Abstract

One of the important stored-grain pests is *Rhyzopertha dominica* causing considerable grain loss once high level of population is established. A promising alternative to currently used chemicals is the use of entomopathogenic fungi for suppressing its populations. Several previous studies established the pathogenicity of *Beauveria bassiana* against *R. dominica*. After screening a series of native wild fungal isolates, one *B. bassiana* isolate (151138) was found promising (data not presented). This study was conducted to increase the virulence of the isolate against *R.dominica* in order to reduce the amount of fungal conidia to be used in microbial control practices. The fungus was re-isolated from dead *R. dominica* adults and five single spore colonies were established. They were used in a bioassay using 500ppm conidia and 60-76% mortalities within 14 days were found. Considering variation amongst repetitions, one was selected for a further re-isolation study and other five single spore colonies were obtained. The bioassay was repeated with latter isolates and 98.75-100% mortalities within 14 days were achieved. Similar increases in mortality levels on 7^{th} day of incubation were also noticed. All the bioassays were conducted in centrifuge tubes with 40gr of wheat grains and 20 adults at 25^{o}C and 65% relative humidity in darkness. As initial mortality rate was 50-65% in the same conditions with 500ppm concentration, almost two fold increase in the efficacy of the fungus was resulted. Although wild entomopathogenic fungal strains are good source for finding promising microbial control agents, selecting virulent once from wild strains is valuable for further investigations.

Keywords: *Microbial control, stored-product pest, lesser grain borer.*

Introduction

Cereals are commonly subjected to storage and during which infestations by pest insects can be a serious problem for both qualitative value and quantity of the commodity. One of such important stored-grain pests is *Rhyzopertha dominica* causing considerable grain loss once high level of population is established. Currently, synthetic chemical insecticides are applied for its management. These chemicals can cause several problems like mammalian toxicity, residues on commodities, and increasing resistance by targeted pests (Arthur, 1996). Furthermore, consumer demands for residue free products and environmental concerns directed researchers for alternative means of controlling pests (Inglis *et al*., 1997; Lomer *et al*., 2001). The use of entomopathogenic fungi for suppressing pest populations was considered promising alternative to currently used chemicals (Shams *et al*., 2011). Several previous studies established the potential of entomopathogenic fungi including *Beauveria bassiana* against stored product pests such as *R. dominica* (Searle and Doberski, 1984; Adane *et al*., 1996; Hidalgo *et al*., 1998; Moino *et al*., 1998; Rice and Cogburn, 1999; Dal Bello *et al*., 2001; Meikle *et al*., 2001; Sheeba *et al*., 2001; Cherry *et al*., 2005). It is also noticed that isolates of the same fungal species vary considerably in

their effects on targeted hosts (Cherry *et al*., 2005; Wakefield *et al*., 2005). After screening a series of native wild fungal isolates, one *B. bassiana* isolate (151138) was found promising in our studies (data not presented). Increasing its effectiveness is one of our purposes and this study was conducted to increase the virulence of the isolate against *R.dominica* in order to reduce the amount of fungal conidia to be used in microbial control practices.

Materials and methods

Insect culture

Rhyzopertha dominica cultures have been maintained in the laboratory of Department of Plant Protection at University of Kahramanmaras Sutcu Imam on wheat, and originally obtained from insects collected from grain storages in Adana province in Turkey. In order to obtain adults at the same age, adults were left in clean wheat for two days for oviposition, and thereafter removed from jars. New generation adult emergence was monitored and 7-10 days old adults were used for experiments. Culturing conditions were 30±2^{o}C, 65±5% relative humidity in darkness.

Fungus culture

The *Beauveria bassiana* isolate (151138) was chosen from our entomopathogenic fungal culture collection. The fungus was originally isolated from an adult *R. dominica* and later found promising due to its high pathogenicity after a screening test (data not presented). All fungal cultures were grown on Potato Dextrose Agar (PDA) at 25±2^{o}C in darkness.

Fungus re-isolation and establishing single spore cultures

Rhyzopertha dominica adults were exposed to the fungus and incubated as described below (Pathogenicity tests). Dead insects were gathered, surface sterilised and placed within humidity chambers to promote fungal development and sporulation on the surface of the cadavers. Those with good sporulation were chosen to re-isolate the fungus. Spores from the surface of the cadavers were transferred to PDA including antibiotics. From the developing fungal cultures, a small amount of conidia was suspended into sterile 0.02% Tween 80 and 100µl of the suspension was spread on PDA. After two days of incubation the plates were examined under a microscope to mark germinated single spores away from the others. Marked germinated-spores were transferred individually on new PDA plates to establish single spore cultures.

Pathogenicity tests

Five single spore colonies derived from re-isolated fungus from dead *R. dominica* adults were used for the first pathogenicity test. The bioassay was conducted by using 500ppm (w/w) conidia. Considering variation amongst repetitions, one was selected for a further re-isolation study and other five single spore colonies were obtained. In the second test, the bioassay was repeated with latter isolates. All the bioassays were conducted in centrifuge tubes (50ml in capacity) with 40gr of wheat grains and 20 adults at 25±2^{o}C and 65±5% relative humidity in darkness. Insect mortalities were evaluated after 7 and 14 days.

Results and discussion

In the first test, after passing through the host and single spore isolation, mortalities were 33-51% and 60-76% after 7 and 14 days of incubation, respectively (Table 1). The culture number 5 was chosen for further investigation due to its higher mortality level and deviation. Five cadavers from this treatment were used to obtain other five single spore colonies for the second test.

According to the second test results the mortalities increased to 72.50-81.25% and 98.75-100% after 7 and 14 days of incubation, respectively (Table 2).

Table 1. Mortalities of *Rhyzopertha dominica* adults caused by the first single spore cultures of *Beauveria bassiana* 151138 (n=5).

Mortalities (%) after 7 days of incubation						
Culture number	3	2a	1a	4b	5	Control
Overall mortality	46	33	46	51	41	0
Standart deviation	4.2	4.5	18.8	7.4	20.7	0
Mortalities (%) after 14 days of incubation						
Culture number	3	2a	1a	4b	5	Control
Overall mortality	76	60	69	72	76	6
Standart deviation	8.2	11.7	20.7	9.7	23.8	8.2

Table 2. Mortalities of *Rhyzopertha dominica* adults caused by the subsequent second single spore cultures of *Beauveria bassiana* originated from the Culture Number 5 (n=4).

Mortalities (%) after 7 days of incubation						
Culture number	5-1	5-2	5-3	5-4	5-5	Control
Overall mortality	72.5	72.5	75	73.75	81.25	0
Standart deviation	25	12.6	5.8	10.3	21.7	0
Mortalities (%) after 14 days of incubation						
Culture number	5-1	5-2	5-3	5-4	5-5	Control
Overall mortality	100	100	100	100	98.75	1.25
Standart deviation	0	0	0	0	2.5	2.5

Pooled data of the first and the second test results were given in Figure 1. One week incubation mortality increased from 43.4±2.7% to 75±3.4%, and two weeks incubation mortality increased from 70.6±3.2% to 99.75±0.3%. As initial mortality rate of the fungus was 50-65% after two weeks of incubation in previous tests (data not presented) almost two fold increase in the efficacy of the fungus was resulted reaching to almost 100% mortality.

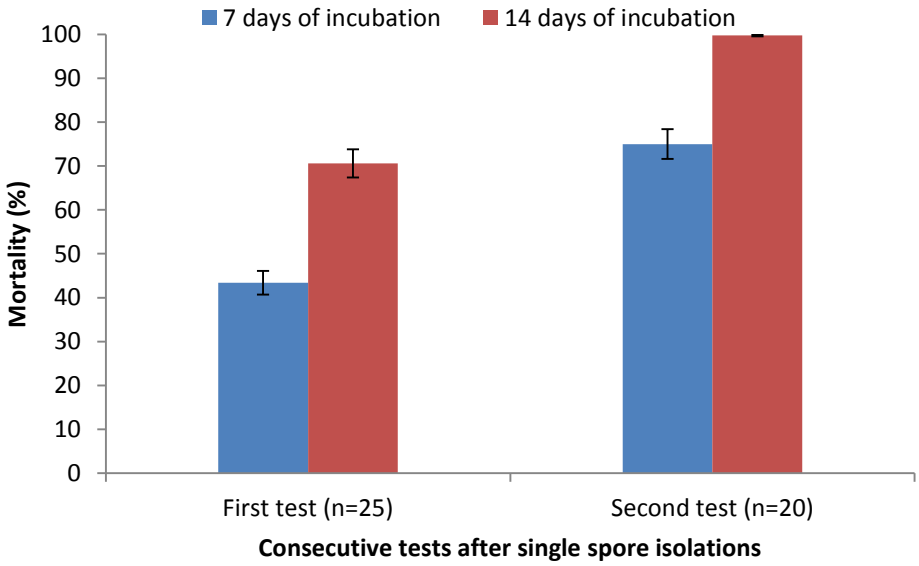

Figure 1. Pooled data of *Rhyzopertha dominica* adult mortalities after one and two consecutive single spore isolations from *Beauveria bassiana* 151138 (bars represent standard errors).

In previous studies, successive passages of entomopathogenic fungi through host insects have been shown to increase their virulence (Adames *et al*., 2011; Quesada-Moraga and Vey, 2003; Santoro *et al*., 2015; Song and Feng, 2011). The passages of the fungus through the targeted host in this study should have a great effect on increasing virulence; however the increase was quite fast reaching 100% only after two passages. This is possible due to isolation of a single spore after each passage speeding up the selection process. Adames *et al*. (2011) and Santoro *et al*. (2015) increased virulence of entomopathogenic fungi even after 7, 15 passages, respectively towards their targeted pests.

Conclusion

In the search for fungal biological agents for microbial control of insect pests, isolation of entomopathogenic fungi from targeted host or its surroundings is a common practice. These fungi have been useful for further investigations; however, wild fungi comprise genetic and adaptive diversity. This study presents the utility of selecting single spores from wild fungal isolates for studies towards developing microbial control agents. Although wild entomopathogenic fungal strains are good source for finding promising microbial control agents, selecting virulent once from these strains can increase their value.

EFFECT OF SHORT TIME EXPOSURE OF RHYZOPERTHA DOMINICA ADULTS TO BEAUVERIA BASSIANA CONIDIA MIXED IN WHEAT GRAINS

Mehmet Kubilay ER*, Ali Arda IŞIKBER, Hasan TUNAZ

Department of Plant Protection, Faculty of Agriculture, KahramanmaraşSütçü İmam University, Kahramanmaraş, Turkey

Abstract

Due to various problems of chemical insecticide use against pest insects of stored-grains, alternative control techniques have been investigated. One approach is utilization of entomopathogenic fungi for biological control of these pests and has commonly been considered promising. Previous experiments measured mortalities of insects kept in fungus treated cereals for 1-3 weeks or longer. This study was conducted to reveal the effect of shorter exposure time on *Rhyzopertha dominica* adults challenged with *Beauveria bassiana*. Adult insects (20 for each treatment) were left in wheat grains with fungal conidia(600ppm) for 15 mins, 1 h, 2hs, 6hs, 1 day and 2 days. Thereafter, they were transferred into clean wheat grains and incubated until mortality evaluations on the 7^{th} and 14^{th} days. One additional treatment (full time exposure) was to keep insects in wheat with fungal conidia throughout the experiment. Insects in control treatment were kept in untreated grains. The experiment had five repetitions and conducted at 25^{o}C and 65% relative humidity in darkness. An expected general trend of increasing mortality with increasing exposure time was observed. However, statistical differences amongst mortalities after full time exposure (46%), 1 day (32%) and 2 days (58%) exposure treatments were insignificant in 7 days of incubation. Full time exposure treatment (83%) was also not statistically different from 2 days exposure treatment (64%) in 14 days of incubation. These findings are particularly important for protecting cereal bulks from new insect infestations, and in the cases of uneven distribution of fungal spores in cereal bulks in management of stored-grain pests.

Keywords: *Microbial control, stored-product pest, lesser grain borer.*

Introduction

Stored grains are frequently infested by various insect pests, and in the cases of their high populations, considerable qualitative and quantitative damage occurs. Although chemical insecticides are applied to suppress the populations, due to various problems of these insecticides (Arthur, 1996), such as undesirable chemical residues, their environmental threats, and resistance development of pests to the chemicals, alternative control techniques have been investigated (Inglis *et al*., 1997; Lomer *et al*., 2001). One approach is the use of entomopathogenic fungi in biological control approach and has been considered promising (Shams *et al*., 2011). Some species of entomopathogenic fungi have been tested against several stored-grain pests, mostly coleopteran, with encouraging results (Meikle *et al*., 2001; Sheeba *et al*., 2001; Dal Bello *et al*., 2001; Cherry *et al*., 2005 Wakil and Ghazanfar 2010; Shams *et al*. 2011; Barra *et al*. 2013; Khashaveh and Chelav 2013; Sewify *et al*. 2014). Developing such biological agents to suppress pests of stored cereals can at least reduce the use of chemicals and thus their negative side effects. The previous experiments measured mortalities of insects kept in fungus-treated-cereals for 1-3

weeks or even longer. It can not be realized from their results whether insects die due to attached conidia in early period of time or throughout long exposure period. Clarifying this process can help developing entomopathogenic fungi for the control of stored-product pests. Therefore, shorter exposure of the insects needs to be investigated for better understanding the effects of these biological agents. This study was conducted to reveal the effect of shorter exposure periods on a stored-grain pest, *Rhyzopertha dominica*, when *Beauveria bassiana* was used as the biological control agent.

Materials and methods

Insect culture

Rhyzopertha dominica cultures were originally started with insects collected from grain storages in Adana province in Turkey and have been maintained in our laboratory on wheat. Adults at the same age were used in the experiments. They were obtained by leaving adults in clean wheat for only two days for oviposition and then by gathering new generation adults 7-10 days after the onset of adult emergence. All the cultures were kept in controlled conditions at 30±2^{o}C, 65±5% relative humidity in darkness.

Fungus culture

The *Beauveria bassiana* isolate (151138) was originally isolated from an adult *R. dominica*. It has been kept in our entomopathogenic fungal culture collection. All fungal cultures were grown on Potato Dextrose Agar (PDA) at 25±2^{o}C in darkness. The cultures that completed sporulation were kept at room temperature with open lid to dry them for two days. Conidia were vacuumed and collected in small vials, and kept at +4^{o}C until use. Before the experiment a small amount of conidia were incubated on PDA for 24 hours at 25±2^{o}C in darkness for germination test. After incubation, spores were examined under microscope and those with a germ tube at least as long as the conidium were considered germinated. Spores with at least 95% germination ratio were used for the experiment.

Conducting the test

Centrifuge tubes of 50ml capacity with 40gr of wheat grains homogenously mixed with 600ppm (w/w) conidia were used. After placing 20 *R. dominica* adults, they were kept at 25^{o}C and 65% relative humidity in darkness for various periods of exposure (15 mins, 1 h, 2hs, 6hs, 1 day and 2 days). The adults were transferred into clean wheat grains and incubated under the same conditions until mortality evaluations on the 7th and 14th days. One additional treatment (full time exposure) was set by keeping insects in wheat with fungal conidia throughout the experiment (14 days). Insects in control treatment were kept in untreated grains. The experiment had five repetitions. The obtained data were subjected to ANOVA and Tukey multiple comparison tests, after arcsine transformation by using Minitab statistics program.

Results and discussion

Rhyzopertha dominica adult mortalities varied between 11% and 58% at the end of 7 days of incubation (Figure 1). Although exposure time to fungal conidia significantly affected the mortality level ($F=14.12$; d.f.=5, 29; $P<0.000$), mortalities after 1-2 days of exposure were not statistically different from the full time continuous exposure treatment (Figure 1). Shorter exposure times (≤6 hours) however resulted with significantly lower mortalities. The results of 14 days of incubation were similar with the exception of 1-day exposure treatment (Figure 2). Mortalities were between 29% and 83% with significant differences ($F=17.11$; d.f.=5, 29;

P<0.000). The difference between the mortality after 2-days exposure and that of the full time continuous exposure was statistically insignificant while the mortalities of the other treatments were statistically lower. Insect exposure to the conidia for 15 mins – 1 day did not change the resultant mortality level. Considering the final mortality levels after two weeks of incubation, the results show that full time exposure of the insects to the fungal conidia can be better for pest control, but a 2-days exposure can give quite similar results in terms of pest suppression. Even short time exposure (15 mins – 1 day) to the fungus causes considerable mortalities, almost half the level obtained with full time continuous exposure.

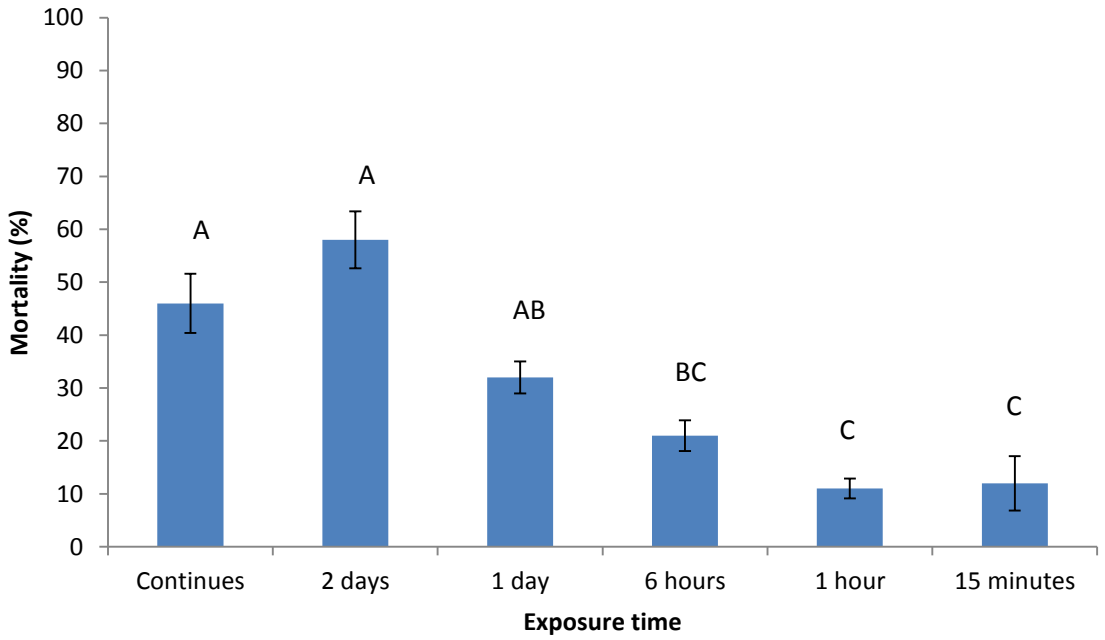

Figure 1. *Rhyzopertha dominica* adult mortalities seven days after exposure to *Beauveria bassiana* conidia (According to Tukey multiple comparison test, statistically significant differences are marked with different letters; control mortality=0%; bars represent standard errors; n=5)

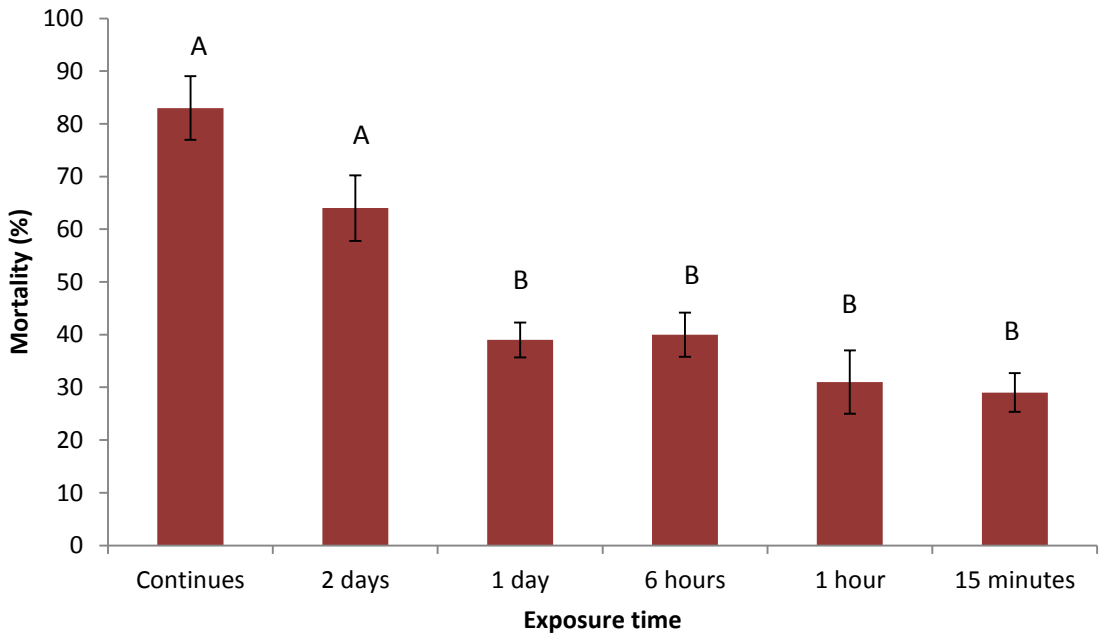

Figure 2. *Rhyzopertha dominica* adult mortalities 14 days after exposure to *Beauveria bassiana* conidia (According to Tukey multiple comparison test, statistically significant differences are marked with different letters; control mortality=2±1.2%; bars represent standard errors; n=5)

Conclusion

Although in previous studies targeted pests were kept in continuous contact with fungal conidia for the whole period of experiments, this results show that a much shorter exposure period can also be enough to yield high mortalities and to evaluate pathogenicity of entomopathogenic fungi. After shortening exposure period, however, fungi still require a period of time to kill. These indicate that entomopathogenic fungi can be more effective than expectations at suppressing pest populations in grain storages. According to the results, the conidia attached in early period of exposure time are mostly responsible for the mortalities even though the insects are exposed to conidia for a longer period. These findings are particularly important for protecting cereal bulks from new insect infestations, where they will be affected by early contacts with conidia leading to early mortalities with a possible result of faster management of stored-grain pests by using entomopathogenic fungi.

Abstract

Insect immunology is an active research arena. However, the vast majority of research in the area is conducted on model species taken from laboratory cultures. In this study, the hypothesis tested is that insects are usually exposed to infections or invasions in nature and this paper reports on results of a field study designed to assess the extent of natural infections in insects collected in the fields around Osmaniye, Turkey. Specimens were dissected to assess numbers of nodules. Nodulation is one of the insect cellular to microbial infection, In about 600 tested insect specimens, at least some nodules were found in 99%. Number of nodules in each insect was from 1 to 105. From these data, we can speculate that insects are mostly challenged by microbial diseases from which they rescued themselves. Importance of our data is that insect immune systems may limit the host range and effectiveness of agents deployed in biological control programs. Knowledge of insect immune systems may contribute to increase use of biopesticides globally.

Keywords: *Insect immunology; Naturally occurring infections; Biological control.*

Introduction

Natural entomopathogen microbes are virulent insect pathogens, including viruses, fungi and bacteria. Some of these organisms can serve as important natural regulators of insect populations by invading insect bodies, often coming through the alimentary canal (Lacey *et al.,* 2001). Because of their actual or potential influence on insect populations, many insect pathogens are exploited as biological control agents (ref.). Commercially useful pathogens include viruses, fungi, bacteria, protozoans and nematodes, all deployed in as agents in biological control of insect pests,. The relative success and failures of microbial control of insect pests depends on a wide range of factors. One of them is biological issues in which successful microbial control products and processes will depend on them. These issues span a range of biological organization from the ecological level of microbe-host population dynamics to the molecular and cell biology of host defense mechanisms. One of the greatest barriers to increased deployments of microbial control agents may lie in insects' robust and complex innate immune effectors. Insect physiologically produce two different immunity to microbes which are cellular and humoral immunity. These cellular defense reactions begin immediately after an infection is detected within an insect. Some hours after an infection is detected, insects unleash an array of anti-microbial peptides that constitute the humoral immune system (Lemaitre and Hoffmann, 2007). The combined arsenal of immune effector mechanisms allows insects to overcome invasions, infections and wounds. And these mechanisms can limit the effectiveness of microbes deployed for biocontrol of insect pest populations. Therefore, it was hypothesized and tested that insects experience natural infections in fields and they recover and pass through their life.

Materials and Methods

Insects

Insects have been collected from fields of Osmaniye city area (Turkey) in 2012-2013. The collected species, collection sites, site altitudes, and biological stages are indicated in results. The specimens were transferred to the laboratory (20 ± 1 ^{o}C, RH 60 ±5) at Kahramanmaras Sütçü İmam University. Most individuals were identified to species.

Nodulation assay

Following identification, the extent of nodulation was assessed following the protocols formalized by Miller and Stanley (1998). Insects were anesthetized by chilling on ice and then their hemocoels were exposed. Melanized, brownish-black nodules were counted under a stereo microscope at 45x. The nodules were distinct, and direct counting reliably reflected the extent of the nodulation response to infections (Miller *et al.,* 1999). After the first counting, the alimentary canal was removed. Nodules in the previously unexposed areas and remaining internal tissues were then counted.

Statistical Analysis

Data on nodulation were analyzed using the General Linear Models procedure, and mean comparisons were made using Tukey test (SAS Institute Inc., 1989).

Results and Discussion

Two categories of defense responses to microbial infections were seen in insects, humoral and hemocytic defence reactions (Dunn, 1986; Gupta, 1991). Humoral reactions take quietly long time for their full expression, and involve induced synthesis of antibacterial proteins, such as cecropins, attacins, diptericins, and defensins (Dunn, 1986). In the presence of these proteins, bacteria lose their cellular integrity because of the detergent properties of peptides. Insects also synthesize lysozymes, which enzymatically attack bacteria by hydrolyzing their peptidoglycan cell walls (Dunn, 1986; Russell and Dunn, 1996). Hemocytic reactions involve direct cellular interactions between circulating hemocytes and bacteria. In contrast to humoral defense reactions, hemocytic responses are very quick, typically occur within minutes of an infection cycle. Specific cellular defense mechanisms include phagocytosis, nodulation and encapsulation (Gupta, 1991).

One of insect cellular or hemocytic defense actions is nodulation. Dunn and Drake (1983) indicated that following an injection of bacterial cells into tobacco hornworm *Manduca sexta*, the insects were capable to clear most bacterial cells from their hemolymph circulation by nodulation in the first 2 h following the artificial infection. Occurence of nodulation involves more than one steps. First, insect granulocytes attaches to infecting microbe cells, second, the granulocytes are degranuted that causes attraction of insect plasmatocytes to the growing nodule, and the spreading of plasmatocytes around the nodule (Dean *et al*., 2004). Finally, the darkened, melanized nodules attach to an internal organ or body wall, where they remain through the life of the insect.

From insect hemocoels, nodules are not easilly moved away when insect has experienced a microbial infection. The presence of nodules in insect hemocoels indicates that the insect was infected with microbes in the past or has a past microbial infection. Many researchers report nodulation reactions in insects following infections of insects with microbes including bacteria, fungal spores and some viruses (Miller *et al*., 1994; Dean *et al.,* 2002; Lord *et al.,* 2002; Büyükgüzel *et al*., 2007; Durmuş *et al*., 2008). Howard *et al.* (1998) also reported that some bacterial species evoked far more nodules than similar infections with other species

In this study, nodulation was assessed in a total of 60 insect species collected during 2012-2013. In the broadest description, we recorded nodules in 99% of the 600 specimens examined, although there was a very wide range of nodules/specimen (from 1 nodule/insect to >105 nodules/insect). We note a relatively small number of clear patterns in natural microbial infections. We usually determined more nodules in the insects associated with soil than in those collected from plants (Table 1). Specifically, we have seen higher number of nodules in orthopteran specimens and sunn pest adults. There were more nodules in orthopteran specimens and sunn pest adults associated with soil (Tables 1). It was also noted that the overwintered generations of *Eurygaster integriceps* had much more nodules compared to new genaration adults (about 105 nodules for overwintered generations; about 8-12 nodules for new genaration adults). Examining insect orders for nodulation assay, significantly more nodules were recorded from orthopteran species than lepidopteran, hemipteran and coleopteran species (Table 3), which is logical because orthopteran species were mostly collected from soil. There were no nodulation differences in number among biological stages of insects. It was recorded statistically similar numbers of nodules in larvae, nymphs and adults of insect species (Table 2). Putting together, insect orders in contact with soil are probably the main associations with higher number of nodules. However, the actual occurrence of natural infection may be a random event with no predominant patterns. On the other hand, the data indicate virtually all insects had experienced infection(s) in nature.

Table 1. A single-factor ANOVA across species for collection sources differences

Year	Collection sources	Nodules /insect[a]	Number of individuals
2012	Plant material	17.034 ± 2.6^{b}	730
	Soil	61.338 ± 7.2^{a}	60
2013	Plant material	9.3 ± 0.81^{b}	1100
	Soil	59.5 ± 4^{a}	200

[a]Mean number of nodules in a column followed by different letters are significantly different for each year ($F_{(1,77)}$ =21.86, P <0.0001 for 2012) and ($F_{(1,128)}$ = 388.53, P < 0.0001 for 2013)}

Table 2. A single-factor ANOVA across species for developmental stage differences

Year	Developmental stages	Nodules /insect	Number of individuals
2012	Adults	19.9 ± 3.3^{a}	570
	Larvae	19.4 ± 3.9^{a}	160
	Nymphs	14.8 ± 5.1^{a}	40
2013	Adults	17.7 ± 2.29^{a}	1060
	Larvae	16.6 ± 3.14^{a}	130
	Nymphs	27.1 ± 7.65^{a}	130

No significant differences were detected for each year{($F_{(2,74)}$ = 0.09, P=0.9109 for 2012) and ($F_{(2,129)}$ = 1., P=0.3711 for 2013)}

Table 3. A single-factor ANOVA across species for insect order differences

Year	Insect orders	Nodules /insect[a]	Number of individuals
2012	Lepidoptera	19.1 ± 3.7^{b}	170
	Hemiptera	16.9 ± 6.9^{b}	190
	Coleoptera	9.0 ± 1.3^{b}	240
	Orthoptera	58.0 ± 6.9^{a}	70
	Hymenoptera	4.5 ± 1.3^{b}	30

2013	Lepidoptera	12.8 ± 2.3^{b}	210
	Hemiptera	14.3 ± 4.4^{b}	300
	Coleoptera	6.5 ± 0.9^{b}	410
	Orthoptera	58.8 ± 4.1^{a}	200
	Hymenoptera	8.4 ± 2.2^{b}	50
	Diptera	10.4 ± 2.0^{b}	70

[a]Mean number of nodules in a column followed by different letters are significantly different for each year { ($F_{(5,67)}$ = 84.24, P<0.0001 for 2012) and ($F_{(5,118)}$ = 34.97, P<0.0001 for 2013)

Conclusion

It was known that pest insects cause crop losses. Therefore understanding of insect immunity and pathogens on insect immunity are very important for controlling pest insect in agriculture, in which microbial insecticides are used. Insects have the ability to recover from infections in nature which is important for biological and agricultural implications. On the other hand, biologically, many microbes have the ability to overcome insect immune systems. Therefore, we need to understand evolutionary mechanisms of insect immunity and inhibitory actions of insect pathogens for getting effective result on insect pest management. It is known that insect immunity systems may limit use of biopesticides, which are environmentally friendly insecticide. Hence, in this paper, we tried to understand insect immune reactions in nature in which the insects were collected from Osmaniye Province of Turkey. We conclude that insect orders in contact with soil are probably the main associations with higher number of nodules. However, the actual occurrence of natural infection may be a random event with no predominant patterns. On the other hand, the data indicate virtually all insects had experienced infection(s) in nature.

Abstract

Alfalfa (*Medicago sativa* L.) is economically the most important forage crop in Serbia. During the period of 2005-2010, intense occurrence of alfalfa anthracnose was observed in Serbia (Srpska Crnja, South Banat District). Alfalfa plants showed characteristic symptoms of anthracnose disease ("shepherd's crook") including wilting and dying of the upper parts of the stems. Collected isolates formed light green to dark olive-green colonies on potato dextrose agar (PDA) and developed black acervuli around the center of the colony. In cultures on PDA medium acervuli were formed. Conidia were hyaline, aseptate, straight with one end pointed and the other slightly rounded, with dimensions 12.5 to 25.0 × 2.5 to 7.5 μm (mean 19.83 × 4.42 μm). In cultures on PDA medium after 5 days, numerous setae were formed. The setae were slightly darker at the bottom and lighter at the top, septate with 3 septa. Setae dimensions were with dimensions 100 to 185.5 × 2.5 to 5 μm (average 160.9 × 3.12 μm). PCR amplification using ITS1-ITS4, GSF1-GSR1, GDF1-GDR1 and T1-Bt2b primer pairs yielded fragments of approximately 495 base-pairs (bp), 900 bp, 200 bp and 750 bp, respectively. Based on the morphological characteristics and molecular characterization, the analyzed isolate Coll-44 from alfalfa was determined as *Colletotrichum linicola* Pethybr. & Laff.. According information we have on disposal this is the first report of *C. linicola* causing alfalfa anthracnose in Serbia.

Keywords: Anthracnose; Alfalfa; *Colletotrichum linicola*; PCR analysis

Introduction

Many diseases cause the dying of alfalfa plants, reduction of yield, and negative impact on quality of animal feed. Anthracnose of alfalfa is one of the most important diseases that reduce alfalfa yield (O'Neill et al., 1997; Vasić, 2013) and is caused by fungi of the genus *Colletotrichum*. Damage induced by presence and development of the pathogen causes the reduction of quality and quantity of fresh mass from 10-30% depending on the alfalfa cultivar, species of pathogen, climatic and edaphic factors (Latunde-Dada et al., 2007; Vasić, 2013). *C. trifolii* and *C. destructivum* spread rapidly during warm, wet weather. Conidia forms in the acervuli on stem lesions. Wind and rain splash carry conidia to the growing petioles and stems. Infected hyphae proliferate within susceptible host tissue and form oval-shaped lesions. In hot, dry weather, infected stems may wilt and die. The fungus grows down in infected stems into the crown and taproot, causing killing of tissue, predisposition to winter injury, wilting or plant dieback (Vasić, 2013). Anthracnose of alfalfa, caused by *C. destructivum* is prevalent on wide area in Serbia and the induced damages are of great economic importance (Vasić, 2013).

Material and methods

Morphological traits

The isolates studied in this survy were obtained from infected alfalfa plants collected from 2005-2010 in Serbia (Srpska Crnja, South Banat District). All samples were placed in paper bags and delivered to the phytopathological laboratory of the Institute for Forage Crops, Kruševac. The pathogen was isolated from the stem, the top of the root, and root of alfalfa. Potato dextrose agar (PDA) medium was used for the isolation of the pathogen (Dhingra and Sinclair, 1995). Petri dishes were incubated in thermostat at 24 ± 2°C in the dark.

Morphological traits of selected isolates of *Colletotrichum* sp. were studied on PDA and carnation leaf agar (CLA) (Waller et al. 1998) according to the method by Baxteret et al. (1983). Hyphal appearance was prepared according to the method by Baxteret et al. (1983) on PDA medium and in hanging drops over the glass according to the method described by Hawksworth (1974). Size of conidiomata was determined by measuring the diameter (10 fully formed acervuli on PDA) and calculating the mean values. The presence or absence of setae in the cultures was determined by the method of Smith and Black (1990) by observation of 10-day-old cultures under the light microscope. The form and dimensions of conidia in the selected isolates of *Colletotrichum* sp. were examined according to the method of Smith and Black (1990). Dimensions of conidia were determined by measuring the length and width of 30 randomly selected conidia in the selected isolates grown on PDA, using a light microscope (Olympus CX41). Morphological traits of appresoria of the studied isolates were determined using a modified method by Hawksworth (1974). The shape, color and dimensions of appresoria were studied in selected isolates. Twenty-five appresoria per isolate were observed and measured. To observe the formation of teleomorph stage, studied isolates were grown on PDA. Cultures were incubated at 25°C in the day and night cycle, and the formation of perithecia was observed on three occasions, after 30 days, 6 months and 12 months. Petri dishes were kept in a thermostat at 25°C. The trial was set to 10 repetitions per isolate.

Molecular detection and identification

Isolates were grown on PDA in the dark, at 25°C for 7 days. DNA extraction was done according to the method described by Day and Shattock (1997). Polymerase chain reaction (PCR) was done using four sets of primers. The 5.8S rDNA, ITS1 and ITS2 region (ITS) was amplified with the primer pair ITS1-ITS4; an intron region of the glutamine synthetase gene (GS) with GSF1-GSR1 primer pair; an intron region of the glyceraldehyde-3-phosphate dehydrogenase gene (GPDH) with the primer pair GDF1-GDR1; and 5' end of the β-tubulin gene (TUB2) with T1-Bt2b primer pair (Table 1).

Table 1. The list of primers used for the detection and identification of *Colletotrichum* sp.

PCR tests were performed in a TPersonal thermocycler (Biometra, Germany). PCR products were analyzed by 1.5% agarose gel electrophoresis, stained with ethidium bromide and visualized under UV light on a transilluminator (Biometra, USA). The appearance of the fragment of the expected size was considered as a positive reaction.
Amplified products of the ITS and TUB2 regions of Coll-44 isolate were custom sequenced (Macrogen, the Netherlands). Obtained sequences were compared with the available sequences of *Colletotrichum* sp. from the NCBI GenBank database using BioEdit software (Hall, 1999).

Results and discussion

Morphological traits

On PDA medium, the isolate Coll-44 was characterized as *C. linicola*. It formed cottony colonies, velvety gray to light olive green in color. Analyzed isolate of *C. linicola* formed fruiting bodies - acervuli. Dimensions of acervuli were ranged from 100-280 µm. Similar results were earlier reported by Tunali et al. (2008), Vasić et al. (2014) and Damm et al. (2014). The Coll-44 isolate formed setae within conidiomata, slightly darker at the bottom and lighter at the top, having from 1 to 3 septae. Dimensions of septae were 100-185.5 x 2.5-5 µm (average 160.9 x 3.12 µm). The isolates identified as *C. linicola* formed cylindrical conidia, tapered at one end and rounded at the other, dimensions 10-25 x 2.5-7.5 µm. Our result is in accordance with Tunali et al. (2008) and Vasić et al. (2014). During this study it was found that *C. linicola* isolates forme septa in the equatorial part of the conidia during germination, which is a characteristic trait of this species. Based on this characteristic traits, *C. linicola* differ from close related species which do not form septae. Latunde-Dada and Lucas (2007) and Tunali et al. (2008) noted that the species *C. linicola* forms septae during germination of conidia. The Coll-44 isolate formed numerous appresoria, dimensions 5-17.5 x 2.5-7.5 µm (average 11.8 x 5.9 µm). The results obtained from our study coincide with the results of Latunde-Dada and Lucas (2007), Tunali et al. (2008), Vasić et al. (2014) and Damm et al. (2014). During this experiment was performed the isolate Coll-44 from Serbia (Srpska Crnja, South Banat District) did not form perithecia. This result is in accordance with Baxter et al. (1983), Latunde-Dada and Lucas (2007). Pure culture of the tested isolate was deposited in the public collection of CBS-KNAW Fungal Biodiversity Centre, Utrecht, the Netherlands (specimen no. CBS 138125).

Molecular detection and identification

The polymerase chain reaction (PCR) has been successfully applied for the identification of the isolates from alfalfa, including *C. linicola* isolate Coll-44. Universal primer pair ITS1-ITS4 yielded a product of approximately 495 bp in all tested isolates (Figure 1).

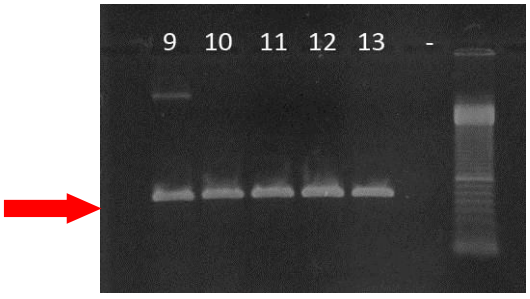

Figure 1. Electrophoretic analysis of PCR products with ITS1-ITS4 primer pair. Lines: 13-isolate Coll-44, (-) - negative control, M - 100-base pair ladder (Amersham Biosciences).

The presence of the fragment of approximately 900 bp was determined for most of the tested isolates using the primer pair GSF1-GSR1, an intron region of the GS gene had poor efficiency for Coll-44 isolate (Figure 2).

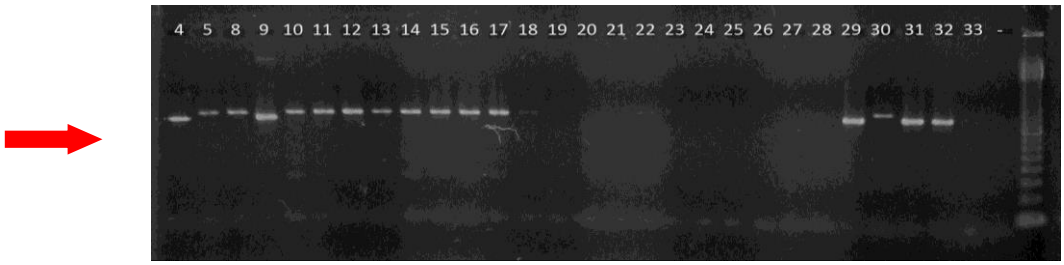

Figure 2. Electrophoretic analysis of PCR products with GSF1-GSR1 primer pair. Lines: 18 - isolate Coll-44, M- 100-base pair ladder (Amersham Biosciences).

PCR analysis with GDF1-GDR1 resulted in a positive reaction for tested isolates. Using these primer set, an intron region of the GPDH gene was successfully amplified for Coll-44 isolate (Figure 3).

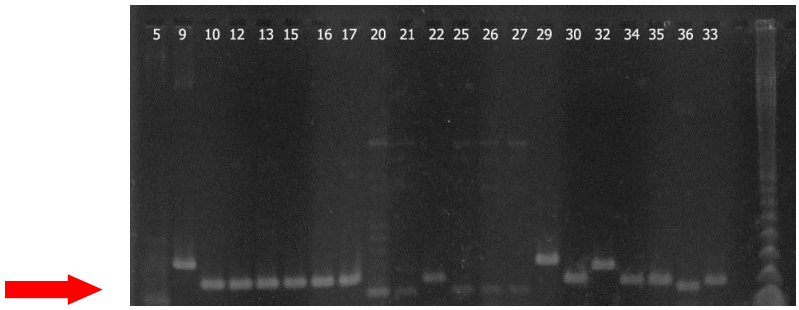

Figure 3. Electrophoretic analysis of PCR products with GDF1-GDR1 primer pair. Lines: 13 - isolate Coll-44, M - 100-base pair ladder (Amersham Biosciences).

In fourth PCR reaction with the primer pair T1-Bt2b the expected fragment of 750 bp was obtained for Coll-44 isolate (Figure 4).

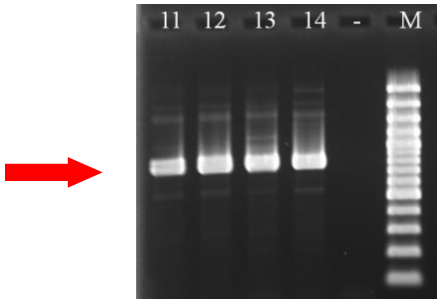

Figure 4. Electrophoretic analysis of PCR products with T1-Bt2b primer pair. Lines: 13 - isolate Coll-44, (-) - negative control, M- 100-base pair ladder (Amersham Biosciences).

The extracted fungal genomic DNA was of high quality and suitable for PCR amplification, allowing successful detection of isolates selected for this study. By using different primer pairs for PCR detection *C. linicola* isolate was successfully detected. Amplified PCR products of ITS and TUB2 regions of the isolate Coll-44 were sequenced and obtained sequences were deposited

in the NCBI Genbank under accessions numbers JX908364 and KJ556347, respectively. The sequences of Coll-44 isolate were compared with the available sequences from the GenBank database. Blast analysis confirmed 100% nucleotide identity of the Coll-44 ITS sequence with the GenBank accessions AB046609 and JQ005765 of *C. linicola*. Additionally, Coll-44 TUB2 sequence showed 99.6% nucleotide identity with the GenBank accession JQ005849 of *C. linicola* isolate CBS 172.51.

Freeman et al. (2000) have successfully distinguished 230 different isolates of *Colletotrichum* species using universal primers ITS1-ITS4 and sequencing PCR products of 450-490 bp of the tested isolates. Johnston and Jones (1997) used an analysis of LSU rDNA sequences of isolates derived from different crops in New Zealand. Moriwaki et al. (2002) successfully distinguished 236 isolates by studying ITS-2/LUS rDNA of *Colletotrichum* species in Japan using rDNA ITS1 region for sequencing products of size of approximately 157-190 bp. Liu et al. (2007) stated that the use of RFLPs of a intron regions in the glutamine synthetase (GS) gene has proved successful for the identification and characterization of closely related species within the genus *Colletotrichum* which were previously difficult to distinguish based on morphological traits. PCR reaction with GSF1-GSR1 primer pair had poor efficiency for Coll-44 isolate and gave product of not sufficient quality for further RFLP analysis. On the other hand , the intron region of the gene for GS is suitable for the detection and further characterization of Serbian *C. destructivum* isolates (Vasić, 2013). Detection of the isolates using the GDF1/GDR1 primers proved to be reliable and allowed the amplification of a portion of the second intron of the GPHD gene. These primers produced fragments of about 200 bp in all tested isolates. Talhinhas et al. (2002) performed the first multilocus phylogenetic analysis of the genus *Colletrichum* by studying *C. acutatum* community on lupins (*Lupinus* sp.) using ITS, TUB2 and HIS4 sequences, while Guerber et al. (2003) used the intron region of a gene for GS and GPHD nucleotide sequences for the analysis of *C. acutatum*.

Conclusions

Based on morphological characteristics and molecular detection and characterization, the analyzed isolate from alfalfa was determined as *C. linicola*. Molecular detection with the primer sets targeting different genomic regions is useful tool for the detection of *C. linicola* in alfalfa, but sequence analysis is needed to distinguish this from other species.

According information we have on disposal this is the first report of *C. linicola* causing alfalfa anthracnose in Serbia.

SUSCEPTIBILITY OF ONION THRIPS, THRIPS TABACI LINDEMAN (THYSANOPTERA: THRIPIDAE) TO OLD AND NEW GENERATION OF SPINOSYN PRODUCTS UNDER LABORATORY CONDITIONS

Sobhy A. TEMERAK

Plant Protection Department, Faculty of Agriculture, Assiut University, Egypt
*Corresponding author: stemerak@hotmail.com

Abstract

The spinosyn products are large family that shows potent insecticidal effects against large scale of insect pests . Rapid development of resistance to old generation of insecticides has been established in Onion thrips, *Thrips tabaci* production areas and being a key problem. Testing a new and relatively safe products may facilitate and help to find the best effective product.
The lethal effects of spinosad and spinetoram against nymphs and adults of onion thrips, *Thrips tabaci* Lindeman (Thysanoptera: Thripidae) were done under laboratory conditions, utilizing IRAC method no.10a and 10 b. The results revealed that nymphs were more susceptible than adults. Further, spinetoram (new generation) was 8.3- and 9.3- fold stronger than spinosad (old generation) against nymphs and adults, respectively . Application of spinetoram in conjunction with naturally occurring beneficial arthropods are an excellent example of a functional onion integrated pest management (IPM) program . .Spinetoram will be an excellent and promising tool to the integrated pest management (IPM) programs and insect resistance management (IRM).

Key words: spinosyn products, *Thrips tabaci*, efficiency, toxicity.

Introduction

Onion thrips, *Thrips tabaci* Lindaman (Thysanoptera: Thripidae), is a key insect pest in most onion production regions of the world. Immature (nymphs) and adult thrips feed with a punch-and-suck behavior that removes leaf chlorophyll causing white to silver patches and streaks. Interestingly, thrips populations increase rapidly under hot, arid conditions and can lead to economic crop loss. However, the early bulb enlargement stage of onion growth is the most sensitive to thrips feeding. Consequently, insecticides are the most common tactic for onion thrips management. Despite their ease of use and availability of numerous classes or modes of action, rapid development of resistance to insecticides has been a key problem. The main reasons lay as follows:

1- In the life history characteristics of onion thrips: reproduction by parthenogenesis (eggs develop without male fertilization so females pass all of their genes to their offspring),
2- Highly reproductive potential and short generation time (Diane and Daniel, 2008).
3- Most currently available insecticides only kill the nymphs or adult, with no activity on eggs. As such, repeat applications are typically warranted to kill the life stages that were not affected by previous applications, such as nymphs that were in the egg stage and adults that were in the pupae stage (Kontsedalov et al;, 1998; Diane and Daniel, 2008).
4- Recent research has shown that the majority of onion thrips on a plant are in the non-feeding egg stage (60- 75% of total population on an onion plant during late June to

August), and thus, not exposed to insecticides and other suppressive tactics (Diane and Daniel, 2008).

5- Widespread resistance across the western U.S. to organophosphate (e.g., azinphosmethyl, iazinon, methyl parathion) synthetic pyrethroid (e.g., cypermethrin, permethrin) and to new chemicals imidacloprid , abamectin and spinosad insecticides has been documented. (Immaraju et al., 1992, Zhao et al.,1995, Jenson 2000, Herron and James 2005 ; Bielza et al., 2007 ;,Diane and Daniel, 2008; Wang et al., 2011 ; Chen et al., 2011 ; Gao et al., 2012).

The spinosyns have a unique mechanism of action (MOA) involving disruption of nicotinic acetylcholine receptors (nAChR). When compared with many other insecticides, the spinosyns generally show greater selectivity toward target insects and lesser activity against many beneficial predators as well as mammals and other aquatic and avian animals. Their insecticidal spectrum, unique MOA and lower environmental effect make them useful new agents for modern integrated pest management programs. As a result, this work has received U S Presidential Green Chemistry Challenge Awards. (Kirst, 2010; El-Geddawy et al., 2014; Ahmed et al., 2015a, b, c . There was possibility of resistance creation of thrips to spynosins in many areas of the world wide (Loughner et al., 2005; Zhang et al.,2008 ,Gao et al., 2012,Sparks et al., 2012. To prolong activity of the new novel insecticides such as spynosins (spinosad or spinetoram), the necessity of rotating insecticides and implementing alternative methods of managing is a potential requirement (Loughner et al., 2005; Dripos et al., 2010). Peterson et al (1997) indicated that application of spinosyns in conjunction with naturally occurring beneficial arthropods are an excellent example of a functional cotton integrated pest management (IPM) program. Cloyd and Sadof (2000) reported that spinosad and acephate were effective at controlling thrips on greenhouse-grown plants. Basically, Spinosad and spinetoram are classified by EPA as reduced-risk product and awarded the green chemical from the white house in USA in 1999 and 2008, respectively.

Rapid development of resistance to old generation of insecticides has been established in Onion thrips, *Thrips tabaci* production areas and being a key problem. Testing a new and relatively safe products may facilitate and help to find the best effective product.

Materials and Methods

Product used

Spinosad 24%SC (Tracer): is a metabolite of the Actinomycete, *Saccharopolyspora spinosa* Martz & Yao. It is a naturally occurring mixture of two active spinosyns (spinosyn A & D). It is a trademark of Dow AgroSciences Co. It is considered the 1st generation from the spinosyn group. Spinotoram 12% SC (Radiant): is the 2nd new generation of the spinosyn group with the same mode of action as spinosad. It is a mixture of two active spinosyns (spinosyn J & L). It is a trademark of Dow AgroSciences Co.

Laboratory tests (IRAC method no 10 a and b

Thrips as adult and nymph, almost at same age, were collected using an aspirator from highly infested onion field, anaesthetized them with CO_2 .The white leaves of onion bulb were separated and leaf discs as squares 2 x 2 cm was prepared. These discs were soaked for few seconds in different concentrations from the insecticides uses and left to be dray. The thrips were then

tapped into leaf discs .This almost in line with IRAC method no. 10 a and b discs were placed in petri dishes under room temperature 26 C and relative humidity as 55%. Spinosad concentrations as ppm were 100-1600 for nymph and 200-3200 for adult respectively. Radiant concentration was 10-80 ppm for nymph and from 20-160 pmm for adults, respectively. Similar technique was done by Thalavaisundaram et al. (2008), and by Dağh and Tunç (2007).

Results and Discussion

In laboratory test utilizing IRAC method no.10a and 10 b:

The lethal effects of spinosad and spinetoram against nymphs and adults of onion thrips, *T. tabaci* were done under laboratory conditions , utilizing IRAC method no.10a and 10 b (Table 1). Within spinosad or spinetoram treatments, nymphs were more susceptible than adult. The last may be attributed to the nymph eat more than adult in which more molecule was taken inside the target. Radiant was 8.3- and 9.3-fold stronger than tracer against nymph and adult, respectively. These results are in agreement with Srivastava et al 2008 who indicated that Spinetoram at 61 g ai/ha was as effective as spinosad at 140 g ai/ha against the western flower thrips and the other common thrips in Florida, *Frankliniella tritici* and *Frankliniella bispinosa*.(Spinetoram is compatible with the key natural enemy of *Frankliniella* species thrips in pepper. Also with Palumbo and Ichardson, (2008).

Insecticides	**Slope ± SE**[1/]	**LC_{50} (ppm) (95% FL)***	**LC_{90} (ppm) (95% FL)***	**Fold RR**
Nymph stage				
Spinosad	0.92 ± 0.37	282.84 (194.19-411.98) [3/]	1748.08 (929.54- 8269.62)	8.37
Spinotram	0. 60 ± 0.38	33.76 (26.91-41.06)	112.92 (81.11-200.43)	
Adult stage				
Spinosad	1.02± 0.37	422.51 (254.62-608.08)	2965.61 (1579.83-15415.44)	9.23
Spinotram	0.69 ± 0.39	45.74 (32.57-60.89)	202.15 (129.47-504.71)	

* FL: fiducial limits,

In this interim, Lopez et al (2008) indicated adult vial technique (AVT) and spray table bioassays were conducted to evaluate toxicity of selected insecticides against immature and adult thrips, *Frankliniella* spp. (Thysanoptera: Thripidae). In AVT, technical insecticides compared with organophosphates (dicrotophos and methamidophos), spinosyn (spinosad) and neonicotinoids (thiamethoxam and imidacloprid) were used. The LC_{50} values for contact with the insecticides were all significantly different, with spinosad being most toxic and imidacloprid being least toxic

to thrips. Furthermore, Cloyd and Sadof (2000) reported that, spinosad and acephate were effective at controlling thrips on greenhouse-grown plants. Radiant will be an excellent addition to our IPM programs, however because it has the same mode of action as tracer, it will not provide an additional rotational partner for our resistance management programs.

Table 2: Spinetoram was more effective than spinosad based on gram active

In this regards, several published research were indicated that the new generation as Spinetoram (Radiant 12 SC) proved to be stronger than the old generation as spinosad (Tracer 24 SC) when gram active was considered (Table 2). It was 3-fold when Potato tuber worm *Phthorimaea operculela* (Zeller) utilized in the field (Temerak and Rizk, 2009). It was 4-fold when the Almond Moth *Cadra* spp was tested in the field (temerak and sayed 2009). It was 2.6 fold when the Lesser date moth *Baterachedra amydraula* Meyrick was combated in the field (Temerak and Sayed, 2009). It was 2-fold when the Pomegranate fruit butterfly *Viracola livia* (Klug) was controlled in the field (Sayed and Temerak, 2009; Lysandrou et al., 2010). It was 3-4 times when the Grasshopper, *Catantops axillaris* Thunburg was faced in the field (El-Gammal and Mohammed, 2008) Spinotoram was 12 SC 3-4 times stronger than spinosad based on g.a.i/fed. It was 5 fold and 7 fold when cotton leaf worm *Spodoptera littoralis* was tested in the field and laboratory , repectively (Temerak, 2007). It was more than 5-fold when the greater date moth, *Arenipses (Aphomia) sabella* Hampson (Lepidoptera: Pyralidae) was tested in the field (Temerak unpublished data). It was 4 fold more active , The tomato borer, *Tuta absoluta* (Merycik) was tested in the field (Temerak, 2011). Further investigation should be conducted to illustrate in terms of molecular biology and biochemistry of spinosyn compounds, plus synthesis new spinosyn compounds are considered paramount.

Conclusion, Rapid development of resistance to old generation of insecticides has been established in Onion thrips, *Thrips tabaci* production areas and being a key problem. The last increase amount of insecticides with more cost and added pollution to the environment.Testing a new and relatively safe products may facilitate and help to find the best effective product.

Spinetoram is among the most efficacious insecticides against western flower thrips. This insecticide also tend to be compatible with natural enemies of thrips, making them highly valuable in IPM programs. (Gao et al 2012). Both spynosin products can not alternate to each other because having the same mode of action.

EFFECT OF HERBICIDES ON MAIZE (*ZEA MAYS* L.) LINES

Milan BRANKOV*, Milena SIMIĆ, Vesna DRAGIČEVIĆ, Branka KRESOVIĆ, Snežana MLADENOVIĆ DRINIĆ

Maize Research Institute „Zemun Polje“, Belgrade, Serbia
Corresponding author: mbrankov@mrizp.rs

Abstract

Herbicide application is one of the most important meashures of weed control in maize production. In case of maize inbred lines herbicide use is even more present than in hybrid maize. On the other hand, many factors limits herbicide application, due to lines, herbicides or meteorological impacts. Five herbicides were applied to test their selectivity to 14 maize lines. Herbicides isoxaflutol + thiencarbazone-methyl (Adengo), terbuthylazine + dimethenamid-p (Akris), mesotrione + terbuthylazine (Callaris Pro), thiencarbazone-methyl + foramsulfuron (Monsoon active) and tembotrione (Laudis) were applied in recommended dose for use in maize hybrid. First two herbicides were applied in maize stage 11-12 (BBCH), while other three were applied in stage 15-16 (BBCH). Experiment was set up on Zemun Polje, Belgrade, Serbia in 2013 and 2014. With two opposite years in meteorological conditions (first one was with drought, second with high amount of precipitations) herbicides induced slight damages in the first visual evaluation, with no visible symptoms in the second evaluation. Also, maize grain yield was not affected by herbicides.

Key words: *herbicides, maize lines, phytotoxicity evaluation, grain yield*

Introduction

In maize field production herbicide application is one of the most important measures for achieving greater grain yield. When herbicides are not used in maize crop, grain yield can be reduced down to 50% (Spasojević, 2014), especially in seed production. On the other hand, one of the problems with herbicide is their selectivity to maize plants. It is known that maize seed crop is often more sensitive to herbicides than hybrid maize. One of the reasons could be maize line homozygosity what carry out smaller habit, slower growth and higher sensitivity towards stresses (Stefanović et al., 2007). Differences in herbicide selectivity are almost present with all herbicides in use, which is due to differences in maize genotypes. Great problems begin with introduction of sulfonylurea herbicides (Malidža, 2007; Stefanović et al., 2010). According to de Carvahlo et al. (2007) herbicides can cause temporary stress, with no influence to growing, while the permanent stress could lead to irreversible damages, yield loss and plant death. It is known that for activity of pre-emergence and early post-emergence herbicides the most important is precipitation amount. In seasons with higher amounts of rainfall, herbicides can negatively affect maize plants. The aim of this research was to evaluate herbicide fitotoxicity through visual plant damages and grain yield.

Material and Methods

Two years field experiment (2013 – 2014) was set up on chernozem soil type in experimental field of the Maize Research Institute „Zemun Polje“, Serbia (44° 52′ N, 20° 19′ E, 18 asl). Five

herbicides (Table 1) were applied to test their selectivity to 14 maize inbred lines (L1-L14). Herbicides were applied in recommended dose for use in hybrid maize.

Table 1. Herbicides applied in experiment

Active ingredient (a.i.)	Herbicide	a.i. in herbicides	Applied dose per ha
control	-	-	-
isoxaflutol + thiencarbazone-methyl	Adengo (H1)	70 g/l + 225 g/l	0,44 l
dimethenamid-p + terbuthylazine	Akris (H2)	280 g/l + 250 g/l	1 l
mesotrione + terbuthylazine	Callaris Pro (H3)	50 g/l +326 g/l	2 l
thiencarbazone-methyl + foramsulfuron	Monsoon active (H4)	10 g/l + 30 g/l	1,5 l
tembotrione	Laudis (H5)	420 g/l	1,5 l

First two herbicides (Adengo and Akris) were applied in early post emergence – in 1-2 leaf stage (11-12 BBCH) and other three in post emergence – 5-6 leaf stage (15-16 BBCH). In control (C), weeds were removed by hoeing. The four-replicate trial was set up according to split-plot arrangement. Herbicide phytotoxicity was evaluated twice: 2-3 weeks after herbicide application and 2-3 weeks after first evaluation. Damages were estimated according to the modified EWRC scale (FELDFERSUCHE MANUAL, 1975) following scale: 1- no damages, 9 – plant death. At the end of the vegetation cycle, grain yield was estimated and calculated at 14% of moisture. Obtained data were statistically processed by ANOVA and differences between means were tested by LSD test.
Meteorological data for experiment are present in Table 2. In the first year weather conditions were optimal for maize production with proper distribution of precipitation, but in the second part of the season deficiency in precipitation was present. On the other hand, in the second year precipitation level was high during whole growing season. In May of 2014 in three days fall about 180 mm and the same sum was present in July.

Table 2. Precipitation and average air temperatures for the period April-September

Months	Precipitation (mm)		Temperature (°C)	
	2013	2014	2013	2014
April	14.9	84.8	14.9	13.7
May	93.9	192.5	19.7	17.4
June	37.8	71.2	21.9	21.1
July	16.0	187.4	23.8	23.2
August	12.7	41.0	23.7	22.6
September	70.1	75.6	16.9	18.0
Σ/Average	245.4	652.5	20.1	19.3

Results and Discussion

All applied herbicides did not cause significant phytotoxicity on maize lines plants (Table 3). Taking into consideration that applied herbicides belongs to different groups, and have diverse mode of action, they did not cause expected symptoms of phytotoxicity even on susceptible plants. Also, according to this test it can also be claimed that tested lines are tolerant to

application of recommended doses of these herbicides. Maize reaction to herbicides is strongly depended on meteorological conditions (Stefanović and Zarić, 1991), as well as on genotypes (Brankov et. al, 2015). In these two years there was enough precipitations after herbicide application that is needed for expression of activity to the first three herbicides (Adengo, Akris and Callaris Pro). It is known that higher amount of rainfall can cause herbicide rinse into deeper soil layers, what could have negative impact to cultivated plants. In this study such situation was not present, especially in 2014, when high amount of rainfall a lot of rain in May (in three days – 150 mm). Also, herbicide Monsoon active (H4) did not cause changes on maize plant, although it contain foramsulfuron, an active ingredient reported as problematic in maize seed crop (Brankov et al. 2012). Herbicide tembotrion (Laudis) belongs to triketone group that is known as good selectivity to maize (Gitsopoulos et al., 2010).

L1-L14 for H1-H5 $p>0,05$ – no significance differences for all treatments

Applied herbicides did not caused significant decrease in grain yield of tested maize plants. Maize grain yield differs significantly among years, but herbicides did not influence significant variations in maize yield, although in some treatments lower yield was observed but it wasn't significant. In 2013, lines L3, L8, L9 and L12 in all herbicide treatments achieved higher grain yields in comparison to control. Similar situation was observed in lines L2, L5, L8, L10, L11, L12 and L14 in 2014.

L1-L14 for H1-H5 $p>0,05$ – no significance differences for all treatments

Conclusion

According to data obtained from our experiment it can be concluded that applied herbicides showed good selectivity to tested lines, so their application in recommended doses for weed control in maize lines crop is safe.

EVALUTION OF PRECISION FARMING RESEARCH AND APPLICATIONS IN TURKEY

Bahattin AKDEMIR

Namik Kemal University Faculty of Agriculture Department of Biosystems Engineering, Tekirdag-Turkey
*Corresponding author: bakdemir@nku.edu.tr

Abstract

Precision farming as farm management system is very important for Turkey because Turkey has 24 million ha of arable land and Turkish farmers used 10.6 million tonnes of fertilisers and 39222 tonnes of pesticides for agricultural production in 2014. Optimal use of agricultural inputs is vital for environment, health and production cost. Objective of this paper is to summarize precision farming applications and research studies. Farmers' interest in precision farming has been getting increasing. Big private and state farms started to use steering assistance systems in tractors and Turkish Government bought 300 yield monitors for combine owners. In addition, General Directory of Agricultural Research has been started to support to Regional Research Institutes for carrying out National research projects and to join international projects related to precision farming. The universities has been developing control systems for variable rate applications and field scouting robots in order to collect data and measure spatial variability in the fields. There are a few representative companies of precision farming technologies in Turkey. They generally sell Global Position System (GPS) and steering assistance systems for tractors. Farmers are suspicious about profitability of precision farming. Companies look for market to sell precision agriculture systems. After adoption projects and decreasing cost of the system give encourage the farmers to apply precision agriculture. In addition, Turkish government should develop policies to support farmers for sustainable agriculture.

Keywords: *Precision farming, variable rate application, yield mapping, Turkey*

Introduction

Precision Agriculture (PA) is a farming management concept based upon observing, measuring and responding to inter and intra-field variability in crops, or to aspects of animal rearing (Anonymous, 2014). It is a management strategy that employs detailed, site specific information to precisely manage production inputs. This concept is sometimes called precision agriculture, prescription farming, or site-specific management. The idea is to know the soil and crop characteristics unique to each part of the field, and to optimize the production inputs within small portions of the field. The philosophy behind precision agriculture is that production inputs (seed, fertilizer, chemicals, etc.) should be applied only as needed and where needed for the most economic production (Searchy, 1997). Precision Agriculture: an integrated information- and production-based farming system that is designed to increase long term, site-specific and whole farm production efficiency, productivity and profitability while minimizing unintended impacts on wildlife and the environment (Anonymous, 2005). Precision farming (PF) is also defined as a holistic system approach to manage the spatial and temporal variability within a field in order to reduce costs, optimize yield and quality and reduce environmental impacts. This can be achieved by using appropriate technologies within a coherent management structur (Reichardt and Jurgens, 2009).

Turkey is the world's 7th largest agricultural producer and one of the biggest producers of large range of agricultural commodities, such as hazelnuts, apricots, lentils, cherries, figs, olives, tobacco and tea. About one third of Turkey's total land area is devoted to agriculture. There are approximately 3 million agricultural farms in Turkey most of which are family farms employing family labour, nearly two thirds of Turkish farms are less than 5.5 hectares. Although the share of agriculture in the economy has declined significantly, it is still important in both social and economic terms. In 2011 it represented 7.9 percent of GDP, 25.5 percent of employment (Giray, 2012). Turkey has 24 million hectares of arable land, Turkish farmers used 10.6 million tonnes of fertilisers and 39.22 tonnes of pesticides in 2014 (TUIK, 2016). Precision farming as farm management system is very important for Turkey because Optimal use of agricultural inputs is vital for environment, health and production cost. Objective of this study is to evaluate precision farming research and applications in Turkey. Information about research projects has been carried out by Universities and Research Institutes on precision agriculture will be summarized. In addition, precision farming applications, obstacles and possibilities in front of precision farming in Turkey will be discussed.

Precision farming research projects in Turkey

First precision agriculture research was about determination of spatial variability of soil texture, nutrients, weeds and yield. It was carried out by Ankara University and General Directory of Agriculture Research (Turker and Gucdemir, 2004, Turker, 2005)

A variable rate controller for centrifugal fertiliser developed by Tekin (2005), Tekin and Sindir (2013), In addition, different type variable rate controller was also developed by Akdemir et al. (2007). Step motors were used to realize variable rate application for these machines. A special electronic control system was designed for control step motors. A Differential Global Positioning System (DGPS) system was also used to determine positioning. Specific software was used to communicate variable rate system such as step motor, computer, DGPS. These systems were tested for determination of the performance (Tekin, 2004, Akdemir, et al., 2014)

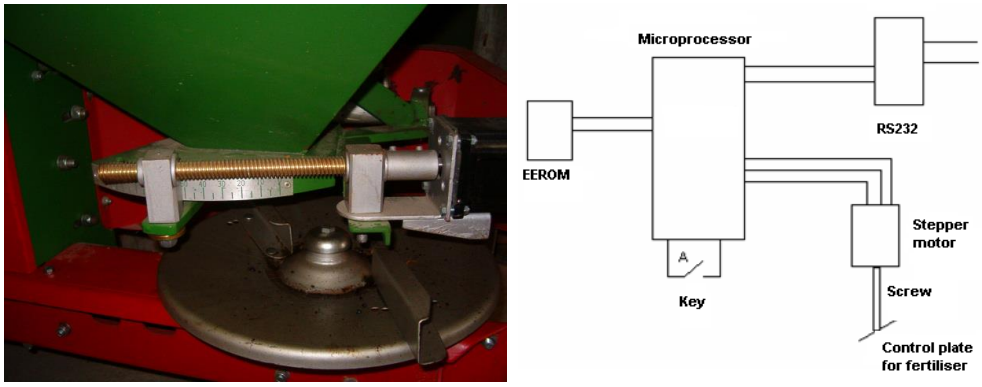

Figure 1. Variable rate controller for centrifugal fertiliser spreader

A variable rate controller was developed for combine cereal planting machines. This modular system was controlled by step motors. Elements of the control system were stepper motors, GPS antenna, and electronic control circuit. During laboratory tests any problem were found communication between stepper motors and control unit (Ozyuruyen and Akdemir, 2010).

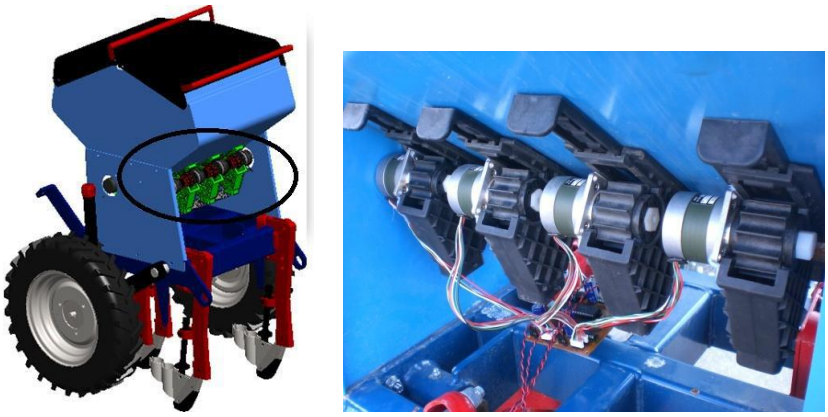

Figure 2. Variable rate controller for cereal sowing machine

An automatic steering system was developed by Akdemir et al., (2012), Altinkaradag, 2014 Akdemir et al. (2014). The system consists of a central control unit, touchable user interface, positioning system, and electro-hydraulic control unit. These subsystems will work simultaneously and whole system will work by developed software. Steering control unit includes a n electro-hydraulic valve and an electronic control circuit which controls the electro-hydraulic valve. The steering control system provides rotation of the steering wheel at required ~~amount~~ angle (?) according to the order of the central control unit. The routes and maps of the tractor can be loaded on Touchable User Interface, and it can create commands to realize these routes. The Touchable User Interface gives information about system working. In addition, it undertakes a duty as control panel which some adjustments can be on it. Positioning system is a system that can takes coordinate data from RTK-GNSSS by using CORS-TR system which has 147 reference stations in Turkey and measurement errors will be approx. 3-4 cm. The positioning system will transfer data. The software consists of steering control software, graphic interface software, software for determination of positioning and motion, and system communication and integration software. The steering control software was developed by using Software Development.

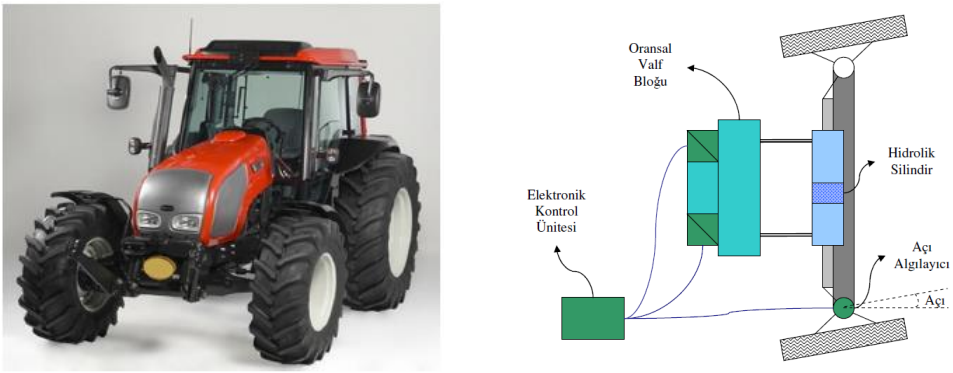

Figure 3. Automatic steering system

All variable rate control systems require a prescription or application map software. Commercially available software can accept electronic communication protocol of nonregistered devices and generally companies doesn't give permission for this process. A special application map software was developed by Ungor and Akdemir (2010).

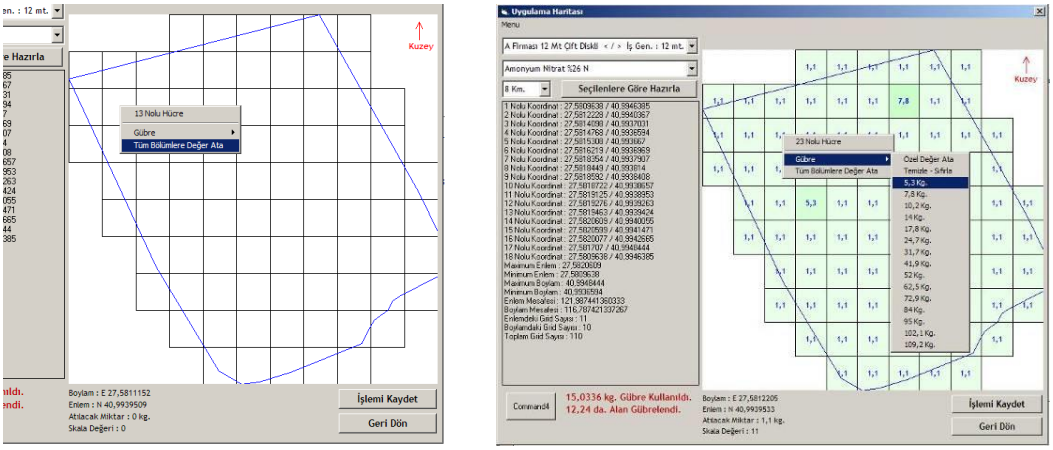

Figure 4. Prescription map software

A Test Software for Servo Motors And Electronic Control Unit Used In Variable Rate Controller was developed by Turen et al. (2014)

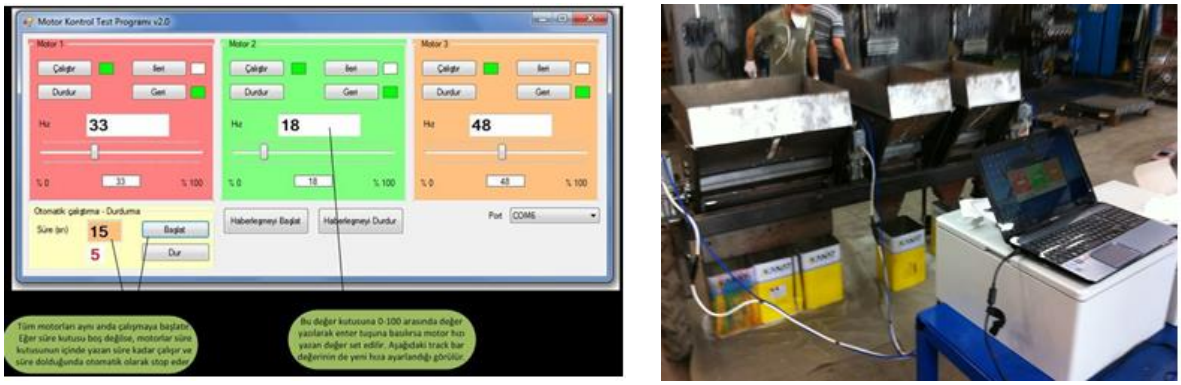

Figure 5. Laboratory test software for variable rate controllers

Soil sampling is one of the problems to get spatially variable data. Turkey has a large areas and it is not easy to take soil samples by simple tools. Turen (2013) and Dalmis et al., (2014) developed an automatic soil sample machine to take and make a package with geo reference data.

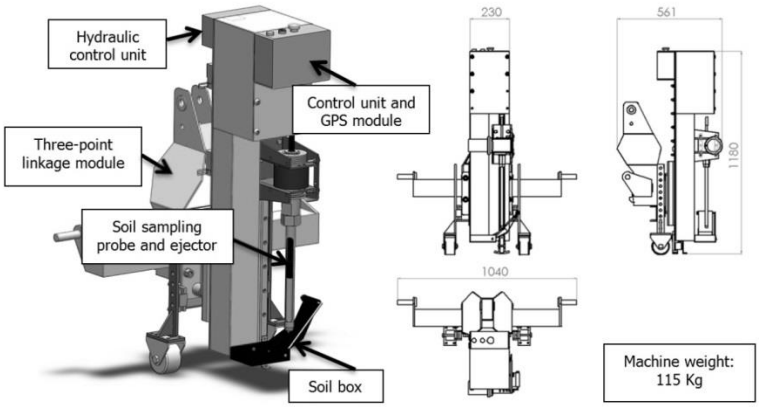

Figure 6. Automatic soil sampling machine

Spatial variability of the different crops were also worked for onions by Akdemir et al. (2005) and for olive Belliturk et al. (2010-a), Belliturk et al. (2010-b).

Albayrak (2010) developed a weight measurement system for tuber crops on a belt scale for dry onions and potatoes.

Figure 7. Weight measurement system of conveyor for tuber crops

Precision farming applications in Turkey

According to the representative companies of precision farming systems in Turkey, 105-110 automatic steering systems, 25 steering assistance systems and 310 yield monitors have been sold to the farmers. There are some imported variable rate applicators but their number is just less than 20. Some sensors such as Greenseeker, EM38, Spadmeter , UAV have been used by research institutes. According to the companies number of the Greenseeker is 45 in Turkey

Conclusions

Agriculture is important for Turkey. Turkish farmers generally apply conservative agricultural practices for production. A few of them apply for precision agriculture. Because cost of variable rate controllers, yield mapping systems and software are so high for small scale Turkish farmers. To solve this problem some software and variable rate controllers have been developed by Universities or Research Institutions but these systems are not available in the Turkish market. Some big farmer use precision agriculture technologies such as GPS, yield monitoring, automatic steering etc. but number of these systems is not so much. Turkish Government decided to support precision agriculture research and adoption projects to extend precision farming but it will take time. Farmers are suspicious about profitability of precision farming. Companies look for market to sell precision agriculture systems. After adoption projects and decreasing cost of the system give encourage the farmers to apply precision agriculture. In addition, Turkish government should develop policies to support farmers for sustainable agriculture.

SPATIAL AND TEMPORAL VARIABILITY OF NECROPHAGOUS DIPTERA IN AL-BALQA REGION IN JORDAN

Hazem S. HASAN

Department of Plant Production and Protection, Faculty of Agricultural Technology, Al-Balqa' Applied University, Al-Salt, 19117, Jordan. Email: Hazem@bau.edu.jo

Abstract

Necrophagous fly assemblages were surveyed in a three habitats from Al-Balqa governorate from residential to country- side regions using bottle traps technique from January 2008 to January 2009. From 81 sampling locations and 46048 collected insects from four dipteran families 9 species were identified as follows: family Calliphoridae: *Calliphora vicina* ROBINEAU-DESVOIDY, 1830, *C. vomitoria* (LINNAEUS, 1758), *Chrysomya rufifacies* (WIEDEMANN, 1819), *Lucilia cuprina* (WIEDEMANN, 1830), and *L. sericata* (MEIGEN, 1826); family Muscidae: *Musca domestica* LINNAEUS 1758 and *Muscina stabulans* (FALLEN, 1817); family Fanniidae: *Fannia scalaris* (FABRICIUS, 1791); family Sarcophagidae: *Sarcophage carnaria* RHDENDORF, 1937. Rrelative abundance values of *Calliphora viciina*, *C. vomitoria*, *Chrysomya rufifacies*, *L. sericata*, *Musca domestica*, *Muscina stabulans*, *Fannia scalaris* and *Sarcophage carnaria* were 28.7, 0.4, 2.6, 1.9, 35.0, 24.3, 2.7, 1.5, and 2.9%, respectively for species. No significant difference among these species in spatial distribution was detected, except for *Fannia scalaris* and *Lucilia sericata*. Both species showed a significant difference between Al Salt location habitat and Wadi Shabi location habitat.

Keyword: *Forensic entomology, Variability, Habitat association, Necrophagous Diptera, Jordan*

Introduction

Forensic entomology is the application of insects' study and other arthropods to legal issues (Benecke 2001, Kulshrestha and Satpathy 2001, Bajerlein *et al.* 2011, Bugajski *et al.* 2011). In fact, insects that attack animal corpse can be used as important source of data for forensic entomology application. These insects have high economic importance and important medical applications (Archer 2003, Abdel-Hafeez *et al.* 2015).

Necrophagous Diptera belongs to several taxonomic groups such as blowfly (Calliphoridae) flesh fly (Sarcophagidae). Necrophagous Diptera has important forensic uses such as estimation of Postmortem interval (PMI) (de Carvalho and Linhares 2001, Aballay *et al.* 2012) based on a composite of taphonomic factors that are affected by the geographic region or biogeoclimatic zone (Kulshrestha and Satpathy 2001, Arnaldos *et al.* 2005). In Jordan, the Necrophagous Diptera, mainly blow fly that attacks animal corpse, had been studied in recited area. However, further investigation is needed to identify necrophagous fly and its ecological abundance (Hasan 2008).

When a death is not witnessed, PMI is a crucial and fundamental step in any death scene investigation procedure (Poloz and O'Day 2009). PMI is defined as the length of time between death and corpse discovery. The medical parameters begin to degrade that are needed to establish the cause, manner, and death time at the onset of death, (Arnaldos *et al.* 2005, Tabor *et al.* 2005).

Blowflies that are distributed worldwide cause medical problems and losses to the animal productivity (Ghandour 1988). There are some species of blowflies (*Chrysomya megacephala* (Fabricius) that are dangerous Dipteran vectors of enteric pathogens (Greenberg 1990, Greenberg 1991).

The objectives of this study are: collecting the common Necrophagous Diptera that are distributed in Al-Balqa governorate, identifying specimens, determining of relative abundance and habitat association patterns, studying the spatial and temporal variability of Necrophagous Diptera and establishing a data base for species of necrophagous diptera in Al-Balqa governorate.

Materials and Methods

Trapping methods using olfactory stimuli have been developed for sampling blow flies (Hall and Farkas 2000). To obtain specimens in good condition for identification a modified cone trap, based on a soft drink plastic bottle with a baited target was used (Hwang and Turner 2005). In total 81 bottle traps were made from two 1.5-L clear- plastic soft drink bottles of 8 cm in diameter. The bottle consists of two parts: the upper collection chamber and the lower, bait chamber, contains 30 g of lamb liver that is fixed to the inner bottom by tape. A 15 ml glass vial, contains 10 ml of a 30% sodium sulphide (Na_2S) solution and a 5 g piece of liver was fixed on the inner wall as a chemical attractant.

The study area (Al-Balqa) was categorized into three region according to the level of urbanization. Those regions are: Al-Salt (Urban), Al-Homra (Rural), and Wadi Shabi (Natural), (Table 1).

Table 1. Descriptions of the sampling sites study area

Place	Urbanization	Altitude (M)	Descriptions
Al-Salt	Urban	1100	High dense housing with private gardens, and commercial activities.
Al-Homra	Rural	400	Semi-natural habitat with little human interference.
Wadi Shabi	not residential area	-120	natural habitat without human interference

In total 27 traps were fixed approximately 1.5 m above the ground for each studied site. Shaded positions were selected for the traps to avoid thermal stress on the captured flies. The coordinates of the collection sites were determined and recorded using GPS. Traps were inspected twice a week for one study year. Larvae, pupae and adults that fed on the liver piece were collected and identified. The liver pieces represented a "dead body". Air temperatures and relative humidity were recorded every 1 hour using data loggers that was placed in the center point between the five traps of a site. Flies were killed by putting the trap in a -25ºC freezer for 10 min. The flies was either preserved in 80% ethanol or oven dried. Identification was conducted using Taxonomical key (Buttiker *et al.* 1979, Borror *et al.* 1989, Rognes 2002).

Descriptive statistics such as, the number of species, and number of insects/month were calculated. The spatial and temporal activities of the commonest species were measured. Statistical analysis was conducted using SAS 9.4 software (Institute 2014).

Results and Discussion

A total of 46048 individuals belonging to 4 dipteran families were identified from 81 sampling occasions and 9 species confirmed; family Calliphoridae*: Calliphora vicina* ROBINEAU-DESVOIDY, 1830, *C. vomitoria* (LINNAEUS, 1758), *Chrysomya rufifacies* (WIEDEMANN, 1819), *Lucilia cuprina* (WIEDEMANN, 1830), and *L. sericata* (MEIGEN, 1826); family Muscidae: *Musca domestica* LINNAEUS 1758 and *Muscina stabulans* (FALLEN, 1817); family

Fanniidae: *Fannia scalaris* (FABRICIUS, 1791); family Sarcophagidae: *Sarcophage carnaria* RHDENDORF, 1937, accounted of relative abundance 28.7, 0.4, 2.6, 1.9, 35.0, 24.3, 2.7, 1.5, and 2.9%, respectively for species (Figure 1).

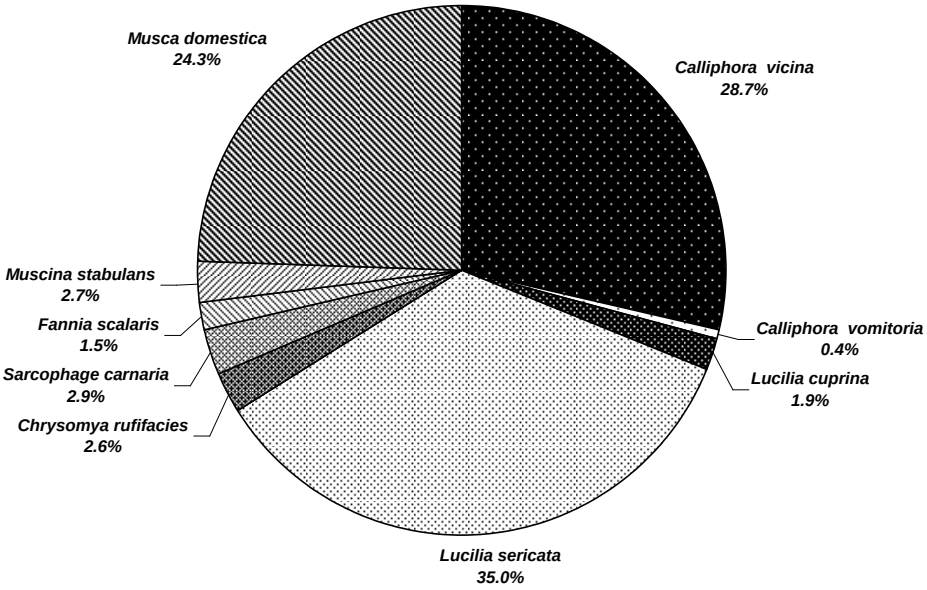

Fig. 1. Relative abundance of Necrophagous Diptera in Al Balqa governorate, Jordan during (2008-2009)

The highest monthly average captured numbers were for *Lucilia sericata* in Al Salt habitat (218.52) individuals followed by *Calliphora vicina* in the same habitat (178.96) individuals (Table 2). The lowest monthly average captured numbers were for *Calliphora vomitoria* Al Salt habitat (2.63) individuals. No significant difference was detected among *Calliphora viciina*, *C. vomitoria*, *Chrysomya rufifacies*, *Musca domestica*, *Muscina stabulans*, and *Sarcophage carnaria*. *Fannia scalaris* and *Lucilia sericat* both showed a significant difference between Al Salt habitat and Wadi Shabi habitat.

Table 2. Monthly average captured numbers of necrophagous Diptera in Al Balqa area during 2008-2009

SITE	*Calliphora vicina*	*Calliphora vomitoria*	*Lucilia cuprina*	*Lucilia sericata*	*Chrysomya rufifacies*	*Sarcophage carnaria*	*Fannia scalaris*	*Muscina stabulans*	*Musca domestica*
Al-Salt	178.96a*	2.63a	12.15a	218.52a	16.00a	18.03a	9.67a	16.74a	151.93a

Al-Homra	168.67a	3.48a	12.85a	183.59ab	15.41a	16.22a	8.37ab	14.56a	165.3a

*Means followed by different letters are significantly different according to LSD at (P<0.05)

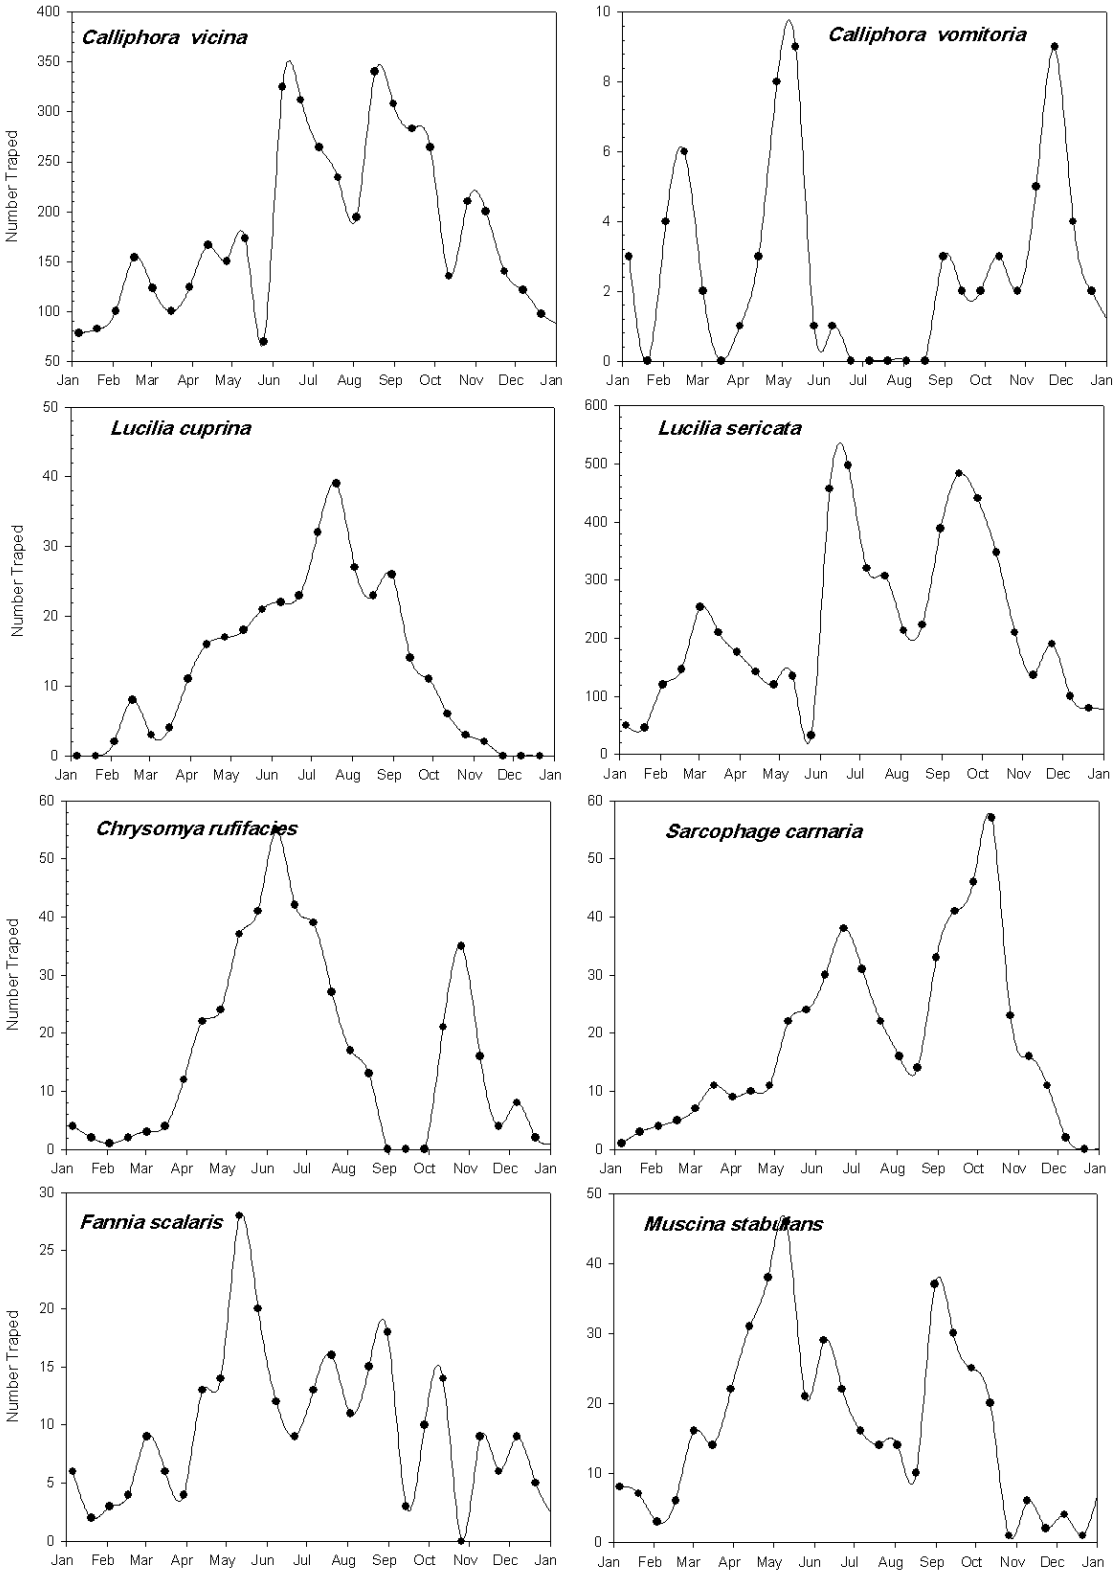

Fig. 2. Temporal variability of *Necrophagous Diptera* in Al-Salt region from 2008 to 2009

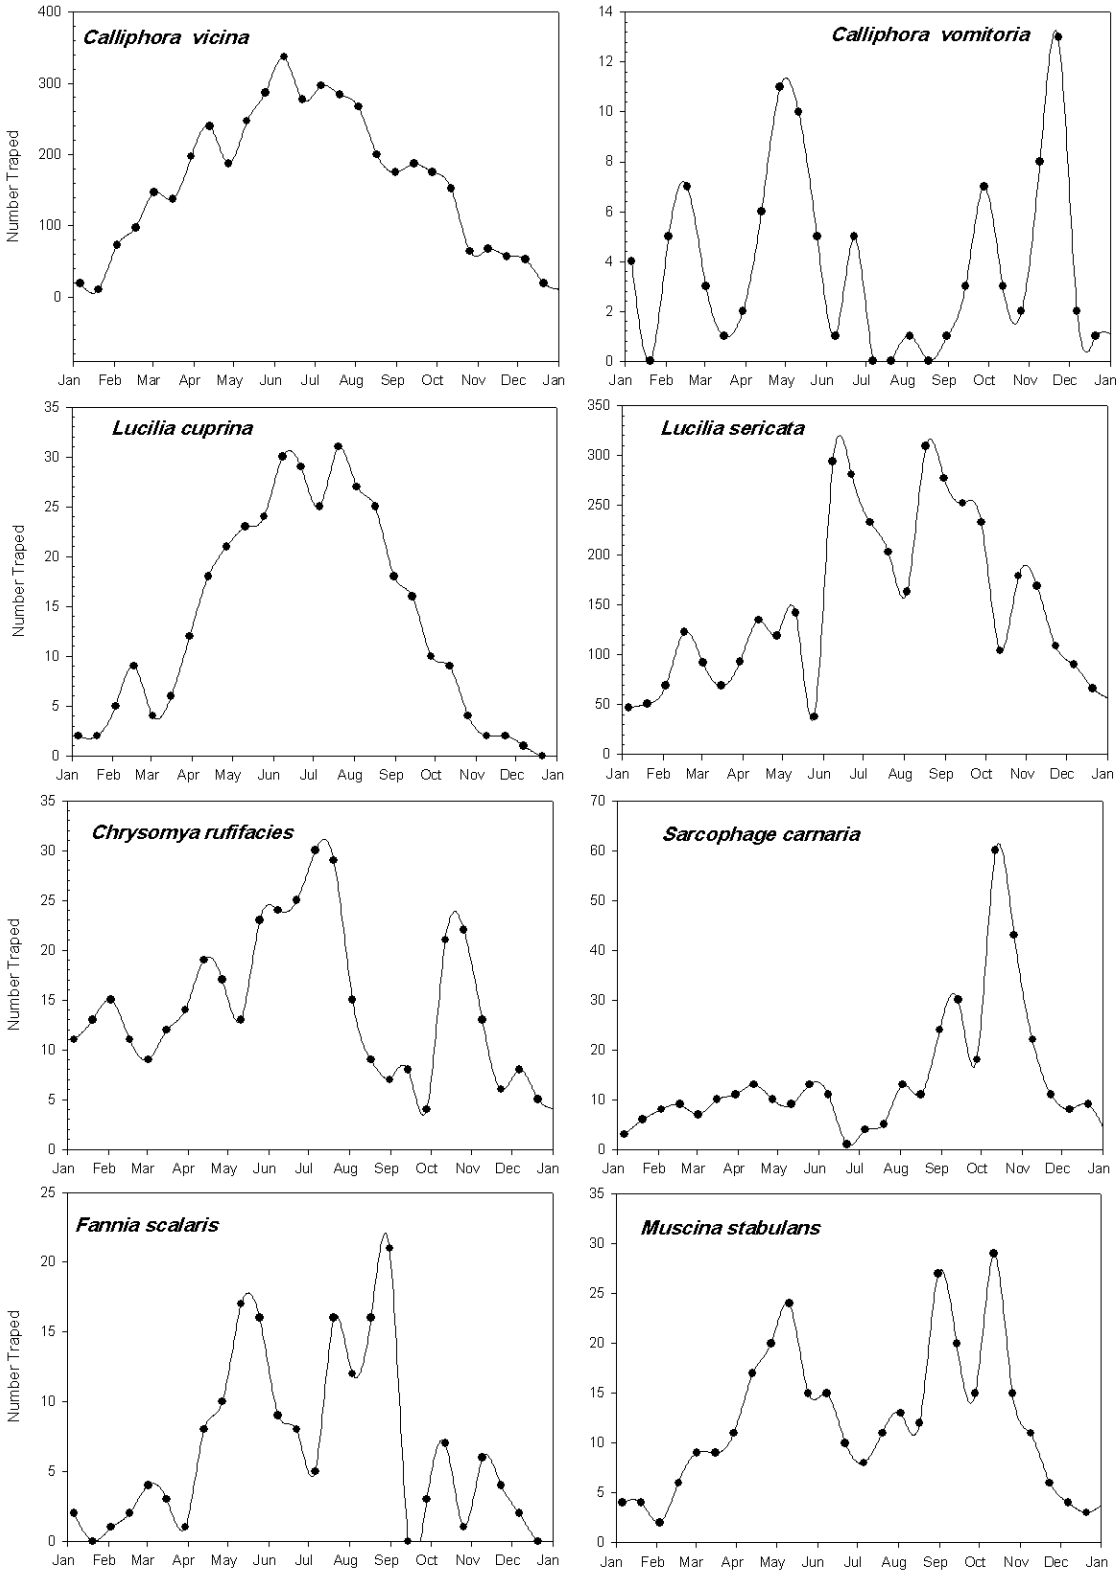

Fig. 3. Temporal variability of *Necrophagous Diptera* in Wadi Shabi region from 2008 to 2009

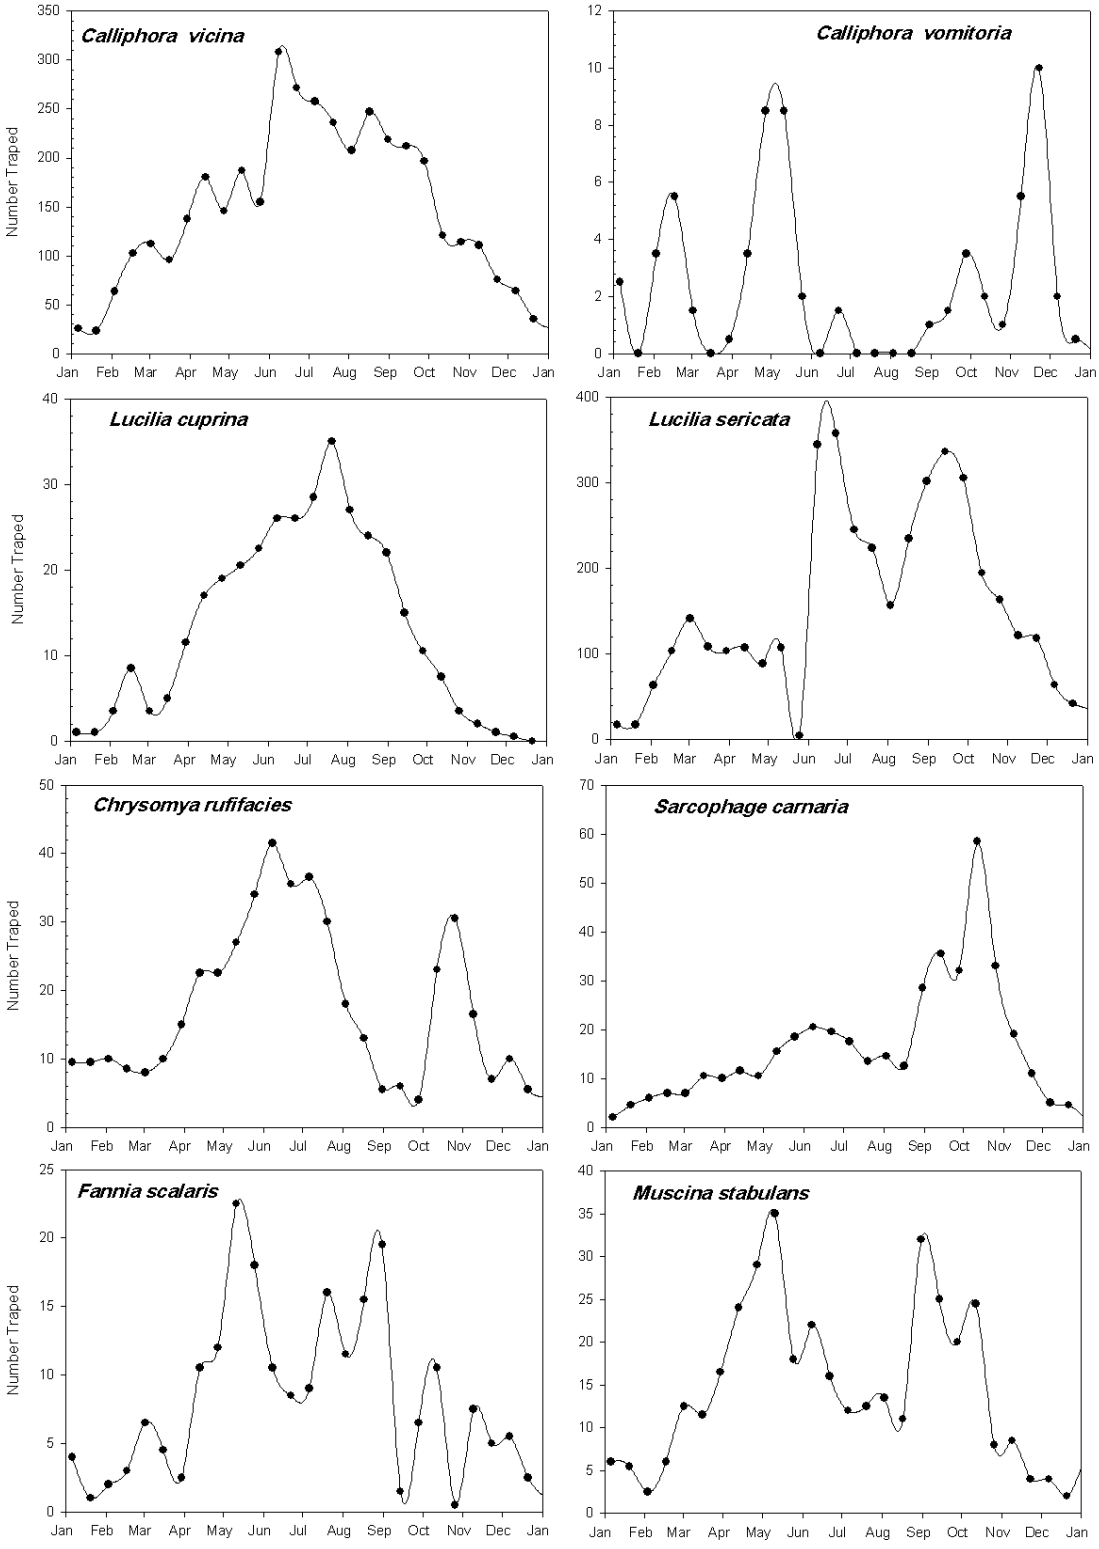

Fig. 4. Temporal variability of *Necrophagous Diptera* in Al-Homra region from 2008 to 2009

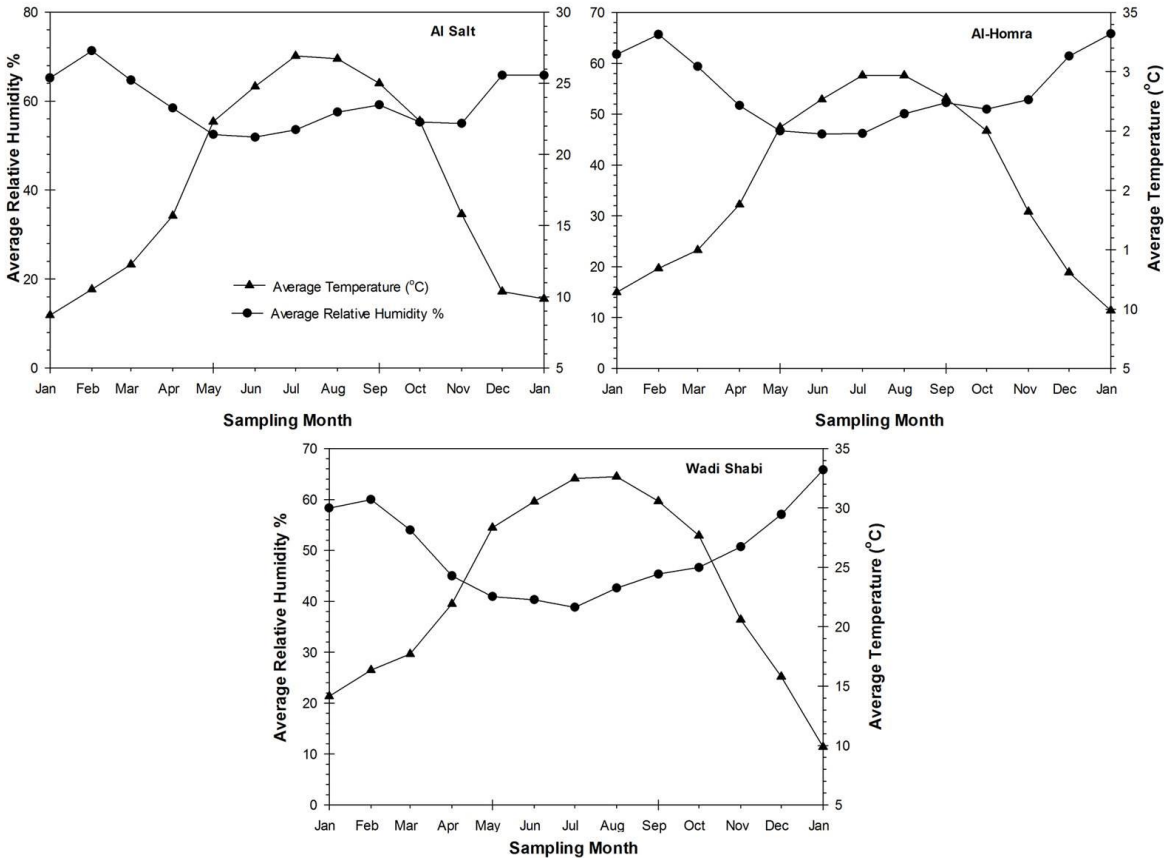

Fig. 5. Average temperature and relative humidity from 2008 to 2009

In Figures 2, 3, and 4 temporal variability of Necrophagous Diptera in Al-Salt, Wadi Shabi and Al-Hummra from 2008 to 2009 are presented. The most common Necrophagous species of Diptera were observed in May and July except *S. carnaria* and *L. sericata*, for which maximum captures were in October and November. This study show that the number of insects declined with the increase of the relative humidity and temperature (Figure 5). This indicates that increasing temperature and the relative humidity decreases the insect intensity.

Temperature and relative humidity influenced the stages of carcass decay and insect activity and abundance: This is in accordance with results of other researcher (de Carvalho and Linhares 2001, Barton *et al.* 2014). Results showed that nine species are forensic indicators in Al-Balqa governorate. Out of this five species are more important as forensic indicators due to their occurrence over long period of the year (*C. vicina*, *C. vomitoria*, *Chrysomya rufifacies*, *L. cuprina* and *L. sericata*).

Conclusions

I identified four dipteran families with nine species in three different habitats from Al-Balqa governorate, Jordan. *Calliphora vicina* species was the most abundant species, accounting for 28.7% of all the diptera specimens. In fact, temperature and relative humidity influenced, the population density of Necrophagous Diptera species, significantly. The average monthly number of *Lucilia sericata* was significantly different than the average monthly number of *Fannia scalaris* collected from the different habitats.

Abstract

This study aimed to assess the impacts of severe parasitic plants (*O.crenata, P.ramosa, P. aegyptiaca*) on to grain yield, some quality characteristics and marketing price of red lentil in the South-east Anatolia. Farmer field trials were carried out in the Adıyaman and Viransehir locations in 2010-11 and 2011-12 crop growing seasons respectively. Randomly distributed twin plots throughout the field relaying on required number of broomrape infestation in Adıyaman field trial in 2010-11 (1+ 1 m^2 each) as experimental units were nominated as follow; A_0B_0: control, A_1B_1: 30-39 broomrape flowering in twin plots; A_2B_2: 40-49 broomrape flowering twin plots; A_3B_3: 50-59 broomrape flowering plots and A_4B_4: over 60 broomrape flowering plots. (4 treatments) Twin plots (2 replications) in Viranşehir in 2011-12 (1+ 1 m^2 each) as experimental units were nominated as follow; A_0B_0: control, A_1B_1: 2-3 broomrape flowering in twin plots; A_2B_2: 4-5; A_3B_3: 6-7 and A_4B_4: 8-9 broomrape flowering plots. Grain yield, hectoliter weights and 1000 kernel weights were scored. All grain samples were presented to randomly chosen grain purchasers in local commodity market and marketing price offers were scored respectively. Results revealed that broomrape infestation under both low and high levels of epidemic reduced the grain yield ranging from 51.5% to 97.7% significantly. Some visual purchasing criteria such as hectoliter and 1000 kernel weights were not affected seriously. Purchasers offered very similar marketing prices for pulse grains with all severity levels. Economic losses were huge varying from \$396.77 to 678.50 ha^{-1} It was concluded that regression equations derived from grain yield vs. infestation densities were found to be reliable with high coefficients of determinations and can be perfectly used for yield estimates under various levels of broomrape infestations

Key words: *Red lentil*, *Orobanche*, *Phelipanche*, grain yield, quality, marketing prices

Introduction

Lentil is a nutritious food legume; the seed has a relatively high content of protein (22%), carbon hydrate and calories (3250 kcal kg^{-1}) with fast cooking characteristic (Muehlbauer, 1985; Saskatchewan Agriculture and Food, 2005). Lentil (*Lens culinaris* Medic.) is a cool –season annual cash crop, classified as a grain legume or pulse in South East Anatolia (Ozberk et al., 2006).

Turkey is one of the major lentil producer after Canada and India with a 422.000 tons annual production at 216.000 ha acreage (Anonymous, 2010). Green lentil is grown in the central and transitional zones of Turkey while red lentil is grown in the South-east of Anatolia (Ozberk et al., 2006).

By far the most economically damaging root parasitic weeds in Europe and neighboring regions are member of the Orobachaceae, mainly species belonging to the genera *Orobanche* and *Phelipanche* (broomrapes) (Joel et al, 2007a; Parker, 2009). In Turkey, 36 species of Orobanche have been recorded (Gilli, 1987). But only four of them result in a considerable damage to crops. *Phelipance ramosa* (L) Pomel (syn.*O.ramosa* L.) *Phelipance aegyptiaca* (Pers) Pomel (syn. *O. aegyptiaca* Pers.) (Joel et al, 2007; Parker, 2009) and *O crenata* Forsks. result in damage in lentil (Aksoy &Uygur, 2003). In legumes, the most intensive growth of Orobanche usually coincides with the flower and pot stage of the host. This results in flower dropping and low amount of podding due to increase competition from the parasitic sink. The wilting symptoms occur due to the reduced water uptake because of a deficiency of energy in the host roots, as a result of flow of carbon hydrates to the parasite (Anonymous, 1997).

Yield losses due to Orobanche ranged from 5 to 100% (Bulbul et al., 2009, Australian Department of Agriculture and Food, 1999, Anonymous, 1997). An economical loss of lentil of about 60 million Euros is estimated annually (Bulbul et al., 2009). Several strategies have been developed for the control of broomrape, from cultural practices to chemical control (Parker and Riches, 1993; Joel et al.,2007b), but none with unequivocal success. Good broomrape control can be achieved in faba bean by glyphosate at low rates. However, insufficient selectivity was found in lentil (Arjona- Berral et al., 1988). Lentil tolerates pre and post emergence treatment of other herbicides suitable for bromrape control, such as imazapic and imazetgapyr (Jurada-Exposito et al., 1997). Imazapic (10 g l^{-1}) is widely used in SE Anatolia. Phytotoxicity has been observed at higher doses of some herbicides and depends on the level of water stress and lentil cultivar (Henson and Hill, 2001). A number of cultural practices including delay sowing, hand weeding, no-tillage, nitrogen fertilization, intercropping, rotations can contribute to seed bank demise. Other strategies such as suicidal germination, activation of systematic acquired resistance, bio control or target site herbicide resistance are promising solutions that are being explored but are not yet direct application. The only methods currently available for farmers are the use of resistant varieties and chemical control (Rubiales &Fernadez-Aparicio, 2011). Resistance breeding is hampered by scarcity of proper source of resistance and of a reliable and practical screening procedure (Fernandez -Aparicio et al., 2007b).

This study aimed to assess the effect of broomrape damage on grain yield, some visual quality characteristics and marketing price of lentil in the local commodity markets.

Material and methods

This study was carried out in the farmer fields in Adıyaman and Viransehir locations (S.Urfa) in 2010-11 and 2011-12 growing seasons respectively. Wherein, broomrape infestations are common. *O. crenata* Forsk**.** (white flowering) , *P.ramosa* (pale blue flowering and branched) and *P.aegyptica* Pers. (blue flowering) were found to be wide spreading in lentil fields (75,51%) in Eastern Mediterranean region (Bulbul et al., 2009, Temel et al., 2012 and Aksoy, 2011a).

Preceding crop was tobacco in Adıyaman and barley in Viransehir. Adıyaman experiment was carried out under Dolycoris infestation. 8 ha in Adıyaman and 10 ha in Viranşehir were planted by drill with a 120 kg ha^{-1} seed rate in both fields respectively. A50 kg ha^{-1} di ammonium phosphate (DAP, 18 and 46% of N and P) was applied at sowing. All other necessary agronomical measures were taken for health crop production. Chemical weed control for narrow-leaf –weeds was employed but not pest control. Twin plots in Adıyaman in 2010-11 (1+ 1 m^2 each) as experimental units were nominated as follow; A_0B_0: control, A_1B_1: 30-39 broomrape flowering in twin plots; A_2B_2: 40-49 broomrape flowering twin plots; A_3B_3: 50-59 broomrape flowering plots and A_4B_4: over 60 broomrape flowering plots. Twin plots in Viranşehir in 2011-

12 (1+ 1 m^2 each) as experimental units were nominated as follow; A_0B_0: control, A_1B_1: 2-3 broomrape flowering in twin plots; A_2B_2: 4-5 broomrape flowering twin plots; A_3B_3: 6-7 broomrape flowering plots and A_4B_4: 8-9 broomrape flowering plots. Twin plots were assigned at flowering stage of broomrape and early pod stage of lentil. Five twin plots (surrounded by strip at the corners) possessing various amount of infestation were randomly selected throughout the broomrape infested field. Control twin plots have no broomrape infestation at the early pod stage of lentil crop. Numbers of broomrape flowers were counted in each twin plots at the flowering and pod filling stage of lentil. Each twin plots were harvested by hand and threshed for weighting grain yield. Highest yield loss was calculated as;

HYL%= (mean grain yield of A_4B_4 / mean grain yield of A_0B_0) x 100.

Hectoliter and 1000 kernel weights (Williams et al., 1986) of lentil grains were also scored. Seed samples of both year experiments with increasing amount of broomrape damage were presented to four randomly chosen grain purchasers in the local commodity market at mid-September in 2012. ANOVA and mean separation were performed for marketing price estimates. Coefficients of correlation among such characteristics were estimated Regression relation between grain yield, hectoliter weight and 1000 kernel weights vs. broomrape infestations were further investigated (Finlay &Wilkinson, 1963; Eberhard &Russel, 1966). Economic loss was calculated as;

EL= HYL% x mean grain yield of A_0B_0 marketing price of A_0B_0

SPSS statistical software (Efe et al., 2000) was employed for statistical analysis and figures.

Results and discussion

O. crenata Forsk**.** (white flowering) was dominating species in Adıyaman in 2010-11 while *P.ramosa* (pale blue flowering and branched) and *P.aegyptica* Pers. (blue flowering) were found to be complex in Viranşehir in 2011-12.

Adıyaman experiment (2010-11)

Annual rainfall and its distribution throughout the cropping season was adequate (676.5 mm).But field trial was carried out under sting bug (*Dolycoris baccarum* L.) and heavy broomrape infestation. No control measure was taken for sting bug. Broomrape infestation and. The grain yield of lentil crop is also given in Table 1.

Broomrape	A_0= 0	A_1=30	A_2=50	A_3=60	A_4=70
infestations	B_0=0	B_1=40	B_2=55	B_3=65	B_4=80
(no. m^{-2})					
Grain yields	A_0=102.67	A_1=10.65	A_2=10.47	A_3=9.50	A_4=2.83
(g m^{-2})	B_0=94.82	B_1=10.49	B_2=9.40	B_3=9.40	B_4=3.08
1000 Kernel	A_0=27.86	A_1=26.35	A_2=28.86	A_3=23.44	A_4=27.62
weights (g)	B_0=29.58	B_1=24.77	B_2=26.27	B_3=24.02	B_4=26.93

Grain yield reduction seems to be dramatic due to increasing amount of broomrape infestation (HYL=97.3%). There was no adequate amount of seed sample to score hectoliter weight. 1000 kernel weights ranged from 23.44 g (A_3) to 29.58 g (B_0). Hectoliter weight was only scored for plots of A_0 and B_0 giving 84.63 kg and 83.64 kg respectively. Coefficient of correlation between grain yield vs. broomrape infestation (r= -0.893**) and 1000 kernel weights vs. broomrape infestation (r=-0.695*) were found to be significant and negative.

Regression between grain yield vs. broomrape infestation turned out to be significant (F=31.63**) indicating the presence of the effects of broomrape infestation onto grain yield clearly. Regression equation was estimated as y=85.78**-1.279x** with a R^2 %=77.3. Yield reduction due to increasing broomrape infestations is given in Figure1. Regression relation between 1000 kernel weights vs. broomrape infestation also turned out to be significant (F=7.45*). Regression equation was found to be as y=29.12**-5.25x* with a R^2%=41.8. Analysis of variance (not given here) for marketing prices indicated that broomrape infestations were found to be significant (F=24.52*) and the replications (purchasers) non-significant. Joint seed samples of A_0B_0 plots (controls) were received the highest marketing price offer (\$ 412.99 ton^{-1}) and the others received same price offer (\$330.39 ton^{-1}) (Table 2).

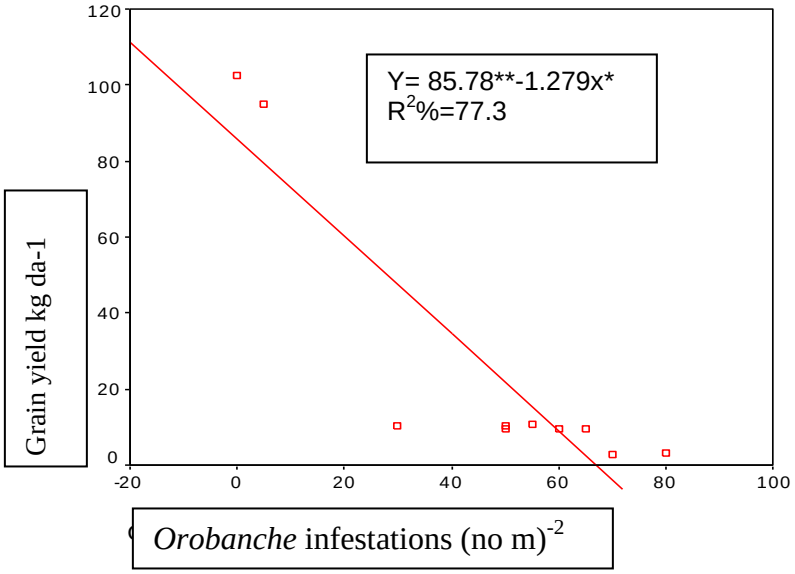

Figure1. Regression relation between broomrape infestation vs. yield in Adıyaman in 2010-11 cropping season.

Table 2. Means and groups for marketing price estimates for various broomrape infestations in Adıyaman in 2010-11.

Average Broomrape infest (no m^{-2})	Marketing price estimates (\$ ton^{-1})	Groups
Control	412.99	a
35	330.39	b
52.5	330.39	b
62.5	330.39	b
75	330.39	b

Economical loss (EL) for the first year of experiment was approximately = 0.973 x 0.9874 x \$412.99 ton^{-1} =\$ 396.77 ha^{-1}

Viransehir experiment (2011-12)

Farmer field was 10 km. northwest of Viransehir town of Sanliurfa province. Lentil variety of Firat-87 was planted in mid-November under barley- lentil crop rotation .Sowing time was quite early than common practice. Annual precipitation (351.4 mm) and distribution into cropping season was favorable for lentil production. Chemical weed control for broad leaves was employed for preceding barley crop. Number of broomrape m^{-2} for twin plots and grain yields are given Table 3.

Table 3.Field plan of Viransehir experiment (2011-12) and scored characteristics

Broomrape	A_0= 0	A_1=3	A_2=4	A_3=7	A_4=8
infestations	B_0=0	B_1=2	B_2=5	B_3=6	B_4=9
(no. m^{-2})					
Grain yields	A_0=223.96	A_1=199.22	A_2=167.19	A_3=125.67	A_4=114.09
(g m^{-2})	B_0=226.58	B_1=207.15	B_2=158.70	B_3=128.54	B_4=105.43
1000 Kernel	A_0=41.38	A_1=42.42	A_2=41.25	A_3=41.94	A_4=42.24
weights (g)	B_0=41.92	B_1=41.79	B_2=42.62	B_3=42.15	B_4=40.95
Hectoliter	A_0= 80.94	A_1=83.77	A_2=82.38	A_3=79.30	A_4=83.98
weights (kg)	B_0=77.69	B_1=80.54	B_2=80.49	B_3=82.56	B_4=81.52

Although being less than 10 m^{-2}, broomrape reduced grain yield approximately 50% comparing control (HYL=51.5%). Regression between grain yield vs. broomrape infestations turned out to be significant (F=286.92**). Coefficient of correlation was also found to be significant(r=-0.986**) and negative. Regression equation was estimated as y= 228.96**-14.39x** with a R^2%=97.3. (Figure 2) .

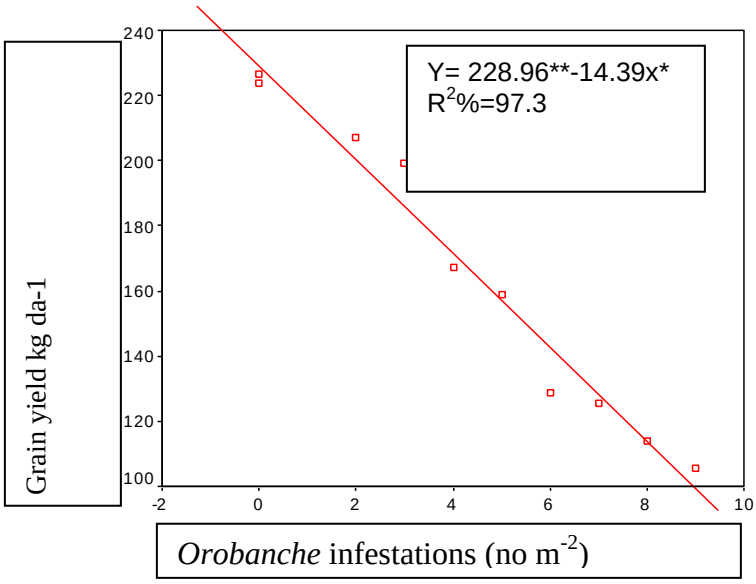

Figure 2. Regression relation between broomrape infestation vs. yield in Viranşehir in 20-11-12cropping season

1000 kernel weights (g) and hectoliter weights (kg) are also given in Table 3. Coefficients of correlation between broomrape infestations vs. hectoliter and 1000 kernel weights were found to be non-significant. Regression also between above characteristics turned out be no significant indicating the absence of negative effects of broomrape on to such quality characteristics.
Analysis of variance for marketing price offers indicated that broomrape infestation and replications (purchasers) were found to be non-significant. Although being non-significant the means and the groups for marketing price offers depending upon increasing broomrape infestations are given in Table 4.

Table 4. Means and groups for marketing price estimates for various broomrape infestations in Viransehir in 2011-12

Average Broomrape infest (no m^{-2})	Marketing price estimates ($ ton^{-1})	Groups
Control	585.07	a
2.5	587.83	a
4.5	585.73	a
6.5	587.83	a
8.5	590.58	a

Although rainfalls were adequate and distributed regularly for lentil production in both years, grain yields were affected by some other factors giving less grain yield than expected. Early planting seems to be beneficial for broomrape competition. When lentil is planted into humid soil lately it cannot compete with parasitic broomrape and affected by severely. But there is a conflict between early planting vs. late planting. Late planting of early maturing types of lentil is recommended (Temel et al.,2012; Rubiales &Fernadez-Aparicio, 2011) whereas farmer practice in the region is to plant lentil relatively early for emergence and rapid vigorous seedling development. Therefore plant can compete with broomrape development as partially suggested by Silim et al., (1999). Grain yield reductions seem to be dramatic under low or high amount of broomrape infestations as indicated earlier (Australian Department of Agriculture and Food, 1999). Average a 75 broomrape m^{-2} can reduce grain yield average 97% and an average 8.5 broomrape m^{-2} can reduce the grain yield about 51.5% as pointed out (Anonymous, 1997). Hectoliter and 1000 kernel weights seem to be affecting slightly. Decrease in 1000 kernel weights in the first year experiments might also be due to severe sting bug infestation. This pest sucks lentil grain and results in chalky spot damage. Regression equations with high coefficients of determination indicated the presence of the effects of broomrape infestation on grain yield clearly. In the first year experiments, significant regression relation between 1000 kernel weights vs. broomrape infestation with moderate value of coefficient of determination showed the presence the importance of other factors rather than broomrape infestation only. But the non significant regression and correlation between above characteristics revealed the absences of broomrape infestation on such characteristics. Some negative influence of broomrape infestation on lentil quality was discussed by Australian Department of Agriculture and Food (1999). Broomrape infestations in first year affected marketing prices negatively. But the appearance of *Dolycoris* damaged lentil grains were the major factor for less marketing price offers. In second

year marketing price offers were not affected by infestation. Purchasers were found to be expert about identifying healthy grains offering the highest marketing prices. Economical losses were huge for two consecutive years. Economic losses show the importance of broomrape management in the red lentil growing belt of the country. Breeding resistance is the most economic, feasible ad environment friendly method of control. However, resistance against broomrape is difficult to access, scarce of complex nature and low heritability, making breeding for resistance a difficult task (Rubiales , 2003). So far no source of resistance is available in lentil (Muehlbauer et al., 2006). But Fernadez-Aparicio et al., (2008) have observed a wide range of response to crenate broomrape resistance under field conditions. Low infection rates seemed to be based on a combination of various escape and resistance mechanism Moreover some in-vitro screening techniques may be used to rank and identify lentil accessions with potential broomrape resistance. There are numbers of cultural practices including delay sowing, hand weeding, no-tillage, nitrogen fertilization, intercropping, and rotations to contribute to seed bank demise. Taking into account simplicity in application, planting time modifications can be employed as an agronomical measure.. Crop rotation and the use of trap plant such as *Linum usitatissimum* L.are other possible measures (Aksoy & Uygur, 2003).

Conclusion

Broomrape is one of major yield limiting factor in the red lentil belt of Turkey. This parasitic plant reduce grain yield severely even with a low infestations but not some quality characteristics and marketing prices. Economic loss due to the yield decrease is huge and control measures should not be neglected.

Abstract

The objective of this study was to develop and validate analytical method for simultaneous determination of cyprodinil and fludioxonil residues in lettuce, based on QuEChERS sample preparation procedure and high performance liquid chromatograph (HPLC) equipped with diode-array detector as detection device. The validation of method was carried out in accordance with SANTE/11945/2015 guidelines. The accuracy of the method, evaluated by recovery studies at three fortification levels (0.1, 15 and 40 mg/kg) in blank lettuce samples, were 87.1% and 85.9%, with relative standard deviations (RSDs) of 1.1% and 2.4%, for cyprodinil and fludioxonil, respectively. Within a concentration range from 0.02-40.0 µg/ml, cyprodinil and fludioxonil showed linear calibration with correlation factor (R^2) of 0.994% and 0.995%, respectively. The detection and quantification limits of 0.02 and 0.05 mg/kg are below MRLs for cyprodinil and fludioxonil residues in lettuce, set by Serbian (15 mg/kg) and EU (15 mg/kg and 40 mg/kg) legislation. The results obtained in this study confirm that proposed method is easy and reliable for the determination of the analyzed fungicides residues in lettuce.

Keywords: *Cyprodinil, Fludioxonil, Lettuce, Residue.*

Introduction

Food production, with permanent demand for higher yields, represents an imperative of contemporary agricultural production (Lazić et al., 2014). According to the official FAO data, if pesticides had not be used in the course of the year, plant diseases, pests and weeds would reduce the world food production for 25-30%, and losses of stored foods would increase for additional 10-15% (Vuković et al., 2013).

However, pesticide use is often followed by a risk of environmental endangering, having in mind presence of pesticide residues. They can contaminate surface and groundwater, exhibit harmful effects on cultivated plants and useful organisms, cause the occurrence of resistance of biological agents, or can be found as residues in food (Lazić et al., 2013). The population is mostly exposed to pesticides through food, as certain quantities of these matters can remain in fruits or crops after harvesting, which particularly relates to fruits and vegetables that are mostly used fresh.

Nowadays, lettuce (*Lactuca sativa* L.) is frequently grown vegetable. In many countries, it is grown all year round, combining field and greenhouse production. However, lettuce production is obstructed by greater number of predominantly, fungi diseases. According to significance and frequency of occurrence, the most important pathogen of lettuce in our agro-ecological conditions is *Botrytis cinerea*, the agent of grey mould disease. Beside this, the disease that regularly occurs during lettuce growing in greenhouses is white mould, whose agent is *Sclerotinia sclerotiorum*. Lettuce is a plant of short vegetation period, which additionally hardens choice and dynamic of fungicide application, due to the necessity to respect the pre-harvest interval (PHI) of the applied products. The occurrence of resistant isolates of *Botrytis cinerea* toward fungicides that are used

for control of this pathogen represent a great problem. When to this issue are added increasingly strict criteria in relation to pesticide residues in food, as well as the fact that fresh leafs are directly used in nutrition, mainly immediately after harvesting, it is not hard to conclude that chemical protection of lettuce is to be approached with a lot of attention. Recently, for protection of lettuce against the named pathogens are introduced fungicides from groups of anilinopyrimidines (cyprodinil) and phenylpyrrole (fludioxonil).

Anilinopyrimidines are relatively new class of fungicides with protective and systemic action against several plant pathogens that belong to classes *Ascomycetes* and *Deuteromycetes.* A comprehensive field monitoring showed high efficiency of fungicide from this group in a several years lasting period, and cases of the resistance to all target pathogens, including *Botrytis* and *Venturia*, have not been detected. After foliar application, a plant uptakes anilinopyrimidin fungicide cyprodinil and it is transported by tissues and xylem. It inhibits penetration and development of fungi mycelia inside the leaf and on the surface; it controls a wide spectrum of pathogens such as *Tapesia yallundae* and *T. acuformis*, *Erysiphe* spp., *Pyrenophora teres*, *Rhynchosporium secalis*, *Botrytis* spp., *Alternaria* spp., *Venturia* spp. and *Monilinia* spp. (Savčić-Petrić, 2015).

On the other hand, phenylpyrroles are compounds with a wide spectrum of biological activity, especially against root rot and powdery mildew, caused by fungi from the classes *Ascomiceta, Basidiomiceta* and *Deuteromiceta.* They are primarily used for treatment of wheat seeds for control of seed pathogens (Roberts and Hadson, 1999). This class of fungicides includes fenpiclonil that is used as a fungicide for seed treatment and fludioxonil, that is used for seed treatment, as well as a fungicide for foliar application against *Botrytis cinerea*, the agent of grey mould disease.

In the European Union, including neighbouring countries, for control of the described pathogens in lettuce is applied the product SWITCH 62.5-WG (cyprodinil + fludioxonil 375 g/l + 250 g/l; Syngenta), which is still not registered in our country (Republic of Serbia). According to the Regulation of the European Union (Reg. No 2015/400) and the Republic of Serbia, the maximum residue level of cyprodinil (MRLs) in lettuce is 15 mg/kg, while according to the regulation of EU, the maximum allowed quantity of fludioxonil in lettuce is 40 mg/kg and according to Serbian regulation, MRL is 15 mg/kg.

In order to check presence of pesticide residues in agricultural products, and determine usually very low quantities of prescribed MRLs values, use of sensitive and reliable methods is needed. In this paper, a method for simultaneous determination of the fungicide cyprodinil and fludioxonil in lettuce was developed and validated, according with the requirements of SANTE/11945/2015 standard.

Material and methods

Chemicals and standard solutions

Certified reference standards of cyprodinil and fludioxonilof >98% purity were obtained from Dr Ehrenstorfer, Germany. Acetonitrile (MeCN; HPLC grade) and acetic acid (CH_3COOH) were purchased from "J.T.Baker" (Darmstadt, Germany), while ultrapure water was obtained from TKA apparatus (Germany). The dispersive SP extraction (Cat. No. 5982-5650) and clean-up (Cat. No. 5982-5356) kits for QuEChERS sample preparation were purchased as ready-to-use from Agilent Technologies (USA). A stock solutions of cyprodinil and fludioxonil were prepared in acetonitrile at a concentration of 100 µg/ml. Working standard solutions for HPLC analysis were prepared by appropriately diluting the stock solution with acetonitrile, achieving concentrations from 0.02 to 40.0 µg/ml. Stock solutions were stored at temperature of −20 ± 2 °C, and working standard solutions were stored in the dark at temperature of 4 °C.

Sample preparation

Extraction of cyprodinil and fludioxonil from the lettuce was accomplished by original QuEChERS method (Anastassiades et al., 2003). The analysis was carried out by use of untreated lettuce that was kept in the regime of deep freezing until the analysis. Untreated lettuce samples were previously grinded and homogenized. For the recovery experiment, to in this manner prepared sample (10 g) a corresponding quantity of cyprodinil and fludioxonil – of final concentration of 0.1, 15 and 40 mg/kg was added and left in the fridge over night. After that, 10 ml of acetonitrile was added, vigorously shaken by hand for 1 minute, than 1 minute on vortex and after that a prepared buffering mixture of salt (Agilent Cat. No 5982-5650) was added. It was instantly shaken by hand for 1 minute and 1 minute in vortex. Cuvettes were then placed in an ultrasonic bath for 10 minutes and centrifuged at 3000 rpm for 5 min (Figure 1).

Figure 1. The procedure of cyprodinil and fludioxonil extraction from lettuce

An aliquot of 6 ml was transferred from the supernatant to a clean-up tube with 855 mg of magnesium-sulphate, 150 mg of PSA and 45 mg of bulk carbongraph. Afterward, centrifugation was carried out at 3000 rpm for 5 min. An aliquot (3 ml) from the supernatant was evaporated till volume of 1 ml, filtered through a 0.45 µm filter and analyzed by HPLC–DAD (Figure 2).

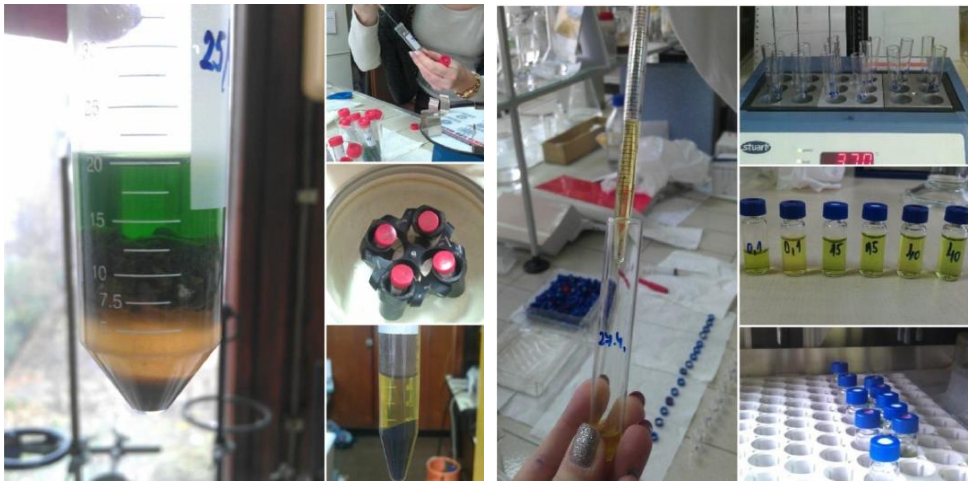

Figure 2. The purification process

Apparatus and chromatographic analysis

Pesticide residue analysis was performed with Agilent technologies 1100 Series high-performance liquid chromatographic system equipped with a diode array detector. The separation was performed on a C18 column (50 × 4.6 mm, 1.8 μm). The mobile phase was (0.5% acetic acid/MeCN, 40:60 v/v) with a flow rate of 0.9 ml/min and detection wavelength of 254 nm. Data analysis was performed using ChemStation software.

Results and discussion

The proposed method for cyprodinil and fludioxonil determination is based on reverse-phase high performance liquid chromatography and detection with a series of photo-sensitive diodes. Previously, those fungicides were determined using gas chromatography with a nitrogen-phosphorus detector (GC-NPD) (Marin et al., 2003). Also, HPLC-DAD method for determination of cyprodinil and fludioxonil in lettuce were described, while the separation was done with solid-phase microextraction (SPME) (Melo et al., 2012). However, the method allowed the determination of analyzed fungicides in lettuce at concentrations above 0.8 mg/kg.

Figures 3 and 4 present chromatograms of cyprodinil and fludioxonil standard mixture in acetonitrile and in a matrix of lettuce, as well as their spectra, obtained under previously given conditions.

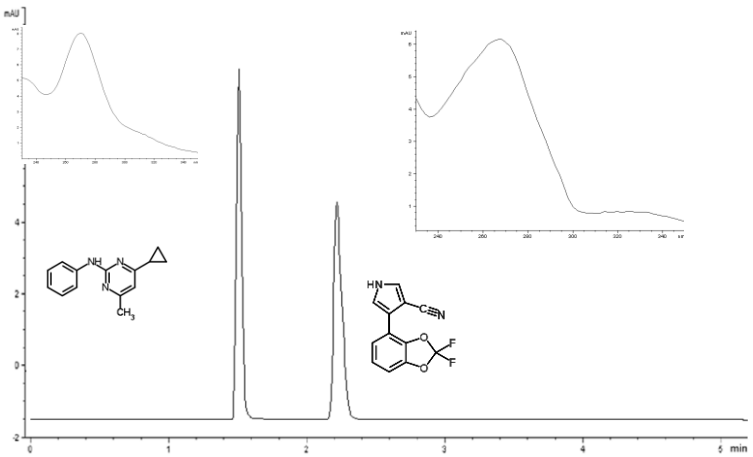

Figure 3. Chromatogram of cyprodinil and fludioxonil standard mixture and their spectras in acetonitrile

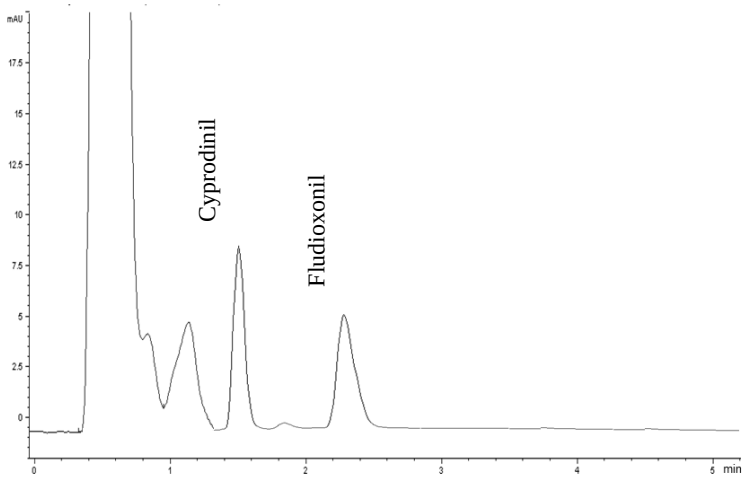

Figure 4. Chromatogram of cyprodinil and fludioxonil standard mixture in lettuce matrix

The analysis of analytical standards of cyprodinil and fludioxonil solution resulted in the maximum established peak of 265 nm, i.e. 275 nm, respectively. Chromatography of lettuce extract with added cyprodinil and fludioxonil standards, under the same conditions resulted with maximum of obtained peaks at the same wavelength.

The retention time of cyprodinil under the set conditions was found to be 1.507 min. The obtained chromatograms showed no interfering peak at the retention time of the cyprodinil, i.e., at 1.507 min showing good specificity of the method. Also, the retention time of fludioxonil was found to be 2.310 min, without interfering peak at that time.

The check of chromatographic conditions was carried out by linearity of the detector response, precision and accuracy of the method, and matrix effect, as well as determination of limits of detection (LOD) and quantification (LOQ).

The linearity of the detector responses was evaluated at a concentration range between 0.02–40.0 µg/ml using five calibration solutions prepared in acetonitrile. The calibration curve of analyzed fungicides showed a good linearity and strong correlation between concentrations and area in the studied range with correlation coefficient of 0.994 and 0.995, for cyprodinil and fludioxonil, respectively. The LOD and the LOQ for cyprodinil and fludioxonil in lettuce were 0.02 mg/kg and 0.05 mg/kg, respectively.

Precision value was evaluated trough repeatability and expressed as relative standard deviation (RSD). The repeatability was checked by analysis of the cyprodinil and fludioxonil standard prepared in lettuce matrix (1.0 µg/ml) five times in the same day. RSD of the peak areas were 0.80 and 0.38%, respectively, fulfilling the criteria of RSD $\leq$20%.

A critical aspect of pesticide residue analysis is the purification process, which is required to isolate the residues from matrix components and to reduce matrix effects (Lehotay et al., 2005). The matrix effect, i.e., signal suppression or enhancement, of the studied fungicides in the lettuce matrix, was evaluated. For this study, matrix effects were examined comparing the slopes of calibration curve obtained for matrix-matched standards (MMC) and solvent-based standards (SC). Cyprodinil and fludioxonil standards were prepared in blank matrix extract in five concentrations between 0.02-40.0 µg/ml. The values of 105.9% and 104.9% indicate that the impact of the lettuce matrix on cyprodinil and fludioxonil determination can be ignored.

The accuracy of the method was carried out using blank sample spiked with a standard solution of cyprodinil and fludioxonil fungicides at three levels. Calculations were done using calibration curve of MMC standards. The mean recoveries for cyprodinil and fludioxonil were 87.1% and 85.9%, respectively. According to the EU validation guideline for pesticide residues, mean

recovery values should be within the range of 70–120%, which was achieved by this method. Results of the recovery achieved in this study confirmed that the optimal recovery was obtained for cyprodinil and fludioxonil in lettuce samples.

Conclusions

A relatively simple and fast HPLC-DAD method for the simultaneous determination of cyprodinil and fludioxonil fungicide residues in lettuce was developed. Reverse phase and isocratic elution conditions enable efficient separation and quantification of investigated fungicides. The proposed method has been validated with good recoveries and linearity, as well low LODs and LOQs values, lower than MRLs set by the EU and R. Serbia. Finally, the results obtained in this study confirm that proposed method can be applied for determination of cyprodinil and fludioxonil fungicide residues in lettuce.

RESPONSE OF THE PARLATORIA CITRUS SCALE INSECTS (HEMIPTERA, COCCOIDEA) TO COLOURED STICKY TRAPS

Hanen JENDOUBI*, Pompeo SUMA, Agatino RUSSO

Department of Agriculture, Food and Environment, University of Catania, Italy
*Corresponding author: hanan_bari@hotmail.com

Abstract

The black scale *Parlatoria ziziphi* (Lucas) and the chaff scale *Parlatoria pergandei* Comstock (Hemiptera, Diaspididae) are some of injurious scale insects to citrus crops. A better understanding of stimuli to which male adults respond is essential to develop more effective monitoring techniques and establish pest flight phenology to use in control programs. We sought to study relative attractiveness of coloured sticky traps to males of both citrus scale insects in citrus orchards, and to find a suitable coloured trap to estimate their populations in the field. Consequently, field tests on the colour and position response of *P. pergandei* and *P. ziziphi* males were conducted in two citrus orchards located in Eastern Sicily (Catania), using square coloured sticky traps (30 x 30 cm) placed in and outside the canopy of trees. Significantly high numbers of males of both species *P. pergandei* and *P. ziziphi* were caught with yellow traps. Adults were also attracted by white and green traps but less by red and blue ones. Few significant differences in the captured males were observed when the two trap positions were compared. In conclusion, the yellow traps represent a good tool for monitoring parlatoria citrus scale populations in the field and, correlating those data with the population density on fruits and leaves samples on the trees, their management in citrus orchards is possible.

Key words: *parlatoria citrus scale insects, coloured sticky traps, males, captures, monitoring*.

Introduction

The present study completes previous research carried out on citrus scale insects in Tunisia Jendoubi (2012). Authors reported two key pests of citrus in the northern region, the black scale *Parlatoria ziziphi* (Lucas) and the chaff scale *Parlatoria pergandei* Comstock. High infestations were related directly to the failure of management strategies applied by farmers due to the inefficient surveillance programs available for growers. In this context, a dedicated monitoring activity of citrus parlatoria scale insect species is presented in order to acquire useful information for the development of pest management programs in citrus orchards.

The black scale and the chaff scale are reported as important pests occurring on citrus in many citrus growing regions over the world. The black parlatoria scale or citrus parlatoria is one of the five species of *Parlatoria* known to infest citrus (Ben-Dov, 2016). Miller and Davidson (2005) reported this scale as the only truly monophagous species attacking citrus; plant hosts are apparently restricted to the family Rutaceae. From southern China (Asia), the species is established on all continents with a tropical or semi-tropical climate, but has also extended into temperate and Mediterranean regions. Many authors considered the black parlatoria scale as a serious world pest and one of the major pests of citrus in many countries. *P. ziziphi* was listed as economically important pest in Algeria, Morocco, Tunisia, and Southeast Asia (Talhouk, 1975; Jerraya, 2003; Pellizzari and Germain, 2010 and Bouazza and Guenaoui, 2015). Perhaps the most characteristic damage is the virtually irremovable black scale cover on the fruit. The chaff scale

or ‘le pou gris’ is considered a cryptogenic species of unknown origin by many authors (Pellizzari and Germain, 2010). Nowadays, it is widely distributed throughout the tropical and subtropical areas of the world. It occurs in Europe, Africa, Australasia, Pacific Islands, West Indies and America. It is a polyphagous species, reported in 36 plant families. Citrus is by far the most commonly reported host followed by Hibiscus, Jasminum and Viburnum (Heu, 2002 and Ben Dov, 2016). Miller and Davidson (1990) list this insect as a serious world and widespread pest. Since the 1970s, *P. pergandei* has become one of the main pests in all citrus-producing areas and has been recorded as such in several countries from the Mediterranean region (CABI, 1968). The infestation of the Chaff scale is generally relevant; a greenish blotch remains at the feeding point on mature fruit. Heavy infestations of both pests cause chlorosis and premature drop of leaves, die back of twigs and branches, deformations and premature drop of fruits. This reduces commercial value of fruits, causing rejection in most fresh fruit markets. In many countries worldwide, there are many studies on both of these scale insect species including excellent regional monographs and several articles treating bio-ecological features. However, few studies have so far been carried out on enhancing systems of monitoring citrus parlatoria populations within the integrated pest management strategies. The predicting infestation level is limited to visual scanning or sampling (growers and fieldsman) of sessile populations living on trees. This method reveals the presence of scale insects, but not the life stage distribution or population density. Catches of males by either chromatic or pheromone traps (as in the case of the citrus mealybug and the California red scale) should be used for monitoring these scale insects. Currently, coloured sticky traps have been widely used to monitor flying pests in many agro-ecosystems and are more preferable method in management systems. The use of yellow sticky traps is an effective tool in terms of pest management and this colour was proven to be the most effective one to screen flight activity of several insects as whiteflies, aphids, leafhoppers and thrips (Hill and Hooper, 1984; Hoback *et al*., 1999; Wallis and Shaw, 2008 and Hazır and Ulusoy, 2012). Literature data on the male activity and colour preference are scarce or absent and there were no records on chromatic trapping for *P. pergandei* and *P. ziziphi*. A better understanding of the stimuli to which male adult respond is essential for the development of effective monitoring techniques to reliably estimate the dynamic population and flight phenology of these species.

This study aimed to determine the colour preference of parlatoria citrus scale males and to assess the utility of colour sticky trap catches in estimating their populations in the field. Consequently, the attractiveness of colour and placement of sticky traps on insect captures were examined. Our findings can be useful in the development of sampling techniques to support the growers in making management decisions against scale insects in citrus orchards.

Materials and methods

The colour and position preference of citrus Parlatoria males experiment were conducted in two citrus orchards located in Catania (Southern Italy) during summer 2010. Traps were designed by clear polypropalene card, square shaped and 30/30 cm in size, coated with Beetle-Glue®. Differently coloured traps were hanged on each citrus tree: yellow, blue, white, dark green, orange, red and black. The experimental design was a completely randomized block with three replications and the samples were collected each week (table 1). On each sampling date, two traps of each colour per tree were placed in exposed or shaded location. Placement and retrieval of traps required approximately half a day of labor per sampling date. At each time of collection, the single sticky trap was covered with cellophane wrapped and brought to the laboratory for the count of captured males under a stereoscope.

The data related to the males captures for each coloured traps were analyzed by analysis of variance (ANOVA) using the SAS software; means were separated using the Least Significant Difference (LSD) Multiple Comparison Tests.

Table 1: Experimental design of Colour traps trial

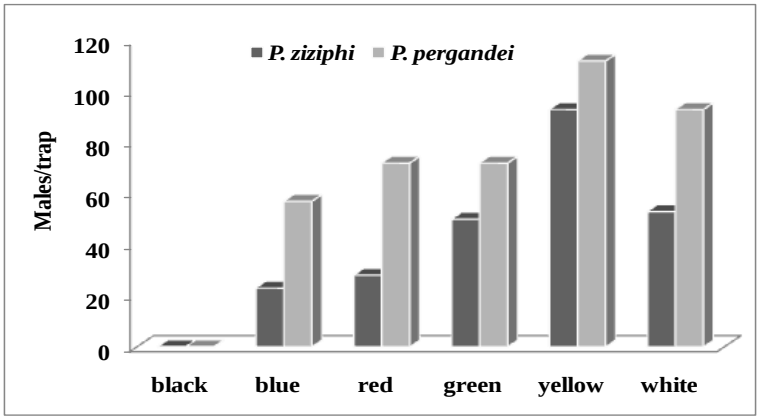
Results and discussion

Trap colour and position

In figure 1, the different responses of the males of both parlatoria species to the tested coloured traps, were reported. The yellow (112 males) and white (93 males) traps were more attractive for *P. pergandei*. This was followed by red (72 males), green (72 males), and blue, with blue recording the lowest number of adults captured (57 males). For *P. ziziphi*, the yellow traps captured 38% of male catches followed by white 22%, green 20%, red 11%, and the lowest one was the blue 9%.



Mean±SE	
White	4.75±1.76 *b*
Yellow	7.75±3.78 *b*
Blue	0.58±0.15 *a*
Red	0.48±0.17 *a*
Green	0.61±0.14 a

Figure 1: sticky trap colour preference of the chaff scale and black scale males in citrus orchards. a: capture means within a row followed by different letters were significantly different at $p < 0.05$ based on the LSD Multiple Comparison Tests.

Accordingly, from the statistical analysis of data, the yellow traps caught significantly more *P. pergandei* and *P. ziziphi* adults than other colours tested (F=2.66, df=5, 60, P=0.03; F=2.79, df=5, 60, P=0.02; $p < 0.05$) (table 2). The highest male captures reached a total of 186 males for both species on yellow sticky traps (7.75±3.78). The second highest captures were obtained with the white trap (4.75±1.76) capturing 146 males of *P. pergandi* and *P. ziziphi*. A previous study had also indicated yellow and white colours as being attractive to many hemipterans species including coccids group (Hoback et al., 1999). Compared with species belonging to the same genus, the

parlatoria palm scale males mostly preferred white traps. Whereas to parlatoria citrus scale, yellow was the most preferred colour and white ranked second in the order of preference (Abd El-Kareim, 1998). The black scale and the chaff scale share with the parlatoria palm scale the lowest response to green, red and blue colours. A similar low response to these colours was shown by males of *Aonidiella citrina* (Newstead) (Moreno *et al.*, 1974), which is an armoured scale insect considered as important citrus pest.

With the black cards, no captures were recorded in this study. Literature searches carried out on species level differences in colour preference demonstrated that most of insects are indifferent to black colour like Parlatoria species. In fact, only the Ceratopogonidae family was attracted to the black colour (Hill and Hooper, 1948).

It is necessary to point out as the males of others diaspids (e.g. *Aonidiella aurantii* Maskell and *Lepidosaphes beckii* Newman) were found in glutted yellow cards, showing a positive response to chromatic traps.

No statistical significant differences in the captured males were observed comparing the two trap positions, which are indicative of microhabitat preferences (table 2). Male flights seem to be less affected by the location, sunny or shadow; but they are extremely dependant of yellow colour, recording high values.

Table 2: Summary of LSD Test results (p=0.05) of the response of citrus Parlatoria males to colour and position traps trial

	df	SE	***F***	***p-level***
Colour- *P. pergandei*	5	0.24	2.67	<0.03
Colour-*P. ziziphi*	5	0.23	2.79	<0.02
Position	1	0.24	0.48	0.49
Colour*position	5	0.24	0.59	0.71

Promoting results are recorded within this study, supporting the idea that the yellow trap represents a useful tool for pest management programs for *P. pergandei* and *P. ziziphi* and others armoured scale insects affecting citrus trees.

Efficiency of yellow traps on the population density

The yellow colour trap turned out to give indications on abundance of males but they can also provide interesting information on the pest population level of the monitored scale species. In fact in respect to the exposure time, high numbers, of males for both species *P. pergandei* (406 males) and *P. ziziphi* (247 males) were caught with the traps. Focusing on yellow cards, 112 males were counted for the chaff scale and less than the half (74 males) for the black scale. And so, the first one is much more abundant than the latter in the prospected citrus orchards, being both in an injurious status. This allows classifying *P. pergandei* as a key pest of citrus trees in those orchards, needing urgent intervention with systemic agro-chemical products. At the same time, this should prevent the spread of *P. ziziphi* populations and keep it under the economic threshold. Additionally, the yellow trap might affect the mating frequency chance for female copulations due to these high catches and the sexual reproduction model of most scale insect species. It will result in reduction of off-spring production and therefore it could be incorporated in an integrated management control program for the two pests.

Efficiency of yellow traps on the male flights

The yellow coloured trap may also be used as indicator of the population's flight activity of both parlatoria species, providing useful details when studying the phenology of male captures throughout the year.

In the figure 2, we tried to draw the male flights of *P. pergandei* and *P. ziziphi*, choosing best attractive colours, yellow and white. Accordingly, emergence of *P. pergandei* and *P. ziziphi* males start on 22 June, registering higher values or 'peaks' on 29 June. Data is clearly more expressed with the yellow sticky cards (186 males) which were more attractive to males than the white cards (146). If this type of trap is used for longer period, it will effectively detect the beginning of male activities and determine the flight peaks which are helpful in control practices timing. Hence, trapping by sticky yellow cards may be very helpful in the detection of first male flights of both citrus parlatoria scale insects.

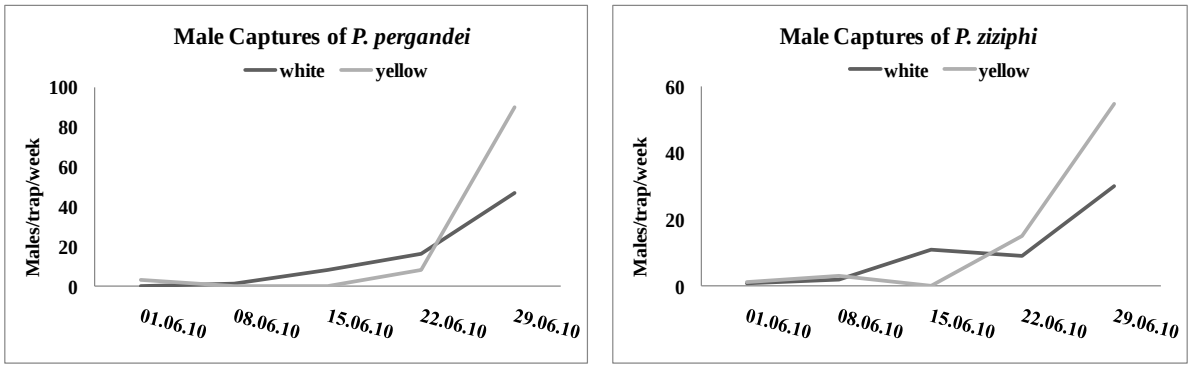


Figure 2: Monitoring male flights of *P. pergandei* and *P. ziziphi* using sticky coloured traps

At this step, a calendar (Informative Sheet) for growers and interested people, containing first preliminary data on how to use yellow sticky traps in monitoring males of citrus parlatoria scale insects and eventual others species from Diaspididae occurring in citrus orchards, can be proposed.

Informative sheet

Sticky trap color.

Yellow Traps is most recommended to be used in a monitoring program that will include citrus scale insects, belonging to Parlatoria genus.

Number of traps needed.

It can get a fairly good idea of males activity with 4 traps per 1ha. But, you need often to determine your main target pest(s) and then check with your state extension specialist.

Mode of sticky trap deployment.

The basic suggestion has been to hang traps vertically, at heights of 1,5m, slightly below the top of trees, where they will be most efficient. Also, place traps around orchard perimeters as well as within the orchard will detect pest injury before most other crops show symptoms.

Frequency and examination period.

Use sticky traps along with regular plant inspections: once a week would be ideal during spring and summer, twice a month in automn and once a month in the Winter.

Learning pest Identification.

Males of diaspids are generelly winged, red with black eyes; but some particular differences for each species should be known by users. Perhaps, farmers can face some difficulties to identify

males but with using pictorial guides, hand lens, and attending grower meetings they will become acquainted with the major pest groups and will be able to easily identify them.

Insect counts.

Be certain to wrap the sticky traps in clear plastic. Insect count can be facilitated by using sticky traps with a background grid. Numbers should be written down in forms that should allow growers to start their monitoring process. we suggest correlating results of yellow cards to those of visual prospections befoe starting treatment.

Conclusion

This study reports first results dealing with the usefulness of the coloured sticky traps as tool for the monitoring activities of *P. pergandei* and *P. ziziphi* in citrus orchards.

Both male's species showed a strong preference for yellow colour, resulting in highest captures. Captures on sticky traps provided good informations on male abundance and revealed the pattern of adult flights to be considered of extreme importance for the early detection of male emergences and management of the black and the chaff scale in citrus orchards. Also, trap catches showed fluctuations in population sizes similar to visual counts attesting the overall reliability of the traps. Hence, the yellow sticky cards may be considered a practical, accurate and low cost technique for pest diagnostic, infestation level assessment or control practices timing of parlatoria citrus scale populations and other diaspids occurring in citrus orchards. We encourage owners/growers to use these informations during monitoring periods. Moreover, we suggest conducting studies on economic thresholds based on male flights of scale insects using yellow glutted cards in correlation with the sampling methods.

THE EFFICACY OF SOME ESSENTIAL OIL COMPONENTS AGAINST CONFUSUED FLOUR BEETLE, TRIBOLIUM CONFUSUM DUVAL. (COLEOPTERA: TENEBRIONIDAE) AT DIFFERENT TEMPERATURES

Özgür SAĞLAM*, Nihal ÖZDER

Namık Kemal University, Agriculture Faculty, Department of Plant Protection, Tekirdag, Turkey
*Corresponding author: osaglam@nku.edu.tr

Abstract

Fumigant toxicity of essential oil components: α-pinene, *p*-cymene, eugenol, cuminaldehyde, linalyl acetate, linalool, α-terpinene, gamma terpinene, limonene, β-pinene, allyl isothiocyanate and diallyl disulphide against all life stages of Confusued Flour Beetle, *Tribolium confusum* DuVal. at three different temperatures (20, 25, 30 °C) and 65±5 % R.H was determined. In preliminary biological tests all life stages of *Tribolium confusum* were exposed to 100 µl/l concentration of compounds during 24 h. Results of preliminary tests were Cuminaldehyde, allyl isothiocyanate and diallyl disulphide showed highly toxicity to *T. confusum* eggs. Allyl isothiocyanate and diallyl disulphide had high fumigant toxicity to other life stages of *T. confusum*. The results obtained from effective components indicated that values of lethal concentration for effective compounds were decreased. However, toxicity increased with increasing temperature. According to results it can be concluded that Allyl isothiocyanate would be a potential compound in controlling stored-product insects, since it had high toxicity to all biological stages of *Tribolium confusum*.

Keywords: *Essential oil components, fumigant toxicity, Tribolium confusum, temperature*

Introductıon

Insect control in stored products at present based on the use of gaseous fumigants and residual insecticides, both of which pose serious hazards to mammals and the environment (Shaaya et al. 1997; Ren et al. 2008). Fumigation is still one of the most effective methods for prevention of storage losses. Phosphine and methyl bromide (MB) are the most common fumigants used for stored-product protection throughout the world. MB phased out end of the 2015 in all over the world. Insect resistance to phosphine is a global issue now and control failures have been reported in field conditions in some counties (Taylor 1989; Collins et al. 2002;Opit et.al. 2012, Saglam et al. 2015). Essential oils are potential sources of alternative compounds to currently used fumigants. Essential oils and components are among the best-known substance tested against insects. These compounds act as fumigants (Regnault-Roger and Hamraoui, 1995; Shaaya et al., 1997), contact insecticides (Schmidt and Streloke, 1994), repellents (Plarre et al., 1997), antifeedants (Harwood et al., 1990) and may affect some biological parameters such as growth rate, life span and reproduction (Regnault-Roger and Hamraoui, 1995).Various studies have demonstrated fumigant activity of various essential oils against various stored product insects (Shaaya et al., 1991; Shaaya et al., 1997; Tunç et al., 2000; Lee et al., 2003; Isıkber et. al. 2009). Furthermore, interest as been shown in plant products, i.e., essential oils and their components, for fumigants action since it is believed that natural compounds from plant sources may have the advantage over conventional fumigants in terms of low mammalian toxicity, since some of monoterpenoid compounds such as β-asarone, estragole, safrole, (+) - fenchone are known to be

carcinogenic (Kim and Ahn, 2001), rapid degradation and local availability (Isman, 2006). Previous laboratory evaluations of monoterpenoids on various insect pests have established their biological activity as ovicides, fumigants, and contact toxicants (Karr and Coats 1988; Rice and Coats 1994; Tsao et al. 1995; Saglam and Ozder,2013). The present study was carried out to determine the fumigant toxicity of twelve monoterpenoids with different chemical groups; α-pinene, p-cymene, eugenol, cuminaldehyde, linalyl acetate, linalool, α-terpinene, γ-terpinene, limonene, β-pinene, allyl isothiocyanate and diallyl disulphide, against all life stages (adult, egg, larva and pupa) of confused flour beetle at three different temperatures.

Materials and methods

Insect culture:

Biological tests were carried out on all life stages (egg, larva, pupa and adult) of *T. confusum*. *Tribolium confusum* were obtained from cultures reared in 1 l glass jars at 25 ± 1°C and 65± 5 % relative humidity (RH) on a diet of wheat flour mixed with dry brewer's yeast (17:1, wt:wt) (Donahaye 1990). The experiments were conducted with eggs (1-2 days old), old larvae (4-7th instar), pupae (1-2 days old) and adults (7-10 days old). Eggs were separated daily from oviposition jars by sieving (70 mesh, 210µm sieve; Retsch, Germany). Eggs were transferred into the 10 ml glass tubes for exposure to treatments. 10 ml glass tube (2 cm diameter and 4.5 cm long), each containing 50 eggs 1–2 days old, were exposed to each treatment. Old larvae were removed from culture jars and exposed to the treatments 25-30 days after oviposition. Two day-old pupae were obtained by daily separation from culture jars and held in wheat flour for 48-h before the exposure. Newly emerged adults were held in pre-exposure jars containing wheat flour, and were exposed to treatment 7-10 days after emergence. Each glass tube, except of the egg stage, included 4 g wheat flour as food.

Tested monoterpenoid compounds:

Twelve monoterpenoid compounds; α-pinene (Aldrich, 147524, 98 %), p-cymene (Sigma-Aldrich, C121452, 99 %), eugenol (Fluka, 46129, Ph eur), cuminaldehyde (Fluka, 28210, 85 %), linalyl acetate (Fluka, 45980, 95 %), linalool (Fluka, 62140, 95 %), α-terpinene (Aldrich, 223182, 85 %), γ-terpinene (Fluka, 86478, 97 %), limonene (Sigma-Aldrich, 183164, 97 %), β-pinene (Aldrich, 112089, 99 %), allyl isothiocyanate (Merck, 800260, 95 %) and diallyl disulphide (Sigma-Aldrich, 317691, 80 %) were tested against all life stages of *T. confusum*. Experiments were carried out at 3 different tempereature in laboratory condition. After purchase, the monoterpenoid compounds were collected in sealed glass containers with frangible septum which allows easy penetration by a syringe needle to permit withdrawal of the compounds. Containers were kept at refrigerator temperature (4°C) at dark until use.

Bioassay Tests and Experimental Procedures:

Tested stages of *T. confusum* were collected from the cultures and placed in the glass vials covered with a fine mesh to allow penetration of any volatiles emanating from the monoterpenoid compounds. Fifty eggs and twenty five larvae, pupae and adults were used in each replicate. Bioassays were carried out in 3-l glass jars closed with metal screw-on lids, which served as fumigation chambers and were kept at 20, 25, 30 ± 1°C and 65 ± 5 % RH. An aqueous saturated magnesium nitrite solution ($Mg(NO_3)_2$) was placed in small glass petri dishes of 7 cm diameter to provide 60 ± 5 % RH in the glass jar (Greenspan 1977). The single-dose biological tests were carried out to determine the effective concentrations of each compound against the all biological stages of tested species of *T. confusum*. Each tested stages were exposed to a constant concentration of 100 µl l-1 air of each compounds for 24 h. Monoterpenoid compounds were applied on filter paper (2 cm x 5 cm) attached to the under-side of the lids of fumigation chambers

by using micropipette. The jars were immediately closed. After eggs, larvae, pupae and adults of *T. confusum* in glass vials were transferred separately into fumigation chambers, the fumigation chambers were closed with screw-on lids, which were made air-tight. Each treatment and control were replicated three times.

Monoterpenoid compounds that cuminaldehyde, diallyl disulphide and allyl isothiocyanate with high fumigant activity on biological stages of *T. confusum* in preliminary biological tests were subjected to lethal concentration tests to determine their LC_{50} and LC_{90} values. With diallyl disulphide a range of 6 concentration levels ranging from 0.25 to 10 µl l-1 for the eggs, from 5 to 75 µl l^{-1} for the pupae, from 1 to 75 µl l^{-1} for the adults and 9 concentration levels ranging from 1 to 120 µl l^{-1} for the larvae were used. With allyl isothiocyanate the ranges consisted of 6, 7, 8 and 5 concentrations, from 0.1 to 5 µl l^{-1} for the eggs, from 0.25 to 5 µl l^{-1} for the pupae, from 1 to 5 µl l^{-1} for the adults and from 0.5 to 7.5 µl l^{-1} for the larvae respectively. With cuminaldehyde the ranges consisted of 5 concentrations from 0.25 to 10.5 µl l^{-1} for *T. confusum* eggs. Concentrations were selected for the eggs of insect species on basis of preliminary bioassay tests. Three replicates were set up for each concentration and control. Fumigation procedures were the same as in above mentioned bioassay tests.

Data processing and analysis:

After each treatment, larvae, pupae, and adults were transferred to clean 10 ml jars containing food medium and were held at 25 ± 1°C and 65 ± 5 % RH until examined for mortality. The eggs in their Perspex slides were held under the same conditions until the oviposition sites were examined for egg hatch. Mortality counts for adults were made 4-5 d after exposure; for larvae they were based on those insects that had failed to pupate 9 d after exposure; pupal mortality was based on those pupae that failed to produce adults 9 d after exposure, and egg hatch was counted 7 d after treatment. Mortality data obtained from bioassay tests were corrected by using Abbott's formula (Abbott, 1925).Mortality data obtained from preliminary bioassay tests were normalized using arcsine transformation and then were analyzed using two-way analysis of variance (ANOVA). The means were separated using the Duncan's test at the 5 % level (SPSS, 2009). Data obtained from each zero dose control and concentration- mortality responses were subjected to probit analysis by using maximum likelihood program software (POLO-PC) (LeOra Software 1987) to determine LC_{50}s (Lethal $Concentration_{50}$), LC_{90}s (Lethal $Concentration_{90}$) and their respective 95 % confidence intervals. Differences in toxicity were considered significant when 95 % confidence intervals did not overlap. The slopes and intercepts of concentration-mortality regressions for each tested insect were compared with the POLO-PC maximum-likelihood procedures (LeOra Software 1987).

Results and dıscussıon

Preliminary bioassay tests indicated that percentage mortalities of all biological stages of *T. confusum*, exposed to a concentration of 100 µl l^{-1} air of tested monoterpenoid compounds for 24 h are given in Table 1, Table 2 and Table 3. at different temperatures.

Table 1. Percent mortality of *Tribolium confusum* eggs, larvae, pupae and adults exposed to 100 µl l^{-1} concentration of tested monoterpenoid compounds for 24 h at 20°C.

* Two-way ANOVA was applied to the data. Means within a row with the same lower-case letter and a column with the same uppercase letter do not differ significantly (Duncan test at 5% level). **: F value didn't calculate because of Ally isothiocyanate showed high toxicity.

According to results of single-dose biological tests, cuminaldehyde, allyl isothiocyanate and diallyl disulphide resulted in 100% mortality of *T. confusum* life stages. And toxicity levels of essential oil components were increased with higher temperature levels. Huang et al. (2000) reported that main components of garlic oil, diallyl trisulphide, diallyl di sulphide ve metil allyl tris sulphide, had high fumigant toxicity on *Tribolium castaneum* (Herbst) and *Sitophilus zeamais* Motschulsky and can be considered as potential alternative fumigant for controlling stored product insects. According to some researcher already decribed that Diallyl disülfid and Allyl isothiocyanate components showed high toxicity life stages of *T. confusum* and *T. castaneum* (Gözek 2007, Karcı 2006, Wu et al. 2009, Işıkber et al. 2009).

The results of probit analysis (LC_{50} and LC_{90} values (µl l^{-1})) for all biological stages of *T. confusum* exposed to various concentrations of cuminaldehyde (only egg stage), allyl isothiocyanate and diallyl disulphide for 24-h at three different temperatures are given in Table 4.

Table 4. Probit analysis data of garlic essential oil, its main compounds and their mixture for Tribolium confusum eggs, larvae, pupae and adults following 24-h laboratory fumigation at 3 different temperatures.

	30 °C	Allyl isothiocyanate	519	2.79 ± 0.33	0.98 (0.52 - 1.33)	2.84 (2.09 - 5.44)	73.36
		Diallyl disulfid	520	2.60 ± 0.28	10.37 (8.2 - 12.43)	31.47 (26.48 - 39.14)	16.92
Adult	20 °C	Allyl isothiocyanate	450	7.25 ± 0.6	2.41 (1.97 – 2.78)	3.62 (3.11 – 4.72)	86.31
		Diallyl disulfid	599	2.59 ± 0.2	17.52 (15.15 – 20.10)	54.54 (45.2 – 69.44)	23.16
	25 °C	Allyl isothiocyanate	600	6.38 ± 0.44	2.20 (2.03 - 2.37)	3.50 (3.19 - 3.93)	36.99
		Diallyl disülfid	525	2.54 ± 0.17	14.90 (11.66 - 19.04)	47.57 (34.81 - 74.66)	49.65
	30 °C	Allyl isothiocyanate	599	7.58 ± 0.56	2.13 (1.91 - 2.36)	3.15 (2.78 - 3.85)	89.58
		Diallyl disülfid	598	4.15 ± 0.46	15,18 (13.08 - 17.11)	30.89 (26.44 - 39.24)	29.64

[a]: Number treated, excluding controls, [b]: Slopes are non-parallel and unequal where noted,
[c]: Value in parentheses refers to the 95% confidence range, [d]: Chi-square,
[e]: Calculated LC_{50} ve LC_{90} values were found to be far beyond tested application dose ranges

It appears that allyl isothiocyanate was the most toxic to *T. confusum* eggs, followed by diallyl disulphide and cuminaldehyde respectively. LC_{90} values for allyl isothiocyanate against larva, pupa and adult stages of *T. confusum* were significantly lower than those for diallyl disulphide, since 95 % confidence intervals (CLs) of allyl isothiocyanate did not overlap those for diallyl disulphide. Therefore, allyl isothiocyanate was more toxic to *T. confusum* larvae, pupae and adults at three different temperature conditions.

Conclusion

The results obtained from this study indicated that the toxicity of the most effective compounds (Cuminaldehyde, Allyl isothiocyanate ve Diallyl disulphide) to different biological stages of both species increased with increasing temperature. In conclusion, it was found that Allyl isothiocyanate would be a potential compound in controlling stored-product insects, since it had high toxicity to all biological stages of *T.confusum.*

Abstract

This study was performed in the national forest of Nador (Tiaret west of Algeria) on the population of pine processionary moth Thaumetopoea pityocampa Schiff.-. It highlighted infection rates by this pest because it varied greatly from one locality to another. It depends on several factors, among others, the forest structure and exposure. Three plots were established with an area of 1are for each. They were exposed to different altitudes ranging from 1050m to the EzZeg station and 1250m of Chemekh station and 1150 m from the Hassi El Hadjel station. The emergence began on August 7 and was conducted over one month; egg laying began in late August to early September. Embrional period lasted 30 to 45 days, the hatching occurred during the first decade of October.The damage to leaves increase with larval growth. The caterpillars of the 4th and 5thinstars are the most dangerous and cause more damage. The last instar larvae leave their nest, following each other in long, head to tail processions to the end of March and seek out pupation sites in the soil in early of April. A biological control test by application of Bacillus thuringiensis in the field seems to be promising, because recorded larval mortality exceeded 32%. In the El Hassi Hadjel station, the weight of live caterpillars is 0.15g, while for dead caterpillars is 0.1g. While the measures of the lengths of live and dead caterpillars is almost the same is 2.3cm. However, in the station Chemekh it was noticed a difference in weight between live and dead caterpillars (0.5g to 0.1g for live larvae and dead larvae, respectively) and a variation between the measurement lengths of dead and live caterpillars which is 2.7cm to 2.4cm.respectively.

Keywords: pine processionary, *Thaumetopoea pityocampa, development cycle, Nador forest, Bacillus thuringiensis.*

Introduction

Algerian forest covers an area of 4.1 million hectares preserved through afforestation. Plantation development caused increasingly attacked populations of insect pest species that can cause extensive damage when the population is not controlled (Maatoug 1992). Our forest still suffers from the same problems this is not only due to the absence ofscientific studies and forestry research but the uncontrollable development of the Pests. Forestry area planted by Aleppo pine in our country each year suffer particularly severe attacks of insect pests including from the pine processionary *Thaumetopoea pityocampa* .

Therefore, a study of development cycle of this pest either in the field or laboratory conditions, allows to identify the conditions that favorits development (Mezali, 2003). So, a better

understanding of a pest such as the pine processionary moth *T .pityocampa*, is essential for the implementation of a rational and effective control (Maatoug 1992).
Our study has focused on the development cycle of the pine processionary of Aleppo pine forest in Nador. Also, a biological control test using *Bacillus thuringiensis* was performed.

Material and methods

1. Sampling

1.1 Sample Selection

Systematic sampling is recommended in such cases. The inventory method in the truest straight line possible is that of straight transect of studying the environment, not on a given surface, but in a straight line (Rondeux, 1999).

1.2 Stations Study

Our study area is located in region of Tiaret; This allowed us to choose three experimental plots which differ in the exposure. We have chosen the following stations:
Plot 1: EzZeg with an area 700 ha, is characterized by a stand of Aleppo pine, whose average height is 2 m. This station in a Northern exposure, and 1,050 m of altitude.
Plot 2 : Chemekh with 1250ha area, it is composed of stand Nature reforestation of Aleppo pine, with an average height of 2.20 meters it is a East exposure and 1250 m altitude.
Plot 3: "Hassi Hadjel" composed of an Aleppo pine with an average height of 2.20 m. This resort to a South exhibition, located on flat land, the little rocky soil and 1150 m altitude.

1.3 Sampling Technique

The experiment lasted one year ((July 2010 à July 2011) in order to complete the development cycle of the insect. Sampling each development stage was performed 2-4 times per month. The samples were taken randomly. The each plots consisted of then trees for each station.

2. Observations of insect development cycle

2.1. Emergence of adults

Adult were catched using by pheromone trap composed of a plastic bag, a circular plate contains a sticky material and the capsule with pheromone to capture male. We have placed four traps per plot with aim to determine number of adults and duration of the flight period.

2.2. Egg laying

Egg hatching were observed simultaneously in the laboratory at the temperature 24±2°C and relative humidity 70±4% in the field. The Monitoring of hatching eggs was conducted between 26 September and 18 October. For this, a significant number of eggs was taken different plots.

2.3. Distribution of eggs on trees

The daily observation of laying eggs gave us the frequency curve of F. R. outbreaks (first hatched larvae for each egg). The distribution for average x = 13.40 (August 20) and standard deviation = 4.67. Note that we have grouped the data from classes 3 days for the calculation of the theoretical frequency (F.T.) (Demolin and Millet, 1981).

2.4. Larval hatching

From daily observation of egg laying, both in the field and in laboratory, we obtained the results of larval hatching taken from the station EzZeg. The egg mass were taken for ten trees.

2.5. Larval development

To determine the larval development period, track samples from the beginning of their hatching until their departure in procession were performed. Nests were taken randomly from each tree with pruning shears. Tweezers and a scalpel were used to open the nests and scale to weigh the samples.

3. Microbiological control against **caterpillar**

To assess the effectiveness of the biological control on field, was used for our experimentation, Chemekh plot and Hassi el Hadjel plot. Each plots consists of four small plots containing 3 trees. The first 3 plots are treated with the bacteria (*Bacillus thuringiensis*) while the fourth plot is treated with distilled water. After treatment that was performed on 19/01/2011), sampling was done on 27/01/2011. In each plot, we removed the nests each nest, count the number of dead larvae and the number of live larvae and makes length measurements and weight of larvae living and dead.

Mortality rate (%) = the number of dead larvae / total number of larvae x 100

4. Statistical Analysis

The results were reported as mean ± standard deviation and compared by two-way ANOVA test (XL STAT software 6.0 -. ANOVA- of 95% confidence interval). The differences between averages are studied using the Newman-Keuls test and were considered significant at probability <0.05.

Results

1.Spatio-temporal dynamics of *T. pityocampa*

1.1 Dynamics of adult male *T. pityocampa* by pheromone by traps

There were significant differences (p <0,05) of the population dynamics depending on the period It appears that from August 7 to 31, the number of captured adult males is low at the beginning of August, and then begins to increase for decline at the end of this month. The peaks of emergence of adults males was in the middle of August, we have catch maximum from the beginning of August the emergence station for Hassi El Hadjel.The emergence of adults males, used to determinate the exact date that presents 50% of emergencies.

The emergence of butterflies, allow us to determine the precise date that presents 50% of emergencies. From that date, we can have an idea about the different period, larval stages of the pine processionary, knowing that the incubation period is 30 to 45 days (Figure 1).

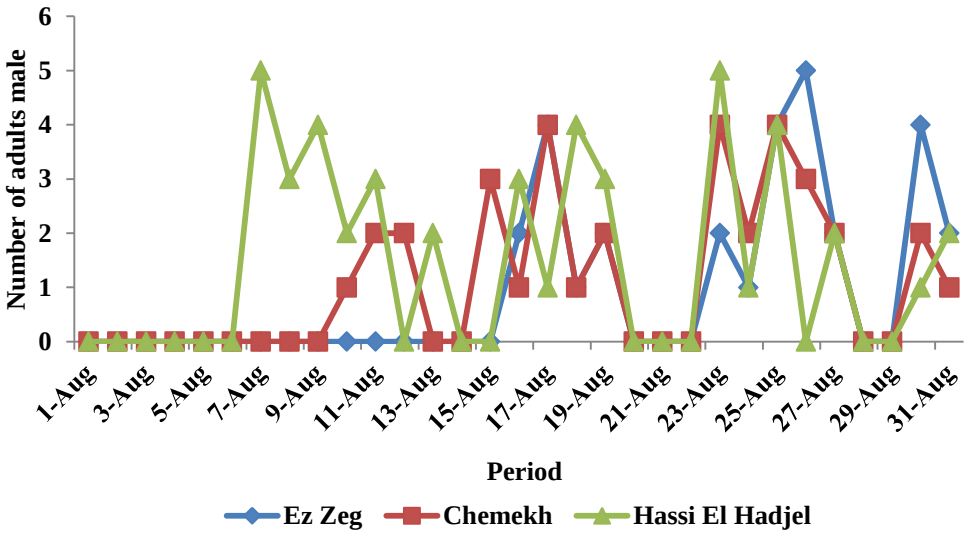

Figure 1: Number of male adults captured by pheromone traps

1.2 Distribution of eggs on trees

The analysis of results obtained on the distribution of layings on trees, shows that most layings are not deposited in a regular and similarly on the trees is especially trees, whose height is 1 to 2m and which are most sought after by processionary for issuing eggs. Indeed, it is at this height, that there is the largest percentage of the presence of laying on trees. Trees from 0 to 1m heights, are less affected (figure 2).

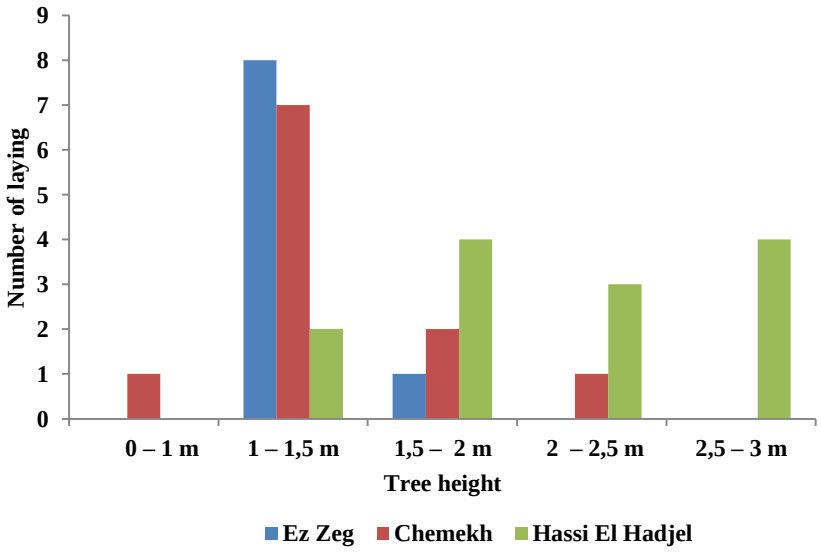

Figure 2: Distribution of eggs *T. pityocampa* according to the tree height

1.3 Hatching of eggs in the laboratory

Hatching of eggs laying in laboratory have started on 2 October 2011. The latest hatching were recorded 18 October 2011. Thus, the mean date of laboratory eggs hatching is recorded between

3 and 19 October for the pundits EzZeg plot, the incubation period of the eggs is from 16 to 25 days.

The hatching of eggs curve observed in the laboratory, Hatching are especially early (2 to 18 October), and it extends over the longest. From Figure 3 of hatching clutches, we can determine the date can be considered treatment.

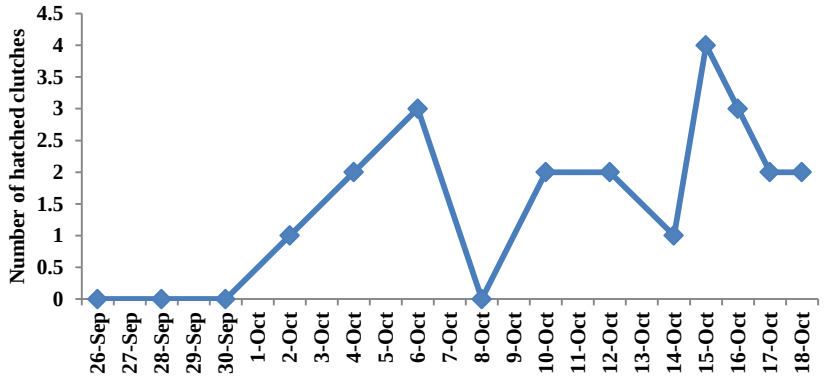

Figure 3: Number of hatched clutches in Ez zeg station

1.3. Dynamics of numbers of nests of *T.pityocampa*

The number of nests is influenced by plots. Most nests were not deposited in a regular and identically in stations. Indeed, a high distribution of nests was obtained in the most infested Chemekh station where the number was between 3-8 nests per tree. By cons, in other stations EzZeg and Hassi El Hadjel we observe the number of nests are between 0-2 respectively for the first station and between 1-4 nests per tree to the second station (figure 4).

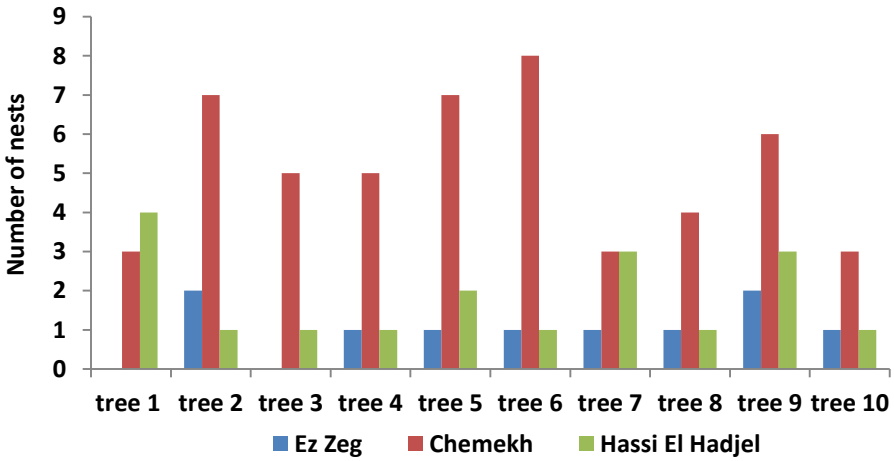

Figure 4: Number of nests in the three study sites

1.4. Dynamics of larval stages of *T.pityocampa*

The beginning of egg hatching were determined directly from the clutches previously taken and kept in the laboratory. The first larvae were observed on 26/09/2010 in Chemekh station, on 29/09/2010 in El Hassi El Hadjel station, and the station Ez 02/10/2010 Zeg. The larval period is dependent on the overwintering period, the average time to development of the larvae, varies from one site to another. Thus, this time in the three plots is 14 days for the 1stinstar larvae, 17

days for 2nd instar larvae, L3 of 31 days for 3rd instar larvae, 82 days for the 4th instar larvae, and 55 days for the 5th instar larvae. It was found that the first two instars have a shorter developpement period. By cons, for the 4th instar larvae, we see a longer developpement period. There is also an overlap between the different larval stages (Figure 5).

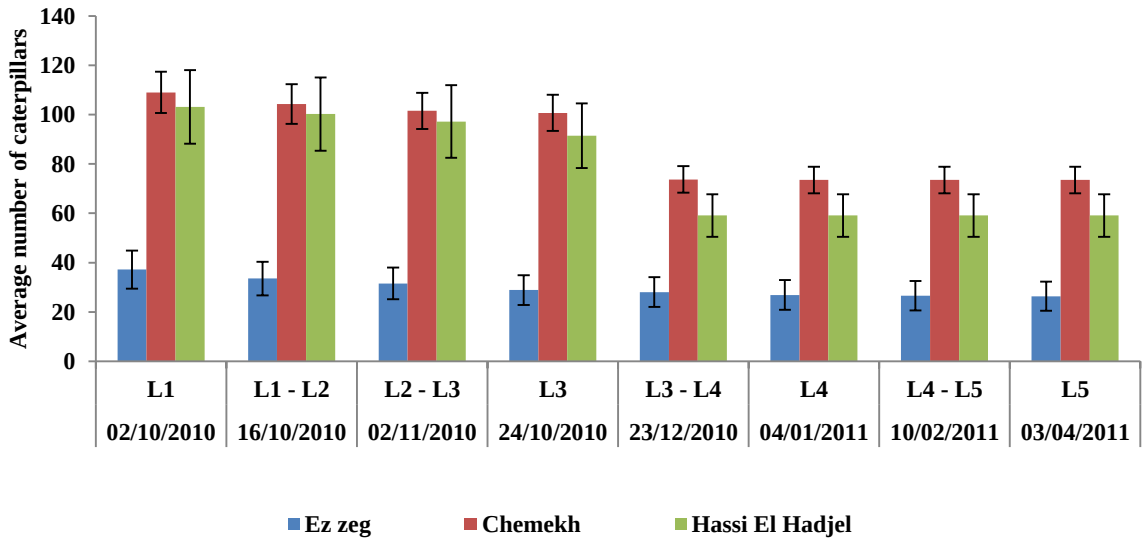

Figure 5: Population dynamics of the different stages of the larvae of *T. pityocampa* in the three plots (EzZeg, Chemekh, Hassi El Hadjel).

2. *Bacillus thuringiensis* effect on mortality of the *T. pityocampa*

2.1. Effect on mortality

The results from different samples showed very low mortality (23.5%dead larvae/nest to Chemekh plot, and 39% dead larvae/nest in Hassi El Hadjel plot). So that the number of live larvae are (73.5% larvae/nest for Chemekh plot and 51.9% larvae/nest for Hassi El Hadjel plot) (Figure 6).

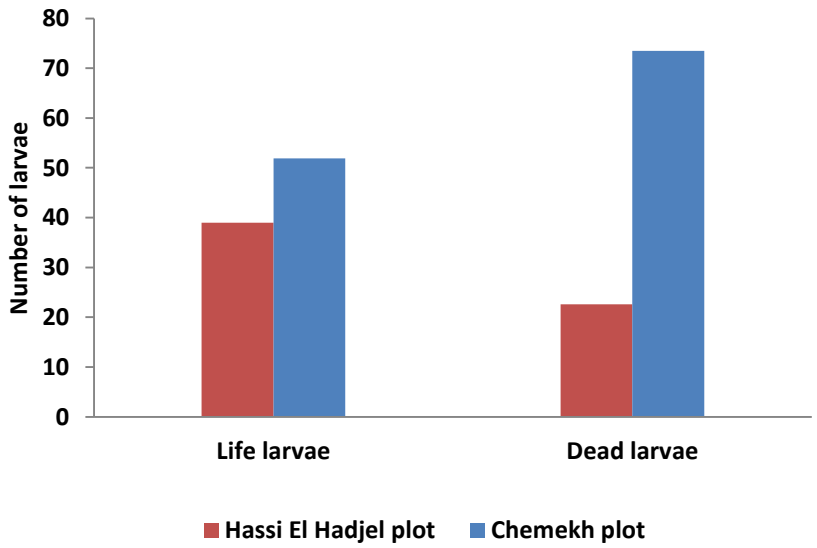

Figure 6: Mortality of larvae of *T.pityocampa* after biological treatment with *Bacillus thuringiensis* at stations Hassi El Hadjel and Chemekh.

2.2. Biometrics treated larvae

In the El HassiHadjel station the weight of live larvae is 0.15 g, while for dead caterpillars is 0.1g. However, By cons, the measurement of the lengths of live and dead caterpillars is almost identical is 2,3cm. But in the station Chemekh we noticed a clear difference in weight between the live and the dead caterpillars (0.5g to 0.1g for live caterpillars and dead caterpillar, respectively) and a variation between the measurement of the lengths of live and dead caterpillars followed respectively 2,7cm to 2,4cm respectively (Figure 7).

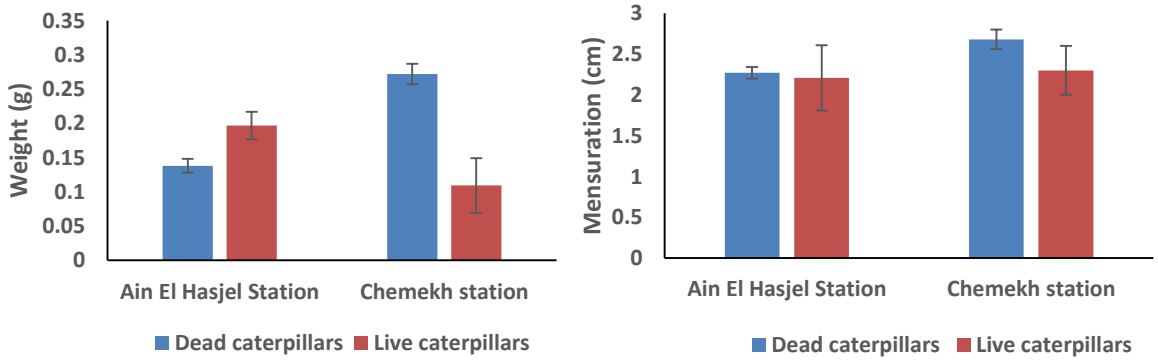

Figure 7: Effect of *Bacillus thuringiensis* on some weight and biometric parameters on track of *T.pityocampa* at Hassi El Hadjel and Chemekh plots).

Discussion

The population dynamics of *T.piytocampa* was studied during the period from July 2010 to July 2011 on the pine forest of Nador (Tiaret). The dynamics of male adult population using pheromone traps started from August in 2010 to 3 plots.

For Hassi el Hadjel plot, the first flight of the adult males was reported during the first decade of August. However, at the Chemekh plot it was recorded from the 10th of this month with a delay of 3 days compared to the first plot.

However, to the station EzZeg, the first flight was reported from 16 August, 9 days from the first station. Indeed, a cumulative of 45 males was recorded for the first station, while it is around 34 and 29 males for Chemekh and EzZeg stations.

The laying distribution of dynamic appears also vary from significantly between stations ($p = 0.000$). It is much more important in the station of Chemekh compared to the other two stations,. This is due to the forest stand that result is much more dense and abundant. Our data appear to be comparable to Zamoum et *al.* (2006) Tortricidae, They found that during spawning, the female may have to encounter in the wild more of its plants hosts "pine and cedar," one after the other. It probably compares sequentially involving a form of short-term memory (Singer, 1986; Courtney et al., 1989).

Many authors (Wiklund, 1981; Thompson & Pellmry, 1991; Singer & Lee, 2000) considers that a preference for hierarchical laying between the various species composing the host range of an insect. It appears that under ideal conditions, many eggs were laid on the preferred species, and fewer eggs on the less preferred species, even fewer eggs on species that occupy a lower rank of preference. Theoretically, this preference laying should be correlated with the performance of the offspring on different host plants. However, in practice this is not always the case (Thompson, 1988; Degen et al., 1999; Cunningham et al., 2001).

Maher (1997), as part of a study on laying the choice of behavior *Lobesia botrana*, was able to establish a range of preferences between the bays of different plants, it also showed that the sensory equipment of the female eudemis has sensory receptors that mediate the role of tasting and mechanoreception in the choice of nesting site in this insect.

In this study it seems to us clearly that there is a difference between the plots studied. So they can be considered as a key criterion for selecting the nesting site. In this context, several hypotheses can be discussed. We can suggest that the increase in infestations of this resort is the result of two complementary attitudes: either the insect estimates the size of the needles, and other abiotic parameters (Zamoum, 1998). These two behaviors reflected that spawning is performed to reduce the competition between future larvae by spreading it according to the biotic and abiotic characteristics.

The review of the number of nests shows that it is relatively high at the Chemekh plot compared to the two other plots where we have counted 58 nests, whereas that of el Hadjel El Hadjel and Ez Zeg are respectively 28 and 18 nests (Demolin 1969 &1988).

The examination of the observed mortality appears to be relatively small compared to the desired results,. This is probably due to the leaching of the biopesticide by rain water that occurred the day of treatment, or the applied dose.

This new possibility of action on the 3^{rd} and 4^{th} instars larvae of *T. pityocampa* by microbiological preparations of *B. thuringiensis kurstasi* (Btk) offers prospects for integrated control against this pest. Indeed, the winter treatments as they were recommended by Demolin (1986) allow to avoid systematic aerial applications and intervene only in infestations while saving a zoocénose inactive at this time the year.

According noticed mortalities during the single *B. thuringiensis* tests are assumed to be due mainly to the effect of the ingestion of the crystals of this bipopesticide containing endotoxin.

Conclusion

The study carried out in Nador forest on pine processionary populations shows that the rate of pest infestation vary greatly from one location to another. It depends on several factors, among others the forest structure and exposure.

On the biology of this insect, the results show that since the emergence to to complete the cycle, we were allowed to distinguish five larval instars. The pupal stage period is 4 months. The duration of each stage was closely related to the action of climatic factors. It was found that *T. pityocampa* causes major damage in the Chemekh station with a total spawning nests 58. The most affected plot is that of the East with a percentage of 57.09% this is due by the presence of all the optimal conditions exist for its development.

One generation per year was obtained. The adult emergence began at 7 August 2010 and was conducted over one month. The egg laying began in late August - early September 2010. Incubation period lasted 30 to 45 days ; hatching occurred during the first decade of October. Damage to leaves increase with larval growth. The caterpillars of the 4th and 5th instars are the most dangerous and cause more damage. The fifth instar larvae, following each other in long, head to tail processions to the end of March and seek out pupation sites in the soil in early of April.

Biocontrol trials *Bacillus thuringiensis* seems to be s promising because C of mortality rates exceeding 32%.

Abstract

The impact of Stomp 33 EC (330 g/l pendimethalin) and Wing P (pendimethalin 250 g/l + dimethenamid P 212.5 g/l) on the vegetative growth of grafted vine cuttings of Bolgar X CO4 variety during their rooting was studied during 2011-2013 at IVE – Pleven (Bulgaria).Comparing the impact of Stomp 33 EC and Wing P, both on the annual weed species, infesting the nurseries, as well as on the grafted vine cuttings, the objective of this study was to establish the applicability of Wing P for maintaining the soil surface in the propagation material production.
The trial was conducted on leached chernozem soil type. The herbicides were introduced once, immediately after planting of the cuttings in the nursery.. Stomp 33 EC and Wing P were introduced in two doses and the trial variants were as follows: V1 Stomp 33 EC (4 l/ha), V2 Stomp 33 EC (6 l/ha), V3 Wing P (4 l/ha), V4 Wing P (6 l/ha) and an untreated, weeded out control - K. The tested herbicides reduced the germination rate in the first ten-day period after treatment. However that effect was overcome and it did not affect negatively the final value of that indicator. Contrary to Wing P, Stomp 33 EC caused specific symptoms of phytotoxicity. It was accounted minimal decrease in the yield of grafted rooted vines. The rate of obtained premium vine propagation material after treatment with Wing P was equal to the manually weeded out control. Stomp 33 EC and Wing P efficiently controlled the available annual weed species except *Solanum nigrum* and *Xanthium strumarium*.

Keywords: *germination, herbicides, phytotoxicity, vine cuttings, vine propagation material*

Introduction

Vine nurseries create optimal conditions for the development of a number of weed species. Their great competitiveness requires continuous development of methods for their control. The proper selection of herbicides and their timely inclusion into the scheme for harmful vegetation integrated control is of great importance. The main objective of the studies in this area is the identification of suitable active substances, combinations and doses that enable not only the soil surface to be maintained, but also to create optimal conditions for the biological processes going on in grapevines. It has been found that pendimethalin (in the form of various commercially available products under the name Stomp) at a dose of 3 – 4 l/ha controlled efficiently the annual gramineous and some broadleaf weeds for at least ten weeks, and may be applied in vineyards both on heavy and light soils (Tucker and Chambers, 1990; Prodanova-Marinova, 2014). In some studies, the efficacy of Stomp 330 EC has reached 98-99% (Sarpe, 2011). Further to weed control in fruit-bearing plantations, studies of IVE - Pleven have demonstrated that pendimethalin was suitable for use in vine nurseries (Prodanova-Marinova, 2012; Prodanova-Marinova et al., 2014). In combination with dimethenamid (Wing P) it was recommended in various crops - maize, sunflower, etc. (Andr et al., 2014; Petcu et al. 2015). However, data on the application of this broad spectrum herbicide in the production of vine planting propagation material have not been available.

Comparing the impact of Stomp 33 EC and Wing P, both on the annual weed species, infesting the nurseries, as well as on the grafted vine cuttings, the objective of this study was to establish the applicability of Wing P for maintaining the soil surface in the propagation material production.

Material and Methods

The trial was carried out for three years (2011 – 2013) at the Institute of Viticulture and Enology – Pleven, Bulgaria. It was studied the efficiency of the herbicides Stomp 33 EC *(330 g/l pendimethalin*) and Wing P *(250 g/l pendimethalin + 212.5 g/l dimetenamid P)* for the annual weed species within the vine nursery. For finding out the effect of both products on the vegetative growth of grafted vine cuttings during their rooting it was used the variety – rootstock combination of Bolgar/Berlandieri x Riparia (CO4). The grafted and stratified cuttings were rooted by the technology adopted by IVE - Pleven (Dimitrova et al., 2007). The herbicides were introduced once, immediately after planting of the cuttings in the nursery. Spraying was carried after the treatment. Stomp 33 EC and Wing P were introduced in two doses and the trial variants were as follows: V1 Stomp 33 EC (4 l/ha), V2 Stomp 33 EC (6 l/ha), V3 Wing P (4 l/ha), V4 Wing P (6 l/ha) and an untreated, weeded out control - K. The trial was conducted on leached chernozem soil type. It was monitored the dynamics of the weed species density (plants/m^2) on the thirtieth, sixtieth and ninetieth day after the treatment and the dynamics of germination of the grafted cuttings (%) to the fiftieth day after their planting in the nursery. The signs of phytotoxic response were determined visually. At the end of the vegetation the yield of standard rooted vines (%) was accounted.
The data were processed by analysis of variance (Dimova and Marinkov, 1999).

Results and Discussion

During the examination of the trial plots throughout the three years of the study it was found eight annual species, representatives of the late spring weeds: red-root amaranth */Amaranthus retroflexus* L./, lamb's quarter /*Chenopodium album* L/., European heliotrope /*Heliotropium europaeum* L./, flower-of-an-hour /*Hibiscus trionum* L./, pigweed /*Portulaca oleracea* L./, hound's berry / *Solanum nigrum* L./, common cocklebur /*Xanthium strumarium* L./ and green foxtail / *Setaria viridis* L./. Table 1 presented the data on their density on the average for the period of the study. Thirty days after the introduction of the herbicides in all treated variants the weed density was significantly lower compared to the control (22.3 plants /m^2) as it was formed only by two species – common cocklebur and hound's berry. It was typical for them that they were not sensitive to pendimethalin (Fetvadzhieva et al., 1986; Tonev, 2000, Tonev et al., 2007).
In the conditions of increased soil moisture typical of the vine nursery, the action of Stomp 33 EC weakened during the second month and apart from those two weed species, on the sixtieth day in V1 and V2 were reported respectively 0.1 plants / m^2 (V1) and 0.5 plants / m^2 (V2) of green foxtail. With Stomp 33 EC at a dose of 4 l/ha it was found presence of 0.1 plants / m^2 of amaranth. In the variants treated with Wing P the density of weeds had also increased (9 times in V3 and 2.7 times in V4), but no changes in the species diversity were observed. The increasing of the weed infestation was due to the rise in the number of common cocklebur and hound's berry.
The persistence of both herbicides was strongly reduced after the sixtieth day of the treatment. Between the second and the third accounting, the weeds density had increased in times, both because of the growing number of the already found species in the plots, as well as because of the germination of the suppressed to that period lamb's quarter (V1, V3 and V4), amaranth (V3 and V4), European heliotrope (V3 and V4) and flower-of-an-hour (V3).

Table 1. Average density of the weeds during the period 2011-2013, (number/ m^2)

Weed species	V1			V2			V3			V4			K		
	30 day	60 day	90 day	30 day	60 day	90 day	30 day	60 day	90 day	30 day	60 day	90 day	30 day	60 day	90 day

Setaria viridis L.	-	0.1	1.2	-	0.5	0.8	-	-	1.2	-	-	0.03	12.1	8.0	0.5
Total:	*1.5*	*2.7*	*4.3*	*1.3*	*2.5*	*3.3*	*0.15*	*1.4*	*2.4*	*0.11*	*0.3*	*1.59*	*22.3*	*13.3*	*2.33*

In the variants treated with Stomp 33 EC (V1 and V2) weed infestation was more significant compared to those treated with Wing P (V3 and V4), however in V3 and V4 the increase of the density to the thirtieth day was greater. The total density in V3 went up from 0.15 to 2.4 plants /m^2, while in V4 - from 0.11 to 1.59 plants / m^2.

In monitoring the dynamics of weed infestation in the control it was seen that due to the cultivation practices, the density of the species decreased from the thirtieth to the ninetieth day. However, in the last accounting the number of weeds per m^2 did not differ significantly from that in the treated variants. The herbicides Stomp 33 EC and Wing P showed good efficiency against the annual species found in the trial plots.

The germination dynamics in the first fifty days after treatment was investigated for finding out the impact of the tested products on the vegetative manifestations of the grafted vine cuttings. The germination ratio was indicative for the cuttings response to the herbicide solution.

The most significant effect of the treatment was observed at the end of the first ten-day period. In all variants it was recorded a decrease in the ratio of germinated shoots compared to the untreated cuttings (57.25%) - Table 2. The most significant impact had Stomp 33 EC at a dose of 6 l/ha (V2). The indicator rate in this variant was the lowest (45.9%) and the analysis of variance showed significant difference from the control. In Wing P the higher dose (6 l/ha - V4) also resulted in a greater reduction in the germination ratio.

Over the next ten-day periods the negative impact of the herbicides was overcome and the ratio was growing smoothly. At the end of the fifth ten-day period the number of germinated cuttings in the treated variants became equal (in V1 and V4) or slightly exceeded (in V2 and V3) that of the control (74.75%). The decrease compared to the recorded rates at the end of the fourth ten-day period was due to the natural dying out of some cuttings with poor bond between the graft and the rootstock and was not caused by the action of the tested herbicides. The differences between the separate treated variants remained unproven in all ten-day periods and did not give reason to be believed that either of both herbicides inhibited the germination of the grafted cuttings to a greater degree than the other one.

Table 2. Germination dynamics of grafted cuttings during the period 2011 -2013, (% with respect to the planted cuttings)

V	Germination (%)						
	I ten-days		II ten-days	III ten-days	IV ten-days	V ten-days

GD - border difference (GD = t.S_D; t - Student criteria; S_D - error of the difference)

It has been shown that pendimethalin in certain doses caused limited manifestations of phytotoxicity on the leaves, both in the grafted cuttings and young vines as well as in adult plants (Beuret and Niggli, 1990; Prodanova - Marinova, 2012). Yellowish spots of irregular shape were clearly visible on the leaf blades that were not found on the stems and shoots. However spotting was relatively weak and soon faded away. In some cases at higher doses it

was observed also deformation of the leaf blade - wrinkling and distortion of the edges. In this study a similar effect was found in the variants treated with Stomp 33 EC of both doses. Thirty days after planting of the cuttings and treatment of the plots it was reported presence of characteristic spots on the leaves, but necrosis and changes in shape were not observed.

The quantity of pendimethalin in Wing P composition was significantly lower (250 g/l) and the cuttings treated with it at doses of 4 and 6 l/ha did not exhibit signs of a phytotoxic response.

The relatively early overcoming of the herbicidal effect of Stomp 33 EC (about the sixtieth day after treatment) allowed the grafted cuttings to continue their development normally and did not result in significant reduction in the quantity and quality of the propagation material.

When analyzing the yield of standard rooted vines all treated variants had lower but close to the result obtained for the control (37.63%) - Fig. 1.

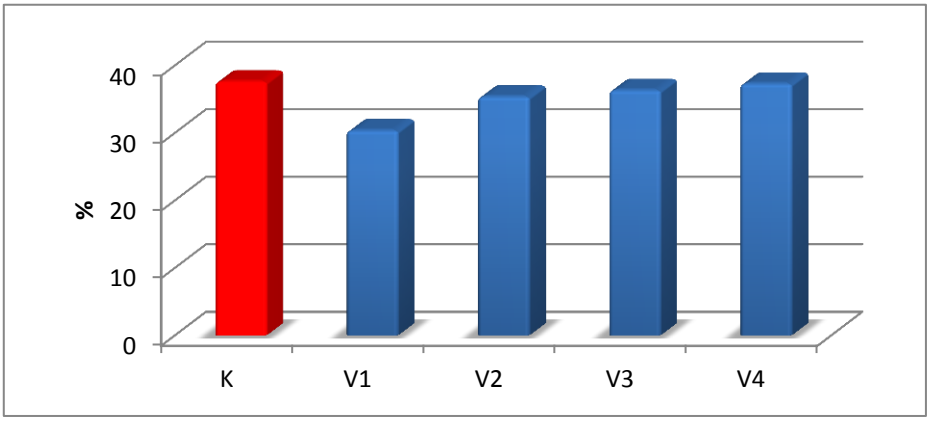

Figure 1. Average yield of rooted grapevines during the period 2011 - 2013 (% with respect to the planted cuttings)

The lowest rate of first-class propagation material throughout the three years of the study was obtained from V1 (Stomp 33 EC at a dose of 4 l/ha) – 30.38%. In the variants treated with Wing P (V3 and V4) the yield was higher compared to those treated with Stomp 33 EC, but the differences were insignificant. The ratio of standard rooted vine in V3 and V4 remained lower than in the control, but the differences were minimal (1.28% in V3 and 0.31% in V4). The analysis of variance did not prove the differences both in relation to the control, and between the separate variants (GD 5% = 10.072; GD 1% = 14.654; GD 0.1% = 22.018).

Conclusions

Stomp 33 EC and Wing P efficiently controlled the present annual weed species except *Solanum nigrum* and *Xanthium strumarium*. Their action decreased after the sixtieth day of treatment and it was determined by the dose of application and the specific soil conditions in the vine nursery.

The tested herbicides reduced the germination rate in the first ten-day period after treatment, however that effect was overcome and it did not affect negatively the final value of that indicator.

Unlike Stomp 33 EC, Wing P did not cause phytotoxic response after falling of the working solution on young shoots and leaves.

The treatment of the grafted cuttings of Bolgar variety with the tested herbicides did not affect significantly the yield of standard rooted vines. The ratio of first-class propagation material obtained after treatment with Wing P was equal to that of the manually weeded out control.

The study results showed that Wing P could be successfully applied for annual weed species control in the vine nursery.

Abstract

The efficacies of the entomopatogenic nematodes (EPN), *Rhabdits blumi*, and the entomopatogenic fungi (EPF), *Beauveria bassiana* as a biocontrol agents were determined for the date palm tree borers, *Oryctes* spp. (Coleoptera: Scarabaidae: Dynastinae) in laboratory and field trials, during 2015 season. Laboratory results demonstrated that direct spray of 1000 infective juveniles (IJs) per mL of *R. blumi* on Arabian Rhinoceros Beetle (ARB), *Oryctes agamemnon arabicus* caused 71.67% and 15% mortality in the larvae adults respectively. Treating the food source of the larvae (pieces of fresh tissue of the frond bases) with the same dose and period resulted in 48.33% mortality in larvae and 10% in the adults. Laboratory results also showed that using concentration 1×10^9 conidia/mL^{-1} of *B. bassiana* as direct spray of the ARB larvae, led to 66.7% and 60% as treatment of the food source. Field experiments results showed that injection of 50 mL per palm tree with a concentration of 1000 IJs/mL of *R. blumi* inflected about 42% mortality in ARB larvae infested the tree. Meanwhile, injection 50 mL of 1×10^9 conidia/mL^{-1} of *B. bassiana* imposed 50% mortality in larvae. Results of this investigation illustrate the possibility of using *R. blumi* and, *B. bassiana* as a bicontrol agents against palm borers in IPM programs.

Key words: *Biocontrol, Endophyta, Palm borers, Oryctes spp.*

Introduction

Palm borers, especially *Oryctes* spp. are considered as an economically important insect pest of date palm trees in Iraq and most adapted to climatic conditions of the region (Khalaf *et al*, 2011; Khalaf, *et al*, 2014). Arabian Rhinoceros Beetle, *Oryctes agamemnon arabicus* caused severe damages to the bases of fronds and bunches making long tunnels inside tissue, which acting as weakening and breaking factors for these parts (Khalaf and Al-Taweel 2015). Entomopathogenic nematode (EPN) and fungi (EPF) have been used to enhance biological control measure of many insect pests (Ehier, 1990; Hazirs *et al*, 2003). France *et al* (2015) reported that the farmers usually based their pest management practices on chemicals pesticides, but the growing restrictions and concerns, encourage the use of microbial control agents, like EPF and EPN. Krell *et al* (2015) mentioned that the endophytic EPF like *Beauveria* spp. or *Metarhizium* spp were used in biological crop protection against many different insects. Eidt and Thurston (1995) and Simoes and Rosa (1996) reported the applications of EPN as a biocontrol agents against many insect pests especially soil insects. In Iraq, EPN *Steinernema* sp. isolated for the first time from the long horn date palm stem borer, *Jebusaea hammeschmidtii* and fruit stalk borer, *Oryctes elegans* in the date palm cultivation areas (Al-Jboory, 2007). Meanwhile Khudhair *et al* (2015) illustrated that the entomopathogenic fungi *Metarhizium anisopliae* and *Beauveria bassiana* were tested against Arabian Rhinoceros Beetle, *Oryctes agamemnon arabicus* larvae, and both were found to be effective. The aims of this study are to investigate the efficacy of EPN, *Rhabdits blumi*, and EPF, *Beauveria bassiana* as endophytic biocontrol agents against palm borers, *Oryctes* spp.

especially ARB, *Oryctes agamemnon arabicus* under laboratory and field conditions in date palm orchards.

Materials and Methods

Collection of Samples

Samples of ARB were collected from severely infested trees in date palm orchards at South of Baghdad. Borer's larvae were collected by using hand collection from tissues of the frond bases. While, adults were collected using light traps that distributed in the orchards during June to August, hence the high peak of adult activity. EPN, *R. blumi* was isolated from collected ARB larvae and reared on wax moth *Galleria mellonella* larvae under laboratory conditions. EPF, *B. bassiana* was isolated from both contaminated tree tissues and infected adult's borer.

Nematode and Fungal identification

EPN identified by Dr. Brian Darby, Nematology Department, University of North Dakota, USA using molecular biology of high quality sequence, and blast-matched them to the NCBI database, which classified the EPN as R. blumi (Personal communication). EPF isolates were identified by pathologist in the Directorate of Agricultural Research using microscopic characteristics which showed that the EPF isolated was B. bassiana.

Oryctes borer culture

O. agamemnon arabicus borer larvae (last instar) were kept in special plastic containers 30×20×22.5 cm supplied with small pieces of frond base tissue. Larvae were reared at 25±2°C, complete darkness and 65% RH. Fresh frond bases pieces were added regularly every two weeks to keep enough fresh food to the larvae. Larvae were kept until used for different experiments.

Experimental Design

The laboratory trials were conducted in Biological Control Dept. of IPM Center. Field trials were conducted in date palm orchard Global positioning system, GPS: latitude 33.12740, longitude 44.82124 located in Almadain district (30km South of Baghdad), planted with mature date palm trees of 25 -30 years old with 6-7 m high and 50 – 55 cm diameter.

Laboratory experiments include using four concentrations (0, 250, 500 and 1000 EJs per ml) of *R. blumi* and one concentration 1×10^{9} conidia/mL^{-1} of *B. bassiana* as direct spray on the larvae or their food (pieces of frond bases tissue). Fresh food pieces were added regularly every two weeks to keep enough fresh food to the larvae. Three replicates, 5 larvae each were used for each treatment as for laboratory experiments. Larval mortalities were counted in all treatments on daily basis through 4 weeks period.

For field experiments, injection of 50 mL solution of EPN 1000 EJs/mL or 1×10^{9} conidia/mL^{-1} of EPF were done through tree trunk using 50 mL syringes after drilling holes with a brad point drill- bit (diameter, 20mm and length, 200mm) 1m above the ground level. Three replicates (trees) were used for each treatment.

Larvae of ARB in trees crown were collected after four weeks of injection EPN or EPF, dead and live larvae were counted in each treatment and kept in plastic containers. In addition, fresh frond bases tissues were collected and healthy larvae of *G. mellonella* were added to test if it contains EPN, *R. blumi* in each treatment. Observations were taken pieces frond bases as a test of transfer EPN by plant tissues in each treatment. Observations were taken after 48, 72, 96 and 120 hr. of treatment. Larval mortalities that infected by EPN and EPF in each treatment were counted. The experimental designs implemented were complete randomized

design and complete randomized block design, and the results were analyzed according to the least significant differences (LSD) using GenStat 3 program.

Results and Discussion

Mortality percentages of ARB larvae after direct spray under laboratory conditions with EPN *R. blumi* revealed that the highest concentration used (1000 EJs/mL) inflect the highest percentage reaching 71.67% after 120 hr., while the lower concentrations of 500 and 250 EJs/ml recorded mortality of 50.0% and 16.67% respectively (table 1). Meanwhile, mortalities reached 38.33%, 46.33% and 48.33% at concentrations of 250, 500 and 1000 EJS/mL respectively in experiments of using treated larval food (table 1). Adult mortality for direct spray and treated food were: 0%, 6.67%, 15.0% and 0%, 5.0%, 10.0% at concentrations 250, 500 and 1000 EJS/mL respectively (table 2). It is obvious from the results above that larvae of ARB were more sensitive to infection by EPN than the adults, and this could be due to that larvae have soft body wall compared to the hard cuticle of adults (Kaya and Gaugler,1997). Moreover, direct spray treatment was more effective than treated food trail.

Field efficacy results (table 3) indicated that the mortality percentage of ARB larvae after direct spray of the tree grown with 1×10^{9} conidia/ml^{-1} of *B. bassiana* spore suspensions reached 66.7 while it reached 60.0% in injection of EPF spore suspension after 4 weeks of treatment.

Table 3 .Effect of direct spray and food treatment of entomopathogenic fungi (EPF) *Beauveria bassiana* as biocontrol agents against palm borer, *Oryctes agamemnon arabicus* larvae under laboratory conditions.

Treatment of EPF, *B. bassiana*	Total of larvae treated	Number of larvae after 28 day		% corrected Mortality
		life	dead	
Control	15	15	0	0.0
Direct spray	15	5	10	66.7
Food Treatment	15	6	9	60.0

LSD at 5% for concentration 11.33

Results in table 4 indicated that the field trials of EPN, *R. blumi* and EPF, *B. bassiana* revealed that trunk injection of 50 mL of each biocontrol agents inflict moderate mortality percentage of 41.7% and 50% among larvae of ARB reaching after 4 weeks in EPN and EPF treatments, respectively.

Table 4. Effect of entomopathogenic nematode (EPN) *Rhbditis blumi* and entomopathogenic fungi (EPF) *Beauveria bassiana* as biocontrol agents against on palm borer, *Oryctes agamemnon arabicus* larvae under field conditions.

Treatment (Trunk injection)	Number of larvae per three trees (in tree crown only)			
	Before treatment	After 4 weeks of treatment		%corrected mortality
		Live	dead	
control	20	20	0	0
50 mL per tree of EPN	12	7	5	41.7
50 mL per tree of EPF	10	5	5	50.0

LSD at 5% for treatment 8.01

The present results revealed that there was an acceptable efficacy of applying either of the two biocontrol agents, isolated locally from Iraqi date palm orchards ecosystem, EPN *R. blumi* and EPF *B. bassiana* reflected by the reducing survival percentage of ARB, *O. agamemnon arabicus* larvae and adults under laboratory and field trials. In addition, results indicated that the EPN and EPF solution could translocated through date palm tissue after injection. Ricaño *et al.* (2013) found that using more than one formula of *B. bassiana* can remarkably reduce survival and increase mortality rate among red palm weevil, *Rhynchophorus ferrugineus* larvae and adults. Abbas and Mahmoud (2009) reported that IJs of EPN, *Steinernema riobrave* caused 44-100% mortality in third instar larvae of *O. agamemnon* under laboratory conditions, and 33 – 78% mortality when applied to soil of fig orchard. Yang et al. (1993) have been successfully controlled banana weevil by injecting EPN suspensions directly into borer holes. In addition to the most common application method for EPN is to use the same type of equipments used for spraying chemical pesticides, nematodes could be applied to target site with most commercially available spray equipment such as hand or ground sprayers, mist blowers and aerial sprayers on helicopters (Georgis *et al*. 1995).

Conclusions

The results of this investigation depicted the possibility of using EPN, *R. blumi* and EPF, *B. bassiana* as effective biocontrol agents against ARB, *O. agamemnon arabicus* and probably to other palm borers species in date palm orchards either by direct spray or trunk injection through IPM program.

ANTITERMITIC ACTIVITIES OF PINUS ROXBURGHII WOOD EXTRACTIVES AGAINSTHETEROTERMES INDICOLA (WASMANN) (ISOPTERA: RHINOTERMITIDAE)

Babar HASSAN[1]*, Sohail AHMED[1], Muhammad MISBAH-UL-HAQ[2], Mark E. MANKOWSKI[3], Nasir MEHMOOD[1]

Abstract

Pinus roxburghii Sargheart wood extractives were examined for antitermitic activities against *Heterotermes indicola* (WASMANN). Heart wood extractives were removed from wood shavings by Soxhlet extraction by using ethanol: toluene(2:1)as the solvent system. Filter paper bioassay was conducted too bserve concentration dependent feeding response and mortality of termites. Results indicated that the highest termite mortality was occurred at 10 mg/ml with an LC_{50} at 6.48 mg/ml. *P. roxburghii* extractives showed maximum repellent activity after 12 hours of exposure of termites at the highest concentration (10 mg/ml). In choice and no-choice feeding bioassays with extracted and un-extracted *P. roxburghii* wood blocks, increased wood loss due to termite feeding was observed on extracted blocks compared to un-extracted blocks. More number of termites were found dead after feeding on un-extracted blocks compared to extracted blocks. Results also disclosed that extractives from *P. roxburghii* imparted resistance to vacuum-pressure treated Southern pine (SYP, *Pinus taeda* L.) and Cottonwood (CW, *Populusdeltoides*W. Bartram ex Marshall) against *H. indicola*.The results of this study indicate thatextractivesfrom *P. roxburghii* may be potentially useful in the development of environment-friendly termiticides.

Keywords:*Pinus roxburghii**,extractives,antitermitic,Heterotermes indicola, repellant*

Introduction

Heterotermes indicola (Wasmann) is considered akey termite pest species in South East Asia. It is a very common wood destroying termite, predominantly in zones north of 20°N latitude which comprises India, Pakistan, and Afghanistan (Maiti, 2006). In addition to causing substantial damage to wooden structures in houses, this species is also described to abolish paper, clothes and other stored products with cellulosic constituents. These termites feed internally within the wood but leave an outer shell intact to protect them from desiccation. In domestic infestations, termites create galleries which can be seen running along walls and ceilings to reach wooden materials (Roonwal and Chhottani, 1989). Out of 50 described species known to occur in Pakistan, 11 have been recorded damaging man-made wooden structures (Akhtar, 1983). One of the most important termites in urban and rural areas of Pakistan is *H. indicola*, which is extensively distributed throughout Pakistan (Sheikh et al., 2008).

Susceptible woods that are vulnerable to termite attack are usually well-preserved with synthetic chemicals/preservatives (Evans, 2003). These man-made compounds are expensive and often detrimental to the workers and the environment. This has impelled an increased interest in finding less toxic alternatives to wood protection use (Asamoah et al., 2011). The heartwood of numerous tree species has been publicized to be impervious to deprivation by biological agents, including fungi and termites. This opposition/resistance, or durability, is

mostly due to the accumulation of non-structural components/extractives in the heartwood (Kityo and Plumptre, 1997). Several studies have shown that after elimination of extractives, resistant/durable wood loses its natural resistance and makes them more prone to decay (Oliveira et al., 2010, and Kirker et al., 2013). Organically based wood extractives have a presumably less health risks and are very easy to depollute and dispose of without impairing the environment (Chen et al., 2004; Kirker et al., 2013). The practice of treating wood with natural extractives for the controlling of termites has been formerly studied. By eliminating extractives from a resistant wood species the durability could be relocated and distributed more uniformly into a non-durable species, such as southern yellow pine or cottonwood. It has been stated that the extractives exhibit toxicity and repellency against many species of termites (Dungani et al., 2012; Kirker et al., 2013; Kadir et al., 2014; Hassan et al., 2016).

In the current study, extractives of *Pinus roxburghii* Sarg were usedto treat two non-durable wood species, Southern Yellow Pine (SYP, *Pinus taeda* L.) and cottonwood (CW, *Populusdeltoides*), and resistance against termite feeding were evaluated. Previous studies have indicated that the extractives of *P. roxburghii* contains α-pinene, longifolene, β-pinene, car-3-ene and careen (Kaushik et al., 2010). *P. roxburghii* Sarg is a staple wood species in Pakistan.It commonly found at lower elevations (500-2000m) than other pines in the Himalaya. *P. roxburghii* named after William Roxburgh is a native pine to the Himalaya. The range of this pine extends from northern Pakistan (North-West Frontier Province, Azad Kashmir), across northern India and Nepal to Bhutan. It has wide-ranging uses including building material, heating and has published medicinal value (Tewari, 1994). Though*P. roxburghii* is documented as non-resistant (class IV) to decay (Scheffer and Morrell, 1998) extractive of this species have been found to have medicinal and antibacterial properties. Heartwood extractives of *P. roxburghii* have been described to contain abietic acid, longifolene and low levels of several stilbenes which are known to have antifeedant activity against termites (Shuaib et al., 2013; Morimoto et al., 2006). The present work addresses the potential use of *P. roxburghii* heartwood extractives in improving the termite resistance property of southern pine and cottonwood.

Materials and Methods

Wood Material and Preparation of Extractives

Logs of*P. roxburghii* were obtained from the Timber Market located at Faisalabad, Pakistan. After air drying inUSDA-FS Forest Products Laboratory, Starkville, Mississippi (USA), logs of *P. roxburghii*, southern pine, and cottonwood were cut into large boards from and evened with a planer then cut into 19×19×19 mm blocks. Shavings from this process were used for the preparation of extractives. Air dried wood shavings were soxhlet extracted using 300 ml of ethanol: toluene (2:1) as a solvent according to ASTM D1105-96 "Standard Test Method for Preparation of Extractive-Free Wood" with minor modifications (ASTM, 2015). Shavings (12 g) were added to soxhlets with a small amount of cotton placed below and above, to contain the shavings, and extracted for a total of six hours. The resulting aliquot was evaporated under reduced pressure using a rotary evaporator (BUCHI, Rotavapor R-114) and extraction yield was calculated per gram of wood shavings. Extractives were then prepared in stock solutions (100 mg/ml) and stored in small vials at 4°C.

Preparation of Extractive-Free Wood

Heartwood blocks of P. roxburghii were extracted according to ASTM D1105-96 with the following modifications. Conditioned blocks (33°C, 62±3%) were numbered and weighed before being placed in the soxhlets and extracted for six hours using ethanol: toluene (2:1). Blocks were then washed with alcohol to remove excess toluene and secondarily extracted for

six hours in ethanol (95%) alone. Ethanol-extracted blocks were air dried overnight and then boiled for six hours with 3L of distilled water and water was changed after every hour.

Toxicity and Repellency against Termites

Tests against *H. indicola* were conducted in NIFA (Nuclear Institute for Food and Agriculture) Peshawar, Pakistan. Oven dried (60°C) and weighed Whatman No. 1 filter paper (42.5 mm diameter) was treated with five different concentrations (1.25, 2.5, 5.0, 7.5, and 10.0 mg/ml) of extractives.Concentrations were prepared from stock solution using ethanol: toluene as a solvent and 200 µlof this solution was applied to each filter paper. Treatments were done in triplicate along with control treatment, which was treated with ethanol: toluene alone.A total of50 worker termites (laboratory maintained) were released into jars containing 20 grams of sand, 3.6ml water and treated filter papers, and maintained in an incubator at 27°C and 75% RH for 15 days. At the end of the test, termite mortality was calculated by counting the number of live termites.ImageJ software (Developed by Wayne Rasband, Bethesda, Maryland) was used to calculate the area of filter paper consumed by the termites.

For repellency tests, the method outlined by Kadir et al. (2014) was used. Assessment of repellency was performed after 1, 2, 3, 4 and 12 h by counting some termites on treated and untreated filter paper. The following formula was used to calculate percent repellency:

Repellency (%) = (Nc - Nt)/ (Nc + Nt) × 100, where

Nc is the number of termites in control

Nt is the number of termites on the treated filter paper.

Antifeedant indices were determined by weight loss of the filter paper (Absolute coefficient of antifeedant (A), which was calculated using following formula:

A (%) = [(KK - EE)/ (KK + EE)] x 100, where

KK is the weight loss of the filter paper in the control treatments

EE is the weight loss of the treated filter paper. All treatments were divided into four classes according to antifeedant values(Dungani et al., 2012).

Choice and No Choice Test on Extractive-Free Wood

Extracted and un-extracted *P. roxburghii* heartwood blocks were subjected to choice and no-choice feeding tests according to a modified AWPA E1-15 standard (AWPA 2015). Screw top jars were filled with 150 grams sand along with 27 ml distilled water and held for two hours to equilibrate. For the nochoice test, extracted and un-extracted blocks were conditioned (33°C, 62±3%), weighed and placed on top of the damp sand with one block in each jar. For the choice test, each jar received one extracted and one un-extracted block. The experiment was replicated five times. A total of 400 termites (396 workers and 4 soldiers) were released in each jar and jars were kept in the conditioning chamber at 27°C and 75±2% relative humidity for 28 days. After four weeks, the number of live termites were counted. Blocks were brushed to remove sand, conditioned for one week, and re-weighed to determine weight loss. All blocks were rated visually using 0-10 scale as described in the AWPA standard.

Transfer of Durability Test

Weighed and conditioned (33°C, 62 ± 3% R.H.) SYP and CW sapwood blocks (19×19×19 mm) were pressure treated with different concentrations (2.5, 5 and 10 mg/ml) of *P. roxburghii* extractive. For controls, blocks were treated with solvent only (ethanol: toluene) or water. Blocks were pressure treated by placing five blocks in a 300 ml beaker containing the treatment solution in a vacuum-pressure chamber. Blocks were held under vacuum for 30 min and after that pressure was applied at 40 psi for 60 min. After pressure treatment, blocks were blotted dry using paper towels, weighed, and re-conditioned at 33°C and 62±3% RH.

A termite bioassay was conducted according to a modified AWPA E1-15 (AWPA, 2015). Modifications were the test block size of 19×19×19 mm and the amount of water added was27ml.Screw top jars were filled with 150 grams sand along with 27 ml distilled water and left for two hours to equilibrate. After two hours, treated and control blocks were added to the jars so that each jar received only a single block. All treatments were replicated five times. A total of400 termites (396 workers + 4 soldiers) were then added to each jar, and jars were placed in the conditioning room at 27°C and 75±2 %R.H. for 28 days. After four weeks, the number of live termites was counted. Test blocks were brushed to remove sand and conditioned for one week before being re-weighed to determine weight loss. All blocks were rated visually using 0-10scale as described in the AWPA standard.

Results and Discussion

Termite mortality is one clue of antitermitic activity of extractives. Mortality of *H. indicola* was reliant on concentrations of *P. roxburghii* heartwood extractives (Fig. 1). All treatments were considerably different from one another (F= 13.44; p < 0.005; df= 6).). *P. roxburghii* heartwood extractives showed antitermitic activity with an LC_{50} of 6.48 mg/ml (n=50; χ^2 =1.74; Slope ±SE = 2.53 ± 0.17; FL 95% = 6.15- 6.83) after 15 days of exposure. Maximum mortality was 80 % at the highest extractive concentration (10 mg/ml), while 10.8 % mortality was found at the lowest extractive concentration (2.5 mg/ml). The percentage of filter paper consumed was found to be lower in treated filter paper groups than the controls and results showed a strong correlation between the amount of filter paper consumption and termite mortality. Overall, all treatments were significantly different from the control treatments (F=4.63; P< 0.005; df= 6).

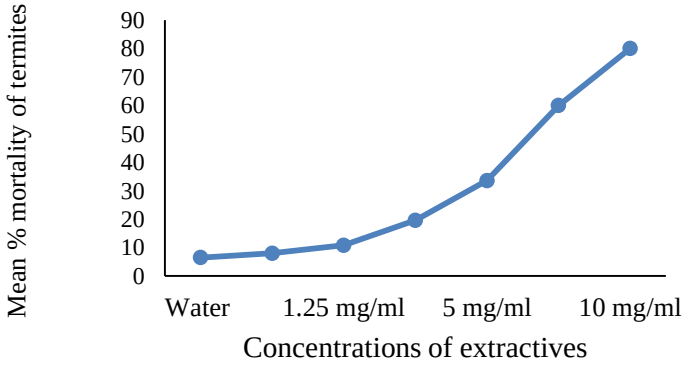

Fig. 1.Effect of different concentrations of *P. roxburghii* extractives on mortality of *H. indicola*

A similar trend was also found between mortality of termites and percent weight loss of filter paper. Minimum weight loss (3.67%) was found at the highest concentration (10 mg/ml) where there was maximum termite mortality (Fig. 2). While maximum weight loss was observed on the control filter paper which was treated with solvent and water.

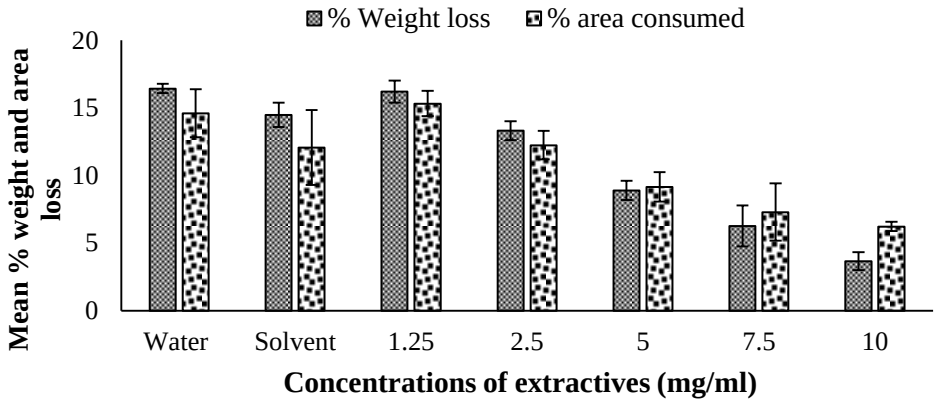

Fig. 2. Consumption (%) and weight loss (%) of filter paper treated with different concentrations of *P. roxburghii* extractives after 15 days exposure to termites

These results were similar to González et al. (2013) who found concentration dependent mortality and feeding rate of dry wood termites using aqueous extracts of *Enterolobium cyclocarpu*m(Jacq.).They found a six-fold reduction in consumption of treated filter paper (10 mg/ml) compared to the control treatment (0 mg/ml).Several other researchers have found dose-dependent mortality of termites after feeding on extractive treated filter paper against *Incisitermesmarginipennis* Latreille, *Coptotermesgestroi*(Wasmann) and *Coptotermescurvi-gnathus* Holmgren (González et al., 2013; Se Golpayeganiet al., 2014; Kadir et al., 2014; Hassan et al., 2016).

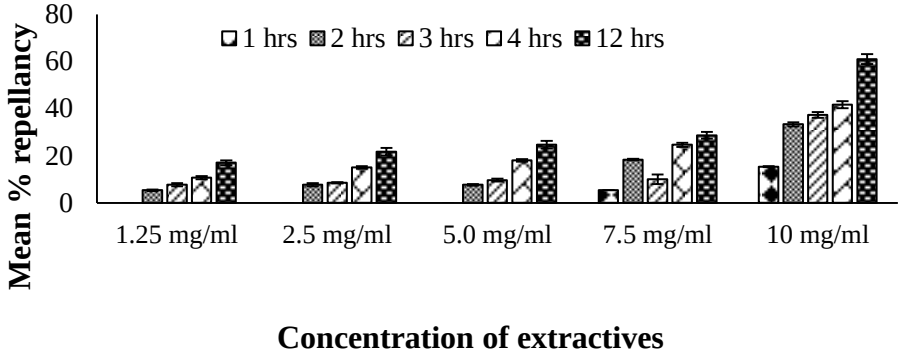

Fig. 3. Repellent activity of *P. roxburghii* heartwood extractives against *H. Indicola*

To determine the repellent properties of *P. roxburghii* heartwood extractives, a simple laboratory experiment was setup using similar methods to other repellency studies (Smith, 1979; Sharma et al., 1994). In this experiment heartwood, extractives did not show any repellent activities at lower concentrations even after 12 hours(Fig. 3). Maximum repellent activity was observed after 12 hours at highest concentrations. At the highest concentration (10 mg/ml) 61% of termites were repelled towards control filter paper section compared to lowest concentrations after 12 hours. There is no published literature on repellent activities of heartwood extractives of *P. roxburghii* except Pinus oil against the mosquito. The antifeedant activity of extractives obtained from *P. roxburghii* was 2 to 63% which was similar to an earlier study on Purkwakarta teak extracts (Dungani et al., 2012). The concentration of extractive is a vital factor for termite mortality and antifeedant (Dungani et al., 2012). This was most likely due to the presence of some phenolics compounds (Asima Chatterjee et al., 1977) in wood which are strong antioxidants (Kaushik et al.,2010; Salem et al., 2014) /

antifeedants. These compounds also act as natural protectants for the living tree (Ates et al., 2015).
The results of bioassays on un-extracted and extractive-free wood of *P. roxburghii* were examined by percent wood consumption and termite mortality (Fig. 4 a, b)

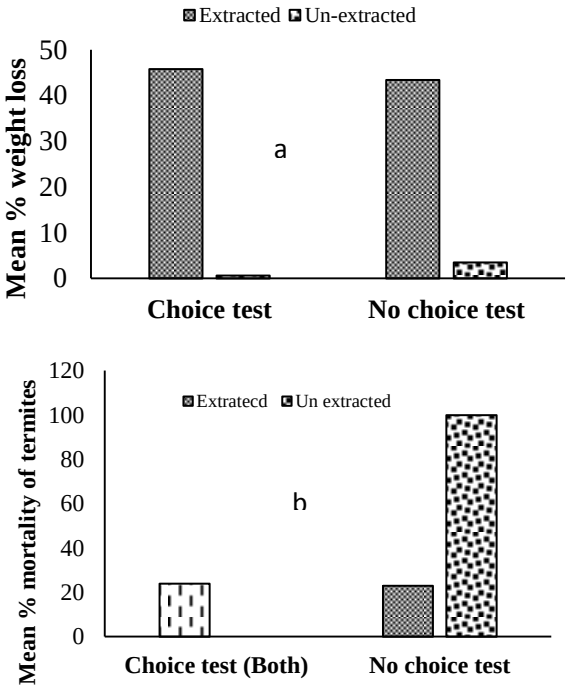

Fig 4 a, bMean percent weight loss (a) and termite mortality (b) in choice and no-choice bioassay on un-extracted and extractive-free wood.

In the choice test, termites ignored the un-extracted block and consumed more of the extracted block (45.77%), while in the no-choice test weight losses for extracted blocks were almost similar (43%) to the choice test. In the case of un-extracted blocks, consumption was less than 1% in case of the choice test while under no choice test consumption of un-extracted wood was 3.5% after 28 days.All termites were dead in the no-choice test with un-extracted blocks, while in the case of the extracted blocks, mortality was 22.9 % which was similar to the choice test where both extracted and unextracted blocks were offered to termites.
P. roxburghii heartwood extractives were lethal to termites at each concentration and caused 100 % mortality of *H. indicola* at maximum concentration (10 mg/ml) after feeding on treated SYP. At lowest concentration-mortality was 54% (F=5.84, $P < 0.05$). A similar trend of mortality of termites was found after feeding on Cottonwood. At maximum concentration (10 mg/ml) there was maximum (81%) mortality of termites while at minimum concentrations there was less number of termites found dead in the jars (Fig. 5).

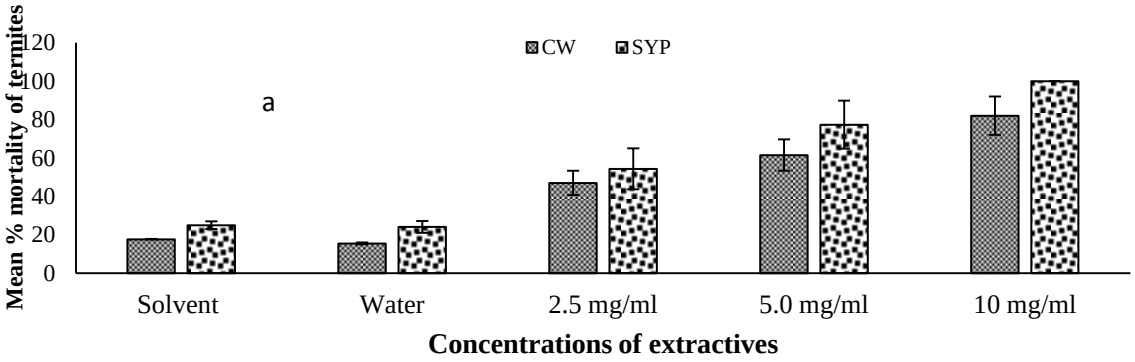

Fig. 5.Mean percentage mortality of termites after feeding on vacuum-impregnated SYP and CW blocks at 3 concentrations (mg/ml) of *P. roxburghii* extractives

All treatments differed significantly from each other and also from control treatments (F=4.44, P<0.05). Average weight loss of treated and untreated SYP and Cottonwood exposed to *H. indicola* is shown in Fig. 6. Solvent and water treated SYP controls lost 28 and 25% respectively, while cottonwood showed a weight loss of 42.5 and 42.2% respectively for solvent and water treated blocks

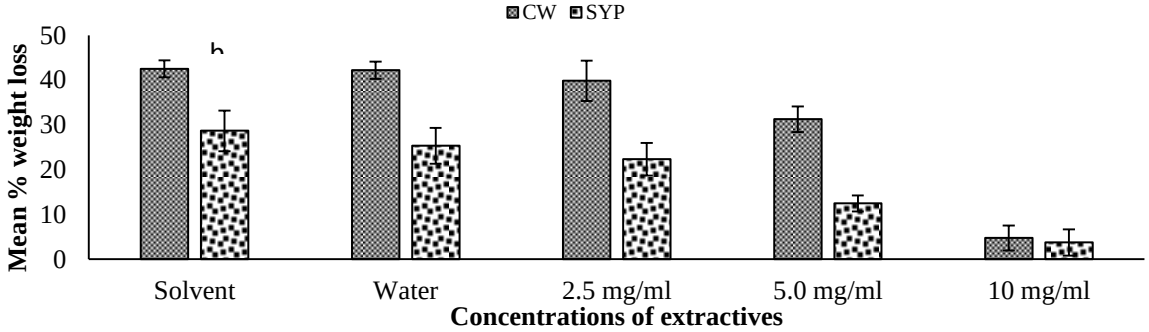

Fig. 6.Mean percentage weight loss of SYP and CW blocks vacuum impregnated with *P. roxburghii* extractives after termites feeding.

Conversely, SYP and CW treated with *P. roxburghii* extractives showed minimum weight loss (3.76 and 4.75% respectively) at the highest concentration (10 mg/ml). Weight loss was found to be inversely related to the extractive levels. Weight loss of control treatments of SYP was statistically higher than all other treatments (F =53.08; *df* 4, 20; P< 0.005). A similar trend was found in Cottonwood (F= 142.03; *df* 4, 20; P< 0.005). Results from the current study are comparable to that reported by Yamaguchi *et al.* (2002) who found the treatment of sugi with mimosa tannin had lower weight loss and higher termite mortality. Similar results were also found by Tasciogluet al. (2012) who saw minimum feeding with highest mortality of termites for mimosa and quebracho extract-treated Scots pine at a 12% concentration level. Our results were also similar to Agatha et al. (2012) who found extractives from *Miliciaexcelsa*, *Albiziacoriaria* and *Markhamialutea* can increase termite resistance of susceptible woods up to 50% compared to control treatment.

Conclusion

Heartwood of *P. roxburghii* extracted with ethanol: toluene (2:1) yielded 7.40 % extractives. The results of this study showed a positive relationship between extractive contents and the resistance of termite which strongly proposes that these extractives can play a significant role in protecting not-durable woods from feeding by the subterranean termites. Moreover, this

also specifies that the durability can be relocated from a durable to a non-durable wood species. The maximum concentration was very efficient on both non-durable kinds of wood. Field trials of SYP and CW sapwood treated with *P. roxburghii* extractives are now under way

Abstract

The aim of this study was to determine the effect of storage and time intervals on fatty acid composiotion of seeds of some promising genotypes belonging to different rose species. Study was carried out in research and treatment area of Horticultural Department of the Agricultural Faculty of the Gaziosmanpaşa University (Tokat/Turkey). Seeds of *Rosa dumalis, R. canina* and *R. villosa* rose hip species that selected as promising for domestication were used in the experiment. Mature fruits of rose hip genotypes were harvested then part of them dried and stored in dark room (20°C) and the other part of them stored in deep freezing (-20°C) conditions as fresh fruit. Fatty acid composiotion of the seeds of the species were analyzed three-month intervals during the full year. As a result; some changes occurred in fatty acids profile during storage period depending on species but it could not be determined any significant change depending on the storage media. Oleic, linoleic and linolenic acid contents were higher when compared to others in all the genotypes. However; it has been generally concluded that the protection methods do not have any important impact on the change of fatty acid ratios.

Key Words: *Rosa, fatty acid profile, dumalis, canina, villosa.*

Introduction

Another component of rose hip fruit needed to be utilized beside its pulp is its seeds. The seeds of rose hip constitute 30-40% of the weight of the fresh fruit. The seeds being removed away from the fruit in the process of retention are usually processed as waste product. However, the seeds of rose hip with fatty acids and other components they include both could be processed in the cosmetic industry and also be valued by being added into the feed of bovine and ovine as well as chicken (Nichita *et al*., 1981; Macit *et al*., 2003). In the process of storage, the change in the content of fatty acids of the seeds has importance in terms of cosmetics and nutritional value. Specifying of the chemical contents of the seeds of rose hip in parallel with the storage form and the storage process may contribute to more effective usage for different purposes. The essential fatty acids of the seeds of rose hip are linolenic, linoleic, oleic, stearic and palmitic acids. The fatty acid composition of the fat of the seeds of rose hip, showing change depending upon different factors, is generally in the proportion of 50% linoleic, 20% oleic, 15% linolenic, 6% palmitic, and 5% stearic acid (Ozcan, 2002; Ercisli *et al*., 2007; Celik *et al*., 2010a). Of these fatty acids, linoleic, linolenic, and oleic acids are unsaturated whereas palmitic and stearic ones are saturated fatty acids. It has been detected in a study conducted to determine the contents of fat and fatty acids of some species of rose hip belonging to the group '*Caninea*' naturally growing in Poland that the results are quite different from each other; the average content of fat changes from 2,9% (*Rosa tomentosa*) to 5.9%. It has been determined that the fat of rose hip is high (59.5%) in terms of unsaturated fatty acids (PUFA), and is also low (0,3%) in terms of erucic acid. It has been detected that there is a strong correlation between the amount of erucic acid and linoleic acid (Adamczak *et al*., 2011).

Rose hip cannot be processed immediately due to two important reasons. The first reason is the obligation of protection by freezing or drying in the period until the food factories or plants processing rose hip process their other raw materials. The second reason is that the substance of pectin existent in body of the fruit of rose hip causes to a more homogenous fracture after freezing and the attainment of

a more consistent product material. The reason for the mentioned consistency is due to the fact that a part of the cell juice is separated from the fruit after freezing and dissolution of the cell wall.
The main purpose of this study planned by taking into consideration the reasons for keeping the rose hip before processing is to determine the impact of drying rose hip in open air and storing it in deep freeze on the change of the fatty acid contents of its kernels.

Material and Methods

The study material consists of the seeds of hopeful genotypes belonging to the species of *Rosa dumalis* (MR-15), *Rosa canina* (MR-26) and *Rosa villosa* (MR-84) whose garden has been established in the research and implementation area at the Department of Horticulture of the Faculty of Agriculture (Gaziosmanpasa University) selected as the hopeful rose hip genotypes as a result of the study called "A Research on the Improvement of the Rose Hips (*Rosa spp.*) by Selection and Propagation With Cuttings, Wild Growing in Tokat Province" (Gunes, 1997). The study and implementation area of the Department of Horticulture of the Faculty of Agriculture (Gaziosmanpasa University) takes place in the city of Tokat (Turkey), campus of Tasliciftlik, in the northern latitude of +40° 20' 1.91" and in the eastern longitude of +36° 28' 38.44". The rose hip garden formed by the hopeful genotypes was established in 2000. The soil on which the garden was established has a slightly alkaline body. Genotypes were reproduced with cuttings, 3 plants belonging to each genotype were planted on condition that the order distance will be 3x3 m or more in the parcel. The garden was watered with drip irrigation system. The plants are regularly pruned in every year in January-February. No special breeding system has been applied in pruning; it has been carried out by combing out the branches which exceeded the pit, which was dry, which was competing with others and which had diseases. The garden was manured with farm and commercial manures in the establishment stage and in next years. The plants were disinfected with chemical struggle drugs in certain periods against the diseases, pesticides and especially the fruit worms every year.
Analysis has been made with the purpose of determining the phytochemical changes occurring during the conservation of rose hip genotypes by being frozen in deep freezer and dried in shadow environment under room conditions.
Fresh fruit samples having reached the technological crop maturation in rose hip genotypes have been taken and stored until the time of analysis as a part of them under dark ambiance conditions at 20±2 °C by drying in shadow environment and the other part in the deep freezer at -18 °C. The analysis of fresh, frozen and dried fruits has been conducted for five times with the interval of three months. Analysis has three replications and the seeds of 20 fruits have been extracted in each replication and the analysis of fatty acids has been conducted.
The samples have been weighed as 5 grams and extracted with 10 ml hexane for 24 hours of duration in order to determine the fatty acid constituents of rose hip seed. At the end of this duration, the extract has been drained with vile filter paper and the filtrate has been evaporated at 40 °C. The obtained fatty has been kept at +4 °C till the analysis by being transferred to storage bottles of 5 mL.
The composition of fixed fatty acids has been done according to the method summarized in Turkekul *et al*., (2006). Briefly, 30 mg has been weighed from the obtained fatty and it has been vortexed for 3 minutes by adding 1 M KOH solution prepared in 3 mL methanol. After waiting for 5-10 minutes in ambience conditions for the phases to separate, 1 mL hexane has been added and then analyzed with GC-FID directly after 0,5 mL has been taken from the supernatant. The proportion of each constituent in the fatty has been identified by the ratio of peak area. HP- innovax column as column 30m x 0,32 mm ID x 0.25µm film thickness), helium as carrier gas and FID as dedector (if needed MS) have been utilized. In the determination of fatty acids, standard fatty acids composition (*Supelco* 37 Component *FAME Mix*, 47885-U) .

The attained data have been exposed to statistical analysis in SPSS 15.0 as three replications. The differences between the averages in the variance analysis for the applications have been detected in %5 level ($P<0.05$). The differences between the attained averages have been determined with Duncan multiple comparisons.

Results and Discussion

In the study; the analyses of the fatty acid contents of the fruits stored by freezing and drying have been conducted with the interval of three months during a year and they have been examined. As a result of the conducted analyses, the data belonging to the fatty acid ratios of the rose hip genotypes attained under various storage conditions and periods are submitted in Table 1, Table 2 and Table 3.

Linoleic acid has been determined as 48.74% and oleic acid has been determined as 39.40% in *Rosa dumalis*. While the ratio of oleic acid decreases depending on time, linoleic acid has increased. Both acid ratioss have been found statistically important. Linolenic acid ratio has been determined between 13.60-19.40%, palmitic acid ratio has been determined between 3.47-8.44%, stearic acid ratio has been determined between 1.98-4.02%, arachidic acid ratio has been determined between 0.20-1.18%; cis-11.14-eicosadienoic acid ratio has been determined between 0.16-0.61%, benenic acid ratio has been determined between 0.01-0,25% and lignoseric acid ratio has been determined between 0.01-023% and they have been found statistically important (Table 1).

As it is in *Rosa dumalis*; oleic acid (40.33%) and linoleic acid (46.75%) have been attained in the highest ratio in *Rosa canina*. While the oleic acid ratio decreases depending on time when compared to fresh seed, linoleic acid ratio has increased depending on time. Both acid ratioss have shown changes depending on time and this change have been found statistically important. Linolenic acid ratio has been determined between 11.79-14.25%, palmitic acid ratio has been determined between 3.70-9.21%, stearic acid ratio has been determined between 2.03-4.98%, arachidic acid ratio has been determined between 0.12-1.54%; cis-11.14-eicosadienoic acid ratio has been determined between 0.10-0.55%, benenic acid ratio has been determined between 0.01-0.20% and lignoseric acid ratio has been determined between 0.01-0.32% and they have been found statistically important (Table 2).

As it is in the other two species; oleic acid (38.19%) and linoleic acid (53.72%) have been attained in the highest ratio in *Rosa canina*. While the oleic acid ratio decreases depending on time when compared to fresh seed, linoleic acid ratio has increased depending on time. Both acid ratios have shown changes depending on time and this change have been found statistically important. Linolenic acid ratio has been determined between 13.04-17.30%, palmitic acid ratio has been determined between 3.59-5.59%, stearic acid ratio has been determined between 1.92-3.18%, arachidic acid ratio has been determined between 0.18-1,03%; cis-11.14-eicosadienoic acid ratio has been determined between 0.08-0.56%, benenic acid ratio has been determined between 0.06-0.23% and lignoseric acid ratio has been determined between 0.04-0.18% and they have been found statistically important (Table 3).

There are studies conducted in limited number both in our country and abroad regarding the fatty acids belonging to the kernel of rose hip. Among them; Yoruk *et al*., (2008) have determined the linoleic acid content between 0.73-3.15 µg/g and determined oleic acid content between 0.22-0.57 µg/g, Celik *et al*., (2010a) have determined palmitic acid content between 4.25-5.15%, palmitioleic acid content between 0.22-0.89%, stearic acid content between 1.80-2.87%, oleic acid content between 20.35-23.03%, linoleic acid content between 41.14-51.06%, linolenic acid content between 19.66-23.03% and arachidic acid content between 0.94-1.29% µg/g. Adamczak *et al*., (2011) have detected palmitic acid content between 2.72-4.08%, stearic acid content between 1.41-2.37%, oleic acid content between 11.12-16.28%, linoleic acid content between 33.54-41.01%, linolenic acid content between

12.72-25.65%, arachidic acid content between 0.20-0.51% and ve erucic acid content between 0,17-0,51%. In the analyses conducted in the kernels of some fruit species except for rose hip; as an example, Celik and Ercisli, (2009) have determined linoleic acid content in raspberry between 42.18-52.61% and linolenic acid content between 17.83-24.10%. In pistachio species; Dogan *etal.*, (2010) have detected the oleic acid content between 70.24%, linoleic acid content between 0.84-0.97%, palmitoleic acid content between 0.62-1.04%, arachidic acid content between 0.09-0.23% and gadoleic acid content between 0.15-0.25%. In different almond species growing in our country, it has been determined by Celik *et al*., (2010b) that palmitic acid content is between 5.61-16.48%, palmitoleic acid content is between 0.32-0.69%, stearic acid content is between 1.23-3.89%, oleic acid content is between 68.99-81.71%, linoleic acid content is between 7.70-21.65%, linolenic acid content is between 0.08-0.21% and myristic acid content is between 0.22-0.91%. In another study conducted in different almond genotypes growing in our country; palmitic acid has been found between 6.29-6.48%, palmitoleic acid has been found between 0.41-0.64%, stearic acid has been found between 1.76-1.60%, oleic acid has been found between 72.02-76.41%, linoleic acid has been found between 18.92-21.65%, linolenic acid has been found between 0.07-0.09% and myristic acid has been found between 0.26-0.62% (Celik and Balta, 2011). Bayazit and Sumbul (2012) have reported in different walnut genotypes that palmitic acid is between 6.98-8.77%, stearic acid is 3.22-4.99%, oleic acid is between 19.33-36.76%, linoleic acid is between 41.55-59.89% and linolenic acid is between 8.44-11.0%. It has been expressed that the genotype and the environment and conditions of growing may cause to significant differences on the amount and ratios of the fatty acid (Sathe *et al*., 2008). Yoruk *et al*., (2008) have specified that the fatty acids may show differences depending on the ecological and environmental conditions and harvesting time. The values belonging to the fatty acids attained from the studies conducted on the rose hip and our findings have a general similarity. In our study; the difference between the fatty acid ratios of the species and genotypes grown under the same ecology has been found important. Oleic and linoleic fatty acid ratios have been found higher than other fatty acid ratios.

Conclusion

In general, fatty acid content has come out as decrease in the oleic, arachidic, eicosadienoic, benenic and lignoseric acid content and as increase in others during the protection process as of the commencement of storage (zero time). No important difference could be detected among the protection methods. The difference in fatty acids shows variability depending on the genotypes and acid species. Oleic, linoleic and linolenic acid contents are higher when compared to others in all the genotypes. However; it has been generally concluded that the protection methods do not have any important impact on the change of fatty acids.

Abstract

Grape vine is an important crop in Algeria, it is harmed by many pests, thrips are amoug them. There is a lake of knowledge of pest thrips species of grape vine in this country. The aim of this study is to identify these species in some Algerian vineyards. A survey of thrips on grape vine was conducted during 2013 on three vineyards located in Mitidja, Tipaza and Isser areas (north Algeria). Leaves and flowers of grape vine were sampled for thrips, from March to November, each two weeks at the same day. Each vineyard was composed by 3300 grape vines, 6 plots, where 200 leaves are sampled from each plot; 50 plants are chosen aleatory, four leaves per plant are sampled following Bastide (1989) method. Thrips are separated, counted, mounted on slides, and identified using authors keys. The data shows the presence of four thrips species, three belonging to the Thripidae family (*Frankliniella occidenalis, Drepanothrips reuteri, Aeolothrips fasciatus*) and one specie belongs to the Phlaeothripidae family (*Liothrips sp.).* The most abundant species are *Frankliniella occidentalis* and *Drepanothrips reuteri.*

Keys words: *thrips, table grapes, occurrence, vineyards, Algeria*

Introduction

Grape vine culture is the fourth important perennial crop in Algeria in terms of surface occupation and it is ranged in the second place in terms of exportation (Anonymous, 2006). Vineyards are attacked by a number of pest organisms such as whiteflies, mites and thrips (Bounaceur, 2010).

Thrips are insect belonging to the order of Thysanoptera, with fringed wings, known as cosmopolitan insects. They are slender and tiny, measuring 0.1 to 15 mm in length, and have a singular buccal apparatus of which only the right mandible is fully developed (Mound and Marullo, 1986).

There are around 7400 thrips species worldwide, of which 1% is identified as agriculturally important pests, and most of these belong to the Thripidae (Mound and Marullo 1996; Mound 1997). This insect harms plant by feeding and piercing cells with their mouthparts and sucking out the cellular contents or by transmitting diseases.

Thrips are not commonly recognized as being a problem in Algeria. However, there is a lack of knowledge regarding the most common thrips species on Algerian crops and vineyards. The proper identification of insect pests is fundamental for their effective control and their ability to transmit phytopathogenic viruses makes necessary to identify the species associated with crops, as well as to describe the damage. The aim of this study was to determine the

species of thrips (Thysanoptera) present on vineyard crops in 3 zones (Mitidja, Tipaza and Isser) located in north Algeria.

Material and methods

The study was conducted in three vineyards; one vineyard is located in Mitidja plain, the second is located in Tipaza and the third one is located in Isser, from March to November 2013. Each vineyard was composed by 3300 grape vines, divided on 6 plots, 200 leaves are collected from each plot (50 plant are chosen aleatory, where four leaves per plant are sampled following Bastide (1989) method). Thrips are collected from flowers also, one flower is cut from the same vine where leaves are sampled. The samples were stored in labelled zip bag and transferred immediately to the laboratory of animal ecology at Tiaret university. Thrips were sampled each two weeks at the same day.

The leaves and flowers collected from the vineyards are washed for thrips extraction. These insects are removed using a fin brush into a labeled vials containing Ethanol at 70%.

All thrips collected were examined under dissecting microscope, counted and separated using their morphologic criteria for identification. Then, they are mounted on slides with Hoyer's medium (50ml water, 30g gum arabic, 200g chloral hydrate, 20ml glycerine), and identified under a compound microscope using published keys (e.g., Mound and Kebby, 1998; Moritz, 1994) at the laboratory of zoology of Biskra university

Results and discussion

Four thrips species are identified in the three vineyards. Two species (*Frankliniella occidentalis* and *Drepanothrips reuteri*) belong to the Thripidae family (at the rate of 82%), one (*Aeolothrips fasciatus*) specie to the Aeolothripidae (at the rate of 10%), and the last one to the Phlaeothripidae family (*Liothrips sp*) at the rate of 8% (Table 1).

Table 1. Taxonomy of thrips species found at the vineyard of the three sites and their occurrence

Species	Family	Occurrence
Frankliniella occidentalis	Thripidae	82%
Drepanothrips reuteri		
Aeolothrips fasciatus	Aeolothripida	10%
Liothrips sp	Phlaeothripidae	8%

A high part of thrips individuals were collected from flowers (95% of *F. occidentalis*, 85% of *D. reuteri* and 65% of *A. fasciatus*) (Table 2).

Table 2. Thrips species occurrence on the leaves and flowers

Species	Leaves (%)	Flowers (%)
Frankiniellela occidentalis	5	95
Drepanothrips reuteri	15	85
Aeolothrips fasciatus	35	65
Liothrips sp	45	55

Also the data shows that *F. occidentalis* presents an important population level from the beginning of sampling, until the end, with the total average of 120 thrips. The number of thrips is raising to show two peaks, the first one (with the average of 39 individual) during the second decade of April, and the second (with the average of 63,13 individuals) by the first

June. Afterwards, it falls to the end of the season, with an average of 25 individuals (Table 3). However, for *Drepanothrips reuteri* similar observations were taken with high population in April with 110 individuals to raise to 15 individuals in September.

Table 3: Evolution of Thrips *Frankiniellela occidentalis and Drepanothrips reuteri* populations on Table grapes in Mitidja vineayards

Species	**March**	**April**	**May**	**Jun**	**July**	**August**	**Septembre**
Frankiniellela occidentalis	39	120	117	95	65	35	25
Drepanothrips reuteri	29	110	92	78	62	28	15

This study shows the presence of four thrips species in grape vine at the north of Algeria, the same species are recorded on citrus plant by Belaam and Boulaehia-kheder (2012) in Tunisia, and by zur Strassen (1968) in Morroco. Lewis (1973) reported that Thrips are known us polyphagus pests, they can have several host plants and attack different parts of the vegetal (Mound, 1997).

The two important species *Frankliniella occidentalis* and *Drepanothrips reuteri* are phytophagous species, they are the more abundant in the three vineyards, and are responsible for serious damages (Bournier, 1957; 1983).

F.occidentalis is recorded in grapes vine at the Mediterranean region by Ciampolini *et al*., (1990) ; Guario and Laccone (1996) ; Moleas *et al*., (1996) and Laccone and Guario (2000) and also in South Africa by Allspo (2010). For *F. occidentalis*, this thrips breeds and feeds on leaves and also flowers, it is recorded in fava bean crop at an arid region of Algeria by Razi *et al.*, (2013). It can transmit tospovirus diseases. It is a highly polyphagous pest (Lewis, 1997).

For *Drepanothrips reuteri*, this specie is known to be specific to vineyard table (Lacasa, 1989; Lacasa and Llorens, 1996). Recoded the first time from North America, it causes a scarring of the fruits resulting from feeding (Bailey, 1942). Damages on the leaves and the flowers were recorded by Bailey (1942), Bournier (1957), Roditakis and Roditakis (2007). For *Aeolothrips fasciatus* and *Liothrips sp* there are no recorded damages for this species; but the first one is recorded as predatory specie (Bournier, 2002).

Conclusion

Various thrips species were found at table grapes in the vineyards of north Algeria, four phytophagous species are recorded: *Frankiniellela occidentalis, Drepanothrips reutei,* and *Aeolothrips fasciatus* an another unknon Phlaeothripidae (*Liothrips sp*).

Frankiniellela occidentalis and *Drepanothrips reuteri* are the most abundant species they may be classified as harmful organisms for this crop.

SEASONAL DYNAMICS OF AEROALERGENIC WEED POLLEN IN BANJA LUKA CITY AREA (BOSNIA AND HERZEGOVINA) DURING 2011-2015

Gordana BABIĆ*, Bojana ĆURKOVIĆ, Vojislav TRKULJA

Public institution „Agricultural institute of Republic of Srpska, Banja Luka“, Bosnia and Herzegovina
*Corresponding author: brkljacg@hotmail.com

Abstract

Around the world as well as in our area, in recent years, phytoallergens, which include taxa of various botanical families, present actual social and health problem. In that sense determination and monitoring the pollen types and pollen counts in the aero plankton of cities is of relevant medical importance. Considering the mentioned issues, as well as the results of monitoring carried out in previous years, the main objective of the study was to analyze the seasonal dynamics of aero allergenic weed pollen in Banja Luka area during the five- year period 2011-2015. Sampling of aero allergenic weed pollen during the pollination period 2011-2015 is conducted in urban, industrial part of Banja Luka in the Public Institution “Agricultural Institute of the Republic of Srpska, Banja Luka” (PI AIRS, BL) (N 44º47`41.0``, E 017º12`22.6``) with Hirst's pollenometar type (Hirst, 1952) using the method defined by the International Association for Aerobiology (IAA). Comparative analysis showed that among weed pollen the most dominant was ragweed pollen on an annual level during the five year monitoring of weed pollen in Banja Luka.

Keywords: *seasonal dynamics, pollen aeroallergens, weed, Banja Luka*

Introduction

Phytoallergens include taxon of various botanical families. According to their migration they are classified on anemophilous or entomophilous allergens. Anemophilous species, often causing allergic diseases, produce a huge quantity of readily airborne pollen grains (Bartkova-Ščevkova, 2003). It is now known that pollen grains of several plant groups such as *Alnus* spp., *Betula* spp., *Cupressaceae*, *Quercus* spp., *Platanus* spp., *Juglans* spp., *Moraceae*, *Pinus* spp., *Fraxinus* spp., *Acer* spp., *Corylus* spp., *Gramineae*, *Chenopodiaceae*/*Amaranthaceae*, *Urticaceae*, *Compositae*, *Plantago* spp., *Artemisia* spp., *Rumex* spp. and *Umbelliferae* cause allergic reactions in people (Levetin & Buck, 1980; Bousquet *et al*., 1984; Eriksson *et al*., 1984; D’Amato & Spieksma, 1990; Spieksma, 1990). Among these species, according to Hao *et al*. (2013), pollen from weeds is common source of allergens worldwide. The most well described wind pollinated genera are *Artemisia* (mugwort) and *Ambrosia* (ragweed) belonging to the family *Asteraceae*. The problem of human sensitivity to allergenic pollen around the world is characterized by increasing trend. A recent survey shows that in USA 2–10% of the residents were affected by pollinosis, in Europe the incidence has increased from 1% at the beginning of the 20th century to current 20% (Dai *et* Lu, 2000), and will even be approximately 35% in the next two decades (Editorial, 1999). Research conducted in the ten-year period (2001-2010) in Clinical Center Banja Luka (B&H) pointed out to positive results of skin "Prick" test, where 88% of the surveyed population is allergic to plant pollen. From that percent 17.2% is allergic to trees pollen, 32.1% to grass pollen and 38.7% to weeds pollen, of which 28, 9% is allergic to the ragweed pollen (Balaban & Balaban, 2012).

Considering the above mentioned issues, as well as that mugwort comprises several closely related species of which *A. vulgaris* is the most widespread across Europe (Oberhuber *et al*.,

2008), but also fact that on the annual level total amount of *Ambrosia artemisiifolia* pollen exceeds the amount of all other plants with the exception of grass (Medzinradsky *et* Jarai-Komlodi, 1995), the main aim of this study was to analyze the seasonal dynamics of aero allergenic weed pollen during five year period, from 2011 to 2015.

Material and method

Sampling of aero allergenic weed pollen during the pollination period 2011-2015 was conducted in urban, industrial part of Banja Luka in the PI Agricultural Institute of the Republic of Srpska, Banja Luka (N 44º47`41.0``, E 017º12`22.6``) with Hirst type sampler (Hirst, 1952), using the method defined by the International Association for Aerobiology (IAA). The trap brand Burkard (Burkard Manufacturing Co., Uxbridge, Middlesex, England) was calibrated for sampling 10 l/min of air through an orifice of 14 x 2 mm in diameter, that is always pointed in the direction of wind and protected from direct rainfall. As air passing through the orifice, pollen grains are fixed on glass slides coated with silicone gel, which moves at a speed of 2 mm/h. Visual identification of representative samples of aero allergenic weed pollen was performed daily during the pollination period, based on morphological characteristics under a light microscope Olympus BX51 at magnification x400. Just before reading, 24 hour segment of microscopic slide area was prepared by placing the substrate polyvinyl alcohol (Gelvatol), phenol, glycerol and color Fuxin that allows staining of pollen grains, and makes easier to distinguish pollen grains from the dust and fungi spores. After preparation and drying of microscopic preparation slides, determining the number of pollen grains is carried by the method of longitudinal lines at two hour intervals, by reviewing three horizontal lines, with the determination of ragweed pollen grains (p/m^3) performed by translating obtained numbers with correction factor (F). The results are presen ted to the public media in the form of aero pallinological reports or so called "Pollen forecast" on the official web site of City of Banja Luka (Table 1).

Table 1. Number of ragweed pollen grains in the air with the corresponding percentage of persons in whose is possible occurrence of symptoms of allergic reactions Forsyth County Environmental Affairs Department Pollen Rating Scale, PRS)

Level of pollen	***Number of pollen grains /m^3 air***	***Occurrence of symptoms of allergic reactions***
	Weeds	
Not present	0	No symptoms
Low	1-10	Only in extremely sensitive individuals
Moderate	11-50	In 50% of sensitive individuals
High	51-500	Almost all allergic people
Very high	>500	In all allergic people

Results and discussion

During the five-year monitoring (2011-2015) of aeroallergen weed pollen in the city of Banja Luka seasonal dynamics, i.e. the beginning, duration and end of the pollination period with presenting daily low, moderate, high or very high concentrations, as well as a total weed pollen number on annual level (p/m^3) was monitored. Among the types of aeroallergen weed pollen in the area of Banja Luka during the pollination period 2011-2015, monitoring included six weed species from five families: *Ambrosia artemisiifolia* (ragweed) and *Artemisia vulgaris* (mugwort) from *Asteraceae* family, *Chenopodium album* (meldweed) from *Amaranthaceae* family, *Plantago* sp. (plantain) from *Plantaginaceae* family, *Rumex* sp. (sorrel) from *Polygonaceae* family and *Urtica dioica* (nettle) from the *Urticaceae* family.

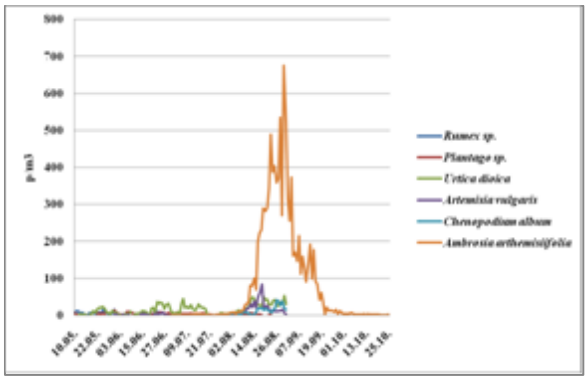

Photo 3. *Seasonal dynamic of weed species pollination in 2011*

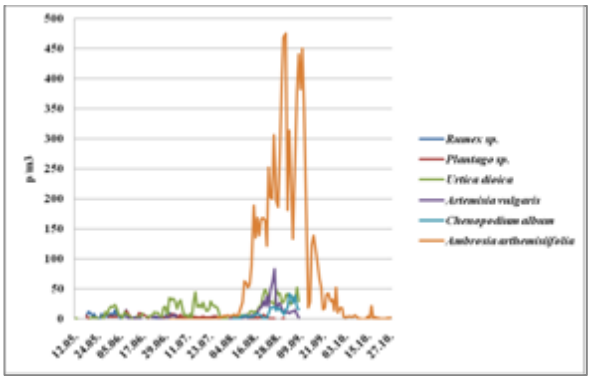

Photo 4. *Seasonal dynamic of weed species pollination in 2012*

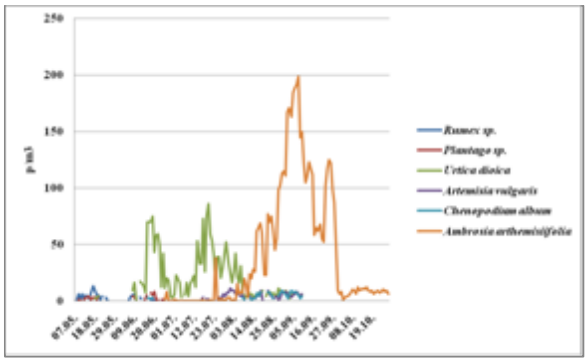

Photo 5. *Seasonal dynamic of weed species pollination in 2013*

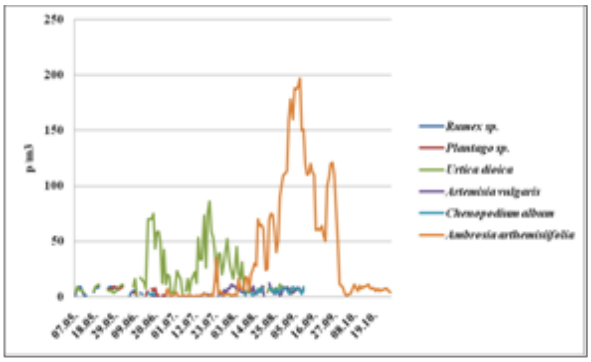

Photo 6. *Seasonal dynamic of weed species pollination in 2014*

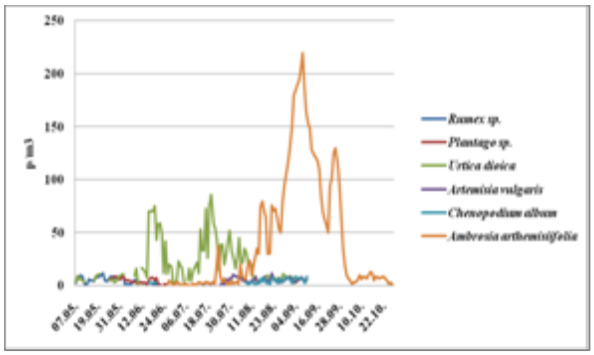

Photo 7. *Seasonal dynamic of weed species pollination in 2015*

During the five year monitoring, beginning of pollination season of aero allergenic weed species in Banja Luka has been recorded from the first decade of May with exception in 2012. In 2012 the beginning of weed pollination started in second decade of May, while the season of pollination lasted until third decade of October. Pollination season of *Rumex* sp. (sorrel) from *Polygonaceae* family, among the first aero allergenic weed pollen, lasted in average 60 days and it was characterized by low to moderate concentration. In case of *Urtica dioica* (nettle) from *Urticacea* family, as well among the first aero allergenic weed pollen, pollination season lasted in average 105 days and it was characterized by low to moderate concentration during 2011 and 2012. From 2013 to 2015 high concentration was recorded during ten days period with high temperature. Aero allergenic pollen of *Plantago* sp. (plantain) from *Plantaginaceae* family was characterized by low to moderate concentration in five year monitoring. Pollination season lasted in average 49 days and during 2011 and 2013 first pollen grains were recorded in first decade of May, in 2012 in second decade of May and in 2014 and 2015 pollination season started in third decade of May. First

grain pollen of *Artemisia vulgaris* (mugwort) from *Asteraceae* family was recorded in the end of May in 2011, in the first decade of June in 2012, and during 2013 – 2015 in second decade of June. Pollination season lasted in average 55 days and it was characterized by low to moderate concentration. In case of *Chenopodium album* (meldweed) from *Amaranthaceae* family pollination season lasted in average 36 days and it was characterized by low to moderate concentration. The longest period of pollination season was recorded in *Ambrosia artemisiifolia* (ragweed) from *Asteraceae* family. In average it lasted 115 days. The highest concentration was recorded during second decade of August until the third decade of September. Very high concentration, above 501 p/m^3, was recorded only in 2011 (photo 3-7). On annual level not only *Ambrosia artemisiifolia* (ragweed) had a longest pollination season, but monitoring results and comparative analysis showed also that the highest portion of weed pollen grains belongs to the ragweed pollen respectively (photo 8-12).

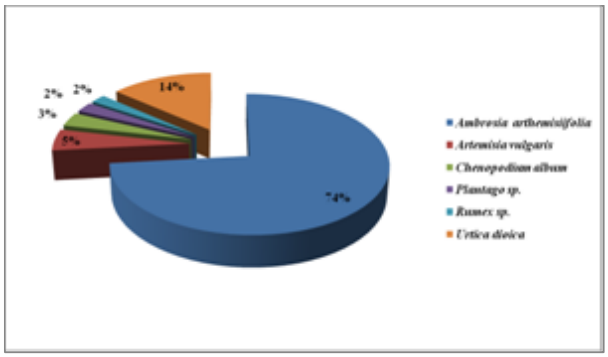

Photo 8. *Comparative analysis of weed pollen grains in 2011*

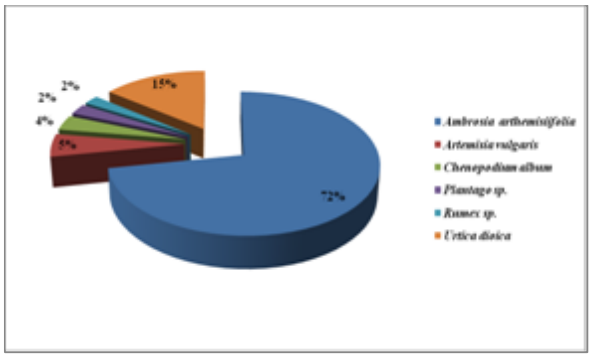

Photo 9. *Comparative analysis of weed pollen grains in 2012*

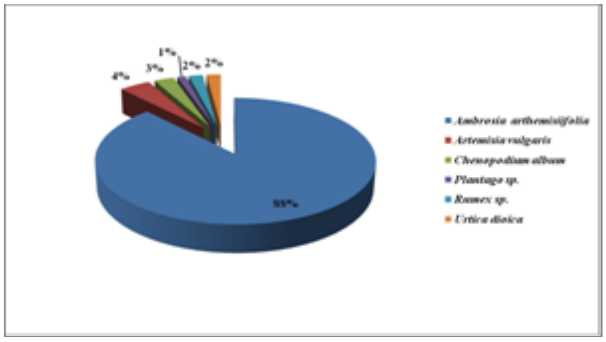

Photo 10. *Comparative analysis of weed pollen grains in 2013*

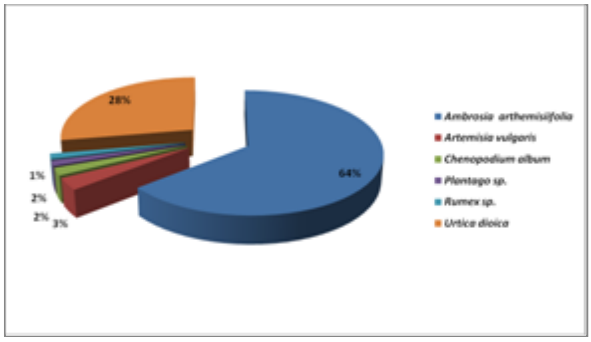

Photo 11. *Comparative analysis of weed pollen grains in 2014*

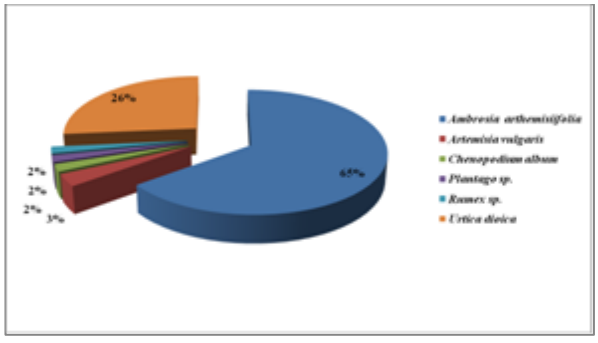

Photo 12. *Comparative analysis of weed pollen grains in 2015*

Conclusion

Regarding the current research in the studied region, conducted monitoring and comparative analysis of aero allergenic weed pollen in the period from 2011 to 2015 pointed out to a significantly domination of ragweed pollen. Hence *Ambrosia artemisiifolia* L. is considered as a biological pollutant responsible for severe allergic diseases (Déchamp *et* Méon, 2003), as well as facts that ragweed represents one of the most invasive weeds in our area, can move at up to 300 km (Jones, 1953; Comtois, 1998; Deen *et al*., 1998, Genton *et al*., 2005, Trkulja *et al.*, 2010) to large distance of 10 to 100 km, clinical thresholds that lead to the symptoms of allergy etc., further monitoring process for our area on local level is of a great social and medical importance.

HERBICIDE EFFICIENCY TESTING IN SOYBEAN DURING 2014 AND 2015– COOPERATIVE DANUBE-SOYA PROGRAM

Gordana BABIĆ*, Bojana ĆURKOVIĆ, Vojislav TRKULJA, Miloš NOŽINIĆ, Drago SPREMO, Jovo STOJČIĆ

Public institution „Agricultural institute of Republic of Srpska, Banja Luka“, Bosnia and Herzegovina
*Corresponding author: brkljacg@hotmail.com

Abstract

As participant of a cooperative Danube-Soya Program, Public institution „Agriculture Institute of Republic of Srpska, Banja Luka“(PI AIRS) takes an active role in the implementation and the intensification of research Programme in the production of non-genetically modified soybean with the application of European Union (EU)standards and legal regulations. Speaking of the limiting factors of production, special emphasis, apart fromothers, is placed on effective weed managment programs, scienceweed species as direct competitors have an extremely negative impact on the achievement of high and quality yield. Considering the mentioned,the main objective was to test the efficacy of a total 11 herbicide combinations on weed populations in soybean in the Banja Luka region. Efficiency test of 11 herbicide combinations was carried out during 2014 and 2015 on the experimental fields of PI AIRS,Banja Luka.In 2014, due to heavy rainfall, which caused constant emergence of weed species throughout the vegetation period of soybean, using similar, almost identical pre. em. combination achieved satisfactory efficiency. Compared with the previous year, in 2015, pre. em. combination with corrective treatments showed high efficiency, wich indicates theimportance of testing in different ecological conditions of production.

Keywords:*Danube-Soya Program, herbicide efficiency, soybean*

Introduction

By signing a cooperative Program B&H with the Danube Soya Association, Public institution „Agriculture Institute of the Republic of Srpska, Banja Luka“(PI AIRS, BL)took an active role in the implementation and the intensification of research Programme in the production of non-genetically modified soybean. Among them crop protection program is of a great importance. Considering the limiting factors of production, especially when we are talking about direct competitors, increase the yield of soybean in addition to intensive crop management, optimized application of fertilizers and a more efficient protection against pests and diseases, always implies the effective protection against weeds. Not only that they: decrease yield, make harvest more difficult, reduce the quality of grain and increase the humidity, but also transmit a variety of diseases and pests.According to Öerke *et al*.(1994) grain yield can be reduced in average 13% or 10% (Maceljski, 1995).

In soybeans, as in the other row crops, there is a wide range of weed species of which are dominated broadleavesweeds(Konstantinović*et al*., 1998). Beside theagrotechnical measures, key role in weed control has herbicide application. Selection of herbicide is of outmost importance that it is highly effective and selective, to avoid potential adverse effects on the cultivated plant (Konstantinović, 1999). As well, it is important to be familiar with the history field, in reference to predict the composition and abundance of weed flora in areas designated for planting, all in order to choose an effective combination for the dominant weed species (Bilandžić*et al*., 1997; Ostojić, 2000). The density of weeds and spread of weeds in soybean depend on the type of soil, amount of rainfall during the growing season, soil and air temperatures (Vratarić *et al*., 2007).

Therefore, in order to ensure high quality and yield ofnon-GMO soybean, primarily in order to strengthen the competitiveness of the EU market in relation to GMO soy producers, but certainly to intensify production on domestic manufacturers, the basic aim of this study was to investigate the efficacy of 11 different herbicides on weed populations in soybean in the Banja Luka area.

Material and method

The herbicidetrial in 2014 and 2015 was conducted in the experimental field of the PI AIRS, Banja Luka according to the European and Mediterranean Plant Protection Organization guidelines (OEPP 1998; OEPP 1999; OEPP 2012). In 2014 herbicide efficiancy trail was set up on 14thApril in randomized block design, with elementary plots of 60 m^2 in 3 repetitionin locality Maglajani. Weed control included one treatment before sowing and immediately after planting (pre.em.), while four others combinations were appliedpre. em. (table 1).

Table 1. *Technical data and variants of appleid herbicides in soybeanduring 2014in Maglajani*

Herbicide variant	Active substances	Time of applications/date	Concentration/Unit
Zanat + Lord + Galolin mono	Pendimethalin +Metribuzin +Linuron	pre. sowing and pre. em	4 l/ha +0,5 kg/ha +1,5 l/ha
Galolin mono +Lord	Linuron +Metribuzin	pre. em	2,5 l/ha +0,5 kg/ha

Pulsar 40	Imazamox	post.em.	1,2 l/ha
Dynox +Okvir	Oxasulfuron +Thifensulfuron-methyl	post. em.	80 g/ha +10 g/ha
Untreated variant			n/a

The basic pre. em. plotsweredivided into two equal areas and on each were performed corrective treatments (table 4).

Table 4. *Technical details and variants of corrective treatmens in soy during 2015in locality Kalino imanje*

Herbicide	Active substances	Time of applications/date	Concentration/Unit
Pulsar 40	Imazamox	post. em.	1,2 l/ha
Dynox +Okvir	Oxasulfuron +Thifensulfuron-methyl	post. em.	80 g/ha +10 g/ha

The weed population of each herbicide trail plot and untreated control was recorded in terms of numbers with absolute assessment. In terms of absolute assessment individual plants were counted for each weed species. These assessments were made on randomly selected marked quadrats in each plot. Based on the obtained data, the coefficient of efficiency Ce (%) of herbicides is calculated by the formula Dodel*loc. cit*. Janjic (1985) and represents a relative ratio between the number of destroyed weeds compared to the weeds number in the control.

Results and discussion

In 2014during the evaluations of the herbicide variants efficiency revealed the presence of 11 weed species. Target organisms were presented in table 5.

Table 5. *Scientific names, EPPO Codes and common names of target weeds*

Scientific name	EPPO Code	Common name
Agropyron repens	AGRRE	Common couchgrass
Amaranthusretroflexus	AMARE	Common amaranth

Ambrosia artemisifolia	AMBEL	Ragweed
Cirsium arvense	CIRAR	Canada thistle
Convolvulus arvensis	CONAR	Field bindweed
Hibiscus trionum	HIBTR	Venice mallow
Matricaria chamomilla	MATCH	Wild chamomile
Polygonum aviculare	POLAV	Prostrate knotweed
Setaria sp.	SETSS	Foxtail Grasses
Sorghum halepense	SORHA	Johnson grass
Viola sp.	VIOSS	Wild Violet

The total number of weed population in control plots (photo 1) ranged from 109,3-162,4 plants/m^2, and among them the most dominant (63-75 plants/m^2) was*Ambrosia artemisiifolia*, which was to be expected given that it isthe most invasive weed species in our area. The high efficiency of 92.82% was achieved in the variant applied after sowing and before emergence of soybean (Galolin mono + Lord) at a dose of 2.5 l/ha + 0,5 kg/ha with a corrective treatment (photo 2), while satisfactory efficiency (>80%) achieved by applying of all other combinations (table 6).

Table 6.*Efficiency of different weed control treatments in soybean in 2014*

Herbicide variant	**Ce %**
Zanat + Lord+ Galolin mono + post.em. variant	84,17
Galolin mono + Lord + post.em. variant	92,82
Galolin mono + Lord+post.em. variant	88,59
Frontier 900 EC + Lord + post.em. variant	87,25
Lord +Dual gold 960 EC + post.em. variant	86,37

In 2015 during the evaluations of the herbicide variants efficiency revealed the presence of 9 weed species. Target organisms were presented in table 7.

Table 7. *Scientific names, EPPO Codes and common names of target weeds*

Scientific name	EPPO Code	Common name
Ambrosia artemisifolia	AMBEL	Ragweed
Chenopodium album	CHEAL	Common lambsquarters
Cirsium arvense	CIRAR	Canada thistle
Convolvulus arvensis	CONAR	Field bindweed
Hibiscus trionum	HIBTR	Venice mallow
Polygonum aviculare	POLAV	Prostrate knotweed
Setaria sp.	SETSS	Foxtail Grasses
Sorghum halepense	SORHA	Johnson grass
Xanthium strumarium	XANST	Common cocklebur

The total number of weed population in control plots (photo 3) ranged from 125.3-173.4 plants/m^2 and among them, as in previous year, the dominant species (69-92 plants/m^2) was*Ambrosia artemisiifolia*. High efficiency (>90%) was achieved in the variant applied after sowing and before emergence of soybeans with a corrective treatment, one of which is a variant Galolin mono+ Lord achieved the highest efficiency (94.82%), while satisfactory efficiency (>80%) was achieved by applying both post. em. combinations (table 8).

Table 8.*Efficiency of different weed control treatments in soybean in 2015*

Photo 1. C*ontrol untreated plots in 2015*

Photo 2. *Variant Galolin mono + Lordin 2015*

Conclusion

In 2014, due to heavy rainfall, which caused constant emergence of weed species throughout the vegetation period of soybean, pre.em.combination with corrective treatments achieved satisfactory efficiency. Compared with the previous year, in 2015, pre.em. combination with corrective treatments showed high efficiency, which point out the importance of testing herbicide efficiency in different ecological conditions of production.In that sense these studies have a great importance for agricultural producers as well as significant role in the selection of the most effective combination in the production of non-GMO soybeans in our area.

Abstract

Chickpea is an important food legume cultivated and consumed across the Indian subcontinent. Fusarium wilt is the major constraint in chickpea production. The wilt race confined to Northern-Karnataka region is caused by soil borne fungus *Fusarium oxysporum* f. sp. *ciceris* (*foc* 4). Thus marker assisted backcrossing (MABC) was attempted to introgress the *foc 4* loci from WR-315 (wilt resistant) to elite cultivar Annegeri-1(A-1: wilt susceptible) (A-1 × WR-315). For MABC three markers TA96, TA27-F and TR19-V conferring the *foc 4* loci were used in foreground selection. Background selection was employed using 40 SSR markers that were evenly distributed on to all the 8 LG of chickpea genome. After two backcrosses and two rounds selfing, 67 families were found to be resistant to wilt under wilt sick garden and possessed good background genome recovery (78.85 – 94.83 %). Of the 67 BC_2F_3 families top ten elite families with recurrent parent genome recovery of 91.07 – 94.83 % were selected. The selected lines were homozygous and stable. Stringent phenotypic evaluation of advanced lines of BC_2F_3 families in wilt sick garden could confirm resistance to fusarium wilt Race-4. These elite lines are being evaluated for yield and yield attributing traits in multi-location trails to identify the best possible line as compared to local check for release and general cultivation in Northern-Karnataka region. The present investigation was accomplished with speedy development of elite "Super Annigeri-1" cultivar resistant to fusarium wilt, grain yield advantage that was otherwise susceptible, as early as in two backcrosses and selfing.

Keywords: *Chickpea, Fusarium wilt, MABC, Foc 4, Super Annigeri-1*

Introduction

Chickpea is commonly known as Bengal gram or Garbanzo (*Cicer arietinum* L.). It is an important food legume, cultivated and consumed across the globe. In India it is being cultivated throughout the semi arid-tropics. The crop occupies first position both in area and production among the pulses grown in Northern Karnataka state of India, especially in dry areas of Zone 2 and 3. In spite of its wide spread area in Northern Karnataka the yield levels are curtailed to greater extent by wilt disease. Fusarium wilt (FW), caused by *Fusarium oxysporum* Schlechtend: Fr. f. sp. *ciceris* (Padwick) Matuto & K. Sato, a soil-borne fungus is major constrain in chickpea cultivation and the pathogen race confined to Northern-Karnataka is *Fusarium oxysporum* f. sp. *ciceris* (Foc 4). The average annual losses to wilt have been estimated to the tune of 10 to 90% (Jimenez-Diaz et al., 1993; Cortes et al., 2000) under disease favourable conditions, epidemics can be devastating to individual crops and cause 100% loss (Halila and Strange 1996; Navas-Corte´s et al., 2000). The pathogen can survive in soil even in the absence of host plants for many years and build up the permanent disease inoculum (Haware et al., 1996) thus it is difficult to control. In this direction deployment of

host plant resistance by use of resistant cultivars is the preferred strategy for managing the wilt disease, as it is the most economic, effective and eco-friendly means of controlling chickpea wilt. Even then effectiveness of such a cultivar is further limited by the existence of different races of pathogens. Integration of genomic resources with conventional breeding approaches might enhance the precision and speed of developing resistant chickpea cultivars. Genomic resources including various mapping populations, linkage maps, QTL maps, markers linked to fusarium wilt have been developed in chickpea. Molecular markers associated with resistance to different races (0, 1A, 2, 3, 4, and 5) have been identified. Resistance genes for FW races 1 (*foc1*), 3 (*foc3*), 4 (*foc4*), and 5 (*foc5*), forming a cluster were located on CaLG02 (Mayer et al., 1997; Ratnaparkhe et al., 1998; Tullu et al.,1998; Winter et al., 2000; Sharma et al., 2004). Three simple sequence repeats (SSR) markers TA96, TA27-F and TR19-V conferring resistance to wilt were successfully employed for marker assisted backcross breeding (MABC) in chickpea (Varshney et al., 2014). Annigeri-1 is an elite chickpea variety with medium bold seeds, early maturing, tolerant to drought and recently accorded the status of national check for drought tolerance in frontier chickpea research. However, in recent past it is susceptible to wilt.

In this study, an effort was made to develop wilt resistant Annigeri-1 (Super Annigeri-1) by adopting MABC where WR315, a solitary source disease resistant to all the known races of fusarium wilt was used as the donor and markers associated with wilt resistance were employed for selection.

Material and methods

Annigeri-1 was used as the recurrent parent, while WR 315 was used as the donor parent in the MABC (Fig. 1). A crossing programs involving Annigeri-1× WR315 was employed for generation of F_1 seeds. Three SSR markers TA96, TA27-F and TR19-V associated with resistance to FW on genomic region of LG 02 were employed for selecting hybrid plants and such plants were used for developing backcross progenies. Further, foreground selection (FGS) of target genomic regions and background selection (BGS) using SSR markers were employed for identification of plants for further backcrossing. After two rounds of backcrossing, selected plants were selfed twice (BC_2F_3) for making plants homozygous as well as for multiplication of improved seeds of Annigeri-1 (Super Annigeri-1) for FW. For molecular analysis, DNA extraction and genotyping was carried out at ICRISAT, Pattencheru Hyderabad (India). DNA was isolated from young leaves of 15-d-old seedlings of parental genotypes, F_1s, and backcross progenies using the modified cetyl trimethyl ammonium bromide (CTAB) extraction method, as described in Cuc et al. (2008). Quality and quantity of DNA were checked on 0.8% agarose gel and concentration was normalized to ~5.0 ng μl^{-1}. Polymerase Chain Reaction (PCR) of SSR markers for FGS and SSRs from complete genome (Varshney et al., 2014) for BGS was performed in 5.0µl reaction volumes as mentioned in Thudi et al. (2011). PCR amplicon were separated by capillary electrophoresis using an ABI Prism 3730 DNA Sequencer and analyzed using GeneMapper software of Applied Biosystems, USA (Carlsbad, CA). Genotypes developed under MABC were screened against FW in sick plot developed at Agriculture Research Station, Kalaburagi (India). A field screening technique for wilt developed at ICRISAT (Nene et al., 1981) was adopted with wilt susceptible check (JG-62) sown intermittently after every five entries so as to monitor disease pressure. Observations on number of wilted plants was recorded at seedling stage (30 DAS), pod initiation stage (60 DAS) and physiological maturity stage (90 DAS). Per cent wilt incidence was calculated using the formula given below and wilt scoring scales developed by Nene et al. (1981). Data on FW reaction of the entries were classified as resistant (0-10%), moderately resistant (10-20%), moderately susceptible (20-30%), and susceptible (30-50%) and highly susceptible (above 50%)

$$\text{Per cent wilt incidence} = \frac{\text{Number of wilted plants}}{\text{Total number of plants}} \times 100$$

Result and discussion

Markers assisted backcrossing (MABC) for fusarium wilt: For introgressing *foc 4* locus conferring resistance to *race 4* of FW, three SSR markers (TA96, TA27-F and TR19-V) associated with resistance present on the linkage group LG 02 (Sharma and Muehlbauer, 2005; Varshney et al., 2014). All the three markers were polymorphic between parents (A-1 and WR 315), hence they were used for selection of target genomic region in segregating generations. MABC scheme used to introgress from WR 315 into Annigeri 1 is shown in Fig. 1.

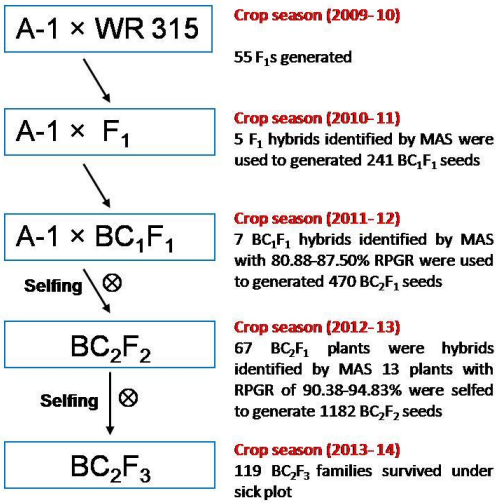

Figure1: MABC scheme for introgression of resistance to Fusarium Wilt race 4 (*foc 4*)

Backcrossing was initiated by hybridization of A-1 (recurrent and female parent) with WR 315 (donor) during the post rainy season of 2009-10. A total of 55 F_1 plants were produced. Of the 55 F_1 plants five hybrids were identified with the markers (TA96, TA27-F and TR19-V). As a result 241 BC_1F_1 seeds were obtained by pollinating A-1 with pollens collected from three F_1 plants. All the BC_1F_1 seeds rose in the crop season 2010-11 of which DNA from 188 BC_1F_1's was isolated and used for FGS and BGS. FGS could yield 14 heterozygote plants at all the three marker loci. Due to the minimal polymorphism in the chickpea genome (Kazan Muehlbaure 1991; Ahmad and slinkard 1992; labdi et al 1996 Mayer et al 1997) a total of 38 SSR markers that were polymorphic for A-1 and WR 315 were used for BGS which showed a considerable genome recovery ranging from 76.39-87.50% among the heterozygote plant. Of the 14 BC_1F_1, seven plants with genome recovery of 80.88-87.50% were used for making second backcrossing to develop BC_2F_1 in the crop season 2011-12. Further, 470 BC_2F_1 were sown in the field during the crop season 2012-13. Of the 470 BC_2F_1, 376 plants that survived in the field were subjected for FGS and BGS. A total of 67 BC_2F_1 plants were confirmed with three makers in FGS. All the 67 plants were screened for BGS with 38 SSR markers that were found polymorphic. BGS could yield recurrent parent genome recovery (RPGR) of 74.85-94.83%. In the present study only round backcrossing was made and desired genotypes were selected with the aid of markers, followed by selfing. In a simulation study selection of backcross progenies with just two rounds of backcrossing would maximizes the recurrent parent genome faster as compared to additional third and/or four rounds of backcrossing provided negative linkage drag is not anticipated (Frisch *et al.*, 1999). Of the 67 BC_2F_1, 13

plants with highest RPGR of 90.38-94.83% selected selfed to produce 1181 BC_2F_2 seeds. The population size can be increased in order to recover the genetic background of the recurrent parent by only two backcrosses in the BC_2F_2 generation. If a small portion of the donor genome still persists, another backcrossing is usually needed to recover the recurrent parent genome by BC_3F_2. Otherwise, an additional selfing generation can also be used. Also, a large population size may not be required when the donor is an adapted, high yielding variety, and introgression of deleterious alleles would not be so likely (Iftekharuddaula *et al.*, 2011).

Screening MABC lines under wilt sick plot: Evaluation of chickpea lines for resistance to FW under the wilt sick plot with sufficient inoculum load ensures uniform infection of plants at same vegetative stage under well defined environmental conditions, thus helps in stringent screen of the test plants for FW. Since there are no linked markers for FW in chickpea that can be relayed upon for the effective MAS as in other crops, field screening of the MABC lines and selfed progenies would increase the precision of screening the plants carrying wilt resistance gene(s) which is complemented by MAS (Sharma et al. 2005; Sharma and Muehlbauer 2007). Thus in the present study, wilt sick plot prepared with heavy inoculum of FW (*foc 4*) was used to screen the selfed progenies of second backcross (BC_2F_2). Plant to progeny rows was followed for sowing all the 1181 BC_2F_2 seeds, 33 rows ranging from 1-5 rows were constituted during the cropping season of 2013-14 (Table 1).

Table 1. Evaluation of BC_2F_2 families against FW under wilt sick garden during 2013-14

Sl. No.	BC_2F_2 Families	Seeds sown	TP	TWP	TRP	Per cent Wilt Incidence	BC_2F_3 Seeds collected

TP: Total number of plants; **TWP**: Total number of wilted plants; **TRP**: Total number of resistant plants; **WI:** Wilt Incidence (per cent)

The observation on the incidence of wilt at different days after sowing (30, 60 and 90 DAS) was recorded, of the 952 total plants 833 showed the wilting symptoms at different stage and could not serve till harvest. Only 119 plants survived at 30, 60 and 90 DAS showing resistance towards FW. A total of 9157 BC_2F_3 seeds were collected from 119 BC_2F_2 plants. All the 119 BC_2F_3 families were sown again in the wilt sick plot during the cropping season of 2014-15. These 119 families were divided into eight groups based on their pedigree. Overall, there was high wilt incidence (87.55) facilitating proper selection of the MABC lines. Families screened at 30, 60 and 90 DAS could generate 71 resistant (R), 16 moderately resistant (MR), 6 tolerant (T) and 26 susceptible families. Data was also collected on seed yield/ family among the 71 resistant families from these eight groups. The families were categorized to know seed yield/family producing less than 100 gm, more than 100 gm, more

than 200 gm, 300 gm and 400gms. Over all, of the 71 resistant families constituted from eight classes could show nine families with more than 400 gm seed yield/ family, six families (>300 gm), 17 families (>200 gm), 21 families (>100 gm) and 18 (<100gm) (Table 2). The advanced families (Resistant, Moderately resistant or tolerant) constituted the BC_2F_4.

Table 2. Reaction of families against FW under wilt sick plot and seed yield during 2014-15

FG: Family Groups; **R**: Resistant; **MR**: Moderately Resistant; **T**: Tolerant; **S**: Susceptible

Conclusion

In the present study use of three markers associated with the FW race 4 (*foc 4*) enabled in selecting the proper genotype in MABC coupled with the stringent screening enabled us to precisely identify the resistant MABC plants/families. The mortality in the wilt sick condition of segregating plants with a variable genotypic constitution, expressing its race virulence in variable environment in different years cannot be disregarded. Environment influence the race to a greater extent, fortunately the dry spell prevailing for two consecutive years in the Northern-Karnataka region was highly favourable for FW. Therefore, proper expression of the pathogen and the host resistance was witnessed, this has led to identification of better MABC lines showing high resistance to FW. Stabilized families are being evaluated for their genetic potentiality for yield and yield attributing traits in station trails and multi-location trails this may yield us the Super Annigeri-1 in one or two years for release to farming community in Northern-Karnataka.

Abstract

Pistacia species and cultivars have been placed among the important fruit trees of the world for consuming their nuts and using them as rootstocks. Along with the ecological factors, several practices performed during the plant growing causes a positive and sometimes negative effects The purpose of this study is to hasten the growth of seedlings derived from the seeds of several *Pistacia* species and cultivars for a better growth in order to study their developments in different ecological conditions. This study has been conducted between the years of 2010 and 2011 at the greenhouse of Kahramanmaras Sutcu Imam University Greenhouse. In the experiment, the seeds of *P. khinjuck* Stock., *Pistacia atlantica* Desf., *Pistacia terebinthus* L. and of three cultivars of *P. vera* L.. (Ohadi, Siirt, Kırmız) were used. Seed vitality tests were performed using Triphenyl Tetrazolium Chloride (TTC). The vital seeds were kept in GA_3 solutions prepared with three concentrations (0-250-500 ppm) for 24 hrs. Then the seeds were divided into three groups. First group of seeds were sown in pots (8x8 cm in height and diamater) in a heated greenhouse; second group of seeds were sown in pots with the same size which were placed on the steel shelves in outdoor condition; third group seeds were sown into soil outdoor. The decrease in air temperature to -2 degree C in mid-February damaged to to newly germinated seedlings. This damage was exaggerated with the increase in the concentration of GA_3.

Keywords. *2,3,5- Triphenyl Tetrazolium chloride, Gibbrellic acid, Scarification, nursery tree.*

Introduction

Pistachio (*Pistacia vera* L.) was first cultured during the Hitit Era in the southern part of Turkey. The Pistachio nut was on the table of ancient kings which indicates it's value. *Plenchon* reported the antiquity of the pistachio nut. Since Anatolia is the center of origin of Pistachio, its culture is widely spread in Southern Anatolia where ecological conditions are suitable for economical production (Özbek, 1978; Bilgen *et all*., 1994). Recently, pistachio culture has been gaining importance in many Mediterranean and MiddleEast countries as well as in USA and Australia. The reasons for this trend can be summarized as following: the nut has high nutritional value; the tree can thrieve in dry and marginal lands and bring good income for farmers.

Pistachio belongs to *Anacardiceae* family with 11 species which are cultured as nut trees or ornamental purposes. The all *Pistacia* spp trees as well as the crosses in the genus can be used as rootstocks, and the wild species grown in nature can be topworked to *Pistacia vera*, the edible nut (Mehanna *et all*.,1995; Ak *et all*.,, 1994). The Pistachio nut is an important part of agricultural economy, especially in the southern part of Turkey. However, there are many problems in nursery tree production. The number of nursery trees is relatively low. Traditionally farmers sow seeds directly to land or plant seedling for budding with *Pistacia vera* scions. Also some farmers topwork the wild *Pistacia* shrubs and trees around or in their properties. Wild *Pistacia* species have good characteristics for using as rootstocks, however the outer layer of their seeds should be worked for improving seed germination percatage

(Nikpeyma*et all*., 1995:Xu,and Gu, 1984). The technic for this improvement needs suitable growing media and proper adjusment of chemicals. In this study, the effects of several plant growth regulators with different doses on the seed germination (Cainiand Conticini, 1981;Crane and Forde, 1974) percentages, seedling growth, stem lenght and diameters, time for budding and propagation of healthy budded nursery trees were investigated.

Material and Method

This study was conducted between the years of 2010 and 2011 at the greenhouse of Kahramanmaras Sutcu Imam University (Turkey). In the experiment, the seeds of *P. khinjuck* Stock., *Pistacia atlantica* Desf., *Pistacia terebinthus* L. and of three cultivars of *P. vera* L. (Ohadi, Siirt, Kırmız) were used. The outer layer of the shell of the seeds were carefully cracked. The seeds were placed in paper filters for an overnight and then the inner shell of the seeds were removed using grip pincer. Three seeds from each Pistachio cultivars and of Pistacia species were put in glass jars and then 0.05 % TTC were poured to glass jars covering the seeds completely. The glass jars were covered with aluminium paper and they were put in drying room at 27 ^{o}C for 24 hrs. The red stained seeds were accepted as vital ones, and low or non stained ones as non-vital. The scarification of exocarp, mesocarp and endocarp of the seeds from wild Pistacia species (*Pistacia khinjuk* Stock, *Pistacia atlantica* Desf., *Pistacia terebinthus*) were done with using H_2SO_4. The scarification period was 1 or 1.5 hrs. The seeds were then placed in water for 12 hrs; the water was refreshed at 4 hrs interval. The seeds were then tratead with 0-250-500 ppm GA_3 in room temperature for 24 hrs. The seeds were then divided into three groups for determining germination percentages and seedling measurements as following: first group of seeds were sown in pots (8 x 8 cm in height and diamater) in a heated greenhouse; second group of seeds were sown in pots with the same size which were placed on the steel shelves in outdoor condition; third group seeds were sown in raised berms in field outdoor. The experiment was set up as a factorial design with 3 replication and each replication had 10 seeds,

Result and Dscussion

The emergence and seedling growth of Pistachio cultivars and *Pistacia* spp. sown in three different growing media were first seen in heated greenhouse conditions 2 weeks after sowing and secondly in tubes in outdoor conditions 4 weeks after sowing and 6 weeks after sowing directly in open field. Acording to observations, seeds sown in tubes (8 x 8 cm) outdoor conditions made growth of 5-8 mm beneath the soil surface. However, since the air temperature suddenly dropped to below -2^{o}C, the new growth of root tips were damaged from frost. Especially, in GA_3 treated seeds the higher the concentration the higher the frost damage on the root tips was observed. This damage was from radicula to cotyledone of newly germinated seeds.As seen in Table 1 when the temperature drop below -2°C'ın the highest frost damage was apparent in 500 ppm GA_3 treatment with 30.79 % germination. The seed germination rate of 250 ppm GA_3 treatment was highest with 65.67 % . When comparing the Pistachio cultivars and *Pistacia* spp, the germination of P. *terebinthus* was lowest with 35.67 % which was appearently most affected from frost, followed by Pistacio Kırmızı cv. with 37.94 % and Ohadi with 46.85%.

Table 1. The germination percentage of seeds of Pistachio cultivars and *Pistacia* spp grown in mini tubes outdoor.

Seed germination percentage (%)				
Pistachio cultivars and *Pistacia* spp.	**0 ppm GA_3**	**250 ppm GA_3**	**500 ppm GA_3**	**Mean**
Kırmızı	66.83	26.83	20.16	37.94 **cd**
Ohadi	80.31	33.60	26.56	46.83 bc
Siirt	72.50	26.70	24.63	41.28 **bc**
P. *khinjuk*	60.60	46.70	40.10	49.13 a**b**
P. *atlantica*	66.80	46.50	46.63	53.31 **a**
P. *terebinthus*	47.03	33.33	26.66	35.67 **d**
Mean	65.67 **a**	35.61 **b**	30.79 **b**	

The highest seed germinating rate with 87.43 % was in control seeds (0 ppm) and lowest germination rate with 53.42 % was in 500 ppm GA_3 treatment (Table 2). In this part of experiment the seeds sown in field was less damaged from frost then ones grown in mini tubes. The soil might have partly protected seeds from frost. However, the seeds treated with 500 ppm GA3 might have more cell division and much more water which made them highly sensitive to frost damage. When comparing the Pistachio cultivars and *Pistacia* spp, the highest germination rate was in Ohadi cultivar with 78.04 % and lowest in P. *terebintus* with 55.59 %.

Table 2. The germination percentage of seeds of Pistachio cultivars and *Pistacia* spp grown in field conditions.

Seed germination percentage (%)				
Pistachio cultivars and *Pistacia* spp.	**0 ppm GA_3**	**250 ppm GA_3**	**500 ppm GA_3**	**Mean**
Kırmızı	86.96	60.36	46.73	64.68 **e**
Ohadi	93.70	73.66	66.76	78.04 **a**
Siirt	100.00	60.40	46.66	69.02 **c**
P. *khinjuk*	86,86	60.43	53.43	66.90 **d**
P. *atlantica*	90.33	65.10	60.33	71.92 **b**
P. *terebinthus*	66.76	53.40	46.63	55.59 **f**
Mean	87.43 **a**	62.22 **b**	53.42 **c**	

As seen in Table 3, the best germination rate was obtained in greenhouse condition. The highest germination rate was in 500 ppm'lik GA_3 treatment with 87.84 % followed by 250 ppm treatment with 85.61 % and 0 ppm (control) treatment with 74.4 %. As a result 500 ppm treatment appears the best. And when comparing results from tubes outdoor and field sown seeds, the seeds in small pots grown outdoor was much affected from frost, closely followed by the seeds treated 500 ppm'lik GA_3 sown in field. The highest frost damages which resulted in low germinatin percentage were in Pistachio cultivars such as Ohadi, Siirt and Kırmızı

followed by . *Pistacia spp* such as *Pistacia atlantica* Desf., ,*Pistacia khinjuk* Stock, and *Pistacia terebinthus*

Table 3. The germination percentage of seeds of Pistachio cultivars and *Pistacia* spp in mini pots grown in greenhouse conditions.

Seed germination percentage (%)				
Pistachio cultivars and *Pistacia* spp.	**0 ppm GA_3**	**250 ppm GA_3**	**500 ppm GA_3**	**Mean**
Kırmızı	73.56	86.63	86.70	82.29 **d**

The growth of seedlings of Pistachio cultivars and *Pistacia* spp 7 weeks after sowing under field conditions was presented in Table 4. Under normal field conditions, the height and diameter of seedlings were better in Ohadi and Siirt pistachio cultivars,followed by others. When condsdering the mean values, the height and stem developments of seedlings were best with either 250 ppm or 500 ppm GA_3 treatments.

Table 4. The seedling growth of Pistachio cultivars and *Pistacia* spp 7 weeks after sowing under field conditions.

Pistachio cultivars and *Pistacia* spp.	**0 ppm GA_3**		**250 ppm GA_3**		**500 ppm GA_3**		**Mean**
	Seedling height (cm)	**Seedling diameter (mm)**	**Seedling height (cm)**	**Seedling diameter (mm)**	**Seedling height (cm)**	**Seedling diameter (mm)**	
Kırmızı	32	5.10	38	5.40	41	5.00	21.08**b**
Ohadi	38	6.40	41	7.00	48	6.14	24.42**a**
Siirt	35	6.11	39	6.30	37	6.14	21.59b

P. *atlantica*	32	4.43	35	5.30	30	5.61	18.72c
P. *terebinthus*	22	4.00	24	4.20	25	4.00	13.86
Mean	30.33c	5.04c	33.83b	5.48a	35a	5.33b	**19.16**

As seen in Table 5. The seedling growth of Pistachio cultivars and *Pistacia* seeds sown in heated greenhouse conditions were better than the those of sown and grown in field conditions. The first ones came to budding height and diameter earlier with healthy conditions. The shorter time from seed sowing to budding is an important criteria in modern fruit growing and nursery technic. For that reason it is generaly advised to use heated greenhouses for fast plant development. The height and diameter of seedlings were appearntly better with especially 250 ppm and 500 ppm GA3 treatments. The mean stem height in control treatments was 48,16 cm, however it was 54,66 cm with 250 ppm and 57,50 cm with 500 ppm treatment.When comparing the cultivars and *Pistacia spp*, Ohadi cultivar showed the

best seedling development with mean 68 cm height and 8.40 stem diameter, followed by cv Siirt, cv Kırmızı and P. *atlantica* seedlings.

Table 5. The seedling growth of Pistachio cultivars and *Pistacia* spp 7 weeks after sowing in pots in greenhouse.

Pistachio cultivars and *Pistacia* spp.	0 ppm GA_3		250 ppm GA_3		500 ppm GA_3		Mean	
	Seedling height (cm)	Seedling diameter (mm)	Seedling height (cm)	Seedling diameter (mm)	Seedling height (cm)	Seedling diameter (mm)	B	C
Kırmızı	50	6.34	58	8.74	60	7.6	5600	7.38b

P. *terebinthus*	30	4.00	36	6.00	33	5.19	33.00	5.07c
Mean	48.16b	5.79b	54.66a	7.96a	57.5a	7.11a	53.22	6.78

Conclusion

In this study it appeared that many ecological factors could affect the generative and vegetative developments of Pistachio cultivars and *Pistacia* spp. In this study under different growing media with different GA3 treatments, the developments from seed germination to budding stage were investigated.The seeds of all plants grown in mini pots outdoor conditions were much affected from frost with decreased air temperature below -2^0C while increased the GA3 concentration. İn other words, cold air slowed the germination processes. However, generally the field sown seeds showed a better germination percentage than those sown in tubes outdoor. The germination difference was as much as two fold. The cold air did not affect the seeds 1-2 cm benath the soil surface. However, the best result for germination during the experiment was obtained in heated greenhouse, also seedling development was best in this condition.

When considering fast plant develepment for reaching budding height and diameter of seedlings after 7 weeks, 250 ppm GA_3 treated seedlings were earliest in this respect. As a result of this study, in the case of early seed sowing, the fast plant development and shorter time for budding could be obtained in the heated greenhouse or normal field conditions.However, in the case of outdoor sowing in cold period, the bigger tubes or pots should be considered rather than small tubes (8 x 8 cm) for a succesful nursery plant growing.

Abstract

Wheat leaf rust, caused by *Pucciniarecondita*Dietel*et*Holw. is the most common rust disease of wheat (*Triticumaestivum* L.) and occurs world-wide. The fungus is an obligate parasite andcan cause rust epidemics on a continentalscale.Some BL cultivars and breeding lines of wheat from collection of PI Agricultural Institute of Republic of Srpska, Banja Luka showed very good to excellent resistance to *P. recondite* even during years that were favorable for disease development. These cultivars and breeding lines were sampled during tillering stage and analyzed in order to identify wheat leaf rust resistance genes by molecular markers. Extracted plant DNA was amplified by Polymerase Chain Reaction (PCR) and molecular markers were used to identify ten *Lr* resistance genes against the fungal pathogen of wheat *Pucciniarecondita* (*Lr*13, *Lr*19, *Lr*24, *Lr*26, *Lr*34, *Lr*35, *Lr*36, *Lr*37, *Lr*39 and *Lr*46) in Institute's11 wheat breeding lines and fourcultivars. Results showed that the most common genes in tested breeding lines and cultivars are*Lr*34, *Lr*35, *Lr*39 and *Lr*46 that are identified in all tested samples. Seven tested lines and cultivars (46.6%) had *Lr*37 gen. *Lr*13, *Lr*19, *Lr*24, *Lr*26 and *Lr*36 genes weren't identified in tested samples. The objective of this study was to identify resistant wheat breeding lines that carry wheat leaf rust resistance genes and these breeding lines will be included in further selection and creation of new domestic wheat cultivars with higher genetic potential. All this should result in higher wheat yield as well as decreased import since wheat is very important grain for our country.

Keywords: *wheat leaf rust, leaf rust resistance genes, molecular markers*

Introduction

Wheat leaf rust, caused by *Pucciniarecondita*Dietel*et*Holw. is the most common rust disease of wheat (*Triticumaestivum* L.) and occurs world-wide. It is also common disease in Europe and it is considered to be important in northwest, southern and southeast Europe (Zadoks&Bouwmann, 1985), as well as in eastern Europe (Mesterhazy*et al*., 2000).Hosts are winter and spring wheatequally, especially in wet and moderately wet areas of Central and Southern Europe, Russia, Australia, USA and Canada with losses ranging 5-50%.Besidesaffecting wheat yield, it also adversely affects wheat quality. The fungus is an obligate parasite capable of producing infectious urediniospores as long as infected leaf tissue remains alive. When conditions are favorable, urediniospores are formed every 7-17 days. Urediniospores can be wind-disseminated and infect host plants hundreds of kilometers from their source plant, which can result in wheat leaf rust epidemics on a continental scale.

The use of resistant cultivars offers the most effective and ecologically sustainable method of control of the disease; therefore, incorporating genetic resistance to this pathogen into adapted germplasm is a major goal in most wheat breeding programs (Vanzetti *et al*., 2011). Growing resistant cultivars is probably themost efficient, cost-effective and environment-friendly method to control this disease (Singh*et al*., 2004). More than 70 specific leaf rust resistance genes are known (KOMUGI, 2008).Resistance genes are expressedat seedling stage (qualitative resistance genes) than at adultplant (quantitative resistance genes). Certain adult

plantresistance genes like *Lr34* and *Lr46* are very important forbreeding because they proved to confer durable resistanceover a long period of time in different environments, as wellas against diverse pathotypes of the fungus (Schnurbusch*et al.*, 2004).Themolecular markersmost closely linked to *Lr*genes are based on thePCRtechnique, as the majority of these can be applied relativelyeasily in wheat breeding programs.Molecular markers are used for two purposes in resistancebreeding: (1) to monitor the incorporation of designatedresistance genes or QTLs into elite wheat genotypes(i.e., MAS, marker-assisted selection) and (2) to identifyresistance genes in varieties and lines where the geneticbackground is unknown (i.e., gene detection).DNA marker technology has been used in commercial plant breeding programs since the early 1990's and has proved helpful for the rapid and efficient transfer of useful traits into desirable cultivars and hybrids. Markers linked to disease resistance loci can now be used for marker assisted selection (MAS) programs, thus also allowing several resistance genes to be cumulated in the same genotype („pyramiding" resistance genes).

Visual identification of cultivars or breeding lines, tolerant or resistant to leaf rust in field conditions and confirming the presence of resistance genes,allowsgreater certainty in breeding process. Certain number of ourbreeding lines showed very good to excellent resistance against leaf rust, even in years that were extremely favorable for the development of this disease,likeit was 2014. Winter wheat breeding lines were selected for the identification of leaf rust resistance genes (*Lr* genes) using molecular markers, based on the visual assessment and previous results related to the yield.A better knowledge on the identity of effective *Lr* genes present in cultivars and breeding lines, that can be used as donors of resistance in wheat breeding programs,could greatly improve the efficiency of developing resistant cultivars by using these genes. The objective of this study was to identify *Lr* genes that condition leaf rust resistance in 15BL cultivars and breeding lines of wheat from Agricultural Institute's collectionusing molecular markers.Growing resistant wheat cultivars is the most economical and environmentally safe approach to eliminate the use of fungicides and to reduce crop losses due to leaf rust.

Material and method

A number of BL cultivars and breeding lines from collection showed very good to excellent resistance against leaf rust, even during years that were extremely favorable for disease development, likeit was 2014. Infection rate of breeding lines and cultivars wasscaled according to Stakman*et al*.(1962): 0-nearly resistant; 1 - very resistant; 2 – mediumresistant; 3 – mediumresistant tomedium sensitive; 4 - very sensitive.For evaluation of tolerance/resistance of winter wheat breeding lines and cultivars, i.e. presence of wheat leaf rust resistance genes,sampleswere collected in the field duringtillering stage.

DNA was extracted using QiagenDNEasy Plant Mini Kit according to manufacturer instructions. What we did first, was that we mechanically disrupted plant material and thenadded lysis buffer in order to chemically disrupt plant tissue. RNAase A from lysis buffer degraded RNA in the sample. After incubation proteins and polysaccharides were precipitated with salts. Cell debris was removed by centrifugation through QIAShredder column.Binding buffer and ethanol are added to a purified lysate in order to improve DNA binding to the DNeasy spin column.DNA bound to the membrane of the column while the contaminants such as protein and polysaccharide are efficiently removed in two washing steps.Purified DNA is diluted in a small amount of buffer with a low salt content.DNA concentration, as well as purity(A260/A280ratio), is measured in the Eppendorf BioPhotometer.Extracted DNA of selected cultivars and breeding lines is analyzed using Polymerase Chain Reaction (PCR).Molecular markers for ten different *Lr* genes have been included in this study in order to identify wheat leaf rust resistance genes: *Lr*13, *Lr*19, *Lr*24, *Lr*26, *Lr*34, *Lr*35, *Lr*36, *Lr*37, *Lr*39 and*Lr*46 (Imbaby*et al*., 2014).Polymerase chain reaction (PCR) was performed in 25µl

volumes withREDTaq®ReadyMix™ PCR Reaction Mix-a (Sigma-Aldrich). This mixcontains all PCR reagents including Taqpolymerase.PCR mixture consists of PCR mix, primers in final concentration of 0.6 µM, molecular biology grade water and sample DNA. Primer name and sequences, PCR annealing temperature, expected product size and referencesare shown in Table 1.Amplifications were performed in a EppendorfMastercycler ep gradient S. Amplification products were separated inmicrochip electrophoresis in MCE®-202 MultiNA(Shimadzu, Japan) using DNA-1000 kit.This system provides fast, accurate and easy separation of PCR products and results are analyzed in MultiNA Viewer software.

Results and discussion

An important field in which molecular markers are used in wheat resistance breeding, is the determination of designated resistance genes in genotypes.Genetic background areas like breeding lines and and commercial cultivars has not yet been clarified. Using this approach we screened fourdomestic wheat cultivarsand 11 breeding lines by gene postulation for presence of 10 *Lr* genes (table 2), and five genes were detected. Results showed that the most common genes in tested breeding lines and cultivars are*Lr*34, *Lr*35, *Lr*39 and *Lr*46 that are identified in all tested samples. Seven tested lines and cultivars (46.6%) had *Lr*37 gen. *Lr*13, *Lr*19, *Lr*24, *Lr*26 and *Lr*36 genes weren't identified in tested samples.

Table 2. shows results of visual assessment of resistance in BLwinter wheat breeding lines and cultivars, as well as detected *Lr* genes. SomeBL varieties (Bosanka, Jelena and Nova Bosanka) have already been present in production for a long time and can be used as standards. Detection of resistance of our breeding lines and cultivars using new technology provides the basis for incorporationof resistance to leaf rust. The table shows that breedingline BL 9875 is nearlyresistant to *Puccinia recondita*. Most of our breeding lines is in the range of mediumresistant to very resistant. From a total of 15 of BLcultivars and breedinglines that were analyzed, almost all are in this category.Only BL 225-11 and BL 121-11 showed very high susceptibility.

Table. 2. Resistance assessment and detected *Lr*genes

Cultivar / Breeding line	**Resistance assessment**						
	Sample	**0 – nearly resistant**	**1- very resistant**	**2- medium resistant**	**3- medium resistant to medium susceptible**	**4- very susceptible**	**Identified*Lr*genes**
BL 38-06	14			+			34, 35, 37, 39, 46
BL 45-10	16		+				34,35, 37, 39, 46
BL 12-10	17		+				34,35, 37, 39, 46
BL 52-10	18			+			34,35, 37, 39, 46
BL 69-10	19				+		34,35, 37, 39, 46
BL62-06	8				+		34, 35, 39, 46
BL 225-11	13					+	34,35, 37, 39, 46
BL 121-11	9					+	34,35, 39, 46
BL 9807	10		+				34,35, 39, 46
BL 9877	11			+			34,35, 39, 46
BL 9875	12	+					34,35, 37, 39, 46
Bosanka	3		+				34,35, 39, 46
Jelena	4				+		34,35, 39, 46
Orion	5			+			34,35, 37, 39, 46
Nova Bosanka	6			+			34,35, 37, 39, 46

In recent years developments in molecular marker techniquesand marker identification have facilitated the spreadof molecular-assisted selection (MAS). This is particularlytrue in the field of breeding wheat for leaf rust resistance,where PCR-based markers are alreadyavailable for almosthalf of the designated resistance genes and alleles (Imbaby*et al*., 2014).

*Lr34*genewas found in all tested breeding lines and cultivars, although this gene aloneis capable of reducing the level of infection to almost half, asreported by (Singh&Rajaram,1992); resistance that is both excellent and durablecan only be achieved if *Lr34* is combined with 2 or 3 othergenes (Hysing*et al*, 2006).Gene *Lr37* confersmainly adult plant resistance.Marker-assisted selectionoffers the opportunity to select desirable lines on the basisof genotype rather than phenotype, especially in the case ofcombining different genes in a single genotype.With the helpof molecular marker, the pyramiding of leaf rust resistancegenes which are active at the seedling and/or adult stage,should facilitatemore efficient breeding for durable resistanceagainst this disease.The mechanism for durable resistance toleaf rust is poorly understood, but durability appears to beenhanced when genes are combined (Long *et al*., 1994).

Experience gained so far suggests that markers flanking*Lr* genes can be used simply and effectively inmarker-assistedbackcross programmers.Nevertheless, as the linkage betweenmarkers and resistance genes is not complete, regular phenotypicmonitoring will be required if satisfactory parentalgenotypes are to be selected. However, molecular markers can prove the presence of therequested resistance gene in the genetic background and inthe case of plants carrying adult plant resistance genes like*Lr35* and *Lr37* this is the only way to choose appropriateparents for crossing programmer. The use of MAS, wherebybreeders selectmolecularmarkers linked to *Lr*genes, enablesthe pyramiding of more than one effective resistance gene.With the help ofmolecular markers, resistance genes are easyto detect in wheat varieties of unknown parentage. This informationcan then be used to design crossing programmers(Imbaby*et al*., 2014).

Conclusions

The applied methods of molecular markers (marker assisted selection) enabled selectionof the desired breeding line based on the genotype and not phenotype, which is significant especially in the case of combination of different genes in one genotype (breeding line or cultivar). With the help of molecular markers, identification of wheat leaf rust resistance genes facilitates efficient selection for permanent resistance to this pathogen. This allows selection of optimal breeding lines that will serve as a suitable material for the selection of new wheat cultivars resistant to *Puccinia recondita*. Also, molecular markers enable detection of resistance genes in BLcultivars and breeding lines of wheat, which is the most convenient and quickest way for the best selection of parents in crossbreeding programs.

Abstract

Genetically Modified Organisms (GMO's) are organisms which undergo modification on their DNA structure that involves inserting external genes from one species in order to alter the property of another species which would otherwise not be achieved by conventional reproductive means. With the general public aware of the existence of genetically modified foods, consumers are concerned regarding the contents of the GMO in food products. This served as pretext for caring out the research whether the food or feed that is used for human or domestic animals consumption are genetically modified or not. A total of 96 samples of food and feed are tested for the presence of genetic modifications. Samples have been collected by the Republic PhytosanitaryInspection Agency (RPIA) and Republic Food Inspection Agency as well as samples were taken in the field by the RPIA and several samples were submitted by farmers and food exporters. DNA was extracted according to CTAB method and Real Time analysis was performed using a Stratagene Mx3005P QPCR with MxProdata analysis system. Real time PCR system enables easy and reliable detection and amplification of specific DNA sequences in GM products. Samples have been tested on presence of specific GMelements such as: promotor 35S, NOS terminator, CP4epsps gene,CTP2-CP4epsps construct, pat gene and nptII gene. Results showed that 19 samples were positive: 4 samples of soybean meal and 6 samples of feed mixtures imported from abroad, as well as 9 samples of soybean that are taken from fields in the entity of Republic of Srpska. The other 77 samples were negative for all tested elements.

Key words:*GMO, GM plants, samples, analysis of GMO*

Introduction

Genetically Modified Organisms (GMO's) are organisms which undergo modification on their DNA structure that involves inserting external genes from one species in order to alter the property of another species which would otherwise not be achieved by conventional reproductive means.GM plants may be altered to provide better protection against insect pests or diseases, or to withstand herbicides to enable better weed control. As a result of the achievements in molecular biology techniques, thesedays, scientists are able to transfer genes for herbicide toleranceand insect and disease resistance into traditionalcultivars of agricultural plants(Block *et al.*,1987; Moellenbeck*et al.*, 2001; Trkulja*et al.*, 2014). The actual trait endowed on the plant can differ, but the one feature all GM plants have in common is addition of new genetic material, DNA, to complement the DNA already present in the plant.

In the last years, the number of GM events being commercialized worldwide has been increasing steadily(James, 2015; Stein *et* Rodriguez-Cerezo, 2009).Genetic engineering in crops is becoming more and more widespread; a cumulative hectarage of 2 billion hectares of biotech crops were cultivated globally in the 20-year period from 1996 to 2015. The 2.0 billion accumulated hectares comprise 1.0 billion hectares of biotech soybean, 0.6 billion hectares of biotech maize, 0.3 billion hectares of biotech cotton and 0.1 billion hectares of

biotech canola (James, 2015). In spite of the rapid adoption of these "transgenic" crops by farmers around the world, some people remain skeptical and even fearful of these plants, demanding strict controls on their cultivation, distribution and consumption. Considering that GMO is not allowed in our country, many genetically engineered plants, as well as the foods and feeds derived from them should be monitored for the presence of genetic modifications.

Material and method

Samples

A total of 96 samples of food and feed were screened for specific elements present in GM events: promotor 35S, terminator NOS, CP4epsps gene,CTP2-CP4epsps construct, pat gene and nptII gene. Samples were taken by the Republic PhytosanitaryInspection Agency (RPIA) and Republic Food Inspection Agency during 2015. Also, samples were taken in the field by the RPIA and several samples were submitted by farmers and food exporters.

DNA extraction

DNA extraction has been performed according to publicly available CTAB protocol. The basic principle of DNA extraction consisted of first releasing the DNA present in the sample into aqueous solution and further purification of the DNA from PCR inhibitors. CTAB-based method started with a lysis step (thermal lysis in the presence of CTAB and EDTA). About 200 g of sample wereground using a ZM 200 Retsch GmbHmill. A total amount of 2 g of each sample,3 ml of dH2O and 7 ml of CTAB buffer solution were lightlymixed and incubated at 65°C for 30 min. For positive controls 200 mg of reference material, 300 µl of dH2O and 700µl of CTAB buffer solution were used. After incubation 1.5 ml of the solution was transferred into new tubes and 10 µl of RNase A solution (10 mg/ml) was added in order to remove RNA; the mixture was heated at 65°C for 15 min. Afterwards, 10 µl Proteinase K (20 mg/ml) were added, andthe mixture was heated at 65°C for 30 min. After centrifugation step supernatant was transferredto a new tube followed by removal of contaminants such as lipophilic molecules and proteins by two extractions with chloroform. After centrifugationthe upper layer was mixed with 2 volumes ofCTAB precipitation solution (under low salt conditions DNA precipitates in the presence of CTAB) and incubated at room temperaturefor an hour. The mixture was centrifuged for 10 min at 16000*xg*and 4°C.The precipitate was dissolved in 350 µl of 1.2 M NaCl solution,and then 350 ml chloroform were added, mixed and centrifuged for 10 minat 16000*xg*. The upper layer was mixed with 0.6 volumesof isopropanol and centrifuged for 10 min at 16000*xg*and 4°C. Theprecipitate was washed with ice-cold 70% ethanol and dissolved in TE buffer. Certified Reference Material (CRM) consisted of 0.05-2% GMO soybean was used as control and reference material.The quality and the quantity of the DNA solutions weredetermined by UV-spectroscopy (NanoPhotometer Pearl, Implen). The absorbance of the DNA solutions was measuredusing a spectrophotometer. The purity of the extracted DNAs was determined by the ratio of the absorbance at 260 and280 nm.

Real Time PCR

Due to theincreasing number of GMO, a screening approach using qualitativescreening methods has become an integrated part ofGMO detection. Real Time analysis was performed using a StratageneMx3005P QPCR system.Samples are analyzed for detection of specific elements present in GM events: promotor 35S, NOS terminator, CP4epsps gene,CTP2-CP4epsps construct, pat gene and nptII gene. All reactions of the real-time PCR wereperformed in duplicate using 2 wells. Reactions were performed in a final volume of 25 µl using 1X Taqman Universal Master Mix (Applied Biosystems, Foster City, CA). Primers and probes used in PCR reactions are shown in Table 1 and qPCR reactionconditions are shown in Table 2.

Table 1.Primers and probes used in PCR reactions

Results and discussion

The DNA isolated by CTAB method was quantified using aspectrophotometer at the absorbance of 260 and 280 nm. The results show that the CTAB-based protocol produced optimumDNA yield. First, amplification of specificsoybean gene, lectin, was done from isolated DNA. The results obtained showed that all tested samples had lectingene.Thisresult showed that the isolated DNAs were amplifiable andcontained soy DNA (Figure 1). After PCR amplifications of thelectin gene, all samples were subjected to qualitative real time PCR amplification to determine the presence of GM plant specific sequences: 35S promoter, NOS terminator,CP4epsps gene,CTP2-CP4epsps construct, pat gene and nptII gene(Figure 2).Many availableGMOs contain these genetic elements:35S promoter from *Cauliflower mosaic virus* (CaMV), terminator of the nopalinesynthase gene from *Agrobacterium tumefaciens*(T-NOS), 5-enolpyruvylshikimate-3-phosphate synthase gene from the strain CP4 of *Agrobacterium tumefaciens* (CP4epsps),CTP2-CP4epsps – junction region between the chloroplast transit peptide 2 (CTP2) and the synthetic version of 5-enolpyruvylshikimate-3-phosphate synthase gene from the strain CP4 of *Agrobacterium tumefaciens* (CP4-epsps), phosphinothricin N-acetyltransferase gene from *Streptomyces viridochromogenes* strain Tu 494 (pat gene) and neomycin phosphotransferase II gene from *Escherichia coli*(npt II gene).

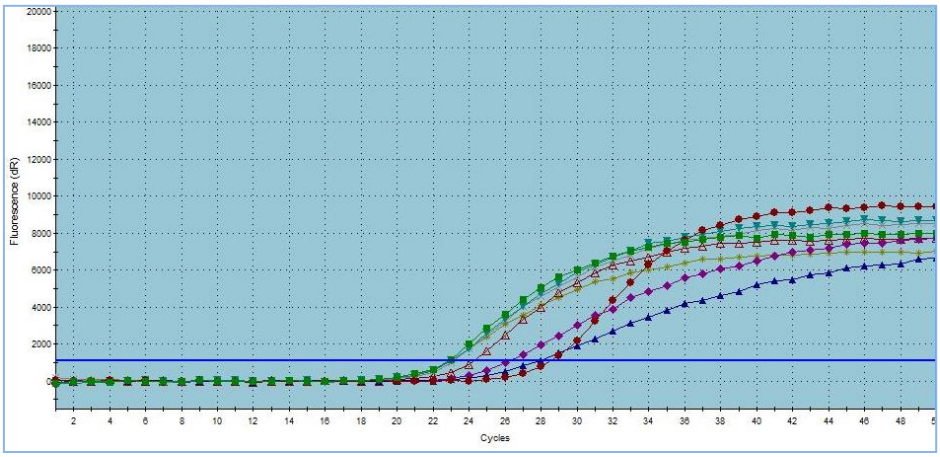

Figure 1.Real time PCR amplification of lectin gene.

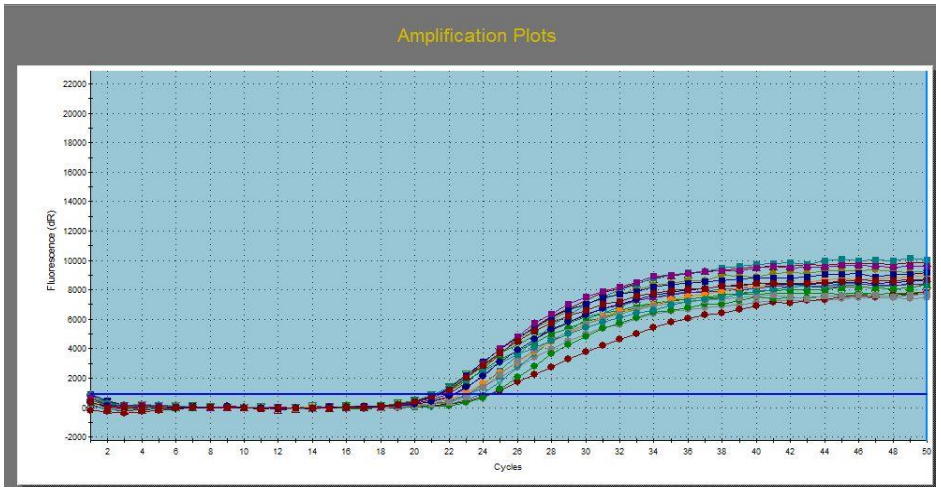

Figure 2.Real time PCR amplification of GM plant specific sequences.

Screening food and feed products for the presence of GMOs hasbeen performed by real time PCR because the specific DNA sequences inGM products can be detected and amplified

easily and reliably.Detection of GMO in food and feed consists of two steps: extractionand purification of DNA and amplification of the inserted DNAby real time PCR. Very low concentrations of isolated DNA could be adequate forthe detection of GMO material. In theory, PCR could determinea single target molecule in DNA mixture (Holst-Jensen &Berdal, 2004).Results showed that 19 samples were positive: 4 samples of soybean meal and 6 samples of feed mixtures from import, as well as 9 samples of soybean that are taken from fields in the entity of Republic of Srpska.The other 77 samples were negative for all screened elements.

Conclusions

Considering that from total number of analyzed samples, 19 were positive on genetic modification, as well as that according to legislation in Bosnia and Herzegovina GMO'sin food and feed are not allowed and demands of consumers,it would be essential to continue this research to update and confirm the results.

PRESENCE OF AFLATOXIN B1 IN FOOD AND FEED SAMPLES IMPORTED TO THE ENTITY OF REPUBLIC OF SRPSKA (BOSNIA AND HERZEGOVINA) DURING 2013-2015

Vojislav TRKULJA*, Bojana VUKOVIĆ, Jelena VASIĆ, Dragana KOVAČIĆ JOŠIĆ, Jelena MIHIĆ SALAPURA, Jovana PRIJIĆ

Public institution „Agricultural institute of Republic of Srpska, Banja Luka“, Bosnia and Herzegovina

Abstract

Extremely dry and warm weather conditions recorded during 2012 were favorable for intensive development of mold. As a result of these very stressful conditionsunusually high contamination of corn with Aflatoxin B1 was established which caused huge economic losses in milk production in Republic of Srpska and in surrounding countries. The production of corn and other cereals in Bosnia and Herzegovina is not satisfactory and it is characterized by low average yields. In order to satisfy all needs, in terms of human and animal nutrition, we are forced to import food and feed from other countries. Considering the situation occurred in 2012, starting from 2013, a continuous control of imported food and feed has been carried out. During the three-year research 434 samples of imported food and feed were analyzed for the presence of Aflatoxin B1. Samples were analyzed by competitive enzyme immunoassay (ELISA) with microplate based kit produced by EuroProxima, the Netherlands. Results of the analysis showed that 91 analyzed samples (20.97%) was contaminated with Aflatoxin B1 according to Regulations of maximum level for certain contaminants in food.

Keywords: *Aflatoxin B1, food, feed, Entity of Republic of Srpska.*

Introduction

Wide variety of agricultural, food and feed products can be contaminated with secondary metabolites of moulds known as mycotoxins. Mycotoxins are considered to be one of the best known and most common chemical contaminants of food and feed which after ingestion can result in illness or death of animals and humans. Infection may occur in the field, particularly where the plant experiences water, temperature or nutrient stressand accumulation of mycotoxin may increase if harvested material is inappropriately stored (Moreno and Kang, 1999). Despite efforts to control fungal contamination of many cereal and other crops in the field or during storage, toxigenic fungi are present in agricultural products and occur regularly in worldwide food supplies. For that reason, monitoring for the presence of mycotoxins in food and feed is therefore needed at the global level. As these can never be completely removed from the food supply, many countries have defined levels in food (tolerances, guideline levels, maximum residue levels) that are unlikely to be of health concern (Magan and Olsen, 2004).

Aflatoxins are the main toxic secondary metabolites produced by *Aspergillus parasiticus*and *Aspergillus flavus*and have carcinogenic, hepatotoxic, teratogenic and mutagenic effects in human and animals when ingested, inhaled or adsorbed through the skin. A wide range of food commodities may be contaminated with aflatoxins, but the highest levels are usually found in commodities originating from areas with warmer climates. Since AFs could contaminate a wide variety of agricultural product, which presents an important part of food chain, indirectly it can cause a great number of toxic effects in human and animal organisms. Furthermore, the presence of AFs could also be a cause of great economical losses (EFSA, 2013). The liver is the main target organ, but high levels of aflatoxins have also been found in

other organs such as lungs, kidneys, brains and hearts of individuals dying from acute aflatoxicosis. From a food safety point of view, chronic toxicity is probably more important certainly in more developed countries. Low level ingestion over a long period has been implicated in primary liver cancer, chronic hepatitis, jaundice, cirrhosis and impaired nutrient conversion in many animals and therefore potentially in humans. The major members of aflatoxins are aflatoxin B1, B2, G1, G2 as well as two additional metabolic products M1 and M2. According to International Agency for Research on Cancer (IARC) AFB1 is listed as a group I carcinogen and is more frequently present in cereals thanthe B2, G1 and G2 type. Due to the extreme carcinogenic effects, significant adverse impacts on human and animal health, as well as a great influence on economic losses, aflatoxins make an enormous challenge for research around the world (Kos, 2014). The aim of this study was to monitor all imported samples of food and feed for the presence of Aflatoxin B1.

Materials and methods

During three-year period (2013-2015) 434 samples of food and feed intended for human and animal consumption were analyzed. Samples were taken on the borders by the representatives of the Republic administration for inspection affairsand analyzed in Laboratory for Plant Protection of Agricultural Institute of Republic of Srpska, Banja Luka. Each sample was dried at a temperature of 60°C for 72 h and a 100 g of each sample was ground and homogenized to a fine powder. 9 ml of methanol was added in each sample and the tubes were stirred for 10 min and then centrifuged for 10 minutes at 2000 xg. Further dilution were prepared by transferring 50 µlof the supernatant obtained after centrifugation with 150 µlof dilution buffer. For further testing 50 µl of the dilution is used, and each sample was tested in two replicates.
Samples were analyzed by competitive enzyme immunoassay (ELISA) with microplate based kit produced by Euro Proxima, the Netherlands. The aflatoxin B1 ELISA is a competitive enzyme immunoassay based on antibodies which enables the detection and quantification of very low concentrations of aflatoxin B1. Standards and samples are pipetted into the wells ofmicrotiter plate and according to protocol we added antibodies and conjugate in all wells except H1 and H2 wells. Microtiter plate was incubated for one hour at 37°C. After a washing procedure ready-to-use substrate is added and plate was incubated for 30 minutes at 20°C - 25°C. Photometric measurements were carried out on the Thermo Scientific™ Multiskan™ FC microplate photometer. The mean optical density (O.D.) of blank wells is subtracted from individual O.D. values of wells containing standards and samples. The O.D. value of six standards and the samples (value of the duplicates) are divided by the mean O.D. value of zero standard (wells A1 and A2) and multiplied by 16.Values (% maximum absorbance) calculated for the standards are plotted on the Y axis versus the aflatoxin B1 equivalents concentration (ng/ml) on a logaritimic X-axis. The amount of aflatoxin B1 in the samples has been expressed as aflatoxin B1 equivalents. The aflatoxin B1 equivalents in the extracts (ng/ml) corresponding to the % maximal absorbance of each extract can be read from the calibration curve. Calculated equivalents are multiplied by a factor 16. All these calculations were done using the Thermo Scientific™ SkanIt™ software.

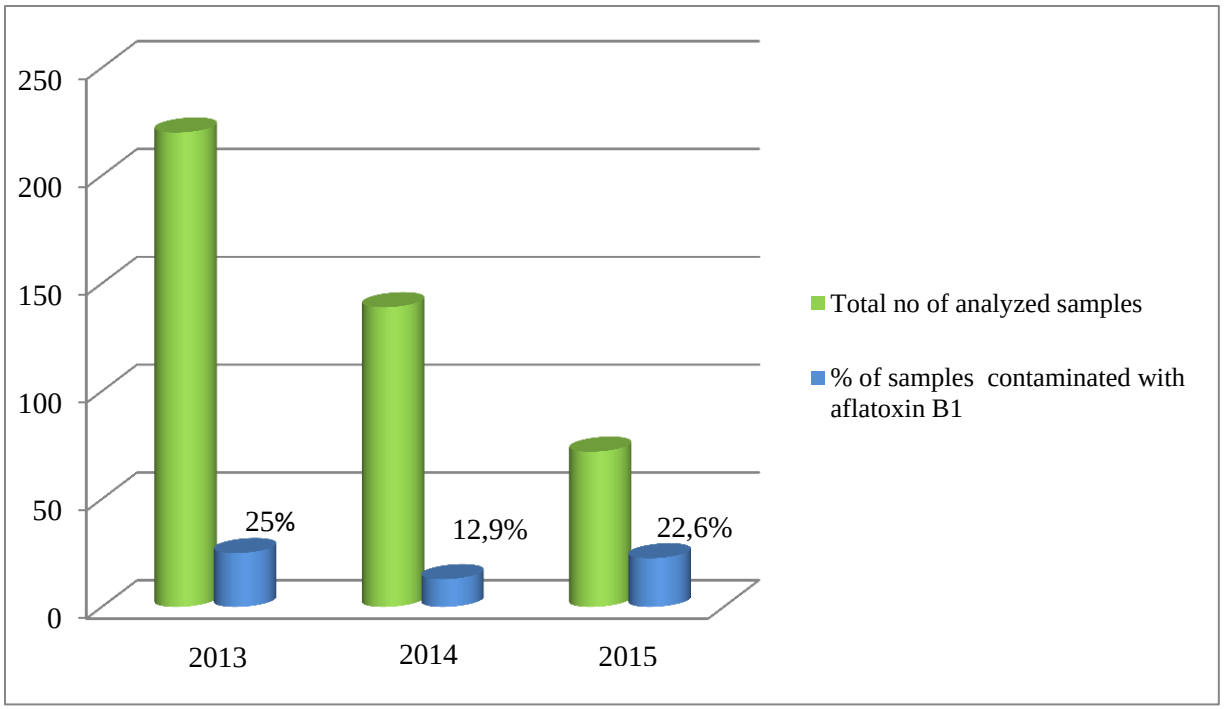
Results and discussion

Results of the analysis of imported samples of food and feed from different countries to the Republic of Srpskaduring three years of survey have shown contamination levels of 60,5%. 34,3% of analyzed samples was contaminated with aflatoxin B1 in the amount of 2-5 µg/kg (ppb) while in 26,2% of the analyzed samples established aflatoxin B1 content was over 5 µg/kg. According to Regulations on maximum levels for certain contaminants in foods (Official Gazette B&H 68/14),cereals and all products obtained from cereals, dried fruits (except dried figs), nuts, peanuts and other oilseeds and their products intended for direct

human consumption with the content of aflatoxin B1 over 2 µg/kg, cannot be used for direct human consumption. According the same Regulation, corn and rice, which will be subjected to sorting or other physical treatment before human consumption or use as a component in food, hazelnuts and Brazilian nuts with the content of aflatoxin B1 above 5 µg/kg (ppb) cannot be used for direct human consumption.In Bosnia and Herzegovina content of aflatoxin B1 in animal feed is regulated by Regulations on undesirable substances in animal feed (Official Gazette B&H 72/11) and content of aflatoxin B1 in animal feed over 20 ppm (20 mg/kg) cannot be used for direct human consumption. All analyzed samples can be used for animal feed according to this Regulation. Analyzed by each year (Table 1, Graf. 1), in 2013 from total analyzed samples number of food and feed (220)25,0% was contaminated with aflatoxin B1. 8,6% analyzed samples was contaminated with aflatoxin B1 in the amount of 2-5 µg/kg. In 16,4% analyzed samples content of aflatoxin B1 was over 5 µg/kg. In 2014, from total analyzed samples number (139)12,9% was contaminated with aflatoxin B1. 7,1% of samples was contaminated with aflatoxin B1 in the range of 2-5 µg/kg while 5,8% analyzed samples had aflatoxin levels higher than 5µg/kg. From total analyzed samples numberin 2015 (72)22,6% was contaminated with aflatoxin B1, 18,6% were contaminated with aflatoxin B1 in the range of 2-5 µg/kg and only 4% had aflatoxin B1 levels that exceeded 5 µg/kg.

Tab. 1. Review of analyzed samples number during the three-year survey.

Year	Total number of analyzed samples	% of samples with concentration of aflatoxin B1 2-5 µg/kg (ppb)	% of samples with concentration of aflatoxin B1 >5 µg/kg (ppb)	Total %
2013	220	8,6	16,4	25,0
2014	139	7,1	5,8	12,9
2015	72	18,6	4,0	22,6
TOTAL	**431**	**34,3**	**26,2**	**60,5**



Graf 1. The total number of analyzed samples and % of samples contaminated with aflatoxin B1 per year.

Conclusion

The levels of contaminated food and feed samples reported in this study with AFB1 shown that monitoring of imported raw materials and feed samples is necessary to prevent human and cattle exposure to aflatoxin B1. Also, Aflatoxin B1 concentration in feed may result in excretion of AFM1 in milk and eventually causing human exposure through consumption of contaminated milk. Many countries monitor imported commodities that are susceptible to aflatoxin B1 contamination by sampling and analysis. However, moulds and aflatoxins in bulk food shipments tend to be highly heterogeneous and it is essential to ensure that an adequate sampling method is used to monitor imported materials.

A NEW BACTERIAL ENDOSYMBIONT OF SUNN PEST, EURYGASTER INTEGRICEPS

Nurper GUZ

Ankara University, Insect Molecular Biology Laboratory, Department of Plant Protection, Faculty of Agriculture, Ankara, Turkey
Corresponding author: nurperguz@agri.ankara.edu.tr

Abstract

Most insect species harbor endosymbiotic bacteria that play key roles in their hosts' fitness by providing essential nutrients and manipulating their reproduction, also protecting them from natural enemies. Spiroplasmas, most commonlyassociated with arthropods, exhibit great diversity with respect to both their modes of transmission and effects on their hosts. In this paper weevaluated the prevalence of Spiroplasma infections in the field populations of Eurygasterintegriceps, one of the most serious pests of wheat and barley. Whole genomic DNA was extracted from surface sterilized individual sunn pest samples from 16 different geographic localities in Turkey. PCR-based screening of DNA was undertaken by using the 16S rDNA locus in terms of Spiroplasma infection. To our knowledge, this study represents the first report of sunn pest naturallyharboring Spiroplasmainfection in Turkey. We detected widespread Spiroplasma infections whereas infection frequencies varied among different populations. The results obtained in this study showed that Spiroplasma infections in E. integriceps in Turkey had a higher frequency, indicating that symbionts appear to be an important tool in developing alternative control strategies against sunn pest populations.

Keywords: Sunn pest, endosymbiont, *Spiroplasma*, *16S rDNA*

Introduction

Symbiotic bacteria are ubiquitous organisms that have major roles in supplying essential nutrients to their hosts such as essential amino acids, vitamins and other potentially beneficial compounds that restricted host diets typically lack (Buchner, 1965; Douglas, 2009; Hosokawa et al., 2010; Feldhaaret al., 2007). In addition toprovisioning nutrientsto thehostthey have also been implicated in the detoxification of dietary compounds and insecticides as well as contribute to resistance toward natural enemies, provide tolerance to heat shock or impact host transmission of viruses (Douglas, 2009; Wilkinsonet al., 2007;Haine, 2008).Among these bacterial fauna,Spiroplasma is one of the most common microbial species found in insects.Spiroplasma is less studied than the other well-known bacteria, Wolbachia, hence the evolutionary consequences of harboringSpiroplasma are unclear.Wolbachia, is a member of α subdivision of the classProteobacteriawhileSpiroplasmas aremembers of the class Mollicutes.Similar to Wolbachia, Spiroplasma is a heritable endosymbiont which is transmitted transovarially from mother to offspring however Wolbachiahas been known to induce cytoplasmic incompatibility whileSpiroplasmais famous as male killer in thefruit fly Drosophila spp.(Poulson and Sakaguchi 1961;Williamson et al. 1999), ladybird beetles (Hurstet al., 1999;Jigginset al.2000;Majerus et al. 1999;Tinsley and Majerus 2006), and a butterfly (Jigginset al. 2000). On the other hand there are species of DrosophilaharborSpiroplasma that do not cause male-killing, and no obvious phenotypic effects of this infection have yet been found (Ota et al. 1979; Williamson and Poulson, 1979).

The sunn pest, Eurygasterspp., is one of the most devastating pests of wheat crops in the Near and Middle East, West and Central Asia, North Africa, Eastern and South Europe (Brown, 1962; Critchley, 1998; Parker et al., 2002) causing up to 90 % losses and seriously damaging the remaining grain quality. The current management strategy for this pest mainly relies on chemical control. In addition to the high cost, insecticides pollute the environment, as well as killing non-target insects, whilst resistance has developed to various types of insecticides in this species (Critchley, 1998; Bandaniet al., 2005; Sukhoruchenko&Dolzhenko, 2008). In recent years, bacteria-insect interactions have emerged as a promising area for development of novel methods to control insect pests. The infection density ofendosymbiontsis one of the most important factors forunderstanding the consequences of harboring endosymbionts.
Objective of this paper was to learn the prevalence of Spiroplasma detected in sunn pest populations in Turkey.

Material and Methods

E. integriceps adults were collected from wheat fields between 2015 and 2016. Information about the collection sites and geographical coordinates of different sunn pest specimens are listed in Table 1.
Specimens were morphologically identified using recent taxonomic keys and confirmed byDNA barcoding (data not shown), as well.
Sunn pest adults were homogenized in lysis buffer (50 mMTris, 50 mM EDTA, 0.4 M LiCl, 1% CTAB, 2% PVPP and 0.5% Tween 20) with a sterile pestle in order to isolate genomic DNA. The homogenate was incubated at 65°C for 15 min and extracted with chloroform-isoamyl alcohol (24: 1) followed by isopropanol precipitation. The pellet was washed with 70% ethanol and re-suspended in sterile water. The bacterial *16S rRNA* gene was amplified by PCR with the primers 16SA1 (5′-AGAGTTTGATCMTGGCTCAG-3′) and TKSSspR (5′-TAGCCGTGGCTTTCTGGTAA-3′) (Fukatsu *et al.*, 2000) under the temperature profile of 94°C for 10 min, followed by 35 cycles consisting of 94°C for 1 min, 55°C for 1 min, and 72°C for 1 min. The PCR product was electrophoresed in an agarose gel, excised, purified by using a Gel Extraction Kit (Promega), and cloned with the TA cloning vector pT7Blue (Novagen) and Escherichia coliDH5α competent cells (Promega), in which ampicillin and X-Gal (5-bromo-4-chloro-3-indolyl-beta-D-galactopyranoside) were used for the blue-white selection system. Plasmids were purified by using a MiniElute kit (Promega). Sequencing reactions were performed by using the plasmids as template DNA with a GenomeLabDTCS Quick Start kit (Beckman Coulter). Sequencing analyses were performed with a GeXP Genetic Analysis System (Beckman Coulter). The following sequencing primers were used: M13M4 (5′-GTTTTCCCAGTCACGAC-3′) and M13RV (5′-CAGGAAACAGCTATGAC-3′) in the flanking regions of the vector. The DNA and deduced amino acid sequences were analyzed using the BLAST tool at the National Center for BiotechnologyInformation (NCBI) (www.ncbi.nih.gov/BLAST) and EXPASY (http://expasy.org/). The sequences obtained with these general primers allowed us to design species specific primers. New primers were designed using Primer-BLAST program (Ye *et al.*, 2012). Sunn pest specific primers amplifying approximately 400bp fragment of bacterial 16S rRNAwere as follows: EinSpiF: 5’ TCT TCC CTT ACA ACA GAC CTT TAC 3’ and EinSpiR: 5’ CTG GCG GCA TGC CTA ATA 3’. PCRs were performed in a total volume of 50 µl using 1 µl of DNA template and GoTaq Flexi DNA polymerase (Promega) according to the manufacturer’s instructions: 5× buffer, 10 mM each dNTP, 10 mM each primer and 1.25 u/µl DNA polymerase. A final primer set (12 SAI: 5’ CTA GGA TTA GAT ACC CTA TT 3’and 12 SBI: 5’ AAG AGC GAC GGG CGA TG 3’) was used to assess the quality of the template DNA. 12S primers are considered universal for insect mtDNA amplifying an approximately 400 bp DNA fragment (Simon *et al.*, 1991). 2 µl of PCR products were visualized by gel electrophoresis on 1.5%

agarose gels stained with ethidium bromide. In the case of negative amplification, PCRs were repeated with higher DNA template concentrations to ensure that the dilutions used were not below the sensitivity of the PCR technique. Data were excluded in cases in which the 12S control primers were unable to amplify a product from a given DNA extraction.

Results and Discussion

This study is thefirsttoreportof the presence ofSpiroplasmainfection in *E. integriceps*. In total, 64 individual females belonging to *E. integriceps* species were screened for *Spiroplasma* by PCR assay using species specific *16SrDNA* gene primers (Figure 1). The infection status of each samples tested and the number of specimen screened are listed in Table 1. In total, 49 of 64 tested samples were PCR positive which means that 76.5% were infected with*Spiroplasma*. Results showed that infections could be detected in 100% of the individuals in İzmit, Sakarya, Gaziantep, Adıyaman, Adana, Balıkesir, Hatay and Kırklareli, whereas none of the populations from Mersin were found to harbor*Spiroplasma*. On the other hand half of the populations from Şırnak, Elazığ and approximately 75% of the populations from Ağrı, Çanakkale, Diyarbakır and Şanlıurfa were found to harbor*Spiroplasma*. Screening more samples will give more accurate infection frequencies of *Spiroplasma* in sunn pest populations.

Table 1. The *Spiroplasma* infection status of *E. integriceps* species collected from various sites. The values (+ve and –ve) refer to the number of sunn pests sampled by PCR analysis and found positive and negative for the presence of *Spiroplasma*, respectively.

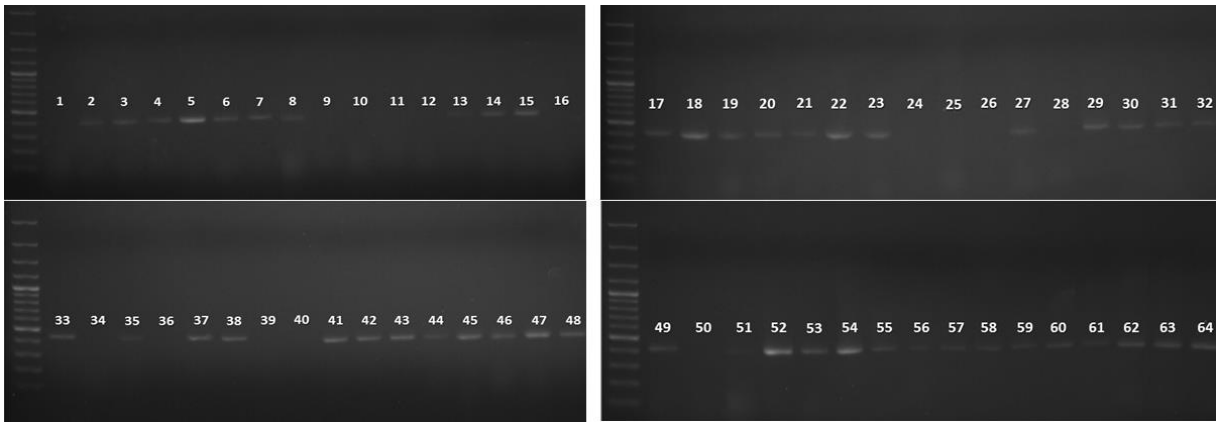
Figure 1.PCR screening for the presence of**Spiroplasma**in *E. integriceps* using species specific *16S rDNA* gene primers.GeneRuler 100 bp DNA Ladder used as marker. Lanes 1-64 represent sunn pest samples from the following areas: Lane 1-4: Ağrı, 5-8: İzmit, 9-12: Mersin, 13-16: Çanakkale, 17-20: Sakarya, 21-24: Diyarbakır, 25-28: Tunceli, 29-32: Gaziantep, 33-36: Şırnak, 37-40: Elazığ, 41-44: Adıyaman, 45-48: Adana, 49-52: Şanlıurfa, 53-56: Balıkesir, 57-60: Hatay, 61-64: Kırklareli



Most of our understanding of the critical parameters influencing the dynamics of symbiotic bacteria spread and maintenance in insect populations comes from studies of *Drosophila*. While the prevalence and fitness cost of *Wolbachia*have been widely studied in *Drosophila*, theincidence of *Spiroplasma*infections in *Drosophila* are far less clear (McGraw & O'Neill, 2004; Werren 1997).The highest levels of *Spiroplasma* infection rates 85% in certain populations of *D. mojavensis* and 66% of females from the field surveys from wild populations of *D. hydei* have been reported in previous studies (Watts *et al.*, 2009; Kageyama*et al.*, 2006). In contrast, infection of wild *D. willistoni* and *D. nebulosa* by male-killing *Spiroplasma*ranged from 1-6%, varyingseasonally (Williamson and Poulson, 1979).Our initial analyses of the prevalence of *Spiroplasma* infections in sunn pest populations have shown that there is a heterogeneous infection profile with 76.5% infection rate in Turkey.

Spiroplasma is a male-killer in some species of *Drosophila* (Williamson & Poulson, 1979), however many other species of *Drosophila*, are infected with *Spiroplasma* that do not cause male-killing, and their fitness effects are unclear (Kageyama*et al.* 2006; Mateos*et al.* 2006; Watts *et al.* 2009).Some species of *Spiroplasma* are horizontally transmitted insect pathogens in the gut while many lineages exhibit vertical transmission via transovarially (i.e. from mother to offspring) and affect their hosts in different ways (Gasparich, 2002). The mode of transmission route of *Spiroplasma* in sunn pest populations and how sunn pest is affected from *Spiroplasma* infection is still unknown. On the other hand, sunn pest is a hemimetabolousunivoltine species feeds and completes its development in grain fields during spring and summer and then migrates as an adult to the mountains in late summer where it enters an obligatory diapause. Due to its genetically programmed diapause and reproductive strategy it is difficult to measure the fitness effect of *Spiroplasma* in sunn pest populations.

Conclusions

In the present study, we assessed the prevalence of *Spiroplasma* in *E. integriceps* in sixteen different geographic localities in Turkey. Due to intensive sampling effort, we are able to test *Spiroplasma* presence by PCR analysis. Further experiments need to be conducted in order to detect the phylogenetic relationship and phenotypic effect of *Spiroplasma* in *Eurygaster* populations which will conferits potential in terms ofsuppressingsunn pest species in the future.

Abstract

Tomato (*Solanum lycopersicum* L) is universally one of the most important vegetable crops worldwide. In Egypt, the crop is cultivated annually in 2-3 plantations. The tomato leaf miner, *Tuta absoluta* (Meyrick) (Lepidoptera: Gelechiidae) is one of the recent devastating pests attacking tomato crop worldwide. It is a new exotic pest in Egypt in 2009. A study to evaluate the efficacy of integrated control methods against the pest was carried out at Fayoum Governorate, Egypt in the tomato Nili plantation (September – December) of 2014. The control methods tested based on the use of bio-rational solutions (use of biopesticides) or biological control agents in integration with mass trapping (use of sex pheromone). The evaluation was measured by counting the aggregation pheromone trap catches twice a week and the reduction rate of pest infestation (weekly inspection of no. of mines/plant). Based on the infestation reduction rate, release of the egg parasitoid, *Trichogrammatoidea bactrae* + mass trapping (plot B) showed best results, followed by the application with Biotrine and Fytomax + mass trapping (plot A) and lastly use of insecticides (control) (plot C). Respective seasonal rate of infestation was 9.2, 11.1 and 29.3%. Highest yield production was recorded (38 ton/hectare) in plot (B) (*T. bactrae* + mass trapping), whereas the loweerone (33.5 ton/hectare) was recorded in plot (C) (control). The general means of cost benefit for plots A, B and C attained 6150.5, 6635 and 5630.5 Euro/ hectare, respectively.

Keywords*:*Tomato, *Tutaabsoluta*, IPM, Cost benefit, Egypt.

Introduction

Tomato (*Solanum lycopersicum* L.) is universally considered one of the most important vegetable crops worldwide. This crop is subject to attack with scores of insect pests and diseases that affect its production.The tomato leaf minor (TLM), *Tuta (Scrobipal puloides) absoluta* (Meyrick) (Lepidoptera: Gelechiidae) is one of the major devastating insect pests attacking tomato in many of the tomato-producing regions worldwide. It is originated from south America, rapidly invaded various European countries and spread very fast along the Mediterranean Basin including Egypt (Desneux *et al.*, 2010). Tomato is known as the main host of *T. absoluta*, but it also feeds, develops and reproduces on other solanaceous plants such as potato, tobacco, eggplant, pepper, aubergines, black nightshade and several related weeds such as jimson weed (Pereyra and Sanchez, 2006). Severe infestation with *T. absoluta* can potentially result in significant damage by feeding on all aerial parts of tomato plant, causing economic losses of up to 80-100%, if the pest is not properly managed (Desneux *et al.*, 2010).

At present, depending on the cropping system and infestation intensity, the main control tools used against TLM rely too heavily on conventional insecticides that have led to the development of insecticide resistance (Haddi, 2012). Therefore, the use of insecticides has become subordinated to other control methods, such as biological control singly and/or in

integrated with other methods as use of aggregation pheromones and biopesticides that have gained more credibility in the last decades (Senior *et al.*, 2001; Agamy, 2003 and Mandour *et al.*, 2012). Biological control using natural enemies would be the concerted use as a major component of any integrated pest management (IPM) program for controlling TLM. Egg parasitoid species of family Trichogrammatidae are considered efficient biological control agents and are widely used commercially for the suppression and control of lepidopterous pests on many crops (Agamy, 2003). They are easy to rear and release either in open fields or protected crops (Chailleux *et al.*, 2012) mostly through innudative releases (Mills, 2010). Selection of the appropriate *Trichogramma* species for controlling a given insect pest is a crucial factor to the success of biological control program (Desneux *et al.*, 2010; Mills, 2010 and Chailleux *et al.*, 2012).

The present study aimed to testing an IPM package based on use of sex pheromone aggregation traps + use of biorational solutions or a biocontrol agent comparing with use of conventional pesticides. Cost-benefit of the package was also estimated. .

Materials and methods

Materials

Biorational solutions

The tested biorational solutions used in this study were Fytomax N and Biotrine produced by Russell IPM Company UK. These two products are highly recommended for controlling T. absoluta in vegetable crops.

1-Fytomax N: is a bio-rational solution based on Azadirachtin 1% (10000 ppm) extracted from the neem tree seeds *Azadirachta indica* in ULV formulation. Fytomax N prevents or interferes with an insect's development. It has an ovicidal effect and control target pests by contact as well as by ingestion. It acts as a repellent, antifeedant, and interference with the molting process of insect pest. Treated insects stop feeding and growing.

2-Biotrine:is a bio-rational solution based on a natural fermentation of the soil bacterium *Streptomyces avermitilis***.** It is a broad spectrum in its action, killing insects through contact and as they feed on treated plants. Biotrine works by paralyzing the insect, contact, ingestion and by suffocation. It acts as an antifeedant product with residual protection for the crop.

Soapy water traps

Pheromone lures used in this study were obtained from Russell IPM Company, UK. Rubber septa dispenser of 120 days was used. Water traps were used for monitoring and mass-trapping program. Trap designs vary and can be as simple as deep plastic trays filled with soapy water and with the pheromone lure suspended over the center of the tray just above the water line attracted moths become trapped when they touch the soapy water.

Trichogrammatoidea bactrae Nagaraja and Nagarkatti

The egg parasitoid speciesT. bactrae was recommended to be used against the pest. Parasitoid cards,included parasitized Sitotrogacerallela eggs, provided by El–Heneidy (Dept. of Biological Control, Agriculture Research Centre, Giza, Egypt), were kindly hanged directly in the field on the tomato plants.

Methodology and Experimental Design

An experimental area of one hectare (equal 2.5 feddan) (feddan = 4200 m^2) located at Fayoum governorate in Egypt, cultivated with tomato plants, variety Gold stone (planted in the nursery on 20th of June and transplanted to the permanent field by early August), was subdivided into

three experimental plots. The experiment was carried out at the tomato plantation (September-January), which is so-called Nili plantation. Plot A (one feddan) was subdivided into 4 subplots (A1 – A4) as replicates and treated with Bio-rational solutions. Plot B (one feddan) was subdivided into 4 subplots (B1 – B4) as replicates and was treated by releasing *T. bactrae* (at two release rates; 60000 and 100000 parasitoids per feddan). Plot C (control) (½ feddan) was subdivided into 2 subplots (C1 and C2) as replicates and left for regular practices carried out by the grower himself, depends mainly on the use of pesticides. The pheromone-soapy water basin traps were placed at all the experimental plots. Meteorological data (minimum, maximum temperature and relative humidity (RH) in the region of the experiment throughout the experimental period was obtained from the meteorological station of Fayoum, located in the Agricultural Research Station, Fayoum, Egypt.

Monitoring of pest population

A total of 10 pheromone traps per hectare (4 per feddan), obtained and recommended by Russell IPM, UK was placed as 4, 4 and 2 traps in plots A, B and C, respectively, as mass-trapping.Trap catches were examined and counted twice a week throughout the tomato growing season that extended from early September 2014 to early January 2015.

Estimation of the rate of infestation with *T. absoluta*

A total of 100 plants (25 plants/ replicate)/ plot was examined weekly and rate of infestation (no. of mines in the leaves, stems and fruits/plant) were counted and recorded at the three experimental plots A, B and C, starting early September until harvesting.

Experimental plot A (Bio-rational solutions' trial)

Four pheromone–soapy water traps were placed, one trap/ replicate, at each of the subplots A1, A2, A3 and A4. By catching the first *T. absoluta* moth in any of the plot traps, the plot was treated weekly by one of the two tested compounds; Biotrine and Fytomax N, alternatively until harvesting.

Experimental plot B (Parasitoid's trial)

Four pheromone–soapy water traps were placed, one trap/ replicate, at each of the subplots B1, B2, B3 and B4. By catching the first *T. absoluta* moth in the plot traps, the plot was treated bi-weekly by releasing the egg parasitoid *T. bactrae* at two release rates; 60000 and 100000 parasitoids per feddan. The first rate (15000 parasitoids per subplot) was applied in subplots B1 and B2, while the second rate (25000 parasitoids per subplot) was applied in subplots B3 and B4. Each was considered as a replicate. Releases were applied until harvesting.

Experimental plot C (Control)

Half feddan (2100 m^2) was subdivided into 2 subplots (2 replicates) (C1 and C2), each replicate (about 1000 m^2). Two pheromone– soapy water traps were placed, one trap/ replicate at the subplots C1 and C2. The plot was sprayed by the grower himself using recommended pesticides in the region, without any interference. Pesticides names, rates and dates of application were recorded.

Cost-benefits of IPM packages

At the end of harvesting, cost-benefits of using each of the IPM packages; bio-rational solutions, biological control and pesticides application (control) were estimated. The costs included the costs of purchasing the traps, materials and labor cost at each plot.

Statistical analysis

Obtained date was subject to statistical analysis using the computer program one way ANOVA and T test. Means were compared by Duncan's Multiple Range test.

Results and discussion

Trap catches

Data of the trap catches of *T. absoluta* moths in the pheromone traps placed in the experimental field at Fayoum Governorate, Egypt in tomato Nili plantation of 2014 were summarized in table (1). By early September 2014, the beginning of the study in the permanent field, 2 pheromone traps was placed in plot C (control plot) for monitoring the pest population. The first catches (7 moths/ trap) were found on September 9th. Accordingly, other traps were placed in plots A and B (treatments) (4 traps/ plot = a rate of 10/ hectare) to serve for monitoring as well as mass-trapping control method. The first records 3.75 and 7.75 moths/ trap in plots A and B, respectively were recorded on September 12th. Occurrence of the moths continued throughout the whole study period September 2014 – January 2015. The month of October represented the highest mean numbers of moth catch/ traps (46.8 moths), followed by November (27.6 moths), while the months of September and December were the lowest (16 moths) (Table 1).

Table (9): Monthly mean numbers of *T. absoluta* moth catches/ trap in pheromone traps placed in different experimental plots at Fayoum Governorate, Egypt in the tomato Nili plantation of 2014

Date of Inspection	Trap Catches (No. of moths/trap)													Mean /trap
	Plot A (Plant extracts)					Plot B (Release of *Trichgrammatoidea*)					Plot C (Control)			
	A1	A2	A3	A4	Mean	B1	B2	B3	B4	Mean	C1	C2	Mean

The technique of mass trapping with pheromone has been widely used for the control of different insect species (Rodriguez-Saona and Stelinski, 2009). These findings agree with those reported earlier by Ltd (2009b) who mentioned that mass trapping can be used to reduce *T. absoluta* populations and it is particularly useful in production of greenhouse tomatoes. Also, Salas (2004) reported that water traps were the most common pheromone traps used for mass trapping of T. absoluta, as they are easier to maintain and less sensitive to dust than Delta or light traps and also have a larger trapping capacity than Delta traps. Cocco *et al.* (2012) stated that use of mass trapping alone for controlling male *T. absoluta* populations was not effective in reducing leaf and fruit damage.

Seasonal general mean of trap catches in plot C (control) was 23 and 27% higher than that in plots A and B, respectively. Total catch difference between plots A and B was 8% in favor of plot A. Number of moth catches in plot C was lower than that in plots A and B in September, while it was higher in the other three months, especially in December.Peak numbers of the moth catches (60, 82 and 84 moths/ trap) was recorded on October 27th, 19th and 19th in plots A, B and C, respectively. As well, the month of October represented the highest mean numbers of moth catches/ trap (43.6, 42.5 and 54.5 moths/ trap) in plots A, B and C, respectively (Table 1).

Percentages of infestation

Percentage of infestation with *T. absoluta* at Fayoum Governorate, Egypt in the tomato Nili plantation of 2014 was summarized in tables (2, 3 and 4).

Plot A: treated weekly with each of Biotrine and Fytomax N alternatively, started September 21st and ended November 23rd. Each compound was treated 5 times**;** Biotrine on 21/9, 5/10, 19/10, 2/11 and 16/11/2014 and Fytomax N on 28/9,12/10, 26/10, 9/11 and 23/11/2014. The monthly rate of infestation started with (7.3%) in September, increased in the following months to reach (8.2%) in October, (16.3%) in November and then reduced to (12%) in December (Table 2). Rates of infestation have been always less, following the application with Biotrine than that following Fytomax, except the application practiced by early November (Table 2). Seasonal rate of infestation at plot A was 70% less than the control (pesticides treatments). Statistical analysis showed highly significant difference between the use of Bio-rational solutions (t= 0.00111**) and the control.

Table (10): Monthly mean rates of infestation with T. absoluta (no. of mines/ plant) at Plot (A) (sprayed with biorational solution) at Fayoum Governorate, Egypt in the tomato Nili plantation of 2014.

Date of inspection	Mean				
	A1	A2	A3	A4	Mean
September	9.3	9.3	5.3	5.3	7.3
October	9.6	10.4	8	7.2	8.2
November	19	23	13	10	16.3
December	10	18	13	7	12
Grand mean	12	15.2	9.8	7.4	11.1

Current management of TLM in Egypt as a part of Mediterranean Basin is mainly based on treatment with chemical insecticides (González-Cabrera *et al.*, 2011). Nevertheless, few bio-rational solutions are effective against TLM and selective to beneficial insects at the same time. Obtained results revealed that it is possible to reduce the tomato leaf miner impact by applying Biotrine and Fytomax N alternatively + mass trapping combination which showed promising results in controlling the pest. The Azadirachtin based-bio-rational solution Fytomax N had great efficacy towards *T. absoluta*. These findings agree with those reported earlier by Servicio de Sanidad (2008) who recommended use of Azadirachtin as a preventive spray and for light infestations (< 30 adult catches per week) of *T. absoluta* in Spain. Abamectin based bio-rational solution Biotrine efficiency was also confirmed under field conditions. These findings are in agreement with those reported earlier by Zalom *et al.* (2008) who recommended abamectin for controlling the tomato pinworm in IPM programs. Moussa *et al.* (2013) mentioned that abamectin provided excellent control against *T. absoluta* in Egypt. Mass trapping and using of Biotrine alternatively with Ftyomax N induced showed a better control of the pest. Generally, seasonal rate of infestation was much less than the control (pesticides' treatments).

Plot B: treated biweekly by 2 rates of the egg parasitoid, *T. bactrae;* 60000 (in subplots B1 and B2) and 100000 (in subplots B3 and B4) parasitoids/ feddan. Dates of releases were on25/9, 9/10, 23/10, 6/11 and 20/11/2014. Releases started on September 25th and ended November 20th. Both release rates were applied 5 times. Monthly rate of infestation started with (5%) in September, increased in the following months to reach (8.6%) in October, (12%) in November and continued around the same level (11%) in December (Table 3).Rates of infestation were almost similar at the 2 different rates of releases in September, increased slightly in October at the high rate of release and then a vice versa was recorded in November

(Table 3).Total seasonal mean rate of infestation with *T. absoluta* at Fayoum in the Nili tomato plantation of 2014 was nearly equivalent in plots A and B (11.1 and 9.2%, respectively).Seasonal rate of infestation at plot B was 75% less than the control (pesticides' treatments) and 17% less than applying Biotrine or Fytomax. Statistical analysis showed highly significant difference between the use of *T. bactrae*(t=0.003587**) and the control. Also, insignificant difference was found between the two rates of releasing *T. bactrae* (t= 0.086433) in plot B.

Table (11): Monthly mean rates of infestation with *T. absoluta* at Plot (B) (release of *Trichogrammatoidea*) at Fayoum Governorate, Egypt in the tomato Nili plantation of 2014

Date of inspection	Mean				
	B1	B2	B3	B4	Mean
September	8	1.3	5.3	5.3	5
October	7.2	7.2	13.6	6.4	8.6
November	11	17	13	7	12
December	10	10	17	7	11
Grand mean	9.1	8.9	12.2	6.4	9.2

T. bactrae is one of the most effective parasitoid against TLM as indicated by the higher percentages of parasitism (Abd El-Hady, 2014). In the present study, obtained results revealed that these oophagous parasitoid would play crucial role for management of TLM. Abd El-Hady (2014) stated that increasing the number of released parasitoids caused significant increase of parasitization and the seasonal rate of infestation was obviously less than the control (pesticides' treatments) and relatively than the bio-rational solutions. Such result is evidence of the efficacy of the combining of mass trapping technique and release of T. bactrae in management of TLM.

Plot C: (control plot), treated 7 times by the grower, using three different pesticides; Nomolt 15% SC, Pleo 50% EC and Oshin 20% SG. Dates of application were as follow: Nomolt 15% SC on 18/10 and 22/11/2014 &Pleo 50% EC on 7 and 13/11/2014& Oshin 20% SG on 22/10, 28/11 and 2/12/2014. The monthly mean rate of infestation with the pest increased from 13.3% in September to 26.8% in October, to 60.5% in November and then decreased to 29.3% in December (Table 4).Seasonal mean rate of infestation was obviously higher in plot C (29.3%) than in the other 2 plots, 11.1 and 9.2% at plots A and B, respectively. This indicates that application of either Biotrine or Fytomax or release of parasitoid achieved about 70-75% less rates of infestation than using pesticides**.**

Table (12):Monthly mean rates of infestation with *T. absoluta* at Plot (C) (control -sprayed with pesticides) at Fayoum Governorate, Egypt in the tomato Nili plantation of 2014

Date of inspection	Mean				
	C1		C2		Mean
	I	II	I	II	
September	18.7	0	8	0	13.3
October	24	0	29.6	0	26.8
November	60	0	61	0	60.5
December	46	10	47	14	20
Grand mean	37.2	10	36.4	14	29.3

I = < 3 mines/plant II = 4 -10 mines/plant III = > 11 mines/plan

Although plot C was treated 7 times by the pesticides (Nomolt 15% SC, Pleo 50% EC and Oshin 20% SG), the highest total rate of infestation (36.8%) was recorded in it. Percentages of infestation did not exceed a level one (< 3 mines/ plant) in plots A and B throughout the experimental period. Level 2 (4-10 mines/ plant) was recorded twice in the pesticide plot (C) in late December (Table 4). Highest monthly mean percentage of infestation (60.5%) was recorded in plot C (control) in November, while it was 16.3 and 12% in plots A and B, respectively in the same month (). Generally, the peak number of moths/ trap, recorded in the pheromone traps in October (46.8 moths), led to an increase in the pest's rates of infestation in the all experimental plots in November. Treatment with the parasitoid releases in plot B (5 times) showed least mean percentages of infestation (9.2%) compared with (11.1%) in the bio-rational solutions treatment (plot A) (treated 10 times).

Cost Benefits

Plot B showed 11.8 and 5.3% higher in yield production (ton/feddan) than plot C and A, respectively and correspondent less control costs 57.19 and 42.18%. Seasonal cost benefit achieved in the experimental plots was 15.14 and 7.31% higher in plot B than that in plot C and A, respectively.

In conclusion, applying an IPM packages depended upon mass trapping plus either release of the parasitoid, *T. bactrae* or applying Biotrine or Fytomax achieved best rates of reduction of T. *absoluta* infestation at Fayoum in the Nili tomato plantation of 2014. Further studies are needed for other tomato plantations as different rates of the pest population are expected.

NOZZLES APPLICATION QUALITY IN WHEAT: EFFECT OF SINGLE, DOUBLE AND TRIPLE FLAT FAN NOZZLES

Aleksandar SEDLAR, Vladimir VIŠACKI, Rajko BUGARIN, Jan TURAN, Lazar PAVLOVIC, Sanja LAZIĆ, Dragana ŠUNJKA

Abstract

Protection of wheat must be done in an efficient and economical way to protect against diseases and pests. The price of wheat prevents enough space for the calculation in the protection and further subsequent corrective walkthrough. The protection is usually done in two passes, one for weed control and the other for diseases and pests. For several years back, wheat pass through the critical period when flowering. High temperatures and humidity cause invasive attacks of several different diseases and pests. This protection is the most important because it directly affects the grain quality. For efficient protection, besides of respecting norm and dose, it is necessary to use adequate nozzles. Density of wheat and leaf surface is at a maximum. For good protection, it is necessary that the working fluid cover leaf and ear of wheat. During the experiment three types of nozzles were used. The common characteristic is that they have a flat T jet, spray angle of 110^{o} and a flow rate of 1.6 l / min at 3 bar. They differ in the number of jets. Nozzles are used with one, two and three jets. The first nozzles have vertical jet, second have jets at 30 ° from the vertical on both sides and third, one jet is positioned vertically while the other two at an angle of 30 ° on the opposite side. Because they have two or three jets, expected result is to have better pesticide applications. This would achieve effective protection of wheat and thus ensure high yield and quality of grain.

Keywords: *nozzle, nozzle jet, pesticide application, wheat, sprayer.*

Introduction

Wheat is the most important raw material for the food and the animal population in Vojvodina province (Serbia). The sowing is performed on about 30% of arable land, depending on the year. Mainly winter wheat is sown. The protection is performed several times in the spring when the conditions are acceptable for the application of pesticides. These are the two most common treatments for weed and fungal diseases, insects rarely. The first was carried out in early spring, in March after fertilization, which was conducted in February, a second suppression of in May. The optimal deadline was in mid-May. In order to combat fungal diseases is very important to treat the entire surface to a pesticide application is uniform. In order to achieve uniform application of pesticides play an important role nozzles.

The most important and most critical point of the production of wheat and other cereals is to protect crops and pesticide application (Ágoston-pepo, 2005; Czövek et al., 2006). Chemical treatments are harmful to crops and the environment, and their efficiency should be at the maximum level. Weeds, insects and fungal diseases are in an environment that allows them to extremely rapid growth and development, and further threaten the crop. Control weeds and pests has great influence on the yield and therefore economic profit (Knežević et al. 2008). Accordingly, pesticides play a role to increase the protection of food production and an increase in living standards (Delcour et al., 2015). For the reduction of pests and diseases and increasing economic effects of agricultural production, farmers resort to using more pesticides (Nazarian et al., 2013). But the use of pesticides must be carried out at the right time with the

correct quantity and in the right way (Khan et al., 2010). Accordingly, the use of pesticides must be based on environmental conditions, the applied knowledge and current research in order to obtain a healthy safe and economically viable product (Yilmaz, 2015).
Task work represents pesticide application in wheat using three different types nozzles for different exploitation parameters. The paper determines flexibility of pesticide application using chemical tracer. Conducted research is needed to determine which nozzles utilization is the best for the application of pesticides in wheat.

Materials and methods

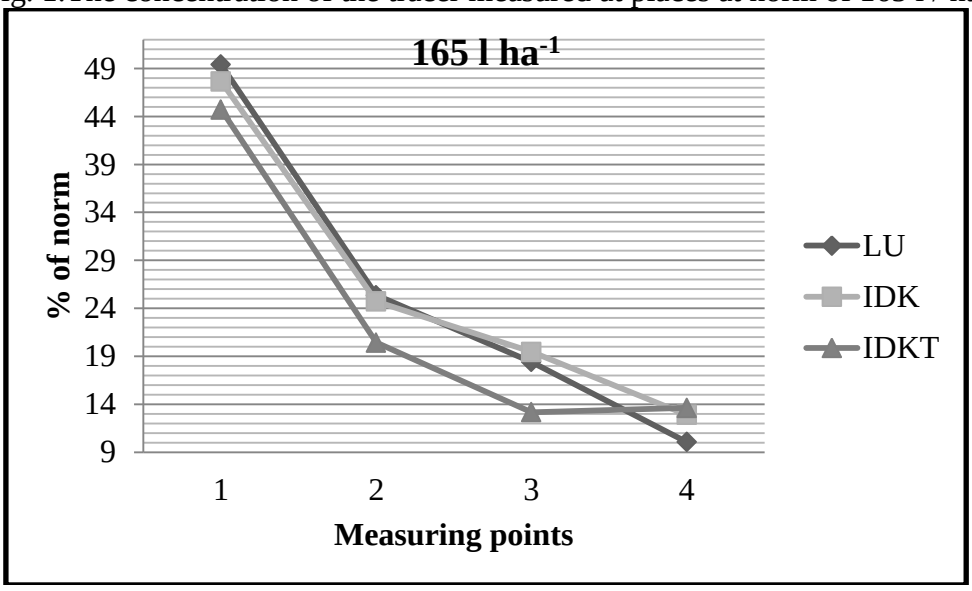
All trials are performed at open filed which is located in Vrsac. It was used tractor mounted sprayer Agromehanika AGS 800 which was aggregated tractor Case Farmal 115U (IH Farmall 115U). Capacity is 800 l sprayers a width of 15 m. Pivoting wings are coupled to the frame at one point and two springs were doing the leveling, and formed a mechanical system to copy field. Pump low pressure BM 105 the same manufacturer, type of piston-diaphragm with a capacity of 105 l / min at 20 bar and 540 o / min, serving 30 nozzles working fluid and performs the same mixing. Height applications was 0.5 m as recommended by the producers, set the height of the most common applications in Vojvodina province. Carriers nozzles can carry maximum of 3 nozzles, triplex carrier. The same number nozzles were used in the experiment. The first nozzles with flat jet, spraying angle of 120 °, red color by color marking, labels LU 120-04. The following nozzles are injector type with single jet of the same technical characteristics as the first, marks IDK 120-04. Last, was same characteristics as the previous one but instead of one has two jets, a mark is IDKT 120-04.
On tractor Case Farmal 115U set four-cylinder engine with a nominal output of 84 kW at 2300 min-1 (ECE R120), water-cooled engine with over boost as turbo compressors. Maximum torque is achieved at 1500 min-1 (ECE R120) in the amount of 463 Nm. Transmission semi-automatic with a choice of 12 + 12 speeds, permanent four-wheel drive with electro-hydraulic turning on and turning circle of 4.05 m. Force hydraulic lifters that the pump flow rate of 65 l / min which allows lifting 3190 kg at the rear linkage. A total length of 4161 mm and wheelbase of 2350 mm. Standard tire sizes are 480/65 R 24 front and 540/65 R38 ago.
Treatment norm amounted to 175 l / ha at the speed of the tractor aggregate of 9.5 km / h and pressure of 2 bar applications. Also, the norm of 200 l / ha and 235 l / ha were used in the test at a pressure of 3 bar 4 bar person respectively. Wind speed was 1-2 m / s. The temperature was 26 ° C and the humidity was about 60%. Environmental conditions did not change during the execution of the experiment. Wheat was the average height of about 1.3 m, the leaves were about 1 m. She was very good and high density planting.
Using tracer obtained more correct information on the amount of active substance due to the target surface. This method of measuring is a cheap and easy method unlike chemical methods for determining the deposits of chemical plant protection products on the treated surface, which are more expenses. Tracer is a compound that fluoresces under the influence of light of a certain wavelength. Most often it is sold as a solution, or in solid, powder form, with the content of 89% tatrazine. Under the influence of light, it starts to degrade and also react differently with a change in pH. Characteristic of this tracer is as easy to use, non-toxic when handling. The lack of the aforementioned degradation is due to the effects of sunlight. It was stirred directly into the spray tank with water. Do not react with chemicals that contaminated a sprayer in the application it is necessary to properly wash sprayer or machine protection products. Most often used for determining the quality of deposition, measurement drift or contamination level of the operator, or the environment in which it is applied. For determining the quality of the application used in was tracer Tatrazine concentration of 5 g / l. Petri dishes are set at 4 places. First place was with the class and leaves, the second position is below the

sheets (upper leaves), the third location in the lower part of the tree and the last position is close to the land-surface. Petri dishes after pesticide application, washed with 0.05 l of deionized water and then analyzed on a spectrophotometer Shimadzu UV-Vis 1100 a wavelength of 427 ± 2 nm. All tests were done with water whose pH was slightly acidic and it was 5.7.

Results and discussion

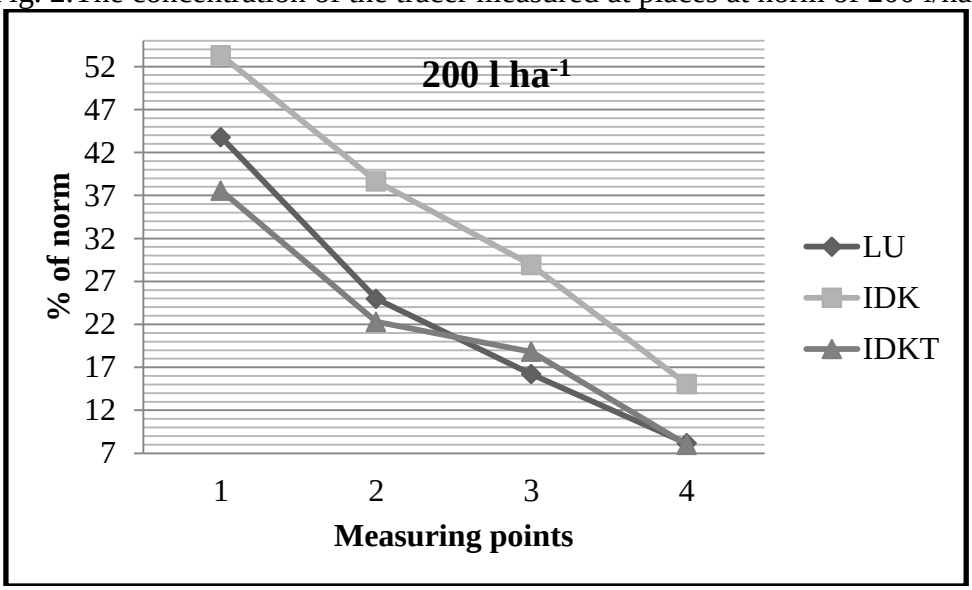
The research results are presented by following photos. They shows the concentration of tracer in petri dishes on all four points of measurement. The first point is the top part and the rest are on the lower parts, described above.

Fig. 1.The concentration of the tracer measured at places at norm of 165 l / ha.



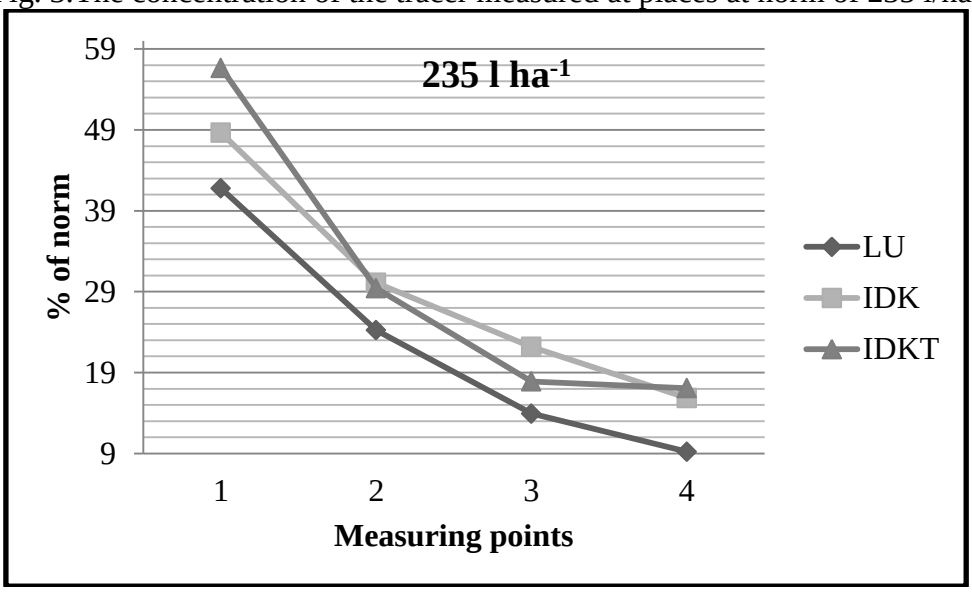
In the norms of 165 l / ha measured tracer concentration is the highest at the application of LU from 120 to 04 and the nozzles amounted to more than 49.4% relative to the concentration that has been in the working fluid. Something small amount was deposited nozzle IDK while the least deposited injector nozzle with two jets IDKT in the amount of over 44%. Double small amount of tracer was observed on the second measuring point, which was under the leaves of wheat. An average of less than 14% of the working fluid was deposited by all three nozzles at the lowest measuring point. Extracting the nozzle IDKT which recorded a smaller amount of liquid deposited on almost all counts except the lowest, for about 10.13% and 23.46% compared to the other two investigated.

Fig. 2.The concentration of the tracer measured at places at norm of 200 l/ha.



With increasing norm leads to reduced efficiency nozzles. In the norm of 200 l / ha, over 53% of the total amount of tracer nozzle IDK successfully distributed to the class and leaves of wheat. This is not the case with the other two where the injection nozzle with two jet retains the trend of distributed fluid at least the first two measuring points. These values range close from 43% up to 25% for nozzle with a flat jet of 37% and to 22% for IDKT nozzle. At the measuring points 3 and 4 the volume of distributed fluid both these nozzles is similar. An injection nozzle with a flat-jet recording of a greater amount of deposited nozzles of the examined in an amount of 22% to a high of 100%.

Fig. 3.The concentration of the tracer measured at places at norm of 235 l/ha.



The photograph 3 is registered to both injector nozzles have better pesticides application with increasing standards and pressure in relation to the LU nozzle. This continues the trend of improving the quantity of liquid deposited with the increasing norm. So the top of the crop nearly 58% and 49% was deposited tracer injection nozzles. On counts 2 and 3 quantity is similar to the last measuring point 4. It is not case by the nozzle on point 4 where application quality is lower.

Conclusion

The method of measuring the quality of work of different nozzles using tracer provides reliable information. In examining the three nozzles can be concluded that the quality of the application of pesticides in wheat necessary to use the injector nozzles at high pressure applications.

Thus, the total quantity of liquid, more than 50% is due to the treated surface at application rates from 200 l ha $^{-1}$ and 235 l ha $^{-1}$. Higher pressures are not conducive to the nozzles applications with flat fan-shaped spray deposited because less than 45% of the working fluid. The rest misses the target or disappear as a drift.

It is necessary to do the effectiveness of treatment to determine the influence of pressure and type nozzles on the quality of apps, pesticides.

BREAD PRODUCTION LEFTOVERS AS POTENTIALLY VALUABLE RAW MATERIALS IN BIOTECHNOLOGY

Zvonko NJEŽIĆ[1*], Jasmina ŽIVKOVIĆ[1], Dragan PSODOROV[2]

[1]University of Novi Sad, Institute for Food Technology, Novi Sad, Serbia

Abstract

The total production of bakery products in Serbia is around 800,000 tons per year, whereby the most frequently consumed product is wheat bread. The average consumption of bread per capita is about 106 kilograms. According to the statistics of this product consumption, regardless to the growth of prices, the total production has been increased in recent years. Increase of food production for humans and animals could be achieved through the application of new technologies in the food sector, i.e. in the bio-industry. Nowadays, there are many different ways for thermal processing of cereals: extrusion, hydrothermal processing, micronization, microwave treatment, while in Serbia, the most frequently used processes are extrusion and hydrothermal processing. Baking industry is highly developed in Serbia. Thus, bread consumption per capita in Serbia is far above average consumption in the EU. According to the survey conducted in January-February 2016 by The Institute of Food Technologies in Novi Sad, there is a significant amount of bread leftovers in Serbia. Bread leftovers represent an environmental problem. On the other hand, they are potentially valuable raw material for human food and animal feed. Therefore, bread leftovers could be considered as a potentially valuable raw material in the food industry. Corn grits (13 %) and bread crumbs (12.87 %) were used as the main ingredients of extrusion mixes. The result shows a significant increase of the total energy of mixes in comparison to the basic ingredients. Extruded mixes did not contain any of determinate pathogenic bacteria with an exception of an excessive number of microorganisms.

Keywords: *bakery products, food waste, raw materials, bread leftovers.*

Introduction

The food waste created in the bakery industry or in the large chains of supermarkets, hotels or other mass food storages, could become an excellent ingredient, in the case of the proper use. This paper suggests a solution for an application of stale bread, waste oil from the cold pressed soy bean, damaged corn grains in the production of proper healthy animal feed.

In accordance with the results of the survey, conducted in January-February (2016) by The Institute of Food Technologies in Novi Sad (FINS), the amount of the stale bread in retail is in the interval between 5 and 20%, which is slightly more in comparison to results from the same survey conducted in 2010 (from 5 to 10%) (Nježić et al., 2010). Mentioned increase of the total amount could be attributed to the novel practice on the market, which implies the dump selling price from 10 to 25 dinars of the yesterday bread. However, the amount of wasted bread is still 10% of the total production. The question is: "How much bread we throw away on the daily basis?". The conclusion is that from one million and five hundred bread loaves produced in Vojvodina, a hundred thousand of them has been thrown away, which is almost fifty tons of bread on the daily basis. Depending on safety-health condition of the ingredient, we have either extremely attractive or potentially dangerous raw material (Nježić et al., 2010). It is possible with a good coordination to obtain a relative low price for the half of the total available samples. We have been managing to get a price of 10 dinars per kg of the stale bread, which is almost five times cheaper than ingredients created from flour T-500, and two times cheaper from wheat.

The price of the organized collecting of the stale bread would be certainly lower, thus we have a very commercial ingredient for the extrusion purposes for bread crumbs production.The solution to an increase of human and animal food production is an application of novel technologies in biotechnology, i.e. bio-industry (Lazarević et al., 2005). Basic orientation is presented by the new technological procedures. The objective of these procedures is an increase in the human and animal food nutritive value, also as a valorisation of byproducts in food and agricultural industry. Many methods for wheat and oilseed thermal processing were applied so far in the industry such as: extrusion, hydrothermal processing, micronization, microwave treatment, dialectical heat treatment (Marsman et al., 1998; Sakač et al., 2001), while in Serbia the most frequent processes are the extrusion and the hydrothermal processing (Filipović et al., 2008). An adequate operation of the thermal processes provides a reduction of a thermo-labile anti-nutrient content on the decent level, beside itseffects on the increase ofcertain ingredients digestibility (protein, oil and carbohydrates), also as improving of sensorial characteristics and microbiological frame of the final product (Filipović et al., 2007).Considerable quantities of damaged corn grains were selected from the animal food factory silo. Furthermore, damaged grains were converted to corn grits.Corn is the basic ingredient for the most of feeds in the animal nutrition. By the application of corn extrusion process, as the basic ingredients in animal feeds, it could be obtained a better valorisation of food in the animal feed (Filipović et al., 2008). Along with the reduction of the antinutrient content, it is necessary to save the nutritive valued thermo labile components, therefore the process demands an achievement of compromise between these two efforts (Jensen et al., 1995).The mix of 50:50 corn grits and bread crumbs was created, before the extrusion process, with addition of wasted oil from soy cold pressing in quantity of 10%, which is the byproduct ofthe near locating factory. The objective was the increase of the final product energy value and resolving of the domestic waste problem.The extrusion process creates some changes of corn grits and bread crumbs carbohydrate complex structure, namely to decreasing of starch content until dextrins. Changes like that cause *in vitro* and *in vivo* digestion of starch, considering the fact that starch gelatinisation provides the increased availability of starch degradation enzymes, water and amylase inhibitor inactivation (Douglas et al., 1990).
The aim of this work was to define the extrusion effect on the quality of corn grits and bread crumb mix, also as how extrusion affects health and hygiene condition of a product from the microbiological standpoint. Furthermore, was examined theeffect of the soy cold pressed wasted oil on nutritive value of the product.

Material and Methods

Starch content as well as the total content of reducing sugars was defined in accordance to the physical and chemical analysis for the control of wheat, mill and bakery products, pasta and quick frozen dough manual (Rule Book, 1988), while the volumetric mass was conducted in accordance to the methods for taking samples and utilisation of physical, chemical and microbiological analysis of cattle feed (Rule Book, 1987). The basic chemical composition (moist, crude proteins, crude cellulose, crude fat and mineral content) of corn grits and bread crumb mix was determined in accordance to the Association of Official Analytical Chemists (A.O.A.C.) methods (Douglas et al., 1990). Corn grits with 13% and bread crumbs with 12.87% were used in corn grits and bread crumb mix extrusion process. The mix was assembled as 50:50 ratio in a counter current Homogenizer, besides the mix was moistened with 10% of the oil precipitate. Oil was the waste product of soy cold pressed oil process, grits were from damaged corn, and bread crumbs originates from stale bread and bread leftovers. Installed force of extruder electromotor was 85 kW. Temperature of extrusion was between 135°C and 145°C, and the diameter of nozzle with 4 holes was 10 mm.The total

number of microorganisms, yeasts and molds was determined in accordance to the methods for microbiological analysis and superanalysis of food manual (Rule Book, 1980).

Results and Discussion

Table 1 presents the chemical composition of corn grits, whereby the energy value, starch, protein and fat content are 1548 kJ, 72.93%, 6.88%, 1.14%, respectively. The obtained result implies that corn grits poses the potential for a protein cattle feed.

Table 1. Chemical composition and energy value of corn grits

Quality parameters	**Content (%)**
Moisture	13.57
Crude ash	0.24
Crude proteins	6.88
Total sugars	2.29
Reduced sugars	0.48
Starch	72.93
Fat	1.14
Energy value	1548kJ/100 g

One gram of the sample contains 80 molds and 500 microorganisms, which indicates the feed hygienic safety, according to the methods for microbiological analysis and superanalysis of food manual (Rule Book, 1980), number 25.
Table 2 shows the chemical composition and energy value of bread crumbs.

Table 2. Chemical composition and energy value of bread crumbs

Quality parameters	**Content (%)**
Moisture	12.87
Crude ash	2.24
Crude proteins	11.44
Total sugars	2.72
Reduced sugars	2.08
Starch	63.34
Fat	3.18
Energy value	1589 kJ/100 g

Bread crumbs are the food product created by the subsequent production process from bread leftovers. Mentioned product contains 63.34% of starch, 11.44% of proteins and 3.18% of fat. Furthermore, the total energy value is 1589 kj/100 g, thus it could be used as a quality protein cattle feed. One gram of bread crumbs contains 30 microorganisms. Therefore, it is safe for the animal feed.
Chemical composition and energy value of corn grits and bread crumbs mix is shown in Table 3.

Table 3. Chemical composition and energy value of extruded mix

Quality parameters	**Content (%)**
Moisture	12.87
Crude ash	2.24
Crude proteins	11.44
Total sugars	2.72

Reduced sugars	2.08
Starch	63.34
Fat	3.18
Energy value	1817.38 kJ/100 g

By following results of the experiment, the decrease of moisture content in comparison to start samples is obvious, also as the decrease of starch content and the increase of reduced sugars, which is a consequence of thermal decomposition of starch, affects the digestibility of starch (Douglas et al., 1990). Increased sweetness or sensorial characteristics change is the result of physical-chemical changes of starch. Microbiological analysis of corn grits and bread crumbs extruded mix confirmed the total reduction of microorganisms, owing to mutual processing factors such as relatively low extrusion temperature (135–145°C), very short time of extrusion (6 -10 s) and very high pressure (30–40 bar) (Kormanjoš et al., 2007). Extruded mixes did not contain bacteria from *Salmonella ssp. genera, coagulase positive staphylococcus, sulfurreducens Clostridium, Proteus spp*., *Escherihia coli*. However, an exception is the total number of microorganisms, that is still in boundaries of legislation in accordance to the Maximum amount of harmful substances and ingredients in cattle feed manual (Rule Book, 2014). An increase of the total energy value of mixes in comparison to basic ingredients is significant.

Conclusion

Extruded mixes of corn grits (from damaged corn grains) and bread crumbs presents a highly valuable energy ingredient in animal feed industry. It has been determined that the main causes of wasted and returned bread are: bread is still a social category, a relatively low price of bread, a relatively low quality, the habit of consumers to buy more bread than is necessary, the tradition whereas the stale bread is not represented in the domestic menu. Extrusion process is responsible for a beneficial nutritive value of corn grits and bread crumbs mixes, due to increase of the total sugar and reducing sugar content, also as a positive change in the starch complex of the extrudate, which leads to increase of digestibility and utilization of food and feed. Thermal treatment that occurs in the cylinder and the screw of the extruder, along with the high pressure created during the friction process, results in the decrease of the total number of microorganisms in extruded product. Whereas, the temperature of 135°C in combination with the high pressure affects lethally on the most of microorganisms, while decreasing the total number of microorganisms contributes to food and feed safety. Extrusion of corn grits and bread crumbs along with the other mill waste could present a quality solution for the problem of stale bread increase in the bakery industry, furthermore reduces the mill waste as wellas the amount of oilsprecipitate. The optimisation of oil waste will be conducted in the forthcoming period. Created extrusion mixes are recommended primarily for the nutrition of young animals, especially in the fish feed industry.

BIOLOGICAL CONTROL AGAINST SOILBORNE FUNGI OF CUCURBITS

Yosraben M'HENNI, Ibtissemben SALEM, Naima BOUGHALLEB-M'HAMDI*

UR 13AGR03, Department of Biological Sciences and Plant Protection, High Institute of Agronomy of ChottMariem, University of Sousse, Tunisia
*Corresponding author: n.boughalleb@laposte.net

Abstract

In Tunisia, the incidence of cucurbits soil-borne diseases caused by *Fusarium* sp., *Monosporascus cannonballus* and *Macrophomina phaseolinae* is a yield limiting factor of these crops. Two bacteria species *Bacillus subtilis* (B27) and *Bacillus amyloliquefasciens* (B29) were tested against six isolates of *Fusarium* sp., two isolates of *Macrophomina phaseolinae* and one isolate of *Monosporscus cannonballus*. According to confrontation tests between these two bacteria and pathogens, a significant reduction of colony diameter of all species was observed with the lowest values by B29 (2.46 cm). To confirm the *in vitro* antagonism activities, both preventive and curative treatments were performed on melon and watermelon plants. The damage caused by different plant pathogens was tested based on rating scales symptoms of infestation. These results revealed that these treatments using bacteria strains B27 and B29 reduced the incidence of plants disease of melon and watermelon inoculated with all pathogens. For watermelon plants inoculated with *Fusarium solani cucurbitae* and *Monosporascus cannonballus*, both *Bacillus subtilis* and *Bacillus amyloliquefasciens* were more effective than the synthesis active ingredients (Mefenoxan and Azoxystrobin) and Hymexazol. The treatment with B27 seemed to be more effective than the active ingredients(Mefenoxan and azoxystrobin), reducing the incidence of disease caused by *Macrophomina phaseolina* with disease severity index of 1.76 and 2.23 compared to the synthetic product (2.43 and 2.46) according to preventive and curative treatments, respectively.

Keywords: *Antifungal activity, Bacillus subtilis, Bacillus amyloliquefasciens, soilborne fungi.*

Introduction

Fusarium oxysporum, F. solani cucurbita, Macrophomina phaseolina and *Monosporascus cannonballus* are the main soilborne pathogens affecting cucurbits (Stanghellini *et al.*, 1996; Boughalleb and ElMahjoub, 2006).Different soilborne bacteria and fungi are able to colonize the rhizosphere with different beneficial effects on plant growth and health. The use of plant growth-promoting (PGP) bacteria intended as biological control agents is an environmentally friendly alternative to agricultural chemicals and could be combined with other strategies in the integrated management of soilborne diseases such as *Monosporascus* root rot and vine decline (Pliego *et al.* 2011).Thus, the selection of antagonistic microorganisms should take into account the efficacy towards the target pathogen along with the conditions where the bioagent could develop (Alabouvette and Steinberg 2006).*Pseudomonas* and *Bacillus* spp. can promote plant growth directly by providing the plant with nutrients or growth hormones, or indirectly by decreasing the pathogens growth (Lugtenberg and Kamilova 2009). *Bacillus subtilis* is an ubiquitous bacterium that grows in diverse environments including soils, plant roots and within the animal gastrointestinal tracts (Earl *et al.*, 2008). Many *B. subtilis* isolates from different origins are considered as beneficial bacteria for their ability to produce antibiotics exerting antifungal and antibacterial activity (Stein, 2005) and to activate host resistance mechanisms (Kloepper *et al.*, 2004). For this reason *B. subtilis*, as well as other

Bacillus species is an ideal candidate for use as biocontrol agent in seed treatment programs against soilborne pathogens (Foldes *et al.*, 2000).*B. subtilis* and *B. amyloliquefasciens* are effective for controlling plant diseases caused by soil-borne agents, which are *Bacillus subtilis* and *Bacillus amyloliquefasciens* (Zhang *et al*., 2008; Chen *et al*., 2010; Antonelli *et al.*, 2012, 2013).

The use of a biological control approach through the antagonistic bacteria of the genus *Bacillus* which have antifungal properties in several pathogenic species causing soil-borne diseases could be proposed against *Fusarium* sp., *Macrophomina phaseolina* and *Monosporscus* sp. wilt and dieback affecting cucurbitacea. The objectives of the present work are to (i) study the inhibition of mycelial growth of *Fusarium oxysporum melonis, Fusarium solani cucurbitae, Monosporascus cannonballus* and *Macrophomina phaseolina* and (ii) evaluate the effectiveness of the use of antifungal agents on the *in vivo* disease incidence of these soilborne pathogens.

Materials and Methods

Bacterial strains

Two strains of *Bacillus subtilis* (B27) and *Bacillus amyloliquefaciens*(B29) are used in this study, which belongs to the collection of laboratory of Phytopathology in higher agricultural institute of Chott Mariem (Tunisia). Strains were cultivated in Nutriment Agar (NA) at 30°C and incubated at 4°C for experimental use.

Fungal strains

For this study, two isolates of *F. o.niveum* (FON1, FON2) and one isolate *Monosporascus cannonballus* (MT14) was collected from watermelon plants, three isolates of *F. o.melonis* (FOM1, FOM2 and FOM3) was isolated from root infected melon, were used. Morover, two *F. s. cucurbitae* (FSC1 and FSC2) and two isolates of *M. phaseolina* (MP1 and MP2) were isolated from infected roots of watermelon and melon, and watermelon, respectively. All isolates were grown on Petri dishes containing PDA medium for 5 -7 days at 25°C. All strains were included in the collection of the laboratory of phytopathology (High Institute of Agronomy chott Mariem, Tunisia).

Plants material

Watermelon (*cv. Ananas d'Amérique*) and melon (cv. Charleston Gray) were used for the *in vivo* experiments.

In vitro screening of antifungal activity of *B. subtilis* and *B. amyloliquefasciens*

Dual culture

The efficiency of *B. subtilis* (B27) and *B. amyloliquefasciens*(B29) was evaluated *in vitro* by applying a dual culture technique. Petri dish containing PDA medium was divided into two compartments, which is placed a mycelial plugs of 5 mm in diameter of each pathogen fungi at each side of the bacterial strip. The distance between the two plugs was 2.5 cm. After incubation for 6 days at 26ºC, the inhibition of fungal growth was evaluated by the reduction of mycelium percent using the formula adopted by Hmouni et *al.* (1996):$I\ \% = [(1-C_n) / C_0] \times 100$ where I % is the percentage of growth inhibition, which C_n is the colony diameter of the pathogen in the presence of the antagonist and C_0 is the colony diameter of the pathogen without antagonist. The values were recorded as the means of three replicates. Experiments were repeated twice.

In vivo antagonism test

Watermelon and melon plants were used to evaluate the biocontrol activity of strains B27 and B29 on enhancing the growth of roots and reducing the disease. The bacterial inoculum was

prepared in nutrient broth (NB) in a shaker at 15000 rpm for 2 days at 30°C. The fungal pathogens were prepared and the concentration was adjusted $2x10^7$ conidia/ml. The experimental protocol was a randomized complete block. Ten plants of watermelon and of melon were used for each treatment, and the values were recorded as the means of three replicates for each treatment. Two *in vivo* essays were undertaken, preventive and curative treatments. Both tests are intended to assess the effectiveness of the use of antibacterial agents on the infestation of soilborne pathogens. Two controls were used in this trial, the negative control consist of the inoculation of watermelon and melon only by each pathogen and the positive control plants are inoculated and treated by a fungicide and depends on the pathogens; concerning *M. cannonballus* and *M. phaseolina* plants are inoculated and treated with F3OACM (Mefenoxan and azoxystrobin), and for the *Fusarium* species, plants are inoculated and treated with Tachigazol (Hymexazol).

Disease severity index

During the experiment, the plants were carefully removed from the pots at45days after inoculation. The root systems were gently washed in tap water. Each root system was rated for the severity of the pathogen as described in Table 1.

Table 1. Disease severity of watermelon plants inoculated with *F. oxysporum*, *F. solani*, *M. phaseolina* and *M. cannonballus*.

Fungi	Rating scale	Reference
F. oxysporum	0 = no symptoms; 1 = light vascular discoloration in the stem with or without stunting; 2 = vascular discoloration in the stem, stunting, wilting with or without yellowing of cotyledons; and 3 = dead seedlings.	Vakalounakis and Frangkiadakis (1999)
F. solani	0: healthy; 1: slight yellowing of leaves with slight rot pivot and lateral roots and crown rot; 2: significant yellowing in leaves with or without wilting, stunting of plants, severe rot at the pivot and lateral roots, significant rot and browning of vessels in the stem; 3: death of the plant.	Boughallebet *al*. (2005)
M. phaseolina	0: symptomless, 1: 1 to 3% of shoot tissues infected, 2: 10% of shoot tissues infected, 3: 25% of shoot tissues infected, 4: 50% of shoot tissues infected and 5: more than 75% of shoot tissues infected.	Ravf and Ahmad (1998)
M. cannonballus	0 = no symptoms; 1 = few lesions (covering <10% of root), secondary root rot slight; 2 = rot of secondary roots or lesions covering approximately 25% of the root; 3 = lesions covering at least 50% of the root and dead secondary roots; and 4 = general root rot, most of the root affected.	Aegerter *et al.* (2000)

The Disease severity index was analyzed with the GENMOD procedure using the multinomial distribution and the cumulative logit as link function, and means of the values were separated by χ^2 test at $P < 0.05$ using SAS program (SAS Institute, Cary, NG). The variable was compared by analysis of variance (ANOVA) and means of the values were separated with Duncan test at $P < 0.05$ using SPSS 20.0 for Windows (SPSS Inc., Chicago, IL, USA).

Results and Discussion

In vitro effect of *Bacillus subtilis* and *Bacillus amyloliquefaciens* on cucurbits soilborne fungi

B. subtilis (B27) and *B. amyloliquefasciens* (B29) have significantly reduced the mycelial growth of *F. o.niveum*. The most important inhibition is obtained with B29 which caused a significant reduction in colony diameter of FON2 (2.16; control=3.45cm). B27 and B29 decreased the mycelial growth of the two *F.s. cucurbitae* isolates compared to control; For FSC1, B27 was more effective in reducing the colony diameter with 2.69 cm (control=3.93cm); FSC2 was more sensitive to the action of B29. The decrease of the growth inhibition of *M.*

phaseolina (MP1) with B29 was higher than B27; the diameter of the colonies is 2.73 and 3.15 cm (control=4.3cm), respectively. The two bacterial strains B27 and B29 reduced significantly the mycelial growth of *Monosporascus cannonballus* (MT14) with 1.9 and 0.85cm (control=4.16), respectively (Table 2).

Many species in the *Bacillus* genus are considered as an important potential biocontrol agents that have induced a strong antifungal activity against some plant pathogens (Pretorius *et al.*, 2015). The *in vitro* results are consistent with several previous studies. Asaka and Shoda (1996) and Okigbo (2005) reported the antagonistic properties of different strains of *Bacillus subtilis*. In this sense, the antagonist activity of *B. subtilis* has been indicated by Antonelli *et al.* (2012), according to *in vitro* tests against *M.cannoballus*. Others investigations mentioned that *B. amyloliquefaciens* strains showed antifungal properties against plant pathogenic fungi based on the production of antimicrobial compounds such as cyclic lipopeptides (Yuan *et al.*, 2014; Ben Abdallah *et al.*, 2015).Koumoutsi *et al.* (2004) confirmed the inhibitory effect produced by *B. amyloliquefasciens* since this species revealed to be *in vitro* and *in vivo* efficient for controlling several plant pathogenic fungi.

Effect of *B. subtilis* and *B. amyloliquefasciens* on disease incidence

B. subtilis and *B. amyloliquefasciens* were assayed in the greenhouse to determine the ability to suppress *Fusarium*sp., *Marcrophomina* and *Monosporoscus* sp. of melon and watermelon plants. The isolates of pathogens were selected from the results obtained previously *in vitro* test

Watermelon

The two selected strains B27 and B29 were tested for their biocontrol activity in the pathosystem watermelon-pathogen. On untreated control plants (negative control) and treated with fungicide (positive control), the pathogen caused severe root rots of lateral and tap rots. Preventive treatments by the two bacteria determined a significant reduction of the disease severity index of all pathogens ($p<0.05$). Obtained results indicated that watermelon plants inoculated with *M. phaseolina* and *M. cannonballus* combined with each *Bacillus* strains showed less symptoms of root rot ($p<0.05$) in comparison with the other pathogens. For *M. phaseolina*, *Bacillus subtilis* (B27) applied preventively recorded the lowest value of 1.76 (negative control=2.8). Concerning *M. cannonballus*, the same treatment showed more efficiency with a value of 2.07 (negative control=3.83).

Melon

Treating plants after the inoculation with pathogen and fungicide did reduce disease severity index compared to untreated plants (only pathogens). The results indicated that preventive and curative treatments differed significantly ($p<0.05$) (Table 4). Concerning *M. cannonballus* both *Bacillus* strains showed antifungal activities as preventive treatment with values of 1.17 and 1.03 (negative control=3.33), respectively. *B. subtilis* B27 applied preventively and curatively generated an inhibitory effect against *F. o. melonis* (1.1 and 1.13 (negative control=2.23)), only curatively against *M. phaseolina* (1.13 (negative control=2.83)).*Bacillus amyloliquefaciens*(B29) applied preventively exhibited a significant reduction of disease severity index in presence of *M. phaseolina* (1.4)and *M. cannonballus* (1.03).

[c] Probabilities associated with individual F tests.

The importance of the root microbiome in plant health is underlined by much experimental evidence and it is becoming increasingly clear that the plant is able to control the composition of its microbiome (Berendsen *et al.*, 2012). This research paper showed the antifungal activity of the two *Bacillus* species in vivo against some of the major soilborne pathogens of melon and watermelon. Indeed, *Pseudomonas* and *Bacillus* spp. can promote plant growth directly by providing the plant with nutrients or growth hormones, or indirectly by decreasing the growth of pathogens (Lugtenberg and Kamilova, 2009). Previous studies revealed that antibiosis was one of the primary mechanisms of *Bacillus* spp. against plant pathogens. Various antibiotics are produced by *Bacillus* spp. (Kilian *et al.*, 2000). *Bacillus amyloliquefaciens* and its close relative *B. subtilis* have been reported to be effective in controlling plant pathogens through the production of non-ribosomally synthesized antibiotics, mainly cyclic lipopeptides (Xu*et al.*, 2013).

Conclusion

Our results indicate that *Bascillus* strains are beneficial to growth and health of melon and watermelon. Potentially, plant treatments with *B. subtilis* (B27) and *B. amyloliquefasciens* (B29) display a biocontrol against root rot and may provide a practical supplement to environmentally friendly disease management in combination with appropriate sustainable agricultural practices.

SCREENING OF SOME CUCURBITS CULTIVARS FOR TOLERANCE TO BACTERIAL FRUIT BLOTCH PATHOGEN ACIDOVORAX CITRULLI IN TURKEY

Nursen USTUN*, Neziha ARSLAN

Plant Protection Research Institute, Bornova, Izmir, Turkey
*Corresponding author: nursen.ustun@tarim.gov.com

Abstract

Bacterial fruit blotch of cucurbits, caused by *Acidovorax citrulli* is a devastating disease threatening the watermelon and melon industries all over the world. In this study the susceptibility of various commercial cultivars of cucurbits (Suha and Eyfel for squash, Aswan and Crimson Tide for watermelon, Golden West for melon, and Divan and Beith Alpha F1 for cucumber) commonly grown in Turkey was evaluated using seedling-inoculation assays. Emerging pot growing seedlings were grown in climatic room (25-28 ^{o} C, 60-70% RH and 16 hours daylight. Artificial inoculation was performed by spraying of two weeks old seedlings with bacterial suspension of two different melon strains of *A. citrulli* adjusted to 10^{6} CFU/L^{-1}. Ten plants per cultivar were inoculated with the same strain. Control plants from each cultivar were sprayed with sterile water. Following inoculation, plants were covered by plastic chambers in order to keep 90-100% humidity for the first 48 hours. Then the chambers were removed and plants were incubated at the 25-28°C and 70-80 % humidity for subsequent 12 days after inoculation. At the end of incubation, the severity of the disease for the strains was scored using 0-9 scale. Statistical analyses were performed by comparing mean severity index values according to Duncan multiple range test at P= 0.05 level. All of tested cultivars were found to be susceptible to the disease. However, some differences in the severity of the disease symptoms were observed.

Key words: *cucurbits, fruit blotch bacterium, cultivar susceptibility*

Introduction

Cucurbits are economically important vegetable crops commonly cultivated in the world. Turkey is among the biggest producers of cucurbits with world ranking 3rd for watermelons and also 3rd for melons (FAO, 2012). Many plant pathogens can limit productions of cucurbits by inducing serious disease epidemics.

Bacterial fruit blotch of cucurbits, caused by *Acidovorax citrulli (Ac)* is a devastating disease threatening the watermelon and melon industries all over the world. The disease first observed in the USA in areas of commercial watermelon production in 1989 (Hopkins, 1989; Latin & Rane, 1990) was reported from many different countries. Because of its seed-borne nature the pathogen has the great potential of spread across long distances and this evidence is of particular concern to the cucurbit industry.

Fourteen haplotypes of *Ac* determined on the basis of Pulsed Field Gel Electrophoresis DNA analyses (Walcot et al., 2000) fall into at least two distinct groups, Group I and Group II strains. Group I strains are isolated from different cucurbit crops, including muskmelons and watermelon, whereas Group II stains are predominantly associated with bacterial fruit blotch of watermelon (Walcott et al., 2004).

Ac was detected for the first time in 1995 in Turkey (Demir, 1996) only in some fields of Sultaniçi village, Enez town, Edirne province (Marmara Region) and then eradicated by taking some phytosanitary measures in the contaminated locality. The pathogen emerged

again in the Eastern Mediterranean Region (Cukurova) of Turkey in 2006 and caused severe losses in some watermelon fields (Mirik et al, 2006;). Horuz ve Aysan (2012) reported it not only from different watemelon cultivars (Blade, Zeugma, Crispy and Starburst) but also from Sürmeli melon cultivar. The bacterium listed in Plant Quarantine Regulation (Annex 2B) is under eradication in Turkey.

The management of watermelon fruith blotch is based primarily on seed desinfection, pathogen exclusion by seed health testing, cultural practices and regulation of environment in the transplant houses and application of copper compounds able only to reduce the disease in field/greenhouse but not to eliminate it. Using of resistant cultivars can be one of the most reliable approaches for the disease control. No complete resistance has been found in commercial cucurbit cultivars up to now. However differences in the disease response and relative tolerance were reported in some watermelon and melon cultivars or lines (Hopkins and Thompson, 2002; Hopkins and Levi, 2008).

In this study the susceptibility of various commercial cultivars of cucurbits commonly grown in Turkey was evaluated using seedling-inoculation assays.

Materials and Methods

Commonly grown cultivars in the Aegean Region of Turkey (Suha and Eyfel for squash, Aswan and Crimson Tide for watermelon, Golden West for melon, and Divan and Beith Alpha F1 for cucumber) were selected for screening. For inoculation two different bacterial strains (Ac1 and Ac2) isolated from melon and identified previously were used.

Seeds of the cultivars were sown in pots (two seeds per pot) containing soil mixture with equal parts of perlite and peat. Emerging seedlings were grown in climatic room (25-28 ^{o} C, 60-70% RH and 16 hours daylight. Two weeks old seedlings were artificially inoculated by spraying with bacterial suspension of 2 different melon strains of *A.citrulli* adjusted to 10^{6} CFU/L^{-1}. Ten plants per cultivar were inoculated with the same strain. Control plants from each cultivar were sprayed with sterile water. Following inoculation, plants were covered by plastic chambers in order to keep 90-100% humidity for the first 48 hours. Then the chambers were removed and plants were incubated at the 25-28°C and 70-80 % humidity for subsequent 12 days after inoculation. At the end of incubation, the severity of the disease for the strains was scored using 0-9 scale (1 = no symptoms; 2 = single, small necrotic lesions on less than 1% of the leave; 3 = small necrotic lesions on 1% to 10% of the leave; 4 = necrotic lesions on 11% to 20% of the leave; 5 = necrotic lesions with chlorosis on greater than 20% to 40% of the leave; 6 = necrotic lesions on 40% to 60% of the leave; 7 = necrotic lesions on 61% to 80% of the leave; 8 = large spreading lesions, greater than 85% of leave; and 9 = dead plant) proposed by Hopkins and Thompson (2002) applied for true leaves instead of cotyledons. Statistical analyses were performed by comparing mean severity index values according to Duncan multiple range test at P= 0.05 level.

Results and Discussion

Two watermelon (Crimson Tide and Aswan), one melon (Golden West), two squash (Eyfel and Suha) and two cucumber (Beith Alpha F1 and Divan) cultivars commonly grown in the Aegean Region of Turkey were screened for resistance to watermelon fruit blotch pathogen. In the seedlings-inoculation assay all of tested cultivars were found to be susceptible to the disease. However, some differences in the severity of the disease symptoms between the cultivars were observed. According to Duncan multiple range test at P= 0.05 level, compared the mean severity index values, the cultivars based on their reaction to Ac1strain were grouped in 5 different statistical groups. Three statistical groups were formed for Ac2 strains (Table 1). The melon cultivar Golden West was the most susceptible cultivar to both tested strains followed by squash cultivar Eyfel. Watermelon cultivars Crimson Tide and Aswan and squash cultivar Suha were less affected from Ac1 strain than other tested cultivars. In reaction

to another bacterial strain Ac2 cucumber cultivars Beith Alpha 1 and Divan, watermelon cultivar Aswan and squash cultivar Suha fell into same statistical group and were less affected than others.

Table1. Response of some cucurbits cultivars to watermelon fruith blotch pathogen *Acidovorax citrulli*

Cucurbits Plant species	**Cultivar**	**Ac 1**	**Ac 2**
melon	Golden West	7,7 a	8,2 a
cucumber	Beith Alpha	6,6 abc	5 b
	Divan	5,7 bcd	5,4 b
squash	Eyphel	6,9 ab	6,8 ab
	Suha	4,8 cd	5 b
watermelon	Crimson Tide	4,2 cd	5,2 ab
	Aswan	4,2 cd	6,4 b

Ac1, Ac2 –*Acidovorax citrulli* strains from melon; cultivars: Eyfel and Suha -squash; Beith Alfa 1 and Divan-cucumber, Golden West-melon; Aswan and Crimson tide-watermelon

Mean severity index values were calculated on the basis of 0-9 scale ((1 = no symptoms; 2 = single, small necrotic lesions on less than 1% of the leave; 3 = small necrotic lesions on 1% to 10% of the leave; 4 = necrotic lesions on 11% to 20% of the leave; 5 = necrotic lesions with chlorosis on greater than 20% to 40% of the leave; 6 = necrotic lesions on 40% to 60% of the leave; 7 = necrotic lesions on 61% to 80% of the leave; 8 = large spreading lesions, greater than 85% of leave; and 9 = dead plant) proposed by Hopkins and Thompson (2002) and applied for true leaves instead of cotyledons. Mean severity index values were compared according to Duncan multiple range test at P= 0.05 level.

In general, the reaction of the cultivars was similar for the both tested strains. However some of the cultivars showed different reaction. For example watermelon cultivars Crimson tide and Aswan were more susceptible to Ac 2 strain. In contrast cucumber cultivar Beith Alfa-1 was more affected from Ac 1 strain. This results indicated that cultivars the susceptibility of the cultivars can be strain related and they can react differently to various strains.

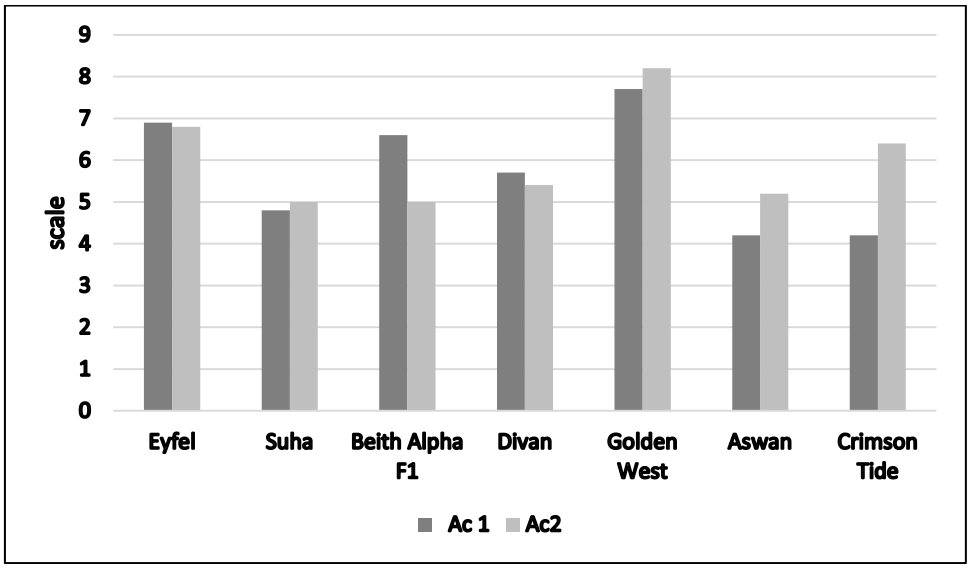

Figure 1. Strain related response of some cucurbits cultivars to watermelon fruith blotch pathogen *Acidovorax citrulli*

Ac1, Ac2 –*Acidovorax citrulli* strains from melon; cultivars: Eyfel and Suha -squash; Beith Alpha F1 and Divan-cucumber, Golden West-melon; Aswan and Crimson tide-watermelon

Conclusions

The study provide evidence that the tested cultivars of cucurbits (Eyfel and Suha -squash; Beith Alpha F1 and Divan-cucumber, Golden West-melon; Aswan and Crimson tide-watermelon) commonly grown in Turkey are susceptible at different degree to the watermelon blotch pathogen. However many cucurbits cultivars grown in Turkey (including cultivars of local origin) are not evaluated for their resistance in this study. Determination of the reactions of local cucurbits cultivars are recommended in the future studies in order to find the sources of the resistance.

Abstract

The use of synthetic pesticides is now in frequent use in crop protection. But they are considered as a major problem on the environment, the flora and fauna or human health. Biopesticides of botanical origin are a good alternative to remedy this evil. Our study aimed at assessing the toxicity of hydro-methanoic, hydro-ethanoic and synergistic extracts of two toxic plants, including *Nerium oleander* and *Ricinuscommunis* growing spontaneously in Mostaganem area, on larvae of the tomato leafminer*T. absoluta* (Meyrick), which is considered as a serious pest on tomato crop in Algeria. The extraction yields (Method of Soxhlet) obtained by the twohydro-methanoicandhydro-ethanolicextracts are (26%, 18%) for *N. oleander* and (35%, 29%) for *R. communis* respectively. However, the hydro-methanoic extract remains the most effective. These extracts were tested adopting the method of toxicitybydirectcontact orspray". The biological tests on the larvae of *T. absoluta*have shown that there is a difference between the toxicity of hydro-méthanoic and hydro-ethanolic extracts within the same plant. The synergistic extract caused a remarkable mortality rate that exceeded 90%. *N. oleander*et*R. communis*presented a low toxicity not exceeding 30% for the hydro-ethanolic extracts and 40% for the hydro- methanoic extracts.After 24hours of exposure to the test,theLD50 values werevery high (above 50%) for hydro-ethanolicandhydro-méthanoicextracts for the two plants used. However, theLD50 values wererelatively low forthesynergisticextract(19%).The results showedthatL2andL1larvaeare most sensitiveto allextracts used. TheL3andL4are the most resistant, exceptforthesynergistic extract.

Key words: *Bioinsecticides-Tutaabsoluta- Nerium oleander- Ricinuscommunis-Toxicity-Hydro-alcoholic*.

Introduction

The tomato borer *Tutaabsoluta* (Meyrick) (Lepidoptera: Gelichiidae), a key pest of tomato invaded Algeria in March 2008, It is now devastating pest in tomato crops in Mediterranean basin and Maghreb. According to Gilardon*et al*. (2001) and Tropea*et al*. (2012), in most countries where *T. absoluta* occurs, the main control strategy consists of frequent sprays with chemical insecticides, because without control *T. absoluta* causes yield losses up to 100% and dramatically decreases fruit quality in both field and in greenhouse tomato crops.Both control *T. absoluta* population and care ecosystem, natural products are increasingly required for sustainable agriculture, the indiscriminate use of conventional synthetic pesticides have had a negative ecological and health impact (pest resistance, contamination of environment and ecosystems, loss of biodiversity, etc.).

The use of vegetable kingdom and molecule that allowed the plants to protect against natural enemies becomes indispensable (Regnault-Roger, *et al*., 2008; Lacava and Azevedo, 2014). Plant derived insecticides and insect hormones are receiving significant interest as alternatives

to chemical pesticides and key components of integrated pest managements systems, which are cheaper, safer, and ecofriendly (Attathom, 2002; Adedire and Ajayi, 1996 in Adedire and Akinkurolere, 2005). We can cite as active elements of plants: phenols, flavonoids, tannins, anthocyanins, saponins, vitamins, and minerals glucosides (Chevallier, 2001).

Material and Methods

To improve the bio-insecticide effect of the natural plants substances, we have chosen two plants known for their toxicity and high content of active ingredients: oleander (*Nerium oleander* L.) and Ricin (*Ricinuscommunis* L.) in order to use it to control larval population of *T. absoluta* on tomato crop and to secure the production by reducing the damage caused by this pest; also for limiting the harmful effects of these on the environment and human Health. It is also important to encourage and promote the production of organic crops in Algeria. Other studies have highlighted the effectiveness of plant extracts on *T. absoluta*larvae (Da Cunha *et al*., 2008; Nilahyane*et al*., 2012; Moreno *et al*., 2011; De Brito *et al*., 2015).The larvae sensitivity of extracts varies from one plant to another.

a) Extraction Method (The Soxhlet Extractor)

We treated 20g of Ricin fresh leaves by ether petroleum, and then allowed to dry for 10 minutes at room temperature. After, the solute is introduced in a cartridge placed in Soxhlet. Extraction solvents used are: a hydro-methanoic mixture and hydro-ethanoic (Jordan *et al*., 2009).The flask contents (more solvent materials dissolve) are concentrated by rotary evaporator.

b) Larvicidal Activity (Test Contact)

The use of plant extracts to control *T. absoluta* larvae has been proposed by many authors. Moreira (2007) tested extracts of such toxic plants, *Datura stramonium* and *R. communis*.

In Algeria, the studies on the larvicidal activity of toxic plant extracts to the lepidopteran larvae are so limited. In this context we have been able to evaluate the larvicidal activity of the hydro-methanoic extracts and hydro-ethanoic of toxic plants (*N. oleander*, *R. communis*), and a synergistic extract.

The tests were carried out as of T°= 25±3°C, H°= 48±8% and natural photoperiod. *T. absoluta* larvae were levied by a brush and placed in airy Petri dishes containing agar;each box carrying a healthytomato's leaflets that serve as food support for the larvae. The concentrations of each extract (hydro-methanoic, hydro-ethanoic, and synergistic of two plants used) were tested: at 10, 20, and 30%, then the control treated with distilled water. The mortality rate (%) is determined for each treatment after 24h, 72h, 48h, 7 days, and 15 days after spraying. The larval mortality rate depending on time contact is estimated with Abbott's formula (Busvine, 1981).

Results and Discussion

Humidity Rate of Plant Material

Plants are rich in water, the analysis of the samples showed a high humidity, between 39 and 50%, which means approximately half weight of fresh plant is constituted by water.*N. oleander*leaves gave us an approximate weight to equivalent proportions of dry matter and water (50%). whereas*R. communis* is very rich in dry matter (61%) and only 39% water.The results show a variability of the water content between different species (Fig. 1).

Extraction Efficiency

Hydro-methanoic extract noted a higher yield compared to hydro-ethanoic. Then it was recorded higher yield for *R. communis* compared with *N. oleander* (Fig. 2). Mohadjerani

(2012) showed that aqueous methanol and pure methanol were the most effective solvents for the extraction of phenolic compounds from the leaves and flowers of *N. oleander* in Iran.
The difference between yields' extraction for the same plant is rated on the solvent used. The highest yield was observed by hydro-methanoic extracted with 26% and 35% for respectively *N. oleander* and *R. communis*, followed by hydro-ethanoic extract with 18% and 29% respectively for both plants tested (Fig. 2).

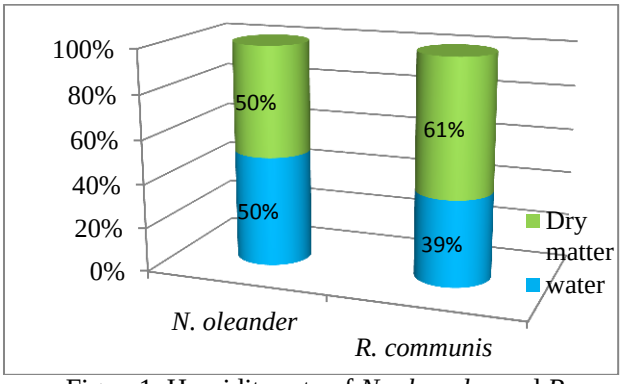

Figure1. Humidity rate of *N. oleander* and *R. communis*on *T.absoluta*

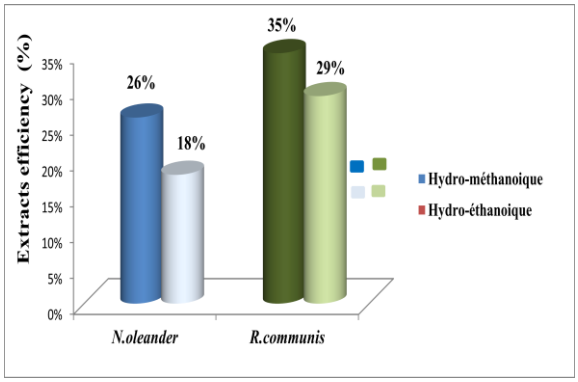

Figure2.Comparison of *N. oleander* and *R. communis*hydro-alcoholic extracts fresh leaves

Larvicidal Activity

T. absoluta larvae were exposed to different treatments of hydro-methanoic and hydro-ethanoic extractsfrom fresh leaves of *N. oleander* and *R. communis* at different periods: 24, 48, 72 hours, 7,and 15 days. The results showed that the same mortality was obtained after 24 hours which is explained by the larvicidal activity that is not related to the duration of exposure to treatment but by the action of extracts that have had an immediate effect. Moreover, the live larvae were able to continue their development after 24 hours to reach pupation. No mortality was recorded in all control groups we tried even after 15 days (the development of larval instars was not unaffected).

Larvicidal Activity of *N. oleander* Extracts of *T. absoluta*

The results presented in Figure 3, indicate that the two hydro-alcoholic extracts of *N. oleander* caused more or less significant larvicide efficiency compared to the control. This activity increases proportionally with the concentrations tested and it varies from one sample to another for the same plant.For both *N. oleander* extracts, larval mortality lower rate reached 50% even for the highest concentration (30%).
The LD50 (dose causing the death of 50% of *T. absoluta* population) have been very high for both extracts of *N. oleander*, which values are 54% and 75% for hydro-methanoic and hydro-ethanoic extracts respectively. And for even extracts the LD90 obtained are exceeded 100%. All these lethal doses explain the low toxicity of the extract of this plant. A positive correlation was obtained between the dosages of the extracts and mortality with a correlation coefficient of 0.933 and 0.9 respectively for the two extracts.
Furthermore, the Sankarasubramanian *et al*. (2007)tests carried out onto *Bipolarisoryzae* have revealed that, in vitro studies of Nerium oleander leaf extract, wasexerted a higher percent inhibition to mycelial growth (77.4%) and spore germination (80.3%).

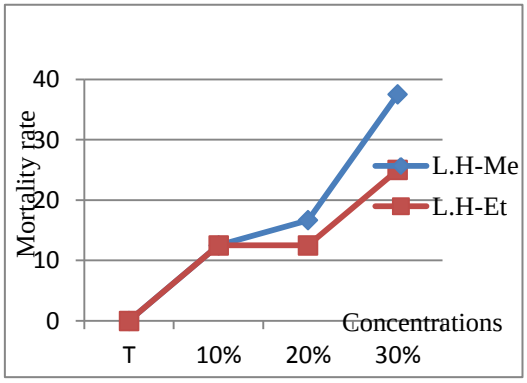

Figure3.Larvicidal activity of hydro-methanoic and hydro-ethanoic extracts of *N. oleander*

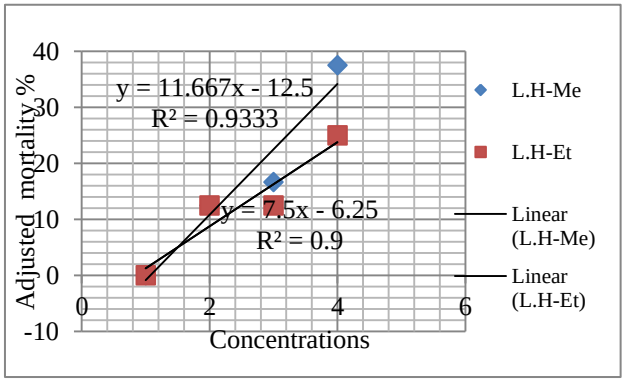

Figure 4. Mortality adjusted of hydro-methanoic and hydro-ethanoic extracts of *N. oleander*

Larvicidal Activity of *R. communis* Extracts on *T. absoluta*

The results shown in Figure 5, indicate that the two hydro-alcoholic extracts of *R. communis*illustrate a significant larvicidal efficacy compared to control. For both extracts of *R. communis* larval mortality reached rate below 50% even for the highest concentration (30%).The observations indicate that the hydro-methanoic extract has a higher mortality rate thanhydro-ethanolic extract.

LD50 values were very high for both hydro-alcoholic extracts of *R. communis*. LD50 values obtained are 51% and 63% respectively for hydro-methanoic and hydro-ethanoic extracts. While the LD90 obtained were very important. We recorded 86% and 100% rates respectively for the two extracts raised; this explains the low toxicity of these extracts. A positive correlation obtained between doses extracts and mortality with respective correlation coefficients of 0.956 and 0.968 for both extracts.

The synergistic extract caused remarkable mortality rate exceeded 90% mortality. While *N. oleander* and *R. communis* showed only low toxicity not exceeding 30% for hydro-ethanoic extracts and 40% for hydro-methanoic extracts (Fig. 7).

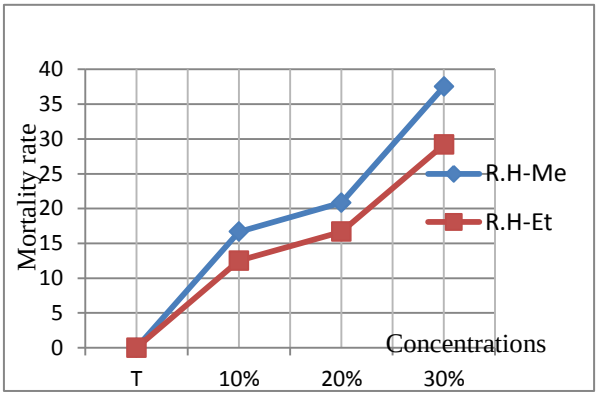

Figure5.Larvicidal activity of hydro-methanoic and hydro-ethanoic extract of *R. communis*on *T. absoluta*

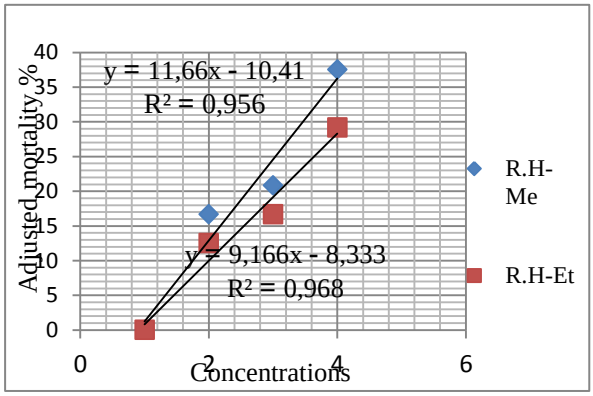

Figure6. Mortality adjusted of hydro-metanoic extracts of *R. communis*on *T. absoluta*

The results of comparison between all the extracts used report that the best rate of mortality is caused by the synergistic extract; in fact, by a concentration of 10% it's caused the death of 87% to *T. absoluta* larvae. While at the same concentration, the other extracts showed only a low efficiency about 12 and 17% for *N. oleander* and *R. comminus*.

The larvicidal activity of the extracts of *N. oleander* and *R. communis* remains low for both extracts even at 30% compared to the synergistic extract which presented a very high rate around 92% (Fig.7).

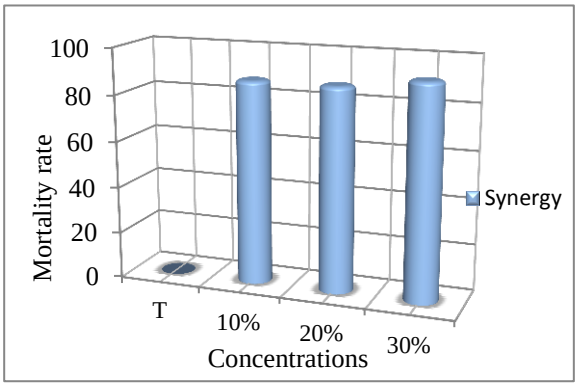

Figure 7. Evolution of the larvicidal synergistic extract activity on *T. absoluta*

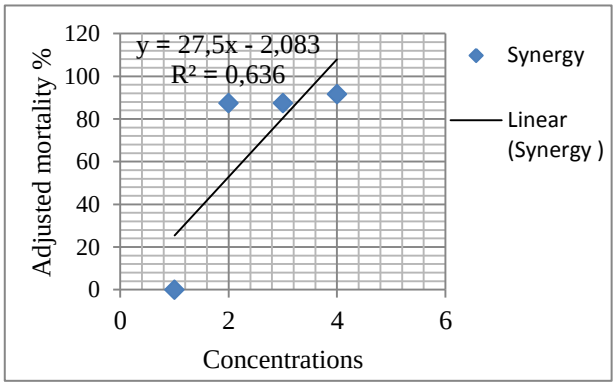

Figure 8. Mortality adjusted of synergetic extracts on *T. absoluta*

Table 1. Result of Lethal dose (50 and 90) for the different hydro-alcoholic extracts

Extracts / Dose	N.H-Me	N.H-Et	R.H-Me	R.H-Et	Synergy
LD50	54%	75%	51%	63%	19%
LD90	88%	128%	86%	107%	33%

According to the results shown in Table 1, we observed that the hydro-methanoic extracts and hydro-ethanoic of *R. comminus* and *N. oleander*, require doses greater than 50 and 86% to cause a death 50 and 90% respectively. While the synergistic extract requires a low dose of 19 and 33% for the respective mortality rates of 50 and 90%. These indicate the high toxicity of the product after mixing the two plants' methanolic extracts.

Larvicidal Activity of Hydro-Alcoholic Extracts on *T. absoluta* Larval Instars

During *in vivo* assay should be taken into account mortality in the general population. The best way for using our extracts in biological control, is to define in the first the sensitivity *in vitro* of each instars.

The effect of different hydro-alcoholic extracts of the two plants tested on *T. absoluta* biological instars showed a high sensitivity of the first two instars (L1 and L2). While L3, L4 were more resistant. The synergistic extract showed a very interesting effectiveness on the four larval instars, it has been enabled us to record a 100% mortality for L1 and L2 and a respective rate of 83 and 67% for L3and L4, for 10 and 20% of extract doses (Fig. 9-10).

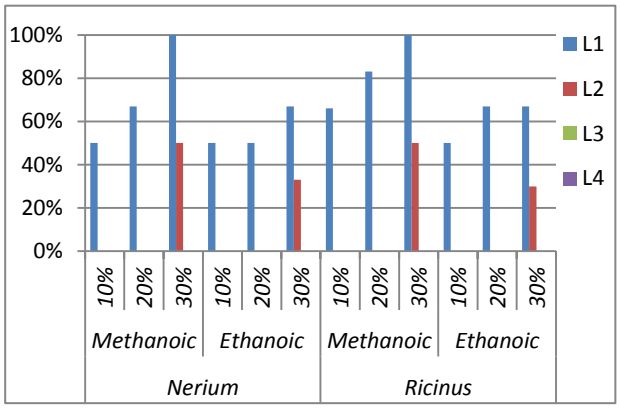

Figure 9.Larvicidal activity of hydro-alcoholic extracts on *T. absoluta* biological instars

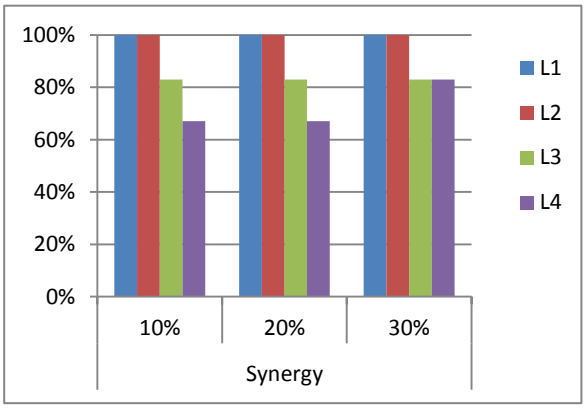

Figure 10.Larvicidal activity of synergistic extract on *T. absoluta* biological instars

Conclusion

The main objective of this work was to find an alternative to synthetic insecticides via insecticides solely of natural and organic compounds by testing the hydro-alcoholic extracts of medicinal plants. The tests were performed on tomato leafminer*Tutaabsoluta* in order to control its population, by extracts of medicinal plants: *Nerium oleander* and *Ricinuscommunis* and their synergistic extract. The results obtained during this research note that hydro-alcoholic extracts of the two plants show insecticidal activity of *T. absoluta*. Hydro-methanoic extract was more efficiencies than a hydro-ethanoic extract. Further, the synergistic extract showed greater results compared to Ricin and oleander; indeed, very significant mortality rates were recorded for the synergistic extract by the different doses tested, 10, 20, and 30%, when a respective percent mortality 87, 87, and 92% was registered. The *T. absoluta* larval instars have showed the highest sensitivity to different extracts on the two first larval instars namely the L1 and L2 with greater sensitivity to the effect of the synergistic extract, where a mortality rate of 100% was recorded. These results need to be deepened by the various polyphenolic's study compounds of different substrates used for a better assessment of the quality of the solute.

Abstract

Silicon (Si) is not considered as an essential element but it is beneficial. It has been found to help improving tolerance against insects increasing stem strength, plays a very important role in drought tolerance, enhance nutrient deficiency. Tissue levels of Si vary within plant species or cultivars. The aim of this study was to determine silicon concentration in maize leaf under different levels of irrigation, nitrogen fertilization and various genotypes and relationship with ECB larvae damage. Field experiments were conducted during three years (2012-2014) at the Agricultural Institute in Osijek (Croatia) with natural infestation of European corn borer (ECB). At the end of each growing season ear weight (g), tunnel length (cm), ear shank damage (cm), the number of larvae in maize stalk, number of larvae in the ear shank, and total number of larvae in plant were determined. In silking stage, ten leaves (below the ear), from 10 maize plants were sampled on each variant (total 1,080 plants) and silicon concentration was determined (%). There was no statistically significant difference between irrigation levels in silicon concentration while the variant with the highest level of nitrogen fertilization had the lowest concentration of silicon and the greatest damage from ECB larvae ($P<0.05$). Hybrid resistance didn't entirely depend on silicon concentration, even though damage was reduced with higher concentration of silicon at some hybrids. Silicon availability to plants is low in the soil and it is necessary to apply silicon fertilization to enhance plant resistance.

Keywords: *European corn borer, silicon, irrigation, nitrogen fertilization, hybrid*

Introduction

European corn borer, *Ostrinia nubilalis* (Hübner) (ECB) is major maize pest in Croatia. ECB larvae damage all above-ground part of maize plant so yield losses can vary between 2 and 25% (Maceljski, 2002). According to Szőke et al. (2002) losses from ECB range from 250-1000 kg ha^{-1} depending of the year and intensity of ECB attack. Some researchers found positive correlation between silicon content and plant resistance to ECB (Coors, 1987; Meyer and Keeping, 2005; Santiago et al., 2013). Silicon (Si) is classified as beneficial nutrient, not essential in plant biology. Plants contain silicon in concentrations from 1% of the dry matter to 10% in some plants or even higher (Epstein, 1994). Si improved insect resistance to stem borers, leaf spider mites, and various hoppers and also helps to protect plants from different disease and also from environmental stress (Heckman, 2013). Rojanaridpiched et al. (1984) negatively correlated second generation of ECB larval damage with silicon content, they also conclude that feeding activity of first generation of ECB depend of different levels of DIMBOA, silica and lignin. Resistance (higher Si concentration) has also been recorded in other crops such as vegetables (Chelliah, 1972; Puzyrkov et al., 1996), sugarcane (Keeping et al., 2014), rice (Hou and Han, 2010). Higher silicon concentration led to bigger leaf water

potential, leaf area index, the specific leaf weight, chlorophyll contents and the dry matter, increased root growth, improve the crop stand under stresses (Mukhtar et al., 2011). Increases in biomass production were also seen by Gong et al. (2003) in wheat. Decreased silicon concentrations in plant tissue can increase susceptibility to fungal diseases and pest injury (Volk et al., 1958; Buendgen et al., 1990). In spite of that, high concentrations of nitrogen in plants can increase susceptibility to pest attack and disease as observed by Slaton et al. (2003) where nitrogen rates with higher yields also increased percent of damaged plants. Deren (1997) reported decreases in nitrogen and phosphorus concentrations with increases Si concentration in rice plants. Soil water deficit significantly reduces agro-morphological and physiological properties of plants. Silicon applied with irrigation increase water use efficiency (Mukhtar et al., 2011). According to Kvedaras et al., (2007) stalk damage and reduction in borer numbers (Eldana saccharina Walker) in plants with higher Si concentration was greater for water-stressed cane than non-stressed cane.
The aim of this study was to determine silicon concentration in maize leaf under different levels of irrigation, nitrogen fertilization and various maize genotypes and also relationship with ECB larvae damage.

Material and methods

Field trials was set up during three years (2012 – 2014) at the Agricultural Institute in Osijek (45° 33′ 27.11″ N, 18° 40′ 46.52″ E). Maize was in rotation with soybean every year since 2000. Experiment variants were: A1- non-irrigated, A2– 60% - 80% field water capacity – FWC and A3– 80% -100% FWC), three nitrogen fertilizer levels (B1-0, B2-100 and B3-200 kg N ha^{-1}) and four different maize genotypes (C1-OSSK 596; C2–OSSK 617; C3–OSSK 602 and C4–OSSK 552). Field size was 0.5 ha. Basic plot planted with two rows of maize 10 m long (maize hybrids, 14 m² (10 m x 2 rows x 0.7 m = 14 m²)). On each variant were three rows of safety belt. Nitrogen introduced as urea (46% N) in the basic soil cultivation and pre-sowing. Top-dressing done with KAN (calcium-ammonium nitrate - 27% N) in phase 6-8 leavess and 8-10 leaves. At the end of each vegetation season dissection of maize stalk was done. From each variant of the experiment 10 maize plants were cut (total 1,080 plants)and tested tunnel length (cm) related to ECB feeding activity. In silking stage of maize plants, 10 leaves below the ear was taken and silicon and nitrogen concentration was determined.
The data of ECB larvae injury evaluated by analysis of variance using the SAS software (SAS Institute Inc., 2009) after normality data test. Log transformation (log (n+1)) used to normalize the data. Least square means with the Tukey adjustment for multiple comparisons were then calculated and reported for significance at the 95% confidence level. After that it was made back transformation to see original values.

Results and discussion

In drought-stressed plants silicon application significantly increased plant height, stem diameter, number of leaves, cob length, number of cob, grain yield along with improvement in photosynthetic rate and lowered transpiration rate, respectively (Muhammad et al., 2016). In our experiment, irrigation treatments didn't affect significantly on silicon concentrations except in 2013 where statistically differences between control variant (A1) and variant with higher level of irrigation (A3) were recorded (Table 1). Irrigation variant with longest tunnel length in maize stem was control variant (A1) and A3 variant had significantly the lowest damage from ECB larvae. Nitrogen fertilization had a huge impact on silicon concentration in maize plants. All tested years had statistically significant lower concentration of Si on variant with higher level of nitrogen fertilization (B3) compared to control (B1). Wallace (1989) showed that Si concentrations decrease in plant tissue with increasing nitrogen concentration. Differences between control variant of fertilization (B1)

and variant with lower level (B2) was not statistically significant. Significantly the highest damage from ECB larvae on nitrogen fertilization variants was recorded on B3 variant and same variant had the lowest Si concentration. Same results were published by Szulc et al. (2008). Similar studies were conducted by Setamou et al. (1993), they conclude that silicon applications reduced survival of stem borer larvae from 26% to 4% on maize at 0.56 g Si plant^{-1}. Hybrid C4 had significantly the lowest Si concentration in all tested years compared to other hybrids. In spite of small Si concentration hybrid C4 had the lowest damage from ECB larvae. That is contradictory to many studies (Marschner, 1986; Sétamou et al., 1993; Carvalho et al., 1999; Matichenkov et al., 2000.; Keeping and Meyer, 2002). This fact it could be explain by different genetic resistance to ECB larvae feeding especially in years with optimal or deficit water regime. Laing et al., (2006) showed that maize resistance to the second generation of ECB was significantly correlated with the silica content in the sheath and collar tissue. Rojanaridpichet et al. (1984) explained that maize genotype with 1.52% dry weight silica had 0.14 tunnels per plant and other genotype with 0.46% dry weight silica had 8.80 tunnels per plant.

A1 – control, A2 – from 60 to 100% WFC, A3 – from 80 to 100% WFC, B1 – control, B2 – 100 kg N ha^{-1}, B3 – 200 kg N ha^{-1}, C1- OSSK 596, C2 – OSSK 617, C3 – OSSK 602, C4 – OSSK 552; TL – tunnel length

In 2012, statistictically significant negative correlation was determined at all irrigation variants between Si and N concentration but the stongest was on variant with higher level of irrigation (A3) (Table 2). Same parameters (Si and N) on nitrogen fertilization variants and different maize genotypes were statistically significant only at B2 variant and C3 hybrid. In 2013, three of four hybrids had statistically neagtive medium correlation between Si and N concentration. In 2014, only variant with higher level of irrigation (A3) had significant positive correlation between tunnel lenght and Si concentration. Calatayud et al. (2016) reported that climate change can affect on Si concentration and also on insect distribution and abundance which coincides with our research. They also noted different susceptibility to Si presence between several maize pests and low temeratures at high altitudes were negatively correlated with Si assimilation by maize. According to Vilela et al. (2014) it was impossible determined the effects of silicon on the insect incidence due to the low infestation.

** ss P<0,05

* ss P<0,01

Maize hybrids was more or less susceptible on ECB injury independently on Si concentration. It was reported that Si provided greater protection for susceptible cultivars for borers than for resistant ones. Also different plant parts which accumulate Si can vary a lot in concentration so in fact it's important which part of plant is necessary for insect nutrition (Keeping et al., 2014).

Conclusion

Irrigation treatments did not significantly affect on silica concentration in maize leaves while nitrogen fertilization decreased silicon concentration. Genetic resistance had a significant role in ECB larval damage and resistance was not directly related to the concentration of silicon. It is necessary to provide additional studies with different levels of silicon fertilization in order to determine the effect of silicon in plants resistance on ECB damage.

Abstract

The present investigation aims to throw a light on the efficiency of *Bt* corn on biochemical parametersof 4th larval instar of pink corn borer *Sesamia cretica* (Led.) under laboratory conditions. The resultsshowed that 24 h post feeding on *Bt* corn, caused a 36.05% increase in the larval protein content than their value in the control. Although, total carbohydrates was decreased by 49.13% in larvae than their value in the control. The disturbance in the carbohydrate level was expressed by impairment in the activity of carbohydrate enzymes in treated 4th instar larvae. In treated instar larvae there was a significant increase in the enzyme activity of alpha and beta esterase as well as in acetyl choline esterase. Also, a significant increase in the enzyme activities of both Glutamic pyruvic transaminase and glutathione S-transferase was recorded in treated larvae the values were 24.68% and 69.78% respectively. Meanwhile there was no significant in Glutamic oxaloacetic transaminase level in treated larvae.

Introduction

The pink stem borer Sesamia cretica is considered the most serious corn borer in Egypt and attacks young maize plants shortly after emergence devours the whorl leaves and may kill the growing points, causing dead hearts. It is capable of damaging older plants and excavatingtunnels into the stem, ears and/ or cobs. This pest lays its eggs during March, so its larvae cause complete death of small maizeplants in April and May causing drastic yield losses (Mostafa, 1981; Simeada, 1985; El-Metwally, 1987; El-Naggar 1991). These losses are mainly attributed to decrease in number of dead hearts, increase in plant lodging and ear drops and predisposing infested plants to disease organisms. Chemical insecticides are an effective mean for the control and prevention of major damage caused by this insect pest. However, the extensive and continuous use of traditional insecticides creates environmental contamination and could lead to development of insect resistance. Reduced pesticides risks are considered to be safer for human health and the environment and therefore are in constant demand as new control agents (Gamilet al., 2011). Genetically-engineered corn by Bacillus thuringiensis (Bt) genes which expressing Cry toxins is increasingly developed mainly against targeted pests. One type ofBtcorn expressing Cry1Ab protects against the European corn borer Ostrinianubilalis and the Mediterranean stalk borer Sesamianonagroides. The widespread cultivation of Btcorn reduces many problems associated with the use of chemical pesticides, as the toxins are produced continuously within plant (Saxenaet al., 2002).Transgenic maize engineered to express insecticidal proteins from the bacterium Bacillus thuringiensis (Bt maize) has become widely adopted worldwide with 51 million ha planted in 2011 (James, 2011). Bt maize cultivars based on the event MON810 (expressing Cry1Ab) have shown high efficacy for controlling corn borers.(Shelton et al., 2002; González-Cabrera et al., 2013).

The objective of the present work is to evaluate the efficacy of Btcorn which genetically modified by Bacillus thuringiensis (Bt) gene and non Bt corn onbiochemical aspectsof 4th instar larvae of S. cretica.

Materials and Methods

Test insect: Infested corn plants with *S. cretica* (larval stage) were collected from the field and transferred to the laboratory. The larvae of *S. cretica* were reared on maize pieces according to Aly *et al*., 2011.

Biochemical bioassay

After 24 h following the feeding of 4thinstar S. cretica larvae on Bt corn and non Bt corn, any surviving larvae exhibiting toxic symptoms were selected. The insects were prepared as described by Amin (1998). They were homogenized in distilled water (50 mg/ 1ml). Homogenates were centrifuged at 8000 r.p.m. for 15 min at 5°c in a refrigerated centrifuge. The deposits were discarded and the supernatant, which is referred as enzyme extract, can be stored at least one week without appreciable loss of activity when stored at 5°C.

Main metaboliccontents

(i) Total soluble protein according to Bradford (1976).
(ii) Total carbohydrates according to Dubois *et al.*,(1956).
(iii) Total lipids as described by Knight *et al.* (1972).

Enzymes assay

The following enzymes activity was determined:
(i) Proteolytic activity was measured as described by Tatchell *et al.* (1972).
(ii) Carbohydrates hydrolyzing enzymes; amylase, trehalase and invertase were determined according to the modifications of Amin (1998) to the method described by Ishaaya and Swiriski (1976) using trehalose, sucrose, and soluble starch as substrates for trehalase, invertase and α-amylase, respectively.
(iii) Non-specific α and β esterase activity was measured as described by Van Asperen (1962) using α- naphthyl acetate and β- naphthyl acetate as substrates, respectively.
(iv) Acetyl choline-esterase (AchE) activity was determined using acetylcholine bromide (AChBr) as substrate according to the method described by Simpson *et al.* (1964).
(v) Glutamic pyruvic transaminase (GPT) and glutamic oxaloacetic transaminase (GOT) were determined calorimetrically according to the method of Reitman and Frankle (1957).
(vi) Glutatione S-transferase activity (GST) was determined spectophotometrically at 340 nm according to the method of Habig*et al.* (1974).

Statistical analysis:

All experiments contained 3-4 replicates (insects homogenates), and the results of chemical determinations were pooled from the triplicate determinations. The variability degree of results was expressed as Means ± Standard Deviation of means (Mean ± S.D). The data were statistically analyzed T- test by using SPSS program.

Results and discussion

Biochemical effects

Effect on main contents

As seen in Table (1) 24h post feeding of 4th instar *S. cretica* larvae on*Bt* corn caused an increasment in the total protein content from 25.8 to 35.1 mg/ml giving 36.05 % increase than their value in the control.

A marked reduction of 49.13% in total carbohydrates content, as its value was reduced from 9.77 in the control to 4.97 mg/ml.

Meanwhile, there is non-significant difference between the determined values of the total soluble lipids of *S. cretica* after feeding on *Bt* corn and non *Bt*corn. The values were 7.43 and 7.37 (mg/g).

Enzyme assay

Digestive Enzymes activities:

Protease activities of 4th instar*S. cretica* larvae feeding *Bt* corn and non *Bt* corn was presented in Table (2). Data revealed that the activity of protease values were 94.1 and 95.83 ug D, L alanine/ min./g.b.wt for *Bt* corn and non *Bt* corn respectively. These values show a slight elevation by 3.62 % after feeding on *Bt* corn. Statistically, there is non-significant difference between *Bt* corn and non *Bt* corn.

Carbohydrates hydrolyzing enzymes:

Effect on carbohydrate enzymes activity. As seen in Table (2), feeding of 4th instar larvae on *Bt* corn caused a significant 43.92% reduction in amylase activity than that in untreated larvae. Values were 40.0, 71.33 (ug glucose/min/g.b.wt). However, activity of invertase was significantly decreased by 14.49 % than the control, respectively. Meanwhile; a mild decrease of 4.23% in trehalase activity compared with that in untreated larvae.

Non-specific esterases, acetyl choline esterase, activities:

Effect on alpha, beta esterase and acetyl choline esterase activity. As seen in Table 2, The activity of alpha in 4th instar larvae 24 hours following feeding on *Bt* corn was 1262.0 ug α-naphthol /g /min, as compared to 1217.0ug α-naphthol /g /min in non *Bt*corn. Statistical analysis showed that there is a mild significant difference between *Bt* corn and non *Bt*corn. Meanwhile, the activity of beta esterase in 4th instar larvae of *S. cretica* after feeding on *Bt* corn caused a significant increase than those which fed on non *Bt* corn; values were 1284.0 and 1039.0 (ug β -naphthol /g/min.) respectively, being an increase by 23.58

Estimated acetyl choline esterase activity in 4th instar *S. cretica* larvae which fed on non *Bt*corn was 54.53 ugAchBr/ min/g.b.wt which was significantly lower than that recorded in those which fed on *Bt*corn. Where; feeding larvae on *Bt* corn led to a marked increase in acetyl choline esterase activity reached to 106.2 ugAchBr/ min/g.b.wt(i.e. 94.76% increase).

Effect on transaminase enzymes activities

The activity of GPT (ALT) as affect by feeding 4th instar*S. cretica* larvae on *Bt* corn and non *Bt* corn are shown in Table (2). Values were 55.77 and 44.73 U/g.b.wt respectively. Statistical analysis showed that there is significant difference between *Bt* corn and non *Bt*corn.

The effect of *Bt* corn and non *Bt* corn on AST(GOT) activity of *S. cretica* was presented in (Table 2) data revealed that the activity of GOT values were 72.67 and 73.5 U/g.b.wt for *Bt* corn and non *Bt* corn respectively. Statistically, there is non-significant difference between *Bt* corn and non *Bt* corn.

Glutathione S-transferase activity showed a significant increased following the feeding of 4th instar *S. cretica* larvae with *Bt*corn,where it was 54.5 m mole sub. conjugated/min/g.b.wt versus 32.1 m mole sub. conjugated/min/g.b.wt non *Bt* corn one giving a 69.78% increase than their value in the control.

Table 1. Enzyme activities in 4th instar larvae of *S. cretica* 24h post feeding with *Bt* corn

Dose	*Bt*Corn	Non *Bt*corn	% of change

Bt maize cultivars based on the event MON810 (expressing Cry1Ab) have shown high efficacy for controlling corn borers.(Shelton *et al.*, 2002 and González-Cabrera *et al.*, 2013).In the present work, 4th instar *S. cretica* larvae were found to be more susceptible to *Bt* corn. Biochemical changes were measured in the 4th instar *S. cretica* larvae 24h post feeding on *Bt* corn. Total proteins, carbohydrates and lipids are major components necessary for an organism to develop, grow and perform its vital activities (Gamil *et al*, 2011). A significant decrease in the quantities of total carbohydrates while a significant increase in total proteins was detected in 4th instars treated larvae. The disturbance in carbohydrates was expressed by impairments in the activity of carbohydrate enzymes in treated larvae. In the many studies, pesticides including *B.thuringiensis*, synthetic chemicals and botanical components significantly decreased the activity of *α*- amylase in the midgut of different insects (El-Ghar*et al.*, 1995; Shekari*et al*., 2008; Zibaee*etal*., 2008; Zibaee and Bandani, 2010, Soliman *et al.*, 2012). In treated instar larvae there was a significant increase in the activity of alpha, beta esterase and AchE. The results of *S. cretica*haemolymph enzymes after feeding *Bt* corn are in

harmony with those obtained by El-Ghar*et al.* (1995) who determined the effect of *B. abamectin* and *thuringiensin* (beta-exotoxin of *B. thuringiensis*) on the main digestive enzymes and non-specific esterases in larvaeof *Spodoptera littoralis*. Furthermore, glutathione S-transferase enzyme activity was increased in treated larvae, this enzyme plays a role in detoxification mechanism in insects, therefore maybe an over production of this enzyme occurred as a result of treatment. Glutamic pyruvic transaminase (GPT) activity increased in *Bt*-corn treatment while decreased in non *Bt*-corn. Results revealed that the activity of Glutamic oxaloacetic transaminase (GOT) not affected of *Bt*-corn compared with non *Bt*-corn. George and Gatehouse (2013) found thatthere was significant difference between GST activity for insects fed control plants and those fed *Bt*plants. Insects fed on 28 days control plants had lower (34%) activity than those fed on 28 days *Bt* plants. Glutathione Stransferase protects tissues against oxidative stress and oxidative damage. They expected insects fed *Bt* plants to be under more oxidative stress than those fed control plants hence more Glutathione Stransferase activity. However, the insects may not have been feeding on the *Bt* plants due to the effects of the toxin. *Bt* plants have been found to have ant- nutritive effects on insects.

Conclusion

Corn is the second most plentiful cereal grown for human consumption, and many cultures around the world have lived on this grain. Corn is a versatile crop, and everything on a corn plant is useable. Allot of insect pests are attack the corn crop, specially corn borers

Chemical insecticides are an effective mean for the control and prevention of major damage caused by insect pests. However, the extensive and continuous use of traditional insecticides creates environmental contamination and could lead to development of insect resistance. Reduced pesticides risks are considered to be safer for human health and the environment and therefore are in constant demand as new control agents. The pink stem borer Sesamia cretica is considered the most serious corn borer in Egypt and attacks young maize plants shortly after emergence devours the whorl leaves and may kill the growing points, causing dead hearts. It is capable of damaging older plants and excavating tunnels into the stem, ears and/ or cobs. Transgenic maize engineered to express insecticidal proteins Cry 1Ab from the bacterium Bacillus thuringiensis (Bt maize) has become widely adopted worldwide with 51 million ha planted around the world Bt maize cultivars have shown high efficacy for controlling corn borers. The objective of the present work is to evaluate the efficacy of Btcorn which genetically modified by Bacillus thuringiensis (Bt) gene and non Bt corn onbiochemical aspectsof 4th instar larvae of S. cretica. In the present research, results revealed that feeding4th larval instar of pink corn borer; Sesamiacretica, on Bt corn, has a direct influence on some physiological parameters of S. cretica under laboratory conditions. Bt corn makes a noticeable disturbance in the activities of main contents and enzymes of S. cretica larvae. Results also reveal that using Bt corn could give some promising results. This fact can help us in the future to minimize S. cretica number in corn fields.

Abstract

Bur cucumber (*Sicyos angulatus* L., SIYAN) is a troublesome invasive vine. Seeds of the plant possess a water-impermeable, hard seed coat exhibiting physical dormancy. Seed dormancy is employed by the invasive plants for persistence in soil seed bank, seedling recruitment and avoiding unfavorable environmental conditions. The seed dormancy differences among populations offer valuable insights for understanding biology and devising effective management practices against invasive plants through experimental studies. Therefore this study was carried out to evaluate the dormancy differences among 3 populations collected from Black Sea region of Turkey. Chemical scarification with H_2SO_4, wet and dry pre-chilling (for 2 weeks) and mechanical scarification (girdling with scalpel) were tested along with an untreated control for comparison. Seeds were dipped in concentrated (98%) H_2SO_4 solution for 1, 2, 3, 4 and 6 minutes for chemical scarification. Whereas, a small portion of the seed coat was removed with the help of scalpel in mechanical scarification. Experiments were incubated at 25 ºC with 12 hours light and dark period for 30 days and repeated. Freshly harvested seeds exhibited higher dormancy with slight differences among populations. Chemical scarification and pre-chilling treatments were ineffective in overcoming the dormancy. Mechanical scarification significantly promoted the final germination percentage with slight differences (82-90%) among populations. The results of the mechanical scarification were consistent in both experimental runs. It is concluded that slight scarification of SIYAN seeds imparts water-permeability in seeds leading to higher germination. The persistence of the seeds in soil seed banks probably leads to the deterioration of seed coat till next growing season resulting in effective seedling recruitment. Mechanical scarification can be successfully employed to break the dormancy in SIYAN for experimental studies.

Introduction

Biological invasions are considered as the most serious threat to native biodiversity throughout the world (Lee *et al*., 2015). Among invasive plant species, vines are more dangerous as they readily get established in introduced ranges, spread and replace native biodiversity by blocking sunlight and competing for resources. *Sicyos angulatus* L. (Bur cucumber, SIYAN) is an annual vine, native to North-eastern USA and currently invades several regions of the world (Kurukowa *et al*., 2009; Onen *et al*., 2015a, b; Lee *et al*., 2015;). It has been regarded as invasive plant in Europe as well and its range is continuously expanding (Hulina, 1996). SIYAN interferes with several crops, such as maize, soybean, hazelnut, and pumpkin etc. (Hulina, 1996; Shimizu, 1999; Esbenshade *et al*., 2001; Watanabe *et al*., 2002; Larché, 2004; Gibson *et al*., 2005; Onen *et al*., 2015a, b). SIYAN is also commonly observed along watercourses, forest sites and in other open spaces in the natural habitats where it suppresses native vegetation by completely covering the ground and

blocking sunlight (Watanabe *et al*., 2002; Onen *et al*., 2015a, b). The presence of the plant alongside rivers and streams restricts water flow and creates several problems for stream managers (Lee *et al*., 2015). SIYAN is currently infesting considerable portion of Black Sea region in Turkey and exerted several negative effects on the native plant communities (Onen *et al*., 2015a, b).

Different invasive plant species and/or even different populations of the same species successfully manipulate seed dormancy to persist and germinate under diverse range of environmental conditions. Dormancy influences the survival, colonization, adaptation, speciation and extinction both at population and species levels (Willis *et al*., 2014). However, different life forms of plants exhibit different extent and type of seed dormancy (Willis *et al*., 2014). The type and degree of dormancy strongly affects the germination especially in newly colonizing populations (Huang et al., 2010). Therefore, seed dormancy is considered as the major determinant of species distribution as seeds first need to get germinated for the evolution of adaptive traits (Donohue *et al*., 2010).

Environmentally cued seed dormancy through evolving specialized structures is known as physical dormancy. Physical dormancy has been documented in nine orders and 17 families of angiosperms (Baskin and Baskin, 2003; Baskin *et al*., 2006). Cucurbitaceae is one of the families containing species which exhibit physical dormancy via developing water-impermeable seed coat. To date physical dormancy has been reported only in the two plants of genus Sicyos in the Cucurbitaceae family i.e., *Sicyos deppei* (Orozco-Segovia *et al*., 2000) and *Sicyos angulatus* (Lim *et al*., 1994). The existence of physical dormancy in SIYAN seeds and role of mechanical scarification in overcoming it is well documented (Qu *et al*., 2010). However, seed dormancy differences among different populations of SIYAN have been less explored although, higher genetic diversity has been reported for the plant (Kurokawa *et al*., 2009; Dlugosch *et al*., 2015).

SIYAN can grow under different shade and water availability conditions indicating the presence of higher genetic diversity (Oh *et al*., 2015). Therefore seed dormancy differences among different populations may help to infer the mechanisms of introduction and further spread (Kurokawa *et al*., 2009; Dlugosch *et al*., 2015). As described earlier, seed dormancy is the most initial trait expressed in the life history of plants, hence it is critical determinant of survival and colonization success (Willis *et al*., 2014). Therefore a thorough understanding of seed dormancy differences among different populations might help to understand population dynamics and further invasion trends. Although invasion status of SIYAN is well studied in Black Sea region of Turkey however, no literature exists on the germination biology of different populations infesting the region.

The current study was therefore planned to infer the seed dormancy differences among different SIYAN populations and potential of different dormancy breaking techniques to overcome dormancy. The results of the study will help to better understand the germination biology of different populations infesting the region.

Materials and Methods

Seed Collection:

Sicyos angulatus have extensively infested the eastern parts of Black Sea region in Turkey and started to interfere with different agricultural crops. Seeds were collected from three different sites (Dernekpazar, Dereli and Camlihemsin counties) highly infested with the plant. Physiologically mature fruits were collected and brought to the laboratory where they were dried under shade and seeds were separated from fruit coats. Seeds were stored in glass jars until the start of experiments.

Experimental treatments

Mechanical and chemical scarification techniques along with pre-chilling were tested to evaluate their role in overcoming the dormancy of SIYAN seeds. A small proportion of the seed coat was removed with the help of a scalpel (girdling) in mechanical scarification treatment. Seeds of the tested populations were dipped in concentrated (98%) H_2SO_4 solution for different time intervals (1, 2, 3, 4 and 6 minutes). Seeds were then thoroughly rinsed, surface dried and used. Seeds were also stratified (pre-chilling) either wet (between moistened layers of filter paper) or dry at 4 °C for two weeks. The untreated seeds (control treatment) was also included in the study for comparison purpose.

Experimental Layout

Experiments were conducted in randomized complete block design with split plot arrangements. The SIYAN populations were taken as main plots whereas dormancy breaking techniques were randomized in sub plots.

Experimental procedure

Twenty five seeds were placed on the double layer of Whatman no. 1 filter paper in 5 replicates and the papers were moistened with deionized water. The moisture was supplied to the germinating seeds throughout the experimental duration according to the needs. The petri dishes were kept at 25 °C for 30 days with 12 hours light and dark period. The cool, while fluorescent lamps were used for the provision of light in the incubators and relative humidity was adjusted to 60%. The place of the petri dishes was changed every day within the incubators. Germination was observed on daily basis and germinated seeds were counted up to 30 days after the initiation of experiments. A seed with 2mm radicle prolonged was considered as "germinated". The germinated seeds were removed from the petri dishes. Final germination percentage of the seeds was computed at the end of experiments and used in the statistical analysis.

Statistical Analysis

All of the tested seed dormancy breaking techniques except dry pre-chilling and chemical scarification for lesser time (i.e., 1, 2 and 3 minutes) improved final germination percentage compared to control. Therefore the treatments resulting higher germination than control were included in statistical analysis. A two way analysis of variance was used to test the significance for populations, treatments and their all possible interactions. Least significant differences test at 5% probability was used to separate means where ANOVA indicated significant differences. The SPSS computer program version 23 was used for the statistics analyses whereas graphical representation of the data was accomplished using Microsoft Excel version 2013.

Results and Discussion

The individual and interactive effects of SIYAN populations and dormancy breaking techniques proved significant in the current study (Table 1). Freshly harvested seeds of different SIYAN populations exhibited extensive dormancy (92.8 to 94.8% dormant seeds). Similarly, different seed dormancy breaking techniques significantly affected the final germination percentage of tested SIYAN populations (Table 1). Mechanical scarification with scalpel proved as the most effective in breaking dormancy. Chemical scarification with H_2SO_4 for 6 minutes also slightly stimulated the germination whereas chemical scarification for lesser time proved ineffective in this regard (Figure 1). Among the remaining seed dormancy breaking techniques, wet pre-chilling slightly stimulated the germination whereas dry pre-chilling proved ineffective. Therefore these treatments cannot be considered as potential

techniques for breaking dormancy of SIYAN seeds. Regarding interactions among populations and seed dormancy breaking techniques, highest final germination in all populations was observed with mechanical scarification while the untreated (control) seeds result in the lowest germination (Figure 2). The population collected from Dereli exhibited slightly higher final germination compared to the other SIAYN populations studied.

Seed dormancy delays or prevents germination under unfavorable conditions thus ensuring germination over the next growth season (Willis et al., 2014). It is evident from the results that SIYAN seeds exhibit physical dormancy as all the seed dormancy breaking techniques except mechanical scarification failed to promote germination of different tested populations. Physical dormancy allows the plants to colonize in novel environments by adjusting timing of germination (Donohue et al., 2005). The results of the study reveal that all of the populations undergo similar adaptations for persistence in the currently invaded region of Turkey. The development of water impermeability in SIYAN seeds soon after physiological maturity is well reported (Qu et al., 2010). Different weed populations exhibit high genetic variations among different populations or even within the same population (Dlugosch et al., 2015). Large scale genetic variations have been observed in different populations of SIYAN collected from Japan (Kurokawa et al., 2009). Therefore the difference in seed dormancy of different Turkish SIYAN populations are probably the result of genetic variations among populations.

Table 1. Two-way ANOVA different seed dormancy breaking techniques, bur cucumber populations and their interactions on final germination percentage.

Source	df	SS	MS	F value	P value

Total	75.00	128336.00			

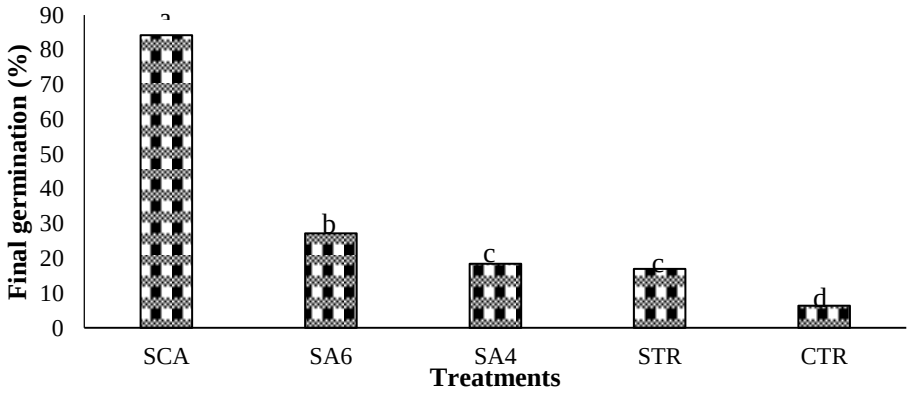

Figure 1. Effect of different seed dormancy breaking treatments on the final germination % of different populations (average of 3 populations). Here; SCA = mechanical scarification, SA4 and SA6 = chemical scarification with H_2SO_4 for 4 and 6 minutes, respectively, STR = wet pre-chilling at 4 °C for 15 days, and CTR = control treatment, (LSD 5% = 2.20).

Dormancy breaking requirements are highly specific for a given taxa which indicate that dormancy is developed by complex adaptations (Donohue et al., 2010). Physical dormancy due to the presence of water-impermeable seed coat have been widely cited in different studies (Lim et al., 1994; Qu et al., 2010). Seeds of SIYAN become water-impermeable after drying followed by physiological maturity (Qu et al., 2010). Since, the water imbibition is the

core requirement of the seeds for enzymatic activities during seed germination. Therefore, it was hypothesized that chemical scarification will impart the water permeability to SIYAN seeds and possibly overcome the seed dormancy. However, the results indicated that chemical scarification, even for longer time (6 minutes) almost failed to stimulate germination and hence proved ineffective for breaking dormancy. As chemical scarification slightly improved the germination with increasing exposure time, it is predicted that chemical scarification for longer time may possibly overcome dormancy.

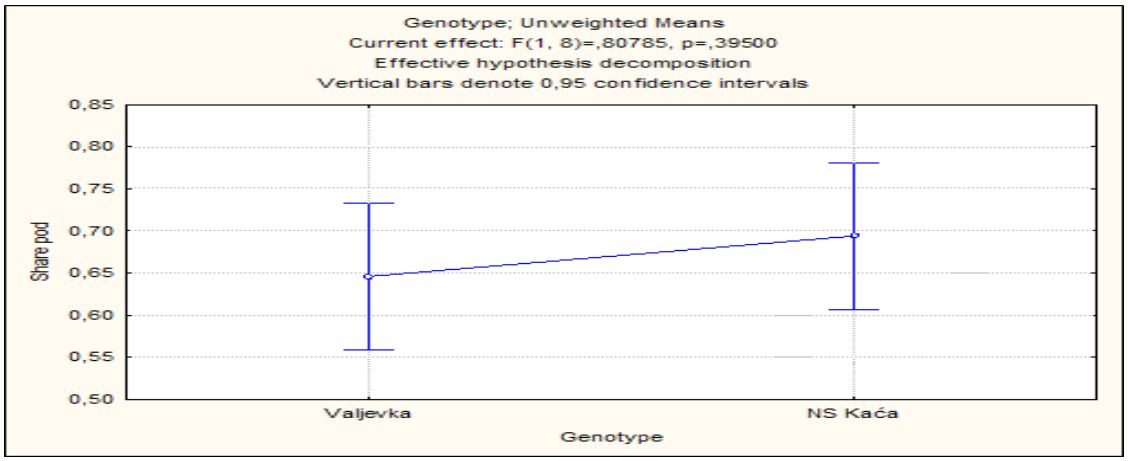

Figure 2. Effect of different seed dormancy breaking treatments and on the final germination % of different populations (effect on individual population). Here; SCA = mechanical scarification, SA4 and SA6 = chemical scarification with H_2SO_4 for 4 and 6 minutes, respectively, STR = wet pre-chilling at 4 °C for 15 days, and CTR = control treatment, (LSD 5% = 3.81).

Conclusion

It is concluded that SIYAN populations undergo similar adaptations to develop physical seed dormancy for persistence and colonization in novel environments. The presence of physical dormancy will help the plant to explore and invade novel environments in the country. Slight differences in the populations are owed to inherent genetic variations among populations. Secondly, the seed coat must be ruptured prior to germination which naturally happens due to longer burial time and presence of ample soil moisture in the currently invaded range of the plant in Turkey. It is recommended that proper management measures must be taken to tackle the existing populations and to prevent the further spread.

Abstract

It is not possible to completely eliminate chemical protection and fertilization in horticulture. As an cost-effective alternative that could be used is limited NPK and application of microbial metabolites that are able to stimulate growth and yield of crops. One of the possibilities offered by the company, the BioPuls Microlife, is a line of products that based on the special composition of yeast *Yarrowia lipolytica* and their metabolites as bioactive substances and health-promoting nutrients for plants and soil. Use of beneficial microorganisms and bio-products have several advantages: (i) development of sustainable methods of horticulture, (ii) improvement of production quality and, (iii) protection of the environment and human health. The aim of this study is to comprehensively assess impact of the BioPuls on growth and yielding of three species of cultivated plants. Experiment was conducted in the Research Institute of Horticulture in Skierniewice (Poland) in 2013-2014. Experiment compared the growth and yelding of tomato (*Lycopersicon esculentum* Mill.), cucumber (*Cucumis sativus* L.) and strawberry (*Fragaria ×ananassa* Duchesne) var. 'Elkat'. Results shows that The BioPuls has a positive effect on the vegetative growth, develop and yield of tomato, cucumber and strawberry in greenhouse cultivation.

Keywords: *Yarrowia lipolytica,* yeast, plant biostimulation, microorganisms, bio-products

Introduction

Contaminated soils and an imbalances in the microbial rhizosphere population can be observe more often. The main reason is the technology of cultivation based on the excessive use of chemicals and artificial fertilizers. As a result, there is a condition in which the soil is completely devoid of useful microorganisms that mainly determine the normal processes within the soil. Restricting use of the plant protection products and mineral fertilizers carries the risk of fruit and vegetable production to become less attractive, thus leads to lower income of the farm. Nevertheless, is it not possible to completely eliminate chemical protection and fertilization. However, effective and economically viable alternative is to use limited NPK combined with application of microbial products that stimulate growth and yield of crops and protects the environment and health of consumers. It is possible to enrich orientation of biological life in the soil, thus the dominant species of microorganisms increased the fertility, better growth and development of plants (Barabasz and Smyk, 1997; Bashan, 1998; Barabasz et al., 1999; Doran et al., 2006; Jodelka et al., 2008; Dahm et al., 2010; Frąc and Jezierska-Tys, 2010).

The BioPuls Microlife, that is a line of products that based on special composition of yeast, *Yarrowia lipolytica,* and their metabolites, containing a high quality of protein-rich bioactive substances and health-promoting nutrients for plants and the soil. Use of the beneficial microorganisms and bioproducts, that are enriched microbiologically, presents several

opportunities: (i) development of sustainable methods of horticultural production, (ii) improvement of the quality in produced yields, and (iii) protection of the environment and human health.

Yarrowia lipolytica can be found in many plants and food products. This non-pathogenic microorganisms have the safety status of GRAS (Generally Recognized As Safe), awarded by the US Food and Drug Administration (FDA). *Y. lipolytica* has been identified in some kinds of cheeses, yogurts and dry sausage. Currently, it is used as an vaccine in the industrial production of cheese. Contrary to other yeast processing monosaccharides, *Y. lipolytica* is using fats as a source of carbon and energy, and does not occurs a fermentation process. Unofficially they are classified as a group of non-conventional yeasts. *Y. lipolytica* is a reservoir of valuable macronutrients, organic forms of micronutrients and trace elements, such as: selenium, chromium, iron, manganese, zinc, iodine, copper. Their metabolites – organic acids, hydrolytic enzymes, lipolytic enzymes and oxidoreductases – have positive effect on soil microflora, other organisms growth, process of germination and plant growth. It has been shown that the introduction of Y. *lipolytica* also favors plants rooting. These yeasts have a high survival rate in soil and high genetic and phenotypic stability. They also increase resistance of plants against some pathogens. Yeasts *Y. lipolytica* also have large assimilation capacities and it was used in bioremediation of contaminated water and soil, and detoxification of various harmful substances. Due to their lipolytic properties it was also used to treat waste from production of oil. Their specially selected and patented strain were used to develop a unique technology with the use of vegetable fats (Barth and Gaillardin, 1996; Barth and Gaillardin, 1997; Horn, 1997; Musiał et al., 2003; Fickers et al., 2005; Kordowska-Wiater, 2011; Krzyczkowska i Fabiszewska, 2015).

The aim of this study was to comprehensive assessment of impact of the BioPuls on growth and yielding of three species of cultivated plants: tomato, cucumber and strawberry.

Materials and methods

Experiment was conducted in greenhouse on three plant species: tomato (*Lycopersicon esculentum* Mill.), cucumber (*Cucumis sativus* L.) and strawberry (*Fragaria ×ananassa* Duchesne) var. 'Elkat', at the Research Institute of Horticulture InHort in Skierniewice (Poland), in 2013-2014.

Products of yeast *Y. lipolytica* were used in 3 combination with reduced to 30% NPK fertilizer. The control plants were fertilized with 100% dose of NPK. Yeast were used as a liquid form by spraying plants with an aqueous solution of 5% each of yeast products. Plants were sprayed three times at intervals of 1 month. Cucumber and tomato plants were sprayed first time on day of planting, the second spraying was performed after one month of growing, and the third after two months of growing. Planted cucumber plants were well developed and had approx. 12 cm high. Planted tomato plants had approx. 14 cm high. Strawberry plants were sprayed two weeks after planting, after the formation of roots and leaves. Next spraying was performed on a monthly basis.

In the experiment were used 4 combinations:

1. Control, standard fertilized with 100% NPK, the ground without yeast
2. Formula 1: 30% NPK + liquid yeast *Y. lipolytica* after cavitation 5%
3. Formula 2: 30% NPK + *Y. lipolytica* liquid yeast milk 5%
4. Formula 3: 30% NPK + *Y. lipolytica* forage yeast 5% + rhizosphere bacteria from the collection of Research Institute of Horticulture in Skierniewice.

During growth of plants and after completion of the experiments, the measurements and observations of: plant height, leaves width, average rate of plant growth, fresh and dry weight

of shoots and roots, surface area of plant shoots, root length, surface area, volume, diameter and number of vertices roots, fruit number and fruit yield per plant were performed.

Results and discussion

The BioPuls used in the first phase of tomato growth significantly influenced on plant height using a limited NPK fertilization – only 30%. All tomato plants on the time of planting had aligned height. The first treatment of the BioPuls, that was used on the day of planting, had a positive impact on young plants and increased plant growth by 80% after 15 days of growth. Average daily rate of the plants growth showed positive effects of the BioPuls on young plants. After one month of growth plants treated the BioPuls were higher than the control plants (Figure1). Dobromilska (2009) also confirms that the use of bio-stimulators has a positive effect on the vegetative growth of tomato plants and causes an increase of yielding. The plants which were treated with biostimulators were higher, had thicker stems and more leaves. The treatments significantly increased the yield of fruits. The stimulating influence of biostimulator treatment on fruit setting was also observed.

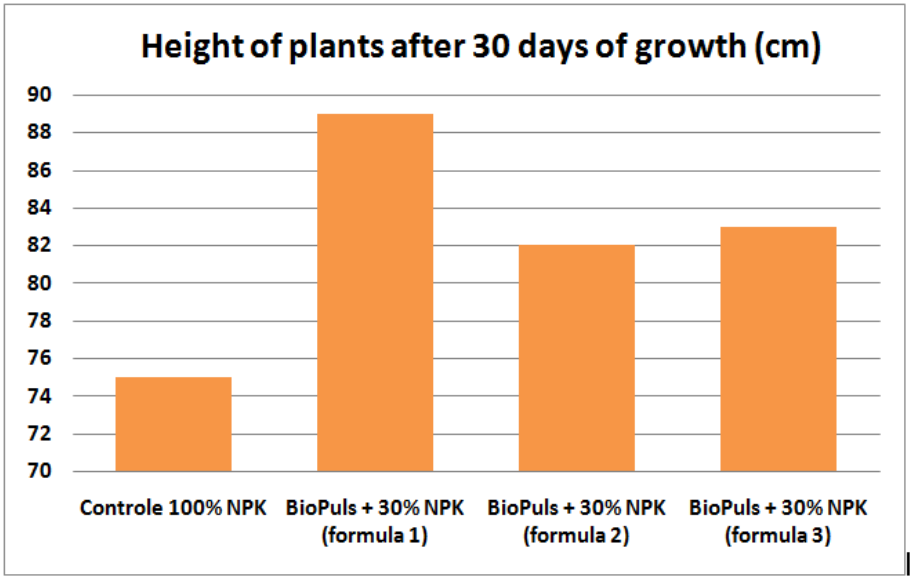

Figure 1. Height of tomato plants after 30 days of growth.

After two weeks of growth significant differences between height of cucumber plants treated the BioPuls and control plants were observed. Height of control plants (100% of NPK) was significantly lower than plants treated the BioPuls (+ 30% of NPK). During the first two weeks of growth plant sprayed with the BioPuls + 30% NPK had significantly higher average daily dynamics of growth than plants fertilized with 100% of NPK. The BioPuls significantly stimulated growth of cucumber plants. Impact of the BioPuls on width of the leaves was also tested. Results showns a significant increase of surface area of cucumber leaves after treatment with the BioPuls with combination of 30% of NPK compared to the control plants fertilized with 100% of NPK. Larger surface area of the cucumber leaves significantly increased photosynthetic activity in plants. It has been confirmed by growth dynamics in the initial phase of growth and development studied plants. Cucumber plants in the early phase of growth positively reacted to the BioPuls, that proved to be easily absorbed by plants and effective in the stimulation of vegetative growth. After first month of growth, cucumber plants treated with the BioPuls and 30% of NPK were significantly higher compared to the control. Application of the BioPuls, significantly stimulated growth of cucumber plants in early phase of development. Control plants fertilized with 100% of NPK had significantly lower daily

growth. Differences in plant height in favor of the BioPuls was also confirmed in fresh weight of cucumber plants after a month of growth. The results showed that cucumber plants fertilized reduced to 30% of NPK and the BioPuls were significantly higher mass (approximately 30-35%) compared to control plants. After one month of growth plants treated with the BioPuls + 30% of NPK had 21% more fruit in comparison to the control plants. Analyzing the whole period of growth of cucumber plants it has been shown higher mass plants treated with the BioPuls + 30% of NPK compared to control plants treated with 100% of NPK. The BioPuls treated plants had an average of 28% higher mass compared to control plants. Also the average height of cucumber plants treated with the BioPuls + 30% of NPK was significantly higher than the control plants. Based on the number of fruits and their mass was estimated commercial yield. The lowest yield trading characterized by control plants fertilized with 100% of NPK (Figure 2-3). Boehme et al. (2006) showed enhancing the cucumber root growth after the application of bio-stimulators. The results of Shevchenko (2010) showed that the cucumber plants treated with a biostimulators were more resistant to suboptimal growing conditions than the plants on variants without treatment. However Tomczyk and Elkner (2015) shown, that biostimulants was not significantly affected on yield of cucumber.

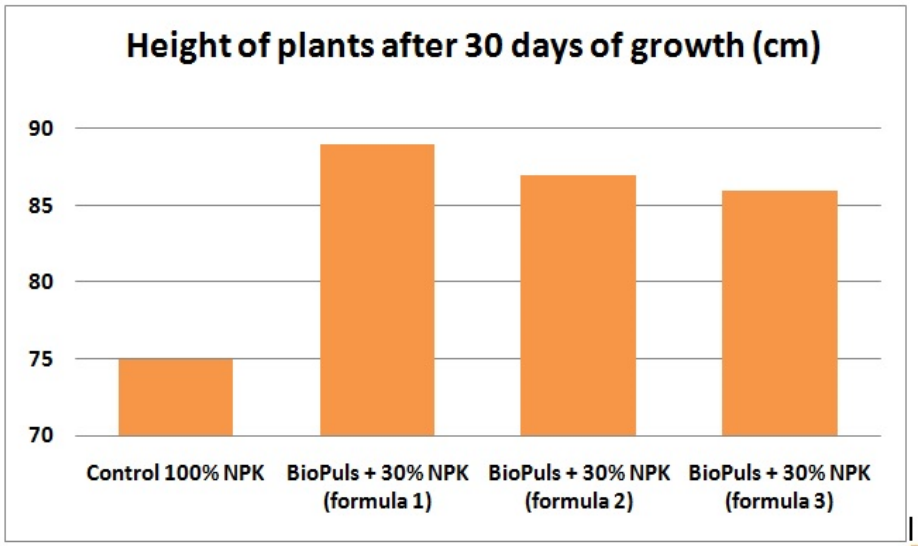

Figure 2. Height of cucumber plants after 30 days of growth.

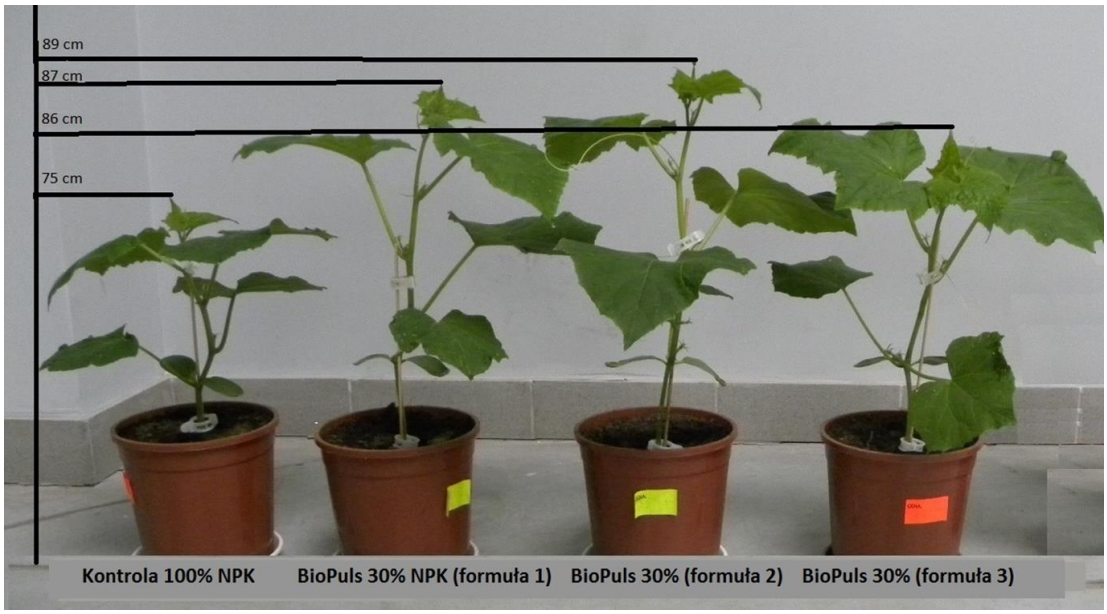

Figure 3. Height of cucumber plants after 30 days of growth.

Strawberry plants sprayed with the BioPuls + 30% of NPK had 100% higher number of leaves compared to control plants. The BioPuls + 30% NPK influenced for increasing more than 100% of fresh weight of leaves compared to the control (100% NPK). The BioPuls + 30% of NPK also affected on significant increase of surface area of leaves compared to control. Control plants had significantly lower fresh weight of root system than plants treated with the BioPuls + 30% of NPK. The BioPuls stimulated growth of roots and shoots of strawberry plants compared to the control. The BioPuls + 30% of NPK also influenced on significant increase of surface area of roots compared to the control. Control plants (100% NPK) had a smaller volume of root system compared to plants treated with the BioPuls + 30% of NPK. The BioPuls + 30% of NPK positive influenced on increasing the length of strawberry roots. The roots of control plants (100% NPK) were shorter (Figure 4). Results obtained by Glinicki et al. (2010) indicate the need for further research in field conditions to confirm the beneficial effects of use of bio-stimulators on growth, development and yield strawberry plant.

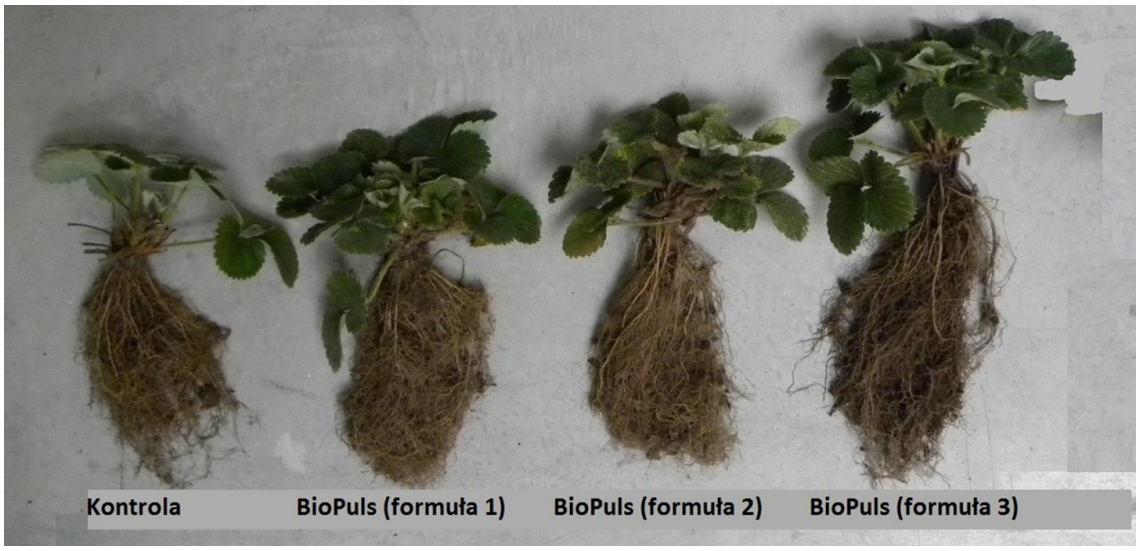

Figure 4. Strawberry plants treated with the BioPuls + 30% of NPK compared to control plants fertilized with 100% of NPK.

It has been shown intensity of flowering strawberry plants after application of the BioPuls. Due to the difficult pollination in greenhouses and autumn-winter period inflorescences were cut and counted to assess impact of the BioPuls on vegetative plants growth. Compared to control plants (100% NPK), foliar application of the BioPuls + 30% of NPK influenced increasing fresh weight and number of inflorescences per plant (Figure 5). Marjanska-Cichon and Sapieha-Waszkiewicz (2011) shown a slight tendency towards a positive influence of biostimulants on strawberry yielding. However Lisiecka et al. (2011) shown that application of biostimulant did not have a beneficial influence on number of strawberry runners, their length anddiameter. Applied biostimulant did not also affect quantity of strawberry daughter plants, their crown diameter as well as number of leaves.

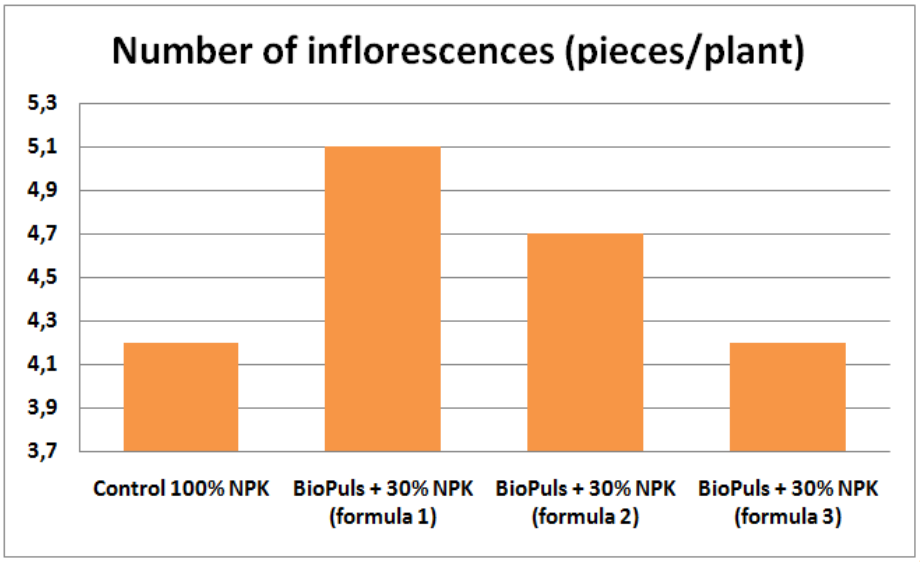

Figure 5. Strawberry plants treated with the BioPuls + 30% of NPK compared to control plants fertilized with 100% of NPK.

Conclusion

- Results shows that the effects of the BioPuls on growth and yield of tomato and cucumber have positive impact on production of seedlings, proper vegetative growth, development and yield of both species of tested plants in the greenhouse cultivation.
- Obtained results from the experiments shows effects of the BioPuls on vegetative growth of strawberry cultivar 'Elkat' and shows its positive impact on proper growth and development in the greenhouse cultivation.
- Based on the study it is possible to show positive effect of the BioPuls on vegetative growth and mass of strawberries inflorescences in greenhouse cultivation. Application of the BioPuls can help to obtain better yields and faster growth of strawberry plants in the early and later phase of development.
- In cultivation of cucumber and tomato could be observe reduction of NPK fertilization of 20-30% in conjunction with foliar or soil application of the BioPuls in order to stimulate the vegetative growth and yielding cultivated plants.

LOSSES CAUSED BY DISEASES ATTACK QUINOA IN EGYPT

Tawfik H. ABD-ELMOITY, Ayat M. ALI

Central Lab of Organic Agriculture, Agriculture Research Center, Giza, Egypt
*Corresponding author: tawfikabdelmoity@yahoo.com

Abstract

Quinoa is a very recent crop was introduced to Egypt. Quinoa is considered as important crop due to it can grow and gives considerable yield in new reclaimed salty soil with salty water (1800 ppm) where wheat or many other cropscannot grow. This work was designed to illustrate different losses may occurred due to different diseases attack quinoa under Egyptian conditions. Obtained data show that soil borne pathogens *Fusarium solani, Rhizoctonia solani* and *M. phaseolina* were the most destructive pathogens for quinoa crop and caused more than80% losses of yield. Foliage diseases came in the second rank causing about65% in Egyptian variety. This work also included biological and chemical methods to control soil borne or foliage disease. Obtained data show that these losses can be reduced and yield increase six times in case of control soil borne pathogens. Foliage diseases were reduced to be 14 %using approved pesticides according to organic agriculture laws. Two different biocides were used to control soil borne pathogens. Obtained data indicated that product Clean root (a.i group of *Bacillus subtilis* isolates) was the most effective one compare with the other product Trichoderma (a.i isolates of *Trichoderma harzianum*). When downy mildew assessed use of Copiral max (Copper fungicide)show highest effects compare with the biocide Blight stop(contain *B. subtilis* and *T. harzianum*).

Keywords: *Quinoa- Diseases- Biological control- Losses*

Introduction

Quinoa is a very old crop belongs to the genus Chenopodium (*Chenopodium quinoa*). Quinoa was used thousand years ago by Andean people (Rasmussen *et al*. 2003). It is grown for its edible seeds in some cases and places. Green leaves are eaten as vegetables. After harvest, the seeds must be processed to remove saponin which gives bitter taste for unprocessed seeds (Gee *et al.*, 2006). Quinoa was introduced to Egypt few years ago as pseudocereal crop. Quinoa requires cool temperature especially during flowering, for most genotypes, and short day length to flower and produce seeds. Therefore quinoa fits to the Egyptian winter climate (Oelke*et al*., 2015).

Quinoa seeds contain essential amino acids, Calcium, Phosphorus, iron and high amount of protein. Due to these essential amino acids and high content of protein (Shukla and Ohri, 2006), quinoa can improve and replace part of animal protein, especially in poor rural area. Quinoa is attacked by numerous pathogens causing considerable losses. Danielsen (2001) announced that most attention is paid to downy mildew, caused by *peronospora farinose*. He also added there is scant knowledge about other quinoa pathogens that infect seeds or seedling and lead to decreased reduction in yield. These diseases are less widespread than downy mildew.

Recently, in 2015 Abd El-Moity *et al*. carried out complete survey for diseases and pests attack quinoa under Egyptian conditions. They stated that the most destructive diseases are soil borne diseases *i.e* damping off and root rot, these diseases can cause considerable losses under Egyptian conditions. Abd El-Moity *et al*. (2015) also, added that quinoa plants are susceptible to downy mildew.

Downy mildew reduces the photosynthetic area of the plant due to the development of chlorotic and necrotic spots in the leaves and lead premature leaf to fall. As declared by Danielsen and Munk, (2015) significant reduction in yield was registered in all cultivars due to downy mildew incidence. Late and semi-late maturing cultivar had the lowest yield loss of 33% and 35%, respectively, due to downy mildew, while the earliest maturing cultivars were heavily damaged with yield losses between 75% and 99%.
The purpose of this paper was to determine losses in yield caused by soil borne diseases and downy mildew. Also different approved fungicides, according to organic agriculture laws, were tested to illustrate their capacity on different disease control.

Materials and methods

To predict and measure losses may be occurred in quinoa due to diseases attack this crop, the five suggestions laid by Madden (1983) were considered and implemented during this work. These suggestions are:

1- "The experiments should be conducted in more than one location". All experiments in this work were conducted in two different locations (Fayium and Giza governorates) where this crop is normally grown and where the pathogens are exist.
2- "Experiments should be performed for more than one year". The experiments were preformed for two years in 2014/2015 and 2015/2016 in the same governorates.
3- "The experiments should be conducted in more than one cultivar represent a range of susceptibilities to the pathogens". Two quinoa cultivars were used, Egyptian white one and Rainbow cultivar.
4- "Multiple levels of treatment should be applied to potentially achieve levels of crop losses". Two different fungicides, approved according to organic agriculture rules, in addition to control treatment were used to control soil borne pathogens. These two fungicides were Clean-root (a.i. isolates of *Bacillus subtilis*, 30 x 10^6c.f.u) produced by Central Lab of Organic Agriculture (CLOA), Agriculture Research Center, Giza, Egypt. Whereas the other fungicide is Trichoderma (a.i. isolates of *Trichoderma harzianum*, 30 x 10^6c.f.u) produced by CLOA. Effects of these common commercial fungicides were tested in comparison with control treatment. On the other hand another two approved commercial fungicides were used to control downy mildew (Blight stop and Copiral max). Blight stop contain mixture of isolates *Bacillus subtilis* and *Trichoderma harzianum*. Copiral max, approved commercial fungicide contain 8 % Copper as Copper sulfate produced by CLOA).
5- Diseases intensity were determined and correlated with yield.

In addition to previously mentioned five suggestions, experiments were designed in randomized complete block as recommended by Hicks (1973).

Field experiments

General:
In all field experiments, unless otherwise indicated, plots each 12 m^2 were used. Eight plots were used for each treatment, and fifty plants were planted in each plot (replicates). Different treatments were distributed on plots in randomized complete blocks.

Losses due to soil borne diseases

To figure out losses occurred due to soil borne diseases, three groups of plots, each contains 8 plots, each plot 12 m^2 and contain 50 quinoa plants either Egyptian or Rainbow varieties were used. Different treatments were distributed on different group as follow.
The first group (8 plots):

In these plots all pests and diseases were intensively controlled to obtain ideal yield and the minimum percentage of diseases or pests. To achieve this target these plots received intensive program contain effective fungicides either against soil borne or foliage diseases. To avoid interference of different pests attack quinoa, an additional group of pesticides to control these pests was implemented, beside the main program to control soil borne and foliage diseases. The main and additionalused programs include:

1- Seeds of quinoa were treated using Clean-root product at the rate of 10 gm / kg seeds. This product is used against soil borne pathogens {active ingredient (a. i) group of *Bacillus subtilis* isolates $30X10^6$}.
2- Spray every 10 days using the commercial insecticide (Antinsect) this product is approved to be used against sucking insects (Aphids, White fly and Mealy bug) in addition to leaf miner in organic farming.
3- Spray every week using the commercial product (B. t) contains *Bacillus thuringiensis* bacterium to control larvae of Lepidoptera.
4- Spray every 10 days using Blight Stop to control foliage diseases.

The second group (another 8 plots each contains 50 plants). This group of plots was used for the second treatment. This treatment is exactly the same as mentioned in previous group with only one exception the used fungicide against soil borne pathogens was Trichoderma product (a. i: isolates of *Trichoderma harzianum*,30×10^6 c.f.u) instated of Clean-root.
The third group (another 8 plots): plots in this group received all treatment but without fungicide against soil borne pathogen to illustrate the size of damage can be occurred due to soil borne pathogens.

Losses due to foliage disease(downy mildew)

To determine looses occurred due to foliage disease another three groups of plots (each contain 8 plots) were used. The used strategy depends on removing any sources of losses except the target pathogen. To implement this strategy different treatments were distributed on the three groups as follow:-
Group one: all plots received sufficient plant protection program to protect quinoa against all soil borne and insects may attack quinoa exactly as mentioned in "first group in soil borne pathogens". Blight stop was used as an effective fungicide to control downy mildew.
Group two: another 8 plots were used. All treatments were exactly as previous group with one exception, where the Copper fungicide (Copiral max) was used instead of Blight stop.
Group three: in this group all pesticides and fungicides against pests and soil borne pathogens were used whereas no control against foliage disease downy mildew) was taken to allow pathogen to attack quinoa to be able to determine the size of losses may be taken place if control of these diseases were ignored.

Losses assessments

1- Soil borne pathogens:

The three groups of plots used to determine damage occurred due to soil borne diseases (one group used Clean–root, another group used Trichoderma in addition to control treatment) using two quinoa cultivars during seasons 2014/2015 and 2015/2016 were examined periodically and percentage of damping off, either pre emergence or pest emergence were determined. At harvesting time quinoa plants were harvested by hand, throughout certain period. This is due to those quinoa panicles ripe at different times. At the end of harvesting process, yields of seeds were determined. On the other hand all plants were uprooted and percentages of root rot severity were determined in different treatment using disease index contain 10 rates of severity. Disease severity was calculated using following formula:

$$\% \text{ Disease severity} = \frac{\Sigma(\text{rating no. x no. of plants in each rating})}{\text{Total no. of plants x highest rating}} \times 100$$

The relation between disease severity and yield per acre was put in linear relationship as illustrated by Larsson and Gerhardson (1991).

2- Foliage disease (downy mildew):

Downy mildew was the only disease appeared and attack quinoa in the two tested governorates. Downy mildew was assessed in the different groups of plots, one group where all soil borne and pests were controlled whereas downy mildew was controlled using Blight stop (*Trichoderma harzianum + Bacillus subtilis*). In another group downy mildew was controlled using Copper product (Copiral max).

In the third all pests and soil borne pathogens were controlled whereas no materials were used group to control downy mildew just to determine size of losses may be occurred due to downy mildew. At harvest time a disease index contain 10 rates was designed by author and formula mentioned by Whitney *et al*. (1983) was used to determine disease severity. Seed yield was harvested and yield per acre was calculated. Relation between disease severity and yield was but in diagram.

Results and discussions

Efficacy of used biocides on soil borne disease control and obtained yield:

Data in Table (1) indicate that use any of commercial biocides (Clean-root or Trichoderma) lead to clear reduction in disease severity compare with control treatment. Data also indicate that Rainbow variety show resistance against soil borne disease compare with the Egyptian variety. Percentage of disease severity in Egyptian variety reached 88 and 84.7% during 2014/2015 and 2015/2016 respectively compare with only 38 and 32.4 % in case of rainbow variety. When effects of the used biocides were compared, obtained data indicate that the product Clean-root was more effective than the other biocide Trichoderma. This may be due to Clean-root contains several isolates of *Bacillus subtilis*. *B. subtilis* produce many types of antibiotics and antifungal substances (Constantinescu, 2009). This broad spectrum in mode of action lead to inhibition of the pathogenic soil borne fungi. The pH of soil in Egypt is alkaline, which is favorable factor for *B. subtilis*.

Losses in quinoa yield due to soil borne disease:

Data obtained from replicates of the previous experiment, percentages of disease severity and obtained yield, were used to figure out a liner relation between percentage of disease severity and losses in yield (Fig.1).

Table (1): Correlation between percentage of soil borne disease severity and obtained yield in case of use two different quinoa varieties during two successive seasons

Treatment		% of disease severity		Yield (Ton)	
	variety	Season 2015	Season 2016	Season 2015	Season 2016
Clean root	Egypt	30.0	22.3	0.63	0.82
	Rainbow	15.3	14.0	1.52	1.5
T. harzianum	Egypt	42.0	34.7	0.46	0.61
	Rainbow	20.0	18.0	1.1	1.25
control	Egypt	88.0	84.7	0.23	0.25
	Rainbow	38.0	32.4	0.65	0.47

Correlation between percentage downy mildew severity and obtained yield:-

To estimate losses may be occurred due to different degrees of downy mildew severity, this experiment was conducted. Two fungicides were used to show different levels of disease also two quinoa varieties were used. Obtained data indicate that Copiral max and Blight stop showed highly significant effect in disease control compare with control treatment. Rainbow quinoa variety showed resistant to disease compare with the Egyptian one, and only 35% disease severity was recorded in case of Rainbow variety in 2015\2016 compare with 91.7% in Egyptian variety in the same season. Data also indicate that the fungicide Copiral max showed highest effectin downy mildew control and percentage of diseasewas only 25 % in Egyptian variety compare with 91.7% in control and 36% in case of use the biocide "Blight stop". This may be due to, Copiral contain chelated Copper sulfate. Copper as heavy metal negatively affect on the bioactivities of the pathogen cause downy mildew. Copper ions also can penetrate plant tissues and reach the pathogenic mycelium interplant cells causing inhibition for pathogengrowth and development **(**Trdan, *et al*., 2004).
Percentage of disease severity was correlated with obtained yield. The minimum yield 310 kg/acre was obtained in control treatment of Egyptian variety. Whereas the highest yield 2210 kg/acre was achieved when Copiral max was used with Rainbow variety. Egyptian variety also show highest yield 1820 kg/acre when Copiral max was used against downy mildew. Obtained data were put in liner relationship to estimate losses at any levels (Fig. 1).

D) Relation between Quinoa Rainbow variety and Downy mildew
Each value represent mean of 8 different values (replicates).

Table (2): Correlation between percentage of downy mildew disease severity and obtained yield in case of use two different quinoa varieties during two successive seasons

Treatment	variety	% of disease severity		Yield (Ton)	
		Season 2015	Season 2016	Season 2015	Season 2016
Blight stop	Egypt	36.0	40.2	1.45	1.32
	Rainbow	24.3	27.3	1.71	1.54
Copiral max	Egypt	25.0	32.0	1.82	1.61
	Rainbow	16.0	18.2	2.21	2.0
control	Egypt	91.7	94.0	0.35	0.31
	Rainbow	35.0	42.0	0.92	0.80

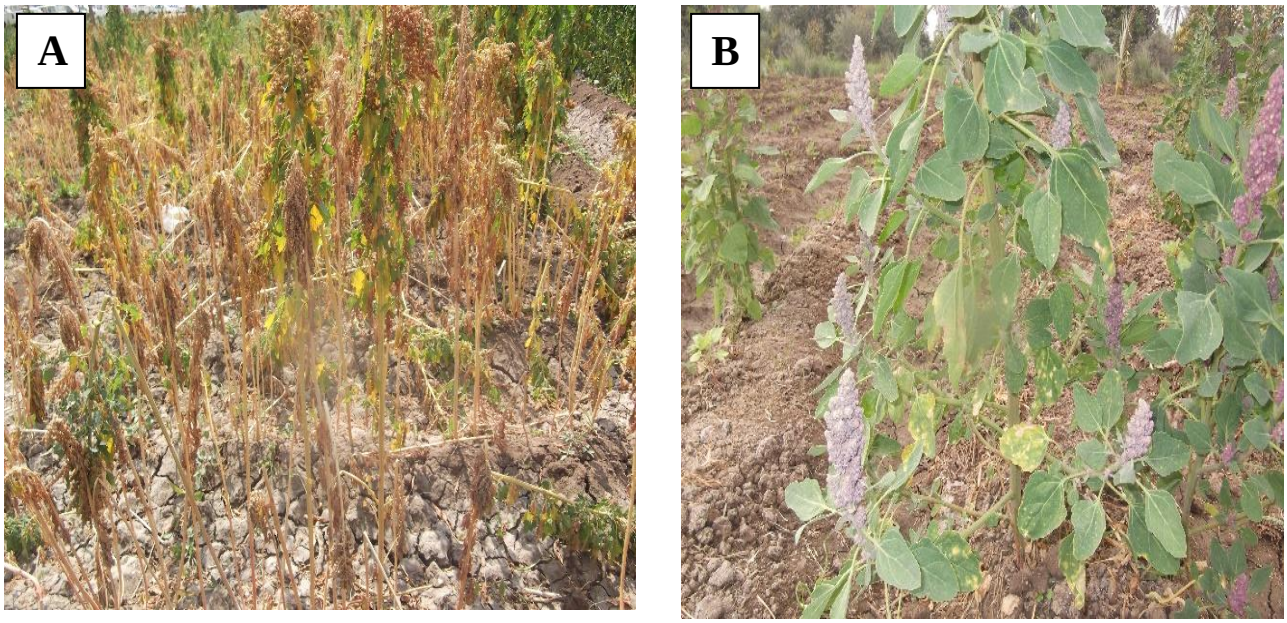

Fig. (2): Destruction of Quinoa plants due to soil borne diseases and downymildew.
A) Quinoa plants at harvesting stages suffering from soil borne diseases.
B) Quinoa plants show Downey mildew symptoms.

Conclusion

Soil borne diseases and downy mildew should be controlled at any level of infection. This control resultant in considerable yield can compensate cost of diseases control. Breading for resistant or tolerant varieties must be considered.

Biological control can play very important role in quinoa protection against soilborne diseases and downy mildew.

By combination between biological control and approved chemical control, according to organic agriculture laws, it can be completely control all pathogens attack quinoa and produce high quality and quantity organic seed yield.

THE ORGANIC MILK PRODUCTION IN POLAND – ECONOMIC ASPECTS AND PROSPECTS FOR DEVELOPMENT

Marcin ŻEKAŁO

Institute of Agricultural and Food Economics – National Research Institute, Warsaw, Poland
*Corresponding author: zekalo@ierigz.waw.pl

Abstract

The production of organic milk shows a continuous growth in Europe but the market supply still does not meet the demand for organic milk and its products. In Poland, the organic milk production is conducted on a small scale, mainly due to an underdeveloped market of organic products. However, among the consumers the interest in such products is increasing, as well as for the farmers the organic milk production may be considered as a one of profitable agricultural production. The purpose of this article is to reflect the economic situation of organic milk production in Poland and the attempt to define prospects for further development. Accounting data for 'dairy cows' activity were collected since 2006 and processed according to the rules of the Agricultural Products Data Collection System (AGROKOSZTY). Surveyed farms were selected from a sample of Polish Farm Accountancy Data Network. Under the AGROKOSZTY system, the methodology of the gross margin was used (in accordance with the EU rules) which may give a full insight on actual direct costs and helps to determine the competitiveness of organic milk production. The income from 'dairy cows' activity account is based on the Polish FADN accounting data collected from the same farms. The survey indicate that the production results of organic dairy farms were significantly lower than an average results of dairy farms in Poland. In that case, the income of organic milk production strongly depends on the low level of production costs and the support of subsidies.

Keywords: *dairy cows, organic milk production, profitability.*

Introduction

According to the statistical data of Organic Data Network, in 2013 the organic production sector in the European Union covered 10.2 million ha of organic agricultural land (in 2002 it was about 5.7 million ha). Most organic agricultural land was situated in Spain, Italy, France, Germany and Poland (figure 1).

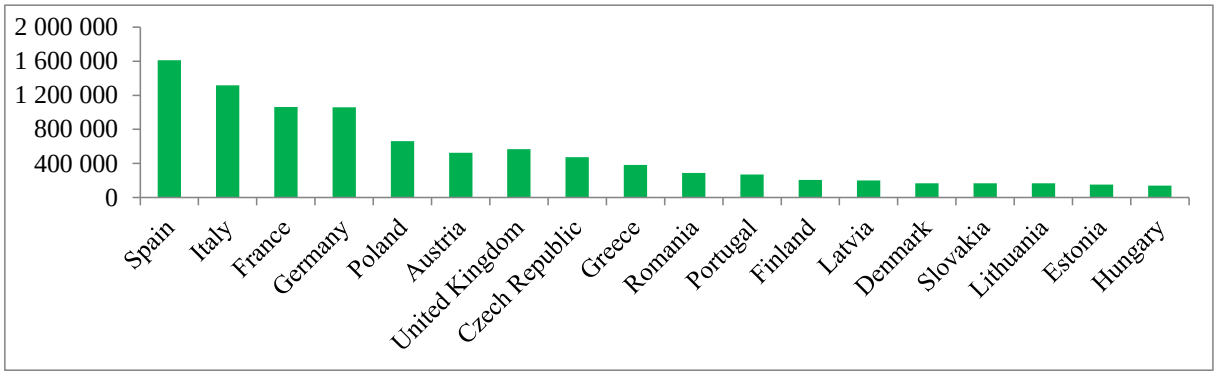

Figure 1. The area of organic agricultural land (in ha) in selected EU countries in 2013.
Source: own studies based on FiBL&IFOAM, The World of Organic Agriculture 2015. Organic Farming and Market Development in Europe, Organic Data Network 2015.

However, it is worth noting that the area for the organic production amounted to only 5.7% of the total agricultural area in the EU. Among the organic crops, a significant part were grassland and permanent crops (together amounted to more than 60% of the area of organic

farming). One of the main activities of the organic livestock production is cattle rearing. According to by the European Commission report, in 2011 in organic farms around 28% of the population accounted for dairy cows as a part of the cattle production. In the EU countries, 0.7 million dairy cows were kept in organic farms which was about 3% of all dairy cows in the EU. In Poland, according to the statistics from 2011, the population of dairy cows in organic farms remains at the level below 20 thousand head, which accounted for only about 1% of the population of dairy cows in the country. The number of dairy cows in organic farms in the EU countries in 2011 is shown on the chart 2. The largest share of the organic milk production in the domestic market of agricultural products is held by Austria (18%), Sweden (13%), Denmark (about 11%) and United Kingdom (8%).

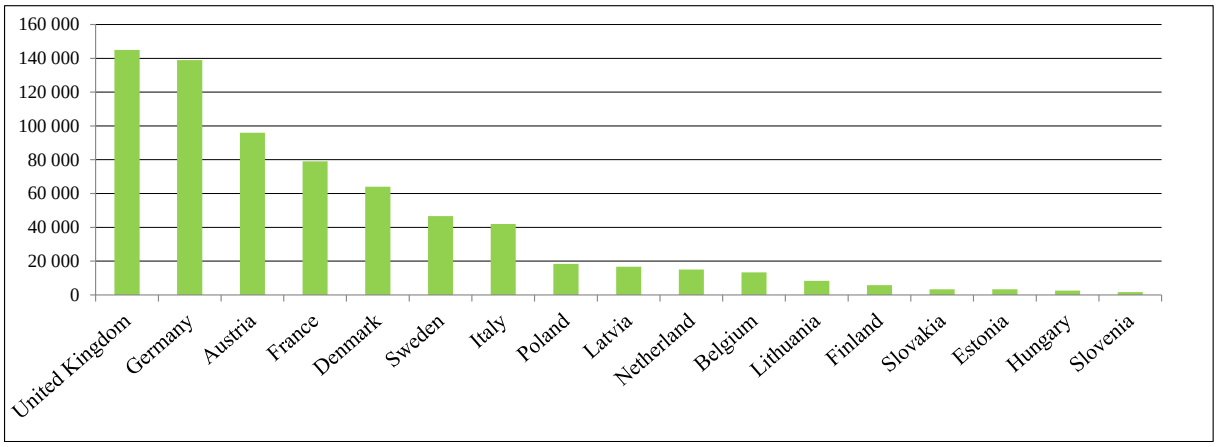

Figure 2. Number of dairy cows in organic farms in EU countries in 2011.
Source: own studies based on http://ec.europa.eu/agriculture/markets-and-prices/morereports/pdf/organic-2013_en.pdf.

In Poland, organic certified land and land under conversion covered in total 657.9 thousand ha which accounted for 6.38% of the area of EU organic land. It is worth noting that in the years 2013-2014, within the structure of organic agricultural area the largest share was held by fodder crops, meadows and pastures. Their total area in 2013 was 66.0% (in 2014 – 67.3%) of the total area of organic agricultural land in Poland. The high share of fodder crops, meadows and pastures could indicate to the popularity of the livestock production, including dairy cows, in organic farms. Unfortunately, the share of organic farms involved concurrently in the plant and livestock production is decreasing – only 19.3% of farms were involved in such simultaneous production in 2014 (in 2013 they accounted for 44.2% of all organic farms). When farmers quit the livestock production, including keeping dairy cows at the farm, the decreasing organic milk production in the country can be observed over the years. According to the statistical data, in 2011 the organic milk production amounted to 39.5 million liters while in 2014 it was only 25.2 million liters.

Organic farms involved in the milk production must provide feed from an organic farm, preferably from own farm, and for this purpose it is necessary to provide a sufficient fodder area. Pastures, from which roughage comes (forage, dried fodder or silage) are primarily used. Rearing and breeding of animals based on permanent grassland is beneficial for both the environment and from the point of view of the production economics [Radkowska 2012]. Organic feedstuffs purchased are relatively expensive, and their availability in the market is still very limited. On the other hand, the use of industrial concentrated feedingstuff in animal diet is strictly prohibited in organic farming.

Organic farms, conducting the extensive production mainly based on their own resources incur lower costs. However, the consequence may be lower production results and some limitations as regards the herd size of dairy cows. In case of farms keeping dairy cows in an extensive manner, we may observe the lower milk yield (lower by up to 30% than in conventional farms), however, we must point to a longer productive life of cows, which directly translates into the lower costs of herd replacement [Żukowski 2009]. Data provided for the EU countries show that the milk yield

of dairy cows in organic farms was very diverse. The highest milk yield was achieved in Sweden (more than 8,200 kg/cow), Finland (more than 7,000 kg), Denmark (6,700kg), the Netherlands (6,600kg). In polish organic dairy farm (based on the group of organic farms in a survey in Agrokoszty system), the milk yield is only 75-80% of the milk yield achieved on average in the dairy farms in Poland (Figure 3).

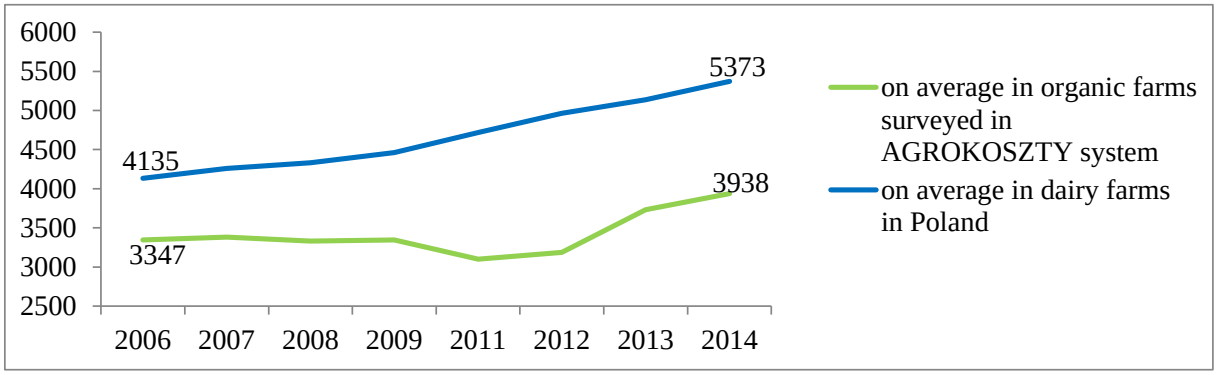

Figure 3. Milk yield (in liters) in organic farms surveyed in Agrokoszty system and on average in dairy farms in Poland in years 2006-2014.
Source: own studies based on Agrokoszty system database and CSO database.

The main product of the dairy cows activity is milk production (also calves weaned and cull dairy cows, to a small extent), and an important factor determining the obtained value of this production is the selling price of milk. Reports from the European market show that farmers often receive a higher price for the sale of organic milk when compared to milk from conventional farms [Offermann, Nieberg 2000]. The price premium for the sale of organic milk compared to the selling price of milk from conventional farms was often higher up to 30% (in Denmark), 20% (in Czech Republic, France, Great Britain), 13-14% (in Germany, Netherlands, Sweden). In a survey in Agrokoszty system, in Poland the selling price of organic milk was 8-16% lower than selling milk price achieved on average in the dairy farms in Poland (Figure 3).

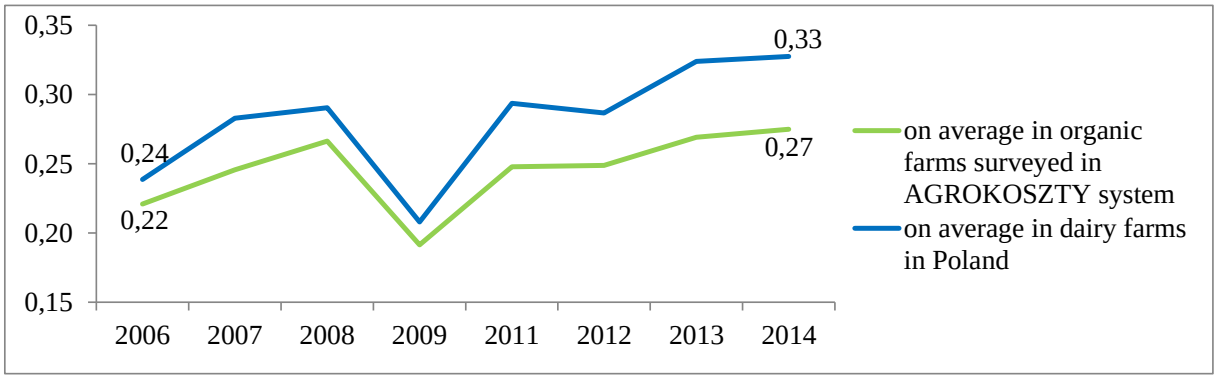

Figure 4. Selling milk price (in EUR) organic farms surveyed in Agrokoszty system and on average in dairy farms in Poland in years 2006-2014.
Source: own studies based on Agrokoszty system database and CSO database.

Farmers taking up activities in organic farming may also count on support in the form of payments addressed to this sector, which may significantly affect the level of income achieved from the agricultural activity. In addition, there are opportunities to acquire financial support from the animal genetic resources conservation programme. In the case of the type of activity of 'dairy cows' subsidies are calculated per forage area and include supplementary payments, agri-environmental payments and payments per animals.

The aim of this study is to present the production and the economic situation of organic dairy farms in Poland. An attempt has been made to assess the potential for the further development of the organic milk production in Poland, in the context of competitiveness in the domestic milk market, as well as with some regard to the EU market.

Materials and methods

Materials to study were the actual accounting data collected in the years 2006, 2009, 2012 and 2014 in organic farms participating in the studies of the Polish Farm Accountancy Data Network (FADN) and AGROKOSZTY system. The economic and production results of the analysed organic farms have been referred to the average milk results of conventional farms (selected farms with a similar scale of production i.e. number of dairy cows kept at the farm), participating in the studies in both systems, in the same years. All those farms were market-oriented and were economically stronger than production units, on average, in the country. For this reason (and due to low number of surveyed farms), the results obtained should not be directly translated into national average results for the organic farms. These are only average results for the surveyed sample of farms. However, multiannual surveys indicate, that the calculations carried out provide a reliable picture of the economic situation in organic dairy farms and correctly reflect milk price trends.

Accounting data were collected according to the methodological assumptions of the Agricultural Products Data Collection System AGROKOSZTY. For the researched type of activity 'dairy cows', the methodology of calculating the gross margin was used (Augustyńska-Grzymek et al. 2000). It is the first income category, calculated by deducting the direct costs incurred for producing the output from production value. In the case of dairy cows, the production value is calculated per one dairy cow. In estimating the price of production value, the average annual sales prices are used – the sales price of milk, the price of weaned calves and the price of culled dairy cows. The production value does not take into account the value of manure and slurry, which are produced at the farm. For dairy cows, direct costs include: livestock replacement, feedingstuff purchased and produced on the farm, rents paid for using forage area for less than 1 year, animal insurance, medicines and veterinary measures as well as specialised costs (including specialised expenses, services and employment of staff for specialised works). Moreover, a register of own and hired labour spent on works related to the type of activity 'dairy cows' is kept. Maintaining an account for income allows for obtaining information regarding activity (e.g. indirect costs, forage area, annual average number of animals), which comes from accounting data collected on the same farm for the Polish FADN system.

The calculation of income for agricultural production activities is given as follows:

Production value
– Direct costs
= Gross margin without subsidies
– Total indirect costs (actual indirect costs, depreciation, cost of external factors)
= Income from activity without subsidies
+ Subsidies
= Income from activity

On the basis of the obtained accounting data, it is also possible to define the profitability of production as a ratio of production value to total costs, in percent (Skarżyńska 2011). Subsidies per forage area were recognized as support to farmers income from activity of 'dairy cows'. The calculation of income from activity includes subsidies that have a direct impact on the discussed production activity, i.e. supplementary area payment for basic crops, the payment for animals, and in the case of organic farms – agri-environmental payments.

Results and discussion

Surveyed organic farms were conducting the extensive production mainly based on their own resources, mostly they had bigger permanent grass land area and the forage area involved in feeding of dairy cow. The average milk yield of dairy cows on surveyed organic farms was lower (up to 21%) than in the groups of conventional farms. It should be noted that the total amount of work on 1 cow remained at a similar level (190-250 hours) in both groups compared groups of farms (with a similar number of dairy cows in the herd). General informations about surveyed groups of farms were shown in table 1.

Table 1. General information of surveyed group of conventional and organic dairy farms.

Specification		on average in surveyed farms in years							
		2006		2009		2012		2014	
		Organic	Convent	Organic	Convent	Organic	Convent	Organic	Convent
Number of surveyed farms		29	35	20	31	15	40	22	49
Utilised agricultural area per farm	[ha]	24,6	16,7	18,5	19,8	20,5	21,5	18,1	23,0

Source: own studies based on Agrokoszty system database.

Generally, in organic farms a lower milk yield of cows and a less favorable selling milk price than in conventional farms, can be observed. This resulted in lower (on average by 10-16%), total production value obtained in organic farms (with the exception of research in 2009, in which organic farms received favorable sales price, and the milk yield remained at the same level as in the group of conventional farms) – table 2.

Table 2. General information of surveyed group of conventional and organic dairy farms.

Specification		on average (per 1 dairy cow) in surveyed farms in years							
		2006		2009		2012		2014	
		Organic	Convent	Organic	Convent	Organic	Convent	Organic	Convent
Total production value	[EUR]	1025	1143	953	910	1049	1252	1335	1553
Direct costs total	[EUR]	260	482	306	438	328	610	355	646
Gross margin without subsidies	[EUR]	765	661	647	472	720	642	980	907
Indirect costs total	[EUR]	258	357	395	377	470	446	618	582
Income from activity without subsidies	[EUR]	507	304	252	95	250	196	362	325

Milk production profitability index	[%]	197,8	136,2	135,9	111,6	131,3	118,5	137,2	126,4

Source: own studies based on Agrokoszty system database.

Milk production in both groups of farms allowed to generate income from this activity. However, the level of this income was much higher than the income obtained in conventional farms, taking into account the adopted scale of production in the considered groups.
The milk production profitability index in the group of organic dairy farms stood at a higher level compared to conventional farms – table 2. It should be pointed out that the total production costs in the group of organic farms were significantly lower than the earned value of production (costs accounted for 50-76% of the value of production), and in the case of conventional farms the total production costs were only slightly lower than total production value (accounted for 73-89%). What is important, the ratio of the amount of subsidy in relation to income from activity in the case of organic farms was relatively high (around 20-47%), which makes organic milk production more dependent on the financial support.

Conclusion

Among the EU countries, Poland has one of with the biggest organic land area, in which the permanent grassland have the largest share of. Despite good conditions for the development of animal production of ruminants the milk production is still a niche production in organic farms in Poland, only less than 1% of total number of dairy cows in Poland are keeping in organic farming system. In polish agricultural condition, farms with a small scale of milk production (especially in regions with lower intensity of agricultural production) may consider changing the method of farming to organic methods, which can greatly reduce production costs and increase income from activity due to subsidies to the organic sector. According to results of the survey in Agrokoszty system organic farms in a small scale of milk production achieved better economic results than in conventional farms at the same production scale, despite lower milk yields and lower selling milk prices, in general. In order to improve the price the milk production in organic farms should be more concentrated and then it could be a good conditions for the development for organic milk processing. Only in such cooperation the producers of organic milk can expect a premium prices for an organic milk (as in case other EU countries) and the dairies may expect a sufficient amount of organically produced milk for processing. In other way organic milk is sold to conventional dairies without any price premium. So far the organic production sector is still financially supported but producers of milk on organic farms should be aware of reliance only on supporting the income with subsidies.

Abstract

The article deals with an important issue of yield capacity improvement through using water retention agents. As a result of a laboratory experiment a special superabsorbent was developed as a moisture retention ingredient and successfully tested in the field conditions. The experimental part of the study focused on the development of cross-linked polymers including biodegradable nitrogen synthesized by free radical copolymerization, on polymers swelling kinetic and dependency of swelling rate versus cross-linking agent. The research describes the method sand stages of obtaining superabsorbent containing microelements or humic acid. The superabsorbent was then tested in the laboratory and in an experimental micro plot in the territory of the Botanical Garden of the Voronezh State Agricultural University to verify its water retention characteristics and ecological efficiency. The sprouts and further development of the tested barley plants demonstrated a positive influence of the used superabsorbent. The obtained results clearly show the vivid advantages of the superabsorbent which can both contribute to sustaining the environment and enhance an increase in microorganisms promoting soil humification and mineralization. The research statistics show that using such type of absorbent definitely leads to growth in barley yield capacity without producing and undesirable impact on the local environment.

Keywords: *superabsorbent, humidity sorption, microbiological activity of the soil, barley yield.*

Introduction

One of the major objectives the farmers of Black Earth Region is the further improvement of agrarian techniques and ensuring food safety in the region.

On account of the global climate changes we are faced with today, it seems extremely important to adapt the local arable farming to new natural and climatic conditions. These changes also require us to implement soil-protective and water-efficient farming techniques, involve using natural resources and consider using alternative crops, locally adapted species, high quality seeds, effective plant protection techniques, and apply complex fertilizers. This will ensure sustainable horticulture.

The major challenge for the regional farming, which is located in a risky zone, is that we enjoy favorable weather conditions only during three years out of five. Often, in the southern parts of the region snow melts at the beginning of March, and the soil is ready to be used only at the end of March. The moisture storage capacity before the sowing period starts is 70-80% of the required level. The lack of rainfall in May and June prevents crops from normal development, which badly affects plants in general. Consequently, spring crops have to be sowed in a very limited time period, so that the crops could effectively use the moisture supply in the soil (Lukin, et al., 2015, Malešević et al, 2010; Popović et al., 2011, Đekić et al, 2014).

Another problem farmers have to deal with is that field irrigation is often quite expensive and of little efficiency. Thus, one of the most effective ways to eliminate moisture deficiency in soil could be the application of water sorption materials, which are able to retain water. Such materials include polymeric superabsorbent, a great variety of which can be commercially obtained. However, all currently known polymeric superabsorbent are based on methacrylic acid derivatives, hence possessing a huge water sorption rate, which has significant disadvantages. First, they are characterized by longer half-life (up to 300 years). Also, the application of such products pollutes soil with some undesired components such as derivatives of polyethylene, which is the result of destruction of superabsorbent macrostructure. In order to decrease their polluting effects as well as anthropogenic influence on soil, it is important to obtain new eco-friendly polymeric materials, whose properties could both meet the needs of the farmers and contribute to the healthy environment rather than destroy it.

This study was aimed to obtain rare cross-linked polymer material based on biodegradable polymer which could both show superabsorbent properties and improve barley crop capacity.

Materials and methods

Synthesis of rare cross-linked polymer material is carried out by free radical copolymerization by ref. (Kuznetsov et al., 2016) with using redox initiator system (H_2O_2-Fe^{2+}/Ni^{2+}/Co^{2+}). In order to produce humic acids containing superabsorbent at the final step of polymerization, we added humic acids substance (4:1 mass ratio) to the reaction mixture.

FTIR spectra of the superabsorbent were recorded by Bruker Vertex 70 spectrometer. Swelling kinetic of all examples was carried out by gravimetrical method. The sample of superabsorbent (m=0.1 g) was placed in flat-bottom flask containing 100 mL of water. The sample was removed from the flask every 15 minutes, then dried by filter paper and weighed during 5 hours.

To find out the effect of the superabsorbent on the soil characteristics and barley yield capacity, a micro-plot test was conducted in the territory of the Botanical Garden named after B.A. Keller (Voronezh State Agricultural University). The experimental variants were as follows: 1 – the control plot; 2 – the sorbent (the application rate - 200 kg/ha); 3- the sorbent (the application rate - 200 kg/ha).

The amount of ammonifying bacteria causing disintegration of proteins and their derivatives was defined on the basis of analysis of the bacteria colonies in meat-and-peptone agar (MPA). Starch-and-ammonia agar (SAA) was used to define the amount of amylolytic, or starch-splitting, microbiota involved in disintegration of non-nitrogenous compounds and at the same time providing for nitrogen. The catalase activity was analysed on the basis of well-established methods (Selyavkin, et al., 2015).

The experimental soil was leached medium-humic chernozem with a very higher containment of P and K, which classically makes it one of the most fertile soil types (Table 1).

Table 1. Agrochemical characteristics of the leached chernozem used in the experiment.

Amount of humus,%	pH KCl	mg-eq. per 100 g of soil		V,%	amount mg/kg	
		Hr	S		P_2O_5	K_2O
3.25	5.53	5.6	27.3	80.2	165	94

Barley yield record was estimated on the basis of common methods (Maraeva et al., 2015).

Results and discussions

Polymeric materials with superabsorbent property containing biodegradable fragments were synthesized by free radical copolymerization with using redox initiator system. The ratio *biodegradable component: monomer: cross-linking agent* varied as follows: 0.05-0.2: 0.8-0.98: 0.05-0.005-0.1 mass. Rare cross-linked polymeric superabsorbent with different cross-linking degree was produced. The yield of polymerization products in all cases was quantitative. The wet products were dried in warm air flux.

In order to produce the superabsorbent type containing microelements Fe^{2+}, Ni^{2+} and Co^{2+} , metal salts were added to redox initiator system at the polymerization stage.

The structure of synthesized polymeric materials was confirmed by IR spectrum (Fig. 1). The IR spectrum contained absorption bands at 1647 *и* 1605 cm^{-1} attributed to stretching vibrations C=O bond and bending vibrations of NH_2 group in amide fragment (Bellamy, 1964). The wide bands in range 3180-3300 cm^{-1} showed the presence of OH and NH_2 groups of biodegradable fragment (Bellamy, 1964). We could observe the shifts of characteristic absorptions bands at adding microelements and humic acids to superabsorbent. It demonstrated the complexation between additives and functional groups of the polymeric materials.

Investigation of swelling kinetic was carried out by weight method. The swelling kinetic dependency versus cross-linking density can be seen in Fig. 2. It shows that as cross-linking density increases, the swelling decreases alongside swelling time rising. The swelling curves of polymeric materials with additives are represented in fig. 3. It was found that the presence of humic acids and microelements in polymer structure led to decreasing of swelling ability.

It should be also noted that synthesized hydrophilic superabsorbent preserves safe water uptaking properties at wide range of temperature from -40 to +40 °C, hence, it can be used in different climate zones.

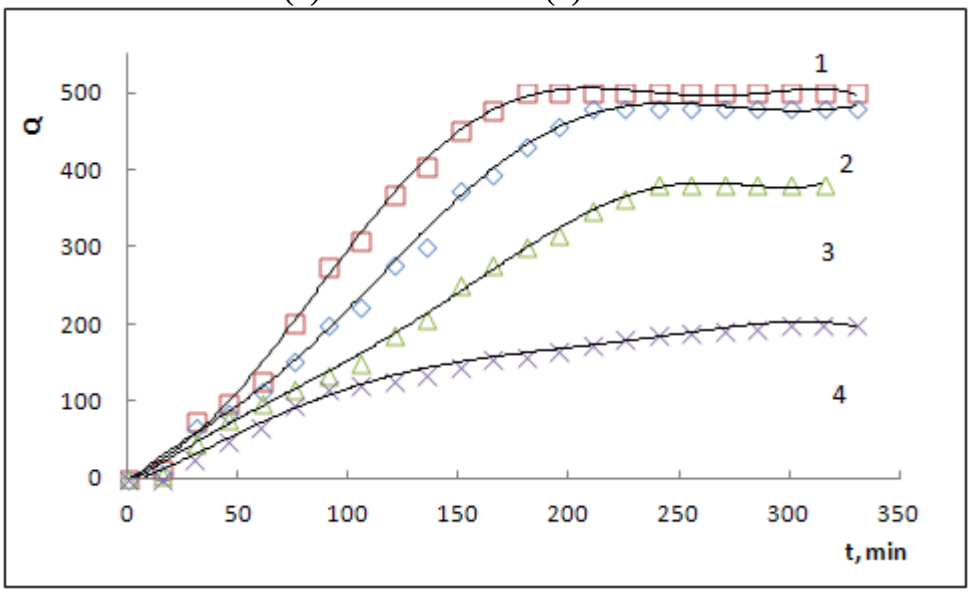

Fig. 2. The swelling kinetic dependency of polymeric material versus cross-linking density: 1 – 1% of cross-linking agent, 2 – 2 % of cross-linking agent, 3 – 5% of cross-linking agent, 4 – 10% of cross-linking agent.

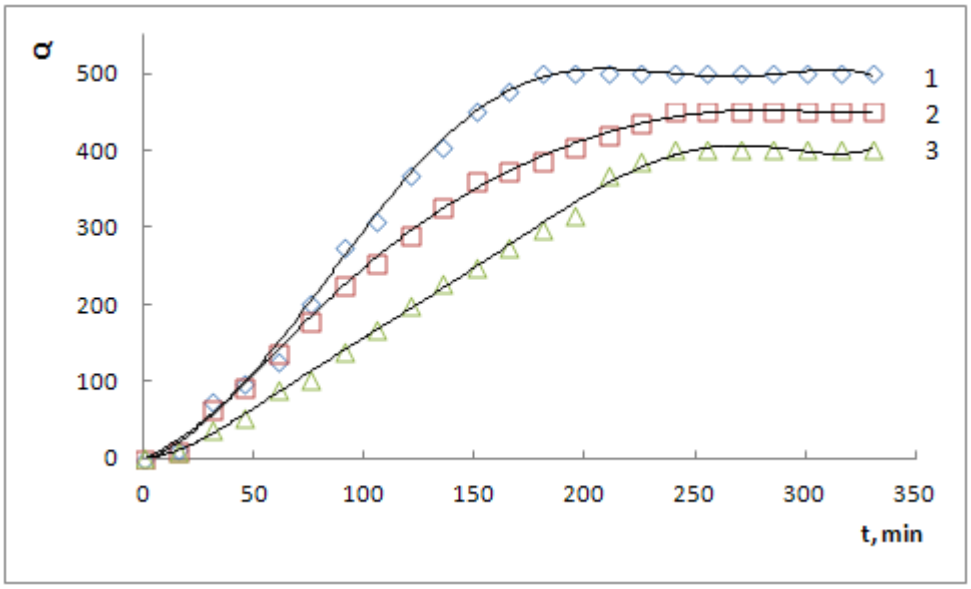

Fig. 3. The swelling curve of polymeric materials with additives:
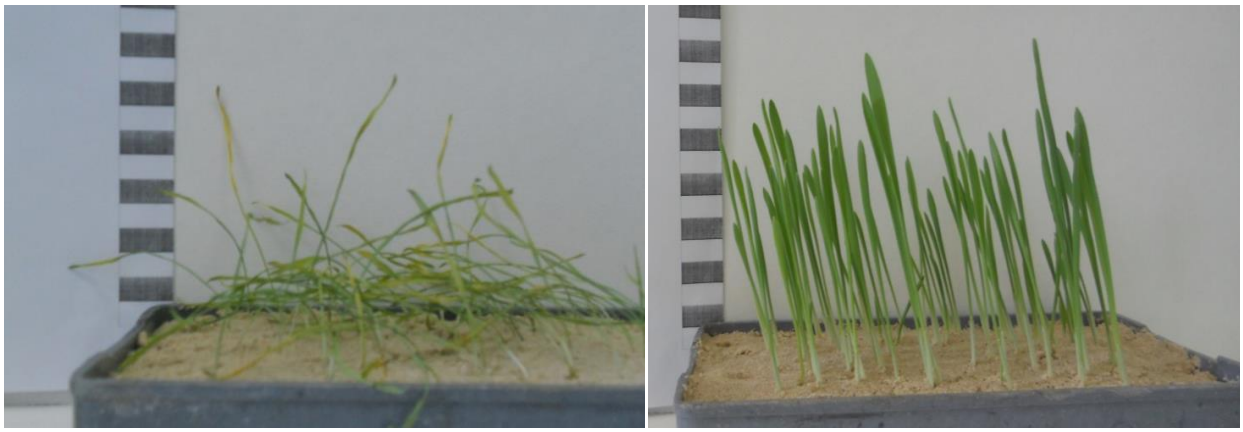
1 – without additives, 2 – with microelements, 3 – with humic acids.

Having analyzed the super absorbent polymeric materials, we conducted a laboratory experiment aimed at defining its ability to retain water and give it off to the plant roots. The experimental amount of the superabsorbent was mixed with a sand substrate (200 kg/ha). Then the water was added at the actual ratio of water retention of 114% in regard to the control substrate sample. The figure below illustrates the results of seeds development on the 21st day.



1 2

Fig 4. Barley plants on the 21st day: 1 – the control sample; 2 – substrate with the superabsorbent (200 kg/ha)

The obtained results clearly demonstrate that the superabsorbent undoubtedly contributes to the moisture retention, thus enabling the plants to resist unfavorable conditions. It was also discovered that the superabsorbent produces a non-toxic effect on soil. It neither pollutes the soil nor marshes it. At the end of their life the granules decompose into non-toxic components, releasing combined, fixed nitrogen, which then additionally functions as mineral fertilizer.

To evaluate possible toxic properties of the water extract from the experimental soil, we used a traditional method of phyto-testing. 100 g of fresh soil was weighed within an accuracy of 0.1 g, than placed into a 250 cm^3 flask where 100 cm^3 of distilled water was added. Next, the flask was shaken in a rotator for 2.5 hours. Finally, the ready suspension was filtered out, and

4 cm^3 of the aliquot was taken for treatment of the prepared 165 seeds, all placed in special containers.
24 hours later 50 seeds, taken from each container, were placed in Petri dishes with three paper filters in each dish. 5 cm^3 of distilled water was added to each dish. High quality seeds of garden radishes (the sort is called "French breakfast") were used for the experiments, which were conducted in triplicate. The seeds were germinated in the environmental cabinet, or incubator, during 48 hours at 25ºC.
Table 2 illustrates data on the effect of the soil extract on biometric characteristics of the radish seeds.

Table 2. Biological testing of soil

№	Variant	Replication	shoot	root
1	Water	1	0,74	2,70
		2	0,62	2,24
		3	0,58	2,23
		average	0,65	2,39
2	Sand	1	1,02	3,0
		2	1,18	2,92
		3	1,01	3,85
		average	1,07	3,25
3	Sand + superabsorbent	1	2,29	2,58
		2	2,42	2,62
		3	2,24	2,64
		average	2,31	2,61
HCP(0,5)			1,05	0,78

Table 2 demonstrates that the superabsorbent treatment of the seeds, as described above, produces a stimulating effect on them. The combination of the substrate with the superabsorbent increased the length of the shoots and roots by 1.66 mm and 0.22 mm, respectively, in comparison with the control sample.
In order to test the effect of the superabsorbent in the natural field conditions, it was placed in seed beds together with the barley seeds. The plants were not watered additionally. During different vegetation phases we collected samples to estimate the conventional degree of mineralization and then the amount of microorganisms (Table 2).
The variants treated with superabsorbent showed the increase in bacteria using mineral nitrogen. For example, during harvesting phase we could observe doubling of amylolytic microbiota (at the rate of 200kg/ha of the superabsorbent) in comparison with the control sample. There was also an increase in the amount of ammonifying bacteria in the soil treated with the superabsorbent. As is seen in Table 2, the value of the mineralization degree of the soil organics (SAA/MPA) is gradually decreasing in the phases of booting and harvesting. This indicates humification process and thus improvement of the soil productivity. As a result of application of the superabsorbent (200 tons/ha), the amount of the barley yield was 1,83 as high than the control yield.

Table 3. Microbiological soil activity (104 CFU\ 1g of absolutely dry soil) and barley yield capacity (tons/ha) during the period 2014-2015

N	Plant vegetation phase												YIELD CAPACITY
	tillering				booting				harvesting				
	MPA	SAA	SAA\MPA	CATALASE	MPA	SAA	SAA\MPA	CATALASE	MPA	SAA	SAA\MPA	CATALASE	
1	9	14	1,6	1,35	14	18	1,3	2,15	10	11	1,1	1,4	1,14
2	19	29	1,5	1,5	22	42	1,2	2,15	15	6	0,4	1,4	
3	7	23	1,3	1,5	20	23	1,2	2,3	23	24	1,0	1,45	2,10

Catalase - ml 0,1M KMnO4 per1g of soil within 20 min

It is a well-known fact that catalase destroys hydrogen peroxide, which is toxic for plants and which is produced as a result of breathing and oxidation of organic compounds (Lukin, et al., 2015). The factors affecting catalase activity include organics, particularly, humus, temperature, moisture, etc. The obtained data show an increase in catalase activity at all stages of plant vegetation, especially during the booting phase (2.3). It is apparently connected with moisture retention in the root zone, due to which microorganisms can work more effectively.
Naturally, the efficiency of the suggested techniques can be tested by estimating the yield capacity of the studied crops. The conducted experiment demonstrated the increase in the yield record, which was twice as much. That means an increase in nutrient availability for plants due to additional moisture retention in the soil.

Conclusions

The obtained data clearly show a highly positive effect of the application of hydrophilic superabsorbent. First, it contributes to moisture retention, which is extremely important for enhancing yield capacity. Also, it proved itself to be eco-friendly for developing plants. Finally, it enhances microbiological activity of the soil and thus the yield capacity of barley.

Abstract

Investigation was carried out at the Institute of Horticulture, Lithuanian Research Centre for Agriculture and Forestry in 2012-2013. The object of investigation was tomato cultivars – Slapukai BS, Balčiai, Viltis. Plants were sprayed with homeopathic extracts – Silicea (two times in early plant growing stage) and Carbo vegetabilis (two times at the middle of plant vegetation) of different solution concentrations (dilution rate: *SI6 + CV6; Si30 + CV30; Si200 + CV200)*. The solutions were sprayed every 10 days. The obtained results showed that the preparations influenced the yield and biochemical composition of tomato fruit. It was determined that plants sprayed with the homeopathic extracts *Si30+CV30* formed the highest yield (10.2-11.8 kg m^{-2}). The average amout of soluble solids in the tomatoes fruit reached 4.3-4.5%. The highest amount of ascorbic acid (19.33 mg $100g^{-1}$) was detected in the fruit of cultivar Balčiai, which was sprayed with homeopathic extracts *Si30+CV30* and *Si200+CV200.* Our results showed that the highest amount of lycopene (7.34 mg $100g^{-1}$) and (1.034 mg $100g^{-1}$) β-carotene was detected in fruits of cultivar Viltis. The highest amount of total sugar (5.01%) and less acidity (0.63%) were detected in cultivar Slapukai BS.

Keywords: *biochemical composition, extracts, yield, fruit, quality.*

Introduction

Tomato fruits are rich in soluble sugars, organic acids, minerals, carotenoids and other valuable substances (Johnson *et al*., 1998; Radzevičius *et al*., 2009). At present time, people are more interested in the environmental problems caused by agricultural activities; special attention is focused on the health risks related to the use of various chemical substances. Therefore, it is very important to choose the right plant growing technologies (Bettiol *et al*., 2004). There are some research has been done according to different tomato growing techniques. Studies in Poland have shown that the organic tomatoes accumulated more total sugars and ascorbic acid but had less amount of lycopene compared to tomatoes growth under intensive growing technology (Hallmann and Rembialkovska, 2007). Yield quality of fruiting vegetables and are determined by the growing conditions and technology, cultivars resistance and other aspects (Dorais *et al*., 2001; Survilienė and Duchovskienė, 2008). Fruiting vegetables, growth under Lithuanian climatic conditions, are more susceptible to various diseases, which leads to the harvest losses. Tomato cultivation becomes unprofitable, and researches are focused on the tomato yield and quality improvement using plants extracts. Influence of fertilization and growing condition to the tomato yield and biochemical composition were investigated in alternative cropping systems (Tample et al., 2000). Klocke and Baumgartner (2009), Sakalauskienė *et al*. (2012) reported, that using various plant extracts may vary photosynthesis in plants and other processes. It is known that the effectiveness of photosynthesis process in plants depends on the optimal temperature conditions, but there is a lack of knowledge about the biochemical processes of

photosynthesis changes according to the use of homeopathic and botanical extracts. Homeopathic remedies acting whole symptoms at time heals organism. Such treatment helps the body to recover itself, to preserve the nutritional properties of the plants. Homeopathy is a promising alternative to the use of the chemical substances, because homeopathic material is non-toxic and does not pollute the environment (Kaviraj, 2006).
The aim of investigation is to evaluate homeopathic extracts impact on the tomato fruit quality and yield.

Material and Methods

Investigation was carried out at the Institute of Horticulture, Lithuanian Research Centre for Agriculture and Forestry in 2012-2013. Plants were sprayed with homeopathic extracts – Silicea (two times in early plant growing stage) and Carbo vegetabilis (two times at the middle of plant vegetation) of different concentration solutions (dilution rate: *SI6 + CV6; Si30 + CV30; Si200 + CV200)*. Silicea - mineral homeopathic treatment made of *Acidum Silicicum* (silica, H_2SiO_3). Carbo vegetabilis - organic homeopathic treatment, made of birch wood charcoal. Solutions were sprayed 4 times in every 10 days; the first spray was performed after 15 days after planting. The object of investigation was tomato cultivars – Slapukai BS, Balčiai, Viltis.
Slapukai BS – fertile, moderately resistant to disease, medium early, deterministic type tomato cultivar. The fruits are red, flat round, medium-sized and good taste. Unripe fruits are dark green with a green shoulder on the peduncle.
Viltis – early deterministic type tomato cultivar. Ripen fruits are red coloured with a good (sweetish) taste, flat round, fleshy, multi seed-beds. Unripe tomato has a green shoulder.
Balčiai – medium early, deterministic type cultivar. The fruits are red, flat round, medium-sized and have a good taste. The unripe fruit is light green colour, without green shoulder at the base.
Seedlings were planted in natural soil in polyethylene non-heated greenhouse on the 5th of June in 2012 and on the 6th of June in 2013. Tomatoes were growing according planting system 0.3X0.7 m. Record field area was 2.1 m^2. The experiment was conducted in three replications. Biochemical analysis were performed with fully ripen fruits on the 18-21th of August. After assessment of total yield, the economic efficiency of homeopathic extract (Y) was calculated using the formula:

(Dabkevičius and Brazauskienė, 2007): $Y = \frac{b-a}{a} \cdot 100$;

b – yield of variant with homeopathic treatment; a – yield of variant without homeopathic treatment.

Biochemical parameters were established in fresh weight (f.w.) of tomatoes at the Laboratory of Biochemistry and Technology of LRCAF Institute of Horticulture. The amount of was determined total sugar by Bertrane method, soluble solids by a numeric refractometer and ascorbic acid (vitamin C) was determined by titration with the indicator 2.6-dichlorphenolindophenol sodium Natrium solution (AOAC, 1990). Carotenoids (β-carotene and lycopene) content was determined spectrophotometrically according to Scott (Scott, 2001). The results mathematically processed using Microsoft Excel (Tarakanovas and Raudonius, 2003). Reliability of the data was evaluated using statistical software "Anova".
Meteorological conditions. In 2012 y. June's average temperature was 1.3 °C lower and in 2013 - 2.1 °C higher than the standard rate of climate (SRC), so in 2013 tomato plants were stronger and had more bunches. In 2012-2013 July's average temperature was 17.6-19.6 °C (1.5-3 °C higher (SRC), and the sun shine duration reached 265-295 hours (which is 25-40 hours more than SRC). 2012 August's average temperature was 15.6-18.2 °C in 2013 -16.4-18.6 ° C and were close to the standard climate rate (16.4-17.0 °C). In 2012 y. sunshine

duration decreased up to 25-40 hours compared with 2013 and SRC, so it caused prolonged tomato fruit ripening process and slightly reduced the amount of sugar in tomatoes. The average temperature of September in 2012 and 2013 was close to the standard climate rate (LHMT data base).

Results and Discussion

Two years investigation and evaluation of tomato total yield showed that the most productive variety was Balčiai, where produced total yield varied from 10.9 up to 11.8 kg m^{-2}. Meanwhile, total yield of variety Viltis varied from 9.9 up to 11.6 kg m^{-2} and total yield of tomato variety Slapukai BS varied from 9.5 up to 10.9 kg m^{-2}. Previous research results confirm that the total tomato yield depend not only on the selected plant growing technology, but also is determined by the features of chosen cultivar (Radzevičius *et al*., 2009). According to obtained data of this investigation, it was established positive effect of used preparations on total yield increase in all investigated cultivars. Tomato fruit yield depends on plant health. One of the most damaging plant diseases is *Phytophthora infestans*, which reduces tomato yield. For this purpose, in order to slow down negative effect of *Phytophthora infestans,* homeopathic extracts were used in this experiment. Researcher's data showed that this disease reduces harvest of different vegetables over 50 percent (Survilienė and Duchovskienė, 2008). It is very difficult to stop and control the spread of *Phytophthora infestans* due to the fungus biological characteristics – develops a resistant strain of the fungus (race) to fungicides. Particular attention must be paid to the greenhouse microclimate control, agro-technical and phyto-sanitary measures. The economic efficiency was calculated in order to evaluate effectiveness of homeopathic extracts. Tomato plants sprayed with *Si30 + CV30* concentration solution provided maximum economic efficiency (4.72-11.71%) among all tested tomato cultivars (Table 1).

Table 1. Homeopathic extracts effectivenes on tomatoes, Babtai, 2012–2013

Years/Cultivar	Economical effectiveness of homeopathic extracts, %

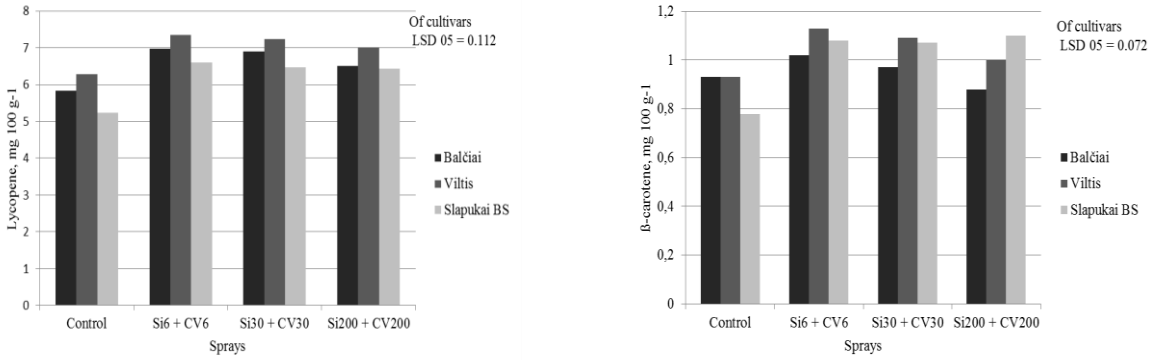
Mean cultivars	4.52	8.64	3.38	5.51

Biochemical composition is the most important feature of all the tomato quality attributes, because it determines fruit taste and aroma. Nutrition value of tomato fruit is mainly determined by environmental conditions and by cultivar features (Beckles, 2011). Tomato fruit colour essentially depends on content of lycopene and β-carotene, as well as their concentration and distribution also plant-growing conditions and genetic nature can have a significant impact on the lycopene content in tomato fruits (Tomlekova *et al*., 2007). In investigation, red fruit colour cultivars were selected. In the red tomatoes, lycopene content consists up to 80-90 percent of the total carotenoids amount (Heinonen *et al*., 1989). Our results showed that the highest amount of lycopene (7.34 mg $100g^{-1}$) was detected in fruits of

cultivar Viltis. Meanwhile, lycopene amount in tomato fruits cultivar Slapukai BS varied from 5 up to 6.24 mg 100 g^{-1} and in tomato fruits cultivar Balčiai – 5.83-6.9 mg 100 g^{-1} (Fig. 1A). Similar results were obtained on other investigations, where average amount of lycopene in different tomato cultivars in different years varied from 7.8 up to 8.6 mg 100 g^{-1} (Radzevičius et al., 2009). Plants sprayed by *Si6+CV6* concentration solution showed positive effect on the amount of lycopene in all investigated varieties. According to our investigation, the amount of β-carotene content in tomato fruits ranged from 0.78 up to 1.13 mg 100 g^{-1} (Fig 1B). Amount of this carotenoid is mainly determined by the plant genetic factors and cultivar characteristics, and usually it ranges from 0.33 up to 11.2 mg 100 g^{-1} (Adalid *et al*., 2010). Spraying plants *Si6+CV6* concentration solution obtained β-carotene in the fruit. Various concentrations of homeopathic extracts increased β-carotene content of tomato fruit. Plants sprayed by *Si6+CV6* concentration solution showed positive effect on the amount of β-carotene.



A B

Fig 1. Amount of Lycopene (A) and β–carotene (A) in tomato fruit, Babtai, 2012-2013

Tomato fruit taste mainly depends on its content of sugar, acids and their ratio. The higher amount of sugars gives sweeter and more pleasant taste for tomato fruits (Malundo *et al*., 1995). The highest amount of total sugar (5.01%) and less acidity (0.63%) were detected in cultivar Slapukai BS (Table 2). The lowest amount of total sugar was found in cultivar Viltis (4.63–4.74 %) and their titratable acidity reached 0.75–0.90%. Plants sprayed by Si6+CV6 solution showed positive effect on the amount of total sugar and reduced titratable acidity in tomato fruits.

Ascorbic acid and soluble solids content in tomato fruits are not constant; they are mostly determined by growing conditions and plant varieties. An average amount of ascorbic acid in tomato fruits varies from 10 up to 20 mg 100 g^{-1}. Many factors contribute to this variation, but environmental growing conditions and cultivar have been reported as having major effects on the ascorbic acid composition (Stern *et al*., 1994; Radzevičius *et al*., 2009). According to data of our investigation, the highest amount of ascorbic acid (17.29-19.71 mg 100 g^{-1}) was detected in fruits of cultivar Balčiai (Table 3). The similar results were obtained by the previous researches, where amount of ascorbic acid in tomatoes reached 18.8 mg 100 g^{-1} (Radzevičius *et al*., 2009). Our investigation showed that homeopathic extracts of different concentration had positive impact on the amount of ascorbic acid in tomato fruits. The soluble solids content determines vegetables nutritional value and affects their storage time and quality during storage (Radzevičius *et al.*, 2009; Karklelienė *et al.*, 2014). Soluble solids content is an important factor determining tomato fruit quality. The amount of soluble solids in ripe tomatoes range between 4 and 6% (Dorais *et al.*, 2001; Radzevičius *et al.*, 2016). That confirmed our results while the smallest quantity of these substances set out in a cultivar Balčiai - 4.02% and the largest amount was detected in cultivar Viltis - 4.56% (Table 3).

Homeopathic extracts had no reliable influence on the amount of soluble solids in all investigated variants.

Conclusions

Results of investigation prove a positive effect of used preparations on total yield increasing in all cultivars. Total yield varied from 9.5 up to 11.8 kg m^{-2}. Different concentration of homeopathic extracts solutions Silicea and Carbo vegetabilis have positive impact for the tomatoes growing parameters. Tomato sprayed with *Si30 + CV30* solution provided maximum economic efficiency (4.72-11.71%) among all tested tomato cultivars. Homeopathic extracts of different concentration had reliable impact on the amount of lycopene and β-carotene, ascorbic acid in tomato fruits. Plants sprayed by *Si6+CV6* solution showed positive effect on the amount of total sugar and reduced titratable acidity in tomato fruits. Homeopathic extracts had no reliable influence on the amount of soluble solids in all investigated variants.

Abstract

Seed priming is a pre-sowing treatment in which seeds are exposed to an external water potential that is low enough to restrict germination by various agents (i.e. polyethylene glycol, potassium nitrate, vermiculite) but permits pre-germinative physiological and biochemical activities. Seeds of watermelon (*Citrullus lanatus* (Thunb.) Matsum. & Nakai.) cv. Crimson sweet were primed with leonardite (30 g moistened with 25 ml distilled water, 25 °C, 24h); waste tea (12 g waste tea moistened with 40 ml distiled water, 25 °C, 24h), potassium nitrate (KNO_3, 3%), polyethylene glycol, (PEG-6000, -1.25 MPa), and patula herbal tea (2 and 10 g dried petal / L) along with hydropriming and unsoaked control to study the effect of seed priming. The seed priming significantly increased the rate of as well as percentage of seed germination. Further, survival of primed seedlings was better than those of control seeds subjected to low temperature (15 ^{o}C) and greenhouse optimal condition (25 ^{o}C). Although priming agents weren't positive effect in germination stage, they showed higher performance in greenhouse condition. Especially, emergence percentage of watermelon seeding subjected to waste tea, leonardite, and patula were higher than control and others agents in greenhouse condition. In addition, the low temperature emergence performance of leonardite primed seeds was better than control. Organic seed priming with leonardite, waste tea and patula was a cost-effective and eco-friendly approach to develop low temperature emergence in watermelon cv. Crimson sweet.

Keywords: *Abiotic stress, germination, priming agents, seed treatment*

Introduction

Watermelon is a summer vegetable species which is established by transplanting seedlings in early spring in open fields, or in late summer into protected cultivation. It is one of the most important vegetable crops in the Turkey and classified as sensitive to low temperature stress. Low temperature can lead to asynchronous seedling emergence after the sowing of many warm season vegetables like a watermelon. However, various treatments have been shown to improve seedling performance at low temperatures. These include chemical treatments (Nelson and Sharples, 1980), osmoconditioning (Sachs, 1977; Demir and Van De Venter, 1999; Park et al. 2016), hidropriming (Sachs, 1977; Demir and Van De Venter, 1999), salt priming (Demir and Oztokat, 2003), plant growth regulators (Nerson, et al 1985; Korkmaz, et al., 2004), but they did not use any organic priming agents.

Today the environmental issues and concerns are growing rapidly as humans advance their technology and pursue industrial development across the globe. Organic farming has been put forward as a positive response to these issues and concern by encouraging the organic material use at all stages of farming. Organically produced seeds and seedlings of crops should be used in organic farming, i.e. seeds should not be treated with synthetic materials like pesticides, pelleting and priming agents. The use of organic materials for increasing seed germination rate and uniform seedling emergence has gained importance in the recent years. Different organic materials, such as, seaweed, humic acid and fulvic acid, *Moringa oleifera*

leaf extract, herbal tea of marigold flower and grapefruit juice were investigated as possible priming agents (Mavi, 2014).

Seed priming is promoted as being simple and effective due to shortening of the time from sowing to emergence in optimal and suboptimal conditions such as low temperature stress. There are many agents that can be used for priming watermelon seed but most of these are not cost effective and eco-friendly. Therefore, this study was conducted to investigate different priming agents for low temperature stress and optimal condition of watermelon cv. Crimson Sweet seeds in regard to better emergence and lower mean emergence time.

Materials and methods

Watermelon (*Citrullus lanatus* (Thunb.) Matsum. & Nakai.) cv. Crimson sweet) seed lot was obtained from commercial seed company in Turkey. Lot had 81% of initial standard laboratory germination percentages (ISTA, 2009). All organic priming agents were performed by placing 150 seeds in 15 cm Petri dishes. The seeds were allowed to imbibe water for 24 h at 25 °C in the dark. The seeds were primed with leonardite (LEO, 30 g moistened with 25 ml distilled water, 25 °C, 24h); waste tea (TEA, 12 g waste tea moistened with 40 ml distilled water, 25 °C, 24h), potassium nitrate (KNO_3, 3%), polyethylene glycol, (PEG-6000, -1.25 MPa), and patula herbal tea (PAT, 2 and 10 g dried petal/L, Mavi and Matthews, 2013) along with hydropriming (HYDRO) and untreated control to study the effect of seed priming.

After the treatments, standard germination test was conducted by keeping 3 × 50 seeds in rolled germination paper (20 × 20 cm) for 14 days at 25 °C. Mean germination time (MGT) (Ellis and Robert, 1980) was calculated by daily counting.

To determine the effect of priming treatments on emergence under low temperature stress (15 ^{o}C) and optimal condition (25 °C), seeds were sown at depths of 1-2 cm in peat moss (Klasman, Germany). Three replicates of 50 seeds per treatment were sown in the peat moss in aluminum containers (30 × 19 × 5 cm). While seedlings at low temperature condition were grown in the growing cabinet at 15 ^{o}C for 35 days, optimal condition seedlings were grown in greenhouse at 25 ^{o}C for 35 days. The appearance of the hypocotyl hook on the compost surface was used as an emergence criterion and emerged seedlings were recorded by daily. To find out the effect of the treatments on uniformity, mean emergence time (MET) (Ellis and Robert, 1980) were calculated.

One-way analysis of variance (ANOVA) was conducted on all data and means were separated with Duncan's multiple range tests at 5% level. Percentage values were arcsine transformed prior to analysis, and SPSS was used for all statistical procedures.

Results and discussion

Germination and mean germination time(MGT)

Germination percentages of watermelon were used for comparison of treated and untreated seeds. TEA primed seeds reached to 89%, while untreated seeds had 81% germination percentage. KNO_3 primed seeds showed 77% germination percentages. But all primed agents were not statistically significant (Fig. 1A). Similar results have been reported different cultivar of watermelon in 25^{o}C germination test conducted by Demir and Van De Venter (1999). Depending on the watermelon cultivar, germination rate under low temperature (15℃) was improved by up to 15~66% in primed seeds, as compared to untreated seeds (Park, et al. 2016).

The difference between treated and untreated seed for mean germination time (MGT, days) was statistically significant. The treatments PEG, and control took maximum time of 4.01-3.88 days for germination. These treatments were statistically similar. The lowest MGT (3.00 days) was obtained by the TEA primed watermelon seeds. The MGT of HYDO primed seeds

was 3.15 days and KNO_3 primed seeds was 3.23 days. All of these treatments (TEA, HYDRO and KNO_3) were in same statistically group (Fig. 1B).

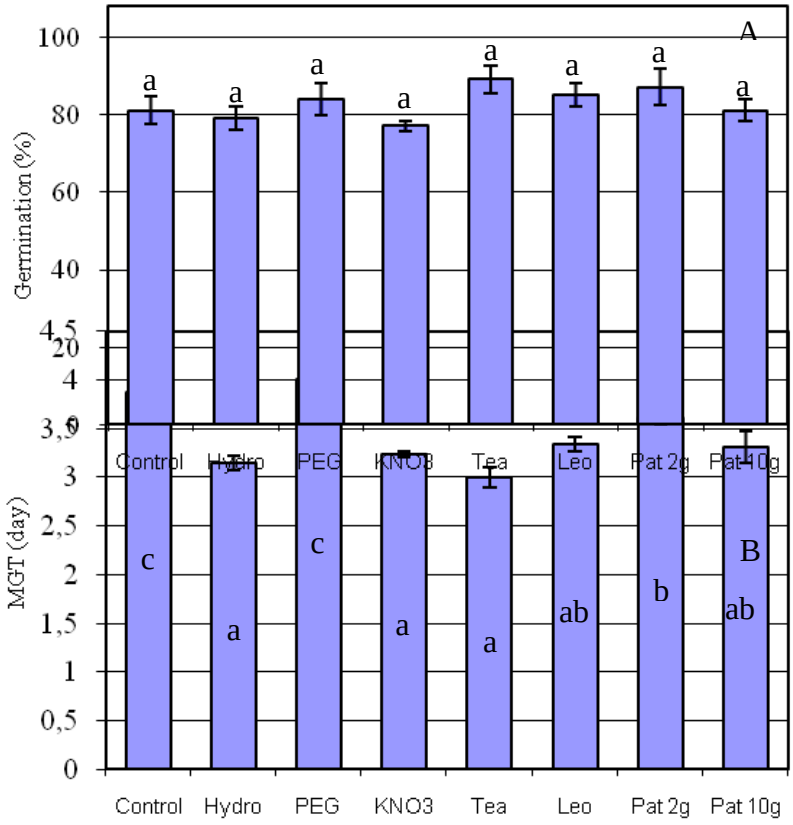

Fig. 1. Effects of priming treatments on total germination (A) and mean germination time (B) of watermelon seeds lot

Emergence and mean emergence time(MET)

The primed seeds emerged earlier and maintained a higher level of emergence throughout the emergence period in optimum conditions (Fig. 2A). Final emergence percentages of untreated seeds were significantly lower than each organic primed seeds in emergence tests. TEA primed seeds showed 73% emergence percentages. The maximum and significant ($P < 0.05$) advancement from priming was obtained in primed seeds in which, unprimed seeds had 50% emergence but corresponding values were 73% (TEA), 72% (PAT, 10g) and 70% (PAT, 2g), in organic primed seeds grown in optimal condition, respectively (Fig 2A). Supporting this finding, Mavi and Matthews (2013) found that PAT treatment increased emergence percentage of aubergine (*Solanum melongena*) seeds. TEA is also showed good performance for matrix priming.

MET decreased when the seed primed with TEA and PAT in optimal condition and was at minimum value of 23.2 daya in control and 21.4 days in TEA and PAT organic primed seeds in optimal condition, respectively (Fig 2B).

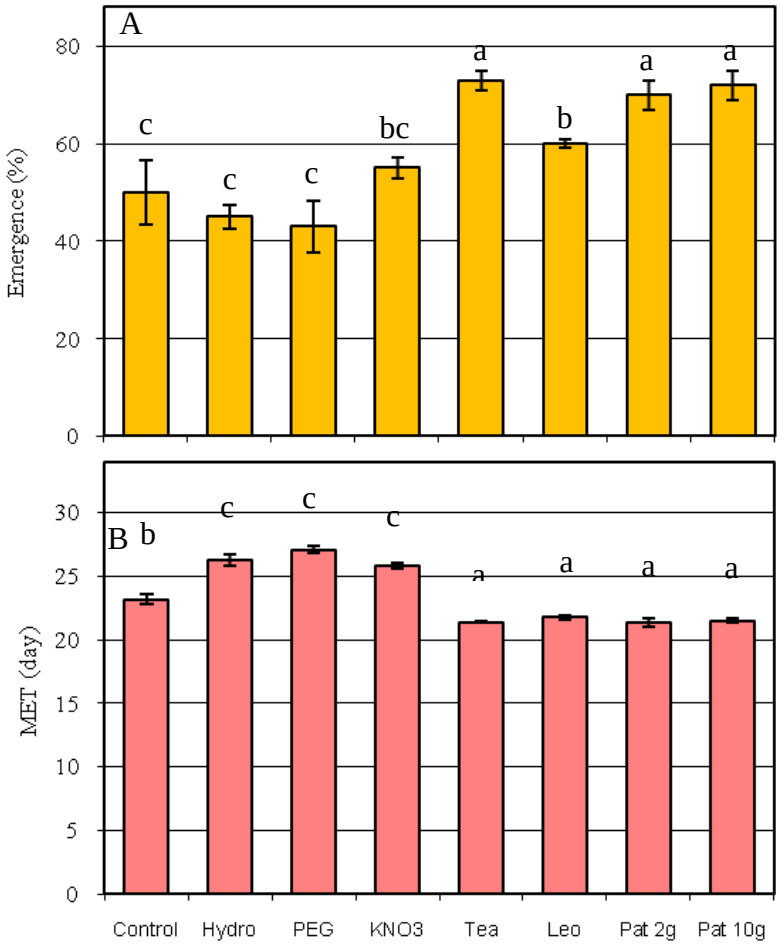

Fig. 2. Changes in emergence percentages (A) and mean emergence time (B) of watermelon seeds following various priming treatments

Low temperature emergence and mean emergence time

Analyses of variance showed that priming treatments were significant ($P < 0.05$) for low temperature stress conditions (Fig. 3). The primed seeds emerged earlier and maintained a higher level of emergence throughout the emergence period in low temperature stress condition except for PAT (10 g) (Fig. 3A). Final emergence percentages of untreated seeds were significantly lower than TEA, LEA and PAT (10 g) organic primed seeds in emergence tests. LEA primed seeds showed 73% emergence percentages. The maximum and significant ($P < 0.05$) advancement from priming was obtained in primed seeds in which, unprimed seeds had 35% emergence but corresponding values were 73% (LEA), 58% (KNO3) and 57% (PEG), in primed seeds grown in low temperature stress condition, respectively (Fig 3A).

Priming not only improved seedling emergence but also enhanced the seedling vigour as indicated by lower mean emergence time and higher seedling uniformity. The beneficial effect of priming on glasshouse watermelon emergence confirms previous findings on the germination of watermelon seeds at low temperatures in laboratory conditions (Sachs, 1977; Nerson et al., 1985; Demir and Van de Venter, 1999; Demir and Oztokat, 2003). PAT priming promoted earlier emergence percentages of aubergine seedlings are in agreement with previous findings (Mavi and Matthews, 2013).

MET was decreased when the seed primed with TEA and KNO_3 in low temperature stress condition and was at minimum value of 20.1 day in untreated seeds and 16.9 day in TEA and 16.7 day in KNO_3 primed seeds, respectively (Fig 3B).

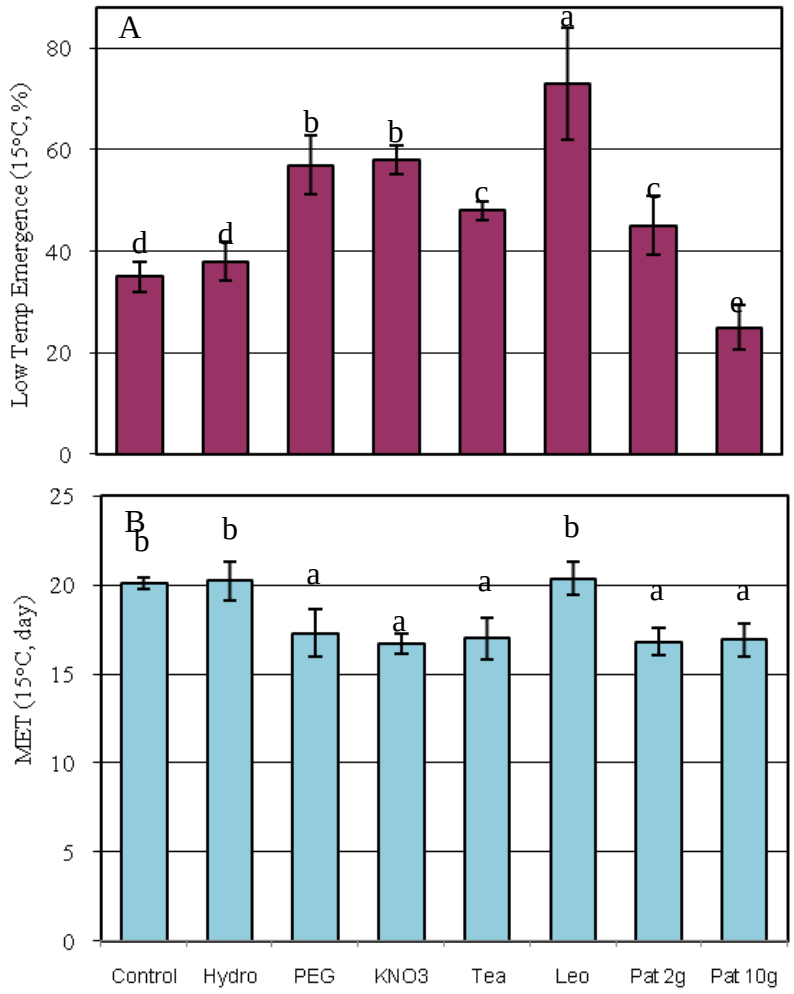

Fig. 3. Changes in low temperature emergence percentages (A) and mean emergence time (B) of watermelon seeds following various priming treatments

Conclusion

Organic priming (PAT, LEO and TEA) can be used as a tool in watermelon seed (1) to improve germination in laboratory condition, (2) to increase low temperature stress emergence of seeds in seedling tray and (3) to increase emergence and mean emergence time of seeds in optimal greenhouse condition.

Abstract

The aim of this study was to compare abundance of microorganisms in the rhizosphere of four different medicinal and aromatic plant species (basil, mint, dill and marigold) grown under both conventional and organic management. The trials were set up on chernozem soil at experimental field of Bački Petrovac, Institute of Field and Vegetable Crops, Novi Sad (northern Serbia). Rhizosphere soil samples were collected in two sampling terms during 2015 (June 2 and July 28, 2015) and analysed by the indirect dilution method followed by plating of soil suspension on selective nutritive media. The obtained results showed significant differences in microbial abundance between plant species, growing systems and sampling terms. The highest number of azotobacters and cellulolytic microorganisms were obtained in rhizosphere of marigold, while total microbial number and fungi were the most abundant in rhizosphere of basil. The most common population of ammonifiers, free N-fixing microorganisms and actinomycetes were recorded in rhizosphere of dill. Significantly higher number of microorganisms was found in organic growing system compared to conventional, while the number of most tested microbial groups was higher at the first sampling period.

Keywords: *basil, dill, marigold, mint, organic production*

Introduction

Microorganisms are one of the indicators of the overall soil biogeny since they are actively involved in the processes of mineralization of organic compounds to inorganic and mobilization of difficult soluble inorganic compounds in the soil. In addition to nutrient cycling, soil microorganisms are involved in other important ecosystem functions, such as the formation and preservation of soil structure (Bastida et al., 2008). Number and composition of microorganisms in the rhizosphere can be affected by several factors including soil management practices, which strongly influence the quality and fertility of agricultural soils and consequently, the size, composition and function of the soil microbial community (Wu et al., 2011). Conventional growing systems lead to the disturbance of these relationships, which is manifested by reduced number and enzymatic activity of microorganisms, especially because modern agricultural production involves the use of large amounts of pesticides and fertilizers (Zhang et al., 2012). Low-input systems such as organic farming, substantially reduce the use of synthetic fertilizers, pesticides, energy and mechanic stress, and mitigate these negative impacts in order to improve sustainable production (Gomiero et al., 2011).

Beside management practices and soil type, the diversity and composition of microbial community in the rhizophere also depend on plant species. A wide range of organic compounds secreted by plant roots increase microbial density and activity in the rhizosphere compared to bulk soil. Medicinal plants harbour a distinctive microbiome due to their unique and structurally divergent bioactive secondary metabolites that are most likely responsible for

the high specificity of the associated microorganisms (Ramesh et al. 2012). With the increased population pressure, costs and side effects and the development of resistance to allopathic drugs for infectious diseases, the uses of medicinal plants for a wide variety of human ailments are increasing. Using modern cultivation technologies to meet the demand for medicinal plants may degrade the quality of medicinal plant products, lead to resource degradation and negatively affect several soil ecological functions (Solaiman and Anawar, 2015). Development of innovative technologies and better understanding of short- and long-term responses of microbiological soil properties to different management practice in the cultivation of medicinal plants is required.

Therefore, the objective of this study was to compare the effects of conventional and organic system production on microbial number in the rhizosphere of different medicinal and aromatic plant species.

Material and Methods

The trial was set up on chernozem soil at experimental field of Bački Petrovac, Institute of Field and Vegetable Crops, Novi Sad (northern Serbia). Rhizosphere soil samples were collected from both conventional and organic grown four medicinal and aromatic plant species: mint (*Mentha x piperita* L.), marigold (*Calendula officinalis* L.), basil (*Ocimum basilicum* L.), and dill (*Anethum graveolens* L.). Samples for microbiological analyses were collected in two sampling terms (June 2 and July 28, 2015). Samples were analysed by the serial–dilution method followed by plating on different selective media (Bloem et al., 2006). Total number of microorganisms was determined on an agarized soil extract (dilution 10^7). Nitrogen–free medium was used for the determination of free N-fixing bacteria (dilution 10^6) and *Azotobacter* sp. (dilution 10^2). Ammonifiers (AMN) were determined on a mesopeptone agar (dilution 10^6). Cellulolytic microorganisms was determined on Waksman-Carey medium (dilution 10^5). The number of fungi was determined on Czapek–Dox medium, and actinomycetes on a synthetic medium (dilution 10^4). The microbiological analyses were done in three replications and the average number of microorganisms was calculated at 1.0 g absolutely dry soil (Jarak and Đurić, 2006). The variables were analysed in accordance with three–way model of analysis of variance (ANOVA) using Statistica software (StatSoft Inc. 2012), followed by mean separation according to Fisher's LSD test.

Results and Discussion

Determining the presence of certain systematic and physiological groups of microorganisms, provides insigh into general microbiological activity, potential soil fertility and general causes of the certain condition of soil (Marinković et al., 2007). In this study, the number of microorganisms depended on the plant species, growing system, and sampling term. Number of tested microbial groups significantly differed between four plant species, with exception in number of actinomycetes and cellulolytic microorganisms. Significant differences in microbial abundance were also obtained between growing systems and sampling terms, except in number of fungi for both factors, and total microbial number for sampling terms (Tables 1-7).

Table 1. Number of *Azotobacter* sp. in rhizosphere of medicinal and aromatic plant species in conventional and organic growing systems (CFU/ml g^{-1} absolutely dry soil)

Plant/Growing System	I sampling period		II sampling period		Plant Average
	Organic	Conventional	Organic	Conventional

Dill	54 defg	30 fgh	102 b	91 bc	69 ab

The different letter above the number indicates a significant difference at $P < 0.05$

Observed by plant species, the highest number of *Azotobacter* sp. was recorded in rhizosphere of marigold, significantly higher than number of this microbial group in the rhizosphere of mint and basil. Also, a higher number of azotobacters was obtained in an organic growing system compared to conventional at both sampling periods, while significant differences were recorded in rhizosphere of basil at first sampling period, as well as in mint, marigold and basil rhizosphere at second sampling (Table 1).

Table 2. Total number of microorganisms in rhizosphere of medicinal and aromatic plant species in conventional and organic growing systems (CFU/ml g^{-1} absolutely dry soil)

Plant/Growing System	I sampling period		II sampling period		Plant Average
	Organic	Conventional	Organic	Conventional	
Mint	80 bcde	31 e	110 abc	51 de	68 b
Marigold	66 cde	64 cde	91 abcd	42 de	66 b

Dill	50 de	49 de	54 cde	73 bcde	57 b

The different letter above the number indicates a significant difference at $P < 0.05$

On average, significantly higher total number of microorganisms was recorded in the rhizosphere of basil compared to other plant species. Total microbial number was higher in organic growing system, except in rhizosphere of basil and dill at second sampling period. Significant differences between growing systems were established only in mint rhizosphere at second sampling (Table 2).

Table 3. Number of ammonifiers in rhizosphere of medicinal and aromatic plant species in conventional and organic growing systems (CFU/ml g^{-1} absolutely dry soil)

Plant/Growing System	I sampling period		II sampling period		Plant Average
	Organic	Conventional	Organic	Conventional	
Mint	77 def	73 def	97 bcde	60 def	76 b
Marigold	99 bcd	45 f	96 bcde	128 ab	92 ab

Dill	95 bcde	53 ef	152 a	124 abc	106 a

The different letter above the number indicates a significant difference at $P < 0.05$

The highest number of ammonifiers was recorded in rhizosphere of dill, while the smallest number was obtained in the rhizosphere of mint. Significant differences in the number of this group of microorganisms were obtained only between these two plant species. Organic growing system had a positive effect on the number of ammonifiers, while a higher number in

conventional growing system was recorded only in the rhizosphere of marigold and basil at the second sampling period (Table 3).

Table 4. Number of N-fixing microorganisms in rhizosphere of medicinal and aromatic plant species in conventional and organic growing systems (CFU/ml g^{-1} absolutely dry soil)

Plant/Growing System	I sampling period		II sampling period		Plant Average
	Organic	Conventional	Organic	Conventional	
Mint	224 a	108 bc	96 c	63 c	123 a
Marigold	161 ab	166 ab	90 c	76 c	123 a
Basil	98 c	62 c	71 c	65 c	74 b
Dill	177 a	203 a	88 c	86 c	138 a

The different letter above the number indicates a significant difference at $P < 0.05$

On average, the highest number of N-fixing microorganisms was recorded in rhizosphere of dill, while significantly smaller number compared to other plant species was obtained in the rhizosphere of basil. A larger number of nitrogen-fixing microorganisms was recorded in an organic growing system, except in the rhizosphere of marigold and dill at the first period of sampling (Table 4).

Table 5. Number of fungi in rhizosphere of medicinal and aromatic plant species in conventional and organic growing systems (CFU/ml g^{-1} absolutely dry soil)

Plant/Growing System	I sampling period		II sampling period		Plant Average
	Organic	Conventional	Organic	Conventional	
Mint	9.6 abcd	8 abcd	8 abcd	3 d	7 b
Marigold	7 abcd	5 bcd	6 abcd	4 cd	6 b
Basil	11 ab	9 abcd	10 abc	12 a	11 a
Dill	7 abcd	4 cd	6 abcd	6 abcd	6 b

The different letter above the number indicates a significant difference at $P < 0.05$

The number of fungi was significantly higher in the rhizosphere of basil in comparison to other plant species. Larger number of fungi was observed in the organic growing system, except in the rhizosphere of basil at the second sampling period (Table 5).

Table 6. Number of *Actinomycetes* in rhizosphere of medicinal and aromatic plant species in conventional and organic growing systems (CFU/ml g^{-1} absolutely dry soil)

Plant/Growing System	I sampling period		II sampling period		Plant average
	Organic	Conventional	Organic	Conventional	
Mint	28 a	6 bcd	0 d	6 bcd	10 a
Marigold	20 ab	6 bcd	0 d	2 cd	7 a
Basil	16 abc	3 cd	3 cd	11 bcd	8 a
Dill	30 a	7 bcd	0 d	12 bcd	12 a

The different letter above the number indicates a significant difference at $P < 0.05$

The highest number of actinomycetes was recorded in the rhizosphere of dill, but significant differences between plant species were not established. At the first sampling period, a higher number of actinomycetes was recorded in organic growing system. On contrary, at the second sampling period, a larger number of actinomycetes was recorded in conventional system (Table 6).

Table 7. Number of cellulolytic microorganisms in rhizosphere of medicinal and aromatic plant species in conventional and organic growing systems (CFU/ml g^{-1} absolutely dry soil)

Plant/Growing System	I sampling period		II sampling period		Plant Average
	Organic	Conventional	Organic	Conventional	
Mint	24 bc	10 cd	14 cd	5 d	14 a
Marigold	42 a	13 cd	14 cd	10 cd	20 a
Basil	30 ab	9 cd	12 cd	12 cd	16 a
Dill	19 bcd	17 bcd	10 cd	10 cd	14 a

The different letter above the number indicates a significant difference at $P < 0.05$

On average, the most common number of cellulolytic microorganisms was recorded in the rhizosphere of marigold, but significant differences in relation to other plant species were not observed. A larger number of cellulolytic microorganisms was obtained in an organic system in both sampling periods, except in the rhizosphere of basil and dill at second period of sampling (Table 7).

These results are in agreement with those of Bjelić et al. (2015) who revealed significant differences in microbial abundance between plant species, growing systems and sampling periods. Similar results were obtained by Ahmed et al. (2014) who determined that microbial community composition differed between eleven medicinal plant species. Research conducted by Mrkovački et al. (2012) also indicated a significantly higher number of microorganisms under organic production system compared to conventional. Research of Adamović et al. (2015) showed that organic growing system affected the abundance of microorganisms in rhizosphere of species investigated, especially in the second term of sampling. According to Hartmann et al. (2015), fertilization scheme, the application and quality of organic fertilizers in particular, is the major determinant of microbial diversity. However, the presence of organic and inorganic materials in soil is connected to the increase in nutrient content and further impact on soil properties, including the soil microbiological activity, as Zhong et al. (2010) concluded.

Conclusion

Microbial abundance significantly differed between four plant species. On average, the highest number of azotobacters and cellulolytic microorganisms were obtained in rhizosphere of marigold. Total microbial number and fungi were the most abundant in rhizosphere of basil. The most common population of ammonifiers, free N-fixing microorganisms and actinomycetes were recorded in rhizosphere of dill. Significantly higher number of microorganisms was found in organic growing system compared to conventional, which confirm the positive effect of this agricultural practice on microbial activity in soil compared to conventional management. The number of most tested microbial groups was higher at the first sampling period.

EVALUATION OF ANTI-FUNGAL EFFECTS OF PROPOLIS EXTRACTS

Yusuf YANAR, Sabriye BELGÜZAR*, Dürdane YANAR

Gaziosmanpasa University, Agricultural Faculty, Plant Protection Department-Tokat, Turkey
*Corresponding author: sabriye.yazici@gop.edu.tr

Abstract

This study was carried out to determine the antifungal activity of ethanol extract of propolis on *Macrophomina phaseolina, Cylindrocarpon destructans, Rhizoctonia solani* and *Fusarium oxysporum.*Propolis was collected from Tokat, Sivas and Corum provinces of Turkey. Ethanol extracts of propolis were mixed with Potato Dextrose Agar (PDA) media to obtain the final concentrations of 0.5, 1 and 3% (v/v/). Discs (5-mm diameter) of the mycelial plugs from the actively growing edge of the fungal colonies were transferred on the PDA plates. The media without extract were used as the negative controls. Three replicates were used for each treatment. PDA plates were then incubated in the dark at 25 ºC. Mycelial diameter of the fungus was measured after 7 days incubation periods. Based on the results of the study, increase in extract concentration resulted in increase of the extract efficacy. Tokat, Sivas and Corum propolis ethanol extract at 3% concentration inhibited the growths of all pathogens at the rates of 100%. Tokat, Sivas and Corum propolis ethanol extract at 1% concentration inhibited the growths of the pathogens between 58 and 100%. While Tokat and Corum propolis extract at 0.5% concentration inhibited the growths of all pathogens at high proportion, Sivas propolis extract was low on *F. oxysporum* ve *C. destructans.* In conclusion, propolis ethanol extract has antifungal activity on pathogens.

Key Words: *Propolis, Macrophomina, Cylindrocarpon, Rhizoctonia, antifungal.*

Introduction

Strawberry (*Fragaria ananassa*) is an economically important berry crop worldwide. However, commercial strawberry production is severely affected from soil-borne fungal pathogens and management is mainly reliant on chemical fumigation. Commercial strawberry production was severely conceded by crown and root diseases caused by *F. oxysporum*, *Rhizoctonia spp.*, *Cylindrocarpon destructans*, and *Macrophomina phaseolina*, Among these, *F. oxysporum* was most frequently isolated from crowns at a frequency of 41%; *Rhizoctonia* spp. were most frequently isolated from roots at a frequency of 12%. *F. oxysporum*, *Rhizoctonia* spp. and *M. phaseolina* were found to be the most virulent pathogens on strawberry, and their virulence and consequent disease severity was influenced by the prevailing seasonal temperature. The development of effective strategies for disease management is limited due to the success of methyl bromide as a soil sterilant, currently restricted. In addition, the management includes cultivar selection, use of certified planting stock, replacement of plants annually, biological control, rotation crops, soil fumigation prior to planting, soil solarization and use of systemic fungicides during the crop cycle (Yigal et al., 1981; Yuen et al., 1991; Elmer and LaMondia, 1999; Benlioğlu et al., 2005). Alternative methods to control fungal diseases have been studied by using compounds derived from plant sources in an attempt to reduce the use of syntheti fungicides. Extracts of *Allium sativum, Coriandrum sativum, Curcuma longo* and *Cuminum cyminum* possessed a strong antifungal activity (Lalitha et al., 2011). Forty plants of different families were tested against *Fusarium oxysporum* f.sp. *cicero*, with *Chenopodium ambrosioides* having the highest inhibition (Minz et al. 2012). More recently, the antifungal activity of more than 500 plant species has been assessed (Rongai et al. 2012). Of all plants tested, only 3% showed a high antifungal activity.

Many authors have also studied the importance of secondary metabolites in fungal inhibition. Beside plant secondary metabolites other natural product like propolis contains similar types of antimicrobial compounts. Propolis is a resinous hive product collected from plant buds by bees. Propolis is a resin and its color changes from green to dark browning according plant source. Investigations have indicated that propolis contains wax, flavonoids, amino acids, essential oils, pollen, minerals and organic matters (Crane 1990, Scheller et al., 1990) Propolis is thought to be used to seal the beehive (Lotti et al., 2010) to exclude draught and protect it against external invaders. However, its main function is to prevent the decomposition of organic matter (*i.e.*, organisms that have been killed by the bees after invasion) within the hive by inhibiting microbial growth. Therefore, the presence of propolis may provide an environment that is unsuitable for the growth of fungi and other microorganisms, thus maintaining an aseptic hive (Falcão et al., 2010). Over 300 compounds have been detected in propolis, and 160 of these have been identified of which 50% are phenolic compounds, mainly flavonoids (flavones, isoflavones, and flavones), aromatic acids and esters (caffeic acid, cinnamic and others),aromatic aldehydes (vanillin and isovanillin),coumarins and phenolic triglycerides. In addition, other groups of compounds and minerals are of fundamental importance for the biological activity of propolis, including provitamin A, certain B vitamins, lactones, polysaccharides, amino acids and other substances not yet identified (Quiroga et al., 2006; Kalogeropoulos et al., 2009; Falcão et al., 2010). Numerous studies have demonstrated the pharmacological activities of propolis, including antibacterial, antifungal, antiviral, antioxidant, and antitumorproperties (Tolosa and Cañizares, 2002; Castagna et al., 2004; Garedew et al., 2004; Quintero-Mora et al., 2008; Herrera et al., 2009; Saavedra et al., 2011). In different Countries, the local propolis have been evaluated by Őzcan et al. (2004), Quiroga et al. (2006), Giovanelli (2008), Meneses et al. (2009), and Özdemir et al. (2010) who obtained interesting results against phytopathogenic fungi. This study has been established for evaluation of antifungal activity of ethanol extract of propolis on *Macrophomina phaseolina, Cylindrocarpon destructans, Rhizoctonia solani* and *Fusarium oxysporum.*

Materials and Methods

Fungal Isolates

Macrophomina phaseolina, Cylindrocarpon destructans, Rhizoctonia solani and *Fusarium oxysporum* were obtained from the Department of Plant Protection, Agricultural Faculty, Gaziosmanpasa University, Tokat (Turkey). The fungal isolates were maintained at 4ºC on potato dextrose agar slants and kept in refrigerator prior to subculture.

Exctracting Propolis

Ten propolis samples belonged to *Apis mellifera* colonies were collected from Tokat, Sivas and Corum provinces of Turkey. Ethanolic extract of propolis was prepared by adding 100 g of propolis sample to 200 ml obsolute ethanol in 500 ml flask and shakin on orbital shaker (at 120 rpm) for one day. At the end of one day, extract was passed though muslin cloth to remove solid phase. Ethanol was evaporated at 32 ºC using rotary evaporater. The solid phase was dissolved in 10% aceton to get 50% stock solution.

Antifungal activity of propolis

The antifungal potential of propolis was evaluated using the agar dilution method according to Quintero-Mora et al. (2008). The potatodextrose- agar medium (PDA) was sterilized at a temperature of 121 ºC for 15 min, and were prepared with the propolis selected extract, obtaining concentrations of 0.5, 1.0, 3% (v/v), according to the volume of medium used, and a

control medium without propolis. The mixture was homogenized and poured into sterile Petri dishes (60 mm in diameter). The control treatment contained 10% aceton. Fungal plugs (5 mm in diameter) obtained from the actively growing edge of the fungal colonies were placed at the center of Petri dishes. The cultures were incubated at 25 ± 2 ºC, and the radial growth of the mycelia were measured daily. For each fungus when the mycelial growth reached the edge of the plates in the control treatments experiment was completed. Inhibition percentage was calculated by using the following equation: (Deans and Svoboda 1990).

1= (C-T/C)x100
I: Inhibition (%),
C: Colony diameter of mycelium from control petri plate (mm),
T: Colony diameter of mycelium from test petri plate (mm),

Statistical analysis

The results were analyzed using an Analysis of Variance (One-Way ANOVA), and the comparisons between the means were performed using the multiple comparison test of Tukey, with a significance level of 5% ($P \leq 0.05$). The statistical program demo SPSS 11 was used.

Results and Discussion

The susceptibilities of four plant pathogenic fungi (*Macrophomina phaseolina, Cylindrocarpon destructans, Rhizoctonia solani* and *Fusarium oxysporum*) to the ethanolic extracts of propolis were evaluated in solid culture. There were significant differences ($P < 0.05$) between concentrations of propolis extract used in this study (Table 1, 2, and3). In a agar diffusion assay, *M. phaseolina, C. destructans, R. solani* and *F. oxysporum* isolates were sensitive to propoli obtained from Çorum province at all concentration (0.5, 1.0, and 3.0% v/v) tested. As the concentration of the propolis extract increased, the diameter of the zone of inhibition also increased (Table 1). Inhibition rates of Corum propolis were 90% and over on mycelial growth of the test fungi at 1 and 3% concentrations. Propolis extract from Tokat province exhibited the similar results with the Corum propolis at 1 and 3% concentrations (Table 2). But *F. oxysporum* was less sensitive to Tokat propolis extract than the other fungus isolates. The propolis obtained from Corum, Tokat and Sivas provinces gave between 96% and 100% inhibitions Table 1, 2, and 3) . The control (50% dimethyl-sulfoxide, v/v) did not form an inhibitory zone against any of the fungi tested. But inhibition rates of Sivas propolis were lower than the other two propolis at 0.5 and 1% concentration against the test fungi (Table 3). Results of the present study are in agreement with the results of previous studies on the antifungal effect of propolis against plat pathogenic fungi and molds. It was stated that the application of 1%, 5%, and 10% concentrations of ethanol-extracted propolis inhibited in vitro growth of *Penicillium digitatum* (Soylu et al., 2004, Soylu et al. 2008) and limited the growth of *Botrytis cinerea* on strawberry (La Torre et al. 1990). Yanar et al. (2005) reported that four of propolis methanol extracts concentrations (10, 7, 5, and 3 µg/ml) copletely inhibited the mycelial growth of the three *Phytophthora* species. An other study Özcan (1999) showed that treatment with 4% water-extracted propolis resulted in more than 50% inhibition of some plant pathogens in vitro. The application of 2% and 5% concentrations of propolis methanol extract inhibited the growth of *Alternaria alternata* and *Fusarium oxysporium f.* sp. *melonis*. However, *F. oxysporium* was found to be more sensitive than *A. alternata* (Özcan, et al. 2004). In an other study, The ethanolic extract of Chilean propolis inhibited the growth of *Alternaria alternata, Fusarium* sp., *Ulocladium* sp., *Botrytis cinerea, Penicillium expansum* and *Trichoderma reesei* at four different concentrations (0.5,1.0, 2.5 and 5.0 %) (Curifuta et al. 2012). Propolis has been found to possess antimicrobial activity and this has been attributed to specific chemicals in the propolis (Shehu et al. 2015, Temiz et al., 2013, Curifuta et al. 2012, Katircioglu and Mercan, 2006). Inhibition activity of propolis was

studied by many authors, these studies were conducted to an inhibition activity of propolis depending on factors, these factors were the area geographic and concentration of the collected propolis in these studies. Also propolis composition varies from region to region and therefore, the difference in the composition of the extract may lead to the inhibition of a difference in percentage from propolis extracted from one area to another (Shehu et al. 2015, Chee, 2002). Inhibition percentage is also different from one study to other according to the concentration of extracts, In addition, the method that is used to extract propolis may lead to variation in the results.

Conclusion

In conclusion, present results indicate that the ethanolic extract of Turkish propolis has the capacity to inhibit some of the economicaly important plant pathogenic fungi *in vitro*. The results obtained in this study are promising and support the importance of further *in vivo* investigations into the antifungal capacity of propolis from the Corum, Sivas and Tokat provinces of Turkey.

Abstract

The trial tests of special herbal preparation (SHP) in the capacity of PGR were executed on cucumber, pepper and tomato at a large glasshouse in Orenburg Region of Russian Federation. Special preparation was based on wild growing herbs: comfrey (*Symphitum officinale*), dandelion (*Taraxacum officinale*), horsetail (*Equisetum arvense*), lemon balm (*Melissa officinalis*), nettle (*Urtica dioica*), valerian (*Valeriana officinalis*) and yarrow (*Achillea millefolium*). In order to extract the active matter without application of chemical means, an unique production process has been developed. The foundation of this process is based on a special combination of water extraction and biofermentation with continual oxygen enrichment. The experiment was executed as per following treatments: 1. Control, 2. Basic fertilization + SHP, 3. Basic fertilization, 4. Basic fertilization + additional fertilization + SHP, 5. Basic fertilization + additional fertilization. Treatments were repeated twice with random allocation on 100 m^2 sample plots for cucumber and tomato and 50 m^2 for pepper. The examinations have shown that SHP had a positive impact on growth and development of vegetable crops planted in the glasshouse.

Key words: *special herbal preparation, PGR, cucumber, pepper, tomato*

Introduction

Plant tissue is capable to synthesize a wide range of natural products that can be removed with neutral organic solvents or water to yield extractives, a mixture of naturally occurring organic compounds. From ancient times to the present days extractives, together with exudates, have provide a number of human needs such as: food, medicines, cosmetics, dyes etc. Extracts of wild plants and their derivatives also have their place in agriculture where are used as: mild fertilizers, plant growth regulators (PGR), plant protection means etc. (Ljubojević, 2015). Analogous or somewhat different behavior can be found among: herbal nutrients (Chang et al., 2014), biostimulants (Bulgari et al., 2015; Calvo et al., 2014; Stirling et al. 2016), plant-growth promoters (Stirling et al, 2016), plant strengthening products (Kuhne et Jahn, 2010), biological controlling agents (Nega, 2014), biopesticides (Zarins et al., 2009), botanical insecticides and repellents (Pavela, 2013), soil improvers/conditioners and uptake improvers (Calvo et al., 2014; Khan et al., 2009). Besides extractives as a mixture of organic compounds, from plant material can be isolated particular compounds such as phytohormones (auxins, cytokinins, gibberellins, ethylene, abscisic acid) and similar ingredients (betaines, sterols etc.). These endogenous PGR today are replaced by synthetic substitutes. Moreover, plant extracts are used in animal nutrition as appetite and digestion stimulants, stimulants of physiological functions and for prevention and treatment of certain pathological conditions (Frankič et al. 2009).

Main herbal raw material for the production of PGR and related phytopreparations are seaweeds. According to Zemke-White et Ohno (1999), at least 221 species of seaweeds are utilized globally, with 145 species for human food production and 101species for animal feed,

herbal nutrients and PGR. Apart from seaweed extracts, on some regional markets can be found: active dry yeast extracts (Hanafy et al., 2012), Siberian fir (*Abies sibirica*) needle extract and essential oil, as well as oleoresin (Komykova et al., 2012), natural growth regulators obtained from the seeds of corn cockle (*Agrostema githago*) weed, (Jelačić et al., 2007), plant growth promoting rhizobacteria (Ahemad et Kibret, 2014). Furthermore, extracts of wild growing herbs can also be used as a raw material. The grounds for such approach are numerous and they are elaborated in author`s previous work (Ljubojević, 2015).

This paper presents results of the experiment with SHP produced in industrial plant on the basis of selected wild growing herbs. Efficiency of SHP in the capacity of PGR were tested on cucumbers, peppers and tomatoes in the greenhouse conditions. The article also describes the procedure of SHP production and gives relevant manufacturing parameters. In this way it is possible to repeat and examine the results of the experiment.

Material and methods

Special herbal preparation and its production

SHP is designed to act as a plant growth regulator and as an uptake improver, behaving as a kind of catalyst and an accelerator of complex relations in the plant-soil system. SHP cannot provide a sufficient amount of nutrients for crops. It is only auxiliary means which helps existing stocks of nutrients to be better and faster utilized by crops.

SHP production was realized through the following working operations: 1. Disinfection and sterilization, 2. Water treatment, 3. Water extraction and aerobic fermentation, 4. Separation, 5. Filtration, 6. Pasteurization, 7. Finalization. All production vessels (containers, tanks etc.) and pipes ought to be disinfected and sterilized before a new batch start, using upgraded "Formalintec" aerosol device. Water treatment implies softening and heating. In order to increase the affinity of water towards extraction, tap water was softened with softener and then heated to 40 ^{o}C temperature. A total of 131 kg of dried herbs was flooded with 1,160 l of thus prepared water according to the following recipe: comfrey root (*Symphitum officinale*) - 22 %, dandelion leaf (*Taraxacum officinale*) - 10 %, horsetail herb (*Equisetum arvense*) - 8.5 %, lemon balm leaf (*Melissa officinalis*) - 8.5 %, nettle leaf (*Urtica dioica*) - 28 %, valerian root (*Valeriana officinalis*) - 15 %, yarrow herb (*Achillea millefolium*) - 10 %. This assortment is mainly based on personal research supported by works of Molisch (1937), Omahen (1985), Steiner (1993), Stickland (1989) and some other authors. Raw materials were purchased from two companies: "Krka-Zelišča", Slovenia and "D.co Ulrcih", Italy. Goods were cut and delivered in bags.

It is known that water is not an impeccable solvent. Some of the substances dissolve completely, another ones partially, while the rest do not dissolve at all. Among the substances which dissolve in pure water only partially, there are a lot of those very useful for plants. For this reason we use microorganisms to break down such raw material and to incorporate its ingredients in SHP. The foundation of this process is a special combination of water extraction and biofermentation with continual oxygen enrichment. Simultaneous extraction and fermentation take place in specially designed tanks. "Slow air" comes with a blower (wind machine) in large quantities, while "high-speed air" comes with a compressor in smaller amounts. During the entire extraction and fermentation processes waterfall flow takes place, using an eccentric screw pump, and eddy currents, using mixer with propellers. Cascade and vortex, unless have direct repercussions on the quality of the final product, also contribute to its "biodynamic dimension" as it is understood by R. Steiner (1993). It takes around 48 hours after the sinking of raw material, before the permanent sampling of the so-called "soup" (mixture of herbs and water) begins with conductometer. As long as the value of conductivity increases, processes of extraction and fermentation should not be considered complete. But as soon as there is not change in three consecutive readings, the process is

interrupted and separation begins. Hence, the conductivity is used as an indirect measure of the total amount of dissolved material in the "soup".
Separating liquid from the solid phase performs on "FAN press screw separator" designed for fibrous suspension separation in agriculture and respective industries. Drained solid phase is directed to the production of vermicompost, while the liquid one passes through the 300 micron filter (sieve mesh 50). Batch intended for microfertigation is additionally filtered through the 130 micron filter (sieve mesh 120). The filtered out material is pasteurized in the tank for pasteurization. The overall process lasts for 90 minutes and takes place at 70 ^{o}C temperature.
After liquid is being cooled, finalization begins. A component with a fragrant and protective features being added in the form of infusion. This infusion was prepared according to the following recipe: mixture of herbs – 1.5 kg, boiling water – 36 l. The mixture of herbs is made of: lavender flowers (*Lavandula x intermedia*) – 50 %, leaf of wormwood (*Artemisia absinthium*) - 25 % and Dalmatian pyrethrum flower (*Tanacetum cinerariifolium*) - 25 %. Aforementioned set of plants was selected on the same basis as the previous one. Later studies by other authors have confirmed the exacitude of such a choice, including Al-Naser et Al-Abrass, 2014; EFSA, 2014; Grdiša et al., 2009. Since SHP was intended for foliar application, one more ingredient has been added. It was surface-active component, to act as a biosurfactant and a bioemulsifier. The ingredient was made as an infusion of baby's breath rhizome (*Gypsophila paniculata*) in a ratio: 1 g of drug (*Radix Gypsophilae levanticae*) to 100 ml of boiling water. Apart from this source, such a component can be also extracted from soapwort (*Saponaria officinalis*) (Jang et al., 2013) or even obtained from soil microbes (Sachdev et Cameotra, 2013).
SHP is to be dissolved in water in proportion which is adjusted to the need of each crop. Performing spraying on leaves is the most efficient way of application. On the other hand, whenever foliar application is not possible, SHP can be applied through soil by watering around the plant, or through microfertigation. Also, SHP can be used for hydroponics culture.

Field trial

SHP was produced at the Agyos Athanasios Industrial Estate, Limassol, Cyprus, according to the author's prescription. Sample taken from the regular production was brought to the glasshouse combine „Frendship" in Orenburg, Russia. The trial was performed under the auspices of The Russian Academy of Agricultural Science, Scientific – production department "South Ural", together with Agricultural farm „Frendship". Field trial lasted from March to July 1996. The results of the experiment were considered as a kind of trade secret and have not been published before.
Agrochemical characteristics of soil were determined as per standard procedure of The Russian Academy of Agricultural Science. Soil was sampled from the layer 0-30 cm from each experimental section (there were three sections for three crops). The following characteristics were determined from each sample: content of the humus, salinity, total P and K, HCO_3, Ca, Mg, Na, Cl. Experiment was executed as per following treatments: 1. Control, 2. Basic fertilization + SHP, 3. Basic fertilization, 4.Basic fertilization + additional fertilization + SHP, 5. Basic fertilization + additional fertilization. Field trial included following crops: cucumber, sort "Russian Emerald", pepper, sort "Mercury" and tomato, sort "Rusich". Treatments were repeated twice with random allocation on 100 m^2 sample plots for cucumber and tomato and 50 m^2 for pepper. Fertilization inputs are given in table 1.

Table 1: Fertilization inputs

Kind of fertilization	Treat-ments	Components	Units	Crops		
				Cucumber	Tomato	Pepper
Basic fertilization	2 3 4 5	Manure	t/ha	300	300	300
		Sawdust		150	150	150
		N - P - K	kg/ha	480 – 800 - 480	230 – 800 - 230	480 – 800 - 480
		$MgSO_4$		250	250	250
Additional fertilization	4 5	N - P	kg/ha	37 - 55	-	-
		N - P - K		-	37 – 55 - 37	27 – 92 - 28
		$SiSO_4$		8	8	-
		H_3BO_3		2	2	2
		$KMnO_4$		2	1.5	1.5
		Frequency	days	once	10 - 12	10 – 12

Nitrogen in NPK mineral fertilizer was applied in the form of urea, phosphorus as a granular double superphosphate and potassium as potassium sulphate. Application of SHP was executed according to the following scheme (table 2).

Table 2: SHP inputs

Application	Cucumber		Tomato		Pepper	
	Timing	l/ha	Timing	l/ha	Timing	l/ha
I	Stage of 6 leaves	20	Stage of the first flower cluster	47	Stage of 6-8 leaves	70
II	Stage of blossoming	20	Stage of the second flower cluster	47	Stage of fruit formation	70
III	-	-	Stage of the third flower cluster	47	-	-

Yield was monitored every day throughout the complete process of fruit development. Changes in moisture, nitrate and protein concentration in fruits were observed three times per season – during initial, main and final harvest. Morphological characteristics such as plant height, distance between trusses, stalk diameter and number of fruits were also permanently monitored on tomato and pepper.

Results and discussion

Soil under the glasshouses was chernozem. The determined humus content was almost two times higher than the average for this type of soil in Russia, but at the same time chlorine content was very high as well. Another unfavorable feature of the observed soil was compaction. To avoid hardening of soil there used to enter sawdust. Such measure leads to improvement of air-water soil regime, but also lowers the pH of soil because wood is by nature an acidic substance. Agrochemical characteristics of soil sections with sample plots are given in table 3.

Table 3: Agrochemical characteristics of soil sections with sample plots

Crop	Humus	Salinity	Total P	Total K	HCO_3	Ca	Mg	Na	Cl
	%				meq/100 g				
Cucumber	11.6	0.24	0.13	2.59	0.76	1.6	1.0	0.93	5.5
Tomato	12.5	0.33	0.12	2.74	0.78	3.4	1.5	1.33	7.5
Pepper	12.5	0.31	0.16	3.14	0.85	2.0	1.0	1.28	6.8

Cucumber

The highest seasonal yield of cucumber (15.9 kg/m^2) was achieved with application of basic and additional fertilization plus SHP (table 4). In comparison to the control treatment, increment was 20.4 %. If we focus on treatments No. 2 and No. 3, we will notice that yield increment directly attributed to the SHP was 0.6 kg/m^2, or 4.2 % of the treatment without SHP. Also, due to the application of SHP with basic and additional fertilization, yield was raised by 1.2 kg/m^2, or 8.2 % of the treatment without SHP. Hence, two times sprinkling with 20 l/ha of SHP increases the yield of cucumber by 0.6 - 1.2 kg/m^2.

Table 4: Seasonal yield of cucumber

No.	Treatments	Yield kg/m^2	Yield increase	
			kg/m^2	%
1	Control	13.2	-	-
2	Basic fertilization + SHP	14.9	1.7	12.9
3	Basic fertilization	14.3	1.1	8.3
4	Basic fertilization + additional fertilization + SHP	15.9	2.7	20.4
5	Basic fertilization + additional fertilization	14.7	1.5	11.4

Period of cucumber fruit formation lasted five months (table 5). Most intense fruiting happened in May and June. At that time, treatments with SHP gave 76 % and 77 % of the total seasonal yield. In the interim, fruiting occurs a little bit earlier in comparison to the conventional way of growing.

Table 5: Variation of cucumber yield during the season

Treat-ments No.	Month										Total kg/ha
	March		April		May		June		July		
	kg/ha	%	kg/ha	%	kg/ha	%	kg/ha	%	kg/ha	%	
1	0.26	2	1.0	7	3.66	28	5.89	45	2.39	18	13.2
2	0.30	2	1.21	8	4.37	29	6.95	47	2.08	14	14.9
3	0.29	2	1.10	8	3.96	28	6.38	44	2.57	18	14.3
4	0.32	2	1.58	10	4.87	31	7.31	46	1.83	11	15.9
5	0.29	2	1.18	8	4.12	28	6.79	46	2.35	16	14.7

Changes in the quality of cucumber during the season have the following features: the content of moisture in all treatments and stage of harvest are not essentially different; in treatments with SHP the level of nitrate is reduced.

Table 6: Changes in cucumber quality during the season

Treat-ments No.	Initial harvest			Main harvest			Final harvest		
	Moisture %	Nitrate mg/100 g	Protein %	Moisture %	Nitrate mg/100 g	Protein %	Moisture %	Nitrate mg/100 g	Protein %
1	97.24	763	0.75	97.77	334	0.49	97.93	284	0.38
2	97.04	588	0.71	98.12	226	0.49	98.47	231	0.45
3	97.21	602	0.60	97.86	275	0.44	98.16	175	0.32
4	97.16	654	0.65	97.90	265	0.50	98.11	183	0.43
5	98.14	771	0.70	98.13	401	0.38	97.85	271	0.35

Tomato

The highest seasonal yield of tomato (7.9 kg/m^2) was achieved with application of basic and additional fertilization plus SHP (table 7). In comparison to the control treatment, increment was 14.5 %. If we focus on treatments No. 2 and No. 3, we will notice that rise in yield directly attributed to SHP was 0.2 kg/m^2, or 2.7 % of the treatment without SHP. Also, due to the application of SHP with basic and additional fertilization, yield was raised by 0.1 kg/m^2, or 1.3 % of the treatment without SHP. Hence, two times sprinkling with 20 l/ha of SHP increases the yield of cucumber by 0.1 - 0.2 kg/m^2.

Table 7: Seasonal yield of tomato

No.	Treatments	Yield kg/m^2	Yield increase	
			kg/m^2	%
1	Control	6.9	-	-
2	Basic fertilization + SHP	7.5	0.6	8.7
3	Basic fertilization	7.3	0.4	5.8
4	Basic fertilization + additional fertilization + SHP	7.9	1	14.5
5	Basic fertilization + additional fertilization	7.8	0.9	13.0

Period of tomato fruit formation lasted four months (table 8). The highest yield was recorded in May-June, but treatments with SHP provided almost 50 % of the seasonal yield already in May.

Table 8: Variation of tomato yield during the season

Treat-ments No.	Month										Total
	March		April		May		June		July		
	kg/ha	%	kg/ha	%	kg/ha	%	kg/ha	%	kg/ha	%	kg/ha
1	-	-	0.54	8	2.50	36	3.52	51	0.33	5	6.9
2	-	-	0.64	9	3.02	40	3.67	49	0.17	2	7.5
3	-	-	0.57	8	2.64	36	3.72	51	0.38	5	7.3
4	-	-	0.74	9	3.17	40	3.68	47	0.31	4	7.9
5	-	-	0.61	8	2.82	36	3.98	51	0.40	5	7.8

Changes in tomato quality during the season have similar features as of cucumber: the content of moisture in all treatments and stage of harvest are not essentially distinctive; in treatments with SHP the level of nitrate is reduced and that of protein increased during initial and main harvest.

Table 9: Changes in tomato quality during the season

Treat-ments No.	Initial harvest			Main harvest			Final harvest		
	Moisture %	Nitrate mg/100 g	Protein %	Moisture %	Nitrate mg/100 g	Protein %	Moisture %	Nitrate mg/100 g	Protein %
1	96.31	332	0.71	96.73	210	0.60	95.34	152	0.45
2	96.06	280	0.80	96.18	176	0.71	96.73	144	0.40
3	96.16	310	0.73	97.03	188	0.65	96.60	144	0.44
4	96.51	292	0.78	96.21	241	0.70	97.02	163	0.42
5	97.24	351	0.76	96.03	312	0.38	96.73	212	0.46

The influence of SHP on tomato appearance was manifested through the increased number of fruits per truss. However, this phenomenon does not contribute to the significant increment of the overall yield. On the contrary, treatment with SHP gave trusses with extra but smaller fruits, which is not favorable and at the same time it decreases the harvest quality. In order to avoid such occurrence it will be necessary to undertake further investigations towards a better-tuned composition and dosage of SHP. When comparing treatments with basic fertilization (No. 2 and No. 3), application of SHP leads to a greater plant height, greater distance between trusses, but also thinner stalk. When it comes to treatments with additional fertilization (No. 4 and No. 5), all of this features are slightly smaller in treatments with SHP.

Pepper

The highest seasonal yield of pepper (4.6 kg/m^2) was achieved with application of basic and additional fertilization plus SHP (table 10). In comparison to the control treatment, increment was 27.8 %. If we focus on treatments No. 2 and No. 3, we will notice that yield increment directly attributed to SHP was 0.3 kg/m^2, or 7.5 % of the treatment without SHP. Also, due to the application of SHP with basic and additional fertilization, yield was raised by 0.4 kg/m^2, or 9.5 % of the treatment without SHP. Hence, two times sprinkling with 20 l/ha of SHP increases the yield of cucumber by 0.3 - 0.4 kg/m^2.

Table 10: Seasonal yield of pepper

No.	Treatments	Yield kg/m^2	Yield increase	
			kg/m^2	%
1	Control	3.6	-	-
2	Basic fertilization + SHP	4.3	0.7	19.4
3	Basic fertilization	4.0	0.4	11.1
4	Basic fertilization + additional fertilization + SHP	4.6	1.0	27.8
5	Basic fertilization + additional fertilization	4.2	0.6	16.7

Pepper fruit formation period lasted five months (table 11). Most intense fruiting occurred in April and May. In that period treatments with SHP gave 90 % of the total seasonal yield. At the same time, period of fruit formation was shifted to an earlier period in comparison to the standard way of growing.

Table 11: Variation of pepper yield during the season

Treat-ments No.	Month										Total
	March		April		May		June		July		
	kg/ha	%	kg/ha	%	kg/ha	%	kg/ha	%	kg/ha	%	kg/ha
1	0.08	2	1.2	33	1.68	47	0.24	7	0.40	11	3.6
2	0.13	3	1.63	38	2.11	49	0.23	5	0.21	5	4.3
3	0.09	2	1.33	33	1.87	47	0.27	7	0.44	11	4.0
4	0.14	3	1.81	39	2.22	48	0.22	5	0.22	5	4.6
5	0.09	2	1.4	33	1.96	47	0.28	7	0.46	11	4.2

Similar to other crops, content of moisture in all treatments and at stage of harvest was not essentially different (table 12). In treatments with SHP, the level of protein was increased during the entire harvest season. However, with nitrates it was a different case. In principle, their content decreases with time, but the intragroup variability was rather strong to draw unambiguous conclusions.

Table 12: Changes in pepper quality during the season

Treat-ments No.	Initial harvest			Main harvest			Final harvest		
	Moisture %	Nitrate mg/100 g	Protein %	Moisture %	Nitrate mg/100 g	Protein %	Moisture %	Nitrate mg/100 g	Protein %
1	94.63	212	0.77	95.34	208	0.71	93.66	176	0.68
2	94.89	183	0.83	95.45	153	0.84	93.30	151	0.73
3	94.70	167	0.81	95.50	156	0.71	93.45	159	0.70
4	94.67	108	0.88	95.26	202	0.82	93.16	180	0.76
5	94.34	232	0.85	95.22	192	0.74	94.17	188	0.74

Treatments with SHP gave higher plants and greater distance between trusses, in both variants – with additional fertilization (treatment No. 4) or without (treatment No. 2). In variant without additional fertilization, treatment with SHP (No. 2) had more branches and fruits compared to its counterpart (No. 3). Finally, with increased fertilization (treatments No. 4 and No. 5) the observed differences got lost.

Conclusions

The obtained results clearly indicate that observed SHP has the capacity of a PGR. In variant when observed crops were provided with basic fertilization, a higher seasonal yield had always been achieved whenever SHP was added. The same applies with variant when observed crops were provided with basic and additional fertilization.

The results also suggest that SHP has the capacity of an uptake improver. For each of the observed crops, other than tomatoes, yield increment directly attributed to SHP was higher in variant when observed crops were provided with basic and additional fertilization, i.e. when larger amounts of nutrition were available.

Nevertheless when we consider the quality of the yield, specifically of tomato, the results are not so unambiguous. Treatments with SHP gave trusses with more but smaller fruits, which is not favorable and at the same time decreases the value of harvest. In order to avoid such occurrence it will be necessary to undertake further investigations towards better-tuned composition and dosage of SHP. Partial explanation for such manifestation probably lies in the fact that observed growing conditions were not optimal for tomatoes. This arises from a rather limited yield. In comparison, average yield of tomato achieved under greenhouses in Cyprus during the same growing season was 15 kg/m^2 and there increment influenced by the same SHP exceeded 15 %, or 2.2 kg/m^2 (personal data base).

COMPARATIVE EVALUATION OF SUPPRESSIVE EFFECTS OF ESSENTIAL OILS ON FUNGAL PATHOGENS

Raoudha KHANFIR BEN JENANA*, Chourouk ZAHAF, Hazem BEN BRAHIM, Cherif HANACHI

Higher Institute of Agricultural Sciences of ChottMariem,Tunisia
*Corresponding author: bjnkh@yahoo.fr

Abstract

Four organic aromatic species: *Artemisia absinthum* (Aa), *Pelargonium graveolens* (Pg), *Cymbopogon citratus* (Cc) and *Santolina chamaecyparissus* (Sc), cultivated in the experimental field of the Technical Center of Organic Agriculture, were harvested. The essential oils of these four species were extracted by hydro-distillationandanalyzed by GC/MS and GC-FID/IK methods. The suppressive effects of the essential oils were tested on four fungal pathogens *Fusarium solani*(Fs), *Fusarium oxysporum* (Fo), *Aspergillus niger* (An) and *Penicillium digitatum* (Pd). The confrontations essential oils /fungi were performed by the disk method. The results show that *Artemisia absinthum* gave the highest rate of essential oil (0.21%) while *Pelargonium graveolens* gave the lowest rate (0.07%). However, the suppressive effects of essential oils are not proportional to the performance; in fact we recorded after 7 days of confrontation in Petri dishes, a total inhibition (100%) of the four fungi by the essential oils of *Pelargonium graveolens* and *Cymbopogon citratus* species. *Santolina chamaecyparissus* had a total suppressive effect (100%) on *Fusarium solani* and on *Fusarium oxysporum*, a partial inhibition on *Aspergillus niger*(21%) and none on *Penicillium digitatum*. Essential oil of *Artemisia absinthum* had a partial suppressive effect on the four fungal strains tested (inhibition ratesregistered were 21% on *Penicillium digitatum*, 24% on *Fusarium oxysporum* and *Fusarium solani*, and 33% on *Aspergillus niger*). Therefore, we may conclude that essential oils can constitute an effective organic antifungal agent that could substitute chemical fungicides.

Keywords:*antifungal effects, essential oils, aromatic species.*

Introduction

Between 60 and 70% of pharmaceutical products are primarily from natural products, including medicinal and aromatic plants. Teixeira da Silva (2004) and Svoboda and Hampson (1999) have shown that aromatic and medicinal plants possess several biological activities with antimicrobial effects, insecticides and herbicides. Several research have focused on the anti fungal effect of the essential oils of plants (Cakir et *al*., 2004, Vidyasagar, 2013, Amri et *al* ., 2013). Other effects of essential oils (EO) have been described such as the reduction of competition from other species (allelopathy) by chemical inhibition of seed germination and protection against the infectious microflora with the fungicidal and bactericidal properties ... etc. (Porter, 2001). Meyer (1989) defines the essential oils as oily substances, volatile and fragrant, aromatic and present in localized plants, in flowers, leaves, fruits, seeds, bark, roots. Moreover, Bruneton (1993) added that essential oils are generally quite complex composition of products containing volatile principles contained in plant and more or less modified during the preparation. According to a study by Deans (2002), the essential oil of geranium inhibits filamentous fungi such as *Aspergillus* and *Fusarium*. The citronella oil also has an antifungal effect by inhibiting several fungi such as Fusarium, *Aspergillus, Alternaria* and *Penicillium* (Onawunmi et al., 1984). The antifungal activity of essential oils of *Biotaorientalis* was studied by Cakir et *al*., (2004) on different strains of phytopathogenic fungi including *Fusariumoxysporum* strains on different crops. Juteau et *al*., (2003) found that the oil

composition of the species *Artemisiaabsinthium* is variable depending on the geographical origin and is mainly antibacterial and antifungal. Citronella gasoline also has an antifungal effect on *Fusarium, Aspergillus, Alternaria* and *Penicillium* (Onawunmi et *al.*, 1984).
In this study, we determined the chemical composition and studied the antifungal activities of EO isolated by hydrodistillation from the fresh leaves of four aromatic species *Artemisia absinthium, Pelargonium graveolens, Cymbopogoncitratus* and *Santolinachamaecyparissus*.

Material and methods

Plant material

The collected plants*Artemisia absinthium, Pelargonium graveolens, Cymbopogoncitratus* and *Santolinachamaecyparissus* were planted in the field in 2008 in an experimental plot of the Technical Centre for Organic Agriculture of ChottMariem (Sousse, Tunisia). Planting distances was25m × 80m. These aromatic plants were grown in rows, irrigated by a drip irrigation system. They were conducted in biological mode and fertilized by compost is well decomposed organic manure and treated with certified organic produce.

Extraction and analysis of essential oils

EO from the fresh leaves of the four species were found by hydrodistillation using a Clevenger type apparatus (Benyelles et al., 2014, Suwei and Dongke, 2014 and Okoh et al., 2010). Essential oils were stored in Eppendorf tubes at 4°C until use. The yield was expressed in percentage (%) and calculated according to the plant fresh weight using the following formula:
R = (PH / PV) * 100
PH: weight of the EO
A: essential oil yield
PV: Plant weight

Essential oil analysis

The identification of essential oil components was performed by GC and GC/MS. GC diagnostic were carried out on an HP5890-series II gas chromatograph (Agilent Technology, California, USA) with Flame Ionization Detectors (FID) characterized by: a fused silica capillary column, non polar HP-5 and polar HP Innowax (30 m × 0.25 mm ID, film thickness 0.25 µm). The temperature of the oven was 50 °C for 1 min, then it is programmed to achieve heating rate up to 5–240 °C/min and held isothermal for 4 min. Injector temperature: 250°C, detector temperature: 280 °C; nitrogen used as a carrier gas (1.2 ml/min); and injected 0.1 ml diluted in hexane1%. The percentage of the constituents was calculated by electronic integration of FID peak areas without the use of response factor correction. Hewlett-Packard 5972 MSD system served for GC/MS analyses: HP-5 MS capillary column (30 m × 0.25 mm ID, film thickness of 0.25 mm) was directly coupled to the mass spectrometry. The comparison of the component mass spectra with those in the Wiley 275 GC/MS library and of their retention indices with literature data (Adams, 2001) served to their identification. Retention indices (RI) were calculated by the retention times of a series of n-alkanes.

Fungal material

Four strains of fungi were used for the antifungal tests *Fusarium solani, Fusarium oxysporum, Aspergillus Niger* and *Penicilliumdigitatum.* The micro-organisms were collected from Plant Pathology Laboratory of the Regional Centre for Research in Organic Agriculture and Horticulture of ChottMariem.

Isolation of fungal strains and study of the antifungal activity of EO

Fungal colonies were regenerated in PDA media and autoclaved. The conidial suspensions prepared from the regenerated colonies were distributed in Petri dishes. Antifungal studies have been evaluated by the method of disc-diffusion described by (Mayachiev and

Devahastin, 2008) and (Hussain et al., 2010). Under aseptic conditions, 8 µl of EO were applied to sterilized Whatman filter paper discs N° 3 (6 mm diameter). Plates were incubated at 25°C for 7days. Diameters of inhibition were measured in millimeter.

Statistical analysis

Statistical analysis of the different parameters was carried out by comparison of means by Duncan testusing the SPSS 20.0 software. The means were separated on the basis of least significant difference at 5% probability level.

Results and discussion

Essential oil yield

Fresh leaves essential oils yields vary from 0.07% to 0.4% (v/w) (Table 1).

Table 1: Essential oil yield of leaves of the species studied.

Species	*Artemisia absinthium*	*Pelargonium graveolens*	*Cymbopogon citratus*	*Santolina chamaecyparissus*
Essential oil yield (%)	0.21	0.07	0.4	0.4

Composition of essential oils

Essential oils of the 4 studied species *(*Aa), (Pg), (Cc) and (Sc)contain respectively 40, 49, 54 and 61 components identified, representing respectively 100%, 98.13%, 99.59% and 99.22% of the total fresh leaves oils. The essential components are illustrated in Table 2.

Table 2: Main components of essential oils extracted and analyzed

	Cymbopogon citratus(Cc)	*Santolina chamaecyparissus*(Sc)	*Artemisia absinthium*(Aa)	*Pelargonium graveolens* (Pg)

Antifungal effect of essential oils

Antifungal activities of the fresh leaves essential oils registered after 7 days are reported in Figures 1 to 4.

Antifungal effect on *Penicilliumdigitatum*

All EO have a variable effect on *Penicilliumdigitatum*(Figure 1). The essential oils of (Cc)and (Pg)completely inhibited the mycelial growth of *Penicillium* (100%). This growth was inhibited by 21% essential oil of (Aa)while the essential oil of (Sc)had no inhibitory effect.

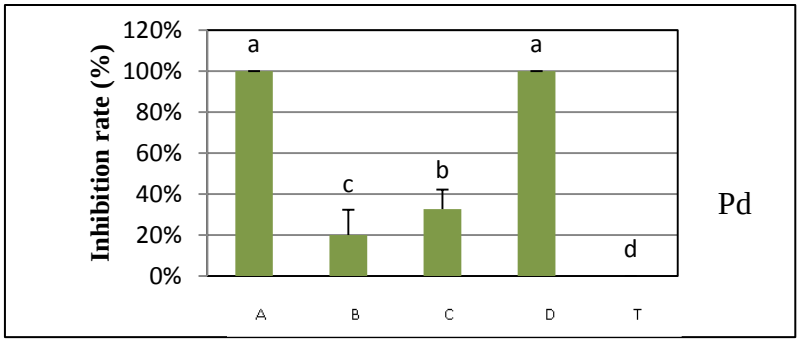

Figure 1. Percentage of inhibition of *Penicilliumdigitatum* (Pd) by the essential oils of *Cymbopogoncitratus* (A) *Santolinachamaecyparissus* (B), *Artemisia absinthium* (C), *Pelargonium graveolens* (D) and control (C) 7 days after confrontation . Values with different letters are significantly different at p<0.05 (Dancun)

Antifungal effect on *Fusarium solani*

Measurements of mycelial growth of *Fusarium solani* showed that the essential oils of Cc, PgSc and have a 100% inhibition whereas inhibition of the essential oil of Aa does not exceed 24 % (Figure 2).

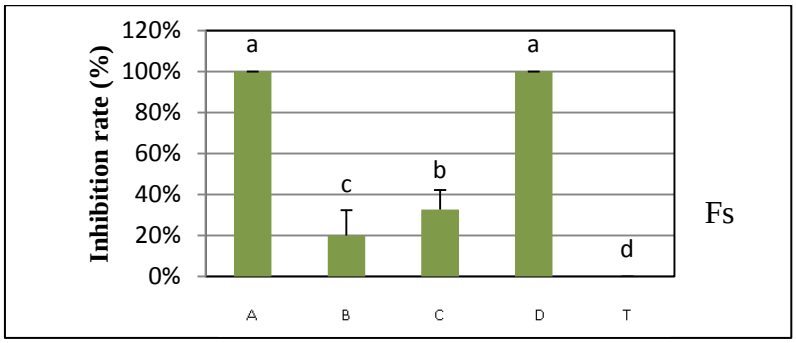

Figure 2: Percentage of inhibition of *Fusarium solani* (Fs) by essential oils of *Cymbopogoncitratus* (A) *Santolinachamaecyparissus* (B), *Artemisia absinthium* (C), *Pelargonium graveolens* (D) and control (T) 7 days after confrontation. Values with different letters are significantly different at p<0.05 (Dancun)

Antifungal effect on *Fusarium oxysporum*

All essential oils have shown an inhibitory effect on *Fusarium oxysporum* (Figure 3). The measurements of mycelial growth of *Fusarium oxysporum* showed that the essential oil of Cc, Pg and Sc have a 100% inhibition, while the Aaessential oil gave an inhibition rate of 24%.

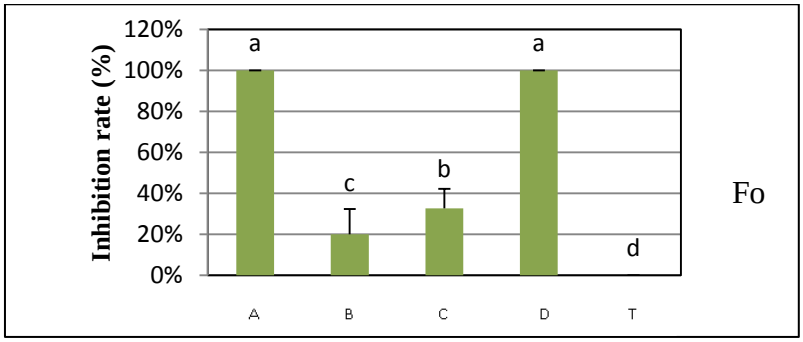

Figure 3. Percentage of inhibition *of Fusarium oxysporum* (Fo) by essential oils of *Cymbopogoncitratus* (A) *Santolinachamaecyparissus* (B), *Artemisia absinthium* (C), *Pelargonium graveolens* (D) and control (T) 7 days after confrontation. Values with different letters are significantly different at p<0.05 (Dancun)

Figure 4 shows that both essential oils of Cc (A) and Pg (D) completely inhibited the mycelial growth of *Aspergillus niger*. Whereas EO of Sc (B) and Aa (C) partially inhibited the fungal growth (21% and 33% respectively).

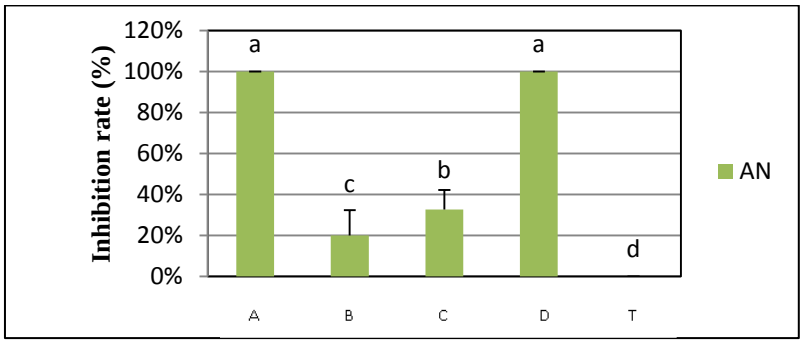

Figure 4. Percentage inhibition of *Aspergillus Niger* (An) by the essential oils of *Cymbopogoncitratus* (A) *Santolinachamaecyparissus* (B), *Artemisia absinthium* (C), *Pelargonium graveolens* (D) and control (T) 7 days confrontation. Values with different letters are significantly different at p<0.05 (Dancun)

All the essential oils tested showed antifungal activities. Our results confirm that several volatile oils are recognized to acquire antifungal and antibacterial properties (Bel Hadj Salah-Fatnassi et al., 2016). Many scientific investigations have been conducted to evaluate the biological activities; of about 60% of the essential oils possess antifungal and 35% of them exhibited antibacterial properties (Chaurasia and Vyas, 1977). A few series of studies have demonstrated the potential antimicrobial effect of essential oils from various *Santolina* species, (Rossi et al., 2007). Our results concerning the antagonist effect of EO on *Penicillium* confirm those of Onawunmi et al. (1984) and Vidyasagar (2013) who described an essential oil inhibiting effect on *Penicillium.* Inhibiting action of Pg established by this study confirms the work of Deans (2002) which shows that the essential oil of Pg inhibits filamentous fungi such as *Fusarium solani*. Our results confirm also those found by Vidyasagar, (2013) which shows the inhibitory effect of essential oils on *Fusarium*. Otherwise, our results showed 100% efficiency for Cc and Pg against all tested fungal species. The reaction of Sc was variable.

Fusarium solani and *Fusarium oxysporum* were most sensitive while *Penicilliumdigitatum* was very resistant.

Conclusion

This research aimed to evaluatethe antagonistic effects of the essential oils of four aromatic species *Cymbopogoncitratus* (A) *Santolinachamaecyparissus* (B), *Artemisia absinthium* (C), *Pelargonium graveolens* through against four fungal strains *Fusarium solani, Fusarium oxysporum, Aspergillus Niger* and*Penicilliumdigitatum* to contribute to biological control on fungal diseases. However molecular tests would be required to accurately determine the mechanisms of action and the molecules responsible for the removal of fungi. Field trials would also be interesting to demonstrate the practical use of essential oils studied.

SUSTAINABLE WHEAT VARIETIES FOR ORGANIC PRODUCTION FOCUSING HARD CONTINENTAL CLIMATE

Zoran JERKOVIĆ*, Željana PRIJIĆ, Radivoje JEVTIĆ

Institute of Field and Vegetable Crops, 21000 Novi Sad, Serbia
*Corresponding author:zoran.jerkovic@nsseme.com

Abstract

Different of sustainable meaning economical and safe the organic production was limited by no use of pesticides. By residua content most critical were underground mostly formed vegetables also applicable after wheat. However, wheat had been important in crop rotation as weed most reductive. Generally for organic production, use of local naturally adapted genotypes by durable resistance to wide spectrum of pathogens was suggested. Level of such wheat varieties resistance to obligate parasites was correlated to growth parameters also. Different by last parameters in controlled and field conditions grain yield as respond to prevalent diseases were estimated in field trials 2011-2016th as well as technological quality parameters partially. Adequate by growth type main in production were of higher grain yield potential at least for 5% of above ones. Even accounted was application of fungicides before variety replacement because of unpredictable yield losses up to 30% by *Puccinia triticina* resistance overcome appeared more economical respecting continual of five years period. Novel race of stripe rust relative former more aggressive caused suggestion that complete resistant ones surround adequate variety type 1:5 in mercantile production. Expected benefit was also across accelerated nearby spreading of most effective insignificant yield influential rusts antagonist and practically increased technological quality by amylase presence. Seed productions of however minor varieties require protection of high seed categories while for mercantile ones untreated could be adequate single for stable organic production. Beside parasite overdevelopment temporary risk, some of could be also valuated trough stable gliadin share decrease and higher protein content.

Key words: *wheat varieties, organic production*

Introduction

Of organic farming area was 1,8 milion hectars involving wheat while basic was no apply of pesticides requiring not treated seed also (Konvalina et al., 2011). The inclusion of wheat in hard continental climate become logical trough results of pesticides residua in underground mostly formed vegetables trough soil while suitable to be sown post harvested without risk to be diseased, toxified or over amounted by heavy metals. Critical throw water deficit appeared to be ten days period after sowing. Maximal rainfall in focused climate was mostly at the end of June as drought-heath stress around middle or earlier by temperature increase more often these century (Jevtić et al., 2010). Also there was no other solution for weed control (Kruepl et al., 2006) and avoiding of same technology for soil preparation, however. The local adapted genotypes or such based varieties had to be propagated by organic farmers (Haring et al., 1999) meaning without processed seed. Wheat was mostly recognizable by long stem respecting addaptation to poor soils and permanent drought stresses (Koepke, 2009). Otherwise, at poor soils the grain yield of intermediate toll varieties with lower protein content appeared higher without significant influence of planting date (Darby et al., 2013). Also, focused was stored protein content of common and organic production (Krejčirova et al. 2006; Capoushova et al., 2007).

The leaf rust cause, most often disease in focused climate characterized by heath-drough stresses during grain filling, effect investigated Jerković and Jevtić (2012) while further were limited borders of possible mistake accounting facultative ones. Simultaneous, deffined were antagonisms between facultative parasites and leaf rust causer. Stable, 3,2 - 3,8% percent of grain yield was lost by 10% increased pathogens severity (Jerković et al. 2103). The location of new rust races appearance could not be predicted annually and such, it become clear that wheat organic production without risks of epyphitotia require apply of varieties with high level of durable nonspecific resistance. The growth parameters as were SAGR and LGR were highly correlated while same values could be achieved by different genes or their combinations. The major such effective gene produced amylase confirmed by its influence on loaf volume also trough results of Denčić et al. (2011) while protein content was however more influential. From side of interactions with facultative parasites, recently questionable appeared *Septoria tritici* transfer other words to find minimal decreased stem lenghts of varieties with durable resistance to obligate parasites enough to susteinable reduce its appearance on upper leaves (Tomerlin, 1985).

Generally, aimed was to investigate of some regionally novel viable varieties expected to be adequate for organic production potential and real grain yield and compare them with those of widespread ones. Nearby sowing and such accelerated anthagonists spreading was predicted to be solution for sustainable production in future. However, the economical difference of these from organic production had to be stated.

Material and Methods

Maximally ten of wheat varieties were simultaneous tested in the field trials 2011-2016th. The trial design was special by parallel same distanced 2m sown 3600 kernels at 6m2 about November while stable performed at experimental fields of Institute of field and vegetable crops, Novi Sad. Stable was added about 50 kg of N at stage of first visible node while 70 kg before sowing was however present. The foliar protection by tebukonazole based fungicide was performed 2011-2013th at beginning of June while grain potential calculated directly. 2014th bentazone was applied in June, 2015th at 8th May while 2016th bentazone was at 22nd May and thiametoxam additional 8th June while controls and these results averaged for real grain yield calculation by maximal severity of each parasite however. Differences between varieties by grain yields were estimated by date of leaf green area disappearing (LAD), stem length, growth parameters as SAGR (the length from the spike to second nodus below divided with stem one) after 3rd June as well as last two levaes distances. LGR or of seedlings first leaf plus stem divided with second leaf length was estimated at seedlings in glashouse during Mart. Additionally during last decade of May and near the end of the vegetation were recognized severities of stable prevalent parasites *Septoria tritici, Pyrenophora tritici repentis* (Ptr) and *Puccinia triticina* and contemporary appeared at last two years *Puccinia striiformis. A*ll of maximal severities were presented in percent of diseased middle or two last leaves. Generally the potential grain yield was accounted by increasing of realized fo r 3% by each 10% of assumed diseases severity on last two leaves as described above. The grain yield potential data was presented directly 2011-2013th by treated plots. Last three years when applied was bentazone compared were simultaneous present varieties same by parasites intensity on flag leaf and LAD.

Results and Discussion

The varieties were classified in three groups according o SAGR values, character not correlated with stem length. In the first group with values ranged 0,58-0,69 in the whole focused period were Evropa 90, Sonata, Simonida and NS 40S while added Ilina. Behind the character were genes with minor nonspecific influence on rust population as Lr Tc and Lr 34 or from Lr 13 same cluster (Prijić et al., 2016). These combination was almost equal by the value when single were present Lr 13 or Lr 14a while Lr Tc replaced Lr 2a as appeared to be

in NS 40S according to reaction to new race stripe rust during last two years and no necrosis due to novel defined gene Lr Tc. In the group with obligate Lr 22b and some of above genes by SAGR 0,66-0,76 always of higher SAGR for et least 0,05 were Rapsodija and Helena as Radojka, Brazda and Azra added during last years (Tab. 1). By the forecasting model it was defined that each 0,01 increase of SAGR from 0,5 decrease these parasites severity for about 2% confirmed by results of in focused period susceptible varieties by specific Lr genes as were Sonata and Evropa 90 while Simonida was such last three years. Longer stem of Azra prolonged LAD while SAGR was exclusive higher than was of Rapsodija. Of Brazda LAD was intermediate by increased sink capacity. The spreading of main rusts antagonist as was *Pyrenophora tritici repentis* from lower leaves was stopped at their middle ones while increased was the intensity at other variety type consequent by larger pustules with prolonged latency period at the beginning of May 2011-2013th. At Sonata infection by facultative parasites was from Rapsodija while of Evropa 90 from Helena stable near sown. Recognized was difference 5-10% in Ptr severity stable higher than was on other varieties in that period, while further intensity was stable lower due to drought before May (Tab. 2). The lesions on varieties with lower SAGR were larger, while such differences also previous recognized Lamary et al. (1989) without related parameters. Former the chance for nearby infection was increased by introduced varieties of other type. By above stated also could be explained the differences of results in trials and wide production.

Tab.2. Maximal severities of prevalent disease causers 2011-2016th

Variety	*Puccinia triticina*	*Puccinia striiformis*	*Pyrenophora tritici rep.*		*Septoria tritici*		
			Middle Leaves	Last	Middle leaves		Last 2011-2016th (2016th)
Helena	30	10	20	10	30	(20)	30
Rapsodija	20	10	25	15	40	(20)	50
Azra	20	T	10	5	20	(10)	
Brazda	20	T	10	5	30	(20)	
Radojka	20	10	20	10	30	(15)	
Evropa 90	40	40	15	10	20	(10)	10
Simonida	30	30	20	10	30	(20)	30
Sonata	50	30	15	5	30	(15)	10
Ilina	40	20	10	5	20	(10)	10
NS 40S	40	20	15	5	25	(10)	10

The Ptr toxins were formed maximal in the period when leaf rust parasite was in latency period and such the effects on chloroses (Strelkov et al., 1998; Manning et al., 2012) avoided as their transfer in seed original formed. It was possible also to compare those different by SAGR but of parasites equal severities as were 40S and Ilina with those with similar LAD. Such focused, difference between NS 40S and Helena was than 9% in average lowest 2011th of 5%. Previous, recognized was also lowest grain protein content of Sonata while 11,9-13,6 of NS 40S near by however maximal achieved grain yield potential. Beside commented, on Sonata leaf rust cause *(Puccinia triticina)* severity was about 30% when treated were controls while stable reached was maximal severity of 50%. About 30% was decreased by antagonists and 20% by SAGR while Ptr was not stable effective from upper leaves. The 2014th was special by early fructification of yellow rust cause (*Puccinia striiformis*) wide visible in Mart. Even than the main losses were by such accelerated *Septoria tritici* fructification on all of genotypes. Trough nearby LAD and stem length Simonida was compared with Rapsodija focusing grain yield while average difference in potential appeared again 5% respecting this time similar protein content. Former maximal severity of both rusts was up to 50% at controls less than on by bentazone treated because of its effect to *Septoria tritici* 2015 and 2016th while 2014th was applied to late proving above stated anthagonism to both rusts (Jerković at al., 2015). Only 2014th Ptr appearance was in traces at middle leaves. However, temperatures below -12^{o}C with snow, continual periods of six days with at least -5^{o}C, intensive draught causing wind, before or after described period inhibited stripe rust cause early appearance as parasite with lowest optimal temperature. Continual cool and wet periods during the May in

last two years allowed late infections of upper leaves simultaneous with *Septoria tritici* transfer while most suitable for both mentioned appeared Simonida partial by no effective specific resistance genes to rust cause. However, the decrease from maximal 10% on varieties with high SAGRs was not possible without at least one adequate gene for specific resistance. When opposite two of could be such effective only when sucrase (Lr 13) was activated by pH fell. Specific Lr genes were predicted to decrease the gliadin share degrading disulphide linkages in gluten formed in leaves as recognized at seedlings Jerkovic et al. (2013a). Unfortunately the major hydrolytic stable genes adequate for the climate whent grain filing begin were not effective to the parasitic population of both rusts (Jerkovic et al. 2014; Jerković et al., 2015). However, the rusts or assumed parasites on varieties with SAGR ranged from 0,66 2014^{th} to 0,75 2012^{th} never could reach severity over 40% at upper leaves. Trough LGR in Mart at about 20^0C in glasshouse values were ranged from 0,8 (Azra) to 1,45 (Ilina). Faster growth of second leaves on account of first one had to be useful especially in spring as weeds competitive character as was also stem increased lenght. Lodging consequential were saprophytes, another motif directed to for safe food production use varieties with as possible short stem with sustainable other consequences. At varieties by stem length about 1 m of systemic parasites reproduction was rare (Jerkovic, pers. comm.). *Septoria tritici* on upper leaves such was decreased compared to Rapsodija. Its severity was 50% 2014^{th} while on Simonida similar by stem length was 30% proving no transfer of inoculum between varieties and difference in pycnide appearance. Higher SAGR was related to shorter flag leaf than one bellow in conditions optimal for the *Septoria tritici* infection in May. Unstability of the character was recognized on Rapsodia while 2016^{th} on Azra caused *Septoria tritici* decrease for 10% comparing to similar high Helena indicating difference in flag leaf growth after infection. Expleinable was by Lr 34 addition to Lr 22b and Lr 13 constelation. 2016^{th} of Azra upper two leaves leaf distance was near equal to Helena but also of NS 40S and Ilina while Rapsodija one was aproximate such shorter as stem lenght. Of last mentioned varieties with lower SAGR stable late resistance to *Septoria tritici* was by replacement of Lr 22a or Lr Tc by Lr 2a on 2D chromosome with Lr 13 resulting less sugar but more water then by Lr 22b during drought conditions. However, could not be achieved in wheat suitable for organic production by respecting other proposed characters.

Conclusion

Focusing parasite and host interactions genotypes with stem length maximaly around 1m and SAGR higher for et least 0,5 of potentially highest yielding varieties in the trial could be stable introduced to organic production without risk of not predictable temporary losses upp to 30% due to obligate parasites. Whenever, *Septoria tritici* with Lr 22b was dicreased for 20% by temporary increased stem for 12cm and susteinable reduced to grain losses stable bellow 10%. Seed could be wide facilitated trough nearby sowing of varieties adequate for organic production around higher yielding ones in ratio 1:5. Mentioned could result proposed grain quality for the first class of 13% while major component had to have at least 12,5%. Expected was average yield increase by rusts antagonist spreading of about 2%. By avoided one tratmant of seed its price for organic production could be decreased insignificant because its selecting was obvious for highest yielding varieties, however. Before system involvement it was more real to extra valuate proposed organic wheat by obligate enzymatic products as amylase presence and protein content while lower gliadin one was also stable opportunuty. However, sustainability of varieties predicted for organic production have to be found previous trough above mentioned former crops extra valuation. At poor fertilized soils or less annual rainfall of organic proposed varieties, profit was predicted to be equal. Otherwise by applied proposed varities of highest SAGR, organic productioner minimal minus of 3% have to be if leaf rust resistance was overcome during five years when accounted were one foliar

protection costs (10% of 5t/ha) at widespread varieties, while the real average had to be about doubled.

Abstract

Bean is known as profitable crop and good preceding crop. Being a short season legume and possible second crop or intercrop, it is suitable in intensive agricultural systems under irrigation but also in sustainable ecological agricultural systems. The aim of this study was to compare the effect of bacterial inoculations on morphological and yield parameters of bean (*Phaseolus vulgaris*). Organic production was conducted on the field in the village Pivnice, while conventional production was conducted in the village Curug (Serbia) during 2014 on the chernosem type soil. Cultivars of beans Belko, Dvadesetica, Maksa, Slavonac, Sremac, Zlatko were used. Before sowing, the bean seeds were inoculated by biofertilizers NS-Nitragin. NS-Nitragin contains a mixture of selected strains of symbiotic bacteria *Rhizobium leguminosarum* bv. *phaseoli*. Laboratory analyses were performed in the Institute of Field and Vegetable Crops, Novi Sad. Determined parameters were: height of plant, height of first pod (distance from the ground to the first pod height), plant weight, number of pods per plant, number of seeds per plant, seed weight. The results showed that there were differences on morphological and yield parameters of bean (*Phaseolus vulgaris*). In organic system cultivar Slavonac had biggest mass of the plant (48.20), number of pods per plant (20.53), highest numbers of seed per plant (68.83), and the largest seed mass (27.29), while the cultivar Sremac in conventional system had the biggest mass of the plant (44.20), number of pods per plant (20.46), and the largest seed mass (21.87).

Keywords: *Dry bean, Morphology, Inoculation, Rhizobium.*

Introduction

Beans (*Phaseolus vulgaris*) are the main crops grown in Serbia to over 20,000 ha with the average annual yield of around 1.3 t/ha. In structure of total vegetable consumption in Serbia, beans take 4.3%. World level of beans consumption is 2.4 kilograms. In Europe consumption is very low and it is 0.7 kilograms, which is for 4.5 kilograms lower than in Serbia. Bean consumption is increasing in Serbia (Webster *et al*., 1997). Beans, grown for seeds, have great economic importance, in addition to protein contains a large number of amino acids necessary for human consumption. Thus, the bean seeds composition are: tyrosine (0.5%), tryptophan (0.17 to 0.70%), lysine (0.68 to 2.18%) arginine (1.47 to 2.66%), cystine and histidine methionine (Govedarica and Jarak 1995). Considering different amino acid composition (Tepic *et al*., 2007), they excellently complement with cereals. With cereals, they make the most important source of starch and energy. They are important as fiber sources, also important in diet (Costa *et al*., 2006). Studies show that eating dry beans is helpful in prevention of heart and blood vessel deceases, diabetes and cancer (rich in fibers, poor in fats). It is recommended in diet of diabetics (assimilates slowly, has a low glycemic and insulin response), individuals with problems with high blood pressure, high cholesterol level,

obesity (Anderson *et al.,* 1999). Substitution of animal with proteins of plant origin protects diabetics from nephropathy (Anderson *et al*., 1999). Besides the seeds beans are used for food and as young pods (Spasojevic, *et al*., 1984).

Today it is widespread crop and can be grown in different environmental conditions.

Because bean is grown on different soils, it is necessary to produce such a mixture of microorganisms that the commercial preparation can be used as inoculants on different soil types or inoculants which contain strains of these microorganisms for soils of extreme acidity values.

There are symbiotic relations between plants and root nodule bacteria in soil under leguminoses. Specific root nodule bacteria for bean is *Rhizobium leguminosarum bv. phaseoli,* and nitrogen quantity that these bacteria can fix is between 20 and 115 kg N ha (Rennie and Kemp, 1983; Rushel *et al*., 1982). Results showed that bacterial inoculation had positive impact on number of pods per plant and number of seed per pods on beans and content of nitrogen in the soil (Milic *et al*., 2003). The species *Phaseolus vulgaris* grows in symbiosis with *Rhizobium leguminosarum bv. phaseoli* whose most effective strains have been incorporated into commercial microbial fertilizers (Milic and Mrkovacki, 2000). The application of rhizobium fertilizers increases the number of bacteria in the rhizosphere, soil microbial activity and the amount of fixed nitrogen (Alexander, 1977; Milic *et al.,* 1999).

An integral part of the system of sustainable agriculture is organic farming. The most efficient production of organic products is on integral organic farms that have crop and livestock production in one unit (Djurovka 2003). For organic fertilizers is used compost, peat, manure, wood ash, as well as other matters arising as a by-product in the food technology and industry. The conventional way of producing food over time based on the fulfillment of the growing demands with a large amount of food is a factor that has significantly influenced the deterioration of the situation with the conventional production, this method is certainly the moment that the trend of society with a magnification of capital contributed to the quality of conventional foods from year to year is reducing with greater use of pesticides, herbicides, chemicals and genetic modification in order to increase profits. The use of increasing doses of mineral nitrogen fertilizers leads to rapid mineralization of humus and other nitrogen compounds, an increase of gaseous nitrogen losses and losses of nitrates from the soil (Knowles 1982).

The aim of this study was to compare the effect of bacterial inoculations on morphological and yield parameters of bean (*Phaseolus vulgaris*) in organic and conventional production. Determined parameters were: height of plant, first pod height (distance from the ground to the first pod height), plant weight, number of pods per plant, number of seeds per plant, seed weight.

Materials and Methods

Studies were conducted at two sites. Production of beans in organic system in the experimental field in the village of Pivnice and production of beans in conventional system in the experimental field in the village of Curug on Chernosem soil type. Determining of morphological characteristics was performed in the laboratory of the Institute of Field and Vegetable Crops in Novi Sad. The experiment was set in 2014 according to the block system in four repetitions. Number of plants taken from each repetition was 3, so 12 plants in total were used for determination. Cultivars that have been used were: Belko, Dvadesetica, Maksa, Slavonac, Sremac, Zlatko. All cultivars were sown in six rows, a total of 42 rows were sown. All six cultivars of beans originate from the Institute of Field and Vegetable Crops in Novi Sad. Sowing was carried out at the optimum time in early May and applied all the necessary agro-technical measures. Spacing between rows was 60 cm, while spacing between plants was 6 cm. The seed beans were inoculated by the microbiological preparation NS-Nitragin

(produced by the Institute of Field and Vegetable Crops). NS-Nitragin containing a mixture of selected strains of symbiotic bacteria *Rhizobium leguminosarum* bv. *phaseoli.*
Samples of plants were taken after harvest for morphological analysis. Determined morphological and yield parameters were: height of plant, first pod height plant weight, number of pods per plant, number of seeds per plant, seed weight.
All data obtained were processed statistically by StatSoft 'STATISTICA 12.0' program. The results were statistically analyzed according to the model of two-factor analysis of variance and consequently used Fisher's LSD test, the homogenity of variance (Excel 2010, DSAASTAT 2014).

Results and Discussion

Within morphological and yield parameters of plant beans in this research was determined the influence of the organic and conventional production on plant height, first pod height (distance from the ground to the first pod height) and plants weight (Tab.1), number of pods per plant, number of seeds per plant and seed weight per plant (Tab. 2). Previous studies of the application of inoculation in the production of beans showed that inoculation of bean seed to individual strains of *rhizobium* or their mixture, beans provide nitrogen almost completely, while nodulation, number of pods, the content of nitrogen in seed and seeds weight depends on the cultivar of bean and properties of *rhizobium* (Marinkovic, 2006).

Table 1: Determination of height of plant, first pod height (distance from ground to first pod height) and plant weight.

	Cultivars	Height of plant (cm)	First pod height (cm)	Plant weight (g)
Conventional	Belko	54.40 a	18.86 c	34.39 b
	Dvadestecia	37.53 d	20.00 c	23.08 d c
	Maksa	43.90 b	19.83 c	34.64 b
	Slavonac	36.30 d	19.06 c	30.10 c b

Determination of plant height

In the conventional production plant cultivar Belko had the longest stem (54.40cm), followed by the cultivars: Maksa and Zlatko, while the lowest and no significant difference in bean had cultivars Dvadesetica, Slavonac and Sremac. Same as in conventional production cultivar Belko had the longest stem in organic production (45.20cm), followed by cultivars Slavonac and Dvadesetica, while lowering plant cultivars were Sremac (31.30cm) and Zlatko (30.23cm).

Determination of first pod height (distance from ground to first pod height)

In cultivation of beans in conventional production the lowest length of the first pod (distance from ground to first pod height) had a cultivar Sremac (16.30) while the other cultivars had a uniform length of the first pod, and significantly higher than the cultivar Sremac. In the organic production Sremac had the highest length of the first pod (16.43) while the other cultivars not a statistically significant different.

Determination of plant weight

The largest mass in the conventional production had cultivar Sremac (44.20) and it is statistically the biggest compared to other cultivars. Cultivar that had a minimum mass is Dvadesetica while the other studied cultivars Belko, Maksa, Zlatko, Slavonac, Sremac have a uniform mass of plants, and there is no statistically significant difference. In organic production, cultivar Slavonac had statistically maximum mass plant (48.20) while other cultivars had a significantly lower weight and not statistically significantly different.

Determination of pods per plant

The highest number of pods per plant was recorded in the production of conventional

cultivars Belko and Sremac with amounts to over 20 pods per plant. In the organic production Sremac had the smallest number of pods per plant, while the highest number of pods per plant had cultivar Slavonac (20.53).

Determination of seeds per plant number

The number of pods per plant and number of seeds per pod as a result give the number of seeds per plant, so many authors are looking at this feature as a component of yield (Stoilov, 1994, Vasic *et al.*, 1997).
The number of seeds per plant in conventional production was the largest established in cultivars Belko, (71.96) and Sremac (61.26). In organic production the largest number of seeds per plant had cultivars Slavonac (68.83) and Belko (66.76). In the experiment, the average number of seeds per plant under the conventional production was estimated at 49.05, while in the organic production the average number (37.81).

Determination of seeds weight

In the conventional production the largest seed weight was observed in the cultivars Sremac and Maksa, while Belko and cultivars Zlatko, Dvadesetica, Slavonac have statistically significantly lower seed weight per plant.
In organic production the largest mass of seeds per plant had a cultivar Slavonac, over 27 seeds per plant and it is statistically the largest weight. The lowest seed weight per plant has a cultivar Sremac 10.35 also in organic production.

Conclusions

In organic and conventional production cultivar Belko has the longest stem.
In case of determining the height of the first pod (distance from ground to first pod height) in the organic production Sremac had the highest length of the first pod, while in conventional the lowest.
In determining the mass of the plant biggest mass has Sremac in the conventional production and Slavonac in organic production.
In the experiment, the average number of pods per plant in the conventional production is at 15.33, while in the organic production 12.9. The number of pods per plant in conventional production is highest at the cultivar Sremac, while in organic production the cultivar Slavonac and is over 20 pods per plant.
The highest numbers of seed per plant had cultivars Belko and Sremac in conventional production while the cultivar Slavonac in organic production.
Within conventional production the largest seed mass was observed in the cultivar Sremac, while cultivar Slavonac in organic production.
When comes to the recommendations of growing beans in organic and conventional production in selecting assortments recommended cultivation of cultivar Slavonac in organic production, while cultivar Sremac in conventional production. For other varieties there are no statistically significant differences in the investigated parameters of the plant so that they can cultivate in all systems of production.

COMPOST EFFECT ON THE YIELD AND COMPOSITION OF ESSENTIAL OILS OF *OCIMUM BASILICUM* "FIN VERT"

Raoudha KHANFIR BEN JENANA*, Ferdaws SMARI, Cherif HANACHI

Higher Institute of Agricultural Sciences of Chott Mariem, Tunisia
*Corresponding author: bjnkh@yahoo.fr

Abstract

Three crops of (*Ocimum basilicum* var Grand Vert) were conducted in the experimental field of the Technical Centre for Organic Agriculture of Chott Mariem (Tunisia). Plants fertilized with sheep manure served as a control and other plants were fertilized with two composts C_1 and C_2 with the respective compositions (30% cattle manure, 30% sheep manure, 30% poultry manure 5% straw and5% olive mill) and (70% cattle manure, 25% poultry manure and 5% straw) and irrigated with the respective juices of both composts prepared with 1volume of compost and 5volumes of water. The extraction of essential oils from leaves was carried out by GC-MS. The results showed that the yields of essential oils have been improved by the tested composts (0.36% with compost C_1, 0.38% with compost C_2 against 0.28% in the control). The composition of essential oils has been modified by the composts. Indeed, rates of the major components of essential oils in the plants fertilized with compost increased: compost C_2 gave the highest levels of the following components Methyl cinnamate, Linalool, 1,8-Cineole 8- and ß-elemene. However, 15-Octadecenoic Acid present in the essential oils of the control plants was not detected in plants treated with composts.

Keywords: *Essential oils, Ocimum basilicum, Chemical composition*

Introduction

At least 60 species and numerous varieties are included in the genus of *Ocimum*, of the family Lamiaceae (Labiatae), include (Sirvastava., 1982). Some *Ocimum* spp. are traditionally used in many Asian and African countries in medicine. (Yusuf et al., 1994). *Ocimum basilicum* L. is an aromatic herb used to add a distinctive aroma and flavor to food (Lee et al., 2005). Essential oils extracted from fresh leaves can be used in food, pharmaceuticals cosmetics and agriculture (Javanmardi et al., 2002; Koba et al., 2009). On the other hand, fertilization with composts and organic juice reduces the risk of toxicity and pollution caused by the use of chemical fertilizers (Zheljazkov et al., 2003). Otherwise, Khalid et al. (2005) established that treated plants with different combinations of organic fertilizers showed a significant increase in growth, yield characters, essential oil percentage and main components of essential oil extracted from dill plants In this context, this work aims to study the effect of compost on the basil essential oil percentage and chemical composition performance.

Material and methods

Plant material

Three rows (25cm × 80cm) of *Ocimum basilicum* var "Grand Vert" plants were cultivated under a greenhouse in the experimental field of the Technical Centre for Organic Agriculture of Chott Mariem (Tunisia). The trial lasted four months and the plants were irrigated by a drip irrigation system and fertilized at the beginning of the assay.

Composts and composts juices

One row of plants was fertilized with well decomposed organic sheep manure and used as control. Two rows were fertilized with two composts respectively: C_1 (30% cattle manure,

30% sheep manure, 30% poultry manure 5% straw and5% olive mill) and C_2 (70% cattle manure, 25% poultry manure and 5% straw) and irrigated with the respective juices of both composts. The composts juices were prepared as follows: Each compost was suspended in tap water(1:5 vol/vol) in a loosely covered 10-liter plastic container. The suspension was incubated for 6 days at 15 to 20°C and daily stirred 5 to 10 minutes (Weltzein, 1992).

Extraction of essential oils

Essential oils (EO) were extracted from 500g of fresh leaves of *Ocimum basilicum* var Grand Vert by hydrodistillation using a Clevenger type apparatus (Benyelles et al., 2014 and Dongke, 2014; Okoh et al., 2010).

Essential oil yields

The yield of essential oil (Y) is defined as the ratio between the mass of the oil obtained after extraction (W') and the mass of the plant material used (W). It is given by the following formula:

Y= W'/W*100

Y: essential oil yield (%);W': essential oil weight (g);W: fresh leaves weight (g).

Essential oil analysis

The identification of essential oil component was performed by GC and GC/MS. GC diagnostic were carried out on an HP5890-series II gas chromatograph (Agilent Technology, California, USA) with Flame Ionization Detectors (FID) characterized by: a fused silica capillary column, non polar HP-5 and polar HP Innowax (30 m × 0.25 mm ID, film thickness 0.25 μm). The temperature of the oven was 50 °C for 1 min, then it is programmed to achieve heating rate up to 5–240 °C/min and held isothermal for 4 min. Injector temperature: 250°C, detector temperature: 280 °C; nitrogen used as a carrier gas (1.2 ml/min); and injected 0.1 ml diluted in hexane1%. The percentage of the constituents was calculated by electronic integration of FID peak areas without the use of response factor correction. Hewlett-Packard 5972 MSD system served for GC/MS analyses: HP-5 MS capillary column (30 m × 0.25 mm ID, film thickness of 0.25 mm) was directly coupled to the mass spectrometry. The comparison of the component mass spectra with those in the Wiley 275 GC/MS library and of their retention indices with literature data (Adams, 2001) served to their identification. Retention indices (RI) were calculated by the retention times of a series of n-alkanes.

Results and discussion

Essential oil yield

The yields of essential oils are higher in plants treated with both composts compared to yields recorded in control C. In fact, results show that the highest yield (0.38%) is recorded with the C_2 treatment, 0.36% are obtained in essential oil fertilized with compost C_1, while the essential oil yield recorded for the control plants is 0.28% (Table 1). Both composts have therefore increased the essential oil extracted rate. This confirms the results of Khalid et al. (2006) who mention in a study on the effect of compost and compost tea on *Ocimum basilicum* that the highest values of herbal essential oil percentage were resulted from the treatments of static compost and its tea.

Table 1: Effect of the composts on the essential oil (%) extracted from *Ocimum basilicum* L. plants

Treatments	**Yield (%)**
C	0,28
C_1	0,36
C_2	0,38

C: Control (decomposed organic sheep manure); C_1 (30% cattle manure, 30% sheep manure, 30% poultry manure 5% straw and5% olive mill) and C_2 (70% cattle manure, 25% poultry manure and 5% straw).

Essential oil composition

The effect of compost on the components number of essential oils is shown in Table 2. The results show that the total number of components is higher in essential oils of plants treated with the compost compared to control plants. Indeed, in the control we recorded 33 components in the essential oil extracted while the plants treated with C_1 compost gave essential oil containing 36 components and those treated with C_2gave essential oil with 38 components. Similar results were found by Kalil et al. (2006), who showed that compost increases the vegetative growth parameters and essential oil contents.

Table 2: Effect of composts on the total compounds number of the essential oil extracted from *Ocimum basilicum* L. plants

Treatments	**Number of components**
C	33
C_1	36
C_2	38

C: Control (decomposed organic sheep manure); C_1 (30% cattle manure, 30% sheep manure, 30% poultry manure 5% straw and5% olive mill) and C_2 (70% cattle manure, 25% poultry manure and 5% straw)

Data in Table 3 show the effect of composts on the compositions ofessential oil in fresh leaves of basil. Our Results show that the major component is Methyl cinnamate while in a study conducted by Khalil et al., (2006), Linalool appears as the major constituent of essential oils extracted from basil leaves. On the other hand, composts affect differently the chemical composition of essential oils analyzed in the leaves of basil. Indeed, the major components 1,8-Cineole, Linalool and Methyl cinnamate increased by the effect of composts compared to control. 15- Octadecenoic Acid and Bornyl Acetate are present only in the control plants (with respective percentages of 3.37% and 1.30%). Composts used affect differently the rate of β-elemene and Epi-bicyclosesquiphellandrene which decreased under the influence of compost C_1 and increased with C_2. These results confirmpartially those mentioned by Khalil et al., (2006)who indicate that herbal essential oil percentage of Linalool and 1.8 cineol increased by compost treatment and with results of Zheljazkov et al., (2003) who found that addition of compost to the growth medium increased Linalool and did not change other constituents such as 1,8-cineole, and Bornyl Acetate.

Table 3: Effect of the composts on the composition (%) of the essential oil extracted from *Ocimum basilicum* L. plants

Components	C	C_1	C_2
15- Octadecenoic Acid	3,37	-	-
1,8-Cineole	11.02	11,65	11,91
Linalool	17,46	17,56	18,21
β-Elemene	4,22	3,42	8,14
Methyl cinnamate	33,79	40,29	43,81
Cis-3-hexene-1-ol	0.14	0.14	0.13
Bornyl Acetate	1.30	-	-
Epi-bicyclosesquiphellandrene	3.23	3.03	5,21

C: Control (decomposed organic sheep manure); C_1 (30% cattle manure, 30% sheep manure, 30% poultry manure 5% straw and5% olive mill) and C_2 (70% cattle manure, 25% poultry manure and 5% straw)

Conclusion

At the end of this study, we determined that the essential oil contents and components were affected by the compost fertilization. The highest essential oil content was determined at plants fertilized with compost C_2 and the lowest content was found in the control. The essential oil composition was also modified by the effect of compost fertilization, three main components (1,8-Cineole, Linalool and Methyl Cinnamate) increased. On the other hand, 15-Octadecenoic Acid and Bornyl Acetate were only detected in essential oil of control. Fertilization with compost might be a mean to modify the composition according to further use of the essential oil.

Abstract

Soil mycoflora analysis from watermelon rhizosphere showed remarkable diversity. The screening revealed the presence of antagonist and pathogenic fungi belonging to 16 species. The highest isolation frequency was for *Aspergillus terreus* (13.82%), then *A. niger* (12.59%), *A. pseudoelegans* (10.81%) and *A. flavus* (9.88%). According to this work, both mesophilic and thermophilic pathogens are *Cladosporium cladosporioides* (6.92%) and *Colletotrichum gleosporioides* (2.59%). For thermophilic fungi, *Gliocladium viridian* (21.44%), *Scytalidium thermophilum* (18.42%) and *Arthrinum* Kunze (17.13%) are the most frequent. *In vivo*, *Trichoderma* species have demonstrated their effectiveness on the degree of symptoms caused by soil-borne pathogens. Indeed, in the case of plants inoculated with *R.solani,M. phaseolina, F. oxysporum, F. solani* treated preventively with both antagonists *T.viride* and *T. harzianum*, the disease severity index did not exceed 0.83. Treatment by *A. niger* (0.17) seemed the most effective against *M. phaseolina* and *F. solani*. Preventive treatment was the most effective for plants inoculated with *F. oxysporum*, treated by *Penicillium italicum* (0.33), and plants inoculated by *M. cannonballus*, treated with *T. harzianum* and *A. niger*.

Introduction

The soil is considered one of the most suitable environments for microbial growth (Kumar et *al*., 2013). The role of the diverse soil organisms could be beneficial or pathogens and soil fungi fulfil both roles and are ubiquitous (Hao-quin *et al*., 2008; Abo *et al.*, 2011). A number of fungi species are known for their role in the agro-ecosystem either because they are associated with crop diseases or because they are used in the biological control of pest or involved in organic matter decomposition (Abo *et al.*, 2011). Fungi are among the most diverse group of organisms on earth (Hammond, 1995). Fungi could be divided according to their tolerance to temperature. Accumulation of organic matter where in warm, humid and aerobic environment provides the basic physiological condition, in these habitats thermophiles may occur either as resting propagules or as active mycelium depending on the availability of nutrients and favourable environment (Khushaldas, 2009). The most available temperature for the development of the majority of fungi is between 20 and 37°C, which are called mesophilic (Maheshwari, 2011). Soil-borne fungi affecting cucurbits caused serious disease known as collapse and vine decline has identified in melon and watermelon, whereas many studies were established on sudden wilt of melon and several soil-borne pathogens such as *Fusarium oxysporum, F. solani* f.sp. *cucurbitae, Macrophomina phaseolina* (Tassi) Goid, *Rhizoctonia solani* and *Monosporascus cannonballus* have been isolated (Boughalleb et ElMahjoub, 2006). *M. cannonballus* Pollack & Uecker was first reported in commercial watermelon field of Gabes (Martyn *et al.*, 1994; Ben Salem, 2009). Resistance to biocontrol microorganisms of fungal pathogens has not been reported and is considered an environmental-friendly approach (Freeman *et al.*, 2002; Eziashi *et al.*, 2007). The mycoparasite ability of *Trichoderma*,

Gliocladium and *Aspergillus* species against some important aerial and soil-borne plant pathogens lead to the development of biocontrol strategies (Dubey *et al.*, 2007; Hajieghrari *et al.*, 2008). In the present investigation a detailed survey of mycoflora of watermelon cropping area was under taken. The screening of the mycoflora was done to quantify, identify and to determine the diversity of fungal species. Based on the above mentioned literatures, this study is an attempt to evaluate the interaction between antagonists and pathogens fungi isolated from the soil.

Material and methods

Mycofloral analysis

Soil samples were collected from experimental plot cultivated previously by watermelon in High Institute of Agronomy Chott Meriem (Sousse, Tunisia). Rhizosphere soil samples were collected from six randomly selected plots in July 2015. Each sample was a mixture of three subsamples per plot collected along transects spaced 2 m apart. The mycofloral analysis of soil samples was conducted. The fungal population of the soil samples was determined by serial dilution agar plate method as described by Waksman (1922). For this, 1g of soil sample was suspended in 10 ml of double distilled water to make microbial suspensions (10^{-1} to 10^{-7}). One ml of microbial suspension of each concentration were added to sterile petri dishes (triplicate of each dilution) containing PDA media (15 ml). One percent streptomycin solution was added to the medium before pouring into petri plates for preventing bacterial growth. The Petri dishes were then incubated at 28°C in dark. The plates were observed daily for three days. Population densities are expressed in terms of Colony Forming Unit (CFU) per gram of soil with dilution factors. The percent contribution of each isolate was calculated as followed: Isolation percent = (Total No. of CFU of an individual Species / Total No. of CFU of all species) x 100. After 2-7 days, fungal colonies appeared on the PDA media. The fungal isolates were transferred to other plates for purification and identification.

Potential antimicrobial activity*in vivo*

This work presents in understanding the mechanisms involved in the interaction of some antagonists with phytopathogenic fungi and plants.

The isolates identified as antagonists were tested *in vivo* for their antagonistic activity against *Fusarium solani*,*F.oxysporum*, *Rhizoctonia solani*, *Macrophomina phaseolina* and *Monosporascus cannonballus*. *In vivo* experiments, was divided into two parts. The first is a preventive treatment of fungal antagonists and the second consisted of simultaneous treatment of watermelon seedlings (*cv.* Crimson Sweet) by pathogens and antagonists isolates. The seedlings were then planted with fifteen plants (5 per replicate) per each treatment. The inoculum was obtained according to each fungal pathogen. *Fusarium* sp. were grown on PDA at 25°C for 4 days until sporulation, then an erlenmeyer flasks containing 50 ml of potato dextrose broth (PDB, 20 g/l) were inoculated with four pieces of each *Fusarium* sp. isolate. Spore production was induced in an orbital shaker and the spores were recovered from culture by filtration and adjusted to 10^6spores/ml. In the case of *R. solani*, *M. phaseolina* and *M. cannonballus*, the isolate were grown on PDA, 20 plates mixed with 2500g of autoclaved potting mix and placed in 20 cm pots. A haemocytometer was used to determine the concentration of the spores (10^7spores/ml).The application of fungal antagonist was carried out by root dipping watermelon seedlings 15 days old into flask containing a conidial suspension of the different antagonist for 30 min, 24h before inoculation and 24h after inoculation by watering each plant a fungal antagonist suspension (10 ml).The pots are then placed in agreenhouse for 60 days. Controls were performed by inoculated the plant with only pathogen in case of positive control (10 ml) and a distilled water (negative control).The experimental protocol was a randomized complete block. For each fungal species one cucurbit

plant randomly distributed with 5 plants per replicate (3 replicates) in each treatment. During the experiment, the plants were carefully removed from the pots at two times (30 and 45 days after inoculation).Disease incidence (%) for the five pathogen was assessed with a scale varying from 0 to 4 (0 = no collapse; 1 = initial wilting – reversible turgor loss (overview of the whole plot); 2 = collapse of up to 50% of plants; 3 = collapse of up to 75% of plants; 4 = total collapse of all plants) (Cohen *et al.*, 2000).The root systems were gently washed in tap water. Each root system was rated for the severity of the pathogen as described in Table 1.

Table 1. Disease severity of watermelon plants inoculated with *F. oxysporum*, *F. solani*, *M. phaseolina*, *R. solani* and *M. cannonballus*.

Fungi	Rating scale	Reference
F. oxysporum	0 = no symptoms; 1 = light vascular discoloration in the stem with or without stunting; 2 = vascular discoloration in the stem, stunting, wilting with or without yellowing of cotyledons; and 3 = dead seedlings.	Vakalounakis and Frangkiadakis (1999)
F. solani	0: healthy; 1: slight yellowing of leaves with slight rot pivot and lateral roots and crown rot; 2: significant yellowing in leaves with or without wilting, stunting of plants, severe rot at the pivot and lateral roots, significant rot and browning of vessels in the stem; 3: death of the plant.	Boughallebet *al.* (2005)
M. phaseolina	0: symptomless, 1: 1 to 3% of shoot tissues infected, 2: 10% of shoot tissues infected, 3: 25% of shoot tissues infected, 4: 50% of shoot tissues infected and 5: more than 75% of shoot tissues infected.	Ravf and Ahmad (1998)
R. solani	0= healthy, 1= 1-20% diseased, 2= 21- 40% diseased, 3= 41-60% diseased, 4= 61-80% diseased and 5= 81-100% diseased.	Mathew and Gupta (1996)
M. cannonballus	0 = no symptoms; 1 = few lesions (covering <10% of root), secondary root rot slight; 2 = rot of secondary roots or lesions covering approximately 25% of the root; 3 = lesions covering at least 50% of the root and dead secondary roots; and 4 = general root rot, most of the root affected.	Aegerteret *al.* (2000)

The Disease severity index and disease incidence were analyzed with the GENMOD procedure using the multinomial distribution and the cumulative logit as link function, and means of the values were separated by χ^2 test at $P < 0.05$ using SAS program (SAS Institute, Cary, NG). The other variables were compared by analysis of variance (ANOVA) and means of the values were separated with Duncan test at $P < 0.05$ using SPSS 20.0 for Windows (SPSS Inc., Chicago, IL, USA).

Results and discussion

Mycofloral analysis

A total of 15 different fungal genera and 33 species were isolated from the soil samples. All fungi were identified on the basis of their cultural and morphological characteristics. The results of this study revealed the presence of mesophilic and thermophilic fungi. Among the mesophilic isolates the genera *Aspergillus* (42%), *Penicillium* (13.21%) were dominant. The most common species are *Aspergillus terreus*, *A. niger*, *A. pseudoelegans*, *A. flavus*, *Cladosporium cladosporioides* and *Penicillium italicum*. For the thermophilic isolates, *Gliocladium catenulatum*, *Scytalidium thermophilum* and *Arthrinum Kunze* were found to be the most identified isolates (Table 2).

***% Contribution= (Total No. of CFU of an individual Species / Total No. of CFU of all species) x 100, (means of nine values per fungal species).*

The environmental factors such as the soil pH, moisture, temperature, organic carbon and nitrogen play an important role in the mycoflora distribution (Kumar *et al.*, 2015).These are the main factors affecting the fungal population that was very high in the soil samples

analyzed. The mycofloral analysis was in agreement with other studies such as Ratnasri *et al.* (2014) and Megha Bhutt *et al.* (2015). Serial dilution method adopted in this study displays highest number of fungal species isolates belongs to different fungal groups (Hussain *et al.*, 2014). This finding indicated that a reservoir of thermophilic and thermotolerant fungi always coexists (Kumar *et al.*, 2015). In relation to genus detected, the prevalence of *Aspergillus* and *Penicillium* in the soil samples is consistent with the reports of Soderlund (2009) and Onyimba et *al*. (2014).

Potential antimicrobial activity *in vivo*

The effectiveness of inoculation of watermelon plants with antagonists applied preventively and simultaneously in reduction of each pathogen infection was indicated according to the parameters measured. Antagonistic activities were also detected *in vivo* using the disease severity index data and specified a significant difference between watermelon plants inoculated with all pathogens and all antagonists, and between sampling date (p<0.05).

Rhizoctonia solani

The preventive treatment of watermelon plants by *T. harzianum*, after 30 and 45 DAI, and by *P. italicum* after 45 DAI, revealed n no typical symptoms of *R. solani* (Disease incidence 0%) (p<0.05). When plants are treated simultaneously, all antagonists showed the same potential antifungal activity at 30 and 45 DAI (p>0.05). Obtained results indicated that *T. viride* applied preventively or simultaneously reduces root infecting fungi (p<0.05), presenting the lowest values at 30 (0 and 0.67) and 45 DAI (1 and 1.33) (control= 2 and 3.5) (Table 5).

Macrophomina phaseolina

M. phaseolina which causes charcoal rot disease in plants is reported to be suppressed preventively by *T. harzianum, P. italicum* and *P. digitatum* according to the disease incidence (%) recorded at 30 DAI (p<0.05). The efficiency of these antagonists was more pronounced at 45 DAI (33.33% (control=100%)). However, only *P. italicum* treated simultaneously generated an inhibitory effect against *M. phaseolina* at 30 DAI (p<0.05). Biocontrol efficacy of all antagonists was more noticed at 45 DAI with disease severity index varied between 0.83 (*A. niger*) and 1.83 (*P. digitatum*) (control=3.67) (Table 5).

Fusarium oxysporum niveum

No wilt symptoms were noticed in watermelon plant inoculated with *F. o. niveum* and treated preventively with *P. purpurascens* and *P. italicum* and simultaneously with *T. harzianum* according to disease incidence (%) at 30 DAI (p<0.05). Among the six antagonists evaluated for potential biological control ability against *F.o. niveum*, only three *T. viride, T. harzianum* and *P. janthinelum* significantly (p<0.05) reduced disease severity index of Fusarium wilt , the first one applied preventively and the other simultaneously at 30 DAI (Table 5).

Fusarium solani cucurbitae

In this study, *A. niger* and *T. harzianum*, applied preventively, effectively controlled *F. s. cucurbitae*, based on the results of disease incidence noted at 30 and 45 DAI, respectively (p<0.05). The protective effect of *T. harzianum* and *Humicola insolans* was higher than *A. niger* following the two sampling date according to the simultaneous treatment. Disease severity index was also significantly low (p<0.05) in combination: antagonists/ *F. s. cucurbitae* inoculated plants and treated preventively and simultaneously. Obtained values were between 0.17 (*T. viride*) and 0.67 (*Humicola insolans*) and from 0.33 (*Humicola insolans*) and 1.67 (*T. harzianum*) at 30 and 45 DAI according to these antagonists applied preventively, respectively (control=2.33). Further protection was observed in combined use of *T. viride* and *T. harzianum* applied simultaneously (0.83; control= 3.83) (p<0.05) (Table 5).

Monosporascus cannonballus

Reduction in disease incidence caused by *M. cannonballus* was detected in the treatments with *T. viride*, *A. niger* (0%) and *T. harzianum* (16.67%) applied preventively ($p<0.05$), and the efficacy of the two *Trichoderma* species was more prominent at 45 DAI (33.33%). These biocontrol agents *T. harzianum* and *T. viride* caused also reduction in incidence when they are applied simultaneously with 0 and 33.33 at 30 DAI ($p<0.05$) and 33.33% at 45 DAI, respectively. In the presence of only the pathogen, disease severity index was significantly high compared with the negative control, addition of any of the biocontrol agents resulted in less root infection. Preventive treatment with *T. harzianum*, *T. viride* (0) and *P. purpurascens* (0.17; control=2) decrease the disease severity in root caused by *M. cannonballus* at 30 DAI ($p<0.05$). However, root infection was less at 45 DAI in the treatments with *A. glaucus* and *Paecilomyces victoriae* ($p<0.05$). Compared with the other biocontrol agents applied simultaneously in the presence of *M. cannonballus*, *T. harzianum* and *T. viride* ($p<0.05$) exerted a significant antagonistic effect showing the lowest values (Table 5).

In vivo essay, dipping root in different spore suspensions of antagonists prior to inoculation of the culture substrate proved their efficiency to reduce the incidence of the soil-borne pathogens in Tunisia. Indeed, Sreedevi *et al.* (2011) have demonstrated that among the five

isolates of *Trichoderma* sp., *T. harzianum* and *T. viride* had maximum antifungal activity against *M. phaseolina*. Monteiro *et al.* (2010) reported that *T. harzianum* were capable of overgrowing and degrading *Rhizoctonia solani* and *M. phaseolina* mycelia. The effectiveness of biological control against *Monosporascus cannonballus* by *Trichoderma* sp. (Khalifa *et al.*, 2008) and indicates that the potential antimicrobial activity is more effective when combined as part of an integrated strategy against this pathogen. Many antagonistic strains have been proved to be effective biocontrol agents in controlled laboratory or greenhouse conditions. *Penicillium* spp., *Aspergillus* spp. and *Trichoderma* spp. (Sabuquillo *et al.*, 2006; Suarez-Estrella *et al.*, 2007; Rojo *et al.*, 2007) are a few among the long lists.

Conclusion

The study revealed that all samples were rich in fungal diversity and among all the fungal species identified *Aspergillus* sp. and *Penicillium* sp. were dominated. This may be due to the toxins produced by *Aspergillus* sp. and antibiotic produced by *Penicillium* sp. prevent the growth of other fungal species. The current study of the interaction antagonists-pathogens provides evidence that suppression of *Fusarium* sp., *M. phaseolina*, *R. solani* and *M. cannonballus* causing the principal soil-borne disease of watermelon and melon in Tunisia can be controlled by using these selected bioagents.

Abstract

Seed health testing to detect seed borne pathogens is an important step in the management of crop diseases. Seed borne pathogens were isolated from vegetable crops (melon, cucumber, tomato and pepper) and their impact on organic farming was evaluated. A direct confrontation of each pathogen and antagonist collected from the same plant was performed. For melon, *Macrophomina phaseolina, Rhizoctonia solani*, *Cladosporium* sp., and *Trichothecium roseum* were confronted against *Aspergillus niger, Aspergillus terreus, Penicillium digitatum, Trichoderma harzianum, Trichoderma atroviride* and *Aspergillus flavus*. The highest inhibition rate was recorded by *T. harzianum* and *T. atroviride* with 60%. For tomato, only *T. harzianum* has reduced the mycelial growth of *Fusarium oxysporum* f. sp. *lycorpersici* (51.80%). Concerning pepper, mycelial growth inhibition rate of *Phytophthora parasitica* was performed by *A.niger* (44.23%) and *T. harzianum (*43%). For cucumber, *Alternaria alternata* was confronted with *T. harzianum, P. digitatum*, and *P. italicum* and showed an inhibition rate of 77.65%, 79.37% and 6.6%, respectively. *In vivo* essay, a disease severity index caused by various pathogens alone and combined with antagonists compared with control plants was accomplished. The pepper plants inoculated by *Ph. parasitica* and treated curatively by *T. harzianum* have recorded a low value (0.26). Treatment by *A. tereus* (0.56) seemed the most effective against *M. phaseolina*. Preventive treatment was the most effective for melon plants inoculated with *R. solani*, treated by *Penicillium digitatum* (0.78), similarly against *T. roseum* (1.33), and for tomato plants inoculated by *F.o. lycopersici* and treated with *T. harzianum* (1.5).

Keywords: *biological control, in vitro, in situ, seedborne fungi.*

Introduction

Plant pathogens present a serious threat to seedling establishment and the potential for plant disease epidemics. Hence, pathogen exclusion by detection and elimination of infested seedlots remains a requisite tactic for seedling production and disease management. Unfortunately, the numbers of contaminated seed within a lot may be low and infested seed may be asymptomatic making their detection difficult. To address these issues seed detection assays have been developed, but many of them have shortcomings that reduce their effectiveness (Walcott, 2003). Seed borne diseases are very important from the following points of view; (i) introduction of new pathogens (ii) quantitative and qualitative crop losses and (iii) permanent contamination of soil (Anselme, 1981; Ora *et al.*, 2011). Fungi are the principal organisms associated with seed in storage (Ora *et al.*, 2011). The fungus is both internally and externally seedborne (Ramachandran *et al.*, 2007). In some cases infected seeds display characteristic symptoms, including discoloration and shriveling (Murakishi, 2002). Additionally, seeds infested by fungi, bacteria and viruses may display no macroscopic symptoms, making visual or physical inspection of seeds useless as a detection assay. Seed-borne fungi decrease protein, carbohydrate, cholesterol contents, iodine values and increase acid quantity (Ahmad *et al.*, 1994; Morrison, 1999). A direct method of testing seeds is by

allowing pathogens to grow from them onto appropriate artificial media. Many selective and semi selective media have been developed for seedborne fungi and bacteria (Toussaint *et al.*, 2001). Seedling grow-out is one of the most applicable and widely used seed detection assays (Lee *et al.*, 1990; Yang *et al.*, 1997) but for successful implementation, infected seedlings must display obvious and characteristic symptoms. Testing seeds for plant pathogens can be a difficult task. Unlike infected vegetative plant tissues, infested seeds can be asymptomatic, making visual detection impossible. Additionally, pathogen populations on seeds may be low, and infested seeds may be non-uniformly distributed within a lot. Many detection assays exist for different seed borne pathogens. Seed treatments with biological, physical and chemical agents and techniques applied to seed to provide protection and improve the establishment of healthy crops (Neergaard, 1977). Biological control is a nature friendly approach that uses specific microorganisms. Commercial preparations of plant disease biocontrol agents are based on the practical application of rhizosphere competent species of bacteria or fungi (Amand and Reddy, 2009). The mycoparasite ability of *Trichoderma* species against some important aerial and soil borne plant pathogens (Elad, 2000; Freeman *et al.*, 2004, Dubey *et al.*, 2007) lead to the development of biocontrol strategies (Hajieghrari *et al.*, 2008). Numerous researches have been focused on searching and selecting antagonist microorganisms on diverse soil pathogens. The aim of this present study is to determine i) isolation and identification of seed borne fungi and ii) the association of pathogens and antagonists.

Material and methods

Screening of seed-borne fungi of vegetables crops

Organic seeds samples were provided by the technical center of organic agriculture (CTAB, Tunisia), which four vegetable crops are collected: melon (cvs. Maazoun, local, Oasis chnini, 2012, Mahdia), cucumber (cv. local), tomato (cv. Rio Grande), and pepper (cvs. Bar-abid, Chaabani) (CTAB, 2013/2014). The collected seed samples were analyzed for the presence of major seed borne fungal. Two hundred seeds were tested for each variety maintaining four replications. Twenty-five seeds were placed on three layers of moist blotting paper (ISTA, 1996) in each glass Petri dish. The Petri dishes were incubated at 25±1°C under 12/12 hrs light and darkness cycle for 7 days. Each seed was observed under strereomicroscope in order to record the presence of fungal colony. In doubtful cases with temporary slides were prepared from the fungal colony and observed under compound microscope. For proper identification of fungi another method was performed, the agar plate method. Surface disinfected seeds (0.1% mercuric chloride) were plated on the PDA medium and plated seeds were usually incubated for 5-7 days at 22-25°C under 12h altering cycles of light and darkness. At the end of the incubation period, fungi growing out from the seeds on the agar medium were examined and identified. Identification was done based on colony characters and morphology of sporulation structures. The results were presented as percent isolation for individual pathogen.

Potential antimicrobial activity

This work presents in understanding the mechanisms involved in the interaction of some antagonists with seedborne fungi and plants. The antagonists isolates identified were tested for their antimicrobial activity *in vitro* and *in vivo*.

Potential antifungal activity *in vitro*

Mycelial disc (4mm diameter) was obtained from the peripherical of five day old mycelial antagonist isolate was placed in front of the pathogen from the opposite edge of the plate. For the control, a mycelial plug of pathogen was placed in the center of the plate. Three replicates were prepared per treatment (pathogen/ antagonist). The plates were incubated at

28ºC and the mycelial lengths of colonies of each pathogen were measured. The inhibition percent was determined by the formula of Hmouni *et al.* (1996): I (%) = (1- C_n/C_0) x 100, which C_n is the radial growth of the pathogen in the presence of the antagonist and C_0 is the radial growth of the pathogen without antagonist.

Potential antifungal activity *in vivo*

This experiment was carried out in greenhouse, sowing the pre-germinated seeds was made in indented trays containing peat sterilized. Germinated seedlings are displaced in a pot at a rate of 3 to 5 plants in each pot. The substrate used in the experiment is a mixture of peat and vermiculite (1:1). The inoculum was obtained according to each fungal pathogen. *Fusarium* sp. and *Trichothecium roseum* were grown on PDA at 25°C for 4 days until sporulation, and an erlenmeyer flasks containing 50 ml of potato dextrose broth (PDB, 20 g/l) were inoculated with four pieces of each isolate. Spore production was induced in an orbital shaker and the spores were recovered from culture by filtration and adjusted to 10^6spores/ml. In the case of *R. solani*, *M. phaseolina*, the isolate were grown on PDA, 20 plates mixed with 2500g of autoclaved potting mix and placed in 20 cm pots. *Phytophthora parasitica* was prepared by placing mycelial disc in distilled water contained in erlenmeyer flasks for 5 days and then they are retained in freezer for one hour for sporulation. Spores of the antagonist were recovered by rinsing the Petri plates with sterile distilled water and the suspension filtering. A haemocytometer was used to determine the concentration of the spores (10^6spores/ml). The application of fungal antagonist was performed 24 h before and after inoculation by watering each plant by fungal antagonist suspension (10 ml). The pots are then placed in a greenhouse for 45 days. Controls were performed by inoculated the plant with only pathogen in case of positive control (10 ml) and a distilled water (negative control). The experimental protocol was a randomized complete block. For each fungal species one plant randomly distributed with 5 plants per replicate (3 replicates) in each treatment. The root systems were gently washed in tap water. Each root system was rated for the severity of the pathogen as described in Table 1.

Table 13 *: Disease severity of seed borne pathogens identified.*

Fungi	Rating scale	Reference
F. oxysporum	0 = no symptoms; 1 = light vascular discoloration in the stem with or without stunting; 2 = vascular discoloration in the stem, stunting, wilting with or without yellowing of cotyledons; and 3 = dead seedlings.	Vakalounakis and Frangkiadakis (1999)
Ph. parasitica	0 = healthy plant, no necrosis on the roots, 0.5 = necrosis limited to the rootlets extremity, 1 = necrosis stopped at the lower half of the primary roots 2 = necrosis up to the collar, 3 = necrosis reaching the collar and adventitious roots, 4 = hypocotyl rot, 5 = death of the plant due to widespread necrosis.	Palloix *et al.*, 1988
M. phaseolina, R. solani and T. roseum	0: symptomless, 1: 1 to 3% of shoot tissues infected, 2: 10% of shoot tissues infected, 3: 25% of shoot tissues infected, 4: 50% of shoot tissues infected and 5: more than 75% of shoot tissues infected.	Ravf and Ahmad (1998)

The Disease severity index was analyzed with the GENMOD procedure using the multinomial distribution and the cumulative logit as link function, and means of the values were separated by χ^2 test at $P < 0.05$ using SAS program (SAS Institute, Cary, NG). The other variables were compared by analysis of variance (ANOVA) and means of the values were separated with Duncan test at $P < 0.05$ using SPSS 20.0 for Windows (SPSS Inc., Chicago, IL, USA).

Results and discussion

Screening of seed-borne fungi of vegetables crops

A total of 12 seed born fungal species were identified. The highest isolation percent was recorded by *M. phaseolina* with 40%, isolated from melon and the morphology of this fungus was in agreement with Snesana *et al.* (2014). Other pathogen was predominant in melon like *R. solani* (13%) showing characteristics consistent with Parmeter (1970). *Trichoderma harzianum* was also detected from melon and cucumber seeds with 21 and 5% respectively. The description is identical to Ahsanur *et al.* (2009). *Aspergillus terreus* was isolated only from melon seed with 13% and the identification was in agreement with Deak *et al.* (2009) and Samson *et al.* (2011).

Table 14 *: Isolation percentage of fungal species identified from vegetables crop.*

Vegeteable crop	**Fungi**			
	Pathogenic	**Antagonists**	**Isolation percent (%)***	
Concombre	*Alternaria alternata*	*Trichoderma harzianum*	10%	5%
Melon	*Macrophomina phaseolina*	*Aspergillus niger*	40%	33%
	Rhizoctonia solani	*Aspergillus terreus*	13%	15%
	Cladosporium sp	*Penicillium digitatum*		7%
	Trichothecium roseum	*Trichoderma harzianum*	8%	21%
		Trichoderma atroviride		10%
		Aspergillus flavus		10%

* **Isolation percent (%) ;**

Potential antifungal activity *in vitro*

Statistical analysis ($p < 0.05$) reveals that all bioagents more or less significantly, inhibited the mycelial growth of all pathogen. Differential biocontrol ability among the six antagonists against pathogens collected from melon, cucumber, pepper and tomato are presented in Table 3. Growth inhibition in the pathogen differed significantly ($p < 0.05$). *T. roseum* isolated from melon displayed a good resistance against all antagonists with potential antimicrobial activity values between 13.97 and 45.56%. *Trichoderma harzianum, T. atroviride P. digitatum* proved to be the most potent bioagents. *F. o. lycopersici* ($p < 0.05$) and *Ph. parasitica* ($p > 0.05$) exhibited a moderate resistance in dual culture with *A. terreus, T. harzianum* and *A. niger*. *T. harzianum* and P. digitatum reduced the radial growth of *Alternaria alternata* successfully with 77.65 and 79.37%, respectively (Table 3).

Potential antifungal activity *in vivo*

The effectiveness of inoculation of plants with antagonists were perceived *in vivo* using the disease severity index data and specified a significant difference between vegetable crop plants among all pathogens and all antagonists (p <0.05). Melon plants seems healthy of *M. phaseolina* (0.56) (p < 0.05) when *A. terreus* was used. When plants are inoculated with *T. roseum* alone or treated with *P. digitatum* obtained results didn't showed differences (p>0.05). The same antagonist generated an inhibitory effect against *R. solani* (0.78). *T. harzianum* (0.27) and combined with *A. niger* (0.53) significantly (p<0.05) reduced disease severity index of *Ph. parasitica.*

This work presented the first seed borne screening from local and varieties vegetable crop seeds. The detected antagonists proved their efficiency to reduce the incidence of the major vegetable crop seed borne pathogens in Tunisia. Most of effective Trichoderma strains produced cell wall lytic enzymes and volatile and nonvolatile toxic metabolites that impede colonization by antagonized microorganisms. Among these metabolites, the production of harzianic acid, alamethicins, tricholin, peptaibols, antibiotics, 6- penthyl-α-pyrone, massoilactone, viridin, gliovirin, glisoprenins, heptelidic acid and others have been described to protect plant from disease (Chet *et al.*, 1997; Vey *et al.*, 2001). Indeed, Etabarian (2006) and Sreedevi *et al.* (2011) have demonstrated that among the five isolates of *Trichoderma* sp., *T. harzianum* and *T. viride* had maximum antifungal activity against *M. phaseolina*. Monteiro *et al.* (2010) reported that *T. harzianum* were capable of overgrowing and degrading *Rhizoctonia solani* and *M. phaseolina* mycelia. Many antagonists strains have been proved to be effective as biocontrol agents in laboratory or greenhouse conditions; *Penicillium* spp. (Sabuquillo *et al.*, 2006), *Aspergillus* spp. (Suarez-Estrella *et al.*, 2007), and *Trichoderma* spp. (Rojo *et al.*, 2007) are a few among the long lists. The antagonists revealed different reactions for the reduction of the mycelial growth of *F.o. melonis. P. digitatum, A. flavus, A. fumigatus, A. terreus* and *A. niger* are classified as the most effective against this pathogen, *P. italicum* is moderately effective (Suarez-Estrella *et al.*, 2007). Hibar *et al.* (2005) showed that tomato plants in a mixture of perlite inoculated with *F.o. radicis-lycopersici* and *T. harzianum* reduced root rot infection. In addition, plants revealed a better vegetative and root growth. Most biocontrol success has been achieved in greenhouse cultivation (Xu *et al.*, 2011), where ecological parameters are less variable. Biocontrol using antagonists represents a potentially attractive disease management approach to reduce the Phytophthora blight, caused by either *Phytophthora capsici* or *P. parasitica* (*P. nicotianae*) (Marini *et al.*, 2014).

Conclusion

The result of the present study reveals that seed borne pathogens are present on most vegetable crop analyzed. Although in certain instances they occurred in trace levels but under suitable environmental condition they may create the disease in epidemic level. Pathogen free seed is the vital input in agriculture. The imported hybrid varieties are treated with seed treating chemicals for maintaining quarantine regulations. But from the present study it was revealed that seed borne pathogens were associated with untreated organic seeds, and it was also noticed that a particular pathogen was observed in a particular variety. So the seed health status was assessed by studying the potential antimicrobial antagonists against the major seedborne pathogens

CHLORINE IN RENEWABLE FUELS - MOBILITY AND EFECTIVENESS OF BINDING IN THE BOILER FURNACE

Danuta KRÓL[1], Sławomir POSKROBKO[2]

[1]Silesian University of Technology, Konarskiego 18, 44–101 Gliwice, Poland

Abstract

The aim of this study is to identify the transformation of chlorine during the combustion process of biomass fuels and waste, and the possibility of its binding in the boiler. The forms of chlorine in the biomass (animals waste) and waste are quite different. Biomass is mainly a chlorine carrier in inorganic combinations. In waste, apart from mineral bindings, chlorine is bound in organic compounds. It affects the behavior of this element in the boiler: the way, the speed and the form in which it is released from the combustible material. This in turn is reflected in its removal (binding) from the gas space of the combustion chamber. This paper presents the results of chlorine migration and binding by lime sorbent in industrial, two-stage combustion installation (I^0 - gasification, II^0- afterburning), during the combustion of fuel formed from municipal and industrial waste. Fuel choice was dictated by the fact that rational management of waste is about their maximum recovery and recycling (in this case the energy recycling). As a binding material hydrated lime was used. Purposefulness of studying the physicochemical and functional properties of solid fuels formed from waste is justified by the fact that only fuels that meet specific technical and operational requirements, including emission, can be used directly in energy sector.

Keywords: *waste, chlorine, calorific value, combustion.*

Introduction

Biomass is mainly a chlorine carrier in inorganic combinations (Johansen et al., 2013), Wei et al., 2005). In waste chlorine, in addition to mineral calls (mainly NaCl), is mostly present in organic compounds, e.g. PVC, PVDC (Nasrullah et al., 2015, Ma et al., 2010). The nature of the chlorine binding determines the behavior of this element in the boiler furnace, i.e. the method, speed and the form in which it is released from the combustible material. Combustion of fuel containing the composition of organically or inorganically bound chlorine, causes serious operational disturbance (Gruber et al., 2015), Shao et al., 2012): (i) the reduction of the softening temperature of ashes due to the presence of alkali and heavy metal chlorides, (ii) high temperature chlorine corrosive degradation of structural steel boiler furnace elements. It is also the cause of the excessive emission of HCl and PCDD/F - harmful and toxic to the environment (Ruokojarvi et al., 200, Abad et al.2002).

The issue presented in this paper is an excerpt from our own experience and operational research in the field of combustion of chlorine-rich industrial waste fuels and waste biomass (in this case animal) (Poskrobko et al., 2012, Poskrobko, 2013). Combustion processes was carried out in a two-stage technology i.e. the I^o - solid fuel gasification and II^o- burning combustible gas (syngas) obtained in I^o. In both cases, the purpose of the study was to observe the HCl capture process in the furnace of the boiler. In the case of fuel from waste incineration, $Ca(OH)_2$ limestone sorbent was used to bind HCl. During combustion of animal waste, HCl was created at a high temperature (about 1100-1200°C), II^o combustion. Reducing the share of HCl in the flue gases took place in an environment of reactive calcium oxide.

Calcium oxide was a product of thermal decomposition of bone material (hydroxyapatite). Fuels from waste were gasified continuously on the grid in I^o installation. In contrast, animal waste were gasified (in continuous operation mode) in adapted for this purpose rotating chamber. The paper presents the possibility of emission reduction (capture) of HCl in thermal conversion processes: (i) fuel from waste, (ii) animal biomass. But not always presented methods can improve boiler operating conditions in terms of their corrosive effect. Such difficulties occur when the animal biomass rich in NaCl is combusted. The test results indicated which dechlorination technologies can be used for recycling wastes significantly different from each other.

Materials end Methods

Fuel properties of the waste fuel

Studies included fuel Pas-r – formed from industrial wastes. This fuel is produced by grinding to an appropriate granulation such waste as: paper, cardboard, foils, textiles, plastic wrap, tape, cables, cleaning rags or tires. Tables 1-3 show the fuel and physicochemical properties - PN-93-Z-15008/02; PN-EN-ISO 9029:2005; PN-ISO 1171:2002 and chlorine gram fraction was denoted in compliance to Polish Standard PN-ISO 587/2000, HHV - PN–ISO 1928:2002 nd PN-Z-15008-04:1993.

Table1. Fuel properties Pas-r

Fuel	Moisture [%]	Flammable fraction [$\%_{dry\ m.}$]	Inflammable fraction [$\%_{dry\ m.}$]	HHV [$kJ/kg_{dry\ .m.}$]	LHV [$kJ/kg_{dry\ m.}$]
Pas-r	5.74	82.80	17.20	20974	19315

Table 2. Elemental composition of flammable substance in fuels and PVC [%]

Fuel	C	H	N	S	Cl	O
Pas-r	63.90	7.60	3.55	1.26	0.52	23.17
PVC	48.91	6.11	0.25	0.05	17.21	27.47

For the purpose of the study, the fuel Pas-r was grained up successively with admixture of recycled polyvinyl chloride PVC. Therefore a number of fuels different in gram share of chlorine was received (Table 3) (Poskrobko et al. 2012).

Table 3. Elemental composition of the fuel flammable substance Pas-r supplemented with PVC recyclate granules [%].

Fuel	Addition of PVC [%]	C	H	N	S	Cl	O
Pas-r 1	0	63.90	7.60	3.55	1.26	0.52	23.17
Pas-r 2	0.5	63.83	7.59	3.53	1.25	0.61	23.19
Pas-r 3	1	63.75	7.59	3.52	1.25	0.69	23.20
Pas-r 4	2	63.60	7.57	3.48	1.24	0.86	23.25

Only the type of chlorine, which was in addition of recycled PVC was clearly defined. Obtained model fuel were mixed with different amounts of limestone sorbent $Ca(OH)_{2,}$ in order to reduce the mobility of chlorine in the gasifier chamber. Limestone sorbent was in the form of a fine powder. Then the gasification of the fuel Pas-r 1÷4 was carried out. In these processes, concentrations of basic gas products or hydrogen chloride were measured. HCl emission measurement results were converted into relative emission (Φ) - extensively discussed in papers (Poskrobko et al. 2012).

Fuel properties of animal waste

Chlorine in animal waste is associated with alkali metal chlorides KCl, NaCl. Hydrogen chloride is formed in the high temperature environment of the combustion chamber (II^o) in an indirect way. Substrates belonging to the waste gases are $NaCl_{(g)}$, $KCl_{(g)}$, SO_2, H_2O and O_2.
The study included slaughterhouse waste (tripe, fat, bones, feathers, sludge, slush, bristles, blood), and meat and bone meal.. Each time the waste came from another supplier (Tables 4) . The heat of combustion is determined using the LHV calorimetry technique. If the tested material is animal waste, it creates great difficulties in applying the calorimeter bomb to tests. It is very difficult to obtain a representative and homogeneous sample. As the results in Table 5 show, the LHV for particular types of waste are very diverse. In addition, the caloric content of the same type of waste with each supply varies greatly. This creates big difficulties, not only analytical but also technological.

Table 4. Results of the first series of research on calorific value

Type of sample	Moisture [%]	Sulfur S [%]	LHV [kJ/kg]
MBM	5.5	0.3972	23244
Sediment	61.9	0.0071	10277
Bones	46.1	0.0071	8456
Tripes	66.0	0.0064	22980
Bristles	66.1	0.7202	10393
Feather	64.4	0.6943	22645
Tripes 2	738	0.0080	6889
Fat	2.9	1.3860	39063
Bones 2	56.5	0.1019	7726
Slush*	48.6	0.1096	28308
Bristles 2	75.1	0.6421	9734
Feather 2	65.5	0.5142	8575
Sediment 2	66.2	0.0046	17066
Blood	20.2	0.3768	21076
MBM 2	6.0	0.4860	19092

*Sample described as slush contained 2 layers: at the bottom-slush, on the top-fat. The bottom layer was taken for studies.

In practice, there is no possibility of charge calibration. With so much different values for calorific values, it creates enormous difficulties in maintaining stable parameters of the combustion process and emissions of SO_2, HCl, CO i NOx.
This shows that in given conditions of the combustion process, one has to deal with the thermal decomposition of hydroxy and carbon-apatites. They are basic constituents of the bone material. At temperatures >700°C they decompose with emiting (among other things) a porous CaO. The reactive CaO is associated with HCl according to the equation:

$$CaO + 2HCl \rightarrow CaCl_2 + H_2O \quad (1).$$

However, the efficiency of HCl capture in high temperatures (1100 - 1200°C) is low, which is extensively discussed in papers (Poskrobko, 2013).

Combustion of fuel Pas-r from industrial waste

Fuels formed from industrial waste were burned in a two-stage combustion technology in plants with a capacity of 1MW (Fig. 1), (Poskrobko et al., 2012). The temperature in the gasification chamber was T_1 = 650°C, in secondary combustion chamber T_2= 1000°C.

Ultimately, the system is designed for thermal disposal of medical waste. Capture of HCl in the furnace was carried out using a limestone sorbent - hydrated lime $Ca(OH)_2$. This was added to the fuel in different proportions. The scope of mobility limitations of chlorine coming out from the fuel in the furnace (chamber) of the gasifier cooperating with a secondary combustion chamber (Fig. 1) was compared and defined (Poskrobko et al., 2012).

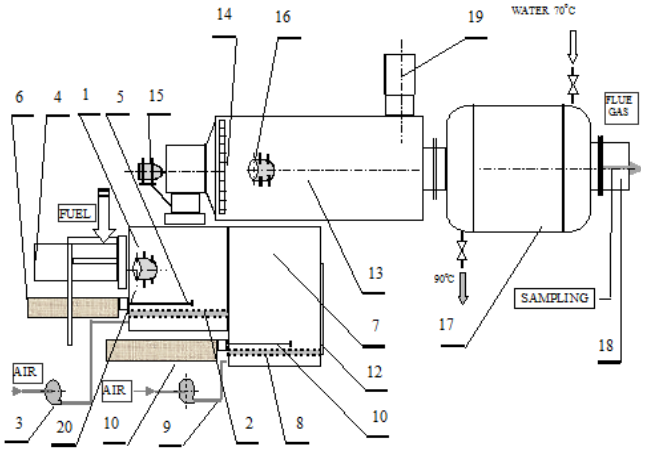

Fig. 1. Diagram of two-stage combustion plant with a capacity of 1 MW: (1) gasification chamber, (2) grid with air nozzles (3) installation of blowing air into the gasification chamber (4), loading system, (5) fuel and ash scraper, (6) drive and mechanism of scraper, (7) combustion cham-ber (8), grate of incineration chamber with air nozzles (9) installation of air blower (10) scraper for removing ash (11) drive and mechanism of ash scraper (12) bleed gates, (13) secondary combustion chamber (14) blinds of combustion air blower, (15) primary burner, (16) burner support, (17) regenerative heat exchanger (18) exhaust

Animal waste combustion

It is contemplated, as in the case of industrial waste fuel, a two-step process of thermal destruction of animal waste. In the first stage I^o gasification was carried out at a temperature of 650-700^{0}C. In the second stage II^o, in the secondary combustion chamber, at a temperature of 1100^{0}C-1200^{0}C, gaseous and solid products of gasification were burned. The study was conducted in a full technical scale. Oxygen test method (Poskrobko 2013) consisted of dispensing variable secondary air through nozzles placed at the outlet of the synthesis gas from the gasifier chamber to the combustion chamber. Loading capacity of waste was 1000kg/h. Fat and meat-and-bone meal constituted fixed caloric input ensuring autothermal combustion. Therefore, for combustion of the mentioned mass flow of waste was consumed 200kg/h of fat and 100kg/h of flour were used. At the same time, in the combustion chamber, thermal decomposition of bone material was taking place. Diagram of the thermal part of the installation is shown in Fig. 2. The hot exhaust gases were cooled in the waste heat exchanger (steam generator) at temperature 200-180^{0}C, and then emitted into the atmosphere through the system of multicyclones, exhaust fan, a bag filter and a chimney. The installation worked continuously. Secondary air blown into the secondary combustion chamber, in each case of the test, was carried out for 1.5 hours, continuously adjusting the performance of the fan 7 (Fig. 2). Measurements of exhaust components emission was made in a continuous manner, by means of exhaust gas analyzer system produced by Environment SA (MIR-IS and Grab HIT 52M models).

Results and discussion

Fuel from waste

During the studies, the scale limit of the mobility of chlorine liberating from the fuel in the gasifier chamber was set. Breakdown of the combustible substance during heating of fuel Pas-R leads to release of chlorine in the form HCl, which is easily released from the PVC, already in the temperature above 180°C. The liberated HCl, on the grill gasifier was bound by

calcium sorbent. The higher the temperature, the more the binding of HCl did not keep the rate of its release from PVC. The resulting calcium chloride $CaCl_2$ underwent partial decomposition at elevated temperatures, releasing HCl again, but the higher the temperature, the faster the process. The obtained experimental data and specific functional dependencies enable: (i) selection of the percentage addition of $Ca(OH)_2$ for fuels with different proportions of chlorine gram share (according to the desired concentration of HCl in the flue gas); (ii) determination of the maximum addition of PVC, which can be loaded to fuel formed from waste; (iii) concluding on the binding efficiency of chlorine in the fuel combustion using calcium sorbents.

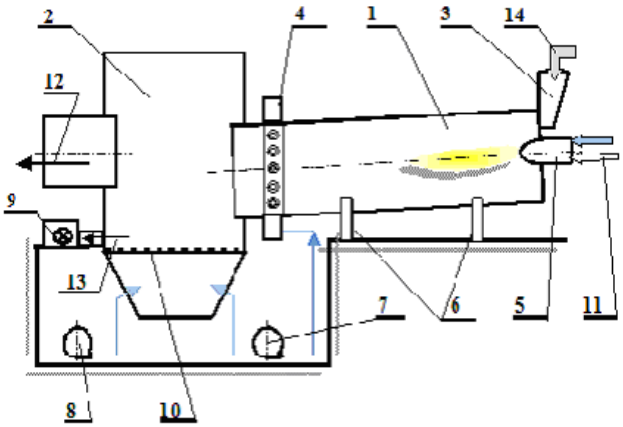

Fig. 2. Diagram of installation for thermal treatment of animal and post-mortem waste, [17] where: (1) rotating gasifier chamber, (2) fluidized bed afterburning synthesis gas, (3) hopper (4) secondary air blower manifold, (5) fat burner, (6) rotating rollers, (7) secondary combustion air blower, (8) tertiary combustion air blower, (9) skimming mechanism (10) grate of secondary combustion chamber, (11) powe-ring the burner with fat and primary air, (12) the direction of the flue gases flow to the waste heat

Determining the percentage of PVC additive for fuels, we can decide of the scale limit of HCl emissions, depending on the percentage addition of $Ca(OH)_2$ to the fuel (Fig. 3). This emission decreases linearly, with the rate of decline being the greater, the greater the addition of PVC to fuel.

Linear relationships: 1, 2, 3, 4 correspond to the consumption of sorbent in cases where the percentage of fuel additive PVC Pas-r was respectively 0%, 0.5%, 1%, 2%. Experimentally determined characteristics allow selection of $Ca(OH)_2$ amount for fuels containing different amounts of PVC. These characteristics make it possible to model the fuel so formed, as not to exceed the specified emission of HCl. Thus, it is possible to make an optimal choice for the treatment of exhaust gases installation. Furthermore, Fig. 3 shows, that fuels with higher content of PVC, thus chlorine in the combustible material, are characterized by greater susceptibility to the calcium sorbent activity, than those with less fuel recyclate.

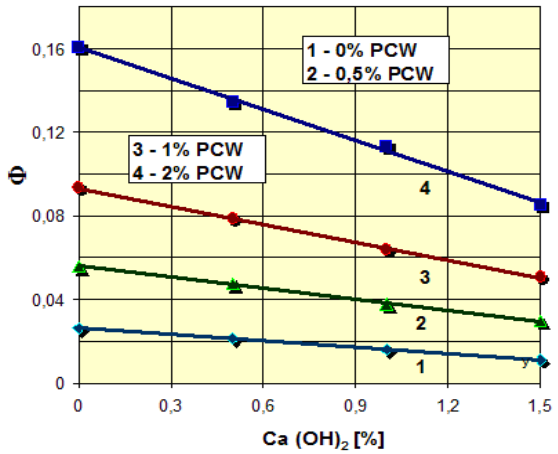

Fig. 3. The dependence of relative concentratio in of HCl in the wet exhaust gas from the sorbent rela- addition $Ca(OH)_2$ to fuel Pas-r 1.

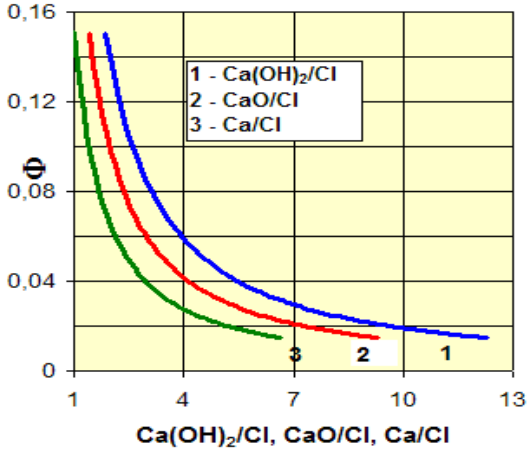

Fig. 4. The relative concentration of HCl wet exhaust gas in comparison to gram tions of calcium forms to chlorine in the fuel.

In Fig. 4 HCl concentration referred to gram relationship: $Ca(OH)_2/Cl$, CaO/Cl i Ca/Cl, in which calcium contained in the fuel and sorbent $Ca(OH)_2$ was recalculated to form: an oxide and elemental. The results are therefore hypothetical. This relationship allows to evaluate the potential use of the sorbent, e.g. in the form of CaO, wherein to this use the same range of HCl concentrations is attributed, which corresponds to the application of the sorbent. It follows that the CaO sorbent can more effectively bind the HCl in the exhaust gas than $Ca(OH)_2$.

Animal waste

The increase in the concentration of HCl in the flue gases is due to the presence of potassium and sodium sulfatizing reaction, affecting simultaneously reduction in SO_2 concentration. It is ndicated by the results presented in (Poskrobko 2013). The formation of HCl may also be promoted by of secondary processes of HCl formations from Cl_2.

Fig.5 illustrates HCl concentration changes as a function of the percentage share of oxygen in the exhaust gas. It can be seen that most of the measuring points is in the range of high HCl concentrations of 40-80 mg/Nm^3. The data presented in Fig.5 initially indicate that with the increase of the oxygen content, we may have to deal with the Deacon reaction in the process: $4HCl + O_2 \rightarrow 2Cl_2 + 2H_2O$. The condition for the occurrence of this reaction is the presence of fly ash, which in this case form deposits on the tubes of the waste heat exchanger, where the temperature may fall to 400^{0}C. Two-stage combustion technologies are characterized by relatively high emissions of fly ash when compared to other technologies e.g grate technologies, which promotes intensification of the deposition on the tubes of the heat exchanger. After cleaning the tubes in the waste heat boiler (after removal of deposits from the walls of the tubes), in conditions of excess air - oxygen saturation (> 12% O_2 in gases), there was no decrease in the concentration of HCl in the flue gas (Fig.6). This may indicate that in the absence of sediment, which catalyze the oxidation of HCl, Deacon reaction does not occur. This is a process which negatively affects the stability of heating surfaces (superheating, Cl_2 diffusion) and the heat exchange efficiency decreases.

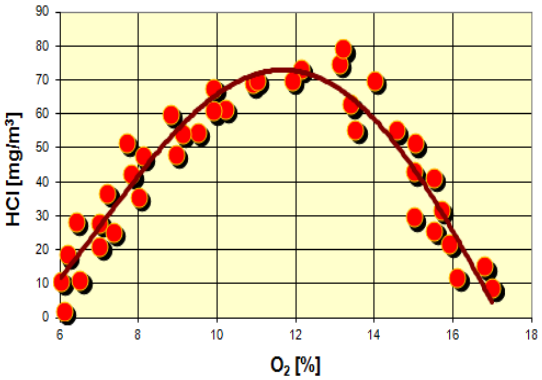

Fig. 5. HCl = f(%O_2)

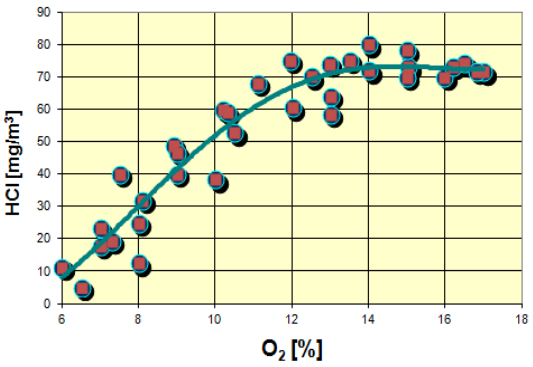

Fig.6. HCl = f(%O_2) – after removal of sediments

Fig. 7 shows the effect of SO_2 concentration on the formation of HCl for the O_2 content in the exhaust gases from 6 to 16% (according to the oxygen test carried out in the experiment). As has the conducted test cycle shown, reduction of the SO_2 in the flue gas causes and increase of HCl to a maximum value of about 80-90 mg/Nm^3, corresponding to the O_2 content in the flue gas of approx. 11 to 13%. In a further step to increase the flow of air (up to a content of O_2= 12-16%) we note a downward trend of HCl, due to the initiation of Deacon reaction on the surface of the waste heat boiler exchanger. The observed phenomenon suggests that in the secondary combustion chamber, at a high temperature occurs the process of HCl formation by sulfatizing $(NaCl)_g$ and $(KCl)_g$.. These process conditions may create reactions of molecular chlorine Cl_2 formation, and secondary processes of hydrogen chloride. It should be noted that the high concentration of SO_2 in the gaseous combustion products (approx. 1600 mg/Nm^3, related to low O_2 share in the exhaust gas) is due to a relatively high sulfur content of animal waste for disposal. Phenomena that occur at high temperature in the secondary combustion chamber (with the participation of reactive CaO) do not affect the HCl emission reduction, on the contrary, the concentration of HCl increases. This process is accompanied by a decrease in the concentration of SO_2. Dependence disclosed during the animal biomass incineration (rich in alkali metal chlorides) HCl = f(SO_2) shown in Fig. 7, requires a testing research in laboratory scale. It seems that such research can significantly bring closer qualitatively and quantitatively the processes forming gaseous environment during the combustion of biomass rich in alkali chlorides.

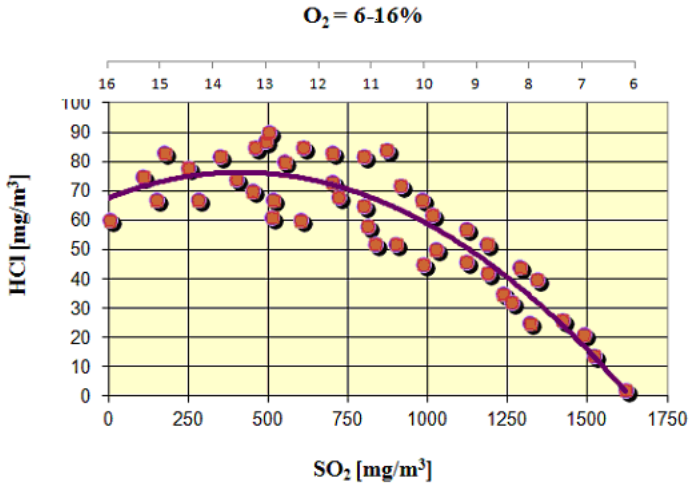

Fig. 7. HCl = f (SO_2) for O_2 = 16-6%

Conlusions

In an experiment conducted in a full technical scale, the capture of HCl intensively proceeded in case of combustion of fuel from waste (Pas-r) rich in chlorine. The process of HCl capture with lime sorbent $Ca(OH)_2$ was ran in the furnace, mainly in its first stage (I^o), i.e. on the grill of the gasifier. On the gasifier grate the fuel was fed, with different Cl and limestone sorbent $Ca(OH)_2$ share. Dechlorination process proceeded more intensively for fuel with a high percentage of the element Cl i.e. fuel with a large addition of recycled PVC. For example, the fuel Pas-r 4, where the proportion of Cl = 0.86, dechlorination of gaseous products was intense - the process was of about double the efficiency. Fuels with lower rate of Cl (0.69%, 0.61%, 0.52%)- dechlorination process was less intense with the same amount of lime sorbent added. During the two-stage combustion of animal waste, the presence of reactive waste lime sorbent CaO, does not produce significant results in the dechlorination process. In general, HCl formed in the oxidizing zone (T = 1100-1200°C) due to sulfatizing of pairs NaCl(g) and KCl(g), does not react with highly reactive CaO, which in turn arises from the decomposition of bone material. It should be noted that the proportion of CaO in the secondary combustion chamber is high and the ash content is approx. 35 - 45%. At the same time CaO is actively involved in the flue gas desulfurization. Looking for a way to dechlorinate waste gases, the share of air in the combustion process was increased. Firstly noted was the growth of HCl formed by sulfatizing alkali chlorides, and then in the share O_2 in the flue gases, from 12 - 16.5% followed a rapid decline of HCl. That is, this process could take place under conditions typical for the Deacon reaction, on volatile dusts polluting the heating surfaces of the heat exchanger. This phenomenon was confirmed after cleaning the heat exchanger of mineral deposits. The share of HCl in the flue gas, regardless of the O_2 share, was determined at a constant maximum level.

The nalysis of the results shows that much better ecological effects, as regards to the emission of HCl, are obtained in the case of two-stage combustion of fuel from waste, i.e. gasification of fuel and afterburning of synthesis gas in a secondary combustion chamber. In case of fuels formed from waste with a high proportion Cl, the method of HCl capturing from gaseous products of combustion described in the paper (dechlorination), can be successfully implemented. In case of animal waste (because of the nature of the chlorine binding – mineral), the dechlorination process in a two stage furnace practically does not occur. However, it may occur at sufficiently low temperatures (about 400°C) outside the furnace, on mineral sediments deposited in the waste heat exchanger tubes.

EROSION PROCESSES IN THE DRAINAGE BASIN OF THE PREDEJANE RIVER (SOUTHEASTERN SERBIA) IN THE PERIOD 1953-2012

Sonja BRAUNOVIĆ*, Mihailo RATKNIĆ, Tatjana RATKNIĆ, Ljubinko RAKONJAC, Aleksandar LUČIĆ

Abstract

The first organised torrent control works in Serbia started in Grdelica Gorge in the late 19th century because the area was the locus of the most intensive erosion processes. They required the implementation of various methods and structures for torrent control and soil protection against erosion. The works were carried out in drainage basins (biological and biotechnical works) and in torrent channels (technical works). The effects of the performed works on the state of erosion in the drainage basin of the Predejane River were studied through a comparative analysis of the situation in 1953 and in 2012, with the aim of upgrading the methods of water erosion and torrential flood control. The intensity of erosion processes in 1953 was determined on the basis of available erosion maps, whereas in 2012 it was determined by using satellite images and field research. The values of Z erosion coefficient for all reference periods were calculated after Prof Gavrilović's methodology and then used to conduct a comparative analysis of the obtained data.

Key words*: erosion process intensity, drainage basin, torrent control works, Serbia*

Introduction

A large part of the territory of Serbia is threatened by water erosion of different intensity. It must be stressed that 36% of the territory is affected by extensive, intensive and medium erosion processes. There are more than 12 000 registered torrential streams which cause enormous damage and often endanger human lives. The damage includes removal of soil and sediment accumulation in reservoirs and regulated riverbeds (water management aspect), the loss of soil nutrients and sediment accumulation on arable land (agricultural aspect), damage to roads, industrial facilities, settlements, etc (economy in general) and chemical - mechanical pollution of watercourses and reservoirs (ecological aspect).

In order to improve the methods of controlling water erosion and torrential floods, it is necessary to examine the effects of the works carried out so far and their impact both on the state of erosion in the basin and on the protection against torrential floods.

Materials and Methods

The Predejane River (*Predejanska reka in Serbian*) drainage basin is located in southeastern Serbia, in Grdelica Gorge (*Grdelička klisura in Serbian*). It belongs to the municipality of Leskovac (cadastral municipalities of Predejane and Crveni Breg). The Predejane River is a right tributary of the South Morava River (*Južna Morava in Serbian*), into which it flows near the village of Predejane. It has a relatively long course (8.5 km), with a fan-like basin and very narrow and steep gorge-like river valleys. The drainage area is 19.68 km^2, with an east-west direction. The field research was conducted in the period from 2011 to 2012 and together with satellite images and thematic (topographic, geological, soil, land use, erosion, etc.) digital maps it formed the basis for assessing the effects of natural factors, land use changes and anthropogenic factors on the state of erosion in the basin. Land use pattern was studied and defined in 2011 (Braunović and Ratknić, 2010). The structure of the area was

determined by using homogeneous plots, within which productive and unproductive areas were identified and digitized. The following productive areas were distinguished: forests, degraded forests, meadows and pastures, degraded meadows and pastures, alpine meadows and pastures, plough land, vineyards, orchards, house yards and gardens. Unproductive areas included: gullies, rocky grounds, gravel, road network, waterways and construction zone of settlements. This classification was then used to define land use and create a thematic map. We studied the state of erosion in 1953 (before the start of erosion control works) and in 2012 (the current state). The intensity and distribution of erosion processes in 2012 were determined on the basis of a 1:50 000 digital map of erosion. The coefficient of erosion (Z) was determined using land survey data, data on bedrock, soil, climate, and distribution of vegetation for each homogeneous plot (Gavrilović, 1972).

Results and Discussion

Orographic and hydrographic characteristics of the basin are presented in Figure 1. Starting from the mouth of the Predejane River, which is at a height of 295 m, the watershed reaches and exceeds 800 m on both sides, and then gradually increases to the highest point of 1284 m, which is also the farthest point from the mouth. The average decrease in the longitudinal profile is 10.36%. The decrease is the biggest in the section upstream of its confluence with the Samarski Creek (*Samarski potok in Serbian*) (14%). The section is 5.3 km long with a height difference of 739 m. The average decrease downstream of the confluence with the Samarski Creek is 6.04% (a 4.4 km long section) and the height difference is 266 m. The longitudinal profile of the upper and partially of the middle part of the course is very steep, which points to the tremendous energy of the topography and results in erosion and accumulation of sediment in the lower course.

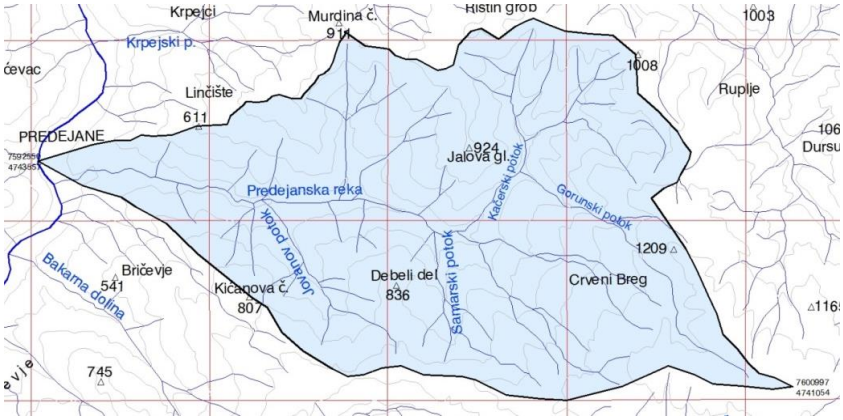

Figure 1. Topographic map of the Predejane River basin (Source: Original)

Table 1. Areas per altitudinal zones in the basin

Area	Altitudinal zones					
	below 300 m	300-500 m	500-700 m	700-1000 m	above 1000 m	Total
km^2	0.3	1.93	4.37	9.38	3.7	19.68
%	1.52	9.81	22.21	47.66	18.80	100.00

Source: Original

The largest part of the basin, or 47.66%, is located in the altitudinal zone from 700 to 1000 meters, while 18.80% of the area is above 1000 meters above sea level. (Table 1).

The bedrock is composed mainly of muscovite schists. Together with large falls and inadequate use of land, it favors the occurrence of erosion processes of different types and intensity. The distribution of bedrock in the basin is shown in Figure 2. Albite-chlorite-

muscovite schists and (dotted) gneisses are found on 86.94% of the total area, while dacites and andesites make 13.6% of the area in the upper part of the basin.

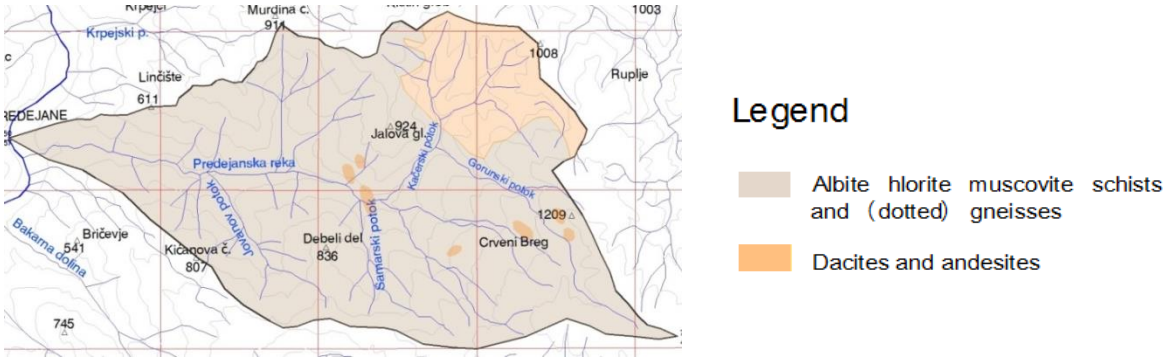

Figure 2. Geological map of the Predejane River basin (Source: Original)

Regarding soil characteristics, it was found that distric cambisol accounts for 19.32 km^2, or 98.1%, while regosol makes only 2.9% of the total area of the basin (Figure 3). Both types of soil are subject to erosion processes.

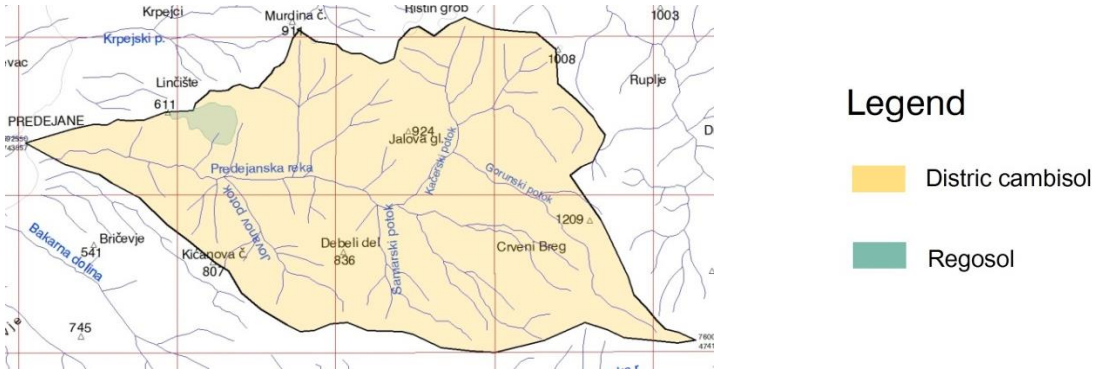

Figure 3. Soil map of the Predejane River basin (Source: Original)

The Predejane River basin is located on the territory of 3 cadastral municipalities. They are characterized by a constant population decline, especially in the CM Crveni breg, located at an altitude of 1083 m (Tables 2 and 3). According to the population projections, Crveni breg will be a depopulated village in 2021 (Penev, 2007). Socio-demographic characteristics of the drainage basin had a significant impact on the development and intensity of erosion processes (Braunović and Ratknić, 2010a).

Table 2. Population statistics by census years

Cadastral municipality	AL masl	Census year							
		1948	1953	1961	1971	1981	1991	2002	2011

Crveni breg	1083	400	392	416	287	169	69	30	13
Total		1500	1545	1809	1760	1894	1959	1743	1500

Source: Original

The basin covers 94 homogeneous plots within which the following productive and unproductive areas were distinguished: arable fields, meadows, pastures, settlements, road network, alluvium (gravel). Land use changes were caused by population migration and agricultural land abandonment. There are now arable fields only in the lower part of the basin, but their surface area has been significantly reduced (Table 4; Figure 4). The abandoned arable fields in the upper parts of the basin have had their vegetation cover recovered, so today there are meadows and pastures and in some parts forests (Braunović, 2011).

Table 3. Population density in the drainage basin of the Predejane River

CM	Area (km^2)	Population density							
		1948	1953	1961	1971	1981	1991	2002	2011

Source: Original

Regarding the distribution of erosion processes in 1953, there were processes of excessive (48.77%), intensive (13.38%) and medium (37.84%) erosion in the basin. On the other hand, the erosion processes were intensive (1.63%), medium (6.95%), weak (48.67%) and very weak (33.50%) in 2012 (Braunović, 2013). Based on Z_{mean} in 1953, the basin was generally

affected by intensive erosion processes (Z_{mean} -0.93), but after performing minor erosion control works the basin had the processes of weak erosion (Z_{mean} - 0.23). However, despite the low values of Z_{mean} in 2012, it was observed that the basin still had the erosion processes caused by poor maintenance of technical structures in the riverbed and inappropriate management of the forest plantations which were established in order to mitigate the erosion processes.

The basin was rehabilitated by performing technical and biological works (Table 8). 9 dams were built of stone in cement mortar, and reforestation was done with Austrian pine (bench terraces and pits). The required technical works in the basin have not been completely conducted. Therefore, the Predejane River, regardless of the general state of erosion in the basin, still poses a potential danger. This has been aggravated by the small scale of the reforestation conducted in the basin (only about 5% of the basin area). Furthermore, the applied forest management does not take into account that these are special-purpose forests. This has caused the occurrence of small erosion loci in the area that was considered to be rehabilitated.

Conclusions

In order to improve the methods of controlling water erosion and torrential floods, this study deals with the effects of conducted erosion control works and their impact on the state of erosion, through a comparative analysis of the situation in the Predejane River drainage basin in 1953 and in 2012.

The natural characteristics of the area are favorable for the development of erosion processes (climate, topography, soil, bedrock, developed hydrographic network).

The intensity of erosion registered in 2012 was primarily the result of the active fight against erosion and the changes in social and demographic factors that caused changes in land use. Positive changes affected the uppermost parts of the basin (the slopes of Kačer, Čemernik and Crveni Breg), areas further away from settlements, where the erosion control works were actually performed.

The land use changes registered in the observation period, along with other factors, contributed to the decrease in the intensity of erosion processes in the Predejane River basin. The Predejane River, regardless of the general state of erosion in the basin registered in 2012, still poses a potential threat. Technical works in the basin have not been completely carried out, the structures are not maintained and the scope of reforestation in the basin is small (only about 5% of the basin). The applied forest management contributes to the recurrence of erosion processes in the areas that have been rehabilitated. This requires continued monitoring of the changes in the erosion processes in the basin, because of the potential risk of torrential floods affecting the lower part of the basin (Predejane village and Predejane town) and the road infrastructure.

GIS BASED LAND USE MODELLING USING SOIL DATA: A CASE STUDY IN THE SURUC PLAIN, SOUTHEASTERN TURKEY

Yüksel ŞAHIN, Mehmet Ali ÇULLU

Ministry of Food, Agriculture and Livestock, General Directory of Plant Production, Turkey
University of Harran, Faculty of Agriculture, Department of Soil Science and Plant Nutrition, Turkey

Abstract

The aim of this study was to develop land use model for Suruc Plain using detailed soil, climate, topographical and spatial land values data. For modeling, detailed soil maps data, topography, geology, climate and socio-economic factors were loaded into a geographic information system (GIS). Soil parameters representing the land characteristics were converted into raster formats and attribute tables. A Digital Elevation Model (DEM) was generated using topographical maps and they were converted into raster format. Aspect (slope direction), slope, and elevation layers were extracted from the DEM. Climate data, consisting of minimum, maximum, and mean temperatures and precipitation, obtained from 16 weather stations were loaded into the GIS media and converted to a map by using geostatistical analyses methods. All these databases in the GIS media were used to model land suitability classes. The model was designed using the Model Builder tools using more files regarding suitable land use type. The analysis suggested that the model allows using various data in the GIS media and it is easily/quickly utilizable and works efficiently for decision making in land use evaluations at agricultural plains.

Keywords: Soil Information Management, Geostatistics, Land Use Evaluation Modeling

Introduction

Land/soil uses are changed according to soil, climate and socio-economical characteristics. In the recent years, increased population and intensive agriculture practices for tackling food security are main purposes of landuse changes. When the lands are used inefficiently, they lose their fertility. Land use systems designed and change according to their potential for high agricultural yield and agricultural sustainability.

Evaluations of the suitability of lands to any sort of activities including agriculture is crucial in terms of maintaining sustainability of land sources, utilizing them more efficiently and also reach to optimum production capacity of soils to achieve reasonable yield. Suitability assessment also guarantees that lands can be used for future generations Agricultural developments not taking into account land capacities will likely fail to stay sustainable and in lands which are utilized inefficiently, productivity will decrease and ecosystems will degrade (Hamdan et al., 2006).

Because of the close relationship between lands and the way they are used, the result of wrong and unplanned land management is irretrievable damage to the lands and eventually, they became useless in terms of agriculture activities. Therefore, another key goal of the assessment of land use is to explain the adverse affects of mismanagements of lands and also give the farmers and decision makers a chance to compare the best management of them (FAO, 1976).

Some soils are good for growing crops and others are inherently unsuitable. Some lies in between. Many lands have limitations because of the conditions in which they have existed. Knowing their potential and limitations can protect soil from degradation by applying optimal management practices. Our goal is to reach their optimum potential for soils (Magdoff and van Es, 2000). Sustainability of agricultural lands have been evaluated on the basis of soil

properties, terrain data, climatic data and Development of Climate Change Scenarios Models (Ahmed et al., 1998; Hamdan et. al., 2006) and DEM (Baja et al., 2002).
In this research, soil polygons, attribute and ancillary data, topographic structure, climate characteristics of plant for optimum growth and spatial land values were integrated to GIS media for modeling lands of Suruc Plain.

Material and Methods

The Study Area

The study area, Suruc plain, is located in southwestern part of Sanlıurfa city, Turkey (37^o 05' N Lat, 38^o 45' Long) covering a total area of 73500 ha (Fig.1). The Suruc plain is a part of the Southeastern Anatolia Project (SAP) as one of the planned regions for open to irrigation.

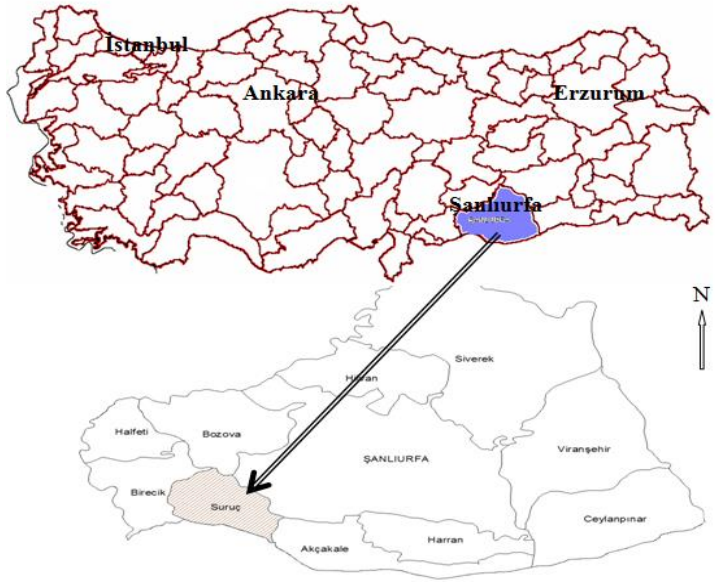

Figure 20. Study Area

Required Data

In the study, soil data were gathered from detailed soil maps prepared by Dinc et al. (1988) (at scale of 1:25000) for General Directorate of Rural Services and storie index maps (at scale 1:5000) with auxiliary soil profile data. A digital elevation model (DEM) was created using topographical maps (at scale of 1:25000) produced by General Command of Mapping. In order to determine the non-agricultural areas (such as roads, residential, industry and other infrastructure sites) geological maps produced by General Directorate of Mineral Research and Exploration (Turkish acronym, MTA) (at scale of 1: 500.000) were used. Long term monthly temperature and precipitation data were obtained from climate stations located nearby the study areas by Turkish State Meteorological Services. Actual land use types were derived from remote sensing data (Landsat TM 7) obtained in 2004. ERDAS Imagine 8.1software was used for image processing and interpretation. The analysis, storage, inquiry and mapping of geographical data, integration vector with raster data were performed using ArcView 3.2 and ArcMAP 9.2; digitization of geographical data using NetCad 4.0 and calculations and reports using SPSS and MS office. Visual Basic was used for programming language.

Parameters used in the database

The digital soil database of the plain was formed by using basic soil parameters and their corresponding table information. All the soil chemical, physical and mineralogical characteristics were integrated with their polygons. This soil attribute table was compiled not only for root depth, but also for each soil horizons. This detailed soil database can give a wide query possibility for different land suitability classes. Suitability of the soils in the study area was evaluated for cotton, lentil wheat and pistachio production. Topographical suitability classes were determined according to the crop requirements for topographical parameters such as aspect (slope direction), elevation and slope. Geology maps at the scale of 1:500.000 was digitized and converted into raster format according to fault zones. Suitability classes for land use types were identified by evaluating the impact of geological structures on land use types. After the analysis of the fault zone and the formation suitability classes, the most suitable areas for land use types were identified.

Long term temperature and precipitation data obtained from 16 meteorology stations were used in the model. Climate data as well as the spatial information including geographical locations and altitude of the climate stations were entered into the GIS environment. The long term monthly, minimum and maximum, the mean temperatures and precipitation data were spatially interpolated using kriging and co-kriging analyses to generate the regional precipitation and temperature surface layers. These layers were used to develop suitability classes for the minimum and maximum temperature and the average precipitation according to the specific requirements of land use types. Profitability and social impact for cotton, lentil, and wheat and pistachio production was evaluated as an effecting parameter.

GIS Analysis and Model Development

A GIS based model was performed in order to carry out the land suitability analysis for specific crops (Sahin, 2007). The model compares existing land uses derived from satellite images with the land suitability classes derived from the GIS analysis. In the actual landuse, farmers make their choices according to custom, local consuetude and marketing situation. This model will compare the actual landuse with ideal suitability usage of land by model running.

The model is comprised of seven stages performed within the GIS environment (Fig 2, 3).

The suitability assessment of the model is based on the requirements of land use types for soil, topography, climate and geology. The model works in the ArcMap environment and model parameters and variables can be identifiable in this environment.

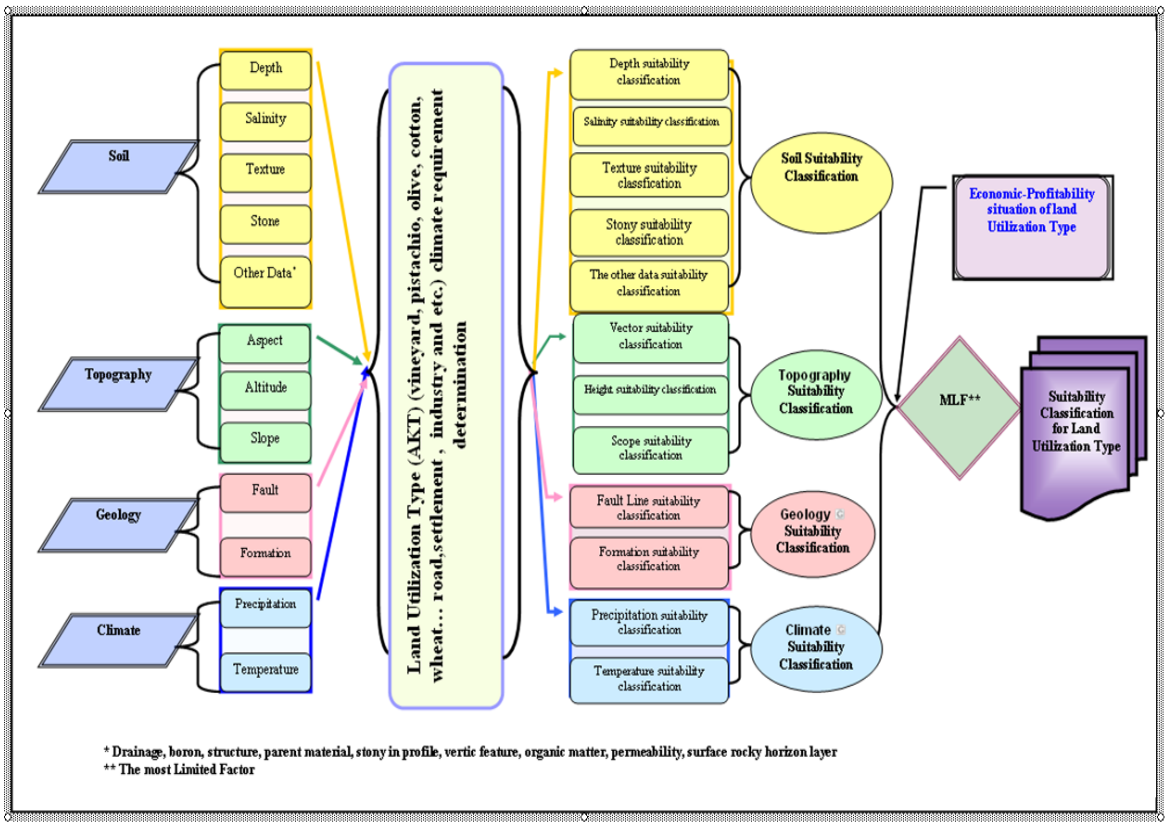

Figure 21. Model Flow Chart Diagram

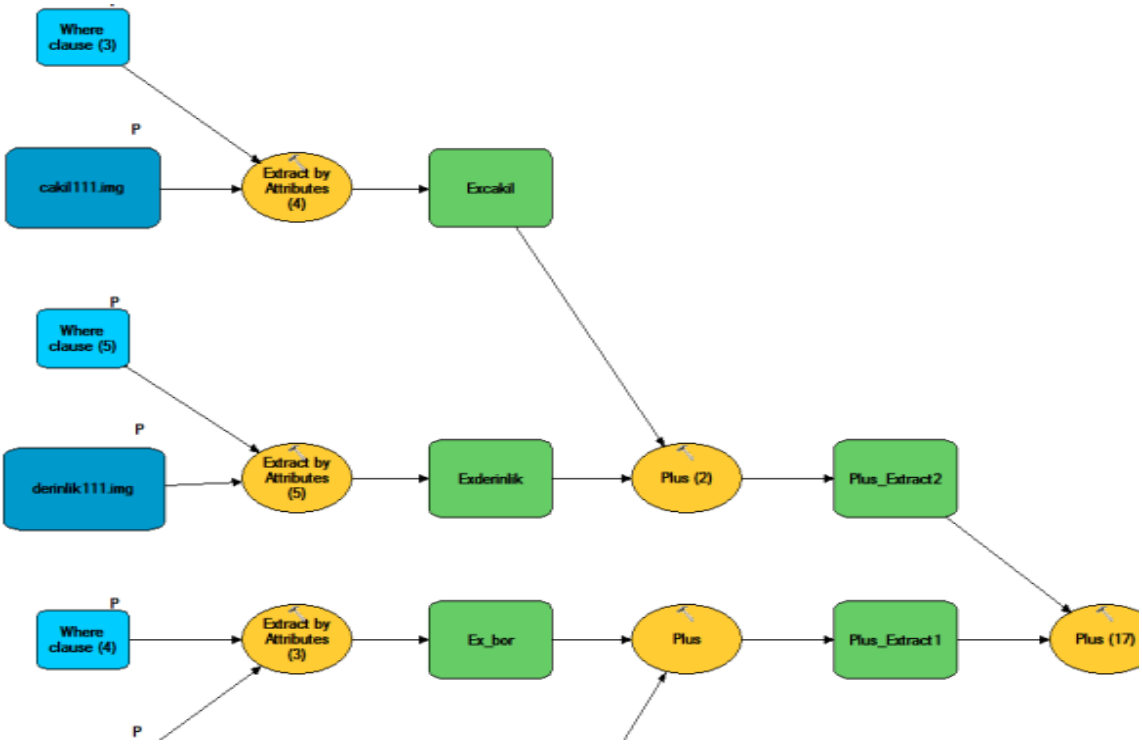

Figure 22. On Model Builder Flow Diagram

Identification of Different Lands Use Type (LUT)

Soil and climate characteristics are main databases in determining of each Land Use Type (LUT). In the study, 5 different groups including horticulture (apple, pear, peach), vegetables

(tomato, potato, and cucumber), dry agriculture (apricot, pistachio), field crops (wheat, barley and lentil) and settlement were evaluated in the model.
In the study area, cotton, lentil, wheat and pistachio were the major crops recently grown at the studied areas and these landuse types mapped by using satellite images (Fig 4).
In the research, the most suitable areas for cotton, lentil, wheat and pistachio potentially and economically grown were determined by model (Sahin, 2007) then the model output were combined with actual land use (Fig 5a,5b,5c,5d). For determination of suitable areas by using the model, the environmental parameters required by Lands Use Type (LUT) soil, topography, climate, geology and social and economical factors were integrated in the GIS environment. All these parameters loaded into model with each ideal grown parameter for each crop groups. The lands of Suruc Plain classified according to FAO (1976) evaluation procedures (Table 1).

Table 17. Determined Land Use Type (LUT) Classes According to Value of Physical Survey Unite Index (PSUI)

PSUI	**Symbol**	**Suitability Class**
100–90	S1	More Suitable
89–70	S2	Suitable
69–50	S3	Moderate Suitable
49–30	S4	Less Suitable
29–10	N1	None Suitable (Temporarily)
9–0	N2	None Suitable (Permanently)

Results and Discussion

As input, a total of five representative soil, topography, geology, climate and spatial land values data were used for modeling the land use of the Suruc Plain. These kind of data can be displayed spatially and include attributes in tabular format, making them suitable for Geographical Information System. When soils are planned in terms of their ability, they can be protected from degradation. Soils are used according to their characteristics which play an important role on the plant growth. In the plant growth, soils characteristics are not only sufficient, other affecting factors such as climate slope and spatial values play important roles. Therefore, modeling data about lands gives an advantage to reach data easily in GIS environment. In this study a land use model was conducted for the Suruc Plain, Southeastern Turkey.

The model was carried out at two stages;

a) Mapping of actual land use from the satellite images (Fig 4).
b) Potential Suitable Map was derived by analyzing the soil, climate, topography, geology and spatial land values of the study area in the GIS media (Fig 5a, 5b, 5c).

After the running the model, six suitability classes were mapped and combined with actual land use.

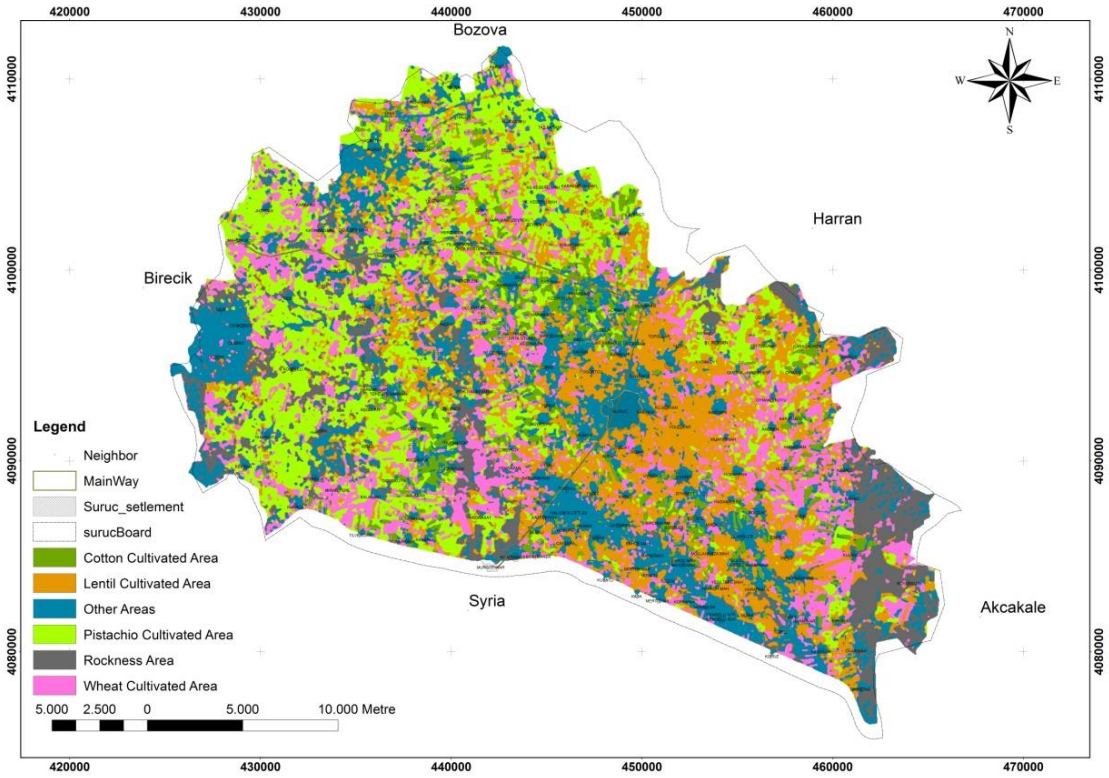

Figure 23. Actual Land use Map Derived from the Satellite Images

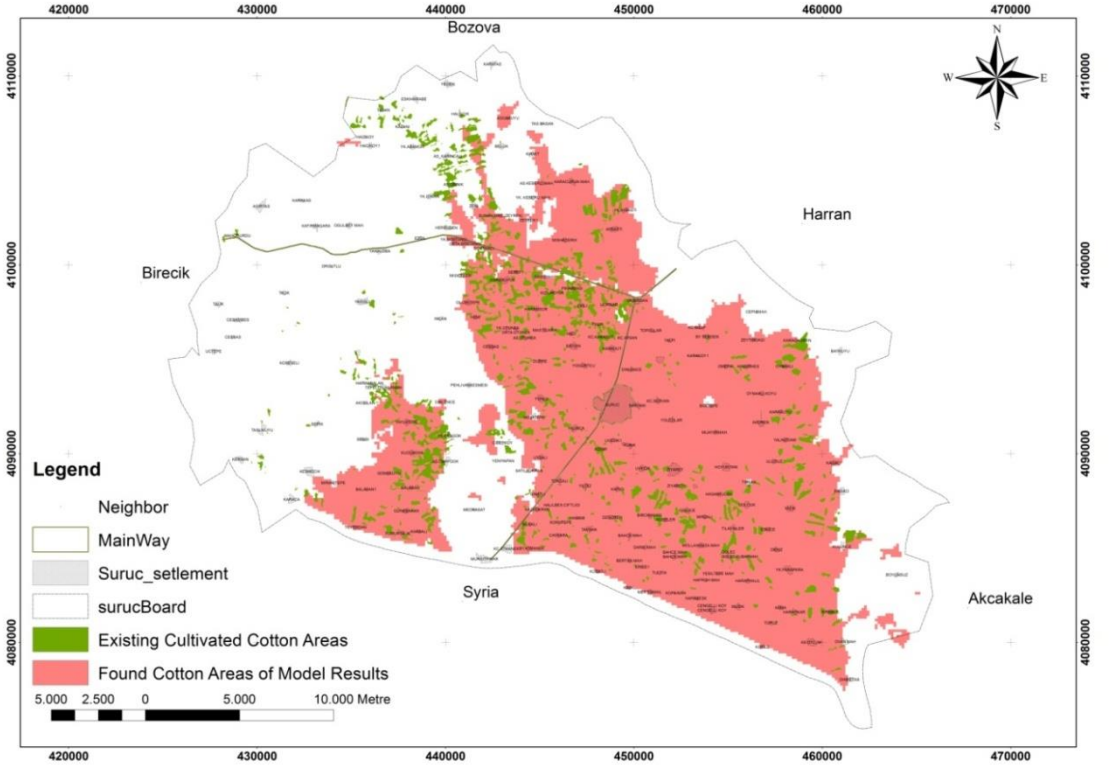

Figure 24a. Integration of Potentially Suitable and Actual Planted Lands for Cotton

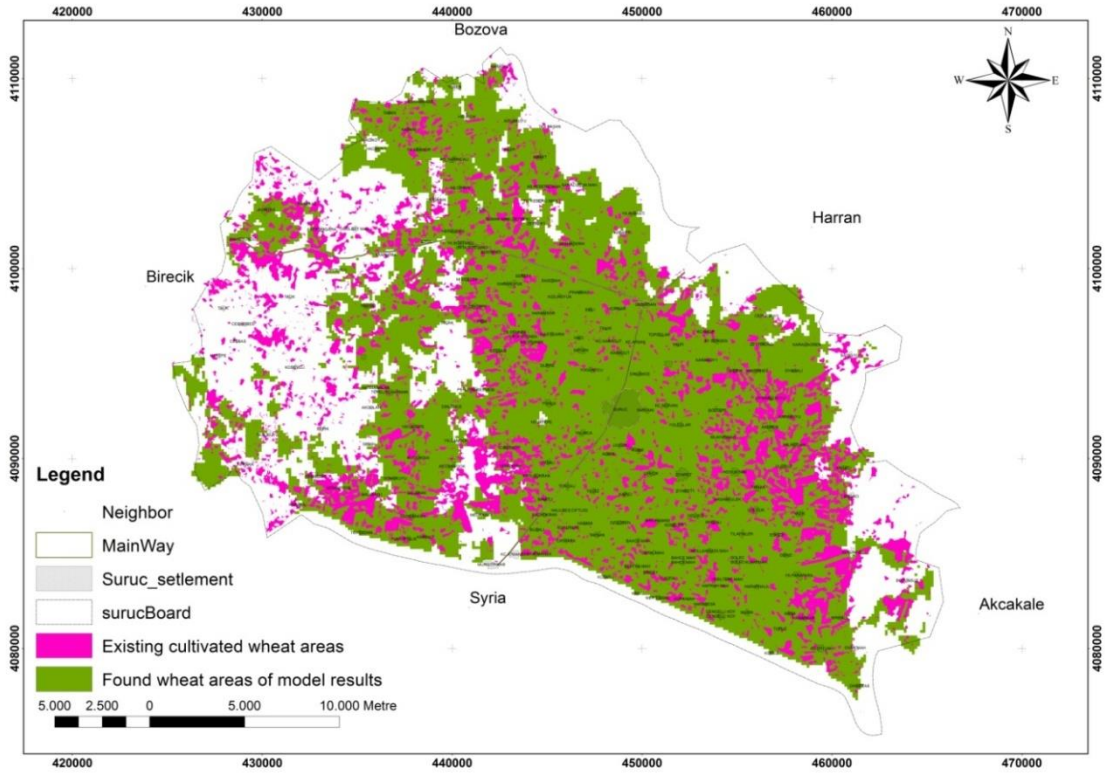

Fig 5b. Integration of Potentially Suitable and Actual Planted Lands for Wheat

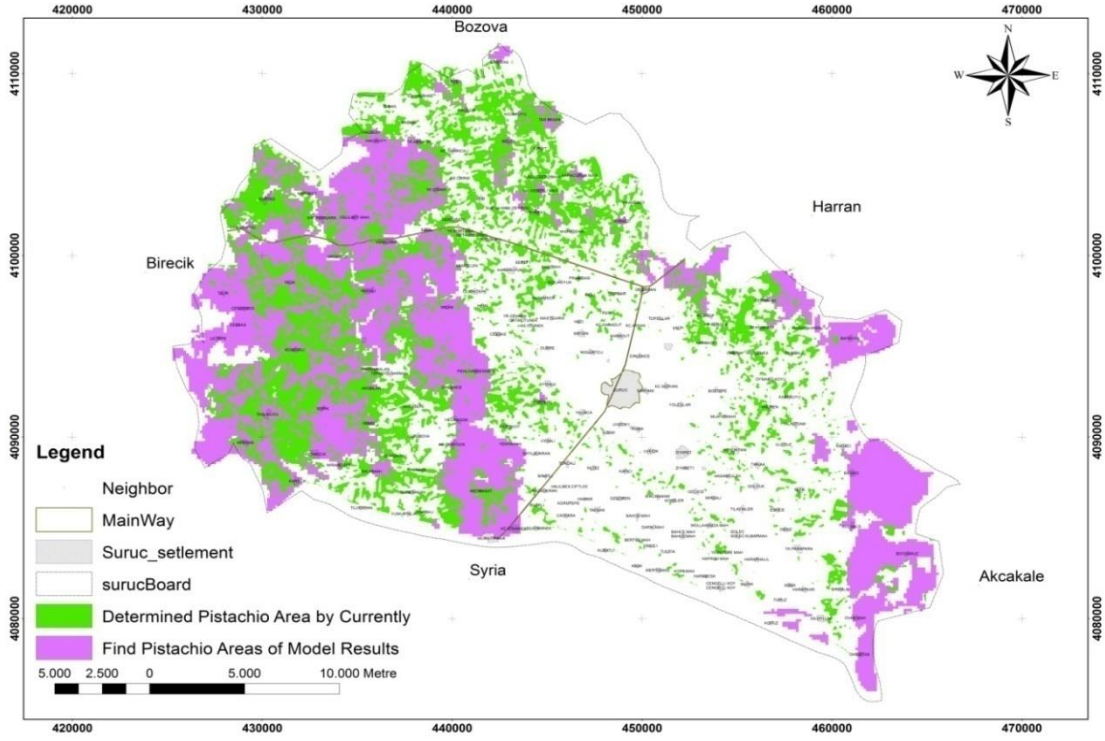

Fig 5c. Integration of Potentially Suitable and Actual Planted Lands for Pistachio

In the study area, when the actual land use map combined with potential map, the differences clearly can be seen. The data suggested that farmers cannot use their land according to soil capabilities. The latter may cause significant yield losses and land degradation. If we evaluate pistachio crop in the model we can see considerable differences between actual and potential use. The most suitable areas for pistachio was determined according to the model and

integrated to the actual pistachio planted lands. According to the model evaluation, only 28 % of pistachio planted lands are planted in ideal soil/land conditions. The cotton, lentil, wheat and barley planted lands were mapped for 2004 using satellite images. According to this result, totally planted areas of these crops were 17254 ha, whereas, potentially suitable areas obtained by the model were 30785 ha. This model gives accurate data for choose land use type according to soil, topography and climate. Farmers or industrial sectors can give a right direction using this data.

This study showed the efficiency of GIS in the analysis of multilayer spatial data simultaneously and delineation of the suitability classes of the lands provided the data from sources such as soil, topography, climate, geology and remote sensing using GIS techniques and interpretation of satellite images. Using this approach lands can be better managed and determination of land suitability can be improved which in turn help sustainable agriculture.

Conclusion

A GIS based multi criteria land evaluation was performed in Suruc Plain. The model output has a good potential to be used as a support tool for decision makers, land manager and politician for agricultural investment.

Land use planning is based on a combination of factors including zoning, population density, soil suitability, locations of floodplains and the types of existing land uses.

We conclude that there is a big difference between actual and potential land uses according to the model output.

GIS capability gives a wide possibility to use and integrate soil, climate, and topography map and attributes tables. These wide integrated data evaluated in GIS media contributed to give a right direction to land manager for ideal land planning.

DEVELOPMENT OF IRRIGATION AUTOMATION SYSTEM (IAS) USING BY PROGRAMMABLE LOGIC CONTROLLER (PLC) AND ITS APPLICATION ON IRRIGATION SCHEDULING CREATED USING CLASS A PAN

Cafer GENÇOĞLAN*, Serpil GENÇOĞLAN

Biosystem Engineering, Faculty of Agriculture, University of Kahramanmaraş Sütçü İmam, Kahramanmaraş, Turkey
*Corresponding author: gencoglan@ksu.edu.tr

Abstract

Aims of this study are to develop irrigation automation system (IAS) using PLC and to measure water level automatically in Class A Pan by IAS for daily evaporation and to refill certain level with pressure transducer, to calculate amount of water to be given irrigation treatments from daily evaporation, to control drip irrigation control unit and to irrigate pear plots when total daily evaporation reached about 35 mm. The two years of the study, scheduled three years, was conducted (*Pirus communis* L.) in the Department of Biosystem Engineering, Faculty of Agriculture and University of Kahramanmaraş Sütçü İmam. In the first year, IAS was installed and its program code was written in CODESYS language and loaded into PLC and tested in the workshop. In the second year, the system was also tested irrigating 11 years old dwarf pear during irrigation season. Water depth in Class A Pan was measured using one pressure transducer at 10:00 am. IAS started to irrigate Dwarf pear orchard at 10:10 am during irrigation season when total evaporation from Class A Pan reached about 35 mm. Irrigation management treatment was created as 120%, 100%, 80%, 60% and 40% application of 35 mm evaporation from Class A Pan. Using randomly block design, there were totally 5 irrigation treatments, namely, I_{120}**,** I_{100}, I_{80}, I_{60}, and I_{40} and which were replicated 3 times. Irrigation started in June and terminated in October. Irrigation automation system successfully completed the test conducted in both workshop in 2014 and also pear orchard during irrigation season in 2015 in accordance with program code. As a result of study, it could be stated that IAS could decrease labor and labor cost of irrigation and increase irrigation water use efficiency. If the IAS is used by famers, crop production cost would lessen and farmer income would increase.

Keyword: *PLC, automation, irrigation, pear.*

Introduction

Turkey's total land area is 78 million ha. Almost one third of this, 28 millon ha, can be classified as cultivable land. Recent studies indicate that an area of about 8.5 million ha is economically irrigable under the available technology. Presently irrigated area is about 4.9 million ha (DSI). Turkey is located in the semi-arid climates and therefore, crop production cannot be done without irrigation. Irrigation, especially surface irrigation, needs much more labor. Labor cost has increased day by day and also there is no agricultural worker. On the other hand, Moutonnet (2002) reports that water is a finite resource for which there is increasing competition among agricultural, industrial and domestic sectors. The allocated water to agricultural irrigation should be used effectively without causing environmental pollution. In addition (Cote et al., 2003) states that the increased use of trickle irrigation is seen as one way of helping to improve the sustainability of irrigation systems around the world. However, irrigation scheduling should be determined in the trickle irrigation. Preparing irrigation scheduling is time consuming, needed labor, sometime expensive and

also hard to follow it. Irrigation automation system could decrease all irrigation scheduling processes, labor and labor cost.
For this reason, aims of this study are to develop irrigation automation system using (IAS) by PLC and to measure water level in Class A Pan for daily evaporation and to refill certain level with pressure transducer, to calculate amount of water to be given irrigation treatments from daily evaporation, to control drip irrigation control unit and to irrigate pear plots when total daily evaporation reached about 35 mm.

Material Methods

The study was conducted at the Faculty of Agriculture, University of Sütçü İmam (37° 32′ 08″ N and 36° 54′ 59″ E and altitude 700 m above sea level) in Turkey. An experiment was set up for three years - in 2014 in the experimental field of the Department of Biosystems and second (2015) and third (2016) year in the orchard of dwarf pear with 11 and 12 years old trees (*Pirus communis L.*). However, results ware only from 16.06.2015 to 09.10.2015. Pear trees with Comice variety had been planted on 4.5X0.6 m spacing. The experimental area was under Mediterranean climate conditions with cool, rainy winters and hot, dry summers. Long-term average rainfall in the area is 712 mm.
The soil is classified as an Entisol with a clay-loam texture. Some physical and chemical properties of the experimental soil are given in table 1.

Table 1. Some soil physical properties of experimental area

Soil depth (cm)	Texture	Field Capacity (g g^{-1})	Wilting point (g g^{-1})	Bulk density (g cm^{-3})	pH	EC (dS m^{-1})	$CaCO_3$ (%)	Organic Matter (%)
0-30	CL	35.04	22.39	1.38	7.61	0.022	9.29	0.88
30-60	CL	35.99	24.17	1.36	7.76	0.018	7.96	1.76
60-90	C	41.19	20.43	1.50	7.80	0.019	9.29	2.67

(FC=388.52 mm and WP=210.054 mm)

Irrigation water is obtained from a deep well in the experimental area, and its quality is classified as C_2S1, with pH 7.0, and an average electrical conductivity is 0.41 dSm^{-1}.
An electrical panel of IAS for this study seen in figure 1 was installed according to PLC system variables given in Table 2. There were 16 digital input, 23 digital outputs, 18 analog input and 1 analog output for the IAS. In order to control 58 end elements in this study, one PLC's CPU and 7 modules were used. A program was written using CODESYS-ST language (ABB, 2015) considering 58 end element and below items:

1- It was irrigation time when total evaporation was equal or greater than 35 mm.
2-Water tank refilled up to 174 cm when level of water in tank was below 150 cm.
3- Class A Pan refilled up to 200 mm when level of water in Class A Pan was below 150 mm.
4-One pulse generated by digital water meter was equal to 1 liter when volume of water was measured by digital water meter.
5-Volume of water to be applied to treatment parcels was calculated by Equation 1

$$V=W*L*E0*Kcp \quad (1)$$

Where:
V-volume of water (L), W- parcel width (m), L- parcel length, E0- evaporation (mm), Kcp: crop-pan coefficient.

6- Soil moisture above the field capacity assumed as deep percolation.
7- In the evapotranspiration calculation of dwarf pear, water budget method was used.

8. Data of Class A Pan, soil moisture, irrigation water, evapotranspiration and precipitation were saved into SD card.

Table 2. PLC system variables (inputs and outputs) and control magnitudes

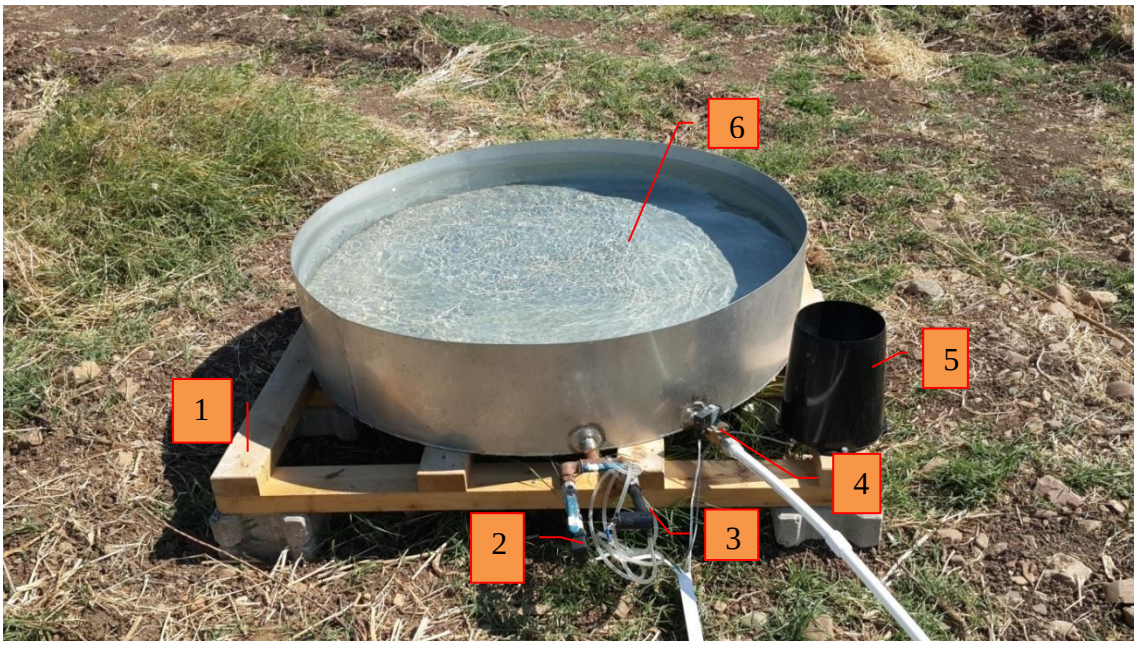
Depth of water in Class A Pan was measured by IAS using a pressure transducer at 10:00 am during the pear irrigation season (fig. 2). In order to obtain same water depth value between directly measured water depth by micrometer and calculated by IAS according to pressure transducer output, adjustment was made using by pressure transducer line in Picture 2. The minimum level of water in Class A Pan was 150 mm and maximum level was 200 (Güngör et al., 2004). Class A pan was filled automatically up to 200 mm level when water level is equal or drop below 150 mm at 10:00 clock am.

Fig. 1. IAS electrical panel



1: Slatted Platform, 2: Pressure transducer, 3: Motopump, 4: Selenoid valve, 5: Rain gage, 6: Class A pan

Fig. 2. Class A Pan and water depth measurement system.

Dwarf pear orchard was irrigated when total evaporation from Class A Pan was equal or greater than 35 mm. Irrigation management treatment was created as 120%, 100%, 80%, 60% and 40% application of 35 mm evaporation water from Class A Pan. Using randomly block design, there were totally 5 irrigation treatments, namely, I_{120}, I_{100}, I_{80}, I_{60}, and I_{40} and which are replicated 3 times. Length of each parcel with 16 dwarf pear tree was 10 m. Width of parcels assumed to be equal to canopy diameter of the dwarf pear. So, it was taken as 1.42 m. Amount of irrigation water was calculated using Equation 1. It could be re-written as V=1.42*10*Kcp*E0. Kcp coefficients were taken as 1.2, 1.0 0.8, 0.6 and 0.4 for I_{120}, I_{100}, I_{80}, I_{60}, and I_{40} irrigation management treatments, respectively. Amount of water irrigation was applied irrigation treatments through digital water meter (fig. 3). One pulse generated by digital water meter was equal to 1 liter. At the beginning of irrigation time, IAS opened the solenoid valves to irrigate irrigation parcels and in the meantime the pulses generated by digital water meter were counted by the IAS. When the counted value was equal to volume of water to be applied to parcels, stopping the solenoid valves, irrigation ended. Irrigation started in June and terminated in October.

Fig. 3. Digital water meter

Irrigation water source is a deep well, near the pear orchard. A plastic tank of 7 ton was placed close to irrigation treatments and connected to deep well with a ∅40 PE pipe. Water level in the water tank was controlled by pressure transducer. When water level was below 150 cm, water tank was refilled to 174 cm water level. Water in the tank was applied to irrigation plots through 2 kW motopump, controlled by driver, via hydrocyclone, media filter, disc filter, solenoid valves, digital water meters and finally laterals. But also, there was fertilizer tank in the drip control unit.

Results and Discussion

Only the second year's results were given in this paper, and irrigation of Comice dwarf pear started 16.06.2015 and with the start of leaves to turn yellow, ended 09.10.2015. IAS measured totally evaporation of 1104 mm from Class A Pan during the irrigation period. In the first irrigation, amount of 52 mm irrigation water was applied to effective rooting depth of 60 cm to refill available water to field capacity. When total evaporation from Class A Pan was equal or above 35 mm, IAS calculated amount of irrigation to be applied to I_{120}, I_{100}, I_{80}, I_{60} and I_{40} irrigation management. IAS started irrigations at 10:10 am. In 2015 irrigation season, IAS irrigated 27 times Comice dwarf pear. Irrigation interval changed between 3-12 days depending on climatic conditions and crop development stage. In the second half of June, and July and August irrigation interval was 3-4 days, in September 3-6 days and in October increased to 12 days. In each irrigation, amount of water applied to I_{120}, I_{100}, I_{80}, I_{60} and I_{40} irrigation management treatment varied between 62-40, 52-33, 42-26, 31-20 and 21-13 mm, respectively and the mentioned irrigation treatments were applied totally 1314, 1104, 894, 683 and 473 mm water, respectively.

In temperate climates Comice pear varieties generally harvested towards to end of September. Taking into consideration this knowledge, the fruits of pear were harvested manually on date of 04.10.2015 (Fig. 4).

Fig. 4. A view from the harvested dwarf pear orchard.

IAS irrigated irrigation management treatments of dwarf pear in accordance with the written program code without any problems during the irrigation season. Applied by IAS different amount of irrigation water according to irrigation management, the dwarf pear fruit yields given in table 3 were harvested from I_{120}, I_{100}, I_{80}, I_{60} and I_{40} irrigation management treatment, respectively. As seen in Table 3, mean fruit yields per dwarf pear tree for the irrigation treatments were 4.1, 3.4, 3.4, 3.0 and 2.6 kg/per tree, respectively. The highest fruit yield harvested from I_{120} and the lowest fruit yields from I_{40}. Yields of the other treatments changed between the yields of two treatments. Fruit yields of sunrise and Bartlett cultivars changed from 0 to 30 kg per tree and from 0.1 to 19.3 kg per tree by 2000-2008 years, respectively

(Bell and Zwet, 2011). Yield of Comice dwarf pear took place among the yields of sunrise and Bartlett cultivars, changing by years.

Table 3. Fruit yields harvested from irrigation treatments (kg/per tree)

Irrigation treatments	Replication			Fruit yield (kg/per tree)
	1	2	3	
I120	4,9	3,9	3,6	4,1
I100	2,8	5,2	2,1	3,4
I80	4,7	3,9	1,8	3,4
I60	3,3	3,1	2,6	3,0
I40	2,7	2,6	2,6	2,6

Conclusion

The test of IAS performed in the workplace during 8 month and at dwarf pear orchard was completed successfully according to the written program code during irrigation season in 2015. As a result of study, it could be stated that IAS could decrease labor and labor cost and increase irrigation water use efficiency. If the IAS is used by famers, production cost would lessen and farmer income would increase.

Abstract

In this study, distribution of air velocity in a tractor cabin was analysed with Computational Fluid Dynamic method. Spatial distributions of air velocity on different planes were determined in the tractor cabin. Materials were tractor with air-conditioned cabin, Testo 435 air velocity sensor. Air velocity were modelled and measured in a tractor cabin for winter conditions. ANSYS Fluent software was used to estimate distribution models of ambient factors. Estimated and measured data were compared each other. Measurements were realised when driver was inside and outside temperature 8^{o}C for winter condition. One sensor was used for air velocity measurements in this research. Number of the elements in mesh was 1074644. Types of meshes were prismatic and hexagonal. Air has a certain temperature in the model. There was heat flux from surface of engine and human body. In addition, convection and radiation heat transfer was accepted in the CFD models. Mean measured and estimated air velocity for winter conditions were calculated as 4.1 m/s and 4.15 m/s, respectively. Mean difference between measurements and CFD model estimations was 0.05 m/s. Accuracy of the model estimation was 11.18%.

Keywords: *Tractor, cabin, modelling, Computational Fluid Dynamics, air velocity*

Introduction

The conditions inside a tractor cab have significant impact on the performance of the operator, and in that way on the total efficiency of the operator-tractor-environment system as well. The main principle for both the improvement of the microclimatic conditions and the reduction of air-conditioning energy consumption in any type of cabin is the cooling the operator's body by the effective use of airflow from the air-conditioning system. Cabs usually have an air distribution system with air vents (outlets of ventilation system) placed on the ceiling. The vents mostly have a circular cross-section and the operator can change the velocity and direction of the air jet, and optionally, temperature. Vapour compression systems are (Ruzic, 2014). Thermal environment in tractor cabs differs from typical working places in buildings and usually is highly non-uniform and asymmetric, also characterized by following features: cab interior volume is small, changing of microclimate parameters could be rapid (when cab changes the orientation to the sun, etc), glazing area is large in comparison to the cab surface area, operator is not able to change position within the cab, changes of body posture are limited etc. From these reasons, obtaining both the uniform and comfortable conditions in the cab is not a simple task. Homogenous environment is preferable from the aspects of thermal comfort, and this is achievable in a later stage of staying in the cab, if steady state conditions are reached (Ruzic and Poznic, 2011).

In this research; distribution of air velocity in a tractor cab with air-conditioning was modelled by Computational Fluid Dynamics (CFD) methods and validated by sensor measurements. CFD analysis results of air velocity were shown on plains in the tractor cab. Differences between CFD Model and measured data of air velocity were investigated. ANSYS Finite elements model of tractor cab carrier system known its load-elasticity curve

were created and boundary conditions were defined by Kalkan (2007). Solutions of fluid mechanics for biological cleaning processes of different ventilators were compared by using Computational Fluent Dynamics (CFD) Akbulut (2010). Air conditioning system is the only active method for control of microclimate conditions in a cab. The system has a direct effect on heat exchange between an operator and a cab interior. This paper deals with an analyze of heat losses from individual body parts as well as whole body, for different air nozzles positions and different settings. The research was done with virtual operator model in tractor cab, using the computational fluid dynamic (CFD). The results showed that in this case the airflow direction has more significance on the operator heat loss than the air nozzles positions (***Ružićand*** and ***Časnji***, 2011). CFD models were developed and tested by sensor measurements for determination of temperature and relative humidity distribution in an experimental cold store Akdemir *et al*. (2012).

Materials and Methods

Hattat A 110 Maxi model tractor with air-conditioned cab was used in this research (Hattat, 2015). Technical specifications of tractor were given table 1. Air velocity was measured by using Testo 435 sensor. Measurement rage was 0.2 - 40 m/s (Testo, 2015). Measurements were realized in cab when outside temperature was 8°C. Air velocity was measured from 14 points as shown in Figure 1. In addition, air-condition was worked at highest as 4th level and 1500 rpm of tractor engine for determining maximum capacity of it.

Table 1. Technical specifications of tractor

Model	A110 4WD
Emisison type	Euro3
Max. power KW/HP/rpm (ISO 14396)	74,9/102/2200
Max. Motor torque Nm/Rpm	416/1400

Aspiraiton	Turbocharge with Intercooler
Total unloaded wieght - (kg)	3740
Cab	Air-conditioning, wide cab, with second seat

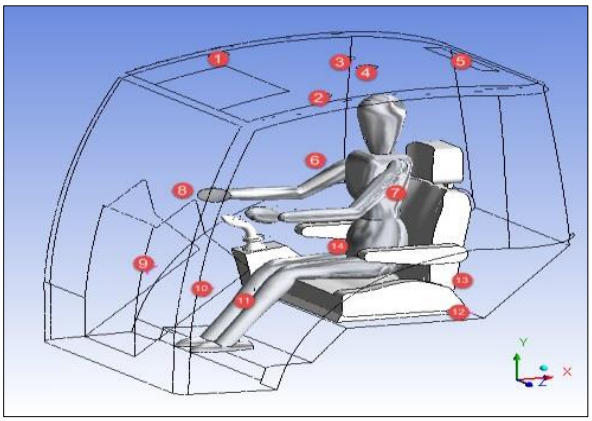

Figure 1. Measurement points in the cab

Flow analysis of air ventilated by air-condition in tractor cab was modelled by Computational Fluid Dynamics (CFD). Solid model of tractor cab was created by using Pro-Engineer software (Figure 2). File extension was STP was introduced with Design Modeller module after tractor solid model were created and flow volume of solid models and name of boundary conditions were entered by opening the mesh module. Required corrections were made on solid model created using Design Modeller. Then mesh module used to establish flow volume

of the model (Figure 3). Mesh structure was also created by Mesh Module (Figure 4). Number of the prismatic and hexagonal elements in the mesh structure was 1074644.

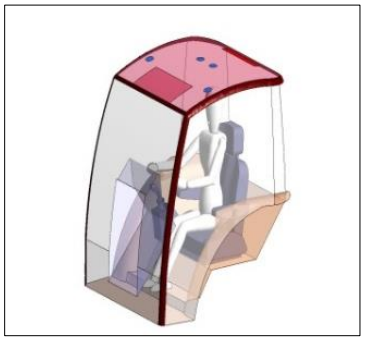

Figure 2. Solid model

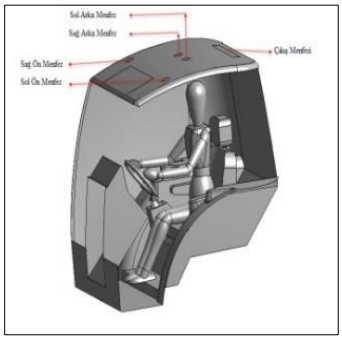

Figure 3. Flow volume of model

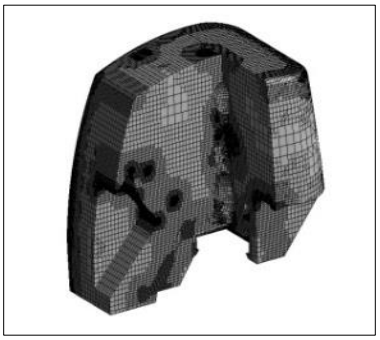

Figure 4. Mesh structure

Air at certain temperature and humidity enters through vents. There were heat fluxes from motor and human surface. Heat exchange by convection and radiation from other surfaces was concerned. Names of the boundary conditions for tractor were given in Figure 5 and Table 2.

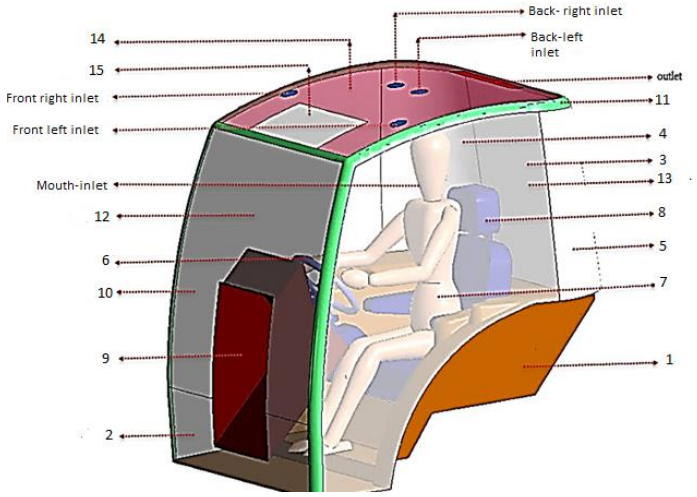

Figure 5. Names of the boundary conditions

Table 2. Boundary conditions of tractor cab

Boundary Conditions	Material	Thick (m)	Thermal Conductivity (W/m^2.K)	Heat Dissipation Capability	Heat Flux (W/m^2)

Material specifications of the tractor cab were given in Table 3.

Table 3. Technical specifications of tractor cab materials

Malzeme	Heat capacity (j/kg.K)	Heat conductivity coefficient (W/m.K)
Vents	1006.43	0.0242
Polyurethane	1500	0.024
PVC	900	0.19
Polyester	1400	0.17
Steel	502.48	16.27
Glass	840	0.8

As a method of this research; CFD models were developed by using ANSYS Fluent software to estimate distribution of the air velocity for winter conditions in the tractor cab. Different points were determined in the tractor cab to measure air velocity by sensor. Value of the air velocity at same points was also determined using ANSYS Fluent software. Differences as value and as a percentage between model and measured data were calculated to compare model and measurements.

Results and Discussions

Hattat A 110 MAXI brand tractor's CFD analysis was carried out and then distribution of the air velocity of air coming from vents were determined. Air velocity of behind the driver's seat section was 0.2 m/s from Figure 6. Air velocity of the outlet orifice cross section was determined as 4.5 m/s (Figure 7).

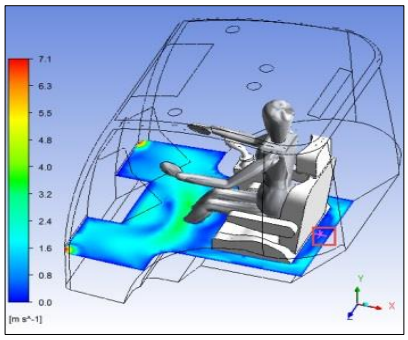

Figure 6. Behind seat

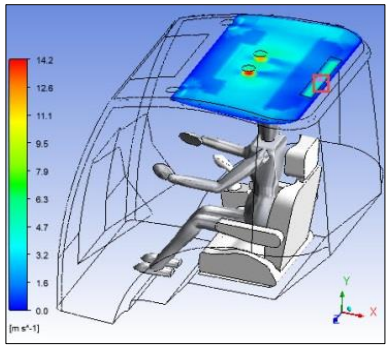

Figure 7. Outlet orifice

Speed values for the right and left rear vent respectively 12 m/s and 14.2 m/s were observed from Figure 8, and Figure 9. Right and left front of the vents points respectively 6.5 m/s and 5.5 m/s were determined. Air velocity value of the point on the knee was 2.7 m/s (Figure10). and for portion located on the right front console speed value was observed as 1.2 m/s (Figure11).

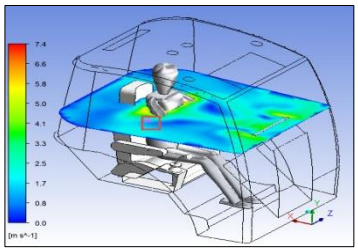

Figure 16. Right side of the cab

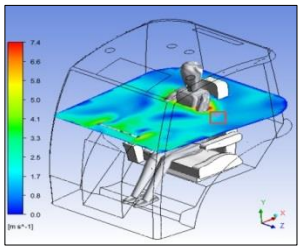

Figure 17. Left side of the cab

The comparison of the values CFD model ($v_{\_CFD}$), measurements (v_m) and differences (□v) for winter conditions in the Tractor cabin are given in Table 4.

Table 4. The comparison of the values CFD model and measurements for air velocity

Sensor No and location	$v_{\_m}$ (m/s)	$v_{\_CFD}$ (m/s)	□□□□□v (m/s)	%□□□□□v
1 (right front vent)	5.85	6.50	0.65	11.1
2 (left front vent)	5.71	5.50	0.21	3.7
3 (right rear vent)	12.36	12.00	0.36	2.9
4 (left rear vent)	14.68	14.20	0.48	3.3
5 (outlet vent)	4.50	4.50	0.00	0.0
6 (left side of the driver)	2. 00	2.30	0.30	15.0
7(right side of the driver)	1.20	1.40	0.20	16.7
8(Middle of front console)	3.60	3.30	0.30	8.3
9(right of front console)	0.90	1.20	0.30	33.3
10 (left of front console)	1.50	1.70	0.20	13.3
11 (the below knee)	2.50	2.70	0.20	8.0
12 (left the rear of seat)	1.40	1.20	0.20	14.3
13 (behind the rear of seat)	0.10	0.20	0.10	10.0
14 (right the rear of seat)	1.20	1.4	0.20	16.7
Mean	4.10	4.15	0.05	11.18

The maximum air velocity was determined as 14.68 m/s for left rear vent and the minimum air velocity was measured as 0.1 m/s at behind the rear of seat in the tractor cab. It can be seen from Table 4 that there were only small differences as 0.05 m/s between CFD model estimations (mean 4.1 m/s) and data logger measurements (mean 4.15 m/s) and relative error as percentage was calculated as 11.18%.

Conclusions

Variations in air velocity depend heat from the engine, differences between heat transfer coefficient of materials, angle of solar radiation and heat caused by tractor driver. According to the results of this research; differences between CFD model and measurements were within acceptable limits as error of 11.18 %. Created CFD model was successful to estimate air velocity in the tractor cab in 11.18. Even more sensitive studies than that the tractor cab 15-20% model error were evaluated (Moureh and Flick (2004) and Chourasi A and Goswami (2007). When the subject is discussed in terms of air velocity; air velocity value around driver except of the inlet and outlet air sections were above air velocity value 1.5 m/s, reported by Anonymous (1981).

Abstract

The World Reference Base for Soil Resources (WRB) is the internationally-accepted soil classification system. In our age of increasing globalisation, however, international communication has become an urgent requirement. The WRB is intended to serve as a common denominator of national soil classification systems to facilitate such international communication. The aim of this study is to determine the characteristics of soil investigations of certain types of soil, using the example of eastern Herzegovina, harmonization of the national classification system of soil, with WRB classification, in order to adapt the existing system and become comparable with the WRB classification system and allow communication at the international level. Field research was carried out in 2010 to 2015. A total of 44 profiles of soil were open on the surface, which covers about 30,000 hectares. The external and internal morphology is described for all pedological profiles (Munsell Soil Color Charts, 1954), soil samples in a disturbed state were taken for all genetic horizons. Laboratory testing of physical and chemical properties of the soil were carried out according to generally accepted methods in laboratory Faculty of Agriculture in East Sarajevo, Bosnia and Herzegovina. WRB classification will provide a high degree of comparability, but also the international applicability of the results. The paper, based on detailed field and laboratory tests, show the cartographic unit area of eastern Herzegovina to the classification system of the World reference base for soil (WRB) and according to the criteria of classification of land that is now applied in the BiH (Resulović, 2008) and Serbia (Soil classification of Yugoslavia, Škorić et al., 1985). WRB classification will provide a high degree of comparability, but also the international applicability of the results.

Keywords*: Soils of Eastern Herzegovina, WRB classification, Soil classification of Yugoslavia*

Introduction

The World Reference Base for Soil Resources (WRB) is the internationally-accepted soil classification system, endorsed by the International Union of Soil Science (IUSS), and hence by the International Council of Scientific Unions (ICSU). It is intended for correlation of soil individuals as defined by the pedon concept and for defining map units of medium- and small-scale maps. It is ideally suited to discussing world soils, their major properties and genesis. The WRB is a two-level classification: 30 reference groups which have major differences in terms of pedogenesis, geography, and use potential. These are further specified by a set of qualifiers: strong expression, intergrades, and weak expression. As many qualifiers as apply to a soil may be used (Rossiter, 2007).

Anyone working in a natural science discipline will be aware of the necessity and importance of classification and systematic structuring. This naturally includes pedology. In fact, every country possesses its own pedological classification system tailored to its specific natural features. In our age of increasing globalisation, however, international communication has become an urgent requirement. The WRB is intended to serve as a common denominator of national soil classification systems to facilitate such international communication; some basis ideas of the WRB will, therefore, be outlined below by way of introduction: Globalization and

global environment issues necessitate harmonisation and correlation of technical languages, such as the one used by science. A common language is vital to the functioning of any science; The WRB is designed as an easy mean of communication amongst scientists; The Reference Base is not meant to substitute for national soil classifi cation systems but rather to serve as a common denominator for communication at an international level. This implies that lower-level categories, possibly a third category of the WRB, could accommodate local diversity at country level. Concurrently, the lower levels emphasize soil features that are important for land use and management. (Deckers et al.,1998 in Nestroy, 2007)
The aim of this study is to determine the characteristics of soil investigations of certain types of soil, using the example of eastern Herzegovina, harmonization of the national classification system of soil, with WRB classification, in order to adapt the existing system and become comparable with the WRB classification system and allow communication at the international level.

Materials and methods

Field research was carried out in 2010 to 2015. A total of 44 profiles of soil were open on the surface, which covers about 30,000 hectares (Tunguz et al., 2015).
The external and internal morphology is described for all pedological profiles (Munsell Soil Color Charts, 1954), soil samples in a disturbed state were taken for all genetic horizons. Soil samples in undisturbed condition were taken from individual genetic horizons, in three repetitions, by cylinders of Kopecký and average soil samples were taken too.
Laboratory testing of physical and chemical properties of the soil were carried out according to generally accepted methods in laboratory Faculty of Agriculture in East Sarajevo.

Results and discussion

Setting aside systematic soil units of the studied area was done according to the principles of valid soil classification of soils in Yugoslavia (Škorić et al., 1985). The investigated soils in this area shown in Table 1.
From the order of automorphic soils, the following types of soil were singled out:

Table 1. Pedosystematic units of the studied area

Order	Class	Type	Subtype	Profile structure	WRB
Automorphic soils	Humus-accumulative soils	Limestone-dolomite black soil	Organo-mineral black soil	A-R, A-C	Molic Leptosol
		Rendzina or humus-calcareous soils	On soft limestones	A-R, A-C	Rendzic Leptosols
			On dolomite	A-R	Rendzic Leptosols
			On calcareous gravel	A-C	Rendzic Leptosols
	Cambic soils	Brown soil on limestone and dolomite	Typical	A-(B)-C	Cambic Umbrisols; Calcic Cambisols

25 profiles represented limestone-dolomite soils (Calcomelanosol). According to the classification of the soil of Yugoslavia (Škorić et al., 1985), they belong to the order of automorphic soil, to the humus-accumulative class, subtype organo-mineral black soil, variety: lytic, with A-C profile structure, with mollis horizon. Resulović et al. (2008) denote horizons of limestone-dolomite black soils as A_h-$_m$C, and there is no transitional AC horizon.

According to WRB classification, limestone-dolomite black soil is Molic Leptosol (FAO, 2006; 2014).

Figure 1. The external morphology of limestone-dolomite soils at the site Slivlja

Profile 5
Location: Slivlja
Elevation: 1120 m
Relief: flat
Vegetation: Pasture
On the pedological map of BiH R 1: 50000 soil described as:
Rendzinas on compact limestones, brown soil on limestones and cherts and delluvial soils of sinkholes $_{c}RZ +_{C,\ Rž}$ B+DV (40% + 40% + 20%)

Figure 2. The internal morphology of limestone-dolomite black soil

Order: Automorphic
Class: humus-accumulative
Type: limestone-dolomite black soil
(Calcomelanosol)
Subtype: Organomineral black soil
Variety: lytic
Profile: A-R
Form: With mollis horizon
A_{mo} (0-20 cm) - mollis, accumulative-humus horizon of brown color (7.5YR 4/2) when dry and when wet dark brown (7.5 YR 3/2). Texture is silty loam, powdery structure, non-carbonate, strongly imbued with veins of grassy vegetation.

Rendzine or humus-carbonate soils are in 9 profiles. According to the classification of soils of Yugoslavia (Škorić et al., 1985), they belong to the order of automorphic soils, the class of

humus-accumulative; subtype on the soft limestone, calcareous variety, low skeletal (profiles 19, 30, 55, 59, 70); subtype on dolomitic erosion, variety carbonate (profile 12); subtype on calcareous gravel (27, 61, 72), with the AR, A-C profile structure. According to Resulović et al. (2008), rendzinas are denoted as A_h-IC. The transitional horizon which is referred to as A_hIC is one of the characteristics by which rendzina differs from the black soil on limestone. According to WRB classification rendzina is Rendzic Leptosols (FAO, 2006; 2014).

Figure 3. The external morphology of rendzina, on the site Medanići

Figure 4. The internal morphology of rendzina

Order: Automorphic soils
Class: humus-accumulative soil
Type: Rendzina
Subtype: On calcareous gravel
Variety: Carbonate

Profile: A_{mo}-A_{mo}C-C
Form: Deep
A_{mo} (0-12 cm) mollis, accumulative-humus horizon of light gray color (10YR 6/2) when dry and when wet dark gray (10YR 5/2). Texture is silty clay loam, powdery structure, calcareous.
A_{mo}C (12-25 cm), gray (10YR 5/1) when dry and when wet dark gray (10YR 4/1). Texture is silty clay loam, powdery structure, calcareous.
C (25-50 cm) of light gray color (10 YR 6/2) when dry and when wet dark gray (10YR 5/2). Texture is silty clay loam, prismatic structure.

Brown soils on limestone and dolomite (10 profiles), according to the classification of the soils of Yugoslavia (Škorić et al., 1985), they belong to the order of automorphic soils, class cambic soils, subtype of non-carbonate (profiles 1, 2, 10, 11, 15, 18, 22, 60), carbonate (profiles 3, 29), with the A- (B) -C profile structure. According to Resulović et al. (2008) these soils are denoted as A_h-Brz-Cn. According to WRB classification, the brown soil on limestone and dolomite is Cambic Umbrisols; Calcic Cambisols (FAO, 2006; 2014).

Figure 5. External morphology of brown soils on limestone and dolomite (Calcocambisol), site Vrtine

Profile 3
Location: Vrtine
Altitude: 960 m

Order: Automorphic
Class: Cambic soils
Type: Brown soil on limestone and dolomite (calcocambisol)
Subtype: Typical
Variety: Medium deep
Profile: Amo- Amo II- (B)
Form: loamy
A_{mo}I (0-5 cm) - mollis, accumulative-humus horizon of light brown color (10 YR 5/4) when dry and when wet brown color (10 YR 4/4). Texture is loam, crumb structure, non-carbonate, imbued with veins of grassy vegetation.
A_{mo}II (5-15 cm) - light brown (10 YR 5/4) when dry and when wet brown color (10 YR 4/4). Texture is loam, crumb structure, calcareous, imbued with veins of grassy vegetation.
(B) (15-42 cm) - light brown (10 YR 5/6) when dry and when wet dark brown color (10 YR 4/4). Texture is clay loam, large grained structure, calcareous.

Conclusion

Work on pedological study and mapping of Bosnia and Herzegovina are in the seventies and eighties of the last century. Map-making unit of land are defined in accordance with current soil classifications of time in which the soil maps made. We used the different terms and have been applied different criteria for defining the mapping unit of land.

The paper, based on detailed field and laboratory tests, show the cartographic unit area of eastern Herzegovina to the classification system of the World reference base for soil (WRB) and according to the criteria of classification of land that is now applied in the BiH (Resulović, 2008) and Serbia (Soil classification of Yugoslavia, Škorić et al., 1985).

WRB classification will provide a high degree of comparability, but also the international applicability of the results.

Abstract

Atmospheric pollution causes serious damage for human health and to all natural ecosystems. Nowadays, the biggest provocative of atmospheric pollution is anthropogenic human activities and transport sector, main pollutants being heavy metals (HM). Study and evaluation of air pollution level from heavy metals in south – eastern Albania region was performed with mosses (specie *Hypnum cupressiforme)* as bio-monitor. Active biomonitoring technique for determination of atmospheric deposition level of heavy metals was applied in Albania since 2010. Based on the fact that the mosses are plant with un-development root system, consequently they take the nutrients mainly from rain and atmospheric deposition, the amount of heavy metals in those, reflect direct the air quality. The mosses were collected in 7 different stations in south- estern region of Albania. Sampling was performed in accordance with the LRTAP Convention – ICP Vegetation protocol and sampling strategy of the European Program on Bio-monitoring of Heavy Metal Atmospheric Deposition. The ICP/AES analysis of 11 elements (Al, Cr, Cu, Fe, Li, Mg, Mn, Ni, Pb, V and Zn) was performed by the Institute of Chemistry, Faculty of Science, Sts. Cyril and Methodius University, Skopje, Macedonia. Statistical analysis and correlation analysis, was applied to distinguish elements mainly of anthropogenic origin from those predominantly originating from natural sources and to point out the most polluted areas. The study of the contamination factor for the analyzed elements show that the region south - eastern Albania is slightly contaminated by heavy metals.

Keywords: *moss, ICP/AES, heavy metal, contaminated factor.*

Introduction

The study of atmospheric deposition of trace elements through bio-monitoring technique and analytical treatment with special methods, is performed for the first time in Albania in 2010. The aim of this study is to assess the level of air contamination by heavy metals in south-eastern region of Albania, as an important touristic region..

Monitoring of air pollution using bioindicators is emerging as a potentially effective and more economical alternative performing by direct ambient air measurements. This is especially relevant for monitoring large areas (Rühling and Tyler, 1968). The usefulness of mosses in determining trace- and heavy-metal concentrations in different geographical areas has been discussed and demonstrated in several studies (Gjengedal and Steinnes, 1990; Markert *et al*., 2003). In practice, controlling anthropogenic air pollutants is a very complex problem where sources and emissions have to be managed and monitored, and economic aspects have to be integrated.

Suspended particulates are introduced into the atmosphere from a variety of natural and anthropogenic sources, although the latter are predominant in the urban and industrial areas. Some of the well known anthropogenic processes contributing to the airborne particulate pollution include transportation, mine and industrial activities, biomass burning and

agricultural activities. In the case of anthropogenic pollution, the particulate matter can contain metal trace element like Cr, Cu, Zn, Ni, Pb, and so forth (Berandovky *et al*. 2012).
The group of mosses *Hypnum cupressiforme* (family of bryophytes) are plants that have no real roots, thus they have a close relationship with the atmosphere, and get their food from wet and dry atmospheric depositions. (Rühling and Steinnes, 1998; Puckett, 1998).
The qualities, that make the mosses usable as bio-monitors, primarily depend on their ability to absorb and fixed metals in their tissues The stability of metal organic complexes and chelates and the great cation exchange capacity of the tissues are primarily conditions for the sorption of heavy metals by mosses (Tyler, 1970).
Heavy metals are stable in the atmosphere and soil. Being such, they contaminate the soil and air. From contaminated soil through crops, they passed to humans and animals, so enter the food chain. Through the process of bioaccumulation and their contents biomagnifikimit grow from one to the next link in the chain, so those in low concentrations are dangerous for health
Combustion processes are the source of contamination by heavy metals, as these are ingredients (although in small amounts) of fuels such as coal, diesel or gasoline (Lammel *et al*. 2006). Uncontrolled combustion processes of waste disposal in their fields or burning in incinerators are source of pollution from heavy metals. (Nriagu 1989). The aim of this study is to assess the air pollution in south-eastern region of Albania by heavy metals, and determine the sources of this pollution.

Material and Methods

Study area

The study are was situated in south- eastern Albania. The study area has comprised of diverse geographical representation, composed of mountains and plateau at altitudes above 700m from sea level being characterized from a continental climate.

Moss species and sampling

Moss sampling was performed according to the guidelines of the UNECE-ICP Vegetation monitoring manual for air pollution monitoring of the atmospheric deposition of heavy metal deposition using bryophytes, as well as the procedure used in the previous European moss surveys Monitoring Manual 2010. Samples were collected at least 300 m from main roads and populated areas and at least 100 m from local roads, and 200 m from villages or single houses.

Figure 1. Monitoring station in the area study

Sample preparation and digestion

In the laboratory, the samples were cleaned but not subjected to any further washing and dried to a constant weight for 48 hours at room temperature. Green and green-brown parts of the moss that correspond to three years of moss growth were sorted and prepared for analysis. For digestion, moss samples (0.5000 g) were placed in Teflon digestion vessels, and 7 ml of trace

pure HNO_3 (Merck, Germany) and 2 ml H_2O_2 p.a. (Alkaloid, Macedonia) were added, and the vessels were capped closed, tightened and placed in the rotor of a Mars microwave digestion apparatus (CEM, USA). Plant samples were digested at 180º C. After cooling, the digested samples were quantitatively transferred into 25 ml calibrated flask.

Instrumentation

The analyses were performed at the Institute of Chemistry, Faculty of Natural Sciences and Mathematics in Skopje. All analyzed elements (Al, Cr, Cu, Fe, Li, Mg, Mn, Ni, Pb, V and Zn) were determined by the application of ICPAES (Varian, 715-ES) applying an ultrasonic nebulizer CETAC (ICP/U-5000AT+).

Results and discussion

Based on obtained date, aiming to evaluate contamination level and element distribution, the analytical results were statistically treated by using descriptive statistics.
High differencies exists between max and min concentrations values of Al, Fe, Ni, V and Mn in the moss samples. Coefficients of variation (CV) for Cu, Mg, Fe and Mn are moderate (20-45%) and for Zn, Pb and Ni are higher than 70% . The elements Zn,Pb and Ni presents thi highest statistical parameters (CV, kurtosis and skewness) see Table 1.

Table 1. Descriptive statistics of the data analysis(in mg/kg DW)

Element	Al	Cr	Fe	Li	Mg	Mn	Ni	Pb	V	Cu	Zn
Mean	1401	12.63	1798	1.43	2146	70	39	2.82	3.21	9.31	30
Median	1046	10.50	1861	1.19	2246	60	23	1.38	2.38	8.76	18
Kurtosis	-0.10	2.96	-0.81	-0.16	-1.48	-1.0	5.00	8.09	-0.9	2.42	7.66
Skewness	0.83	1.74	0.62	0.18	0.28	0.69	2.13	2.81	0.65	1.50	2.71
EuroMed	200	0.55	209	-	1730	256	1.14	1.17	0.92	3.6	26.5
CV%	57	58	36	62	30	43	89	82	73	20	70

Generally, the highest values of these elements (Al, Fe, Cr. Ni) were measured near the industrial centers positioned mainly in central part of the country. The influence of the wind is stronger in the southeast direction , which is reflected in the increase of aluminum content in mosses of south – eastern region of Albania.
The high concentretation values of the elements Al. Li. Fe, Ni, Mn and Pb typically are associated with soil particles (in the study are have operated different Fe and Ni mines). The present median values are generally comparable with those from Macedonia and other neighboring countries. (Qarri *et al* 2013). The metals concentrations are substantially higher than the corresponding values from most European countries (except Zn) carried over the years 2010-2011. (Harmens *et al* 2013)

Table 2. The results of correlation between elements in the studied moss.

Eleme	Al	Cr	Fe	Li	Mg	Mn	Ni	V	Pb	Cu
Cr	0.14 0.71									
Fe	0.77 0.65	0.02 0.06								
Li	0.99 0.00	0.26 0.51	0.80 0.01							
Mg	- 0.69 0.09	0.32 0.39	-0.08 0.83	0.52 0.15						
Mn	0.91 0.01	0.19 0.63	0.81 0.01	0.84 0.01	-0.50 0.17					
Ni	0.63 0.07	-0.64 0.43	0.30 0.78	-0.11 0.09	-0.60 0.07	-0.42 0.26				
V	0.62 0.07	0.03 0.94	0.31 0.42	0.70 0.03	-0.40 0.30	0.28 0.47	-0.72 0.03			
Pb	0.93 0.00	0.39 0.30	0.87 0.00	0.96 0.00	-0.37 0.33	0.84 0.01	-0.44 0.24	0.55 0.13		
Cu	0.29 0.45	-0.67 0.05	-0.26 0.51	0.19 0.62	-0.83 0.01	0.25 0.52	-0.39 0.30	0.15 0.71	0.06 0.88	
Zn	0.28 0.47	0.20 0.60	0.20 0.61	0.29 0.46	-0.27 0.49	0.18 0.65	-0.48 0.20	0.40 0.28	0.12 0.76	-0.20 0.61

To distinguish some relations on the origin of the elements in moss samples, correlation amnalysis between elements concentrations was carried out. The results are shown in Table 2. Significant correlations were found for the pairs of elements Al-Li, Al-Mn and Al-Fe.

Multivariate analysis

In order to identify the main source categories of moss samples regarding the site contamination and element distribution as well as to detect the similar patterns of element concentrations, cluster analysis (CA), and factor analysis (FA), were applied.
The results of cluster analysis clearly explain the geogenic associations of these elements, which may be caused by wet and dry depositions of soil dust in moss samples as described down here for each cluster.

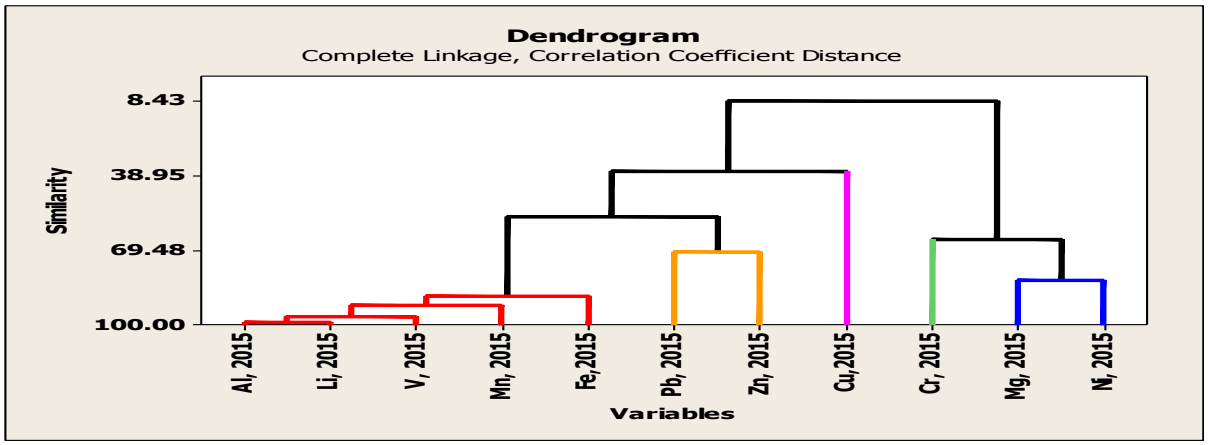

Figure 2. Dendogram Cluster analysis (CA)

Cluster 1 is associated with the elements Al, Li, Mn, V and Fe typically chromite mineralisations in Shibeniku and Pogradeci areas. Cluster 2 is associated with Pb and Zn that were related with nickel-silicate and iron-nickel mineralisations in this region of Albania. Cluster 3 is associated with Cu as typical element of sulphure ores in the region. Cluster 4 is associated with Cr. Elevated level of Cr concentrations in moss samples were observed in the vicinity of chromium mines in the region. Cluster 5 is associated with Mg and Ni originating from magnezite cliffs of area and chrome mines.

This classification supports the results obtained through factor analysis by distinguishing two main factors on element distribution: geogenic origin and industrial pollution.

The results of Factor Analysis are summarized in Table 3 and Figure 3. Through the results of Factor Analysis three main factors that represent 88.5 % of total variance were identified through the Factor Analysis (Table 3, Figure 3).

Factor 1 is the strongest factor representing 51.6 % of the total variance. It is associated with the elements Al, Li, Mn, V, Pb, Cr and Fe (see Table 3 the values of each element). This associations may bee attributed to their geogenic origin related with soil particles. The association of Cr and Fe is also related with air pollution from industrial emissions.

Factor 2 is the second strongest factor with 24.5% of the ttal variance. It is mainly influenced bu the high loadings of Cu, as typical element of sulphure ore as chalcopyrite. The main deposits of this mineral are situated in Pogradeci area. This factor probably related to soil dust emissions

Factor 3 represent only 12.4 % of the total variance. This factor influenced from high loadings of Zn and Pb and is negatively loaded by the elements Cu, and Ni. The negative loading values may indicate a reverse tendency on the concentration of these elements when the total metal concentrations increase.

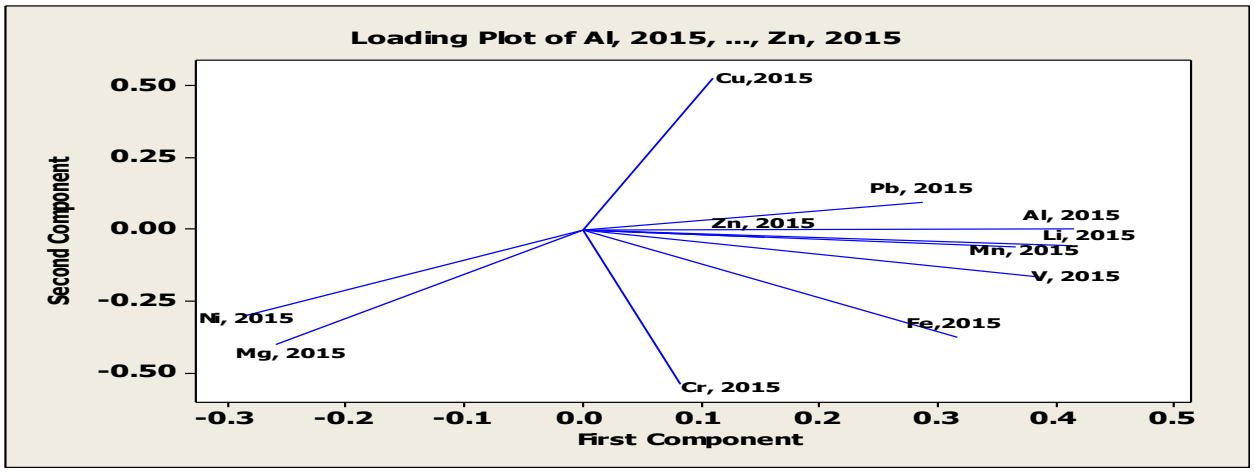

Figure 3. Loading plot of elements.

Conclusion

From the obtained results, we can say that the south-eastern region Albania (Korça - Pogradeci-Erseka-Gramshi region) is generally a region less contaminated are from heavy metals.

By comparing the concentrations of metals in moss with the European Union carried over the years 2010-2011, we see that they are lower than the European average.

Higher values than the European average represent Fe, Ni, Cr and Ca (approximately 3 to 5 times higher), fact that related to mineral characteristics of the area and industrial activities operating in this region as nickel iron mines, nickel - silicate, chromium or quarry industry (Zemblaku area).

LONG TERM VARIATION OF RAINFALL IN SOUTHEASTERN ANATOLIAN PROJECT (GAP) AREA

Kadri YUREKLI

Agriculture Faculty, Department of Biosystem Engineering, Tokat-Turkey,
Corresponding author: kadriyurekli@yahoo.com

Abstract

In this study, variation in annual and seasonal rainfalls in Southeastern Anatolian Project (GAP) area was analyzed by using the non-parametric and parametric approaches. According to Mann-Kendall (MK) test, there were significance monotonic trend in the five of the considered rainfall stations, whereas unit root test was incompatible with the MK.

Key Words: *GAP, Mann-Kendal, unit root test*

Introduction

The increased concentrations of greenhouse gases caused by human activities would alter the magnitude and seasonal variations in temperature and precipitation patterns in many parts of the globe (IPCC (2007). According to IPCC (2013), in the last half of the 20th century, there has been an upward trend in the number of heavy precipitation events in many parts of the word. Giorgi (2006) emphasized that Mediterranean basin was among the most sensitive regions in term of the future precipitation extreme conditions. Unal et al. (2012) reported that a dominating trend in decreasing annual precipitation existed throughout Anatolia, including west, and southwest sections while an increased trend in annual precipitation was observed only in northeast Black Sea region of Turkey.

Due to the foregoing described facts, the analysis of long term variation of seasonal and annual rainfall in Southeastern Anatolian Project (GAP) region, planned in the boundaries of the upper Euphrates and Tigris river basin is very crucial owing to the inherent climate characteristic in the GAP area. The GAP project is the largest investment in terms of regional development throughout the history of Turkish Republic and the fourth largest irrigation project in the world. The development of the GAP region was originally deliberated on its water and land resources. Therefore, a probable drought event would cause the failure of the GAP because of the water resources development program as relating to the GAP consists of 13 groups of irrigation and energy projects, seven of which are on the Euphrates River and, the largest and comprehensive project including Atatürk Dam and Urfa Tunnels is on the lower Euphrates. (Altınbilek 2004; Kibaroğlu and Unver 2000). The main objectives of this study were: to make up new data set to be analyzed by summing up monthly precipitation of the stations in the study area, and to apply Mann-Kendal (MK), Sen Slope estimators tests and unit root test to new data set in order to detect the direction and magnitude of a trend.

Material and Methods

The Euphrates–Tigris basin is largely fed from snow precipitation over the uplands of north and eastern Turkey, Iraq and Iran. Precipitation in the basin largely falls during the winter months from October to April. A large proportion of precipitation in this period occurs as snow on the uplands and it remains in solid form until temperatures increase up to the spring or early summer. Thereupon, snow-melt is decisive on the flow characteristics of both the Euphrates and Tigris. A substantial amount of precipitation which converts to runoff or groundwater in the basin takes places over Turkey (Beaumont 1998). In the GAP region, including 9 provinces, monthly rainfall amounts from 9 rain gauges (site) operated by Turkish

State Meteorological Service were used in the analysis. The geographical locations, characteristic information and data availability of the 9 stations in the GAP are presented in the Figure 1 and Table 1. The data quality control of monthly rainfall series was performed in the context of the missing data and homogeneity. Each station performed the homogeneity condition according to Mann-Whithney U.

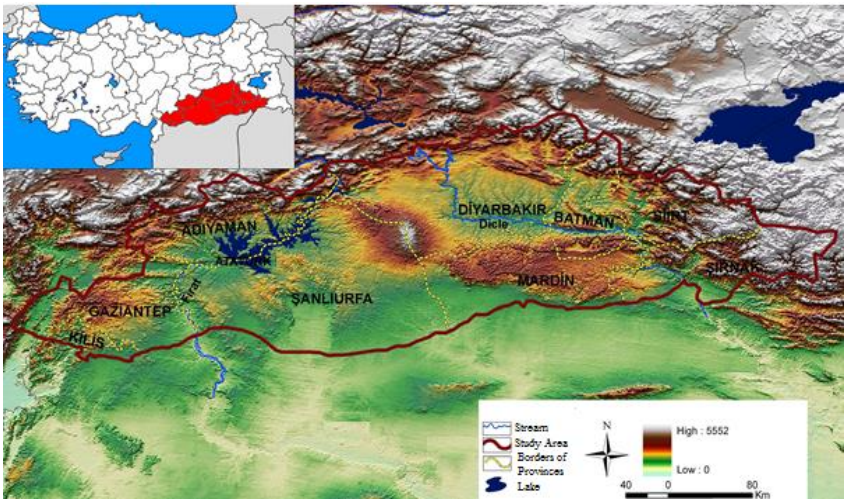

Figure 1. Rainfall stations in GAP region

In the analysis, the monthly data sets of the 9 sites were arranged at seven different categorical data sets, namely period one (from January to March), period two (from April to June), period three (from July to September), period four (from October to December), period five (from January to June), period six (from January to September) and period seven (from January to December). Monthly precipitation time series were summed up to obtain the data set to be analyzed for each station at time scales of interest.

Table 1. Characteristics of the sites in the GAP area

Siirt	41°57´	37°56´	895	718	1938-2013

Analysis of change in the data

Variation in meteorological variables has been tested using both parametric and non-parametric approaches (e.g., Abdul Aziz and Burn 2006; Espadafor et al. 2011; Hamed 2008; Liang et al. 2010; Tabari and Talae 2011).The non-parametric approaches have some advantages over the parametric. The most attractive one is the assumption that values have any distribution form for non-parametric approaches, the requirement is the normally distributed variables (Huth 1999; Zhang et al. 2008). The Mann-Kendall (MK) method is the most popularized non-parametric method to define variation in hydrologic variables. The null hypothesis (H_o) of the MK test assumes that time series values are independent, and identically distributed while alternative hypothesis (H_1) is that there is a monotonic trend in the data set. Mathematical formulation of this test is given as following:

$$S=\sum_{i=1}^{n-1}\sum_{j=i+1}^{n}\operatorname{sgn}\left(x_j-x_i\right)\quad \operatorname{sgn}\left(x_j-x_i\right)=\begin{cases}+1 & \text{if } \left(x_j-x_i\right)>0\\ 0 & \text{if } \left(x_j-x_i\right)=0\\ -1 & \text{if } \left(x_j-x_i\right)<0\end{cases} \tag{1}$$

According to Eq.(1), a positive or negative S value indicates upward and downward monotonic trend in the data, respectively. It is assumed that the statistic S is approximately normally distributed with the mean zero and, in case where the sample size n >10, its variance and the MK test statistics (Z_{MK}) are calculated by the equation 2 and 3.

$$\sigma_S^2=18^{-1}\left[n(n-1)(2n+5)-\sum_{i=1}^{m}t_i(t_i-1)(2t_i+5)\right] \tag{2}$$

$$Z_{MK}=\left\{\frac{S-1}{\sqrt{\sigma_S^2}}\ \text{ if }\ S>0,\ 0\ \text{ if }\ S=0,\frac{S+1}{\sqrt{\sigma_S^2}}\ \text{ if }\ S<0\right\} \tag{3}$$

The Z_{MK} test statistic here follows a standard normal distribution. This value calculated from the Eq.(3) is compared to the value of $Z_{1-\alpha/2}$ from standard normal distribution table at 5% significance level. The null hypothesis associated with no trend is accepted if the Z_{MK} test statistic is smaller than the critical value of the standard normal distribution at the significance level of α. The Z_{MK} test statistic having a positive or negative value signifies an increasing or decreasing trend.

Theil-Sen's estimator (Q_{med}) (Sen 1968; Theil 1950) has been substantially considered in specifying the magnitude and direction of the trend in hydrologic variables. The brief descriptions of the statistical method are in Yurekli (2015). In order to directly apply the MK test to the raw data, there should be no serial correlation among the observations; otherwise the presence of serial correlation in the raw data would lead to misinterpretation over trend (Hamed and Rao 1998). According to Yue and Wang (2002), the existence of serial correlation in any data set would result in a significant positive trend. To avoid the undesirable situation, Yue and Pilon (2003) suggested a new modified technique called as a trend-free pre-whitening (TFPW), and was used in the study. The percent change related to the seasonal and annual rainfall data set with monotonic trend was found by the following equation given in Petrow and Merz (2009).

$$\Delta x_R=(x_{end}-x_{start})\times(\bar{x})^{-1} \tag{4}$$

In equation, X_{end}, x_{start} are the values associated with the trend line at the end and at the start of observation period. $\bar{x}$ is the mean of observations. In this study, parametric unit root test was also applied to data sequences.

Results and discussions

In the first attemp, The $Q(r)$ statistic suggested by Ljung and Box (1978) was applied to all of the series to detect the presence of serial correlation among the observations. For this purpose, the statistic for every data was calculated for lag one and was compared to critical value of the χ^2_{Table} at 5% significant level. This statistic value was shown in bold characteristic when this value was greater than critical value of the reference table (Table2). The TFPW method was applied to the data found statistically significance in terms of serial dependence.

Mann-Kendal test using one-sided hypothesis at 5% significance level was applied to the seasonal and annual rainfall data sets. The results of this test are presented in Table 3. As can be seen in the table, monotonic trend was detected for the rainfall series of five provinces in the GAP region. The seasonal and annual rainfall series belonging to Kilis, Mardin and Siirt provinces showed downward trend while the rainfall series in PIII and PIV periods for Gaziantep and Sirnak provinces have significance upward trend.

Table 3. The results of Mann-Kendal test for each station in the study area (Yurekli, 2015)

Gauging Stations	Z_{MK} test statistic						
	P-I	**P-II**	**P-III**	**P-IV**	**P-V**	**P-VI**	**P-VII**
Gaziantep	-1.12	0.60	1.13	1.77^{++}	-0.27	-0.04	0.79
Kilis	-1.98^{**}	-1.00	1.64	-0.12	-2.39^{**}	-2.05^{**}	-1.77^{**}
Adiyaman	-0.41	-0.64	0.51	0.06	-0.68	-0.63	-0.33
Sanliurfa	-1.43	-0.33	***	0.16	-1.30	-1.20	-0.72
Mardin	-2.10^{**}	-0.76	***	-0.71	-2.03^{**}	-1.99^{**}	-2.11^{**}
Diyarbakir	-0.47	-0.41	-0.67	0.30	-0.37	-0.39	-0.47
Batman	-1.44	-0.92	-0.47	-0.50	-1.30	-1.47	-1.47
Sirnak	1.33	-0.85	2.96^{++}	1.92^{++}	1.19	1.36	1.56
Siirt	-2.38^{**}	-0.79	0.89	-0.63	-1.42	-1.30	-1.66^{**}

The "++,**" shows increasing and decreasing monotonic trend in the data of interest

The MK test for the PIII period of Sanliurfa ve Mardin sites could not be carried out due to many years with no precipitation. Theil-Sen's estimator results of five stations having monotonic trend are in the Table 4. In the same table, the highest and lowest values of the

TSE at 99 % confidence level were also given. The TSE values were located between the highest and lowest values.

Surprisingly, the results of parametric unit root test were quite different from that of Mann-Kendall test. The unit root test found to be monotonic trend in the period III of Sanliurfa site and the period V of Sirnak site while there was no trend for the other data sets. For the sites with monotonic trend in the Table 3, percent change varied between 19 and 57%. The highest percent change was in the period III for Sirnak site while the lowest percent change was in the period VII for Kilis site.

Table 4. The TSE results in quantifying the slope of the trend line (Yurekli, 2015)

Gauging Stations	Q_{med}						
	P-I	**P-II**	**P-III**	**P-IV**	**P-V**	**P-VI**	**P-VII**

Q_{max}	0.45	1.41	1.69	6.11	0.48	0.58	0.97

Conclusion

In conclusion summarize the main findings of trend analysis in the context of GAP. The most comprehensive attempt to the date have been achieved by Turkish Republic with Southeastern Anatolian Project (GAP), which is the largest investment for regional development in the history of Turkey and the fourth largest irrigation project in the world. In this sense, having information on rainfall variation in the region with dominant arid and semi-arid climate characteristic are crucial in terms of a sustainable water resources management. Especially, the decrease in precipitation would affect the failure of the GAP because the water resources development program in the GAP is composed of 13 groups of irrigation and energy project.

USE OF PASSIVE SAMPLING TECHNIQUES FOR MONITORING OF PESTICIDES IN SURFACE WATER

Dragana ŠUNJKA*, Sanja LAZIĆ, Slavica VUKOVIĆ

University of Novi Sad, Faculty of Agriculture, Serbia

Abstract

The Water Framework Directive (2000/60/EC) (WFD) adopted in 2000, with its daughter directives, provides a common framework for water management and protection in Europe. The goal of the WFD was to achieve good qualitative and quantitative status of all aquatic systems by 2015. However, this has been prolonged to 2021. Among other things, this refers, also, to the control of pesticide residues presence in surface waters. Directive 2013/39/EU defines the list of 45 priority substances for surface waters, which must stay below the specified levels that are safe for water bodies and human health, including 15 pesticides. According to NORMAN list, number of pesticides labeled as emerging substances is significantly higher. In order to achieve this, it is necessary to carry out continuous monitoring program. Representative monitoring of organic micropollutants such as pesticides in aquatic systems is a challenging issue. Most studies that report the occurrence of these contaminants in water were conducted using traditional sampling methods, with a spot or composite samples. Recently, passive sampling, a new innovative method for sampling of a wide range of pesticides and other POPs, is applied. These new techniques (SPMD, POCIS, LDPE, silicon rubber, etc.) have many advantages compared to spot sampling. Some of them are enabling the preconcentration of contaminants, increasing the capability for detecting trace concentrations that otherwise requires large volumes of water and enabling the determination of time-weighted average (TWA) concentration over extended sampling periods. However, the use of passive samplers needs sampling rate (R_s) of the targeted compounds, which is usually determined via laboratory calibration experiment. In this study, a review on use of passive sampling technology for monitoring of pesticides in surface water is given, with the special emphasis on laboratory calibration experiments with the aim of R_s determination.

Keywords: *Passive sampling, Monitoring, Pesticide residues.*

Introduction

The presence of organic contaminants in the environment has recently become a great concern, with paying attention to pesticides that represent emerging contaminants. The main pathway through which pesticides enter the aquatic environment is agricultural activity. Runoff over fields, spray drift and infiltration caused by precipitations are the major causes of the presence of these agrochemicals in surface and ground waters, and as a consequence, residues of some harmful pesticides can be detected in water samples. Pesticide pollution can be not only problematic for human health, but it also endangers aquatic organisms.

EU Water Framework Directive (WFD) 2000/60/EC established protection of aquatic environment and establishing a strategy against the chemical pollution of water bodies. For surface waters, this protection is partly achieved by identification of Priority Substances that include 12 pesticides, and the establishment of Environmental Quality Standards for priority substances at European level in the daughter Directive 2008/105/EC, amended in 2013 by 2013/39/EU. According to the latest one, priority substances comprise 10 additional

pesticides. The WFD includes the obligation for Member States to identify pollutants of national concern as river basin specific pollutants and to set environmental quality standards for them at national level. According to their analysis of pressures and impacts, Member States need to set up monitoring programs for surface waters covering a wide range of contaminants in order to characterize the risks, and the need for action. In addition, new Watch List, introduced by Commission Decision (EU) 2015/495 requires the monitoring of substances that might pose a risk at EU level for which monitoring data are not yet sufficient to confirm the risk.

In addition to EU WFD, the NORMAN (Network of reference laboratories, research centers and related organizations for monitoring of emerging environmental substances) database of emerging substances lists over 700 non-regulated environmental contaminants with potentially harmful effects. The NORMAN prioritization scheme ranks compounds based on their occurrence, toxicity and use. In the NORMAN scheme none of the substances is discarded from the prioritization because of lack of monitoring or toxicity data (Vrana *et al*., 2016).

In order to achieve this, it is necessary to implement a continuous monitoring program which should provide a comprehensive and interrelated overview of water status (WFD Guidance WG 2.7), which requires the application of appropriate sampling and determination techniques.

Until now, the procedure for sampling and quantification of residual pesticide quantities in water environment based upon application of traditional sampling techniques which imply periodic taking of individual samples. However, this type of sampling provides only temporary overview of pollutant presence in water; it gives inappropriate information on variability of their concentrations, making difficult registration of timely oscillation of water contamination level, as well as extreme, accidental emission incidences; it demands large amounts of water for determination of compounds present in low concentrations and use of highly sensitive equipment during instrumental analysis. In order to overcome the named deficiencies, it is possible to increase the frequency of individual sampling or use automatic *on-line* monitoring systems. Both of these solutions are extremely costly and impractical; imply long lasting labor process, choice of the appropriate locality, and etc.

In recent times, as the alternative, a technique of passive sampling of pollutants in water, including pesticides (ISO 5667-23:2011) was introduced.

Passive sampling

Passive sampling represents a contemporary technique for timely integrated measurements of the levels of pollutants present in different environmental mediums, suitable for different types of monitoring. Since seventies of the last century, this sampling method has been used for environmental monitoring, by development and use of the first samples for assessment of air quality and exposure of the working area to potentially hazardous pollutants in the air. This method of sampling of the seventies used for environmental monitoring, development and implementation of the first samplers for assessing air quality and exposure to the working area of potentially hazardous pollutants in the air (Vojinović-Miloradov *et al*., 2014). As opposed to this, passive samples adapted to monitoring of water, soil and sediment quality are in the phase of development and introduction.

Beside simple construction and handling, this contemporary technique is characterized by low price and the possibility of multiple uses. The base of the technique is accumulation of analytes in corresponding sorption material in device for passive sampling. Generally, passive sampling techniques are based on the diffusion of chemicals from a medium to a receiving phase, basically due to a difference in the chemical potential gradients. The uptake of the analytes depends on several factors such as the properties of the receiving phase, the

physicochemical properties of the compounds, and environmental parameters such as temperature, water properties (pH, salinity, etc.), water turbulence and flow, biofouling, etc. (Vrana *et al*., 2005). Depending on the kind of the compound, for pollutant sampling in surface waters different devices such as PDMS (*polydimethylsiloxane*), SPMD (*semipermeable membrane device*), LDPE (low density polyethylene), DGT (Diffusive Gradient in Thin-films), MESCO (membrane enclosed sorptive coating), POCIS (*polar organic chemical integrative sampler*), Chemcatcher are available (Figure 1). Among them, POCIS, SPMD and Chemcatcher® samplers have been successfully applied for the determination of TWA concentrations of pesticides (Schafer *et al*., 2008; Alvarez *et al*., 2005, 2007; Arditsoglou and Voutsa, 2008) in various aquatic environments (wastewater effluents, streams, lakes, rivers, and coastal waters).

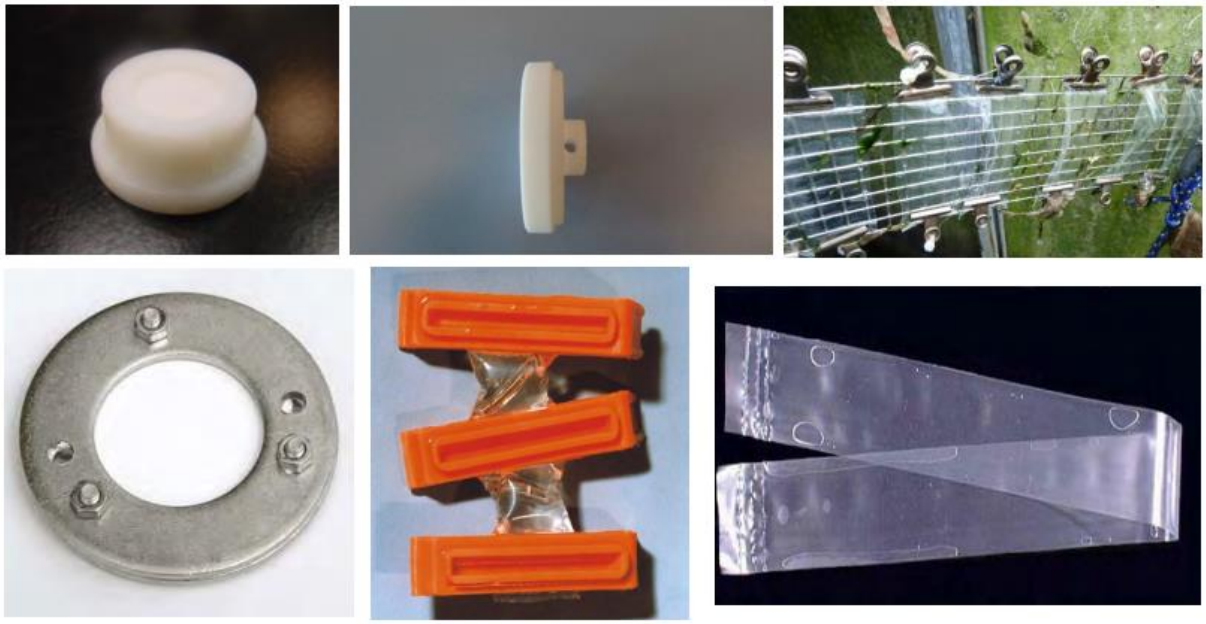

Figure 1. Passive samplers (Mills, 2015)

The technique involves placing of the device in water environment for a longer time period which varies from several days to several weeks, depending on the kind of the compound. In such a manner the average concentrations of pollutants dissolved in water during defined time period (*time-weighted average concentrations, TWA*) are obtained as results, which enables monitoring the trend of spatial and seasonal variations.

Sampling rate, R_s

For application of the technique for determination of pesticides in real conditions of aqueous environment, it is necessary to determine the value of the sampling rate (R_s), specific for each compound. R_s can be stated as the number of liters of water per day that are sampled 'through' the sampler during the exposure time. However, for the most of the pesticides there is a lack of data on the sampling efficiency and sampling rates. The available data on R_s have been obtained by laboratory or *in-situ* calibration of devices for passive sampling and refer to smaller number of pesticides, mainly those from WFD list of priority pollutants.

Different calibration methods have been described over the last years, which makes comparison between sampling rates hard (Harman *et al*., 2012) and leads to that an overall model is lacking for correlating different compounds and sampling rates (Harman *et al*., 2011). Until now, laboratory calibration experiments were mainly conducted in static systems (Hernando *et al*., 2005; Mazzella *et al*., 2007, 2010; Lissalde *et al*., 2011) or in static system

under stirring conditions (Alvarez *et al*., 2004, 2007; Thomatou *et al*., 2011). These tests imply exposure of a sampler to a beaker with spiked water, but they also have important drawbacks for the achieved R_s values; do not include the influence of the parameters of the exposure media.

Constant flow conditions, that include impact of the listed parameters in a laboratory calibration experiment, have been applied only in several studies (Harman *et al*., 2009; Mazzella *et al*., 2007).

Calibration procedure implies exposure of passive sampling devices to water spiked by corresponding concentration of the studied compound. During a certain period of time, lasting the most frequently 2-4 weeks, samples are removed from water at regular time intervals. After that, compounds accumulated in medium of the sampler are separated by extraction and then quantified by specified analytical procedure, by corresponding chromatograph method.

The accumulation of a compound in a passive sampler is assumed to follow first-order kinetics, which consists of three phases: linear, curvilinear and equilibrium partitioning (Alvarez *et al*., 2004) (Figure 2). In the linear phase the adsorbent can be assumed to be an infinite sink (Alvarez *et al*., 2004). This assumption makes an estimation of the TWA concentration possible for a specific period of time (Alvarez *et al*., 2004). Moreover, for this purpose a linear regression model with zero intercept was often used (Mazzella *et al*., 2007; Arditsoglou and Voutsa, 2008).

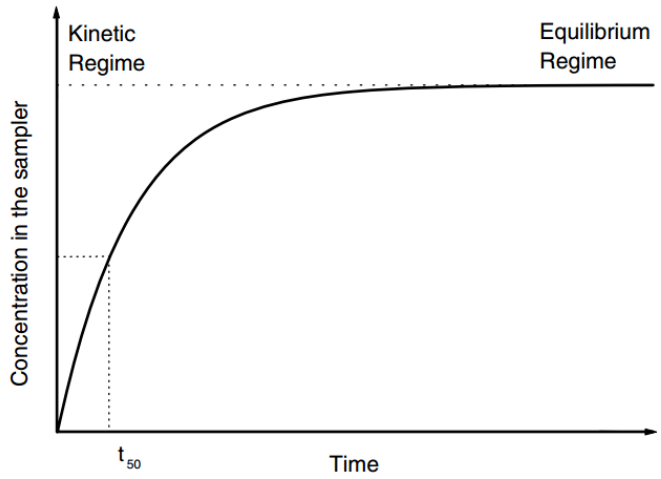

Figure 2. First-order kinetics for accumulation of a compound in a passive sampler over time. The three phases (linear, curvilinear and equilibrium) and the half-life time ($t_{1/2}$) are shown (Vrana *et al*., 2005)

Determination of pesticides content

Application of the passive sampling technique leads to the increase in sensitivity of analytical methods, having in mind that pre-concentration of analytes runs inside the sorption medium. Unlike many traditional methods, the described type of sampling enables increase in sensitivity and improvement of stability of analytes in the sample, without additional treatments (adjustment of pH values, etc.) In some cases, use of passive samplers enables reduction, or even total elimination of use of high quantities of extraction solvents.

In accordance with the restrictive European Union (EU) regulations, that limit the maximum amount allowed for a single pesticide in drinking water to 0.1 μg/l and the sum of the pesticides to 0.5 μg/l including toxic transformation products (Council Directive 98/83/EC), very sensitive analytical methods for monitoring drinking and surface water samples are required.

In line with these, the application of sensitive instrumental analysis techniques is required. For water soluble and thermally labile pesticides, HPLC is the preferred approach, extensively used with ultraviolet (UV) or diode array detection (DAD). Nowadays, HPLC coupled with mass spectrometry (MS) or tandem mass spectrometry (MS/MS) methods, which have the advantages of high sensitivity and high degree of selectivity, have been proven to be a powerful tool for pesticide residues determination in environmental samples (de Lafontaine *et al*., 2014). Thermally stabile pesticides are successfully analyzed by gas chromatography, using electron capture detector (ECD), or coupled with mass spectrometry (MS, MS/MS).

Performance reference compounds, PRCs

Calibrated R_s is necessary to correct the variability of the exposure conditions. Recently, the use of performance reference compounds (PRCs) has been successfully applied for the assessment of the R_s and correction of laboratory-derived sampling rates (Mazzella *et al*., 2010). PRCs are non-interfering compounds not found in environmental waters to be sampled (such as deuterated compounds) (Alvarez *et al*., 2007). It is a compound that is added to the sampling device during the device production and is lost into surrounding water during the experiment.

Measured values of PRC loss rates are used to account for any rate affecting differences between field and calibration study exposure conditions. This approach to *in situ* calibration is based on the principle that the rate of residue loss is proportional to the rate of residue uptake. How much sampling rates are affected by environmental conditions is hard to determine without the use of PRCs (Harman *et al*., 2011). The purpose of this is to obtain a correction factor (elimination constant rate, k_e) in order to compensate environmental conditions in the field and, therefore, to provide a better estimation of the TWA water concentrations.

Instead of conclusion

Passive sampling represents one of the most acceptable techniques for timely integrated measurements of pesticides concentration levels and other pollutants present in different environmental media, especially in water. One of the major advantages of passive sampling is higher sensitivity and the possibility of measuring TWA concentrations. Finally, the development of efficient method-validation schemes for passive sampling techniques is essential to gain broader acceptance for the technology in regulatory programs (Vrana *et al*., 2005) and application of passive sampling methods for monitoring organic chemicals within the framework of the WFD.

EFFECT OF CLIMATE CHANGE ON AGRO HYDROLOGICAL BALANCE FOR SOME REGIONS IN BOSNIA AND HERZEGOVINA

Sabrija ČADRO*, Jasminka ŽUROVEC, Ajla MRKULIĆ, Dženita ŠEHIĆ, Amela ŠERO, Gvozden MIĆIĆ

Abstract

The main characteristic of agro-hydrological balance (AHB) in Bosnia and Herzegovina (B&H) is the occurrence of surplus water during the cold months and water deficit during the warmer months. In the southern regions, surpluses and deficits of water are significantly more pronounced than in the central and northern regions of B&H. Among other things, within the research of agro-hydrological balance made for the period up to 1991, it was found that B&H agriculture covers most of the water needs throughout precipitation inputs (around 83%). Based on the comparative analysis for the period of 1981-2010, with respect to the reference period of 1961-1990, average yearly air temperature in B&H increased from 0.4 to 0.8ºC, whereas temperature increases during vegetation period were up to 1.0 ºC. Significant variability in precipitation has not been recorded within the same period. The main objective of this paper is to determine the significance of changes in AHB in some regions B&H as a result of climate change, with a special focus on the trend of water surpluses and deficits and their impact on agricultural production. Data from weather stations: Banja Luka, Tuzla, Zenica and Mostar, for the period 1991 - 2015 were used for analysis of AHB components by Thornthwaite-Mather method (TM). Potential evapotranspiration (PET) calculated with Thornthwaite method was used as input for water balance calculation. A significant increase in air temperature (1981 – 2015) resulted in change of PET value, and therefore the value of other AHB components, primarily water surplus and deficit.

Keywords: *Bosnia and Herzegovina, climate change, agro-hydrological balance, water deficit*

Introduction

The knowledge about the water cycle at a specific smaller area for a certain period of time has a very practical significance because in this way we come to the water balance (agro-hydrological balance), the term that was introduced to hydrology from commercial balance (Vlahinić et al. 1972).

Information gained through the AHB are significant especially for understanding the possibilities of organizing agricultural production in a given area. If the inflow of water from precipitation (P) in the soil is less than potential evapotranspiration (PET) plant available water content in the soil will decrease and through balance procedure soil water deficiency will indicate the need for irrigation. If the inflow of water is bigger it will result in occurrence of excess water in the soil, which will indicate the potential runoff and drainage needs (Žurovec, 2012).

In the area of B&H, researchers are analyzing the AHB of the soil for almost six decades. The mostly used methods of Potential evapotranspiration (PET) calculation are first of all empirical method by Thornthwaite (1948), the method by Penman (1948) and Turk (1961). Compared to other methods, Thornthwaite method requires least input data (average temperature and geographical position) and according to some authors on regional level provides the best results (Čustović et al., 2012). The obtained PET values are then used in

Thornthwaite-Mather (TM) (1957) model of the AHB for obtaining data about the soil water deficit, runoff (Blue Water) and actual evapotranspiration (Green water).
During the war period (1991-1995), most of the meteorological stations (MS) in the area of B&H have stopped working, but most of them were again put in operation in 2000s. Because of discontinuity in the monitoring of the climate data, it was not possible to determine the current situation and changes in the values of AHB parameters and most of the researchers used previously obtained values (timer series until 1991). Today, 25 years after the war, it is possible to create a reliable and actual water balances for the MS that had continuous climate data collection or where discontinuity did not last long.
B&H has experienced serious incidences of extreme weather events in the past two decades, causing severe economic losses. Based on available data and currently available climate projections, exposure to threats from climate change will continue to increase (Žurovec et al., 2015). Observed climate changes are reflected through an increase in average temperatures in B&H. For the last hundred years, the average temperature has increased by 0.8 °C (which is in line with global trends), with a tendency to accelerate, the decade of 2000–2010 is warmest in the last 120 years (INCBIH, 2009). The first decade of the twentieth century in B&H can be characterized as distinct periods of extremes in terms of excessive humidity, severe droughts and heat waves (Žurovec et al., 2011; 2015).
This significant increase in air temperature for the result has a change of Thornthwaite PET value based mainly on mean air temperature data and connected with PET, change in the value of other AHB components, primarily water surplus and deficit.
The main objective of this paper is to determine the significance of changes in AHB in some regions B&H as a result of climate change, with a special focus on the trend of water surpluses and deficits and their impact on agricultural production.

Materials and methods

Determination of changes in AHB for selected regions of B&H was achieved by: (i) analysis of secondary data related to AHB for B&H; (ii) climate data collection for the time series 1991-2015 and calculation of all AHB components for selected MS; and (iii) a comparative analysis of the values of AHB components between the two analyzed periods (period 1961-1991 and 1991-2015). Collected secondary data where cross-checked for avoiding inconsistence and contradictions.
Data from several weather stations (Banja Luka, Tuzla, Zenica and Mostar), for the period 1991 – 2015, were used for analysis of agro-hydrological balance components by Thornthwaite-Mather method (TM). Potential evapotranspiration (PET) calculated with Thornthwaite method was used as input for water balance calculation. Required input parameters used: monthly precipitation (P), monthly potential evapotranspiration (PET) and readily available soil water holding capacity of 100 mm (RAW).
Selected MS with their locations may represent the northern (Banja Luka, Tuzla), Central (Zenica) and south (Mostar) region of B&H. In addition, these are the MS that were in operation during the war and have a continuous series of data for a period of 25 years.
To make the two data sets (the period until 1991 and the period from 1991 to 2015) comparable, the calculation of AHB for the period 1991-2015 is made by the same method (TM) and with the same RAW values (100 mm) used by researchers in previous years.

Results and discussion

In the *Long-term B&H Land Reclamation Program* by the *Republican Committee on Agriculture, Forestry and Water Management Sarajevo*, for the period 1986 - 2000 (RKPŠV, 1986) determination of irrigation water need is based on agro-hydrological analysis of long-term time series (20-60 years long) for a larger number of MS in B&H. It was found that the average annual soil water deficiency or irrigation water requirement in the northern parts of

the country is around 100 mm, with up to 200 mm in one part of Semberija. Soil water deficiency in the central parts of the country is 50 mm, while in the south deficiency increased up to 300.

In the study of Vlahnić and Hakl (1989), the analysis of AHB included two distinct climatic ambients; one with mediterranean (Mostar), and the other with continental (Tuzla) climates. AHB are made for the time series of 30 years (1951-1980). The average PET for the Mostar area is 807 mm, average water deficiency 182 mm while AET was 625 mm. In the area of Tuzla PET amounted 660 mm, water deficiency 53 mm, and AET 607 mm.

The study *Hydro-melioration Problems of Agricultural Land of B&H* done by the FZAP (1994) treated 27 MS for time series of 20 years (1959-1978). In table 1 extracted values for weather stations: Banja Luka, Tuzla and Mostar are shown:

Table 1. Agro-hydrological balance for the selected stations (FZAP, 1994)

Part of B&H	Station	Precipitation	PET	Runoff – Blue Water (V)	Soil water deficiency	AET
Northern	Banja Luka	1050	695	411	56	639
	Tuzla	913	658	864	46	612
Southern	Mostar	1465	846	301	245	601

In the period after 2000, the results of another AHB for the entire B&H appeared in the literature. Results of this AHB (table 2) are used in many publications (Vlahinić, 2000a, 2000b, 2000c, 2004; Vlahinić et al. 2001a, 2001b; Alagić, 2003; Čustović, 2005; INCBH, 2009; Čustović et al., 2012; Hodžić et al., 2013).

Table 2. Main agro-hydrological balance for B&H

Average annual hydrological component in mm	B&H average	Southern parts	Central parts	Northern parts
Precipitation (P)	1200	2000	1000	800
Potential Evapotranspiration (PET)	725	900	650	700
Runoff – Blue Water (V)	600	1400	400	200
Soil water deficiency (M)	125	300	50	100
Actual Evapotranspiration - Green water (AET)	600	600	600	600

This AHB (table 2) is in the literature often referred as the main agro-hydrological balance of B&H, but to the best of our knowledge, it is nowhere precisely defined for which time series was made, which MS were used, nor the southern, central and northern regions of B&H were spatially determined. According to it, precipitation represents the greatest water resource in B&H. Average annual precipitation is about 1200 mm, which in terms of volume amounts to 61.6 billion m^3. However, precipitation is the most variable hydrological parameter in terms of space and time. Average annual precipitation in the southern parts of B&H amounts to about 2000 mm, in central parts about 1000 mm and in northern parts about 800 mm (Vlahinić et al., 2001a; INCBH, 2009). Annual precipitation in all three parts of B&H is higher than annual potential evapotranspiration, but because of uneven precipitation distribution the potential evapotranspiration is not covered by precipitation.

A significant contribution to the analysis of AHB is achieved through the study done PPF (2004), titled "*Water Balance of Land in Bosnia And Herzegovina in Order to Prevent Erosion, Droughts and Floods*." In this study balance is based on data obtained at 68 meteorological stations with different lengths of time series in seven large river catchments (Una, Vrbas, Bosna, Drina, Neretva and Trebišnjica, Cetina and Krka, immediate catchment of the Sava). The water balances (table 3) for the B&H state level (total area of 5.1 million ha) show the following average state:

Table 3. Agro-hydrological balance for B&H (Čustović, et al., 2004, 2012; Vlahinić, 2007)

Average annual hydrological component	mm	billion m^3
Precipitation (P)	1120	57.3
Potential Evapotranspiration (PET)	660	33.7
Runoff – Blue Water (V)	547	28.0
Soil water deficiency (M)	87	4.4
Actual Evapotranspiration - Green water (AET)	573	29.3

If we compare the results of the previously mentioned AHB, although the balancing was done for the relatively similar time series, differences in the values of the components can be observed. Thus, by comparing the results of the last AHB (table 3) with the previously mentioned (table 2) the lower values of all hydrological components were determined. The biggest change is the average amount of precipitation which is lower by 80 mm, and the value of PET which is lower by 65.

To determine the effect of climate change on AHB for some regions in Bosnia and Herzegovina for the time period 1961-1991 data for four analyzed MS from study by PPF (2004) were used, and compared with calculated data for 1991-2015 time series. Fig. 1-5 are showing the change in the values of average annual AHB components between the two analyzed time series.

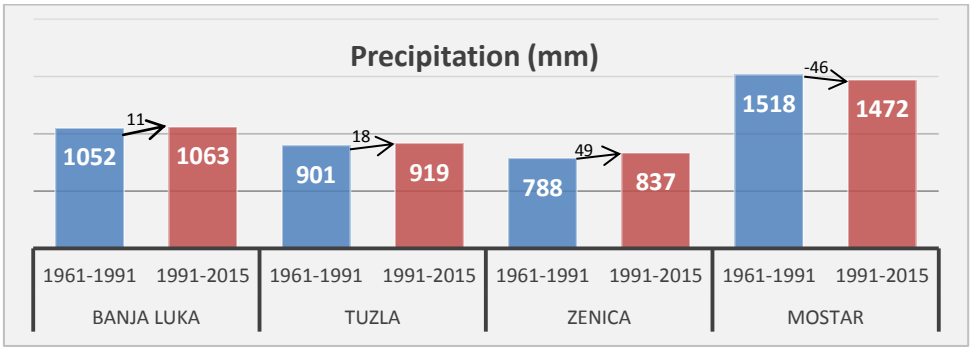

Fig. 1. Average annual precipitation (mm), difference between analyzed time series

On MS Banja Luka, Tuzla and Zenica, there was an increase of precipitation amount (Fig. 1). The largest increase of 49 mm is in the central part of B&H (Zenica). Southern parts, represented with MS Mostar had noticeable decrease in the amount of rainfall of 46 mm.

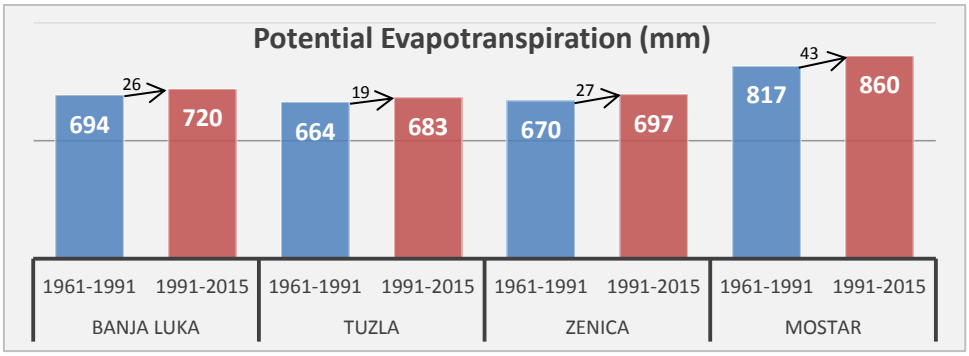

Fig. 2. Average annual PET (mm), difference between analyzed time series

As expected, PET values for second time series (1991-2015) for all analyzed MS are higher from 19 to 43 mm (Fig. 2). The largest increase was determined in the Mostar area (South part).

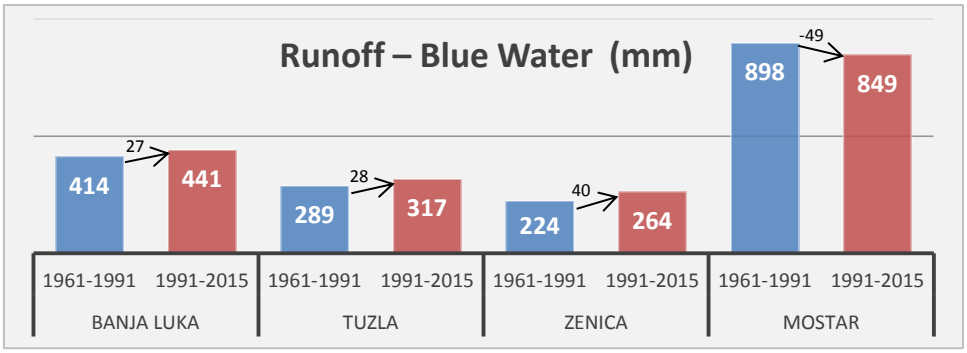

Fig. 3. Average annual runoff (mm), difference between analyzed time series

Like Precipitation, and the amount of runoff increased on all analyzed MS except Mostar (Fig. 3). A significant increase of 40 mm was determined in the central part or MS Zenica, as well as the northern part - MS Tuzla (28 mm) and Banja Luka (27 mm).

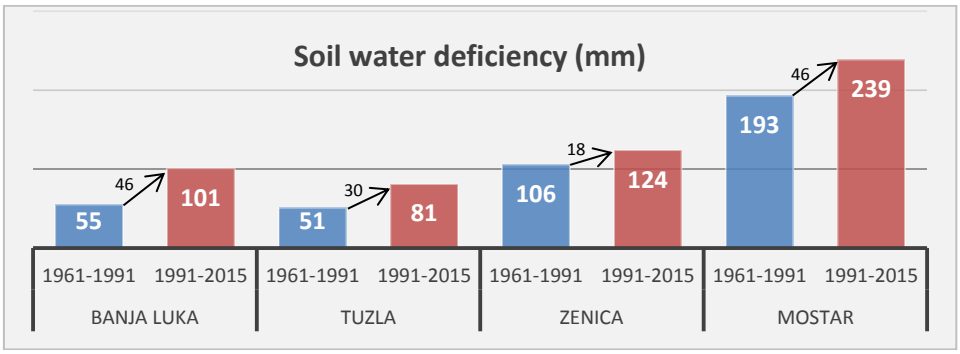

Fig. 4. Average annual soil water deficiency (mm), difference between analyzed time series

As a result of the increase in air temperature, soil water deficiency is increased at all analyzed MS. This highest increase of 46 mm is at the area of MS Banja Luka and Mostar (Fig. 4). Thus, annual irrigation water requirements for southern and central part of B&H, in relation to the period until 1991, increased for 430 m^3/ha.

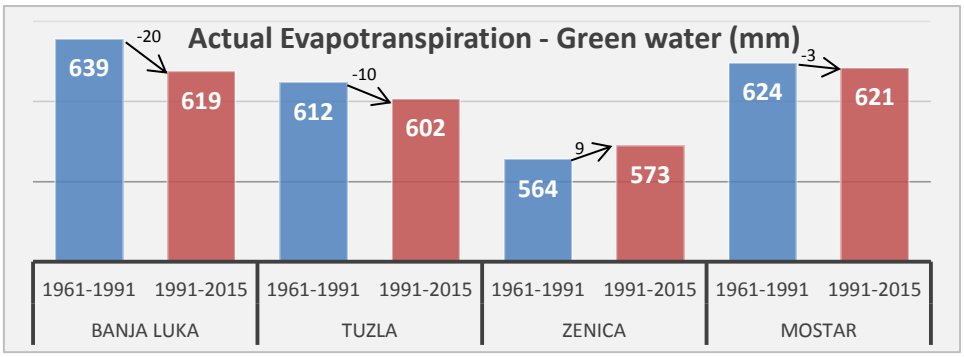

Fig. 5. Average annual AET (mm), difference between analysed time series

Values of AET are slightly changed. By increasing the value of PET (Fig. 2) at all analyzed MS, there was a reduction of the annual value of AET. This is not the case for MS Zenica where a significant increase in the amount of rainfall of 49 mm results in AET increase of 9 mm.

Conclusion

Based on the analysis of the secondary data related to agro-hydrological balance, as well as a comparison of the water balance time series 1961-1991 and 1991-2015, it can be concluded

that there is a significant need to develop new agro-hydrological balance for specific parts and the entire area of Bosnia and Herzegovina.

As result of climate change and increased climate variability, significant changes in agro-hydrological balance in some regions of B&H occurred. At the all analyzed meteorological stations (Banja Luka, Tuzla, Zenica and Mostar) there has been an increase in the annual value of PET and soil water deficit. These changes have important impact on the agricultural production, particularly in irrigation water requirements, which in relation to the period prior to 1991, increased up to 430 m^3/ha.

Abstract

A comparative research on the impact of compost on the chemical composition and quality of Oriental tobacco Krumovgrad 90 has been carried out. The experiment was performed on an agricultural field contaminated by the lead zinc smelter near the town of Kardzali, Bulgaria (Ostovitsa village). The field experiment was a randomized complete block design containing two treatments and four replications (8 plots). The treatments consisted of a control (no organic amendments) and compost amendments (40 t/daa). Heavy metals were measured in roots, stems and leaves of Oriental tobacco Krumovgrad 90. The compost treatments had significant effects on the uptake and allocation of plant nutrients and heavy metals. It can be concluded, that heavy metals were accumulated mainly in the tobacco leaves. Soil contamination with heavy metals did not affect the quality of tobacco leaves. Application of the compost leads to increased content of potassium, calcium and magnesium in the leaves of tobacco and therefore may favorably affect burning properties of tobacco. Incorporation of compost in the soil affect plant height and number of leaves formed, leads to an increase in the size of the leaves and to a lowering of the quality of the tobacco. Application of compost to soil resulting in increased mineral substances (pure ash) and quantity of proteins, and reduces the amount of reducing sugars in tobacco leaves in relation to the control. The application of compost to the soil affects more negatively as regards quality and typicality of oriental tobacco variety of Krumovgrad 90.

Keywords: *Compost, Oriental Tobacco, Quality, Chemical composition*

Introduction

Tobacco is a major agricultural crop for many countries, including Bulgaria. Appropriate climatic conditions in the country determine the cultivation of high-quality oriental tobaccos that are distinguished by their specific smoking and technological properties. Among the Bulgarian oriental tobaccos, Krumovgrad origin is most common in the production and best realizing in the international markets. The quality of the tobacco is largely determined by its chemical composition. The study of the chemical composition of the tobacco is primarily associated with its technological qualities, mainly with the combustibility but tobacco consumption makes them significant also in terms of their biological effects on human health. This issue is particularly important given the ability of the tobacco to accumulate heavy metals, and the ability of part of them to be emitted in the main and side tobacco smoke stream (Stoilova and Markova, 2004). Chemical properties of tobacco depend on many factors, among which the following should be noted: variety, habitat (soil and climate), as well as the impact of agro-technical practices on the physical, chemical and biological properties of the soil. Soil conditions and nutrient content are crucial for the growth and development of plants. Yield and quality of tobacco is strongly influenced by fertilization and especially by the introduction of nitrogen and potassium fertilizers (Bozhinova and Bozhinov,

2006). The use of organic fertilizers can affect the physicochemical properties of the soil and can improve the conditions for crop development. Also, the organic fertilizer can neutralize or reduce the acidity of the soil and can increase the content of certain trace elements such as zinc and copper. Organic fertilizers can increase the weight of tobacco leaves and yield. The efficiency of organic fertilization is manifested in rapid growth, earlier senescence of leaves, and improvement of the combustibility of the leaves (Wang *et al*., 2009). The increasing application of organic fertilizers leads to improvement of the soil's ability to deliver nutrients, in this way providing enough quantities of N, P, and K for the development of tobacco (Cao *et al*, 2004).

The purpose of this study was to conduct a comparative study that would allow us to determine the influence of compost on chemical composition and quality of Oriental tobacco variety Krumovgrad 90.

Material and Methods

The study included oriental tobacco (variety Krumovgrad 90) grown near Lead-Zink Complex /LZC/ - Kardzhali. Field trials were set in 2 variants under the block method in four repetitions (8 plots): 1- introduction of 40 t/daa of compost to the soil and 2 - control variant. Characteristics of soil and compost are shown in Table 1. Soil samples taken from the area of LZC – Kardzhali (Ostrovitsa village) are slightly polluted with Pb and Cd and are characterized by acidic reaction (pH 6.3) and average content of organic matter (2.2%). Soil characteristics are a prerequisite for low to medium mobility of metals, which is confirmed by the results of the amounts of Pb, Cd, Zn and Cu (weak mobility for Pb, Zn and Cu, and an average for Cd) extracted with DTPA.

Technically senescenced leaves of various stem positions were taken for analysis. As the leaves of oriental tobacco ripen sequentially, harvesting is done in stages (harvests) by following the sequence of senescence of leaves. Harvesting of leaves is carried out for 4 harvests (primings). The collected technically senescenced leaves were strung on a single needle and dried in natural conditions, observing the technology of solar drying of oriental tobacco.

In the dried leaves, the content of substances was determined, directly related to the quality and the smoking properties of tobacco - total nitrogen, protein, reducing substances, mineral substances, nicotine. Analyzes were carried out according to conventional methods (ISO 15154, BDS 9142), as they are expressed in percentage by dry matter. The content of heavy metals, micro and macronutrients in tobacco leaves was determined by the method of dry mineralization. The total content of metals in the soil was determined in accordance with ISO 11466. The mobile forms were extracted by a solution of DTPA (1 M NH_4HCO_3 and 0.005 M DTPA, pH 7.8) (Soltanpour and Schwab, 1977). The quantitative measurements were carried out with inductively coupled plasma emission spectrometry (ICP) (Jobin Yvon Emission - JY 38 S, France).

Table 1. Characterization of the soil and compost used in the experiment

Parameter	Soil		Compost
pH	6.3		6.9
EC, dS/m	0.3		0.2
Organic matter, %	3.9		72.1
N, %	0.22		1.49
P, mg/kg	1223.5 *	32.5**	12653.9 *
K, mg/kg	6300	570.1	6081.7
Ca,mg/kg	12937.5	323	32158.7
Mg,mg/kg	8310	559	2086.5
Fe, mg/kg	33400	41.3	3177.3
Mn,mg/kg	864.5	70.3	360.5
Cu, mg/kg	34.4	6.3	14.2
Pb, mg/kg	130.4	30.9	12.0
Cd, mg/kg	3.3	0.55	0.19
Zn, mg/kg	267.7	46.0	170.8

*Total content; **DTPA –extractable; Maximum permissible concentrations (pH 6.0-7.4): Pb-60 mg/kg, Cd-2.0 mg/kg, Zn-320 mg/kg

Results and Discussion

The height of the plant is directly connected with the formed leaves, and hence this indicator can be used as an indicator of the possible number of leaves (Ali *et al.,* 1984). Incorporation of compost in the soil has a positive effect on plant height and number of leaves formed (data not shown).

Besides the number of leaves suitable for picking, yield and quality of the leaves is determined by their size. Length and width of leaves in technical senescence vary depending on the harvesting zone. Fig. 1 presents data on the size of leaves from four stem positions - 7th, 14th, 19th and 28th leaf. In all stem positions the leaves of the smaller sizes are obtained in the control. A relationship is established between the amount of leaves (length and width) and the stem position. Plants are distinguished by smaller leaves of a lower zone and bigger from middle and upper zone (Fig. 1). Typical of the oriental tobaccos is that the smaller the size of the leaves, the more typically expressed is the type (Gyuzelev, 1983). The incorporation of compost results in increasing the length of the leaves and exceeding the limit value for the quality (20 cm).

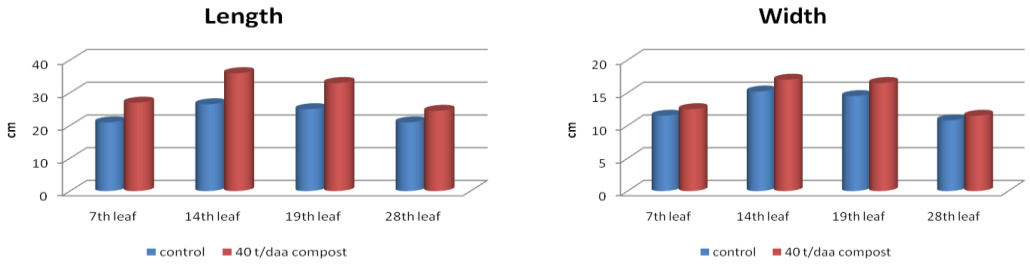

Fig.1. Length and width 7th, 14th, 19th and 28th leaf (cm), representative of a lower, middle and upper harvesting layer

The results of the influence of organic amendments on the accumulation of heavy metals, micro and macronutrients in the leaves of Oriental tobacco are presented in Fig. 2.

The lead content in tobacco leaves varies from 135.6 to 272.5 mg/kg in the control, and from 149.9 to 310.4 mg/kg in variants with incorporation of compost. Visible symptoms, caused by

high levels of Pb, which occur in tobacco - dark green leaves, leafroll of old leaves, dark brown and short roots, were not observed in our experiments. According Tso (1991), the content of Pb in tobacco leaves varies widely - from 0 to 200 mg/kg, and depends largely on the soil characteristics, the type and variety of tobacco, as well as the place of cultivation (Lugon-Moulin *et al*., 2004). The significantly higher results, received by us, are probably due to soil and aerosol pollution. The incorporation of compost leads to an increase of the lead content in tobacco leaves from the lower and middle zone (Fig.2).

The cadmium content in tobacco leaves varies from 6.4 to 9.0 mg/kg in the control, and from 5.2 to 9.8 mg/kg in variants with incorporation of compost. Visible symptoms caused by the increased content of Cd in plants, such as growth arrest, damage to the root system, chlorosis on leaves, reddish to dark brown colour on their edges, were not observed. According Golia *et al.* (2007) the content of Cd in tobacco ranges from 0.5 to 3.5 mg/kg, while Tso (1991) reports values reaching up to 11.6 mg/kg.

The content of lead and cadmium is lowest in the leaves from the first harvest. Our results are inconsistent with those of Wagner (1994), according to whom the highest values of Cd are found in the leaves from the lower zone of tobacco and significantly lower in the leaves of top zone, assuming gradual accumulation over time. Incorporation of compost leads to a reduction of cadmium in tobacco leaves from the middle and upper zone.

The zinc content in tobacco leaves varies from 151.1 to 218.2 mg/kg in the control, and from 134.6 to 220.5 mg/kg in variants with incorporation of compost. Symptoms of zinc toxicity which manifest themselves as chlorosis and necrosis at the edges of the leaves, inter-veinal chlorosis in young leaves, plant growth arrest as a whole, damage to the roots, were not observed as well. According to Jones *et al.* (1991) and Campbell (2000) the optimum amount of Zn in the tobacco is in the range from 20 to 60 (80) mg/kg, and excess were observed in values above 80 to 100 mg/kg.

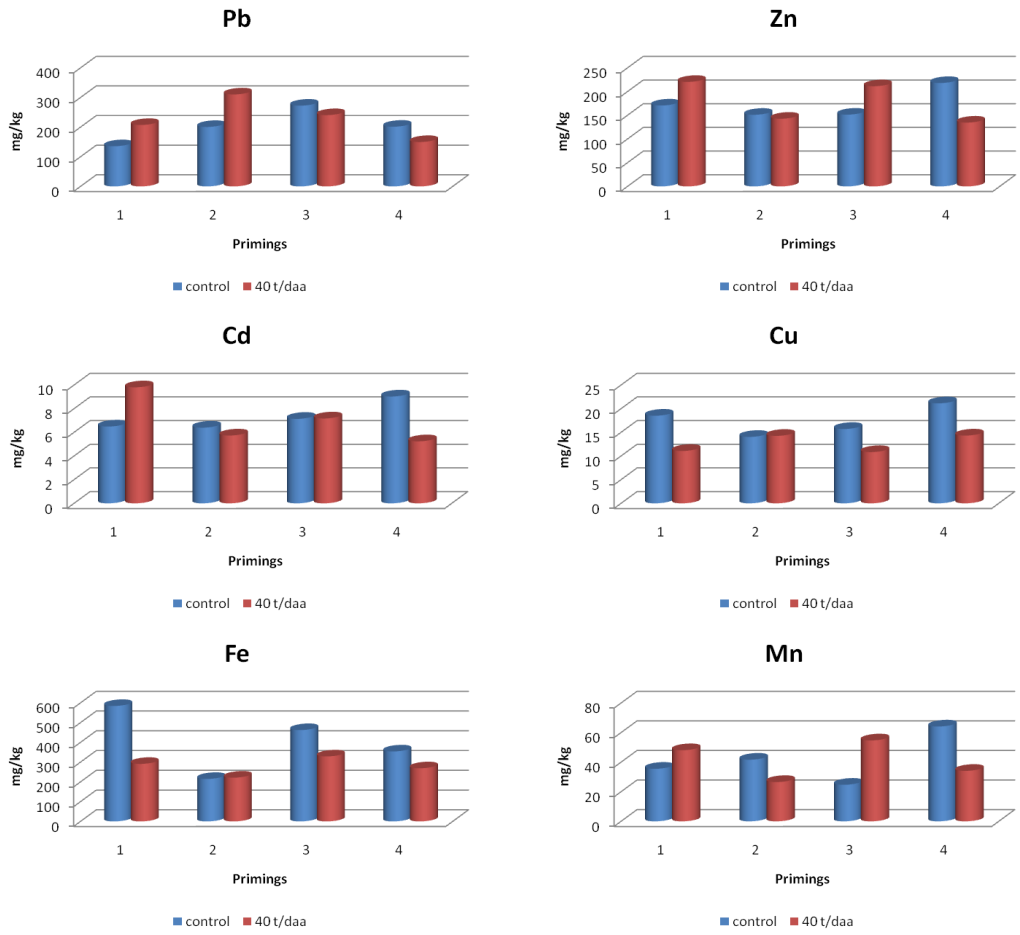
According to Campbell (2000) the optimum values of copper for tobacco are 5-10 mg/kg. The values identified by us for Cu in leaves are in the range 14.1 - 21.1 mg/kg. The content of zinc and copper is higher in the leaves from the first harvest, in comparison with the leaves of the second and third harvest. Possible reason for this is the poor mobility of these elements in tobacco plant (Tso, 1991). The incorporation of compost increases the content of zinc in tobacco leaves from the lower zone and reduction of the copper content (Fig. 2).

The iron content in tobacco leaves varies from 215.2 to 584.4 mg/kg in the control, and from 221.6 to 329.1 mg/kg in variants with incorporation of compost. In scientific literature the optimal iron content in tobacco leaves is 50 to 300 mg/kg (Campbell, 2000), whereas 40-50 mg/kg is considered low concentration depending on the stage of plant development (Jones *et al.*, 1991). The iron content established by us in the technically senescenced leaves is above the indicated critical value for tobacco. The incorporation of compost leads to decrease of the iron content in the tobacco leaves from the middle and upper zone.

The manganese content in tobacco leaves varies from 24.5 to 64.1 mg/kg in the control, and from 26.6 to 54.7 mg/kg in variants with incorporation of compost. Although the content of mobile manganese in the soil is not high, tobacco leaves contain manganese above the lower limit of 20 ppm indicated by Campbell (2000). The incorporation of compost results in increased manganese content in leaves of the tobacco from the lower zone (Fig. 2).

Phosphorus content in tobacco leaves, depending on the stage of development, ranges from 0.1 to 1% (Jones *et al.,* 1991). Observed concentrations in technically senescenced leaves of oriental tobacco are around the lower limit, despite the good preservation of the soil by mobile phosphorus (Table 1). Most rich in phosphorus are technically senescenced leaves from the upper harvesting zone. This zone is enriched directly from the soil and by the re-utilization of phosphorus from the lower leaves that become poorer. The influence of compost on the phosphorus content in leaves is relatively weak. A trend for reduction of phosphorus in

leaves is observed in the leaves of the upper and lower harvesting zone while increase in the concentration is observed in the leaves of the 4th harvest.
The content of K in the leaves of tobacco plants varies depending on the stem position (Fig.2). These values are similar to those reported by Volodarskiy (1971), according to whom the content of K in the leaves 2.5-4.2% has a positive influence on tobacco combustibility. The content of potassium in leaves is the highest in the lower harvesting zone. In the middle and lower zone the content is reduced more than 2 times, probably due to reuse of potassium by inflorescences. Despite the good soil preservation with assimilable potassium, the concentration of potassium in leaf tissues decreases. This may be due to the high content of calcium and therefore of antagonism between potassium and calcium, where the intensity of the absorption of potassium is greatly reduced (Enikov and Benevski, 1984). Similar are the results obtained following the incorporation of compost in soil. There is a notable trend of reduction of K at the above-situated leaves.
The calcium content in tobacco leaves varies from 1.9 to 4.3% in the control (Fig.2).These values are similar to those reported by Yancheva (2002). The concentration of Ca in tobacco leaves depends on the stem position. Most Ca is accumulated in senescenced leaves from the bottom harvesting zone and senescenced leaves from the middle and upper harvesting zone have a significantly low content due to the lack of re-utilization of elements and its focus in older tissues (Fig. 2). The incorporation of compost in soil results in an increase of the calcium content in tobacco leaves (up to 5.0% in the leaves of the lower zone and 3.5% in the leaves of the upper zone).



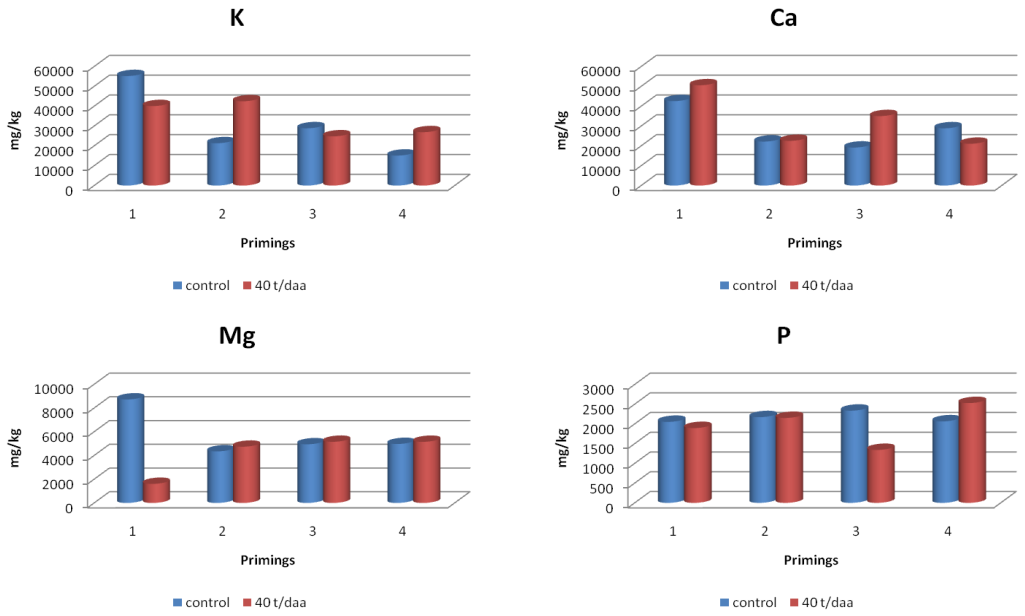


Fig. 2. Effect of compost on uptake of heavy metals, micro and macronutrients in Oriental tobacco leaves variety Krumovgrad 90

The minimum magnesium content in tobacco leaves, where symptoms of insufficiency do not appear, is about 0.25% (Tso, 1991). According to Yancheva (2002) the content of magnesium in technically senescenced leaves of oriental tobacco is changed in a narrow range - from 0.33 to 0.69% and depends mainly on the location of the leaves to the stem. According McCants and Woltz (1967) plant in Mg deficiency have a lower content of the element in the lower leaves in comparison to the upper ones, while in normal supply, the highest concentration of Mg in the lower leaves. The magnesium content established by us in technically senescenced leaves is above the critical value for tobacco. The highest concentration of magnesium is in the leaves of the lower harvesting zone. Apparently, the good preservation of the soil with Mg provides enough direct intake of magnesium in the above organs, which reduces the need for reuse, of which this element is subject to Bozhinova and Bozhinov (2006). The organic additives lead to increase in the magnesium content in tobacco leaves from the middle and upper zone (Fig. 2).

The K/Ca ratio is important for the quality of tobacco raw material and mainly associated with it is the structure of tobacco leaf and combustibility. When calcium prevails over potassium, raw material is obtained with poor elastic properties and volume. Our results show that K content in tobacco leaves from control plants prevails over the content of Ca. The exception only occurs in the leaves of the 4th harvest. The incorporation of compost in the soil leads to increased contents of potassium and calcium, the K/Ca ratio is changed, in the leaves of the 1st and 3rd harvest it is reduced, while in the leaves of the 2nd and 4th harvest it is increased.

Table 3 presents the results of the impact of compost on chemical parameters (content of ash, sugars and total nitrogen).

Ash. The content of mineral substances (ash) has well-expressed correlation with the fleshiness of tobacco leaves, and from there with their quality. Ash content in dried leaves of oriental tobacco ranges from 12% to 15% (Gyuzelev, 1983). The increase in the ash content compared to the control sample is evident in the incorporation of compost in the soil. A relationship is established between the content of potassium and magnesium in tobacco leaves and ash content. The increase in the amount of macro elements leads to the increase of ash content.

Table 3. Chemical composition (%) of dried tobacco leaves, variety Krumovgrad 90

Primings (Harvests)	Mineral substances, %	Soluble carbohydrates, %	Proteins, %	otal nitrogen, %	Nicotine,%	Schmuck's number
Control						
I	26.62	6.58	14.30	2.90	0.88	2.27
II	18.66	13.94	15.07	2.41	0.84	5.78
III	15.48	18.67	12.33	1.97	0.60	9.48
IV	17.87	15.46	13.90	2.22	0.66	6.96
40 t/daa compost						
I	28.17	6.79	14.14	2.26	0.62	3.00
II	18.24	13.52	16.07	2.57	0.88	5.26
III	19.51	7.98	15.90	2.55	0.94	3.13
IV	18.92	11.17	15.25	2.44	0.88	4.58

Protein substances. The influence of protein substances on consumer qualities of tobacco is generally negative, since pyrolysis of proteins produces nitrogenous substances in tobacco smoke with unpleasant odor and irritating taste. The content of proteins in tobacco leaves varies from 4 to 16% while in the oriental tobaccos it reaches up to 8.5%. The increase in protein in leaves from the four harvests compared to the control sample is strongly expressed in the incorporation of compost. A correlation is established between magnesium content in tobacco leaves and the content of proteins. The increase in the amount of magnesium leads to the increase in the content of protein substances.

Soluble carbohydrates. Oriental tobaccos contain significant amounts of reducing sugars and small amounts of protein. According to Gyuzelev (1983) the average content of soluble sugars in oriental tobaccos ranges from 10 to 18%. At very high content of soluble carbohydrates - over 16 % for oriental tobaccos and low content of nitrogen compounds, a lopsided taste with insufficient completeness is obtained, and the burning sensation is enhanced. The incorporation of compost in soil leads to lower content of soluble carbohydrates in tobacco leaves.

For the objective determination of the quality of light tobaccos, especially important is the balance between the main components of the chemical composition expressed in various ratios. With the help of the Schmuck's number (ratio of soluble carbohydrates and proteins) the main quality categories of oriental tobaccos can be objectively characterized (Schmuk and Nauk, 1953). Quality tobacco has value over 1.0, average quality - between 0.5 and 1.0, and low-quality - below 0.5. Schmuck's number ranges from 2.2 to 9.48 in the control sample, and from 3.0 to 5.26 in the variant with compost.

The indicators of the chemical composition characterize the material from the four harvests as quality and of average quality, which correlates very well with the results of the expert evaluation of the tobacco samples (data are not shown). The results obtained show that soil pollution with heavy metals do not affect the performance of the chemical composition, determining the quality of tobacco. The normal course of amendment of the chemical indicators is expressed by harvests, characteristic of the oriental tobacco. The resulting values are typical for tobacco of Krumovgrad origin (variety Krumovgrad 90) grown in field conditions, with the exception of the content of nicotine, which is significantly less than the typical for this variety and origin.

The chemical composition in tobacco with compost shows higher content of mineral substances, total nitrogen and nicotine and lower - of reducing substances, i.e. quality deterioration (particularly in the third and fourth harvest). This is also confirmed by the

following indices: (1) reducing substances/pure ash that characterizes fleshiness - in samples without compost it is 0.25-1.21; in those with compost – 0.24-0.74; (2) reducing substances/nicotine - without compost 7.5-31.1, with compost 8.5-12.7. The incorporation of compost in the soil affects negatively as regards to the quality and typicality of the oriental tobacco of variety Krumovgrad 90.

With regard to the smoking properties, in first and second harvests there is almost no difference between samples with compost and those without (but these are harvests with mediocre quality of oriental tobacco), but in third and fourth harvests the samples with compost fall far short of those without compost.

Conclusions

Incorporation of compost affect plant height and number of leaves formed, leads to an increase in the size of leaves and a decrease in the quality of tobacco.

The introduction of compost resulting in increased uptake of macro elements potassium, calcium and magnesium, and leads to improvement of the life status of the tobacco plant, and has a beneficial effect on burning properties of tobacco.

Compost affects the indicators defining the quality of tobacco (ash content, protein and reducing sugars). Application of compost to soil resulting in increased mineral substances (pure ash) and quantity of proteins, and reduces the amount of reducing sugars in tobacco leaves in relation to the control.

The application of compost to the soil affects more negatively as regards quality and typicality of oriental tobacco variety of Krumovgrad 90.

VISUAL IMPACT OF WIND TURBINES IN LITHUANIAN LANDSCAPE

Jonas ABROMAS[1], Dovilė KALKĖ[2]

[1]Klaipėda University, Klaipėda, Lithuania, Corresponding author: j.abromas@gmail.com
[2]Klaipėda University, Vilnius Gediminas technical University, Lithuania, dovilekalke@gmail.com

Abstract

In the 21st century, wind energy has started to be seen as a national asset. It is estimated that by 2020, wind turbines should produce 12% of all the consumed electric energy. Wind energy benefits include very eco-friendly source; efficiency of the generated electric power is up to 25-30 % (solar panel efficiency is up to 20 %); independent and safe source of energy which is getting increasingly affordable (Kytra, 2006). Due to their visual – spatial parameters, these sites are becoming dominant verticals, thus, changing the local landscape and its visual quality, which in turn determines the quality of the living environment. In order to preserve the identity of the regional landscape, it is important to estimate the potential impact of both existing and planned wind turbines on the landscape. Visual impact of wind turbines depends on a number of features: the size, colour and shape of the turbine, observation distance, landscape diversity, time of day, and many other factors.

Considering visual-spatial parameters of wind turbines in Lithuania, landscape features with their potential, and the impact of anthropogenic environment, the basic methodological principles for the assessment of visual impact of wind turbines have been developed. The main phases are distinguished: determining the zones of visual impact; creating GIS (geographic information system) database; visibility modeling; assessment of nature, significance and contrast of the impact.

Keywords: Wind turbines, *visual impact, zones of visual influence, environmental impact assessment.*

Introduction

Wind turbines are becoming an integral part of the landscape in Western Lithuania. The hub height of the wind turbines currently under construction reaches 80-120 m, while the blade-tip height is 120-150 m. Under good visibility conditions, wind turbines can be visible from up to 25-30 km distance. Their construction in the area is initiated by the average annual wind speed, reaching 6-7 m/s. Although this region has important protected areas, resorts (Palanga, Neringa), intensive tourist routes, as many as six wind farms operate in Kretinga district alone (which borders the municipality of Palanga). Also, quite often problems arise when wind turbines are built in the area of natural framework, in the approaches to the national and regional parks, near the important site of cultural heritage and their visual protection zones, and villages. Due to these aspects, the valuable landscape has changed in some areas, since the future impact of the wind turbines under construction had not been adequately estimated.

Due to their visual - spatial parameters, these sites are becoming dominant verticals thus changing the local landscape and its visual quality, which in turn determines the quality of the living environment. In order to preserve the identity of the regional landscape, it is important to estimate the potential impact of both existing and planned wind turbines on the landscape (Kamicaityte-Virbašienė J., Abromas J. 2012).

Materials and methods

Subject matter of the research is the visual impact of wind turbines on the cultural landscape of Lithuania.

The developed methodology for the assessment was tested during the research on wind turbines and wind farms in the districts of Kretinga, Šilutė, Tauragė, Pagėgiai, and Šilalė. Photofixation and assessment (determining the nature and significance of the impact of wind turbines, and degree of contrast) was carried out during the research in situ.

Results and discussion

The world is experiencing rapid development of wind turbine construction. Up until 2008, the European continent was in the lead according to the installed capacity of wind power. At a later period (and now), new wind power has been mostly installed in Asia. At the end of 2015, the total capacity of wind turbines installed worldwide reached 432,883 MW (Global…, 2015). The total amount of wind energy installed in Lithuania is not relatively high (amounted to 438 MW at the beginning of 2016) (LITGRID 2016). The big wind turbines and their farms are concentrated in the western Lithuania. The majority of wind turbines were built in Kretinga, Šilutė and Tauragė district areas. Although this region has important protected areas, resorts (Palanga, Neringa), intensive tourist routes, as many as six wind farms operate in Kretinga district alone (which borders the municipality of Palanga).

Visual impact of wind turbines depends on a number of features: the size, colour and shape of the turbine, observation distance, landscape diversity, time of day, and many other factors *(table 1)*. Visibility itself usually includes even several types of landscapes. Therefore, in order to properly assess the visual impact, the size of the landscape area to be visually impacted should be determined, i.e. it is important to determine the extent of the visual impact zone of a wind turbine. As a result, determining the visual impact zone of a wind turbine as a visual dominant of the landscape, and estimating the nature of the impact becomes especially relevant (University of Newcastle, 2002).

Table 1. Factors that influence wind turbines visibility

Factors	Comment
Wind turbine general parameters	Current wind turbine tower manufacturing technologies make it possible to build towers high and reliable. In Lithuania wind turbines Enercon E 82 (2 MW) prevail over the others. These wind turbines are of two types: with metallic tower and those with reinforced concrete tower. The characteristics of wind turbine with metallic tower: height of the tower is 86 m; diameter of the wheel is 82 m; total height is 126 m. The characteristics of wind turbine with reinforced concrete tower: height of the tower is 121 m; diameter of the wheel is 82 m; total height is 150 m. The wind turbine visibility when observing them from certain viewing points depends very much on the height of a tower and the length of a blade.
The number of wind turbines	Wind farm produces a great amount of energy. Due to its general height it can become a dominant, just like a standalone wind turbine. One of the main reasons why a wind farm gets very conspicuous in landscape is the vastness of area it occupies. For example, in six wind farms in Kretinga district 61 wind turbine is located. Together with 8 standalone wind turbines operating over there, too. Different layout of wind turbines at the wind park itself may also make an impact on the landscape quite differently.
Colour and materiality	Colour and materiality of wind turbine are two of the main factors of wind turbine visual impact size and significance. In Lithuania, the wind turbines with metallic as well as reinforced-concrete-and-metallic towers prevail. The colour of wind turbines being operated in Lithuania usually is white or a combination of green and white (green at the bottom of the tower with gradual transition to white at the top of it). The wind turbines of such a colour in rural landscape make visual contrast to green agricultural surroundings.
Second infrastr.	Electric substations, access roads, power transmission lines and other infrastructure enhance the wind turbine's visual impact on landscape, too (Homewood, 2011; Cialdea, 2010).

Factors	Comment
Observing distance	Observing distance is one of the most important aspects in evaluating wind turbine visual impact. With increase of the distance both the vertical and horizontal viewing angle of a wind turbine proportionally decreases. When observing a wind turbine from a greater distance, the sight is also affected by an atmospheric effect caused by small dust particles and humidity of the air. Because of this effect wind turbines attain a greyish hue, and grey colour decreases visual contrast between the background and the wind turbine
Observer's dynamism	Wind turbine visibility differs depending on whether the wind turbine is being observed in a static or dynamic state. When wind turbine is being observed from a static position, its view doesn't change in time. But when we study motor vehicle traffic and are in a dynamic state of observing, the visual relationship between wind turbines and landscape is in constant change. The field of view may be partly restricted by the lack of physical possibilities to observe wind turbines from the vehicle (e.g. due to window size).
Wind turbine location and weather conditions	In cases when we look at a wind turbine from the place lower than the wind turbine is the most part of it is seen in the background of the sky. A visual contrast forms between the white colour of wind turbine and clouds, together with their colour. The clouds of dark grey colour contrast with wind turbine more sharply than white clouds do. The level of contrast also depends on the sun's position and the location of a wind turbine. When the sun is in front of the observer, the wind turbine's visible part is in the shade. If background is dark, the contrast between it and the wind turbine is not so sharp. When the sun is behind the observer, the entire wind turbine gets lightened. If background is lighter, then the contrast is not so sharp in comparison with when the background is dark. Under cloudy weather conditions wind turbines are usually less visible. In some cases wind turbine blades can be totally invisible in the background of clouds (Enviromental Resources Management. 2009).
Purpose of land use	Wind turbines (especially wind farms) are usually installed in terrains with small population where the land is of agricultural use. Agrarian territories, if they are not hilly, can be overviewed widely (because open visual spaces prevail), so wind turbines can be seen from afar. The forests that are present on these territories camouflage wind turbines so their visual impact is reduced. In such cases the towers of wind turbines or their bottom parts are usually prevented from being seen. Only the wheel and cabin are visible. Villages and towns, due to vertical elements present in them, also reduce the visibility of wind turbines.
Territory relief	In hilly territories there are places from which wind turbines are easier, or, in contrary, harder to see. With relief being uniform, the wind turbines visibility gradually decreases with a distance.
Time of the day	The time of the day is of special importance for the wind turbines visibility. During bright period of the day, wind turbine's visibility is at its highest, and, when it's getting dark, it decreases. At night, only wind turbine signal lights are visible.

Visual impact zones. Observation decks and their number become the main object of the visual impact assessment in the analysis of wind turbine impact zones. It is important to select properly the observation (assessment) points, and to evaluate the local landscape, the deployment of important natural as well as anthropogenic activity elements. The degree of visual influence is determined by taking into account the observation distance and wind turbine's visibility. It is important to note that the adjacent visual impact zones (away from a wind turbine (>10 km)) are slightly different from one another in the degree of influence. At a distance of 0 – 3 km wind turbines usually dominate in landscape, at a distance of 4 – 7 km – they become accents, at a distance of 7 – 10 km – subdominants and at a distance of >10 km – background elements *(table 2)*. Subdominants (about 7-10 km). Wind turbines are less clearly visible, the size is visually diminished, but the movement is noticeable. With the increasing distance, wind turbines become general elements of the landscape. Remote elements of the landscape (background elements) (>10 km). The turbines are no longer clear, of a small shape and look insignificant. The movement of the blades is generally unnoticeable. The overall size of the turbines is very small (authors of the article, and Jallouli, Moreau 2009).

Table 2. Theoretical visual impact zones of wind turbines

Distance to the wind farm (km)	Visual impact degree	Exposure zones of anthropogenic elements
0-1	Wind turbines **dominate** because of their large scale, movement of blades, close proximity and the number of them.	Scale domination zone (up to 500 m)
1-3	Wind turbines **generally dominate** in a landscape. The impact is more significant due to the proximity, visual parameter of wind turbines, which dominate in landscape.	Sight domination zone (up to 3.5 km)
3-5	Wind turbines are clearly seen, and their impact is average. Also, with the distance their domination decreases. The blade movement is seen. Though wind turbines are seen, they are not totally dominating when being observed from the observation point (with enough level of visibility). They become landscape **accents**.	Psychological effect zone (up to 6.0 km)
5-7	Wind turbines are seen but do not stand out clearly from the overall picture. The blade movement is seen when visibility is good and average. They become landscape **accents**.	Psychological effect zone (up to 6.0 km)
7-10	Wind turbines are less clear, and, visually, their size is decreased, but movement can be noticed (level of **subdominants**).	Object is visible but it becomes impersonal in the background of landscape.
10-13	The visual impact is weak, and the movement can be noticed on a bright day – wind turbines get among all the common elements (**background elements**).	
13-16	Wind turbines become indistinct, with slight impact on the remote landscape. The movement of blades can be seen, but with greater distance they become **background elements**.	
16-20	Wind turbines and movement of blades can be seen on a bright day but their visual **impact is insignificant.**	
>20	**No impact or it is insignificant.** Visibility is influenced by weather conditions, wind turbine visual parameters (rotor diameter, hub height), the local terrain, single trees and forest arrays.	

Map of wind turbine visibility. GIS modelling of the visibility of future wind turbines in the landscape is carried out during construction of wind turbines (especially if the territory is near the populated areas, important cultural heritage sites or observation decks). This is particularly true for expressive Lithuanian territories. With the help of GIS system, the map distinguishes the zones by visibility schemes, which include: *the whole wind turbine; blades only; the rotor (fig. 1)*.

The GDB50 vector map of the territory and Spatial Relief Model of the Republic of Lithuania SRM_LT were used for modelling the visibility of wind turbines. Wind turbine coordinates as well as parameters of the hub height and blade-tip height are entered into the GIS system. The wind farm in Šilutė District was chosen for modelling. This is the only wind farm in Lithuania built on the hilly terrain (Žemaičiai Upland), whereas the influence of the local relief on the visibility of wind turbines is especially relevant.

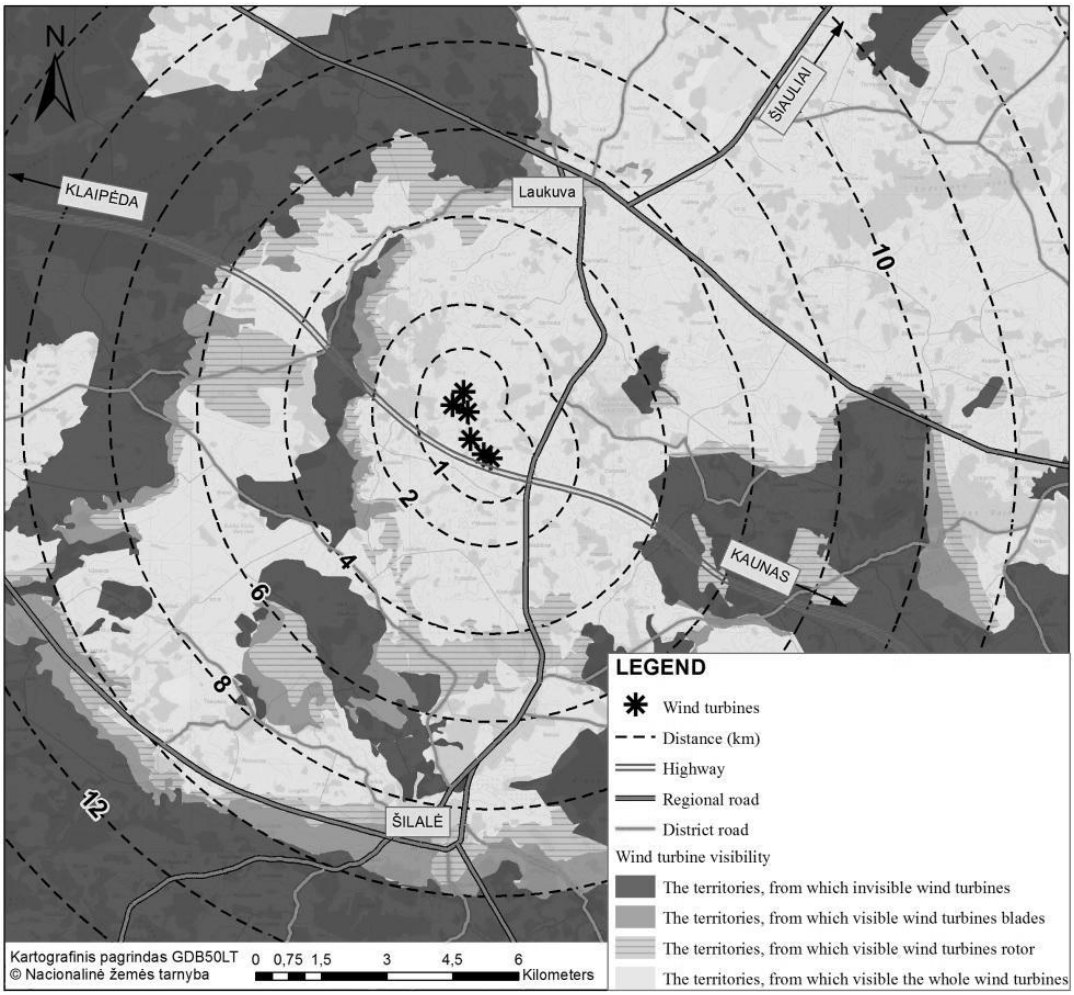

Fig 1. Visibility zones of separate wind turbine parts according to the example of the wind farm in Šilalė district (cartographic base LTDBK50LT © Nacionalinė žemės tarnyba)

Calculating the size of viewing angles. Taking into account the parameters of the vertical field of human vision, *it is important to determine the size of wind turbine's viewing angle* when observing from the particular observation deck chosen *(fig. 2-4).*

When the vertical viewing angle of wind turbine is up to 0.5° – the visual impact is not significant. The referred viewing angle is determined by an observation distance. With shorter observation distance and the vertical viewing angle of 0.5°- 2.5° – visually, wind turbines become potentially visible. When observing wind turbines from even smaller distance, and with the viewing angle of 2.5° - 5° – wind turbines become visually dominant.

It is particularly important to assess the size of the viewing angle when observing wind turbines from important observation deck in terms of cultural heritage and tourism. In determining the size of the viewing angle, Siements SWT-2.3-101 wind turbines in Šilalė district were analyzed. The visible angle was calculated under three different situations: when the wind turbine is fully visible; when the wind turbine's rotor and tower's upper part is visible; when only the blades are visible. Parameters of the referred wind turbines: tower height – 99,5 m; rotor diameter – 101 m; blade-tip height – 150 m; and blade length – 50,5 m. In all cases, the wind turbine was observed from a 1000 m distance.

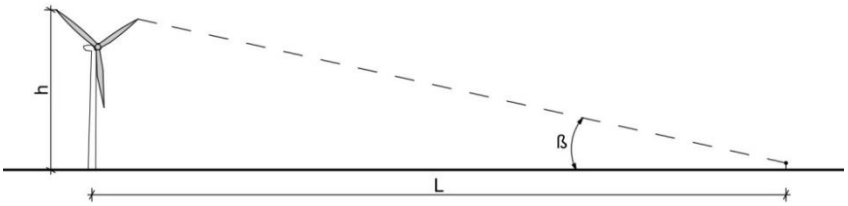

Fig 2. Observation angle of openly visible wind turbine, and its calculation (author of the scheme: J. Abromas, 2016)

h – Height of wind turbine (150 m)
L – Distance between the observer and wind turbine (1000 m)
ß – Observation angle of wind turbine

Calculation of the angle ß of an openly visible wind turbine

$$ß = \arctan\frac{h}{L} = \arctan\frac{150}{1000} = 8{,}53°$$

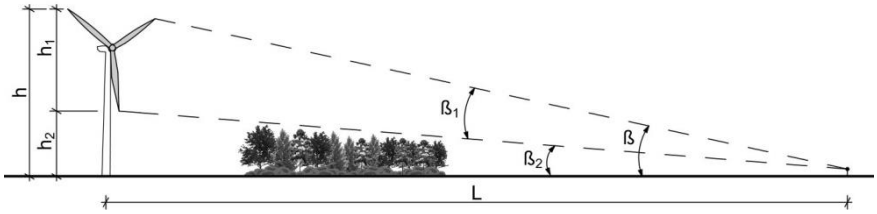

Fig 3. Observation angle of wind turbine and its calculation, when wind motor and tower's upper part is visible (author of the scheme: J. Abromas, 2016)

h – Height of wind turbine (150 m)
h_1 – Rotor diameter (101 m)
h_2 – Tower height up to the blade's lowest point
$h_2 = h - h_1 = 150 - 101 = 49$ m
L – Distance between the observer and wind turbine (1000 m)
ß/ $ß_1$/ $ß_2$ – Observation angles of wind turbine
$ß = 8{,}53^0$ (see calculation in Fig. 2)
Calculation of the angle $ß_1$ when the rotor and the tower's upper part is visible

$$ß_2 = \arctan\frac{h_2}{L} = \arctan\frac{49}{1000} = 2{,}81°$$

$ß_1 = ß - ß_2 = 8{,}53^0 - 2{,}81^0 = 5{,}72^0$

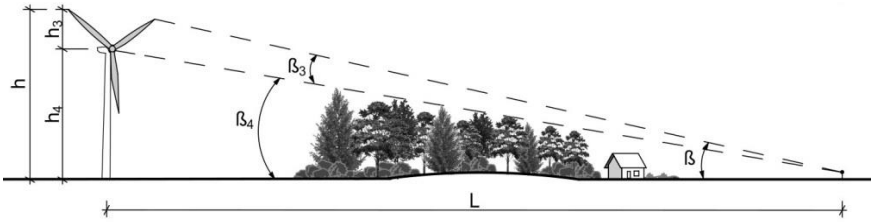

Fig 4. Observation angle of wind turbine and its calculation, when only wind turbine blades are visible (author of the scheme: J. Abromas, 2016)

h – Height of wind turbine (150 m)

h_3 – Blade length (50,5 m)
h_4 – Tower's height (90,5 m)
L – Distance between the observer and wind turbine (1000 m)
ß/ $ß_3$/ $ß_4$ – Observation angles of wind turbine
$ß=8,53^0$ (see calculation in Fig. 2)

Calculation of the angle $ß_3$ when only the blades are visible

$$ß_4 = \arctan\frac{h_4}{L} = \arctan\frac{99,5}{1000} = 5,68°$$

$ß_3 = ß - ß_4 = 8,53^0 - 5,68^0 = 2,85^0$

Determining the contrast, and significance of the impact on the landscape. After discussing the assessment methodologies of different countries, and their relevance to Lithuania, *principles for determining the contrast of the surrounding area (low, medium, high)* have been distinguished. Significance of the principles lies in their determination based on the *factors relevant to the assessment* of the impact of wind turbines on the landscape, namely the distance, time of observation, relative size, scale of observation, season, lighting conditions, spatial relationships, atmospheric conditions, and movement.
Determination of the visual significance of the impact of wind turbines on the landscape is based on the following criteria: visual insignificance, slightly significant impact (slight impact), the average impact, and substantial impact (table 3).

Table 3. Visual significance of the impact of wind turbines on the landscape

Landscape Visual Sensitivity	**Magnitude of Landscape Visual Change**			
	Negligible	Low	Medium	High
High	Visual insignificance	The average impact/ Slight impact	Substantial impact/ The average impact	Substantial impact
Medium	Visual insignificance	Slight impact	The average impact	Substantial impact/ The average impact
Low	Visual insignificance	Slight impact	Slight impact	The average impact/ Slight impact

Discussion

Following the research and systemised data, visual impact zones have been revised *(table 2)*. Distance zones under assessment have been compacted at the 0-7 km distance from a wind farm. Also, the zones have been divided by the nature of dominance, general dominance, highlights, subdominants, and background elements.
When being at the distance of 0-7 km from the wind farm, it can be noticed that 1-2 km interval is of great importance to the visual impact evaluation. When the distance is greater, the interval of 1-2 km loses its previous importance.
During the assessment procedure, it was found that visual significance is characteristic not only to huge woodlands and spatial structures of the villages, but also to minor objects at small distances from the observer (roadside bushes, single buildings, trees, etc.) which also change the visual influence of wind turbines. The turbines seen on the road perspective axis are of special importance not only because they are observed for a bigger length of time, but because they often become a vertical landmark. In constructing wind turbines it is essential to

take into consideration that the visual domination of the existing important vertical objects is to be preserved.

Atmospheric conditions such as cloudiness also have a big influence on the visual impact of the wind farm. The color of the wind turbines is light grey. When clouds are of the same or similar color the set of blades in some cases can be invisible or on the contrary can be visible more clearly if the clouds are darker.

Evaluating visual impact of wind turbines in Šilale region visibility of the turbines was conditioned by the additional factor – terrain undulations. Due to this aspect (as well as forested areas) going by highway in the direction of Vilnius the wind turbines become visible only at 6 km distance.

The more anthropogenic objects are in the visual space the more visual impact of the wind farm is decreased. In some cases wind farm can become a background element.

Even though the blade-tip height of the major wind turbines (up to 120-150 m) are observed at the distance of 30 km at good visibility, the visual effect on the landscape is produced only by background elements located at the distance of 15-20 km. When viewed from the roads and from a dynamic position, a more significant effect is produced by the wind turbines located nearer the roads. The turbines located farther from the observer (at a distance of 10-20 km) make visual influence only when seen on the road perspective axis.

Conclusion

1. The visual nature of landscape and its visual-aesthetic quality is changing due to wind farms and single wind turbines built mostly in the Western Lithuania. There are six wind farms in Kretinga district alone (which borders the municipality of Palanga). The hub height of current wind turbines reaches 80-120 m, while the blade-tip height is 120-160 m. These objects are becoming dominant verticals. The documents of territorial planning already provide for the construction of wind turbines in Šilutė and Pagėgiai district areas with the blade-tip height of 200 m. Under ideal weather conditions, the wind turbines can be seen from up to 25-30 km distance. It is important to evaluate the impact of both existing and planned wind turbines on the landscape.

2. The research *in situ* and the summarized data allowed to distinguish factors mostly determining visual impact of wind turbines: visual-spatial parameters of wind turbines, the local terrain, forest arrays and smaller natural and anthropogenic elements between an observer and wind turbines, village deployment, weather conditions and arrangement of wind turbines in the farm/ group.

3. Considering visual-spatial parameters of wind turbines in Lithuania, landscape features with its potential, and the impact of anthropogenic environment, the basic methodological principles for the assessment of visual impact of wind turbines have been developed. The main phases are distinguished: determining the zones of visual impact; creating GIS database; visibility modelling; assessment of nature, significance and contrast of the impact.

Abstract

Viroi Lake is one of the most important lakes in Gjirokastra district, south of Albania. This lake has a surface of 17 ha, which is supplied by the limestone source 'Mother of Viroi', a natural monument. This study aims to assess quality of fresh water of this ecosystem, the eutrophication process and the determination of trophic status referring to the Carlson's equations. The water samples for their physico-chemical assessment were collected in 5 sampling sites of Viroi Lake during 2011 - 2014. Immediately after collection water samples were transported to the laboratory in ice boxes in a constant temperature of 4^{o}C, according to the standard procedures. The methods that were used during the analysing were ISO standard methods. The water of Viroi Lake, according to Water Framework Directive (WFD) 2000/60/EC, for the maximal values of nutrients has been classified as follow: for nitrites N-NO_2^- from class II to IV and for the concentration of nitrates, ammoniums and orthophosphates in water, class I and II. The values of calculated trophic index (TSI) for Viroi Lake according to the total phosphor, total nitrogen, chlorophyll-α and Secchi disc depth, resulted in the average values showing the ***Mesotrophic*** status of this water ecosystem.

Keywords: *water, eutrophication, nutrient, trophic state index, mesotrophic*

Introduction

Water is a vital matter for all aspects of human and ecosystem survival and health. Thus, its quality is also important (Hamid Zare Abyaneh, 2014). Surface waters are a great asset to the economy of a country. They are important for many traditional uses like irrigation, fishing, tourism and industry. Next to the rivers and lakes are many inhabited and industrial areas in addition to agricultural and animal farming ones. Thus, almost all the rivers, lakes and coastal areas, serve as sites for urban waste discharge and industrial liquid and in some cases solid ones (Miho et al., 2005).

Aquatic habitats are very sensitive due to the degradation from extensive uses of the people. The influence of humans in the water ecosystems leads to the increase and circulation of chemical substances and its organic pollutants (Alikaj et al., 2014; Alikaj, 2015). In addition human activities influence in the influx of nitrogen and phosphor in water ecosystems. The increase of anthropogenic nitrogen and phosphor in the rivers, lakes and seawaters is the main reason of eutrophication. In general the increase of concentration of nutritional elements in the water ecosystems, is accompanied with the growth of phytoplankton and it spoils the balance between algae production and consumption.

Since coastal eutrophication has become more common over recent years, words like oligotrophic, mesotrophic and eutrophic have also become more frequent in scientific literatures; oligotrophic means low productive and eutrophic means high productive aquatic environment. Several indicators and indices are available for assessing trophic status and quality of aquatic ecosystems and their evolution under different anthropogenic pressures and inherent threats (Jayachandran & Nandan, 2011).

In this context the use of trophic state index according to Carlson (1977), for the estimation of trophic status of water ecosystems is the most widely used. Therefore the aim of this study was to evaluate the occurrence of nutrients in the waters of Viroi lake and the trophic status using abovementioned index. Using Carlson equations, were calculated the concentration of chlorophyll-α and Secchi disc depth, taking into account the concentration of total phosphor. Evaluation of trophic status in Viroi lake is not only a good option in environmental assessment but it is essential in its planning and menagment.

Materials and methods

The study area

Viroi lake (40°6'1"N 20°7'24"E) is located in the north-west of Gjirokastra district and 3 km distance from the town itself. It has a karstic water source called "Mother of Viroi", with a flow of 17 m3/second, and its yearly average temperature is 13-14°C (Rogo et al., 2008). Viroi Lake has a water area of 17 ha and its surrounding area of 11.13hectares, which is mainly wooded with pine.

Sampling method

In the water ecosystem of Viroi lake are performed 8 expeditions during June 2011-April 2014 and water samples were collected in all seasons, taking in the consideration:

- the existence of the source
- anthropogenic and natural factors in the lake
- the estuary of water lake

Figure 1. Sampling points in Viroi lake (Google earth)

Samples were collected in 5 sampling sites, taken in 1.5-L plastic containers and transported in a cool box at a temperature of 4ºC. The water analyses were performed within 24 h at the scientific laboratory of the Department of Agro-Environment and Ecology, Agricultural University of Tirana. The chemical parameters such as $N\text{-}NH_4^+$, $N\text{-}NO_2^-$, $N\text{-}NO_3^-$, $P\text{-}PO_4^{3-}$, TP, and TN were analyzed by using ISO standard methods. *In situ*, pH, DO, conductivity and temperature were measured by using a portable apparatus Multi 340.

Through Carlson and (Kratzer and Brezonik, 1981) equations were calculated trophic index (TSI) for total phosphor and total nitrogen.

TSI (TP) = 4.15 + 14.42 ln (TP) (total phosphor, in **µ**g/L); TSI(TN) = 54.45 + 14.43 ln (TN) (total nitrogen in mg/L). Taking into consideration the concentration of total phosphor were

calculated the values of chlorophyll-α and Secchi disc depth and then TSI(CHl-α) and TSI(SD).

Ln Chl = 1.449 lnTP – 2.442 (for Chl-α) and SD = 48(1/TP) (for Secchi disc depth)

TSI (CHL) = 30.6 + 9.81 ln (CHL) (chlorophyll -α, in**μ**g/L)

TSI (SD) = 60 - 14.41 ln (SD) (Secchi disc depth in m)

Results and discussions

The results for physico-chemical parameters that were measured in situ are presented in Table 1. The results showed that pH values ranged in the interval 7-9, in the average values from 7.72 in V1 to 8.16 in V4. Since the pH is an important parameter in the dissolution of many chemical substances, it is also important for aquatic ecosystems. Therefore waters of Viroi lake are classified as high quality based on pH values, but pH values between 6.9-8 do not favour the transformation of NH_4^+ ions into NH_3 which are toxic for fish (Abazi & Balliu, 2012), thus the waters of Viroi lake satisfy this condition. The average values of electrical conductivity ranged from 324 **μ**S/cm to 412 **μ**S/cm. This parameter that relates directly to the content of ions dissolved in water, it is not a problem for aquatic ecosystems. However, its measurement helps on identifying a number of problems in aquatic systems and finding the source of these problems. Dissolved oxygen values ranged from 6.46mg/l to 7.46mg/l and according to the WFD, the waters of Viroi lake corresponds to class III (moderate) and II (good).

Table 1. Average values of in situ physico-chemical parameters in Viroi lake

Parameters	**V**	**V2**	**V3**	**V4**	**V5**
pH	7,72 ± 0.22	7,99 ± 0.57	8,09 ± 0.26	8,16 ± 0.56	7,88 ± 0.25
Temp ^oC	13,18 ± 2.92	17,11 ± 3.95	16,1 ± 3.31	17,7 ± 4.83	14,65 ± 3.3
DO mg/l	6,46 ± 0.32	6,79 ± 0.72	7,24 ± 1.32	7,08 ± 1.83	7,46 ± 1.45
EC μS/cm	395 ± 75.41	412 ± 61.8	324 ± 143.5	368 ± 44.96	393 ± 74.84

The average, maximum and minimum values of nutrients are shown in Table 2.

The values of ammonium in lake waters vary from 0.022mg/l at V5 station to 0.08mg/l in V4 station and according to WFD, the Viroi water lake are classified in the I class (<0.2mg/N/l) of the environmental quality for the ammonium content. On the other hand the average pH values in Viroi lake between 7.72-8.16, do not allow the transformation of the anion of NH_4^+ in to toxic form of NH_3. The average values of nitrites range from 0.012mg/l in V2 station to 0.031mg/l in V3 station. In maximal values, $N\text{-}NO_2^-$ in the waters of Viroi lake range from 0.03mg/N/l to 0.14mg/N/l, classifying thus the waters according to WFD from class II(0.03mg/l) in to class IV(<0.3mg/l) of the environmental quality (figure 2). Even though nitrites pass to nitrate during nitrification, in the lake such values are due to on average low temperatures. It is believed that for temperatures lower then 17^{o}C, mainly 12-14^{o}C, the proportion of nitrites oxidation to nitrate gets lower, thus leading to nitrification process control (Randall and Buth, 1984).

Figura 2. Maximal values of $N\text{-}NO_2^-$ in the waters of Viroi lake according WFD

The high level of nitrates is the source for the eutrophication process, flourishing of algae and diminishing of oxygen in water ecosystems. In Viroi lake the average values of nitrates have varied from 0.205mg/l in V2 station to 0.487mg/l in V1 station. The highest value of nitrates is obtained at the water source in a value of 1.22mg/l. According to WFD in maximal values, the waters of Viroi lake are classified as the I class (<1mg/N/l) and II class (<3mg/l), within these values the process of eutrophication can be controlled (figure 3).

Figure 3. Maximal values of $N\text{-}NO_3^-$ in the waters of Viroi lake according WFD

Total nitrogen has resulted with values from 0.265mg/l in V2 station to 0.568mg/l in V1 station and the obtained maximal value is 1.27mg/l. Based on average values of total nitrogen and according to WFD, the waters of Viroi lake are of a very good quality (<1.5mg/l). Phosphor is an element that in phosphate forms or total phosphor affects mainly the growth of algae in the lake. Its concentration in waters varies not only between seasons but even from one year to the other, therefore the collection of samples through all the monitoring period it is very important. Thus, the waters of the lake had average values of phosphate content from 0.017mg/l in V5 station to 0.036mg/l in V1 station. Meanwhile, the total phosphor values varies from 0.025mg/l in V2 station to 0.037mg/l in V1 station. The content of total phosphor is considered as a key parameter in many monitoring programs for the assessment of trophic status of rivers and lakes. Regarding to the content of phosphor, the water of the Viroi lake can be considered as of excellent quality.

Assessment of trophic status in Viroi lake with Carlson trophic index (TSI)

In Table 3, for obtained samples in each station are presented the calculated values of TSI trophic index according to total nitrogen, total phosphor as well as to the chlorophyll a and Secchi disc. The last mentioned parameters are calculated through application of Carlson equation taking into consideration the concentration of total phosphor in every analysed sample. Referring to classification according to Carlson and Simpson 1996, the waters of the lake present a trophic index from 40.99 in V3 station to 45.19 in V2 station, which shows the Mesotrophic status 40<TSI<70 (Table 4**).** From Table 3 showing a consequence of TSI according to the parameters respectively as: TSI(SD)≧TSI(TP)>TSI(CHLa)>TSI(TN). In average values the trophic index according to Secchi disc and total phosphor are almost equal, TSI(SD) = TSI(TP) > TSI(CHL), which respectively show conditions, non-algae particles or colour domination towards the diminishing of light.

Table 3. Trophic indexes and trophic status for Viroi lake

Stations	Chl,aµg/l	Secchi disc(m)	TSI (TP)	TSI(TN)	TSI(CHLa)	TSI(SD)	Carlson TSI	Trophic status
V1	0,85	2,48 ± 1.8	45,56 ± 21.34	44,11 ± 8.9	38,93 ± 10.89	47,24± 8.89	43,91	**MESOTROPHIC**
V2	0,64	2,38 ± 1.34	49,09 ± 7.80	26,27 ± 18.11	36,94 ± 4.33	49,54 ± 7.66	45,19	**MESOTROPHIC**
V3	0,1	3,75 ± 2.68	45,22 ± 13.74	32,84 ± 18.69	31,62 ± 10.81	46,14 ± 13.3	40,99	**MESOTROPHIC**
V4	0,52	2,87 ± 1.9	48,68 ± 13	32,78 ± 20.31	35,78 ± 6.36	48,97 ± 12.7	44,47	**MESOTROPHIC**
V5	0,42	3,17 ± 1.82	47,01 ± 13.55	37.05 ± 16.9	34,8 ± 6.26	47,65 ± 13.16	43,15	**MESOTROPHIC**

Table 4. Trophic status according to Carlson and Simpson

TSI	**Trophic status**
<30	Oligotrophic
30-40	
40-50	Mesotrophic
50-60	Eutrophic
60-70	
70-80	Hipereutrophic
>80	

Conclusions

Based on obtained values the water quality of Viroi lake, resulted under the average level of the quality according to the contents of nutrients. The trophic status of the lake resulted in mesotrophic state according to Carlson's trophic index. The values of nutrients nitrogen and phosphor compared to WFD, showed that the phenomenon of eutrophication can be kept under control. The high TSI values according to Secchi disc can be explained by the fact that erosion lead to adding the small particles floating in the lake. The actual situation of the lake requires continuous assessment and better management in order to prevent further deterioration of this ecosystem and its biodiversity.

Abstract

The aim of this paper is to present floristic diversity of the family Asteraceae in the flora of the Jahorina Mountain in Bosnia and Herzegovina (BIH). The Jahorina Mountain is located in the central part of BiH and entity of Republic of Srpska, southeast of Sarajevo city It belongs to continental Dinarides with the direction of the main ridge from northwest to southeast. Jahorina massif is long about 30 km, with the highest peak Ogorjelica (1916 meters above sea level). Research was carried out in the period 2010-2011. Taxonomic analysis of the Asteraceae family was found in 203 tax (135 species, 49 subspecies, 13 varieties and 6 forms). The analysis of the areal spectrum shows the dominance of the endemic areal group with 24 species and Euroasian group with 20 species. The biological spectrum of the Asteraceae family indicates the dominance of plants belonging to the hemikryptophytes life forms.

Key words: *Asteraceae, flora, Jahorina Mountain*

Introduction

The Jahorina Mountain is located in the central part of BiH and entity of Republic of Srpska, southeast of Sarajevo city. The Jahorina Mountain range is determined with coordinates 43˚ 39´ to 43˚ 47´ north latitude and 18˚ 31´ to 18˚ 43´ east longitude. It belongs to continental Dinarides with the direction of the main ridge from northwest to southeast. Jahorina massif is long about 30 km, with the highest peak Ogorjelica (1916 meters above sea level). In geological terms Jahorina is composed of a variety of rocks of Paleozoic, Mesozoic and Permkarbon Triassic age. The base consists of Carbon and Permian sandstones and shales, and above them there are Mesozoic Triassic limestones. From the land, on carbonate surface, the following have been developed: lithosols, organogenic and organomineral calcomelanosol, calcocambisol, luvisols, and on a silicate substrate: brown podzols, podzols, swampy gley peat and ranker. The lowest altitude position is in the climate which is temperate continental, in a central part of Jahorina is subalpine climate, and in the highest mountain areas is alpine continental climate.

The oldest data relating to the research of flora of Jahorina date back from the works by Fiala (1893, 1895), Back-Mannagetta (1986-1898, 1903-1923), Maly (1938, 1939), Bjelčić (1964-1965). Herbarium collection that was created as a result of these studies is well-preserved and located in Sarajevo at the National Museum of Bosnia and Herzegovina. Numerous floristic data were described in the ecological papers (Maly 1931-1932; Kusan, 1952 Bjelcic, 1965; Pavlovic, 1976; Lakusic, 1981; Petronic, 2000). The aim of this paper is to present floristic diversity of family Asteraceae in the flora of the Jahorina Mountain.

Material and methods

Research was carried out in the period of 2010-2011. Along with field research, the literature, relating to the nature of the study area, was studied. Herbarium collection created as a result of

these studies is well-preserved and located in the Republic Institute of the Protection of Cultural and Natural Heritage of RS.

Identification of species was based on floristic literature (Beck, 1903; Beck, 1927; Josifovic ed.1970-1977; Javorka and Csapody, 1979). The nomenclature is in line with Flora Europaea (Tutin, et al. 1964-1980). Floral elements are given by Oberdorfer (2001) and Gajić (1980). Life forms are given by Oberdorfer (2001).

Results and Discussion

Table 1 shows the tax of the family Asteraceae in the flora of Jahorina mountain with its life forms and floral elements. Data of life forms are given before the name of tax, a phytogeographical affiliation behind. For life forms and floral elements used are given appropriate abbreviations.

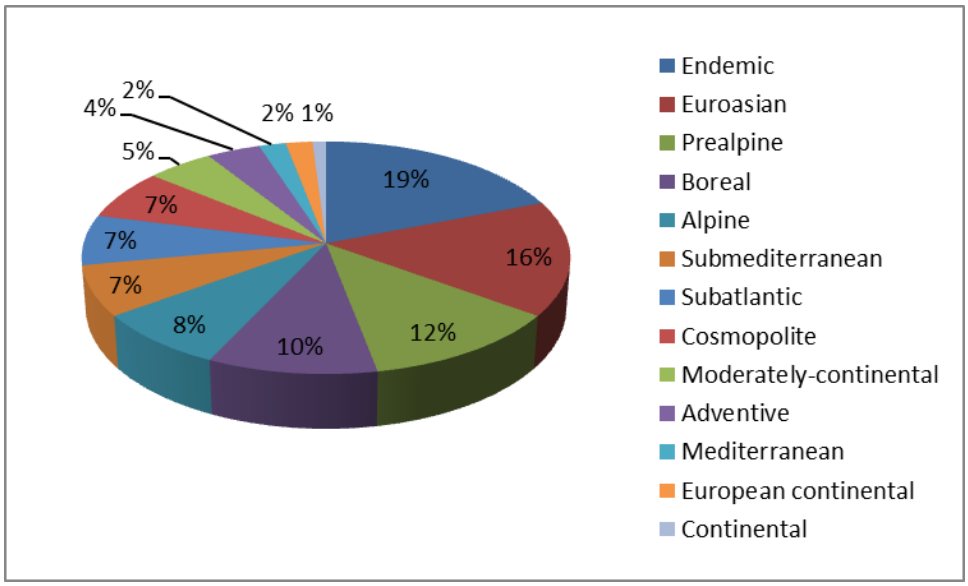
Taxonomic analysis of the Asteraceae family found 203 tax, of which 51 genus, 135 species, 49 subspecies, 13 varieties and 6 forms (tab. 2).

Table 2. Taxonomic review of the family Asteraceae

The family Asteraceae	
Genus	51
Species	135
Subspecies	49
Variety	13
Form	6
Total:	**203**

Extensive studies of the flora of Jahorina mountain explored by Bjelicic (1965: 109-157) noted 1044 tax. Recent studies of the flora of the Jahorina mountain, shows 1159 tax (Petronic, Pavlovic, 2012: 13). In the flora of BiH in the family Asteraceae, there are 260 tax stated (Redzic et al., 2008: 18-19). In the area of Jahorina, Bjelcic (1965: 142-147) recorded 163, and Petronic, Pavlovic (2012: 24-27) 203 tax. These results show a remarkable floristic diversity of the family Asteraceae in Jahorina.

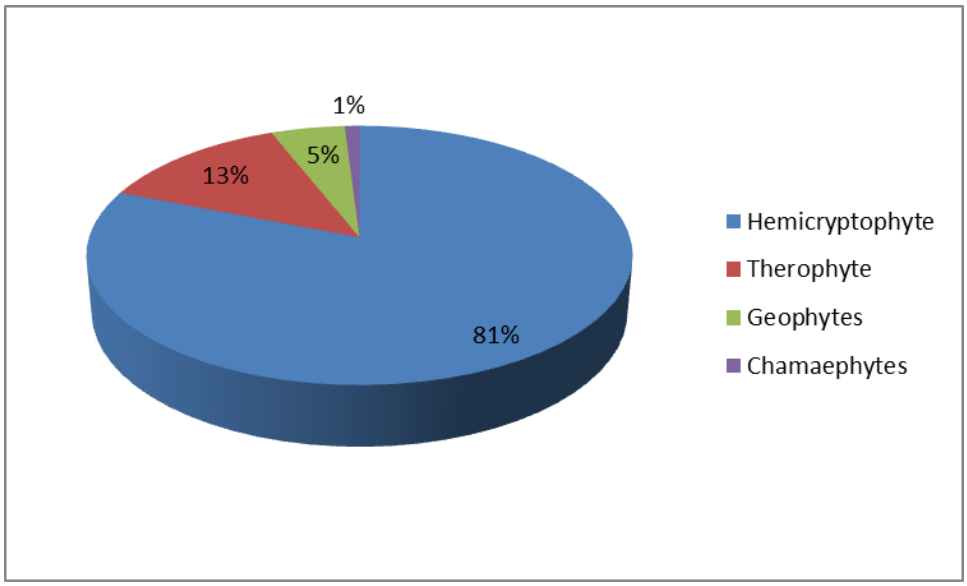
The areal spectrum of the family Asteraceae (Graph 1) consists of 12 areal groups. There were a dominance of endemic species with 23 (19%) and euroasian 20 (16%) areal groups. Besides these groups, significantly present are species of prealpine 14 (12%), boreal 12 (10%) and the alpine 10 (8%) areal groups. Less represented in the construction of areal spectrum are species of the submediterranean, subatlantic, cosmopolitan, moderately continental, adventive, mediterranean, european and continental areal groups.



Graph 1. Areal spectrum of the family Asteraceae

Endemic areal group includes species with relative distribution restrictions. These are mainly subendemics or hemiendemics spread to larger geographic units: dinaric *(Crepis froellchiana* subsp. *dinarica),* balkan (*Centaurea kotschyana, Petasites kablikianus, Cirsium candelabrum, Cardus candicans),* alpine-carpathian-balkan (*Erigeron atticus)* submoesian-subcarpathian (*Achillea lingulata),* subbalkan (*Matricaria trichophylla, Jurinea mollis),* subbalkan-apennine (*Doronicum columnae*), illyrian (*Senecio papposus),* alps-carpathian (*Hieracium villosum, Hieracium pilosum, Cirsium waldsteinii, Cirsium waldsteinii, Crepis aurea),* balkan-apennine (*Cardus micropteris)***,** carpatho-balkan-apennine (*Cardus personata),* illyrian-apennine (*Cardus carduelis*), west moesian-south illyrian (*Cicerbita pancicii),* moesian-carpathian *(Crepis viscidula)***,** submediumbalkan (*Hieracium pavichii*)**.** Among the endemic species mezoendemic is dominant, while few species of stenoendemic can be found in infraspecific forms of subspecies, varieties and forms.

Chart 2 shows the results of analysis of life forms. Among the species of the family Asteraceae percentage dominance have hemiocryptophyte with 103 species (81%). In the construction of the biological spectrum the following participate: therophytes with 17 species or 13%, geophytes with 7 species or 5% chamaephytic with 1 species or 1%.



Graph 2. Biological spectrum of the family Asteraceae

A significant number of species of the family Asteraceae is on the preliminary Red List of threatened plants of Bosnia and Herzegovina (Šilić, 1996: 323-367). Category of vulnerability is determined by the current IUCN criteria. Rare and endangered species from the preliminary Red List of Bosnia and Herzegovina are: *Erigeron atticus* (K), *Telekia speciosa* (V), *Achillea lingulata* (V), *Achillea clavennae* (V), *Leucanthemum praecox* (V), *Petasites kablikianus* (R), *Centaurea kotschyana* (V), *Hypocrepis illyrica* (R), *Cicerbita pancicii* (V), *Crepis bosniaca* (R), *Crepis dinarica* (R), *Hieracium trebevicianum* и *Hieracium waldsteini* (R).

According to the Regulation on the Red List of endangered species of flora and fauna of RS („Official gazette of Republic of Srpska“ no: 124/12) the following species are protected: *Achillea lingulata*, *Achillea clavennae*, *Centaurea kotschyana*, *Centaurea ruperists*, *Cirsium rivulare*, *Cicerbita pancicii*, *Crepis froellchiana* subsp. *dinaricum*, *Erigeron atticus*, *Hieracium trebevicianum*, *Hieracium waldsteinii*, *Hypochaeris maculata* subsp. *pelivanovic*, *Leucanthemum praecox*, *Omalotheca norvegica*, *Senecio papposus* subsp. *papposus*, *Taraxacum palustre*, *Telekia speciosa*. For these species, categories of threat are not specified.

Conclusions

Data of the flora of the Jahorina mountain, which refer to the Asteraceae, have been obtained on the basis of research and literature data. After analyzing the obtained data the following conclusions were drawn:

The high degree of diversity of the family Asteraceae from the Jahorina mountain is reflected in the presence of 135 species, 49 subspecies, 13 varieties and 6 forms.

In the areal spectrum the dominant percentage has been shown by the plants that belong to the endemic areal group. Among the endemic species mezoendemic are dominant, while few species of stenoendemic can be found in infraspecific forms of subspecies, varieties and forms.

In the biological spectrum of the family Asteraceae, the most frequent are hemicryptophytes while therophytes, geophytes and chamaephytic are less represented. A significant number of species of the family Asteraceae are on the Preliminary Red List of threatened plants of BiH as well as on the Red List of endangered species of flora and fauna of RS.

Abstract

The efficient and economical use of water in agricultural areas is an extremely important element. Evapotranspiration, which has a very important place in plant-atmosphere cycle, is an indispensable element for agricultural area and planning, construction and operation of the irrigation projects. The study was carried out during the period 2012-2013 in the district Çukurçayır of Kırşehir Province of Turkey. In the study, the evaporation values measured from the Class A Pan were used to determine the irrigation water requirements of the sugar beet grown in Kırşehir conditions. For this purpose, it was used the three different plant-pan coefficients aimed of the water shortage. The actual evapotranspirations of treatments were determined with the gravimetric method. The values of evapotranspiration obtained in the present study were compared with estimation methods of some evapotranspiration (FAO-56 Penman Monteith, FAO-24 and USDA-SCS Blaney Criddle, Radiation (R-FAO), Hargreaves-Samani (HS) by utilizing the region's climate data. In the comparison; correlation coefficients of the relationships between actual ET and estimated ET, the ratio of calculated ET using different methods to the measured actual ET as percentage, and root mean square error (RMS) were considered to determine the most appropriate of estimation methods. Results indicated that the Blaney Cridle (USDA-SCS Modifikasyonu) and FAO A Pan methods are appropriate alternatives for estimation of ETo under climatic conditions of Kırşehir, Turkey. Results showed that empirical methods used for estimation of plant water consumption were compatible with direct measurement methods.

Keywords: *Evapotranspiration, empirical method, sugar beet, Kırşehir province*

Introduction

Water is an indispensable source of all life. Demand for water increasing dramatically in all major use sectors, namely, agriculture, production of energy, industrial uses and human consumption. Worldwide, agriculture accounts for 70% of all water consumption, compared to 20% for industry and 10% for domestic usage (Food and Agriculture Organization, 2016). For this reason, the efficient and economical use of water in agricultural areas is an extremely important element. Appropriate irrigation scheduling based on timely measurements or estimations of soil moisture content and crop water requirements, is one of the most essential applications for irrigation management (Hoffman *et al*., 1990). Evapotranspiration, which has a very important place in plant-atmosphere cycle, is an indispensable element in planning farm irrigation systems and for improving irrigation practices. Evapotranspiration (ET) is the sum of evaporation and plant transpiration. Evapotranspiration can be measured directly or determined by estimation methods from meteorological parameters. Methods obtained by direct measurement are the most reliable method in the estimation of crop evapotranspiration. However, due to time-

consuming and costly of the devices and equipment, human laborious, global-warming problem and climate changes recently, evapotranspiration values determined for previous years will not be viable in the future (Ertek, 2011). For this reason, prediction methods for crop water requirements are used owing to the difficulty of obtaining accurate field measurements (Doorenbos and Pruitt, 1977; Jensen *et al*., 1990). Many factors such as climate, water supply, soil and topography affect the amount of water consumed by agricultural crops. Climate among these factors is one of the most important factors that determine crop water needs for optimum growth and yield. The crop water requirement is defined as the amount of water required to compensate the evapotranspiration loss from the cropped field (Allen *et al*., 1998). Many researchers describe it as the total water needed for evapotranspiration. Therefore, the water requirement can be decided by determining the actual evapotranspiration. The crop water requirement can be related to the amount of water used by a reference crop. The reference crop typically is grass or alfalfa that is well irrigated and covers 100 % of the ground. The reference evapotranspiration (ETo) includes the water evaporated from the soil surface and the water transpired by the plants. The methodologies of ETo estimation redefined by the Food and Agricultural Organization of United Nations (FAO) were successfully applied at different time scales in various climatic regions of the world (Allen *et al*., 1998). There are many studies on the comparison and calibration of evapotranspiration estimation equations under local climate conditions (Thornthwaite, 1948; Penman, 1948; Blaney and Criddle, 1950; Jensen and Haise, 1963; Hargreaves and Samani, 1985; Allen *et al*., 1989; Jensen *et al*., 1990; Smith *et al*., 1996; Walter et al., 2000; Landeras, 2008). In the present study; evapotranspiration values measured by Class A-Pan are compared with estimated evapotranspiration values (Penman Monteith (FAO-56), Penman (FAO-24 modification) and USDA-SCS Blaney Criddle, Radiation (R-FAO modification), Hargreaves-Samani (H-S) Class A Pan Evaporation (FAO- A Pan) under the climate conditions of Kırşehir Province situated in middle of the Anatolia region of Turkey.

Materials and methods

Agro-Climatic conditions:The experiment carried out during the period 2012-2013 under the field conditions in the Çukurçayır district of Kırşehir Province, situated in middle of the Anatolia region of Turkey. Çukurçayır is located at a 36°42′ and 39°16′ N latitude, 31°14′ and 34°26′ E longitude and at an elevation of 1017 meters above sea level. The climate is semi-arid climate characteristics, with cool and rainy winters, and hot and dry summers. The long-term (1970-2012) annual mean temperature, relative humidity, total annual precipitation, wind speed, and sunshine duration per day in the area were 11.4°C, 55%, 384.4 mm, 2.7 m s^{-1}, and 7.2 h, respectively. During the vegetative periods (from April to the end of October) of the years 2012 and 2013, an average temperature of 19.1 and 18.0°C, total precipitation of 121.1 and 121.6 mm, and an average relative humidity of 50.7 and 48.5% were recorded, respectively (Kiymaz and Ertek, 2015). The soil of texture is clay loam at 0-30 cm soil depth, silty-clay loam at 30-60 cm and 60-90 cm soil depth. Field capacity and wilting point ranged between 26.0 and 29.6 percent, 13.7 and 15.0 percent, and bulk density was 1.30 g cm^{-3} at 0-90 cm soil layer. The soil was alkaline. The average pH, limy and organic matter values of 7.52-7.61, 53.89% to 61.07% $CaCO_3$, 1.10%-1.99% , respectively (Kiymaz and Ertek, 2015).

Plant variety: In the study, the Isella sugar beet (*Beta vulgaris* L.) variety common-growing by producers in this region was used as the plant material.

Irrigation and Evapotranspiration: Irrigation water was supplied from a well using a pump. The water was classified as C_3S_1 with a low sodium risk and a high electrical conductance (USSL, 1954). The 16 mm diameter lateral pipes carrying 4 l h^{-1}water had inline drippers with 20 cm

spacing. Soil water contents were measured by the gravimetric method from the soil samples taken from soil depths at 30–60 and 90cm increments in each plot at sowing, pre-irrigation, and at the final harvesting date. Experimental plots were irrigated by precipitation at the beginning of uniform plant establishment. After the emergence of sugar beet seedlings, the plants were irrigated by drip irrigation for a soil profile of 0–90cm to field capacity. Subsequent irrigations were applied according to the prescribed irrigation rates at 7 day intervals. Cumulative evaporation between the irrigations was measured in a class A pan located near the plots. In calculating irrigation water volume, class A pan evaporation, whose fundamentals were described by Doorenbos and Pruitt (1977) and Ertek *et al*. (2012), was used, as Eq. (1):

$$Ir = E_{pan} \times K_{cp} \times A \quad (1)$$

Where: I - the volume of irrigation water applied (liter); Epan - the cumulative evaporation at class A pan in the irrigation intervals (mm); Kcp - the plant-pan coefficient; A - the plot area (m^2). Thus, treatments constituted from three different irrigation levels
(I_1 =Epan ×Kcp_1 ×A, I_2 =Epan ×Kcp_2 ×A and I_3 =Epan ×Kcp_3 ×A).
Soil water measurements were taken throughout the crop growth season. The water in the soil profile, up to the 90cm depth in 30cm increments, was measured gravimetrically (oven dry basis) at sowing, pre-irrigation, and at final harvest. Evapotranspiration was calculated for each treatment by the water balance method (Eq. (2)) (James, 1988):

$$Et = Ir \times P \times Cr - Dp - Rf - Ds \quad (2)$$

Where: Et - the evapotranspiration (mm); Ir - the irrigation water (mm); P - the precipitation (mm); Cr - the capillary rise (mm); Dp - the water loss by deep percolation (mm); Rf - the surface runoff (mm); Ds - the change in profile soil water content (mm).
Precipitation was measured daily at a nearby weather station. Cr was considered to be zero because there was no high underground water problem in the area. If the available water in the root zone (90 cm) and total volume of applied irrigation water were above the field capacity, it was assumed that any water leakage would be the deep percolation value (Kanber *et al*., 1993; Ertek *et al*., 2006a). On the other hand, due to the fact that irrigation water volume was calculated and applied according to pan evaporation, there was no surface runoff (Ertek *et al*., 2006b).
The empirical equations:Considering the evapotranspiration forecasting methods are FAO24 Blaney-Criddle method (B-C), Blaney-Criddle method (USDA-SCS modification), FAO56 Penman-Monteith (P-M FAO), FAO modification of the radiation method (FAO-R), Hargreaves-Samani (H-S), FAO modification of Class A Pan Evaporation (FAO- A Pan). Evapotranspiration estimation methods were calculated with equations mentioned Doorenbos ve Pruitt 1977, 1992; Cuenca, 1989; Allen et al., 1989; Jensen et al., 1990; Burman, 1994; Kanber et al., 2000 method. All climate data were taken Kırşehir Center Meteorology Station, placed about 3 km from the experimental area.
In the comparison, the highest correlation coefficients (r) of the relationships between actual ET and estimated ET, ratio of calculated ET using different methods to the measured actual ET as percentage, the smallest root mean square error (RMSE) and seasonal mean crop coefficients (kc) which is closest to 1 value were considered the criteria for assessing the most appropriate method. In the study, the crop coefficients (Kc) were obtained by comparing with the values of references evapotranspiration (ETo) obtained empirical methods and the actual evapotranspiration value calculated in the field (Figure3).

Results and Discussions

For the experiment conducted in 2012 and 2013 measured evapotranspiration values with reference evapotranspiration values obtained by empirical methods are given in Table 1. As seen from Table 1, in the first year, evapotranspiration values 7 daily-measured were between 2.18 and 14.66 mm day^{-1}, in the second year, it shows between 0.81 and 14.61 mm day^{-1} . The highest evapotranspiration (ET) values were observed as 14.66 mm day^{-1} the last period of July, in 2012; the highest water consumption as 14.61 mm day^{-1} in 2013 was observed during the end of June. The water consumption was realized as 84 mm and 88.5 mm respectively. Reference evapotranspiration (ETo) values calculated by evapotranspiration estimation equations evapotranspiration values were 45.4-138.7 mm in 2012, while in 2013 it ranged from 46.2-133.0 mm. There is a linear relationship between values of seasonal evapotranspiration and irrigation water applied to treatments (Figure 1). As seen in Figure 1, evapotranspiration values were increased in parallel to applied irrigation water. The highest ET value was determined in the I_3N_4 treatments as 873.7 mm and 844.6 mm, respectively in 2012-2013 (Kiymaz and Ertek, 2015)

The monthly cumulative potential evapotranspiratin values estimated using empirical equations with actual evapotranspiration shown in Figure 2. As seen in Figure 2, FAO-A Pan and Blaney Criddle (USDA-SCS modification) methods give the closest values to the actual evapotranspiration. The average results for two-year relating to the parameters taken into account to determine the appropriate evapotranspiration estimation method given in Table 2. The highest compensation rate (ET %) of actual ET by applied irrigation water with 83.2% and 82.9%, the smallest RMSE with 3.56 and 6.89, highest correlation coefficient (r) of the relationship between measured and predicted water consumption with 0.96 and 0.93, and the closest seasonal average crop coefficient (Kc) to 1 with 1.03 and 0.97. With Blaney Criddle (USDA-SCS modification) and FAO A Pan methods gives the best results in estimated the closets evapotranspiration to reality. The crop coefficients (Kc) by suggested this method obtained and seasonal mean values for two-year are shown in Figure 3. When examined the Kc obtained, it usually has been seen as having reached the lowest at the beginning of the season of plant growth, high mid season, the lowest value again at the end season. Kc values empirically determined in the III period for a peak period, the highest values of 1.06 with FAO A Pan and 1.10 with Blaney Criddle (USDA-SCS modification) method has reached.

Factors affecting the value of the crop coefficient (Kc) are mainly the crop characteristics, crop planting or sowing data, rate of crop development, length of growing season and climatic conditions (Doorenbos and Pruitt, 1977).

The relationships between the ET values determined according to treatments and Class A pan values measured from the *Class A Evaporation Pan* in the same period were detected. Equations and regression coefficients (R^2) indicating the relationship between Evapotranspiration and Pan evaporation values according to the two-year mean values are given in Table 3. As seen from the table, significant linear relationships determined in all treatments at 1% significance level between evapotranspiration and A evaporation pan.

Conclusions

At the end of the study, USDA SCS- Blaney-Criddle and FAO Pan equations gave the closest values to the water consumption obtained by gravimetric moisture method. Results indicated that the Blaney Cridle (USDA-SCS Modifikasyonu) and FAO A Pan methods and the crop coefficients (K_C) are appropriate alternatives for estimation of ETo under climatic conditions of Kırşehir, Turkey. Results showed that empirical methods used for estimation of plant water consumption were compatible with direct measurement methods.

Abstract

Discharge of untreated wastewater into the environment and/or especially in the superficial freshwater like rivers, lakes and the coast is the main cause of pollution. Untreated wastewater consists of liquid wastes discharged by domestic residences, commercial centres, industries, and/or the agriculture sector and can include a wide range of potential pollutants. For this purpose, considerable work was done to assess the quality of contaminated residence's wastewater near the Agricultural University of Tirana, before and after treatment, using a pilot plant. Physical and chemical parameters of wastewater were examined, and the necessary recommendations were suggested in order to improve water quality. Quality assessment of untreated and treated wastewater, analysing physical and chemical parameters, was performed for a period of three years, from 2012 to 2014. Physical and chemical pre-treatment parameters (pH 8.10, TSS 213.4 mg/l, N-NH_4 38 mg/l, 1.03 mg/l for N-NO_3, N-NO_2 0.21 mg/l, N-Total 44.4 mg/l, P-Total 4.26 mg/l, COD-Total 270 mg/l and BOD 176.28 mg/l) and after treatment parameters (pH 7.9, N-NH_4< 0.05 mg/l, N-NO_3 0.1 mg/l, N-NO_2< 0.02 mg/l, P-Total < 0.05 mg/l and COD 40 mg/l) were analysed. Results confirmed that the quality of the treated water through the use of the pilot plant, referred to the content of COD, BOD_5, TSS, N and P, is within the standard norms set by the Albanian and EU standards, for the third level treated water.

Keywords: *wastewater, pilot plant, physical and chemical parameters, permissible level*

Introduction

Wastewater is the liquid end-product of municipal, agricultural and industrial activity. So, due to its value, wastewater is treated and then discharged to a receiving stream. As such the chemical composition of wastewater naturally reflects the origin from which it comes. Consequently, the water we use for drinking, washing, bathing etc. ultimately ends up back in the stream, river, lake, or groundwater where it will be withdrawn, treated, and used again (Duka et al, 2013).

Today, however, human pressure on natural environments is greater and more negative changes in the environment caused by human activities, such as urban discharges, industrial, agricultural and livestock, the use of pesticides and other chemicals on agricultural lands. One of the main sources of surface water pollution in our country are urban discharges, which contain organic matter, soluble compounds of phosphorus and nitrogen that favour the process of eutrophication, pathogenic bacteria and viruses, heavy metals and subjects that spoil the appearance of water and give them a bad smell (Duka et al, 2012). For this reason, special attention is dedicated in assessing the quality of surface waters and determining the primary pollutants discharged into them, in order to protect the environment and enable the creation of a database for integrated management and sustainable use of water resources.

Materials and methods

Physical and chemical parameters play an important role in the dynamics of water. Evaluation of physical and chemical parameters was performed for a three-year period (2012-2014). The samples for which these characteristics have been determined were taken at two different points, in the entrance and the exit of wastewater. In the main sewers, the first sampling point is selected during the period from 6 March 2012 until 22 July 2014. Wastewater samples were collected in 1.5 L bottles, which were previously washed with distilled water and then, at the time of sampling, were rinsed three times with water that was taken as a representative sample for analysis. Temperature and dissolved oxygen were measured 'in-situ', by a thermometer and a portable dissolved oxygen meter; all of these devices have been calibrated before.

Results and discussions

Untreated wastewater

Below we present the data obtained for the four study periods, using the respective tables and figures. Table 1 presents the average values of the physical and chemical analysed parameters of untreated wastewater. These values vary: pH 8.10, TSS 213.4 mg/l, N-NH_4 38 mg/l, 1.03 mg/l for N-NO_3, N-NO_2 0.21 mg/l, N-Total 44.4 mg/l, P-Total 4.26 mg/l, COD-Total 270 mg/l and BOD 176.28 mg/l.

Table 1: Summary of results of physical and chemical parameters in untreated wastewater for the years 2012-2014

Parameters	Unit	Min	Max	Average	Stdev	CV %
pH	-	7.69	8.63	8.10	0.23	2.83

Domestic wastewaters at the area around University were found not to be significant fluctuations in terms of pollution, during different seasons of 2012, as well as during other years of study.

Data analysis

The collected data was organized in Excel tables. The arithmetic mean (average), standard deviation (SD), coefficient of variation (CV) was defined using Excel formulas. The coefficient

of variation represents the ratio of standard deviation to the arithmetic average, and was used as a statistical tool to compare the degree of change from one series of data to another, even when the averages differed from each other dramatically. If CV is lower than 2%, parameters measured are considered as more homogeneous; when CV values are between 2% and 30% (2% < CV < 30%), measured parameters are considered homogeneous; and when CV is greater than 30%, the measured parameters are considered as heterogeneous. According to this table, we noticed that the various parameters measured fall under the classification of heterogeneous (CV > 30%), with the exception of pH, EC and N-NO_3, where measurements make these parameters homogeneous (CV < 30%) (Wolfgong et al, 2012).

The changing value of COD and BOD_5 during 2012-2014

The main difference between COD and BOD_5 is the fact that through BOD_5 determined organic matter may oxidize in the biological pathway, while through COD determined substances may oxidize in the chemical pathway (Wayne Bayles, 1997). As expected, the COD values are higher than the values of BOD_5, but it seems quite clear that there is a similar trend between them. Referring to the chart below, fluctuations in the values of COD in untreated waters range from the minimum value of 92 mg/l DO to the maximum value of 896 mg/l DO and for the BOD_5 parameter, the values range from 30 mg/l DO in its minimal value to the maximum value of 450 mg/l DO (Fig. 1). These changes in the values of COD and BOD_5 are directly related to the status of sewage pollution. Also, the high values of COD and BOD_5 measured in March 2012 show the presence of biodegradable organic material. During the months of May and June of 2013, the COD values at the entrance of the plant range from a minimum value of 120 mg/l DO to the maximum value of 317 mg/l DO.

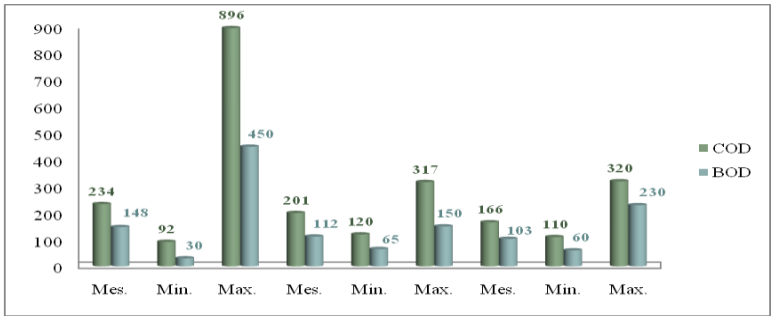

Figure 1. The changing values of COD and BOD_5 during the 2012-2014 periods

The changing value of TSS during 2012-2014

Referring to our study, the TSS values range from the minimum value of 4 mg/l, reaching an average of 85.42 mg/l, with a maximum value of 688 mg/l in 2012. While continuing in 2013, these values range from a minimum value of 4 mg/l, to the maximum value of 57 mg/l, with an average of 26.15 mg/l. (Fig. 2). In 2014, the values range from 14 mg/l which is the minimum value, to the maximum value of 255 mg/l, with an average value of 75.13 mg/l. High values of total suspended solids (TSS), often come due to heavy load of minerals and organic materials generated by the population. For this reason, the wastewater can be classified as strong and as such must be treated before being discharged into the receiving water environments (as cited Wolfgang et al 2012).

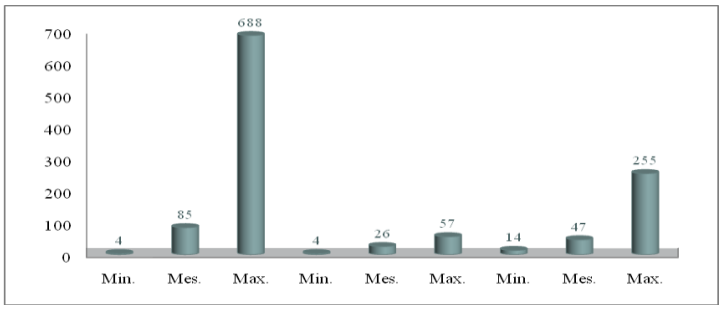

Figure 2. The changing values of TSS during the 2012-2014 periods

Measurements of the level of N-Total and its components ($N\text{-}NO_3$, $N\text{-}NO_2$, $N\text{-}NH_4$) in wastewater

In the figures below are presented the summary results of each nutrient content in water samples analysed for each year of study. Results represent the average of three years. In untreated wastewater, total nitrogen levels range from 16 mg/l to 74 mg/l. So, referring to our study, the concentration of total nitrogen in all samples analysed ranges from a minimum value of 16 mg/l, to a maximum value of 74 mg/l, with an average value of 39.56 mg/l during 2012 and then continues with a minimum value of 16 mg/l, an average value of 39.62 mg/l and a maximum value of 70 mg/l in 2013. In 2014, values range from 21.2 mg/l as the minimum value to 39.7 mg/l as the maximum one, and have an average value of 28.75 mg/l. Ammonia is a component of wastewater, resulting from the degradation of proteins. Raw wastewater typically has ammonia concentrations in the range levels of 20 to 30 mg/l, as ammonium N (Johal et al, 2014). Figure 3 shows that concentrations of ammonia ($N\text{-}NH_4$) differ, on average, between 24.94 mg/l in 2014 and 35.07 mg/l in 2013. The minimum values range from 10.2 mg/l in 2013 to 15.21 mg/l in 2014. Also, Figure 4 shows that concentrations of nitrate nitrogen ($N\text{-}NO_3$) vary, with the minimum value of 0.5 mg/l recorded in 2013 and the maximum value of 1.4 mg/l recorded in 2012. Nitrites nitrogen ($N\text{-}NO_2$) is a strong poison for fish, reducing their ability to transfer oxygen into the bloodstream (Murphy, S., 2007). In polluted waters, it varies between 0.04 mg/l to 0.67 mg/l with an average of 12.21 mg/l, analysed in 2012, and in 2013 its values range from 0.05 mg/l as the minimum value to 12.21 mg/l as the maximum value, with an average of 0.12 mg/l. Similarly, its measured values during 2014 are exactly 0.04 mg/l as the minimum value, 0.2 mg/l as the maximum value and 0.12 mg/l as the average one.

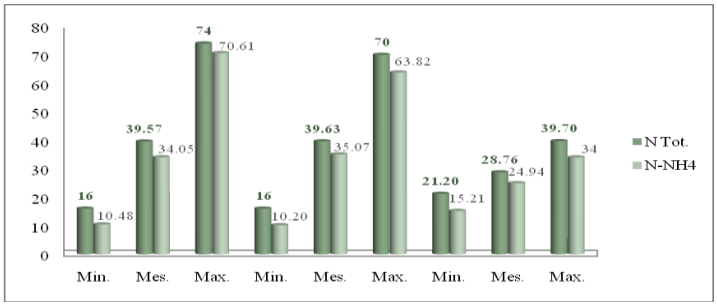

Figure 3. The change of N-Total and $N\text{-}NH_4$ values during the 2012-2014 periods

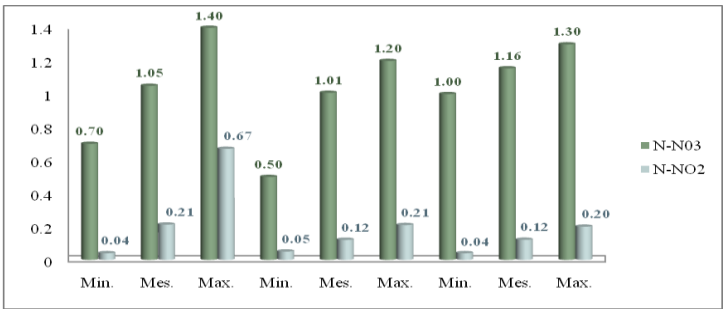

Figure 4. The change of N-NO_3 and N-NO_2 values during the 2012-2014 periods

Total Phosphorus (TP)

Phosphorus is a nutrient for living species. He serves as a pollutant if is found in high concentrations in specific environmental conditions. The measurements show that the concentration of phosphorus in the untreated wastewater in the study, range in more or less the same levels. For this reason, since they are household waters, phosphorus is derived from the same source, from human waste, food and detergents. Then, referring to the years in which the study was conducted, phosphorus ranges from 1.7 mg/l which is the minimum value to the maximum value of 6.55 mg/l and the average value of 3.89 mg/l, as analysed in 2012, while in 2013 it ranged from 1.6 mg/l to 5.64 mg/l, with an average value of 3.47 mg/l. For 2014, were registered slightly lower values than the previous two years, ranging between 1.14 mg/l to 3.85 mg/l with an average value of 2.3 mg/l (fig.5).

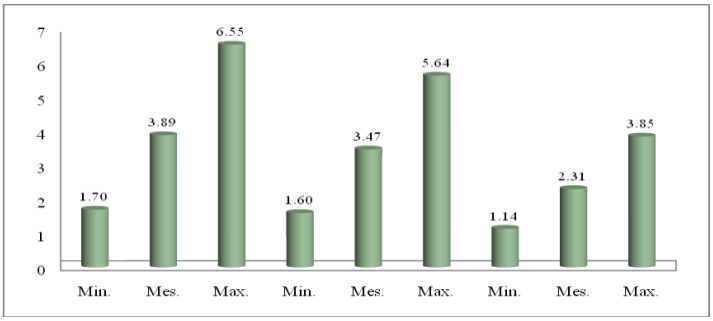

Figure 5. Change the value of P-Total during the 2012-2014 periods

Treated water after using the pilot plant

The study was conducted using wastewaters from1.000 residents, with a total flow rate of 2 m^3/d. The aim was to assess the quality of treated water in terms of compliance with national and international standards.

COD and BOD in treated water

The main focus of wastewater treatment plants is to reduce the COD and BOD in the effluent discharged to natural waters. Wastewater treatment plants are designed to function as bacteria farms, where bacteria are fed oxygen and organic waste. If effluent with high BOD levels is

discharged into a stream or river, it will accelerate bacterial growth in the river and consume the oxygen levels in the river (Brown and Caldwell, 2001).
At the exit of the plant, COD values ranged from the minimum value of 16 mg/l DO to the maximum value of 47 mg/l DO, while BOD_5 values ranged from the minimum value of 4 mg/l DO to the maximum value of 9 mg/l DO. Based on the values obtained, we can suggest the idea of a high percentage reduction in the COD, respectively 95%, the same as defined in the literature (Fig.6).

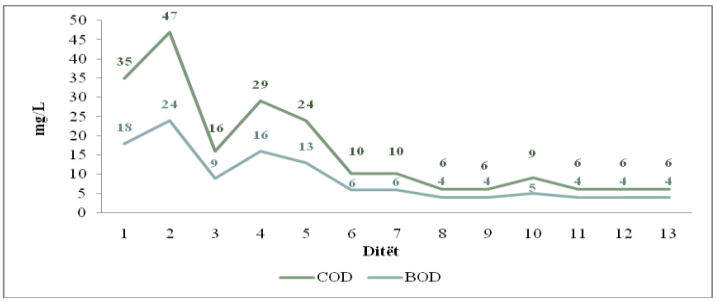

Figure 6. COD and BOD_5 change in discharges of treated water

The degree of reduction of total nitrogen and its components

N-Total and its components are measured as concentrations of $N\text{-}NH_4$, $N\text{-}NO_3$, $N\text{-}NO_2$ in treated waters, during the three years of stable operation, taking in consideration the processes of partial nitrification and denitrification, that require special aerobic and anoxic conditions. What is striking is the fact that the concentration of total nitrogen decreased from 71 mg/ l to 0.4 mg/l. After the wastewater treatment, $N\text{-}NH_4$ was reduced to 0.01 mg/l. As can be seen, the nitrogen components in the treated water were and mainly formed of gaseous nitrogen, showing a stable behaviour of nitrification.

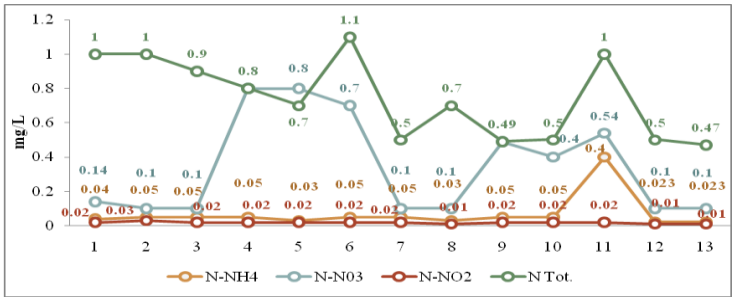

Figure 7. The rate reduction of N-Total and its components from using SBR pilot

The values of total phosphorus in treated water

Phosphorus values after the water treatment using SBR pilot, reduced to 99.6%. So phosphorus values were reduced from 6.55 mg/l which is the maximum value, to the value of 0.01 mg/l.

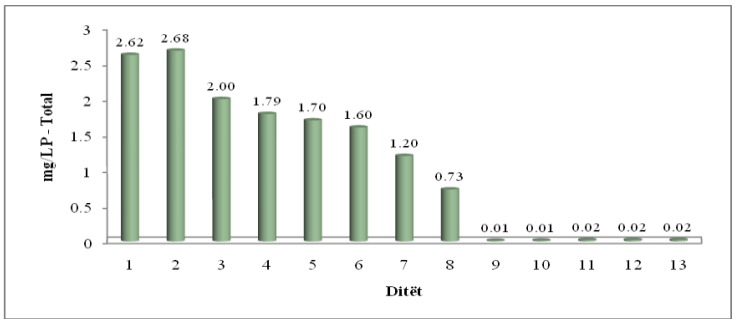

Figure 8. P-Total change in discharges of treated wastewater

By (Strom, 2006) the removal of phosphorus from wastewater, biological assimilation was achieved through the inclusion of phosphorus as an essential element in biomass, mainly through increased photosynthetic organisms (plants, algae, and some bacteria, such as cyanobacteria). This is achieved through treatment ponds containing algae or plankton, root vegetables, or even floating plants (e.g. aquatic plants, hyacinth, duckweed, etc.). Also, as Peter F. Strom pointed out, concentrations of phosphorus in values less than 0.1 mg/l can be achieved for long periods (more than a month), values of 0.03 mg/l for a week, and values even under 0.02 mg/l for several days following.

Conclusion

The study showed that the values obtained from the analysis of household untreated wastewater are higher than the limits recommended by the Albanian Standard and European Directive on the discharge of treated wastewater into the aquatic environment. Based on physical and chemical wastewater characteristics and their sources, classified and adapted from Metcalf and Eddy Inc. (2001), values of those parameters in untreated wastewater are classified as low. The reducing of pollution, assessed by the indicators of BOD_5 and COD is respectively 94.7 %, for the nutrients P Total and N Total is 99.8% and 98.6% respectively, whereas for $N\text{-}NH_4$ and $N\text{-}NO_3$ is 99.8% and 92.8 % respectively. These results show that the quality of treated water through the use of the pilot plant, referred to the content of COD, BOD_5, TSS, N and P, is within the standard rates set by the Albanian and EU for treating water at the third level.

DETERMINATION OF BIOGAS PRODUCTION POTENTIAL AND ENERGY VALUE FROM ANIMAL MANURE IN TURKEY (AFYONKARAHİSAR PROVINCIAL EXAMPLE)

Cengiz KARACA

Mustafa Kemal University, Faculty of Agriculture, Department of Biosystems Engineering, Hatay, Turkey
Corresponding author: ckaraca@mku.edu.tr

Abstract

The aim of this study was to determine biogas amount and the energy value, being produced from animal manure in Afyonkarahisar (or Afyon) province, Turkey. For this purpose, biogas potential is calculated considering the number of cattle and laying hens. Afyonkarahisar has a total of about 350 thousand cattle, 5 thousand buffalo, and 18.5 million laying hens. The annual total of 4 million tons of manure is obtained from these animals in the province. There are 3.5 million tons of cattle manure, 51.5 thousand buffalo manure, and 540 thousand tons of laying hens manure. Annually 84.8 million m^3 of biogas can be produced from the usable amount of this manure. The heating value of biogas produced from this manure is about 1.9 PJ. The electricity production from this biogas is about 214 GWh_{el}. These values can provide 16.6% of Afyonkarahisar's annual electrical energy consumption (1,284 GWh_{el}). The distribution of these calculated amounts by districts was mapped. When districts are arranged according to amount of biogas production, the top ten Afyonkarahisar districts are Central district (27.7%), Bolvadin (10.2%), Başmakçı (9.6%), Sinanpaşa (7.4%), Sandıklı (7.2%), Çay (6.8%), Şuhut (6%), İhsaniye (4.6%), Emirdağ (4.1%) and Dinar (3.7%).

Keywords: *Biogas potential, Animal manure, Turkey, Afyonkarahisar*

Introduction

Energy plays an important role in the world's future. Energy is central to economic development, and there is a clear correlation between energy consumption and living standards. Energy sources are split into three categories: fossil fuels, renewable sources and nuclear sources (Karaca, 2015).
Renewable energy systems, such as biogas, based on national and regional biomass resources, can increase the security of the national energy supply and reduce dependency on imported fuels. Biogas from anaerobic digestion does not only improve the energy balance of a country, but also makes important contributions to the conservation of the natural resources and environmental protection (Al Seadi *et al.,* 2008).
Anaerobic digestion is a simple technology that allows for decentralized energy production from various biomass, such as animal manure, energy crops, and food industry wastes. In addition to the direct effect of producing energy, anaerobic digestion has several other environmental benefits, including reduced greenhouse gas emissions. (Møller *et al.,* 2008).
Turkey's primary energy demand is met by natural gas (35%), coal (28.5%), oil (27%), hydro-power (7%), and other renewable resources (2.5%). Turkey's total electricity power demand has been increasing rapidly. It reached 264 TWh in 2015. The structure of other energy sources used for electricity generation in 2015 was composed of coal (28.4%), hydro-power (25.8%), wind-power (4.4%) geothermal (1.3%), fuel oil, diesel and naphtha (1.6%), and biogas (0.6%) (MENR, 2015).

The objective of this study was to determine the production potential of biogas from animal manure (only cattle and laying hens) and mapping in Afyonkarahisar with separate districts. For these purposes, biogas potential and its energy potential of animal manure were evaluated by ArcGIS which is a geographical information system (GIS) program. The differences in data among the districts for seeing more clearly were created maps in GIS. A database was created within the GIS for Afyonkarahisar and its districts. The number of animals, calculated biogas potential, and its heating value in the province for the year 2015 were inputs to this database.

Materials and methods

Afyonkarahisar (previous name Afyon) province in Turkey has located between 37°45′-39°17′ N latitudes and 29°40′-31°43′ E longitudes and covering 14,570 km^2 areas. Afyonkarahisar is located as a gateway to the Aegean Sea and inner regions of Anatolia, located at the crossroads of 3 different regions of Turkey (Figure 1). The province is divided into 18 districts. These districts include Central (Afyonkarahisar), Başmakçı, Bayat, Bolvadin, Çay, Çobanlar, Dazkırı, Dinar, Emirdağ, Evciler, Hocalar, İhsaniye, İscehisar, Kızılören, Sandıklı, Sinanpaşa, Sultandağı, and Şuhut.

Within the scope of this study, Turkish Statistical Institute's 2015 animal statistic data has been used as material (TUIK, 2015). The data used in the calculation of the biogas production potential were considered only cattle, buffalo and laying hen population. Because the attainability of animal manures, as determined by staying time in the barn, provides the highest value in a cattle farm (65%) and laying hens farm (99%) (Başçetinçelik *et al*., 2005). Another animal data is not used in calculating of biogas amount for this ratio be lower.

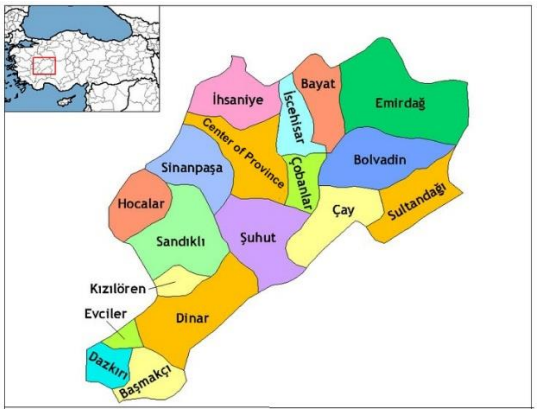

Figure 1. The districts of Afyonkarahisar and their locations

Animal manure and biogas production calculation methods

The following methods were used to calculate the amount of animal manure and biogas production (Başçetinçelik *et al*., 2006; Ozsoy and Alibas, 2015; Ayhan, 2015).

$$AFM = \frac{NA \times MPPA}{1000}$$

Where, AFM is the amount of fresh manure as a daily value (t/d); NA is the number of animals; MPPA is the daily manure production per animal (kg/d. animal). The MPPA is 27.24 for cattle and 0.08 for laying hens.

$$ASM=AFM \times SMR$$

Where, ASM is the amount of daily solid manure (t/d); SMR is solid manure ratio (%).

$$TUSM=ASM \times AOM \times 365$$

Where, TUSM is annual total usable solid manure (t/a); AOM is the attainability of manure (%).

$$AB=TUSM \times BCR_{SM}$$

Where, AB is the amount of biogas (m^3/a); BCR_{SM} is biogas conversion ratio of solid manure (200 m^3/t).

$$THV=AB \times HV$$

Where, THV is the total heating value (MJ/a); HV is the heating value of unit biogas (22.7 MJ/m^3).
Electricity generation from biogas with a gas engine was calculated by the following equation.

$$EP=\frac{THV}{3.6} \times EPE_{Net}$$

Where, EP is electricity production (MWh_{el}/a); EPE_{Net} is the net electricity production efficiency of biogas engine (40%) (Clarke Energy, 2016).

For each district, the calculated values, the total amount, the total biogas production, and the total energy potential of animal manures, were mapped using ArcMAP Software.

Results and discussion

Total animal manure potential of Afyonkarahisar in 2015 as a solid matter depending on the number of cattle and laying hens is presented in Table 1.

Table 1. Number of animals, and total amount of animal manure as fresh and solid matter

Animal	**NA**	**AFM** (t/d)	**SMR** (%)	**ASM** (t/d)	**AOM** (%)	**TUSM** (t/a)
Cattle	348,608	3,466,070	12.7	440,191	65	286,124
Buffalo	5,183	51,532	12.7	6,545	65	4,254
Laying hens	18,468,607	539,283	25	134,821	99	133,473
TOTAL		**4,056,886**		**581,556**		**423,851**

According to Table 1, the total amount of usable solid manure, obtained from cattle and laying hens, is 424 thousand tons in 2015. Its distributions by the sources are cattle (68.5%) and laying hens (31.5%).
The amount of biogas which can be obtained from the total animal manure as a solid matter along with the electricity generation from this biogas is presented in Table 2.

Table 2. The biogas potential and the energy potential of biogas in Afyonkarahisar

Animal	**TUSM** (t/a)	**AB** (m^3/a)	**THV** (GJ/a)	**EP** (MWh_{el}/a)
Cattle	286,124	57,224,814	1,299,003	144,334
Buffalo	4,254	850,802	19,313	2,146
Laying hens	133,473	26,694,525	605,966	67,330
TOTAL	**423,851**	**84,770,140**	**1,924,282**	**213,809**

Table 2 presented that the total biogas potential of Afyonkarahisar was calculated to be 84.77 million m^3/a. Besides, its heating value was calculated to be 1,924 TJ/a. It was determined that almost 214 GWh_{el}/a. energy can be obtained by the conversion of all the biogas potential from animal manure into electrical energy by means of a gas engine. These values can provide 16.6% of Afyonkarahisar's annual electric energy consumption (1,284 GWh_{el}).

A study carried out by Kizilaslan and Onurlubas (2010) in Tokat Province, Turkey indicated that the total biogas derived from animal manure was 37.9 million m^3/a.

Ozsoy and Alibas (2015) reported the amount of biogas production from animal manure was about 52 million m^3/a, equivalent to about 400 GWh/a. of energy.

The potential of biogas from animal manure was determined in Yozgat province, Turkey. The total biogas potential was determined as 45 million m^3/a in the province. (Eryilmaz, *et al.,* 2015).

As a result, the biogas potential of Afyonkarahisar province only from cattle, buffalo and laying hens is greater than the three provinces (Bursa, Tokat, Yozgat).

Table 3. Amount of fresh manure, biogas potential and energy values in the districts of Afyonkarahisar

Districts	**Fresh Manure (t/a)**	**Biogas Potential (m^3/a)**	**Heating Value (GJ/a)**	**Electric Energy (MWh_{el})**	**Share in total (%)**
Center	866,286	23,507,131	533,612	59,290	27.7

Sinanpaşa	355,284	6,302,464	143,066	15,896	7.4
Şuhut	307,759	5,107,548	115,941	12,882	6.0
Sultandağı	87,245	1,441,697	32,727	3,636	1.7
TOTAL	**4,056,886**	**84,770,140**	**1,924,282**	**213,809**	

Considering 17 districts of Afyonkarahisar for the year 2015, animal fresh manure, biogas potential obtainable from solid manure, the heating value of this biogas potential, and the electrical energy produced from this biogas, were presented in Table 3.

Central of the province has the highest potential with 23.5 Mm^3/a value and 27.7% of the share in total. This is followed by Bolvadin, Başmakçı, Sinanpaşa and Sandıklı districts with 8.6 Mm^3/a. and 10.2%, 8.1 Mm^3/a. and 9.6%, 6.3 Mm^3/a. and 7.4%, 6.1 Mm^3/a. and 7.2%, respectively.
While the amount of cattle manure in all districts generates the majority of the total manure, these rates vary only in the Centre and Başmakçı district. The share of cattle manure inside of the total manure is 67.8% and the share of laying hen manure is 32.2% in the Central district. In the district of Başmakçı, the share of cattle manure and laying hens manure within total manure are 52% and 48%, respectively. Because Afyonkarahisar is the center of the egg production in Turkey, the vast majority of egg production is carried out in these two districts. Therefore, laying hens manure generates a major problem because of its large amount yearly.
The amount of biogas and their energy values were calculated separately for each district and were mapped using ArcMAP Software. The distribution map of biogas potential and its energy values for 18 districts of Afyonkarahisar are given in Figures 2 and 3.

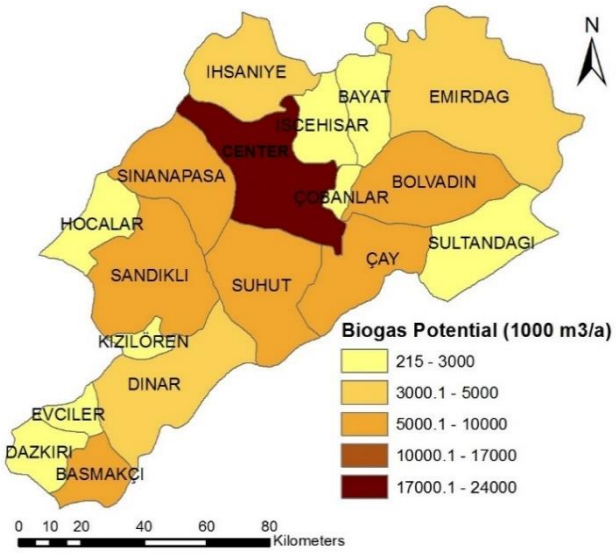

Figure 2. The distribution map of biogas potential in Afyonkarahisar

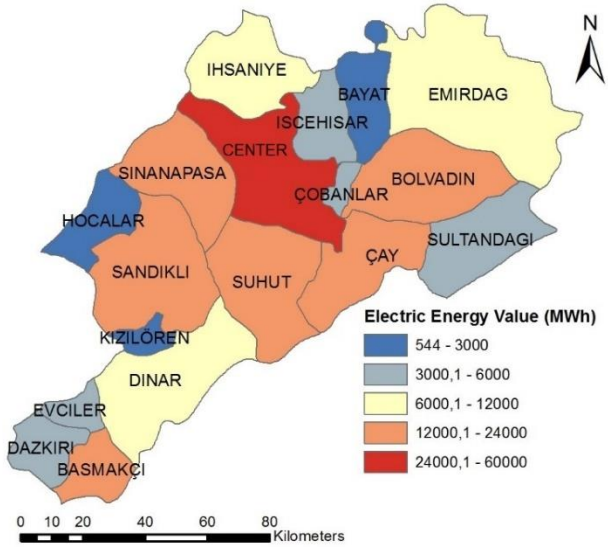

Figure 3. The distribution map of electricity generation from biogas in Afyonkarahisar

These maps show that the biogas potential is concentrated in the Center of the province and decreased from center to outward in the region. Başmakçı district is excepting. This means that the biogas production plants can be established in the central and districts nearing. This situation is an advantage in terms of raw material supply for biogas production plants.

Conclusion

In this study, it was detected that the biogas potential of Afyonkarahisar from cattle, buffalo and laying hens manures was 84.77 million m^3/a depending on the number of the animals in the years 2015. A 27.7% of this potential was enabled by the Centre of the province while 10.2%, 9.6%, 7.4%, and 7.2% of it were supplied by Bolvadin, Başmakçı, Sinanpaşa, and Sandıklı, respectively.

If all the biogas potential from animal manure are converted into electricity by means of a gas engine, it can be obtained almost 214 GWh_{el}/a. electrical energy. These values can provide 16.6% of Afyonkarahisar's annual electric energy consumption (1,284 GWh_{el}).

Although Afyonkarahisar province has a large biogas potential, this potential has not been able to be adequately assessed. At present in the province, there are two biogas plants installed capacity with 4.254 MW_{el} and 2.4 MW_{el}. While the electricity generation potential of biogas in Afyonkarahisar is 24.43 MW_{el}, today only 27% of this potential is evaluated.

In this study, the created maps were provided to visualize more clearly the differences of data from the districts. The mapping can provide the rise of public awareness, and policy-makers' reference about these matters.

Turkey has a great potential of renewable energy sources. Unfortunately, it is an energy-importing country. The country needs to use more of its renewable energy sources in order to be independent with regards to energy. Therefore, biogas can be a very attractive choice because it is sustainable, environmentally friendly and a native energy source for Turkey.

Abstract

A bioreactor was filled with different substrates at once and left to degrade anaerobically without any interference until the end of the cycle phase. Experiments were performed in usual 1.5-l digester flasks in the batch process and measurement of biogas was done by standard water displacement method. The biogas production was recorded up to 50 days. Different agricultural and animal wastes have been tested. In most of the cases pretreatment in the form of soaking in water, acid or alkali was found to increase the biogas content on digestion mixed with chicken manures or any other animal waste the yield was higher. Our study has been firstly focused in preparing biomass for the anaerobic digestion for methane profit, using calculated mixtures of different agro-forestry residues such as spent organic substrates, wheat straw, corn straw, corncob and a mixture of leaves and thin sticks etc., premixing them with animal wastes like manures and other organic wastes. Experimental series have been performed with wide ratios C:N in range 23-40. So, we have followed a systematic procedure for the anaerobic biologic digestion process design simulated in a fixed capacity chosen. At the end as a result we have recommended an engineering flow sheet for the specified biochemical process.

Keywords : *Renewable energy, Biogas, Biomass, spent substrate, anaerobic digestion.*

Introduction

This article focus on the overall analysis of the organic raw materials, which will be used for the development of experiments. The intention was to analyze the physical - chemical properties of the samples, which will be used as raw material for the pre-treatment process for biogas production (Amon *et al*., 2007; Bernard *et al*., 2000). There are a lot of recommended and explained methods for pretreatment of the biomass.

We were focused more on the acidic and alkaline pretreatment and on the development of experiments, analysis of raw materials, taking samples before and after appropriate pretreatment (Batstone *et al*., 2002; Colussi *et al*., 2009). It has been determined characteristics such as: humidity, dry matter, ash, the carbon to nitrogen, ratio, pH value, electrical conductivity and biological oxygen demand (BOD). Raw materials to be analyzed were: alfalfa, wheat straw, corn straw, corncob and a mixture of leaves and thin and dry wooden sticks. The aim of pretreatment process was to overcome this recalcitrance, to separate the cellulose from the matrix polymers, and to make it more accessible for enzymatic hydrolysis. During this process it was expected a certain change of the composition ratio within lignin: hemicelluloses: cellulose, which influence on the particle size, degree of polymerization, pore volume, solubility rate etc. Although there are

different types of pretreatment such as mechanical, thermique, acidic, alkaline, (said chemical), as well as biological method.
From other studies has been shown that the anaerobic digestion (AD) was an alternative method recently studied for breaking down biodegradable material in an oxygen- free environment to produce a solid digestate along with biogas. Anaerobic digestion converts organic matter into carbon dioxide (~40%) and methane (~60%) via four defined stages: hydrolysis, fermentation, acetogenesis and finally methanogenesis. The anaerobic degradation process is suitable for waste treatment; based on the biological oxidation of organic matter by the action of specific microorganisms (in the absence of atmospheric oxygen) as a result of this process, organic matter is converted into stable end products and still, at the same time it generates biogas (mainly methane and carbon dioxide) [5-7] with a considerable energy potential while producing an energy rich biogas (55-70% methane, CH4) that can be valorised energetically.
Most literature sources report substantial differences in the yields and kinetics of methane on anaerobic digestion depending of type of substrate.

Materials and methods

Materials preparing for anaerobic digestion

Raw materials for the anaerobic disintegration have been taken from one chicken farm located in Tirana. As biomass were used alfalfa, corn straw, wheat straw, wood chips and dried leaves, humus, chicken manure and livestock (cattle). At the beginning, physical pretreatment was performed. After collecting the crude raw materials, drying was done at room temperature and then in thermostat at 105 ° C ± 2 ° C for 4 hours. Once the plant residues was dried up, they were cut off into very small pieces, 2 mm sizes in order to have a greater contact surface between biomass, water and other substances for biogas production.

Raw materials (organic wastes) analysis

Organic wastes were physically characterized with the moisture content, dry matter, organic matter, ash, free carbon, total nitrogen (method Kjeldalh) and pH value.

Biomass Pretreatment for degrading of ligno - celullosic material

For the biomass pretreatment the following method was used (Yadvika *et al*., 2004). At first 10g catalyst CuSO4: K2SO4 (1:10) was mixed with the sample, about 20 ml sulfuric acid was then added to the solution. After that, digestion temperature was increased up to 40 °C and 200 ml distilled water, antifoaming agent and 70 ml NaOH 40% were added. The solution was cooled to the environment temperature. In order to determine the nitrogen content the following formula was used:

$$\%N = \frac{14 \bullet T}{W(100 - M)}$$

Where; **T**= standard acid used for titration, **W**= sample weight,

M= moisture sample.

Results and discussion

The results of the experiment are presented in various graphs and tables, which are presented below. Set of samples shown in table 1 have been pretreated according to standard procedure in different condition varying from acid and alkaline added and finally were let to rest in 500 ml bottles for 40 days. The experimental set-up which has been build for the process is showed in the figure 1.

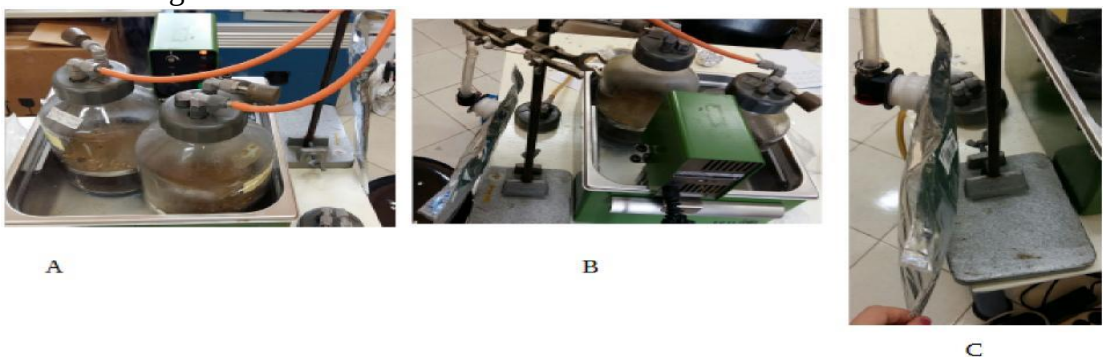

Figure 1. Experimental set up of the biomass pre-treatment . In A) is presented on the first day, B) is after a week pre-treatment, which has just started production of biogas and C) for the final amount of biogas collected after 40 days of experiment.

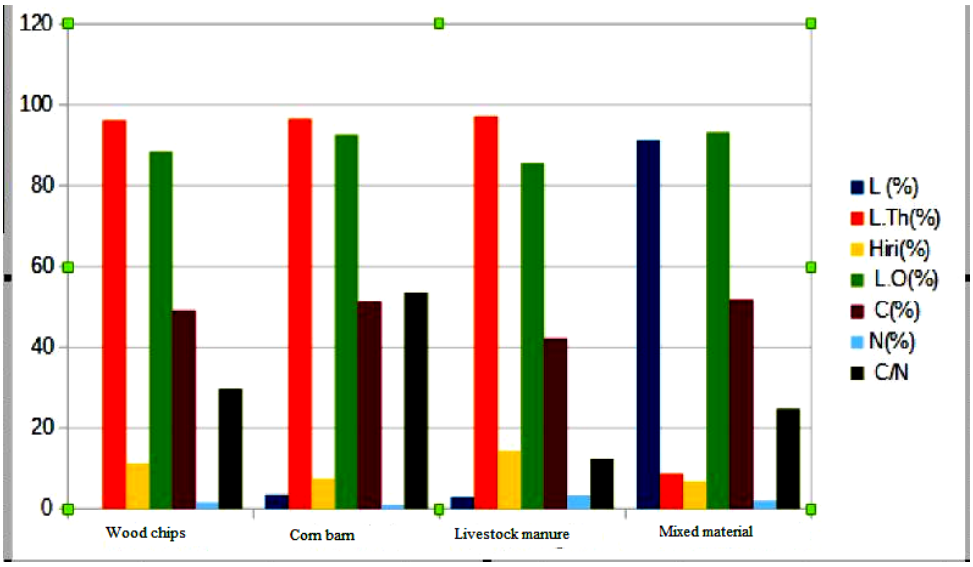

Figure 2. The graphical presentation of the analyzes on raw materials.

Then tests were performed for aerobic digestion during 14 days at 70^{o}C. Then sample bottles were kept at 40 ^{o}C for other 26 days.

Table 1. Analysis of the first day for the material used in 3-liter bottle

	R (%)	D.S (%)	Ash (%)	O.M (%)	C (%)	N (%)	C/N
Woodchips	3.75	96.25	11.28	88.5	49.17	1.65	29.8
Corn bran	3.45	96.55	7.48	92.52	51.40	0.96	53.54
Livestock manure	2.97	97.21	14.4	85.6	42.2	3.42	12.34
Mixed material	91.23	8.77	6.78	93.22	51.79	2.09	24.78

Table 2. Consistently determination of pH throughout the experiment time

Day	*0*	*10*	*20*	*30*	*40*
pH	*10.78*	*9.45*	*8.26*	*8.06*	*7.96*

Characterization of waste

Chicken manure that was used for the experiment, was taken from one chicken farm located in the region of Tirana. Samples were left to dry several days before use. Chicken manure was very rich in nitrogen which was needed for the biogas production.

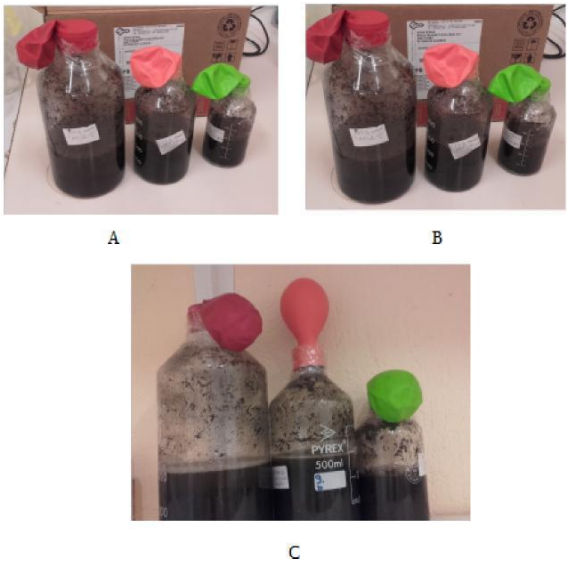

Figura 3. Experiments conducted with bottles balloon, A) the first day of the experiment, B) as anaerobic conditions were set for 24 hours, and C) observation of biogas production.

Table 3. Result of analysis of chicken manure

	R (%)	**D.S (%)**	**Ash (%)**	**O.M (%)**	**C (%)**	**N (%)**	**C/N**
Manure	**69.93**	**30.07**	**10.09**	**89.01**	**48.75**	**2.9**	**16.81**

During 40 days of experiment manure is constantly mixed in the bottle, in order to increase the contact surface between the biomass and alkaline treatment. It was observed that due to the composition process was first lightly alkaline, but after the dissolution of the material and the production of biogas the ph becomes at value pH 6.5 - 7.5. In this way we can take the desired result. Increased the % of nitrogen proves the fact that the dissolved ligno cellulosic material has created the conditions for the production of biogas (Deublein *et al*., 2008). The amount of biogas is expected to be generated based on data from the literature. According to the references obtained from various studies conducted in many countries, it said that from 1 kg chicken waste must be generated approximately 50 L biogas (Cioablă *et al*., 2009). The data obtained give us a solid content of 30% ± 1. These value was decisive for modeling analysis used. Theoretically has been described this value to be 31% ± 1, so close to our analysis results.

Table 4. Solid content measurements

Measure before drying (g)	Measure after drying (g)	Solid content (%)
50.136	15.071	30.06
51.243	15.865	30.96
49.854	15.023	30.14

It can be clearly seen that the organic matter was consumed in a great portion from the beginning, which was caused by the degradation of it from the hydrolysis during pretreatment. Further one can see that during basic pretreatment we got a smaller decrease of organic matter, than from acidic pretreatment. Also ash content was decreased during pretreatment, due to the decrease of O.M. On the other hand the Nitrogen content was increased during pretreatment, due to the fact of mineralization of Nitrogen into the form of ammonia, nitrates, nitrites etc.

Conclusion

It should be emphasized that a great importance in the pre-treatment process has not only the choice of ligno cellulose material to be treated, but the storage, drying and its fragmentation. To have a pre-treatment as well, and a performance in the production of biogas must not only make a combination of pretreatment methods but also the raw material that will be pre-treated. In this way become possible attacks on faster ligno cellulosic wall, biodegradable material growth and enable increasing the amount of biogas.

The anaerobic digestion converts organic residue (agricultural and food residue, animal waste) in energy (in the form of biogas or electricity).

Production of biogas from anaerobic decomposition of bacteria depends on the ability to operate with biomass. The survival of bacteria depends on the temperature, pH, and physical anaerobic digestion conditions.

The main purpose of the pre-treatment for biogas production was to increase the interaction of the hemicelulloze and lignocelulloze compound, as well as the decomposition of complex structure.

To improve the process of pre-treatment of biogas, can be suggested a combination of pre-treatment methods, with at least the use of two types of pretreatment. From our experience we justify the fact that in some studies have been found very effective combination of thermal pre-treatment with the chemical in order to increase the biogas amount profited. The combination of pre-treatment methods need to be used in order to improve the anaerobic process performance for the production of biogas must be based also on the economic analysis.

Chicken manure were selected for an application model that describes the experimental data and model in order to describe the real case. Chicken manure were chosen because they have a high potential for production of biogas and is a very good opportunity to achieve anaerobic digestion.
The amount of biogas produced from chicken manure was distinguished after 5 days of the experiment. It should be noted that another important parameter influencing the performance of the regular experiment was repeatedly mixing the manure in the bottle. Mixing took place throughout the day with an interval of about 5 minutes every 2 hours.

Abstract

Dichondra repens is the most widely used vegetation as ground cover plant that has a creeping habit in the landscape. Increasing seeding rates may help decrease weed pressure in *Dichondra repens* with proper sowing methods. The objectives of this paper are to analyse two different sowing methods (1.the agricultural nonwoven fabric (agril) method and 2. the conventional sowing method) at different seeding rates (10, 20, 30, 40, 50,100, 150, 200, 250 and 300 ha^{-1}) on covering rate of *Dichondra repens* on ecological conditions of Igdır plain. The obtained data were analysed by repeated measures design with two factors, sowing method and time. The results showed that there was a significant difference between in both sowing methods and times in terms of covering ratio ($p<0.05$). Weeds were difficult to control in Dichondra on the conventional sowing method compared with the agril nonwoven method in the experimental area. The covering on the surface of the plots with biodegradable nonwoven material (the agricultural nonwoven fabric method) before seeding had a positive impact on covering ratio of *Dichondra repens* compared with the conventional sowing method. While the plant covering ratio reached up to 85 % in the agricultural nonwoven fabric method, but the covering ratio was 1% in the conventional sowing method at T6, respectively. However, strong linear relationships are obtained between the plant covering ratio and seeding rates in both the agricultural nonwoven fabric method, R^2 (0.96, 0.89, 0.88, 0.85 and 0.70) and the conventional sowing method, R^2 (0.95, 0.97, 0.98, 0.98 and 0.93) at (T1, T2, T3, T4 and T5), respectively. Consequently, the agriculture nonwoven fabric sowing method to be used in parks, gardens and landscapes will provide a very significant savings, reducing the use of seed and for weed control and will be particularly prominent in terms of health maintenance.

Keywords: *Dichondra repens, Sowing methods, Seed rates and Plant covering rate*

Introduction

Dichondra repens is a warm season ground cover that grows close to the ground. It has broad, almost circular leaves and when mown low establishes a thigh dense carpet look. Originally weed; it is now used in many ground cover situations where normal grasses may not do as well. It has a bright green colour and a cushion feel underfoot (http://www.univagro-iasi.ro/vvintu/images/5/5c/Dichondra_repens.pdf). *Dichondra repens is originally described from a Nex Zealand collection, but* subsequently the name became used in a broad sense to cover a complex fo related plant in tropical to warm-tempereature areas fo both hemispheres (Margot B. Forde, 1978).

Zhu at al. (2009) conducted a pot experiment to study the biomass allocation and morphological characteristics of Dichondra repens under different levels of shading (100%, 66 %, 20%, and 9%

transparency that with the increasing of shading, the biomass per plant decreased after an initial increase. *Dichondra repens* had definite adaptability to varied light environment.

Dichondra repens is low growing, creeping perennial the spreads by underground runner. The leaves are kidney shaped and dark green in colour. Ideally spring planting is most rewarding, but Dichondra may be planted at any time of the year. In addition to this, Dichondra is not recommended for sunny position, but in shady or part shade position it will provide a good low maintenance lawn substitute (http://www.zanthorrea.com/info/Dichondra_Lawn.pdf).Turkey is recognized as an important gene source, because of the rich genetic diversity found in Turkey's flora.Turkey has a great variety of native plant species. However, the number of cultivated plant species doesn't reflect this richness (Bülent and Şirin, 2005). In addition to this, since the seeding technology in Turkey was not developed, we are forced to import a very large body of seeds and therefore economic losses were increasing. The related reports are still needed in literature since many research has not been carried concerning with Dichondra. *Dichondra repens* is a type of ground covering and it is expected to covering the soil surface after planting, as soon as possible.
The aim of this research is to choose the best sowing method by using the least amount of seeds of Dichondra.

Material and Method

The research was carried out to compare two methods (1: the agricultural nonwoven fabric (agril) method and 2: the conventional sowing method) at different seeding rates (10, 20, 30, 40, 50,100, 150, 200, 250 and 300 kg ha^{-1}) on covering rate of *Dichondra repens* on ecological conditions of Igdır plain at the Agricultural Faculty, Iğdır University in Turkey in 2013. The average annual temperature 12.08 ° C, the hottest month is July (26 ^{o}C), the coldest month in January (-3.5 °C), the highest temperature in July (33.6 °C), the lowest temperature in January (-8.0 °C) the total annual rainfall 260.3 mm, the average number of rainy days 85 days 24 days number of days covered with snow, the average number of days of frost is 97.5 days (Anonymous 2014). Sowing was conducted by hand in May, 2014.
The experimental site had previously been used for producing barley. Parcel size was 2 x 1=2 meter square. We applied the agricultural nonwoven fabric and the conventional at different seeding rates (10, 20, 30, 40, 50,100, 150, 200, 250 and 300 kg ha^{-1}) on covering rate of *Dichondra repens* on ecological conditions of Igdır plain. The coated Dichondra seed was shown on 22nd of May, 2014. On the surface of all the plots were broadcasted for 1 cm turf as cover soil. Half of 120 ha^{-1} N (ammonia sulphate with 46% N) and all of the phosphorus (triple super phosphate) 80 kg ha^{-1} P_2O_5 were applied before sowing and the half of the nitrogen were applied for T3:30 10 July 2014. The experimental design was analysed by repeated measures design with two factors, sowing method and time. To ensure homogeneity the data obtained in the conventional sowing method was transformed as $\sqrt{(x-1)}$.
Bonferroni multiple comparison test for times and Duncan multiple comparisons was applied for seed rates. It was measured the covering rate of the soil of *Dichondra repens* in each plot by using quadrates at different times (T1:10 June 2014, T2: 20 June 2014, T3:30 10 July 2014, T4: 10 July 2014, T5: 20 July 2014, and T6: 30 July 2014.

Results and Discussion

The coating rates of *Dichondra repens* at different sowing methods (1.the agricultural nonwoven fabric method, 2. the conventional sowing method) in different seed rates are seen in Table 1. Both sowing methods increased plant covering rate and that is to say when the seed rate increased the covering rate of plant increased. In the nonwoven sowing method, at different seeding rates (10, 20, 30, 40, 50,100, 150, 200, 250 and 300 kg ha^{-1}) at T1, the covering of the plant were 1.0%, 1.9%, 3.7% 3.1%, 6.9%, 20.0%, 38.0%, 37.8%, 40.0% and 42.9 %, respectively. The plant's soil coverage rates at the same time (T1) in the conventional method were found 0.7%, 0.9, 2.2, 2.4, 6.3, 10.7, 23.1, 27.1, 38.5, and 37.7 respectively and statistically was different from each other. The plant's soil coverage in the conventional sowing method by using 10 kg ha^{-1} seed rate at T1, T2, T3, T4, T5 and T6 were 1.0%, 1.4, 1.9, 7.0, 21.0, and 84.8 % respectively. At the same time, the plant's coverage rate as in traditional methods according to the order of 0.7%, 0.4, 1.0, 0.5, 1.0 and 1.0% was found. *Dichondra repens* covering rate was 84.8% at T6 in the agricultural nonwoven sowing method by using 10 kg ha^{-1} seed and plant growth rate was 1% in the conventional methods in the same amount of seed. Plant covering rate was about 85% at T6 by using 10 kg seed per hectare and plant covering rate was 100 % in the other seed rates in the all plots. Whereas the plant covering rates were measured the lower and covering rate reached 98 % at T6 measurement time, by using 300 kg seed ha^{-1}in the conventional sowing system. Covering rates were higher in the agril nonwoven method than the conventional sowing at T6.

Uncovered soil is more prone to weed problems but, a ground cover with a fast rate of spread is usually desirable to minimize weed invasion. Plant covering rate was 100 % at T6, with using 20 kg ha^{-1}without weeds in the plots of the agricultural nonwoven fabric method and whereas the rate of weeds in the plots of conventional sowing method was higher. However, covering rate was about 2 percent in applying 20 kg seed ha^{-1} at the end of the experiment, T6. Hence, the rates of weeds were approximately 98 % in the plots of conventional sowing methods.

Plant covering rate reached 100 % by using 100 kg seed rate ha^{-1} at T4 time in the agricultural nonwoven fabric method. Therefore, if the long-term, full covering of the land is the purposes of the landscape, sufficient seed is suitable for as 20 kg ha^{-1}. Therefore, when the plant covering ground in a short time is very crucial in landscape establishment, it is necessary to use 10 kg of seeds.

The covering rate of 85% was obtained from the plots received 10 kg seed rate ha^{-1} at T6 and on the other hand, the covering rate was able to reached to 88 percent by seeding 100 kg seed rate ha^{-1} at T3. Consequently, in a short time, to reach maximum coating rate is necessary to be used about 10 times more seed.

The covering rate could reach to 100 % using 100 kg dichondra seed per ha at T4 time in the agricultural nonwoven fabric method whereas covering rate was be able to reached to 44.8%. As the average of seeds, plant covering rates at T1 T2, T3, T4, T5 and T6 in the *Dichondra repens* were 37.6%, 46.9, 50.7, 61.1, 79.0 and 78.5 respectively. Eyduran at al. (2013) stated that the time effect was identified that continuous variables in the data of repeated measures. However, T4, T5 and T6 also had the highest covering rate and but there was no significant differences between times (T4, 5, 6).

The coverage rate increased in all the times in the agricultural nonwoven fabric method, by using the amount of 150 kg of seed ha^{-1}. While this increasing was found in the conventional sowing methods in the norm of 300 kg of seed ha^{-1}. Weeds was not found in the plots which were applied at least amount of seed rates in the agricultural nonwoven fabric method.

As expected, the lowest covering rate speed was recorded for T1 time, up to 1 month after planting time. The conventional methods of cultivation, as average seeds norms at T1, T2,

T3, T4, T5 and T6, the plant soil covering rate were 14.9%, 25.5, 37.0, 38.4, 39.9, 42.9 and was significant differences between times. Repeated measurement design are recommended with research that focuses on performance trends over time. The sphericity assumption is met if all the differences between pairs of treatment condition scores are equally variable, and if variances of differences for all treatment conditions are homogenous. Eyduran at al. (2016) mentioned that in repeated measurement data of laying hens, cumulative age weight per hen as a dependent variable was recorded per week, and treatment, time and treatment x time interaction effects were added as independent variables. Harrington at al. (2005) reported Dichondra (*Dichondra micrantha*) gave a good ground cover for the first few years but slowly regressed to hard-to-control weed species.

However, the strong linear relationships were recorded between the plant covering rates and seeding rates in both the agricultural nonwoven fabric method and the conventional sowing method all the times except for T6 time. Figure 1, 2, 3, 4, 5 show that R^2 (0.96, 0.89, 0.88, 0.85 and 0.70) in the agricultural nonwoven fabric method, however, Figure 1a, 2a, 3a, 4a, 5a show that R^2 (0.95, 0.97, 0.98, 0.98 and 0.93) in the conventional sowing system at (T1, T2, T3, T4 and T5), respectively.

Figure 1. The agril nonwoven method, T1

Plant covering rate (%) = -1,618 + 1,4456 * Seed rate kg/m^{-2}

Correlation: r = ,96307

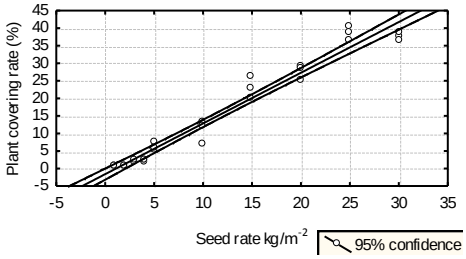

Figure 1a. The conventional method, T1

Plant covering rate (%) = ,23617 + 1,6082 * Seed rate kg/m^{-2}

Correlation: r = ,94813

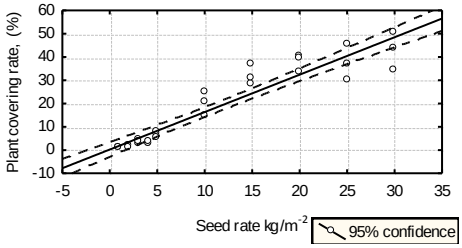

Figure 2. The agril nonwoven method, T2

Plant covering rate (%) = 3,0995 + 3,8177 * Seed rate, kg/da

Correlation: r = ,89886

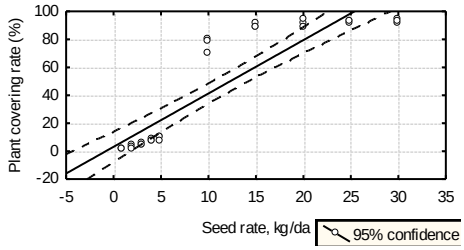

Figure 2a. The conventional method, T2

Plant covering rate (%) = -7,466 + 2,8666 * Seed rate kg/ m^{-2}

Correlation: r = ,97316

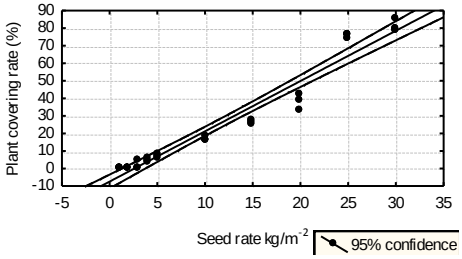

Figure 3. The agril nonwoven method, T3

Plant covering rate (%) = 7,0220 + 3,8204 * Seed rate, kg/da

Correlation: r = ,87991

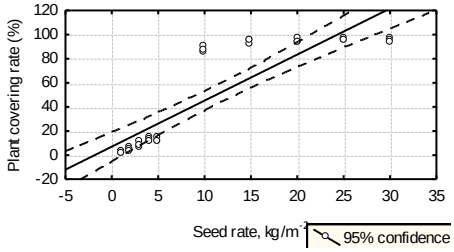

Figure 3a. The conventional method, T3

Plant covering rate (%) = -3,705 + 3,5091 * Seed rate kg/ m^{-2}

Correlation: r = ,98632

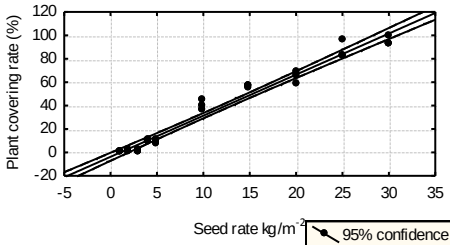

Figure 4. The agril nonwoven method, T4

Plant covering rate (%) = 24,380 + 3,3287 * Seed rate, kg/da

Correlation: r = ,84937

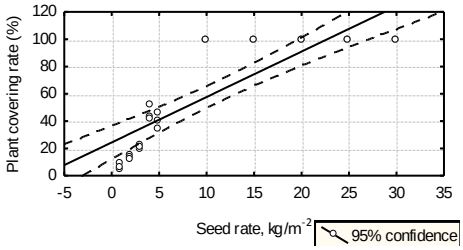

Figure 4a. The conventional method, T4

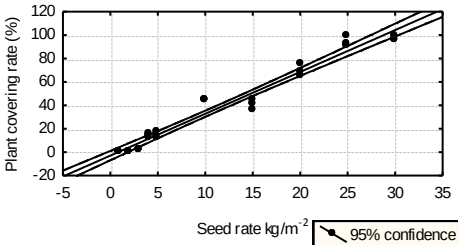
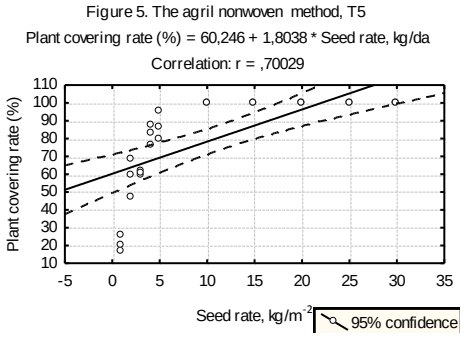
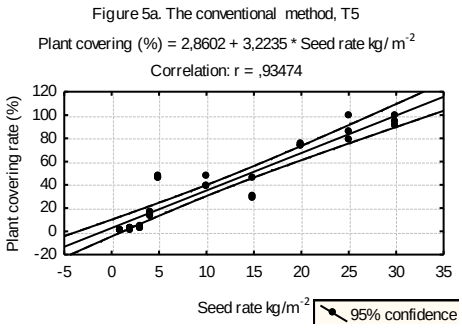
Plant covering rate (%) = -2,925 + 3,5740 * Seed rate kg/ m^{-2}

Correlation: r = ,98244







Consequently, the agricultural nonwoven fabric method to be used in parks, gardens and landscapes will provide a very significant savings, both reducing the use of seed and for weed control and will be particularly prominent in terms of health maintenance.

Conclusion

As results of this trial, the agricultural nonwoven fabric method compared to the conventional sowing method had most crucial advantages as following:

1. The coverage rate of dichondra was the highest in all times by using 150 kg seed ha^{-1} in the agricultural nonwoven fabric method.
2. In the conventional sowing method, the rate of covering of plant was the lowest than the other method.
3. The increasing of covering rate was found in the conventional sowing methods in the norm of 300 kg of seed ha^{-1}.
4. Weeds was not found in the plots which were applied at least amount of seed rates in the agricultural nonwoven fabric method although of the weeds were in the soil.
5. It is recommended that the norm of 150 kg seed ha^{-1} in the agricultural nonwoven fabric method and the norm of 300 kg of seed ha^{-1} in the conventional sowing methods.
6. The nonwoven fabric material prevented the growth and the germination of weeds by covering the ground with a carpet of the soil.

Abstract

The aim of this paper is to present the floristic composition, syntaxonomic affiliation, ecological and phytogeographical characteristics of the association. The studies were performed using the method of transect (Braun-Blanquet, 1965). Identification of species was based on floristic literature (Beck, 1903 и 1927; Josifovic ed. 1970-1977; Javorka et Csapody, 1979). Floral elements and life forms of plants have been given by Oberdorfer (2001). The floristic composition of this plant association is built out of 91 species. The dominant species *Sambucus ebulus* L. shows the highest level of presence (V) and ground cover (2150). The analysis of the areal spectrum shows the dominance of the Euroasian species (38%). The association has hemicryptophytic character, 43 species (47%).

Key words: *ruderal association, areal spectrum, biological spectrum, Pale*

Introduction

The municipality of Pale (entity of Republic of Srpska, Bosnia and Herzegovina) is situated in a valley between mountain ranges, Jahorina from the south, Gosina from the east, Romanija from the northeast, Ozren from the north and northwest and Trebevic from the west. The municipality of Pale is located at an altitude of about 820m. The main flow of water makes river Miljacka. Climatogenic vegetation of Pale make beech and fir forests *Abieti-Fagetum illyricum* Fuk. Et Stef. 1958, *Fagetum montanum illyricum* s.l., fir-spruce forests *Abieto-Piceetum* s.l., and smaller areas belonging to the vegetation of oak forests *Quercetum petraea montanum* s.l. Meadow vegetation of the area belongs to the class *Arrhenatheretea* Br.-Bl. 1974 and order *Arrhenatheretalia* Pawl. 1928.

Materials and methods

Floristic research field and taking phytocoenological recordings were conducted during 2011 and 2012, a period of optimal association development. The studies were performed using the method of transect (Braun-Blanquet, 1965). Identification of species was based on floristic literature (Beck, 1903 и 1927; Josifovic ed. 1970-1977; Javorka et Csapody, 1979). Floral elements and life forms of plants are given by Oberdorfer (2001).

Results and Discussion

Association *Sambucetum ebuli* Felfödy 1942, developes in villages and the suburbs of town, along the roads, gardens and fields, beside rivers, railways, waste dumps, the edges of the surrounding forests. Habitats are nitrified, and trampling and mowing is reduced to a minimum.
Data on the floristic composition and other structural characteristics coenological, of that community, are based on the 10 phytocoenological records which are integrated into the phytocoenological table 1.

Sintaxonomic position of the association *Sambucetum ebuli*:
Class: Artemisietea vulgaris Lohm., Prsg. et Tx. 1950.
Order: Artemisietalia vulgaris Lohm., Prsg. et Tx. 1950.
Alliance: Arction lappae Tx. (1937) Oberd. 1950.
Ass.: *Sambucetum ebuli* Felfödy 1942.

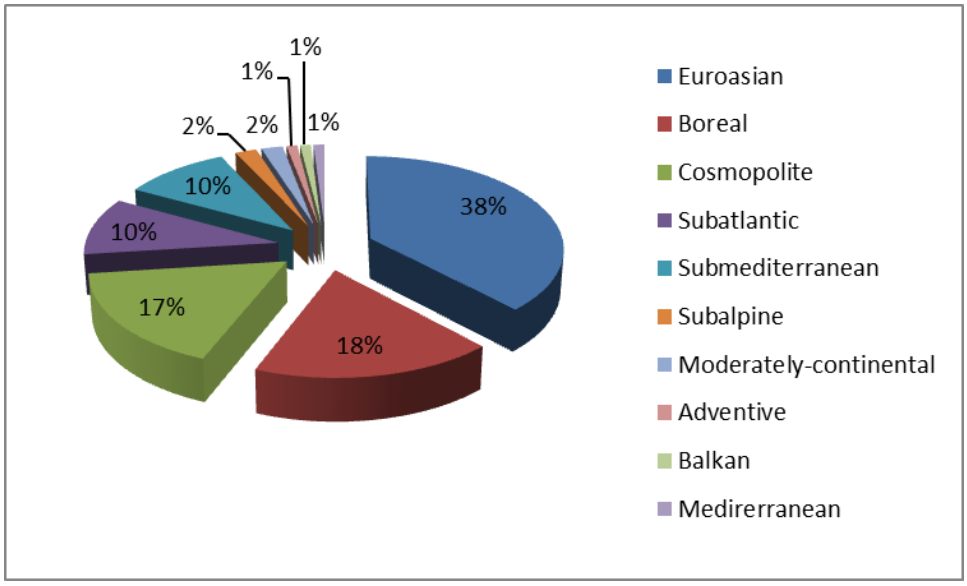
Hill, *Arctium lappa* L., *Calystegia sepium* (L.) R. Br., *Cirsium candelabrum* Gris, *Cichorium intybus* L., *Mentha longifolia* (L.) Huds., *Torrilis aevensis* (Huds.) Lk., *Sonchus oleraceus* (L.) Gou., *Rumex obtusifolius* L., *Senecio erraticus* Bertol, *Viola tricolor* L., *Geum rivale* L., *Linaria vulgaris* Mill., *Sanquisorba minor* Scop., *Bellis perennis* L., *Rubus hirtus* W. et Kit., *Petasites albus* (L.) Gaert., *Lathyrus venetus* (Mill.) Wohlf., *Plantago lanceolata* L., *Ononis spinosa* L., *Cherophyllum aureum* L., *Trifolium pratense* L., *Solidago virga-aurea* L., *Valeriana montana* L., *Daucus carota* L., *Festuca pratensis* Huds., *Melanpyrum arvense* L., *Agrimonia eupatoria* L., *Medicago lupulina* L., *Anthriscus sylvestris* (L.) Hoffm., *Veronica chamaedrys* L., *Scrophularia nodosa* L., *Cruciata laevipes* Opiz., *Lisimachia nummularia* L., *Leucanthemum vulgare* Lam., *Rumex acetosa* L., *Barbarea vulgaris* R. Br., *Ligustrum vulgare* L., *Rosa canina* L., *Ranunculus ficaria* L., *Stellaria holostea* L., *Glechoma hederacea* L., *Chelidonum majus* L. и *Poa bulbosa* subsp. *vivipara* L.

The floristic composition of the association consists of 91 plant species and 50 is represented in only one shot. A dominant species *Sumbucus ebulus* gives a distinctive look to the association, building a completely closed circuits, almost pure facies. The characteristic combination of species are: *Sambucus ebulus, Convolvulus arvensis, Artemisia vulgaris*. Those species are found in all phytocoenological records.

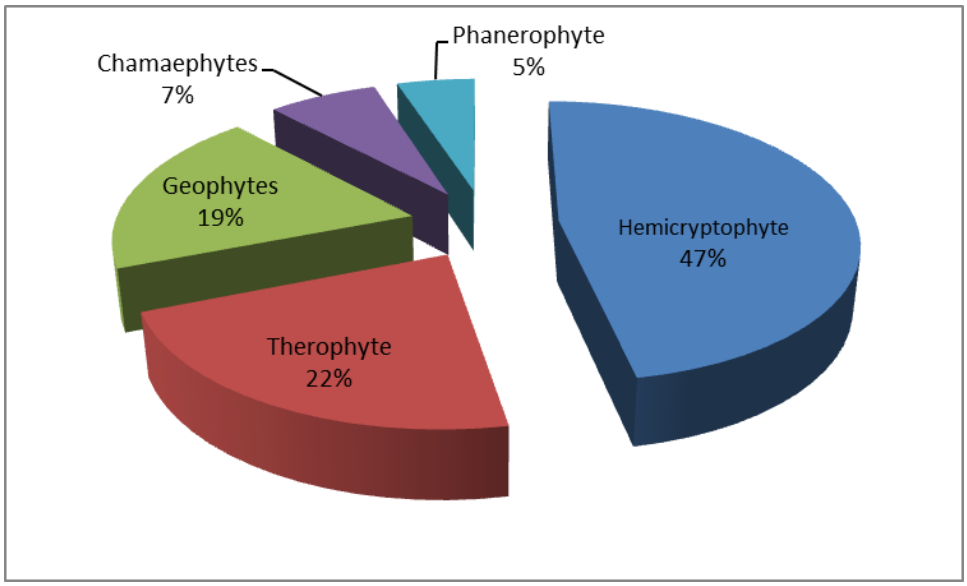
The areal spectrum of the association *Sambucetum ebuli* (Graph 1) consists of 10 areal groups. By analyzing the areal spectrum established dominance of species broader geographical distribution, eurasian 35 species (or 38%), boreal 16 species (or 18%) and 15 cosmopolite species (or 17%). Species of subatlantic, submediterranean, subalpine, moderately-continental, balkan

and mediterranean area groups are less represented. Dominant species *Sambucus ebulus* belongs to a submediterranean floral element, whit the center of the areal in the area of submediterranean deciduous forests which extends to the deciduous-coniferous forests of western Europe. Areal of association *Sambucetum ebuli* generally encompasses the area of Central Europe and the Balkan peninsula.The association was first described in Hungary (Felfödy, 1942: 87-138).



Graph 1. Areal spectrum of association

Chart 2 presents the results of the analysis of life forms of plants that build association *Sambucetum ebuli*. There are a dominance of hemicryptophyte with 43 species (or 47%) of which *Artemisia vulgaris* and *Urtica dioica* have a higher cover value. Species *Sambucus ebulus* belongs geophytes, thanks to the most important quantitative and qualitative participation largely determines the ecological character of the association. Therophytes are present with 20 species (or 22%), geophytes with 17 species (or 19%), while chamaephytes and phanerophytes mostly represent the elements of the surrounding vegetation and the recent degradation of forest ecosystems.



Graph 2. Biological spectrum of association

Lakušić this association stated in Prodromus plant communities of Bosnia and Herzegovina (1978: 54), and in a manuscript describes the association in several locations in Bosnia and Herzegovina.

A large number of researchers has described the association *Sambucetum ebuli*, for Hungary Felfödy (1942: 87-138), Croatia (Marković, 1964: 257-272), Macedonia (Matvejeva, 1982: 1-70), Czechoslovakia (Hejný et al., 1979 : 1-100), Serbia (Jovanović 1994: 129-134), Bosnia and Herzegovina (Topalić-Trivunović, 2006: 100-110) and others. In Macedonia, the association differentiated into three subassociations (typicum, parietarietosum and urticetum piluliferae (Matvejeva 1982: 1-70), and for Czechoslovakia (Hejný et al., 1979: 1-100) states subassociations: typicum, brometosum tectorum and brometosum inermis. Association *Sambucetum ebuli* of the municipality of Pale, exhibits considerable floristic similarity (43.08%) (Petronić, 2006) with the same name association of Banja Luka (Topalić-Trivunović, 2006: 100-110), less similarity with the association of Belgrade (28.88%) (Jovanović 1994: 129 -134). The analysis of the biological spectrum ass. *Sambucetum ebuli* of Pale and Banja Luka (Topalić-Trivunović, 2006: 100-110) show to the dominance of perennial herbaceous plants hemicryptophytes.

Conclusions

Association *Sambucetum ebuli* Felfödy 1942, developes in villages and the suburbs of town, along the roads, gardens and fields, beside rivers, railways, waste dumps, the edges of the surrounding forests. Habitats are nitrified, and trampling and mowing is reduced to a minimum.

The floristic composition of the association consists of 91 plant species and 50 is represented in only one shot. A dominant species *Sumbucus ebulus* gives a distinctive look to the association, building a completely closed circuits, almost pure facies. The association has hemicryptophytic character, 43 species (47%).

Areal spectrum of the association *Sambucetum ebuli* consists of 10 areal groups. By analyzing the areal spectrum established dominance of species broader geographical distribution, Eurasian 35 species (or 38%), Boreal 16 species (or 18%) and 15 cosmopolite species (or 17%).

Abstract

Crude oil refinery units are basic components in process plants of petroleum refinery. Changes in these units have a great impact on product yield and quality, so it is recommended to operate these units at optimal conditions, especially the distillation unit. The process of crude oil distillation impacts the refinery economy greatly. Design of crude oil distillation systems, which consists of distillation columns and heat recovery systems, are of great importance in the overall processes. The main objective of this paper is the evaluation of simulation results, in order to improve and archive optimized process units of crude oil distillation which will lead to a higher quality in natural source management. This way, we can reach better fractioning stages, reduced power and an overall integrated process. We have made the characterization of some natural oilfiled in Albania through distillation and evaluation of their physical characteristics. During the sampling process we also observed their environmental impact and determined the constituent components of crude oil. The aim of the study includes drawing true boiling curves based on our experimental measurements of crude oil sources in Albania and also interpretation of differences between simulation results and experimental results, in order to get an optimal characterization of crude oil.

Keywords: *Crude Oil, Simulation, Distillation unit, Albania.*

Introduction

Crude oil distillation units are an important part in petroleum refinery as this operation is carried out in large equipments that normally consume considerable amount of energy. Changes in this units have a great impact on product yield and its quality and, therefore, it is recommended to operate these units at optimal conditions from technical and economical points of view; that means operating conditions such as temperatures, pressures and flows of the unit that maximize their economic performance, subject to their real physical restrictions and their design capabilities (Yela *et al*., 2009). Crude distillation is the process that has been used for very long time and it constitutes the most important part of any refinery. The distillation of crude oil provides refined products such as gasoline, diesel, etc. With the advent of large, highly integrated refineries, it is critical to understand the operation of major units and predict desirable and undesirable changes in unit performance as function of key operating conditions (Chang *et al*., 2012). Crude distillation has a long history and refiners have developed hundreds of empirical correlations for feed conditions and process variables. It is very difficult to develope general correlations applying a variety of operating scenarios that modern refineries face (Lopez *et al*., 2009). Crude oils are the most important feedstocks for refining processes. To properly simulate the refining

processes we must have good understanding of the compositional information and thermophysical properties of crude oils and petroleum fractions (Chang *et al*., 2012). A typical crude assay includes two types of information for an oil sample: (1) bulk properties; and (2) fractional properties. Bulk properties include specific gravity, sulfur content, nitrogen content, asphaltene content, flash point, viscosity, carbon residue, boiling point curve, etc. Bulk properties provide a quick understanding of the type of the oil sample such as sweet and sour, light and heavy, etc. However, refineries require fractional properties of the oil sample that reflects the property and composition for specific boiling-point range to properly refine it into different end products such as gasoline, diesel, and raw materials for chemical process. Fractional properties usually contains paraffines, naphthenes and aromatics content, nitrogen, sulfur content for each boiling – point range, octane number for gasoline, cetane index, etc. The aim of the study is the drawing of true boiling curves for samples taken during the study from crude oil natural sources in Albania and to compare the differences between the simulation results and experimental data for an optimal characterization of crude oil, also to determine the constituent components for Marinza and Cakran-Drenova oilfield. To run the simulation we used Design II software (Design II, 2016).

Materials and methods

Evaluation of crude oil parameters like API gravity, viscosity, determination of heavier components like saturates, asphaltenes, resins and aromatics are important in order to effectively estimate the reservoir performance, the volume in the reservoir and its recoverability. Characterization of crude oil is made from; 10 individual wells in Marinza, decantation plant in Marinza and decantation plant in Cakran-Drenova. In this study crude oil assay contains the following:

1. TBP (True Boiling Point) indicating start and the end temperature in °C or in °K
2. Yield of cut (wt% and vol% of Crude).
3. Determination of Aromatics wt%, Olefins wt%, Saturates wt%.

Aromatics, Olefins and Saturates are determined by ASTM D 1319 and expressed in wt%.

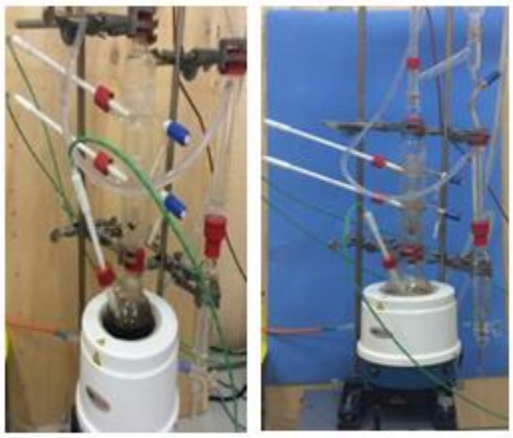

Figure 1. Fractional distillation laboratory scheme

The true boiling point (TBP) distillation of crude oil results from using the ASTM D- 86 test procedure. The key results from a distillation test are achived from the boling point curve, that is, the boiling point of the oil fraction versus the fraction of oil vaporized. The initial boiling point (IBP) is defined as the temperature at which the first drop of liquid leaves the condenser tube of the distillation apparatus. The final boling point or the end point (EP) is the highest temperature recorded in the test (Chang, 2012). The ASTM D 2892 method details procedures for the production of a liquefied gas, distillate fractions, and residuum of standardized quality on which analytical data can be obtained, and the determination of yields of the above fractions by both mass and volume. From the experimental data information, a graph of temperature versus mass % distilled can be produced. The experimental procedure is presented in figure 1. During the process is followed the volume % and is noted the temperature. To record the temperatures we connect the measuring instrument to a computer and so digitally are record the temperatures. As soon as sufficient

distillate has condensed in the reveiver flask- both trays should be saturated (Phywe, 2016). The purpose of this separation technique is to better track the distribution of crude oil compounds and to carry out the distillation of at least two petroleum fraction by taking into account the procedure of ASTM D 2892. As results, we can calculate the mass concentration and the cumulated weight of each crude oil fraction.

Results and Discussion

Crude oil wells sample (Table 1) is composed mainly by heavy compounds (66.5 wt%). They have a low amount of water and sediment. IBP-266 fraction is composed by 76 wt% of saturates. 266- 343 ˚C is composed mainly by 57 wt% aromatics.

Simulation allows the designer or plant engineer to reasonably optimize the operation or the design of the plant using experimental data for the pilot plant or the current plant (Mendez *et al*., 2006). In this case it is shown a simple simulation based on Design II, in which are used specifications for real case of refinery crude oil unit in Albania, composed by two distillation columns (preflash and atmospheric unit). The experimental data from distillation are used as input in Design II program (software) to simulate the preflash column, to dertemine the constituent components and true boiling point of crude oil. The distillation schemes used in Design II is shown in figure 3. To make a complete simulation it is required more specifications per unit. In this case are used specifications for the top and bottom temperatures of the column, the flow inlet pressures and temperature, temperatures at the outlet of heat exchangers, the amount of the raw material and the quantity of steam. Based on the specifications, we defined characteristics by design II (flow speeds, temperatures, pressures) for each stream, also characteristics of equipment and crude oil constituent components. In the study are used two samples from two oilfileds; Cakran-Drenova and Marinza. Design II program is used to simulate a process which is composed of a preflash column, a condenser and two heat exchangers. We set specifications for temperature, pressure and distillation curve defined by

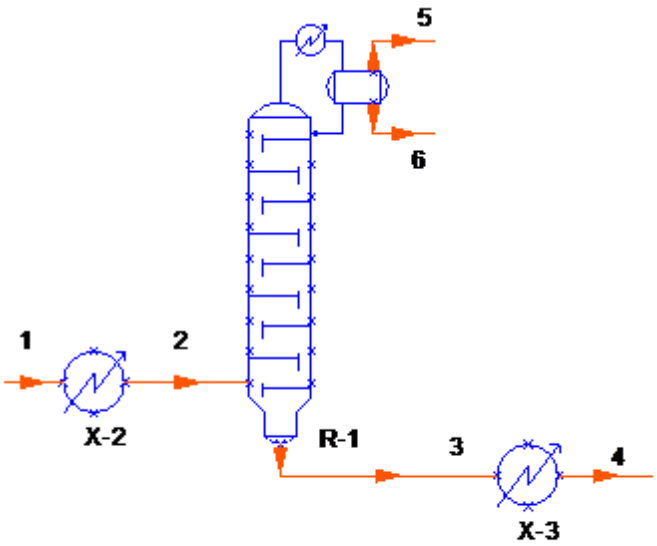

Figure 3. The simulation scheme in Design II, for preflash unit in crude oil distillation process

Engler distillation (ASTM D86) and the amount in the entry of raw material (crude oil) also the specifications for temperature and heat transfer coefficient for the heat exchanger. It used a column with seven trays. After the simulation is finished, the results appear in an excel spreadsheet, where are defined all the characteristics of currents and equipment used in the process. In this study, the part that interests us from the simulation are; crude oil constituent components used and the distillation curves, in order to make the comparisons between the distillation curve determined by laboratory data and distillation curve from Design II simulation. From the simulation is concluded that:

Cakran-Drenova oilfiled: 5 and 6 stream mainly consisting of light compounds (from CH_4 to n-pentane). While 3 and 4 stream consist of compounds that have a high content in heavy compounds (compounds that are boiling at temperatures 325°K and 616 °K).

Marinza oilfield: The particularity of the oil fields is the 0 kmol/s compounds content that boiling at 388°K-421°K temperature and a higher compounds content that boling at 513°K. Also these mainly consist of compounds with boiling temperature from 571°K to 631°K.

The laboratory distilation results are roughly the same as simulated by the distillation curve, for bottom product of preflash unit, (figure 4). To determine the distillation curves for crude oil by-product, the distillation process must be carried out together with the atmospheric distillation column.

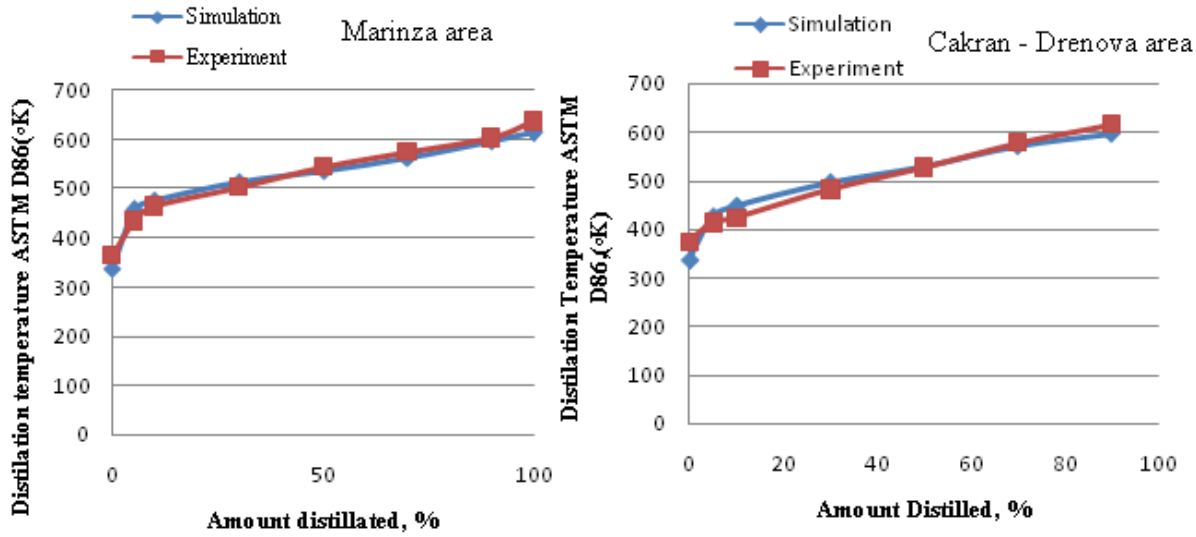

Figure 4. Simulation and experiment ASTM D86 of bottom product in preflash column

Conclusions

Crude oil Marinza oilfield is classified as heavy crude oil with a large percent of the heavy compounds. Crude oil wells sample is composed mainly by heavy compounds (66.5 wt%). They have a low amount of water and sediment. IBP-266 fraction is composed by 76 wt% of saturates. 539- 616 °K is composed mainly by 57 wt% aromatics. Decantation crude oil have a maximum content of 33.38 % paraffins, 45.93 % Iso-paraffins, 25.4% naphtenes and 22.3 % aromatics. Cakran-Drenova oilfiled consist of heavy compounds (compounds that are boiling at temperatures 598°K and 616 °K).

To make a complete simulation it is required to have a higher number of specification per unit. In this case study we used specific temperatures for the top and bottom of the column, the flow inlet

pressures and temperature, temperatures at the outlet of heat exchangers, the amount of raw material and the quantity of steam, also the laboratory true boiling point. Based on the specifications we defined characteristics by Design II (flow speeds, temperatures, pressures) in each stream, characteristics of equipment and also the components of crude oil used during experimental measurements. The simulation software is the optimal tool to evaluate crude oil refinery efficiency. With Design II we can determine the constituent component and the true boiling point for by-products of crude oil.

Abstract

Myrtus communis L. is a common shrub of the Mediterranean basin, well known for its medicinal properties, content of essential oils and ornamental value. In Albania, myrtle grows wild, mainly in the western part of the country, where it forms a vegetation belt. Morphological and genetic diversity of wild *Myrtus communis L*. populations in Albania have not been evaluated yet. This research explored and morphologically evaluated 16 wild myrtle populations collected from four localities in Albania in order to provide the first characterization and obtain important data for the management and conservation of myrtle genetic resources and also for future domestication and breeding programs. The data showed high variability among myrtle populations for some of the examined traits, such as plant height, branch height, leaf height and width. The Unweighted Pair Group Method with Arithmetic mean (UPGMA) clustering revealed morphological diversity, the mean similarity value among populations was low (0.18); the populations grouping was not clearly related to their geographical distribution. The Principal Coordinate Analysis (PCoA) performed on Nei's unbiased genetic distance matrix showed no grouping of populations based on their geographical origin, supporting the results obtained in UPGMA cluster analysis. The results obtained in this study highlighted a high level of variation of wild myrtle populations in Albania, which represents a valuable resource to be conserved.

Keywords: *Myrtis communis L., morphological traits, diversity, Albania.*

Introduction

Myrtle, (*Myrtus communis* L.), is a common shrub of *Myrtaceae* family widespread in the Mediterranean basin. This plant has been used since ancient time for its ornamental and aromatic value (Agrimonti *et al.,* 2007). Nowadays it is widely used for its medicinal properties as antibacterial and anti-inflammatory (Barboni *et al.,* 2010).

The knowledge on the level of diversity among populations is important to provide the basic data for elaboration of future conservation strategies. The exploration of genetic diversity of Mediterranean myrtle was carried out using morphological characters (Bruna *et al*., 2005), molecular markers *Random Amplification of Polymorphic DNA* (RAPD) (Messaoud *et al*., 2007), Inter Simple Sequence Repeats (ISSR) (Messaoud *et al*., 2007; Melito *et al.,* 2013***),*** *Amplified Fragment Length Polymorphism* (AFLP) (Bruna *et al*., 2005; Messaoud *et al*., 2011). The correlation among morphological, chemical and genetic characters in wild myrtle populations is also reported by Melito *et al*. (2016).

In Albania myrtle grows wild in different geographical areas and different types of soil and plant associations. It is found in calcareous soils associated with kermes oak *(Quercus coccifera),* ash *(Fraxinus ornus),* field maple *(Acer campestre),* narrow-leaved mock privet *(Phillyrea angustifolia),* holm oak *(Quercus ilex),* stone pine *(Pinus pinea)* and flax-leaved daphne *(Daphne*

gnidium). In silty soil *M. communis* L. grows associated with cluster pine (*Pinus maritime)*, stone pine (*Pinus pinea)*, European wild pear (*Pirus pyraster)*, mastic *(Pistacia lentiscus)*, autumn heather *(Erica manipuliflora)*, holm oak *(Quercus ilex)*, wild blackberry *(Rubus ulmifolius)*, narrow-leaved mock privet *(Phillyrea angustifolia)*, while in regions with *flyschy* sandstone soil, myrtle is associated with Mediterranean *maquis* element like heather *(Erica arborea)*, ash *(Fraxinus angustifolia)*, mastic *(Pistacia lentiscus)*, bladder-senna *(Colutea arborescens)*, wild blackberry *(Rubus ulmifolius)*. In regions with sandy soil *M. communis* is associated with stone pine *(Pinus pinea)*, Aleppo pine *(Pinus halepensis)*, ash *(Fraxinus angustifolia)*, autumn heather *(Erica manipulifolia)*, mastic *(Pistacia lentiscus)*, wild blackberry *(Rubus ulmifolius)*, Mediterranean smilax *(Smilax aspera)*, ivy *(Hedera helix)*, field elm *(Ulmus minor)*, evergreen rose *(Rosa sempervirens)*, sweet-scented virgin's bower *(Clematis flammula)*, silk vine *(Perploca graeca)*.

To our knowledge there are no data on the level of genetic diversity of myrtle populations in Albania. In this paper, we investigate the morphological variation of 16 wild myrtle populations collected from four localities in Albania in order to provide the first characterization and obtain important data for the management and conservation of myrtle genetic resources and also for future domestication and breeding programs.

Materials and Methods

Sixteen wild populations of *M. communis* L. in four regions; Spille, Divjake, Pishporo, and Dukat (Table 1); were sampled to assess their morphological diversity. Plants were sampled at distances of 20 to 30 m to avoid multiple sampling of the same genotype. The myrtle populations grow at altitudes from 1.8 m (Pishporo 1) to 365.7m (Dukat) above the sea level. Their distribution regions are composed of different soil types as *flyschy* sandstone, sandy, silty and calcareous at Spille, Divjake, Pishporo, and Dukat, respectively. The location sites of sampling are presented in table 1.

Morphologic characteristics as plant length, leaf length and width, leaf length / leaf width ratio, petiole length, peduncle length, fruit length and width, fruit length / fruit width ratio, branch length and qualitative traits as the type of branches, leaf arrangement and fruit color were measured and examined in each of accessions collected.

A dendrogram based on the similarity matrix, generated using Dice similarity coefficient from obtained data, was constructed using the UPGMA cluster analysis and the Principal Coordinate Analysis (PCoA) was performed on Nei's unbiased genetic distance matrix in NTSYS-pc v. 2.1 software (Rohlf, 2000).

Table 1. The geographical sites of 16 wild *Myrtus communis* L. populations analyzed.

No	Population code	Latitude	Longitude	Altitude (m)
1	Spille 1	41º 06' 23"	19º 28' 16.1"	20

14	Pishporo 1	40º 39' 8.67"	19º 22' 4.78"	1.8
15	Pishporo 2	40º 39' 8.7"	19º 22' 4.6"	2.4
16	Dukat	40º 15' 13.3"	19º 33' 8.78"	365.7

Results and Discussion

The assessment of diversity among 16 wild myrtle populations from four important localities carried out by morphological characters showed a remarkable variation among populations for traits such as; plant height, branch height, leaf length and width. The mean plant height varied from 0.5 m at Spille 7 and Spille 8 to 4 m at Divjake 1 and Divjake 2, populations. The mean of values of leaf length ranged from 2.5 cm (Pishporo 1) to 4.2 cm (Spille 8), while the leaf width mean values ranged from 0.8 cm to 2.5 cm in Spille 3 and Divjake 2 populations, respectively (Table 2).

The studied populations were less variable for traits as petiole length and peduncle length, while there were no observed variations among populations regarding qualitative traits; all populations had the opposite leaf arrangement which is one of the common form of branch morphology found also in Italian myrtle (Bruna *et al*., 2006). No variation was observed in fruit color, all populations had black berry, which is far more common than the white colored one in wild populations (Şerce *et al*., 2008).

Table 2. Morphological characters as observed in 16 Albanian myrtle populations

Population	Plant Length (m)	Leaf Length (mm)	Leaf width (mm)	L/ W leaf ratio	Petiole length (mm)	Penducle length (mm)	Fruit length (mm)	Fruit width (mm)	L/W fruit ratio	Branch Length (cm)

Divjakë/4	4±0.4	42±2.5	20±2.7	2.1±1.18	0.3±0.1	35±3	8±1.5	6±1.5	1.3±0.7	30±5.8
Pishporo/1	2.7±0.3	25±1.6	13±2.4	1.9±0.28	0.3±0.07	17±4	6±2.2	5±2.2	1.2±0.7	35±1.5
Pishporo/2	3±0.38	34±3.6	14±2.7	2.4±0.37	0.2±0.1	3±6	7±1.5	6±1.5	1.1±0.7	30±5.8
Dukat	3±0.41	28±1.5	11±1.9	2.5±0.4	0.3±0.2	16±4	8±1.5	7±1.5	1.1±0.7	21±1.5

A similarity matrix was generated using Dice coefficient, the mean similarity value was 0.18, with a minimum of 0.14 and a maximum value of 0.28, indicated the high level of diversity among 16 myrtle populations.

The dendrogram, obtained by cluster analysis based on similarity matrix and the UPGMA algorithm (Figure 1), highlights the formation of three distinct clusters. The first clade comprised four populations from Spille and one from Divjaka and one from Pishporo. The second clade comprised seven populations belonging to the four locations. The third clade comprised three populations from Spille and one from Divjaka. It was not observed a clear grouping of populations according to their geographical origins or to the ecological factor (type of soil). This may be due to the high level of variability among these populations or related to geographical continuity of Mediterranean *maquis* vegetation along the coast allowing gene flow along populations of different areas as suggested by Bruna *et al*. (2005)

The PCoA performed on Nei's unbiased genetic distance matrix showed no grouping of populations based on their geographical origin (Figure 2), supporting the results obtained in UPGMA cluster analysis. The total variation was 60.3%, the first three PCO explain 23.3, 20.1 and 16.8 % of the total variation respectively.

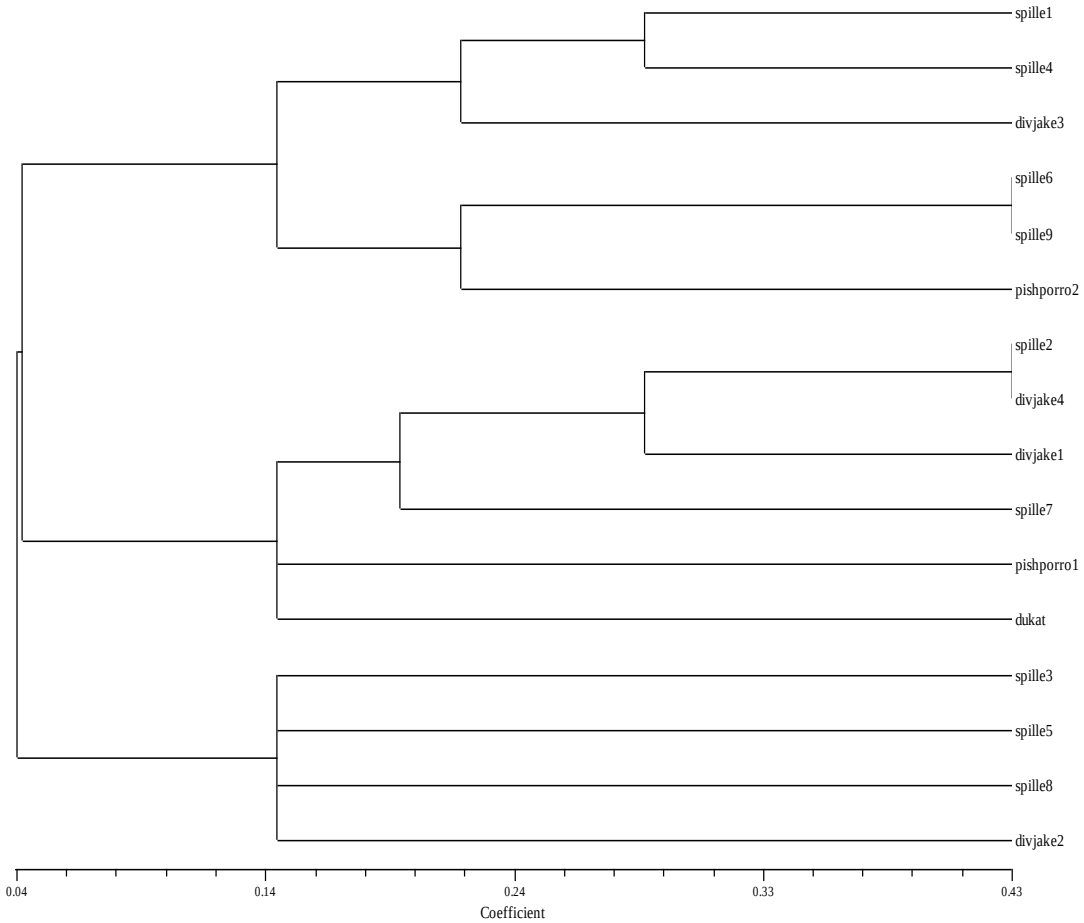

Figure 1. UPGMA dendrogram based on Dice coefficient of similarity for 16 wild *Myrtus communis* L. populations.

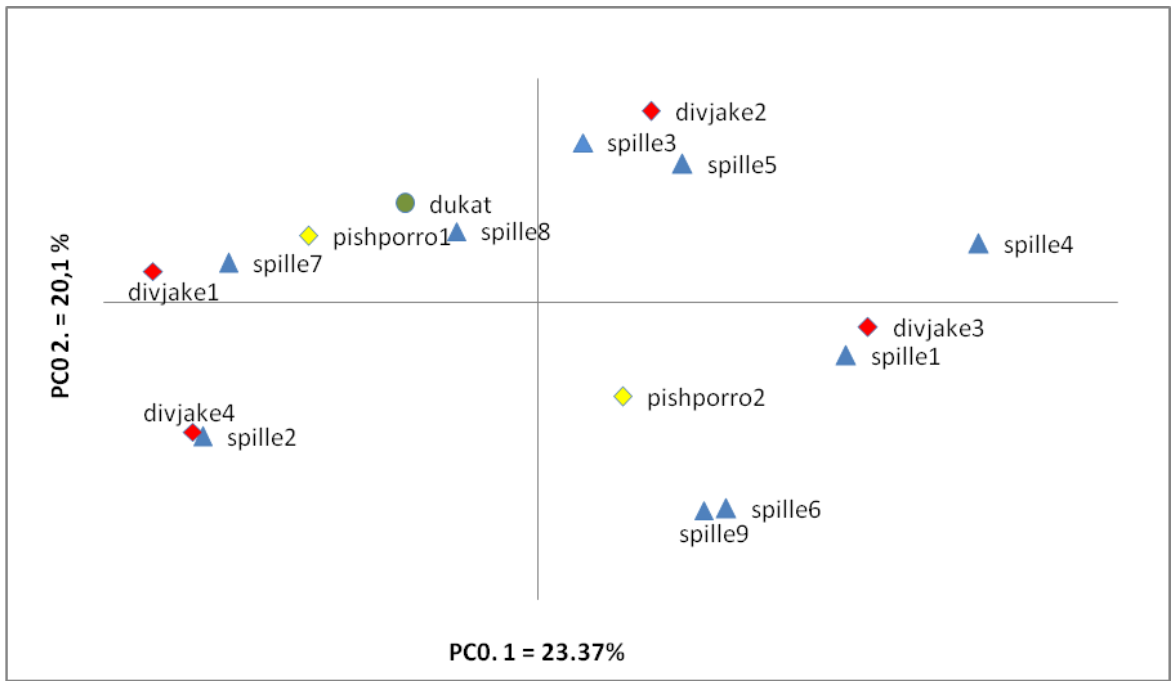

Figure 2: Principal Coordinate Analysis (PcoA) plot of 16 myrtle populations based on two principal coordinates (PCO 1 = 23.37%; PCO2 = 20.1%).

Conclusion

This study explored and morphologically evaluated 16 wild myrtle populations collected from four localities in Albania in order to provide the first characterization and obtain important data for the management and conservation of myrtle genetic resources and also for future domestication and breeding programs. The populations showed high variability for some of the examined traits, such as plant height, branch height, leaf length and width that can be used to select the superior genotypes. The UPGMA clustering and PCoA analysis showed no grouping of populations clearly related to their geographical origin or ecological factor (type of soil). The results obtained in this study highlighted a high level of variation of wild myrtle populations in Albania, which represent a valuable resource to be conserved.

Abstract

Irrigation management is one of the key factors for the sustainability of irrigated agriculture. There has been a good number of performance indicators developed for the assessment of irrigation schemes. The most important one among them is the irrigation intensity indicator. In this paper, obtained the data that regarding irrigated area and command area that is transferred irrigation schemes for 2015. This data was used to calculate irrigation intensity. In this study, three climatic zones (Continental, Mediterranean and Black Sea) fourteen irrigation schemes, more than 20.000 ha of command area for each scheme, were assessed. The average irrigation intensity of the irrigation schemes in Turkey is around 62%. Of the 14 irrigation schemes assessed in this study, 5 of them are found to be below the national average in terms of their irrigation intensities. The most important factors that determine the non-irrigated lands in the irrigation schemes include fallowing, socio-economical reasons and sufficient rainfall. The average values of these irrigation intensities for the transferred irrigation schemes were always higher than that of the government-operated schemes. This study suggest that the transfer of the SHW-operated schemes to the water use associations must be initiated and encouraged, in addition to the set up of legal procedures for participatory irrigation management, in order to cope with the possible operation and maintenance (O&M) problems of irrigation schemes. In order to mitigate the factors reducing the irrigation intensity, the agricultural publications intended for farmers and the policies in favor of irrigated farming practices should be materialized.

Keywords: *Irrigation scheme, Irrigation intensity, Cluster analysis, Water users associations*

Introduction

The last 50 years have seen significant developments in farming and water resources. A good number of irrigation schemes have been built and allocated to the use of the farmer. Today, water and irrigation still retains its importance, as the water becomes more and more a strategic commodity due to the failure of the water supply to meet the ever increasing world population demand. In the future, the single most important factor determining the use and quality of water will be the population. For this reason, the sustainable and efficient use of our land and water resources (and the operation and management of irrigation) in particular is a vitally important issue. The total surface area of Turkey is 78 million hectares (783.577 km^2), 28 million hectares of which are cultivable agricultural lands. In 2014, a total of 6.09 million hectares of land has been put into operation in Turkey. Of the irrigation areas put into operation, approximately 81% of them are irrigated by surface water resources, while the remaining 19% of them by underground water resources. In Turkey, the management of irrigation schemes have been assigned to the water user organizations since 1994. According to this irrigation management

assignment scheme, the irrigation areas that were previously run by the state have been assigned to the irrigation associations (89.1%), cooperatives (5.1%), municipalities (3%), legal village entities (1.6%) and the unions of village delivery service (0.9%) (DSI, 2015). Following the completion of assignment procedures, monitoring and assessment activities and the performance of the assignees have gained significance. Various researchers have developed performance indicators for such monitoring and assessment activities (Molden *et al*., 1998; Malano *et al*., 2004; Bos *et al*., 2005). The indicator that best represents the agricultural activity in assessing the performance of the irrigation schemes is the irrigation intensity. It is the intensity of the irrigation area to the total irrigation area, which is represented in percentages. Knowing the reasons behind the poor irrigation intensity and developing solutions accordingly is very important for the irrigation economy. Irrigation intensity is one of the most commonly used performance indicators in assessing the irrigation schemes in Turkey and in the world. In this respect, numerous studies have been conducted on different irrigation schemes by various researchers in Turkey and in the world (Beyribey *et al*., 1997; Vermillon *et al*., 2000; Çakmak, 2001; Değirmenci, 2001; Mishra *et al*., 2009; Mateos *et al*., 2010; Garcia-Balanos *et al*., 2011; Tanrıverdi *et al.*, 2011; Akkuzu and Mengü, 2012). This study has attempted to assess 14 irrigation schemes in Turkey that comprise an irrigation area of more than 20.000 hectares by using the irrigation intensity indicator. The cluster analysis and statistical charts have been used in the assessment. The aim of this study is to identify irrigation management performance of irrigation schemes with irrigation intensity indicator and to benchmark of the irrigation schemes.

Materials and Methods

The climate of Turkey is semi-arid with some extremities in temperature. Average annual precipitation is 643 mm, ranging from 250 mm in the Central Anatolia, to over 2500 mm in the coastal area of north-eastern Black Sea. Approximately, 70% of the total precipitation falls during the period between October and April, and there is a little rainfall during summer months. The average annual temperature varies between 15°C and 20°C on the coastal zones, falls to 4°C and 18°C in the inland areas. The majority of Turkish agricultural soils have alkaline characteristics, generally with low organic matter contents, with high and medium level lime contents. The majority of soils in Turkey are of loam texturing, and high potassium level. Two of the irrigation schemes that have been assessed are located in the Central Anatolian region (Çumra and İvriz) and under the influence of continental climate. The winters are cold and the summers are hot. Two irrigation schemes are located in the eastern Anatolian region (Erzincan and Iğdır) where the summers are short and chilly whereas the winters are cold and longer. Another irrigation scheme is located in the Southeastern region (Şanlıurfa-Harran) where the summer is very hot and the winter is mild. 6 of the irrigation schemes are located in the Mediterranean and Aegean regions that are under the influence of Mediterranean climate. In those places, the summers are hot and dry whereas the winters are mild and rainy. Another irrigation scheme is located in the Black Sea region where is rainy in all seasons. The summers are chilly and the winters are mild on the coasts, but colder and snowy in the higher areas. Data on the reasons of non-irrigated areas were determined with the face to face interviews of the farmers of irrigation association managers and with the field observations. These data were obtained from the assessment reports of the irrigation schemes (DSI, 2016). The locations of the irrigation schemes being assessed are provided in the Figure 1, whereas the characteristics of each irrigation scheme are listed in the Table 1 below.

The following equation has been used in calculating the irrigation intensity of the irrigation schemes for the year 2015:

$$Irrigation\ Intensity\ (\%) = \frac{Irrigated\ Area\ (ha)}{Command\ Area\ (ha)} X100$$

Fig. 1. Location of the selected fourteen irrigation schemes in Turkey.

Table 1. Characteristics of Fourteen irrigation schemes

Code	Irrigation Scheme	Surface (ha)	Water Diversion (Percentages by area)		Main Crops(Percentages by area)		
			Gravity	Pumped			
1	Menemen	22865	91	9	Cotton (56%)	Corn (18%)	Vegetables(8%)
2	Ahmetli	50232	100	-	Corn (53%)	Grape (35%)	Fruit trees (4%)
3	Çumra	59560	88	12	Cereals (53%)	Corn (35%)	Sugarbeet (12%)
4	İvriz	36108	81	19	Cereals (46%)	Corn (31%)	Sunflower(10%)
5	Seyhan	142274	99	1	Corn (42%)	Citruses (15%)	Nursery tree (11%)
6	Mersin	21762	65	35	Citruses (38%)	Vegetables (20%)	Corn (18%)
7	Ceyhan	101726	89	11	Corn (79%)	Peanut(10%)	Cotton (56%)
8	Tokat	20275	82	18	Corn (24%)	Vegetables (20%)	Fruit trees (15%)
9	Bafra	21550	100	-	Paddy(74%)	Vegetables ((12%)	Corn (9%)
10	Erzincan	29112	63	37	Cereals (50%)	Sugar beet (16%)	Bean (15%)
11	Şanlıurfa Harran	134366	100	-	Cotton (78%)	Cereals (22)	-
12	Söke	26000	100	-	Cotton (100%)	-	-
13	Baklan P	44072	100	-	Sunflower (54%)	Corn (15%)	Fruit trees(10%)
14	Iğdır	61900	94	6	Forage(50%)	Corn (31%)	Grassland(13%)

The irrigation intensity data calculated for each irrigation project has been subjected to the cluster analysis and studied in terms of their similarities to each other. The cluster analysis is a multivariable statistical method that aims to divide a set of observations into a limited number of groups or clusters. Division is done in such a way as to ensure that the similar observations are

gathered in one group while the observations of a different nature are put together in a different group (Neil, 2002). Observations (units) or variables may constitute the subject of the grouping or clustering. In clustering the units, the aim is to classify a set of observations into groups or clusters, in which neither the number of groups nor group membership is known to the researcher. In clustering the variables, however, similarities can be detected by conducting a factor analysis and thereby establishing the interrelated variable groups, and therefore the common factor structures (Özdamar, 2004). Moreover, the irrigation intensities calculated for each irrigation scheme are shown on a graphic (Fig. 3).

Results and Discussion

The cluster analysis dendrogram of the irritation schemes being assessed are presented in the Figure 2 below. As is shown in the dendrogram, the irrigation schemes are gathered in 3 groups. The highest irrigation intensities seem to have been achieved in the irrigation schemes of Çumra, Ceyhan, Seyhan, Söke, Şanlıurfa and Baklan. Such irrigation schemes are located in the regions that are under the influence of the Mediterranean climate. The crops that are planted the most in such lands are corn and cotton. The use of mechanization in planting such crops is very common. The preferential crops in the area are those that do not require labor. The second group includes the irrigation schemes of Menemen, Bafra, Mersin and İvriz. The third group includes the irrigation schemes of Iğdır, Tokat, Erzincan and Ahmetli. The irrigation intensities in the third group are fairly poor.

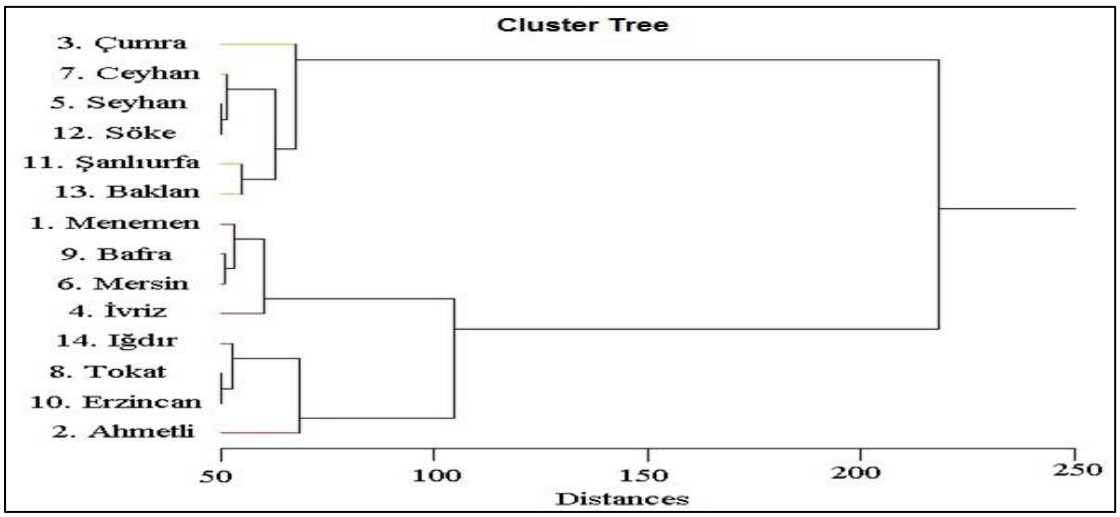

Fig. 2. Dendrogram of hierarchical cluster analysis of fourteen irrigation schemes in Turkey (x-axis reports the level of dissimilarity).

The irrigation intensities of the 14 irrigation schemes that have been assessed are provided in the Figure 3. When reviewing the Figure 3 below, it is seen that 5 irrigation schemes (İvriz, Iğdır, Tokat, Erzincan and Ahmetli) are below the average national irrigation intensity (62%). The factors that most contribute to the reduction of the irrigation intensity are as follows: insufficient water resources, social and economic reasons, fallowing, insufficient rainfall, insufficient repair and maintenance facilities, salinity and insufficient irrigation facilities. The reasons for non-irrigation areas within the irrigation schemes being assessed are provided in the Table 2. The mains reasons for non-irrigation areas in Ahmetli irrigation scheme, which has the lowest irrigation intensity, are respectively listed as follows: sufficient rainfall, insufficient repair and maintenance facilities and insufficient irrigation structures. The following reasons have been

identified for non-irrigation within the following irrigation schemes with the corresponding percentages: Fallowing (68%) in İvriz irrigation scheme, sufficient rainfall (91%) in Baklan irrigation scheme, insufficient irrigation structures (57%) in Bafra irrigation scheme, social and economic reasons (54%) in Şanlıurfa Harran irrigation scheme.

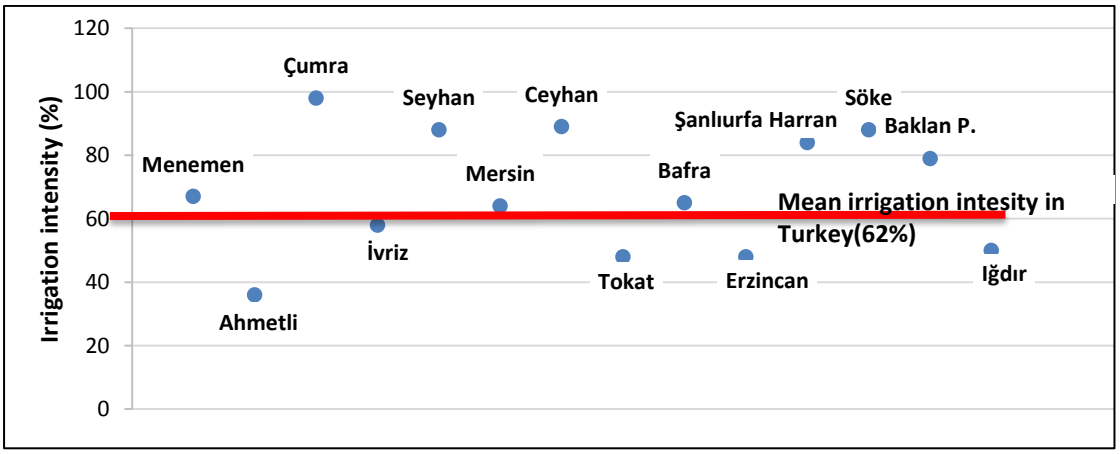

Fig. 3. Irrigation schemes and irrigation intensities.

Table 2. Irrigation schemes and main reasons of non-irrigation areas

Irrigation Scheme	Main reason of non-irrigation area(Percentages by non-irrigation area)		
Menemen	Falloving (55%)	Rainfed cropping(28%)	Economic and social problems(16%)
Ahmetli	Rainfed cropping(36%)	Inadequate maintanence(29%)	Insufficient irrigation structure(20%)
İvriz	Falloving (68%)	Inadequacy of water resources(18%)	Inadequate maintanence(5%)
Seyhan	Rainfed cropping(57%)	Industrial institution (24%)	Economic and social problems(16%)
Mersin	Industrial institution (50%)	Rainfed cropping(33%)	Economic and social problems(12%)
Ceyhan	Economic and social problems(50%)	Falloving (29%)	Industrial institution (11%)
Tokat	Rainfed cropping(47%)	Economic and social problems(20%)	Industrial institution (11%)
Bafra	Insufficient irrigation structure(57%)	Rainfed cropping(19%)	Rainfed Grassland(18%)
Erzincan	Falloving (64%)	Economic and social problems(14%)	Rainfed Grassland(10%)
Şanlıurfa Harran	Economic and social problems(54%)	Inadequacy of water resources(29%)	Drainage problems(9%)
Söke	Rainfed cropping(67%)	Economic and social problems(30%)	Industrial institution (3%)
Baklan P.	Rainfed cropping(91%)	Economic and social problems(9%)	-
Iğdır	Economic and social problems(44%)	Salinity problem(32%)	Rainfed Grassland(11%)

Conclusion

According to the cluster analysis conducted on the 14 irrigation schemes, each having an irrigation area of more than 20.000 hectares, the irrigation intensity of the irrigation schemes in the first group appears to be very high. However, the irrigation intensity of the irrigation schemes in the third group is found to be below the national average. The national irrigation intensity is planned to be increased to 68% as per the development plan for 2014-2018. In order to realize that goal, the reasons behind the aforementioned non-irrigation areas should be addressed first. For minimizing the fallow lands, agricultural publications and training programs for farmers should be promoted. Most irrigation schemes in Turkey perform gravity irrigation. This reduces the irrigation performance directly. Future irrigation investments should be planned according to the pressure irrigation method, and the old irrigation schemes should be modernized soon. One of the reasons for poor irrigation density is the social and economic status of the Turkish farmer. Farmers are unable to cultivate their lands due to social and economic reasons. The marketing infrastructure for the produce should be improved to eliminate social and economic problems, and the product prices and marketing conditions should be brought up to the international standards. Moreover, the policies should be developed in favor of irrigated farming.

Abstract

The sprinkler irrigation systems are often regarded as a hydraulics problem. The average rate of water application is usually fixed at some level below the basic infiltration rate of the soil to avoid surface water runoff. However, water starts to accumulate on the soil surface when the water application rate exceeds the infiltration rate for a sufficiently long period of time. Surface runoff occurs when sufficient water accumulates on the soil surface to overflow shallow depressions and flow over or past surface. A good pasture management is the production of economically optimum forage yield and quality without compromising the environment. This field experiments (Gorki district, Belarus) aims to determine irrigation time for traveling irrigation device Bauer Rainstar T-61, and the required water supply rate without puddles and runoffs formation to loamy soil. Results show that irrigation rate without soil erosion was: in loose soil - 12.8–15.8 mm; then plant are 5–10 cm high - 28.8 mm or more at the vegetation beginning and 19.2–23.4 mm at the vegetation end; then plant are 10–20 cm high - at the vegetation beginning and at the end - the same - 30.0 mm and more. The watering time until beginning to runoff formation consisted from 64 min to 150 min. The average artificial rain droplet diameter for traveling irrigation device Bauer Rainstar T-61 was established from 0.7 to 1.2 mm. Maximum diameter of 1.2 mm and 0.7 mm drops were formed when the 30 mm and 16 mm diameter spray were used respectively. The resulting value correspond to the allowed limits of quality agronomic characteristics of irrigation, without causing damage to irrigated crops using any removable irrigation spray.

Keywords: *erosion, Bauer Rainstar T-6, traveling irrigator.*

Introduction

Agriculture is an important component in the economies of Eastern Europe. It has the potential to become globally important. The sector employs about 17% of the working population of Eastern Europe. Agriculture contributes between 9 and 15% to national GDP (Nikolayeva *et al*., 2012). Irrigated land area has expanded rapidly over the last years. In 1961, irrigation occupied 141 million hectares globally, increasing to 287 million hectares in 2015, and forecasted to 318 million hectares by 2050. Irrigation water withdrawal was 2620 km^3 in 2005, and will increase 2906 km^3 in 2050 (Bruinsma, 2009). Irrigation is the most important water use sector accounting for about 70% of the global freshwater withdrawals and 90% of consumptive water uses (Siebert *et al*., 2010). Climate change is expected to intensify problems of water scarcity and irrigation requirements in the Mediterranean region (Rodriguez *et al*., 2007). Water use efficiency is an important performance indicator of sustainable production, widely used overseas (Martin *et al*., 2006). Irrigated agriculture causes various direct or indirect problems, including leaching of nutrient and pesticides, soil salinization, overexploitation of aquifers (leading to ground

subsidence and sea-water intrusion), modification of natural flow regimes and damages to water dependent ecosystems (Doll and Siebert, 2002; Stigter *et al*., 2006). The use of irrigation is critical to quality crop production and continuous-move irrigation systems are suited to the requirements of sandy soils, however their mobility could be affected by traffic ability problems depending upon soil moisture (Chico-Santamarta *et al*., 2009). Sprinkler systems are used on 50% of the irrigated crop land and have a water use efficiency of 75% (Locascio, 2005). During a sprinkler irrigation event some water is lost due to wind drift and evaporation. After the irrigation event, plant-intercepted water is lost due to evaporation. The water lost causes microclimatic changes which could result in positive or negative plant physiological changes. Sprinkler irrigation during daytime strongly modified the microclimate where plants grow during the irrigation time and for a short period after the irrigation event finished (Cavero *et. al*., 2009). As pressure on water resources increases, pasture species that express traits for improved water-use efficiency while maintaining desirable agronomic and production characteristics are needed (White and Snow, 2012). The dairy industry is under increasing pressure to use water more efficiently in response to water market reforms and restrictions on future irrigation water availability, creating interest in the potential of alternative irrigation methods. Surface runoff was significantly reduced under sprinkler and subsurface drip irrigation. The high water use by gravity fed irrigation methods is attributed to a combination of higher evaporation and groundwater accessions (Wood and Finger, 2006). Potential water savings by new irrigation technology and improved irrigation management may be off set by increases in irrigated areas and appropriate measures are necessary to limit water use to sustainable levels (Wriedt *et al*., 2009). The mobile irrigator was developed for effective utilization of the available water in dry land agriculture instead of following the supplementary irrigation. For the efficient performance of the irrigator, the height of the crop should be less than or up to 1.5 m. (Ravi, *et al*., 2015). The quality irrigation means, at first, water distribution for all areas without forming the surface runoff, causing not only a great loss of water, but also the destruction of soil structure, reducing its air permeability and the formation of soil crust. These conditions depend on the structure of the artificial rain produced by a particular sprinkler installation, soil, climate, the relief and the agro technical characteristics of the irrigated area. The purpose of this study was to investigate the irrigation time and rate for traveling irrigation device for pasture in loam soil by analysing time from irrigation beginning until starts formation surface runoff at different moisture contents and the distribution droplet size of rain, depending on the sprinkler nozzle diameter.

Materials and methods

Field experiments were conducted at the experimental field Gorki district, Belarus in 2012–2015. Soils are soddy-podzolic loamy. The soil characteristic in a layer 0–100 cm: density - 1.62 g cm-3, the density of solids - 2.65 g cm-3, the lowest moisture content - 22.3% by weight of dry soil, the max slope 0.005. The vegetation cover is represented by herbage height from 5 to 20 cm. Traveling gun sprinkler Bauer Rainstar T-61 was used for irrigation. Irrigation was carried out to three levels of pre-irrigation moisture (60–70% of the field moisture susceptibility (MS), 70–80% MS and 80–90% MS) for the following conditions: 1 variant: friable soil after pre-treatment; 2 variant: the soil is dense; 3 variant: herbage height of 5–10 cm, at the beginning of the growing season; 4 variant: herbage height of 5–10 cm, at the end of the growing season; 5 variant: height of 10–20 cm, at the beginning of the growing season; 6 variant: herbage height of 10–20 cm, at the end of the growing season. Before the start of the experiment on the soil surface were established credentials mortise frame. Accounting rules irrigation was performed using rain gauges. The moments of the time then in the surface were form pools of 2-3 cm diameter was the

beginning of the surface runoff. Irrigation rate is 30 mm, pressure 4-5 bar, watering duration 150 min. The rotation speed around the machine axis of the machine gun equals 0.7 circle/min. Droplet size of rain determined using filter paper in multiple 3 replications. Soil moisture was determined at 10 cm and 20 cm depth. The angle of the sprinkler preparations from the horizon was in the standard position (24^0). The diameter of the nozzle sprinkler device was 16-30 mm. All irrigation was carried out in calm weather. Interdependence of the individual factors was analysed, using binomial correlation method: the determined correlation and reliability of the data was checked by autocorrelation analysis. Correlation methods (r) have been used for data analysis. Irrigation intensity by sprinkling time can be described by the equation:

$$i_i = \frac{A}{t^B} + i_r, \quad (1)$$

where A and B - empirical parameters, depending on the soil and relief and other factors affecting the intensity of allowable irrigation; t - time watering until starts formation surface runoff, min; i_r - penetration rate at sprinkling time, mm min^{-1}.

Results and discussion

The results for irrigation system tests for the three considered soil moisture for all 6 variants are presented in fig.1 (soil moisture 60-70 % MS), fig.2 (soil moisture 70-80 % MS) and fig.3 (soil moisture 80-90 % MS). The resulting equation has a high correlation (0.99, table 1).

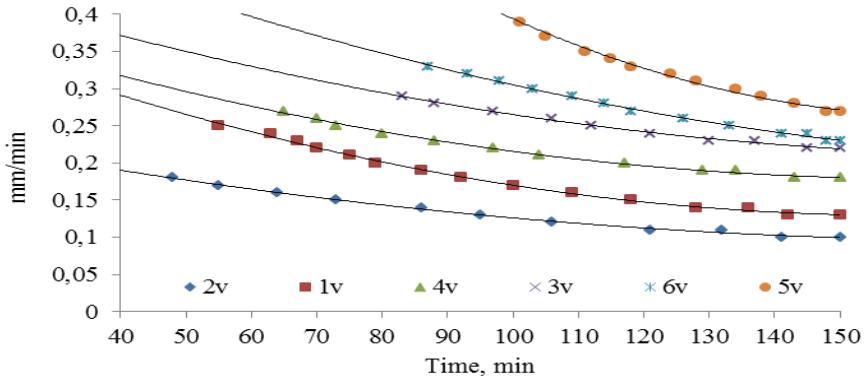

Fig. 1. The infiltration rate (moisture 60-70 % MS) during irrigation

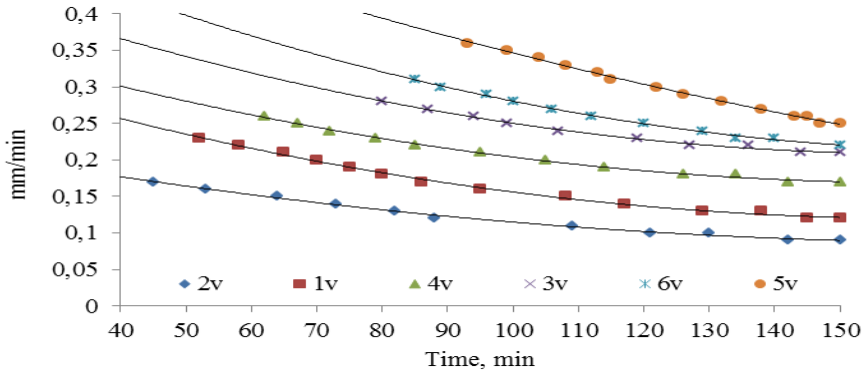

Fig. 2. The infiltration rate (moisture 70-80 % MS) during irrigation

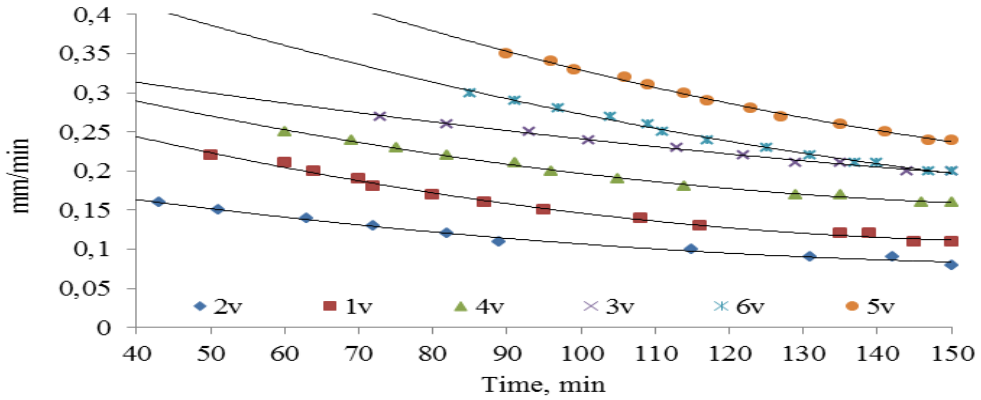

Fig. 3. The infiltration rate of the soil (moisture 80-90 % MS) during irrigation

Table 1. Irrigation intensity by sprinkling time

Variant	i_i, mm min^{-1}	Time until starts formation surface runoff, min	The parameters of the equation		i_r, mm min^{-1}	r
			A	B		
I	0.25–0.11	50–150	3,17–4,36	0,64–0,70	0,13–0,11	0,99
II	0.18–0.08	43–150	1,27–1,48	0,53–0,54	0,1–0,08	0,99
III	0.29–0.20	75–150	1,92–2,42	0,45–0,48	0,22–0,2	0,99
IV	0.27–0.16	60–150	1,98–2,14	0,49–0,52	0,18–0,16	0,99
V	0.42–0.24	90–150	12,26–29,63	0,79–0,94	0,23–0,2	0,99
VI	0.33–0.20	85–150	4,84–9,22	0,62–0,77	0,27–0,24	0,99

The values of the permissible intensity with intermittent sprinkling for sprinkler irrigation, to avoid excess runoff and erosion risk, the following: 1 variant - 0.25– 0.11 mm min^{-1}; 2 variant - 0.18– 0.08 mm min^{-1}; 3 variant - 0.29–0.20 mm min^{-1}; 4 variant - 0.27–0.16 mm min^{-1}; 5 variant - 0.42–0.24 mm min^{-1}; 6 variant - 0.33– 0.20 mm min^{-1}. The intensity of the obtained values was determined erosion-permissible values of irrigation norms and irrigation while providing watering without forming puddles and surface runoff (table 2).

Table 2. Irrigation rates and the time for sprinkling irrigation.

Variant	Soil moisture, % MS	Irritation time until the formation surface runoff, min	Irrigation norm until the formation surface runoff, mm
I	60–70	79	15.8
	70–80	70	14.0
	80–90	64	12.8
II	60–70	Irrigation is not recommended	
	70–80		
	80–90		
III	60–70	Surface runoff was not observed	
	70–80		
	80–90	144	28.8
IV	60–70	117	23.4
	70–80	105	21.0
	80–90	96	19.2
V	60–70	Surface runoff was not observed	
	70–80		
	80–90		
VI	60–70	Surface runoff was not observed	
	70–80		
	80–90	150	30.0

Table 2 shows that the values of the permissible norms of irrigation and irrigation time differ markedly according to the variant of experience. So permissible irrigation rate will be: to loose soil 12.8–15.8 mm; dense soil – watering is not recommended; herbage height of 5–10 cm at the beginning of the growing season of 28.8 mm and above; herbage height of 5–10 cm at the end of the growing season of 19.2– 23.4 mm; herbage height of 10–20 cm at the beginning and end of the growing season of 30.0 mm and above. Time to form irrigation surface runoff was from 64 minutes to 150 minutes.

Also as a result of the experiments, it was found that due irrigation sprinkler apparatus Bauer machine breaks drops a diameter from 0.1 mm to 2.3 mm. But the droplet size distribution is irregular. Experiments have shown that with increasing distance from the sprinkler device amount of raindrops grew, and maximum values recorded in the 0.7–0.8 distance range from sprinkler nozzle (fig. 4). The smallest droplet diameter was 0.1 mm at a distance from 2.5 to 5 m from the apparatus.

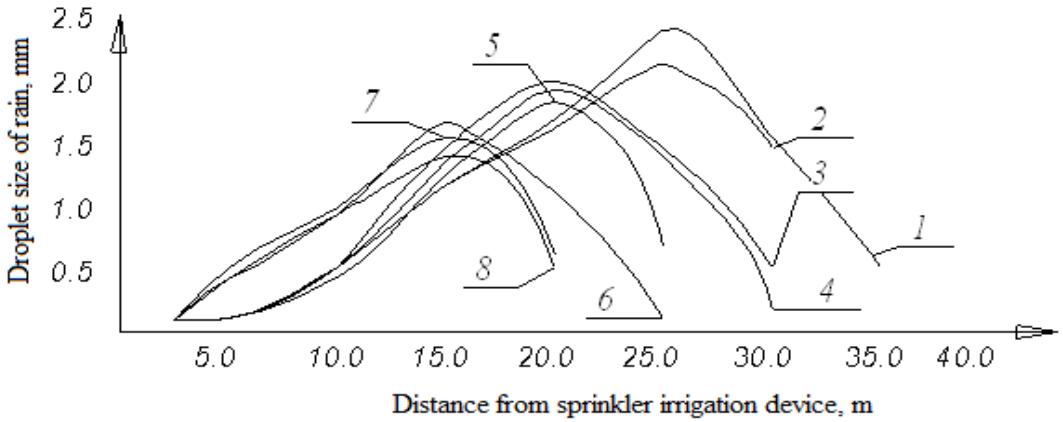

Fig. 4. – Drop size distributions, depending on the sprinkler nozzle diameter
Sprinkler nozzle diameter:
1 – 30 mm, 2 – 28 mm, 3 – 26 mm, 4 – 24 mm, 5 – 22 mm, 6 – 20 mm, 7 – 18 mm, 8 – 16 mm

The highest value of average droplet diameter of 1.2 mm obtained when watering sprinkler nozzle is 30 mm, and the smallest - 0.7 mm at 16 mm. All values obtained are acceptable agronomic characteristics of quality irrigation, which prevents damage to irrigated crops in any replacements sprinkler nozzles. But according (DeBoer, 2002), nozzle diameter had a minimal effect on drop size, but nozzle pressure had a significant inverse influence.

Conclusions

Results show that irrigation rate without soil erosion and time to ensure traveling gun sprinkler Bauer Rainstar T-61 without forming puddles and surface runoff to the sod–podzolic loamy soil depend on the state of the soil surface and the height of the vegetation cover and are: in loose soil - 12.8–15.8 mm; then plant are 5–10 cm high - 28.8 mm or more at the vegetation beginning and 19.2–23.4 mm at the vegetation end; then plant are 10–20 cm high - at the vegetation beginning and at the end - the same - 30.0 mm and more. The watering time until beginning to runoff formation consisted from 64 min to 150 min. The values of the average diameter of the artificial rain produced by the traveling gun Bauer Rainstar T-61vary from 0.7 to 1.2 mm. Maximum diameter (1.2 mm) drops formed then was used the 30 mm diameter sprinkler nozzle and 0.7 mm – the 16 mm sprinkler nozzle. All values obtained are acceptable agronomic characteristics of quality irrigation in any sprinkler nozzles.

Abstract

There are two decades or so, that the biodiversity issue was enriched by a new dimension called "Agrobiodiversity". Geographical indications have been developed for primary and processed products of biodiversity. Geographical indication can be a tool to enhance the value of agrobiodiversity products and promote sustainable rural development. Geographical indications establish a connection between products (or services) and their territorial identity, and the quality, characteristics, and reputation of origin-based products are essentially associated with their geographical origins. The natural and cultural heritage of the Albanian Alps is one of the most rich and varied in Europe. The populations in these areas are, extremely poor and exploiting these natural resources, whether through farming or gathering, is one of the main means of earning an income. Official quality signs, especially Geographical Indications and organic farming, make it possible to improve product prices and value added for producers while encouraging the preservation of biodiversity by introducing this subject in product specifications. The aim of this paper is to present a research-action project aiming at crossing environmental injunction of biodiversity *in situ* conservation and traditional knowledge with economic objectives of rural period October 2015-March 2016P objectives were to identify, promote and protect agrobiodiversity in the poorest part of the country, creating quality signs of the local products (including medicinal and aromatic plants). BiodivBalkan project wants though the preservation of agrobiodiversity to: (i) improve the quality, adopt the standard and quality controls along the value chain; (ii) increase competitiveness of marginal producers in the market to bring higher income to farmers.

Keywords: *Agrobiodiversity, geographical indications, BiodivBalkan Project*

Introduction

This paper is intended to present the situation changed only in the last years when Albania began to embrace GIs as a useful rural development. Northern Albania has rich natural resources with a very high biodiversity and provides a significant contribution to the Albanian natural heritage. Nowadays the system is threatened by the unsustainable use and the degradation of the economic situation.

A geographical indication (GI) is a form of protection highlighted in the Trade Related Aspects of Intellectual Property Rights (TRIPS) Agreement of the World Trade Organization (WTO) Geographical Indication (GI) is a form of intellectual property identifying a product as originating from a region/locality/territory where its quality and reputation is associated with its geographical origin (UNIDO, 2010). GI have been thought to have the potential to protect the traditional indigenous know-how that is associated with agro-food production and to legally regulate land-use strategies and harvesting practices, by means of various specifications. As a

result, GI provides a relevant tool to protect and promote or enhance biodiversity (Larson Guerra, 2004). A geographical indication (GI) identifies a good as originating in a country, a region or a locality where a given quality, reputation, or other characteristics of such a good are essentially attributable to its geographical origin (Garcia et all, 2007) It is important therefore not only to consider the biological characteristics of a geographical area, but also the local knowledge and practices involved (Bérard and Marchenay, 2006) in order to achieve biodiversity benefits.

Today, geographical indications (GI) have an international reputation (Sylvander, 2005). GI are economic tools designed to create a specific market by differentiating products on the basis of their specific link to a given territory. Their founding principle is the legal protection of the geographical name attached to the product.

The European Union has registered some of its agricultural products as GIs and this has added billions of moneys to their economy. The products registered include MAPs whose qualities are determined by the geographical setting and resources, production system, handling, processing and storing methods; thus a human and natural link.

Albania has acknowledged the importance of GI and a law to facilitate GI registration has been in place from 2008.

Wild Bilberry is a potential MAP product for GI registering in two potential regions (Tropoja and Kukes) in Northern part of Albania. This product is unique in taste which is attributed to specific environment and weather conditions (Ibraliu andBeqaj, 2012). Apart from increasing monetary value and employment creation, this product has promoted area and biodiversity conservation through a number of programs.

Legal and institutional framework is very important in protecting of GI product. Giovannucci et al., (2009) emphasise that even with originality of potential GI product, the benefits will not accrue to the actors without the support of the legal and institutional framework. Other factors that support GI registration of products include; collective action, prices and market for the product, specificity and reputation of product, support from other actors along the value chain, production methods and link of the product characteristics to history or tradition of the geographical area (Bramley and Biénabe, 2013).

Perceptions on wild bilberry reputation and quality by the producers and consumers on the bilberry identified as potential for GI registration in northern Albania, have been attributed to the geographical area where the bilberry is produced and the initiatives by the stakeholders in the area. These initiatives include capacity building through trainings on bilberry forest management, bilberry value addition, ecosystem conservation and supply with equipment for product storing and drying, and processing.

The objective of the paper is to identify, promote and protect agrobiodiversity in the poorest part of the country, creating quality signs of the local products (including medicinal and aromatic plants). BiodivBalkan project wants though the preservation of agrobiodiversity to: (i) improve the quality, adopt the standard and quality controls along the value chain; (ii) increase competitiveness of marginal producers in the market to bring higher income to farmers.

The aim of this paper is to present and discuss BiodivBalkan project results which is conducted in Albania during period October 2015-March 2016.

Materials and Methods

This study was conducted in northern part of Albania, on the production of the different agriculture products. Wild Bilberry in two potential regions (Tropoja and Kukes) is considered as a good model for conservation of biodiversity through development of geographical indication.

These areas have already seen the establishment of a GI (Northern bilberry) and its own name is already used by the bilberry associations, established for each area.
In Albanian territory (Kukes and Tropoja regions) bilberry plant grows at high altitudes ranging from 1.000 m – 1.400 m and in steep terrain. Bilberry (Vaccinium L) is a shrub that ranges from 0 - 50 cm in height. From observations made in the field, it is found that the bilberry is a bush that grows as the sub forest element of the oak and subalpine and alpine meadows. Under the shadows of oak trees bilberries are developing little or none, while in subalpine and alpine meadows are develop pretty good giving a considerable amount of production.
in 2012300 , including farmers, pickers, collectors, processors and traders (Ibraliu and Beqaj, 2012). Few reports were used as information sources for the value chain analysis such as: the report of the project "The potentials of bilberry in the areas of Tropoja and Kukes regions in the context of quality signs and development of the respective value chain" (Ibraliu and Beqaj, 2012).
In order to receive qualitative and quantitative data, a field survey was conducted in two districts (Kukes and Tropoja) for a period of 4 weeks, where the team group has conducted face to face interviews in the defined areas with the farmers, pickers, collectors, processors and traders of bilberry product. The idea was to assess the changes that have occurred in qualitative and quantitative terms of bilberry product in two areas of the project.
Regarding to quantitative data, the questionnaire was organized in receiving of information of: (i) changes in the surface area collected from farmers; (ii) changes in the number of farmers involved in the collection of the product; (iii) the increase of the total quantity of product collected; (iv) increasing the quantity of the stored product, and (v) increasing product sold.
Regarding to the quality information and data, during the October 2015, we have collected samples in 10 different localities in Northern of Albania, in order to assess the anthocyanins content.

Results and Discussions

Bilberry producers and other actors in this sector can benefit from GI product registration. This would increase prices premiums and income for producers, forming an incentive to conserve the habitat for sustainable production. More support from political and institutional environment, regional and local organizations, coordination of actors in bilberry sector, creation of awareness on GI is however needed to facilitate registration of bilberry and conservation of the biodiversity around the products origin.
Management guidelines have been devised to protect, maintain or enhance wild bilberry resources. Different techniques and priorities for bilberry management have been implemented on the basis of site capability, survey results, and the rarity of suitable sites and the current age structure of bilberry producing stands within the management unit. Tabulations of currently utilized bilberry patches by location and age indicate an uneven distribution of bilberry picking opportunities, requiring prioritization of berry species for management in each territory or active intervention to rectify unbalanced age class structures. It is suggested that damages to bilberry areas in managed stands can be minimized through careful winter logging with understory protection, the use of partial cutting, light broadcast fire, and the use of selective brushing.
Information on bilberry auto-ecology, historic use patterns, and habitat suitability provides the basis for developing management rules for bilberry production.
A bilberry management plan which identifies specific areas to treat, when and how to treat them, however, cannot be provided until yield targets have been determined and yield curves have been

produced for various habitats. The bilberry quantity production to be targeted will also vary with the balance of resource emphasis options determined for a given landscape unit or territory.
Based on the data and information received and proceeded by the questionnaires, it is concluded that: (i) the total collection area used by farmers is increased with 7%; (ii) the number of farmers involved in the collection of the product is 5% higher in 2015 than 2014; (iii) the total quantity of product collected is increase with 6%; (iv) the quantity of the stored product is increase with 10%, which mean that farmers are more interested in fresh product, and (v) the product sold immediately after the collection is reduced with 12%; (vi) incomes increased 10%.
During the October 2015, we have collected samples in 10 different localities in Northern of Albania.
Total anthocyanins content. Total anthocyanin content was investigated according to the procedure described in Ph. Eur. 6.0 (European Pharmacopoea 6.0., 2008). Briefly, 50g of fresh berries were crushed extemporaneously. To 5g of crushed, accurately weighed drug, 95 ml of methanol were added and mechanically stirred for 30 min then filtered into a 100 ml volumetric flask. Filter was rinsed and diluted to 100 ml with methanol. A 50-fold dilution of this solution in a 0.1 per cent v/v solution of hydrochloric acid in methanol was prepared. The absorbance of the solution was measured at 528 nm, using a 0.1 per cent v/v solution of hydrochloric acid in methanol as the compensation liquid.

Delimitation of territory.

Quality results of the bilberry in two regions.

Kukes and Tropoja regions

Sample	Total anthocyanins	Total phenolics
• *Tropoje-shkelzen-kernaje*	• 0.49 ± 0.02	• 905.4 ± 29.6
• *Cerem Tropoje*	• 0.51± 0.02	• 1027.1 ± 23.8
• *Teblim puke*	• 0.46 ± 0.01	• 719.8 ±51.2
• ***Kolosjan -***	• **0.51 ± 0.01**	• **708.3 ± 32.8**
• ***Gryke Caji***	• **0.41 ± 0.01**	• **662.0 ± 43.1**
• *Komuna fierze*	• 0.45 ± 0.02	• 735.3 ± 12.7
• *Dardhe*	• 0.16 ± 0.02	• 542.3 ± 52.4
• *Komune kelmend*	• 0.45 ± 0.02	• 620.4 ± 33.8
• *Kabash-blerim*	• 0.15 ± 0.00	• 433.9 ± 17.6
• ***Gryke Caji***	• **0.47 ± 0.01**	• **711.5 ± 56.8**

Higher amounts of total phenolics were detected in our samples harvested from localities in Tropoja and Kukesi region, especially the samples exposed to the sun in comparison with berries grown in shadow. It has been reported earlier that light intensity. The highest amounts of total anthocyanins were noticed in the same samples which were also the samples containing the highest amounts of total phenolics. Concerning the quality of tested samples from different sites of the project we believe to the very good potential of the bilberry in North of Albania and through economic development and commercial use of available natural resources populations living in those regions could achieve a better standard of living for farmers in these rural areas.

Conclusions

The rural development of Northern part of Albania can be improved through the creation of value added, and (GI) is a possible means towards that end where product has particularities and a preferential position in markets.

A distinctive sign-GI is created to protect bilberry as a unique product as well as to protect the territories from imitation and fraud with respect to their origin.

The local capacity of producer organizations and municipal governments in the areas where blueberries GIs have potential is also a significant factor when looking at the feasibility of GI implementation.

While there are expectations that GIs will provide protection against copy, imitation, and fraud, their effectiveness is limited by the nature of the products and conditions in local territories and the weakness of regulations and institutional capacity for enforcement. Regarding to bilberry GI since the law and its regulations as well as many other regulations are not in force, there is the risk about the sustainability of bilberries protection against imitation, fraud or false production.

Thus, there is a need for various instruments to protect local products of biodiversity - primary and processed - to allow the benefits to be retained by local communities and committed producers and processors.

A comprehensive sustainable development approach-agro-biodiversity valorization and conservation – requires a reflexive and practical iterative method all along the collective action process. This process brings shareholders and stakeholders together with a common understanding of these challenges, and finds the best fit between private interests, management of

the common good (labels), and public good (agro-biodiversity conservation). It has to be complementary to the product identification process, environmental assessment, production system analyses and support to appropriate practices. A set of various labels can be combined in order to fit with the different challenges of natural resources conservation, product development and market opportunities. Obviously, as shown by previous GI success story, there is no simple recipe: all cannot be done at the same time and collective dynamics may start from a very small coalition (Boutonnet J.P., Devautour H., Danflous J.P. 2009).

Recommendations

Bilberry collector, producers and traders in Northern part of Albania can benefit from GI potential bilberry, if the GI legal and institutional framework is active and other measures as per GI cycle are developed and considered. This would increase prices premiums and income for producers, forming an incentive to protect and conserve bilberry and the habitat for sustainable production. More support from political and institutional environment, regional and local organizations; coordination of actors in the bilberry sector; creation of awareness on GI is however, needed to facilitate GI registration of bilberry and conservation of the biodiversity around the products´ origin.

Capacity within responsible national institutions must be improved to allow for effective enforcement of GI legislation and to promote their establishment in cases with proven potential. Access to information on the benefits, opportunities, necessary commitments, and investment and managerial needs for GIs to lead into successful business must be improved to ensure interested members of society can effectively engage in the process. Technical assistance to local producer organizations with potential to achieve GIs for local primary or processed products must also be improved when compelling opportunities have been identified.

Abstract

Sewage sludge could be a valuable waste all over the world. Its agricultural utilization has high importance because of: i) the decreasing organic matter content of soils, ii) the environmentally sound recycling of a waste, iii) complex nutrient supply of cultivated plants. The quality of sewage sludge can be improved by composting, which process stabilizes the organic matter content of the sludge, disinfects the sludge, and the applied additives can improve the macro- and microelements content and other properties/components of the compost. However, the sewage sludge compost (SSC) application could have negative effects, especially the accumulation of toxic elements in the soil-plant system. The evaluation of the effects of SSCs bases on experiments with different duration. Therefore, we look for answers for the following questions: Do we want to utilize the SSC once or regularly? Can we deduce the effects of regular SSC utilization from the results of a two-year- experiment? Is it important to maintain long-term experiments? Our answers based on the results from a 13-year long-term experiment where 0, 9, 18 and 27 t/ha^{-1} doses of SSC have applied in every third year in a small-plot experiment since 2003. The SSC contains dewatered sewage sludge (40%), straw (20%), rhyolite (25%) and bentonite (5%), designed for acidic sandy soils. Soil was sampled every autumn. The regular SSC application resulted in continuous changes of soil properties.

Keywords: *sewage sludge compost, sandy soil, soil enzymes, soil chemical properties.*

Introduction

Although the circular economy policy of EU is forced the zero waste or at least the minimum waste technologies, today the environmentally sound waste utilization has high importance. Waste utilization could be captured with soil improvement or plant nutrition by utilization especially organic wastes and by-products (Lakhdar et al., 2009; Weber 2014). Although sewage sludge composts (SSCs) have favourable properties and effects like high organic matter and plant nutrient content (Alvangera et al., 2015), increasing the biological activity of the soil (Peña et al., 2015), increasing the crop yield (Warman and Termeer, 2005), but SSCs could have also some negative effects, like toxic elements content (Smith, 2009), organic pollutants (Clarke and Smith, 2011), human pathogens (Alvangera et al., 2015) presenting in compost.

Chemical and microbiological processes of soils take place during different timescales (Targulian and Krasilnikov, 2007). Any treatments could have short- and long-term effects. When we study the effects of a treatment after some month or one year we could not measure long-term effects. However, the repeated use of wastes and different products made from them is the economical

way of their use in practise causing the presence of cumulative effects of these wastes which can be studied only in long-term experiments.
Are there any differences in the effects of one-off or regular treatments? Can we predict long-term effects based on one or two years experiments?
On the bases of our 13-year long-term sewage sludge compost experiment we try to find the answers for the questions of regular or one-off application of SSC and we try to compare the results of short-term and long-term utilization period regarding the effect of applied SSC on different soil parameters.

Materials and methods

A sewage sludge compost experiment was started in 2003 in the field of Research Institute of Nyíregyháza, Hungary, where our common product with Nyírségvíz Ltd., called NYÍRKOMPOSZT has applied in every third year at the rates of 0, 9, 18 and 27 t/ha^{-1} doses. Small-plots are in size of 19 m X 12 m. The SSC was designed for acidic sandy soils therefore it contains dewatered sewage sludge (40% m/m), straw (20% m/m), rhyolite (25% m/m) and bentonite (5% m/m). The chemical parameters of SSC are not constant. The pH of our SSC was about 7, it contained about 25% (m/m, in dry matter (DM)) organic matter, 1.2% (m/m, DM) total-N, 1% (m/m, DM) total P_2O_5 and 0.2% (m/m, DM) total K_2O. The chemical properties of SSC applied in 2006, 2009, 2012 and 2015 met the requirements of Hungarian laws regulated the agricultural utilization of SSCs. Triticale (*x Triticosecale* Wittmack), maize (*Zea mays* L.) and green pea (*Pisum sativum* L.) were the test plants in the crop rotation, sown them in every year.
The soil of the experiment is acidic sand, Dystric Lamellic Arenosol in World Reference Base of soils. Soil was sampled in every autumn after harvesting all test plants and before sowing triticale. Samples were collected from the 0-30 cm soil layer. Main soil chemical parameters were the followings at the start of the experiment: pH $_{(KCl)}$ 5.3, Humus content 0.9%, NO_3-N 9.6 mg kg^{-1}, AL-K_2O 183.3 mg kg^{-1}, AL-P_2O_5 240.1 mg kg^{-1}.
Soil chemical parameters were measured according to the Hungarian Standards. Briefly, the pH was measured in a 1:2.5 soil: KCl (1 N) solution; the humus content was measured after the digestion with potassium dichromate and cc. sulphuric acid; NO_2-NO_3-N was measured in KCl extract; K_2O and P_2O_5 were measured in ammonium-lactate extract. Now we present and discuss the results of the years 2007, 2008 and 2014 which represent the 2nd and the 4th application period of the SSC.
Invertase activity was measured according to Mikanová et al. (2001) on the base of glucose formation. Catalase activity was estimated by measuring the release of O_2 from H_2O_2 amended soil samples according to the Hungarian Standard MSZ-08-1721/4-86. Chemical and microbiological results represent the average measured values of the soils of three test plants.
Statistical analysis was done by MS Excel and SPSS 22.0 programs. The data obtained were statistically analysed yearly by analysis of variance. For pairwise comparison of the means Tukey's test were used after ANOVA. With the whole database (26 soil parameters) of the year 2014, Principal Component Analysis was done. The significance level was $p<0.05$.

Results and discussion

Soil parameters are affected not only by treatments (Debosz et al., 2002) and used agricultural methods (Rusu et al., 2009), but by natural processes like weather conditions (temperature, precipitation), too (Wang and Wu, 2013). These circumstances can modify our activities. Agricultural utilizations of wastes usually are planned for long periods as a regular activity. In

Table 1 we present some soil chemical parameters of SSC treated plots. These are the main soil parameters contributing to nutrient supply of cultivated plants.
Data obtained in 2007 represent short-term (4 years) changes after 1st and 2nd SSC application. The results from 2008 represent a middle-term, while from 2014 the long-term changes caused by regular SSC treatment of agricultural land. The applied doses of SSC are moderate, planned for long-term, environmentally sound utilization.

In 2007 we have not found significant treatment effects on pH and macroelements content of soil samples. However, some trends could be seen in case of pH and phosphorus (P) content: the measured values are higher in SSC treated soils. Based on these results we could state that SSC application does not result in changes of the main soil chemical parameters and we could conclude that the soil can buffer the effects of our treatments. However, Warman and Termeer (2005) found an increase of plant available nitrogen (N) and P content of soil after two years of compost treatment. While the applied compost doses and the macronutrients content of compost was similar to our compost, the different effects could be caused by the different soil types and climatic conditions of experimental sites. But the question arises: if they have found changes in soil properties after 2 years of application, what will be the intensity of changes after 10 years?
In the middle of the 2nd SSC application period (2008) the directions of pH changes stabilized: non-treated soil had decreasing pH while high doses of applied SSC resulted in continuous increase of pH KCl. pH is the main soil parameter determining the soil processes (Nikol et al., 2008; Kemmitt et al., 2006).
The humus (organic matter) content and the concentration of macroelements varied among the years. Generally, the concentrations of the available N and P were increased with increasing SSC doses in every year but we had not found an increasing tendency similar to changes of pH KCl.
However, after examination of data obtained in 2008 and 2014, significant differences were found among treated plots which indicated changes taking place in treated plots after regular application of SSC in the experiment.

Similar effects were found in case of measured soil enzymes (Table 2). In 2007 the measured enzymes activities were similar in all treated soil samples. In the following years we found strong differences between the two measured enzymes. Invertase had significant annual fluctuations with not significant treatment effects in each year. However, the applied SSC resulted in organic matter (OM) input into the soil and the invertase takes place in the destruction of OM, this extra OM could not increase its activity. On the other hand, significant treatment effect was measured in the catalase activity after the 2nd SSC application.

Table 2. Soil enzymes activities in SSC treated soil samples.

Year	Compost dose ($t*ha^{-1}$)	Invertase (mg glucose * 1 g^{-1} dry soil*4 h^{-1})	Catalase (mg O_2 * 1 g^{-1} dry soil*1 h^{-1})

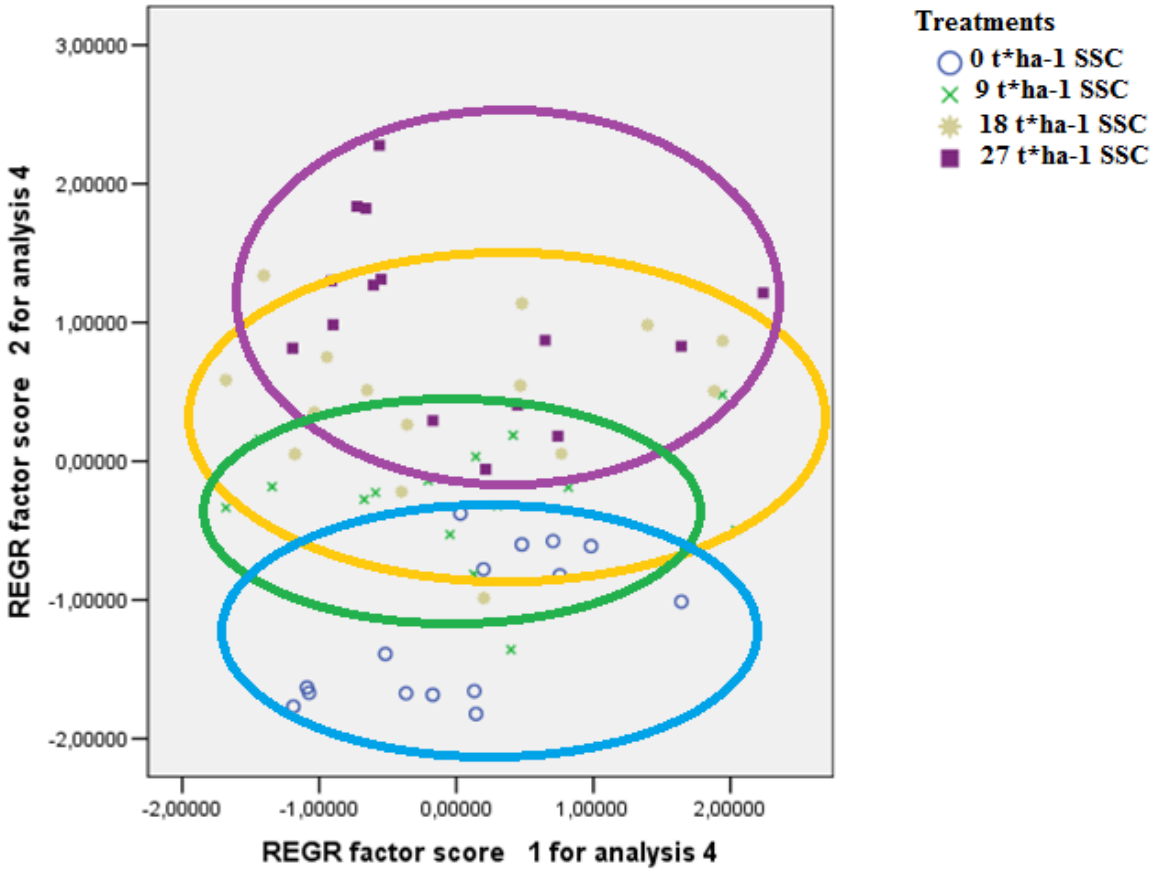
a-c indexes mean different groups of means according to the Tukey's test at the significance level of $P<0.05$.

On the base of the presented results we can conclude that the regular SSC treatment caused some changes in soil chemical and microbiological conditions until 2014. This statement is based on 7 general soil parameters. However, analysing more soil parameters (meso- and microelements, the total of 26 parameters) revealed that after 11 years of regular SSC application the soil properties have changed comparing to the non-treated soil (Fig.1). This result indicated that the measured slight changes appeared year by year could cause a shift of the whole soil properties. These processes could be slow as in our case, depending on the applied treatments therefore long-term experiments have high importance to study the effects of regular activity of humans.

Figure 1. Results of Principal Component Analysis of total database from year 2014.



Conclusion

The activity of humans always affects the nature. If these interventions into our environment are not too strong, their effects occur only after long time. Therefore, it is a hard problem to predict the changes of soil properties after regular and long-term waste utilization. Many research groups work on testing the effects of waste utilization, but the experimental conditions are different which reduces the accuracy of comparing results, especially on the base of the duration of treatments. As our results proved, the results of short-term applications could be different from long-term, regular applications. After 11 years the treatment of soil with our SSC resulted in positive changes with small increase of nutrient content of soil without accumulation of toxic elements. But the changes in soils are continuous processes determined by climate, applied agrotechnical methods, etc. Therefore, we can conclude the expected changes of soil properties after a long-term activity like waste utilization in agriculture but for assessing the real processes, long-term experiments are needed.

Abstract

The biggest change occurring in the area of the highway Zagreb – Split is the degradation of the natural soil, especially its physical properties. The main objectives of this study were: (1) determine the physical properties of the soil in the area impact the highway (damaged soil) and outside these area (natural soil), and (2) determine the level, type and current processes of soil degradation. The research was conducted in 2006 on the section of the highway Zagreb - Split, from Gospić to Sveti Rok. Each of the 20 representative sites is divided into two sub sites: damaged soil and origin/natural soil to determine the condition and quality of the soil before and after the highway construction. The surface layer (0-10 cm) of damaged soils generally was less porous, smaller soil capacity for water and air, higher bulk density of soil, strong compacted, with more clay and unstable to a little stable macroaggregates. Excavation of topsoil, filling, and subsequently spreading new layers of soil in the lower horizons of the damaged soil contributed to the deterioration of its water and air conditions, poor infiltration, and difficulty in growing the plants. The results of the soil analysis as well as the state determinate in the field, indicating that the degree of soil degradation in the area of highway was extremely high. It is necessary to make repairs a unfavorable soil properties by agro ameliorative measures considering the plant requirements. Also, it is important to plan the full protection of the soil.

Keywords: *physical properties of soil, soil quality, highway, soil degradation.*

Introduction

Construction of highways as part of the global transport system is a fundamental condition for developing countries (Crnjak et al., 2008). The dynamic development of road transport leads to many unwanted consequences for man and the environment. The biggest problem in the impact zone of highways is the degradation of the natural soil in terms of pronounced changes in its physical, chemical and biological properties. For example, deterioration of soil structure, loss of organic matter and mineral nutrients in the soil, and loss of soil fertility (Zhao et al, 2007). Particle size distribution of the soil along highways is different than originally –natural soil- soil fertility and nutrient amounts are smaller, as same as the water capacity of soil, leading to a nearly irreversible damage to the soil (Shuqing et al., 2007). Only about 44% of the original soil can achieve quality improvement, and only after 10 years if stored 30% of the natural vegetation. Also along highways increases and bulk density of the soil, and the soil horizons are mixed and not consistent (Auerbach et al., 1997).The construction of the Zagreb – Split highway achieved better interregional connections within Croatian territory, but at the same time it actualized the problems of soil protection nearby the highway.Many relevant information related to the protection of the soil in the zone of the highway are scarce or have not been implemented in practice.

Therefore, the main objectives of this study werre: (1) determine the physical properties of the soil in the impact zone of the highway (damaged soil) and outside this zone (natural soil), and (2) determine the level, type and current processes of soil damage.

Materials and methods

The survey was conducted in 2006 in the area of the field called Ličko polje on the part of the highway Zagreb - Split, from node Gospić to Sveti Rok tunnel with a length of 39,927 m.Mostly part of the field is at 570-608 m a. s. l. with a flat to slightly wavy configuration of the terrain and dominated heaths and grasslands. Athough the route of the highway does not go into space Ličko polje, southern part of the route is nearing the Velebit mountain, and on the section of highway on the field no significant changes caused by the highway construction. As a part of field research, this route divided on 20 representative sites, and each site is divided into 2 subsites: damaged soil (within the 60 m width corridor of the highway) and natural soil (outside this zone), to determine the damage to the soil due to the operation carried out in the area. Ten sites were located along the highway in the direction of Split, and ten in the direction of Zagreb. On each subsites (total 40), was opened soil profile various depth, depending of soil type-and soil samples were taken for physical analysis only from topsoil (0-10 cm). Laboratory analysis of the basic physical properties of soils were determined based on ISO standards, or the manual for Soil Research (Škorić, 1982).

Results and discussion

During the study, at selected locations within the zone of the highway had been identified different causes and types of soil damage, Table 1.

Table 1. Causes and types of soil damage on route of the highway Gospić –Sveti Rok

Causes of soil damage	**Types and processes of soil damage**
Soil removing- the notchs construction	Excavation of entire soil profile- parent material on the soil surface (1,2, 4, 8,13,19 i 20)*
Soil removing – the slope embankment construction	Excavation the soil part and covering it with building and heterogenous soil materials without natural soil layers by filling, spreading and i planning (3,5, 6,7, 12, 14, 15, 16, 17,18)* Unfavorable ecological soil depth (7, 14, 18)*
Very strong slope, soil without vegetation	Active soil erossion processes (1,2,4, 8, 13, 18, 19, 20)* The occurrence of minor landslides (8 i 13)* Very collapsing of rock detritus (l 9, 10, 11)*
Small slopes	Soil erossion by rain (5, 12, 16)*
Soil degradation	Degradation of physical properties by compaction- heavy machinery and deposit of building materials (all locations) Degradation of chemical properties by alkalization – different building materials and waste were incorporated into soil (3, 5, 13, 15)* Degradation of biological properties (all locations)

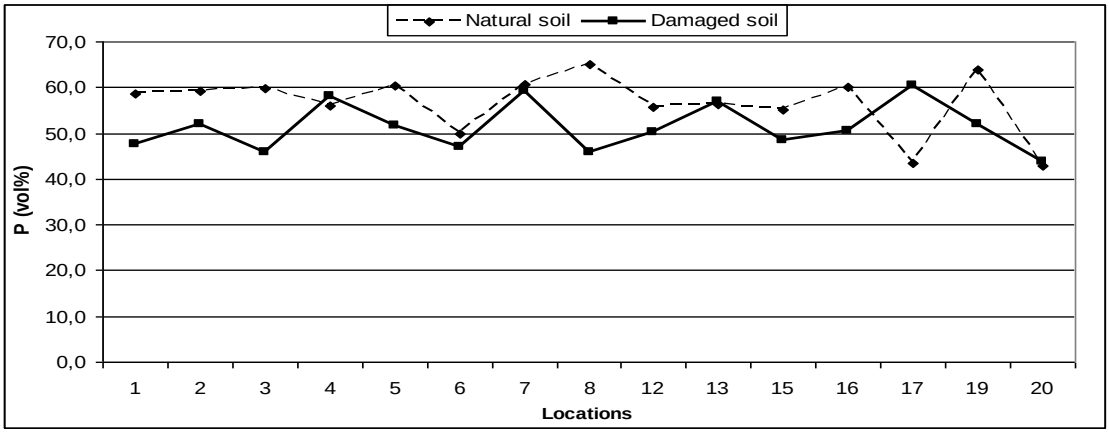
* These numbers is refer to the number of locations-site on the researched route

Rockiness and skeletal structure of soil at locations 9, 10 and 11 cause excessive drainage, as well as poor water retention by soil, and the emergence of strong erosion processes. Ecological soil depth, in the impact zone of the highway, was often limited due to the application of different types of substrates, the foundation (cot, buffer zones), building materials and waste, and

impermeable film and various installations. The slope of the hillside along the highway was often greater than 45 ° which lead to of different types and intensity of erosion processes but also disabled the retention of vegetation.

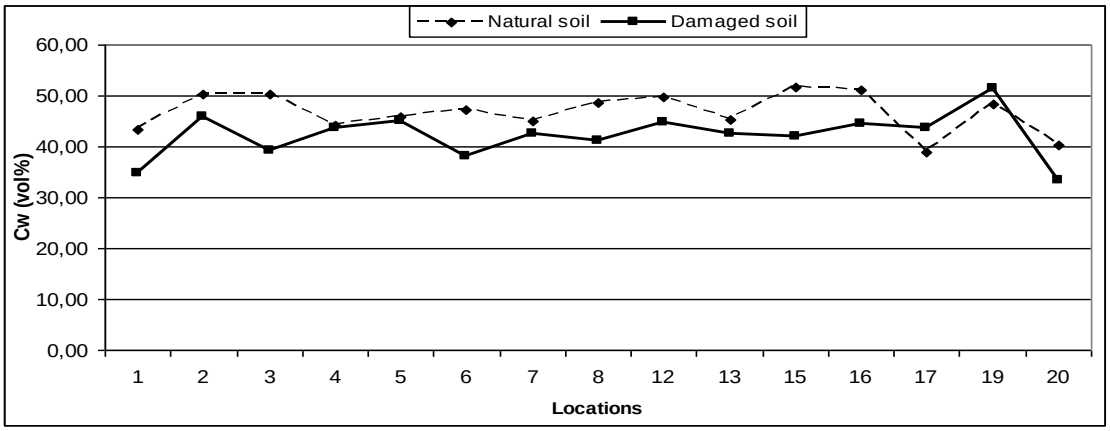
At some locations, the cuts in the highway zone, it was found the parent material on the soil surface as a result of the excavation and construction of cuts. The result is the loss of the entire soil profile. In the other sections, where the embankments were constructed, after opening the soil profile was observed the presence of the reclamation of crushed stone and heterogeneous soil materials, and the location 7 was set also impermeable film for the purposes of the closed drainage system. In these soils has not been natural horizons, but only heterogeneous artificial soil layers, which is confirmed by Jim (1997). The results of our study confirmed the Craul (1992), which is in several soil profiles in urban areas found there pedogenetic discontinuity caused by construction projects. The above construcions have influenced the change water and air relationship in the soil, poor infiltration, and thus difficult penetration of plant roots. Otherwise, in natural soils outside the zone of influence highway were identified the correct stratigraphy in soil profile.

This is a karst area (limestone and dolomite, limestone and dolomite breccia) that are typical proluvial and aeolian sediments from which they developed distric cambisol and luvisol. Due to filling and making watertight layers (cot, tampons) in the construction of the highway, coming to break the influence of the parent material on mineral detritus which entering the soil profile. The effects of the highway to change some important physical properties of the surface layer (0-10 cm) of natural and damaged soils are shown in graphs 1-5. The total porosity (P) on both soils varied from little porous to very porous soils. The porosity of the damaged soil, mainly the lower (43,8- 60,5% vol.) compared to the natural soil (43.0 -65.0% vol.), Graph 1.



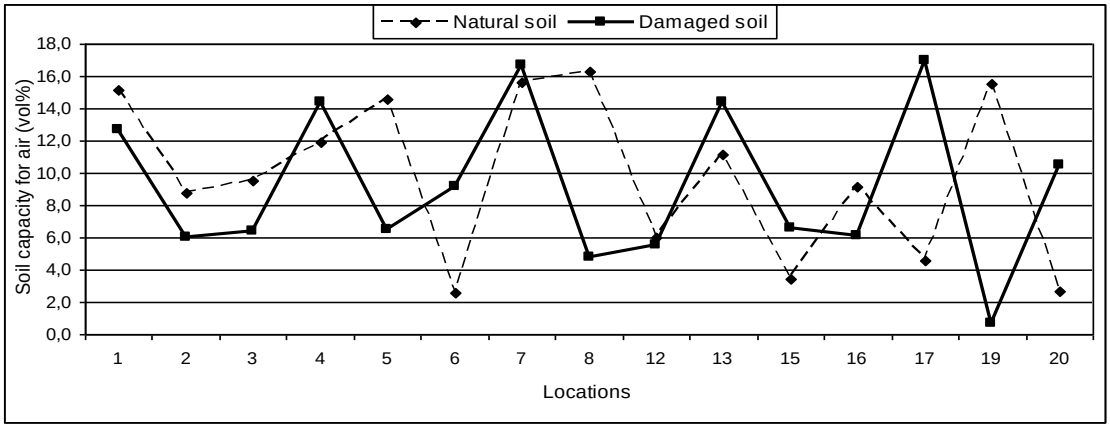
Graph 1. Total porosity (P) in surface layer (0-10 cm) of natural and damaged soil

Soil capacity for water (Cw) in natural soils was mostly larger than damaged soil had medium values. In natural soils, Cw were ranged from 39,0 to 51,8% vol. (medium to large Cw), and a na from 33,3 to 51,3% vol.in damaged soils (low to large Cw), Graph 2.



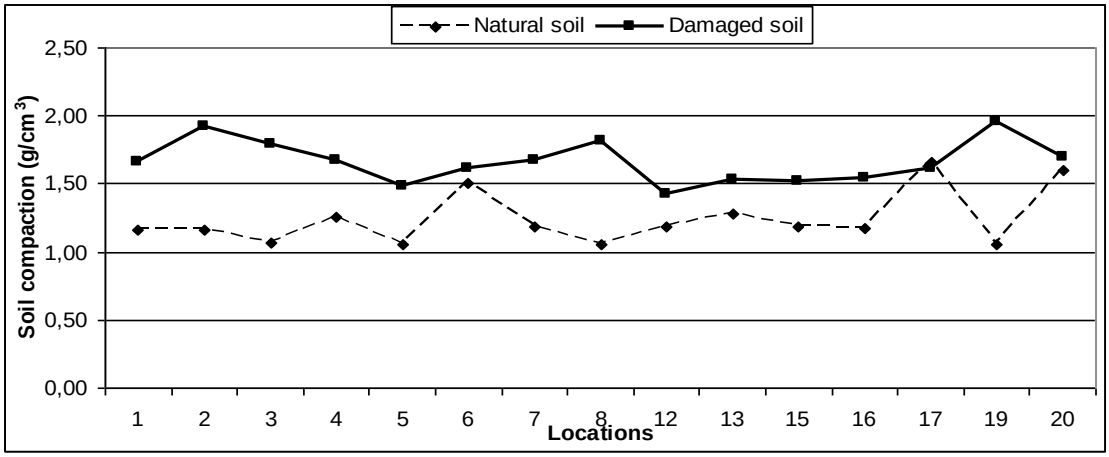
Graph 2. Soil capacity for water (Cw) in surface layer (0-10 cm) of natural and damaged soil

Soil capacity for air were in wide range from 2,6 to 16,3 % vol on natural soils and from 0,7 to 17,0 % vol on damaged soils. It was soils with very low to very large soil capacity for air, Graph 3. For 8 of the 15 locations of the damaged soils, soil capacity for air were less than 10%, and this value was considered as critical limit below which there was stopped of gas diffusion and reduced the hydrodynamic air permeability. In these conditions the roots of the grass stops growing, and other processes in the soil were slow down (mineralization of organic matter, changes of CO_2 and O_2 during respiration of plants and microorganisms in the soil), which stand out and Ćosic et al. (2005).

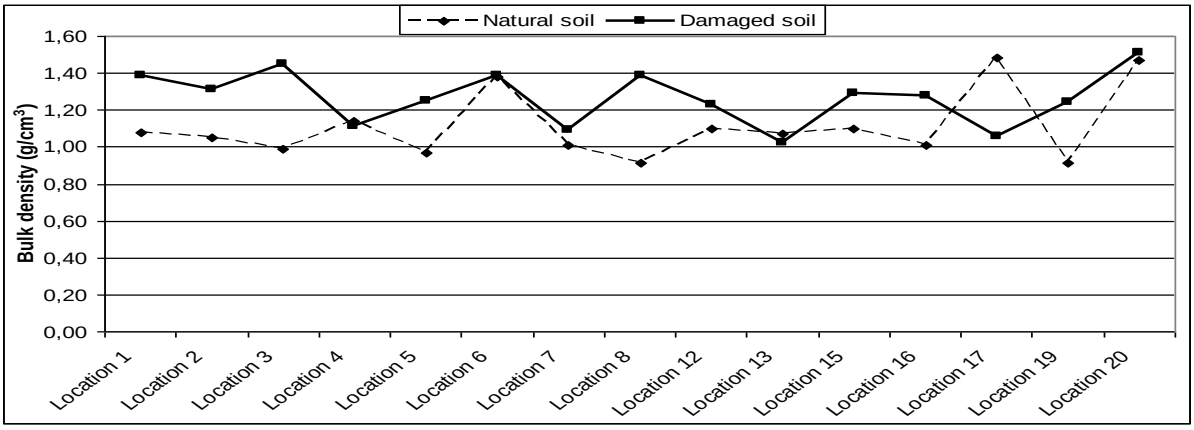


Graph 3. Soil capacity for air in surface layer (0-10 cm) of naturala and damaged soil

Soil compaction varied between the natural and the damaged soil. In the damaged soil, at all locations it was higher than the natural soil. In natural soil compaction is small to medium, from 1.05 to 1.66 g / cm^3, while the damaged soil medium to very strong (1.42 to 1.95 g /cm^3), Graph 4. Increased soil compaction was result of the use of heavy machinery, and various rock and / or soil material adverse hydraulic properties, which are mixed and used for reclamation and planning the slope of the embankment along the highway. Such a compacted layer of the thin material piled loose and shallow surface layer is the limiting factor in the spread of the root system of plants, but it is developed in the surface layer of the soil as evidenced Zisa et al. (1980).



Graph 4. Compaction in surface layer (0-10 cm) of natural and damaged soil



Graf 5. Bulk density (ρ_v) in surface layer (0.10 cm) of natural and damaged soil

Bulk density (ρ_v) in damaged soil was higher (1,02 - 1,51 g/cm^3) than natural soil (0,91 - 1,48 g/cm^3), Graph 5. Because of the increased bulk density of damaged soil,a slowdown water infiltration occurs, as well as increasing runoff of water across the soil surface and increasing the risk of soil erosion. As a result, there was the destruction of the sown grass species, especially on the locations 2,8 and 19, which is in accordance with studies Duffy and McClurkin (1974). Soil texture only at locations 5,6 and 12 was the same on both soils, but in damaged soils (locations 2, 4 7, 8, 13, 17, 19) was increased the clay content relative to the natural soil, Table 2.

Table 2. Analisys of soil degradation by changing soil texture

Intensity of change the soil texture*		**Number of locations**
Natural soil	**Damaged soil**	
SL	C	4
I	C	3
SL	SCL	2
SL	CL	1
SL	L	1
L	SaCL	1
No changes		3

* **Legend**: SL-silty loam; L-loam;SaCL–sandy clay loam;SCL- silty clay loam; CL-clay loam; C- clay

At the damaged soil was less stability of macroaggregates (completely unstable to a little stable), while the stability of microaggregates was higher (quite stable to very stable) in relation to the natural soil, Table 3. These results confirmed by Craul (1992), which found that interventions such as excavation, relocation and spreading influence the unstable structure of the topsoil.

Table 3. Analisys of soil degradation by changing soil structure

Intensity of change the soil macroagregates		No loc.	Intensity of change the soil microagregates		No loc.
Natural soil	**Damaged soil**		**Natural soil**	**Damaged soil**	
complete. stable	completely unstable	8	little stable	very stable	4

complete. stable	little stable	3	quite stable	very stable	3
quite stable	completely unstable	1	very little stable	quite stable	2
little stable	completely unstable	1	little stable	stable	1
unstable	completely unstable	1	unstable	little stable	1
No changes		-	No changes		2

During the construction of this highway, a major problem was a lack of specified measures for soil protection. Eg. It was not specified the manner in which the excavated material must deposit, and were not taken into account the pedological parameters such as porosity, structure, humus and soil capacity for water during the preparatory work on highway construction. In addition, the locations with visible soil and vegetation damages gave the impression of unattractive landscape and reduced visual quality of the landscape.

Conclusion

Soil degradation in the zone of Zagreb-Split highway were result of the relocation, excavation and filling with different building and soil materials. Consequences were: loss of part or the whole soil profile, soil stratigraphy changes, adverse physical soil properties and lack of ecological soil depth. In most locations, damaged soils had a lower porosity, capacity of soil for water and air, and a larger bulk density and soil compaction in relation to the natural soil. At 7 locations was increased clay content in the soil. In accordance with the condition of the soil in the field and the results of analysis of soil physical properties must be detailed corrected and improved conditions in the soil and to align them with the requirements of the plants. During the construction of new highways special attention should be paid to the soil protection.

Abstract

Farmers in the Gaza Strip are affected by the climate changes of temperature, humidity, wind, rain and frost which have caused economic losses of more than 80% of their agricultural production. The researchers conducted 11 workshops in five areas in the southern part of the Gaza strip (Abasan, Khuzaa, Al-Qarara, Al-Shoka and Al-Fokhary) in the period between1-17 December, 2015. It aimed to educate farmers about climate changes and its effects on agriculture sector. A structured interviewed questionnaire was used to collect data on climate change effects on the targeted farmers in SLCAL project. The total number of farmers who participated in the interviews in all areas was 206 participants. The researchers used the questionnaire as a tool for monitoring and identifying these changes in the Gaza Strip and how the farmers are dealing with these changes. The main indicators which were used to measure the climate change effects are: A) Temperature: Through the analysing the farmer's answers in different areas, where they mentioned that the crops affected by high temperature in all areas with a relative weight of 43.7%. B) Rain: The intensity of the rainfall negative impact was the greatest on agricultural crops in all areas and reached 45.3%. C) Humidity: Considering the effect of moisture on agricultural crops, results showed that the high humidity has the greatest impact rate which reached 59.3%. D) Wind: According to the farmers' opinions, it has been shown that all areas affected by wind in terms of intensity, speed and direction, relative weight were as follows 50% - 33.7% - 16.3%.

Keywords: *Evaluation, agricultural crops, climate changes, beneficiaries.*

Introduction

Climate change is considered one of the most important issues that have become the focus of the world attention due to the effects of these changes and their growing impact on the lives of people in all respects. The agricultural sector is considered one of the most important sectors affected by these changes because of its direct relation to the components and elements of climate change, which include temperature, humidity, wind and rain. Perhaps, concern of the impact of these changes on the agricultural sector and studying these impacts objectively is prioritized over the other sectors due to the importance of the agricultural sector in providing food security for citizens. Therefore, the study of the impact of these changes on the production volume of the agricultural sector, from one hand, and to study ways to reduce or adapt to those changes in order to reduce the size of the effects of those changes on farmers, the other hand, are some of the core issues that are of concern and debate in the Palestinian economic circles. This is due to the effect on Palestine in general by these changes and the Gaza Strip in particular. The project of "strengthening livelihoods through community adaptation and learning" (SLCAL) is one of the first pioneering piloting applied research projects in the Gaza Strip. This project is funded by

Federal Ministry for Economic cooperation and Development (BMZ)- Germany in partnership with Care international and implementing by Applied Research - Institute Jerusalem (ARIJ) and Earth and human centre for researches and studies – Gaza Strip (EHCRS). It studies the effects of climate change on the agricultural sector and conducts experiments and applied research to study the impact of these changes on the agricultural productivity of the sector, both on the field crops level or vegetables. Furthermore, this project introduces modern agricultural techniques and modern innovations as one of the experiences and important trends that can be generalized to a regional and international scale to limit the negative impacts of climate change on the agricultural sector, or at least adapt to them. Perhaps, one of the most modern technologies that have been used to reduce these changes is to follow the new patterns in irrigation such as the regular drip irrigation systems, and the use of improved varieties of field crops seeds adapted to climate change. In addition, other technologies can be used such as Hydrogel or mulch to reduce the volume of water losses and other technologies that will be displayed within this research paper. Studies of the Earth Research Centre and human experience of the first quality tests are also considered in this area in the Gaza Strip since this project meets the vision and mission of the centre. This vision focuses on finding new mechanisms and techniques to reduce life problems by using scientific research. Therefore, the results of this project have relied fully on the results of a real research process that used the experimental method to obtain the results that will be displayed. This study is an important reference for dealing with climate changes at the agricultural level. It highlights the most important instruments and methods that the farmer can use to face climate changes such as temperature, winds, humidity and fluctuations in rainfall. The study also constitutes an important tool to evaluate the effect of climate change on the changes of quality of agriculture in the past ten years and therefore to determine the adaptation policies with climate changes and the choice of suitable types of plants amidst these changes. In general, the study is an important tool for directing agricultural policies towards the best practices required to face climate changes according to the study results. The study is an important tool for researchers and specialists in both the agricultural and environmental sectors. This study conforms with the report of adaptation strategy with climate changes in the Palestinian territories (United Nations Development Programme/ Programme of Assistance to the Palestinian, 2009). The main dangers resulting from climate changes in achieving food and water security in the Gaza Strip have been determined. They are: changes in the areas of agricultural crops due to lack of optimal agricultural conditions, a decrease in the production of crops and livestock, increasing danger of water scarcity and drought and increasing irrigation requirements.

Materials and methods

First: Methodology of Data Collection:

Authors relied on the structured interview questionnaire tool in order to assess climate impacts on the target group of the SLCAL project. The methods to deal with these changes were 11 implemented workshops carried out in the intervention areas in various provinces in the southern Gaza Strip (Abassan, Khaza'a, Qarara, Shoka, Fukhary). The workshops explained to farmers the concept and the different forms of climate change and explained and clarified the questionnaire used for purposes of monitoring these changes in the Gaza Strip. It also aimed to identify how the farmers dealt with it during the past period. The researchers depended on the methodology of structured interviews in this questionnaire and the total number of targeted farmers in all implementation regions was 206. They participated in various workshops where their attitudes

about the impact of climate change on them and how to confront these changes in its various forms were monitored. The sample of farmers was chosen according to the various different geographical areas in the southern Gaza Strip.

Second: Systematic Data Analysis:

The researcher has adopted the comparative descriptive approach in the analysis of the data that was extracted. The results of the various questionnaires and workshops were analysed and summarized. The methodology conducted was the descriptive analysis approach and the results were presented using various tools, including charts and graphs, and others.

Results and discussion

First: The Impact of Climate Change on the Agricultural Sector:

The Effect of Temperature on the Agricultural Sector: According to the farmers' orientation and opinions about the effects of temperature in different areas, the table below describes the effect of the degree of temperature on agricultural crops.

Table1: Effect of temperature degree on agricultural crops

#	Climate effects	Degree	Mean	Molecular Weight	Standard deviation
1	Temperature*	Rise	1.69	43.7%	0.79
		Low	2.51	16.3%	0.56
		Frost	1.74	42%	0.79

Source: Analysis of farmers' point of view.

*We have relied on 1-3 scale where 1 is the class of high importance, while Class 3 low importance

Effect of Rain Cases:

According to the farmers' orientations and opinions about the effects of rain in different areas, the table below describes the raining effects on agricultural crops.

Table 2: Raining effects on agricultural crops.

#	Climate effects	Ways	Mean	Molecular Weight	Standard deviation
2	Raining	Quantity	1.96	34.7%	0.7
		Description	2.37	21%	0.69
		Degree	1.64	45.3%	0.87

C. Humidity: The table below describes the ways that the farmers used to deal with changes especially, with humidity and also the percentage of farmers that used each way

Table 7: The farmers used to deal with climate changes especially, with humidity

Humidity	Ways		Farmers %
High humidity	Ventilation the greenhouses		70%
	Decrease Irrigation and use pesticides		15%
	Others	Use fire for heating	15%
Low humidity	Increase irrigation		65%
	Ventilation and heating the crops		14%
	Others	Use pesticides No action	21%

Source: Analyses of Farmers point of view.

How to Deal with the Wind Changes: The table below refers to the ways and mechanisms used by farmers to deal with climate change, particularly with regard to strongly wind.

Table 8: The ways how the farmers deal strongly wind

#	Winds	Ways		Farmers %
1	Speed	Put barrier		43%
		Planting high trees		47%
		Others		10%
2	Direction	Change the direction of farm		30%
		Planting high trees		51%
		Others like planting crops with strong stalks		19%
3	Degree	Planting high trees		80%
		Put nylon around crops		12%
		Others	Put fence around farm	8%
			Spray hormones to Install the flowers	

Source: Analyses of Farmers point of view

Conclusion

The Gaza Strip has been affected by varied temperatures over the past years. The effect of high temperature has had the utmost importance for farmers where this situation led to the burning and wilting of crops, in addition to the droughts of different varieties of crops which led to damage in many seasons. Also, it has been affected by different rain rates over time. Cases of severe rain have had the greatest impact on farmers as one of the most important forms of climatic change. This situation has led in many cases to the erosion of the soil and the destruction of agricultural crops in the Gaza Strip. High humidity levels have had the biggest impact on farmers in the various areas where they have led to plant pathology and burn and damage to the crops. Cases of high winds are important phenomena associated with climate change in the Gaza Strip. The effect was on the largest agricultural crops in different areas where the impact led to cracking and dislocation of crops and trees and damage to the crops. One of the main methods used by farmers to cope with cases of high temperatures are irrigation water workshops (53%), while 17% used ventilation to cope with this situation method and 30% used other methods to cope with those changes. The establishment of fences and barriers are some of the most important methods used by farmers to cope with cases of severe rain. 65% of them use this method. 20% of them set up drainage channels for water to cope with this situation, while 15% of them use other methods. Most farmers resort to ventilate greenhouses in case of high humidity rates. 70% of farmers use this method. 15% of them resort to reducing the rates of irrigation and spraying fertilizers in this case. 15% use other methods. In cases of high winds, 80% of farmers turn to the cultivation of high trees and the establishment of screens to protect agricultural crops, while 12% of them resort to nylon to develop and mesh crops to protect them. 8% resort to the use of other methods to deal with this situation.

Abstract

Study "Behaviour of several apple (*Malus domestica* Borkh.) cultivars grown under agro-ecological conditions of Gjakova, Kosovo", was carried out during the period 2014-2015, in Skivjan, Gjakova, in an apple orchard planted in 2006, using grafted seedlings over M9. Apple trees were planted in distances 3.8 m x 1.8 m (1460 trees/ha). Six apple cultivars (variants) (Montear Gala, Royal Gala, Red Falstaff, Saturn, Jonagored, and Golden Delicious), 4 replications, with 5 apple trees for each variant on each replication, were used. There was found that there were significant differences between cultivars for flowering period and duration. Montear Gala bloomed the first (April 26), followed by Royal Gala (April 27), Red Falstaff (April 29), Saturn (May 10), and Jonagored (May 12). Flowering duration varied from 13 days, for the earliest cultivar (Montear Gala) to 9 days, for the latest cultivar (Jonagored). At harvest time, there were measured, evaluated, accounted and compared several quality indicators, such as moisture content (%), total soluble solids content (^{o}Brix), dry matter content (%), total acidity (mg/100 g), and vitamin C (mg/kg). DMC varied from 14.2% (Saturn and Montear Gala) to 16% (Golden Delicious), TSSC varied from 11.46^{o}Brix (Royal Gala) to 12.8^{o}Brix (Saturn), TA varied from 0.25 (Saturn) to 0.395 mg/100 g, and vitamin C varied from 195 mg/kg (Red Falstaff) to 230 mg/kg (Montear Gala). Observed differences between cultivars were significative and statistically confirmed by ANOVA, while, there was found a strong relationship between chemico-technological features of the apple fruits (r >0.9).

Keywords: *apple cultivar, blooming period, chemico-technological features, duration, orchard.*

Introduction

Apple is one of the most important fruit in the world which, due to its high nutritional value, ranks thirds in consumption, after citrus and banana (UIE, 2013). The total world apple production for 2012 was 76 378 700 tonnes (FAO, 2014), where China is in the first place by 37 001 601 tonnes, followed by USA with 4 110 050 tonnes, Turkey by 2 889 000 tonnes, Poland by 2 877 340 tonnes, India by 2 203 400 tonnes tonnes, Italy by 1 991 310 tonnes, and so on (FAO, 2015; Ferraj & Thomaj, 2014). Apple tree belongs to Family Rossaceae, Genus *Malus*, Species *Malus domestica* Borkh., with several types which can be easily grafted (Pollan, 2001). There are more than 7500 known cultivars of apples, resulting in a range of desired characteristics. Apple tree is very well adapted in different climate conditions, that's why it is widespreaded in different eco-geographical regions. The original wild ancestor of *Malus domestica* was *Malus sieversii*, found growing wild in the mountains of Central Asia in southern Kazakhstan, Kyrgyzstan, Tajikistan, and Xinjiang, China (Pierre-éric *et al.*, 2006; Janick *et al.*, 1996). The most decisive role in the creation of new cultivars and rootstocks belongs to wild apple, *Malus sylvestris, Malus sieversii (Kaukazian apple), Malus pumila,* and *Malus floribunda* (Mehinagic *et al.*, 2004).

Blooming and yield features of apple cultivars depends upon to cultivar and the climate conditions of the region. There exists a strong interaction and relationship between blooming features and yield of apple (Shala, 1995). There is a need for the raise of knowledge of differences and behavior of different cultivars, and relationship between blooming and yield features, as well, for the raise of investments effectivity (Stainer *et al.*, 1996). Such features like starting and ending time of flowering, as well as the duration of flowering, are very important for a good regionalization of apple cultivars and to determine the right variety structure (De Long *et al.*, 1999). Fruit features, such as dry matter content, total soluble solution content, total acidity, mean fruit weight, color and fruit firmness, shape and flavor, etc, are very important for the final product destination (De Jager & Roelofs, 1996). Knowing the expression level of productivity features under certain climate and land conditions helps the improvement of variety structure and the better regionalization of varieties for fresh consumption and for agro-industry (Lind *et al.*, 2003). Starting and ending time of flowering, as well as chemico-technological features, are different for different cultivars, even for the same cultivar in different climate and land conditions (Ingle *et al.*, 2000). Market and consumers require fresh apples with a good commercial appearance, uniform size and color, specific taste and flavor (Aaby *et al.*, 2002). Total soluble solids content, organic acids content, aromatic and phenolic compounds are very important for consumer and alimentary industry. Fresh apple fruits contain mineral salts, vitamins and phytochemicals, such as carotenoids, flavonoids and phenolic acids. Consumer is interested especially for chemical compounds of apples as very important antioxidants for human organizm (Ackermann *et al.*, 1992). Nowadays, the farmers are working for constructing of new, highly sustainable and intensive orchards, which express high biological and productivity characters, using densed planting, with lower crop loads and bound forms, etc (Awad & De Jager, 2002). Observed results of different cultivars for productivity features were subject to ANOVA Test ($p \leq 0.05$), while for the analysis of relationship between features with reciprocal effect, the correlation analysis was used (Lekaj *et al.*, 2014).

Materials and methods

Experimental design. The study of determination of blooming period and fruit chemico-technological features of several apple cultivars grown under agro-ecological conditions of Gjakova, Kosovo, was carried out during the period 2014-2015, in Skivjan, Gjakova, in an apple orchard 400 m elevation, planted in 2006, using grafted seedlings over M9. Apple trees were planted in distances 3.8 m x 1.8 m (1460 trees/ha). A randomized complete design with four replications and six variants (apple cultivars) (Montear Gala, Royal Gala, Red Falstaff, Saturn, Jonagored, and Golden Delicious), with a plot size of 5 apple trees for each variant on each replication, were used. Apple trees were selected with an uniform vigor and size. Study was focused on determination of starting, duration and ending time of flowering, and determination of the chemico-technological features of apples.

Determination of starting, duration and ending time of flowering was evaluated on a representative samples of 5 branches for each apple tree of each cultivar on each replication. Branches were taken randomely in different parts of the crop load. For each branch and apple tree of each cultivar on each replication, there were counted all the buds and flowers. Starting stage was evaluated when 15% of the total buds have bloomed and ending stage when >70% of the total buds have bloomed.

Determination of fruit chemico-technological features. Apple fruits were harvested at the commercial maturity stage (Ullah *et al.*, 2004). Prior to the measurement of quality attributes, fruits were allowed to attain the room temperature. Fruit chemico-technological analyses were

carried out at the Lab of the Agriculture Institute of Peja, Kosovo. There were measured the below mentioned features: fruit moisture content (FMC - %), dry matter content (DMC - %, total soluble solution content (TSSC - ^{o}Brix), total acidity (TA – mg/100 g fresh apple fruit), and vitamin C (ascorbic acid) content (AAC) (mg/kg).

The future investment on apple orchard construction and determination of the variety structure in Gjakova region must take into consideration the chemico-technological features of apples and the production destination.

Statistical analyses. The obtained data were subject to ANOVA-test ($p \leq 0.05$), LSD ($p \leq 0.05$) and correlation analysis (Lekaj *et al.*, 2014).

Results and discussion

Climate conditions of the lower part of Gjakova. The lower part of Gjakova is being characterized by relatively high mean annual temperature (11^{o}C), mean temperature of the hottest months (July and August) is 21.6 and 21.7^{o}C, while for the coldest month (January), mean temperature -0.5^{o}C, with a mean amplitude of 22.2^{o}C. In Gjakova, there is more than 60.5% of the year with full solar radiation, while the annual relative air humidity is about 79.3%. At the driest month (September), the relative air humidity is 68.9% and at the wettest month (November), the relative air humidity is 88.6%. During the period March-September, there is an uniform and normal distribution of precipitation. All the above mentioned climate conditions make the Gjakova's region a very suitable area for apple cultivation.

Starting, ending, and duration period of flowering (days). There were observed significant differences between cultivars for the stage of flowering. Flowering period depends on the cultivar's characteristics, air temperature and realtive air humidity. The earliest apple cultivar for flowering was Montear Gala, which blooms on April 24, followed by Royal Gala (April 26), Red Falstaff (April 27), while the latest cultivar was Jonagored, which blooms on May 10 (Table 1).

There were observed significant differences between cultivars for the duration of flowering period (days). There was observed that between starting of flowering, daily mean temperature and flowering duration exists a strong positive relationship, i.e., Montear Gala, which bloomed the first, when daily mean temperature was lower, showed the longest flowering period (14 days), while Jonagored, which bloomed the last when daily mean temperature was higher, showed the shortest flowering duration (10 days) (Table 1).

Table 1. Starting, ending and duration of flowering period of apple cultivars under Gjakova climate conditions (mean values, different letters indicate significant differences at $p \leq 0.05$)

Cultivar	Flowering		
	Starting (15%)	Ending (>70%)	Duration period (days)
Montear Gala	April 26	May 09	14 c
Royal Gala	April 27	May 09	13 b
Red Falstaff	April 29	May 11	13 b
Golden Delicious (clone B)	April 30	May 10	11 ab
Saturn	May 10	May 22	12 ab
Jonagored	May 12	May 22	10 a

Taking into consideration the starting and duration of flowering, for Gjakova climate conditions, the most interesting cutivars were Jonagored, Golden Delicious (clone B), and Saturn, because of

late and short duration of flowering, avoiding the peak bloom during late spring precipitation, cloudiness and cold temperatures in late April and early May.

Apple fruit quality (chemico-technological) indicators. Ripening time and harvest, as well as fruit quality indicators, depend on the cultivar. Observed results showed that there exist significant differences between cultivars for dry matter content (DMC - %) [as well as, moisture content (MC - %)], total soluble solids content (TSSC - ^{o}Brix), total acidity (TA - mg/100 g fresh apple fruit), and ascorbic acid (vit C) content (AAC - mg/kg). The highest DMC (%) was observed for Golden Delicious (clone B) (16.7%), followed by Royal Gala (16.5%), while the lowest DMC was observed for Montear Gala and Saturn (14.6%). The highest TSSC (^{o}Brix) was observed for Saturn (12.7^{o}Brix), followed by Red Falstaff (12.4^{o}Brix), while the lowest TSSC was observed for Royal Gala (11.33^{o}Brix). The lowest TAC (mg/100g) was observed for Saturn (0.250 mg/100g), followed by Red Falstaff (0.275 mg/100g), while the highest TAC was observed for Royal Gala (0.395 mg/100g). The highest vitamin C (AAC - mg/kg) was observed for Montear Gala (230 mg/kg), followed by Saturn (201.7 mg/kg) and Golden Delicious (clone B) (210 mg/kg), while the lowest AAC was observed for Red Falstaff (195 mg/kg) (Table 2).

Table 2. Fruit chemico-technological indicators [dry matter content (DMC - %), total soluble solids content (TSSC - ^{o}Brix), total acidity (TA - mg/100 g fresh apple fruit), and ascorbic acid (vit C) content (AAC - mg/kg)] of cultivars under study (mean values, different letters indicate significant differences at $p \leq 0.05$)

Cultivar	DMC (%)	MC (%)	TSSC (^{o}Brix)	TA (mg/100g)	AAC (mg/kg)
Montear Gala	14.6 ^{c}	85.4	11.80 ^{a}	0.280 ^{d}	230.0 ^{a}
Royal Gala	16.5 ^{a}	83.5	11.33 ^{a}	0.395 ^{a}	203.3 ^{c}
Red Falstaff	15.6 ^{b}	84.4	12.40 ^{a}	0.275 ^{a}	195.0 ^{d}
Golden Delicious (clone B)	16.7 ^{a}	83.3	12.33 ^{a}	0.314 ^{d}	210.0 ^{b}
Saturn	14.6 ^{c}	85.4	12.70 ^{a}	0.250 ^{e}	210.7 ^{b}
Jonagored	16.1 ^{ab}	83.9	12.10 ^{a}	0.355 ^{b}	206.3 ^{c}

Correlation analysis for fruit quality indicators showed that there existed a strong relationship between MC (%) and DMC (%) (r = 0.9743), a medium strong relationship between DMC (%), TSSC (^{o}Brix), and TAC (mg/100 g fresh fruit) (r = 0.7512 and r = 0.774, respectively), and so on, while between some other indicators existed a weak relationship ($r < 0.7$) (Table 3).

Table 3. correlation analysis for the relationship between fruit quality indicators

Quality indicators	*MC (%)*	*DMC (%)*	*TSSC (%)*	*TAC (mg/100 g)*	*AAC (mg/kg)*
MC (%)	1				
DMC (%)	0.9743	1			
TSSC (%)	0.9764	0.7512	1		
TAC (mg/100 g)	0.58347	0.7743	0.77861	1	
AAC (mg/kg)	0.5140	0.5472	0.1834	0.2764	1

Differences between cultivars for fruit quality indicators were significant and statistically confirmed by ANOVA-test [F_{llog} =23.4782 > F_{crit} = 2.8012 dhe 194.8 > 3.26782, and *P-value* (0.00031 < α = 0.005)] (Lekaj *et al.*, 2014) (Table 4).

Table 4. Results of ANOVA-test for the relationship between apple fruit chemico-technological indicators

Source of Variation	F_{llog}	*P-value*	F_{crit}
Variants (cultivars)	23.4782	0.00031	2.8012
Indicators	194.8	2.7E-12	3.26782

Apple fruit chemico-technological indicators determine the product destination. Apples with higher DMC must be used by the alimentary industry for compotes and marmalades, while them with lower DMC and higher moisture content and higher vitamin C content can be used for apple juice, and so on. Taking into consideration all the above fruit quality indicators, Golden Delicious (clone B), Jonagored and Royal Gala, can be used for fresh consumption, Saturn, Montear Gala and Red Falstaff for apple juice, and so on.

Conclusions

Apple cultivars, grown under Gjakova, Kosovo, agro-ecological conditions, showed significant differences for time and duration of flowering, and apple fruit quality indicators. Montear Gala started the flowering the first (April 24), followed by Royal Gala (April 26), Red Falstaff (April 27), while the latest flowering cultivars were Saturn (May 07) and Jonagored (May10). There existed a strong relationship between flowering duration and daily mean air temperature. Montear Gala, which started the flowering the first, showed the longest flowering duration (14 days), while, Jonagored, which started the flowering the last, showed the shortest flowering duration (10 days). Taking into consideration the late spring precipitations and lowe daily mean temperatures, Golden Delicious (clone B), Saturn and Jonagored showed to be very interesting cultivars. At the same time, those cultivars showed high apple fruit quality, as well. Fruit quality indicators must be taken into consideration for the final product destination, fresh consumption or alimentary industry (apple juice, compotes and marmalades).

QUALITY ANALYSIS OF THE MISCANTHUS X GIGANTEUS BIOMASS CULTIVATED IN AGROECOLOGICAL CONDITIONS OF THE REPUBLIC OF SERBIA

Jelena MAKSIMOVIĆ[1*], Željko DŽELETOVIĆ[2], Zoran DINIĆ[1], Aleksandra STANOJKOVIĆ-SEBIĆ[1], Radmila PIVIĆ[1]

[1]Institute of soil science, Teodora Drajzera 7, Belgrade, Serbia
[2]Institute for the Application of Nuclear Energy, Banatska 31b, Zemun, Serbia*Corresponding author: jelena.maks@yahoo.com

Abstract

The paper presents the results of the quality of Miscanthus biomass grown in two locations in the Republic of Serbia, on two soil types with different production capabilities (Luvic Chernozem and Calcic Gleysol). Chemical parameters of Miscanthus biomass were obtained by analyzing leaf and stem of Miscanthus at the end of the third year of cultivation on experiment variants with the following structure of the rhizomes planting: 2 and 3 per m^2. By examining the content of total forms of potassium, phosphorus, calcium and magnesium, it was found that the values of those parameters are within the range of values that are confirmed and exercised in a variety of research in Europe. By analyzing the values of the results of chemical analysis of biomass, difference is noticeable in the most of the examined parameters obtained in leaf and stem from different localities. The most significant is the increased content of calcium in leaf of Miscanthus grown on Calcic Gleysol. The values of examined parameters obtained are below the critical values for solid fuels. Preliminary research results show that Miscanthus grown in the Republic of Serbia, both on soils suitable for intensive crop production, such as chernozem, could be also grown on soil with slightly unfavorable production capacity as Calcic Gleysol. Research is needed to expand both trials set up on marginal soils, or in areas where it is necessary to conduct remediation and supplemented by additional physical-chemical analyzes of biomass, in order to give a complete assessment of the possibilities for exploitation of the Miscanthus biomass as a biofuel.

Keywords: *Miscanthus, quality biomass, Luvic Chernozem, Calcic Gleysol*

Introduction

The global problem of energy insecurity and effects of climate change are inevitable occurred by emissions of gases causing the effect of "greenhouse" imposes the need to increase the share of environmentally friendly energy sources. Solar energy, wind, water and biomass energy crops are CO_2 - neutral energy sources (Lewandowski and Kicherer, 1997). Crop farming plants that with annual production of biomass can provide sufficient quantities of raw materials for biofuels also belong to the group of energy crops (Glamočlija et al., 2012).

Miscanthus (*Miscanthus x giganteus* Greef et Deu.) is considered to be the most promising crop for the production of bioenergy in Europe (Lesur et al., 2014).

It is harvested each year and has a very high yield potential, which is a prerequisite for the efficient production of bioenergy (Dželetović et al., 2013). Miscanthus biomass combustion is discharging into the atmosphere the same amount of carbon dioxide that plants incorporate into

the organic substance during the growing season, which significantly reduces the "greenhouse effect" (Christian et al., 2008).

Brosse et al. (2012), and Lewandowski and Kicherer (1997) quotes that the biomass of Miscanthus can be used for combustion in the form of bales, pellets or briquettes, or after the transformation of lignocellulose as liquid and gas biofuels. In addition, biomass can be used to produce biodegradable products, as ecological building material and for soil reclamation (Dželetović and Glamočlija, 2011).

Biochar obtained by pyrolysis process of Miscanthus can be used to repair the physical and chemical properties and increase the soil fertility (Melligan et al., 2012). Due to its high productivity, its tolerance to abiotic and biotic stresses, and its biomass with multiple uses, the perennial grass Miscanthus is considered as a suitable candidate plant to couple management of metal-contaminated lands and biomass production (Nsanganwimana et al., 2016). This plant species is an important candidate for phytoremediation of heavy metals in the soil (Hartley et al., 2009) while Jones et al. (2006) proposed it for the remediation of soil leachate. Wanat et al. (2013) emphasize that *Miscanthus* × *giganteus* can grow on contaminated soils and thereby perform short term role of phyto-stabilization without additional investment in soil reclamation.

The final product and the purpose of growing Miscanthus is its combustion or conversion to some other form of fuel. Since the commercial yield is reached only after the third year of cultivation, the content of total forms of potassium, phosphorus, calcium and magnesium during this period is an important indicator of the quality of biomass. High yields and chemical composition of its biomass recommend Miscanthus for combustion (Milovanovic et al., 2011).

Compared with wheat straw or other ligno-cellulosic species, the mineral content of Miscanthus is lower, while is higher than the mineral composition of biomass in dense plantations of willow tree, or in short rotation planting of poplar tree (Lewandowski et al., 2000).

The characteristics of biomass can significantly vary between years and locations of planting (Lewandowski and Kicherer, 1997). These authors point out that the contents of water and mineral salts are significantly lower in biomass of Miscanthus grown in warmer climates.

Harvesting time, preferably, should be after the end of the winter. This is very important due to a fact that by completion of the vegetation period, mineral salts from the aboveground part of the plant move to the rhizomes. This gives the plant strong independence for the following growing season.

Through maturing of the plant, Cl, K, and other elements move from the above ground parts of the plant to the rhizomes, causing the changes in the composition of the leaves (Lewandowski and Kicherer, 1997). During the autumn and winter, fallen leaves remain on the soil surface, increasing the quality of biomass combustion, primarily due to lower content of nitrogen.

Mineralization of the leaves remains enriches the surface layer of soil, and some authors point out that Miscanthus and thus supplying additional nutrients and does not depend excessively on the supplemental feeding. The nitrogen content in the plant material is mainly responsible for the emission of NOx gases during the combustion process; therefore, the primary aim should be the production of biomass with low concentrations of said element (Lewandowski and Kicherer, 1997).

Despite biomass losses during winter, Miscanthus is usually harvested at the end of the winter to improve combustion quality, to reduce the energy demand for drying (Lewandowski and Heinz, 2003) and to enable nutrient recycling between the aboveground and belowground biomass (Cadoux et.al, 2012, Lesur-Dumoulin et al., 2016).

The high efficiency of nitrogen results in biomass with a low concentration of N, which is highly desirable for direct combustion with the aim of minimal environmental pollution (Miguez et al., 2008).

In Serbia, there are relatively a favorable agroecological conditions for growing this plant (Dželetović et al., 2014-a). Except for experimental purposes, surface area for commercial growing of Miscanthus for bioenergy, is constantly increasing.

The aim of this study was to examine the quality of Miscanthus biomass grown on two different locations in wider area of Belgrade, as the basis of its suitability for further use.

Material and

Field experiments were set in the period from 2011 to 2014 at two locations: experimental field INEP, Zemun on soil Luvic Chernozem, and experimental field in Grabovac near the thermal power plant Nikola Tesla Obrenovac on soil Calcic Gleysol. The basic characteristics of the soils are shown in Table 1. According to WRB classification (2014), Luvic Chernozem has clay loam texture, while Calcic Gleysol belongs to the clayey soils. Chemical properties of soils indicate that Luvic Chernozem is acidic in soil reaction, medium provided with easily available potassium, low provided with easily available phosphorus, medium provided with organic matter and total nitrogen and with a high content of tradable calcium and magnesium. Calcic Gleysol is neutral in soil reaction, medium provided with available potassium, medium supplied with available phosphorus and total nitrogen, low in organic matter and with high content of tradable calcium and magnesium (Šestić et al., 1969).

Table 1. Locations of experimental fields planted with Miscanthus, texture class and chemical properties of soils

Location	INEP - Zemun	Grabovac - Obrenovac
Coordinates	44°51' N, 20°22' E	44°37' N, 20°6' E
Texture class	Clay loam	Clay
Soil type	Luvic Chernozem	Calcic Gleysol
Chemical properties	Average values	
pH (H_2O)	6.36	7.84
pH (1M KCl)	5.44	6.76
Total N (%)	0.13	0.16
Available P_2O_5 (mg $100g^{-1}$)	9.26	10.82
Available K_2O (mg $100g^{-1}$)	15.4	20.23
Available Ca (mg $100g^{-1}$)	384.18	750.01
Available Mg (mg $100g^{-1}$)	43.38	111.44
SOM Organic matter (%)	2.22	1.23

The production technology is the standard applied agricultural technology (Dželetović et al., 2006), with the structure of planting the rhizomes: 2 and 3 per m^2. Manual harvesting of Miscanthus was carried out at the end of the winter, during the period when the trees had the lowest moisture content. For the chemical analysis of biomass it is used the yield from the third year of cultivation, because in this period the plant reaches a maximum yield rate (Dželetović et al., 2009). The analyses of aboveground parts of plants were done separately, tree and the leaves were analyzed individually. Chemical analyses of the plant material is determined by the value of biomass for its use as energent. Overall patterns of potassium, phosphorus, calcium and

magnesium were determined by destruction of 1g of plant material after dry ashing at 500°C, added nitric and hydrochloric acid, to complete the destruction of organic matter. From the resulting filtrate it was determined the phosphorus content (spectrophotometrical) and potassium (flame emissionphotometric). Ca and Mg were determined by atomic adsorption analyzer SensA Dual (GBC Scientific Equipment Pty Ltd, Victoria Australia) (Helrich, 1990). The contents of total forms of carbon, nitrogen and sulfur in Miscanthus plant material were determined by elemental analysis on CNS analyzer Vario EL III (Nelson and Sommers, 1996).

The climatic parameters, meaning the data on monthly rainfall and average monthly air temperature for the area of study, were obtained from the Republic Hydrometeorological Service of the Republic of Serbia. Both sites had an unfavorable water regime in 2011 and 2012 because the total rainfalls were less than the long-term average and below 600 mm which is considered the minimum quantity for the growth and development of Miscanthus (Tuck et al., 2006). Slightly more favorable in terms of rainfall was 2013, while 2014 had an annual sum of rainfall of 1095 mm, which is significantly higher than the average for this area. The annual air temperature during the study was higher than the multi-year in average 0.6°C to 1.5°C. Average air temperature during the growing season compared to a multi-year period, was also higher in all four years of research from 0.1°C in 2014 to 2.5°C in 2012.

Results and discussion

By analysing the Miscanthus biomass it was determined low nitrogen content in the stems of Miscanthus grown on Calcic Gleysol (0.15%), which was below the limit of available published results of other authors, while slightly higher range was determined in the stems sampled on Luvic Chernozem (0.15 to 1.23%) (Table 2). Differences in concentrations that depend on location were also recorded by Dželetović et al. (2014). Jorgensen (1997) points out that the average nitrogen content in the dry biomass of plants over a three year growing period was 0.59%. Similar results were obtained by Lewandowski et al. (2000), in the harvest in early spring nitrogen content were ranged from 0.2% to 0.6%. The contents of K and Ca in the Miscanthus plants grown on Calcic Gleysol were within the limits of results obtained by other authors (Beuch, 1998; Lewandowski et al., 2000).

High concentration of K and Ca in plants from Luvic Chernozem was confirmed in previous research of Dželetović et al. (2014). Depending on the location, these authors recorded the varying levels of potassium from 4.35% to 4.43% in the peak part of the stems. The content of phosphorus in the tree Miscanthus grown on Luvic Chernozem ranged from 0.06 to 0.21%, which is similar to the values obtained by Lewandowski et al. (2000). High levels of phosphorus in plants from Calcic Gleysol (0.34%) were confirmed by the results of Dželetović et al. (2014) in Miscanthus biomass grown in the area of Vranje, where it was obtained 0.37% of this element in the tree. The specific content of Mg was also in the range of values established by named researchers. The analyzed plant material contained low concentrations of sulfur (1-2 g kg^{-1}), and the results are within the permissible limit which can furtherly be reduced by proper combustion technology (Lewandowski and Kicherer, 1997). Carbon content (40.91 to 47.91%) in the analyzed plant material is considerably lower than the value of 47.8 to 49.7% by results published by Lewandowski et al. (2000). Content of S does not affect the release of harmful gases with the effect of "greenhouse gases" because the carbon during the growing season was formed by photosynthesis and as such represents a biochemically neutral element. The mineral content in Miscanthus biomass from both tested sites was below the critical values for solid fuels (Lewandowski and Kicherer, 1997).

By observing the chemical composition of the leaf and stem of Miscanthus, there is a difference which is certainly expressed for each element between the localities of Miscanthus cultivation. Besides the differences that occur between sites, for certain elements it has been identified the differences on the site (Table 2). Similar results were also obtained by Lewandowski et al. (2003). This is the most evident for the increased content of Ca in leaf of Miscanthus grown on Calcic Gleysol.

Table 2. Chemical composition of Miscanthus biomass

Location/ soil type	Planting density (m^{-2})	Plant part	Chemical composition (%)						
			N	P	K	Ca	Mg	C	S
Zemun/ Luvic Chernozem	2 rhizomes	leaf	1.55	0.18	0.17	0.48	0.06	42.73	0.18
		stem	0.15	0.06	0.17	0.16	0.05	45.38	0.14
	3 rhizomes	leaf	2.14	0.10	0.28	0.09	0.06	42.60	0.14
		stem	1.23	0.21	2.77	0.25	0.11	40.91	0.17
Grabovac/ Calcic Gleysol	2 rhizomes	leaf	0.95	0.36	0.14	0.68	0.12	45.96	0.15
		stem	0.15	0.34	0.12	0.16	0.09	47.37	0.11
	3 rhizomes	leaf	0.95	0.31	0.11	0.71	0.10	46.16	0.12
		stem	0.15	0.34	0.30	0.14	0.08	47.91	0.10

Conclusion

Chemical analysis of Miscanthus biomass indicates that there is an impact of the site on the quality of Miscanthus biomass. The analysis of the tested parameters of biomass and comparing with critical values proposed for solid fuels, it can be noted that Miscanthus grown at both sites where the research was conducted, is suitable for use as biofuel. In further research, for a more detailed consideration of the use of Miscanthus as a biofuel, it is necessary to expand research on more sites and soil types in order to obtain the valid data on the suitability for cultivation and quality of the resulting biomass. This applies particularly to the research to be carried out on marginal soils and soils that need remediation because the cultivation of Miscanthus is recommended primarily on soils that are not suitable for intensive crop production. Also, it is necessary to determine the calorific value as a key parameter for assessing the energy value and implement a detailed chemical analysis of the ash resulting from combustion of Miscanthus.

FUEL CELLS: A PRACTICAL ANSWER TO THE WORLD'S PRESSING NEED FOR CLEAN AND EFFICIENT POWER

Pramod KUMAR OMRE

*Corresponding author: pkomre@rediffmail.com

Abstract

A fuel cell turns hydrogen the fuel, into electricity using air and other catalysts. The fuel cell harnesses chemical energy trapped in hydrogen gas and converts it into kinetic energy we know as electricity, without fossil fuels, combustion, or polluting emissions. As a remarkably efficient, incredibly clean source of renewable energy fuel cells can take the place of both batteries and engines to power vehicles, laptops and residential power grid. Such a clean power source, guarantees les dependence on the dwindling supplies of fossil fuels, creates less greenhouse gases that contribute to global climate change, and does not explode or malfunction as frequently as engine driven electricity. These sources are pollution free and hence provide clean energy apart from being inexhaustible. Fuel cells offer utilities the opportunity to provide customers with an added value energy service that is not subject to the same competitive or regulatory pressures as exist for conventional electric supply and will be able to do so at overall lower cost. India is the only country in the world to have an exclusive ministry for renewable energy development. Power generation in India has grown in size to around 1 lakh MW. The demand for power is growing rapidly. Under such condition, environment-friendly and pollution-free, non-conventional and renewable energy sources known as 'clean and green energy' have emerged as an important alternative to conventional energy source. The potential available under solar photovoltaic energy is 20MW per sq. km, but the process is rather slow. A lot of work has been done and is being done in the field of wind energy, solar energy, solar thermal energy and biomass, but still its contribution to the nationwide power requirement is less. Now is the time when we need to explore other sources of non-conventional energy. One such source is fuel cell.

Keywords: *fuel cell, non-conventional sources of energy, hydrogen power.*

Introduction

The industrial revolution of the 19th century ushered in new technologies. The spurt in inventions in that century was unprecedented in many ways. Some of these inventions involved use of resources like coal and oil. The thought of exhaustible nature of these resources and the environmental damage from the use of these resources never occurred either to the inventors or the subsequent generation. It has become imperative to look at energy technology with a new perspective. There are abundant renewable sources of energy such as wind, sun, water, sea and biomass apart from even daily wastes. These sources are pollution free and hence provide clean energy apart from being inexhaustible.

India is the only country in the world to have an exclusive ministry for renewable energy development. Power generation in India has grown in size to around 1 lakh MW.

The demand for power is growing rapidly. Under such condition, environment-friendly and pollution-free, non-conventional and renewable energy sources known as ‘clean and green energy’ have emerged as an important alternative to conventional energy source.

Potential and exploitation of renewable energy sources:

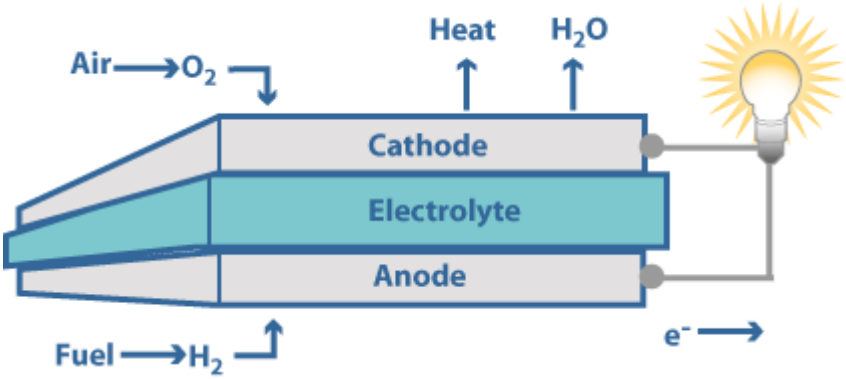
India ranks fifth in the world in wind power with installed capacity of 1612 MW out of an estimated potential of 45000MW. In biomass power the country has an installed capacity of 381MW out of total potential of 1000 MW. The potential available under solar photovoltaic energy is 20MW per sq. km, but the process is rather slow. Under the tenth five year plan government has set the national goal of meeting 10% of grid capacity from renewable sources by 2010 has. Though a lot of work has been done and is being done in the field of wind energy, solar energy, solar thermal energy and biomass, but still its contribution to the nation wide power requirement is less. Now is the time when we need to explore other sources of non-conventional energy. One such source is fuel cell.

What is a fuel cell?

If you want to be technical about it, a fuel cell is an **electrochemical energy conversion** device. A fuel cell converts the chemicals hydrogen and oxygen into water, and in the process it produces electricity. The other electrochemical device that we are all familiar with is the battery. A battery has all of its chemicals stored inside, and it converts those chemicals into electricity too. This means that a battery eventually "goes dead" and you either throw it away or recharge it. With a fuel cell, chemicals constantly flow into the cell so it never goes dead -- as long as there is a flow of chemicals into the cell, the

Technology involved

With no internal moving parts, fuel cells operate similar to batteries. Fuel cells electrochemically combine a fuel (typically hydrogen) and an oxidant without burning, thereby dispensing with the inefficiencies and pollution of traditional energy conversion systems. Fuel cells forego the traditional fuel-to-electricity production route common in modern power production, which consists of heat extraction from fuel, conversion of heat to mechanical energy and, finally, transformation of mechanical energy into electrical energy. Fuel cells function on the principal of electrolytic charge exchange between a positively charged anode plate and a negatively charged cathode plate. When hydrogen is used as the basic fuel, "reverse hydrolysis" occurs, yielding only water and heat as byproducts while converting chemical energy into electricity, as shown in Figure 1. Pollutant emissions are practically zero.



Fuel cell functions

Types of fuel cells:
Fuel cell types are generally characterized by electrolyte material. While there are dozens of types of fuel cells, there are six principle kinds. The following sections describe each of these fuel cell types:

1. Proton exchange Membrane: The proton exchange membrane fuel cell (PEMFC) uses one of the simplest reactions of any fuel cell. A PEMFC contains a layer of solid polymer that allows protons to be transmitted from one face to other. PEMFCs require hydrogen and oxygen as inputs, though the oxidant may also be ambient air (humidified). PEMFCs operate at a fairly low temperature (about 176 degrees Fahrenheit).

2. Alkaline: Alkaline Fuel Cells (AFCs) were the first type of fuel cell to be widely used for manned space applications. AFCs contain a potassium hydroxide (KOH) solution as the electrolyte. AFCs operate at temperatures between 100°C and 250°C. The fuel supplied to an AFC must be pure hydrogen.

3. Molten Carbonate: The electrolyte in an MCFC is an alkali carbonate or a combination of alkali carbonates that is retained in a ceramic matrix of lithium aluminum oxide. An MCFC operates at 600 to 700°C. MCFCs offer greater fuel flexibility and higher fuel-to-electricity efficiencies approaching 60 percent.

4. Phosphoric Acid: Phosphoric Acid Fuel Cell (PAFC) technology is the most mature of the types in use today. PAFCs use a concentrated 100% phosphoric acid (H_3PO4) electrolyte retained on a silicon carbide matrix and operate at temperatures between 150 and 220°C.

5. Solid Oxide: Solid oxide fuel cells (SOFCs) are currently being demonstrated in sizes from 1kW up to 250 kW plants, with plans to reach the multi MW range. SOFCs utilize a non-porous metal oxide. SOFCs operate between 650 and 1000^{o}C, where ionic conduction is accomplished by oxygen ions. SOFCs offer the stability and reliability of all-solid-state ceramic construction.

6. Direct Methanol: The direct-methanol fuel cell (DMFC) is similar to the PEM cell in that it uses a polymer membrane as an electrolyte. However, a catalyst on the DMFC anode draws hydrogen from liquid methanol, eliminating the need for a fuel reformer.

Fuel cell technology benefits:

- Environment benefits because of no combustion
- Flexibility in the types of fuels that can be used with fuel cell technology
- Relieves the reliance on existing natural resources used for energy consumption
- Higher quality of power and energy efficient
- Safe, quiet, and reliable
- Fuel cells can run continuously for long periods of time before servicing is required
- Fuel cells provides another method of generating energy

Applications of the fuel cell technology in the industry:

- Boilers
- Domestic Hot Water (DHW)
- Space Heating Loops
- Absorption Cooling Thermal Loads
- Automobiles
- New bicycle powered by fuel cell
- Home Power Generation

Conclusion:

Fuel cells, with their roots in the space program, have the potential to truly revolutionize power generation. Fuel cells a technology first pioneered by NASA for manned space flight, has been claimed could help countries suffering natural disasters to clean up after the event. According to the Flint Journal, Kettering University in the US sees fuel cell technology as having important applications in cleanup operations where disasters have left people without power. The claims have never been more pertinent in the US, with two hugely devastating hurricanes ravaging the south coast and causing serious damage to the city of New Orleans in particular.
Over the next several years, R&D will enable the widespread utilization of fuel cells for distributed power generation. However, there are other (non-technical) issues and barriers that must be addressed to enable this widespread use of fuel cells (as well as other distributed generation technologies).

Abstract

The study on effects of fruit thinning method on quality indicators of "Royal Gala" apples, trained on slender spindle and improved pyramidal shapes, was carried out during 2015, in Skivjan, Gjakova, in the South-Western part of Kosovo. Two different fruit thinning methods (hand thinning and chemical thinning using a combination of Carbaryl 1000 ppm + NAA 40 ppm, with 1200 L ha^{-1} spraying solution) and two replications, with 10 apple trees for each variant on each replication for each system shape, were used. Fruit thinning was carried out 15 days after bloom, when fruit diameter was 10-12 mm. At the harvest time, there were measured, evaluated, accounted and compared several quality indicators, such as fruit firmness (kg/cm^2), fruit colour (H^o), pH of juice, total soluble solids content (Brix), dry matter content (%), total acidity and malic acid content (% per 100 ml), and were counted the mean values for each thinning method. Observed results showed that thinning method (hand and chemical) significantly affected the fruit quality indicators of "Royal Gala" apple cultivar, of training systems, slender spindle and improved pyramidal shapes. Hand thinning showed more coloured fruits, higher SSC, higher DMC, and lower TA/MA, compared to chemical thinning (CB + NAA). The observed results were statistically confirmed by Anova ($p \leq 0.05$).

Keywords: *Carbaryl, chemical thinning, fruit quality indicators, "Royal Gala", hand thinning, Naphthalene Acetic Acid (NAA).*

Introduction

The most important orchard management practices that influence crop load and fruit quality of apples are the effects of rootstock, and flowers and fruitlets thinning. Rootstock has effects on tree size and crop density, which normally increase with increasing rootstock vigour. Dwarfing rootstocks such as M9 are known for their high yield efficiency and more regular flowering than more vigorous rootstocks (Wertheim, 2000). Fruit thinning is a very well-known agronomic practice which is being used from centuries to control the crop load and productivity of apple, pear, plum, grapevine, olive (Dennis, 2000) and several citrus cultivars (McArtney *et al.,* 2007) which have the tendency of biennial production. Fruit thinning is defined as the removal of certain flowers or clusters of flowers or individual fruitlets after fruit set and natural dropping have occurred. Most apple cultivars have an over-abundant flower density and percentage fruit set. Crop regulation through blossom or fruit thinning can moderate alternate bearing, resulting in more consistent production and improved fruit size, as well as, increasing fruit quality (Davis *et al.*, 2004). Palmer *et al.* (1997) established different crop loads, from completely de-flowered to heavily fruiting, on 4-year-old 'Braeburn'/M.26 trees. A low crop load decreased fruit yield, but

improved fruit weight and fruit quality. Fruit thinning of apple and to the other fruit trees can be achieved mechanically, by hand (which is a very high labour cost practice, used mainly to new orchards and in limited areas), or by applying plant growth regulators at first bloom or at the fruitlet stage. The most common treatment is a combination of chemical thinning followed by hand-thinning, for a final adjustment to the correct crop load. According to Meland (2009), chemical thinning application of apple trees is justified because of three reasons: chemical thinners reduce biennial production, reduce the cost of manual thinning, and their use affect the improvement of apple fruit quality. However, sometimes, except positive effects such as the increase of fruit mass (Pavicic and Paulic, 1989) and reduction of periodical productivity, chemical fruit thinning can cause negative effects such as reduced yield (Duhanaj *et al.*, 2015), fruit deformation at cv "Royal Gala" (Rogers and Williams, 1977), poor fruit coloration at cv Mutsu (Byers and Carbaugh, 1991), low calcium concentration in fruit, etc. Results from the recently published literature point to advantages of combining certain growth regulators and insecticides for apple fruit thinning (Jemrić *et al.*, 2003). Combination of carbaryl and 1-naphtaleneacetic acid has given good results in some years and climate conditions, but caused excessive thinning in some other years and climate conditions (Marini, 2004). The most used chemical apple fruit thinners are Ethephon (ETH), Carbaryl (CB), Naphthalene Acetic Acid (NAA), 6-Benzyladenine (6-BA), and fish oil (Reyes *et al.*, 2008), which are being used for chemical treatment of fruitlets (10-15 mm), 2-3 weeks after bloom, and are being applied as liquid solution in given concentrations (Ferree and Schmid, 2001; Marini, 2002). Through winter pruning and green operations, such as branch top cutting, flower and fruit thinning, etc., fruit growers ams to ensure 30-40 healthy leaves for each fruit and try to avoid the high yield the first growing years of apple trees, which causes premature aging of apple trees (Davis *et al.*, 2004). "Royal Gala" and "Red Delicious" are two of the most widesprout apple cultivars in Albania and Kosovo, which, according to Marini (2002) are difficult to thin by hand, that's why is being used chemical fruitlets thinning using the combination of Carbaryl and NAA. Marini (2004), Jemrić *et al.* (2003), etc., have reported that chemical fruit thinning had affected the year-by-year yield of "Royal Gala", reducing the genetic tendency for biennial yield. The aim of our study was to determine the effect of hand and chemical thinning (Carbaryl 1000 ppm + NAA 40 ppm) on fruit quality indicators of "Royal Gala" apple cultivar, trained on slender spindle and improved pyramidal systems

Materials and methods

Orchard placement. Study was carried out in 2013 in Skivjan, Commune of Gjakova, Kosovo, a much known area for orchard development, in general, and, especially, apple orchards. "Royal Gala" apple orchard was planted in November 2006, with saplings grafted on M-9 rootstock, planted 3.8 m between rows and 1.8 m within a row (1462 apple trees ha^{-1}). Rows orientation was North-South. Orchard was constructed in a hill 400 elevation. Eight years apple trees were healthy and with the same vegetative growth and development. "Royal Gala" apple cultivar is one of the most widely planted cultivar in Gjakova's region, as well as in Albanian and Kosovo's orchards. Apple trees were trained on slender spindle, with hanged shoots, and improved pyramidal shapes, for better use of the solar energy. Space between rows was grassed with tapecant plants and all cultural other cultural practices were applied regularly, as in common apple orchards.

Apple fruit thinning methods: The main objective of the study was to determine the effect of hand and chemical thinning (Carbaryl 1000 ppm + NAA 40 ppm) on fruit quality indicators of "Royal Gala" apple cultivar, trained on slender spindle and improved pyramidal shapes. Apple

fruit thinning was applied 15 days after bloom, when the fruit equatorial diameter was 10-12 mm. There were tested two thinning methods (two variants):

- V1 - hand thinning (mechanical thinning), leaving 1 fruit per cluster
- V2 - Chemical thinning, using Carbaryl 1000 ppm + NAA 40 ppm, with a sprying volume of 1200 L per ha.

There were used two variants and two replications, with a variant size of 10 apple trees per replication. There were used 40 apple trees for each trained shape under study. Fruits were harvested on September 15, 2013. Harvest date has been determined according to the standard method. There were randomly selected 5 apple trees for fruit analysis. Apple trees were marked with plastic labels since at the beginning of the study. Fruits of each tree were kept and analysed separately for every fruit quality indicator and there were calculated the mean values for each thinning method and each trained shape.

Measurements and chemical analysis: Sample for chemical fruit analysis included 30 randomly selected fruits for each thinning method in each replication, and each apple training system. Fruits were taken from different parts of the crop load of 5 randomly and previously selected and marked apple trees. Fruits of each tree were transported separately and were sent immediately for chemical analysis at the Lab of Agricultural Institute of Peja, Kosovo. There were determined, accounted and compared several fruit quality indicators. Fruit colour (Hue angle - H^o) was measured according to CIE Lab Colour System using a colorimeter, which was calibrated with black and white plates supplied with the instrument. Fruit firmness (kg/cm^2) was measured using an Effegi penetrometer with 11 mm probe and was presented as a mean value of four measurements made on opposite sides of the fruit. Apple fruits squeezing was carried out using the instrument Delimano Fusion Juicer. Then, the fruit juice was used for determination of pH, total soluble solids content (TSSC) (^{o}Brix), dry matter content (DMC - %), titratable acids (TA) and malic acid content (MA). pH of juice was measured using a digital pH meter, total soluble solids content (^{o}Brix) was measured using a digital refractometer (PAL BX/RI), while, dry matter content (%) was determined using the MICROWAVE-OVEN QUICK METHOD, placing juice samples at 105^{o}C for 2 hours, as it was described by OECD (2014). Titratable acidity (TA) (%) and malic acid content (MAC - % per 100 ml of juice) was accounted by standard titration method with 0.1 N NaOH, pH 8.1, using phenolphthalein as an indicator, as it was described by OECD (2014).

Data analysis. The obtained data were subject of descriptive and statistical analysis (ANOVA: Two-Factors Without Replication) ($\alpha = 0.05$) (Lekaj *et al.*, 2014).

Results and discussion

Effects of thinning methods on fruit quality indicators of "Royal Gala" apple cultivar were observed for two training systems, slender spindle and improved pyramidal shape. Observed results showed that thinning method (hand or chemical) has significantly affected several quality indicators of "Royal Gala" apple cultivar on both training systems. Fruit firmness (kg/cm^2) and fruit colour (H^o - Hue angle). Obtained results showed that thinning method (hand or chemical) has significantly affected fruit firmness of "Royal Gala" apples on both training systems. Apple fruits from hand thinned trees showed higher firmness and higher colour intensity compared to chemically thinned trees (using CB 1000 ppm + NAA 40 ppm). *Fruit firmness* (kg/cm^2) (mean value) of hand thinned trees was 6.87 kg/cm^2 and 6.79 kg/cm^2, respectively, for slender spindle and improved pyramidal systems, while for chemically thinned trees fruit firmness was 6.42 kg/cm^2 and 6.38 kg/cm^2 , respectively, for slender spindle and improved pyramidal systems. Fruit colour from hand thinned trees showed a higher intensity on both training systems. Data were

similar to McArtney *et al.* (2007) that have reported the increase of fruit firmness of "Cameo" apples as a direct result of reduction of fruit number and yield. Differences between thinning methods for fruit firmness and fruit colour were significant and statistically confirmed at $p \leq 0.05$, but were not confirmed between training systems (Table 1).

Table 1. Effect of thinning method on fruit firmness (kg/cm2) and fruit colour (Ho - Hue angle) of "Royal Gala" apples, trained on slender spindle (SS) and improved pyramidal (IP) systems (mean values, * significant at $p \leq 0.05$).

Fruit thinning method	Fruit firmness (kg/cm^2)		Fruit colour (H^o)	
	SS	IP	SS	IP
Hand thinning	6.87	6.79	102.7	102.5
Chemical thinning	6.42	6.38	101.9	101.7
F-test	*	*	*	*

Note: Chemical thinning = (CB 100 ppm + NAA 40 ppm)

Total soluble solids content (TSSC - ^oBrix) and pH of juice. Total soluble solids content (TSSC) was determined using a digital refractometer (PAL BX/RI), and pH of juice was measured using a digital pH meter. Obtained results showed that thinning method has significantly affected the total soluble solids content and pH of juice of "Royal Gala" apples trained on slender spindle and improved pyramidal systems. Apple fruits from hand thinned trees showed higher TSSC (%) and lower pH of juice compared to chemically thinned trees (using CB 1000 ppm + NAA 40 ppm). Total soluble solids content (%) (mean value) of hand thinned trees was 14.25% and 14.32%, respectively, for slender spindle and improved pyramidal systems, while for chemically thinned trees TSSC was 12.98% and 13.05%, respectively, for slender spindle and improved pyramidal systems. Data were similar to Jemrić *et al*. (2003) and El Salhy (1996) who have reported higher soluble solids content on hand thinned "Golden Delicious" and "Dorset Golden". pH of apple juice showed to be lower on chemically thinned apples. Differences between thinning methods for TSSC and pH of juice were significant and statistically confirmed at $p \leq 0.05$, but were not confirmed between training systems (Table 2).

Table 2. Effect of thinning method on total soluble solids content (TSSC - %) and pH of juice of "Royal Gala" apples, trained on slender spindle (SS) and improved pyramidal (IP) systems (mean values, * significant at $p \leq 0.05$).

Fruit thinning method	Total soluble solids content (TSSC) (%)		pH	
	SS	IP	SS	IP
Hand thinning	14.25	14.32	102.7	102.5
Chemical thinning	12.98	13.05	101.9	101.7
F-test	*	*	*	*

Obtained results showed that thinning method has significantly affected the dry matter content (DMC - %), titratable acidity (TA - %) and malic acid content (MAC - % per 100 ml juice) of "Royal Gala" apples trained on slender spindle and improved pyramidal systems. Apple fruits from hand thinned trees showed higher DMC (%) and lower TA (%) and MAC (%). *Dry matter content* (DMC - %) (mean value) of hand thinned trees was 15.83% and 15.72%, respectively, for

slender spindle and improved pyramidal systems, while for chemically thinned trees DMC was 14.72% and 14.67%, respectively, for slender spindle and improved pyramidal systems.
Titratable acididy (TA - %) (mean value) of hand thinned trees was 7.11% and 7.16%, respectively, for slender spindle and improved pyramidal systems, while for chemically thinned trees TA (%) was 7.45% and 7.49%, respectively, for slender spindle and improved pyramidal systems.
Malic acid content (MAC - % per 100 ml juice) of hand thinned trees was 0.52% and 0.54%, respectively, for slender spindle and improved pyramidal systems, while for chemically thinned trees MAC was 0.45% and 0.47% per 100 ml juice, respectively, for slender spindle and improved pyramidal systems (Table 3).

Table 3. Effect of thinning method on dry matter content (DMC - %), titratable acididy (TA - %) and malic acid content (MAC - % per 100 ml juice) of "Royal Gala" apples, trained on slender spindle (SS) and improved pyramidal (IP) systems (mean values, * significant at $p \leq 0.05$).

Fruit thinning method	Dry matter content (DMC) (%)		TA/MAC (% per 100 ml juice	
	SS	IP	SS	IP
Hand thinning	15.83	15.72	7.11/0.45	7.16/0.47
Chemical thinning	14.72	14.67	7.45/0.52	7.49/0.54
F-test	*	*	*	*

Results of ANOVA showed that the relationship between thinning method and fruit quality indicators was significant. Effects of thinning method on fruit quality indicators of "Royal Gala" apples was statistically confirmed by statistical indicators values (F = 14.2654 > F-crit = 3.2783 and P-value = 2.08E-05 = $2.16/10^5 < \alpha = 0.05$). There were not statistically confirmed differences between training systems for the same thinning method (Table 4).

Table 4. ANOVA: Two-Factor without Replication for testifying the effect of thinning method on fruit quality indicators of "Royal Gala" apples, trained on slender spindle and improved pyramidal systems ($p \leq 0.05$)

Source of variation	*F*	*P-value*	*F-crit*
Rows (training systems)	1.49448	0.223028	2.4876
Columns (thinning methods)	14.2654	2.16E-05	*3.2783*

Achieved results of the study showed that thinning method affects the fruit quality indicators of "Royal Gala" apples, regardless of the training system of the orchard, at least in the ecological conditions of Skivjan, Gjakova, Kosovo. Evethough, there was observed higher fruit quality for hand thinned apples, because of the high cost, it cannot be applied in large areas and it is recommended for small growers and small areas under cultivation.

Conclusions

Obtained results showed that fruit thinning method significantly affects the fruit quality indicators of "Royal Gala" apple cultivar under climatic conditions of Skivjan, Gjakova, Kosovo. Hand thinned trees showed higher fruit quality than chemically thinned trees, using Carbaryl 1000 ppm + NAA 40 ppm. Hand thinned trees showed higher firmness, higher color intensity, higher total soluble solids content, higher dry matter content, lower titratable acids and higher

malic acid content compared to chemically thinned trees. Taking into consideration the cost of hand thinning, it can be recommended that for small growers and small areas under cultivation, is better to apply hand thinning in order to get better quality apples, while for large areas, where the product is being used for the alimentary industry, must be applied chemical thinning. Fruit quality indicators were not affected by the training system, slender spindle and improved pyramidal system. Differences between fruit thinning methods for fruit quality indicators were statistically confirmed by ANOVA-test ($F > F\text{-crit}$ and $P\text{-value} < \alpha = 0.05$).

Abstract

Zinc (Zn) is an essential micronutrient for crop growth. Deficiency of zinc has been frequently detected in soils in Serbia. Soil parent material, pedo-chemical transformations and anthropogenic interventions play important roles in the distribution of zinc (Zn) into its various forms in the soil and ultimately, its bio-availability for plant uptake. This study included 10 cultivated agricultural soils field of Serbian (field) and their uncultivated pairs (meadow). A batch extraction scheme was used to estimate water-soluble and exchangeable adsorbed (I), specifically adsorbed and carbonate bound (II), Mn oxide- and Fe-oxide bound (III), organic bound (IV), and silicate structural bound (residual forms) (V) zinc (Zn) in each soil. The distribution of Zn in the soils on the basis of average concentrations was in the order 60.15 mg kg^{-1} residual Zn (71.93 %) >16.07 mg kg^{-1} oxide bound Zn (19.89%) > 5.31 mg kg^{-1} organic bound Zn (6.69%) >0.68 mg kg^{-1} specifically adsorbed and carbonate bound Zn (0.89%) >0.2 mg kg^{-1} exchangeable adsorbed Zn (0.26%). The correlation analysis showed that exchangeable adsorbed and specifically adsorbed Zn amounts increase by decreasing soil pH, CEC, clay and clay + silt as well as by increasing silt and sand. The residual Zn fraction varied directly with soil pH, clay, CEC, clay + silt. The fact is that the soils in Serbia are dominated by stable fractions of zinc, while its content in easy available forms is low. The zinc present in water-soluble, exchangeable and adsorbed fractions is readily bio-available, while zinc associated with primary and secondary soil minerals is relatively unavailable for plants.

Introduction

Zinc (Zn) is an important essential element which is required only in limited amounts by plants, animals and humans for various physiological and reproductive functions. It influences the quality and yield of crops (Alloway, 2003; Chidanandappa et al., 2008) and in humans it is a necessary cofactor in more than 300 enzymes and numerous transcription factors (FAO/WHO/IAEA, 1996; Haug et al., 2010). The deficiency of Zn in human diet has been recognized to commonly cause impaired growth (stunting) in children and consequently poor human development (Hambridge et al., 1986). Typically soil total Zn ranges between 10-300 mg kg^{-1} with a mean value of 55 mg kg^{-1} (Kiekens, 1995), however knowledge of total Zn provides only limited information about its transformations and bio-availability. For a better understanding, total soil Zn can be broadly described in five mechanistic fractions which can be quantified using sequential or batch fractionation schemes (Fedotov and Spivakov, 2008; Saffari et al., 2009). Generally these are: (1) water soluble Zn in the soil solution, (2) easily exchangeable Zn in electrostatic reaction with soil particles, (3) organic Zn complexed, chelated or adsorbed to organic ligands, (4) inorganic Zn associated with secondary minerals such as

carbonates or insoluble metal oxides and (5) residual Zn held in primary minerals (Alloway, 2003; Saffari et al., 2009). These fractions provide broad information on the biological, geological and chemical processes which have occurred in a soil and are useful for predicting the availability of Zn for plant uptake. The extent to which each fraction is present and the transformations in equilibrium between fractions is influenced by soil properties such as pH, clay, and cation exchange capacity, clay + silt, K_2O as well as presence of metal oxides and soil organic matter. It has been widely reported that the residual Zn and oxide bound Zn are the more stable fractions while the exchangeable Zn and water soluble Zn fractions are rather more soluble (Saffari et al., 2009).

Low levels of bio-available Zn found in soils has been attributed to one or a combination of low native Zn, very slow solubilization of Zn from soil minerals, strong adsorption of Zn on soil surfaces, or co-leaching of Zn with dissolved organic matter (Zimdahl and Skogerboe, 1977; Rieuwerts et al., 2006). Soil Zn has been well studied in Serbia and there is insufficient information that could be used in predicting Zn bio-availability. More than 65% of farmable soils in Serbia have <1 mg kg^{-1} DTPA extractable Zn (0.5-0.8 mg kg^{-1}). The objective of this study was to characterize the distribution of Zn in its various fractions in selected Serbian soils and to determine if cropping affects their distribution.

Materials and methods

Samples were taken from vertisol soil in the Ap horizon at ten different locations in Serbia: 1) Milutovac, 2) Priština, 3) Trnava, 4) Rekovac, 5) Vranje (Neradovac), 6) Zaječar, 7) Bela Crkva, 8) Blace, 9) Salaš and 10) Kragujevac. Sub-samples were taken from field and meadow ecosystems, from a depth of 0 to 20 cm, after which they were air-dried and crushed in a porcelain mortar up to particles of 2 mm in size.

Determination of Soil Characteries

The basic physical and chemical properties of soil were determined using standard methods (Soil. Sci. Yug., 1966). Soil pH was determined in a suspension with water and 1M KCl mixture, with the ratio of soil/solution 1:2.5 after a 0.5 - hour equilibration period; the organic content was determined using the humus method by Kotzmann-y, the available P_2O_5 and K_2O content was determined using the Al method by Egner-Riehm, CEC was determined using the method with 1 M NH_4OAc, pH 7, and particle size distribution was determined by a pipette method. The total content Zn was determined by atomic adsorption spectrophotometry (AAS, Model Carl Zeis Jena, AAS 1N), after digested soil in acid mixture (HF, HNO_3 and $HClO_4$) in Pt pots.

Sequential Fractional Procedures

Zinc (Zn) in different soil fractions was extracted using the procedure proposed by Tessier et al. (1979). The methods followed for the fractionation procedures are outlined below:

1. Water soluble and exchangeable Zn was determined extraction 10 g of soil with 100 ml 0.1 M $CaCl_2$ (pH 7.0) for 20 min.
2. Specifically adsorbed Zn and Zn bound to carbonates were determined by extraction 10 g of soil with 100 ml of 1.0 M NaOAc (pH 5.0) for 5h.
3. Reductant releasable Zn occluded in oxides of Fe and Mn was determined by extraction 2.5 soil g of soil with 50 ml of 0.04 M hydroxylamine hydrochloride in 25% of HOAc, pH 3. for 6h.
4. Zinc bound to the organic matter where determined by extraction with 7.5 ml of 0.02 M HNO3 in 30 % and 12.5 ml of H_2O_2 pH 2.0.

5. Metals structurally bound in silicates (residual fraction) were determined by calculation as the difference between the total content determined with HNO_3–HF–$HClO_4$ and the sum of the first four fractions.

The distribution of Zn n the chemical fractions 1–4 was determined by flame AAS (atomic absorption spectrometry).

The results obtained for the different contents of zinc (total, accessible and different chemical fractions) in the Vertisols were statistically evaluated by the Student's t-test and the Pearson correlation coefficients.

Results and discussion

The analyses have shown that the samples taken from 10 localities in Serbia were considerably differing regarding their physical and chemical properties (Table 1).

The reaction of soil was found to range in a fairly wide interval of pH values from acid to weakly alkaline reaction (from 4.60 to 7.04 in N KCl). The content of humus was considerably varying, ranging from 2.00 to 5.95% (weakly humus to humus soils), being unaffected by land use. In addition, the content of available phosphorous also ranged in a wide interval. Thus, on the smonitzas under meadow soil, the content of available P ranged from 0.8 to 17.8 mg/100g, whereas on those under field, its content ranged from 0.6 to 28 mg/100g. Acording to the content of the available P, the smonitzas in question are low to medium supplied with this element. In contrast to the available phosphorous, the soils were found to be rich in potassium (19.0-53.5 MG/100g). In addition, these soils indicated a high cation exchange capacity and, by mechanical composition, could be defined as medium to heavy clay soils. The above-mentioned average values of the investigated properties proved to be very much the same for the field and for the meadow smonitzas.

Table 1. *Examined physical-chemical characteristics of Vertisols in Serbia (means, standard deviation and range)*

Soil characteristic	Field			Meadow		
	Mean	Range	Standard deviation	Mean	Range	Standard deviation
pH (H2O)	7.1	5.8–8.1	0.9	6.9	5.6-8.1	0.9
pH (KCl)	6.0	4.6-6.9	0.9	5.8	4.7-7.0	0.9
Humus content, %	3.3	2.5-4.0	0.5	3.5	2.0-5.6	1.1
P_2O_5 mg/100 g	7.7	0.6-28.0	8.5	4.2	0.8-17.8	5.0
K_2O mg/100 g	34.4	19.0-59.6	11.8	31.1	20.4-53.5	10.4
CECmeq/100 g	25.1	15.5-31.5	5.6	23.8	16.9-34.7	6.6
Sand, %	29.6	21.4-36.0	4.8	32.2	22.3-50.5	9.0
Silt, %	24.6	18.8-31.2	3.6	22.8	11.9-29.4	5.6
Clay, %	45.8	33.5-54.4	7.2	44.9	28.9-64.3	11.1
Silt + Clay, %	70.4	64.0-78.6	4.8	67.7	49.5-77.7	9.0

Total Zn in the soils ranged between 55-119 mg kg^{-1} and 60-117 mg kg^{-1} in field and meadow respectively with an average concentration of 82 mg/kg. It is higher than its average value of "world soils" (60 mg kg^{-1}, Davies and Jones, 1988). Tagwira et al. (1993) in Zimbabwe and Chahal (2005) in India demonstrated that finer textured soils contain higher concentrations of Zn in all the fractions when compared to coarser textured soils. Contents of zinc in different

fractions of examined soils, presented in mg kg^{-1} and in % in respect to the total content, are given in Table 2.

The presented results of the fractional distribution of soil Zn showed that residual Zn (71.93 %) >oxide bound Zn (19.89%) > organic bound Zn (6.69%) > specifically adsorbed and carbonate bound Zn (0.89%) > exchangeable adsorbed Zn (0.26%).The more stable Ox-Zn and Res-Zn fractions accounted for more than 70% of soil Zn. This is similar to observations reported by, Chidanandappa et al. (2008) and Saffari et al. (2009), Chirva et al. (2012) who found residual Zn to be predominant in soils.

Table 2. *Content of Zn in different fractions for the Serbian Smonitza (Means, Standard Deviation and Intrval), in mg/kg*

Mode of soil utilisation	I	II	III	IV	V	Total Zn
Field	0.17±0.16 0.1-0.6	0.55±0.45 0.1-1.4	13.95±2.96 8.8-18.4	5.33±1.38 3.5-8.0	62.68±16.2 35.2-93.2	82.7±15.3 60.0-117.0
Meadow	0.23±0.22 0.1-0.8	0.81±0.50 0.3-1.7	18.15±3.99 12.2-24.0	5.28±1.58 3.1-8.2	57.65±18.3 34.5-89.7	82.1±19.0 55.0-119.0
t-test field:meadow	0.6794^{NS}	0.81^{NS}	2.5528^{NS}	0.0750^{NS}	0.6503^{NS}	NS

NS-No statistically significant

The fraction of Mn and Zn oxides (III) ranks second in the content of Zn after the residual fraction. Although the total Zn content in the soils from field and those from the meadow are similar, the occurrence of Zn in this fraction is higher in the smonitza from the meadow (22.2%) than in the ones from the field (17.5%). A different distribution of Zn between different chemical fractions of the smonitzes from the field and those from the meadow occurs due to the heterogeneity of the general properties of the smonitza soils.

The presence of Zn in the organic mater fraction is low being about 5.3 % in the smonitzes from the field and meadow.

The fraction of the specifically adsorbed as well as of carbonate bound Zn represents, a reserve of the potentially available Zn. In both group soils, the content of Zn in this fraction is low (0.1-3.1%). A somewhat higher relative occurrence in the samples from the meadow compared to those from the field is probably a result of a considerably higher content of carbonates in the samples.

The content of Zn in the exchangeable fraction (I) is very low with individual relative values of about 0.1 %. Zn in this fraction is weakly bound, soluble and directly available to plants (LeClaire, 1984).

Zinc Fraction According to Soil Characteristics

Relations between the Zn fraction and soil characteristics were determined using the Pearson correlation coefficient (Table 3).

Table 3. *Correlation coefficient between the zinc content in different fractions and some soil characteristics for fields and meadows*

Fraction Properties	I	II	III	IV	V
pH (H2O)	- 0.74**	- 0.60**	NS	NS	0.57**
pH (KCl)	- 0.70**	- 0.59**	NS	NS	0.58**
Humus, %	NS	NS	NS	NS	NS
P_2O_5 mg/100 g	NS	NS	NS	NS	NS
K_2O mg/100 g	NS	- 0.50*	NS	NS	0.53*
CECmeq/100 g	- 0.65**	- 0.58**	NS	NS	0.72**
Sand, %	0.49*	0.50*	NS	NS	-0.67**
Silt, %	0.48*	NS	NS	NS	-0.46*
Clay, %	- 0.62**	- 0.47*	NS	NS	0.75**
Silt + Clay, %	- 0.49*	- 0.51*	NS	NS	0.67**

NS- No statistically significant differences; *Significant at the 0.05 probability level; ** Significant at the 0.01 probability level

Relations between the Zn fraction and soil characteristics were determined using the Pearson correlation coefficient (Table 3). The analysis showed that the content of Zn in water-soluble + exchangeable Zn (I) and specifically adsorbed Zn (II) generally show significant and negative correlations with selected soil properties such as pH value of soil, the content of clay (CEC), silt+ clay and K_2O. The clay content and pH influence the CEC to a large extent, the increase of CEC strengthens the bond between Zn and the solid phase of soil, which reduces the mobility and solubility of Zn in this fraction. Conversely, soil with larger soil fractions (sand and silt) had an increased Zn content in fraction.

The Zn associated with the residual fraction was negatively correlations with sand and silt content and positively with the soil pH values, readily available K2O, clay, CEC and the silt + clay fractions. The negative correlation between the residual Zn and sand and a positive correlation with the clay content and silt + clay indicates that most of zinc his fraction is bound to clay particles. The clay fractions usually contain high amounts of metals (Zn) due to high adsorption,

Conclusion

The fractional distribution of Zn in Serbian soils was in the order residual Zn (71.93 %) > oxide bound Zn (19.89%) > organic bound Zn (6.69%) > specifically adsorbed and carbonate bound Zn (0.89%)>exchangeable adsorbed Zn (0.26%). Res-Zn>CO_3-Zn>Org-Zn>Ex-Zn and they can be clustered into stable (Ox-Zn and Res-Zn), intermediate (CO_3-Zn and Org-Zn) and available (Ex-Zn) forms. Extractable Zn concentrations of these soils are generally low because the stable fraction is the dominant form in soils. Given low levels of bio-available Zn in many Serbian soils, the implication is that in the transformation of soil Zn, the stable form is only very slowly released into the available fraction and the intermediate forms offer a strong buffering to replenishing the soluble form albeit at a slow equilibrium. Soil Zn concentrations were influenced by the colloidal properties of the soils such that soils with high pH and those with finer texture were more likely to have higher Zn concentration in the various fractions. Land cultivation will probably result into lower soil Zn concentration.

CHANGES IN SOIL PHYSICAL PROPERTIES WITH HAZELNUT HUSK AND TOBACCO WASTE APPLICATIONS

Coskun GÜLSER

Ondokuz Mayis University, Faculty of Agriculture, Department of Soil Science and Plant Nutrition, Samsun, 55139 Turkey
Corresponding author: cgulser@omu.edu.tr

Abstract

Recycling organic wastes has been attention to sustain soil quality in agricultural fields recently. In this study, the effects of hazelnut husk and tobacco waste on soil physical properties such as, bulk density, aggregate stability and saturated hydraulic conductivity were investigated. After incorporating 5% rate of hazelnut husk and tobacco waste into a clay loam soil, soil samples were incubated 18 weeks under greenhouse conditions. Both organic waste treatments significantly increased organic matter content, aggregate stability and saturated hydraulic conductivity of soil while they decreased soil bulk densities compared with the control. Soil organic matter content had significant positive correlations with aggregate stability (0.667*) and saturated hydraulic conductivity (0.700*) and a significant negative correlation with bulk density (-0.844**). It was found that hazelnut husk and tobacco waste can be recycled into farmlands and used as a soil conditioner to improve soil physical properties and to prevent soil degradation.

Key words: *Hazelnut husk, tobacco, bulk density, aggregate stability, permeability.*

Introduction

The loss of soil organic matter due to intensive agricultural practices causes soil degradation and decline of soil structure (Dexter, 2004; Usowics and Lipiec, 2009). Organic waste application into soils has a greatest effect on organic matter content and nutrient values, and also improves structure, water and air balance, and microbiological activities of soils (Chenu et al, 2000; Candemir and Gülser, 2010). Soil aggregates are the main units of soil structure, and addition of organic residues to soils improves soil structure by increasing aggregate stability (Gülser, 2006; Gülser and Candemir, 2015). Organic residues contribute to the development of soil structure as a binding agent in the formation of aggregates. The soil organic carbon has a greater effect on aggregation especially in coarse textured soils (Bronick and Lal, 2005). Organic matter and compost application into soils improve soil physical and chemical quality. Addition of organic wastes to soils reduces bulk density, increases total pore space, permeability, microbial activity, mineralization, available nutrient elements and electrical conductivity of soils (Gülser et al., 2015). Hydraulic conductivity is an important soil physical property for determining soil hydrological processes and may change as water permeates and flows in a soil due to various chemical, physical and biological processes (Hillel, 1982).

Hazelnut and tobacco plants are important agricultural products in the Black Sea Region of Turkey. Large quantity of hazelnut husk and tobacco waste as agricultural waste materials are available in the region. Therefore, these waste materials might be reused as an organic matter source in sustainable agricultural management systems. The objective of this study was to investigate possible uses of hazelnut husk (HH) and tobacco wastes (TW) as soil conditioners to improve soil physical properties.

Materials and methods

A greenhouse study was carried out in a randomized plot design with three different treatments (control, HH and TW) and three replications for 18 weeks in 2011. After sieving the air dried clay loam soil sample from 4 mm sieve, pots were filled with 1 kg of soil sample. According to oven dry weight basis, 5% rate of hazelnut husk (HH) and tobacco waste (TW) were incorporated into pots homogenously. Soil samples were irrigated with distilled water to maintain moisture level of soils around field capacity during the experiment.

Soil particle size distribution was determined according to hydrometer method (Day, 1965), soil reaction (pH) and electrical conductivity ($EC_{25°C}$) values in 1:1 soil:water suspension (Kacar, 1994), soil organic matter (OM) by 'Walkley-Black' method and exchangeable cations by ammonia acetate extraction method (Kacar, 1994). According to some soil properties given in Table 1, the soil is a non-saline, moderately alkaline, clay loam, low in organic matter (Soil Survey Staff., 1993). Bulk density (BD) of the each soil core was determined according to Blake (1965). Aggregate stability using a wet sieving method according to Kemper and Rosenau (1986), saturated hydraulic conductivity by constant head method (US Salinity Lab. Sta., 1954) were determined.

Variance analyses of the data were run using SPSS program and pairs of mean values compared using Duncan test.

Table1. Some physical and chemical properties of the soil

Sand, %	41.44	OM, %	0.19
Silt, %	24.57	Exc. K, cmol kg^{-1}	0.51
Clay, %	33.99	Exc. Ca, cmol kg^{-1}	29.70
pH (1:1)	8.40	Exc. Mg, cmol kg^{-1}	7.90
$EC_{25°C}$, dS m^{-1}	0.40		

Results and discussion

Hazelnut husk and tobacco waste significantly increased soil organic matter content according to the control ($P<0.01$) (Figure 1). The highest OM content (3.12%) was determined in HH treatment. Electrical conductivity values were significantly increased by tobacco waste application ($P<0.01$) (Figure 1). Soil EC values in HH and TW treatments increased 33% and 695% over the control. Smith and Doran (1996) reported that electrical conductivity can serve as a measure of soluble nutrients for both cations and anions. EC is also useful in monitoring the mineralization of organic matter in soil (De Neve et al., 2000). Candemir and Gülser (2010) found that application of agricultural wastes increased EC values in soil. They also reported that the highest increment in soil EC value was obtained with tobacco waste application compared with the other treatments.

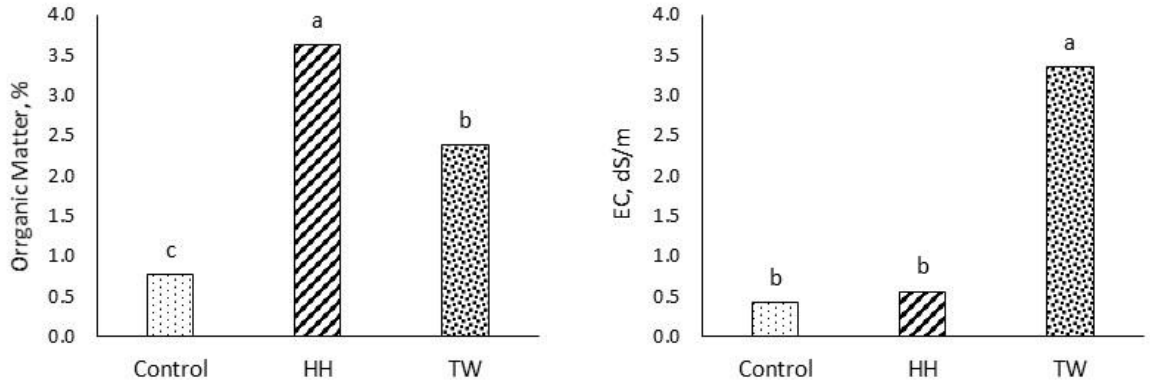

Figure 1. Changes in soil organic matter contents and EC values with hazelnut husk (HH) and tobacco waste (TW) applications.

Increasing organic matter content in soil by the application of agricultural wastes significantly decreased the soil bulk density ($P<0.05$) (Figure 2). The lowest bulk density (1.02 g/cm^3) was determined with HH treatment. According to the control treatment, percentage decreases in bulk density by the applications of HH and TW were 15% and 13%, respectively. There was a significant negative correlation (-0.844**) between OM and BD values (Table 2).

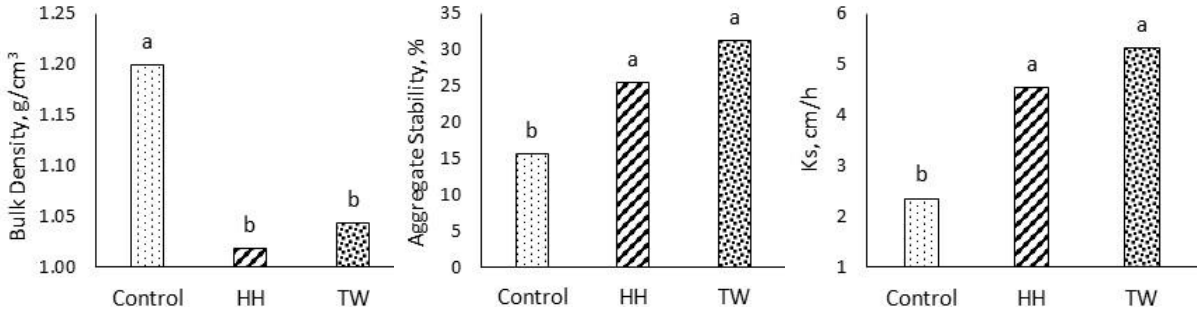

Figure 2. Changes in bulk densities, aggregate stability and saturated hydraulic conductivity (Ks) values with hazelnut husk (HH) and tobacco waste (TW) applications.

Agricultural waste treatments significantly increased aggregate stability of soil compared with the control ($P<0.01$) (Figure 2). Aggregate stability (AS) in HH and TW increased by 63% and 99% respectively, relative to the control. Improved aggregate stability by addition organic residue to soils is a result of released plant phenolic acid interactions during the decomposition of residues structural components and increasing microbial activity due to carbonhydrates metabolisms (Martens, 2000). AS values had a significant positive correlation (0.667*) with soil OM (Table 2). Gülser (2006) reported that increasement in organic C content significantly decreases bulk density and increase total porosity and the proportion of larger aggregates, and that there was a significant positive correlation between OM and AS. In this study, reduce in bulk density caused increase in total porosity and saturated hydraulic conductivity. Applications of HH and TW significantly increased Ks values in soil ($P<0.05$) (Figure 2). Percentage increases in Ks by the HH and TW treatments relative with the control were 92% and 125%, respectively. Soil Ks

values gave significant positive correlations with OM (0.700*) and AS (0.885**), and a significant negative correlation with BD (-0.727*) (Table 2). Candemir and Gülser (2007) reported that during the decomposition period of organic waste in soil reduced soil bulk density and increased soil permeability due to increases in total porosity and aggregate stability. In this study, it was similarly found that increasing OM in soil due to agricultural waste applications helps to increase soil Ks with increasing AS and reducing BD.

Table 2. Correlations among the soil properties after agricultural waste treatments.

	EC	BD	AS	Ks
Organic Matter	0.116	-0.844**	0.667*	0.700*
EC		-0.360	0.762*	0.624
Bulk Density (BD)			-0.852**	-0.727*
Aggregate Stability (AS)				0.885**

** Correlation is significant at the 0.01 level, * Correlation is significant at the 0.05 level

Conclusion

Incorporating agricultural wastes into soil increased EC by mineralization of organic matter and improved soil aggregate stability. Total porosity of soil increased with reducing BD significantly by the HH and TW applications. Soil OM content and AS values had significant positive correlations each other and with Ks. Significant increases in OM after HH and TW applications caused increases in AS and Ks. Recycling of agricultural wastes is a useful technology with respect to environmental protection and also can have an economic benefit for farmers in sustainable agricultural practices.

THE POSSIBILITY OF USING HOUSEHOLD FOOD WASTE IN REDUCING NICOTINE CONTENT IN TOBACCO WASTE

Vesna RADOJIČIĆ[1]*, Nemanja MANDIĆ[1], Maja MALNAR[1], Boris PISINOV[2]

[1]University of Belgrade, Faculty of Agriculture, Belgrade-Zemun, Serbia

Abstract

Tobacco waste is generated during its growth and processing, and represents a significant part of the agro-industrial and municipal waste. Although tobacco waste has a high content of organic matter, its use is limited due to its nicotine content, which is above the limit of 500 mg/kg. Domestic food wastehas also become a significant global issue. The aim of this study was to examine the possibilities of the nicotine reduction through the composting process, by mixing tobacco with the household waste. Through this process we can: solve the problem of generating different types of waste, reduce pollution and get a stable product. In this experiment, we used Virginia tobacco leaves, which are classified as tobacco waste (TW) after processing, as well as the household food waste. Three experimental samples of the same composition percentage (50% TW + 50% household food waste) were formed. The two of them were placed in the chamber, while the third one was held at room temperature. The experiment was carried out in the laboratory of the Faculty of Agriculture, during a period of 44 days. The nicotine content in the samples was determined by High Performance Liquid Chromatography (HPLC) method. Already by mixing tobacco with the household waste, the content of nicotine was reduced by one-third. At the end of the experiment, the nicotine content of the samples that were held in the chamber has fallen below 10 mg/kg. Nicotine content in the batch that has been kept at room temperature was 76.5 mg/kg.

Keywords: *household food waste, tobacco waste, composting, nicotine*

Introduction

Household waste is becoming an increasingly important global issue. One survey has found that consumers throw away 31% of the purchased food. Huge amounts of household waste end up in landfills, which has a negative impact on the environment (Nahman et al., 2012).

According to FAO data, 1.3 billion tons of edible food produced for human consumption, deteriorates every year. This is one-third of produced food, which is sufficient to feed one-eighth of the world's population (Chalak et al., 2016; Gustavsson et al., 2011). The composition of household waste varies considerably depending on the place of origin and to a large extent depends on the eating habits (Chang and Hsu, 2008).

Household waste is the most comprehensive organic component of municipal solid waste by weight, which makes 14-40% of solid waste. Therefore, household waste should be diverted from landfills. After an appropriate technological treatment (especially composting), it could be converted into an economically and environmentally friendly product (Wang et al., 2016). Composting is an acceptable solution, due to the fact that it can reduce the volume and mass of the waste, which can afterwards become a stable end-product (Kopčić et al., 2013). Therefore, composting is recommended in organic waste management (NSCEP, 2000).

The composting process involves a biological breakdown of organic waste under aerobic or anaerobic conditions. The resulting compost is a stable, complex mixture enriched in nutrients, which can improve physical properties of the soil. During the composting process, it is of great importance to regulate and to control parameters, in order to provide optimal working conditions for microorganisms which degrade the organic matter (Lim et al., 2016).

Tobacco waste, which is generated in all processes, from its production to the production of tobacco cigarettes, accounts for a significant percentage of the agro-industrial and municipal waste in Serbia (Radojičić et al., 2009). The largest amount of the waste is collected in the very beginning - while purchasing dry tobacco leaves from the manufacturer. The reason is the poor quality of the sheets, which - according to the current criteria for classification of tobacco (Classification criteria for tobacco leaves JUS.E.P1.110: 2004) - cannot be redeemed or used for the manufacture of tobacco products. Producers have the greatest responsibility for collection, transport, processing and safe disposal of tobacco products (Curtis et al., 2016).

In management of the tobacco waste the use of biological or thermal processes is recommended. Biological waste treatment is more time-consuming, compared with the thermal processes. However, the big advantage of biological methods is their simple technology and lower costs. Also of great importance is the fact that artificially induced natural processes does not pose a riskby creating new chemicals that are dangerous, as it is the case with their burning (Piotrowska-Cyplik et al., 2009).

Despite the fact that tobacco waste has a high content of organic matter, its use is limited because of the nicotine content, which is above the limits set by the EU (Civilini et al., 1997). According to European Union Regulations (Novotny and Zhao, 1999) nicotine content over 500 mg/kg categorizes this waste as hazardous. For this reason, tobacco waste cannot be disposed of together with urban waste (Pichtel, 2005), but must be destroyed under special conditions, which has an economically negative impact on tobacco producers and processors.

The aim of this study was to examine the possibilities of reduction of nicotine content through the process of composting, by mixing tobacco waste with household waste. Composting process cannot only solve the problem of generating different types of waste, but it can also reduce pollution and enables to get a stable product that can be used as an organic fertilizer.

Materials and methods

Virginia tobacco leaves, which are declared as waste after redrying process, were used for the purposes of the experiment. As components in experimental batches, mixed household waste was used: onions, potatoes and carrots. Experiment was carried out during the period of two months, February and March 2016 (total 44 days) at the Faculty of Agriculture, University of Belgrade. Experiment is carried out in several stages:

Preparation of experimental batches - Low humidity is one of the main characteristics of tobacco waste; in the first phase of the experiment were performed wetting, grinding and mixing tobacco waste and household waste. Different compost batches were formed (Table 1).

Table 1. Compost batches ingredients (%)

Composting batch	TW	Household waste
R	50	50
1	50	50
2	50	50

TW - tobacco waste

Monitoring parameters of the composting process - The compost batches 1 and 2 were placed in a chamber with controlled conditions (temperature and humidity), while the compost batch R was the reference sample which was held in the laboratory at room temperature.

During the experiment, temperature and moisture measurements were performed daily in samples 1 and 2, which had been placed in the chamber (WET Sensor, type WET-2, Delta-T Devices Ltd) as well as temperature and relative humidity in the chamber (mini weather stations Kestrel 4000, Nielsen-Kellerman).

Analysis of nicotine content in samples of experimental batches (Radojičić et al., 2015) - Nicotine content in a clean TW and in batches during the composting process was determined by High Performance Liquid Chromatography method (HPLC, Waters Breeze, USA).

Results and discussion

Table 2 shows the results of nicotine content in experimental batches.

Table 2. The nicotine content in experimental batches after mixing (mg/kg)

Composting batch	09.02.2016.	18.02.2016.	02.03.2016.	14.03.2016.	24.03.2016.
R	5687.0	1089.8	311.0	117.7	76.5
1	5687.0	474.4	178.8	45.7	<10
2	5687.0	660.4	258.3	27.5	<10

Nicotine content in a clean tobacco waste (100% TW) at the beginning of the experiment was 17363 mg/kg. Already by mixing tobacco waste with household waste, the nicotine content decreased by as much as 2/3 to the initial value. All experimental compost batches showed excellent dynamics of decomposition of nicotine.

After 44 days, the nicotine content incompost batches 1 and 2 dropped below 10 mg/kg, which is far below the prescribed value according to the EU directives

Although the process of tobacco waste biodegradation was successfully completed in all experimental batches, degradation of nicotine in batch 1 was the fastest. Already after 9 days the nicotine content dropped below 500 mg/kg, which is below the limit prescribed by the EU directive. When it comes to the batch 2, the speed of nicotine degradation has been somewhat slower and after 22 days the nicotine contentwas 258.3 mg/kg, which is also below the permissible limit. In the sample without treatment, the nicotine content fell below 500 mg/kg also after 22 days. At the end of the experiment nicotine content in batches 1 and 2 dropped below 10 ppm, while the untreated sample contained 76.5 ppm of nicotine.

During the experiment, the parameters of the process were also measured (temperature and humidity). They also affect the rate of degradation of nicotine. The chamber temperature was

kept constant. The chamber was active every day during 8 hours, while the temperature was maintained at a value of 52°C. In the afternoon, the thermostat was excluded until the next morning (a total of 16 hours). The temperature inside the chamber did not fell below 21°C.Relative humidity in the chamber was maintained at 60% during the experiment.
Figure 1 shows the mean values of temperature at intervals during the experiment. Temperatures in the experimental batches were nearly identical which has led to a faster degradation of the nicotine, compared with the batch with no treatment. We can conclude that at room temperature an acceptable rate of degradation of nicotine is also achievable.

Figure 1. Temperature means values during the composting process

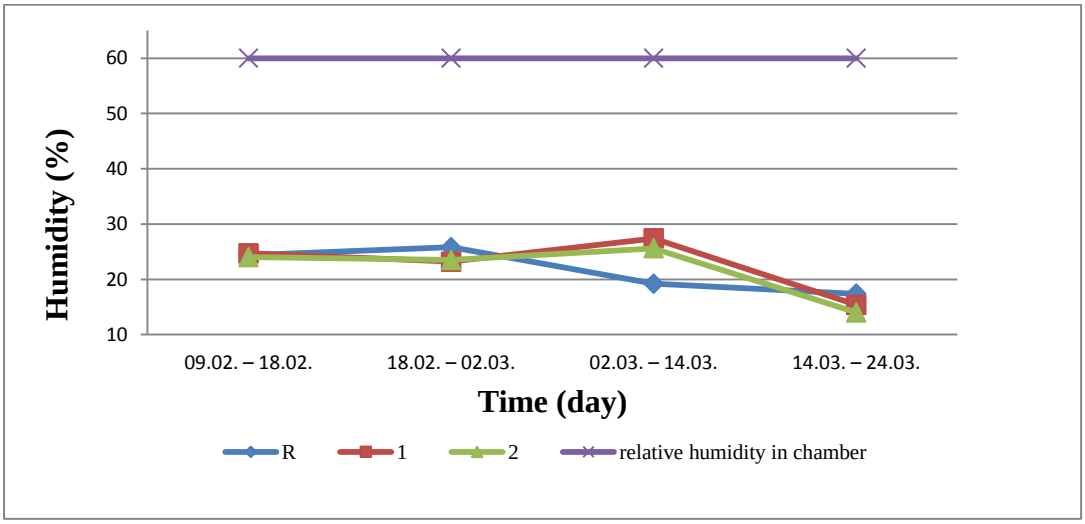

Figure 2. Humidity mean values during the composting process

Based on the mean value of moisture in the experimental batches, in given time periods, shown in Figure 2, we can say that the experimental batch 1 had a slightly higher moisture content, which resulted in a faster degradation of the nicotine than in the batch 2. At the last stage of the experiment, when it was determined that the nicotine content decreased to 27.5 mg/kg in batch2, and 45.57 mg/kg in the batch 1, we stopped with the addition of the water. As a result, after 14.03. there was a sudden drop in humidity in both of the batches, which is evident in Figure 2. In the same period there has been a slight drop in temperature in the batches, from 37°C to 34°C (Figure 1). Regardless of the changes in the values of temperature and moisture in the samples, the degradation of nicotine did continue; the content has dropped below 10 mg/kg in both batches.
During the experiment, the values of the process parameters (humidity and air temperature) were measured in one same place in the chamber. Although batches 1 and 2 had the same composition, the difference in intensity of nicotine reduction can only be explained by non-identical values of temperature and humidity in every part of the chamber.
The results of this experiment confirm that the organic material, in this case the household waste, can be used for composting of tobacco waste, primarily in order to reduce the nicotine content.
Also, the results showed that the process of composting of tobacco waste can be done in a controlled as well as in uncontrolled environmental conditions but the pace of nicotine reduction varies. Comparing with the results of previous studies (Radojičić et al., 2015), in which the

composting of tobacco waste was performed in partially controlled conditions, the process will be shortened by 50 days.

Besides reducing the nicotine content in the samples, there was a reduction in the mass of the samples (Table 3).

Table 3. Mass loss in samples (kg)

Composting batch /mass	09.02.	18.02.	02.03.	14.03.	24.03.
1	1	0.807	0.702	0.603	0.336
2	1	0.754	0.558	0.410	0.256

Experimental batch 1 has lost 66.4% of its weight and the batch 2 has lost more (74.4%). We have to mention that at the moment of measuring the mass at the end of the experiment, batch No.1 had slightly higher moisture content, as it can be seen in Figure 2.

Conclusion

Based on the results of the experiment it can be concluded that the scientific goal of the research was achieved. Eligible dynamics of degradation of nicotine in tobacco was achieved by mixing the waste with household waste. Already by mixing, the nicotine content decreased to one third compared with the initial amount. At the end of the experiment nicotine content in all samples fell below 10 mg/kg, which is far below the 500 mg/kg (the value determined by the EuropeanUnion Regulations).

The results of the experiment also confirmed that the composting of tobacco waste can be done in controlled as well as in uncontrolled conditions, but the pace of nicotine reductionchanges. By controlling the process conditions (regulation of temperature and moisture in compost batches, in a controlled atmosphere) we can increase the efficiency of nicotine degradation.

Abstract

Within species with separated male and female sex, the sex ratio is one of the significant features of the population. The specified aspect of the sexual differentiation is represented in the development of needs for fertilization and realization of total population size and minimal presentation of genetic drift and inbreeding effect. The species *Chondrostoma phoxinus* Heckel, 1843 (known as The Minnow Nase) is described based on samples from Sinj (Croatia), and later it has been found on the territory of Bosnia and Herzegovina, more precisely in Buško Lake. Material, individuals *Chondrostoma phoxinus* Heckel, 1843, has been periodically collected from April 2003 to September in 2004 and during 2008 to 2009 with standard ichthyology methods. The noticed differences are analyzed with chi-square test. In the summed sample from 2003 to 2004 (marked as the first subsample) there were 71 units of the Minnow Nase: 51 males and 20 females (0,7183:0,2817). Summed sample from 2008 and 2009 (marked as the second subsample) included 252 units of Minnow Nase, 87 males and 118 females (0,4244:0,5756), while for 47 units we could not determine the sex. From the specified data it is possible to determine imbalance in the subsamples (first subsample: 2,55:1,00 with chi-square 13,56 and probability of random finding of the noticed differences $P<0,001$; second subsample: 0,74: 1,00 with chi-square 2,50 and probability of random finding of the noticed differences $0,2<p<0,01$) between males and females in samples. However, total sample of 276 individuals have been represented with perfect ratio of 138 males and 138 females and ideal *sex ratio* 1:1.

Keywords: *Chondrostoma phoxinus, Minnow Nase, Buško Lake, sex ratio.*

Introduction

The species of the genus *Chondrostoma* Agassiz, 1835 have a very interesting life area and now take an important place in Biosystematics and Fish morphology. So far there have been described around 18 species, all in the territory of Europe (except for The United Kingdom, Scandinavia, Finland and the basin of the Arctic Ocean), also in the basin of the Black and the Caspian Sea and the waters of the Tigris and Euphrates.

Heckel was the first to describe this endemic species (in 1843) near Sinj in Dalmatia (Croatia) and a little later it was found in the territory of Bosnia and Herzegovina (Buško lake and Livanjsko field). More detailed descriptions of the types *Chondrostoma phoxinus* were given by other authors also, referring to the data by Heckel and Kner (1858), with comparative results of some other scientific methods (cytological, biochemical, physiological, genetic, comparative-anatomical, embryological, paleontological and the like.)

A number of authors including Ćurčić (1916), Karaman (1923; 1928), Kišpatić (1893, 1925) Taler (1954), Vuković (1966), Aganović (1969), Vuković and Ivanović (1971), cite a basic description of this type, representing meristic and morphometric parameters in the formula: D: III 8; A: 8-9 III; Q: I 6-8; Q: I 11-16; LL 80-99 .

Veledar and Kosorić (1972, 1974) analyzed Minnow nase length and weight growth from the water of Livanjsko field. Feeding of this type has partially been analyzed by Jerković et al. (1973), while Kaćanski and Jerković (1978) write about the feeding of some fish species from the Buško Lake in general, including the type of *Chondrostoma phoxinus*. Bozja (1973) analyzed the morphology and histological structure of the intestinal tract of *Chondrostoma phoxinus* type and later Mikavica and Bošnjak (1989) give the morphological characteristics of the digestive tract. In addition to meristic and morphometric characters, Seratlić - Savić (1976) give information about the shape and size of the otolith, material and shape of bones, the number of vertebrae, and some information on the brain morphology of the *Chondrostoma phoxinus*. Elvira (1987) partially speaks/writes about biosystematic position of *Ch. Phoxinus* within the taxonomy elaboration of the whole genus *Chondrostoma* Agassiz, 1835 (Pisces, Cyprinidae). Kerovec et al. (1998) published a paper on the findings *Chondrostoma phoxinus* kinds in Croatia. Žujo (2005) presents the results of biosystematic position and the population status of the *Chondrostoma phoxinus* species in Buško Lake. Kottelat and Freyhof (2007) provide details on the morphology, ecology, distribution, habitat and biology of species referring in particular to the protection status. Mrakovčić et al. (2006) in the Red Book of freshwater fish of Croatia emphasize the status of endangered endemic species *Chondrostoma phoxinus*. Ćaleta et al. (2009) published a paper on endangered fish species in the world, with emphasis on the aforementioned type. Taking all previous relevant research as a starting point in the paper, Žujo Zekić (2009-2010) published his own research of biological diversity of fish populations in Buško Lake with the object of interest on endemics: *Chondrostoma phoxinus, Telestes (Leuciscus) Turskyi* and Aulopyge huegelii.

This research aims at creating the fullest possible introduction of this endemic species, with a directly given confirmation of the current status of the population (gender and age distribution) and the status of the threat through an accurate distribution of the waters of Bosnia and Herzegovina.

Material and methods

Buško Lake is an artificial accumulation since 1974, which belongs to the hydrographic system of Cetina and makes the final southern part of Livanjsko field (Livno karst field). Located at 700 m above sea level with a length of 12.5 km, the width of 11.5 km and an area of around 50 square km, Buško Lake creates a natural hydrographic, uliginous system, the largest of its kind in the fields of Bosnia and Herzegovina. The total area of this aquatic complex at the maximum water level is 56.7 square km.

A representative sample of *Chondrostoma phoxinus* types Heckel, 1843, has been collected periodically from April 2003 to September 2004, and during repeated fishings in 2007, 2008 and 2009. Established differences were analyzed by chi-square test. Durign the first site visits there have been taken specimens from four sites: Prisoje, Cave (Pećina), Marinovac and Široka Draga, where ichthyo-samples have been composed of 71 individuals of *Chondrostoma phoxinus*. The ichthyologic research continued during spring-summer season in 2008, fall-winter season in 2008 and the same seasons in 2009. Repeated field work at the accumulation Buško Lake resulted in fishing out of ten catching sites: Ričine Riverbed, Vrbovi Panji, Marinovac, river Mukišnica, Kazaginac dam, Široka Draga, Matkovača, Kanal (Channel), Bilo Field and Golinjevo. There have been used two types of fishing nets for this research: “popunica” net (diameter mesh 10 mm,

16 mm, 28 mm, 32 mm and 50 mm) and "barracudas" net (70 mm, 80 mm, 90 mm, 110 mm and 120 mm), which have been used in attempt to avoid selectivity of ichthyomaterial.
The indviduals were pre-fixed in 4% formaldehyde and transferred to the laboratory for further processing. Biosystematic determination was made according to Vuković and Ivanović (1971), and Vuković (1977), and Kottelat and Freyhof (2007). More detailed analysis of ichthyomaterial implied determining sexes, which has been performed by dissection and examination of the gonads, where the sex ratio has been elaborated.

Results and discussion

In addition to the clear evidence that genetic material of female and male contains genes for the formation of both sexes and having in mind the sexual differentiation of the individual certainly depends, along with genetic interactions, on some environmental conditions, numerous authors (before us) have identified that the sex ratio in populations of some species is not equal. This ratio can be examined through the different age classes, though, since the first (initial) investigated sample included 71 specimens of Minnow Nase, which belongs to the age class 3+, this part of the research was facilitated. Also, in most of the works that have dealt with this issue it can be evident the phenomenon that in the age class 3+ the ratio of males and females is always in favor of the. In the analyzed sample of 71 individuals of *Chondrostoma phoxinus* from Buško Lake there has been found an unequal ratio, i. e a simple counting revealed 20 female and 51 male, which is almost 2.5 times more males. To define this ratio we have used the *difference test* between the ratio of the studied sample. On the basis of this test, the proportion difference, it has been found that this ratio looks like this (71.8 % males and 28.2% females). The analysis of the *difference test* between males and females show a statistically significant difference ($Z = 5.196$, $p < 0.05$).
Being guided by the fact that introducing numerical ratio and the distribution of the sexes in fish populations represents an important guideline in the analysis of the population growth dynamics, the research has been continued and expanded during the 2008 - 2009 year through several field works. It was important to confirm the theoretic sex ratio in natural conditions, which should be 50:50.
Possessing a data on the quantitative and qualitative structure of different fish populations in Buško Lake, as well as the fact of dangerous domination of allochthonous/non-native fish species over indigenous, particular attention, with regards to the analysis of gender and age structure, has been directed towards endemic fish species. A detailed individual analysis of sex ratio included a total number of 252 individuals Minnow Nase, whose length exceeded 10 cm. By examining the gonads in these individuals it has been stated the disproportion in the ratio between the total number of males and females in a given population.
The Table 1. gives a transparent sex ratio, expressed in absolute and relative values set in a direct relation to the age class of samples of *Chondrostoma phoxinus*.
In this review it is evident that sex gender representation is not homogenized, as it is dominated by the females. From a total number of 252 individuals caught in ten locations in Buško Lake, during four seasons and the two-year research period, there were found and determined 118 female and 87 male individuals. Of the total number of Minnow Nase individuals, 47 individuals have not been sexually specified, which is a relatively small number compared to the total number of this fish population.
Based on ichthyo-sample analysis of Minnow Nase population, it has been ascertained the relative value expressed as a percentage of the ratio between males and females in a given population with 34.5 % of males, compared to a slightly higher share of females, 46.8 %, without

considering individuals with unspecified sex, whose percentage share in the total number of the analyzed sample is 18.7 %.

Table 1. Distribution of samples of *Chondrostoma phoxinus* (Heckel, 1843) based on sexual characteristics, age group and their sex ratio

GENDER		AGE CLASS								TOTAL

	% within sex	**18,3%**	**2,0%**	**6,7%**	**17,5%**	**31,3%**	**17,1%**	**6,7%**	**0,4%**	100,0%
	% within age class	**100,0%**	**100,0 %**	**100,0%**	**100,0%**	**100,0%**	**100,0 %**	**100,0%**	**100,0%**	100,0%
	% of total number of samples	**18,3%**	**2,0%**	**6,7%**	**17,5%**	**31,3%**	**17,1%**	**6,7%**	**0,4%**	100,0%

Also, examining the following chart displays the sex ratio expressed through age classes of individuals present in the catch material, with percentile values within certain age class, as well as within sex category. It follows that the majority of male indivudals caught in the age 3+, which represents 36.8% of the total number of identified specimens of the male sex (87). On the other hand, the least number of male individuals has been recorded in the age class 7+ - only one of them or 1.1%. Considering the representation of Minnow Nase female individuals in certain age classes, surprisingly, there is an extreme number of females aged 4+. Within the total number of female individuals, 60 registered individuals have a high share of 50.8%. Percentage ratio of female individuals in the age class 4+, to the total number of 79 caught individuals in that age class, is quite high at 75.9%. And, finally, the number of female individuals in the age class 4+, compared with the total number of caught Minnow Nase individuals (252), expressed in percentage, is 23.8%. This figure, which refers to the dominance of females in the total population, especially in reproductively expressive period, which has resulted in a trend of growth and dynamics of survival of the population. Following further results of the sex ratio analysis in the remaining age groups, it is registered the prominent number of female individuals. The age group 5+ (30 females) in the total number of caught registered females makes a share of 25.4%, and in the age category 6+, (11 females), it represents 9.3%.

Similar considerations can be expressed for individual males in the age classes 2+, 3+, 4+, 5+, 6+ also. In the age class 1+ there are 4 male individuals, in the class 2+ there are 12 individuals and 32 males are equally present in the age class 3+, resulting a slightly higher number of males over females in these age classes. On the other hand, slightly less (19) individuals of the male sex in the age class 4+, 13 in the age class 5+ and 6 Minnow Nase males in the age class 6+, which is a significant number and representation of female in the mature reproductive age and again

demonstrates the positive trend of growth of this species population. The higher number of female Minnow Nase individuals can be closely related with the spawning period (late spring), when there is a numerically richest fishing throughout the research period. A review of all Minnow Nase individuals (252) caught in the research period, it has been noticed that only 5 of them are trapped in the age class 1+, 4 males and one female. In the age class 2+ there have been caught 17 individuals - 12 males and 4 females. In the age class 3+, number of caught fish specimens is very high at 44, of which 32 males and 12 females. The sex structure in numeric ratio is rapidly changing in higher age classes, thus in the age class 4+, from a total of 79 individuals, 60 of them are females and only 19 individuals are male, etc. A detailed statistical analysis, using $\chi 2$, may show a statistically significant difference between the observed Minnow Nase individuals of a particular gender and with determined age. For this analysis there have been taken only the Minnow Nase specimens with specified both gender and age group, which refers to the 205 individuals of this species. Also, they are logically grouped according to a reproductive period at the level of younger individuals, reproductively mature and older individuals with a pronounced period of stagnation. The statistical analysis in this case indicates the limit of significance in the Minnow Nase sample at the level of 0.004, or 99.6% (Table 2).

Table 2. Distribution of male and female types *Chondrostoma phoxinus* (Heckel, 1843) according to age class and their sex ratio

SEX		AGE CLASS			TOTAL
		Low level of reproductive maturity (1^+, 2^+)	**Sexually mature samples (3^+, 4^+, 5^+)**	**The downtrend of reproductive performance (6^+, 7^+)**	
Male ♂♂	Number of samples	16	64	7	87
	% within sex	18,4%	73,6%	8,0%	100,0%
	% within age class	76,2%	38,6%	38,9%	42,4%

In an attempt to discuss on a given topic about the sex ratio and sex structure of the local population of a species *Chondrostoma phoxinus* from Buško Lake there has not been found a sufficient number of valid data and results to which it would be possible to compare the results displayed in the paper. Therefore, the final observations and discussions are mainly based on some universal data on the state of the Minnow Nase population from watercourses in the Livno field. Valid examples for studying sex ratio of mixed fish population in the Buško Lake are given

by Mučibabić et al. (1973), who analyze the population of Tursky Dace, Dalmatian barbel gudgeon, Dalmatian rudd, Minnow Nase, Brown trout and Rainbow trout. According to this reference, within the population Minnow Nase of Buško Lake water there is a greater representation of females compared to males. The ratio of female to male individuals was 53.68%: 46.32%, which is close to the current actual data given in this paper during the research period 2007/2008/2009 year.

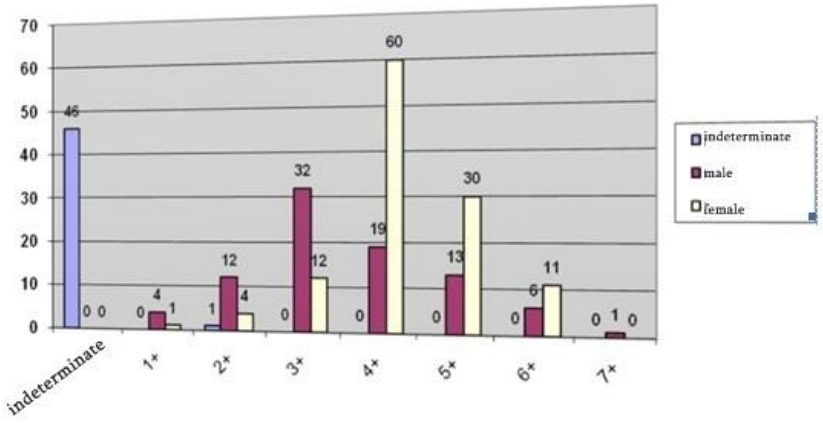

Figure 1. The review of age class and sex structure ratio of *Chondrostoma phoxinus* Heckel, 1843

Similar results are given by Aganović et al. (1974), who notice the increased representation of female individuals, on the basis of extensive research, sex ratio in the population Minnow Nase from Livno watercourses. Cvijović and Kosorić (1985), analyzing the population Minnow Nase conclude that the population is characterized by a greater number of females. Specifically, based on the 150 analyzed specimens of its kind, the relative ratio of the sexes is 46.67%: 53.33% in favor of females, which in just 6.66% deviates from the theoretical ratio.

The results of a similar analysis were recorded in previously referenced papers, including the paper by Mikavica and Kosorić (1987), who analyzed the age structure Minnow Nase from Buško Lake and noted 7 age classes from 3+ to 9+, with the largest number of individuals belonging to the age class 5+ (50 individuals, 33.33%). In the total number of analyzed individuals (150), they recorded 70 males and 80 females and agreed that the older age classes outnumber females. Because of absence of younger age classes, the authors in the coming period foresee stagnation of Minnow Nase population in reproduction, which currently cannot be confirmed by examining the actualized data.

Conclusion

In the discussion and presentation of results regarding the ratio of age groups and sex of certain fish species from the Buško Lake, there is no recent data referring to the 21st century. Therefore, particular attention has been directed to the presentation of the current results of the mentioned area related to the status of endemic ichthyofauna and the requisite to preserve the irrecoverable natural resources. The research tasks which include monitoring populations of species *Chondrostama phoxinus* as an endemic Adriatic catchment area are an immense scientific contribution in ichthyological communities in Bosnia and Herzegovina and the whole Europe. As the reproductive potential of most sexually reproductive population is limited by the number of females included, to the overall size of the population concerned the actual rate of population growth expectedly must have a tendency to equalization of numerous sex relations. Therefore, in

the ordinary meeting of the sexes (any male with any female) the maximum probability of meetings between members of the opposite sex (and the formation of all existing individuals in couples) is in case the sex ratio in the local population is half half.
The total analyzed sample of 276 individuals was presented with a perfect ratio of 138 males and 138 females, or ideal sex ratio 1:1.

Abstract

This study was carried out in order to determine the effects of various organic wastes (tobacco production waste, wheat straw, tea waste and hazelnut husk) under greenhouse conditions on microbial biomass C (Cmic) and basal respiration (BSR) in clay loam soil and rhizosphere (*Zea mays indandata*) soil of maize plant. The organic wastes were thoroughly mixed with the soil at a rate equivalent to 50 g kg^{-1} on air-dried weight basis. Experimental design was randomized plot with the replications in greenhouse. The moisture content in soil was maintained around 60 % of maximum water holding capacity by weighing the pots every day. Changes in the Cmic and BSR were determined in the soil and rhizosphere (*Zea mays indendata*) samples and root free soil taken in 15, 30, 45, 60, 75 and 90 days after the experiment was conducted. At the end of experiment, all organic waste added soil increased Cmic and BSR in comparison with the control (*P<0,01*) at all experimental periods. Moreover, Cmic and BSR in rhizosphere soil were higher than in root free soil at all organic waste application (*P<0,01*). Increased amount of organic wastes had different effects on Cmic and BSR trend (*P<0,01*). The most increases are in the Cmic and BSR in the soil treated with wastes of tea and waste of tobacco production with supplying of low initial C/N ratio compared to the other organic wastes
.

Key words*: Organic waste, Soil, Rhizosphere, Microbial biomass, Basal soil respiration*.

Introduction

The loss of soil organic matter under intensive land use is one of the many factors that degraded agricultural soil of Anatolia. Traditional agricultural practices also leads to decrease fertility and, therefore, to declining productivity. Soil organic matter is extremly heterogenous ranging from only slighlty decomposed plant and microbial residues to higly humified organic substances. The most common practice to preserve and/or restore soil fertility is to add organic matter, which, preferentially, should be sufficiently stabilized to produce beneficial effects (Gallardo-Lara and Nogales, 1987; Mathur et al., 1993). Therefore, different types of organic wastes have increasingly been applied to soils in recent years. Organic wastes applications haven't only increased the soil organic matter, but have also enhanced the soil's carbon (C) and N contents, and have improved biological activity in soil (Vigil et al., 1991).

Plants influence C turnover and organic matter content in soils, both because they provide C inputs for micrbiological caharacteristics in the soil through litter and exudation in the rhizosphere, and because they stimulate the turnover of existing soil C by rhizosphere microorganisms and their activities (Chen et al., 2006). The functional capacity of the soil microbial community, as reflected in the activities of enzymes involved in nutrient mineralization processes, varies among soils dominated by plant roots (Waldrop et al., 2000; Kourtev et al.,

2003). Nevertheless, there have been relatively few studies that have examined root exudation, microbial rhizosphere community composition of plants (Kourtev et al., 2003). Microbial activity plays an important role in regulating soil fertility. Indeed, the microbiological processes taking place in soil are at the centre of many ecological functions (Nannipieri et al. 1990), since microbiological activity is related to soil structure, soil fertility, and the transformation of soil organic matter. Several microbiological parameters have been used to define the status and sustainable development of soil productivity in agricultural ecosystems. There are many methods currently available for studying the microorganisms and their activities at the microhabitat level (Nannipieri et al. 1990). The dependence of the microbiological properties of agricultural soils on site and soil factors has been studied (Vekemans et al. 1989). Some soil microbiological characteristics such as respiratory activity and microbial biomass are used as bio-indicators for soil quality and health in environmental soil monitoring.

The experiment in the present study was conducted in the greenhouse, simulating field conditions of organic matter management with different organic wastes (hazelnut husk, wheat straw, tea waste and tobacco production waste) in soil. The organic wastes used in the research were selected due to their variance in very large interval (C/N; 20 - 171). All organic wastes were sifted from 0.5 mm sieve after grinding in order to eliminate any effect that could be occurred due to magnitude of the particles. Our objectives were to determine the effects of the organic wastes on microbiological properties such as microbial biomass C (Cmic) and basal respiration (BSR) in rhizosphere and root-free soil.

Material and methods

Material

Surface soil (0-20 cm) was taken from Bafra, Samsun (Turkey). The soil used in this experiment is a Typic Udipsamment and contained 20.60 % clay, 18.36 % silt, and 61.04 % sand. Soil texture can accordingly be classified as sandy clay loam (SCL). The pH in water was 8.1, the oxidizable organic matter content was 1.68 %, and the soil C:N ratio was 13.9. The site is located in the Black Sea Region, Northern Turkey (Latitude, $41^0$21'N; longitude, $36^0$15'W). The climate is semi humid, (R_f = 47.21) with temperatures ranging from 6.6 ^{0}C in February to 23 ^{0}C in August. The annual mean temperature is 14.2 ^{0}C and annual mean precipitation is 670 mm.

Hazelnut is one of the major agricultural products in Turkey with a yield of 650,000 tons pear year; it is especially produced in the Black Sea Region. Hazelnut husk (HH) was collected from hazelnut trees in the Eastern Black Sea Region, Turkey. Tea and tobacco plants are commonly grown in the Eastern and Middle Black Sea Region of Turkey. Therefore, there is much tea (TEW) and tobacco (TOW) production waste in this region. These organic wastes were taken from the industry of tea and tobacco production in this region. Wheat straw (WS) was collected during the grain harvest season in Samsun, Turkey. All organic wastes were dried and sieved into less than 0.50 mm. The properties of the organic wastes was expressed on a moist-free basis and analyzed by standard procedures, given in Ryan et al. (2001).

Experimental procedure

The soil samples were air-dried in a laboratory and sieved through 0-2 mm screens. The samples (500 g air-dried soil) were placed in 600 ml cylindrical plastic container. The organic wastes (WS, HH, TOW and TEW) were thoroughly mixed with the soil at a rate equivalent to 5% on an air-dried weight basis. Then, five individuals of maize (*Zea mays indendata*) seeds were placed in the soils. The moisture contents in the soils were adjusted to 60% water holding capacity (WHC) and the containers were incubated in greenhause for 90 days. The moisture content was

maintained throughout the experiment. The maize-planting containers were regarded as rhizosphere and the other containers as root free soil (nonrhizosphere). Changes in the microbiological properties were determined in the root free soil and rhizosphere samples taken in 15, 30, 45, 60, 75 and 90 days after the experiment was conducted. During the sampling of soil the crops were gently pulled out, and the soil remaining on the maize roots was regarded as rhizosphere. At the same time, the root free soil was taken from the nonplanting containers at the same depth. Soil without organic waste addition was used as a control. A randomized complete plot design with three replicates per treatment and soil was used. This greenhouse experiment was total 180 pots. The experiment was performed with the following 10 treatment:

(1) control for soil (without organic waste addition and plant see
(2) + 50 g kg^{-1} hazelnut husk (without plant seed)
(3) + 50 g kg^{-1} wheat straw (without plant seed)
(4) + 50 g kg^{-1} tobacco production waste (without plant seed)
(5) + 50 g kg^{-1} tea production waste (without plant seed)
(6) control for rhizosphere (without organic waste addition and with plant seed)
(7) + 50 g kg^{-1} hazelnut husk(with plant seed)
(8) + 50 g kg^{-1} wheat straw (with plant seed)
(9) + 50 g kg^{-1} tobacco production waste (with plant seed)
(10) + 50 g kg^{-1} tea production waste (with plant seed)

Methods

Microbiological characteristics in soils and rhizosphere

All determinations of microbiological properties were performed for the each soil sample in triplicate, and all values reported are averages of the three determinations expressed on an oven-dried sample basis at 105 ^{0}C for 48 h.

Microbial biomass carbon (C_{mic}) was determined by the substrate-induced respiration method of by Anderson and Domsch (1978). A moist sample equivalent to 10 g oven-dry soil or cats was amended with a powder mixture containing 40 mg glucose. The CO_2 production rate was measured hourly using the method described by Anderson (1982). The pattern of respiratory response was recorded for 4 h. C_{mic} was calculated from the maximum initial respiratory response in terms of mg C g^{-1} soil as 40.04 mg CO_2 g^{-1} + 3,75. Data are expressed as mg C g^{-1} dry sample.

Basal soil respiration (BSR) at field capacity (CO_2 production at 22 ^{0}C without addition of glucose) was measured, as reported by Anderson (1982); by alkali ($Ba(OH)_2.8H_2O$ + $BaCI_2$) absorption of the CO_2 produced during the 24h incubation period, followed by titration of the residual OH^- with standardized hydrochloric acid, after adding three drops of phenolphthalein as an indicator. Data are expressed as μg CO_2-C g^{-1} dry sample.

Results and discussion

Composition of organic wastes

Among the OW used in this study, TEW had the highest organic matter (92.72%) while that of TOW was the lowest (66.21%). Regarding N content, TEW again had the highest N content (2.46%) and the lowest N content belong to WS (0.31%). C:N ratio of the OW ranged from 20 to 171 and the highest level C:N ratio observed in WS while that of lowest is TOW. The order of OW associated with C:N ratio was WS> HH> TEW> TOW. In addition these OW contained major important nutrients such as P_2O_5, K_2O, which are agronomically important (Table 1).

Table 1. Composition of organic wastes in measured variables

Organic waste	Organic matter, %	C/N	N (%)	P_2O_5 (%)	K_2O (%)
TEW	92,72	22	2.46	0.48	5.83
TOW	66,21	20	1.97	0.45	4.71
HH	85,34	52	0.96	0.28	5.17
WS	91,17	171	0.31	0.25	4.77

Microbiological characteristics in rhizosphere and root free soil

The effects of different organic waste treatments on microbial biomass C (Cmic) and basal respiration (BSR) in rhizosphere and root free soils are presented in Table 2 and 3. Considerable variations in Cmic and BSR were found for the different organic wastes and with/without plant roots at different sampling times. Statistically significant variations were found in Cmic and BSR at various organic waste application and sampling times. Microbiological characteristics were also affected by incubation period, organic waste and plant root. The analysis of variance of the results obtained in our experiment on the periodic sampling times with organic waste showed that all factors (organic waste types, plant roots and incubation periods) significantly influenced all microbiological characteristics. After organic waste addition a rapid and significant increase in Cmic and BSR was observed in waste amended soils followed by a progressive increase in Cmic and BSR in rhizosphere amended with the organic waste. At the end of the experiment, Cmic and BSR measured in waste-treated soils were statistically different from those measured in the control soils.

Different organic waste application significantly affected the levels of Cmic and BSR in the rhizosphere, when compared with the control treatment and root free soils. Table 2 and 3 shows that the Cmic and BSR in rhizosphere were higher than in control treatment and in root free soils at all sampling times and organic waste treatments. This situation might be related the supply of organic material from plant roots and plant exudates. The supply of organic material from plant roots is crucial to soil microbial communities whose growth is carbon limited. The type and amount of nutrients released will affect both the microbial biomass and their activity. This primary carbon supply to the soil system arrives through plant litter and more directly from roots. These include the release of plant exudates, many of which appear to be simply lost by leakage from the root. Plant exudates contain carbohydrates, amino acids, organic acids, lipids, hormones, vitamins and enzymes. These organic substances are stimulated for soil microbiological activity. It is well known that root-derived organic C from root exudates stimulates the growth of microorganisms and increases microbial activity in the rhizosphere (Toal et al., 2000; Kourtev et al., 2003). Results from this study also showed the greater Cmic and BSR in all organic waste added soils under plant roots compared with root-free soil. Greater microbiological characteristics in all organic waste added soils under rhizosphere after 90 days contributed to greater under root free soil. It is likely that increased levels of organic C and N due to root exudation could have led to greater microbial activity. The amount of root-derived C flow through the rhizosphere has a significant impact on transformations of soil organic C, N, P and S (Helal and Sauerbeck, 1989). It has been established that soluble organic C and N in mineral soils is mainly derived from root derived from root exudates and root residues (Huang and Schoenau, 1998).

Table 2 and 3 shows that both rhizosphere and root free soils Cmic and BSR in all organic waste treatments were higher than in control treatment at all sampling times. This situation may be related carbon source of organic wastes and increased the organic matter level, which consequently elevated the microbiological characteristics of soil. For this reason, increased soil organic matter content is correlated positivitely with microbiological activity in soil, generally. The organic waste treatments had consistent or significant effect on Cmic and BSR. This indicated accumulation of organic matter and improvement in nutrient status of soil, as microbial biomass and their activity is a labile reservoir of plant nutrients (Jenkinson and Ladd, 1981). The

Cmic and BSR in rhizosphere and root free soil for all organic waste treatments were similar in all sampling times. Addition of organic material increases the microbial activity in soil (Pascual et al. 1997). Garcia-Gilet al. (2000) reported increases microbial biomass and their activity in soil organic waste application application to soil. Such increases in rhizosphere and root free soil BSR and Cmic were probably caused by the higher level of soluble organic-C in organic wastes. Availability of biogenic material for biomass stimulation (Jenkinson and Ladd, 1981) induced the increase in soil microbial activity of enriched soils. The increase may also correspond to the growth of the zymogenous population associated with organic matter enrichment and incorporation of exogenous microorganisms (Perucci, 1992). The highest Cmic and BSR were generally found in rhizosphere and root free soil at TOW and TEW treatments. There have been numerous studies (Pascual et al. 1997; Madejón et al., 2001) on the effects of organic wastes on microbial activity in soil. These studies generally indicated larger effects in organic matter or organic waste treated soils than in control or non-treated soils. However, in most studies it was possible to establish relationships between and microbiological characteristics and the magnitude of the effects of organic waste type's especially chemical composition, nutrient content and C/N ratio.

Conclusion

According to data, this study showed a clear relationship between organic wastes and microbiological activity (Cmic and BSR). We assume that the replacement of organic waste has stimulating effects on Cmic and BSR in rhizosphere and root free soil, due to the quantity and quality of the organic waste incorporated into soil, and the microbial growth caused by the addition of organic compounds to the soil. Organic materials are possibly the most important C source for microorganisms. It consists mainly of root exudates and organic waste degradation products. Differing organic waste inputs in the system were reflected by the C and N contents which, however, varied much more between the systems than did microbiological characteristics. In general, initial low C/N ratios of organic wastes application (TEW and TOW) caused the most beneficial effects on Cmic and BSR in rhizosphere and root free soil among the investigated types of organic waste on clay loam soils. The use of these organic wastes can contribute to an enhancement of the level of organic matter and the fertility of the agricultural soils. Furthermore, organic waste had a stronger impact on Cmic and BSR in rhizosphere compared to root free soil. Hence, it can be concluded that the Cmic and BSR was clearly governed by the organic waste incorporated into soil under the conditions of the investigated greenhouse experiment. At the same time this practice seems to be a potentially effective way of recycling wastes and solving the problem of their disposal.

TREATED SEWAGE SLUDGE APPLICATIONS: HEAVY METAL CONTENTS OF CORN AND SECOND CROP WHEAT SEEDS GROWN IN SANDY CLAY SOIL

Sezai DELİBACAK*, Ali Rıza ONGUN

Ege University, Faculty of Agriculture, Department of Soil Science and Plant Nutrition, Bornova İzmir Turkey
*Corresponding author: sezai.delibacak@ege.edu.tr; sezai.delibacak@gmail.com

Abstract

In this study, effect of treated sewage sludge (TSS) rates and mineral fertilizer applications on heavy metal content of corn and second crop wheat seeds grown in a sandy clay soil was investigated. The experiment was conducted in the experimental fields of Ege Agricultural Research Institute during 2011-2012 in Menemen-İzmir Turkey. The field study was conducted in 20 plots in a randomized-block design with four replications and five different applications including control, mineral fertilizer, treated sewage sludge 12.5 t ha^{-1}; 25.0 t ha^{-1}; 37.5 t ha^{-1} as dry matter. Corn (*Zea mays* L. var. ZP 737) was the first crop, wheat (*Triticum durum* L. var. Ege 88) was second crop. Increasing TSS applications to soil resulted in significantly increased concentrations of Pb in corn seeds. But it was under threshold values. The heavy metal contents of corn seeds were within the normal limits for Cr, Cu, Ni, Pb and Zn while Cd was not present in corn seeds. Increasing TSS and mineral fertilizer applications to soil resulted in significantly increased concentrations of Cu in second crop wheat seeds according to control. But also it was under threshold values. The heavy metal contents of second crop wheat seeds were within the normal limits for Cd, Cr, Ni and Zn while Pb was not present in wheat seeds. It is recommended that 37.5 t ha^{-1} TSS of İzmir city can be used once in a 2-year period for improving properties of sandy clay soil for corn and wheat growth without having any heavy metal problems.

Key words: *Corn, Heavy metals, Treated sewage sludge, Sandy clay soil, Wheat*

Introduction

The use of sewage sludge in agriculture is one of the most important alternatives. Applying sewage sludge determines the modification of soil physical, chemical and biological characteristics and getting higher yields, as compared to the unfertilized control. The sewage sludge, rich in organic matter and mineral elements for plants, can be a substitute for the fertilization but also a source of heavy metals pollution for soil, when high rates are applied or when it is used for many years on the same field (Singh and Agrawal, 2008; Delibacak et al., 2009).

The uptake of trace elements by plants is a function of the soil characteristics, climate, of the concentration of the element and plant species. Many soil and plant factors affect the bioavailability of trace elements and heavy metals to plants. The soil factors that affect trace element uptake are soil pH, organic matter, element interactions, soil water, soil temperature and soil aeration (Epstein, 1971; Epstein et al., 1978).

Absorption, accumulation and tolerating ability of crops vary at different levels of sewage sludge amendment. Davis and Carlton-Smith (1980) reported wide variations in heavy metal accumulation in crops grown on sludgeamended soil. Cd accumulation was highest in different species. With respect to species, the trend of accumulation was tobacco > lettuce > spinach > celery > cabbage for Cd; kale > rye grass > celery for Pb; sugar beet > some varieties of barley

for Cu; sugarbeet > ryegrass > mangold > turnip for Ni; and sugarbeet > mangold > turnip for Zn. Alloway et al. (1990) found a trend of Cd uptake as lettuce > cabbage > radish > carrots. Cadmium generally tends to accumulate in leaves, and therefore is more risky especially for leafy vegetables grown on contaminated soils than in seed or root crops (Alloway et al., 1990). Mondy et al. (1984) also recorded a significant increase in concentrations of B, Cd, Cu, Ni, and Zn in potato tubers grown on sludgeamended soils, but no significant trend was observed for Co, Cr, Fe, Mn and Pb concentrations.

The purpose of this work has been to evaluate the effect of municipal TSS doses on the heavy metal concentration of corn and second crop wheat seeds grown in sandy clay soil.

Materials and methods

Experimental site: The experiment was conducted at the research field of Aegean Agricultural Research Institute in Menemen plain, Izmir, Turkey (38°56′87.96″-38°56′91.02″N; 27°03′57.52″-27°03′58.61″E). The experimental site is in the Western Anatolia region of Turkey, where the Mediterranean climate prevails with a long-term mean annual temperature of 16.8 °C. Long-term mean annual precipitation is 542 mm, representing about 75% of rainfalls during the winter and spring, and the mean relative humidity is 57%. Long-term mean annual potential evapotranspiration is 1,570 mm (IARTC, 2012). The investigated soil is characterized by sandy clay texture with slightly alkaline reaction and classified as a Typic Xerofluvent (Soil Survey Staff, 2006). Some selected properties and total heavy metal concentrations in the experimental soil and TSS used in the experiment are given in Table 1 and 2.

Table 0. Some selected properties and total heavy metal concentrations of experimental soil

[1]Total

Field experiment: The field study was conducted in 20 plots in a randomized-block design with four replications, during 2011-2012. The plot dimensions were 3 m width and 3 m length. The TSS used in the experiment was obtained from the wastewater treatment plant of Metropolitan

Region, Izmir city. It may produce around 600 t (moist basis) sewage sludge per day. Calcium oxide was added to raise the efficiency of the dewatering process of sewage sludge. In addition, the SS produced presented a pH varying between 10 and 13, what increased the pathogen control and decreased the heavy metal availability by added calcium oxide. TSS was added only once during experiment to the soil under investigation at the rates of 12.5 t ha^{-1}; 25.0 t ha^{-1}; 37.5 t.ha^{-1} as dry matter on July 14, 2011. Also 150 kg N, 150 kg P_2O_5, 150 kg K_2O ha^{-1} (1000 kg ha^{-1} 15.15.15. composed fertilizer) were applied to the only mineral fertilizer plots at the same time and mixed with soil to 15 cm depth. Corn seeds were sown with seeding machine on rows 18 cm and in rows 70 cm apart. Drop irrigation was provided when required. Harvest of corn was done by hands on November 17, 2011. Wheat seeds were sown with seeding machine on November 22, 2011 to 5 cm of soil depth as second crop. Also 80 kg N and 80 kg P_2O_5 ha^{-1} (400 kg ha^{-1}20.20.0. composed fertilizer) were applied to the only mineral fertilizer plots at the same time and mixed with soil to 15 cm depth before wheat seeding. Wheat was harvested with machine on July 10, 2012. Second year, without applying any TSS (for determination of its second year effect), corn seeds were sown with seeding machine on July 18, 2012. Also 150 kg N, 150 kg P_2O_5, 150 kg K_2O ha^{-1} were applied to the only mineral fertilizer plots at the same time and mixed with soil to 15 cm depth before corn seeding. Harvest of second year's corn was done by hands on November 1, 2012.

Plant and soil analyses: The Corn and wheat seeds were collected from each plots after harvest, dried in an oven at 65-70°C until the last two weighing were equal. Dry weights of corn and wheat seeds were determined, and seeds were ground in a mill for heavy metal analysis. Results were evaluated on a dry matter (65°C) basis. Particle size distribution of experimental soil was determined by the Bouyoucos hydrometer method (Bouyoucos, 1962), Total salt, OM concentration, $CaCO_3$, pH, total N, P, K, Ca, Mg, Na, Fe, Cu, Mn, Zn, Cd, Cr, Ni and Pb concentrations of soil samples and TSS were all determined according to Page et al., (1982). Heavy metal (Zn, Cu, Cd, Cr, Ni and Pb) concentrations of corn and wheat seeds were also determined according to Page et al., (1982). The concentrations of these elements in the extracts were determined by AAS (AOAC, 1990).

Statistical analysis: Data were analyzed using the Statistical Package for the Social Sciences (SPSS) version 17 (SPSS 17.0, 2008). Variance analysis was performed to determine the effects of TSS rates on heavy metal concentrations of corn and wheat seeds grown in sandy clay soil. Tukey test was used to find if differences in the treatments were significant at $P \leq 0.01$ or $P \leq 0.05$.

Results and discussion

Effect of treated sewage sludge applications on heavy metal (Cu, Cd, Cr, Ni, Pb and Zn) concentrations (mg/kg) of corn seed grown in sandy clay soil were given in Table 3.

Significant differences between treatments at ** P≤ 0,01 or * P≤ 0,05 level indicated by different letters. [1]Small letter in column for applications, [2]capital letter in row for years. N=4 for all measurements.

According to the results, the average Cu, Ni, Pb and Zn concentrations of the corn seeds samples taken in 2 years from the experiment did not show statistically significant changes with increasing doses of treated sewage sludge applications when compared with mineral fertilizer and control. In other words, the average Cu, Ni, Pb and Zn concentrations of the corn seeds samples taken in 2 years from the experiment were not increased by the application of treated sewage sludge doses. On the other hand, average Cr concentrations of the corn seeds samples taken in the experiment showed statistically significant changes with applications when compared with control. The highest average Cr concentration (0,653 mg kg^{-1} Cr) was determined with 12.5 t ha^{-1}TSS application. Despite these increases, Cr concentrations of corn were found under the threshold values in all wheat seed samples. Normal value of Cr in vegetables and fruids changes between 0,1-1,0 mg kg^{-1} for human health (Türkdoğan et al., 2002). Also all heavy metal concentrations of corn were found under the threshold values in all corn seed samples for human health (Türkdoğan et al., 2002). Meanwhile, Cd did not be determined in the corn seeds. Cadmium is regarded as the most hazardous metal element based on its concentration in sewage sludges, its soil chemistry, and the ability of plants to accumulate Cd (Logan and Chaney, 1983). Increase in the dietary uptake of Cd is a potential risk to human health associated with the land application of sewage sludge (US Environmental Protection Agency, 1985).

Effect of TSS applications on heavy metal (Cu, Cd, Cr, Ni, Pb and Zn) concentrations of second crop wheat seed grown in sandy clay soil are given in Table 4. According to the results, Cd, Cr, Ni and Zn concentrations of the wheat seeds samples taken in the experiment did not show statistically significant changes with increasing doses of treated sewage sludge applications when compared with mineral fertilizer and control. In other words, Cd, Cr, Ni and Zn concentrations of the wheat seeds samples taken in from the experiment were not increased by the application of treated sewage sludge doses. On the other hand, Cu concentrations of the wheat seeds samples taken in the experiment showed statistically significant changes with increasing doses of treated sewage sludge and mineral fertilizer applications when compared with control. The highest Cu concentration (11,175 mg kg^{-1} Cu) was determined with 37.5 t ha^{-1}TSS application . Despite these increases, Cu concentrations
of wheat were found under the threshold values in all wheat seed samples. Limit value of Cu in vegetables and fruids changes between 2-20 mg kg^{-1} for human health (Türkdoğan et al., 2002). Meanwhile, Pb did not be determined in the wheat seeds samples taken in from the experiment.

Conclusions

The fertility benefits from sewage sludge amendment can be achieved against the potential hazards of heavy metal contamination by screening the plants sensitivity at different sludge amendment ratios. Plants differ in their heavy metal uptake, accumulation and tolerance levels. The problem related to sewage sludge application arises when it contains high concentrations of potentially toxic heavy metals. The release of heavy metals associated with sewage sludge is strongly influenced by soil pH, cation exchange capacity, organic matter, and mobility and speciation of specific metals. Excessive application of sewage sludge to soil has been found to increase the bioavailability of heavy metals, but the low doses of sewage sludge did not cause a significant increase in heavy metal concentrations. Sewage sludge amendment increases the production of a variety of plants including vegetables, cereals, grasses and trees. Elevated levels of some heavy metals like Zn in corn and wheat grain grown on treated sewage sludge applied soil may be helpful in elevating of deficiency of these micronutrients in humans and animals. In our study, we found that all heavy metal levels of corn and wheat seeds were under threshold values. Therefore, we concluded that TSS could be used to improve for soil properties and plant nutrients in soils of Turkey when the heavy metal concentrations there are taken into consideration. However, further studies must be carried out in the next years to confirm the positive long-term effects of TSS in order to maintain and improve soil properties and fertility.

VARIABILITY ANALYSIS ON WATER QUALITY OF STREAMFLOW FROM YESILIRMAK BASIN IN TURKEY

Kadri YUREKLI

University of Gaziosmanpasa, Agriculture Faculty, Department of Biosystem Engineering, Tokat-Turkey,
Corresponding author: kadriyurekli@yahoo.com

Abstract

In this paper, variability in monthly water quality records at Durucasu monitoring station on the Yeşilırmak River in Turkey was analyzed by considering the Mann-Kendal (MK) and Theil-Sen Slope estimator (TSE) statistical approaches to detect the direction and magnitude of an available monotonic trend in any given data. For this purpose, the data sets of nine analysis parameters, based on monthly measurement at the monitoring station, were considered in the study. The pH, chlorides, sulfates and SAR data sequences for some months had statistically significance upward trend when there was a decreasing trend in streamflow data of the nine months. The largest percent change in streamflow data was found as 153% in November, whereas July in the pH, June in chlorides and January in sulfates and SAR had the maximum percent change.

Key words: *Yesilirmak, water quality, Mann-Kendal, Theil-Sen Slope estimator*

Introduction

Freshwater rivers represent an essential and integral component of the natural source of the world in terms of quantity and quality. But, among the most important issues facing civilization in the 21st century is the growing scarcity of fresh and clean water. Maintaining and improving the quality and quantity of freshwater has long-term economic, health, and ecological implications. In a broad term, water quality refers to the physical, biological and chemical statues of the water body. The quality of life is often judged on the availability of pristine waters. Therefore, water quality is important not only because of its linkage to the availability of water for various uses and its impact on public health, but also because water quality has an intrinsic value. Also, the presence, abundance, diversity and distribution of aquatic species in surface waters are depended upon a myriad of physical and chemical factors, such as temperature, electrical conductivity, suspended solids, nutrients, chemicals, and in-stream and riparian habitats (Kurunc et al, 2005).

Non-parametric approaches by researchers on the subject in many countries are widely used in the analysis of changes in hydro-climatic variables. The study was aimed to detect variation in streamflow and eight water quality parameters from Durucasu monitoring station on Yesilirmak River by using Mann-Kendall test, commonly known.

Material and Methods

The Yeşilırmak Basin is one of the major basins in Turkey. The water of the Yeşilırmak is mostly used for irrigation in agriculture in addition to drinking, bathing, propagation of fisheries and wildlife, etc. Due to population explosion and rapid industrialization the river has been indiscriminately polluted and misused (Kurunc et al, 2005).

The river flows approximately 519 km and reaches to the Black Sea. It drains an area of 38,730 km^2 which is about 5% of Turkey's surface area. The basin of the river is bounded 39º 30' and 41º 21' N latitudes, 34º 40' and 39º 48' E longitudes. The land rises from an altitude of the sea

level to 2800 m. In terms of land use, there are about 39% forest regime, 39% cropland and 19% pasture land in the basin (Anonymous, 1970; Munsuz and Ünver, 1983). The major tributaries to the Yeşilırmak River are Kelkit, Çekerek, Çorum Çat and Tersakan Streams.

In Durucasu monitoring station, water flow is measured and water samples are taken for once every month by the General Directorate of State Hydraulic Works (DSI). The geographic coordinate of this water quality monitoring station is 40º 44' 40" N latitudes and 36º 06' 43" E longitudes. The drainage area of the monitoring station is about 21,650 km^2. Figure 1 shows the location map of the monitoring station.

In addition to streamflow (Q) in m^3/s, among the water quality constituents measured by DSI at Durucasu monitoring station are water specific conductivity (EC) in dS/m, temperature (T) in ^oC, sodium (Na^+), potassium (K^+), calcium+magnesium (Ca^{2+}+Mg^{2+}), chlorides (Cl^-) and sulfates (SO_4^{2-}) in mg/l and pH. In addition to these water quality constituents, calculated sodium adsorption rate (SAR) is also used in this study. The records for these constituents available for the analysis as presented in this paper are on a monthly basis for the period 1984–2002.

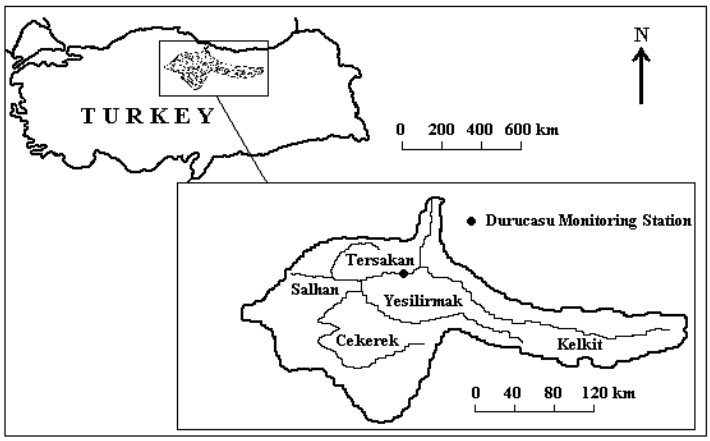

Figure 1. Location of Drucasu monitoring station in the Yeşilırmak River Basin

Testing change in the data: Variation in water quality variables in the study has been analyzed by non-parametric approach (Mann-Kendall, MK), which is commonly used in many areas. The method was given in Yurekli(2015) as detailed. In this study, only test statistic (Z_{MK}) of the MK was presented as follows:

$$Z_{MK} = \left\{ \frac{S-1}{\sqrt{\sigma_S^2}} \text{ if } S>0,\ 0 \text{ if } S=0, \frac{S+1}{\sqrt{\sigma_S^2}} \text{ if } S<0 \right\} \quad (1)$$

In the equation, S is total value based on positive and negative differences among observations. It is assumed that the statistic S is approximately normally distributed with the mean zero. In case where the sample size n >10, the σ_S^2 is its variance.

The Z_{MK} test statistic is evaluated to according to the standard normal distribution. This value is compared to the value of $Z_{1-\alpha/2}$ from standard normal distribution table at 5% significance level. The null hypothesis associated with no trend is accepted if the Z_{MK} test statistic is smaller than the critical value of the standard normal distribution at the significance level of α. The Z_{MK} test statistic having a positive or negative value signifies an increasing or decreasing trend.

In this study, Theil-Sen's estimator (TSE) (Sen 1968; Theil 1950) was taken into account when specifying the magnitude and direction of variation in water quality data. The brief descriptions of the statistical method are as follows:

(I) The slope estimates (Q_k) of N pairs of data series are first computed by sorting data in ascending order:

$$Q_k = \frac{x_j - x_i}{j - i} \text{ for } k = 1,..., N \quad (2)$$

(II) If N is odd or even, the median concerning with the Q_k is obtained from:

$$Q_{med} = \begin{cases} Q_{\left[(N+1)/2\right]} & \text{if N is odd} \\ 2^{-1}\left\{ Q_{\left[(N)/2\right]} + Q_{\left[(N+2)/2\right]} \right\} & \text{if N is even} \end{cases} \quad (3)$$

In equations, x_i , x_j is the ith and jth observations, N is the number of observations, Q_{med} is Theil-Sen's estimator.

The percent change of the upward and downward trend in water quality data is found by the following equation given in Yue and Hashino (2003).

$$\% PC = \frac{Q_{med} \times t}{\bar{x}} \quad (4)$$

Where t is data analysis period (years), the $\bar{x}$ is mean of the data.

Results and discussions

Variation in streamflow, the water quality constituents and sodium adsorption rate (SAR) was tested by Mann-Kendall (MK) in the study. The MK results related to the mentioned data were given in the Table 1. As can be seen the table, according to the critical value of ±1.645 from standard normal distribution table at 5% significance level, the streamflow data sequences of the remaining months had significance downward trend except streamflow data of April, May and June. As for pH, there were upward trend in eight months while the four months (February, Marc, December and November) had statistically insignificance trend. Additionally, an increasing trend was detected in chlorides data sets of January and June. Besides, sulfates and SAR data sequences for January had also upward trend. But, the data sequences concerning with water specific conductivity, temperature, sodium, potassium, calcium+magnesium had statistically significance monotonic trend in none of all months. Theil-Sen's estimator results of streamflow and water quality constituents with monotonic trend at Durucasu monitoring station are in the Table 2.

According to the Equation 4, the percent change of the downward trend in streamflow data varied between 68% (July) and153% (November), whereas the percent change for the upward variation of the pH was between 3.8% (April) and 13.1% (July). The percent change for chlorides data sets of January and June months were 39.4% and 44.5%, respectively. As for sulfates and SAR data sequences for January, The percent change was calculated as 50.3% and 27.3%, respectively.

Conclusion

As mentioned above, at Durucasu monitoring station on Yesilirmak river, monthly data sets of streamflow and water quality constituents in some months showed a monotonic trend in the sense of upward or downward. The reason of this variation may be explained by some socio-economic evolution in the Yesilirmak river basin. The cause of pollution is the increase in industrialized and urbanized areas, animal husbandry without any wastewater treatment and the development of roads and airports. Besides, extreme use of mineral fertilizers, soil degradation and rotation cropping system were very impact on water quality in the basin and have led to variation in concentration of some water quality.

COMPARATIVE STUDY OF COLD PRESS AND ACCELERATED SOLVENT OIL EXTRACTION FROM *CAMELINA SATIVA* AND *BRASSICA CARINATA*

Umesh Chandra LOHANI[1]*, [2]Vijay SUNDARAM, [3]Kasiviswananthan MUTHUKUMARAPPAN

[1]G B Pant University of Agril & Tech, Pantnagar, India
[2,3]South Dakota State University, USA
*Corresponding author: ulohani@gmail.com

Abstract

The aim of the current research was to compare the cold press (CP) and accelerated solvent extraction (ASE) methods for oil yield and qualities of non-edible *Camelina sativa and Brassica carinata* oilseeds. A full factorial design with three levels of extraction temperature (80, 100 and 120°C), and extraction time (40, 65 and 90 min) for ASE and three levels of screw frequency (15, 20 and 25 Hz), and nozzle diameter (5.6, 6.4 and 7.2 mm) for CP were used to extract the oil. Maximum oil yield for both the oilseeds was obtained at 100°C, 90 min for ASE and at 20 Hz, 5.6 mm for CP extraction. ASE produced 6-10% more oil recovery than that of CP for both the oilseeds. The heating values of oil extracted from both oilseeds using ASE and CP were found in the range of 39.4-40.5 MJ/kg and 39.7-40.8 MJ/kg, respectively. Solvent extracted camelina oil exhibited 23% less viscosity than that of cold pressed oil. Density of both the oils ranged from 906.5-930.1 kg/m^3, and 905.3-935.3 kg/m^3 for ASE and CP, respectively. Camelina oil was rich in linoleninc acid, whereas oleic acid was dominant free fatty acid in carinata oil regardless the extraction methods. ASE extracted oil was found more suitable for the upgradation to the biofuel.

Keywords: *accelerated solvent extraction, cold press, camelina, carinata, viscosity*

Introduction

Petroleum based jet fuels have amplified the conundrums associated with energy security, environmental pollution, and energy costs. The United States Federal aviation administration has set a goal to produce one billion gallon of biojet fuel by the year 2018 . Across the world, research works were initiated to develop the biojet fuels from non-food oil crops. Oilseeds are an important economical factor in world trade of agricultural products. The oil content of seed is a key interest to the oil industry because the monetary assessment in the trade of oilseeds is based on this value as now a days, oil from oilseeds is being upgraded to biodiesel or jet fuel to overcome the future crisis of fossil fuels. *Camelina sativa* (camelina) and *Brassica carinata* (carinata) poses a potential business opportunity to develop an aviation biojet fuels .

Prior to upgrade the oil into fuels, extraction of oils from oilseeds is a challenging task and has become the cynosure to all research scientists in last few years. Cold press is being used to keep away the hazardous of solvent extraction, but it is limited to the extraction of edible oils for human food. As far as non-edible oil extraction is concerned, especially for biofuel upgradation, solvent extraction method can be taken into consideration. Conventional solvent extraction can be replaced by accelerated solvent extraction. Accelerated solvent extraction employs organic solvents at elevated temperatures and pressures for oil extraction that reduces extraction time and solvent consumption (Dunford and Zhang, 2003). Cold press extraction involves mechanical pressing of seeds without the application of heat or chemicals, requiring less energy thus extracting oil with better nutritional properties (Thanonkaew et al., 2012). Camelina and carinata

oilseeds have been reported for cold press extraction (Czaplicki et al., 2011; Dobre and Jurcoane, 2011; Dorado et al., 2004; Fröhlich and Rice, 2005; Patil et al., 2009; Ratanapariyanuch et al., 2013; Zhao et al., 2014) extensively, however literatures on accelerated solvent extraction of camelina are limited (Lohani et al., 2015) and none in case of carinata. Therefore, this study involves comparative study of cold press and accelerated solvent extraction techniques for both the oilseeds.

The main objective of the study was to compare oil qualities from *Camelina sativa* and *Brassica carinata* seeds using two different oil extraction methods, viz. cold press oil extraction and accelerated solvent extraction. Specific objectives were to study the effects of screw speed, die nozzle size for cold press oil extraction, and extraction temperature, extraction time for ASE on different oil properties such as viscosity, density, free fatty acids, and heating value.

Materials and Methods

Camelina sativa and *Brassica carinata* oilseeds were procured from Seed house, South Dakota State University. All seeds were ground in a hammer mill (Thomas Wiley laboratory mill, Swedesboro, NJ) to pass a 2 mm screen. Moisture content of all seeds were found in the range of 7.5-9.0% that was suitable (<10%) for solvent extraction. All seeds were packed in airtight poly bags and stored at 4°C for further oil extraction. n-hexane as an extraction solvent was procured from Fisher Scientific and stored in the safety cabinet at room temperature.

1.1 Moisture content

Moisture content (MC) of ground oilseeds was determined by air oven standard methods recommended by AOAC (AOAC, 1980). Initially 5 g of sample in triplicate was dried in hot air oven at 130-133°C for 2 h. After drying, dried sample was again weighed. Following formula is used for calculating the MC.

$$\text{MC (wb, \%)} = \frac{W_i - W_f}{W_i} \times 100$$

W_i= initial weight of sample (5 g),
W_f= weight of sample after drying, g

1.2 Solvent extraction

Accelerated Solvent Extractor (ASE 350, Dionex) was used to extract the oil from camelina, and caronata oilseeds using n-hexane. Oils were extracted at three different temperatures, i.e. 80, 100 and 120°C for 40, 65 and 90 min of extraction time. The solvent to seed ratio was kept constant as 4:1 from preliminary trails. The system pressure was controlled at 1500 psi throughout the experiments. Different treatment conditions employed for oil extraction from ASE are given in Table 1.

1.3 Cold press extraction

Oil extraction was carried out using cold press oil extractor (M70 oil press, Oil press. Co) consisting of VFD motor (2 HP, 1.5 kW) for operating the screw press. A heating collar was wrapped around the barrel to regulate the temperature for oil extraction. This temperature was kept constant at 90 ± 2.0°C. Oils were extracted at 3 different screw frequency, i.e. 15, 20 and 25 Hz using 3 different die nozzles of diameter 5.6, 6.4, and 7.2 mm. About 2 kg of oilseeds were used to extract the oil under different conditions. Extracted oils were stored at 4°C for further analysis. Different treatment conditions employed for oil extraction from CP are given in Table 1.

1.4 Soxhlet extraction

Two g of ground oilseeds were extracted in a Soxhlet apparatus with 30 mL of boiling n-hexane for 8 h. The mixture of oil and hexane was collected, concentrated under vacuum, and dried for 5 min at 105°C. Extraction yield was determined using the official recommendation (ISO, 2009).

1.5 Oil characteristics

1.5.1 Density

Density measurements were carried out using a pycnometer at a temperature of 25°C (±0.1°C). The pycnometer of capacity 25 mL was calibrated with water.

1.5.2 Viscosity

Viscosity measurement was carried out using a viscoanalyzer rheometer (ATS Rheosystems, NJ) equipped with RheoExplorer 39E commercial computer software (Version 5.0, Rheological instruments AB, 1999-2003). The experiments were conduct using a concentric cylinder geometry consisting of a rotational inner cylinder (bob) with an outer radius of 25 mm and 44.5 mm immersed height. Bob rotates in an outer stationary cup having 26 mm inner radius and thus giving 1 mm gap for fluid to be sheared. Measurements were taken for 15 ml sample at 25°C (±0.1°C) controlled temperature. The viscometer operated at forty fixed shear rates from 0 to 200 s^{-1}.

1.5.3 Heating value

Oxygen bomb calorimeter (IKA C2000, Wilmington, NC) was used to determine the heating value of the oil samples. A known quantity of oil was placed in the cup inside the bomb filled with oxygen for combustion. Instrument gave the direct heating value calculated from temperature increased in the water surrounding the jacket after combustion of known amount of sample.

1.5.4 Elemental analysis

Carbon (C), hydrogen (H), nitrogen (N), and oxygen (O) content analysis of oil samples were determined using a CE-440 Elemental Analyzer (Exeter Analytical. Inc., MA, USA) according to ASTM D4057 standard. Acetanilide was used for calibration. For CHN content analysis, the combustion and reduction temperatures were kept as 980°C and 650°C, respectively. The oxygen and helium pressure were maintained at 1.51×10^5 Pa (22 psi) and 1.17×10^5 Pa (17 psi), respectively. For O content analysis, the combustion and reduction temperature were 960°C and 770°C, respectively. Only helium was used as the carried gas at 1.17×10^5 Pa (17 psi). Samples were sealed in a tin capsule and placed in a nickel sleeve. C, H, N, and O (wt%) values were directly recorded from the software attached to the analyzer.

1.5.5 FFA analysis

20 mg oil was mixed with 2 ml hexane and 2 ml BF_3 methanol in a 20 ml conical flask. Mixture was then heated in a water bath at 60°C for 1 h followed by cooling down to room temp. Mixture was topped up by 2 ml distilled water then was shaken for 10 min in shaker to get two different layers. Sometimes, mixture was required to centrifuge at 2500 rpm for 10 min to get layers. The upper layer was decanted in vials and a little amount of sodium sulphate was added in to vial to absorb the water from mixture. After 10 min, the mixture was filtered through 2 µm syringe filter to remove the salt impurities. After diluting the mixture with hexane in 1:1 ratio, derivatized sample was run in GC-MS (Agilent GC- 7890A and MSD-5975C) to identify the free fatty acids present in oil sample. The operating conditions were injection port temperature, 250°C; interface temperature, 250°C; column oven temperature, 75°C for 2 min, ramped at 15°C min^{-1} to 250°C

with a 2 min hold; helium carrier gas (flow rate of 1 mL min^{-1} at 75°C). The injector was operated in the splitless mode for 1 min after injection of the sample and capillary column (30 m × 0.25 mm × 0.25 mm DB-5MS) was used.

1.5.6 Unsaponifiable matter

Unsaponifiable matter of the oils was determined according to AOCS Recommended Practice Ca 6a-40 (AOCS, 2003) and was expressed as a percentage (w/w) of oil.

1.6 Statistical analysis

Full factorial design was used for experimental plan and results were compared by analysis of variance (ANOVA) using SPSS (16.0) statistical software. All data were reported as mean ± standard deviation of replicates. Tukey's tests were used to compare the significant differences of the mean values with the family error rate held at 0.05.

2. Results and Discussion

2.1 Effect of extraction time and temperature on oil yield and oil qualities

Main effect of extraction temperature and time on the oil yield are shown in Fig. 1. It is obvious that with increase in the extraction temperature during solvent extraction, oil yields of camelina and carinata oilseeds increased significantly ($p<0.05$). However, for carinata, transition of temperature from 100°C to 120°C did not make any significant ($p>0.05$) change in the oil yield (Fig. 1a). Similar results were found when the extraction time was varied from 40 min to 90 min (Fig. 1b). More extraction time allows more fat to diffuse into the extraction solvent. As the temperature increased, the viscosity of the solvent is reduced, thereby increasing its penetration to the sample matrix and solubilize the analyte (fat). The addition of thermal energy also assists in breaking analyte matrix bonds and encourages analyte diffusion from the matrix surface (Giergielewicz-Możajska et al., 2001).

The oil yield of camelina and carinata oilseeds exhibited a range of 29.85%-36.22%, and 31.50%-34.40%, respectively (Table 2). These values were in accordance with the findings reported by Budin et al. (Budin et al., 1995); Patil et al. (Patil et al., 2009) for camelina and Cardone et al. (Cardone et al., 2003); Stamigna et al. (Stamigna et al., 2012) for carinata. Treatment condition 6 (100°C-90 min) gave the maximum oil yield of camelina and carinata during accelerated solvent extraction. At low (80°C) extraction temperature, the oil yields of camelina did not show any significant ($p>0.05$) difference when extraction time increased from 40 min to 90 min, whereas carinata oil yield increased significantly ($p<0.05$) from 40 min to 65 min followed by no significant ($p>0.05$) change with further increase in extraction time. At high temperature of 100°C and 120°C, oil yields of both oilseeds showed the significant ($p<0.05$) increase with increase in extraction time from 40 min to 90 min. Similar trend was observed by Lohani et al. (Lohani et al., 2015) for solvent extraction of camelina. At higher temperature, less viscous solvent solubilized more analyte as an effect of increase in extraction time. At 65 min of extraction time, increase in temperature from 80°C to 120°C had no significant ($p>0.05$) effect on oil yield of both oilseeds, whereas, at lowest (40 min) and highest (90 min) extraction time, camelina and carinata oil yields significantly ($p<0.05$) increased with increase in the temperature from 80°C to 120°C, though there was no significant ($p>0.05$) change in the oil yield of both oilseeds when the temperature was elevated from 100°C to 120°C (Table 2).

Camelina had higher oil content than carinata oilseeds. Maximum oil yield was found from both oilseeds at a temperature range of 100°C to 120°C and 90 min extraction time. Oil yields of both oilseeds extracted from ASE were also compared with those using Soxhlet extraction. Maximum

ASE oil yield of camelina and carinata were 3.9%, and 2.3% less than Soxhlet extracted oil yield, respectively (Table 2).

2.1.1 Heating value

Heating value for the oils extracted from camelina and carinata oilseeds ranged from 39.4-39.8 MJ/kg, and 40.0-40.5 MJ/kg, respectively. Lohani et al. (Lohani et al., 2015); and Dobre and Jucoane (Dobre and Jurcoane, 2011) reported the similar values, however, Bernardo et al. (Bernardo et al., 2003); Patil et al. (Patil et al., 2009); and Leung et al. (Leung et al., 2010) reported the higher heating values for camelina oil. Carinata oil did not show any significant ($p>0.05$) change in the heating values with increase in the extraction time and temperature (Table 2). Camelina oil exhibited the significant ($p<0.05$) increase in the heating values with increase in the extraction temperature from 80°C and 120°C for 40 min extraction time. The effect of temperature was insignificant ($p>0.05$) when the oil was extracted for 65 min and 90 min. On the other hand, the effect of extraction time on the heating values of camelina oil was not significant ($p>0.05$) for all the experimental extraction temperatures (Table 2). Lohani et al. (Lohani et al., 2015) found no significant change in the heating values of solvent extracted camelina oil with the variation of extraction temperature and time.

The average heating values for carinata oil was nearly 1.5% higher than that of camelina oil. Oils with higher heating values were obtained at 90 min extraction time and extraction temperature ranged from 80°C to 120°C.

2.1.2 Viscosity

Camelina and carinata oil exhibited the viscosity varied from 42.35-47.65 cp, and 66.75-70.75 cp, respectively (Table 3). Bernardo et al. (Bernardo et al., 2003); and Lohani et al. (Lohani et al., 2015) reported the similar results for camelina. At low temperature (80°C), viscosity of camelina oil increased significantly ($p<0.05$) when the extraction time increased from 40 min to 90 min, whereas, this effect was inverse at 120°C extraction temperature. Viscosity of camelina oil did not show any significant ($p<0.05$) change with extraction time at 100°C. For 65 min and 90 min of extraction time, the viscosity increased and decreased ($p<0.05$), respectively when extraction temperature raised from 80°C to 100°C. However, there was no significant ($p>0.05$) change in camelina oil viscosity after 100°C for both the extraction time. At low extraction time (40 min), viscosity of camelina oil exhibited insignificant ($p>0.05$) change when the extraction temperature increased from 80°C to 120°C. For carinata oil, the extraction time did not show any significant ($p>0.05$) effect on viscosity at all experimental extraction temperatures. For 65 min extraction time, the viscosity of carinata oil decreased significantly ($p<0.05$) with an increase in temperature from 100°C to 120°C, whereas, for the other two extraction times, no significant ($p>0.05$) change was observed in the viscosity when the extraction temperature varied form 80°C to 120°C (Table 3).

Camelina oil was found less viscous (35% on average) compared to carinata oil. Minimum oil viscosities for both the oilseeds were observed at a range of extraction temperature from 100° C-120°C for 40 and 90 min extraction time.

2.1.3 Density

Camelina and carinata oil densities varied from 906-918 kg/m^3, and 922-928 kg/m^3, respectively (Table 3). Bernardo et al. (Bernardo et al., 2003); Patil et al. (Patil et al., 2009); Leung et al. (Leung et al., 2010); Dobre and Jucoane (Dobre and Jurcoane, 2011); Lohani et al. (Lohani et al., 2015), and Bouaid et al. (Bouaid et al., 2005) reported less values for camelina and carinata oil density, respectively. At 80°C and 100°C extraction temperatures, the density of camelina oil

significantly ($p<0.05$) decreased and increased, respectively with increase in the extraction time from 40 min to 90 min. No significant ($p>0.05$) change was observed in the density when the extraction time was 40 min and 90 min at 120°C, though the density dropped significantly ($p<0.05$) for 65 min extraction time. Camelina oil did not exhibit any significant ($p>0.05$) difference in the density at 80°C and 120°C for 40 min and 90 min extraction time. However, there was significant drop and increase in the density at 40 min and 90 min, respectively when the temperature was raised from 80°C to 100°C (Table 3). No significant ($p>0.05$) effect of extraction temperature was observed on camelina oil density at 65 min extraction time. For carinata oil, the density was not significantly ($p>0.05$) affected with increase in the extraction time from 40 min to 90 min at 100°C and 120°C temperature. There was a significant ($p<0.05$) increase in the density at low temperature (80°C) when the extraction time was increased from 40 min to 65 min. However, the density of the oil after 90 min extraction time was not significantly ($p>0.05$) differ than that of 40 min extraction time. Carinata oil did not show any significant ($p>0.05$) change in density when the extraction temperature was varied from 80°C to 120°C for all the experimental extraction time (Table 3).

On an average carinata oil was 1.4% denser than the camelina oil. Maximum density of camelina oil was observed at extraction temperature ranged from 100°C-120°C for 90 min extraction time, whereas, for carinata oil, the maximum density was observed at 65 min extraction time in the temperature range of 80°C-120°C.

2.2 Effect of nozzle diameter and screw frequency on oil yield and oil qualities

Main effect of nozzle diameter and screw frequency on the oil yield are shown in Fig. 2. Apparently, an increase in nozzle diameter from 5.6 mm to 7.2 mm significantly ($p<0.05$) dropped the oil yield of camelina and carinata oilseeds (Fig. 2a). The oil yield of carinata did not exhibit any significant ($p>0.05$) change when the screw frequency was varied from 15 Hz to 25 Hz, whereas, camelina oil yield was significantly ($p<0.05$) higher at 20 Hz screw frequency (Fig. 2b). Smaller diameter nozzle created a back pressure on the oilseeds inside the cold press resulting in more oil extraction. Higher the screw frequency, the oilseed retained for shorter time inside the cold press which cause decrease in the oil yield.

Camelina and carinata oil yield ranged from 22.4%-34.1%, and 27.0%-32.4%, respectively (Table 2). For 6.4 mm and 7.2 mm nozzle diameters, the oil yield of camelina was observed significantly ($p<0.05$) higher at 20 Hz screw frequency and no significant ($p>0.05$) difference in density was observed at 15 Hz and 25 Hz. Zhao et al. (Zhao et al., 2014) also found the maximum oil yield of camelina at 20 Hz screw frequency. Camelina oilseed did not show any significant ($p>0.05$) change in the oil yield with increase in screw frequency at 5.6 mm nozzle diameter. With increase in nozzle diameter from 5.6 mm to 6.4 mm, camelina oil yield decreased significantly ($p<0.05$) followed by no significant ($p>0.05$) change further in the oil yield when the nozzle diameter varied from 6.4 mm to 7.2 mm at all experimental screw frequencies. For carinata oilseed, only for 5.6 mm diameter nozzle, the oil yield was found to be significantly ($p<0.05$) higher at 20 Hz screw frequency. For rest of the two nozzle diameters, carinata oil yield did not show any significant ($p>0.05$) change with increase in the screw frequency from 15 Hz to 25 Hz. When the nozzle diameter increased from 5.6 mm to 7.2 mm, there was significant ($p<0.05$) drop in the carinata oil yield at all experimental screw frequency level.

Maximum oil yield was found from both oilseeds at 20 Hz screw frequency and 5.6 mm nozzle diameter. Oil yields of both oilseeds extracted with CP were also compared with Soxhlet extraction. Maximum CP oil yield of camelina and carinata were 9.5%, and 8.0% less than the Soxhlet extracted oil yield, respectively (Table 2).

2.2.1 Heating value

Heating value of the oils extracted from the camelina and carinata oilseeds varied from 39.7-39.9 MJ/kg, and 40.4-40.8 MJ/kg, respectively (Table 2). For 5.6 mm and 7.2 mm nozzle diameter, the camelina oil did not exhibit any significant ($p>0.05$) change in the heating value when the screw frequency was varied from 15 Hz to 25 Hz. Heating value significantly ($p<0.05$) increased with increase in the screw frequency from 20 Hz to 25 Hz for 6.4 mm nozzle diameter. Oil extracted from the camelina oilseed showed significant ($p<0.05$) increase in the heating value with increase in the nozzle diameter from 6.4 mm to 7.2 mm at 15 Hz and 20 Hz screw frequencies, whereas, at 25 Hz screw frequency, increase in the heating value was significant ($p<0.05$) when the nozzle diameter varied from 5.6 mm to 6.4 mm followed by no significant ($p>0.05$) change in the heating value with further increase in the nozzle diameter (Table 2). For the carinata oil, there was no significant ($p>0.05$) effect of screw frequency on heating value oil was extracted using 7.2 mm nozzle diameter. However, for 5.6 mm and 6.4 mm nozzle diameter, the heating value significantly ($p<0.05$) increased and decreased, respectively with increase in the screw frequency from 15 Hz to 25 Hz. When the carinata oil was extracted at 15 Hz and 20 Hz screw frequencies, heating value of the oil did not exhibit any significant ($p>0.05$) change with the variation in the nozzle diameter from 5.6 mm to 7.2 mm. However, there was significant ($p<0.05$) decrease in the heating value at 25 Hz screw frequency when nozzle diameter varied from 5.6 mm to 6.4 mm (Table 2).

The average heating values for the carinata oil was nearly 2% higher than the camelina oil. Camelina oil extracted using large nozzle diameter had high heating values regardless of screw frequencies. However, carinata oil with higher heating values were obtained using 6.4 mm nozzle diameter and at low screw frequency.

2.2.2 Viscosity

Camelina and carinata oils viscosity ranged from 55.7-57.1 cP, and 69.4-72.1 cP, respectively (Table 3). For camelina oil, nozzle diameter and screw frequency did not exhibit any significant ($p>0.05$) effect on the viscosity. Viscosity of carinata oil increased significantly ($p<0.05$) with increase in the screw frequency from 15 Hz to 25 Hz at 5.6 mm nozzle diameter. No significant ($p>0.05$) effect of screw frequency on the viscosity was observed for rest of the two nozzle diameters. Varying the nozzle diameter from 5.6 mm to 7.2 mm did not significantly ($p>0.05$) affect the viscosity of carinata oil at 15 Hz. However, at 20 Hz and 25 Hz screw frequency, heating value significantly ($p<0.05$) decreased with increase in the nozzle diameter from 6.4 mm to 7.2 mm (Table 3).

For both the oils, minimum viscosities were found for large nozzle diameter regardless the screw frequency. On average, camelina oil was 20% less viscous than the carinata oil.

2.2.3 Density

Density of the camelina and carinata oils ranged from 905-917 kg/m^3, and 923-935 kg/m^3, respectively. Camelina oil did not show any significant ($p>0.05$) change in the density with increase in the screw frequency at 6.4 mm and 7.2 mm nozzle diameter. With increase in the screw frequency from 20 Hz to 25 Hz, the oil density increased significantly ($p<0.05$) at 5.6 nozzle diameter. There was no significant ($p>0.05$) effect of nozzle diameter on the density, when camelina oil was extracted at 20 Hz and 25 Hz screw frequency. At lowest experimental screw frequency, density was significantly ($p<0.05$) higher at 6.4 mm than that of other two nozzle diameters. Carinata oil did not exhibit any significant ($p>0.05$) change in the density with increase in the screw frequency at 6.4 mm and 7.2 mm nozzle diameter. For 5.6 mm diameter, there was significant ($p<0.05$) increase in the oil density when screw frequency was varied from

20 Hz to 25 Hz. Oil density increased significantly ($p<0.05$) with increase in the nozzle diameter from 5.6 mm to 7.2 mm at 15 Hz and 20 Hz screw frequency, whereas for 25 Hz, no significant ($p>0.05$) change in the density was observed with increase in the nozzle diameter.
Carinata oil was denser (22% on average) than the camelina oil. Minimum densities of both the oils were observed at less nozzle diameter and screw frequency range of 15 Hz and 20 Hz.

2.3 Comparison of ASE and CP extracted oils

The optimum conditions for ASE and CP was found as 100°C temperature, 90 min extraction time, and 5.6 mm nozzle diameter, 20 Hz screw frequency, respectively. Oil qualities of both the oilseeds for ASE and CP extraction were compared in these conditions. Camelina and carinata oils extracted at ASE condition were almost 6% more than the cold pressed oils. Heating values of ASE extracted camelina and carinata oils were similar to that of oils extracted from CP (Table 2). Solvent extracted camelina oil exhibited 23% less viscosity than the cold pressed oil, whereas for carinata oilseed, there was no significant difference in the viscosity of ASE and CP extracted oils. As far as density was concerned, solvent extracted camelina oil was found 13% denser than that of cold pressed oil. However, ASE and CP extracted carinata oil had similar densities at respective optimum extraction conditions (Table 3).

2.3.1 Elemental content

Solvent extracted camelina and carinata oils contained higher carbon and less oxygen than that of cold pressed oils which indicated higher calorific values of ASE extracted oils (Table 4). Nitrogen content of all the oils were lower than 1% which indicates low level of phospholipids. The hydrocarbon (H/C) ratio of camelina oils ranged from 1.73 to 1.77, whereas H/C ratio varied from 1.76-1.81 for carinata oils which were lower than petroleum product H/C ratio (2.0). Zhao et al. (2014) also found the similar elemental values for cold pressed camelina oil.

2.3.2 Free fatty acid (FFA) profile

Fee fatty acid profiles for Camelina and carinata oil extracted by ASE and CP at their optimum conditions are given in Fig. 3. Five free fatty acids, i.e. palmitic, linoleic, linolenic, oleic, and stearic acid were identified in all the four oil samples. From the observation of peak heights and areas of chromatogram, it was found that camelina oil was rich in linolenic acid as a polyunsaturated fatty acid, whereas oleic acid (monounsaturated fatty acid) was dominant in carinata oils regardless of the extraction methods (Table 5). Similar reports were found by Jucoane (Dobre and Jurcoane, 2011); Rosie et al. (Ciubota-Rosie et al., 2013); Waraich et al. (Waraich et al., 2013); Lohani et al. (Lohani et al., 2015); Zaleckas et al. (Zaleckas et al., 2012) for camelina and by Dorado et al. (Dorado et al., 2004) for carinata. The fatty acid profiles of solvent-extracted and cold pressed oil samples followed a similar trend.

2.3.3 Unsaponifiable matter

The unsaponifiable matter for camelina and carinata oil extracted from ASE and CP at their optimum conditions are shown in Table 4. It was obvious that the oils extracted by ASE had less unsaponifiable matter than that of extracted from CP for both camelina and carinata oils. Also camelina oil showed less unsaponifiable matter than carinata oil. The values of unsaponifiable matter were found in range reported by Czaplicki et al. (Czaplicki et al., 2011) for camelina oil.

3. Conclusions

Results from this study conclude that the yield and quality (heating value, density, viscosity, elemental analysis, free fatty acid profile, and unsaponifiable matter) of oils removed from Camelina *sativa* and Brassica *carinata* using ASE are better than that of the oil removed by CP.

Extraction time and temperature of 90 min, and 100°C, respectively can be recommended for oil extraction from selected oilseeds using ASE. The optimum condition for CP was found as 5.6 mm nozzle diameter and 20 Hz screw frequency. Though both the oils had potentiality to upgrade in to biofuel, camelina oil exhibited better oil qualities required for further biofuel upgradation. Accelerated solvent extraction can be a best alternative for oil extraction method at commercial scale due to less time and higher oil recovery with better oil qualities.

Abstract

The aim of this study was to examine the possibilities of composting of tobacco waste (TW) with the addition of various organic waste materials, to obtain fertilizer with a high content of organic matter and low levels of toxic elements. Virginia tobacco leaves, which are classified as waste in the tobacco processing, were used in this experiment. Two experimental samples are formed according to the following scheme: I 50% TW + 50% cabbage; II 50% TW + 20% soil + 20% dry forest leaves + 10% cabbage. The comparison was made with the reference sample (only TW).
The experiment was set up in the indoor area at the Faculty of Agriculture, during the winter period, without automatic control of temperature and humidity. Nicotine content in the samples was determined by the HPLC method. Mineral matter content was determined by the atomic-absorption spectrophotometer AAS Perkin Elmer Aanalyst 300th. The results showed it is possible to obtain organic fertilizer from tobacco waste, through the process of composting. At the end of the composting process, the nicotine content had fallen below 10 mg/kg. The content of the basic macronutrients in experimental samples was suitable from the point of agricultural production. The levels of all heavy metals, except cadmium, were all below the allowable limit. Application of obtained products could come into consideration only if they are mixed with fertilizer, which has a low content of cadmium, so that it's content in the mixture does not exceed the allowed 0.7 mg/kg.

Key words:

Introduction

The rapid increase in world population causes an increase in living standards, which inevitably leads to greater consumption of goods and services, and hence creates large quantities of waste per capita (Lim et al., 2016). The global increase of waste causes multiple problems - from the creation of large landfills which occupy the cities arable land to environmental contamination with heavy metals and chemicals (Bijaya et al., 2008; Garg et al., 2008). In the last ten years, the growth of the environmental awareness has led to an attempt to reduce a waste amount, get a useful product and at the same time to protect the environment (Jovičić, 2006).
The largest part of the waste, is certainly solid, municipal waste. Considering the percentage of the agricultural population (about 10%), the Republic of Serbia, in addition to municipal waste, faced with large amounts of agricultural waste. The largest part of the agricultural waste is corn (Jovanović et al., 2009), but a significant percentage of the total waste also makes tobacco waste generated after cultivation, processing, and tobacco, as well as after consumption of tobacco products (Radojičić et al., 2009).
The main characteristics of the tobacco waste are low moisture content, and high-value of organic carbon, nitrogen, and nicotine (Channiwala and Parikh, 2002; Civilini et al., 1997; Kopčić, 2016).

Directly dumping of the tobacco waste can pollute the environment, primarily due to the nicotine which is soluble in water and, as such, represents a threat to groundwater. EU Tobacco Directive classifies tobacco waste as hazardous if the nicotine content is greater than 500 ppm, whiles the Ministry of Agriculture and Environmental Protection and the Environmental Protection Agency of the Republic of Serbia, classifies it as non-toxic, but hazardous waste (Civilini et al., 1997; Pichtel, 2005; Waste Catalogue, 2010). Therefore, tobacco waste cannot simply be disposed of in a landfill along with other waste, but it has to be destroyed with specific procedures entrusted to the companies for tobacco processing.

Before disposal, tobacco waste can be biologically or thermally treated. Biological treatment (composting) involves partially or fully controlled process in which an organic matter gets biologically degraded. Finally, stable biodegradable waste compost is produced. So, composting is an acceptable solution because it reduces a cumbersome tobacco waste, transforming it into a stable organic fertilizer (Kopčić, 2016). Composting of tobacco waste accelerates the degradation of nicotine and produces nontoxic organic waste (Briski et al., 2003; Okur et al., 2008).

If we take into account that in 2005, total global production of tobacco waste amounted to more than 25.1 million tons (Kopčić, 2016), it is evident why the recycling is crucially important, both for environmental protection and in the economy (Novotny and Zhao, 1999; Okur et al., 2008)

The aim of this study was to examine whether tobacco waste (TW) can be composted by adding different organic waste, and would this process produce fertilizer with high organic and low toxic content. This work becomes especially important if we take into consideration that so far tobacco waste has been untapped, and his destruction requires a high economic investment.

Materials and methods

Study material were leaves of the large leaves tobacco (Virginia type tobacco), classified as waste during treatment. Soil and dry leaves collected in the park Faculty of Agriculture, University of Belgrade (Serbia) were added to the experimental batches, as well as commercially available waste cabbage leaves. The experiment was performed from the December 2014 until March 2015 at the Faculty of Agriculture, University of Belgrade. It was carried out in several steps: 1. preparation of experimental batches, 2. monitoring parameters of the composting process, 3. analysis of nicotine content, trace elements and heavy metals in samples of experimental batches.

1. Since all of the samples initially had a low water content, the first phase of the experiment was humidification, then grinding and finally mixing tobacco waste with biodegradable waste. Three diverse compost batches were made: the reference contained only tobacco waste and in the other two had a mixture of tobacco waste and other organic waste (the outline is given in Table 1).

Table 1. Compost batches ingredients (%)

Compost batches	Tobacco waste	Soil	Cabbage leaves	Dry leaves
1	50	-	50	-
2	50	20	10	20
R	100	-	-	-

2. The experiment was performed in a room without automatic parameters control. Thus, the parameters were manually adjusted if necessary (heating, ventilation). During the experiment, temperature and humidity of the samples and the experimental room were controlled daily

(thermometer K-TYPE 5115; microprocessor - moisture meter, model No. RS7825PS, CE ISO-2178, mini meteorological station Kestrel 4000, Nielsen - Kellerman).
3. In the experiment nicotine content in the compost batches were determined by HPLC method. Mineral matter is determined with atomic-absorption spectrophotometer AAS Perkin Elmer Analyst 300th.

Results and discussion

The results depicted in Table 2 indicate a change in the nicotine content during the experiment. The initial nicotine content in tobacco waste was 17363 mg/kg (sample R). Already at the beginning of the experiment when tobacco waste mixed with other forms of waste, there has been the reduction in nicotine content of approximately 50%, in sample 1, and 43% of sample 2.

Table 2. Nicotine content in experimental batches (mg/kg)

Sample	10.12.2014.	26.12.2014.	15.01.2015.	31.01.2015.	15.02.2015.	03.03.2015.	18.03.2015.	03.04.2015.
R	17363.0	13064.5	11234.2	9515.3	8796.3	6902.0	5680.0	5132.0
1	8830.1	5164.6	4862.2	3864.5	938.8	118.2	< 10	< 10
2	9790.6	8767.6	6102.8	782.8	323.3	108.6	< 10	< 10

All samples achieved complete degradation of nicotine during the composting process, but the dynamics of degradation varied in different samples. Sample 2 showed better results in the degradation of nicotine than Sample 1 which needed additional 20-odd days to drop nicotine content below the authorization limit of 500 mg/kg (EU guideline).
The dynamics of nicotine decomposition mostly depended on the temperature and humidity in experimental samples. Temperature and humidity were measured daily. For the better transparency, the results in Figure 1 and Figure 2 give the average values of the process parameters.

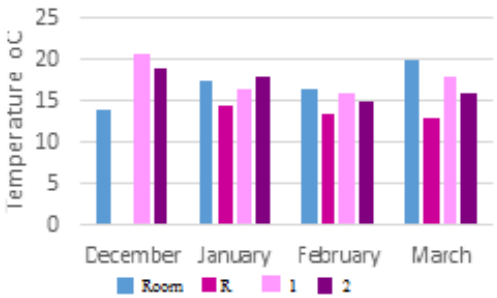

Figure 1. Temperature change during batching

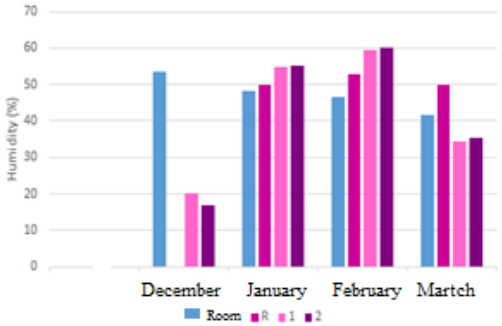

Figure 2. Hudity changes during batching

On the basis of the process parameters depicted in Figures 1 and 2, it can be concluded that the nicotine degradation has increased with rising temperature and humidity. Sample 1 showed a rapid drop in temperature in the first month, which resulted in a somewhat lower degradation of nicotine. In the next month, the temperature stabilized, so the speed of nicotine degradation increased. Sample 2 showed a constant temperature during the experiment which was responsible for the faster nicotine degradation compared to sample 1. Both samples had almost an identical

increase of the humidity. It was noteworthy that the experiment was carried out in the winter in a room without automatic control parameters, which slowed down the process.
Mineral matter content was determined in all samples at the end of the experiment. The results are presented in Table 3.

Table 3. Mineral matter in the compost batches

Sample/ Parameter	R			1			2		
	N	Result	SD	N	Result	SD	N	Result	SD
Nitrogen content, %	3	1.84	0.15	3	1.85	0.26	3	1.01	0.21
Calcium content, %	3	3.37	0.20	3	4.59	0.28	3	4.43	0.20
Potassium content,%	3	1.80	-	3	2.80	-	3	1.90	-
Phosphor content,%	3	0.19	0.04	3	0.25	0.02	3	0.19	0.05
Ash content, %	3	41.16	0.3	3	46.93	0.52	3	57.93	0.61
Cadmium content, mg/kg	3	3.575	0.023	3	4.241	0.145	3	2.905	0,073
Lead content, mg/kg	3	7.800	0.266	3	3.143	0.627	3	27.988	1.842
Arsenic content, mg/kg	3	7.760	0.388	3	5.306	0.265	3	8.617	1.034
Mercury content, mg/kg	3	<0.020	-	3	<0.020	-	3	< 0.020	-
Copper content, mg/kg	3	33.813	0.027	3	25.329	0.099	3	16.578	0.126
Zinc content, mg/kg	3	49.650	0.328	3	75.215	1.053	3	43.630	0.236
Iron content, mg/kg	3	873.980	0.961	3	808.337	0.808	3	905.861	4.167
Manganese content, mg/kg	3	301.302	0.964	3	222.746	0.869	3	337.626	0.169
Magnesium content, %	3	0.197	0.001	3	0.191	0.001	3	0.200	0.001

On the average, compost contains 0.35% N; 0.20% P; 0.25% K, 3.7% Ca and 75% organic matter (Radivojević et al., 1998). The results obtained in this experiment fit in with the expected value.
The content of nitrogen, phosphorus, mercury, and magnesium was the same in all samples. Compared with the sample 1, sample 2 had a slightly higher ash, lead, arsenic, iron, and manganese content. Nitrogen, phosphorus, potassium, calcium and copper values were concordant with the values given by Tedesco et al. (2011). Zinc, copper, magnesium and manganese content in the samples were several times lower than in those produced by Tedesco et al. (2011).
To promote high safety standards, ECOFI in May 2014 proposed a unified approach to organic fertilizers safety criteria. According to this recommendation, secure borders for heavy metals in soil are: 2 mg/kg of mercury, 120 mg/kg of lead, 200 mg/kg of copper and 600 mg/kg for zinc. The experimentally obtained values are several times less than prescribed (ECOFI).
However, according to Official Gazette of the Republic of Yugoslavia (2002), allowed quantities of heavy metals in Serbia are: Cd - 0.7 ppm; Pb - 70 ppm; As - 10 ppm; Hg - 0.7 ppm; Cu - 70 ppm; Zn - 210 ppm. When we discuss the heavy metal contents (Cd, Pb, As, Hg, Cu, Zn) the results in Table 3 point that only cadmium (Cd) was above the permitted limits of these Regulations both in the compost batches and in the reference sample.
Sample 1 (a mixture with 50% of cabbage) had the highest cadmium content, even 6 times above the permitted level. Previous research has found that cabbage, compared with other types of vegetables, absorbs the largest amount of cadmium from the soil (Petrović-Gegić et al., 2007).
The maximum amount of cadmium entered the experimental batches straightly from tobacco waste, which can be documented from the cadmium content in the reference sample (5 times

above the permitted amounts). Since we did not have information about the tobacco waste origin, as well as cabbage origin (location, soil type and pH in which it was grown, use of fertilizers, pesticides, and insecticides, irrigation water quality) we could not conclude what was the reason for such high cadmium content.

Conclusion

This research was primarily carried out to solve the problem of tobacco waste in Serbia, which destruction requires large expenses, mainly due to the nicotine content.

The results showed that it is possible to produce organic fertilizer from tobacco waste through the composting. Nicotine, the toxic waste, drops almost 50%, just by mixing tobacco waste with other forms of available organic waste. At the end of the composting, the nicotine content has dropped below 10 mg/kg, which is much lower than 500 mg/kg, a content required by EU regulations.

In the terms of the agricultural production, the content of the basic macronutrients in the experimental samples is appropriate. The content of all heavy metals except cadmium is below the allowable limit.

If we consider that the experiment took place under conditions similar to the natural (in the winter months, with occasional adjustment of the room temperature and humidity), it is clear that composting can be done in those natural conditions, thus increasing the economic value of tobacco waste. If the composting process took place in the season with higher air temperature, this natural process would be much faster.

Abstract

Due to the different land use, the man significantly influences and changes soil properties, water-air, thermal, biological and nutritious regime. In order to evaluate the influence of different land use (arable fields, meadows and forests) on water physical properties, the research was conducted in selected representative soil samples which were taken on the territory of Vojvodina autonomous province and it covered six soil types. For research purposes, the undisturbed soil samples were taken from different localities (61 localities) from surface horizon (0-30 cm) by Kopetzky cylinders in 3 repetitions. The rate of water permeability through soil sample is determined by method of constant pressure of water column. The majority of soil samples have a value of K-Darcy coefficient of 10^{-3} cm / s, which means that they belong to the class of soil that has good water permeability. Ecologically, the most favourable values of density and porosity have soils under meadows (1.25 g cm^{-3} and 47.24%), followed by soils under forests (1.35g cm^{-3} and 45.05%) and the arable lands have at least a decent level (1.45g cm^{-3} and 41.09%). From the results of statistical analysis it can be seen that land use has a much greater effect on the tested properties than soil type. On the basis of this research it can be concluded that land use significantly affects the water-physical properties. Arable agricultural land subjected to high anthropogenic influence is more likely exposed to deterioration of these properties.

Keywords: *soil, water permeability, land use, water-physical properties*

Introduction

Soils with different chemical, physical and biological characteristics are formed under the influence of different pedogenetic factors and processes on parent material. The function of soil in human history is significant, because the first civilisation appeared on the most fertile grounds (Kastori, 1995). By converting soil in to a medium for agricultural production, the man became crucial factor in pedogenezis and pedoevolution. The development of agricultural engineering and sciences, allows him to change composition and properties of soil according to requirements of plants.Sometimes, human activities cancause deterioration of soil properties and promotion of damaging processes in soil (Đorđević and Radmanović, 2016).On the other hand, natural "virgin"soils are not exposed to anthropogenic influence, and their properties entirely depends on the pedogenetic factors and processes that occur"in situ".

In order to protect soil from negative anthropogenic influence and degradation, it is necessary todefine significant prevention measures,identifythe hazardand find appropriate solutions for their transcendence. Therefore, systematic control of soil fertility and content of harmful and hazardous substancesi.e. monitoring of soil quality was suggested (Ličina et al., 2011; Nešić et al., 2015).

The Ministry of Education, Science and Technological Development of Republic of Serbia initiated and supported the project "Status, trends and possibilities to increase the fertility of agricultural land in Vojvodina Province"TR31072, 2011-2015. The aim of this project isto determinate the quality of agricultural land in Vojvodina and to evaluate the possibility for production of high quality health-certified food. Part of the research from named project, which refers to results of soil water-physical properties, will be presented in this paper. Soil condition is usually assessed in terms of suitability for crop production and soil's impact on the environment (Birkas, 2008). Water-physical properties which describe soil condition are bulk density, total porosity and water permeability.

Bulk density or density of dry land is defined as the mass of solid phase of soil drained on 105 ^{0}C per unit volume of soil, with pores. This soil property depends on structure,moisture, mechanical composition, aggregate composition and packing density of aggregates and particles. It is typically expressed inkg/m^3 or g/cm^3.Unlike specific weight, the values of bulk density are changeable and vary in a wide range (Dugalić and Gajić 2012).

Soil pores, filled out with water or air, are located between primary soil particles and structure aggregates. Total porosity is defined as volume of all pores per unit of soil volume. This soil propertyis expressed in volume percentages (vol. %). Size, shape and ratio between pores are different and depend on mechanical and aggregate composition (packing density, shape and size of soil particles and aggregates), content of organic matter and activity of root system of plants and soil fauna (Vučić, 1987). Total soil porosity varies in wide range because of the same factors thathave influence on bulk density.

Water permeability presents one of the primary hydrological characteristic of soil. When all soil pores are saturated and filled with water, water starts to filter through soil horizons. Water permeability is highly dependent on other soil properties (porosity, mechanical composition, structure, compaction, soil moisture etc.), as well as on properties of water which appear on soil surface through precipitation or irrigation. Water permeability is defined by K- Darcy's coefficient which represents the rate of water filtration, and it is expressed in cm/sec, m/h, and m/day. Stable values of water filtration are developed after 4-5 hours and they are used in different calculations (Vučić, 1987).

Materials and methods

Soil sampling was conducted on territory of Autonomous Province of Vojvodina from June to July 2015. Samples were collected from 61 localities which represent the most frequent soil types of this area. The network of squares sized 4 x 4 km was set over a soil map of Vojvodina R 1:50 000 (Nejgebauer et al., 1971), so that each soil sample represents an area of 1 600 hectare. GPS coordinates of all localities are marked on the digitized soil map of Vojvodina R 1:50 000 (Benka and Salvai, 2005). Undisturbed soil samples were taken with Kopetzky cylinders and undisturbed soil samples were taken in cardboardboxes from surface horizons of each locality.Laboratory analyses were conducted at the Laboratory of Pedology, Faculty of Agriculture in Novi Sad.

The following properties of selected soil samples were analysed:

- Bulk density (Smz) of soil was determined by method with cylinders in 3 repetitions (three cylinders) and classified according to Katzinski (1965).

-Total porosity (UP) was calculated by formula from bulk density and specific weight of soil and classified according to Miljković (1996).

-The rate of water filtration (K-Darcy coefficient) through the soil sample (Kopetzky cylinders in 3 repetitions) was determined by the method of constant water pressure of water column andsoil classification was done according to the Yugoslavian Society for Soil Science (1971).
Statistical analyses of the data on bulk density, total porosity, land use and soil type were processed in software program STATISTICA 7, StatSoft, Inc. The significance of effect of land use and soil types on bulk density and total porosity was determinate using ANOVA. „LSD Fisher"test was used to separate values at the $p<0.05$ level of significance. Arithmetic means, maximum and minimum were calculated for the water permeability results.

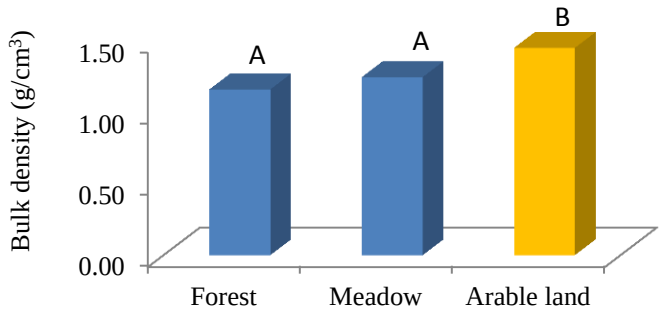
Results and discussion

Undisturbed and disturbed soil samples collected for laboratory analyses represent 6 different types of soil on the territory of Autonomous Province of Vojvodina. The most widespread type of soil is chernozem which occupies 41%, followed by fluvisol occupying 19 %, humoglay 15 %, eutric cambisol and arenosol 10 %, and finally vertisol 5 %.
The tested localities have three types of land use and mainly consist arable land 62 %, followed by forests 21%, andmeadows 17%.

Table 1. Average values of bulk density and total porosity according to land use

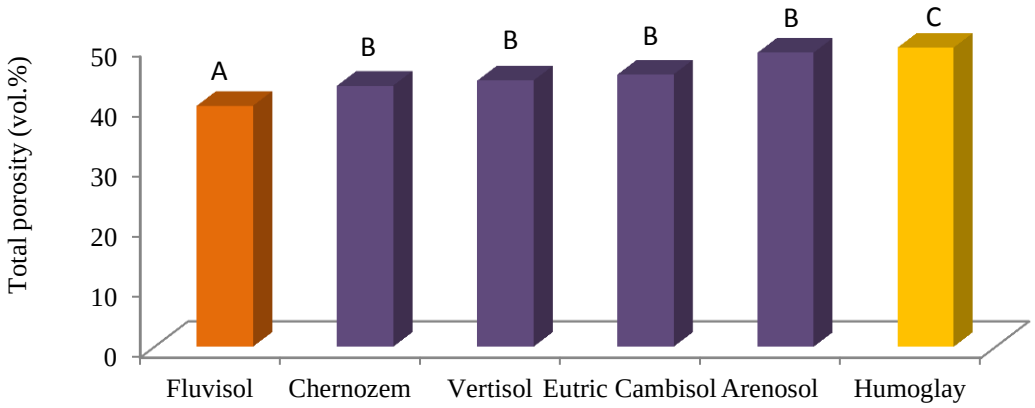
Land use	**Bulk density (g/cm^3)**	**Total porosity (vol. %)**
Meadow	1,25	47,24
Forest	1,35	45,05
Arable land	1,45	41,09

By analysing the bulk density in collected soil samples, the results showed that the highest average value had arable land 1,45 g/cm^3, followed by forest 1,35 g/cm^3, and the lowest value had meadow 1,25 g/cm^3 (Table 1.). According to average values of bulk density, soils under meadows and forests can be classified as slightly compacted, while arable lands belong to class of more compacted soils. Bošnjak et al. (1997) point out that in natural conditions, soil compaction can be caused due to deficiency of organic matter and pressure of upper layers of soil. Ćirić et al. (2008) as main reasons for soil compaction consider untimely and excessive tillage during high moisture content in soil, constant tillage on the same depth, pulverisation of structural aggregates and numerous walkthroughs of agricultural mechanization.
Analysis of variance (ANOVA) of data on bulk density andsoil typeshowedthat there is no significant effect of soil type on bulk density. On the other hand, the effect of land use differs between soils under meadows and forestsand arable lands (Graph 1.). Arable lands have greater effect than soils under meadows and forests, because of different agricultural and amelioration measures applied by man.



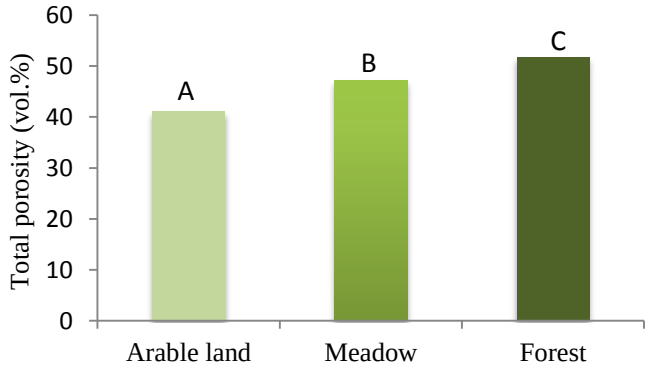
Graph 1.Effect of land use on bulk density (Different letters show significantly different means of bulk density between land uses calculated by Fisher's LSD test ($p<0.05$))

Average values of total porosity in examined samples varied from 47,24 to 41,09 vol.% (Table 5.). Arable lands have the lowest average value of total porosity which is 41,09 vol.% and therefore belong to class of soils with low porosity. According to Vučić (1992), low total porosity decreases aeration and water permeability of soil. Regarding average values of total porosity, soils under meadows (47,24 vol.%) and forests (45,05 vol.%) can be classified as porous soils. Thanks to activity of root system of forest and meadow plant communities and pedofauna, soils with good porosity and looseness occur in natural condition. (Živković and Đorđević, 2003).
The data on soil type, land use and total porosity were also analysed by ANOVA. "LSD Fisher" test separated significant values of total porosityin relation to land use and soil type (Graph 2.). The results of this test show no significant effect of chernozem, vertisol, eutric cambisol and arenosol on total porosity.



Graph 2.Effect of soil type on total porosity (Different letters show significantly different means of total porosity between soil types calculated by Fisher's LSD test ($p<0.05$))

However, fluvisol and humogley are an exception, because these types of soil have an effect on the total porosity. The same statistical test is also used for the data on land use and total porosity and the results indicate that every way of land use have high effect on total porosity (Graph 3.).



Graph 3.Effect of land use on total porosity (Different letters show significantly different means of total porosity between land uses calculated by Fisher's LSD test ($p<0.05$))

The rate of water permeability for analysed soil samples varied in the interval of the order of 10^{-5}(minimum) to 10^{-1} cm/sec (maximum) (Table 2.). Average values of K-Darcy's coefficient in tested soil samples are of the order of 10^{-3} cm/sec, which means that chernozem, vertisol, eutric cambisol, fluvisol, and humoglay belong to the class of soils with high water permeability (Belić et al., 2014). However, arenosol presents the only exception because it has average value of K-Darcy's coefficient in the interval of the order10^{-1} cm/s and it is classified as soil with very high water permeability.

Table 2. Average values, maximums and minimums of K-Darcy's coefficient according to land use

Land use	***K- Darcy's coefficient (cm/s)***		
	Average value	**Minimum**	**Maximum**
Meadow	1.27×10^{-2}	8.75×10^{-5}	1.00×10^{-1}
Arable land	2.98×10^{-3}	1.10×10^{-5}	8.92×10^{-3}
Forest	2.59×10^{-2}	1.25×10^{-4}	1.00×10^{-1}
All samples	$\boldsymbol{9.45 \times 10^{-3}}$	$\boldsymbol{1.10 \times 10^{-5}}$	$\boldsymbol{1.00 \times 10^{-1}}$

When it comes to land use, it has been concluded that arable agricultural soils have lower water permeability compared to soils of forests and meadows. Hadžić et al. (1999) indicate that in certain circumstance, conventional tillage activates processes that can lead to degradation of soil characteristics, and thus to a deterioration of water, air, thermal, biological and food regime. During the production process in intensive agriculture, water-physical properties of ploughing horizon (0-30 cm) are deteriorating due to the mineralization of organic matter and soil compaction (Nešić, 1991).

Conclusion

Based on research results of analysed disturbed and undisturbed soil samples, collected from 61 localities on territory of Autonomous Province of Vojvodina, from 6 different types of soil, the following conclusions stands out:

Average values of bulk density in examined samples range in the interval of 1,25 g/cm^{3}to 1,45 g/cm^3, which means that analysed soils belong to classes of slightly and more compacted soils.

Analysis of variance (ANOVA) of data on bulk density, land use and soil type, obtain results which show that there is no significant effect of soil type on bulk density, however bulk density is significantly affected by land use, especially by arable lands.

According toaverage values of total porosity in examined samples which varied from 47,24 to 41,09 vol.%, it can be concluded that the analysed soils belong to class of porous soils.

The data on soil type, land use and total porosity were also analysed by ANOVA. "LSD Fisher" test separated significant values of total porosity and the results of this test show no significant effect of chernozem, vertisol, eutriccambisol and arenosol on total porosity. However, fluvisol and humogley are an exception, because the results of test show that these types of soil have an effect on total porosity. When it comes to data on land use and total porosity, the obtained results indicate that land use have high effect on total porosity.

Average value of K-Darcy's coefficient in tested soil samples is in the intervalof the order of 10^{-3} cm/sec, which means that chernozem, vertisol, eutriccambisol, fluvisol, and humoglay belong to the class of soils with high water permeability (Belić et al., 2014).The only exception presents arenosol, which has average value of K-Darcy's coefficient in the interval of the order10^{-1} cm/s, and therefore this soil can be classified as soil with very high water permeability.

Overall research results indicated that land use has great influence on water-physical properties of soil. Arable agricultural soils have high values of bulk density, low porosity and water permeability because of incorrect tillage and numerous walkthroughs of agricultural mechanization.During the production process in intensive agriculture, water-physical properties of ploughing horizon are deteriorating as a result of great anthropogenic influence and negative changes of these properties are usually observed in arable soil.

Acknowledgments

Part of this study was conducted as part of the Project No. TR 31072: "Status, trends and possibilities to increase the fertility of agricultural land in the Vojvodina Province", which is supported by the Ministry of Education, Science and Technological Development of Republic of Serbia

Abstract

The reduction of world`s fossil fuel reserves, as well as concern environmental pollution, encourages the use of renewable energy sources. In the Republic of Serbia, biomass from agriculture represents a significant energy potential. The aim of this paper was to examine the possibility of using tobacco stalks as biofuels, considering that each year, after the harvest of leaves, about 70 000 tons of stalks from all tobacco types remains in the fields. The material used in this study were Burley tobacco stalks, sawdust from beech wood and wheat straw, which were chosen due to the fact that they are already in use as biofuel. In the first part of the experiment the ash content in all samples was determined, which is used to predict the higher heating value (HHV). The HHV as a function of ash content (ash, wt %) was calculated using the equation by Sheng and Azevedo. The experimental determination of the calorific value of all samples in a calorimetric bomb was conducted in the second part of the study. Based on predicted (18208.18 kJ/kg) and experimentally determined HHV of tobacco stalks (17504.44 kJ/kg), as well as comparisons with other forms of biomass, it was concluded that Burley tobacco stalks can be used as biofuel. Experimental values of tobacco stalks are only 9% lower in relation to HHV of beech sawdust. Tobacco stalks and wheat straw have the approximate values of HHV.

Keywords: *burley, tobacco stalks, ash, higher heating value (HHV), biofuel*

Introduction

Energy, as life`s base, affects the living standard and technological progress of each country. However, excessive use of conventional forms of energy, primarily fossil fuel has led to many problems; this practice has polluted the planet and minimized fuel reserves. Owing to the decrease of fossil fuel reserves, substantial use of renewable sources of energy has a large, primarily the economic and ecological impact (Demirel, 2012). Renewable energy sources (biomass, geothermal and solar energy, hydropower and wind power) participate with approximately 14% of total world energy consumption; biomass makes up 62% of that amount (Nakomcic-Smaragdakis et al., 2016).

In the Republic of Serbia, agriculture engages about 10% of the population, while its share in GDP makes almost 11%. At the same time, the increase in agricultural production increases waste products and pollutes the environment. Serbia produces about 12.5 million tons of biomass annually; of these more than 1.7 million tons are the byproduct of agriculture. This biomass usually ends up burned or plowed in the field, which increases the ecosystem pollution and causes significant loss of resources (Jovanović et al., 2009). It is imortant to note that the CEI recommends that by 2020 use of biomass from wood must be reduced and substituted with the biomass from agriculture (CEI, 2013).

According to data from the National Statistical Office of the Republic of Serbia, the main agricultural product in Serbia, wheat, was cultivated on 589922 ha in 2015. On average wheat yielded 4.1 t/ha, which made more than 2.4 million tons. In 2015, tobacco were cultivated on 5012 ha; with an average yield of 1.8t/ha, so total production of tobacco in Serbia amounted to 8700 tons (Statistical Yearbook of the Republic of Serbia, 2015).

Tobacco leaves are indispensable in cigarette production, but the tobacco stalks are considered to be a biodegradable waste. The Waste Catalogue (2010) issued by the Ministry of Environment and Spatial Planning and the Environmental Protection Agency of the Republic of Serbia classify them as non-toxic waste. It should be noticed that tobacco stalks yield about 22 000 stalks/ha, and solely in 2015 the total number was greater than 115 million stalks, they represent a significant possible resource. So far, these stalks had no monetary value. However, in recent years, researchers have intensively studied the chemical composition of tobacco stalks and concluded that they are suitable for the production of numerous commodities like paper, cardboard, textiles, cotton, flax, other plant fibers, pesticides, and organic fertilizers (Chaturvedi et al, 2008; Kapadiya et al., 2010; Martin et al.,2008; Shakhes et al., 2011). Depending on the chemical composition of tobacco stalks, they could be utilized in briquettes or heating pellets production. These preliminary results are very noteworthy since useful energy is obtained and waste products decreased simultaneously (Kulić et al. 2011; Malnar et al., 2014; Radojičić et al., 2014; Radojičić et al., 2014).

The higher heating value indicates whether a substance can be used as a fuel. It is established experimentally or mathematically. Experimental assessment of HHV requires particular equipment, but mathematical caloric value computation needs only the biomass chemical composition data, which are easily achieved with the available laboratory equipment. Many researchers have studied the biofuel higher heating value based on the fundamental chemical structure (Demirbas, 1997; Sheng and Azevedo, 2005; Yin, 2011). Comparing with other formulas the formula which links the ash content and HHV ($HHV = 19.914 - 0.2324 \cdot Ash$), proposed by Sheng and Azevedo (2005), provides the highest reliability. It is typically used in practice to predict the biomass HHV; therefore, we applied it in this study.

This study investigate the possibility of using tobacco stalks as biofuels , and how they compare to other sources of biomass. We underline that, unlike other biomass sources, Burley tobacco stalks are dried along with leaves, so they do not prescribe an additional investment of energy for drying raw materials. Predicting tobacco stems HHV made the basis for the cost-effectiveness study of biofuels in Serbia, largely as a heat source for Virginia type tobacco drying.

Materials and methods

In this study, we used briquettes made of Burley tobacco stalks, beech wood sawdust, and wheat straw. Compressing reduced the volume of biomass about 10 times; the produced briquettes were easily transported, stored and incinerated. Since beach wood chips are the most commonly used base for briquettes, we chose them for this study. Wheat straw is selected because wheat is one of the major agricultural products in the Republic of Serbia and it is already used as biofuel. All raw materials are from the same agricultural area in Serbia (Sabac region). The tobacco stalks were taken from the tobacco production company after the drying and after removing the tobacco leaves. This experiment was significant because the briquettes are made without using any binding materials. Briquettes are made on the machine Comafer Dinamic, Italy.

For the experimental determination of ash content and calorific value of the samples, briquettes were milled (Mill Fritsch, Germany) and homogenized. The samples were sifted in a vibrating sieve and the particles 0.5-1mm in diameter were isolated and subsequently analyzed. Moisture

content was given in a standardized method (EN 14774-2, Solid biofuels. Determination of moisture content. Oven dry method. Total moisture. Simplified method) in the oven, Binder FD 240, Germany. Ash content is determined by ignition at 550^{o}C in a furnace, Nabertherm Controller C6, Germany (EN 14775 Solid biofuels. Determination of ash content).
Based on the moisture content, the results were given relative to the sample`s dry matter. Ash content was utilized to predict the higher heating value (HHV) of the test material. The calculation was used with the Sheng and Azevedo (2005) equation:
HHV= 19.914-0.2324·Ash (1)
To determine the experimental values of thermal power, briquettes were burned in an oxygen bomb calorimeter - Calorimeter, IKA C5000, Germany (EN 14918, Solid biofuels. Determination of calorific value). Experimental values were then compared with the values predicted by ash content.
All analyses were repeated five times. However, to simplify we showed only the mean values.

Results and discussion

Table 1 represents the results of this study.

Table 1. Content of moisture, ash and HHV of samples

Sample	Tobacco stalks	Beech wood sawdust	Wheat straw
Moisture content (%)	9.96	7.72	8.24
Ash content (%)	7.34	0.60	8.06
Prediction of HHV (kJ/kg)	18208.18	19774.56	18040.86
Qg (kJ/kg)	15761.00	17612.00	16063.00
HHVexp (kJ/kg)	17504.44	19085.39	17505.45

The moisture content in the tested samples ranged from 7.72% to 9.96%. The higher moisture content of the samples would represent the problem since it would be necessary to consume energy for drying them. Also, the higher moisture content would cause a lower calorific value of samples, and would affect the quality of combustion.
The content of mineral substances in most plants is about 3%. Combustion of mineral substances creates an ash, which accumulates in the oven. Compared to fossil fuels, biomass produces a very small amount of ash during combustion. Also, the ash content is negatively correlated with the high heating value of the fuel; it is considered that an increase of 1% of ash reduces the calorific value by 200 KJ / kg (Monti, 2008). The data in Table 1 show that sawdust has the lowest and wheat straw has the highest ash content. The tobacco stalks briquettes have 7.34% ash content; this data match the data from other literature (Radojičić, 2011). The results is true for wheat straw briquettes which have 8.06% of ash (Brkić et al., 2007).
Based on the ash content we predicted the HHV values of the samples. According to the literature, the calorific value of biomass from agricultural production is between 13000 and 18000 kJ/kg (Brkić et al, 2007). The calorific value of wheat straw, reduced to the dry weight, is about 15800 kJ/kg; sawdust has a caloric value of 18600 kJ/kg, and tobacco stalks about 18000 kJ/kg (www.agroinfotel.net). Predicted HHV values of the samples based on ash content were slightly higher than in the literature. The wheat straw HHV was 14.3% and sawdust HHV 6.3% higher than the values reported in the literature (Malnar et al., 2014), while the tobacco stalks HHV was almost the same. Differences in HHV were the result of the different chemical

composition of samples, which depend on the production area agro-ecological characteristics from which they are taken.

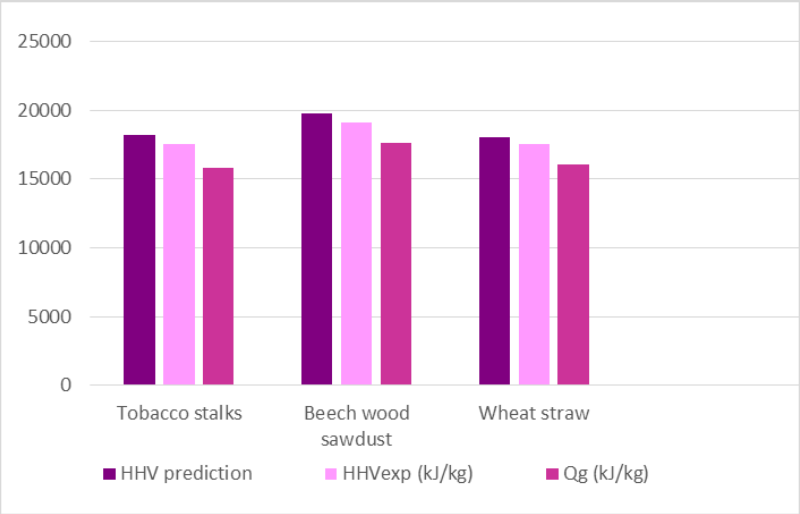

Figure 1. High heating value of the samples

Experimentally, in the caloric bomb, the results of the samples thermal power (Qg) were obtained (Qg) in deliverable state (with certain moisture content). Experimental data show that biomass has about 10% lower Qg value than the chip (Table 1, Figure 1). The comparison of only the biomass from agricultural production, tobacco stems have about 2% lower calorific value than the wheat straw. This result was expected because tobacco stalks had a slightly higher moisture content. Since the heating value of tobacco stalks does not deviate significantly from the heating value of the wheat straw, already used as a biofuel, it can be concluded that the tobacco stems can be used for the same purposes.

To simplify the comparison, the calorific value of samples (Qg) were calculated relative to the dry matter of the sample (HHV exp in Table 1). HHV values obtained experimentally are, on average lower about 3.86% for tobacco stems, 3.49% for sawdust, and 2.97% for wheat straw compared to the predicted HHV values. From the low deviation of the theoretical from the experimental HHV values, it can be concluded that the formula which connects the HHV with the ash content has high reliability, which confirms results from the literature (Sheng and Azevedo, 2005). The paramount importance has the fact that the experimental tobacco stalks HHV value is only 9% lower than the sawdust HHV. Between tobacco stalk HHV and wheat straw HHV has no significant difference.

The results of this study, HHV values determined experimentally and predicted from the ash content, confirm that it is possible to use tobacco stalks as biofuel. This will increase their economic value while reducing environmental pollution caused by their inadequate disposal or destruction in fields with fire. As a benefit, it opens the possibility of reduced investments in fuels (gas, oil fuel, electricity) for drying other types of tobacco, especially tobacco Virginia type.

Conclusion

The aim of this study was to determine the possibility to utilize Burley tobacco stalks as a biofuel, through determining HHV, and comparing it with other forms of biomass already used in Serbia.

Research has shown that Burley tobacco stalks have a low moisture content, which means that no additional energy is necessary for their drying and that certainly increases their energy efficiency. It was experimentally proved that the Burley tobacco stalks have a high HHV (17504.44 kJ / kg), which does not deviate from the wheat straw HHV, and is only 9% lower than the sawdust HHV. The high calorific value of tobacco stalks, in combination with other parameters, shows that they constitute a suitable raw material for the production of energy briquettes. Briquetting is a way to create a significant energy product from monetary insignificant tobacco stalks and solve uncontrolled waste disposal at the same time.

The fact that the tobacco stalks could be used for the production of briquettes founded the way for new research of their profitability as a drying agent for other types of tobacco, primarily the Virginia tobacco.

Abstract

This study was conducted to determine the effects of water holding polymers and water restriction on growth parameters of tomato (Lycopersicon esculentum Mill.) cultivated by different soilless culture techniques. The experiment was designed as a randomized plot in factorial designs (2x3x3) with three replication. Two soilless cultures (perlite and cocopeat), three levels of water holding polymers (0, 2, 4 g gel per pot) and three levels of irrigations based on the percentage of drainage (I1: the amount of water given until 30% of the water becomes drainage, I2: 75% of I1, I3: 50% of I1 applications were examined as the pot experiment in the greenhouse. Plant height, stem diameter, number of leaves, early yield, fresh and dry weight of stem and root were measured at the end of day of trial. The results revealed that; (1) there were no phytotoxic effects of water holding polymers on the growth and development of the tomatoes, (2) water holding polymers improved the general growth status of tomatoes, and (3) the best tomato growth was obtained by treatment of 4 g water holding polymers + I2 water application in cocopeat soilless culture. In conclusion, water holding polymer application provided minimum water saving of 25%.

Key Words: *Water holding polymers, water restriction, soilless culture, tomato*

Introduction

Water is the most significant life source for all living creatures. Seventy percent of the water consumed is used for agricultural purposes, which is followed by industry and domestic use with 19% and 11%, respectively (FAO, 2013). In Turkey, 72% of the water consumption is used in the agricultural sector. The lower the country's development level, the higher its agricultural water consumption rate, which may reach 82% (WWAP, 2003). According to a report by the United Nations, agricultural production is estimated to increase by 67% in developing countries between 2000 and 2030. It is further projected that the available water potential cannot cover this increase, and that it can only be covered if the agricultural water demand is maintained at 14% by increasing yield in agriculture. Hence the agricultural sector will need to produce more agricultural product with less (WWAP, 2006). Today, water resources are decreasing due to environmental effects and improper practices of humankind, and the current water resources are becoming inadequate to cover the needs. Hence it is significant to develop strategies to reduce the amount of water used in agriculture. Gels, also known as water retaining polymers, ensure water that enters the soil as a result of natural precipitations and irrigation to be retained in the roots zone of plants for an extended period of time. Water retaining polymers increase water retaining capacity of the soil and reduce erosion risk as they boost water permeability of soil (Zhang and Miller, 1996; Lentz and Sojka, 1994; Hickman and Whitrey, 1998; Johnson, 1984). As is the case with vegetable species, in the production of other

products that cannot be grown without water, the soil's capacity to retain water and nutrients can be increased with water retaining polymers in order to avoid the negative effects of inadequate water and drought (Sevimay *et al*., 1994). Furthermore, use of gel in agriculture reduces irrigation and fertilization costs, as it ensures water and fertilizers to be used more efficiently. Even if the most significant advantage of soilless agriculture is its ability to avoid soil borne problems, the method brings several other advantages, as well. The soilless agriculture technique ensures plants to be nourished in a more controlled manner, reduces the workforce, and makes agriculture practical for industrial agriculture. It further optimizes fertilizer and water use, increases yield, avoids weeds, and makes it possible to perform agricultural practices on lands that are not appropriate for growing plants (Resh, 1991; Gül, 2008). Solid medium (substrate) culture is preferred to hydroponic culture due to lower installation cost, and it acts like a buffer, thanks to the substrate and provides a medium where the plant can hold on to. The most frequently used substrates in solid medium culture are rock wool, cocopeat, and perlite. As they do not cause any waste material problems and due to their price advantage, cocopeat and perlite have been the most preferred cultures in recent years. Furthermore, Turkey has a significant advantage, as it has half of the perlite reserve in the world. This study was conducted to determine the effect of different irrigation doses and water retaining gel applications on the plant development of tomatoes grown in two different substrates, both frequently used in soilless agriculture.

Material and Methods

This study was conducted in August-October 2015 in the greenhouse used for research purposes belonging to Ahi Evran University, Faculty of Agriculture, Department of Horticulture. Plant material used in the test was indeterminate tomato (*Solanum lycopersicum* cv. Nazal F_1), while two different substrates were used as the growth medium (cocopeat and perlite), and Stockosorb® 400K was used as the water holding polymer. The study covered two different substrates (perlite and cocopeat), three different irrigation levels (I_1: the amount of water given until 30% of the water becomes drainage, I_2: 75% of I_1, I_3: 50% of I_1), and three different water holding polymer levels (0, 2, and 4 g/pot). The study was conducted in three replication, while a factorial test pattern was used in randomized parcels.

The main principle of substrate culture is to avoid salt accumulation in the root zone by allowing a certain amount of nutrition solution to be drained. The amount of drainage is recommended to be 30% during summer and 20% during winter (Gül, 2008; Cantliffe *et al*. 2008; Montesano *et al*. 2010; Jensen, 1997). In this study, the amount of irrigation under I_1 was adjusted daily to ensure that the drained solution was 30% of the total amount of nutrition solution applied.

On August 7, 2015, each plant was planted in a 6 lt plastic pot. The study was conducted with a total of 54 pots in the greenhouse with two substracts, three irrigation dosages, and three gel dosages (2x3x3=18) with three replication. Taking the test subjects into consideration, predefined amounts of water retaining polymers were turned into gels using water and the gels were mixed with substrates and applied to the pots, ensuring they covered the root zones. In order to determine the amount of water to be fed to the pots, control pots with no gel were given water until reaching the 30% drainage rate. This amount was accepted as I_1 irrigation dosage, and 75% (I_2) and 50% (I_3) of this amount were applied to the pots daily within the scope of limited irrigation. The water and nutrition needs of the plants were met using a complete nutrition solution, the content of which is given in Table 1. The amount of the solution to be applied to pots was determined in accordance with the irrigation limits (Hoagland and Arnon, 1950).

Table 1. Concentration of nutrient solution (mg l^{-1})

Element	N	P	K	Mg	Ca	S	Fe	Mn	B	Cu	Zn	Mo
Concentration (mg/l)	210	31	234	48	200	64	2.5	0.5	0.5	0.02	0.05	0.01

As the plant material used in the study, Nazal F_1, has a indeterminate type growth habit, it was attached to the sling, and the axil shoots were regularly pruned during the test period. Other cultural procedures were conducted in accordance with the principles of Sevgican (2002).

As the greenhouse where the test was conducted had no heating system, the study was finalized on October 9, 2015, during the early harvest season. After finalization of the test, early yield, plant height, diameter of stem, number of leaves, and wet and dry weights of the stem and root were measured in each parcel.

The data were statistically analysed by using Windows Version of SPSS (release 16.00). The significant means were groupped according to Duncan Multiple Range Test (Düzgüneş *et al*., 1987; Akgül and Çevik, 2005).

Results and Discussion

Plant Height: The greatest plant height average (136.5 cm for perlite and 140.25 cm for cocopeat) was observed in plants in the I_2 irrigation group with 4g of gel. While the lowest height average (95.75 cm for perlite and 122.5 cm for cocopeat) was observed in plants falling under I_3 irrigation with no gel (Table 2). Even if water restriction caused height loss in plants with no gel application, increasing the amount of gel used for plants falling under I_1 irrigation led to no statistically significant change**.** The heights of plants falling under I_2 (75%) irrigation dosage, which were grown in perlite substrate with an application of 2 g and 4 g of gel, and the heights of the plants grown in the cocopeat substrate with an application of 4 g of gel were determined to be statistically greater compared to the plants falling under I_1 irrigation with gel application. This is deemed to be caused by the fact that gel application increases water and nutrition adherence in the root zone even when the amount of water given is reduced by 25%. All factors and interactions between such factors were determined to have a significant effect on the plant height for both perlite and cocopeat media ($P<0.05$) (Table 2). Maboko (2006) reported that tomato plant height increased as a result of an increase in the gel-polymer application rate. In their studies on other plants such as coarse bean and triticale, Ekmekçi and Geren (2013) and Geren *et al.* (2011) reported that the coarse bean grew to the greatest height when 6 kg da^{-1} gel applied with TK-70 irrigation dosage, while triticale required the application of 18 kg da^{-1} gel with TK-75 irrigation dosage. In the plants subjected to 50% water limitation, plant height loss was observed when the gel dosage was increased. This incident, which was also determined in the studies of Ekmekçi and Geren (2013) and Geren *et al*. (2011), is thought to be caused by the fact that when the amount of gel is increased under limited irrigation conditions, the gel tends to absorb good water with a greater power compared to the roots.

Stem Diameter: Just like the plant height, the greatest figures in terms of diameter of stems (12.06 mm for perlite and 13.09 mm for cocopeat) were observed in plants falling under I_2 irrigation dosage with an application of 4 g of gel. Based on the comparison between the values obtained from the irrigation dosages of I_2 and I_1, the difference was found to less than, especially for perlite. The negative effect of I_3 water limitation on stem diameter was not observed in I_2 dosage due to gel application. The results of the statistical analysis indicated that each individual factor and the interaction between gel dosage and irrigation dosage had an effect on stem diameter; however, other interactions between the factors had no significant effect (Table 2). Maboko (2006) stated that the greatest gel dosage (40 g) had a significant effect on stem diameter compared to the control application, while no other dosage had a significant effect.

[a-k]: The differences between the averages shown in different letters p <0.05 is significant.

Number of Leaves: Gel doses were observed to have no significant effect on the number of the leaves for both of the substrates, while irrigation doses were observed to have significant effect. It is a known fact that the stricter the water restriction is, the greater the leaf loss (Karipçin, 2009; Liu *et al*., 2007). Ekmekçi and Geren (2013) reported that the leaf rate increased when the water dosage was increased from TK-30 to TK-70, while the increase in gel dosage had no effect on leaf rate, except for TK-30 dosage. In this study, the lowest number of leaves was observed in plants subject to 50% water limitation. Only irrigation factor was found to be statistically significant in terms of number of leaves, while the other factors and interactions between them were determined to have no significant effect at all (Table 2).

Early Yield: Based on the yield values, which were determined by weighing all fruits on the plants after completion of the test, the highest early yield was found to be 607.68 g and 619.39 g for perlite and cocopeat substrates, respectively, which were both observed in plants falling under the scope of I_2 irrigation with 4 g of gel application. While the lowest yield was found to be 415.20 g and 338.82 g for perlite and cocopeat substrates, respectively, which were both observed in plants falling under the scope of I_3 irrigation limit with no gel application (Table 2). As it was already argued in our study, several researches reported water resriction to decrease yield (Biber and Kara, 2006; Güneş *et al*., 2008; Kiymaz and Ertek, 2015). However, our study indicated a significant decrease in yield for plants falling under the scope of I_3 irrigation (50% water restriction) with gel application, while no yield decrease was reported for plants grown with I_2 irrigation limit with gel application. In his study on soy plants, Sivapalan (2001) reported that the increase in gel dosages boosted grain yield and water-use efficiency, and that the greatest values were obtained from 0.07% polymer applications. El-Hadi and Camelia (2004) reported water retaining polymers to increase yield in tomatoes. In this study, irrigation and gel dosages were determined to have significant effects on fruit weights, while the substrate factor and the interaction between the factors were observed to bear no significant effect. For both substrates, fruit weights of the plants grown with 50% water restriction were determined to be significantly lower for all gel dosages compared to the values observed in other water dosages. However, the difference between fruit weights falling under the scope of I_2 irrigation, which was 25% shorter in water compared to I_1, was determined to have no statistically significant difference when 2 g and 4 g of gel was applied.

Stem Fresh Weight: In this study, the greatest value in stem fresh weight was 800 g, which was observed in plants grown in the cocopeat substrate within the scope of I_2 irrigation with 4 g gel application. On the other hand, the lowest stem fresh weight, 424 g, was observed in plants grown in perlite with 50% water restriction (I_3 irrigation) with no gel application. Each individual factor (substrate, gel, and irrigation dosage) and the interaction between gel dosage and irrigation dosage were determined to affect stem fresh weight. No significant effect was determined to be caused by other interactions between the factors (Table 2). In their study, Sayyari and Ghanbari (2012) argued that increasing dosages of superabsorbent polymer (SAP) significantly increased stem fresh weight in pepper plant. However, prolonging irrigation intervals led to significant decreases in stem fresh weights.

Stem Dry Weight: The greatest stem dry weight, 120.61 g, was found in plants grown in the coco peat substrate, with I_2 irrigation and 4 g of gel application. On the other hand, the lowest stem dry weight, 71.9 g, was observed in plants grown in the coco peat substrate, with 50% water limitation (I_3) and no gel application. Stem dry weight was observed to be significantly affected by gel dosage, irrigation dosage, and the interaction between irrigation and gel dosages. The substrate type and interaction between other factors were determined to have no significant effect

(Table 2). Hiroshi *et al*. (1999) reported silica gel application to increase plant height and dry weight in rice plants, compared to control plants.

Root Fresh Weight: The greatest root fresh weight, 189.36 g, was determined in plants grown in the cocopeat substrate with I_2 irrigation and 4 g gel application. The lowest weight, 81.64 g, was observed in plants grown in perlite medium with I_3 irrigation and no gel application. Regardless of the irrigation and gel dosages, the plants grown in the cocopeat medium produced better root development compared to those grown in the perlite medium. The gel application boosted root development in both of the substrates. Each individual factor and the interactions among those factors were found to have a statistically significant effect on root fresh weight, except for the interactions between substrate x irrigation dosage and substrate x gel dosage x irrigation dosage (Table 2). Maboko (2006) reported the root fresh weight to be 39.15 g in tomato plants grown in 20 lt pots with 8 g and 16 g of Stockosorb® 400K application with no gel. The weight grew to 67.30 g and 104.68 g when 8 g and 16 g of gel was applied, respectively. As seen in both studies, increasing the amount of gel increased root fresh weight, as well. Hence, increasing root development also supports the plants in terms of water and nutrition absorption, and effects vegetative development positively. Similarly, Hiroshi *et al*. (1999) reported gel application to stimulate a greater number of new root developments in rice plants.

Root Dry Weight: The greatest root dry weight, 18.05 g, was measured in plants grown in the cocopeat substrate with I_2 irrigation and 4 g of gel application. The lowest weight, 6.73 g, was observed in plants grown in the perlite medium with I_3 irrigation and no gel application. Each individual factor and the interactions between those factors had statistically significant effect on root dry weight, except for the interactions between substrate x gel dosage and substrate x gel dosage x irrigation dosage (Table 2). Maboko (2006) reported that gel application in tomato plants significantly increased root dry weight compared to control plants; however, an increase in gel dosages were reported not to effect root dry weight significantly. Sayyari and Ghanbari (2012) reported similar results as well.

Conclusions

The results of the study indicate that the effects of water holding polymers applied in varying dosages on growth and development parameters analyzed for tomato plants subjected to water restrection varied. Results showed that: (1) there was not any phytotoxic effects of water holding polymers on the growth and development of tomatoes, (2) water holding polymers improved the general growth status of tomatoes, and (3) the best tomato growth was obtained with treatment of 4 g water holding polymers + I_2 water application in coco peat soilless culture. In conclusion, water holding polymer application provided a minimum water savings of 25%. The use of soilless of water holding polymers should be extended under greenhouse conditions due to its advantages such as prevention of environmental pollution, fertilizer and water savings.

Abstract

In 2014, in the area of the flooded agricultural soils of the Republic of Serbia, it was conducted the study on the effect of extreme climatic conditions, especially rainfall, on the structural micro aggregates stability and the risk of crust formation. The agricultural soil samples were taken in a disturbed state from the surface soil layer (0-30 cm) from fifty locations affected by the floods.
The degree of the micro aggregates stability was expressed according to Vageler and determined by the ratio between the total content of clay particles in soil samples prepared with sodium pyrophosphate, and the content of such particles in soil suspension prepared with water. The risk of the soil crust formation was determined according to a Van der Watt & Claassen pattern on the basis of the ratio between the content of organic matter, and total content of the clay and silt particles in soil samples. The obtained results showed that the analyzed soil samples had stable to very stable degree of the structural micro aggregates stability and that extreme climatic conditions have not significantly influenced the tested parameter. In the analysed samples the risk of the soil crusting was in limit values in 58% of the samples, than, in high risk values - in 40%, while in one soil sample (2%, respectively) the risk of soil crusting was low.

Keywords: *agricultural soil, floods, structural aggregates stability, soil crusting.*

Introduction

Republic of Serbia in the second half of May 2014 afflicted catastrophic floods, which have left behind a devastated agricultural land. After the withdrawal of the flood, during August and September it was conducted a site visits on sites which was mostly affected by flood wave and collected soil samples in disturbed conditions. On collected soil samples it was conducted testing in order to examine to what extent this natural disaster changed the structural stability of micro aggregates of agricultural soils.
Establishment of crop production after the floods depends on the impact that the floods had on agricultural land. Rehabilitation of soil could last for a long period and require significant involvement of funds.
Land structure is an important factor of fertility of agricultural soil which is gradually formed by the complex physical and chemical processes. The influence of different cropping systems leads to changes in soil structure (Ćiric et al., 2013).
The stability of structural aggregates, according to the Bronicki and Lal, 2005, is considered a key to soil fertility.
Creating structures (Tisdall and Oades 1982, Oades and Waters, 1991) is a very complex process which depends on the interaction between soil types, cement agents, soil management and environmental conditions. Soil structure is very dynamic dimension, especially in the upper

horizon which changes under the influence of climatic factors, crops and processing (Vučić, 1964). Favorable soil structure is necessary to preserve and unfavorable to improve (Belić et al., 2004). According to the Amezketa, 1999, the stability of structural aggregates is very hard to explain and quantify because it is a characteristic of soil that affects the sustainability of soil and plant production.

From the agronomical aspect, the most significant are structural aggregates from 1 to 10 mm (Edwards, 1991; Amezketa, 1999). The most significant properties for the evaluation of soil structure are the content of macro-aggregates, their mechanical strength and water stability, as well as porosity (Sorochkin, 1991). Soil structure is a dynamic value that depends on the soil properties, climate and tillage conditions (Angers, 1998). The factors affecting soil structure and aggregate composition are tillage, irrigation and climate (Guerif et al., 2001). Soil aggregate stability declines rapidly as the consequence of cropping, and the diameter of dry aggregates increases (Kandelero and Murer, 1993; Shepherd et al., 2001).

The data obtained by determining the stability of micro aggregates contribute in defining clearer and more complete overview of the soil structure. In soils with less stable micro aggregates it is reduced the share of stable macro aggregates (Belić et al., 2004). Based on the stability of the micro aggregates it can be predicted the risk of erosion (Igwe and Obalum, 2013). Micro aggregates are mainly formed by coagulation of colloids or colloids and opposite-charged ions, and also can be formed by fragmentation of macro aggregates.

Material and

Area of study included a total of 23 municipalities in Serbia affected by floods in May 2014, as follows: Obrenovac, Šabac, Loznica, Ub, Vladimirci, Valjevo, Surčin, Ljig, Barajevo, Bogatić, Lajkovac, Lazarevac, Koceljeva, Krupanj, Smederevska Palanka, Jagodina, Trstenik, Paraćin, Kraljevo, Čačak, Kruševac, Velika Plana and Kosjerić.

Figure 1. presents the locations of sampling of soil samples in disturbed condition for the purpose of assessing the structural stability of micro aggregates.

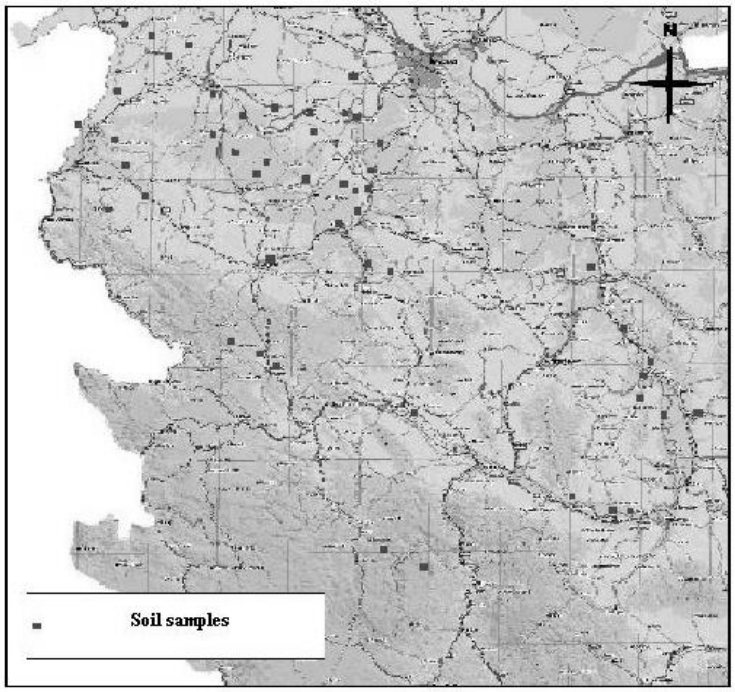

Figure 1.-Locations of soil sampling

Soil samples were obtained from the 0-30 cm depth in period from August-September 2014.
Preparation of collected soil samples implied processes of drying, grinding and screening following the laboratory analysis. The samples were air-dried at room temperature. A portion of the sample was sieved trough 0.25 mm sieve. The content of organic matter (SOM) was determined by Kotzman, JDPZ (1966).
Determination of physical characteristics of the soil included analysis of the stability of structural aggregates in 50 samples of soil material. The principle of determination was based on an analysis of the relationship between the total content of particles smaller than 0.002 mm (clay) in the soil sample prepared with sodium pyrophosphate ($Na_4P_2O_7$ x 10 H_2O) and the content of these particles in the suspension of soil prepared with water (H_2O).
The stability of the micro aggregate is calculated according to the Vageler's index of their stability (Ss) according to the formula:

$$Ss = (FP - FNP) / FP \times 100,$$

where:
FP (%) - particles smaller than 0.002 mm in the soil material prepared with ($Na_4P_2O_7$ x 10 H_2O);
FNP (%)- particles smaller than 0.002 mm in the soil material prepared with H_2O.

Risk of the soil crusting R(%) is determined according to formula Van der Watt & Claassen-a (1990):

$$R = SOM \times 100 / (clay + silt)$$

where:

SOM content of organic matter in the soil (%);
Clay + Silt - content of certain mechanical fraction (%).

The climate characteristics of the studied area were obtained by analyzing available data collected from the Internet site of Republic Hydro meteorological Service of Serbia (RHMS), www.hidmet.gov.rs (accessed May 2016.)

Results and discussion

Weather in spring 2014 in Republic of Serbia was warm and extremely rainy. In the most areas of the country, seasonal maximum of rainfalls were registered, and on five main weather stations it was registered absolute daily maximum of rainfalls.
Average air temperature in spring period was in the range from 10.7°C in Dimitrovgrad to 13.9°C in Belgrade, while in mountain area from 3.1°C on Kopaonik to 7.8°C on Zlatibor.
The total rainfall during the spring in most parts of Serbia were much higher than average.
Table 1. Show the values of total precipitation in the spring of 2014 and the historical data of spring maximums registered at the main meteorological stations.

Table 1. Values of the sum of the quantities of rainfall (RR mm) during the spring and the previous spring maximums at the main meteorological stations (MMS) (source: RHMZS)

MMS	RR max (mm)	Date of registration	Current maximum	Date of registration
Loznica	110.0	15.05.2014.	82.0	24.05.1937.
Sremska Mitrovica	69.1	15.05.2014.	53.5	26.25.1934.
Valjevo	108.2	15.05.2014.	59.0	12.05.1939.
Beograd	107.9	15.05.2014.	75.6	22.04.1892.
Smederevska Palanka	95.3	15.05.2014.	59.6	23.05.2013.

The highest amount of precipitation was registered in the period from 14 to 16 May 2014, when, for example, in Loznica were registered 213.2 mm of precipitation.
The biggest three-day total precipitation was recorded in western and central part of Serbia (over 100 mm), which is more than the average values for the month of May.
According to the percentile method, rainfalls in most parts of Serbia were in the categories of extremely rainy and very rainy.
Table 2. shows the sum of the maximum rainfall during the month of May 2014, registered at the main meteorological stations.

Table 2.- Main meteorological stations (MMS) on which historical maximum of total monthly amount of rainfall (mm) during May was overcome since the starting of measurement (source: RHMZS)

MMS	Σ precipitation 01- 31.05.2014.	Average for May	The current maximum Σ of precipitation during May	Year of registering
Loznica	314.6	82.7	218.6	1938
S.Mitrovica	189.0	58.2	184.9	1939
Valjevo	317.6	88.1	213.2	1957
Beograd	278.5	70.7	191.7	1900

of structural aggregates. The principle of determination was based on an analysis of the relationship between the total content of particles smaller than 0.002 mm (clay) in the soil sample prepared with sodium pyrophosphate ($Na_4P_2O_7$ x 10 H_2O) and the content of these particles in the suspension of soil prepared with water (H_2O).
The stability level of the micro aggregate is estimated by using the classification by Vageler (JDPZ, 1997), shown on Table 3.

Table 3.- Classification of stability level of the structure micro aggregate in soil

Index of stability of micro aggregates (Ss)	Level of stability by Vagler
<10	totally unstable
10-20	unstable
20-30	low stable
30-50	slightly stable
50-70	rather stable
70-90	stable
>90	very stable

The risk of soil crust formation is high if the value of R is less than 5%, on the borderline if R is 7% and low if R is greater than 9% (quote Ćirić et al., 2012).

Results of performed analysis of fifty soil samples in disturbed condition are shown in Table 4.

Table 4.- Locations of sampling and examined parameters

Minicipality	No. of samples	Index of stability of micro aggregates (Ss)	Level of stability by Vagler	SOM (%)	Risk of the soil crusting (R)
Obrenovac	4	71.2-88.1	stable	2.31-6.13	4-9

Jagodina	4	82.4-99.3	stable-very stable	2.29-3.87	4-6
Paraćin	2	98.7-99.0	very stable	2.76-4.30	6-8

The results of the analisys showed that the soil samples have stable to very stable level of stability micro aggregates. On the territory of the municipalities that are heavily exposed to floods, it is noted frequent occurrence of stable degree of stability of micro aggregates, which may lead to the conclusion that this natural disaster had an impact on the eventual deterioration of the structural stability of microaggregates of soils.

Soil organic matter is a key attribute of soil quality that affects the aggregation and aggregate stability (Franzluebbers, 2002). In the analyzed samples organic matter content is in the range from low to high content, which is correlation with a certain value of the risk of crust formation. In the analysed samples the risk of the soil crusting was in limit values in 58% of the samples, than, in high risk values - in 40%, while in one soil sample (2%, respectively) the risk of soil crusting was low.

Conclusion

The aim of this research is to assess the productive capacity and the degree of potential risk of different types of soil affected by floods in May 2014, for plant production.

Soil management after floods requires a clear plan that, among other things, include the removal of sediments and waste from soil, repairing a physical damage of soil, repairing chemical properties of soil, stimulating microbiological activity of the soil, reducing the formation of other consequences (preventing of formation of surface crust).

Water saturation of soils as result of flood, probably led to deterioration of structure, the creation of lumpy aggregates, as well as reducing water resistance of structural aggregates but did not significantly affected the structural stability of micro aggregates.

Abstract

The world mushroom industry has expanded rapidly in the last decade. Total mushroom production was 9.926.966 ton in 2013 in the world. The commercial production of edible and medicinal mushrooms is carried out on substrates formulated with animal manure and lignocellulose materials from different sources (such as wheat straw, sawdust, cotton seed hulls and etc), either alone or mixed with each other. The substrate left after the mushrooms have been harvested is known as spent mushroom substrate (SMS). SMS is a nutrient rich in organic by-product of the mushroom industry. Five (5) kg of SMS will be generated from the production of 1 kg of mushrooms. At least 50 million tons of spent mushroom substrate is produced annually in the world. On the other hand, SMS contain high level of organic material and salts. These contents of SMS may result in environmental pollution if dumped as waste. Therefore it has to be properly disposed of to avoid environmental problems, such as water and soil contamination. In parallel with this, the question of what can be done with it raises. This paper reviews the potential uses of spent mushroom compost as a substrate in horticulture or as an energy feedstock for ruminants.

Keywords: *Edible mushroom, spent mushroom substrate, compost, feedstock, ruminant*

Introduction

Mushrooms are one of the world's greatest natural food resourse. They provide high quantities of fiber, essential amino acids, vitamins and minerals. Thus, cultivated mushrooms may play a greater role in developing countries to decrease malnutrition. Mushrooms have been known for their nutritional and culinary values as well as used medicines by humans for ages. Moever, most of mushrooms use as a complementary medicine and dietary supplements for anticancer, antiviral, antibacterial, immunostimulating, hypoglycemic, hypolipidemic and hepatoprotective agents due to their some medicinal properties.

The world mushroom industry has expanded steadily in the last decade in the world. Total mushroom production was reached in 2013 to 9.926.966 ton (FAO, 2013). About 71% is produced in China, followed by the Italy (8%), the USA (4.1%), Netherlands (3.3%), Poland (2.2%). *Agaricus bisporus*, *Lentinula edodes* and *Pleurotus ostreatus* are popular mushrooms with high commercial values and are thus cultivated worldwide. Seventy percent of world production is derived from only these kinds of mushroom.

Mushrooms do not have chlorophyll and cannot produce carbohydrates by photosynthesis. Instead, during their vegetative growth stage, mushroom mycelia secrete enzymes that break down compounds such as cellulose and lignin present in the substrate. So, they are cultivated on a specially designed and selective medium that supplys the nutritional requirements of the mushroom crop. There are many recipes for this medium, which must provide an adequate supply of all nutrients for mushroom growth. The mushroom industry generates two main types of mushroom substrate, one for *Agaricus bisporus* and other for special mushrooms. The most

commonly cultured mushroom is *Agaricus bisporus* (also called the white button mushroom). *Agaricus bisporus* is grown on compost consisting of cereal straw, manure (poultry and/or horse manure), nitrogen containing compounds and calcium sulphate. On the other hand, the commercial production of special mushrooms as *Pleurotus spp, Ganoderma lucidum, Lentinula edodes* and etc. is carried out on substrates formulated with lignocellulose materials from different sources (such as wheat, rye or rice straw, sawdust, cotton seed hulls and etc), either alone or mixed with each other (Sanchez and Royse, 2009).

At the end of mushroom harvests, the growing material is considered spent. This paper reviews the potential uses of spent mushroom compost as a substrate in horticulture or as an energy feedstock for ruminants.

2. Spent Mushroom Substrate

Mushroom cultivation technology is friendly to the environment and mushrooms are very nutritious and functional foods. In spite of these advantages, the production of mushrooms generates large volumes of solid waste products (called spent mushroom substrate). Many countries have no data on SMS discharge, but it is believed that about 5 kg of waste substrates are generated from the production of 1 kg of mushrooms (Medina *et al.*, 2012). Correspondingly, the SMS production in the world was approximately 50 millions tons in 2013 (Table 1).

Table 1 . Mushroom production and estimated spent compost production around the world (2013)

Country	Mushroom production (t)*	Estimated Spent Mushroom Compost (t)
China	7.076.842	35.384.210
Italy	792.000	3.960.000
USA	406.198	2.030.990
Netherland	323.000	1.615.000

SMS needs heat treatment before being removed from the growing chamber. Without proper treatment, contaminated SMS can cause re-contamination. But it takes extra cost and presents an economic problem for mushroom industry. On the other hand, disposal of SMS is one of the major environmental problems in the mushroom producing countries. Improper disposal of SMS may result in environmental problems such as mildew reproduction (Liu et al., 2008) and water contamination (Liu, 2009) and air and soil pollution (Rajput *et al*., 2009) if it is dumped as waste. Public awareness and the pressure of environmental laws is forcing the mushroom industry to take responsibility for the disposal or recycling of its own spent raw materials. The

waste disposal problems can be reduced by waste minimization, reuse and recycling of its components and converting the organic components of the waste into a valuable product and reused without adversely affecting the environment (Fathi *et al.,* 2014). Morever, recycling of SMS by different ways may increase sustainability and also help farm economy.

2.1. Characteristics of Spent Mushroom Substrate

As mentioned above, preperation is mushroom substrate usually done in two different processes depending on species mushroom and a lot of types of material are generally used for these substrates. So the exact composition of SMS shows a significant variability due to the varying mixes and types of ingredients utilized in the manufacturing of the selective mushroom substrate, composting process and cropping cycle.

SMS exhibits many favourable characteristics, some of which are typical of other organic waste by-products, which include a relatively low bulk density and a high organic matter and moisture content (Maher et al., 1993). The integration of organic materials into soils has proven to improves cation exchange capacity, increase soil aggregation, water-holding capacity, water infiltration, and aeration porosity while it decreases soil crusting, surface run-off (Chenu et al., 2000). It remains, however, a good source of general nutrients (0.7% N, 0.3% P, 0.3% K plus a full range of trace elements) (Bradley, 2004). SMS does not contain any pests or weed seeds, because of the high temperatures associated with the composting and pasteurization processes. Before removing the spent substrate from the mushroom house, the grower "pasteurizes" it with steam. This final pasteurization kills weed seeds, insects and other organisms (Berley, 2016).

SMS displays high level of high pH and soluble salts. The high pH levels originate from the gypsum added during composting and lime added in the casing layer. So it should not be used on acid-loving plants, nor should it be applied too frequently, as it will overly raise the soil's pH levels (Bradley, 2004).

2.2. Fresh and Wheathered Substrate

SMS is a good growing medium for vegetables like cucumber, tomato, broccoli, cauliflower, peppers and spinach. But plant response is varied with SMS application. Fresh SMS contains a lot of salts and unstable organic materials. Availability of some elements such as P, Mn and B (Lucas and Davis, 1961), high Ca content (Dallon, 1988) and high ammonium level may cause to weak plant growth due to either salinity effects or causing in high ammonium concentration in the root zone (Baran et al., 1995). For this reason, sometimes, fresh substrate is placed in fields for at least one winter season before reutilization to reduce the electrical conductivity (EC), resultant from high salt content. Conductivity gradually goes down due to leaching during the weathering process, depending on rainfall. Leaching peaks during the fifth and sixth months of weathering and most of the salts originally present in the SMS are released during the first year of weathering. Obtained material at the end of this process is called “weathered susbtrate”. Most studies have been done with lower salt-containing weathered SMSs. Overall, weathered SMS is preferable over fresh SMS for use in crop production.

Table 2. Avarage analysis of fresh and aged spent mushroom compost (SMS) (adapted from Beyer, 2016).

Contents Units	Units	Avg. Fresh	Weathered 16 mos
Sodium	% Dry Wt	0.21-0.33.	0.06
Potassium	% Dry Wt	1.93-2.58	0.43
Magnessium	% Dry Wt	0.45-0.82	0.88
Calcium	% Dry Wt	3.63-5.15	6.27
Iron	% Dry Wt	0.18-0.34	0.58
Phosphorus	% Dry Wt	0.45-0.69	0.84
Amonia-N	% Dry Wt	0.06-0.24	0.00
Organic nitrogen	% Dry Wt	1.25-2.15	2.72
Total N	% Dry Wt	1.42-2.05	2.72
Solids	% Dry Wt	33.07-40.26	53.47
pH	Standart Unites	5.8-7.7	7.1
N-P-K ratio	ppm Dry Wt.	1.8-.0.6-2.2	2.7-0.8-0.47
% x10.000=ppm			

Polat et al, (2009) reported that as an organic material source and amendment of greenhouse soil application of at least 6 months kept SMS was very effective and beneficiary for cucumber production, quality and recycling the spent mushroom compost.

Çaycı et al. (1998) SMC could be more suitable removing of salts by leaching and decreasing ammonium level by weathering before the use of fresh SMS as growing medium. Weathered SMS is also a good growing medium for the highest yield and quality of tomato seedlings (Lohr and Coffey, 1987).

This aged material has slightly different characteristics because the microbial activity in the field will change the composition and texture (Table 2). Raising environmental concerns and limited natural resources force us to answer the question of "What can use this valuable material from mushroom production have?".

3. Use of SMS

3.1. Use of SMS in Horticulture

SMS are, in general, wastes with a stabilised organic matter, due to the composting or fermentation process carried out in the preparation of the substrates for *A. bisporus* or *P. ostreatus*, respectively (Paredes et al., 2009). SMS does not contain a lot of nitrogen, phosphorus and potassium in comparison to mineral fertilizers. So it is not a good fertilizer. But its improves soil phychical structure by increasing organic matter, soil aggregation, water-holding capacity, water infiltration, buffering capacity and aeration porosity. Uzun (2004) suggested that SMC improved the biological, physical and chemical characteristics of the soil.

Most of researchers suggested the use of spent mushroom substrates in field crops (Wuest, 1991), fruits (Uzun, 2004), vegetables (Segarra et al., 2007), greenhouse crops (White, 1976; Dallon, 1987) and foliage plants (Raymond et al., 1998) to their disposal in an environment-friendly way and reduces the need for peat simultaneously.

Spent compost from the cultivation of *Agaricus* spp. represents a possible alternative substrate for the production of lettuce since the material exhibits some characteristics that are appropriate for the growth of seedlings (Ribas et al, 2009; Zhang et al., 2012; Marques et al., 2014).

Zhang et al (2012) suggested that spent *Flammulina velutipes* mushroom substrate mixed with perlite or vermiculite had suitable physical and chemical properties for the growth of tomato or cucumber seedlings. Chong et al (1994) and Benito et al (2005) suggested that the mixes made of prunning waste compost and spent mushroom compost for ornamental plants in pots. On the other hand, Kwack et al (2012) reported that white button mushroom SMS is the more suitable substrate than tested SMS based sawdust for transplant production when appropriately mixed with substrates. SMSs used sawdust as the main ingredient must be manipulated carefully in order to improve their physical and chemical properties for use as growing media. Ribas et al (2009) found that *Lentinula edodes*- SMS provided negative results when a fertilization objective was selected.

Medina et al (2009) reported that the media containing *Agaricus bisporus* spent- SMS and mixed *Pleuretus ostreatus*-SMS: *Agaricus bisporus*-SMS (1:1) had adequate physical properties, notable contents of plant nutrient and high pH and electrical conductivity values.

Agaricus bisporus spent substrate can be also used as growing substrate for other mushroom species such as *Auricularia auricula (*Sharma and Jandaik 1994), *Lentinula edodes* (Kilpatrick *et al.* 2000), *Pleurotus* spp. (Sharma and Jandaik 1994); *Volvariella* volvaceae (Poppe 2000).

3.2. Uses of SMS in Bioremediation

SMSs are effectively in bioremediation strategies. The bioremediation activity is dependent upon the ability of the fungal species, colonizers of the substrate, to produce oxidative lignolytic enzymes such as laccase, manganese and lignin peroxidase. These enzymes are responsible for lignin degradation (Buswell et al., 1996) Additionally, incorporation of SMSs into soil is responsible for microbial changes on diversity due to nutritional supplementation.

SMS can be utilised successfully in the stabilisation of disturbed and commercial sites such as abandoned coalmines, pipeline construction sites, industrial and mining sites. SMS acts as a slow releasing fertiliser and provides small amounts of $CaCO_2$ which leads to the elevation of the soil pH. SMS microorganisms can degrade many hydrocarbons and insecticide components carbaryl and 1-Naphthol, both of which are toxic to soil and water biota. SMS can also remove biocide PCP (pentachlorophenol) from water, a pesticide and wood preservative, through the presence of a PCP degrading bacterium in SMS.

Ribas et al., (2009) reported that *A. subrufescens*- SMS and *L. edodes*-SMSs presented potential to be used in soil bioremediation.

3.3. Use of SMS as a feedstock

SMS contains more minerals, more protein less cellulose and lignin (Albores et al, 2006) Among many recycling methods, SMSs use as an animal feed seems to be reasonable and promising because the ingredients used as mushroom substrates are used as animal feeds as well. Anyway the use of SMS as a cattle feed, after its use to produce *Pleurotus* spp. was suggested by a lot of researcher (Adamovic et al., 1998; Lee et al., 2008). They reported that by-products of mushrooms could be used as ruminant feed without any harmful effects on eating behavior and blood metabolites in cattle.

Although several species of higher fungi possess ligninolytic activity, *Pleurotus* spp. is the most studied fungi since they improved the digestibility (Kundu et al., 2005) and nutritional quality of straws (Kakkar et al., 1990).

Pleurotus spp. is cultivated by two different methods, a straw-based compost culture and a sawdust-based plastic bottle culture system. Spent straw compost could be directly fed to the ruminant animal or reprocessed by fermenting the compost supplemented with corn meal,

soybean meal and wheat bran using *Aspergillus sp*. and yeast to improve the nutritional value, especially the crude protein level (Adamovic et al., 1998). Straw breakdown is achieved by the influence of *P. osteratus* digestive enzymes, particularly on cell wall components, cellulose and lignin, and these straws can be more easily digested by ruminants. However the sawdust-based SMS was hard to recycle due to the low nutritional value. However, as the digestibility of sawdust-based SMS is low, the sawdust-based SMS should be further processed and improved nutritionally before feeding. Furthermore, SMS is hard to store due to it is wet and putrefactive (Kwak et al., 2008) so SMS should be used quickly because it starts to putrefy within 3–4 days of storage.

4. Conclusions

SMS is by no means a waste product. SMS has the potential to solve several agricultural and non-agricultural issues. It may be considered an inexpensive and an environmental-friendly strategy in agriculture particularly in the bioenergy area, tillage enterprise and in bioremediation of contaminated land remains a largely uncharted area.

The most important limiting factor in the use of SMS as a fertilizer amendment appeared to be its high soluble salts content. Recomposting / weathering is required for added advantages. After weathering, SMS from *Agaricus bisporus* production can be used in wide use in horticulture a component of potting soil mixes, as a casing material in the cultivation of subsequent *Agaricus bisporus*, in the bio-remediation of contaminated soils, in agriculture or landscape trades to enrich soil.

On the other hand, spent substrate from other mushroom species provided negative results when it used a fertiliser. SMS makes a contribution of nitrogen but this is not readily available to the crop until a year after application. Therefore a supplementary N fertiliser must be used. Special mushroom- SMS has found more suitable as food for animals and as ingredients in the cultivation of other mushroom species than as fertiliser. Straw based-SMS is suggested as foodstock for ruminants because of low nutritional value and digestibility of the sawdust-based. But further studies with different application strategies are needed for conclusive results.

Recycling of SMS and converting the organic components of the waste into a valuable product and reused without adversely affecting by different ways may increase sustainability in developing countries and may partially solve the ever increasing problems of feed crisis to livestock and also help farm economy.

Abstract

A long-term use of mineral fertilizers affects many soil properties, including the content of exchangeablecations. The study has been conducted to determine the effect of a thirty-year use of phosphate fertilizers on major agrochemical properties of Vertisol in leaching (pH, Y1, organic matter content, total N, total P, total K, available P, and available K) and the concentration of exchangeable base cations: K^+, Na^+, Ca^{2+} and Mg^{2+}. During the experiment, two doses of phosphorus were continuously applied, a lower one, with which phosphorus has been applied every year in the amount of 80 kg P ha^{-1} and higher than 160 kg P ha^{-1}. Both doses of phosphorus were combined with a constant amount of nitrogen (120 kg N ha^{-1}) and potassium (80 kg K ha^{-1}) The research has been carried out on a stationary model farm in Kragujevac in central Serbia. The thirty-year use of mineral fertilizers has caused an additional acidification of Vertisol. However, continuous use of phosphate fertilizers has provided a smaller effect on the acidification of the surface layer of Vertisol than nitrogen and potassium fertilizers. At the same time phosphate fertilizers has significantly contributed to the increase in total and available phosphorus, the increase in the concentration of exchangeable K^+, and the reduction in the concentration of exchangeable Na^+, Ca^{2+} and Mg^{2+}.

Keywords:*long-term fertilization, Vertisol, phosphate fertilizer, content of exchangeable bases*

Introduction

A reasonable use of mineral fertilizers in a longer period of time can maintain or improve the soil quality, and its production capacity (Belay et al., 2002). One of the best ways to evaluate the effect of fertilization with mineral fertilizers on fertility and other soil properties is the use of long-term experiments (Michell et al., 1991) that provide information on the sustainability of agricultural systems. One of solutions for possible harmful effects of a long-term and unilateral use of fertilizers is the implementation of fertilization management, which takes care of the input and output of nutrients and crop rotation, thus preventing a negative effect of applied fertilizers on some chemical soil properties (Hirzel et al., 2011).

A long-term continuous use of phosphoric fertilizers (MAP, superphosphate, triple superphosphate) can significantly affect numerous soil properties. Their effect can be observed from several aspects, of which two are most prominent. The first is a small utilization of phosphorus by plants, which, in conditions of constant implementation, leads to an inevitable accumulation of this element in the soil, especially its available forms (Berti and Cunningham, 1997; Pizzeghello et al., 2011). The second refers to the fact that phosphoric fertilizers are produced from raw materials containing microelements (Ricchards et al., 2011), as well as some potentially hazardous trace elements, and they remain as impurities in the fertilizer after

fabrication, and in the system of long-term use, cadmium (Mulla et al., 1980; Brennan and Bolland, 2004; Grant and Sheppard, 2008), arsenic and lead (Jiao et al., 2012) have the potential to be accumulated in the soil and transmitted through the food chain. For this reason, the goal of the research was to, after thirty years of continuous application of mineral fertilizers on a model farm in central Serbia, in the system of wheat and corn rotation, evaluate the changes that these fertilizers caused to the soil of Vertisol type.

Materials and methods

The research has been carried out on a stationary model farm of Small Grains Research Center in Kragujevac (44°00′51″ and 20°54′42″). Since 1984, the examination of the effect of long-term application of phosphorous mineral fertilizers on the properties of Vertisol soil has been performed.

During the experiment, two doses of phosphorus were continuously applied, a lower one, with which phosphorus was entered every year in the amount of 80 kg P ha^{-1} (P1 variant) and higher with 160 kg P ha^{-1} (P2 variant). Both doses of phosphorus were combined with a constant amount of nitrogen (120 kg N ha^{-1}) in NP1 and NP2 variants and a constant amount of nitrogen (120 kg N ha^{-1}) and potassium (80 kg K ha^{-1}) in NP1K and NP2K variants. Nitrogen and potassium were applied independently in a special variant (NK variant). Fertilization treatments were compared with the control variant, i.e. with the variant where fertilizers were not applied (O). The total amounts of phosphorus and an appropriate part of nitrogen were entered by the application of MAP fertilizers ($NH_4H_2PO_4$). The remainder of the provided amount of nitrogen was supplemented by applying Urea fertilizers ($CO(NH_2)_2$). An appropriate amount of potassium chloride (KCl) was used for potassium intake. The experiment was performed as a random complete block design (RCBD) in four replications. The average (composite) soil samples were collected in the layer from 0 – 20 cm, and they were formed of five sub-samples for each treatment. By mixing the sub-samples, so-called average or composite sample was singled out, which was chemically analyzed after a proper preparation. Soil samples were taken in the fall of 2013 (after the corn harvest).

The soil pH was determined by the pH meter with a glass electrode in a 1:2.5 suspension with water and 1 M KCl. The hydrolytic acidity, i.e. H, was determined by Kappen's method by treating a soil sample with $(CH_3COO)_2Ca$, and then a neutralization of excess acid with 0.1 M NaOH was carried out. Accessible phosphorus and potassium were determined by Al method, where ammonium lactate (pH = 3.7) was used as anextractant. After the extraction, potassium was determined by flame emission spectrometry, and phosphorus by spectrophotometry after developing color with NH_4MoO_4 and $SnCl_2$. Total phosphorus was determined spectrophotometrically at the wavelength of 400-490 nm after a digestion with $HClO_4$ and a treatment with ammonium paramolybdate-vanadate reagent (Olsen and Sommers, 1982), and total potassium was determined photometrically after the destruction of the sample with a mixture of HF and H_2SO_4. The content of exchangeable bases (Ca^{2+}, Mg^{2+}, K^+ i Na^+) has been determined withthe atomic absorber after an extraction with 1 mole L^{-1} CH_3COONH_4 at pH 7.

Statistical analyses were performed on SPSS software, variant 16. The effects of the treatment on all variants were tested by ANOVA. Statistical differences between the treatments were determined using the t-test (95 and 99%) by Pearson for Fisher's LSD. The significance of correlations between them was analyzed through Pearson correlation matrices (SPSS, 2007).

Results and discussion

The soil on which the research has been carried out was characterized by leaching processes. The main characteristics of Vertisol before the beginning of the experiment are shown in Table 1. Its basic characteristics in the surface layer before the beginning of the experiment were an expressed sour reaction, a low content of available phosphorus, a mean content of organic matter and available potassium.

Table 1. Agrochemical characteristics of Vertisol before the beginning of the experiment

pH		H	OM	tot N	Total		available		Exchangeable			
		c mol			P	K	P	K	K^+	Na^+	Ca^{2+}	Mg^{2+}
H_2O	KCl	kg^{-1}	----- % -----		---------- mg kg^{-1} ----------				---------- c mol kg^{-1} ----------			
5.90	4.60	8.64	2.69	0.170	977.4	15000	26.0	180	0.47	0.22	17.60	6.00

The long-term continuous application of mineral fertilizers has contributed to an additional acidification of Vertisol (Table 2), and the reason should be sought in the fact that it is the fertilizer application zone, thereby the zone of their direct effect. On that occasion, it was established that, in the layer from 0 – 20 cm, the differences between active, substitution, and hydrolytic acidity between the control and fertilization variants were highly significant ($p > 0.01$).

Table 2. Agrochemical properties of Vertisol after 30 years of fertilizing with phosphorus

Variants	pH		H	OM	total N	total P	total K	avail P	avail K
	H_2O	KCl	c mol kg^{-1}	----- % -----		---------- mg kg^{-1} ----------

The contribution to acidification of used fertilizers has not been the same. The highest acidification has been caused by nitrogen and potassium fertilizers, i.e. NK variant. This implies that a long-term use of only nitrogen and potassium fertilizers significantly increases the acidity of soil, rather than when the same fertilizers are used with phosphoric ones. This trend has been expected because soil acidification by long-term application of nitrogen fertilizers is well-known and confirmed by numerous experiments (Khonje et al., 1989; Bolan et al., 1991; Barak et al., 1997; Zhao et al., 2010). However, long-term, continuous use of fertilizers that, in addition to N, contain phosphorus, such as MAP, frequently result in an increased acidification (Magdoff et al., 1997; Belay et al., 2002; Saleque et al., 2004).

In all variants of fertilization, the content of organic matter and total nitrogen in the surface layer has significantly been reduced compared to the control variant ($p < 0.01$). Although the importance of long-term fertilization with nitrogen to maintain or increase the organic matter content (Bundy et al., 2011), total (Tong et al., 2009) or nitrate nitrogen (Zhang, 2012) is often emphasized, in this research, the nitrogen from fertilizers has not had a positive effect on their contents.

After 30 years, in all the variants where P fertilizers were applied, the contents of total and available phosphorus have been increased. In relation to the control and NK variants, the

differences were highly significant ($p < 0.01$) and in proportion with the rates of applied fertilizers, and the long-term application of fertilizers has strongly contributed to the accumulation of available forms in the area of intake (Marocco et al., 1999; Otto and Kilian, 2001; Cakmak et al., 2010; Selles et al., 2011). It has also been noted that, in this layer, the same rates of phosphorus from NPK variants had a significantly greater contribution to the accumulation of this element in relation to the NP variants.

The concentrations of exchangeable K^+, Na^+, Ca^{2+} and Mg^{2+} have been changed in all the variants of fertilization in comparison to the control variant (Table 3). Fertilization has had an effect on an increase in the concentration of only exchangeable K^+, especially in NK variant ($p < 0.01$), while, at the same time, the content of the other exchangeable cations (Na^+, Ca^{2+} and Mg^{2+}) has been reduced. On that occasion, the lowest concentrations of Na^+ and Mg^{2+} has been found in the variant where phosphorus (NK) has not been used, and the lowest concentration of Ca^{2+} was found in the variants with a full regimen of nutrition, especially in NP1K variant.

Table 3. The contents of exchangeable base cations in Vertisol after 30 years of fertilization

Variants	K^+	Na^+	Ca^{2+}	Mg^{2+}
	---------- c mol kg^{-1} ----------			
O	0.42 ± 0.10	0.24 ± 0.04	16.70 ± 0.25	7.20 ± 0.25
NK	0.50 ± 0.09	0.16 ± 0.05	15.90 ± 0.45	5.50 ± 0.60

NP2K	0.45 ± 0.04	0.20 ± 0.05	13.50 ± 0.20	6.60 ± 0.35
Lsd 0.05	0.054	0.036	0.229	0.355
Lsd 0.01	0.073	0.049	0.314	0.486

Immobilization of phosphates from fertilizers can be considered as an important contributor to a decrease in Ca^{2+} concentration. A reduction in the concentration of some cations in the surface layer, in particular Ca and Mg, has primarily been caused by their replacement with H^+ ions and flushing lower in the soil profile (Belay et al., 2002). In addition to flushing, a cause for lower concentrations of the mentioned cations in the adsorptive complex of the surface layer is also their adoption by plants.

Table 4. Pearson correlation coefficients

	pH KCl	H	OM	P tot	P avail	K avail	K^+	Na^+	Ca^{2+}
pH KCl	1								
H	-.702	1							
OM	.654	-.858	1						
P tot	.158	.152	.035	1					
P avail	.129	.274	.013	.948	1				
K avail	-.334	.466	-.319	.114	.146	1			
K^+	-.223	-.712	-.423	-.397	-.427	-.249	1		
Na^+	.607	-.218	.499	.043	.004	-.302	-.366	1	
Ca^{2+}	.080	-.832	.175	-.684	-.774	-.670	.499	.115	1
Mg^{2+}	.671	-.389	.792	.057	.136	-.273	-.491	.728	.027

A consequence of flushing cations from the surface area is their accumulation in the deeper layers. The process of flushing and accumulation in the depths has especially been expressed in Ca^{2+}. Its concentrations have shown a high negative dependence in relation to H (-.832) and a medium negative dependence in relation to total P (-.684), available P (-.774) and available K (-.670), which is shown in Table 4. To a lesser extent, Mg^{2+} and K^{+} flushing has been found, while in Na^{+}, it has been found only in the control and NK variants. On that occasion, a mean dependence ofMg^{2+} concentration was found in relation to pH in KCl (-.671), and organic matter (.792), and in K^{+}, a medium negative dependence in relation to Y1 (-.712), while the Na^{+} concentration was dependent on the pH (. 607) and partly on the organic matter content (.499).

Conclusion

The thirty-year use of mineral fertilizers has caused an additional acidification of Vertisol, and then a reduction in the content of organic matter and total nitrogen. Phosphoric fertilizers, regardless of the amount entered, have had a smaller effect on acidification. The concentrations of total and available phosphorus and potassium have been increased in all cases where fertilizers containing these two elements were used, and they have been proportional to the doses applied.

Exchangeable base cations have reacted differently to the introduction of fertilizers, K^{+} concentrations in the surface layer have increased in all variants where this element was applied, in particular in NK combination, while, in relation to the control variant, the concentrations of Na^{+}, Ca^{2+} and Mg^{2+} have been reduced. At the same time, exchangeable cations in the surface layer have been flushed. The biggest flushing has been found in Mg^{2+} and Ca^{2+}, which suggests caution because, over time, apart from an increase in acidity, a serious deficit in base cations in the surface layer can occur.

*Corresponding author: hamdy@iamb.it

Abstract

In arid and semi arid regions water is the main constraint to agriculture sustainability and food security. Available information characterizing the water status in those regions evidently indicate that water scarcity will escalate with increasingly fall down in the available water resources particularly those allocated to the agriculture sector. In the context of overgrowing water resources scarcity to tackle the challenges of more efficient and sustainable agriculture water use, it is needed to have a sustainable water resources management strategy that is identifying and streamlining policies, governance and practice that can sustainably improve agriculture productivity and food security. In addition, on the national level, sustainable scarce water resources management should include a group of actions to put in place instruments for optimal water allocation between sectors and to ensure that water allocated for agriculture is used efficiently and productivity. The priority areas of actions should be evidence-based-to know what are the components of effective intensive structures that drive farmer behavior, reduce water consumption and support food production improvements. In this paper emphasis will be given to discuss the strategic opportunities to implemented for improving the scarce water resources management in the agriculture sector, as well as the technical options and innovative modalities to tackle the challenges of producing more with less water.

Keywords: *water scarcity. Water productivity, food security, water use efficiency, opportunities, challenges*.

Introduction

On the globe, many arid and semi-arid countries are facing twin challenges of water stress and food security – challenges that are already pressing and projected to grow (Rostrom et al 2009 and Folely et al 2011). Because crop production id the largest global consumer of freshwater, and because water is a key resource in food production, neither of thee challenges can be addressed in isolation. Postel (2003); and Roohafken, and Stewart (2008). Improving crop water productivity and producing more food for each drop of water will be a crucial strategy to address both challenges (Molden, 2007, Abu-Zeid and HAmdy 2010).

In arid and semi arid countries it is well recognized that water scarcity will escalate and that available water resources must be managed more efficiently and sustainably than ever before. This involves actions in national level to put in place instruments for optional water allocation between sectors while providing the institutional and incentive frameworks for efficient and sustainable water resources management at agricultural sector to ensure that water allocated to agriculture is used efficiently and productively.

In arid regions including those of the Mediterranean, water is the binding constraint in agriculture. In addition as water resources are already over allocated and demand is rising from other sectors, improving productivity from existing water must be the principle path to agriculture growth. The pathways to sustaining agriculture growth whilst using less water can mainly be realized through further improvement in agriculture water management – more income for less drop.

In most arid and semi arid countries the key element for achieving both water and food security is fundamentally the function of how water is used and managed in the agricultural sector as agriculture is by far the largest water user, but, at present, it is fairly common to find that more than half of the amount of water withdrawn from the resource does not even reach the fields being irrigated. (FAO, 1993, 2003). Such water losses in enormous quantities is strongly pushing towards finding the appropriate approaches to improve the agricultural water management which it is undoubtedly considered a major conservation option in the future. (Hamdy et al 2002).

Here is should be clearly understood the water allocated to the agriculture sector to be managed more efficiently and sustainably there are significant challenges still remain in the areas of technological management and policy innovation and adaptation, human resources development, information transfer and social environmental considerations.

These issues can not be listed in any order of priority science their importance and relevance may well differ from one country to another, and also over time. Indeed, for most developing countries meeting water scarcity challenges through water saving, efficient use of irrigation water and increasing crop water productivity is still in need to a far greater effort and significant changes in: how is agriculture water is managed? What needs to be changed? What are the technical options and strategic opportunities required for improving agricultural water management?

Agricultural water management: The surrounding questions

In arid and semi arid regions there are several questions surrounding the sustainable use and management of scarce water resources. Among those raised questions, which are seeking for sustainable answers the followings:

- What are the advanced tools to be used to quantify the benefits and the costs of alternative policy options to address food insecurity while sustaining water resources?
- What are the institutional solutions and modern technologies to be adopted to increase the efficiency and productivity of water use in the different sectorial water use and particularly in the agriculture one.
- Which are the incentive frameworks should be established that reposition farmers at the centre of sustainable management of land and water resources.
- How to mainstream gender issues the backbone of strategic visions planning, reuse and management of water resources and management of water resources.
- How to meet this ample increase in water demand at a time when pressure on resources are increasing and their mobilization is becoming increasingly expensive.

The bottleneck and the master key for a reasonable answer to the above questions as well as to the problems deriving from the presence of such water imbalance are focused and they mainly depend on the way water is used and managed in the agricultural sector (Abu-Zeid and Hamdy 2010). The reason for that is not because of water losses exceeding 50%, while most of such water losses could be avoided through water saving and appropriate agricultural water management techniques.

However, for agricultural water management there are several questions to be asked: How efficient really is agricultural water management? How can productivity be boosted? And, how can gender responsive good practice be shared and built on?

Agricultural water management improvement: The difficulties

In most developing countries and particularly those suffering sever water shortage there are numerous difficulties facing appropriate water management and particularly in the agricultural sector due to a wide variety of factors including: (Water Bank, 2007)

- The overall economic situation in some of the countries due to tight budget constraints.
- Making it difficult to government supporting the adoption of better water and land management practices to improve and increase crop water productivity.
- The strategies to increase agricultural production and reduce land degradation to improve agricultural productivity are not location specific, and that at a given context, there are only a few win-win.
- Poor water governance and the incapability of the public institutions and organizations in implementing the world developments reports dealing with agricultural water productivity.
- In most of those countries governments have developed the resource and allocated water between sectors and to users but have not developed the flexible and participatory institutional mechanisms and accountability structures needed and sectoral water conflicts.
- In many areas where increases in water productivity are needed, knowledge exists, but institutional capacity and human capital are inadequate support the knowledge transfer needed to accelerate the adoption of new technologies that leads to increased yields and water productivity. (Hamdy 2016). According to (Lal 2007) in such cases, the top down approach to technology transfer is not effective and should be changed into participatory approach combining traditional knowledge with scientific technology.
- Lack of successful programmes provide for good water governance arrangements, with well designed institutions having clear authorities, the necessary resources and stability.
  Indeed, for many countries in arid and semi arid regions, water sector institutions are not always adopted to new technologies, innovation and the development of the resource.

Improving Agricultural water management: Important measures to be taken

In arid and semi arid regions water scarcity challenges could be met through improving water management in the agricultural sector (Hamdy 2000). However, there are several important measures to be taken among them:

- Create a broad consensus on the water reform agenda among all involved stakeholders.
- Acknowledge farmer's role in promoting a shift in the way water resources are used and managed.
- Involve the private sector as the actual manager of the food value chain and the supplier of the latest available technologies.
- Establish partnerships that are action oriented and result based
- Develop tools to concretely measure results and collect evidence to support policy making and decision making processes.

Practical approaches to improve crop water productivity in irrigated agriculture

Resources management strategies, in general are, coherent statements in directing how particular resource should be developed, and what is the approach that would have to be taken to achieve one or more management objectives successfully. Regarding the water management improvement in the agricultural sector, there are a certain number of strategic principles to be followed Abu-Zeid and Hamdy 2010):

- The strategic options have to be cross-cutting in nature, therefore capable of securing highly integrated solutions, with the aim of involving a variety of interested socio-economic sectors as well as stakeholders;
- The proposed strategic options have to be, on one hand comprehensive enough to encapsulate most of the problems in water sectors in arid and semi arid conditions, as well as have a wide geographic coverage, however, the packages of actions in each of the options, on the other hand, have to allow for the possibility of a adjustment to local situation and conditions;
- The strategic options have to be based on assessment of local situations in order to find what are good existing practices and what could work in the future water resources management.

Options and strategic opportunities for improving agricultural management:

On farm water use efficiency and agricultural several practical approaches could be implemented to improve irrigated agriculture and to increase agricultural crop productivity among them the followings:

- Supporting high input irrigated production using high yielding varieties, fertilizers, pesticides and other inputs.
- Utilization of efficient technology micro irrigation systems, along with plastic houses are effective tools for improving the technical efficiency of irrigation. The effective role of both technologies to reduce evaporation and leakages can cut water use by 50 percent per hectare and still increase yields significantly showing that less can actually produce more.
- The development of best practices that could help, arid countries to establish an incentive framework for promoting water use efficiency and water productivity in agriculture.
- Reallocation of irrigation water supply to low water consuming and high value crops: Crop rotation is an essential part of proper irrigation water demand management, cropping pattern should be modified through the use of less water consuming crops and high value crops. In this regard new strategies are needed for changing cropping patterns to suit future water allocation, such strategies should be based on the availability of water supply and applied through economic reforms and structural adjustments.
- Irrigation techniques to meet insufficient water supply

- Supplementary irrigation: Supplemental irrigation when water supply is insufficient to meet full crop water demand or too expensive, alternative strategies can be used, so called supplemental irrigation. Supplemental irrigation shown large potential to improve water productivity especially in semiarid and dry sub-humid cropping systems with high rainfall variability (Baron, 2004), however, such irrigation technique is not a common practice to supplement rainfed agriculture.
- Deficit irrigation: The potential benefits of deficit irrigation in improving crop water productivity arise from enhanced water productivity and lower production costs if one or more irrigation application can be eliminated. However, the successful implementation of this technique implies that farmers should know the deficit that can be allowed at each of the growing stages and the level of water stress that already exists in the root zone.

- Water harvesting: Water harvesting is the collective name a range of technologies that aim to concentrate water flows and storage, either as in-situ technologies (in principal using the soil as storage for infiltrated rainfall), or in natural or manmade storage structures such as dams, ponds and tanks. With successful water harvesting techniques, over 50% of lost water can be recovered at relatively little costs (Oweis and Hachum. 2006).
- Conjunctive use of water supplies: The conjunctive water use is one of the approaches to be highly recommended in arid and semi arid regions where countries are suffering acute water shortages. It implies the combined use of water resources of more than one type resources their exploitation through efficient management in techno-economic terms by taking advantage of the interaction between them and the impact of one on the other.

  According to Hamdy (2003), through the use of such approach there is high potentiality of improving irrigated agriculture productivity. Indeed, this approach provides high potentiality to the reuse and recycling of each drop of wastewater from the different sectorial uses and thereby providing additional water supply to the irrigation sector and reducing the fresh water use in this field. However, such technique in spite of the advantages it could provide in improving agriculture production and its productivity and good fresh water saving, yet, in most countries suffering water scarcity, the conjunctive water use is rarely practiced.

Improving water management in the agricultural sector: Potential tools

Mobilizing new supplies

In arid and semiarid countries and particularly those of the Mediterranean although most resources are fully developed, there may some potential to develop further storage and optimize release on existing storage. (Hamdy 2003 and Abu-Zeid and Hamdy 2004). However the economic and environmental tests for new development will be hard to pass. Such option will need to be flexible and have low capital operating costs. In this regard(FAO 2007) showed that local hill dams, water harvesting and on farm water storage may prove to be the most economical solution.

The reuse and recycle of treated wastewater and brackish/saline water.

In arid and semiarid countries the reuse of treated wastewater is a fundamental option to fulfil water scarcity in the agriculture sectors. In those countries as cities grow and invest in treatment plants, the resource will increase and can provide a useful –if relatively modest- new source for agriculture. It is a renewable resource, increases day by day, provide energy and supply the needed fertilizers for the growing crops and above all is not affected by climate changes. (Hamdy and Eslamian, 2016).

However, for this source there are barriers of costs, location and incentives to overcome, and a regulatory framework and workable incentive structure are required

Drainage water, brackish saline water and ground water.

For those saline water resources there is a high potentiality to be sustainably used in irrigation. However, to be successfully used In the agriculture sector, it is needed to have in hand an appropriate integrated crop, water, soil management to avoid losses in crop production and maintain soil at a high productivity level without degradation. (Hamdy 1998).

Here it is to be stressed that the potential and the sustainable use on a large scale of the non-conventional water resources (Municipal treated wastewater and saline brackish water) vary by country and from one location to other and for great number of countries there is an urgent need

that each country should have a legal, regulatory and incentive frame work to ensure the sustainability of the use and reuse of such water resources. (Hamdy and Ragab 2005)

Rapid depletion of this vital water resource accompanied by deterioration of water quality and saline intrusion. Sustainability of groundwater quantity and quality with equitable access implies that the country should have: (Romani 2006) i) a rights and regulations approach; ii) an incentive structure to favour conservation and efficiency, iii) decentralization groundwater resource management to the local level supported by iv) monitoring, information, education and communications.

Improving agricultural water management in the Mediterranean: the need for regional cooperation

The development of a regional collaborative strategy focusing on policies, investments and practices that are necessary to sustainable intensification of agricultural production under water scarce conditions.

Such regional collaboration could contribute to improving water scarcity management in the agriculture sector. This collaboration might cover in particular: sharing of data, information and knowledge on agricultural water management, best practices in governance and institution building, benchmarking, research and development, capacity building; technical cooperation, and awareness raising. Furthermore, regional cooperation could be very helpful in providing:

- A regional collaborative review on the implications of the energy/water/food nexus,
- Regional programme on research and development, capacity building and technical cooperation.
- Assessment on yield and water productivity gaps through modern technologies,
- Synergy and joint work across the region in research, exchange of experiences and best practices, etc.

Concluding remarks and recommendations

- In countries suffering shortage in their available water resources efforts should be directed to improve agricultural water management. In the context of those countries should clearly identify: governance reform, economic, institutional and technical options and innovation to tackle the challenges of more efficient and sustainable agricultural water use.
- Within the agricultural sector, strategic opportunities exit for improving management of water resources including: improving water use efficiency and crop water productivity, irrigation modernization, rainfed agriculture enhancement, improved water shed and dry land management, sustainable use of non conventional water resources.
- Improving management of agricultural water resources the priority areas for action should focus on technology and institutions for increasing crop water productivity through: promoting research, innovation and strategies for risk reduction; institutional adaptation accompanying technological innovation; joint monitoring of climate change trends and development of adaptive strategies and introducing innovation sources for financing.
- At community level improvements in agriculture water management by increasing water productivity could be achieved through including conserved agricultural practices, deficit and supplementary irrigation production packages, grey water system for irrigation and establishing water saving knowledge and innovation platform and improving the institutional capacity building.
- Strengthening governance and institutions, integrated approach to water resources management, decentralization and participation, supply side management; demand side management and the

establishment of an incentive frame work are recommended priorities to be put in action to improve agricultural water management in arid and semi arid countries.

- Although there are no simple solutions to the water scarcity, there are smart choices, it is needed to inject innovative thinking into the way water resources are used and managed for the benefit of the food security. Equally, promoting cost effective water investments and management practices is a highly recommended option to be carefully considered.
- Irrigation managers, water specialists, and decision makers as well recognise that if we succeed in increasing water productivity in the irrigation sector through implementing intelligent water conservation and demand management installing efficient and institutional incentives to shift water among users, then new sources of water supply to irrigation can largely be avoided in many countries where water scarcity is rapidly growing.
- Climate change will have a negative impact on agriculture water availability and will increase farmers' vulnerability at regional and national level research should be strengthened on modelling and monitoring and the preparation of adaptation strategies.

THE REDUCTION OF NICOTINE CONTENT IN THE COMPOSTING PROCESS OF TOBACCO WASTE MIXING WITH SHEEP AND CHICKEN DROPPINGS

Gordana KULIĆ*, Nemanja MANDIĆ, Vesna RADOJIČIĆ, Maja MALNAR

University of Belgrade, Faculty of Agriculture, Nemanjina 6, 11080 Belgrade-Zemun, Serbia
*Corresponding author: gkulic@agrif.bg.ac.rs

Abstract

Due to the rise of industrialization and urbanization, the amount of waste is gradually increasing as well, both in developed and developing countries. Tobacco waste generates in all processes it starts in the field and ends up with the production of cigarettes. The total global tobacco waste production in the year 2005 was more than 25.1 million tons. In our experiments we used Virginia tobacco waste (TW) after processing, as well as sheep and chicken drop pings. Two experimental samples were formed according to the following scheme: I 50% TW + 50% sheep drop pings, II 50% TW + 50% chicken drop pings. The comparison is made with the reference sample (100% TW). The experiment was conducted at the experimental farm of the Faculty of Agriculture, under natural conditions, in the open, during a three months period. The nicotine content in the samples was determined by a HPLC method. At the beginning of the experiment, the nicotine content in the tobacco waste was 17 363 mg/kg. By adding sheep and chicken droppings, nicotine content decreased by 66.5%. At the end of the research, nicotine content as dropped below 10mg/kg in both experimental samples. The results confirmed that the organic material, sheep and chicken manure, can be successfully used for composting of tobacco waste, primarily in order to reduce the nicotine content. Composting can be done in the open air and on the site where the waste is made, thereby it reduces energy costs, and what's the most important – the costs of the transport.

Keywords: *composting, tobacco waste, sheep droppings, chicken droppings, nicotine*.

Introduction

The organic solid waste poses a serious threat to the environment. Biological technologies for treating waste materials, between where composting is also classified are considered clean and sustainable methods for organic waste management. Compost production has gained popularity, due to the fact that it is a method by which we can reduce pressure on landfills, extend their use, and minimize environmental pollution. It is the raise in environmental awareness among the society in recent years that caused the increase in people's interest in composting process, so as to prevent or reduce environmental pollution and establish sustainable management of the waste (Radojičić et al., 2009). Composting process can degrade various types of organic waste (Lim et al., 2016).

Composting is a biological decomposition of organic matter, caused by microorganisms in aerobic conditions. Composting process leads to stabilization of biodegradable waste (wet and solid organic matter, food waste, garden waste, paper, cardboard, etc.), and to the formation of a stable product, compost (Jovičić, 2006). This process can be conducted in controlled, partly controlled and uncontrolled environmental conditions. Composting is an acceptable solution, as it reduces the volume (mass) of the organic waste, whereas the material becomes a stable product at the end of the process, which can be used as an organic fertilizer. A substrate with optimal

physical and chemical characteristics for composting can be formed by mixing two or more types of biodegradable waste (Kopčić et al., 2013).

Agriculture production and industry generates large amounts of solid waste that may be suitable substrates for composting. The total global tobacco (Nicotiana tabacum L.) waste production in the year 2005 was more than 25.1 million metric tons (Radojičić et al., 2015). Tobacco waste, which is generated in all processes, from tobacco production in the fields to cigarettes manufacturing, accounts for a significant percentage of the agro-industrial and municipal waste in Serbia (Radojičić et al., 2009). According to the principle of extended responsibility, producers of tobacco products can be held responsible for the collection, transport, processing and safe disposal of tobacco products (Curtis et al., 2016). The main characteristics of the tobacco waste are high value of the total organic carbon (TOC), as well as high contents of nicotine, which is a toxic compound (Civilini et al., 1997).

According to Waste Catalogue issued by the Ministry of Environment and Spatial Planning and the Agency for Environmental Protection of the Republic of Serbia (Waste Catalogue, 2010), tobacco is categorized as nontoxic waste. While this waste is not classified as dangerous, neither as inert, it cannot therefore be disposed of to landfill without treatment (Radojičić et al., 2009).

According to EU Directive nicotine content above 500 ppm declares this waste into the category of hazardous waste (Radojičić et al., 2009). Also, due to the high solubility of nicotine in water, there is a serious risk that, when the waste material is kept, nicotine can be flushed out of the waste and get to the groundwater, which is a particular threat to the environment and human health. For these reasons tobacco waste cannot be disposed of together with urban waste (Pichtel, 2005), but must be destroyed under special conditions, which is an economic burden for tobacco producers and processors.

Previous research has found that the tobacco waste can be used as fertilizer because of its high content of organic matter and low content of toxic elements. But it first needs treatment, because in its original form(primarly due to its content of nicotine) it still toxic (Radojičić et al., 2009, Radojičić et al., 2008). As such it affects human health and the environment.

To release the tobacco waste from toxic elements, primarily nicotine, the composting process is the optimal solution. Clean scrap tobacco has a detrimental effect on the microbial activity in the soil, but compost can stimulate them, primarily due to a significant content of trace elements.

Radojicic et al. examined the possibility of growing mushrooms on compost prepared from tobacco refuse. They found that it is possible to perform microbiological degradation of nicotine in tobacco waste and turn it into such a relatively neutral plant material like any other plant waste. As such, it can be successfully used for producing compost for mushroom growing (Radojičić et al., 2008).

An experiment which was conducted in South Africa examined the changes that have taken place during the composting of solid waste tobacco, along with other types of organic waste (Adediran et al., 2006). By mixing tobacco waste with other organic waste and their dilution, nicotine content was reduced from 12180 mg/kg to 4872 mg/kg, while the composting process further reduced nicotine content to less than 160 mg/kg. The results of the experiment showed that the obtained compost is very suitable for use in horticulture.

In the experiment of Turkish scientists in Izmir in 2006, they treated the land on which one sort of lettuce was cultivated with compost derived from tobacco waste and manure, in different scales, in order to examine the impact of this kind of organic fertilizers on the biological properties of the soil and the growth of lettuce (Okur et al., 2008). Following mixtures were made: TWC 25% + 75% FYM; 50% + 50% TWC FYM; TWC 75% + 25% FYM and TWC 100% and 100% FYM (TWC - tobacco waste compost, and compost derived from tobacco waste

FYM - farmyard manure). Composting is carried out in the open, or under the roof. It has been found that the microbial biomass increased by using all the proportions of compost, and the results indicate that compost waste tobacco is a good alternative to recharge and improve soil characteristics (Okur et al., 2008).

The reasoning for this research was the problem of unused tobacco waste in the Republic of Serbia, expensive process of destruction under strictly controlled, legally prescribed conditions as well as the uncontrolled disposal, with the aim of revitalizing the waste in accordance with the requirements of environmental protection. The goal of this study was to examine the possibilities of reduction of nicotine content through the process of composting, waste mixing tobacco with sheep and chicken droppings.

Materials and methods

Virginia tobacco leaves, which are declared as waste after redrying process, were used for the purposes of the experiment. Sheep and chicken droppings were used as components in experimental batches. Experiment was carried out during the period of three months: begin of March – end of May.The experiment was conducted at the experimental farm of the Faculty of Agriculture, University of Belgrade (Serbia).

Preparation of experimental batches - Tobacco wastewas stirred with sheep and chicken droppings. For the purposes of the experiment the following compost batches were formed:

Table 1. Compost batches ingredients (%)

Composting batch	TW	Sheep droppings	Chicken droppings
1	50	50	/
2	50	/	50
R	100	/	/

TW – tobacco waste
R–control sample

Composting is carried out in the open, under the roof. Aeration is provided by manual tumbling, and humidity is kept constant. The batches were covered with leaves to maintain moisture. The process was completed in three months, when the temperature of compost achieved the same value as the outdoor temperature.

Analysis of nicotine content in samples experimental batches- Nicotine content in the batches (at the begining and at the end of the ewperiment) was determined by High Performance Liquid Chromatography method (HPLC, Waters Breeze, USA).

The method applied in this analysis involves water extraction of the milled material followed by separation of the alkaloids on reverse-phase C18 column with a mobile phase of 40% methanol containing 0.2% phosphoric acid buffered to pH 7.25 with triethylamine. This procedure allows the quantitative analysis of four "major" alkaloids in tobacco and may it be partially automated as to handle a larger number of samples (Saunders and Blume, 1981).

Results and discussion

Table 2 shows the results of the nicotine content in experimental batches.

Table 2.The nicotine content in experimental batches (mg/kg)

Composting batch	Initial value	Final value
R	17363.0	5132.0
1	5790.0	<10
2	5812.0	<10

The initial content of nicotine in tobacco waste was 17363 mg/kg. Already by mixing tobacco waste with other organic waste, the nicotine content decreased by 66.6% in the first batch of compost, and 66.5% in the second. This percentage decrease is even higher when compared with the literature data (Adediran et al., 2006).The experiment which was conducted in South Africa examined the reduction of nicotine in tobacco during composting of solid waste. Mixing tobacco waste with other organic waste reduced the nicotine content from 12180 mg/kg to 4872 mg/kg, with a single dilution (Adediran et al., 2006), which accounted for 60% reduction.

At the end of the experiment, after three months, the nicotine content decreased below 10 mg/kg, in both experimental batches, which is far below the value specified by the European Directive (Radojičić et al., 2009).In a previous study conducted by authors from Serbia ((Radojičić et al., 2015).the process was carried out under partially controlled conditions, also lasted three months. Also, the results obtained in this study were far better than in previous studies, where the composting process decreased the nicotine content in the waste below 160 mg/kg (Adediran et al., 2006).

Our results confirm that the organic material, sheep and chicken droppings, can be successfully used for composting of tobacco waste, primarily in order to reduce the nicotine content.

In experimental batches of compost in addition to reducing nicotine there was a loss of weight (Table 3).

Table 3. Loss of mass during the composting process

Composting batch	Initial mass (kg)	Final mass (kg)	Loss (%)
1	10	3,30	67
2	10	3,50	65

Based on these data we can see that the weight loss of the samples was approximately equal among all samples, or that it was slightly higher in the compost batch number 1. In the first batch the weight loss was 67%, while in the second one it was 65%.

Conclusion

Given that tobacco waste accounts for a significant part of the total agro-industrial and municipal waste in Serbia it is necessary to examine the possibilities of its use. Tobacco waste, as a specific type of agro-industrial biodegradable waste, with the use of composting process can be converted in to a product that has practical agricultural value.

Based on these results, it can be concluded that, already by mixing tobacco waste with sheep and chicken droppings, nicotine content decreased by 66%. Nicotine content at the end of experiment

dropped below 10 mg/kg in both experimental compost batches, which is far below the 500 mg/kg - the value prescribed by the EU directive.

The results of the experiment showed that biodegradation of tobacco waste, by mixing it with chicken droppings and eyes and composting it, can be an effective method of removing nicotine. That way the obtained organic material can be used without posing a risk to the environment.

The importance of this experiment lies in the fact that the process of biodegradation can be carried out in natural conditions. Regardless of the longer duration of the process, it does not require a high economic investment. Also, this experiment has proven the fact that the composting process can take place on the site where the waste is disposed, which can lead to saving on the transport costs.

Abstract

Food industry is a large consumer of water, both as an ingredient as well as for technological purposes. Though food industry doesn't pose any severe environmental threatening in soil or air pollution it produces a large quantity of wastewater which needs to be treated before their discharge in the surrounding environment. In particular, the meat processing industry is one of the major consumers of freshwater besides food and beverage processing facilities, which makes meat processing plants a significant producer of wastewater effluents. Such effluents characterized by high chemical oxygen demand, biological oxygen demand, nutrients, and organic and inorganic contents, if discharged without proper treatment, pollute severely receiving water bodies and disrupts complete ecosystem. Thus, appropriate treatment methods are required to meet the effluent discharge standards. This paper presents the data obtained from the physical chemical analysis performed in wastewater effluent produced from meat processing plants in Albania. Frequent wastewater samplings have been made according to peak plant production. The daily composite samplings have been made to the effluent flow before mixture with the municipal waste water. All samples were analyzed in duplicate for COD, BOD, suspended solid content, pH, chlorides, total nitrogen and phosphorus, oils and grease content. Analyses were done according to methods outlined in Metodi Analitici per le Acque (APAT). The data collected were compared to the existing Albanian Norms outlined in the respective Albanian Regulation for meat processing plants and some alternatives for effluent wastewater treatment are given as well.

Keywords: *meat processing plant, wastewater, effluent, characteristics, effect.*

Introduction

All food sectors including fruit and vegetables; meat, poultry, and seafood; beverage and bottling; and dairy operations consume huge amount of water for processing food. A considerable part of these waters are potential wastewaters to be treated for safe disposal to the environment. There are typical rates of water use for various food-processing sectors. An abundant and inexpensive source of water is a requirement for success in the food-processing industry.

The main constituents of food processing wastewater is often complex to predict because of highly biodegradable organic matter presence and often varietal seasonal nature of processing plants (Christian, 2010)

The meat industry covers slaughterhouses and cutting plants as well as meat products (fresh, cured, or cooked) manufacturing plants. However, these are generally separated into slaughterhouse/cutting plant and manufacturing plant. The meat processing industry uses 24% of the total freshwater consumed by the food and beverage industry and up to 29% of that consumed by the agricultural sector worldwide (Bustillo – Lekompte & Mehrvar, 2015).

From an environmental viewpoint, the production of wastewater differs markedly depending on the type of installation concerned. Thus, whereas slaughterhouses/cutting plants generate large volumes of wastewater with a high organic load, production at manufacturing plants is lower and tends to remain fairly constant over time.

For meat processing plant blood is the main constituent, having a chemical oxygen demand (COD) of 375 000 mg/l. Such wastewater contains as well large quantities of oils and fats, grease, and solid suspended in particular (Christian, 2010).

Killing animals and rendering processes create blood by-products and waste streams, which are extremely high, even in BOD. Waste streams vary per facility, but they can be generalized into the following: process wastewaters; carcasses and skeleton waste; rejected or unsatisfactory animals; fats, oils, and greases (FOG); animal feces; blood; and eviscerated organs.

As can be seen wastewater is generated during almost all the processes involved as well as when cleaning the installations. The final volume produced is high and it has been estimated that around 5 liters of water is required per kilogram body weight for the live animal. (Wastewater Treatment for Meat Processors, 2015) The MPWW (meat processing wastewater) generated generally carries with it slurries, meat remnants, blood, hair, pieces of entrails, and surface fat, which together mean that the water has a content of organic matter, material in suspension, oils and fats, nitrogen (ammonia and organic), phosphates, and detergents and disinfectants used during cleaning. In addition, the load in the wastewater varies markedly depending on the time of day and even from one hour to the next.

Typical parameters related to the organic matter and nutrient content of the effluent generated in a meat processing plant are COD (mgO_2/L), BOD_5 (mgO_2/L), solids in suspension (mg/L), total nitrogen (mg N/L), total phosphorous (mg P/L).

The aim of our study was the inspection of wastewater in the meat and poultry sector, specifically the main physical characteristics of untreated water from meat processing plants near the seaside region in Albania. The basic analysis consisted to estimate pH, TSS (Total Suspended Solids), BOD (Biological Oxygen Demand) COD, TN, TP and FOG (Fats, Oils and Greases) levels connected with the expected total volume of wastewater output each day.

The analysis results may be used as a good start, first to know specifications of meat processing wastewaters in terms of standards limit levels and second to properly set either to municipal wastewater treatment facilities, or if the meat processing plant facility need to develop its own treatment options.

Materials and methods

The target of this study were two of the main meat processing plants in Kavaja city situated near the Albanian seaside with wastewater pouring to a water stream followed next into the sea. These plants consume approx. 3 lt water/kg product, which is high taking into consider the large production rate of both plants. The research was done during March-June 2016 period in order to know and make an overall estimation of the characteristics of meat processing wastewater and to estimate the potential pollution to the receiving surface water. The wastewater samples were collected at the outlet plant wastewater line. It had not undergone any preliminary treatment before discharge.

The sampling was made four times during this period and was analyzed in duplicate for BOD_5, COD, total suspended solids, pH, chloride, P as P_2O_5, organic nitrogen and fat, grease & oil content (FOG).All the samples have been taken more or less at the peak time of plants operating hours in order to properly estimate the maximum environmental risk of wastewater produced. Sampling was made according to the detailed procedure described in literature (Metodi Analitici

per le Acque) and stored at proper temperature until next day when it was not possible testing the same sampling day. Analyses were done mainly according to Metodi Analitici per le Acque for BOD, COD and TSS and according to methods described fully in the text book (Cullhaj A. 2010).) for pH, Chloride content, E_{redox}, organic nitrogen, phosphate content as P_2O_5.

Results and discussion

The experimental results of physicochemical characteristics of wastewater generated from the two meat processing plants, taken into consideration in this research, are presented in table 1. Degree of wastewater pollution is shown by the mean values of pollution indicators: COD, BOD, total suspended solids, pH, chlorides, total organic nitrogen and total phosphorus. No significant difference in values obtained which could affect on the conclusions drawn, was noticed during the four months period of study.

Table1 Physicochemical characteristics of meat processing plant wastewater.

	Pollution indicators	Unit of measure	Mean value
1	COD	mg/l	1200
2	BOD_5	mg/l	980
3	TSS	mg/l	480
4	pH	pH unit	7.14
5	Chlorides	mg/l	144
6	Nitrogen organic	mg/l	280
7	FOG	mg/l	650
8	Phosphorous as P_2O_5	mg/l	20
9	Potential redox	mV	-20

From the data obtained, especially for BOD/COD ratio = 0.81 we can presume that the raw wastewater from meat processing plant are highly biodegradable.

Table 2 Permissible norms of the wastewater from foodstuff production plants (Meat production & processing plants)

Indicators	Albanian norms	EU norms
pH	69	
Total suspended solids	50 mg/l	35 mg/l
BOD_5	50 mg/l	50 mg/l
COD	250 mg/l	125 mg/l
FOG	10 mg/l	
Total nitrogen	10 mg/l	10 mg/l
Total phosphorous	5 mg/l	

Comparing these data to the Albanian permissible norms outlined in the Decision nr.177 dated 31.03.2005 of the Council of Ministers and the respective EU norms shown in the Table 2 we can make the following comments and discussion.

Considering the table nr.1, the level of some indicators as BOD_5 and COD shows the high content of the biodegradable matter consequently we can say that the wastewaters of these two factories may be classified as considerably polluted. Direct discharge of raw MPWW effluents to a water body is impractical due to their high organic strength. An easy way for treatment would be the S*eptic Systems* that in Albania have started with other plants. Anyway a typical septic system will probably not properly work for most meat processing plants because of the high levels of BOD, TSS in the wastewater. So the meat processing plants need to consider other options like connecting to municipal wastewater services, building a pond or lagoon system, building a constructed wetland, especially in case of small or law wastewater discharges. Anyway the most used option for wastewater in meat processing plants is the connection to municipal wastewater system only if they will be submitted to treatment in wastewater treatment plant.(Wastewater Treatment for Meat Processors 2015) Unfortunately this is not the case for most of the meat processing plants located far from these wastewater treatment plants in Albania, so most of the producers discharge the wastewater to raw municipal wastewater without further treatment being so a serious potential for water pollution. It results that meat processing plants in Albania should find alternative ways in order to comply with permissible norms according to Legislation.
Considering the considerable content of N and P compounds specific for meat processing plants we can say that biological combined with chemical method should be applied to minimize the potential risk to the environment. It is interesting to note the higher value of N-compounds compared to permissible norms which is characteristic of meat processing and the lower value of P-compounds which mostly is derived from the detergents used in the plant for sanitary purposes and partly from the polyphosphate used as binder in meat processing technology.
Literature used for the recommended treatment methods for meat wastewater processing plants offer similar technologies used in municipal wastewater and they include conventional treatments such as preliminary, primary, secondary, and even tertiary treatment. The most recommended treatment system for MPWW should be based on the design of a complete system involving water pretreatment to remove large and small solids, along with oils and fats. Screens and fat traps are the minimum means of pretreatment in any system considering the high value of FOG content specific for meat processing industry. MPWW management methods after preliminary treatment are various, but they can be divided into five major subgroups: land application, physicochemical treatment, biological treatment, AOPs, and combined processes.(Bustillo – Lekompte & Mehrvar, 2015) Flotation, in some cases aided by chemical addition, may also be carried out to remove suspended solids and emulsified fats.
The choice of an appropriate biological treatment system will be influenced by a number of factors, including wastewater load and the need to minimize odors. Extended aeration is an effective form of treatment, but care must be taken to minimize odors. Disinfection of the final effluent may be required if high levels of bacteria are detected. Ponding is a simple solution but requires considerable space. Chemical methods, usually based on chlorine compounds, are an alternative. If the biological treatment is anaerobic, the biogas generated can be used to produce electrical energy, thereby reducing the overall consumption of the installation. (Bustillo – Lekompte & Mehrvar, 2015)

Conclusion

Wastewater generated from monitored meat processing plants contains high concentration of degradable organic matter. However the amounts of the pollution indicators varies within a wide range depending from production rate, degree of the water managements policies applied and seasonal fluctuation of the production.

Based on the results collected and fact that companies have not undertaken all the necessary precautions which will allow adequate treatment of the produced wastewater, we can conclude that the reduction in fresh water needs and minimization of the environmental impact of the site is of high importance and measures should be taken to minimize the overall environmental and economic cost of fresh water quantity used and wastewater treatment.

Some treatment options for the considered meat processing plants are available in literature. The simplest option could be the connection to municipal wastewater treatment plant.

Both plants under study are located near these services, so it will probably be worth it to pay the initial connection fees and monthly costs rather than build and manage their own wastewater treatment system. Septic system is another option though it doesn't properly work for such high value of wastewater BOD and COD. Other technologies are fully described in the literature which can be widely used in meat processing plants successively.

Acknowledgment

The authors express their gratitude to the managers and the staff of the meat processing plants in Albania who gave their unsaved assistance for sampling, as well as for willingness & interest to discuss for collaboration in the future for their wastewater treatment options.

Abstract

One of the biggest potential sources of environmental pollution are dumps. Soil around dumpscan be considered as a buffer zone, which retains different types of pollution generated in the process of decomposition of waste. This paper presents the results of analyzes of soil characteristic, located around the main dump in Novi Sad, Serbia. Soil sampling was done at two depths of 0-30 and 30-60 cm, at two sites near the dump. Also, one sample was taken from the sludge in the canal, which drains atmospheric water from the dump. Based on results it can be said that tested soil, around the dump belong to the texture class loamy coarse sand, it is characterized by an alkaline reaction (pH in H_2O of 8.43 to 8.61), it is very carbonate (from 7.87% to 9.11% $CaCO_3$). Also it has very low content of humus, nitrogen, and medium content of and potassium. Content of microelements (Cu, Zn, Co, Mn) and heavy metals (Pb, Cd, Ni, Cr, As, Hg) in all tested samples is significantly lower than the maximum permissible concentrations (MPC) and is at the level of the value of heavy metals in the soils of the wider area of Novi Sad. Based on these results it can be concluded that the land near dump are not contaminated with heavy metals. Considering a highly favorable chemical properties of mud it should be considered the possibility of using the sludge in the future recultivation in terms of increasing soil fertility around dump.

Keywords:*Dumps, soil characteristics, recultivation*

Introduction

With a rapid urbanization and development of cities with massive migration of citizens from rural to urban areas has led to a large increase in population on a relatively small area. One of the consequences of this trend is increasing of production of municipal solid waste (MSW) that must be stored (Arunel. 2010). In many parts of the world, practice is that municipal solid waste need to be stored in landfill prepared for that. Landfills are often the most cost-efficient way to dispose of waste, especially in non developed countries (Jhamnani and Singh, 2009; Longe and Balogun, 2010; Arunet al.,2010) In Serbia generation of MSW per year is about 2, 65 mil. t., while municipality of Novi Sad (Vojvodina province, Serbia) produces about 133 kt per year. (Statistical Office of Republic of Serbia, 2012).

Landfills have the potential to cause a number of issues. One of problems can be pollution of the local environment, such as contamination of groundwater, soils and air and generally landscape (Zhou et al., 2011). Soil around the landfill can be considered as a buffer zone which retains different types of pollution generated in the processes off decomposition of waste. The role of soil around the landfill is multiple, because besides keeping pollution and filtering leachate from the landfill, it also provides a habitat for plants, mostly trees species that act as a windbreaks.The impact of the landfill on the environment can be reduced and isolated through the process of

making a protective green breaksconsisting of trees, shrubs and herbaceous plants. In order to preserve these plants growth, as well as provide the best possible isolation of the landfill, it is necessary to recultivate contaminated soil around the landfill. By definition, recultivation presents a set of actions that lead to the creation of sufficient phytoproductivity on soil that has been previously degraded (Miljkovic, 1996). The aim of this paper is to, based on field and laboratory research and existing literature about this area propose measures for recultivation if necessary.

Material and method

Novi Sad city is located in the southern part of the Pannonian Plain, on the border of the Bačka and Srem regions, on the banks of the Danube river, facing the northern slopes of Fruška Gora mountain. It is the second largest city in Serbia and the administrative seat of both, the province of Vojvodina and the South Bačka District. Since its founding, the population of the city has been constantly increasing and today city has 341,625 inhabitants (Statistical Office of Republic of Serbia). Area in which the trial was conducted is in geomorphologic point of view of the lowest part of alluvial terrace of the Danube. Natural soil type is fluvisol, which is hydromorphic soil and belong to class of under developed fluvial soils with soil profile (A) or G (A)-C. These soils are recent, river, sea and lake deposits with layers. Pedogenetic processes are poorly expressed due to youth of deposit or because of sedimentation prevails pedogenesis. Physical and chemical properties depend on the number of layers and their thickness, texture, origin and sequence. Some typical characteristics are rarely discussed and they are different from profile to profile (Živanov and Ivanisević, 1986, Nešić et al., 2014).

City landfill in Novi Sad is controlled and partially remediated dump. It is located north of the city in the peripheral part of Novi Sad, outside of the construction zone, and occupied area of 35.381 m^2. In order to determine the type and level of soil contamination there were collected five soil samples from tree sites. At first two localities sampling was performed at two depths of 0-30 cm and 30-60 cm, as this is the part of the bulk of the solum that plants developing roots. The third site was the bottom of the leachate canal, which is located around the landfill, and in that period canal was without water. Soil samples were air-dried and manually sieved through a 2 mm sieve for chemical and texture analysis. The collected samples were analyzed at the Laboratory of Soil and Irrigation and Laboratory for Agrochemistry at the Faculty of Agriculture, University of Novi Sad, with contemporary, recognized methods used for this type of research (JDPZ, 1997; Bošnjak et al., 2012; Belić et al., 2014; Ubavić and Bogdanović, 2001). Laboratory studies include the determination of texture according to International B-pipette method with preparation in sodium pyrophosphate; pH value in the suspension of soil with H_2O and KCl, and the measurement is carried out using a pH meter "inoLab"; content of humus, the method of Tjurin; calcium carbonate ($CaCO_3$) - using Scheibler's calcimeter total nitrogen content (elemental analysis of the total sample burning) automatic method - CHNS analyzer; ammonium lactate P_2O_5- spectrophotometric determination of available phosphorus; ammonium lactate K_2O - determination of available potassium by flame photometer; total content of macronutrients, micronutrients and heavy metal destruction with concentrated nitric acid, induced coupled plasma ICP – OES and total Hg content - Direct method for determination of mercury - the machine DMA-80 direct mercury analyzer (Direct Analysis).

Results and discussion

The results of soil texture are shown in Table 1. Based on results soil in this area is characterized by homogeneous and lighter texture composition. Soil in the area that is planned to be protective windbreaks is characterized by sandy texture, while the sludge from channels around the landfill is coarse sandy loam.

Table 1. Granulometric composition of tested soil

Locality	Depth	Coarse sand %	Fine sand %	Dust %	Clay %	Total sand %	Total clay %	Texture class
		2-0.2 mm	0.2-0.02 mm	0.02-0.002 mm	<0.002 mm	2-0,02 mm	0,02 mm	
1	0-30 cm	60.40	27.92	6.40	5.28	88.32	11.68	Loamy coarse sand
	30-60 cm	35,0	58,88	1,32	4,80	93,88	6,12	Loamy fine sand
2	0-30 cm	83.80	14.04	1.24	0.92	97.84	2.16	Loamy coarse sand
	30-60 cm	52.9	42.26	0.40	4.44	95,16	4,84	Loamy coarse sand
Sludge	0-30 cm	70.30	14.70	8.40	6.60	85.00	15.00	Coarse sand loam

Table 2: Chemical properties of tested soil

Locality	Depth	pH 1M KCl	pH y H_2O	$CaCO_3$ %	Humus %	Total N %	Al-P_2O_5 mg/100g	Al-K_2O mg/100g
1	0-30 cm	7,87	8,49	9,11	0,56	0,059	13,3	11,8
	30-60 cm	7,82	8,43	8,28	0,54	0,057	9,6	7,3
2	0-30 cm	8,17	8,55	8,28	0,27	0,028	2,2	2,6
	30-60 cm	8,25	8,61	7,87	0,11	0,011	2,4	2,6
Sludge	0-30 cm	7,63	8,16	19,87	11,82	0,758	29,4	61,5

Localities 1 and 2 are belong to the class of textured loamy coarse sand, they are characterized by an alkaline reaction (pH of the H2 O from 8.43 to 8.61), they are very carbonate (7, 87% to 9.11% $CaCO_3$) and poorly in humus (from 0.11% to 0.56%). Soil on these localities is poorly

provided in total nitrogen, medium provided with easy available phosphorus (from 2.2 mg / 100g 13.3 mg / 100g P_2O_5) and potassium (2.6 mg / 100g 11.8 mg / 100g K_2O). In terms of pH value and carbonate status there is no significant differences between the samples taken from the northern and southern parts of the tested area. Soil on both sites is very alkaline and carbonate. However for content of humus, total nitrogen and easy available phosphorus and potassium it can be seen slightly higher soil fertility in northern than in the south, although the content is still at the level of poorly to medium provided.

On the other hand a sample of mud from the canal near the landfill is characterized by mild alkaline reaction (pH in H2 O 8.16), it is very carbonate (19.87% $CaCO_3$), high content of humus (11.82%), it is very provided in total nitrogen (0.758% N), and excessively to extremely provided with easy available phosphorus (29.4 mg / 100 g of P_2O_5) and potassium (61.5 mg / 100 g of K_2O). According to very favorable chemical properties of sludge from the canal near the landfill, it should consider the possibility of application of it in the future for soil recultivation near the landfill in terms of increasing the fertility of very poor and sandy soils, on which is planned to be applied biological and technical recultivation.

Regulations on permitted amounts of hazardous and harmful substances in soil and water for irrigation (Sl.glasnik. 23/1994) defines the maximum permissible concentration (MPC) and test method for determination of contents of heavy metals in the soil. Results of this study are shown in table 3. At the same time, it is important to determine the content of microelements which high concentration can have negative effect on plant growth.

Table 3: Content of heavy metals and microelements in soil

The amount of available elements for plants depends on of chemical, physical and biological properties of the soil, respectively from pH value, humidity, temperature, microbial activity, and presence of clay fractions in soil, organic matter content and content of hydrated oxide of Fe, Al (Ubavić at al. 1995). The concentration of hydrogen ions (pH) has a huge influence on the

dynamics of trace elements and heavy metals in the soil. In the acidic environment there are more trace elements in the solution, which can lead to the occurrence of the toxicity, particularly in Mn and Cu. This toxicity is usually temporary, if it is a light sandy soil, but in heavy soils with more clay, toxicity of trace elements is manifested in a longer period of time. Content of trace elements (Cu, Zn, Co, Mn) and heavy metals (Pb, Cd, Ni, Cr, As, Hg) in tested soil is less than the maximum permissible concentrations (MPC). In comparing with natural soil in this area, fluvisol, (Sekulić et al. 2007, Nesic et al 2010), it can be said that the soils in around the landfill are not significantly different than natural soil, and that content of heavy metals is not different also. When comparing the value of the contents of heavy metals in the sludge, with values in the tested sites, it shows that the contents in sludge is two to three times higher than the other two localities, but is still far below the MPC. This fact can be explained by the high content of organic matter in the sludge, which has a high adsorption capacity, and has the ability to have higherfixes rate of cations from the solution rather than sandy soil around the landfill. Based on these results it can be said that the land near the landfill are not contaminated with heavy metals, however based on the determined characteristics, to the landfill area and its surroundings, the natural habitat conditions are permanently altered, and it is necessary to perform the recultivation in order to protect environment and give better quality of soil for plant growth.

Conclusion

Based on the results it can be concluded that recultivation of soil around landfill should applied, in order to improve soil characteristics and fertility. Soil on localities 1 and 2 belongs to the class of textured loamy coarse sand, they are characterized by an alkaline reaction, and they are very carbonate and poorly in humus. Also, soil on these localities is poorly provided in total nitrogen, medium provided with easy available phosphorus and potassium. However sludge from the canal near the landfill is characterized by mild alkaline reaction, it is very carbonate, high content of humus, it is very provided in total nitrogen, and excessively to extremely provide with easy available phosphorus and potassium. According to very favorable chemical properties of sludge it should consider the possibility of application of it for soil recultivation in terms of increasing the fertility of very poor and sandy soils. Windbreaksshould be consist trees and shrubs that have shown resistance to the stress caused by the changed environmental conditions. Species that are most appropriate for this area are: Poplars (Populus sp), Willow (Salix sp), Turkish hazel (Corylus colurna L.),Norway maple (Acer platanoides L.), Persian walnut (Juglans nigra L.), birch (Betula pendula Roth.), Hornbeam (Carpinus betulus L.), Black locust (Robinia pseudoacacia L.) and Siberian elm (Ulmuspumila L.).

Acknowledgments

Part of this study was conducted as part of the Project No. TR 31072: “Status, trends and possibilities to increase the fertility of agricultural land in the Vojvodina Province”, which is supported by the Ministry of Education, Science and Technological Development of Republic of Serbia

Abstract

The brown bear (*Ursus arctos* L.) is autochthonous and biggest beast in Bosnia and Herzegovina (BiH), and one of the most attractive species of wild animals. Bears living in BiH are part of the Dinaric-Pindos population, which is the second largest population in Central and Southern Europe. The bears in BiH, together with those in Slovenia and Croatia, are genetically similar to the remaining bears from the Alps and as such are suitable for reintroduction of extinct populations in Western Europe. Bears were once numerous and widely distributed in highland areas of BiH, among other things, due to preserved forests and small openness of the areas. More recently (2004), the estimated number of bear population is 438 individuals on the area of about 12.000 km². This type of game to the current number is not threatened in BiH, but it needs improvement of the management planning of its populations and habitats. This paper analyzes the condition and numbers of listed population as well as the main threats and protection measures for bear and its habitats, both in BiH and in the region.

Keywords: *bear, habitat, population size, analysis of the condition, Bosnia and Herzegovina***.**

Introduction

Brown bear (*Ursus arctos* L.) is one of eight bear species, that evolved from same ancestor predator *Miacid* 25 milion years ago (Huber et al., 2008b). Bear is a mammal class (*Mammalia*), category of beasts (*Carnivora*) and bear family (*Ursidae*). In large part of Europe, brown bear is permanently protected. Exessive hunt in majority of European countries lead to his extermination, that made him listed on Red List of Endagrered Species. European Standard created action plan for saving brown bear that have international character and it is obligating by all countries of European Union (further in text EU) and all signatories of Berne Convention. In majority of countries there is action plan or strategy management of bears. On territory of Republic of Srpska (further in text RS), bear is sporadically spread in forest ecosystems. Because of small quantity and its big importance, in RS he is labeled as endangered (Article 11, Hunting Act, Official Gazette of the Republic of Srpska no. 4/02). Bear is largest autochthonous beast in BiH, and accorting to many people, it is most popular for hunting. Bears from BiH, Slovenia, Croatia, Serbia and Montenegro are genetically similar to other bears and because of that they are good for reintroduction of extinct species of Western Europe. This makes bear most valued in natural heritage of BiH (Sinanović et al., 2008). The main goal of this work is to uncover main factors of endangering and safety measures for bears in territory of BiH, and to give specified recommendations for maintained usage and preservation of it's kinds and habitats.

Material and method

Research and gathering of necessary data for this work is done in last period for which we have data about managing population of brown bear. For puposes of gathering and comparison of data with results of previous research (Adamič et al., 2006; Sinanović et al., 2008), next activities have been performed:

- gathering data about quantity, habitat and results of management in last period;
- analysis of national and international relevant regulations;
- comparative analysation of status and management of bears in BiH and nearby countries (Serbia, Slovenia, Croatia, Montenegro, Macedonia).

Primary material is made of various documents published by BiH official journal (Official Gazette of the Republic of Srpska and Official Gazette of the Bosnia and Herzegoviona), numerous scientific and expert literature, also articles from this domain. For additional data supplement and evaluation about quantity and status of bear population in BiH, there was conducted conversations with people responsible for hunting in Ministry department of agriculture, waterworks amd forestry in both entities. For purpose of better understanding of problems about main factors of endangering and protective measures for bears, analysis of action plans for managing population of bears in nearby countries have been performed. Data involving quantity, habitat and results of managing bears in BiH have been taken from previous research and published texts. Differences in managing bears in BiH and nearby countries, that manage Dinaric-Pindos population, have been displayed in works, with lawful regulation that is associated with international laws and conventions. With comparative analysis of action plans and ways of bear management, measures and given recommendations for protection and management of bears in BiH have been concluded.

Results and discussion

Areal and quantity of bears

Areal of bears is world largest with holarctic distribution in Europe, Asia and North America (Servheen, 1990). It is estimated that total world population of bears is larger that 200.000 individuals. Russia have largest quantity of bears, it's believed to have over 100.000 individuals (IUCN, 2012). In other countries estimated quantity is: 33.000 individuals in USA, 25.000 individuals in Canada, and 17.000 individuals in Europe (without Russia) (Katcensky et al., 2013). In Europe bear is can be found in 22 countries. Based on existing data about distribution, like in many geographic, ecological, social and political factors, 10 populations have been specified: Scandinavian, Karelian, Baltic, Carpathian, Dinaric-Pindos, East-Balkan, Alps, Abruzzo (Central-Alpen), Cantabrian and Pyrenees.

Status and main factors of endangering bears in BiH

Bears in BiH are part of Dinaric-Pindos population. Total Dinaric-Pindos population of bear is 3.500 individuals and it is second in size in Europe, after Carpathians.

Analysation of regulations for bear management

International law regulations

During several international conventions, bear is placed in different categories of/and anexes of protection, according to that signatory countries of those international documents have duty to take necessary measures including measures to members of this kind. Besides, BiH is signatory of next international conventions:

- Bern convention for protection of European wild fauna and flora and natural habitats, organized in Bern (1979), and confirmed by Presidency of BiH in year 2008. (Official journal of BiH, no. 8/08).
- Convention for Biological Diversity (CBD), organized in Rio de Janeiro (1992), and confirmed by Presidency of BiH in year 2002. (Official journal of BiH, no. 13/02).
- Convention for international trading of endangered species of wild fauna and flora (CITES), organized in Washington (1973), and edited and expanded 1979. In Bonn. This convention is confirmed by Presidency of BiH in year 2008. (Official journal of BiH, no. 11/08).

Analysis of bear management

Bear management in BiH exists since year 1893. and it's pronounced as first Hunting law, after occupation by Austro-Hungarian empire (Kunovac et al., 2012). Bears used to be hunted in all possible ways and wasn't protected by law. Already after World War 1 quantity of bears was greatly decreased, and after World War 2. decreased to minimal, critical number of 50 individuals. After that, strict regulations have been made involving hunting and bear became protected and his quantity started to increase. In period 1945-1990., constant increase in quantity of bears was registered, and it reached 1.364 individuals. Areas suitable for bear survival occupied around 1.248.000 ha, and registered maganing capacity of 1.494 individuals (1,2 individuals per 1.000 ha). Approximate culling per year was around 90-100 individuals. Population was vital, and culled individuals had good trophy value. Interest by international hunters for bear hunting was huge. Special hunting managements was formed (Koprivnica, Bugojno), and most valuable wild animal for hunting was bear. Bear is managed in two entities made by splitting of BiH (year 1995.): Republic of Srpska (RS); Federation of Bosnia and Herzegovina (FBiH).

Table 1: Status and management of bears in states that manage Dinaric-Pindos population

State	Lawful status	Associated institution	Action plan	Level of management
Albania	Strictly protected	General direction for forestry and plantations	No	National
BJP Macedonia	Strictly protected	Ministry of agriculture, forestry and waterworks and Ministry for living enviroment and areal planing	No	National and Regional
Bosnia and Herzegovina	**Wild animals protected by hunt stoppage**	**Ministry of agriculture, forestry and waterworks in both entities.**	**No**	**National**
Greece	Strictly protected	Ministry for agriculturak development and food	Yes	National and regional
Slovenia	Strictly protected	Ministry for living enviroment and areal planning	Yes	National and regional
Serbia	Strictly protected	Ministry of agriculture, forestry and waterworks and Ministry for living enviroment and areal planning	Yes	National
Croatia	Wild animals protected by hunt stoppage	Ministry of agriculture, forestry and waterworks	Yes	National and regional
Montenegro	Wild animals protected by hunt stoppage	Ministry of agriculture, forestry and waterworks, and Ministry for living enviroment and areal planning	No	National

Table 2: Management, lawful status and hunting season on bears in BiH, per entities

Entity	Associated institution	Status	Hunting season
Republic of Srpska	Ministry of agriculture, forestry and waterworks, in both entities	Wild animals protected by hunting prevention	1. october - 15. may
Federation of BiH			1. october - 31. december 1. march - 15. may

Distribution of bears

Bear managed to survive on northwest, west, central and eastern mountain massives, relatively around 21,8% of total BiH land territory, or around 11.883,5 km² (Adamič et al., 2006). Habitats can be categorised as permanent and temporary (table 3).

Table 3: Bear habitat territory in BiH

	Habitat territory (km²)	Quantity – current status year 2008.
Current- permanent	10.565,0	438
Temporary	1.318,5	-
Totals:	11.883,5	438

Permanent habitat covers 10.565 km². That is territory in which bear satisfies all needs for food, water, territory, peace, shelter, breeding and nesting, and there he is constantly present through four season periods.

Main factors of bear endangering

Even on global plan (IUCN, 2008), bear is categorized for least concern for extinction „**LC**" (*Least Concern*), numerous factors are affecting his population and they are threatening to his existence. Main factors for endangering bears in countries that manage Dinaic-Pindos population are displayed in table 4.

Table 4: Factors of endangering bears in countries that manage Dinaric-Pindos population

Main factors of endangering	Albania	**Bosnia and Herzegovina**	BJP Macedonia	Montenegro	Greece	Croatia	Slovenia	Serbia

Conclusions

Bear is autochtonous and largest beast in Bosnia and Herzegovina, and it is one of most attractive wild species. Estimated quantity of bear population in BiH is from 432-1.196 individuals, because of that it's considered non endangered species. Main measures of protection of bear in BiH are:

- establishment of monitoring;
- strict protection and limited usage;
- providing of financial support for research and activities in hunting;
- more strict inspection supervision and penalties;
- establishment of breeding areas for bear;
- creation of managment plan;
- constant education and informing of hunters and people.

Based on results of this work and analysis of bear management plans in nearby countries (Croatia, Serbia, Slovenia, Macedonia and Albania) next conclusions can be made: most important factors that endanger bears in said countries are: illegal hunt; degradation, fragmentation and habitat isolation; low degree of acceptance and conflict with people caused by destroying of property.

RESERVOIR TILLAGE TECHNIQUE

İlknur DURSUN, Ergin DURSUN*

Department of Agricultural Machinery and Technologies Engineering, Faculty of Agriculture,
Ankara University, Turkey
*Corresponding author: edursun@agri.ankara.edu.tr

Abstract

Many countries located in arid and semi-arid regions have water scarcity problems due to low rainfall and uneven distribution throughout the season. On the other hand, soil erosion is a serious environmental problem in some region of the world due to intensive rainfalls and the arid and semi-arid regions. Therefore, soil and water conservation is so important in these areas. Different type of soil tillage techniques such as reduced tillage, mulch tillage, ridge tillage, strip tillage, no-till, direct seed and reservoir tillage had been developed to conserve soil and water. Reservoir tillage has been defined as a system in which a large number of depressions or small reservoirs are formed to hold rain or sprinkler applied water. Reservoirs are formed on whole soil surface, between rows or in furrows using different types of equipment or equipment combinations. These equipment are commercially available and their prices are reasonable. Reservoir tillage is used to control both runoff and soil erosion. It can be used with many crops such as potato, corn, sugar beet, cotton, sunflower, sorghum, tomatoe and wheat. Studies have showed that reservoir tillage could increase soil water content, enhance infiltration, reduce soil erosion and increase crop yield. The purpose of this paper is to explain reservoir tillage technique and introduce equipment used for this technique.

Keywords: *Reservoir tillage technique, Runoff, Soil erosion, Soil and water conservation.*

Introduction

Approximately 40% of the world's agricultural land is seriously degraded (Anonymous, 2016a). Each year, 75 billion tons of soil is removed due to erosion largely from agricultural land, and about 20 million-ha of land is already lost (Pandey et al., 2009). Drought is an other important proplem except for erosion. Drylands cover about 41% of earth’s land surface and about one third of world population is affected from drought (Safriel and Adeel, 2005). Approximately 6.6%, 10.6%, 15.2% and 8.7% of drylands are consisted of hyper-arid, arid, semiarid, and dry subhumid, repectively. In dry farming regions, total annual rain is low than 500 mm and distributed unevenly throughout the season.

Soil tillage is a method of soil preparation for seeding and planting. Moulboard plow, disc harrow, field cultivator and other mechanical implements are used to prepare the field for crop production in conventional tillage. However, most of the crop residue are incorporated or burried into the soil. That’s why, conventional tillage leaves soils vulnerable to wind and water erosion and causes to the loss of soil moisture. Different type of soil tillage techniques such as reduced tillage, mulch tillage, ridge tillage, strip tillage, no-till, direct seed and reservoir tillage had been developed to conserve soil and water (Anonymous, 2013a; Dursun, 2015). The purpose of this paper is to explain reservoir tillage technique and introduce equipment used for this technique.

Reservoir Tillage and Its Advantages

Reservoir tillage is defined as a system in which a large number of depressions or small reservoirs are formed to hold and collect rain or sprinkler applied water and to prevent surface runoff from irrigation or rainfall (Longley, 1984; Hacweell *et al.* 1991; Anonymous, 2005a; Anonymous, 2013a; Salem *et al*. 2015). Figure 1 shows a reservoir tillage implement and reservoirs formed on soil surface. Reservoir tillage is applied in the regions where soil erosion is a problem, dry farming regions, and fields irrigated with low-pressure center pivots and lateral move irrigation systems. Distance between reservoirs or holes is 60-90 cm (Busch and Kincaid, 1995).

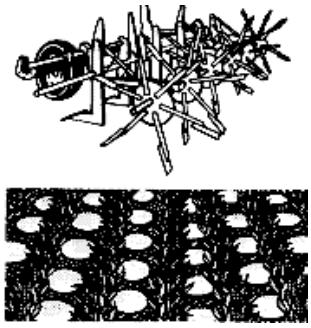

Figure 1. An equipment combination for reservoir tillage and reservoirs created on the soil surface after tillage (Kranz *et al.*, 1996).

Reservoir tillage has a lot of benefits. Small reservoirs or depressions created on the soil surface hold water and reduces surface runoff during irrigation or rainfall (Anonymous, 2016b). Particularly, reservoir tillage prevents soil erosion if there is not enough crop residue on the soil surface (Dursun, 2015). Reservoir tillage enables to in-situ water harvesting in dry farming regions and can increase level of surface storage. The surface area of the soil is increased due to small reservoirs or depressions created on the soil surface and thus infiltration of rain or applied irrigation water is increased. On the other hand, soil warms faster because of greater surface area (http://tillso.co.uk). Moreover, the loss of valuable soil, residual chemicals and nutrients could be reduced by small reservoir or depressions formed on soil surface in the fields irrigated with low-pressure center pivots and wheel-move irrigation systems (Anonymous, 2005a). Reservoirs could increase rainwater or applied irrigation water use efficiency and soil water content. As a result of this, crops could benefit from water more efficiently, crop yield could be increased and irrigation costs could be decreased.

Many research has been conducted on reservoir tillage. We noticed same variations in equipment and terminology interested with reservoir tillage when we examined these research. It is known under different names such as furrow diking, furrow damming, basin tillage, basin listing, microbasin tillage, and tied ridges (Hackwell *et al.*, 1991; Jones and Baumhardt, 2003). The shapes, dimensions and distributions of reservoirs, dikes, basins, dams and ridges created on the soil surface are different by mentioned tillage techniques. Furrow diking is not a new technology. It was used in the U.S.A., in the 1930s (Hasheminia, 1994; Jones and Baumhardt, 2003). But, reservoir tillage is a more new technique (Garvin *et al*., 1986).

Small earthen dams shaped rectangle are formed periodically between furrow ridges in furrow diking (Figure 2). Furrow diking can be adapted to both dryland and irrigated crop production. It is often used on gently sloping land in arid and semiarid areas (Anonymous, 2013b). This practice was mostly used for cotton production in Africa in 1940. But, the practice of furrow

diking for wheat production was abandoned because of slow operating speed of diking equipment, poor weed control, difficulty with seedbed preparation and subsequent tillage, and mainly little benefit in yield in U.S.A., in the 1950s. However, furrow diking had been widely adopted due to improved mechanical equipment for constructing the dikes, herbicide tolerant crops and more effective herbicides to control weeds (Jones and Baumhardt, 2003). It was reported that favorable responses were obtained with some kind of crops such as cotton, sorghum, corn and sunflower in field tests (Hasheminia, 1994; Anonymous, 2013b).

Figure 2. The view of furrow dikes created on the field (left) and the most common type of furrow diker (right) (Warrick *et al.*, 2002; Warrick, 2008).

Tied ridges is also known as furrow blocking, furrow damming, furrow diking, and basin listing. In this practice, ridges and furrows are made firstly and then dams that tied with small mounds are formed in furrows (Figure 3) (Hudson, 1987). This practice has been developed to prevent rain or irrigation water runoff from crops on sloping land (http://www. briggsirrigation.co.uk).

Figure 3. The practice of tied ridges (http://www.briggsirrigation.co.uk).

Basin tillage is also called reservoir tillage and more suitable to crop rows. In this practice, a series of micro-catchments between crop rows are created for retention of water under center pivots and lateral move irrigation systems (Figure 4). This practice is especially preferred when the applied water exceed intake rate of the soil**.** The basins lenght usually ranges from 60 to180 cm (Busch and Kincaid, 1995). It has been reported that this practice has been used successfully for runoff control on field slopes of less than 5 percent. The failure potential of individual basins in furrows is increased as field slope increased (Kranz *et al.*, 1996).

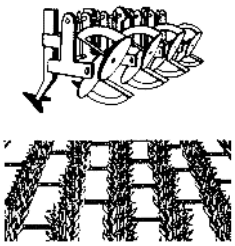

Figure 4. Basin tillage between crop rows (Kranz *et al.*, 1996).

The basins are constructed across the slope using a special implement called basin-lister in the method of basin listing. (Figure 5).This practice increases time to rain water for infiltration into the soil (Anonymous, 2005b).

Figure 5. The practice of basin listing for cotton field (http://agritech.tnau.ac.in)

In microbasin tillage, individual earth blocks or basins are created along furrows. The lenght of each block is about 65-75 cm (Figure 6). This practice has been used successfully on fields with slopes of 5-7 percent (Sui *et al*., 2016).

Figure 6. The practice of microbasin tillage (Sui *et al.*, 2016).

Equipment for Reservoir Tillage

There are three different application of reservoir tillage. In the first application, reservoirs are builded on whole soil surface. In the second application, reservoirs are only builded between rows. In the third application, reservoirs are only builded in furrows. The first application of reservoir tillage is called "New Reservoir Tillage System" (Ventura *et al.*, 2003).

Different equipment or equipment combinations are used for reservoir tillage depend on cultivated crop variety, soil condition and application region. The rollers or soil conditioners used for reservoir tillage have different forms and they are known under different names. The shapes and dimensions of reservoirs changes depend on constructional features of soil conditioners. One type of soil conditioner has durable rubber cones that fixed to a rubber carcase and forms reservoirs shaped in half cone. The other type of soil conditioner known "Imprinting roller" creates reservoirs that are narrow and long. The other soil conditioner has triangle prisms on its roller surface. This type of soil conditioner creates reservoirs shaped with triangle prism. The equipment combinations such as rotovator + soil conditionner, horizontal cut subsoiler + modified row planter + roller formed with plastic wheels, chisel plow + spike-tooth harrow + seed drill + spiked roller, potato planter + soil conditioner, subsoiler or chisel plow + soil conditionner can be used used for tillage (Figure 7) (Ventura *et al*., 2003; Salem *et al*., 2015; http://tillso.co.uk). The weight per unit working width of soil conditioner is about 80 daN/m for vegetable and root crops and 180 daN/m for grain crops (http://tillso.co.uk).

Figure 7. Three different types of soil conditioner used for reservoir tillage and soil surfaces after tillage (Ventura *et al.*, 2003; Anonymous, 2012; Anonymous, 2016c).

The reservoir tillage that including reservoirs only between rows is especially preferred at row crops irrigated with low-pressure center pivots and lateral move irrigation systems. The reservoirs between rows are formed using a soil conditioner roller or an equipment combination such as subsoiler (inter-row ripper) + multi-spoke "spider" or chisel + multi-spoke "spider". The reservoirs are formed by multi-spoke "spider" when using equipment combination (Figure 8) (Schneider *et al*., 2000; Ventura *et al*., 2003). Reservoirs can be created hoes or shovels placed at between coulters of spacing drill during sowing. The shapes and dimensions of reservoirs changes depend on constructional features of soil conditioners. It is reported that reservoirs or holes 15 to 25 cm in diameter, 15-20 cm deep, and spaced about 60 cm on center into the soil (Hansen ve Trimmer, 1997).

Figure 8. A hand type soil conditioner and a combination of inter-row ripper and multi-spoke "spider" (Geisel, 2012; Keith, 2016; http://www.Terramanustech.com; http://www.dammerdiker.com)

Reservoir tillage is widely used for potato grown in ridges and reservoirs are only formed in furrows. Different equipment combinations such as lister + chisel + multi-spoke "spider", subsoiler or chisel + multi-spoke "spider" and subsoiler or chisel + soil conditioner can be used. In these combinations, reservoirs are formed by multi-spoke "spider" or soil conditioner (Figure 9). Reservoirs could be formed before planting, during planting or after planting.

Figure 9. The application of ridge till and formation of reservoirs by an equipment combination (http://www.dammerdiker.com)

Conclusion

Reservoir tillage is a soil and water conservation practice. In this practice, a large number of depressions or small reservoirs are formed to hold rain water or sprinkler applied water and to prevent surface runoff from irrigation or rainfall. Reservoirs are formed on whole soil surface, between rows or in furrows using different types of equipment or equipment combinations. The practice of reservoir tillage can be used with many crops such as potato, corn, sugar beet, cotton, sunflower, sorghum, tomatoe and wheat. Studies on reservoir tillage have showed that it could increase soil water content, enhance infiltration, reduce soil erosion and surface runoff and increase crop yield. Whereas, it has some disadvantages such as difficulty in weed control, need a new equipment and being a new technique for farmers. However, it is reported that reservoir tillage or similar practices is widely used by farmers. Because, nowadays, the price of equipment used for reservoir tillage is resaonable and more effective herbicides is used to control weeds.

Abstract

Soil erosion is a naturally occurring process that affects all landforms. In agriculture, soil erosion refers to the wearing a way of a field's topsoil by the natural physical forces of water and wind. It may be a slow process that continues relatively unnoticed, or it may occur at an alarming rate causing serious loss of topsoil. As the measuring of soil erosion is costly and time consuming process, therefore soil erosion models have been used more and more to estimate soil erosion as well as sediment yield. For calculation of the sediment yield in the S7-1 Watershed of Shirindareh river, Iran we used the IntErO model based on the EPM method. Calculated peak discharge from the S7-1 Watershed was 75 m^3s^{-1} for the incidence of 100 years and the net soil loss was 11034 m^3km^{-2}, specific 242 m^3 km^{-2} per year. The results of the present study and previous experiences of the other researchers revealed that the IntErO model can be used to estimate soil loss in the other regions similar to Shirindareh watershed.

Keywords: *Soil erosion, IntErO Model, sediment yield, Shirindareh watershed.*

Introduction

Healthy soil is the foundation of the food system. It produces healthy crops that in turn nourish people. Maintaining a healthy soil demands care and effort from farmers because farming is not benign. By definition, farming disturbs the natural soil processes including that of nutrient cycling – the release and uptake of nutrients (Benites & Benites, 2005). Soil loss is a serious problem in developing countries (Wolancho, 2010) that cause great ecological concerns (Gholami *et al*., 2013) in various environments worldwide (Kisic *et al*., 2016; Ballesteros-Cánovas *et al*., 2015; Pimentel, 2006; Nikkami, 2012, Stoffel and Huggel, 2012, Ristic *et al*., 2001). There are several types of water erosion, including splash, sheet, interrill, rill, gully and stream bank erosion (Khaledi Darvishan *et al*., 2012; Gholami *et al*., 2013 and 2014; Khaledi Darvishan *et al*., 2014 and 2015, Sadeghi *et al*., 2015a and b; Gholami *et al*., 2016, Sadeghi *et al*., 2016). The soil loss from land surfaces by erosion is widespread and reduces the productivity of all natural ecosystems, agricultural, forest, and pasture ecosystems (Pimentel *et al*., 1995; Troeh *et al*., 2004; Pimentel and Burgess, 2013). With the growing human population, soil erosion, water availability, climate change due to fossil fuel consumption, eutrophication of inland and coastal marine bodies of water, lack of vegetation protection to reduce the water competition and loss of biodiversity rank as the prime environmental problems of the world (Burguet *et al*., 2016; Pimentel & Burgess, 2013).

Study of soil erosion and sediment yield in the watershed is one of the basic necessities to achieve integrated land management and soil and water conservation (Khaledi Darvishan *et al*., 2016). The estimation of the erosion in a watershed is therefore essential to encompass a lot of environmental problems and to evaluate the amount of sediment moved, transported and deposited in and out of the basin. Direct measurements of erosion in a watershed are possible with multi-years measurement of solid transport in the closing-section (Behzadfar *et al*., 2014a and Behzadfar *et al*., 2014b). As the water and sediment sampling in given intervals and drawing hydrograph and sediment graph need a lot of time and costly laboratorial works (Sadeghi *et al*., 2014; Khaledi Darvishan *et al*., 2010; Sadeghi *et al*., 2013), therefore soil erosion models have been used more and more to estimate soil erosion as well as sediment yield (Spalevic *et al*., 2013a, 2013b, 2013c, 2013d, 2013e). The modelling of the erosion process has progressed rapidly, and a variety of models have been developed to predict both runoff and soil loss. We used the computer-graphic models (Spalevic, 2011; Spalevic, 1999a, 1999b) for prediction of soil erosion intensity from the watershed area – IntErO model.
In the present research, the IntErO model was verified and tested in the S7-1 Watershed of the Shirindareh River Basin, Iran. Soil erosion processes, soil erosion intensity and runoff of the Shinindareh River were calculated using the IntErO model.

Material and Methods

The study was conducted in the area of the S7-1 Watershed of the Shirindareh River Basin.

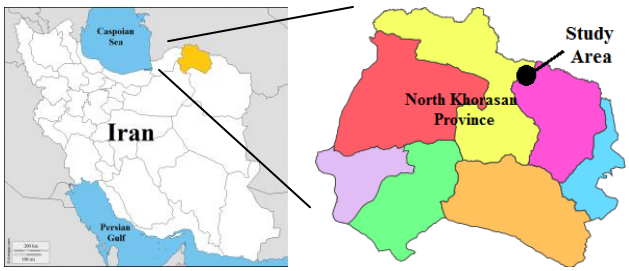

Figure 1. Study area of the S7-1 watershed, the Shirindareh River Basin, Iran

The study area is placed in north eastern parts of Iran are mountainous, in the area of the Shirindareh River Basin, one of the main tributary of the river Atrak. Atrak originates from Hezar-Masjed mountains in the region of Razavi Khorasan and lies between steep slopes and plains till to enter the territory of Turkmenistan on Chaat region and finally drains to Caspian Seaa in the Gulf of Hasan Ghuly (Behzadfar *et al*., 2014a).
The S7-1 watershed is covering an area of 45 km^2. It is one of the medium to big sized watersheds of the natural entity of the Shirindareh region. During the field work, using a morphometric methods, various data on intensity and forms of soil erosion, land use, and the measures taken to reduce or mitigate erosion were recorded.
According to our calculations, the shortest distance between the fountainhead and the mouth, lv, is 8.9 km; and the total length of the main watercourse with tributaries is 87 km. The relief has very pronounced dynamics; the average slope gradient in the river basin, Isr, is calculated on 33% what indicates that in the river basin prevailing very steep slopes. The average river basin altitude Hsr, is calculated on 1823 m; the average elevation difference D, on 279 m.
The geological structures and soil characteristics of the area was analysed based on the research of the National Geological Survey Organization (NGS) led by Bolourchi (1987). He analysed the

physical and chemical properties of all geological formations of North Khorasan province, including those in the study area of the S7-1 watershed. Climatological data were received from the meteorological stations located in North Khorasan province of Iran.

The IntErO model (Spalevic, 2011) as a computer-graphic method, with the Erosion Potential Method – EPM (Gavrilovic, 1972) embedded in the algorithm of this model, was used for obtaining data on estimate of peak discharge and sediment yield from the studied watershed. The basic analytical equation for the calculation of erosion-induced soil losses is as follows:

$$G_{yr \times sp^{/1}} = T \times H_{yr} \times \pi \sqrt{Z^3} \times R_u$$

where: $G_{yr\ sp}^{-1}$ – specific annual total erosion-induced sediment yield reaching the confluence, m^3 yr^{-1} km^{-2}; T – temperature coefficient of the watershed; H_{yr} – amount of rainfall, mm; π – 3.14; Z – coefficient of erosion; R_u – coefficient of retention of soil in the watershed.

This methodology is currently in use in: Bosnia & Herzegovina, Brazil, Bulgaria, Croatia, Czech Republic, Italy, Macedonia, Montenegro, Morocco, Saudi Arabia, Serbia, South Africa and Slovenia (Al-Turki *et al*., 2015; Gazdic *et al.,* 2015; Spalevic *et al.,* 2015a, 2015b, 2015c, 2015d, 2015e, 2015f, 2015g, 2015h, 2015i, 2015k; Vujacic & Spalevic, 2015; Kostadinov *et al.,* 2014; Spalevic *et al*., 2014a, 2014b, 2014c, 2014d; Spalevic *et al*., 1999c). The provided methodology have been successfully used in Iran in the regions of Chamgardalan, Kasilian, Kermanshah, Razavi Khorasan (Spalevic *et al.,* 2016; Draganic *et al*., 2015a; Draganic *et al*., 2015b; Barovic *et al.,* 2015; Behzadfar *et al.,* 2015; Barovic & Spalevic, 2015; Behzadfar *et al.,* 2014a; Yousefi *et al*; 2014; Behzadfar *et al.,* 2014b; Zia Abadi &Ahmadi, 2011; Amiri, 2010; Sadeghi, 2005; Sadeghi, 1993) and other regions.

Results and Discussion

The climate. The climate of studied area is continental, with the absolute maximum temperature and the negative of 34.6°C and -24.4°C, respectively. The temperature coefficient and also the average annual air temperature, t0, is 10.2°C and T, is calculated on 1; the amount of torrential rain, hb, on 37 mm. The average annual precipitation, H_{yr}, is 328.4 mm (Source: Data from the North Khorasan Meteorological stations of Iran).

Vegetation and land use. The studied area is located in Middle- East of the Kope-Dagh geographical region. According to the available literature and the analysis using the Google maps and Google Earth, including the records from the field visits, the pastures and meadows are covering the area of 51% and non-arable land of 49%. The coefficient of the river basin planning is calculated on 0.75. The coefficient of the vegetation cover is calculated on 0.9.

Soil erosion and runoff characteristics. The dominant erosion form in this area is surface erosion and is the most pronounced on the steep slopes without vegetation cover. Problems with overgrazing and livestock traces are recorded also all over the studied area.

Processing the input data by the IntErO model we received the results in relation to the sediment yield of the S7-1 Watershed of the Shirindareh River Basin of Iran (Table 1).

Table 1. The IntErO report for the S7-1 watershed river basin

INPUTS			
River basin area	F	45.59	km²
The length of the watershed	O	22.25	km
Natural length of the main watercourse	Lv	8.91	km
The shortest distance between the fountainhead and mouth	Lm	6.88	km
The total length of the main watercourse with tributaries of I and II class	ΣL	87.64	km
The lowest river basin elevation	Hmin	1544	m
The highest river basin elevation	Hmax	2448	m
A part of the river basin consisted of a very permeable products from rocks	fp	0.14	
A part of the river basin area consisted of medium permeable rocks	fpp	0.73	
A part of the river basin consisted of poor water permeability rocks	fo	0.13	
A part of the river basin under the forests	fs	0	
A part of the river basin under grass, meadows, pastures and orchards	ft	0.51	
A part of the river basin under plough-land and without vegetation	fg	0.49	
The volume of the torrent rain	hb	37	mm
Average annual air temperature	t0	9.1	°C
Average annual precipitation	Hyr	345.1	mm
Types of soil products and related types	Y	1.1	
River basin planning, coefficient of the river basin planning	Xa	0.75	
Numeral equivalents of visible and clearly exposed erosion process	φ	0.53	
RESULTS			
Density of the river network of the basin	G	1.92	
Average river basin altitude	Hsr	1823.93	m
Average elevation difference of the river basin	D	279.93	m
Average river basin decline	Isr	32.84	%
Coefficient of the region's permeability	S1	0.7	
Coefficient of the vegetation cover	S2	0.9	
Maximal outflow from the river basin	Qmax	75	m³/s
Production of erosion material in the river basin	Wyr	41805.46	m³/yr
Coefficient of the deposit retention	Ru	0.264	
Real soil losses	Gyr	11034.77	m³/yr
Real soil losses per km2	Gyr/km²	242.04	m³/km² yr

Conclusions

The study of calculation of the sediment yield in the S7-1 Watershed of Shirindareh River, Iran showed the following results:

- The structure of the river basin, (X_a, is 0.74706) mountain pastures are the most widespread plant form (50.98%). The proportion is as follows: plough-lands (49.02%). The coefficient of the vegetation cover is calculated on 0.9.
- Types of soil products and related types, (Y, is 1.1): The study area was included decomposed limestone and marls, cement rocks (55.45%), serpentines, red sand stone, flishe deposits (29.33%) and epieugleysol and Marshlands (15.22%).
- Calculated soil losses are 11034 m^3yr^{-1} and the peak discharge is 75 m^3s^{-1} (incidence 100yr).

With present study new information about the recent state of the sediment yield of the S7-1 watershed, of the Shirindareh river basin in the North Khorasan province of Iran was provided which is in formats that can simplify the management in the watersheds, demonstrating the possibility of soil loss estimation using the IntErO Model. Some measurements are needed for the

model verification, including additional analysis in relation to the land use changes in order to have more reliable conclusions.

The results of the present study confirmed the findings of Barovic *et al.*, 2015; Behzadfar *et al.*, 2015, 2014a, 2014b; Yousefi *et al.*, 2014; Zia Abadi & Ahmadi, 2011; as well as Amiri, 2010; Sadeghi 1993 in possibility of implementing the Erosion Potential Method in Iran, what leads to the conclusion that the IntErO model may be a useful tool for researchers in calculation of runoff and sediment yield for the river basins of the Caspian Sea with the similar physical-geographical characteristics like the Shirindareh river basins.

Abstract

The composition of surface water is quite different because of specific physicochemical and biological processes that take place in them. The rivers which man uses are variable in their composition and largely depend on the quality of water flowing into them. The purpose of this paper is to determine the content of inorganic nitrogen expressed through ammonia, nitrites and nitrates,and dissolved oxygen and thus determine the water quality in the Eleska River.The Eleska River is a tributary of the Crna River. Its source is on the eastern slopes of Mount Baba in the Aegean part of Macedonia. It flows into the Crna River between the villages Bukri and Brod.In the experimental part were taken water samples from Eleska River after its entry into R. Macedonia near the village of Egri. Samples were taken in the first week of July and September. To make experimental research the following procedures were used: Ammonia and nitrite in the water were assessed spectrophotometricly with device Spectroqvant UV / VIS Pharo 300. Ammonia according to the method 14752 (Mitrovis, 1954), while the nitrites with method 14776. Determination of nitrates was performed with UV PASTEL - a tool for direct readout of values.
The obtained values indicate that there is no greater fecal contamination (according to the content of ammonia), but according to its quality and purpose the water belongs to the third category. This water according to the purpose can be used for irrigation.

Keywords: *Eleshka River, ammonia, nitrates, nitrites, dissolved oxygen*

Introduction

Man with his activity, satisfying their interests increasingly degrade the environment and thus disturbs the balance in aquatic ecosystem (Kannel *et al.*, 2007).Consequently, the natural process of autopurification is disturbed too. Surface water is the most susceptible to these changes. Therefore there is a need to determine the water quality and their proper management (Yanga *et al.*, 2007). Two percent (2%) of the total territory of the Republic of Macedonia is under water.The biggest right tributary of river Vardar is Crna River.Eleshka River, which is the research subject, is right tributary of Crna River.The main goal of this research is to determine the quality and the current state of the water in Eleshka River, thereby to determine its purpose.The main goal will be realized by determining the following parameters: content of ammonia, nitrates, nitrites anddissolved oxygen.

Hydrographic features of Eleshka River

Eleshka river rises above the village. Owl, on the eastern slopes of Baba Mountain at an altitude of 1300 m, in the Aegean part of Macedonia and in the upper course is known under the name

River Blasko.Throughout its course passes through the city Florina- Greece.The river enters in the territory of the Republic Macedonia between the villages Kremenica Germijan, andflows into Black River between the villages Bukri and Brod (Novaci), under the name Eleshka River. The total length of the river is 41 km (Kostov *et al.*, 2010).The main goal of the research is to determine the quality, the current state of water in Eleshka River, thereby to determine its purpose.

Material and Methods
