Abstract: Surgical treatment for stress urinary incontinence (SUI) using trans-obturator tape insertion is widely accepted. However, several postoperative complications were reported in the literature including infections, abscess and fistula formation. Here we report a case of a 57-year-old female who presented with abscess and left vaginocutaneous buttock fistula 7 years after trans-obturator polypropylene tape insertion. Treatment included abscess drainage with dissection of the fistulous tract and removal of the left arm of the trans-obturator tape along with antibiotic coverage. Sinus drainage stopped after 3 days. Stress urinary incontinence didn't recur. Suspicion of fistula formation should rise in patients presenting with bothersome vaginal or cutaneous discharge after trans-obturator tape insertion. This case is particular since it describes a fistula complication with polypropylene tape which is unusual with this type of tapes. Treatment of such complication should always consist of surgical removal of the mesh to allow closure of the fistulous tract.

Abstract

Surgical treatment for stress urinary incontinence (SUI) using transobturator tape insertion is widely accepted. However, several postoperative complications were reported in the literature including infections, abscess, and fistula formation. Here, we report a case of a 57-year-old female who presented with abscess and a left vaginocutaneous buttock fistula 7 years after transobturator polypropelene tape insertion. Treatment included abscess drainage with dissection of the fistulous tract and removal of the left arm of the transobturator tape along with antibiotic coverage. Sinus drainage stopped after 3 days. Stress urinary incontinence didn’t recur. Suspicion of fistula formation should rise in patients presenting with bothersome vaginal or cutaneous discharge after transobturator tape insertion. This case is particular since it describes a fistula complication with polypropelene tape which is unusual with this type of tapes. Treatment of such complication should always consist of surgical removal of the mesh to allow closure of the fistulous tract.
Introduction

Stress urinary incontinence (SUI) is a frequent condition and affects 4 – 35 percent of women.\textsuperscript{1,2} Treatment of SUI can be conservative including behavioral changes, weight loss, Kegel exercises, biofeedback, pessaries, electrical stimulation, or surgical (i.e. Burch colposuspension,...etc). Minimally invasive surgeries for SUI have become popular nowadays with high success rates. However this type of surgeries is not without complications. Many cases of mesh exposure and fistula formation have been reported in the literature.\textsuperscript{3-5} In this article we present a case of vaginocutaneous fistula and buttock abscess formation seven years after transobturator polypropylene tape insertion, an unusual complication with this type of tapes.

Case

A 57 year-old woman with stress urinary incontinence underwent a transobturator tape (polypropylene type: Gynecare TVT-O\textsuperscript{®} based on the operative report we got) insertion in another hospital 7 years prior to presentation. Six years later, the patient had vaginal tape exposure and underwent a surgical repair during which the defect was primarily closed and mesh was left in place. One year later she started to complain of pain and purulent discharge from her left buttock. Physical examination identified a sinus in the left buttock (fig. 1) draining purulent fluid along with an abscess formation at this site. Outpatient Incision and drainage were performed with antibiotic coverage. A magnetic resonance imaging (MRI) of the pelvis done after abscess drainage confirmed the presence of a fistulous tract from the urethrovaginal mucosa till the left ischio-rectal and ischio-anal fossas (fig. 2). Based on these findings, the decision for surgical treatment was taken. During the surgery we identified a defect in left paraurethral vaginal mucosa (fig. 3). Further sharp easy dissection of this defect lead us to the left arm of the tape which was resected by simultaneous dissection and traction (fig. 4). The right arm of the
tape was left in place since it was not exposed. Three days later, sinus drainage stopped. Stress urinary incontinence did not recur in this patient after mesh removal.

Discussion

During the last decade, surgical treatment of SUI using suburethral slings have been widely accepted. However this technique, although being minimally invasive, was associated with a certain risk of complications that have been reported in the literature leading researchers to work on better sling material and techniques. The risk for mesh exposure was directly associated with the type of material used during suburethral sling procedures and this could be due to the tendency for bacterial colonization of the mesh used. Monofilament polypropylene macroporous (> 75 μm) mesh have lesser rate of erosion and infection because of its biocompatibility, tolerance and less inflammatory reaction. However our patient had erosion and fistula formation with this type of mesh. In our case, complications occurred 6 years after tape placement and this is also an unusual finding; since most sling complications occur in the first two years after tape insertion. Sahin et al, reported a case of vaginocutaneous fistula and inguinal abscess formation six years after tension-free vaginal tape sling, which was treated with sling mesh dissection and removal from the fistulous tract. Goldman reported a case of gracilis and adductor muscles abscess formation after transobturator tape insertion and the patient was treated with complete removal of the mesh. Similarly, Lee et al, reported a case of recurrent bilateral thigh abscess 5 years after transobturator tape insertion and the treatment was also by removal of the mesh.

Ugurlucan et al, reported a case of recurrent obturator abscess with spontaneous expulsion of the mesh 4 years after transobturator tape insertion in a 36 year old female. The patient presented with fever, persistent swelling in the left groin, and spontaneous expulsion of the mesh. Fistula formation was diagnosed and the treatment was based on antibiotics and surgical removal of remaining necrotic material after dissection of the fistulous tract. The case that we presented ended up with the same treatment consisting of surgical removal of the mesh and treatment with antibiotics which seems the
only curative way to treat abscess and fistula formation in these cases. Risk factors for mesh erosion and fistula formation include a history of pelvic irradiation, the presence of cancer, infection and menopause. Our patient had menopause alone as a risk factor and this might explain the occurrence of cited complications in the absence of estrogen supplementation. However her menopause occurred at the age of 51 and she did not receive hormone replacement therapy. It is possible that erosion and fistula formation could be secondary to the lack of estrogen, however it’s a late occurring complications. Another explanation for this type of late occurring complication could be very late reaction of body to mesh. One potential way to prevent mesh exposure in postmenopausal patients is to supplement by vaginal estrogen. We hope that in the future, this type of complications will be significantly reduced with the use of mini slings.

Conclusion

Although suburethral sling procedure is a minimally invasive widely accepted surgical treatment for SUI, it is not without complications which might be severe in some cases. We presented a case of vaginocutaneous fistula and buttock abscess formation 7 years after transobturator monofilament polypropylene tape insertion, an unusual invalidating complication with this type of tapes, that was interfering with patient’s daily activities. This case highlights the need for high index of suspicion for fistula formation after transobturator tape placement even when monofilament polypropylene mesh is used. The best treatment in such complication consists of tape removal in order to suppress the inflammatory and infectious process allowing the closure of the fistulous tract.

Abstract

Surgical treatment for stress urinary incontinence (SUI) using transobturator tape insertion is widely accepted. However several postoperative complications were reported in the literature including infections, abscess and fistula formation. Here we report a case of 57 year old female who presented with abscess and left vaginocutaneous buttock fistula 7 years after transobturator polypropylene tape insertion. Treatment included abscess drainage with dissection of the fistulous tract and removal of the left arm of the transobturator tape along with antibiotic coverage. Sinus drainage stopped after 3 days. Stress urinary incontinence didn’t recur. Suspicion of fistula formation should rise in patients presenting with bothersome vaginal or cutaneous discharge after transobturator tape insertion. This case is particular since it describes a fistula complication with polypropylene tape which is unusual with this type of tapes. Treatment of such complication should always consist of surgical removal of the mesh to allow closure of the fistulous tract.
Dear Editors,

Thank you for your comments and consideration of this manuscript. Attached is the new manuscript in the form of case report with the corrections you asked for.

Sincerely yours

Alain Abdallah
