Introduction
With the increase in life expectancy, aging of the population is a well-known phenomenon in western countries. These elderly patients often present acute exacerbation of chronic poly-pathological conditions, representing a specific challenge for the emergency physician. The knowledge of the epidemiologic particularities of these patients could offer interesting perspective in a better understanding of the specific issues of these patients.

Material and methods
This was a 6-year retrospective study including every patient > 75-year-old admitted in the emergency department (ED) of the Liege University Hospital Centre, from January 2009 to December 2014. The epidemiologic data were extracted from electronic medical data files and further analysed.

Results
During the study period, 24564 patients > 75-year-old were admitted to our department (representing 9.8% of overall admissions). Most of these patients (82.9%) came directly from their home and 44.1% on their own initiative. Only 27.6% of these patients were referred by their general practitioner. The annual increase in the admission rate was 3.01%, while it was 2.19% for the global population (Figure 1).

Conclusion
We demonstrate that the increase in elderly patients’ admissions in the ED is greater than the global population. Surprisingly, these patients are mainly self-referring patients, consulting at daytime during working days. Therefore, we believe that collaboration between EDs and geriatric departments should be reinforced during this period in order to identify patients meeting weakening criteria.
