. The infected bud grafted onto each seedling is tightly and completely wrapped with budding tape so that the bud will not flush during thermaltherapy. The citrange seedlings, each with an infected bud grafted on it, are placed into a hot greenhouse with temperatures maintained at 28-40°C daytime and 25°C nighttime for preconditioning to high temperatures for 30 days. After that, the seedlings are placed into a controlled temperature chamber which is set for 16-hour days at 40°C and 8-hour nights set at 30°C. Plants are maintained in the thermotherapy chamber for a period of 3 months. Upon removal of the plants from the temperature chamber, the buds are unwrapped. The rootstock seedling is lopped over, and the top of the seedling is pushed into the potting soil such that the grafted bud will become the terminal bud. The plants are then placed in the greenhouse until sufficient budwood growth is produced from the grafted bud for further indexing. This method is effective against most citrus viruses; however, is not effective against viroids.

Shoot-tip-micrografting is the other form of disease clean-up therapy (Navarro *et al*., 1975). This method has proven effective in recovering citrus cultivars free of tristeza, prorosis, concave gum,

exocortis pathogens (Roistacher*et al*., 1976; Navarro *et al*., 1975) and the resulting virus-free plants were shown to be non juvenile, and available for budwood increase in less than one year after *in vitro* grafting. The young growing flushes on field trees are used as the source of shoot tips, which are excised and grafted *in vitro* to appropriate rootstock seedlings, following the procedure of Navarro *et al*. (1975). Shoot tips are composed of the apical meristem plus two to three leaf primordia and measure 0.1 to 0.2 mm in height. A minimum of ten in vitro grafted plants are retained for growth, transplanting to soil, and subsequent indexing. Ten plants appear sufficient to assure at least one pathogen-free tree (Roistacher*et al*., 1976).

Results and discussion

Varieties belonging the INRAT collection

Indexing tests (biological, serological and molecular), carried out on all cultivars belonging to INRAT and Sbikha collections,revealed that they were infected at least by one viral disease. Infected plants were subjected to thermotherapy and shoot tip grafting for sanitation. Shoot tip grafted plants underwent a re-indexing and healthy ones are maintained as replicates in the conservation repository under screenhouse. After assessing the trueness-to-type, the budwood is collected to produce mother block material (table 1). The prebasic material consisting of 12 plants from each mother tree grafted on sour orange rootstock, are planted in 40 L plastic containers and kept in a screenhouse. The basic material is propagated from the above materials grafted on two different rootstocks (Sour orange and *Citrangecarrizo*) under similar insect-proof conditions and used for production of certified budwood.

Table 1. Certified citrus varieties from INRAT collections and national foundation block of Sbikha

Imported varieties from INRACorsica San Giuliano station

47 citrus varieties belonging to orange, mandarin, lemon and grapefruit groups were imported from INRA Corsica San Giuliano station in the aim to enrich our varietal assortment (table 2). From each variety, 4 grafted plants that constituted mother plants were maintained under screenhouse. After that, these plants were subjected to indexing (biological, serological and molecular tests) in order to check their sanitary state. Virological tests revealed that all of them were free from viral diseases excepted one variety 'Salustiana' which was infected with exocortis. This variety underwent thermotherapy and shoot-tip grafting. Recovered plant material was subjected to indexing and healthy one constituted mother plants.

The prebasic material was constituted with 12 trees for each variety grafted from each mother plant. The basic material was multiplied on 2 types of rootstocks in the registered nurseries from the previous types of material and maintained for production of certified buds.

Nursery operations will be supervised by personnel of the Plant Protection Department of Agriculture with periodic indexing of foundation and grower mother block trees to assure freedom from certain pathogens.

The citrus certification program has a considerable impact on the development of the citrus industry at the national level. The yearly production of 29 registered nurseries in Tunisia has reached about 400,000 certified plants.

Conclusion

Besides efforts made to reach the expected objective, i.e.sufficient number of certified citrus plants covering the national need, the national sanitation program did not succeed to provide satisfactory results (less than 400,000 virus-free plants/year).

However, the national program planned two other actions in order to improve the sector productivity. On the one hand, the Tunisian Ministry of Agricultureis going to introduce new citrus varieties of orange, Clementine and lemon from **Instituto Valenciano de Investigaciones Agrarias (** IVIA) Spain with the aim to enrich the national varietal assortment. On the other hand, it incited the nursery gardeners to install new plant nurseries in new zones outside the Cap Bon region and to substitute gradually the sour orange rootstock by other rootstocks which are tolerant or resistant o tristeza virus (CTV) such as *Citrangecarrizo* and *Citrus volkameriana.*

NITROGEN CONTENT IN VEGETABLES AND NITROGEN EFFECT ON THEIR NUTRITIONAL VALUE

Mariola KODRA*, Ariola DEVOLLI, Edlira SHAHINASI, Dhurata FETA

Agricultural University of Tirana, Faculty of Biotechnology and Food, Department of Chemistry, Albania
*Corresponding author: marjola_mala@yahoo.com

Abstract

Nitrogen plays an important role in nutrition and functions in plants, but because of environmental pollution and uses of organic and inorganic liquid fertilizers it can be accumulated in edible parts of vegetables particularly if excessive nitrogen fertilizer has been applied. Nitrogen content in vegetables has always been a matter of interests. In our study we were focused on evaluating nitrogen content in some vegetables, specifically in tomatoes, cucumber and pepper grown in a glasshouse, without applying specific amounts of nitrogen fertilizers, but just the normal rate used by the farmer. Nitrogen content was assessed by combustion. In most cases, nitrogen content in tomatoes and pepperwere in normal range from 1.12 to 4.49 % N and 1.08 to 4.6% N respectively. Even if these vegetables must contain 2.5-3% N, we also meet cases of high nitrogen content. Cucumbers generally contain up to 2.5-5% N and the data showed a low content of nitrogen varying form 0.9 - 5.65% N. Nitrogen cannot be dangerous by itself, but its metabolites and reaction products e.g., nitrate, nitrite and N-nitroso compounds are of a great concern because they are converted in more toxic forms. Nitrogen sources are air, soil, water and food (especially vegetables) so consuming these crops can harm human health; that is why it is important to control rates of nitrogen fertilizers used in agriculture, in order to have safe products since a reduction in nitrogen forms content can represent added value for vegetable products.

Key words: *nitrogen content, vegetables, nutritional value, nitrogen fertilizers*

Introduction

Nitrogen is one of the most important nutrients that plants need for their growth. It is a key element that takes part in essential biomolecules such as amino acids, vitamins, hormones, enzymes and nucleotides. Nitrogen is the fourth most abundant element found in plant tissues, behind carbon, oxygen and hydrogen and is an integral part of the nitrogen cycle, which interchanges nitrogen between organisms and the environment (Meah MN,Harrison N and Davis A, 1994). Although inorganic nitrogen compounds (i.e., NH_4^+, NO_2^-, and NO_3^-) account for less than 5% of the total nitrogen in soil (EC, 1997), they are the main form of the element absorbed by most plants. Inorganic and organic fertilizers are applied to maintain the nutritional condition of different cropping systems. For an organic agricultural system, continuous application of manure increases the nitrogen (N), phosphorus (P), potassium (K), calcium (Ca) and magnesium (Mg) content in soil (Schuddeboom LJ, 1993). Once organic fertilizers are applied to soils and mineralization begins, inorganic nitrogen is released and absorbed by plants (Cheng-Wei Liu, Yu Sung, 2014) and so it is converted in NO_3^- and NO_2^-. Nitrate (Mensinga TT, Speijers GJA and Meulenbelt J, Health, 2003) *per se* is relatively nontoxic, but its metabolites, nitrite, nitric oxide and N-nitroso compounds, make nitrate of regulatory importance because of their potentially adverse health implications. On the other hand recent research shows that its conversion to nitrite plays an important antimicrobial role in the stomach (EC (European Commission), 2002) and

other nitrate metabolites also have important physiological/pharmacological roles (EC, 2001). Farmers may therefore use manure and nitrogen-based fertilizers to boost crop yields. A range of leafy vegetables can accumulate high levels of nitrate. The concentrations depend on a range of factors including season, light, temperature, growing conditions, fertilizer use, and storage of the crop. Once nitrogen fertilizers are applied to agricultural systems, the fertilizers are absorbed directly by plants or converted into various other forms through the oxidation process. Excess nitrogen is lost in ionic or gaseous form through leaching, volatilization, and denitrification (Cheng-Wei Liu, Yu Sung, 2014).

Objective of this study has been evaluation of nitrogen content in some vegetable, such as tomato, cucumber and pepper in order to evaluate their nutritional values according to this nutrient. This study was conducted in a glasshouse and vegetable were grown under fertilization rates randomly used in this glasshouse.

Materials and methods

In our study vegetable were grown under fertilization rates randomly used in this glasshouse by the producer; rates of approximately 100 kg/ha inorganic N fertilizers for an area of 0.5 ha and the vegetables were planted three times in a year. The tissues of the harvested vegetables were washed with tap water and DI water and oven dried at 65 °C for 72 h, and the dry tissues were further ground using a grinder to a particle size less than 1 mm and then digested using H_2SO_4 (EC, 1999). The total nitrogen concentration in the filtrate of the plants passed through filter papers and N was determined with an automatic distillation unit (Kejdahl method). The results were compared on their mean, minimal and maximal values.

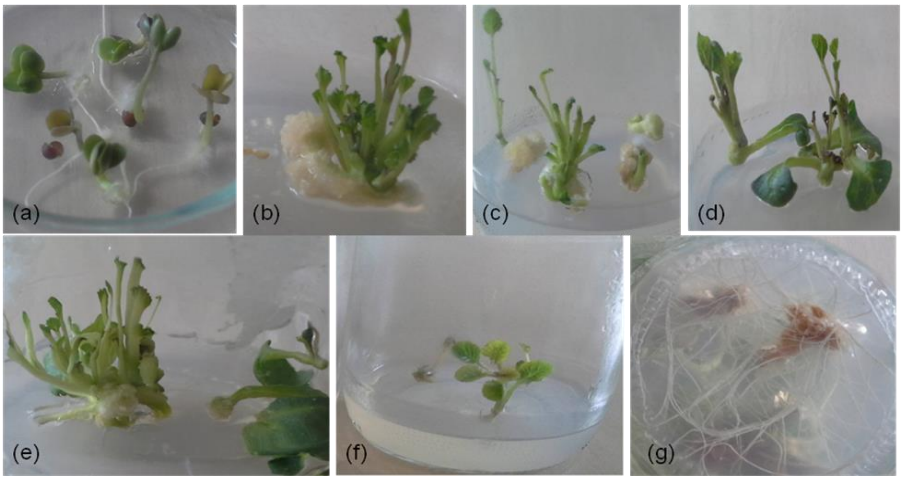
Results and discussion

Not all the soils naturally posses all the nutrients that are needed to produce top quality yields, crop after crop (Diana Moigradean, 2007). That is why fertilizers are used in soils, to improve soil fertility. Fertilizers rate and efficacy depend on many factors such as climate, soil structure and chemistry and method of application. A fertilizer is complete when it contains nitrogen, potassium and phosphorous; these are macronutrients needed in high amounts by vegetables. Nitrogen is added as nitrate-nitrogen that is soluble in water and affects ripening of fruits. Fruits will not ripe properly in low nitrogen concentration than in high. Nitrate global level concentration in tomatoes in concordance with WHO Codex code VO 448 is 15 mg/kg. In our study tomatoes were collected thoroughly fruit maturity. Nitrogen affects growth, production and quality of vegetable's fruits (EC, 1999). Different vegetables have different nitrogen needs, depending on vegetable species, for example, tomato, cucumber, eggplant, been, selectively prefer more nitrate ions (Dessureault-Rompré J.et al. 2009).

In our study we analyzed tomatoes fruits for nitrogen content. Tomatoes fruits were collected after fruit maturity and they contain 2-3% N. In Table 1 and Graph 1 are presented results of these analyses.

Table1. Nitrogen content (%) in tomato

N content %	1	2	3	4	5	6	7	8	9	10	Mean	Min	Max
	1.12	1.96	2.85	1.87	1.47	2.4	2.12	1.18	4.49	3.85	**2.331**	**1.12**	**4.49**



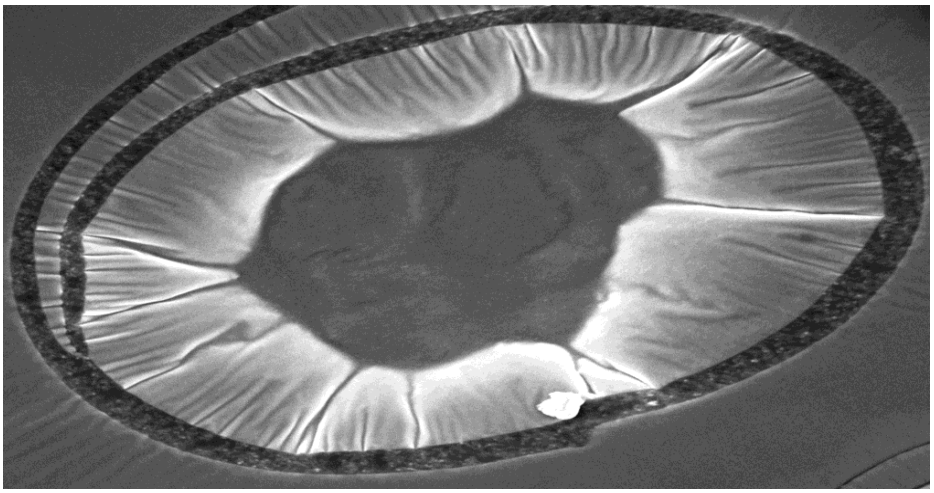
Graph 1. Nitrogen content in tomato (%)

These data show that in most cases N content in tomato fruits, is less than 2%, low than nitrogen content should be and that are considered as absence. But we also meet cases of more than 3% N that are considered as high level of nitrogen content.

In our study we also analyzed cucumber for nitrogen content. Cucumber fruits were collected after fruit maturity. Cucumbers contain 2 – 5% N. In Table 2 and Graph 2 are presented results of these analyses.

Table 2. Nitrogen content (%) in cucumber

N content %	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**Mean**	**Min**	**Max**
	0.9	**1.12**	**1.32**	**4.08**	**4.24**	**2.67**	**5.65**	**1.77**	**1.64**	**5.5**	**2.889**	**0.9**	**5.65**



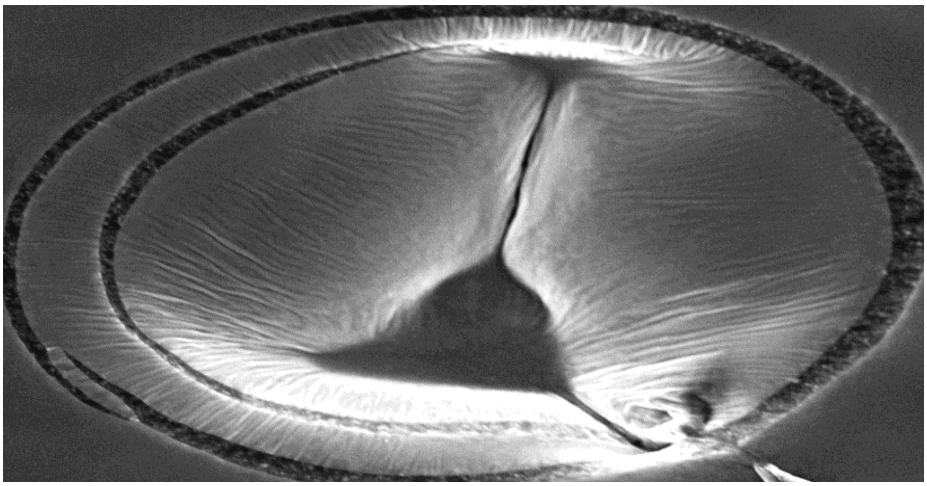
Graph 2. Nitrogen content (%) in cucumber

Most cases show a low content of N in cucumber (less than 2% N), other cases are of normal N content (2-5% N). High N content (more than 5% N) was observed only in some samples but these can't be considered as toxic N contents.

In Table 3 and Graph 3 below, are presented data obtained by analyses of pepper fruits. Pepper fruits were also collected after fruit maturity. Peppers contain 2 – 3 % N.

Table3. Nitrogen content (%) in pepper

N	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**Mean**	**Min**	**Max**
content %	1.08	3.4	1.64	2.96	2.94	4.38	3.85	4.6	1.76	2.68	**2.929**	**1.08**	**4.6**



Graph3. Nitrogen content (%) in pepper

Most cases show a normal (2-3% N) or low (< 2% N) nitrogen content. But as we can see there also cases of very high (4.6% N) nitrogen content (> 3% N) that are considered as toxic levels of nitrogen.

Nitrogen content in vegetable has a close relationship with the amount of N fertilizer applied.
In our study vegetable were grown under fertilization rates randomly used in this glasshouse by the producer; rates of approximately 100 kg/ha inorganic N fertilizers for an area of 0.5 ha and the vegetables were planted three times in a year. Frequent planting and high rates of inorganic nitrogen fertilizers can influence nitrogen content in plant tissues and of the soil. That is why in our study we came across different levels of nitrogen content. In another study, Cheng-Wei Liu *et al.* (Cheng-Wei Liu, Yu Sung, 2014) have shown that applying inorganic fertilizers rezulted in a high concentration of nitrate in lettuce than applying organic fertilizers.
Once adsorbed by vegetables nitrogen is converted in its metabolites and reaction products, nitrate, nitrite and ammonium. Previous studies indicate that vegetables are the major source of nitrate intake by humans and constitute approximately 40%–92% of the average daily intake (Turrini A, Saba A and Lintas C,1991; Schuddeboom LJ, 1993).
According to Schuddeboom LJ, tomatoes and pepper are vegetables classified with a very low nitrate content (< 200 mg kg^{-1} fm) and cucumber with low nitrate content (200-500 mg kg^{-1} fm) and the vegetables fruits are plants part with low nitrogen content (Schuddeboom LJ, 1993; Mensinga TT, et al, 2003). Same results are shown in our study; N content in all the analyzed vegetable's fruit can be evaluated as normal.
To protect public health from nitrates in food, in 1997 the European Member States agreed an EC Regulation setting limits for nitrate in lettuce and spinach (EC Regulation No. 194/97) (EC, 1997) and adopted EC Regulation No. 1881/2006 [(EC (European Commission), 2002)]. The same regulation has been adopted in our country (Directive No. 1. 05/02/2016, Law "For Food" changed) (Regulation of Ministry of Agriculture, Rural Development and Water Administration, 2016). But beside a good law, farmers by themselves must do periodic soil and plant test, in order to provide a good product that can't harm human health.

Conclusion

The obtained results indicate that Nitrogen content in analyzed vegetables in most cases was low or normal. There were also cases of high and even toxic N content. According to N content, vegetable fruits analyzed in our study can't be harmful to human health and can serve as a good source of N.
But although most vegetables have normal N content, we must pay attention to the cases with low or high N content. In order to avoid low or high N content, preliminary soil test should be done and after that we can make the right decision in choosing the appropriate method and rate of fertilization to improve soil productivity and as result vegetable's quality.

ASSORTMENT OF EASTERN PERSIMMON AND THE WAYS OF ITS IMPROVEMENT

Sergey KHOKHLOV

Nikita Botanical Gardens, Yalta, Russian Federation
E-mail: ocean-10@mail.ru

Abstract

High-productive, frost-resistant, immune cultivars with different ripening periods have been selected in the result of the researches on determination of biological potential for eastern persimmon in the conditions of South Coast of the Crimea (Russia). The best cultivars of Nikita Botanical Gardens were obtained as a result of inter-species and intra-species crossings. The detailed study of this gene fund allows to classify the persimmon cultivars and select the most perspective ones according to their characteristics (productivity, fruit quality, resistance to diseases). The specification of biological and morphological characteristics of cultivars has been summarized. The data on phenological observations and evaluation of cultivars on fruits quality have been given. The most promising cultivars for using in breeding processes and laying of industrial plantations of intensive type have been selected.

Keywords: *persimmon, cultivars, group, crop, fruit quality*

Introduction

Eastern persimmon (*Diospyros kaki* Thumb.) according to complex of economically valuable characteristics takes the special place among fruit crops due to its valuable fruits, wide ecological range of growth and plant ornamentally. The determining factor in the expansion of the areal of this crop is the available source of genetic material, the basis for the obtaining highly adapted cultivars satisfied the growth conditions (Bellini, 1982, Zaretsky, 1934, Zhukovsky, 1971).

Eastern persimmon despite its name comes from China. Its cultural areal is quite wide and occupies practically all warm-temperate and subtropical zones of North hemisphere (Zhukovsky, 1971). In the Crimea persimmon as the fruit plant was known at the beginning of the XIX century (Kondaraky, 1872. But only in 1901 the first small plantation of persimmon was founded in Imperial Nikita Economic Botanical Gardens. It became the starting point of persimmon assimilation in horticulture of the peninsula (Pasenkov, 1973).

Persimmon is polymorphic, heterozygous species. Due to cross-pollination there are the wide spectrum of persimmon cultivars with significant variation of main morphological characteristics: form and size of fruits, form of their top and bottom, presence and absence of astringency in the pulp, color. The collected gene fund of persimmon in Nikita Botanical Gardens fully reflects the biological diversity of this species. The high level of natural inhomogeneity of the starting material used in breeding process provides a large selection of combination for deliberate hybridization and obtaining new forms with comparatively high viability and adaptability to environment conditions.

The aim of these researches: to study the existing gene fund of persimmon, to classify the cultivars, to select the most valuable specimen according to certain economically valuable characteristics (productivity, fruit quality, resistance to diseases) or their combinations, to estimate the adaptability of cultivars to growth conditions.

Materials and methods

Research was conducted organized in 2012-2015 at the collection plantation of eastern persimmon presented by 86 persimmon cultivars. Collection is located on two grounds Prymorsky and terraces differed by steep slopes, protection from prevailing winds, mechanical soil composition and predecessors.

The plot Primorsky is located 200 meters from the sea coast at an altitude of 20-40 m above sea level, on gentle South-East exposure slope of 10-20°. Predecessors are roses and vines. The soils are brown-gray, gray, slightly calcareous, powerful, medium and heavy loamy, slightly and medium gravelly, trenching ones.This study was funded by a research grant # 14-5-00079 of the Russian Science Foundation

The plot is fully opened from the South; its west, north and north-east sides are protected by natural forest and park plantations; its east side is surrounded by rocky spur of Nikitskaya Yaila covered by juniper forest.

The Upper terrace of the Gardens is located 20-50 meters north and 5-10 meters higher then plot Primorsky on rather steep slope (up to 30º) of South-East and South exposition. Predecessor is mixed forest. The soil of terrace is the same as for plot Primorsky, but it differs by low power of root zone horizon and by larger content of skeletal particles in the profile.

For evaluation of comparative winter-resistance the quick method of direct artificial freezing of some branches with generative and vegetative organs in refrigerators at different temperatures (from -8° up to -25°C) has been used. The primary study was done using common method (Medov and Ogoltsova, 1999; Eremeev, 1976) and methodological instructions worked out in Nikita Botanical Gardens (Pasenkov, 1973).

Results and discussion

Today new highly productive, regular fruiting cultivars, best adapted to growth conditions are urgently needed for industrial plantations of intensive type for horticulture of the Crimea and South regions of Russia. During last years the new cultivars of persimmon, surpassing the main characteristics not only of the foreign introduced cultivars but also the regionalized domestic ones have been obtained in Nikita Botanical Gardens as a result of intraspecific hybridization.

On the basis of a comparative analysis of collection evaluation data on main morphological characteristics the persimmon cultivars were combined in the following groups:

a) Presence or absence of astringency in fruits pulp

- constant not astringent cultivars (PCNA); their fruits become sweet after typical coloration irrespective of seeds and ripening level
- variable not astringent (PVNA) cultivars; firm, sweet fruits with three and more seeds
- variable astringent cultivars (PVA); seedless fruits, astringent in firm state
- constant astringent cultivars (PCA); fruits are astringent in firm state, it is possible to eat them only fully ripened in 10-30 days after harvesting.

The following cultivars belong to the first group (PCNA): Prevoskhodny, Fuyu, Kiara, Krymchanka 55, Nakhodka, Nadezhda, Prelestnaya, Triumf, Zolotistaya, Sharon.

The second group (PVNA) includes cultivars: Ukrainka, Sputnik, Zarya, Zorka, Shokoladnaya, Doch Saburozy, Konkurent, Opylitel 48, Rubinovaya, Tsyganochka, Tavrichanka, Zvezdochka, Yuzhnoberezhnaya, Urozhainaya, Vostochnaya, Hyakume, Zengy-Maru, Yankin-Tsuru, Kuro-Kuma, Shogatsu-Gaki, Merkheulis, Geily, Maru.

The third very small group (PVA) includes cultivars: Seedless, Suvenir Oseny, Vekovaya, Cibaca, Variruyushchaya.
The fourth group of cultivars (PCA): Rossiyanka, Nikitskaya Bordovaya, Kiara Konstantnaya, Adzhara, Pribrezhnaya, Mechta, Zolotaya Osen, Zamanchivy, Izobilnaya, Yaltinsky, Yuzhnaya Krasavitsa, Kostata, Nitary, Tanenashy, Aizumishirazu, Hiragaki, Yurogaki, Yamagaki, Orest Uzhgorod, Tone Wase, Rojo Brillante, Druzhba, Delishes, Skromnitsa, Kavabata, Zhuravlyenok.

b) mass of fruits

1.1. large-fruited cultivars; mass of fruits is more then 200 g
1.2. middle-fruited cultivars; mass is 150-500 g
1.3. small -fruited cultivars; mass is 100-150 g.

The first group includes cultivars: Hachiya, Hyakume, Zolotistaya, Rojo Brillante, Sharon, Konkurent, Batumsky II, Zamanchivy, Mechta, Yaltinsky.
The second group combines the following cultivars: Adzhara, Prevoskhodny, Yuzhnoberezhnaya, Ukrainka, Sputnik, Zarya, Zorka, Zvezdochka, Shokoladnaya, Doch Saburozy, Zendzhi-Maru, Yanki-Tsuru, Kuro-Kuma, Shogatsu-Gaki, Geily, Maru, Rojo Brillante, Sharon, Vekovaya, Kiara Konstantnaya, Adzhara, Pribrezhnaya, Mechta, Zolotaya Osen, Zamanchivy, Izobilnaya, Yaltinsky, Yuzhnaya Krasavitsa, Kostata, Nitari, Tanenashi, Aizumishirazu, Opylitel 48.
The following cultivars belong to the third group: Hiragaki, Yurogaki, Orest Uzhgorod, Tone Wase, Rossiyanka, Nikitskaya Bordovaya, Zhuravlyenok, Krymchanka.

c) periods of ripening and full coloration of fruits

very early (fruits color at the end of August - beginning of September) - Ukrainka, Izobilnaya, Yankin-Tsuru
early (coloration begins in the second decade - beginning of the third decade of September) - Hyakume, Sputnik, Shokoladnaya, Doch Saburozy, Rojo Brillante, Sharon, Mechta, Zolotistaya, Yuzhnaya Krasavitsa, Zvyezdochka
middle period of ripenning (fruits color up to the 10-th of October) - Yuzhnoberezhnaya, Batumsky II, Zamanchivy, Zarya, Zorka, Prevoskhodny, Rojo Brillante, Sharon, Hachiya, Suvenir Oseni, Mechta, Hiragaki, Yurogaki, Jiro, Yamagaki, Orest Uzhgorod, Tone Wase, Zhuravlyenok, Zengi-Maru, Kuro-Kuma, Shogatsu-Gaki, Merheulis, Geily, Opylitel 48
late (coloration of fruits begins at the end of October - beginning of November) -Rossiyanka, Nikitskaya Bordovaya, Zolotaya Osen, Pribrezhnaya, Izobilnaya, Adzhara
very late (ripening of fruits with coloration is in the second decade of November) - Yaltinsky, Konkurent, Vekovaya.

d) winter-resistance

resistant cultivars (single bud damage on annual shoots)
cultivars with resistance above average (up to 20% damaged buds)
cultivars with average resistance (20-40% damaged buds with partial damage of annual wood)
weakly resistant cultivars (40-80% damaged buds and wood of many last year shoots)
very weakly resistant cultivars (more then 80% damaged buds and partial damage of wood of 2-year and 3-year old shoots).
The main factors limited the areal of distribution of eastern persimmon in the Crimea and South regions of Russia are temperature parameters of winter-summer periods and winter-resistance of plants.

Ten cultivars bred in Nikita Botanical Gardens belong to the resistant group: Rossiyanka, Zolotistaya, Suvenir Oseni, Nakhodka, Zorka, Yuzhnoberezhnaya, Zolotaya Osen, Krymchanka, Nikitskaya Bordovaya and Yuzhnaya Krasavitsa. It accounts for almost 12% of the total number of plants in collection.

Cultivars having the level of resistance higher then average (26.6%) are combined into a group of 23 cultivars of domestic and foreign selection.

The largest group is the group with average level of resistance (55.8%) - 48 cultivars. Groups with weak (14%) and very weak (14%) resistance have 12 cultivars each.

Conclusions

The results of agrobiological study of collection fund of eastern persimmon allow to do the following conclusions:

1. The gene fund of persimmon in Nikita Botanical Gardens according to the varietal diversity is one of the largest in Russia, that allows to solve the selection problems relevant to modern fruit-growing.
2. The most part of studied persimmon cultivars of foreign selection after winter and early spring thaws instigated the plants for vegetation are damaged by slight negative air temperatures (from -9° up to -8°C). Wherein, some cultivars remain quite productive and profitable: Hyakume, Shagotsu-Gaki, Nitari, Seedless, Aizumishirazu, Batumsky II, Tamopan, Hiragaki, Yurogaki, Jiro, Yamagaki, Orest Uzhgorod.
3. Due to more deep period of winter rest persimmon cultivars bred in Nikita Botanical Gardens practically do not suffer from provocative influence of winter thaws. Thanks to that they bear fruits each year.
4. Cultivars can be divided to the following groups according to their economic use:

the most perspective for industry: Zolotistaya, Suvenir Oseni, Nakhodka, Zorka, Yuzhnoberezhnaya, Yuzhnaya Krasavitsa, Krymchanka, Nikitskaya Bordovaya, Rossiyanka, Opylitel 48, Opylitel 87, Zamanchivy, Merchta, Zvyezdochka and Zolotaya Osen

for including in breeding process for obtaining large-fruited cultivars: Hachiya, Hyakume, Zolotistaya, Rojo Brillante, Sharon, Konkurent, Batumsky II, Zamanchivy, Mechta, Yaltinsky

for early ripening period: Ukrainka, Izobilnaya, Yankin-Tsuru.

EVALUATION OF NEW APRICOT CULTIVARS INTRODUCED IN NIKITA BOTANICAL GARDEN

Valentina GORINA*, Vadim KORZIN, Natalya MESYATS

Nikita Botanical Garden, Yalta, Russian Federation
*Corresponding author: valgorina@yandex.ru

Abstract

During 2013-2015 we studied 19 new cultivars of apricot, introduced in Nikita Botanical Garden. The cultivar Kryimskij Amur was used as a control. In 2013-2014 the susceptibility of cultivars Kryimskij Amur, Kioto, Lanyhou Jim Mama, Lednicka and others to *Monilinia laxa* (Aderh. & Ruhland) Honey did not exceed 0.5-1 points. In epiphytotic year (2015) susceptibility of the same cultivars was rated with 3-5 points. Two genotypes were selected due to their *Monilinia laxa* resistance - Novyij 6357 and I-05-6. *Stigmina carpophila* (Lev.) M. B. Ellis damages did not exceed 3 points during the years of studies. Four cultivars demonstrated high resistance to the disease: Aurel, Lanyhou Jim Mama, Novyij 6357 and Sundrop. Increased resistance to both diseases was detected in three genotypes - Morava, Novyij 6357, Holovousy and one form I-05-6. Morava and I-05-6 were selected since the plants bloom one week later than the control. There are 10 cultivars with early fruit ripening (24.06 - 5.07): Kioto, Lanyhou Jim Mama, Holovousy, Sundrop and others. Cultivars Kryimskij Amur and Weslay-25 are of medium-late ripening July 23-24. The fruit quality of genotypes Aurel, Morava and others is not inferior to the control. In complex of signs (later flowering, increased resistance to fungal diseases, good fruit quality) cultivars Morava and Novij 6357 were dominant. Kioto cultivar is promising for breeding. Its plants have an average resistance to *Monilinia laxa* and *Stigmina carpophila*. Also, it is characterized by early fruit ripening and precocity, abundant yield and good fruit quality.

Keywords: *apricot, late flowering, disease resistance, fruit quality*

Introduction

An important task of fruit-growing is to ensure the population with fresh fruits and processed products. The advantage of the apricot (*Armeniaca vulgaris* Lam.) is the high-quality of fruit. Apricot plantations cover about 350 thousands hectares in 55 countries. Every year about 2.4 million tons of fruits are produced in the world. Production is mainly concentrated in southern Europe and Asia. In Europe, annually production is up to 750 thousand tons and in Asia - up to 950 thousand tons. Demand for apricot fruits is constantly increasing (Pedryc et. al., 1999; Witkowski, 2003). A variety of soil and climatic conditions of natural regions determines the requirements for cultivars. Particular importance is the adaptation of created genotype. The main indicators in this case are resistance to diseases, drought resistance, stability of fruiting, high-quality fruits and products (Smykov, 1999). Production needs new high-yielding, precocious and stable fruiting cultivars. Comprehensive assessment of cultivars will identify sources of economically valuable traits. The use of these genotypes in breeding will expand the amplitude of adaptation of new varieties to the environmental conditions.

The aim of the work was to determine the economic and biological value of new introduced cultivars of apricot in Nikita Botanical Garden.

Materials and Methods

The study included 19 introduced cultivars and forms of apricot. Investigations were carried out in the period 2013-2015. Widespread and released in Crimea cultivar Kryimskij Amur was used as a control. During the studies phenological observations, yield, fruit quality parameters, and plant disease resistance were investigated using conventional techniques (Sedov and Ogoltsova, 1999).

Under conditions of the Crimea apricot plants mostly affected with monilia infection, which is manifested in spring and results in rapid wilting of flowers bloomed and later young leaves and shoots, and *Stigmina carpophila* maximum damage of which appears in August. Estimation of monilia infection was made during the flowering period of apricot trees and *Stigmina carpophila* – at the stage of mature leaves. The rate of damage was assessed in points:

0 – no damages of flowers, leaves and shoots;
1 - up to 1% of the flowers, leaves or shoots are damaged;
2 –1-10% of the flowersleaves or shoots on the tree are damaged;
3 – 11-25% of the flowersleaves or shoots on the tree are damaged;
4 – 26-50% of the flowersleaves or shoots on the tree are damaged;
5 - more than 50% of the flowers, leaves or shoots on the tree are damaged.

Determination of drought resistance of cultivars and forms was carried out using the methodological guidelines of Eremeyev and Lishchuk (1974). Statistical analysis was made with the method of analysis of variance and differences between means were tested using LSD test at $P \leq 0.5$ (Zaitsev, 1984) using the Microsoft Office Excel program.

Results and Discussion

The studies of apricot cultivars and forms demonstrated variations of studied features. The rate of drought resistance of apricot cultivars is important for stability of fruiting. The analysis demonstrated that range of drought resistance in the most studied genotypes is not inferior to the control cultivar. The drought resistance of nine cultivars and forms exceeds the control cultivar and was 3.7-4.0 points (table 1).

Table 1.Biological features of introduced apricot cultivars (2013-2015 years).

Cultivar	Drought-resistanc (1-5 scale)	Flowering time		Ripening periods of fruits		The damage of disease (0-5 scale)	
		Start	End	Start	Mass	*Moni-linia laxa*, point	*Stigmina carpo-phila*, point
KryimskijAmur (control)	3.6±0.1	20.03±1	28.03±1	23.07±0	25.07±0	2.0±1	2.0±1

LSD05	0.4	-	-	-	-	2.0	0.8

Evaluation of the introduced cultivars let us to determine the rate of disease damages in plants. It varied greatly from year to year. So the damage caused by *Monilinia laxa* in 2013-2014 in the cultivars Kryimskij Amur, Kioto, Lanyhou Jim Mama, Lednicka did not exceed 0.5-1 points. In epiphytotic year (2015), the damage of the same cultivars was from 3 to 5 points. Two genotypes - Novyij 6357 and I-05-6 demonstrated higher resistance to *Monilinia laxa*.

Scientists from different countries investigated favorable conditions for fungal diseases, various approaches in apricot tree protection, works in revealing of resistant forms and cultivars were carried out for further breeding of new forms resistant to *Monilinia laxa* and other pathogens. Apricot collections in the North of California, Rumania and other countries were studied and the most resistant genotypes were marked out: Riland, Royal, A -105, Viceroy, King, Tonda di

Tossignano, K-55-39, Precoce de Italia, Vivagold, Sulmona, Mamaia, Baneasa 33/11, Sirena, Pike, Umberto and etc. (Balan et el., 1999; Brooks, 1942; Trandafirescu and Teodorescu, 2006).
Ivonne Liverani and Perfection are considered as donors of apricot resistance to *Monilinia laxa* with possible capacity to transmit this property. Fair quantity of resistant seedlings was a result of using these cultivars in crossing (54.0% and 45.5%) (Nikotraet el., 2006).
Another disease widespread all over the Crimea, Russia and other countries is *Stigmina carpophila*, or spot blotch. This pathogen damages all drupaceous cultures and it is especially harmful for apricot plants. In the conditions of the Crimea disease development is more dangerous for leaves. Being extremely damaged leaves fall off, tree crown becomes lighter or even bare, that decreases tree productivity (Kropis et el., 1975).
The damage cause by *Stigmina carpophila* (Lev.) M. B. Ellis, in studied cultivars and forms did not exceed 3 points. Four cultivars - Aurel, Lanyhou Jim Mama, Novyij 6357 and Sundrop demonstrated high resistance to this disease and in some years - control cultivar Kryimskij Amur.
Increased resistance to both diseases was detected in three cultivars -Morava, Novyij 6357, Holovousy and a form I-05-6.
Early flowering apricot cultivars often fall under the influence of spring frosts, which leads to decrease in yield or its complete loss. Therefore, in Nikita Botanical Garden works on the creation of apricot cultivars with late flowering is carried out. Selected genotypes Morava and I-05-6 start to bloom on March 24 - 26, nearly a week later compared to the control cultivar. The problems of generative buds winter hardiness, increasing resistance to other abiotic and biotic factors in combination with the quality of fruits are urgent tasks in the cultivation of apricot not only for Russia, but also all over the world. For example, in California (USA) scientists are trying to create strong winter-hardy and frost-resistant cultivars with the use of the Central Asian cultivars (Ledbetter, 2010).
The study of ripening terms of fruits in the studied genotypes of apricot showed 10 early cultivars: Kioto, Lanyhou Jim Mama, Holovousy, Sundrop, etc. (24.06 - 5.07). Cultivars Kryimskij Amur and Weslay-25 have medium-late ripening (23-24.07). 8 cultivars have medium ripening (6-20.07).
Comparing the quality of fruits to the control cultivar, it is found that 6 genotypes - Aurel, Morava, Holovousy and others are not inferior (table. 2). Fruits of these cultivars are of excellent appearance, characterized with large size (51-80 g), round or oval shape, bright blush colored flesh, high taste of fruits (tasting score 4.1 - 4.5 points). In the introduced cultivars Aurel, Bertiruch, Morava, Nadezda, Skaha, Sirena, 3/6/3, K-604-19 were found the largest fruits (65-102 gr). Taste of the fruits was the best in the cultivar Morava and the form – in 3/6/3 (4.4-4.5 points). The cover color of the fruit skin (up to 75%), was the most intensively expressed in Harlayne cultivar.
One of the main problems is adaptability of new cultivars to the conditions different from those of their origin. Fruiting regularity is a serious problem in several apricot cultivars. Work on the breeding of new apricot cultivars are carried out in different regions of the world (Krška et. al., 2006; Polat, Caliskan, 2013).

Table 2.Pomological characteristics of apricot cultivars (2013-2015 years).

Cultivar	Mean weight of fruit (gr)	Fruit shape	The ground color of skin	Cover color of skin	Flesh color	Taste of fruit, points (scale 1-5)	Stone mass (gr)
Kryimskij Amur (st.)	54±2	flat-round	light-orange	no	orange	4.1±0	2.8±0
Kioto	54±18	round	light-orange	pink, 25%	orange	4.0 ±0	1.7±0.5
Aurel	65±0	widely-oval	orange	dark-red, 25%	orange	4.2±0	3.5±0
LanyhouJimMama	58±0	flat-round	yellow	pink, 25%	yellow	4.3±0	2.1±0
Morava	68±18	round	light-orange	pink, 50%	yellow	4.5±0	2.8±0.6
Kabaasi	61±7	triangular	yellow-orange	pink, 50%	orange	4.0±0	2.5±0.5
Marculesti	49±1	flat-round	orange	dark-red, 50%	orange	4.0±0	2.5±0
Holovousy	51±5	widely-oval	light-orange	pink, 25%	orange	4.2±0,1	3.0±0.5
Bertiruch	65±1	round	light-orange	pink, 50%	orange	4.1±0	2.4±1
Novyij 6357	41±9	oval	orange	dark-red, 25%	orange	4.0±0	1.9±0.1
K-604-19	102±0	round	orange	pink, 25%	orange	4.0±0	2.0±0
Sundrop	43±2	round	orange	pink, 50%	orange	4.0±0	2.2±0.4
Skaha	74±0	round	yellow	pink, 25%	orange	4.0±0	4.5±0
Sirena	79±21	widely-oval	yellow	pink, 50%	orange	4.0±0	2.5±0.5
3/6/3	80±0	round	orange	dark-red, 25-50%	orange	4.4±0	5.5±0
Weslay-25	48±0	widely-oval	yellow-orange	no	yellow-orange	4.0±0	3.0±0
Harlayne	30±0	round	yellow	pink, 75%	orange	4.3±0	2.0±0
Lednicka	38±3	oval	orange	dark-red, 25%	orange	4.0±0.2	2.6±0.1
Nadezda	66±7	round	yellow-orange	pink, 50%	orange	4.0±0	3.0±1
I-05-6	38±0	round	yellow	dark-red, 25%	orange	4.0±0	2.0±0
HCP05	14.3	-	-	-	-	0.1	0.7

Based on the complex of traits cultivars Morava and Novyij 6357 were selected. They are characterized by late flowering, increased resistance to fungal diseases, and the fruits of good quality. Also the cultivar Kioto is promocing. Its plants have an average resistance to *Monilinia laxa* and *Stigmina carpophila,* early ripening of fruits, precocity, abundant yield and good fruit quality.

Conclusions

1. It was found that three cultivars - Morava, Novyij 6357 and Kioto are best adapted to the conditions of the South Coast of the Crimea and have a complex of valuable traits.
2. The following apricot cultivars are recommended as donors of valuable traits:
- field resistance to *Monilinia laxa* and *Stigmina carpophila*: Morava, Novyij 6357, Holovousy, I-05-6;
- late bloom: Morava and I-05-6;
- early period of ripening: Kioto, Lanyhou Jim Mama, Holovousy, Bertiruch, Sundrop, Skaha, Sirena, 3/6/3, Nadezda, I-05-6;
- good quality of fruit: Aurel, Lanyhou Jim Mama, Morava, Holovousy, Bertiruch, 3/6/3, Harlayne.
3. Evaluation of introduced cultivars let us to give needed information about their behavior in the local conditions and to develop adequate technology for them.

Abstract

This study was conducted to determine the distribution, some morphological and bioecological aspects of *Cicada mordoganensis* Boulard (Hemiptera: Cicadidae) that damage fruit trees in Izmir province of Turkey in the period from 2005 to 2008. To determine the distribution of *C. mordoganensis*, investigations were carried out in 17 districts of Izmir and a total of 98 orchards were controlled. *C. mordoganensis* was found in 58,16 % of all orchards. For biology investigation, visual inspections were done in orchards in Kemalpaşa (Yukarıkızılca), Izmir, Turkey. In addition to the visual counting of adults in the shed skins of the nymphs, they were counted at the bottom of the trunk and under the canopy of 10 trees in that orchard. In addition, 10 wooden crates were put under 10 trees in this orchard and checked periodically to monitor the adult emergence. According to the results of these studies, the first adults of *C. mordoganensis* started to appear in the second week of June. The flying period finished at the mid of October. Flight duration of this species is about 110-115 days. The maximum adult emergence occurred between the end of June and mid of July. Population density changed from year to year. Most of the adults were observed in 2007 and least in 2006. Adults were observed on different fruit trees such as olive, cherry, peach, walnut, poplar, plane tree, fig, and pistachio. Females lay their eggs more on the bark of trunk of old trees and a dry stick of young plants. Some morphological characteristics of adult, last nymph instars and shed skins of last nymph of *C. mordoganensis* were also revealed.

Keywords: *Cherry, Cicada mordoganensis, Cicadidae, bioecology, morphology, Turkey*

Introduction

Cicadas (Hemiptera: Cicadidae) are insects drawing attention by the sounds they make during the summer months and the damages of which in agricultural areas are often unnoticeable. The cicadas that cause damage mostly in fruit trees spend most of their lives in the soil, around plant roots in the nymph period. Nymph periods take years in some species.

Females lay their eggs more into the holes they make on one-year shoots of fruit trees in groups. These holes in the shoots on which eggs are laid expand with the growth of the shoots, and wounds occur. These shoots wounded in the later years pave the way for the entry of other diseases and pests. They also cause shoot drying in weak shoots on which eggs are laid. Nymphs do the main damage of the cicadas. Nymphs suck sap in the roots of the host plants and cause shoots to be weak, internodes to be shortened, leaves to shrink, turn yellow and fall off.

There are a limited number of studies regarding the cicadas in Turkey. In these studies (Bodenheimer, 1958; Nizamlıoğlu and Gökmen, 1964; Anbaroğlu, 1967; Kartal, 1974; Lodos,

1986), attention was drawn to the damage of cicadas to some cultivated plants by emphasizing the importance of cicadas. However, the information on this topic is not adequate.
There is a need for accurate identification of the species and accurate knowledge of its biology, damage, and density for accurate and successful management practices in cultivated plants. Therefore, the cicadas found in the cherry orchards in Izmir which is one of Turkey's most important cherry production areas were addressed and investigated, and the findings obtained in regard to the distribution, some morphological and bio-ecological characteristics of *Cicada mordoganensis* (Hemiptera: Cicadidae) species were assessed in this article.

Material and Methods

The samples of the *Cicada mordoganensis* Boulard (Hemiptera: Cicadidae) adult and pre-adult periods and the fruit trees constituted the material of this study.
To determine the distribution area of the pest, survey studies were carried out in all districts of Izmir (Turkey) in the months of May-October in 2005-2006. The studies related to the biology were carried out in an orchard which is located in Yukarıkızılca town of Kemalpaşa and where this species exists in 2005-2008.
The samples delivered to the laboratory were examined in a stereoscopic microscope to reveal the morphological characteristics of the adult, last nymph instars and shed skins of last nymph of *C. mordoganensis*, and the necessary morphometric measurements were made on the color and design situations, head, thorax, abdomen, antennae and wing structures of them. Measurements were made over 20 male and 20 female individuals with caliper and micrometer. It was benefited from Motta (2003) in determining the distinctive features.
The observations regarding biology were made by going to the experimental orchard at least twice a week in the months of June-August during which the adult emergence density is high. To determine the adult emergence density in the orchard, 10 wooden crates covered with mosquito net which were 160x25x10 cm (0,4 m^2) in size were put under the canopy projection of the each of 10 trees. By means of these crates, the adult emergences that occurred under tree canopy projection were checked and directly monitored. Moreover, 10 trees were marked before the first adult emergence in the same orchard by a second method, the shed skins of last nymph of the emerged adults were counted and removed from the environment by checking the under-canopy, trunk and leaves of the trees, and information about adult density was obtained. In addition, it was observed that the time of adult females laid eggs on which plants and plant parts.

Results and Discussion

Morphological characteristics of *Cicada mordoganensis*

Adult

The adult is gray-beige colored and has two black, big and round compound eyes and three red simple eyes on the head. Antennas are black, bristle-shaped and six segmented; the stylet is 10 mm long; the head width is 8.06±0.20 mm in males (n=20) and 8.15 ±0.29 mm in females (n=20).
Vertex, pronotum, and mesoscutellum are gray-brown patterned; mesoscutellum is swaged and there are two adjoining U-shaped brownish patterns on it; prothorax is gray and black, wings cover up the abdomen in the shape of roof; there are seven punctiform blackish spots and four bigger blackish spots on the upper wing; wing veins are greenish black, and the point where the wings are attached to the thorax is gray (Figure 1). In males, the wingspan is 75.61±2.57 mm and

the body length is 39.71±2.12 mm. In females, the wingspan is 77.53±4.47 mm and the body length is 40.53±1.81 mm.
The forelimb femur has two dentiform prominences; there are a total of five thorny prominences, three of them inside the hind leg tibia and two of them in the outer side. There are 12 thorny prominences on the place where the hind tibia is connected to tarsus; the dorsal of the abdomen is line-shaped brown banded and 8 segmented.

Shed skins of last nymph
It is light cream, there are light brown bands in the dorsal of the abdominal segments. The length of the shed skin of nymph is 22.44± 1.07 mm in males (n=20) and 23.04±1.12 mm in females (n=20); the width of the shed skin of nymph is 7.12±0.26 mm in males and 6.55 ± 0.68 mm in females (Figure1).

Figure 1. Adult, shed skin of last nymph and last nymph instars of *Cicada mordoganensis* Boulard.

Last nymph instars
The abdomen and mesothorax of last nymph instars are white, the bands between the wing extensions, prothorax, and abdomen segments are light brown; the compound eyes of the nymph turn red close to the adult emergence. The head capsule width of the last nymph instars (n=10) is 6.27±0.25 mm, its body length is 21,77±1.43 mm and the width is 8,10 ±0.58 mm (Figure1).

Distribution
Cicada mordoganensis adults were found in all districts of Izmir province where the studies were carried out. They were not found in the cherry orchards in some districts (Beydağ, Dikili, Kınık and Menemen), but they were observed in the olive groves and pine trees near the orchards. They were found in 58.16% of 98 orchards controlled.
In the studies carried out previously, it was reported by (Lodos and Kalkandelen, 1981) that this species is an endemic species which is only found in Turkey around the world, and it is found in Antalya, Izmir and Mugla provinces in Turkey

Biology

Adult emergence time and duration
The first and latest observation dates of *C. mordoganensis* adults in nature in 2005-2008 and the period of their existence in nature (days) are determined.
In the four-year study carried out, it was determined that *C. mordoganensis* adults were observed in nature during the period from the second week of June to mid-October. Flight duration of this

species is about 110-115 days. Lodosand Kalkandelen (1981) reported that they collected *C. mordoganensis* adults from nature during the period from the beginning of June until the beginning of August.

Adult densities

The adult density of C.mordoganensis in the orchard in Yukarıkızılca in 2005-2008; while a total of 7 shed skins of last nymph were observed in 10 trees during the year of 2005, no adult could be obtained in 10 crates. In 2006, adult emergence was not determined in 10 trees and 10 crates. While 7 shed skins of last nymph were counted in 10 trees in the same orchard in 2007, 1 adult was obtained in 10 crates. In 2008, while a total of 2 shed skins of last nymph were determined in 10 trees all the year round, there was no adult emergence in 10 crates.

In the observations made in the orchards where the studies were carried out, it was observed that the adult density of C. mordoganensis in cherry orchards was 2-3 per orchard, but the adults were denser in olive groves near the cherry orchards.

The density of last nymph instars was observed to be very low in the orchards where the survey was carried out in Izmir province in 2005-2006, and the shed skin of nymph was found only in 9 orchards. The nymph density (1-25 shed skins of nymph/10 trees) was found to vary in these orchards. However, adults were determined in most of the orchards. From the orchards where the studies were carried out, a nymph belonging to this species was only found in one orchard in 2005. Their nymphs were found in olive trees within and around the cherry orchard. Adults were observed on different fruit trees such as olive, cherry, peach, walnut, poplar, plane tree, fig, and pistachio.

Egg-laying

Females were observed to lay their eggs on the bark of trunk of olive and cherry trees and the dry pine piles put into the soil to support olive seedlings while they were in the head up position. However, when the eggs were hatched could not be determined.

It was observed that C. mordoganensis adults were mostly found on the trunk and thick branches of the trees, and they flew to the nearest trees by zigzagging when being approached.

No information about the egg-laying behaviors and the hatch time of C. mordoganensis adults could be encountered in the literature.

Conclusions

When the results obtained from this study which was carried out in Izmir province in 2005-2008 were assessed as a whole, it was determined that C. mordoganensis was found in fruit production areas in all districts of Izmir province, their adults were observed during an 110-15-day period from the second week of June until mid-October, they were mostly observed on perennial plants such as olive, cherry, poplar, walnut, plane tree, pine, fig, peach and wild pistachio trees, and their eggs were laid on the flaked bark of the trunk of olive and cherry trees and the dry pine piles put into the soil to support olive seedlings. It was not possible to compare the findings obtained with the previous findings because there is not any biological and ecological study which was carried out previously on this species. This study is expected to contribute to future studies.

Abstract

In Serbia, the codling moth (*C. pomonella* L.) occurs regularly in all apple orchards. It is one of the most important pests of apple. Damaged fruits mature and decline prematurely. Their market value is reduced, and during storage they are prone to decay. The pest also attacks pear, quince, peach, apricot, cherry and crab-apple fruits. Thus, exposure of the codling moth, as a target or non-target organism to insecticide effects increases selection pressure on the *C. pomonella*, which results in a decrease of its susceptibility, and finally the occurrence of resistance to the applied insecticides. During 2015, the trials were carried out according to the standard EPPO methods with the aim to establish the level of apple protection against the codling moth, by use of two products based upon acetamiprid (200 g a.i./L product) of SG formulations. In apple orchards at localities Sremski Karlovci, Kovilj and Tavankut, on varieties Idared and Granny Smith, the products based on acetamiprid were foliar applied at a concentration of 0.025%, by backpack sprayer. The experiment was set up in four replications in randomised block design. The efficiency of the insecticides was performed according to Abbott, and significance of differences (ANOVA) for the confidence interval of 95%. Nine days after application of the product based on acetamiprid, the efficacy at locality Sremski Karlovci was 88.9-91.6% and 27 days after the application, the product showed the efficacy 87.2-89.7%. Seven days after insecticides were applied at locality Kovilj, efficacy was 80.5-91.6%, while after 21 days was 93.1-94.8%. At locality Tavankut, 14 days after the treatment, the efficacy of the insecticide based on acetamiprid was 84.4%, and 24 days after the application 81.2%. The applied insecticides showed high efficacy in protection of apple fruits from *C. pomonella* in agricultural production conditions of Vojvodina province.

Key words: *Apple, C. pomonella, Acetamiprid, Efficacy.*

Introduction

Modern technology of apple production is highly intensive, very complex and requires a large investment of human labor and resources in economic terms, and also in terms of human health care it requires very high standards. In the Republic of Serbia apple is the most common fruit species after plum. According to the census of agriculture (2012) apple is produced on 23.737 ha (Anonymous, 2013). In Vojvodina, apple is the most common fruit species and is produced on 6.347 ha. Standard of apple production in developed countries is raising of dense high-intensity orchards with anti-hail nets, irrigation systems and also the introduction of quality standards (Global GAP and Integrated Production) (Keserović et al., 2013). However, traditional seedlings with the outdated assortment and wide distances between plants are still the most common in fruit growing in Serbia. In the last few years in our country, dense high-intensity apple orchards with cultivation technology based on the integral concept and Global GAP standard of food production were raised. Limiting factors for raising of modern orchards include: apple sensitivity to diseases

and pests, inadequate quality of soil, low winter temperatures, frequent spring frosts, lack of rainfall, windiness, etc. (Gvozdenović, 1998).

The apple is a species that requires the greatest number of treatments in control of pests and diseases. The most important pests on apples are codling moth (*C. pomonella* L.), apple aphid (*Aphis pomi* de Geer), woolly apple aphid (*Eriosoma lanigerum* Hausm.), San Jose scale (*Quadraspidiotus perniciosus* Comst.), apple ermine moth (*Yponomeuta malinellus* Zeller), leaf miners (round mines - *Lyonetia clerkella* L.; marble mines - *Phylonororycter blancardella* Fabr.; white mines - *P.corylifoliella* Hübner), rosy apple aphid (*Dysaphis plantaginea* Pass.) and others that occur occasionally (Almaši et al., 2004).

Codling moth occurs regularly every year. It is one of the most important pests in orchards, particularly in apple orchards. Permanent and often causes very high damages, that results in premature fruit drop, worm-eaten fruit and difficult preservation during storage, primarily due to untimely and inadequate protection without which apple cultivation is unimaginable. The fact is that the control of codling moth is difficult, primarily because of the long presence of moths in orchards, stretched and overlapping generations, to which, among other things, affects climate, not just in particular year, but in different localities (Graora, Jerinić-Prodanović, 2005).

In recent years, in a numerous orchards, a high number of damaged apples were detected, which endangered the profitability of production. Codling moth also damages fruit of pear, quince, peach, apricot, cherry and walnut. Therefore, codling moth exposure as a target or non-target organism to the effects of insecticides increases selection pressure which results in a reduction of the sensitivity, and finally with the occurrence of resistance to the applied insecticides. In the regions of Serbia changes in the efficacy of some insecticides have been recorded, but has not been permanent control or monitoring of susceptibility for this pest to insecticides. Due to the necessary application of insecticides for protection of the apple from *C. pomonella*, there are very good reasons to apply insecticides with favourable toxicological and eco-toxicological properties for its suppression.

The aim of this study was to determine the level of protection of apple orchards from *C. pomonella* using an acetamiprid based products.

Materials and methods

The experiments were carried out in 2015 at the localities of Vojvodina (Sremski Karlovci and Tavankut), according to the standard EPPO methods for design of experiments and data analysis (Anonymous, 2012); the efficiency of insecticides in the control of codling moth (Anonymous, 2004) and phytotoxicity (Anonymous, 2014). Acetamiprid Mospilan SG and SG 20 (acetamiprid 200 g/kg) preparations were applied at a concentration of 0.025%, a foliar spray, using backpack sprayer "Solo", with water consumption of 1000 L/ha. The apple varieties Idared and Granny Smith in the locality Sremski Karlovci are 14 years old and are planted at a distance of 3.6 x 1.6m. The same plant spacing of apple variety Idared is in 7 years old orchard in locality Tavankut.

For the suppression of the first generation codling moth the treatment was carried out in Sremski Karlovci on 19th May 2015 and in Tavankut on 23rd May 2015. Apples were in BBCH 74 phenophase (fruits were upright, with a diameter up to 40 mm). The experiment was set up in four replications with basic plot arrangement in a randomised block design. The size of the basic plot consisted of four apple trees. Before the experiment, at both sites, the number of captured codling moths in pheromone traps (Csalomon®) was monitored and identified.

The effect of the product was determined on the basis of the number of damaged fruits (accessed 300 fruits per repetition) caused by codling moth larvae. The first evaluation of the effects in

Sremski Karlovci was perfomed 9 days and the second 27 days after insecticide application. In Tavankut the first assessment was executed on 14 days and the second on 24 days after spraying. Results of the trial are shown through absolute and mean values for the number of damaged fruits, standard deviation of the average values (Sd), efficiency (E%) according to Abotty (Wentzel, 1963) and the significance of differences (ANOVA) for the 95% confidence interval.

Results and discussion

Results of the insecticide acetamiprid efficiency test in apple orchards applied to suppress population of *C. pomonella* are given in Tables 1 and 2. Nine days after insecticide application number of damaged apples, compared to the control, was significantly lower. The efficiency of the tested insecticides is 88.9-91.6%, all at the same level of significance (Table 1). After 27 days from the application, the number of damaged fruits was significantly lower compared to the control. The efficiency of the tested insecticides was 87.2-89.7 %, depending on the product. Both of the acetamiprid based insecticides, with the same content of active substance and the same formulation, achieved efficiency at the same level of significance.

In comparison to the control, 14 days after insecticide application, a number of damaged apples was significantly lower. The efficiency of the tested product was 84.4-86.7% (Table 2). After 24 days of treatment, the number of damaged apples was at a significantly lower level compared to the control with insecticides efficiency of 81.2-85.4%. During this study no phytotoxic effects were recorded in the apple varieties Idared and Granny Smith in both localities.

Table. 1 The average number of damaged apples and efficacy of insecticides in control of *C. pomonella* (Sremski Karlovci, 2015)

Insecticides (%)	**9days after the treatment**			**27 days after the treatment**		
	x	Sd±	E%	x	Sd±	E%
Acetamiprid SG (0,025)	1.0 b	1.41	88.9	1.25 b	0.81	87.2
Mospilan 20SG (0,025)	0.75 b	0.95	91.6	1.0 b	0.95	89.7
Control	9.0 a	2.83		9.75 a	1.26	
LSD (0,05%)	3.44			2.05		

x –average number; Sd± - standard deviation; E %- efficacy

Table. 2 The average number of damaged apples and efficacy of insecticides in control of *C. pomonella* (Tavankut, 2015)

Insecticides (%)	**14 days after the treatment**			**24 days after the treatment**		
	x	Sd±	E%	x	Sd±	E%
Acetamiprid SG (0,025)	1.50 b		86.7	1.75 b		85.4
Mospilan 20SG (0,025)	1.75 b	1.25	84.4	2.25 b	0.5	81.2
Control	11.25a	2.87		12.0a	3.91	
LSD (0,05%)	4.59			5.57		

x –average number; Sd± - standard deviation; E %- efficacy

Comparison of the number of affected and damaged fruits, depending on the location showed very uniform presence of damaged fruits in both locations, considering that the applied measures for C. *pomonella* control were carried out on a regular basis. Having in mind the possibility of changing the sensitivity of harmful species exposed to high selection pressure when suppressing,

the nature and mechanisms of action of registered insecticides that are in use, sensitivity monitoring of insects and prescribed strategies in the application of pesticides in the very near future will be the basis of measures for modern technologies of plant production.

Testing *C. pomonella* resistance to insecticides suggest that the codling moth showed resistance towards azinphos-methyl, phosmet, lambda-cyhalothrin, indoxacarb, but did not evolved resistance towards acetamiprid and spinosad (Mota-Sanchez et al., 2008). Laboratory tests Knight (2010) have shown that acetamiprid exhibits a high efficiency and significantly reduces the fertility of *C. pomonella*. Based on the assessment from response of newly hatched larvae of *C. pomonella* towards three insecticides (azinphos-methyl, acetamiprid and thiacloprid), and a role of cytochrome P450 monooxygenase in their toxicity Cichón et al. (2013) concluded that all the tested populations of *C. pomonella* in field conditions (Argentina) exhibited significantly lower mortality at discriminatory concentrations of azinphos-methyl and acetampirida, while 13 of the 14 populations demonstrated a significantly lower mortality and also with the application of thiacloprid.

Conclusions

Based on the achieved results of field trials and the actions undertaken for codling moth control in 2015 at Sremski Karlovci and Tavankut, the following can be conluded:

- In the locality Sremski Karlovci, 9 and 27 days after application of products Acetamiprid SG and SG Mospilan 20, a number of damaged apples was at a significantly lower level compared to the control. The efficacy of Acetamiprid SG was 87.2 - 88.9%, and of Mospilan 20 SG was 89.7 - 91.6%;
- In Tavankut, 14 and 24 days from the application of insecticides, the number of damaged fruits was significantly lower compared to the control. The efficacy of Acetamiprid SG ranged from 85.4 - 86.7%, while the efficiency of the Mospilan 20 SG ranged between 81.2 - 84.4%.

Abstract

It is known that the essential oils of herbs possess antimicrobial activity against a broad spectrum of microorganisms. The subject of this study was to exam antimicrobial activity of essential oils of thyme and antimicrobial drugs against bacteria: *Escherichia coli WDCM 00013, Pseudomonas aeruginosa WDCM00024*, *Staphylococcus aureus WDCM 00032, Salmonella Typhimurium WDCM 00031, Salmonella enterica* WDCM 00030 coagulase positive staphylococcus *Providencia stuarti*, ß haemolytic *Escherichia coli*, Streptococcus group D, *Staphulococcus aureus* and *Pseudomonas spp*. The essential oil of thyme had expressed an inhibitory effect on all tested pathogens. Zones of inhibition ranged in diameter from 5.00 mm in the case of *Pseudomonas aeruginosa* WDCMA 00024, up to 40.00 mm in the case of *Staphylococcus aureus* WDCMA 00034 and *Staphylococcus aureus* which is isolated from clinical materials (swabs of the nose). Because of these findings, the essential oil of thyme could find the extensive application in the food and pharmaceutical industries.

Key words: *Tymus vulgaris, antimicrobial drugs, inhibition*

Introduction

Thyme is a perennial, semi bushy plant, originating from the Mediterranean, where it grows in dry, sunny, rocky and little fertile soil.

A centuries-old knowledge and the use of thyme is evidenced by the many archaeological evidence and records. Since the ancient time it had been highly prized plant, which had been known and described by Hippocrates, Pliny the Elder and Hildegard of Bingen (Marković, 2013).

In order to protect the food from rotting, in the Middle Ages thyme was used much as a spice, but due to the strong antiseptic effect it began to be used as antiseptic in hospitals and also from a traditional plant it became a drug that is widely used in modern phytotherapy. Germany Commission for drugs officially approved the use of this herb for treating bronchitis and catarrh of the upper airways. Thanks to the experience of tradicionale medicine thyme attributed analgesic, antiseptic and cardiotonic properties and it is now widely used as stimulation of the cardiovascular system, encouraging secretion, urinary tract infections, as powerful vermicida (anti worms and larvae) (Rizk, 1986, Fayad *et al*., 2013, Hanafi *et al.*, 2010).

Thyme is one of the most popular medicinal species. Depending of the place where it grows and small genetic differences can create different compounds. Depending on the chemical composition there are several chemotypes of thyme. Differences in chemotype is essential to the

process of distillation and of obtaining essential oils, while the dried plants are used as a tea drink these differences are not essential.

Some of thyme chemotypes as: thymol, carvacrol, geranyl/geranyl acetate, linalool 1.8 ceneol/ limonene, trans-tujanol, gamma-terpineol, alpha-terpineol, and names chemotypes come mainly from the dominant chemical compounds in certain essential oils.

The concentration of represented compounds is different. The main components, which are usually attributed to the role of the antibacterial properties of oils are present in a significant percentage, while some compounds found only in trace amounts.

Some of the components present in the oil act on the cellular membrane, which may cause certain changes and thus can be prevented further propagation of bacteria. The other component can operate on the other structure in the bacterial cell.

Many researches (researches conducted on the thyme, sage and oregano) have shown that components presented in small amounts have a critical role in the antimicrobial activity of essential oils of explored plants.

This appearance is attributed to the synergistic effect of these components of oil. Because of that essential oils in full composition show much more antimicrobial properties than their individual, the main components (Burt, 2004., Bakkal, 2008., Stojkovic *et al.*, 2013, Nazzaro 2013.).

Thyme essential oil contains thymol (20 to 50%) as a main component and carvachol, which are known as compounds with strong antimicrobial and antioxidant activity (Feizi *et al*., 2013, Janječić *et al.*, 2013.).

Many experiments have shown that some of the active compounds presented in the essential oil (carvachol) can prevent the spread of *Salmonella spp*. in meat, as well as to reduce the number of aerobic bacteria in meat and meat products, and the antibacterial *E. coli, Staphylococcus aureus, Streptococcus pneumoniae, Mycoplasma gallisepticum*, *Clostridium perfligens, Salmonella enterica, Clostridium perfrigens* (Janječić *et al.*, 2013., Feizi *et al.*, 2013.).

Application of essential oils is partly limited due to their intense taste and smell. However, thanks to the advancement of technology it is possible to combine successfully the microbiological stability and sensory quality (Fortino *et al*., 2012, Tajkarimi *et al*., 2010, LvF *et al.*, 2011, Hyldgaard *et al*., 2012).

A growing problem of resistant bacteria on antibiotic, undesirable effects of the antimicrobial drugs, and interest in natural medicines, have led to a reevaluation and taking into consideration phytoterapy treatment of bacterial infections, because the essential oils have antitumor, anticancer, antiinflammatory, antispasmodic, sedative, analgesic, anticoagulant, antirheumatic, vasodilating, hypotensive, hipilipidemic and other effects (Bakkali *et al*., 2008., Reichling *et al.*, 2009., Hieu *et al*., 2010., Neira *et al*., 2010., Hamid *et al*., 2011.).

The aim of this research is to determine antimicrobial activity of various antimikrobial drugs to the increase of the reference culture *Escherichia coli* WDCMA 00013, *Pseudomonas aeruginosa* WDCM00024, *Staphylococcus aureus* WDCMA 00032, 00031 WDCMA *Salmonella Typhimurium*, *Salmonella enterica* WDCMA 00030 (BCCM™/LMG BACTERIA COLLECTION, Belgium), then, *Providencia stuarti*, coagulase-positive staphylococci, ß-haemolytic *Escherichia coli*, streptococcus group D, *Staphulococcus aureus* and *Pseudomonas spp*. which werere isolated from clinical material. As well as to determine the effect of the essential oil of thyme on the growth of these pathogens and to determine whether the essential oil of thyme show bactericidal or bacteriostatic effect on them.

Material and Methods

In this paper commercially essential oil of thyme was used.

To test the antimicrobial activity of essential thyme oil, reference culture of *Escherichia coli* WDCMA 00013, *Pseudomonas aeruginosa* WDCM00024, *Staphylococcus aureus* WDCMA 00032, 00031 WDCMA *Salmonella Typhimurium*, *Salmonella enterica* WDCMA 00030 (BCCM ™ / LMG BACTERIA COLLECTION, Belgium) were used, then *Providencia stuarti*, coagulase-positive staphylococci, ß-haemolytic *Escherichia coli*, streptococcus from group D, *Staphulococcus aureus* and *Pseudomonas spp.* which were isolated from clinical material. Cultures were seeded in tryptone soy broth and incubated at 37 ^{o} C / 18h. Petri plates with the appropriate substrate (Mueller - Hinton agar) were seeded with 0.5 ml of the bacterial suspension in the concentration of 10^5 cfu / ml.

To determine sensitivity of bacteria to reference antimicrobial drugs a method of antibiogram was used. As a standard to determine antimicrobial activity amoxicillin, streptomycin, bacitracin, cefotaxime, ceftazidime, doxycycline, norfloxacin, oxacillin, cefahlor and gentamicin ("Liofilchem" S.R. Italy) were used.

To test the effects of thyme oil to inhibit the growth of bacteria *Listeria monocytogenes* WDCMA 00020, *Pseudomonas aeruginosa* WDCM00024, *Escherichia coli* WDCMA 00090, 00031 WDCMA *Salmonella Typhimurium*, *Salmonella enterica* WDCMA 00030 and *Staphylococcus aureus* 00034 WDCMA agar diffusion method on solid sterile nutrient medium was used (Müeller- Hinton- agaru-MHA) (Kirby Bauer, 1996). Cylinders, 9 mm in diameter were put on the surface of a solid culture medium on which a particular pure bacterial culture was previously seeded. 100 µl of essential oil was instilled in the cylinder with micropipette. 100 µl of 96% alcohol was instilled in the cylinder as a control. Ability of growth and reproduction of the strain depends on its resistence/sensitivity to tested extract, thus around the cylinder it is formed a clear, transparent zone in which there is no growth of microorganisms if the effect exists.

Besides the essential oil, discus slips of paper were placed on the plates as a reference antimicrobial drugs: amoxicillin, streptomycin, bacitracin, cefotaxime, ciprofloxacin, ceftazidime, doxycycline, norfloxacin, oxacillin, gentamicin and cefahlor.

Petri plates which were incubated 24 hours at a temperature of 37 ° C

Fig. 1. Commercial thyme oil

Fig. 2 Antimicrobial drugs

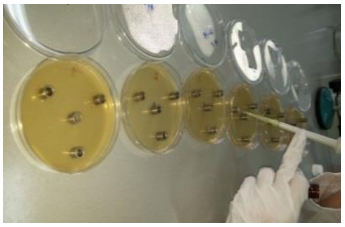

Fig. 3**.** Disk diffusion method

For the essential oil of thyme and the reference antimicrobial drugs three replication were carried out. The results were read as the diameter of the zone of inhibition of growth and expressed as the mean value in millimeters.

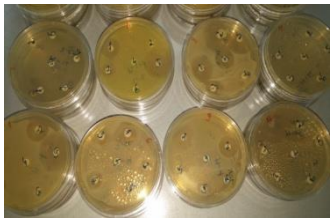

Figure 4**.** Reading the results
Type of activity

The type activity of essential oil was also determined. In order to see whether thyme oil has bactericidal or bacteriostatic effect, a small piece of agar was extracted from inhibition zone and added to the nutrient broth. Incubation was done at 37 ° C / 24 h. If, after the incubation, appears a turbidity of the broth, it is considered that the effect of oil is bacteriostatic, or if after the incubation broth remaines clear, the effect of the oil is bactericidal.

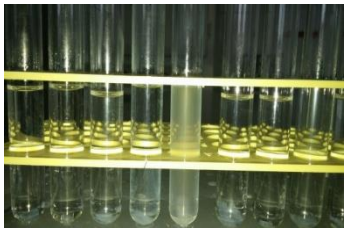

Figure 5. Bactericidal and bacteriostatic effect of the essential oil of thyme

Results and Discussion

Table 1 shows the results which were obtained by testing the effects of different antimicrobial drugs on the growth of tested pathogenic bacteria.

Table 1. Zones of growth inhibition of tested pathogens achieved with antimicrobial drugs

Microorganisms	Antimicrobial drug (inhibition zone measured in mm)									
	AM.	STR.	BAC.	CEFO.	CEFT	DOX.	NORF.	OX.	CEF.	GEN.
S. typhimurium WDCM 00031	0,00	13,00	0,00	20,00	0,00	21,00	36,00	0,00	8,00	18,00
L. monocytogenes WDCM 00020	10,00	24,00	16,00	12,00	12,00	38,00	26,00	0,00	12,00	24,00
E. coli WDCM 00090	0,00	15,00	24,00	18,00	0,00	25,00	39,00	0,00	15,00	20,00
St. aureus WDCM 00034	15,00	16,00	18,00	13,00	0,00	30,00	34,00	0,00	13,00	21,00
Ps. aeruginosa WDCM 00024	0,00	12,00	25,00	0,00	0,00	0,00	34,00	0,00	0,00	20,00
S. enterica WDCM 00030	0,00	18,00	16,00	0,00	15,00	23,00	40,00	16,00	0,00	25,00
Providencia stuartii	0,00	0,00	0,00	0,00	0,00	0,00	0,00	0,00	0,00	0,00
Coagu.pos. Staphylococcus	0,00	15,00	20,00	0,00	0,00	13,00	38,00	0,00	0,00	24,00
ß- haemolytic *E. Coli*	0,00	0,00	0,00	20,00	19,00	16,00	40,00	0,00	0,00	22,00
S. aureus	0,00	21,00	25,00	30,00	0,00	40,00	40,00	0,00	20,00	25,00
Streptococcus Group D	10,00	20,00	30,00	21,00	0,00	25,00	31,00	0,00	20,00	24,00
Pseudomonas spp.	0,00	0,00	21,00	20,00	0,00	0,00	40,00	0,00	20,00	0,00

AM-amoxicillin; STR-streptomycin; BAC-bacitracin; CEFO-cefotaxime; CEFTA ceftazidime; DOX-doxycycline; Norf-norfloxacin; OKS-oxacillin; CEF cefahlor; GEN-gentamicin

As it is evident that tested bacteria of *S. typhimurium* WDCMA 00031, *E. coli* WDCMA 00090, *Ps. aeruginosa* WDCMA 00024, *S. enterica* WDCMA00030, *Providencia stuarti*, coagulase-positive staphylococci, ß hem. *E. coli*, *S. aureus* were resistant to amoxicillin and oxacillin. *Providencia stuartii* isolated from the clinical material was resistant to all antimicrobial tested

drugs. Also, it is evident that all tested pathogens showed multiple resistance. The antimicrobial drug with the mostly expressed zone of inhibition i.e. norfloxacin was used to compare the activity of essential oil of thyme. The results obtained by testing the influence of essential oil of thyme to different pathogens are shown in Table 2.

Table 2. *Zones of inhibition on growth of tested pathogens achieved with essential oil of thyme*

Microorganism	The zone of inhibition in mm
	The essential oil of thyme
Salmonella typhimurium WDCM 00031	31,00
Listeria monocytogenes WDCM 00020	35,00
Escherichia coli WDCM 00090	17,33
Staphylococcus aureus WDCM 00034	40,00
Pseudomonas aeruginosa WDCM 00024	5,00
Salmonella enterica WDCM 00030	19,33
Providencia stuarti	33,33
Coagulase positive *Staphylococcus*	32,00
ß- hemolytic *Escherichia coli*	32,66
Staphilococcus aureus	40,00
Streptococcus Group D	38,00
Pseudomonas spp.	28,33

* The values shown are given in mm and the mean of inhibition zone in three measurements

As it is evident, the essential oil of thyme expressed antimicrobial activity against all tested bacteria. The zone of inhibition ranged in diameter from 5.00 mm in the case of *Pseudomonas aeruginosa* WDCMA 00024, up to 40.00 mm in the case of *Staphylococcus aureus* WDCMA 00034 and *Staphylococcus* isolated from clinical materials (swabs of the nose). If we present maximum inhibition zones of essential oil of thyme and compare to the inhibition zone the most effective antimicrobial drug norfloxacin, then results as in Figure 6 are obtained.

From the displayed graphic it is evident that the essential oil of thyme has more expressed antibacterial activity against *Listeria monocytogenes* WDCMA 00020, *Staphylococcus aureus* WDCMA 00034, *Providencia stuarti*, *Streptococcus* group D, than norfloxacin. It is also notable that the oil has the same effect as norfloxacin on *Staphylococcus aureus* isolated from clinical material.

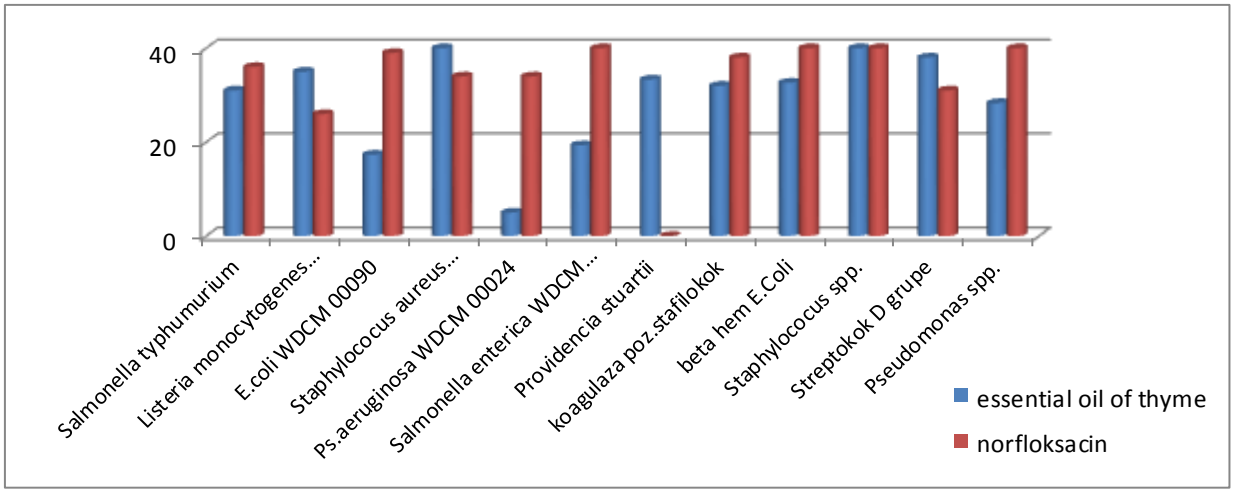

Figure 6. Comparison of maximal inhibition zones of essential oil of thyme and antimicrobial drug norfloxacin

Also, it is important to point out that the essential oil of thyme showed strong antibacterial activity against bacteria *Providencia stuartii* isolated from clinical material that was resistant to all antimicrobial drugs used in this paper.

The essential oil of thyme have bactericidal effect on all tested bacteria, except *Pseudomonas aeruginosa* WDCMA 00024, in which case it showed bacteriostatic effect.

The results of our research are in accordance with the results of the other researchers (Panizzi *et al*., 1989., Griffin et al., 1999, Kalaba *et al.*, 2014., Kalaba *et al*., 2014a., Feizi *et al*., 2013., Janječić *et al.*, 2013., Stojkovic *et al*., 2013., Bajpai *et al*., 2012., Jayasena, 2013., Basho *et al*. 2010., Lopez *et al*., 2007., Lević *et al*., 2011., Ahmad *et al*., 2006., Stanković *et al*.2011.,).

Even though many studies dealt with the antimicrobial activity of essential oil of thyme because of these characteristics, the essential oil of thyme deserves further, more detailed testing because it is necessary to establish the conditions in which the use of essential oil of thyme has positive effects. When testing the food it is important to take into account the interaction of biologically active components with components of food (fats, proteins, etc.) despite numerous advantages that essential oils provide, the use of essential oils can have negative consequences. Therefore, it is necessary to study which concentration and the amount are required to achieve the satisfactory effect.

Conclusion

Thyme as a plant species is a very rich in bioactive components that have found their application since the ancient times in traditional medicine and in the current medicine. It opens the field for new research and application of thyme and its isolated components in the treatment of many diseases (diseases caused by microorganisms resistant to antimicrobials, cancer, and many other infectious diseases) or in the food industry and as a food additive and as an excellent preservative.
