INTRODUCTION: Recent evidence suggests that different commercial beverages promote similar levels of fluid recovery in men when consumed voluntarily with access to food during exercise recovery (Campagnolo et al., 2017). However, it is unclear if this effect persists in trained females, who may exhibit contrasting dietary behaviors. This study investigated the effect of consuming different commercial beverages with food ad libitum post-exercise on fluid, energy and nutrient recovery in females.
METHODS: On 4 separate occasions, 8 trained females (body mass [BM]: 61.8±10.7 kg; VO2max: 46.3±7.5 mL·kg-1·min-1) lost 2.0±0.3% BM cycling (24.2±0.9°C) at 75% VO2max before commencing a 4 h recovery period with ad libitum access to one of four beverages: (1) Water, (2) Powerade® Isotonic (Coca Cola Ltd.) (Sports Drink, 103 kJ·dL-1), (3) Up & Go Sugar FreeTM (Sanitarium®, Australia) (SF-MILK, 279 kJ·dL-1), and (4) Up & Go EnergizeTM (Sanitarium®, Australia) (HP-MILK, 344 kJ·dL-1). In addition, participants had 2 × 15 min opportunities to access food during the recovery period. Beverage intake; total fluid/nutrient intake (from food and beverage); and indicators of fluid recovery (BM, urine output, urine specific gravity [USG] and plasma osmolality [POSM]), gastrointestinal (GI) tolerance and palatability were assessed periodically.
RESULTS: Whilst total fluid intake (Water: 1918±580 mL; Sports Drink: 1809±338 mL; SF-MILK: 1458±431 mL; HP-MILK: 1523±472 mL; p=0.010) and total urine output (Water: 566±314 mL; Sports Drink: 459±290 mL; SF-MILK: 220±53 mL; HP-MILK: 230±117 mL; p=0.009) differed significantly by beverage, the overall quantity of ingested fluid retained was similar across treatments (Water: 1352±462 mL; Sports Drink: 1349±407 mL; SF-MILK: 1238±400 mL; HP-MILK: 1293±453 mL; p=0.691). Total energy intake increased in proportion to the energy-density of the beverage (Water: 4129±1080 kJ; Sports Drink: 5167±643 kJ; SF-MILK: 6019±1925 kJ; HP-MILK: 7096±2058 kJ; p=0.014). Carbohydrate, protein and sodium intakes also differed across treatments (p's<0.05).
CONCLUSION: When consumed voluntarily and with access to food, different commercial beverages promote similar levels of fluid recovery, but alter energy/nutrient intakes during a 4 h recovery period. Providing access to food and understanding the longer-term dietary goals of female athletes are important considerations when providing recovery beverage recommendations.

THE INFLUENCE OF WATER, SPORTS DRINK OR LOW-ALCOHOL BEER ON VOLUNTARY FLUID AND NUTRIENT INTAKE FOLLOWING EXERCISE.

DESBROW, B.1, BARNES, K.1, COX, G.R.2, IUDAKHINA, E.1, MCCARTNEY, D.1, SKEPPER, S.1, YOUNG, C.1, IRWIN, C.1

GRIFFITH UNIVERSITY, GOLD COAST

INTRODUCTION: Availability of different beverages immediately after exercise has the potential to influence fluid and nutrient intake, ultimately influencing acute recovery (Desbrow et al, 2017). This study assessed voluntarily fluid consumption and subsequent nutrient intake when different beverages were provided in a post-exercise recovery area.
METHODS: Participants (n=132) completed two 10km afternoon runs (repeated measures design) separated by 1 week. Immediately after the first run, participants were randomly assigned to a recovery area providing access to one beverage (based on personal preference). "Beer Drinkers" (n=54 (41 male) ((mean±SD) age=23.9±5.8y, body mass (BM)=76±13kg)) received Beer (low-alcohol beer (Hahn Ultra®, (LionCo), 0.9% ABV) or sports drink (SD) (Gatorade® (PepsiCo), orange flavour). "Non-Beer Drinkers" (n=78 (38 male) (age=21.8±2.2y, BM=71±13kg)) received Water or SD (lemon-lime flavour). Participants remained in the recovery area for 30-60 min and consumed the alternate recovery beverage under the same conditions the following week. All fluid was consumed ad libitum and was measured by trained observers (i.e. acute fluid intake). Participants recorded all food and fluid consumed for the remainder of both trial days via food diary and photographs, which were subsequently analysed (energy and macronutrients) by a dietitian. Fluid balance was assessed via nude body mass (BM) before and after exercise and Urine Specific Gravity (USG) before running and the next morning. Paired-samples t-tests assessed differences in hydration and dietary outcome variables.
RESULTS: No differences were observed in pre-exercise USG (~1.01), run time (~65min) or change in BM (~1.5%) between any intervention groups (p's>0.05). Water vs SD: No difference in acute fluid intake between beverages was noted (Water=751±259 ml, SD=805±304 mL, p=0.157). However, the contrast in beverage nutrient profiles influenced total energy and CHO intakes (Water=5691±2491 kJ and 151±77 g, SD=6497±2724 kJ and 187±87 g, Energy p=0.002, CHO p<0.001). SD vs Beer: Access to SD resulted in greater acute fluid intake (SD =1047±393 ml, Beer=850±630 mL, p=0.004). However, differences were not evident when fluid intake was considered at the end of the trial days (SD=2235±1015mL, Beer=2175±835 mL, p=0.581). No differences in dietary variables were evident. Next day mean USG values were not different between any groups (p's>0.05).
CONCLUSION: Provision of a calorie containing drink immediately following exercise influences subsequent dietary intake, whereas beverage choice does not influence markers of rehydration in recreational runners.

INGESTION OF HYDROGEN-RICH WATER REDUCES SERUM CREATINE KINASE ACTIVITY AND MUSCLE SORENESS FOLLOWING DOWNHILL RUNNING

ABDULLAH, R.A., NG, S.K., OMAR, E.A., OOI, C.H.

UNIVERSITI SAINS MALAYSIA

INTRODUCTION: The effects of molecular hydrogen by means of oral administration of hydrogen-rich water, have been reported to be effective in reducing exercise-induced metabolic acidosis (Aoki et al., 2012; Ostojic, 2012; Ostojic and Stojannovic, 2014), muscular fatigue (Aoki et al., 2012), sports-related soft tissue injuries (Ostojic et al., 2014), and ischemia-reperfusion injury in skeletal muscle (Huang et al., 2015). However, we are not aware of any experimental studies that are specifically investigating the effects of hydrogen-rich water ingestion on eccentric exercise-induced muscle damage (EIMD). Therefore, this study aimed to examine the protective effect of hydrogen-rich water during recovery from EIMD.
METHODS: Eleven healthy and physically active male adults were randomly assigned into the double-blind, placebo-controlled, cross-over experimental trials to receive a 14-day treatment of either hydrogen-rich water (H2-water, ~1.0 ppm, -500 mV, 1.8 L/day) or a similar amount of pure water (placebo). On the day 7 of the treatment, subjects undertook a 30-minute continuous downhill run (DHR) on a motorized treadmill at a speed corresponding to 65% of their VO2max and a slope of –15% in a controlled environmental condition (22°C,

40% relative humidity). Serum CK and HSP70 levels, muscle tenderness and soreness, and one-repetition maximum knee extension strength were measured before and after (0, 24, 48, 96, and 168 h) the DHR. Changes in these physiological measures and biomarkers of EIMD were compared between the trials by two-way repeated measures ANOVA. The area under the curve and the maximal responses of these indices for the seven days post-DHR were computed and compared between the trials by the paired t-test.
RESULTS: Serum CK and HSP70 increased at 24 to 48 h after the DHR, but the changes were unaffected by H2-water treatment. DHR also resulted in increased muscle tenderness and soreness within 48 h, and the reduction in muscle strength was observed up to 96 h following the DHR. However, there were no treatment effects on these indices of EIMD between the trials. When the data were expressed as area under the curve, serum CK response and muscle soreness during the seven days post-DHR were attenuated ($P = 0.033$ and $P = 0.022$, respectively) in the H2-water trial. The peak serum CK response following DHR was also lower in H2-water than in placebo trial ($P = 0.029$).
CONCLUSION: Ingestion of hydrogen-rich water seven days before and after a 30-minute eccentric exercise bout may attenuate the serum CK activity and self-perceived muscle soreness. However, it does not seem to ameliorate eccentric exercise-induced increases in circulating stress protein response or strength loss.

DEHYDRATION REDUCES CARDIAC OUTPUT AND STROKE VOLUME DURING PROLONGED EXERCISE LARGELY THROUGH REDUCTIONS IN VENOUS RETURN AND LEFT VENTRICULAR FILLING

WATANABE, K.1,2, STÖHR, E.J.3, WATANABE, S.1, GONZÁLEZ-ALONSO, J.1

1: BRUNEL UNIVERSITY LONDON , 2: UNIVERSITY OF TSUKUBA , 3: COLUMBIA UNIVERSITY

INTRODUCTION: Dehydration accrued during prolonged, whole body exercise in the heat reduces stroke volume (SV), cardiac output (CO), mean arterial pressure (MAP) and blood flow to the brain, skin and active muscles in parallel to concomitant increases in heart rate (HR), core temperature and total peripheral resistance (TPR) (1). The fall in SV is a key feature of the global cardiovascular strain induced by dehydration and hyperthermia, but the extrinsic and intrinsic cardiac factors underlying this multifarious phenomenon remain elusive. The diminished dehydration-induced SV during single leg knee-extensor exercise with stable CO is closely coupled to a blunted left ventricular (LV) filling (2). Whether extrinsic cardiac mechanisms dominate during whole body exercise causing a greater homeostatic challenge has never been investigated. We therefore manipulated hydration status to test this hypothesis during prolonged exercise inducing significant systemic and peripheral circulatory strain compared to exercise with physiological stability.
METHODS: Eight cyclists (3 females) performed 2 h of submaximal semi-recumbent cycling in the heat without (dehydration, DE; 4.0 ± 0.2% body mass loss) and with full fluid replacement (euhydration, EU). LV volumes (Echocardiography), systemic, arm and head haemodynamics, core temperature and haematological parameters were assessed at rest and during the exercise.
RESULTS: DE reduced blood volume (0.4 ± 0.04 L) and increased core temperature (0.6 ± 0.1°C) compared to EU at 2 h (both $P < 0.05$). At this time point, SV and CO were reduced by 27 ± 3 mL and 2.1 ± 0.3 L/min and HR and TPR were increased by 19 ± 3 beats/min and 0.6 ± 0.1 mmHg/L/min in DE compared to EU (all $P < 0.05$), whereas MAP was no different ($P = 0.187$). The lower SV in DE was solely due to reduced LV end-diastolic volume (31 ± 4 mL), as LV end-systolic volume was decreased (3 ± 1 mL; both $P < 0.05$) indicative of enhanced myocardial contractility. Lower bilateral brachial and carotid beat volumes (1.4 ± 0.3 and 1.8 ± 0.5 mL; both $P < 0.05$) suggestive of reduced venous return accompanied the blunted cardiac SV.
CONCLUSION: The SV decline with dehydration and hyperthermia during prolonged exercise is intimately related to the lowering in LV filling secondary to compromised venous return. The decreased venous return and preload of the heart is in turn mechanistically associated with concomitant dehydration-induced hypovolemia, enhanced peripheral vasoconstriction and diminished cardiac filling time accompanying hyperthermia-mediated tachycardia, rather than impaired intrinsic myocardial contractility. These findings advance our fundamental understanding of how heat and hydration impact human cardiovascular function during exercise.

IS-BN05 Effects of aging and training on fatigability and motor control

AGING OF THE NEUROMUSCULAR SYSTEM AND FATIGABILITY

HUNTER, S.K.

MARQUETTE UNIVERSITY

INTRODUCTION: Age-related changes to the motor unit and its neural inputs result in impaired neuromuscular function and functional performance in older adults <>65 years>. Changes in function with advanced age include reduced maximal strength and power, slower contractile velocity, increased variability of motor tasks, and increased fatigability of limb muscles. Fatigability is the acute reduction in force or power of a muscle in response to exercise and can temporarily exacerbate the age-related loss of strength and power in older adults, although this can differ with the task involved. There is minimal understanding of the mechanisms for age-related increases in fatigability particularly in very old adults <>80 years>, and the relevance of laboratory-based assessments of fatigability to functional performances in daily living.
METHODS: This presentation will highlight studies that have tested power and force of the knee extensor and elbow flexor muscles before and after dynamic fatiguing tasks in young <<35 years>, old <65-79 years> and very old men and women <≥80 years>. Techniques used to understand the neural and muscular mechanisms of fatigability of the limb include electrically evoked contractions of the agonist muscle, transcranial magnetic stimulation over the motor cortex, and analysis of muscle fibres from muscle biopsies. Older adults also performed whole-body functional performance tasks to determine their association with fatiguing tasks of a single limb.
RESULTS: The collective results of several studies show that 1> reductions in power during repeated high-velocity dynamic contractions were significantly larger in old adults <65-79 years> and very old adults <≥80 years> than young adults <<35 years>, and these reductions were similar for men and women; 2> this age-related fatigability was greater in the lower limb than the upper limb muscles ; 3> the mechanisms for the age-related fatigability of the lower limb were associated with both neural and contractile mechanisms, but most

strongly correlated with the contractile function; and 4> the greater fatigability of the knee extensor muscles was associated with a slower walking speed and reduced balance among the older adults.
CONCLUSION: Age-related increases in fatigability induced with high-velocity dynamic contractions in healthy community dwelling men and women were greater for the lower limb than upper limb muscles, and for the lower limb was associated with functional performance tasks. The mechanisms for the age-related fatigability were both neural and contractile in origin but their contribution depended on the muscle group involved. Optimal and efficient strategies to offset this age-related fatigability especially in very old who suffer the greatest fatigability, can potentially offset large age-related declines in functional performance.

AGING AND THE AGONIST –ANTAGONIST MUSCLES CO-ACTIVATION: A REVISITED MECHANISM

DE VITO, G.

UNIVERSITY COLLEGE DUBLIN

Introduction: The age-related deterioration in the neuromuscular system not only reduces the ability to generate maximal force and power but also to control force production. These deficits are manifested as a decreased capability of older adults to perform the tasks of everyday living. In this regard an appropriate coordination of agonist and antagonist muscles is essential for the correct execution of movements and normally some degree of agonist–antagonist coactivation is observable during a voluntary muscle contraction. It has been proposed that during voluntary contraction of the knee extensors (KE), the hamstrings (i.e. antagonist muscles) could provide opposing mechanical movement of the agonist muscles in response to variations in joint angular displacement and ligamentous loading, thus contributing to maintain joint stability. Several previous studies reported an increased antagonist co-activation in elderly participants compared to young individuals, whilst some other studies have observed that the level of coactivation remains unchanged with aging.
Methods: This speech will, therefore, focus on recent studies conducted in our laboratory presenting new insights into the age-related modifications in agonist antagonist muscles co-activation and how these can be influenced by mechanical factors (i.e. muscle length and contraction intensity) and gender. In addition, specific attention will be paid to discuss the potential risk of crosstalk contamination related to the use of surface electromyography (sEMG) for the assessment of co-activation. To this purpose, we will describe the effects that adipose tissue, covering the muscle of interest, can have on the level of antagonist coactivation measured by sEMG. Most of the results presented here were obtained in studies involving healthy young (20-30 yr) and older (65-75 yr) participants of both genders who performed isometric KE contractions of different durations, and intensities at distinct muscle lengths.
Results: Taken together our findings suggest that during KE contractions the level of antagonist co-activation: 1) correlates with subcutaneous adipose tissue; 2) it is dependent on knee joint angle (muscle length); 3) tends to increase with agonist contraction intensity. In relation to aging we found that antagonist coactivation was higher in the older at the longer muscle length (60° knee angle) but only after controlling for adiposity. In relation to gender, the higher antagonist co-activation observed in women compared to men, at all level of contractions, disappeared after controlling for adiposity.
Conclusions
In conclusion, fat can be a confounding factor when assessing coactivation using sEMG and this point deserves more attention especially when groups with different level of adiposity are investigated. In addition, it is important to stress that although these results can be of some values they were limited just to healthy participants in their seventies.

EFFECTS OF EXERCISE TRAINING ON NEUROMUSCULAR FUNCTION IN OLD AGE

AAGAARD, P.

UNIVERSITY OF SOUTHERN DENMARK

INTRODUCTION: Mechanical muscle function in terms of maximal muscle strength, power, and rate of force development is negatively affected by progressive aging, which is evident even in lifelong trained master athletes. The impairment in muscle function is accompanied, and in part, caused by age-related impairments in neuromuscular function that includes a loss of spinal motor neurons , a reduction in maximal MN firing frequency, altered agonist and antagonist muscle activation, reduced fine motor control , reduced excitability in descending corticospinal pathways as well as altered spinal circuitry function. Notably, however, these age-related changes in neuromuscular function may be effectively delayed and/or compensated by means of resistance exercise training, with improvements in neuromuscular function demonstrated to occur even into very old age <+80 years>. Thus, experimental evidence will be presented to illustrate that substantial adaptive plasticity in motorneuronal function exists at old age, which can be translated into improved function in various activities of daily living such as chair rising, stair walking and postural balance.

Invited symposia

IS-MI03 Mind over muscle? A psychophysiological approach to pacing and exercise behaviour - FEPSAC Symposium

UNDERSTANDING AND OPTIMIZING PACING BEHAVIOR AND PERFORMANCE

HETTINGA, F.

UNIVERSITY OF ESSEX

To start, dr. FJ Hettinga (FECSS) will begin with describing her recent studies concerning the manipulation of athletes exercise behaviour and pacing strategies during middle-distance and endurance trials.
She will demonstrate the effects of modifying athletes' feedback, fatigue and external environmental cues such as opponents on pacing behavior and performance.
Do these manipulations influence athletic drive or motivation to exercise?
Do they impact on pacing behavior and performance?

THE NEUROPHYSIOLOGICAL DRIVE TO EXERCISE.

ROELANDS, B.

VRIJE UNIVERSITEIT BRUSSEL

In the last decades part of the research on the mechanisms of fatigue during prolonged exercise has focused on the role of the brain. Studies applied pharmacological or nutritional manipulations to affect the serotonergic, noradrenergic and dopaminergic neurotransmitter systems and look at how this influenced fatigue. The outcomes are however not that straightforward. It seems that in human subjects the manipulation of the noradrenergic neurotransmitter system has profound negative effects on performance in a normal ambient setting, while no significant changes were observed after the manipulation of dopamine or serotonin.
Nevertheless, when an additional external stressor was added to the equation, changes in catecholamine levels induced by pharmacological manipulations exerted significant effects on performance. Identical to the outcomes in normal ambient temperature, noradrenergic reuptake inhibition had vast negative effects on performance. The manipulation of dopamine, through methylphenidate or bupropion, significantly improved performance. Subjects pushed harder and became much warmer without perceiving this. This line of work strongly suggests a role for the central nervous system in the onset of fatigue, but obviously fatigue during prolonged exercise remains a complex interplay between both central and peripheral aspects.
The central nervous system is also largely involved in another aspect of fatigue, i.e. mental fatigue. Mental fatigue is a psychobiological state that has already shown to be detrimental for physical and technical performance. Strong links have been made between the occurrence of mental fatigue and changes in brain neurotransmitter concentrations. One of the most mentioned hypothesis is that neural activity increases the extracellular concentration of adenosine , and that brain adenosine accumulation reduces endurance performance. It is speculated that adenosine accumulation in the pre supplementary motor area and anterior cingulate cortex could also partly explain the higher than normal perceived exertion during an endurance exercise in a mentally fatigued state. Finally, very few other studies have looked into the effects of brain chemistry on the development or consequences of mental fatigue, creating an urge for scientists to further unravel the mechanisms behind this phenomenon.

PSYCHOLOGY AND THE DRIVE TO EXERCISE

SCHIPHOF-GODART, L.

THE HAGUE UNIVERSITY OF APPLIED SCIENCES

Middle-distance and endurance sports are booming, both in the general population and at elite level. The investments required for participating and performing in endurance exercise are considerable for all participants, and the lucidity of this behaviour may escape more than one bystander.
In psychology, this complex subject has been addressed by examining athletes' motivation to exercise and passion for sports. The drive to exercise can nevertheless also be approached from a neurophysiological point of view.
Attempts to influence athletes' performance through the manipulation of internal factors such as brain neurotransmitters or pain perception, or by modifying external factors such as athletes' environments, have been made, providing novel insights in the regulation of exercise behavior and pacing.
Although interesting patterns appear, neither psychological nor physiological approaches separately seem sufficient in predicting athletes' exercise behaviour such as pacing during endurance exercise.
It therefore is our belief that both psychological and physiological factors should be examined in combination, in order to study the short and long term effects and outcomes of manipulation of athletes' drive to exercise. In this multi-disciplinary session, we will present different expert views on both internal as well as external factors related to the concepts of drive and motivation that might affect endurance exercise behavior and performance, and we will conclude by providing practical applications and future recommendations that have come forward based on these views.
Dr. L. Schiphof-Godart will provide an overview of psychological research concerning the determinants of motivation and the drive to exercise in elite athletes. Concepts such as passion and perfectionism are important character traits impacting on athletic motivation, and might serve to explain excessive exercise behaviour and the effect on sport performance from a psychological point of view. She will focus in particular on the short and long term effects that an enhanced drive to exercise might have on training, pacing and performance behavior, and provides insight in potential negative consequences in the context of overtraining and athlete drop out.

Oral presentations

OP-BN06 ACL injury: Prevention and rehabilitation

A COMPARISON OF THE EFFECTS OF ANTICIPATION BETWEEN LEGS ON THE BIOMECHANICS OF A NOVEL ONE-LEG DOUBLE-HOP TEST INVOLVING MEDIAL DIAGONAL HOPS IN PERSONS WITH ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

ARUMUGAM, A., MARKSTRÖM, J., HÄGER, C.

UMEÅ UNIVERSITY

INTRODUCTION: Recent evidence on one-leg cutting tasks reports increased knee abduction and internal rotation angles and moments, associated with a risk of anterior cruciate ligament (ACL) (re-)injury, during unanticipated compared to anticipated cutting maneuvers. We proposed a novel one-leg double-hop test (a forward hop followed by a medial diagonal hop (45°)) carried out under unanticipated and anticipated conditions. We compared the effects of anticipation between legs on lower limb biomechanics of the novel test in persons with a unilateral ACL reconstruction (ACLR).
METHODS: Twenty-three persons (age: 24.0±4.2 years, Tegner activity level: 7 (4-9) (median (range)), 18 women) with a unilateral ACLR (37.3±34.5 months after surgery) performed 3 successful unanticipated (UMDH) and anticipated medial diagonal hops (MDH). An 8-camera 3-D motion analysis system (Qualisys, 240 Hz) and 2 force plates (Kistler, 1680 Hz) were used. Participants did medial/lateral diagonal hops (only medial was analyzed) based on a visual cue randomly indicating hopping direction presented about 300 ms before the land-and-cut maneuver for UMDH and about 2 s before MDH. Hip, knee, and ankle peak angles and external joint moments were

calculated during the deceleration phase of the land-and-cut maneuver (initial foot contact to peak knee flexion) for ACLR and non-affected (NA) legs. We conducted 2*2 (leg*condition) repeated measures ANOVAs (post hoc comparisons: paired t-tests) ($p < 0.05$).
RESULTS: Participants demonstrated an overall pattern of hip flexion, abduction, and internal rotation, knee flexion, adduction, and external rotation, and ankle/foot dorsiflexion, supination and internal rotation across conditions and legs. There was a significant interaction between leg and condition for peak knee external rotation (ACLR leg: UMDH > MDH) and ankle plantar flexion angles (NA > ACLR leg in MDH), and hip abduction (NA leg: MDH > UMDH) and external rotation moments (NA leg: MDH > UMDH). Significant main effects were found for condition, regardless of leg, for most angles of the hip (flexion, abduction, int. rotation), knee (flexion, abduction), and ankle (dorsi- and plantarflexion) that were higher while moments of the hip (adduction, ext. rotation), knee (flexion, adduction, ext. rotation), and ankle/foot (dorsiflexion, int. rotation) that were lower during UMDH than MDH. Significant main effects of leg, regardless of condition, were found for hip flexion and adduction angles (ACLR > NA leg), hip abduction angles (NA > ACLR leg), and ankle dorsiflexion moments (NA > ACLR leg).
CONCLUSION: In a sporting context, unanticipated hops might challenge dynamic knee control more than anticipated hops owing to high peak angles in almost all three planes (UMDH > MDH) for ACLR and NA legs. Especially, greater sagittal plane angles for the hip, knee, and ankle reflect a strategy to lower the center of mass during UMDH. However, the higher moments during MDH than UMDH might occur due to pre-planning and rapid execution of MDH.

RETURN TO PLAY, PERFORMANCE AND CAREER DURATION AFTER ANTERIOR CRUCIATE LIGAMENT RUPTURE: A 5-YEAR CASE-CONTROL AND COHORT-STUDY IN TOP LEAGUE FOOTBALL ATHLETES

NIEDERER, D., ENGEROFF, T., WILKE, J., VOGT, L., BANZER, W.

GOETHE-UNIVERSITY FRANKFURT/MAIN

INTRODUCTION: Initial evidence suggests a high return to play (RTP) rate of top-level football players undergoing anterior cruciate ligament (ACL) reconstruction but a lower rate for RTP to the same performance level. As an exclusive look on absolute rates is biased by – inter alia – ageing effects, a comparison with the underlying population, in particular a cohort of matched unimpaired players is needed. A media-based collection and further analysis of the RTP rates and the corresponding quality of play was the aim of our study.
METHODS: We adopted a 5-year cohort and case-control study design. All male players from the first two leagues of five European countries top leagues (England, France, Germany, Italy, and Spain), which sustained an ACL rupture during the season 2010/11 and/or 2011/12, were included. For them and a matched control sample (ratio 1:2; age, market value, playing position, league, and country as matching variables), all data on anthropometrics, injury history, time point of RTP, quantity, and game performance were retrieved by a structured search from the publicly available and validated media-based platforms (transfermarkt.de & whoscored.com; interrater-reliability) 90 %; Cohen's Kappa = .82) until the end of season 2016/17. Injury and return to play-specific data were calculated as absolute incidences, and as rate ratios (RR) to compare the injured and matched control athletes rates and as a survival analysis (log-rank-test; career duration). Factors potentially affecting the RTP duration were further analysed.
RESULTS: Overall, 148 ACL-injuries were documented in 141 players (season prevalence: 1.32 %). RTP-duration was 202±94 days. The RTP rate was 96 % (RR = 100 %), the RTP to same level was 61.5 % (RR = 91.0 %). The RTP duration differed between playing positions ($p < .05$). Five years post RTP, 62.8 % of the ACL group were still engaged in football (RR = 79 %), 40.9 % at the same level (RR = 79.7 %). Survival analysis revealed a systematic group difference in career duration compared to controls (Cox-Mantels $Chi^2 = 12.7$; $p < 0.001$). Game performance (rates/number of completed passes, dribblings, and minutes played) was lower in the ACL athletes than in the matching group during the RTP and post RTP seasons.
CONCLUSION: Although absolute and relative RTP rates after ACL reconstruction are high in professional football, career duration and performance are lower than in the reference group. This calls for a re-rupture and long-term consequences prevention in football players after RTP after an ACL reconstruction.

PATELLAR AND HAMSTRING TENDON AUTOGRAFTS ARE ASSOCIATED WITH DIFFERENT LOADING PATTERN ASYMMETRIES IN A BILATERAL VERTICAL JUMP AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

MILES-COPPARD, J., DANIELS, K.

THE SPORTS SURGERY CLINIC, DUBLIN, IRELAND. THE UNIVERSITY OF BATH, BATH, ENGLAND.

INTRODUCTION: There is a high incidence of anterior cruciate ligament (ACL) injury in many field sports. The gold standard treatment is surgical reconstruction (ACLR), often using a bone-patellar-tendon-bone (BPTB) or hamstring tendon (HT) autograft. Although graft type has been found to affect inter-limb asymmetries in single-leg discrete-point strength (Xergia et al., 2011) and kinetic measures (Webster et al., 2004), its effect on phase-specific loading patterns in bilateral movements has not previously been investigated. Large asymmetries can be associated with poorer knee function and can increase the risk of sustaining a second ACL injury. The aim of this study was to assess counter-movement jump (CMJ) phase-specific impulses and isokinetic strength asymmetries in athletes with a BPTB or HT autograft after ACLR.
METHODS: Male field sport ACLR athletes with a BPTB (n=22) or HT (n=22) autograft completed two testing sessions at approximately 6 and 9 months post-ACLR. An uninjured control group (n=22) completed a single testing session. Vertical ground reaction force during a CMJ was assessed using a dual force plate system. Concentric peak knee extensor torque was measured using an isokinetic dynamometer at 60°/s. Absolute bilateral asymmetry indices (AAIs) were calculated for kinetic impulse during the eccentric deceleration, concentric and landing phases of the CMJ. A repeated-measures ANOVA and post-hoc testing were used to compare jump heights and impulse AAIs amongst all groups over time during all phases. A linear regression model was used to assess the relationship between concentric impulse asymmetry index (AI) and knee extensor strength AI in all groups.
RESULTS: BPTB had a greater impulse AAI than both HT and controls in the eccentric deceleration ($p<0.001$;$p=0.01$) and concentric ($p=0.002$;$p<0.001$) phases, and a greater impulse AAI than controls in the landing phase ($p=0.007$).There were no significant differences in jump height between BPTB and HT ($p=0.95$). The only significant decrease in AAI from 6 to 9 months post-ACLR was in HT during the CMJ concentric impulse phase ($p=0.006$). Isokinetic knee extensor strength AI and CMJ concentric impulse AI were positively correlated in BPTB ($r=0.66$) and HT ($r=0.36$).
CONCLUSION: Graft donor site significantly affected loading patterns during a CMJ in athletes up to nine months post-ACLR, although no differences in jump height performance were identified. BPTB demonstrated greater kinetic asymmetries in all take-off phases than both the HT group and the control group. This group also had greater asymmetries than the control group during the landing phase. Concen-

tric impulse asymmetry was more strongly correlated with isokinetic extensor strength asymmetry in BPTB than HT. Due to these differences in loading patterns, rehabilitation practitioners should consider graft type when evaluating asymmetry post-surgery.
Xergia SA et al.(2011).Knee.Surg.Sport.Traumatol.Arthros.19,768-780

LOWER LIMB ISOKINETIC STRENGTH AND SINGLE LEG DROP JUMP PERFORMANCE IN MALE ATHLETES RETURNING FROM ACL INJURY.

CAFFERKEY, N.

SPORTS SURGERY CLINIC

INTRODUCTION: The anterior cruciate ligament (ACL) is frequently injured in field sports. Symmetrical lower limb strength and jumping ability is important for both injury prevention and sports performance (Menzel et al. 2012). The high rates of ACL injuries during field based activity suggest the need for a better understanding of how strength asymmetries influence single leg jump performance in specific injured populations. The aim of the study was to identify how asymmetries in knee flexor and extensor strength influence bilateral differences in single leg drop jump (SLDJ) performance.
METHODS: Eighty six field sports male athletes, approximately 9 months after unilateral ACL reconstruction (ACLR) from a patellar tendon graft, took part in this study. A 3D biomechanical assessment of 3 maximal single leg drop jumps, on both the injured and non-injured limb, was recorded at 200 Hz using 10 Vicon Bonita cameras and AMTI force plates. Strength of the knee flexors and extensors was assessed by isokinetic dynamometry. Concentric knee extension and flexion strength was assessed at an angular velocity of 60°/s using a Cybex Norm Isokinetic Dynamometer. Inter limb asymmetries in strength and SLDJ performance measures were quantified by a limb symmetry index equation (Schlitz et al. 2009). Linear regression models were defined and fitted between the strength measures (peak torque normalised to body mass and the following SLDJ performance measures: Jump height, contact time, Reactive strength index (RSI) impulse, peak vertical Ground reaction force (GRF) and GRF at lowest vertical position of each subjects centre of mass during the contact phase.
RESULTS: Linear regression analysis examining how the variance between bilateral asymmetries in knee extensor strength predicted the variance in jump height, revealed a significant ($p < 0.001$) moderate relationship ($R2 = 0.25$). A Significant regression value ($p < 0.001$) was also evident between asymmetries in knee extensor strength and RSI scores ($R2 = 0.17$). Lower values of variance were defined ($p < 0.001$) between asymmetries in knee flexor strength and RSI ($R2 = 0.05$), Impulse ($R2 = 0.07$), peak force ($R2 = 0.07$).
CONCLUSION: The results demonstrate that asymmetries in peak torque of knee extensor strength influence jump height and RSI scores during SLDJ. The regression analysis indicates that knee extensor strength was a better predictor of SLDJ performance than knee flexor strength for males returning to field sports after a patellar tendon graft ACLR.

SCREENING AND PREVENTION TOOL FOR ACL INJURY IN BASKETBALL PLAYERS BASED ON KINEMATICS, PLANTAR PRESSURE AND EMG ANALYSIS

DAINESE, M., PAVAN, D., CIBIN, F., GUIOTTO, A., SAWACHA, Z.

UNIVERSITY OF PADUA

INTRODUCTION: Due to the peculiar requirements of a basketball game, jumping-landing is a recurring tasks executed by athletes. The correlations between landing biomechanics and ACL injury risk have been widely demonstrated, along with protocols to assess the landing task execution to predict ACL injuries. The aim of the present study is to develop a landing assessment protocol that can be execute directly in the training court, through plantar pressure insoles, surface electromyography and video based analysis.
METHODS: 10 subjects participated in the study (mean standard deviation (SD) BMI 24,59 ±2,83, age 23,40 ±3,04 years). Subjects, after signing informed consent, performed 9 repeating drop jumps from a 32 cm height, according to previous literature, with 3 different landing approaches: double leg (DL), single leg left (LSL) and right (RSL). Video sequences and plantar pressure (PP) distribution were acquired by means of a Novel Pedar system and 4 synchronized cameras (GoPro Hero3+), with bilateral EMG signals (BTS FreeEMG1000, 8 channels) from: Rectus Femoris (RF), Biceps Femoris Caput Longum (BF), Tibialis Anterior (TA), Gastrocnemius Lateralis (GL). EMG signals were normalized to their peak value during maximum voluntary contraction; EMG peak of envelope and peak of envelope position within the drop jump task cycle were extracted. Hip, knee and ankle joints kinematics were determined on the sagittal plane and their position with respect to the drop jump task evaluated with a purposely developed Matlab code. Specific features were tracked bilaterally on the motion sequences through an automatic tracking of feature software: anterior iliac spine, posterior iliac spine, greater trochanter, lateral femoral epicondyle, calcaneus, two points on the shoes corresponding to the 1st and the 5th metatarsal head. The center of pressure position and the vertical component of the ground reaction forces were extracted from the plantar pressure system. A Matlab code was then developed to calculate and evaluate the knee torque evolution during the performed task, and its association with the joint angle
RESULTS: From kinematic analysis, an imbalance is observed on the right leg. Both in bipodal and monopodal tasks, it can be observed a pre-activation of left Biceps Femoris Caput Longum ($p<0,05$) and left Gastrocnemius Lateralis ($p<0,05$) compared to the right side. This informations supported by the results of the joint torques may be an indication of weakness in the left limb.
CONCLUSION: Differences between left and right leg, along with different approaches to the movements performed by the subjects have been highlighted in terms of EMG data, joint torques and kinematics. The association between maximum joint torque and muscle strategy can be useful in planning ACL injury prevention programs.

FIBRE TYPE TRANSFORMATION IN KNEE EXTENSOR MUSCLE WITH INSUFFICIENCY OF THE ANTERIOR CRUCIATE LIGAMENT IS REVERSIBLE WITH POST-OPERATIVE REHABILITATION AND GRADED TO FOCAL ADHESION KINASE ACTIVATION

FLÜCK, M.

UNIVERSITY OF ZURICH

INTRODUCTION: Transformation of skeletal muscle's contractile and metabolic characteristics has been shown to occur upon reductions and elevations in load-bearing contractile activity (reviewed by Flück and Hoppeler 2003). Whether bona fide fast-to-slow transformation of muscle fibre types takes place in humans, as reported for rodents, is debated (reviewed by Flück and Hoppeler 2003; Wilson et al 2012). We tested whether slow-to-fast transformation of muscle fibres occurs with insufficiency of the anterior cruciate ligament (ACL) and whether this would be reversed with rehabilitation after reconstruction of the ACL in relationship with the molecular index of load-bearing

muscle activity, tyrosine 397 phosphorylation of FAK (pY397-FAK), which governs the slow-oxidative muscle phenotype in rodents (Durieux et al. 2009).
METHODS: 9 patients (29 years, 8 males, 1 female) with unilateral insufficiency of the ACL were included in the investigation. Biopsies were collected from vastus lateralis (VL) muscle of the ACL insufficient and sufficient leg during reconstructive surgery, after 9 weeks of ambulant physio-therapy, following four months of subsequent rehabilitation training and 260 weeks after self-motivated exercise. Slow (I), and fast (IIA and IIB) type muscle fibers, volume density of mitochondria, the expression levels of markers of mitochondrial respiration complexes (I-V), FAK and pY397-FAK, were assessed. Effects were verified with a repeated measures ANOVA or Pearson correlations at a threshold of 5% (SPSS, IBM).
RESULTS: The percentage of type IIB muscle fibres was increased by 115% after 9 weeks of physiotherapy in VL of the ACL- insufficient leg when the percentage of type I muscle fibres (-30%), mitochondrial volume density (-35%) and levels of mitochondrial respiration complex I-III markers (-45-70%) were reduced. Qualitatively similar adaptations were seen in VL from the sufficient leg. All parameters of the slow-oxidate muscle phenotype, including the percentage of type I muscle fibres, recovered 260 weeks after reconstructive surgery. Mitochondrial parameters and percentages of IIB muscle fibres correlated positively (r=0.3-0.6) and negatively (-0.3), respectively, to FAK and pY397-FAK levels.
CONCLUSION: Reversible transformation of the contractile and metabolic fibre phenotype is detectable in human knee extensor muscle after extended durations of altered physical activity. Quantitative linear relationships between slow oxidative characteristics, pY397-FAK levels and time-under tension (Rahnert and Burkholder 2013), suggest that the summed impact of load bearing muscle activity drives plasticity of the metabolic and contractile muscle fibre phenotype.

OP-BN07 Relative age effect and talent selection

THE ROLE OF RELATIVE AGE AND BIOLOGICAL AGE ON TALENT SELECTION IN SWISS YOUTH SOCCER

JAVET, M.1, BORN, D.P.1, MOSER, H.2, FUCHSLOCHER, J.1, ROMANN, M.1
1: SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN SFISM , 2: SWISS FOOTBALL ASSOCIATION

INTRODUCTION: In youth soccer, the chronological age is used to group and select the athletes for training and competition. Within these age groups, individuals can differ by as much as 1 year in relative age, which might affect the talent selection process and benefit the athletes born early in the year. Moreover, the biological age varying by 4 years among athletes of the same age group further challenges the homogeneity of training and competition groups (R Malina, Coelho e Silva, & Figueiredo, 2012). The aim of the study was to investigate the effect of relative and biological age on the coaches` performance rating and the talent selection process for the national U15 team players.
METHODS: Within a three year period 185 players (age 14.0 ± 0.3) were recruited from the U15 Swiss national selection days. Players were grouped by birth quarter (Q1: Jan. to Mar.; Q4: Oct. to Dec.) for relative age. The players DXA hand scan (skeletal age) and the Tanner-Whitehouse 3 classification was used to determine the biological age, as an indicator for maturity. Players were classified as early, on time and late developed (R Malina, et al., 2012). Odds ratios (ORs) and 95% confidence intervals (CI) were calculated for birth quarters (relative age) and biological age. Secondly, the effects of relative and biological age were analyzed on the coaches' subjective performance rating evaluated technical skills, game intelligence, personality, and playing speed.
RESULTS: The average skeletal age of the soccer players was 14.1 ± 1.5 years, and did not differ significantly from chronological age. Early maturing players born in Q1 were 4.6 times (95% CI 1.7, 12.0) more likely to be selected for the national team than early matures born in Q4. Late maturing players born in Q1 in turn showed higher ORs (17.9 (95% CI 2.4, 135.0)) than their counterparts born in Q4. The coaches' subjective performance rating showed significantly higher rating in playing speed (3.5 ± 0.5) for early matures than on time (3.2 ± 0.6) and late matures (2.8 ± 0.4). However regarding technical skills and game intelligence, late maturing players (3.7 ± 0.5; 3.6 ± 0.5) were rated significantly higher than early matures (3.3 ± 0.6; 3.3 ± 0.5, respectively).
CONCLUSION: In conclusion, there is an overrepresentation of players with high relative age (born in Q1) that are selected for the national team. Players born late in the year (Q4) need to be early or on time developed to be selected. Players of Q4 with late maturity might have been deselected in previous selection levels. Secondly, the analysis showed that the coaches` subjective performance rating is highly affected by the maturity. Athletes with early maturity are more likely to have good ratings regarding playing speed, while late developed athletes will have high ratings regarding their technical skills and game intelligence.

EVALUATING THE RELATIVE AGE EFFECT IN A MULTI-SPORT ENVIRONMENT: THE FC BARCELONA PARADIGM

DONCASTER, G., MEDINA, D., DROBNIC, F., UNNITHAN, V.
EDGE HILL UNIVERSITY

INTRODUCTION: The relative age effect (RAE) is present when there is a distinct over-representation of players born earlier in the selection year for a given cohort. While there is a plethora of literature examining the presence and implications of the RAE on talent identification within a given sport, there is limited research investigating the presence of the RAE across a range of team sports, within the same club environment. Consequently, the aim of the study was to evaluate the RAE in a team, multi-sport environment within the same club; with a view to identifying RAE commonalities/differences between disparate team sports.
METHODS: The birth-dates of all players (n = 6542) affiliated to each sport (Basketball [n = 1013], male [n = 3012] and female [n = 449] Soccer, Futsal [n = 761], Handball [n = 999] and Indoor Roller Hockey [n = 308]) within the multi-sport professional club (FC Barcelona) and across all age groups (U10, U12, U14, U16, U18 & Senior) were recorded. These were then categorised into relative age quartiles from the start of the selection year (Q1=Jan-Mar; Q2=Apr-Jun; Q3=Jul-Sep; Q4=Oct-Dec). Birth-date distributions across quartiles were then analysed for; a) each sport, b) each age group, irrespective of the sport and c) each age group within each sport, using the Chi-square statistic and odds ratio's (OR) with 95% confidence intervals.

RESULTS: Birthdates across the entire club (all sports and ages) revealed a RAE (Q1= 46.1%, Q2= 27.1%, Q3=17.1% & Q4 = 9.7%, X2 = 29.8, P < 0.01). Odds ratio analysis, for the entire club, revealed players with birthdates in Q1, Q2 and Q3 were represented 4.76 (95% CI's:1.96-11.57), 2.80 (1.12-7.03) and 1.77 (0.67-4.63) more, when compared to Q4, respectively. Odds ratio's between birth quartiles (Q1 v Q4, Q2 v Q4 and Q3 v Q4) were larger in Basketball and male Soccer, when compared to female Soccer, Futsal, Handball and Roller Hockey. With respect to age group comparisons, OR between birth quartiles, became smaller as age increased, with the smallest OR evident in senior age groups.
CONCLUSION: Despite an over-arching club philosophy for psychological and perceptual-cognitive markers being the major drivers for talent identification at FC Barcelona, the RAE was still present within youth age groups (<18 yrs old). Yet, there was no presence of the RAE within senior squads (both within a sport and across all sports). In addition, when there was a reduced number of players within the sport (i.e. a reduced selection pool) the extent of the RAE was less evident between birth quartiles. The findings from this investigation may suggest that while the RAE is normally linked to physical precocity, within the FC Barcelona model, RAE may be coupled to enhanced psychological and percerptual-cognitive attributes, in those born earlier in the selection year.

SPORT PARTICIPATION AND PHYSICAL ACTIVITY LEVELS OF SCHOOL CHILDREN ARE NOT AFFECTED BY RELATIVE AGE

RÖSSLER, R.1,2, ROMMERS, N.3,4, FAUDE, O.2, VERHAGEN, E.1

1VU UNIVERSITY AMSTERDAM, THE NETHERLANDS; 2UNIVERSITY OF BASEL, SWITZERLAND; 3VRIJE UNIVERSITEIT BRUSSEL, BELGIUM; 4GHENT UNIVERSITY, BELGIUM

INTRODUCTION: The "relative age effect" is specifically known from high-level competitive sport, and is responsible for dropout of children disadvantaged by their chronological age (Lemez et al. 2014). If the relative age effect would also be present in the general population of children, this would result in decreased physical activity (PA) levels in children who dropped out of sport. This could have a negative impact on public health. It could be assumed that these disadvantaged children might also be demotivated to play sport in their leisure-time. Therefore, the present study aimed at investigating whether relative age negatively influences leisure-time PA levels and participation in organised sport in a large sample of Dutch school children.
METHODS: Datasets of three large-scale studies (iPlay, Krajicek Playgrounds, and StuntKids) have been used for secondary analysis. The data were collected in a sample of Dutch school children between 8 and 18 years of age using standardised questionnaires. To analyse the influence of relative age, children were grouped according to four birth quarters (Quarter 1: January-March; Quarter 2: April-June; Quarter 3: July-September; Quarter 4: October-December). Analysis of variance was used to test differences in leisure-time PA levels and participation in organised sport between the four birth quarters and between girls and boys.
RESULTS: Data of 5,864 Dutch school children (57.1% boys) with a mean age of 12.4 (SD 1.9) years were analysed. There was no interaction between birth quarter and sex. Leisure-time PA was lower in girls (4.0 hours per week [95%-CI 3.8, 4.2]) compared to boys (4.5 hours per week [95%-CI 4.3, 4.7]). Also participation in organised sport was lower in girls (2.9 hours per week [95%-CI 2.8, 3.0]) than in boys (3.6 hours per week [95%-CI 3.5, 3.7]). There were no statistical differences between the four birth-quarters regarding participation in leisure-time PA and organised sport.
CONCLUSION: These data show lower leisure-time PA and sport participation levels for girls compared to boys. The results suggest that there is no influence of relative age (i.e. birth quarter) on leisure-time PA or participation in organised sport. From a societal perspective, this is a positive and important finding.

THE INFLUENCE OF BIRTH DATE ON PROFESSIONAL FOOTBALL CLUB ENTRY AND CAREER ATTAINMENT: A 20-YEAR RETROSPECTIVE ANALYSIS

GIL, S.M.1, BIDAURRAZAGA-LETONA, I.1, MARTIN-GARETXANA, I.1,2, LEKUE, J.A.1,2, RODRIGUEZ-LARRAD, A.1, LARRUSKAIN, J.1,2

1: UNIVERSITY OF THE BASQUE COUNTRY , DEPARTMENT OF PHYSIOLOGY, FACULTY OF MEDICINE AND NURSING, BASQUE COUNTRY, SPAIN. 2: MEDICAL SERVICES, ATHLETIC CLUB BILBAO, BASQUE COUNTRY, SPAIN

INTRODUCTION: An overrepresentation of athletes born soon after the cut-off date has been observed in many sports, which is known as the Relative Age Effect (RAE)(1). This phenomenon has primarily been investigated in a cross-sectional fashion; however, longitudinal studies are scarce. Thus, the aim of this longitudinal retrospective study was to ascertain the influence of relative age on entry to a professional football club and also its influence on the long-term career attainment.
METHODS: We analysed the birth dates and the career attainment of 1071 footballers who entered the Athletic Club of Bilbao in the under (U) 12, U14, U16, U19, Reserves and 1st Team groups. A player obtained 1st Team status after playing 10 official matches with that team. The year was divided in 4 birth quarters (BQ): BQ1: January-March, BQ2: April-June, BQ3: July-September and BQ4: October-December. The $\chi 2$ goodness-of-fit test, w effect size and odds ratios (OR) with 95% confidence intervals (CI) were calculated.
RESULTS: There was an overrepresentation ($p<0.001$) of players born in BQ1 in the U12 (BQ1:45.4%, w=0.39), U14 (BQ1: 29.7%, w=0.48), U16 (53.8%, w=0.51) and U19 (38%, $p<0.01$, w=0.23) groups and the total (45.1%, $p<0.001$, w=0.37); but not in the Reserves and 1st Team. The OR (95% CI) for BQ1 vs BQ4 in the U12 was 4.28 (2.86-6.40), U14: 8.88 (3.94-20.03), U16: 10.61 (4.77-23.60), U19: 2.24 (1.08-4.66), Reserves: 1.71 (0.73-3.98), 1st Team: 2.73 (0.68-10.98) and Total: 4.36 (3.33-5.71).
Forty players (4.7%) became professional, 18 born in BQ1 and 9 in BQ4. A larger proportion of players born in BQ4 who had entered the club in the U12 and U14 groups became professional (9.5% and 33.3%, respectively), compared to players born in the rest of the quarters. Once the players were within the club, the odds for a player born in BQ4 to become professional were 3 times larger (95% CI: 1.38-6.56) than players born in the rest of the BQs.
CONCLUSION: Birth date has a relevant influence on recruitment of footballers by a professional club, particularly at young ages. As such, players born in the first BQ of the year have greater chances to play in a professional club and to attain the professional level than those born in the last birth quarter, which confirms the deleterious impact of the RAE for the relatively younger. Interestingly, once a relatively younger player has overcome the selection process and is within the club, the chances of becoming professional are larger than that of relatively older players (2), probably due to their genuine talent and/or mental toughness.

CAN MOTOR TALENT FACTORS HELP TO PREDICT ELITE FEMALE YOUTH SOCCER PLAYERS' LIKELIHOOD OF TURNING PRO IN ADULTHOOD?

LEYHR, D.1, RAABE, J.2, SCHULTZ, F.1, HÖNER, O.1

1: UNIVERSITY OF TUEBINGEN, GERMANY; 2: PENN STATE ALTOONA, USA

INTRODUCTION: In order to promote the players with the highest potential for success as soon as possible, the process of talent identification and selection in soccer has become increasingly important. As a result, various talent promotion programs have implemented motor diagnostics to complement the subjective assessments of coaches with objective data. While researchers have investigated the prognostic relevance of motor talent factors for adult success in youth soccer (e.g., Höner, Leyhr, & Kelava, 2017), to date no such studies have been conducted with female participants. Therefore, the purpose of the current research was to: (I) analyze the long-term prognostic relevance of motor talent factors for female youth soccer players and (II) compare the motor performance of girls and boys.
METHODS: Participants were N = 807 female U12 soccer players born between 1993 and 2000 who participated in motor diagnostics within the German Soccer Association's talent development program. The test battery comprised five individual tests (sprint, agility, dribbling, ball control, and shooting) and a total motor score. Subsequently, girls' U12 motor performance was used to predict their success in adulthood (i.e., whether an athlete played for a club in the first German women division). Independent sample t-tests were used to determine the significance of mean differences in participants' performance at U12 based on their future selection level. In addition, these results were compared to the motor performance of N = 13,666 male U12 players within the German talent development program using one-way ANOVAs.
RESULTS: Except for shooting, all motor variables significantly discriminated between the selection levels (each $p < .05$). Girls who reached a first division soccer club performed significantly better at U12 than non-selected players ($0.40 \leq d \leq 0.81$). When comparing the average performance of all girls and boys, male players were significantly better in sprint, agility, dribbling, ball control, and the total motor score (each $p < .01$). However, no significant difference with regard to the individual tests was found when comparing the performance of girls selected for a first division soccer club and the average performance across all boys.
CONCLUSION
The current findings indicate that assessing motor performance can assist in predicting female U12 players' future success in adulthood. While it seems that boys, in general, already outperform their female counterparts with regard to the assessed motor variables at an early age (U12), the future professional female athletes perform comparably to average boys.

DEVELOPMENT OF TALENTED YOUTH FOR TOP PERFORMANCE – CHALLENGES, ETHICAL AND SOCIAL ISSUES ALONG THE WAY

PILZ-BURSTEIN, R., BETZER-TAYAR, M., LEV, A.

GIVAT WASHINGTON ACADEMIC COLLEGE OF EDUCATION

DEVELOPMENT OF TALENTED YOUTH FOR TOP PERFORMANCE – CHALLENGES, ETHICAL AND SOCIAL ISSUES ALONG THE WAY
Pilz-Burstein, R.1, Betzer-Tayar, M. 2, Lev, A. 3,4. 1: Givat Washington Academic College of Education , 2: Ruppin Academic Center, School for Business and Economy , 3: Sammy Ofer School of Communications Interdisciplinary Center , 4: The Academic College at Wingate, Wingate Institute
Introduction: Optimizing the development of young talented athletes has gained a wide spectrum of scientific and professional attention. Yet, raising young athletes in the framework of a boarding school, away from home and family, involves ethical and managerial dilemmas that the professional team has to face on a daily basis. A case study of the Wingate Academy of Sports Excellence in Israel is reviewed.
Methods: We present firsthand experience for a period of over 12 years, from a professional view of key role positions at the WASE. The first two authors played a significant role in the strategy and decision making of the organization, and also as important figures in the personal and social lives of the young athletes. Using qualitative methods, we analyzed semi-structured and unstructured interviews and also informal conversations with the athletes, as well as organizational memos that were documented. All these provided a fertile ground for discussing the three main conflictual themes, seen as follows, that the athletes and managerial staff confront on a daily basis.
Results: a. High athletic performance versus academic achievements: The main requirement of the Ministry of Education and the athletes parents, i.e., academic achievements, sometimes contradicts with the target of the Ministry of Sport and the coaches, who strive for athletic achievements. Yet it is the Academys responsibility to optimize and provide a balance between the two for developing a well-rounded person and a valuable citizen; b. Athletic career versus a meaningful military service: This is a significant dilemma quite unique to Israeli society. Military service not only is compulsory in Israel, but it also represents a strong national awareness and a sense of commitment to the Israeli social ethos. However, it sometimes means giving up the athletes sport career and his or her life's dream; c. No pain, no gain – A double message? Fulfillment of the athletic expectations causes a professional conflict between the medical staff and the national federations that expect the coaches deliver top results. But "no pain, no gain" refers not only to physical pain, but also to the mental-psychological stress that plays a dramatic role in the wellness and security of the young athlete.
Discussion: All of these dilemmas have more than one single solution, and are solved in various ways in sport academies world-wide. Therefore, this presentation does not claim what is right or wrong, rather it points to the importance of our awareness of the existing complexities in the case of the WASE. Although each of these questions relates to a specific domain – educational, social, mental or medical, they all reflect an ethical-philosophical dilemma: While being committed to values of excellence and to "best practice", is our primary commitment to the sport bodies that aim for national achievements? Or, are we primarily bound to the young talented athletes and their families, who rely on our professional and ethical judgment in taking responsibility for a well-rounded development process of these young athletes.

OP-PM39 Interval training 2

INVESTIGATING THE INFLUENCE OF 6 MONTHS HIGH-INTENSITY INTERVAL TRAINING ON ARTERIAL STIFFNESS IN ADOLESCENTS: COMMANDO JOES' X4A TRIAL

MCNARRY, M.A., ELLINS, E.A., WINN, C.O.N., EDDOLLS, W.T.B., STRATTON, G.S., HALCOX, J.P.J., DAVIES, G.A., MACKINTOSH, K.A.

SWANSEA UNIVERSITY

INTRODUCTION: Cardiovascular disease is one of the leading causes of mortality in Western societies, with deterioration in endothelial function and arterial stiffness early indicators of cardiovascular damage. Whilst the beneficial effects of regular exercise training on cardiovascular performance have been documented in adults, little is known regarding the applicability of such findings to adolescents, despite evidence that arteriosclerosis begins in childhood. The purpose of the present study was therefore to investigate the influence of high-intensity interval training on arterial stiffness in adolescents.
METHODS: Thirty-four children (Int; 12.1 ± 0.9 yrs; 20 boys) were recruited to a six-month, three times a week, high-intensity interval training (HIIT) intervention (30 min sessions, 10-30 s exercise bouts at >90% age-predicted max heart rate, 1:1 exercise-to-rest ratio) with thirty-two children in a separate school acting as a control group (Con; 12.2 ± 1.0 yrs; 18 boys). Augmentation index and pulse wave velocity were measured with applanation tonometry and cardiorespiratory fitness was measured by an incremental ramp cycle ergometer test to determine peak oxygen uptake (O2). A repeated mixed measures analysis of variance was used to investigate the influence of the intervention and time, with Pearson correlations to assess the relationship between parameters.
RESULTS: Despite a significant increase in cardiorespiratory fitness over the six-month intervention irrespective of exercise group (Con: 2.19 ± 0.51 vs. 2.33 ± 0.56; Int: 2.04 ± 0.50 vs. 2.40 ± 0.63 l·min-1; P < 0.05), HIIT did not elicit any significant changes in pulse wave velocity (Con: 5.6 ± 0.51 vs. 5.7 ± 0.5; Int: 5.6 ± 0.6 vs. 5.5 ± 0.6 m·s-1; P > 0.05), augmentation index (Con: 8.8 ± 7.5 vs. 9.3 ± 6.5; Int: 9.2 ± 6.0 vs. 7.4 ± 4.5 %; P > 0.05), central (Con: 52 ± 7 vs. 52 ± 7; Int: 50 ± 6 vs. 50 ± 7 b·min-1; P < 0.05) or peripheral pulse pressure (Con: 62 ± 9 vs. 61 ± 8; Int: 59 ± 7 vs. 60 ± 7 b·min-1; P > 0.05). There was no relationship between cardiorespiratory fitness and arterial stiffness at baseline or in response to the HIIT intervention.
CONCLUSION: The current study demonstrates that despite significant improvements in cardiorespiratory fitness, HIIT does not improve parameters of arterial stiffness in youth. These findings may be related to the healthy baseline arterial compliance, minimising the capacity, or indeed need, for improvement. Future studies should consider the role of HIIT in ameliorating the deleterious changes in arterial stiffness observed in obese youth.

MITOCHONDRIAL RESPIRATION IS REDUCED IN ABDOMINAL ADIPOSE TISSUE IN WOMEN WITH POLYCYSTIC OVARY SYNDROME, AND UNALTERED FOLLOWING 16 WEEKS OF HIGH INTENSITY INTERVAL TRAINING

LIONETT, S., KIEL, I., VANKY, E., MOHOLDT, T.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Polycystic ovary syndrome (PCOS) is an endocrine disorder affecting ≥20% of reproductive-aged women. Beyond causing infertility, PCOS is associated with metabolic disorders such as insulin resistance. The mechanisms underlying the insulin resistance in PCOS are unclear, but are suggested to be related to abnormal adipose tissue function and morphology. Exercise training improves insulin resistance in PCOS, yet the underlying mechanisms for improved whole-body and tissue-specific metabolism in women with PCOS after training are unknown. The aims of the study were to investigate adipose tissue function in sedentary women with and without PCOS as well as the effect of high intensity interval training (HIT) on adipose tissue function in women with PCOS.
METHODS: Adipose tissue biopsies were obtained from abdominal and gluteal subcutaneous regions of sedentary women with PCOS (n=16; 28 ± 5 y, 32.0 ± 7.5 kg/m2) and without PCOS (n=11; 30 ± 5 y, 29.3 ± 6.1 kg/m2). The women with PCOS were randomized to two different HIT groups (3 × per week, either 10 × 1 min "all-out" intervals (n=4) or 4 × 4 min reaching 90-95% of HRmax (n=6)) for 16 weeks, or control (n=6). Following the 16 weeks of HIT, a second set of abdominal and gluteal subcutaneous adipose tissue biopsies were obtained. Currently, pre and post data from 10 × 1 min (n=1) and 4 × 4 min (n=3) are complete, therefore, data from the HIT groups are pooled. Adipose tissue function was measured as mitochondrial respiration using high-resolution respirometry (Oxygraph-2K, Oroboros).
RESULTS: At baseline, a lower uncoupled respiration (P=0.02), as well as reduced electron transfer system capacity through complex II (P=0.03), in abdominal adipose tissue of women with PCOS compared to women without PCOS was observed. Furthermore, a tendency towards a lower maximal mitochondrial oxidative phosphorylation capacity using fat + Complex I and II substrates (P=0.08) and electron transfer system capacity through Complex IV (P=0.06) was observed in abdominal adipose tissue of women with PCOS compared to women without PCOS. There were no between-group differences in mitochondrial respiration of the gluteal adipose tissue at baseline. There was no effect of HIT on mitochondrial respiration.
CONCLUSION: The lower mitochondrial respiration in abdominal adipose tissue in women with PCOS compared to women without PCOS suggests mitochondrial dysfunction may play a role in the pathophysiology of the metabolic disorders observed in PCOS. HIT does not improve the impaired adipose tissue function (i.e. mitochondrial respiration) in women with PCOS.

EXTREMELY SHORT DURATION REDUCED-EXERTION HIGH-INTENSITY INTERVAL EXERCISE IMPROVES 24 H FREE-LIVING GLYCAEMIC CONTROL IN MEN WITH TYPE 2 DIABETES

METCALFE, R., FITZPATRICK, B., FITZPATRICK, S., MCDERMOTT, G., BRICK, N., MCCLEAN, C., DAVISON, G.

SWANSEA UNIVERSITY

INTRODUCTION: High-intensity interval training (HIT) has been proposed as an alternative exercise strategy to improve glycaemic control in people with type 2 diabetes. However, the assertion that HIT is time-efficient is often misleading, with the protocols studied to date requiring 25-60 mins to complete. A genuinely time efficient HIT intervention (reduced-exertion HIT; REHIT) has been shown to improve aerobic capacity and blood pressure in men with type 2 diabetes over 6-weeks of training. However, the acute effects of REHIT on 24 h glycaemic control in type 2 diabetes have not previously been determined.

METHODS: Eleven men with type 2 diabetes (mean ± SD: age, 52±6 years; BMI, 29.7±3.1 kg/m2; HbA1c, 52±9 mmol/mol [7.0±0.8 %]) participated in a randomised, four-trial crossover study, with continual interstitial glucose measurements captured during a 24 h period including either: (1) no exercise (CON); (2) 30 min of continuous exercise (MICT); (3) 10 x 1 min at ~90 HRmax (HIIT; time commitment, ~25 min); and (4) 2 x 20 s 'all-out' sprints (REHIT; time commitment, 10 min). Dietary intake and exercise timing (30-min post breakfast) were standardised across experimental conditions. Magnitude-based inferences were used to interpret mean differences between the experimental conditions expressed with 90% confidence limits. Inferences were made using standardised effect size (Cohens d) thresholds of 0.2 (smallest worthwhile effect), 0.6 (moderate effect) and 1.2 (large effect).
RESULTS: Compared with CON, there were possibly moderate beneficial decreases in mean 24-h glucose with REHIT (mean difference; ±90%CI: -0.58±0.27 mmol/L) and HIIT (-0.36; ±0.37 mmol/L), and a likely small beneficial decrease with MICT (-0.37; ±0.26 mmol/L). Similarly, there was a possibly moderate decrease in the prevalence of hyperglycemia following both REHIT (-110; ±44 min/day) and HIT (-125; ±77 min/day), and a likely small decrease following MICT (-110; ±81 min/day) compared with CON. 24-h incremental area under the curve (iAUC) was also lower following REHIT (-296; ±250 mmol/L/24h; possibly moderate decrease), HIIT (-364; ±310 mmol/L/24h; possibly moderate decrease) and MICT (-494; ±270 mmol/L/24h, likely moderate decrease) compared with CON. Differences between exercise conditions for mean 24-h glucose and the prevalence of hyperglycaemia were all unclear or trivial, but MICT was associated with additional clear beneficial decreases in iAUC compared with REHIT (-198; ±230 mmol/L/24h, likely small decrease) and HIIT (-130; ±160 mmol/L/24h, possibly small decrease).
CONCLUSION: We conclude that acute bouts of submaximal HIIT, supramaximal REHIT and 30 mins of MICT are beneficial for 24-h glycaemic control in men with type 2 diabetes. REHIT may offer a genuinely time-efficient alternative exercise option for men with type 2 diabetes.

JUMPS AS A FORM OF HIGH INTENSITY INTERVAL TRAINING: EFFECT OF REST DURATION ON OXYGEN UPTAKE, HEART RATE AND LACTATE ACCUMULATION

KRAMER, A., POPPENDIEKER, T., GRUBER, M.

UNIVERSITY OF KONSTANZ

INTRODUCTION: High intensity interval training (HIT) has been shown to elicit similar adaptations as high volume moderate intensity endurance training. However, most HIT research has been conducted on running and cycling. The aim of this study was to assess suitability of jumps as a type of intermittent HIT by analyzing the metabolic load during different jump sessions.
METHODS: Respiratory gases, heart rate and ground reaction forces were recorded for 21 healthy young participants during five distinct jump sessions that differed with respect to the rest durations in between series (0, 15 or 30s) and in between jumps (0, 1 or 2s). The following rest combinations were used: 0-0, 30-0, 15-1, 30-1 and 30-2. After each series of jumps, the participants' perceived exertion was documented, and blood lactate was determined three minutes after the last series. The five jump sessions were completed on five different days, separated by at least two days of rest. Prior to the first session, maximal countermovement jump height as well as maximal oxygen uptake during a ramp cycle test was recorded.
RESULTS: Maximal heart rate for all five jump sessions reached at least 96±4% of the maximal heart rate in the ramp test. Perceived exertion on the 6-20 BORG scale reached 17±2 to 19±1 after the last series. VO2peak, time at ≥90%VO2, lactate and average jump height differed between jump sessions, with the 0-0 session eliciting the highest responses and the 30-2 session eliciting the lowest responses.
CONCLUSION: Metabolic load during the intermittent jump HIT training was high. The duration of rest periods in between jumps and in between jump series had a pronounced effect on metabolic load. The results of this study can help to program intermittent HIT that uses specific exercises instead of cycling or running.

EFFECTS OF MODIFIED SPRINT INTERVAL TRAINING ON PHYSIOLOGICAL RESPONSES IN MODERATELY TRAINED FEMALES

KAVIANI, M., TAHERI, M., HEMMATINAFAR, M., NEMATI, J.

ACADIA UNIVERSITY

INTRODUCTION: Sprint interval training (SIT) is a form of high intensity interval training (HIIT) when shorter work bouts performed at peak power intensity. The usage of sprint interval training (SIT) has been on the rise in athletes, recreational, and clinical populations. However, whether there is any potential sex-based differences in the acute and adaptive responses to SIT when controlling for various factors, such as menstrual cycle phase and relative fitness yet to be fully understood. Therefore, this study investigated effects of modified SIT protocols on physiological responses in moderately trained females.
METHODS: Ten moderately trained females (age, 23.8 ± 2.82 years; height, 164.8 ± 7.19 cm; weight, 57.2 ± 6.97 kg; Vo2max, 40.5 ± 3.1) voluntarily completed two SIT sessions in a randomized cross-over design separated by four weeks: (i) 30:240 (4 × 30-s bouts, 240-s recovery); (ii) (3) 5:40 (24 × 5-s bouts, 40-s recovery). Protocols were matched for the total duration of work (2 min) and recovery (16 min), as well as the work-to-recovery ratio (1:8 s). EE and fat oxidation rates, excess post exercise oxygen consumption (EPOC), and respiratory exchange rate (RER) were calculated from gas analyzer collected before, during, and for 90 min post exercise.
RESULTS: Results showed that EE during exercise in 5:40 was significantly higher (p =0.000) than 30:240 protocol. Also, EE post exercise was greater (p = 0.036) in 5:40 versus 30:240. Post exercise fat oxidation was higher (p=0.000) after 30:240 (0.098 g/m) than 5:40 protocol (0.082 g/m). RER in 5:40 (0.78) was greater than 30:240 (0.75) (p=0.000).
CONCLUSION: In conclusion, 5:40 SIT protocol increased EE during exercise thorough targeting peak power generation, while 30:240 SIT protocol promoted greater post exercise fat oxidation. It has been suggested that women tend to have a higher contribution (approximately 25%) of aerobic metabolism to a 30-s compared with men , which could explain in part the greater fat oxidation in 30:240 protocol versus 5:40 protocol.

THE EFFECT OF 8 WEEKS OF HIGH INTENSITY INTERVAL RESISTANCE TRAINING ON E-SELECTIN AND WHITE BLOOD CELL INDICES IN HEALTHY MEN

MORADI, L.

ISLAMIC AZAD UNIVERSITY, NORTH TEHRAN BRANCH

INTRODUCTION: Exercise has positive and negative effects on athlete's immune system and sometime can be increased risk of infection (Del Giacco SR, 2014). The aim of this study was to investigate the effects of 8 weeks of high intensity interval resistance training on E-selectin and White blood cell indices in healthy men.
METHODS: Twenty four active healthy men were selected and randomly divided into two groups: training (n=11) and control (n=12). Training group was performing high intensity interval resistance training for 8 weeks while control group continued their normal daily life styles. Dependent and independent t-test was used for statistically analyses. Level of significance was p=0.05.
RESULTS: Results were shown that 8 weeks of interval resistance exercise significantly decreased level of E-selectin (p=0.001), but differences between control and training groups in monocytes, lymphocytes, basophiles and eosinophils was not significant (p>0.05), also there was significant relation between body weight and E-selectin changes (r=.67, p= 0.001).
CONCLUSION: High intensity interval resistance training did not result in white blood cells indices excitation because of enough recovery between sets and repetitions, but E-Selectin were sensitive to exercise pressure (Ogawa, Sanada, Machida, Okutsu, & Suzuki, 2010)and load imposed on body by training and showing higher adaptation to high intensity interval resistance training.

Introduction: In recent years, there has been an exponential increase in the availability and use of sports-related smartphone applications (apps) (Janssen et al., 2017). Although these apps are mostly used by unorganized sports participants, professionals such as such as lifestyle professionals and personal trainers are confronted with sports apps in their everyday work. For both end-users and professionals, it is difficult to determine which app fits their (clients') needs and wishes. The aim of this study was to develop a decision tool which supports professionals and end-users in their selection of sports apps.
Methods: The development of the decision tool consisted of four phases. First, a screenings protocol for apps was developed based on a literature review and two expert meetings. This protocol was used to evaluate and select sports apps. Second, we conducted online Delphi panels with four expert groups and participatory action research (Koshy et al., 2010) with 20 professionals and their clients to discuss and test the usability of these apps. Third, the decision tool was developed following an iterative design approach to incorporate user feedback in the earliest possible prototypes. Fourth, the logic of the decision tool was tested and validated against baseline measurements in decision-making behavior within app stores to measure the translation from user-specific goals to mobile app specifications.
Results: An online web-based decision tool was developed within six prototyping stages, using paper prototyping, visual mockups, three stages of rapid development and releasing one final production version of the web-based decision tool. The tests with both professionals and end-users revealed basic must-have criteria to assure minimal usability to facilitate the decision process.
Discussion: At the conference, the development process of the decision/selection tool for sports apps will be presented, and the results of the different sub-studies will be discussed.

APP PREFERENCES AND EXPERIENCES OF RECREATIONAL RUNNERS, CYCLISTS AND WALKERS

DALLINGA, J.M., VAN DER WERF, J., JANSSEN, M., LAURIJSSENS, S., VOS, S., DEUTEKOM, M.

AMSTERDAM UNIVERSITY OF APPLIED SCIENCE

APP PREFERENCES AND EXPERIENCES OF RECREATIONAL RUNNERS, CYCLISTS AND WALKERS

Dallinga J.M.1&2, van der Werf J.1, Janssen M.3&4, Laurijssens S.3, Vos S.3&4, Deutekom M.1&2, 1: Amsterdam University of Applied Sciences (Amsterdam, the Netherlands), 2: Inholland University of Applied Sciences (Haarlem, the Netherlands), 3: Fontys University of Applied Sciences (Eindhoven, the Netherlands), 4: Eindhoven University of Technology (Eindhoven, the Netherlands)
Introduction: A huge amount of applications (apps) for running, cycling and walking is available in the App Stores. As recreational athlete, it is hard to choose the best app that matches personal wishes and goals. In the development of a decision tool for sport-app choice, it is important to understand the opinion of individual, recreational athletes about apps. Therefore, the aim of this study is to gain insight in app preferences and experiences of recreational runners, cyclists and walkers.
Methods: First, online surveys were sent to participants of a recreational running, cycling and walking event 2-3 days after the events. The following issues were addressed: frequency and goal of app use, satisfaction and preference for app functions. Frequency analyses were performed. Cluster analyses were performed as well to determine profiles of app and function preferences. Second, the mostly used sport-apps were tested by recreational athletes by means of a participatory action research (Koshy, 2005). In focus groups, their experiences were evaluated. A thematic analysis was conducted.
Results: A large amount of data was collected about app preferences in recreational runners (n=6.019, 14%), cyclists (n=939, 23%) and walkers (n=2.876, 25%). First results show that use of sport-apps ranged from 44% in walkers to 63% in cyclists and 75% in runners ($p<0.001$). Mostly used apps were Runkeeper for running (23%) and walking (26%) and Strava (61%) for cycling. For all athletes the most important goal of app use was monitoring and gaining insight in performance, however cyclists (93%) indicated this more often than walkers and runners (85%; 64%, respectively, $p<0.001$). A large group of athletes was (very) satisfied about the app they used (93% cyclists, 92% runners, 82% walkers).
Discussion: We will elaborate on the distinctive athlete profiles based on the cluster analysis. Additionally, based on the focus groups, experiences with sport-apps such as Runkeeper and Nike+ Run Club will be discussed. The outcomes are relevant for recreational athletes to choose the best app matching their personal wishes and goals, sport professionals to gain insight in what their clients prefer, and developers of sport-apps to fit the wishes and needs of recreational athletes.
This work was supported by SIA RAAK, part of the Netherlands Organization for Scientific Research (Grant 2015-02-32P).

5 Deakin Health Economics, Australia
6 Computer Science, Auckland, New Zealand
7 Exercise Sciences, Auckland, New Zealand
Introduction: Accessibility barriers constrain utilisation of traditional supervised exercise-based cardiac rehabilitation. Home-based interventions improve access but relinquish supervision and coaching from clinical exercise specialists during exercise training. Mobile health technologies can bridge these gaps by distributing clinical expertise to remotely located individuals during exercise; however, such an approach has yet to be evaluated.
Methods: A two arm, parallel non-inferiority design randomised controlled trial was conducted. 162 participants (61±12.7y, 86% men) were randomised to receive 12 weeks of tele- or centre-based exercise rehabilitation (CBexCR; control). REMOTE-CR provided individualised exercise prescription, real-time exercise monitoring/coaching, and theory-based behavioural strategies via a bespoke telerehabilitation platform; CBexCR provided individualised exercise prescription and coaching via established rehabilitation clinics. Outcomes assessed at baseline, 12 and 24 weeks included maximal oxygen uptake (VO2max, primary) modifiable cardiovascular risk factors, exercise adherence, motivation, health-related quality of life, and economic outcomes (programme delivery, hospital service utilisation and medication costs).
Results: VO2max was comparable in both groups at 12 weeks and REMOTE-CR was non-inferior to CBexCR (adjusted mean difference [95% CI]=0.51 [-0.97 to 1.98] ml·kg-1·min-1, P=.48). REMOTE-CR participants were less sedentary at 12 weeks (-61.5 [-117.8 to -5.3] min·day-1, P=.03), while CBexCR participants had smaller waist (1.71 [0.09–3.34] cm, P=.04) and hip circumferences (1.16 [0.06¬–2.27] cm, P=.04) at 12 weeks. No other between-group differences were detected. Per capita programme delivery (NZD1000/EUR627 vs NZD3336/EUR2091) and medication costs (NZD331/EUR207 vs NZD605/EUR379, P=.02) were lower for REMOTE-CR but hospital service utilisation costs were comparable (NZD3459/EUR2168 vs NZD5464/3425, P=.20).
Discussion: REMOTE-CR is an effective alternative exCR delivery model that can increase reach, reduce delivery costs, and satisfy unique participant preferences. REMOTE-CR could enhance overall exCR utilisation if implemented alongside existing services, particularly among those who are unwilling or unable to attend centre-based programmes. Opportunities for future research will be presented and discussed.

OP-PM18 Micronutrients

PROPER NUTRIENT INTAKE AND TRAINING INTENSITY DECREASE MUSCLE DAMAGE DURING COMPETITIVE SEASON IN PENTATHLON ATHLETES.

LOUREIRO, L., VIANA-GOMES, D., AZEREDO, D., SALERNO, V.P., PIERUCCI, A.P.T.R.

FEDERAL UNIVERSITY OF RIO DE JANEIRO

INTRODUCTION: It is well known that exercise training and healthy eating habits can affect redox homeostasis by enhancing antioxidant defenses. However, exhaustive exercise can induce excessive reactive oxygen species production, leading to oxidative stress related tissue injury and performance decrease. Professional athletes may be at high risk for oxidative stress, and consequent muscle injury or decreased performance. In this context, we investigated cell damage, antioxidant capacity, oxidative damage and food intake during pentathlon competitive season in professional athletes.
METHODS: Ten athletes were investigated for three weeks before competition. Blood samples were collected at the beginning and at the end of the last training session of the each week. The athletes' intake was evaluated with 24 hours dietary recall performed three times a week. Training sessions were performed for 2h in the morning and 2h in the evening. Each session consisted on three of the five modalities that comprise pentathlon (running, shooting, swimming, equestrian and fencing). During the first and second weeks the training sessions were conducted in high intensity. The week before the competition, technical training was prioritized with maximum speed 20% lower than previous weeks for running and swimming sessions, and mean heart rate ~7% lower compared with first week (Week 1=90%, Week 3=83%).
RESULTS: Alanine aminotransferase (ALT) decreases significantly (approximately 65%) in the last week compared to previous weeks. Lipid peroxidation, measured by TBARs remained unchanged during 3 weeks. Total glutathione (GSHt) reduced after two weeks of intense training but was recovered in the third week. Another important result was the correlation between nutrient intake and ALT variation. Athletes who ingested more pantothenic acid, copper and manganese presented lower cellular damage, r= -0.85; -0.78; -0.75, respectively.
CONCLUSION: Our data suggest that a 7% decrease in training intensity reduces cell injury the week before the competition and that adequate ingestion of nutrients that are cofactors of antioxidant enzymes is directly correlated to athletes' recovery.

CALCIUM, VITAMIN D AND IRON STATUS OF ELITE RUGBY PLAYERS DURING A COMPETITIVE SEASON.

SMITH, D.R., DUCKWORTH, L.C., KING, R.F.G.J., JONES, B.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Low calcium, vitamin D and iron concentrations are frequently observed in athletes, particularly adolescents, and are therefore key to monitor. Evaluating micronutrient adequacy from diet diaries can be erroneous given athletes typically under-report dietary intakes, and the duration of recording periods required to capture the variability in micronutrient intake is >20 days. Therefore, to accurately measure the micronutrient status of athletes, biomarker assessments are required, which allow comparisons to reference data. This study aimed to measure iron, calcium and vitamin D serum concentrations in elite English rugby league and union players, and determine their adequacy.
METHODS: A total of 39 elite male rugby players (18.0 ± 2.8, range 14.0 – 25.0 years old) completed the study during their respective competitive playing seasons. Fasted total serum calcium, 25-hydroxy vitamin D [25(OH)D] and ferritin were analysed, and compared to reference values where adequacy was assessed as 2.2 to 2.6 mmol.l-1, 50-100 nmol.l-1 and 15-200 mcg.l-1, respectively.
RESULTS: Serum calcium, 25(OH)D and ferritin concentrations were 2.3 (± 0.2, range; 1.9 to 2.6) mmol.l-1, 33.7 (± 34.2, range; 0.2 to 130.9) nmol.l-1 and 89.4 (± 64.9, range; 13.8 to 303.0) mcg.l-1, respectively. Overall, 25(OH)D was significantly less than the lower end of the adequate range (p=0.002), and ferritin and calcium were significantly greater (p<0.001). For calcium, 6 (15%) participants were lower and 33 (85%) were within reference values. For 25(OH)D, 31 (80%) participants were lower, 4 (10%) participants were within, and 4 (10%) participants exceeded reference values. For ferritin, 1 (3%) participant was lower, 35 (90%) participants were within and 3 (8%) participants exceeded reference values.
CONCLUSION: Biomarker assessment of calcium and iron demonstrated the majority of elite rugby players had sufficient concentrations, although given the individual variability, all athletes should be screened for adequacy. Inadequate vitamin D concentrations was common, which may impair muscle and immune function, contribute towards poor bone health and reduce performance measures. Dietary intakes should be optimised and multiple measures of serum 25(OH)D should be obtained across the season to account for exposure to sunlight.

IS THE IRON STATUS OF ADOLESCENT ARTISTIC GYMNASTS A PROBLEM WORTHY OF ATTENTION?

GIRO, R.1, SOUSA, M.2, MARQUES, I.T.3,4, RÊGO, C.3,4,5,6

1: FCNAUP , 2: ESS-IPL , 3: CUF PORTO HOSPITAL , 4: ESB-UCP , 5: FMUP , 6 CINTESIS

INTRODUCTION: Adolescent gymnasts are at risk of iron deficiency due to increased nutritional demands for growth and sexual maturation, exercise-induced iron losses and typically insufficient dietary intakes to cover the needs. Still, few studies have explored this issue, particularly in male gymnasts. This study aimed to evaluate the iron status of adolescent artistic gymnasts of both sexes and to characterize potentially influencing factors.
METHODS: Convenience sample of 22 artistic gymnasts (22.7% males, 13.8±1.9 years). Percentages of body fat (%BF) and skeletal muscle mass (%SMM) were measured (InBody230®). Body mass index (BMI)-for-age zscores were calculated (WHO AnthroPlus®). All athletes filled out a questionnaire to inform about training habits (days and hours of training/week) and self-assess pubertal stage (Tanner). Girls reported age of menarche, regularity of menses and oral contraception usage. Biochemical parameters were studied to characterize iron status (hemogram, ferritin and high sensitivity C-reactive protein). Dietary intakes of energy, protein, carbohydrates, lipids, iron and nutrients that may interfere with its absorption (vitamin C, calcium and fibre) were quantified (3-day food record). The prevalence of inadequacy (PI) was determined considering the percent of athletes below the European Food Safety Authority Average Requirements for

energy (Physical Activity Level of 2.0) and all micronutrient intakes except for iron, where the sum of the individual probabilities of inadequacy was calculated according to the Dietary Reference Intakes. Intakes <25 g/d were considered inadequate for fibre. Sex-specific data was compared using the t-student or Mann-Whitney U tests. Pearson and Spearman correlations were studied.
RESULTS: No significant differences were found between sexes for the training, iron status and nutritional intake variables (p≥0.05). Athletes trained a median of 6 (3-6) d/w in a total of 20.8 (6.0-27.0) h. Depletion in iron stores (ferritin <15µg/L) was observed in 4 (20%) gymnasts with equal prevalence between girls (n=3, 20%) and boys (n=1, 20%) and 1 (4.5%) case of anaemia was registered in a female athlete (haemoglobin <12g/dL). The PI was 100% for energy and fibre, 86.4% for calcium, 50.0% for vitamin C and 22.4% for iron. Moderate correlations between haemoglobin levels (13.6±0.9 g/dL) and BMI-for-age z-scores (0.04±0.88; r=-0.530, p=0.011), %BF (13.7±5.0; r=-0.583, p=0.007) and %SMM (47.0±3.3; r=+0.562, p=0.010) were found. Iron intake [10.2 (5.2–25.7) mg/d] was positively correlated with energy (1745.8±300.1 kcal/d; ρ=+0.694, p<0.001) and protein [1.71 (1.11–3.41) g/kg/d; ρ=+0.623, p=0.002] intakes and protein intake was positively correlated with the number of training d/w (ρ=+0.548, p=0.008).
CONCLUSION: Gymnasts of both sexes are susceptible to iron deficiency. Considering its repercussions on health and athletic performance, targeted nutritional support and regular monitoring of iron status are recommended.

IRON METABOLISM REGULATION IN WOMEN AFTER AN ENDURANCE PROTOCOL DEPENDING ON FERRITIN STATUS

ALFARO-MAGALLANES, V.M., BARBA-MORENO, L., CUPEIRO, R., ROMERO-PARRA, N., RAEL, B., MAESTRE-CASCALES, C., SÁNCHEZ-DÍAZ, C., BODOQUE, M., SALMERÓN, C., PEINADO, A.B.

TECHNICAL UNIVERSITY OF MADRID

INTRODUCTION: Intense endurance exercise produces inflammation and IL-6 elevation, which seems to be one of the most powerful factors up-regulating hepcidin levels (1). Nevertheless, this fact can be conditioned by body ferritin levels prior to exercise (2). In addition, sexual hormones may also influence hepcidin response (1). The purpose of this study was to compare the influence of serum ferritin status and menstrual cycle phases over iron, hepcidin and IL-6 regulation in endurance female athletes.
METHODS: Fifteen endurance trained females (35.5±4 yrs; 58.1±5.6 kg; 163.9±5.9 cm; 50.5±3.7 VO2max) performed a maximal graded test and three continuous running sessions of 40 min at 75% of the VO2max velocity throughout different phases of the menstrual cycle (early follicular phase=EFP, mid follicular phase=MFP and luteal phase=LP). Blood samples were taken pre-exercise, 0h and 3h post exercise. Ferritin levels were measured pre-exercise, whereas iron, IL-6 and hepcidin levels were measured in all samples. Two groups were set depending on ferritin status: <20 µg/L (F1) and ≥20 µg/L (F2).
RESULTS: Mix lineal model showed lower iron levels (p=0.004) for F1 (54.1±8.5 µg/dl) than F2 (91.1±8.7 µg/dl), whereas differences between groups for IL-6 and hepcidin were not observed (p>0.05). Menstrual phase and ferritin group interaction presented differences only for iron concentrations (p=0.005). F1 showed lower levels (p=0.07) in EFP (41.7±9.8 µg/dl) than LP (66±10.2 µg/dl), while F2 presented lower levels in EFP (74.76±10.3 µg/dl) than MFP (100.2±9.9 µg/dl; p=0.01) and LP (98.2±10.3 µg/dl; p=0.08).
CONCLUSION: Menstrual phase showed lower iron levels during EFP as expected due to menstrual bleeding (1). Our results did not show differences between ferritin groups for hepcidin and IL-6, contrary to previous studies (2). These differences could be due to the fact that our study sample was only women, instead of men or both genders. Despite some studies have reported oestrogen and progesterone influence on hepcidin and IL-6 levels, no differences for hepcidin and IL-6 were found along menstrual cycle phases. These studies tested sexual hormones influence in animals, in vitro, isolated or with supranatural doses, which is far away from a natural menstrual cycle (1). Summing up, it seems that female´s iron metabolism response to endurance exercise at different ferritin status is similar, although further investigation need to be performed to clarify sexual hormone influence over iron regulation.

VALINE INTERMEDIATE 3-HYDROXYISOBUTYRATE IS A POSSIBLE BIOMARKER OF MUSCULAR BCAA UTILIZATION FOR ENERGY PRODUCTION IN EXERCISE

MIYAZAKI, T.

TOKYO MEDICAL UNIVERSITY

INTRODUCTION: In skeletal muscles during endurance exercises, carbohydrates and lipids have been well-known to be used as energy sources, but branched-chain amino acids (BCAAs) are also catabolized for energy production. However, the method of evaluating the metabolism of muscular BCAA as energy source during exercises has been unestablished. In the muscles, three BCAAs are catabolized in the mitochondria to acetyl-CoA and/or succinyl-CoA of the TCA cycle via the first common steps and subsequent own steps formed CoA-compounds. In valine catabolic pathway, a small molecule 3-hydroxyisobutyrate (3HIB) is produced from a precursor CoA-compound in the mitochondria, and has been confirmed to be increased in the circulating fluids in situations that increase muscular BCAA metabolic activity such as fasting and diabetes mellitus. Present study purposed to evaluate the changes of 3HIB concentration in serum and skeletal muscles and the influences of BCAA supplementation on the 3HIB concentration in endurance exercises.
METHODS: [1. Animal Study] Wister male rats were loaded to a transient treadmill running at 20 m/min for various durations (0, 30, 60, 120 min, until to exhaustion [135.0 ± 10.5 min]; N=7/group). 3HIB concentration in serum and skeletal muscles (soleus and gastrocnemius), and glucose and free fatty acid (FFA) concentrations in serum were measured after the exercises. [2. Human Study] BCAA (3.2g) or placebo supplementations were given to healthy college males after every meal for two days before a full-marathon race (N=14/group). 3HIB, glucose, and FFA concentrations in serum were measured at two days before, immediately after, and one day after the race. In both studies, 3HIB concentration in serum and muscles was measured by HPLC-MS/MS system.
RESULTS: [Study 1] 3HIB concentration in serum and both muscles significantly increased in a time-dependent manner with significant correlation after the treadmill exercises. Serum glucose and FFA concentrations were significantly decreased and increased, respectively, dependently on the exercise durations. [Study 2] Immediately after the full-marathon race, serum 3HIB concentration significantly increased compared to that before the race, and recovered to basal level after one day. Serum FFA concentration also significantly increased immediately after the race. The increased 3HIB concentration in serum immediately after the race was significantly enhanced by the BCAA supplementation.

CONCLUSION: 3HIB concentration in serum significantly increased correlated with its muscular concentrations by endurance exercise, and the exercise-induced increase of serum 3HIB level was emphasized by BCAA supplementation. Present results suggested that 3HIB in blood could be a possible biomarker of muscular BCAA utilization for energy production in exercise.

OP-PM57 Exercise interventions

FOUR WEEK MODIFIED HIGH-INTENSITY CIRCUIT TRAINING USING BODY WEIGHT IMPROVES PEAK OXYGEN CONSUMPTION, BUT NOT BODY COMPOSITION IN SEDENTARY WOMEN

KHEMTONG, C.

MAHIDOL UNIVERSITY

INTRODUCTION: Nowadays, weight loss exercise programs have become a popular trend among many nations. High-intensity circuit training using body weight (HICTBW) is the combination of exercises that can be completed within 8 minutes per circuit, while it can improve cardiorespiratory fitness effectively (Brett et al., 2013). However, whether the duration of training as short as 4 weeks of modified HICTBW training has beneficial effects on cardiovascular fitness and weight control for sedentary people is unclear. Therefore, the aim of this study was to investigate the effects of 4-week modified HICTBW on cardiorespiratory fitness and body compositions in healthy sedentary women.
METHODS: Twenty-four sedentary women (age: 35±3 years) were equally divided into trained (TNW) and untrained (CNW) groups. TNW group performed 4-weeks, 3 times weekly, a modified HICTBW training which consisted of 30-sec work and 10-sec rest for 12 exercise positions per 1 round, continuously increased by 1 round every 2 weeks for 4 weeks. Whereas CNW group performed the usual physical activity for 4 weeks. Both groups were advised not to change their dietary habit throughout the program. Body composition parameters, i.e. body weight, body fat mass, and skeletal muscle mass as well as cardiorespiratory fitness parameters, i.e. heart rate (HR), exercise workload and relative peak oxygen consumption (VO2peak) using indirect calorimetry method (Oxycon® mobile, Germany) were measured before and after 4 weeks of training.
RESULTS: At baseline, no differences for all parameters were observed between TNW and CNW groups. After 4-week of HICTBW program, TNW group had significantly increased in exercise workload and VO2peak and lower in HR while performing submaximal exercise testing when compared with CNW group. In both groups, no changes were observed for body composition parameters.
CONCLUSION: 4-week modified program of HICTBW can improve cardiorespiratory fitness parameters, but there was no effect of weight loss in sedentary women who did not change their dietary habits. Our observations seem to suggest that a short duration of 4-week modified HICTBW program does not affect body composition in sedentary women.

WALKING TRAINING IMPROVES CARDIOVASCULAR FUNCTION AND REGULATION, SYSTEMIC AND LOCAL NITRIC OXIDE BIOAVAILABILITY, OXIDATIVE STRESS AND INFLAMMATION IN PATIENTS WITH INTERMITTENT CLAUDICATION

FORJAZ, C.1, ANDRADE-LIMA, A.1, CHEHUEN, M.1, SILVA JR, N.1, MIYASATO, R.1, SOUZA, R.1, BRUM, P.1, OLIVEIRA, E.1, WOLOSKER, N.2,3

UNIVERSITY OF SÃO PAULO

INTRODUCTION: The increase in cardiovascular morbimortality in individuals with peripheral artery disease (PAD) and intermittent claudication (IC) is associated with alterations in cardiovascular function, cardiac autonomic modulation, endothelial function, oxidative stress and inflammation (Criqui et al.2010). Walking training (WT) is recommended to improve walking capacity in these individuals (Hirsch,et al., 2001), however, knowledge about WT effects on the above mentioned processes are scarce and controversial. Thus, the present study was design to evaluate, in individuals with PAD and IC, the effects of WT on cardiovascular function and autonomic modulation as well as on blood and muscle markers of endothelial function, oxidative stress and inflammation.
METHODS: Thirty-two men with PAD and IC were randomly allocated in two groups: WT (n = 16, 2 sessions/week, 15 bouts of 2 min walking at an intensity corresponding to the heart rate of the pain threshold interspersed with 2 min of passive pause) and control (CO, n =16, 2 sessions/week, 30 min of stretching). At the beginning and end of the study, the following evaluations were done: cardiovascular function (blood pressure – BP, heart rate – HR, rate pressure product – RPP); cardiovascular autonomic modulation (HR variability); oxide nitric availability (blood nitric oxide – NO and muscle nitric oxide synthase – eNOS); oxidative stress (catalase – CAT, superoxide dismutase – SOD, lipid peroxidation – LPO measured in blood and muscle biopsy); and inflammation (interleukin-6 – IL-6, C-reactive protein – CRP, tumor necrosis factor alpha – TNF-alpha, intercellular adhesion molecules – ICAM, vascular adhesion molecules – VCAM measured in blood and muscle biopsy). Data were evaluated by between-within 2-way ANOVA and $P < 0.05$ was set as significant.
RESULTS: WT decreased cardiovascular overload (reducing systolic BP, mean BP, HR and RPP) and improved cardiac autonomic modulation (decreased sympathovagal balance and increased baroreflex sensitivity). WT increased plasma NO and muscle eNOS. WT improved antioxidant defense (increased blood SOD, blood CAT and muscle SOD). It also improved systemic and local inflammation (decreased blood CRP, TNF-alpha, ICAM and VCAM and reduced muscle IL-6, CRP, TNF-alpha, ICAM and VCAM). All these variables presented significant interaction in ANOVA ($P<0.05$)
CONCLUSION: In men with PAD and IC, WT improves cardiovascular function and autonomic modulation, increases NO bioavailability and decreases systemic and local oxidative stress and inflammation. These positive adaptations were observed in the muscle directly affected by the disease as well as systemically, demonstrating an overall effect of WT in individuals with PAD. These alterations may explain, at least in part, the lower cardiovascular morbidity and mortality of these individuals after WT.

THE EFFECT OF THE MEDEX COMMUNITY-BASED EXERCISE REHABILITATION PROGRAMME ON PHYSICAL FUNCTION AND PHYSICAL ACTIVITY IN INDIVIDUALS WITH CHRONIC DISEASE

SKELLY, F., MOYNA, N.M., MCCAFFREY, N., LOUGHNEY, L., FURLONG, B.

DUBLIN CITY UNIVERSITY

INTRODUCTION: Community-based exercise rehabilitation (CBER) is an effective disease management tool for individuals living with chronic conditions. Research has provided evidence for the beneficial effects of attending CBER on functional capacity and quality of life, however these studies have mainly been focused on cardiac and pulmonary rehabilitation programmes. MedEx is a novel CBER programme located at Dublin City University, which accommodates a diversified population of chronic diseases.
Aim: To determine the effect of the MedEx programme on physical function and physical activity in individuals with a range of chronic conditions.
METHODS: 238 participants (46% male; age (mean ± SD) 62.4 ± 11.3 yr) were recruited following referral to CBER by healthcare professionals. Participants had an established diagnosis of coronary artery disease (n=61), chronic obstructive pulmonary disease (n=54), peripheral arterial disease (n=27), cancer, (n=71), or type 2 diabetes (n=25). Participants underwent assessments of anthropometrics (BMI) strength (sit-to-stand test and handgrip dynamometry), flexibility (sit-and-reach test) and aerobic endurance (6-minute time trial). Physical activity was recorded over 7 days using an activPAL3 accelerometer. Participants were instructed to attend 2 MedEx supervised group exercise classes per week on a continuous basis. The 60 minute classes consist of a combination of aerobic and resistance exercise. Participants attended a group exercise consultation at induction and month 1, 3 and 6, which involved the use of behaviour change techniques to improve exercise adherence. Repeat assessments were conducted at 3, 6 and 12 months. Repeated measures ANOVA were used to detect changes in means over time.
RESULTS: By 12 months, 55 participants had dropped out and 52 were lost to follow-up. Of 131 who completed the trial the mean no of sessions was 33.6 ± 24.6 over 12 months. There was a significant effect of time on BMI, F (3, 303)=9.08, sit-to-stand, F (3, 294)=43.74, handgrip, F (3, 309)=5.49, sit-to-reach, F (3, 249)=2.92, 6-minute time trial, F (3, 294)=54.40, and step counts F (3, 216)=2.61. BMI decreased between baseline and 3, 6 and 12 months and between 3 and 6 months. Sit to stand improved between baseline and 3, 6 and 12 months and from 3 to 6 months and 3 to 12 months. Handgrip increased from baseline to 6 and 12 months. Sit and reach improved between 3 and 12 months. Six-minute time trial distance increase between baseline (499.3 ± 111.7 m) and 3 (568.0 ± 149.6 m), 6 (586.4 ± 157.4 m), and 12 months (587.5 ± 148.9 m) and between 3 and 6 months. Step count increased between baseline (7322 ± 2947 steps/d) and 3 months (8097 ± 3422 steps/d).
CONCLUSION: The MedEx CBER had beneficial effects on physical function and physical activity in individuals with a variety of chronic diseases. Many of these benefits were achieved in the first 3 months and maintained.

SUPERVISED, BUT NOT HOME-BASED, ISOMETRIC TRAINING IMPROVES BRACHIAL AND CENTRAL BLOOD PRESSURE IN MEDICATED HYPERTENSIVE PATIENTS: A RANDOMIZED CONTROLLED TRIAL

RITTI-DIAS, R., FARAH, B.Q., RODRIGUES, S.L., SILVA, G.O., PEDROSA, R.P., CORREIA, M.A., BARROS, M.V., DEMENICE, R., MARINELLO, P.C., SMART, N.A., VIANNA, L.C.

UNIVERSIDADE NOVE DE JULHO

INTRODUCTION: The purpose of this study was to compare the effects of supervised and home-based isometric handgrip training on cardiovascular parameters in medicated hypertensives.
METHODS: In this randomized controlled trial, 72 hypertensive individuals (38 to 79 years old, 70% female) were randomly assigned to three groups: home-based, supervised isometric handgrip training or control group. Home-based and supervised isometric handgrip training was completed thrice weekly (4x2minute at 30% of maximal voluntary contraction, with 1-minute rest between bouts alternating the hands). Before and after 12 weeks brachial, central and ambulatory blood pressures (BP), arterial stiffness, heart rate variability, vascular function, oxidative stress and inflammation markers were obtained.
RESULTS: No significant ($p>0.05$) effect was observed for ambulatory BP, arterial stiffness, heart rate variability, vascular function and oxidative stress and inflammation marker in all three groups. Brachial BP decreased in the supervised group (Systolic: 132±4vs.120±3 mmHg; Diastolic: 71±2vs.66±2 mmHg, $p<0.05$), whereas no significant difference was observed in the home-based (Systolic: 130±4vs.126±3 mmHg; diastolic: 73±3vs.71±3 mmHg) and control groups ($p>0.05$). Supervised handgrip exercise also reduced central BP systolic (120±5vs.109±5 mmHg), diastolic (73±2vs.67±2 mmHg); and mean BP (93±3vs.84±3 mmHg), whereas no significant effect was found in the home-based (Systolic: 119±4vs.115±3 mmHg; Diastolic: 74±3vs.71±3 mmHg) and control groups ($p>0.05$).
CONCLUSION: Supervised, but not home-based, isometric training lowered brachial and central BP in hypertensives.

EFFECTS OF COMBINED PHYSICAL ACTIVITY INTERVENTION PROGRAM ON NUTRITIONAL STATUS AND HEALTH-RELATED PHYSICAL FITNESS IN THAI WORKING-AGE POPULATION

OUTAYANIK, B.

KASETSART UNIVERSITY

INTRODUCTION: One indicator of the quality of Thai working-age population in the country is healthy and the key to healthy living consists of 3-E; Emotion, Eating and Exercise. ACSM recommends that the regular exercise on daily living in adults should include cardiorespiratory exercise, resistance exercise, flexibility exercise and neuro-motor exercise (ACSM, 2018). Therefore, the aim of this study was to examine the effects of an 12-week combined physical activity intervention program on nutritional status and health-related physical fitness in Thai working-age population of Kasetsart University, Bangkok, Thailand.
METHODS: One-hundred and twenty-four male and female personnel of Kasetsart university (aged 23-56) were divided randomly into two groups. Group 1 participated into 12-week combined physical activity intervention that comprises a combined exercise program (5 sessions per week of 60 minutes), nutritional education activity and emotional management activity. Group 2 was not received any activity intervention. Measurement were taken at baseline and after 12 weeks, and include lung capacity (LC), %fat, muscle mass (MM), bone mass BM), weight, body mass index (BMI) and levels of fasting blood sugar (FBS), cholesterol (Cho), triglyceride (Tri), high-density lipoprotein (HDL), low-density lipoprotein (LDL), and health-related physical fitness (PACER), modified sit and reach, 60s sit up, handgrip dynamometer test, back and leg dynamometer test to both group. Statistical analysis included descriptive statistics, Pair Sample t-test, and Independent Sample t-test.

RESULTS: Over an 12-weeks intervention study, the experimental group improved significantly their weight, %fat, muscle mass, BMI, FBS ($p<0.01$), cholesterol ($p<0.05$) and cardiorespiratory fitness (CF), and lower back & hamstring flexibility (LBHF), and abdominal muscular strength and endurance (AMSE), and right & left hand and back & leg muscular strength ($p<0.01$). BM, Tri, HDL and LDL did not change significantly during the study period ($p>0.05$). Experimental group were significant improvement than control group in CF ($p<0.01$), LBHF ($p<0.01$), AMSE ($p<0.01$), and right & left hand ($p<0.05$, $p<0.05$), back & leg muscular strength ($p<0.05$, $p<0.01$), and BMI, LC, %fat, weight ($p<0.05$). There were no significantly differences of MM, BM, FBS, Cho, Tri, HDL, LDL between control group and experimental group ($P>0.05$).
CONCLUSION: This study showed that twelve-week combined physical activity intervention program improved the weight, %fat, muscle mass, BMI, FBS, cholesterol, CF, LBHF, AMSE and muscular strength. Therefore, the combined physical activity intervention programs after work every day should be promoted to all personnel of Kasetsart university and enclosed into the plan or mission of university for develop the quality of the working-age population.

EXERCISE TRAINING DURING CHEMOTHERAPY PRESERVES SKELETAL MUSCLE FIBER AREA, CAPILLARIZATION AND MARKERS OF MITOCHONDRIAL FUNCTION, IN PATIENTS WITH BREAST CANCER

MIJWEL, S., CARDINALE, D., NORRBOM, J., IVARSSON, N., WENGSTRÖM, Y., SUNDBERG, C.J., RUNDQVIST, H.
KAROLINSKA INSTITUTET

INTRODUCTION: Exercise has been suggested to ameliorate the detrimental side effects of chemotherapy on skeletal muscle. In the OptitTrain randomized controlled trial for patients with breast cancer (Mijwel et al. 2018), we found beneficial effects over the intervention on lower limb muscular strength and aerobic fitness in both exercise intervention groups, consisting of moderate-intensity aerobic combined with high-intensity-interval training (AT-HIIT) and resistance- combined with high-intensity-interval-training (RT-HIIT), compared to usual care (UC). Therefore, we hypothesized that the exercise training adaptations found in the exercise intervention groups would be reflected on skeletal muscle showing a maintained or improved muscle fiber area, satellite cells, markers of mitochondrial function and capillarization in response to both RT-HIIT and AT-HIIT. The aim of this study was to compare effects AT-HIIT and RT-HIIT to UC on skeletal muscle morphology and function in patients undergoing chemotherapy.
METHODS: Resting skeletal muscle biopsies were obtained pre- and post-intervention from 23 randomly selected women from the OptiTrain-breast-cancer-trial that underwent RT-HIIT, AT-HIIT, or UC during chemotherapy for 16 weeks. Analyzes included citrate synthase activity, immunoblotting for protein levels, myosin heavy chain typing, and immunohistochemistry. ANCOVA adjusted for baseline values was used. All tests were two-tailed and were considered significant at $p<0.05$.
RESULTS: Over the intervention, citrate-synthase activity, muscle fiber cross-sectional area (CSA), capillaries/fiber, and myosin-heavy-chain isoform type-I were reduced in UC. Exercise was able to counteract these declines (citrate synthase: UC vs. RT-HIIT: $p=0.027$, AT-HIIT vs. UC: $p=0.005$; CSA: UC vs. AT-HIIT: $p=0.007$, UC vs. RT-HIIT $p=0.001$; capillaries/fiber: UC vs. AT-HIIT: $p<0.001$, UC vs. RT-HIIT: $p=0.002$; myosin-heavy-chain type-I: UC vs. RT-HIIT: $p=0.016$). AT-HIIT promoted electron-transport-chain protein levels (complex I: $p=0.003$, complex II: $p=0.007$, complex IV: $p=0.004$ vs UC and RT-HIIT favored satellite cell count vs. both UC ($p=0.007$) and AT-HIIT ($p=0.038$).
CONCLUSION: AT-HIIT and RT-HIIT maintained or improved markers of skeletal muscle function compared to the declines found in the UC group, indicating a sustained trainability in addition to the preservation of function during chemotherapy. These findings advocate the importance to implement exercise programs for patients with breast cancer during chemotherapy to prevent the negative side effects of chemotherapy and inactivity on skeletal muscle.

GROUND REACTION FORCE ASSESSMENT FOR MONITORING ACCELERATION SPRINT PERFORMANCE IN SEMI-PROFESSIONAL SOCCER

WDOWSKI, M.M., GITTOES, M.J.R.
COVENTRY UNIVERSITY & CARDIFF METROPOLITAN UNIVERSITY

INTRODUCTION: The majority of sprint running bouts in professional soccer are over short distances, with rapid accelerations requiring the production of large ground reaction forces (GRF). Typically, sprint acceleration performance in soccer is assessed using split time protocols. Alternative methods that provide extended monitoring and mechanistic insight have been advocated. The efficacy of using GRF monitoring including medio-lateral components instead of typical assessments of acceleration performance in soccer players has however, yet to be fully elucidated. The aim of this study was to investigate the relationship between first foot strike ground reaction force metrics and split time acceleration performance in semi-professional soccer players.
METHODS: Nineteen semi-professional male soccer players participated (Mean±SD: 21.1±1.9 years, 79.4±7.3 kg, 1.79±0.06 m) completed three 20 m acceleration sprints from a left foot forward standing start. Timing gates recorded split times for 0-5 m, 5-10 m, 10-15 m, 15-20 m and 0-20 m intervals. A forceplate captured ground reaction force data (1000 Hz) in the vertical (Z), anterior/posterior (Y) and medial/lateral (X) directions of the first right foot strike contact phase. The ratio and orientation of ground reaction force vectors for the YZ comparison were calculated using the procedures outlined by Morin et al. (2011). Using similar methods, corresponding measures were determined for the XY and XZ components.
RESULTS: Higher accelerating players over the 0-20 m interval tended to have a lower minimum YZ orientation ($R2=0.18$, $p=0.03$). Improved performance over the 5-10 m interval was correlated with a lower average XY orientation ($R2=-0.21$, $p=0.02$). Average YZ orientation was negatively correlated with the 15-20 m interval ($R2=-0.19$, $p=0.03$). Higher accelerating players tended to have a greater peak Y GRF over the 5-10 ($R2=-0.56$, $p=0.000$), 10-15 ($R2=-0.44$, $p=0.001$), 15-20 ($R2=-0.54$, $p=0.000$) and 0-20 m ($R2=-0.43$, $p=0.001$) intervals. Higher accelerations in soccer sprinting may require early stabilisation of lateral loading in the initial step and the development of increased vertical force orientation to benefit late acceleration.

CONCLUSION: Measurement of first foot strike multi-component GRF metrics in soccer players could provide a valid approach for monitoring and developing mechanistic understanding of early and late acceleration sprint performance.

A MODIFIED MODEL EQUATION FOR STEADY LOCOMOTION PREDICTS MECHANICAL INTERNAL WORK IN SPRINT RUNNING.

PAVEI, G.1, MONTE, A.2, OTSU, T.3, NUMAZU, N.3, FUJII, N.3, ZAMPARO, P.2, MINETTI, A.E.1

1UNIVERSITY OF MILAN; 2UNIVERSITY OF VERONA; 3UNIVERSITY OF TSUKUBA

INTRODUCTION: Previous estimate and model of mechanical work or power during sprinting always neglected the role of swinging the limbs, though it has been proved to be a considerable amount in other unsteady locomotion activities such as shuttle running especially at maximal speed (Zamparo et al. 2016). Aim of this study was to measure the internal work during maximal sprinting and related it to mechanical external work and sprint distance.
METHODS: 21 athletes involved in different sport (age 23±2 yrs, mass 66.9±11.4 kg, height 1.73±0.07 m) performed two maximal 20 m sprint in a gym. The 3D position of 18 markers placed on segments endpoints of the subjects was recorded by means of 35 Vicon cameras (Oxford Metrics) at 100 Hz to obtain the trajectory of the body center of mass (BCoM) and segments displacement. From the time course of BCoM total energy the external work (Wext, J/(kg m)) was computed. The internal work (Wint, J/(kg m)), the work necessary to rotate and accelerate limbs with respect to BCoM was calculated. From kinematic data, stride frequency (SF), mean velocity and duty factor (the fraction of contact time in a stride) were also computed. All analyses have been performed on the whole sprint (20 m) and on three shorter distances: the initial 5 m, 10 m and 15 m.
RESULTS: Wint increases by decreasing sprint distance (1.82, 1.95, 2.12, 2.38 J/(kg m) at 20, 15, 10 and 5 meter respectively) and increases its percentage in relation to Wext from 55% on 5 m, to 69% on 20 m. Mean velocity increases with distances (3.9, 4.8, 5.4, 5.8 m/s at 5, 10, 15 and 20 meter respectively), stride frequency is constant (2.07 Hz) whereas duty factor decreases across distances (0.31, 0.27, 0.25, 0.24 at 5, 10, 15 and 20 meter respectively).
CONCLUSION: Wint can be computed only by motion capture and a 20 m sprint required a considerable number of cameras, so that longer distances analyses seem unfeasible or barely manageable. Minetti (1998) developed a model equation to compute Wint during steady walking and running by knowing SF, velocity, duty factor and a compound inertial factor (q) ≈ 0.1. We tested this model on sprint data and found that q values change with sprint distance, so that the equation needs to be adapted by including q=0.2325*x^-0.211 (R2=0.978, p<0.001), where x is sprint distance (1 REFERENCES: Minetti AE (1998). INTRODUCTION: Tendon hypertrophy can occur in situations when tendons are exposed to chronic mechanical loading in humans (Bohm et al., 2014). In particular, long-term training induces Achilles tendon (AT) hypertrophy in endurance runners (Magnusson and Kjaer, 2003). However, whether long-term training in endurance runners also induces patellar tendon (PT) hypertrophy is poorly understood. Furthermore, joint kinetics of lower limb is different among foot strike patterns (FSP), as classified to rearfoot strike (RFS), midfoot strike (MFS), and forefoot strike (FFS) based on initial ground contact position of the foot during running (Stearne et al., 2014). Thus, it can be speculated that degree of AT and PT hypertrophy would be different between RFS and MFS/FFS runners. The present study aimed to determine the differences in AT and PT CSAs between RFS and MFS/FFS runners. Additionally, we examined the relationships of AT and PT CSAs with running performance in RFS and MFS/FFS runners.
METHODS: Twenty habitual RFS runners and 20 habitual MFS/FFS runners participated in this study. Their FSP were determined based on video images during submaximal running. The CSAs of AT and PT in participants were measured using magnetic resonance imaging. The AT and PT CSAs were calculated at its proximal, middle, and distal portions. To obtain overall and relative CSAs for AT and PT, three CSAs of each tendon were averaged, and it was normalized with body weight to the two-third power.
RESULTS: Physical characteristics and personal best 5000-m race time did not differ significantly between RFS and MFS/FFS runners. Similarly, relative AT CSA did not differ significantly between the two groups. There was no relationship between relative AT CSA and personal best 5000-m race time in both groups. Additionally, relative PT CSA did not differ significantly between the two groups. However, we found that relative PT CSA was significantly correlated with personal best 5000-m race time in MFS/FFS runners (r = -0.483; P = 0.031), whereas such a relationship was not observed in RFS runners.
CONCLUSION: The present findings suggest that although difference in FSP may not affect tendon hypertrophy, PT CSA may relate to running performance in MFS/FFS runners, but not in RFS runners. Knee joint stiffness during running is higher in FFS than in RFS (Hamill et al., 2014). Therefore, larger PT CSA may contribute to higher running performance potentially by modifying knee joint stiffness in MFS/FFS runners.

COMPARASION OF DISTANCE RUNNERS AND NON-RUNNERS IN A HOPPING TASK

BALINT, K., ÖRS, S., JÓZSEF, T.

UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: Several studies demonstrated that the shorter Achilles tendon moment arm (MA-AT) are related to a better performance in sprinting, distance running (Lee et. al. 2009, Sholz et. al. 2008, Raichlen 2011 et. al.). However Werkhoven et. al. (2017) suggested that

the longer MA-AT in non-athletes correlated to a better jumping performance and explained by the possible specialized adaptation of elite human athletes. The purpose of this study was to examine and compare the mechanical, neuromuscular and structural behaviour of the lower leg in Caucasian long distance runners (LDR) and non-runners (NR) during hopping task.
METHODS: Seven elite LDR and nine physically active male (NR) volunteered to participate in the study. After ten minutes cycling in a cycle ergometer and several minutes of habituation to repetitive bilateral hopping exercise, the subjects performed 8-12 hopping on a force platform. The hops were filmed with a video camera from the right side perpendicular to sagittal plane. Ultrasonography (US) was applied to record the pennation angle and fascicle length change in (MG) during hopping. EMG activity was also recorded from tibialis anterior (TA), soleus (SOL), lateral and medial gastrochnemius muscles of the right leg (LG and MG) using bipolar surface electrodes. Achilles tendon moment arm was measured in a sitting position using the methods described by Scholz et al. (2008).
RESULTS: The average jumping height was 17% greater in NR than in LDR, but the contact time was similar. The NR had longer MA-AT ($p \leq 0,04$) than LDR. The average EMG (aEMG) data comparison revealed differences between the two groups. The shortening to stretching aEMG ratio of the SOL was 27% lower in LDR than in NR. The US analysis showed no difference in the change of the fascicle length between groups during the hops. The center of gravity (CoG) positive and negative acceleration showed no difference between the two groups. Jumping height was not influenced by the length of MA-AT in either group. The stiffness negatively correlated to the jumping height in both groups ($r=-0,84$ $p \leq 0,02$). A longer MA-AT were associated with higher negative acceleration of CoG in both group ($R=0,74$ $p \leq 0,02$).
CONCLUSION: Our results may indicate that longer MA-AT in NR resulted in higher hopping height. However the correlation analysis has not supported this conception since there was no correlation between the two parameters in either group. It seems short MA-AT is not beneficial for fast movement and the habitual training seems does not affect the jumping performance. However, the LDR groups aEMG ratios shows similar differences between LDR and NR as reported by Sano et.al.(2013) comparing Kenyans runner with Caucasian non-runners.

LOWER LIMB SPRING-MASS ALTERATION AND FOOT STRIKE PATTERN DURING A 1500-M RUN

RIVIÈRE, J.R.1, HINTZY, F.1, MORIN, J.B.2, EDOUARD, P.3, MESSONNIER, L.1, SAMOZINO, P.1
UNIVERSITÉ DE SAVOIE MONT BLANC

INTRODUCTION: Middle-distance running causes severe fatigue impacting runners' lower limb mechanical behavior (Girard et al. 2012) which can be assessed using the spring-mass model providing information on leg stiffness (Kleg). Spring-mass model application to middle-distance running highlighted gradual decrease in Kleg during the run, possibly impacting runners' performance (Butler et al. 2003). However, the observed alteration of Kleg could be biased by changes in velocity within the test or inter-subject difference in the running distance (Rabita et al. 2011; Girard et al. 2012). Moreover, it remains unknown whether changes in Kleg originate from a change in foot strike pattern (FSP). The aim of the study was to assess the concomitant alterations in Kleg and FSP during a 1500-m run performed at constant velocity.
METHODS: On a 400-m track field, seven national-level middle-distance runners performed 500-m and 1000-m runs (separated by 1h30 of rest) on a first session and a 1500-m run on a second session at least 24 h apart. Each run was paced at constant velocity corresponding to 95% of their individual 1500-m best time. Over the three runs, FSP (proportion of fore-foot strikes: FFS, rear-foot strikes: RFS and mid-foot strikes: MFS) and Kleg (Morin et al. 2005) were measured using a 10-m optical system placed at nine different points (50, 150, 250, 450, 550, 650, 950, 1050 and 1450 m).
RESULTS: Kleg decreased gradually with increasing distance ($r=-0.87$; $p<0.01$; -19% at the end of the run) with post-hoc significant differences with values at 50 m only observed from 650 m ($p<0.05$). Concurrently, runners maintained their FSP over the 1500-m run with no change in the mean strike behavior, the latter being 13%RFS/87%MFS at 50 m, 16%RFS/84%MFS at 650 m and 17%RFS/83%MFS at 1450 m.
CONCLUSION: During a 1500-m run performed at 95% of competition velocity, leg stiffness progressively decreased, which confirms the decrease in lower limb mechanical behavior during a middle-distance run independently of running velocity's alteration. In addition, the alteration in Kleg was not associated with changes in FSP and thus may rather be related to the decreasing runner's capabilities to produce force rapidly at ground strike (i.e. neuromuscular fatigue; Girard et al. 2012).

EFFECTS OF SOCCER-SPECIFIC LOADING ON KNEE NEUROMECHANICS IN ACL-INJURED, ACL-RECONSTRUCTED AND HEALTHY SOCCER PLAYERS: A PILOT STUDY.

NUCCIO, S.1, LABANCA, L.1, ROCCHI, J.E.1,2, SBRICCOLI, P.1, MACALUSO, A.1,2
1: UNIVERSITY OF ROME FORO ITALICO; 2: VILLA STUART SPORT CLINIC, ROME, ITALY

INTRODUCTION: ACL injury and re-injury are two of the most common and devastating injuries in soccer. It has been extensively documented that exercise leads to a 20%-30% transitory increase in Anterior Knee Laxity (AKL) which, despite being physiological, increases the tendency toward altered sport-related landing biomechanics (Shultz et al., 2013). The neuromechanical behaviour of ACL-reconstructed (ACL-R) and ACL-injured (ACL-I) knees after specific-loading exposure has been poorly addressed. Therefore, the aim of this study was to investigate the effect of real on-field loading on AKL, muscle strength and neuromuscular patterns of a single-leg drop landing (SLDL) in ACL-R, ACL-I and healthy (ACL-H) soccer players.
METHODS: One ACL-R (height: 1.77 m; body mass: 75kg), 1 ACL-I (height: 1.74 m; body mass: 71kg) and 1 ACL-H (height: 1.76 m; body mass: 70kg) competitive soccer players volunteered in this investigation. A 45-min version of the Soccer Aerobic Field Test (SAFT45) was employed to simulate the mechanical and physiological demands of half soccer-match. To assess the effect of SAFT45 on knee neuro-

mechanics, the following assessments were randomly conducted in both legs, prior and after SAFT45: 1) Anterior Tibial Translation (ATT); 2) Knee extension and flexion Maximal Voluntary Isometric Contraction (MVICext; MVICflex); 3) Biceps Femoris (BF) and Vastus Lateralis (VL) pre-impact EMG duration during SLDL. The difference in percentage between PRE- and POST-SAFT45 in ATT, MVICext, MVICflex and pre-impact EMG duration of VL and BF was calculated.
RESULTS: AKL in the operated leg of ACL-R and ACL-H was unchanged after SAFT45, whereas AKL of the injured leg of the ACL-I and the healthy leg of ACL-R considerably increased (about 28%). MVICext and MVICflex decreased in all participants of about 12.5%, except for the injured leg of ACL-I which showed an increase of 2% in MVICflex. The reconstructed leg of ACL-R showed an increased pre-impact EMG duration of VL of about 10%, whereas both ACL-I and ACL-H showed a decreased pre-impact EMG duration of VL (3% and 2%, respectively). Pre-impact EMG duration of BF was reduced of about 35% in the ACL-R leg and of about 10% and 13% in ACL-I leg and ACL-H, respectively.
CONCLUSION: Alterations in muscle strength, abnormalities in anterior knee laxity and quadriceps dominance during landing tasks were found in response to soccer-specific loading. Since such alterations are all risk factors for ACL injury and re-injury (Hewett et al., 2016) future studies are needed to deeply address this area of investigation.

OP-SH07 Approaches to physical activity / functioning

Y-PATH: TARGETING CHILDHOOD PHYSICAL ACTIVITY THROUGH A NATIONAL WHOLE - SCHOOL APPROACH

BELTON, S.
DUBLIN CITY UNIVERSITY

The Y-PATH programme (Youth-Physical Activity Towards Health) is a whole school physical activity intervention, targeting 12 – 15 year old post primary school youth. The Y-PATH programme of research commenced in 2010 following the MRC's framework for development of complex interventions. Initial cross sectional data informed intervention design, which was followed by an exploratory trial in 2011, and a Cluster Randomized Controlled trial in 2013 – 2015. Subsequently in 2017 the programme was process evaluated, with a view to streamlining resources and training to better meet the needs of teachers and students in schools. The final hurdle for this programme is the critical step of national dissemination.
Methods used across the eight year development and evaluation of Y-PATH (n ≈ 30 teachers and n ≈ 1,000 students) include focus group interviews with teachers and students, questionnaires with teachers and students (including PA self-efficacy, attitude, motivation), and a range of physical measures for students including physical activity via accelerometry, cardiovascular fitness, body composition, and fundamental movement skill (FMS) measurement (using TGMD-2).
Research has shown the Y-PATH programme to be effective in improving the FMS levels of students, and helping to alleviate the age related decline in physical activity. The effects of the intervention were significant and positive for all children in the intervention group regardless of gender, weight status, or PA level. Process evaluation revealed four main themes: 1) material and resource suitability, 2) content suitability, 3) implementation considerations, and 4) current PE curricular context. Teachers and students have highlighted the timely potential of the Y-PATH programme to meet the PE 'Wellbeing' curricular needs of schools, and students. Findings indicate that both teachers and students in schools positively receive the programme. Key stakeholders including many national agencies have been identified as central for a sustainable national dissemination plan.
Though many agencies may agree the need for a programme such as Y-PATH to support PE and Physical Literacy in schools, and to foster a whole school approach to PA promotion, converting this agreement into action is an extremely difficult challenge. The road map so far will be discussed, with remaining barriers and challenges identified.

SCHOOL-BASED HIGH-INTENSITY INTERVAL TRAINING CAN IMPROVE IMPORTANT ASPECTS OF PHYSICAL FITNESS IN ADOLESCENT GIRLS

WESTON, K.L.1, MCLAREN, S.J.1, BARKER, A.R.2, WESTON, M.1
1. TEESSIDE UNIVERSITY 2. UNIVERSITY OF EXETER

INTRODUCTION: Alongside continuing scientific interest on the use of high-intensity interval training (HIIT) in healthy and clinical adult populations, research on HIIT as a health promotion tool in young people is increasing. Nonetheless, the effectiveness of school-based HIIT is unclear with previous studies recruiting relatively small and predominantly male samples. Whether school-based HIIT is feasible and effective in females therefore, is relatively unknown. As such, we examined the effect of a 4-week school-based HIIT intervention on physical fitness in adolescent girls.
METHODS: Using a cluster controlled design, participants (n=132) were recruited from one school in Northeast England; 66 girls (aged 12.4 ± 0.3 years [mean ± SD]) were assigned to the 4-week HIIT intervention, and 66 girls (aged 13.3 ± 0.3 years) acted as controls and continued usual Physical Education (PE) lessons. The HIIT sessions replaced PE lessons for intervention participants, and comprised 10 maximal effort repetitions across two sessions per week (one boxing-based, one running). In week one, repetitions were performed for 45-s, followed by 90-s recovery. Every week thereafter, repetition length increased, and recovery decreased, each by 5-s respectively. To quantify the intensity of the sessions, participants' ratings of perceived exertion (RPE) were recorded on a tablet-based application of the Children's OMNI walk/run scale. Outcome measures were 20 m shuttle-run test (20m SRT) performance, handgrip strength, 10 m sprint time, 20 m sprint time and standing broad jump distance. Data were analysed using an ANCOVA model (covariates; maturity offset and outcome baseline value), with magnitude-based inferences subsequently applied. A linear mixed model was applied to RPE data to separate the variability in RPE between- and within-subjects.
RESULTS: Mean (±SD) HIIT session attendance (expressed as % of total sessions provided) was 76 ± 13%. Mean RPE was 4.9 Arbitrary Units (AU), with a between- and within-subject SD of 1.5 AU and 1.6 AU, respectively. Post-intervention, effects were most likely beneficial for 20m SRT performance (+7 shuttles; 90% confidence interval +4 to +10 shuttles), likely beneficial for left handgrip strength (+1.5 kg; +0.3

to +2.6 kg), and possibly beneficial for right handgrip strength (+1.1 kg; -0.1 to +2.3 kg) and 20 m sprint time (-0.01 s; -0.10 to +0.01 s) in intervention participants versus controls.
CONCLUSION: A boxing- and running-based HIIT intervention, delivered during PE lessons can improve important aspects of physical fitness in adolescent girls. The relatively short duration of the HIIT sessions and overall intervention length may increase the likelihood of such protocols being implemented by schools in the future.

DASH – THE IMPACT OF A PHYSICAL EDUCATION INTERVENTION ON SCHOOLCHILDREN IN TOWNSHIPS IN PORT ELIZABETH, SOUTH AFRICA

PÜHSE, U., WALTER, C., MÜLLER, I., STEINMANN, P., GERBER, M., UTZINGER, J.

UNIVERSITY OF BASEL, SWITZERLAND, NELSON MANDELA UNIVERSITY, PORT ELIZABETH, SOUTH AFRICA, SWISS TROPICAL AND PUBLIC HEALTH INSTITUTE, BASEL, SWITZERLAND

Sedentary behaviour, overweight, obesity and lacking physical activity are a global trend and is particular true for children living in underprivileged urban settings such as townships in South Africa (HAKSA Report Card 2016). Participating in regular physical activity and eating a healthy diet are key behaviours for reducing risk factors for non-communicable diseases (NCDs) such as hypertension, diabetes and obesity, which were explored in the DASH study (Disease, Activity and Schoolchildren's Health, www.dash-sa.com). A multi-fold school-based intervention toolkit was developed that aimed to contribute to the improvement of the health and well-being of schoolchildren in disadvantaged neighbourhoods of Port Elizabeth, South Africa. The intervention was applied in 10-week blocks, and comprised four elements: (i) weekly physical activity and dancing-to-music lessons, (ii) health and hygiene lessons, (iii) nutritional supplementation and (iv) deworming.
In numerous publications the DASH study provides evidence that improvements in children's physical activity and nutrition not only contributes to their cognitive performance in school, but can also have an impact on overall cardiovascular risk factors. Physical activity was also found to correlate with health-related quality of life, and parasite infection appear to have a small, but significant negative effect on the physical fitness of infected children, as expressed by their maximum oxygen uptake. Furthermore, a multidimensional, school-based physical activity intervention can reduce the increase in cardiovascular risk factors (BMI and skinfold thickness).
Taken together a well-designed, multidimensional physical activity programme contributes to the improvement of the health and well-being of schoolchildren in disadvantaged neighbourhoods of Port Elizabeth in South Africa. To increase effectiveness and sustainability of the results, the intervention will be extended to cover the entire school term and adapted to additional age groups. In a follow- up project (the KaziBantu-project) we build on the existing evidence from DASH and scale the intervention program for the entire primary school.
Keywords: Physical fitness, physical education intervention, cardiovascular risk factors, South Africa

THE IMPACT OF THE DAILY MILE ON PHYSICAL HEALTH AND FITNESS IN DUTCH PRIMARY SCHOOL CHILDREN

COLLARD, D.C.M., SCHOLTEN, V.

MULIER INSTITUTE

Introduction: The Daily Mile is a popular, simple and free initiative that sees children run/walk/jog for 15 minutes every day in their primary school. The aim of The Daily Mile is to improve the physical health and fitness as well as social, emotional and mental health of children. The aim of this study was to determine the impact of The Daily Mile in The Netherlands.
Methods: The impact of The Daily Mile was determined by means of the RE-AIM model (Glasgow et al., 1999). The RE-AIM model consists of five elements that relate to health behaviour interventions. The elements Reach, Effectiveness, Adoption, Implementation and Maintenance are essential to improve the impact of an intervention such as The Daily Mile. Teachers (n=53) and primary school children (n=187) who participated in The Daily Mile in The Netherlands filled out a questionnaire. Complementary, interviews were performed with teachers to collect data on factors for success and constraints.
Results: The Daily Mile is mainly performed in primary schools (children aged 8-12 years old). On average, The Daily Mile is implemented by the schools three times a week. At the schools that participated in the research 1757 children are reached. Teachers rate The Daily Mile on average by 7.5. They experience positive effects in children, especially when the children are restless. Positive effects were found on physical fitness, physical health and social health. Children experience that they feel more energetic and they are able to pay more attention in the classroom after running The Daily Mile. Not all teachers are willing to adopt The Daily Mile in the school curriculum and most of the time the intervention is not yet institutionalized or part of the routine organizational practices and policies.
Conclusion
Teachers and children who participated in The Daily Mile are enthusiastic. However, The Daily Mile is not implemented every day as intended. Participants feel positive effects on health and fitness as a result of extra physical activity during school. Many schools experience difficulties with the implementation and sustainability of the program.

THE EFFECT OF SCHOOL, FAMILY AND FRIENDS ON STUDENTS' PERCEIVED AUTONOMY SUPPORT AND AUTONOMOUS MOTIVATION: A CROSS-NATIONAL SURVEY

SOÓS, I., HAMAR, P., DIZMATSEK, I., SZABO, A., LING, J., OJELABI, A., WHYTE, I., BOROS-BÁLINT, A., SZABO, P., SIMONEK, J.

UNIVERSITY OF SUNDERLAND, UNITED KINGDOM, HUNGARIAN UNIVERSITY OF PHYSICAL EDUCATION, BUDAPEST, HUNGARY, EÖTVÖS LORÁND UNIVERSITY, BABES-BOLYAI UNIVERSITY, CONSTANTIN DE PHILOSOHER UNIVERSITY, NITRA

Introduction and Aims
After the fall of the communist regimes, the focus in physical education has shifted from skill-based to health-related activities in most of the East-European nations. Aetiological research and ecological models (Baumann et al., 2012) show that the change has reshaped young people's perceived autonomy support and decisions related to their leisure-time physical activity.
This study aimed to examine the social agents that influence students' perceived autonomy support and autonomous motivation in leisure-time behaviour.
Method

A three-wave prospective design was employed, and data were collected from 11-18 year old students (n=1000, mean age=15.0, male 42%, female 58%) in three East-European countries - Romania, Hungary and Slovakia and the United Kingdom. The Helsinki Declaration's ethical guidelines were followed. Data collection instruments comprised PASSES, BREQ-2 and Godin's Leisure-Time PA Scale and used in the context of three, Theory of Planned Behaviour, Self-Determination Theory and Trans-Contextual Model.
Data were analysed by IBM SPSS v. 24 and AMOS.
Results and Conclusion
Our results demonstrated that PE teachers' autonomy support influenced students' autonomous motivation in schools. However, this correlation was reversed in a few cases due to the traditionally controlling education systems in many Eastern European schools, corresponding to Hein et al. (2016). Nevertheless, students' perceived autonomy support from family and friends positively correlated with their autonomous motivation. British students perceived the strongest autonomy support from PE teachers ($p<.001$), while Eastern European students perceived the highest level of autonomy support both from parents ($p<.001$) and friends ($p<.001$).
We conclude that an optimal relationship should be developed between PE teachers and students, that autonomy support be maintained by family and friends to encourage students to pursue physical activity behaviour.

INTERNET-BASED PROMOTION OF CHINESE TRADITIONAL HEALTH-PRESERVING SPORTS: HEALTH QIGONG

LIU, H., CHOW, B.

HONG KONG BAPTIST UNIVERSITY

Abstract:
Recently, a lack of public attention has become a major impediment to the promotion of Chinese traditional health-preserving sports (Jie, 2015). Although researchers have shown an increased interest in using information technology to promote sports, reports on the mobile-internet-based promotion of Chinese traditional sports are sparse, and there is limited information regarding the status quo of Health Qigong and its social acceptance.
Health Qigong is one of the most widely accepted Chinese traditional health-preserving sport (GAS, 2017; Jahnke, 2010). This paper aimed to investigate the status quo of Health Qigong among practitioners and non-practitioners in Mainland China. Some strategies for Chinese traditional health-preserving sports were proposed.
Cross-sectional surveys were conducted with 362 adult-aged participants (216 practitioners, 146 non-practitioners) in Mainland China. A 40-item questionnaire was designed to assess sociodemographic characteristics, practice/contact situation, transmission channels, perceived values and the internet use behaviors.
It was evident from the survey results that the majority of Health Qigong practitioners were older individuals. The main channel participants got to learn this sport were through social sports sites and university courses. Over 70% of practitioners had more than five friends who also practice Health Qigong. Nearly 90% of practitioners used mobile internet. Furthermore, the findings reflected the barriers to its promotion were (a) a lack of young practitioners resulted in weak sustainable development; (b) non-practitioners perceived that Health Qigong was incommensurate with the group they belong to; and (c) there were limited channels used to promote the sport.
These strategies are recommended to promote Health Qigong: (a) target specific audience groups in promotion; (b) promote the sport culture to build a unique brand; and (c) highlight its distinctive values and characteristics in promotion.

ELITE AGE GRADE PLAYER PERCEPTIONS OF PERFORMANCE ANALYSIS IN RUGBY UNION

HAMMOND, V.1,2, HANNON, J.1, RICHARDSON, A.1, MORAHAN, D.1, GODSON-TREACY, J.1, MACMAHON, S.1, MCGRATH, D.1

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Performance analysis (PA) - defined as the process of recording and analysing the movement of athletes during sports performance - has become an integral part of elite and sub-elite sport. While PA is currently considered to be a burgeoning field of research, there is only a small number of studies evaluating players' perceptions of performance analysis and optimal delivery. Furthermore, little research of this nature exists in elite underage sports, where arguably, the pedagogy of player feedback and the consumption of performance data could play a critical role in player development. This study thus aimed to examine a National Under 20 rugby team (IRFU U20s) players' perceptions of PA.
METHODS: Having received institutional ethical approval, an anonymous questionnaire was administered to the IRFU U20 squad (n= 25; age - 18.8years (+/-.41)) in a training camp environment. Percentage responses were computed across all questions and responses relating to types of feedback are presented here.

RESULTS: 64% of the squad found individual video analysis (i.e. one-on-one with coach) to be "very valuable" compared with 32% finding team/opposition video analysis (i.e. review of match footage in a group setting) "very valuable"; 32% found match statistics (e.g. tackles made, line-outs won) "very valuable", with 16% for GPS. Valuing one-on-one feedback with a coach the most, was a prevalent theme among players: 56% reported that receiving video clips alone (i.e. to phone/laptop) was either "valuable" or "very valuable" (combined); the same proportion applied to whole team video analysis; 100% of players reported receiving video analysis one-on-one with coach as either "valuable" or "very valuable"; 84% found video analysis in positional groups "valuable" or "very valuable". 56% of players perceived the provision of match statistics with respect to positional role (e.g. scrum half: passing, hooker: throwing) as "very important", compared with 28% "very important" for set pieces, 32% for team defence, 36% for team attack, 28% for decision making. An open question asked how PA sessions can be improved and 33.3% of respondents expressed a desire for more one-on-one feedback.
CONCLUSION: These results suggest that U20s IRFU players perceive individual, coach-led performance feedback to be of paramount importance. This may reflect the developmental and competitive nature of underage international rugby, along with the fact that the team does not train or play together frequently. Given the resource constraints that exist at underage level, extensive individualised player feedback from coaches is not feasible. Better exploitation of technology may be required, not simply as a platform for sharing video, but for didactic feedback approaches that facilitate constructive questioning based on the coach's philosophy, requiring self-reflection and self-regulation. This could lead to a deeper understanding within the players of their contribution at the level of the team.

INTER-COUNTY GAELIC FOOTBALL COACHES' PERCEPTIONS OF THEIR PRACTICE ACTIVITIES, SESSION SEQUENCE AND COACHING BEHAVIOURS

KINNERK, P.1, HARVEY, S.2, MACDONNCHA, C.1, LYONS, M.1

UNIVERSITY OF LIMERICK

INTRODUCTION: Game-Based Approaches (GBAs) have been advocated as pedagogies that develop players' decision making and skill execution. However, there is limited evidence to suggest GBAs have been accepted by coaches and that they are being employed in various coaching contexts. Benchmarking of a coaches' practice through examining the time a coach dedicates to 'training form' (technical drills) and 'playing form' (conditioned games), sequencing of activities and coach behaviours provide an indication of a coaches' pedagogical approach to coaching (Hall et al., 2016). Consequently, the aim of this research was to examine Gaelic football coaches' perceptions of their coaching practice and determine whether their practices were aligned with GBA pedagogy. In addition the research seeked to investigate differences in coaching approaches according to time of season (early, peak) and coaching level (academy, adult).
METHODS: 150 Gaelic football coaches coaching at Inter-County level completed an on-line survey describing their coaching practice at two distinct phases of the season (i.e. early and peak season). Descriptive analyses of the survey data were conducted, alongside interpretive analyses using one-way ANOVA.
RESULTS: Coaches reported using more "training form" activities in early season than "playing form" activities. In peak season, coaches reported using a majority of "playing form" activities. In relation to the sequencing of activities within practice sessions, coaches indicated using "training form" activities in the early-mid section of sessions before progressing on to "playing form" activities later on in sessions. Few differences were found in practice activities and reported behaviours across levels coaches coached at.
CONCLUSION: The high percentage use of 'training form' activities reported by coaches coupled with coaches' linear sequencing of practice activities are contrary to the guidelines advocated in GBA pedagogy that emphasises more 'playing form' activities and sequencing the session around the game, thus being the organising centre of the session. Coaches should seek to increase time spent in activities deemed more relevant to game form.

HOW TO USE TIME-TRIAL PERFORMANCE OF ELITES FROM PREVIOUS GENERATIONS TO SELECT THE FUTURE ELITES?

STOTER, I.1, KONING, R.2, VISSCHER, C.1, ELFERINK-GEMSER, M.1

1: UMCG, RUG , 2: FEB, RUG

INTRODUCTION: The aim of the present study is to provide performance benchmarks for future elite athletes in time-trial sports. Becoming an elite athlete is an exceptional performance and scientific support for elite athlete performance development is scarce, due to the limited number of people who reach the elite level. The present study uses longitudinal data of different generations to tackle this issue and introduces a simple method to make the benchmarks useful for future generations.
METHODS: 1500 m Season Best Times (SBT) of Dutch skaters (388 females, 810 males, age 13-26 years), who competed in at least six skating seasons between 1993 and 2013, were corrected for the prevailing world record (WR): rSBT=(SBT/WR)*100%. Three performance groups were defined: elite (rSBT<110%), sub-elite (110% RESULTS: Calendar year explained 17-30% and 24-25% of the improvements in SBT over 20 years for respectively females and males ($p<.001$). Correction for the prevailing WR neutralized this effect ($p>.05$) or diminished it to less than 2% ($p=0.013$). Of all athletes performing within the defined elite benchmarks, the elite group represented <20% up to age 16 and <50% up to age 21. Elites performed better than other performance groups at age 15-24 for female ($p<.05$) and age 13-25 for male skaters ($p<.05$) but did not develop performance faster. Results were confirmed with an out of sample group (n=182). In the out of sample validation group, 100% of the performances of the female elite and 95% of the performances of male elite were within the defined elite performance benchmarks.
CONCLUSION: Correcting SBT for the prevailing WR makes it possible to increase the number of elite athletes to study and create benchmarks useful for future generations. The benchmarks can be used to define the number and level of skaters needed to support the future elites and provide guidelines for performance development from age 13- 26 years.

TEAM PERFORMANCE INDICATORS THAT DISCRIMINATE BETWEEN SUCCESSFUL AND UNSUCCESSFUL TEAMS IN ELITE MENS FIELD HOCKEY

BRADLEY, J.

INSTITUTE OF TECHNOLOGY CARLOW

Introduction: In sports performance, a performance profile can be used to represent typical performance and gain insight into the psychological, physical, tactical, technical aspects of sport (ODonoghue, 2013). Understanding what aspects of performance contribute to success in team sport is crucial to allow coaches to inform their training and preparations for future competitions. Performance Analysis has become an essential tool to enhance coaches decision making. However, despite its use within the applied setting in field hockey,

studies within published literature is sparse. Therefore, the aim of this study was to determine the key events within elite mens field hockey that discriminate between successful and unsuccessful teams.
Methods: Twenty-five, international field hockey matches, played during the World League 3 tournament in 2017, were analysed using the Sportscode Elite (Version 10.3, Sportstec, Warriewood, Austrailia). Each match was analysed by the same analyst who had extensive knowledge of hockey and the software. A coding facility was used to record key events relating to team performance throughout each match. A Mann Whitney U test was utilised to determine whether there was a statistically significant difference ($p<0.05$) between performance indicators for winning versus losing teams.
Results & Discussion: The mean circle penetrations in winning performances (median = 23) was significantly higher than that of losing performances (median = 14) ($U = 107.5$, $z = -3.98$, $p <0.001$). Entries into the attacking area (25m line) were also significantly higher for winning performances (median = 22) than that of losing performances (median = 16) ($U = 185.5$, $z = -2.47$, $p <0.05$). The number of field goals scored affected match outcome with winning teams (2.32 1.80 field goals) scoring more field goals than losing teams (0.36 0.64 field goals). No significant differences were found between penalty corners awarded and winning/losing teams ($p = .739$).
Conclusion
These results identify team performance indicators that discriminate between winning and losing in elite field hockey, with circle penetrations and attacking 25 entries appearing significant. The relationship between circle penetrations/attacking entries and winning highlights the importance of efficient use of territory within field hockey. Coaches and trainers should place great importance on these events when analysing matches and designing training interventions.

ANALYSIS OF SUBSTITUTION TIMES IN SOCCER

SWARTZ, T.

SIMON FRASER UNIVERSITY

This paper considers the problem of determining optimal substitution times in soccer. We review the substitution rule proposed by Myers (2012) and provide a discussion of the results. An alternative analysis is then presented that is based on Bayesian logistic regression.
We find that with evenly matched teams, there is a goal scoring advantage to the trailing team during the second half of a match.
In addition, we provide a different perspective with respect to the substitution guidelines advocated by Myers (2012).
Specifically, we observe that there is no discernible time during the second half when there is a benefit due to substitution.

RESTING CEREBRAL BLOOD FLOW AND PERFUSION USING TRANSCRANIAL DOPPLER AND MAGNETIC RESONANCE IMAGING.

BURLEY, C.V., MULLINGER, K.J., FRANCIS, S.T., WHITTAKER, A.C., LUCAS, S.J.E.

UNIVERSITY OF BIRMINGHAM AND UNIVERSITY OF NOTTINGHAM

INTRODUCTION: Resting cerebral blood flow (CBF) and perfusion measures are used to quantify brain health. Yet, different imaging modalities are used to obtain these measures, and different measurements can be described as representing resting CBF. This study examined whether different approaches alter the resting CBF outcome measure between age and fitness groups. In the same cohort, we examined: (1) imaging modality [transcranial Doppler (TCD) approach measuring middle cerebral artery velocity (MCAv) and cerebrovascular conductance (CVCi) vs. magnetic resonance imaging (MRI) approach using arterial spin labelling (ASL)], and 2) typical analysis approach [resting MCAv and CVCi (TCD) vs. quantitative estimate of cerebral perfusion and blood flow transit times (MRI ASL)] for determining resting CBF.
METHODS: 35 healthy volunteers participated (20 young: 24±7y; 15 old; 66±7y). Participants completed two experimental sessions (TCD/MRI) on separate days. Resting CBF was calculated for TCD and MRI data using typical analysis approaches. Between group ANOVAs examined effects of ageing and aerobic fitness within each imaging modality. CBF measures were correlated (Pearsons) against age and fitness status, and between analysis approaches.
RESULTS: Differences were observed between younger and older participants for resting CBF measures derived using both TCD (MCAv: 69 vs 55 cm/s; $p<0.01$; CVCi: 0.89 vs 0.67 cm/s/mmHg; $p<0.01$) and MRI (transit times: 0.67 vs 0.73 s; $p<0.01$). On average, the younger group had higher grey matter cerebral perfusion (MRI: 69 vs 61 mL/100g/min; $p=0.13$). Older fit participants had higher TCD CVCi (0.77 vs 0.48 cm/s/mmHg; $p=0.02$) compared to their unfit counterparts, and fitness was positively associated with both MCAv ($r=0.52$) and CVCi ($r=0.73$) measures ($p<0.05$). Unexpectedly, the younger fit group had slower MCAv (TCD) and transit times (MRI ASL) compared to their unfit counterparts (61 vs 75 cm/s, $p=0.02$ and 0.70 vs 0.65 s, $p<0.01$, respectively), and fitness was negatively correlated with TCD MCAv ($r=-0.49$, $p<0.05$) and positively correlated with MRI transit times ($r=0.61$, $p<0.05$). No significant difference was observed between fitness groups for the other resting CBF measures. Across the whole cohort, MRI transit times correlated with TCD MCAv and CVCi ($r=-0.60$ and $r=-0.46$ respectively; both $p<0.01$).
CONCLUSION: Findings indicate that TCD and MRI modalities can provide complementary resting CBF measures (e.g. TCD velocity and MRI transit times), with similar differences across the whole cohort and between subgroups (age/fitness) observed across modalities. However, having accounted for differences in transit times between cohorts, tissue perfusion measures obtained with MRI ASL (the most common measure used for MRI), did not show significant age or fitness effects between groups. Thus, to enable comparison of studies across modalities that assess resting CBF the metrics of CBF measured must be comparable (e.g. flow velocity [TCD] vs blood transit time [MRI]).

NORMAL VALUES FOR MAXIMAL INSPIRATORY PRESSURE IN ELDERLY OVER 60 YEARS

ROLDAN, A.1, FORTE, A.2, CORDELLAT, A.1, MONTEAGUDO, P.1, BLASCO-LAFARGA, C.1

UNIVERSITY OF VALENCIA

INTRODUCTION: Maximum inspiratory pressure (MIP), which measures respiratory muscle strength (Schoser et al., 2017), decreases with age (Black & Hyatt, 1969). It's been suggested that this decline accelerates once over-55, but it is unclear how does this specific strength reduces in elderly (Sclauser et al., 2014). On the other hand, different authors have determined normal values for MIP (Black & Hyatt, 1969) and lower limits of normal (Harik-Khan, Wise, & Fozard, 1998), but there are still discrepancies about normal values by age and sex (Rodrigues et al., 2017), and little is known about the influence of being physically active, both of which are aims of this study.
METHODS: 51 healthy non-smokers elderly undergoing a multicomponent exercise training program volunteered to participate in the study (26 females, 72.74 years, range 61.00-84.90 and 25 males, mean age 69.84 years, range 64.40-76.60). Body composition, blood pressure, MIP and spirometry were assessed, followed by lineal regression model analysis by means of R.
RESULTS: Men between 64.00-76.00 years reduces the MIP in 2.87 units each year from an initial average value of 98.53 units, while the reduction in women between 61.00-85.00 years is of 0.19 units/year from an initial average value of 47.40 units.
CONCLUSION: Our results display a different pattern of MIP, with respect to age and gender compared to previous studies (Black & Hyatt, 1969; Enright et al., 1994). Age shows to be an important factor in the evolution/reduction of MIP. We also conclude that its loss for women is progressive with ageing and so remains after 65 years old, while it reduces stronger for men from that age. Similar to general strength losses, average men's strength at 65 years is larger as compared to women, so their loss might also be larger, despite being active. Future studies need to confirm this pattern and analyze new determining factors for the MIP, since it predicts respiratory weakness before changes in spirometry (Schoser et al., 2017).

POSTPRANDIAL VENOUS AND CAPILLARY BLOOD GLUCOSE DIFFERENCES FOLLOWING REST OR EXERCISE IN OBESE INSULIN RESISTANT MALES

ALLERTON, D., STEVENSON, E.

NEWCASTLE UNIVERSITY

INTRODUCTION: Accurate and precise measurement of circulating glucose concentration is essential for diagnosis and management of diabetes. Whilst venous blood is widely used to determine glucose concentration, metabolism at surrounding tissues may lead to differences when compared to capillary or arterial blood, particularly in the post-meal milieu, and previous studies raise doubts about published equivalence values. The magnitude of this difference may also be influenced by prior activity. Therefore, the aim of this study was to compare venous and capillary blood glucose measurements following consumption of a mixed-macronutrient meal after rest or exercise.
METHODS: Twelve centrally-obese males (age: 41±9 years, BMI: 37.8±2.1 kg/m2, HOMA-IR: 6.9±4.9) completed two trials in a randomised order. On each occasion participants consumed a standardised mixed-macronutrient breakfast meal (468 kcal; 70% carbohydrate, 17% fat, 13% protein) and remained seated for 240 min. Prior to the breakfast meal participants either rested or completed 30 min low-moderate intensity treadmill walking exercise (50±4%V̇O2peak). Simultaneous venous and capillary blood samples were taken at regular intervals during the postprandial period. Blood glucose concentration was immediately determined following each sample using a benchtop analyser.
RESULTS: Venous and capillary whole blood glucose did not differ at baseline after rest (p=0.923) or exercise (p=0.793), however post-meal peak glucose in capillary blood was significantly higher than in venous blood, both at rest (8.26±1.14 vs 7.28±1.13 mmol/l, p<0.001) and following exercise (8.45±1.09 vs 7.94±0.98 mmol/l, p=0.004). In both trials AUC across the postprandial period was greater when calculated from capillary in comparison to venous samples (both p=0.001). The magnitude of the capillary-venous difference in glucose concentration was reduced following exercise when compared to rest (0.18±0.11 vs 0.33±0.21 mmol/l, p=0.014).
CONCLUSION: Blood glucose values derived from different sample types are similar in the fasted state, however mean glycaemia is higher in capillary relative to venous whole blood when measured postprandially. The activity status of participants appears to influence the magnitude of this effect, with prior exercise reducing the capillary-venous difference following a meal. Thus it may not be appropriate to consistently apply published equivalence values or correction factors to interpret glucose measured in different blood compartments, and it is recommended that sample type is indicated when reporting values in order for appropriate interpretation of results to occur.

HABITUAL EXERCISE SUPPRESSES AGING-RELATED MUSCLE ATROPHY

KONNO, M., AOKI, K., SHIROMOTO, J., TOKINOYA, K., HONDA, K., TAKEKOSHI, K., OHMORI, H.

TSUKUBA UNIVERSITY

INTRODUCTION: It is well known that aging causes loss of muscle mass and strength, called sarcopenia (1). Declining mitochondrial function and increasing protein degradation are considered as factors of sarcopenia. Thus, promotion of mitochondrial function and suppression of protein degradation may contribute to prevent or alleviate sarcopenia. It is reported that the mitochondrial function improves by habitual exercise training (2). The aim of this study was to clarify whether habitual exercise could suppress a decrease of mitochondrial function and an increase of protein degradation with aging, leading to suppression of sarcopenia.
METHODS: Thirty mail SAMP 8 (senescence accelerated mouse prone 8) mice at 27 weeks age were allowed to acclimate to the environment for a week before the experiment. After acclimatization, these mice were divided into three groups : 28wks sedentary control group (28w Con), 44wks sedentary control group (44w Con), and 44wks habitual exercise group (44w EX) . The treadmill running was conducted in 44w EX mice at a speed of 15 m/min for 30 min at a frequency of 5 days per week for 16 weeks. 28w Con mice were dissected after acclimatization. 44w EX mice were dissected after the training period and 44w Con mice were dissected at the same timing as 44w EX mice. A grip strength test of limbs was conducted one day before dissection in each group. Soleus, gastrocnemius, and plantaris muscles were isolated from the hindlimb and weighed. The gastrocnemius muscle was instantly frozen with liquid nitrogen and stored at -80°C for biochemical measurements.
RESULTS: Respective wet weight of gastrocnemius and plantaris muscles was significantly lower in 44w Con than in 28w Con, but was not lower in 44w EX. The result of grip strength test was similar to that of muscle weight. Cox4, a gene involved in mitochondrial function, was significantly decreased in 44w Con as compared with 28w Con, but did not decreased in 44w EX. There was a significant increase in PGC-1α in 44w EX as compared with 28w Con. MuRF-1 and MAFbx, which are indicators of skeletal muscle protein degradation, did not change in 44w Con as compared with 28w Con, but a significant decrease was observed in 44w EX.

CONCLUSION: It was suggested that habitual exercise during the aging process could suppress the reduction of muscle mass and strength based on an increase of mitochondrial function and a decrease of protein degradation. In the future, we will further examine conditions such as exercise intensity and duration in order to explore the optimal exercise prescription for sarcopenia.

THE RELATION BETWEEN THE OBESITY INDEX AND BODY FATNESS ACCORDING TO AGE IN WOMEN

ODABAS, I., SUNA, N., GULER, L.
HALIC UNIVERSITY, SCHOOL OF PHYSICAL EDUCATION AND SPORT

INTRODUCTION: A lot of indexes have been used in order to define the obesity. The aim of the study was to examine the relation between body fatness according to age and the obesity indexes which have been used extensively today.
METHODS: A total 2860 women (1347 of them were aged 20-29; 1026 of them were aged 30-39; 487 of them were aged 40-49) participated in the study voluntarly. Anthropometric features were measured according to the Anthropometric standardization manuel in the study. Body mass index, waist hip ratio, conicity index, sum of trunk skinfolds (subscapular, chest, suprailiac, and abdominal) and sum of extremity skinfolds (triceps, biceps, thigh, and caf) were calculated. Body fat percentage values were calculated using Yuhazs formula. Normality test was used for the data in SPSS. Pearson correlation was used for the data which have a normal distribution and Spearman correlation was used for the data which do not have normal distribution($p<0,01$).
RESULTS: As a result, It was found a significant correlation between the body fatness of the group aged 20-29 and conicity index, sum of trunk and sum of extremities. Also there was a significant correlation between the BMI, conicity index, sum of trunk and sum of extremities of the groups aged 30-39 and 40-49 ($p<0,01$).
CONCLUSION: Obesity indexes can be used in order to determine the body fatness of adults according to the study results.

DIAGNOSING SARCOPENIA IN OVERWEIGHT PEOPLE

JUNGREITMAYR, S., RING-DIMITRIOU, S.
PARIS LODRON UNIVERSITY OF SALZBURG

INTRODUCTION: According to the EWGSOP (Cruz-Jentoft, 2010) diagnosing sarcopenia can be executed by using the combination of skeletal muscle mass (SMI), handgrip strength and gait speed. However the association of those markers is questioned (Spira, 2015). Thus we applied the proposed EWGSOP-algorithm in overweight and obese community dwelling people to check for its validity in this particular sample.
METHODS: Skeletal muscle mass (seca mBCA525), handgrip strength (Trailite, TL-LSC100) and habitual gait speed (Brower TS, USA) were assessed in 46 participants aged over 60y. SMI (Cruz-Jentoft, 2010) and body mass index were calculated after measuring height (seca217) and body mass (seca813). Individuals were divided into overweight (OW) and obese (OB) by WHO-BMI classification. In order to detect differences between groups t-tests with $p<.05$ were carried out.
RESULTS: Participants consisted of 21 OW (7 males, M: 72.3 y ± 5.7, BMI 27.7 kg/m² ± 1.2; 14 females, F: 71.9 y ± 9.1, BMI 27.3 kg/m² ± 1.3) and 25 OB (10 M: 71.5 yrs ± 6.9, BMI 33.3 kg/m² ± 2.7; 15 F: 70.2 y ± 5.7, BMI 35.5 kg/m² ± 3.6). Mean differences were found between OW and OB in SMI within sex with $p <.01$ (kg/m²; OW-M 8.8 ± 0.7 vs. OB-M 10.6 ± 1.0 and OW-F 6.9 ± 0.9 vs. OB-F 8.3 ± 0.9). No significant differences were found in grip strength (kg; OW-M 37.0 ± 9.7 vs. OB-M 37.4 ± 7.3 and OW-F 26.6 ± 5.6 vs. OB-F 25.6 ±7.1) and gait speed (m/s; OW-M 1.17 ± 0.23 vs. OB-M 1.16 ±0.2 and OW-F 1.21 ±0.23 vs. OB-F 1.1 ± 0.28). Based on SMI calculation, sarcopenia was found at higher rates (All: 41.3%, OW 57% and OB 28%) than in studies including all BMI categories (Spira, 2015). Using the EWGSOP algorithm, SMI combined with hand grip and gait speed, only 19.6% (OW+OB) would have been diagnosed with sarcopenia.
CONCLUSION: The analysis of algorithms revealed that neither habitual gait speed nor handgrip strength were sufficient to detect sarcopenia in community-dwelling individuals compared to the result found with SMI only. These results indicate the need of further research in regard to overweight and obese compared to normal weight people.

BARIATRIC SURGERY REDUCES AEROBIC EXERCISE CAPACITY

FAORO, V., FORTON, K., DEBOECK, G., DEREPPE, H.
FACULTY OF MOTRICITY SCIENCE

INTRODUCTION: Bariatric surgery has a considerable positive effect on weight loss and on metabolic and cardio-vascular risks. It has therefore been extensively used this last decade to overcome obesity. However, the impact of this surgery on aerobic exercise capacity and limiting factors remains unclear.
The aim of this study was to determine how weight loss, 1 year after bariatric surgery, affects the aerobic exercise capacity (VO2max).
METHODS: Fourty-two obese women (Age: 42 ± 12 years, weight : 114 ± 16 kg, BMI: 47 ± 4 kg/m2) underwent a cardiopulmonary exercise test (CPET) before and 1 year after bariatric surgery (weight : 78 ± 15 kg, BMI: 29 ± 4 kg/m2). Exercise was performed on a cycloergometer with an incremental increase of workload (W) of 15 Watt/min until exhaustion. Gas exchange (oxygen uptake (VO2), carbon dioxide release (VCO2)) and ventilation (VE) were measured continuously via a facial mask with additional measurements of heart rate (HR), blood pressure (BP) and arterial oxygen saturation (SpO2). The first ventilatory threshold (VT) was measured according to the V-slope method.

RESULTS: Bariatric surgery allowed for 36 ± 6 kg weight loss in a one year period. VO2max corrected for body weight was increased after weight loss (17 ± 3 vs 22 ± 4 ml/min/kg, p<0.001). However, VO2max was reduced by 10% after surgery when expressed in absolute value (1.9 ± 0.4 vs 1.7 ± 0.3 l/min, p<0.01).
The magnitude of the weight loss was correlated to the decrease in VO2max, maximal workload and maximal O2 pulse (R>0.31, p<0.05).
The ventilatory response to exercise and chemosensibility was not affected by weight loss as maximal ventilation, and the VE/VCO2 slope did not change.
Chronotropic response and the oxygen pulse remains constant after surgery suggesting no cardio-vascular affection.
A lower VT one year after surgery (72 ± 11 vs 65 ± 10 % of VO2max, p<0.01) with a higher respiratory exchange ratio (RER) (1.15 ± 0.08 vs 1.25 ± 0.10, p<0.001) suggest a muscular deconditioning.
The magnitude of the decrease in VO2max after surgery was directly correlated to the changes in VT, maximal O2 pulse (R>0.41, p<0.01) and inversely correlated to the changes in the end exercise RER (R=-0.54, p<0.001), suggesting a probable muscular limitation.
CONCLUSION: While bariatric surgery provides an important weight loss, the aerobic exercise capacity is reduced with no cardio-respiratory changes but a probable muscular deconditioning.

LEVELS OF CHOLESTEROL IN PATIENTS WITH CORONARY DISEASE AFTER A CARDIAC REHABILITATION PROGRAM

ROMERO-ARENAS, S.1, MARTÍNEZ-PASCUAL, M.2

1UNIVERSIDAD CATÓLICA DE MURCIA & 2HOSPITAL UNIVERSITARIO LOS ARCOS DEL MAR MENOR .

INTRODUCTION: Cardiac rehabilitation improves the control of cardiovascular risk factors and decreases the total and cardiovascular morbidity and mortality of patients with coronary disease. In this way, the objective of this study was to analyze the effect of a cardiac rehabilitation program on cholesterol levels of patients with coronary heart disease.
METHODS: All patients with coronary heart disease who participated in a cardiac rehabilitation program were recruited retrospectively between June 2015 and June 2016. The program included eight weeks of progressive physical exercise, recommendations on healthy diet and therapy with statins. The physical exercise program consisted of performing 40 minutes of aerobic exercise on cycle-ergometer, three days per week. Before starting the program, the participants performed an incremental cycling test with gas analysis, and the power output at the anaerobic threshold was obtained. The power output at the anaerobic threshold was used to determine the intensity of the exercise. The first four weeks the participants pedaled with a power output 10% lower than that achieved at the anaerobic threshold, and the following four weeks the participants pedaled with a power output 5% lower than that achieved at the anaerobic threshold. Before and after the cardiac rehabilitation program, a blood test was performed that included cholesterol levels. In addition, patients cholesterol levels were monitored 9 months after the end of the cardiac rehabilitation program. For the statistical analysis an ANOVA was performed.
RESULTS: Thirty-two patients were recruited for this study. After the program, patients improved total cholesterol levels (Pre: 156.3±54.8 mg/dl vs. Post: 123.4±30.1 mg/dl; p=0.001), LDL-cholesterol (Pre: 96.5±40.4 mg/dl vs. Post: 66.5±16.4 mg/dl; p<0.001), HDL-cholesterol (Pre: 37.0±8.1 mg/dl vs. Post: 41.2±12.0 mg/dl; p=0.018) and triglycerides (Pre: 143.9±121.4 mg/dl vs. Post: 101.6±36.7 mg/dl; p=0.049). The differences in the levels of LDL-cholesterol (p=0.001), HDL-cholesterol (p<0.001) and total cholesterol (p=0.040) persist after nine months of follow-up.
CONCLUSION: The participation of patients with coronary heart disease in a cardiac rehabilitation program over a period of eight weeks is associated with a decrease in total cholesterol, LDL-cholesterol and triglycerides levels, and an increase in HDL levels. The differences in the levels of total cholesterol, LDL-cholesterol and HDL-cholesterol persisted after 9 months of follow-up.

EXERCISE INTERVENTIONS AIMING TO IMPROVE CARDIORESPIRATORY FITNESS IN CANCER PATIENTS UNDERGOING ADJUVANT TREATMENT; A META-ANALYSIS OF RANDOMIZED CONTROLLED TRIALS

BJOERKE, A.C.H.1, SWEEGERS, M.2, BUFFART, L.M.2, RAASTAD, T.3, NYGREN, P.4, BERNTSEN, S.1,4

UNIVERSITY OF AGDER

INTRODUCTION: Cardiorespiratory fitness, defined as maximal oxygen uptake (VO2max), is generally lower in patients with cancer, compared to the healthy population. It is important to maintain functional independence, and higher VO2max is associated with higher survival. The aims of the present study were to investigate the effect of aerobic exercise on VO2max compared with usual care, and to determine whether frequency, intensity, duration and exercise volume affect training-induced changes in VO2max among cancer patients receiving adjuvant treatment.
METHODS: Medline and Embase through OvidSP were searched to identify randomized controlled trials examining the effects of aerobic exercise on VO2max in adult patients with cancer receiving adjuvant treatment. Only studies using maximum tests, directly or indirectly measuring VO2max were included. Two independent reviewers extracted data, and assessment of study quality was performed using TESTEX [1]. Effect sizes (ES) and differences across intervention characteristics were calculated using Comprehensive Meta-Analysis software. Exercise duration and exercise volume were analyzed with meta-regression.
RESULTS: 13 randomized controlled trials including 1175 patients with various cancer types, mostly breast, prostate or colon cancer or acute myeloid leukemia receiving adjuvant chemo-, radio- and/or hormone therapy were included. Exercise interventions significantly improved VO2max compared to controls (ES 0.46, 95% Confidence Intervals 0.27, 0.94). The duration of each exercise session (p=0.03) and total exercise volume (p=0.01) were significantly associated with improved VO2max. No other exercise characteristics were significantly associated with VO2max.
CONCLUSION: Results of the present study show that aerobic exercise interventions have beneficial effects on VO2max in patients with cancer undergoing adjuvant treatment. Interventions with larger exercise volumes as well as longer session durations resulted in largest improvements in VO2max. Whether there is a dose-response relationship between exercise intensity, frequency and VO2max has to be explored in future studies. Health professionals should encourage patients with cancer to be physically active from the time of diagnosis.

EXAMINING THE EFFECTS OF DIFFERENT EXERCISE MODALITIES AND INTENSITIES ON CEREBRAL BLOOD FLOW.

FURLONG, R.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Regular exercise positively effects brain health in both clinical and non-clinical populations. It is associated with increased cerebral blood flow velocity (CBFv), which is thought to induce positive cerebrovascular adaptation via shear stress and cyclic strain. The optimal exercise modality and intensity to maximally increase CBFv is yet to be identified. This study examined how exercise modality (running vs. cycling) effects CBFv at a range of exercise intensities, including high intensity interval training (HIIT).
METHODS: Participants completed in both modalities: two maximal oxygen consumption (VO2max) tests to determine workload for each modality, two 5-stage incremental tests (3-minute stages at 35%, 50%, 65%, 80% and 95% VO2max), and two HIIT tests ('Clinical model': four 4-minute bouts of exercise at 90% maximum heart rate (MHR)). The order of incremental and HIIT tests was randomised. Measures of middle cerebral artery velocity (MCAv) via Transcranial Doppler; oxygen consumption (VO2) and end-tidal carbon dioxide (CO2; Vyntus CPX metabolic cart) and heart rate were obtained. Blood velocity and respiratory data between incremental tests were compared using a 2-way ANOVA, while HIIT data within each modality was compared against the 65% VO2max stage data via a one-way ANOVA.
RESULTS: Preliminary findings from 6 completed participants indicates that 65% VO2max elicited the greatest change in MCAv from rest during running (up 13 cm/s) and cycling (up 8 cm/s) incremental tests; thereafter returning towards baseline resting values. These changes in MCAv were in line with the changes in end-tidal CO2 for both modalities. The first 4-minute running and cycling HIIT bout elicited the greatest increase in MCAv (15 and 10 cm/s, respectively), which were similar to those obtained during the 65% VO2max exercise stage (13 and 8 cm/s, respectively). However, subsequent HIIT bouts increased MCAv less (running: ~7 cm/s; cycling: ~2 cm/s for HIIT bouts 3 and 4) for both modalities.
CONCLUSION: These preliminary findings indicate that both running and cycling at 65% VO2max will maximally increase CBFv, increasing the stimulus for positive cerebrovascular adaptation. Further, a singular 4-minute HIIT bout may also provide the same, if not a greater stimulus for positive cerebrovascular adaptation via increased CBFv yet subsequent bouts of HIIT may elicit a lower stimulus for cerebrovascular adaptation (via shear stress and cyclic strain).

EFFECT OF INCREASED CENTRAL ARTERIAL STIFFNESS WITH RESISTANCE TRAINING ON CEREBRAL BLOOD FLOW PULSATILITY

NAKAMURA, N., KUBO, T., MURAOKA, I.

WASEDA UNIVERSITY

INTRODUCTION: Central arteries (e.g. the aorta and carotid artery) buffer blood flow pulsatility. Increased central arterial stiffness decreases buffer function and augments cerebral blood flow pulsatility, which leads to increased risk for cerebral microvascular damage. Resistance training (RT), in the form of moderate-to-high intensity exercises, has recently been recommended for the treatment of muscular hypertrophy and for maximizing strength. RT increases central arterial stiffness (Miyachi et al. 2004, Kawano et al. 2006), which may augment cerebral blood flow pulsatility. However, it is unknown whether increased central arterial stiffness with RT leads to augment cerebral blood flow pulsatility.
METHODS: Eighteen men (RT group: 9 men, 21±1 years; Control (CON) group: 9 men, 23±1 years) participated in the study. The B-stiffness index was measured in the right carotid artery as an index of central arterial stiffness, respectively. The pulsatility index (PI) was measured in the middle cerebral artery (MCA) using ultrasonography. All participants were subjected to these measurements before training and at 4 and 8 weeks after training. Subjects in the RT group completed 3 supervised RT sessions per week. During each training session, the subjects performed 3–5 sets of 6 exercises (leg press, bench press, lateral row, leg extension, shoulder press, arm curl) at 75% of 1 repetition maximal.
RESULTS: The B-stiffness index in the RT group was significantly increased at 4 and 8 weeks after training compared to that before training. In addition, the RT group demonstrated decreased arterial compliance. However, there was no significant change in PI throughout the study period. The B-stiffness index and PI in CON group were not changed throughout the study.
CONCLUSION: The present study showed that RT increased arterial stiffness and decreased arterial compliance 4 and 8 weeks after training. However, there was no significant difference in PI over this period. A previous study reported that increased central arterial stiffness and decreased arterial compliance with aging led to increased cerebral blood flow pulsatility (Tarumi et al. 2011). However, these parameters did not affect cerebral blood flow pulsatility under RT conditions. These results suggest that except central arteries may buffer cerebral blood flow pulsatility in this study.

POST-ISOMETRIC EXERCISE HYPOTENSION IS ASSOCIATED WITH INCREASED NITRIC OXIDE AND DECREASED LIPID PEROXIDATION

OLHER, R.R., SOUSA, I.R., SOARES, B.R., RIBEIRO, T.B., MELO, G.L.R., SOUZA, L.H.R., NEVES, R.P., ROSA, T.S., MORAES, M.R.

CATHOLIC OF BRASÍLIA UNIVERSITY

INTRODUCTION: Hypertension is known to be one of the major risk factors for heart disease in the world. On the other hand, recent scientific evidence suggests that isometric strength exercise (ISE) could be part of antihypertensive treatment. However, little is known regarding acute cardiovascular responses and the possible mechanisms involved in post-isometric exercise hypotension (PIEH) in hypertensive adults. Nitric oxide (NO-) and oxidative stress (OE) may be important elements involved in the pathophysiology of hypertension. The objective of the study was to investigate the acute effects of ISE on cardiovascular responses, NO- bioavailability and OE parameters in hypertensive adults.
METHODS: Fifteen adults with hypertension participated in the study [38.7 ± 9.1 years, 132.1 ± 8.0 mmHg of systolic blood pressure (SBP)]. Subjects were submitted to 5 sessions of ISE, being 2 in the leg-press 45°, 2 in the bench press and a control session. The sessions in each exercise consisted in: i) maximal voluntary isometric contraction (MVIC); ii) 4 sets x 1 contraction at 30% CVIM with 2 rest pause. For cardiovascular measurements, an automatic oscillometric BP monitor (Microlife, BPA100) was used. Venous blood was collected at rest,

immediately after the session and 60-min post-exercise for NO- analysis by the Griess method. The components of OE (Uric Acid, TBARS, TROLOX and SOD) were analyzed using commercial kits. For the statistical analysis, a repeated-measures ANOVA with Bonferroni post-hoc was used.
RESULTS: A significant reduction was observed in SBP (Δ = -5.27 ± 2.3 mmHg). A significant increase in plasmatic NO-bioavailability immediately after the ISE session was also observed (Δ = 23.94 ± 8.45 μL). Regarding OE parameters, TBARS (Lipid peroxidation) presented a significant reduction after the ISE session (Δ = - 094 ± 0.23 nmol / L), whereas uric acid, TROLOX and SOD showed no statistical differences. In comparison to the control session, no statistical differences were observed.
CONCLUSION: In conclusion, short duration ISE model elicited a decrease in reduction in lipid peroxidation, an increase in NO- bioavailability resulting in PIEH in adults with high blood pressure. Further studies should focus on the magnitude of blood pressure lowering and the cause-and-effect relationship between pro and antioxidant parameters.

DO YOUNG ATHLETES HAVE ALTERED VASCULAR STRUCTURE AND FUNCTION?

THOMANDL, L.1, WEBERRUß, H.1, SCHULZ, T.1, HOFMANN, H.1, OBERHOFFER, R.1

1: CHAIR OF PREVENTIVE PEDIATRICS, TECHNICAL UNIVERSITY OF MUNICH

INTRODUCTION: Physical activity (PA) reduces the risk of atherosclerosis and therefore cardiovascular diseases. Cardiorespiratory fitness positively influences cardiovascular health and is inversely correlated with subclinical markers of atherosclerosis (carotid intima-media thickness, cIMT, and arterial stiffness). Studies in adult athletes show that persistently increased vigorous PA can improve this correlation compared to moderate levels of PA. Therefore, the aim of this study is to investigate if young athletes already have an altered structure and function of the vascular system compared to the normal population.
METHODS: From November 2017 to February 2018, 39 healthy competitive athletes (32 boys) between 11 and 17 years were examined in our pediatric outpatient department. PA level was assessed using the activity questionnaire MoMo-AFB. IMT of the left and right common carotid artery is defined as parameter for arterial structure and was measured with B mode ultrasound according to AEPC-guidelines (Dalla Pozza et al., 2015). Arterial function was assessed with stiffness index (β), pulse wave velocity β (PWVβ), and elastic modulus (Ep) as measures for arterial stiffness, and arterial compliance (AC) as measure for elasticity by eTRACKING (M-mode). Age and sex independent z-scores were calculated according to Weberruß et al. (2015), comparisons with the normal population were calculated by one-sample t-tests (p=0.05).
RESULTS: Young athletes performed 12 different types of sports in total (endurance and muscular endurance) for 528.46±186.68 minutes per week. All participants showed a normal vascular structure (cIMT=0.48±0.04mm) and function (β=3.06±0.69, PWVβ=3.58±0.36m/s, Ep=34.73±8.84, AC=1.56±0.41). Compared to normal values, young athletes had significant lower z_PWVβ (-1.13±0.91), z_β (-0.92±0.89), z_Ep (-1.20±1.03) and higher z_AC (0.99±1.02), p<0.001 for all. z_cIMT did not differ significantly between athletes and the normal population (0.27±1.08, p=0.124).
CONCLUSION: Young athletes have a lower arterial stiffness, measured at the common carotid artery, compared to the normal population. However, arterial wall thickness tended to be higher in athletes. This may indicate a physiological adaptation of the vessels to persistently vigorous PA in young athletes. As most of the studies reporting reduced wall thickness in adult athletes refer to endurance exercise, strength sports is associated with higher wall thickness. Therefore, the tendency to increased cIMT in our study could be the consequence of additional strength training in muscular endurance sports. However, increased PA in children and adolescence improves vascular function.

EFFECTS OF EXERCISE DURATION ON PERSISTENT CEREBRAL OXYHAEMOGLOBIN LEVELS IN THE SUPPLEMENTARY MOTOR AREA AND PRIMARY MOTOR CORTEX AFTER MODERATE-INTENSITY CYCLING

TSUBAKI, A., MORISHITA, S., TOKUNAGA, Y., SATO, D., QIN, W., KOJIMA, S., ONISHI, H.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: Measuring cerebral oxyhaemoglobin changes in the supplementary motor area and primary motor cortex using near-infrared spectroscopy shows that the levels increase during moderate-intensity exercise and persist after the exercise . However, the effects of exercise duration on O2Hb persistence are unknown. We aimed to compare the effects of exercise duration on the persistence of O2Hb changes in SMA and M1 after moderate-intensity cycling exercise.
METHODS: We recruited healthy young volunteers to participate in this study. After an incremental exercise test on a cycle ergometer to determine VO2 peak, the subjects performed another cycle ergometer exercise on a different day. After a 3-min rest period, the exercise was initiated at a workload corresponding to 50% VO2 peak. The exercise continued for 10 min <8 women, 12 total subjects> and 20 min <9 women, 12 total subjects>, followed by a 15-min rest. Nine subjects <8 women> participated in both exercises. O2Hb levels in the SMA and M1 were measured using a 34-channel near-infrared spectrometry system. O2Hb level and other parameters were measured. The results were expressed as changes from the mean pre-exercise rest phase values and calculated every 60 s. To compare the effects of exercise duration on the persistence of O2Hb after exercise, the values measured during the 15-min post-exercise rest period were averaged, and an unpaired t-test was performed. Statistical significance was set at $p < 0.05$.
RESULTS: O2Hb levels increased to 0.042 ± 0.010 mM?cm in the SMA and to 0.053 ± 0.041 mM?cm in the M1 during the 10-min exercise period from pre-exercise rest, and increased to 0.055 ± 0.011 mM?cm in the SMA and to 0.069 ± 0.011 mM?cm in the M1 during the 20-min exercise period from pre-exercise rest. O2Hb values during the 15-min post-exercise rest period in the SMA were 0.023 ± 0.006 mM?cm after the 10-min exercise, and 0.040 ± 0.007 mM?cm after the 20-min exercise, and there were no significant differences
. In the M1 area, the O2Hb values during post-exercise rest were 0.027 ± 0.010 mM?cm after the 10-min exercise, and 0.052 ± 0.009 mM?cm after the 20-min exercise; there were no significant differences
CONCLUSION: An O2Hb incremental change was observed in both areas during the 10-min and 20-min 50% VO2 peak exercise. We also observed the persistence of O2Hb levels after exercise. However, the effect of exercise duration on the persistence of O2Hb changes in SMA and M1 were not detected.

THE EFFECT OF AEROBIC FITNESS AND BLOOD PRESSURE IN CORTICAL OXYGENATION AND DUAL TASK PERFORMANCE IN HEALTHY YOUNG ADULTS

GOENARJO, R.1, DUPUY, O.1, PEROCCHON, A.2, BERRYMAN, N.3, FRASER, S.4, BOSQUET, L.1

1: LABORATOIRE MOVE, UNIVERSITÉ DE POITIERS, FRANCE. 2: LABORATOIRE HAVAE, UNIVERSITÉ DE LIMOGES, FRANCE. 3: SPORTS STUDIES DEPARTMENT, BISHOP UNIVERSITY, CANADA. 4: INTERDISCIPLINARY SCHOOL OF HEALTH

INTRODUCTION: In daily life, mobility requires walking while performing a cognitive task. Although previous studies have evaluated dual task performance in young adults, few have evaluated the impact of aerobic fitness and blood pressure on dual tasking. The aim of this study was to evaluate the effects of aerobic fitness and mean arterial pressure (MAP) on prefrontal cortex (PFC) oxygenation during dual tasking in young adults.
METHODS: Twenty-four young adults were allocated according to their VO2peak using Metamax3b into 2 groups (high-fit, low-fit) then sub-grouped according to their 24-hour MAP (higher-MAP, lower-MAP). The submaximal continuous graded exercise test was performed on treadmill. Initial velocity was set at 5.6 km/h and the inclination was increased by 2% every minute until voluntary exhaustion. Cerebral oxygenation and changes in concentrations in deoxyhaemoglobin (HHb) in right PFC were assessed using fNIRS during dual tasking n-back test. On dual-tasking, cognitive performance was measured by counting the percentage of correct responses and gait performance was measured with an instrumented walkway system, GAITRite system. An analysis of variance (fitness x MAP x measures) was performed. The magnitude of difference was assessed by the Effect Size (ES)
RESULTS: Aerobic fitness had no effect on cerebral oxygenation in young adults ($p=0.46$; ES=0.44) but had a large effect on cognitive performance ($p<0.05$; ES=1.05). In low-fit group, MAP had a large effect on cerebral oxygenation ($p<0.05$; ES=0.84) and cognitive performance ($p<0.05$; ES=1.10). Mainwhile, in high-fit group, MAP had no effect on cerebral oxygenation ($p=0.76$; ES=0.18) nor cognitive performance ($p=0.82$; ES=0.13). Both MAP and aerobic fitness had no effect on motoric performance of dual tasking.
CONCLUSION: High-fit individuals, eventhough not showed greater decrease-in-HHb, as the most valid parameter for cortical activation (1), but had a better cognitive performance than young adults with low fitness levels. These condition suggest a more efficient brain processing in high-fit individuals (2). As cerebral blood flow and oxygenation are not independent of changes in blood pressure (3) and PFC oxygenation is related to cognitive performance (2), higher-MAP individuals, showed worse brain oxygenation and cognitive performance in young adults with low fitness levels. Those results seem to support that high aerobic fitness and lower-MAP are associated with greater oxygenation or efficiency in PFC and better cognitive performance in young adults.

THE CIRCULATING PLATELET MICROPARTICLE RESPONSE TO AN EXERCISE STRESS TEST IN OVERWEIGHT MALES

STOREY, A., HARRISON, M.

WATERFORD INSTITUTE OF TECHNOLOGY

INTRODUCTION: High intensity exercise in individuals with elevated cardiovascular risk causes a transient increase in platelet activity with a concomitant increase in the risk of thrombosis (Ikarugi et al., 2003). The number of circulating platelet microparticles (PMP), procoagulant platelet fragments formed during platelet activation, is transiently increased in response to strenuous exercise (Chaar et al., 2011) and may contribute to the exercise-induced increase in thrombotic potential. Being overweight is associated with platelet an endothelial dysfunction and overall elevated cardiovascular risk. The aim of this study was to determine if overweight adult males exhibit a greater exercise-induced PMP response compared to healthy weight males.
METHODS: Ten healthy weight (HW) and fifteen overweight (OW) males (body mass index HW =23.6 ± 0.51kg.m-2 and OW = 28.5 ± 0.61kg.m-2; age HW = 39 ± 4.5 and OW = 38 ± 4.8) completed a treadmill-based exercise stress test according to the Bruce protocol. Venous blood samples were taken pre-, post- and 1hr-post exercise, and platelet free plasma was analysed by flow cytometry for PMP. Nineteen subjects also underwent assessment of endothelial function by means of forearm post-occlusive reactive hyperaemia using venous occlusion strain gauge plethysmography.
RESULTS: Both groups displayed an increase in PMP concentration immediately post-exercise, which returned to resting levels at one hour. The relative increase in PMP from pre- to post-exercise not significantly different between the two groups (HW: 151 ± 76.3%, OW: 301 ± 282.6%, $p > 0.05$). No relationship was observed between the extent of PMP response and various indices of endothelial dysfunction or cardiovascular risk including blood pressure, blood glucose, total cholesterol, HDL, LDL, triglycerides, VO2max and 10 year risk SCORE.
CONCLUSION: The results of the present study support previous evidence of an increase in PMP in response to acute exercise. Being overweight does not modulate this response, which does not appear to be related to endothelial dysfunction or cardiovascular disease risk.

HEART RATE AND SESSIONAL RATING OF PERCEIVED EXERTION BASED ESTIMATIONS OF INTERNAL TRAINING LOAD IN YOUTH SOCCER PLAYERS

VAHIA, D., KELLY, A., KNAPMAN, H., WILLIAMS, C.

UNIVERSITY OF EXETER

INTRODUCTION: When exposed to the same external load, players experience different internal load resulting in varied adaptations in fitness. In adult soccer, Internal Training Load (ITL) is measured using Heart Rate (HR) and sessional Rating of Perceived Exertion (sRPE) scale, but has been under-utilised for youth soccer. Studies on youth soccer players range from only 6 to 16 weeks, reflecting a relatively small portion of the season. The present study investigated the in-season variation in correlation between HR and sRPE estimations of training load for adolescent soccer players, over an entire competitive season.
METHODS: Fifteen male professional adolescent players in a Football League Category 3 Academy were monitored for 7 months over a competitive season. Data was collected and analysed for 160 training sessions. HR was measured for the entire session and converted to

HR training load using Edwards method. sRPE was recorded 20 minutes after the end of the session. Within-participant correlations and Bland-Altman agreement plots for HR and sRPE were calculated for each month to analyse the variation over the season, and for individual players to analyse the validity of the scale. Fisher's r-to-z transformation was used to analyse the difference in correlation between months. Regression equations and standard errors were calculated to quantify the error estimate of reporting for the sRPE scale.
RESULTS: The overall correlation was r=0.64 (95%CI 0.60-0.68; p<0.001). Results showed large to very large correlations for all months, ranging from r=0.60 to r=0.70. Fishers r-to-z transformations found no significant difference between the monthly correlations. Bland-Altman plots showed an agreement of methods for each month as well as individual players. Error estimations report an error of 1 to 2 units in sRPE estimations by players, depending on the duration of the session.
CONCLUSION: We therefore conclude that sRPE is a consistent method of measure of internal training load for the entire season. The large data set and higher statistical strength of this study may provide a more accurate representation of ITL in youth soccer. Validity analysis found no bias in sRPE measurements when compared to HR for all players in the study. This study supports the use of sRPE as a valid and feasible measure of ITL in soccer, when compared to HR measures and there is no bias between the two measures.

RELEVANCE BETWEEN BLOOD VOLUME AND ENDURANCE PERFORMANCE OF FEMALE RUGBY PLAYERS

SUGIMOTO, N., KAMIJO, Y., KANATANI, K., KAWABATA, T.

ENVIRONMENTAL PHYSIOLOGY FOR EXERCISE

INTRODUCTION: The functions of the human circulatory system during exercise include maintaining skin blood circulation necessary for thermoregulation and increasing/maintaining blood flow to active muscles. When these functions are hindered due to higher exercise intensity or workload, retention of performance including judgment ability becomes difficult and may lead to injuries.
Although a highly positive correlation between blood volume and maximum rate of oxygen consumption of players of sports other than rugby has been reported to date, almost no research on the relevance between blood volume and endurance performance of rugby players can be found. This study clarifies the physiological significance of the effect of blood volume on endurance performance as an assessment of physical strength of female rugby players.
METHODS: -Subject: Six female rugby players in a club team in Japan
-Measurement of Blood volume: The subjects rested in a sitting position for 15 minutes in a room at a temperature of 28˚C, and had 7 ml of their blood drawn. Further, Evan Blue dye was injected, and another 7 ml of blood was drawn after 10 minutes. The hematocrit value and hemoglobin concentration was measured with whole blood, and dye concentration in plasma was measured by the absorption method after centrifugation.
-Endurance performance: Bangsbo's YOYO intermittent recovery test level 1
RESULTS: The blood volume of the six players was 63.06–71.46 ml/kg, and the YOYO score was 16.1–18.2.
CONCLUSION: Since repeated work and rest is a characteristic of the sport of rugby and the recovery performance after such actions can be measured on the field, the YOYO score was used as the index for endurance performance. Significant positive correlation with blood volume was also found in this study, and it may be considered that it also impacts recovery performance, given the characteristic of the sport. As a result of analysis by the players' positions, the backs showed higher values than the forwards. Of the results, the highest value was given by a player with the role of the scrum half in Rugby Sevens. These results suggest that the role during a game and amount of body fat impact blood volume and endurance performance.

MUSCLE DEOXYGENATION DURING RAMP TEST IS DEPENDENT ON THE ANGIOTENSIN-CONVERTING ENZYME GENE POLYMORPHISM AND ENDURANCE TRAINING STATUS

FITZE, D.P., FRANCHI, M.V., VALDIVIESO, P., FLÜCK, M.

BALGRIST UNIVERSITY HOSPITAL

INTRODUCTION: The angiotensin-converting enzyme gene insertion/deletion polymorphism (ACE I/D genotype) has been often linked to trainability of muscle-based traits of endurance and strength. However, the associations between the ACE I/D genotype and peak oxygen uptake (VO2peak) are not conclusive [1-3] whereas studies that have focused on skeletal muscle features had more success [4-7]. Near-infrared spectroscopy (NIRS) offers the possibility of non-invasive measurement of skeletal muscle oxygenation during exercise. Therefore, the aim of this study was to investigate the individual and combined effects of the ACE I/D genotype and endurance training status on markers of muscle oxygen saturation (SmO2) during ramp test.
METHODS: 21 healthy subjects (Male: n = 12, age = 28 ± 4 years; Female: n = 9, age = 25 ± 4) performed a ramp test and were screened for the ACE I/D genotype. During the ramp test, VO2peak was measured while SmO2 of the vastus lateralis muscle was assessed using a NIRS device. VO2peak was used to differentiate between endurance-trained (> 50 mL·min-1·kg-1) and untrained subjects (< 50 mL·min-1·kg-1). Individual and combined effects of the ACE I/D genotype and endurance training status on SmO2 markers during ramp test were analysed using two factor analysis of variance (ANOVA).
RESULTS: ACE I/D genotype showed no significant effect on any of the SmO2 markers during ramp test. Endurance training status had a significant effect on the markers SmO2 min (p = 0.017) and delta deoxygenation (p = 0.033) and a highly significant effect on the marker delta 1/2 reoxygenation (p = 0.007). In addition, there was a significant interaction effect between the ACE I/D genotype and training status on the marker slope deoxygenation (p = 0.028).
CONCLUSION: Possible confounders, such as gender and training status, may have influenced a potential individual effect of the ACE I/D genotype. As the depletion of oxygen concentration in contracting muscle is largely affected by contraction-induced mitochondrial oxygen consumption [8]; the observed greater muscle deoxygenation in trained subjects could indicate an increased oxidative capacity in vastus lateralis. Conversely, the larger reoxygenation reflects an improved capacity for muscle oxygenation in endurance-trained subjects. Carriers of the ACE I-allele have been shown to demonstrate superior increases in the volume density of subsarcolemmal mitochondria in response to endurance training [5]. The highly significant steeper slope deoxygenation for trained subjects of the ACE I/I genotype could indicate a higher percentage of slow-oxidative type I muscle fibres and thus a higher mitochondrial volume density in these subjects.

ADDITIVE EFFECTS OF AGING ON ENDOTHELIAL FUNCTION AND OXIDATIVE STATUS IN HYPERTENSION

MASODSAI, K., YANG, A.L.
UNIVERSITY OF TAIPEI

INTRODUCTION: The prevalence of hypertension has been increasing parallel with aging (Bromfield et al., 2014). Some evidences indicate that the decline in cardiovascular function and the increase in oxidative stress are associated with the aging process (Bolton & Rajkumar, 2011). However, whether aging additively affects endothelial function and oxidative status in hypertension remains unclear. Therefore, this study aimed to investigate the effects of aging on endothelial function and oxidative status in hypertension.
METHODS: The male spontaneously hypertensive rats (SHR) were randomly divided into 24- and 48-week-old SHR (24wk-SHR, 48wk-SHR) groups, while the age-matched Wistar-Kyoto (WKY) rats were served as the normotensive control (24wk-WKY, 48wk-WKY) groups. When all animals reached their age setting, the endothelial function, such as insulin-induced vasoactive response of isolated aortic rings, was evaluated by the organ bath system with force displacement transducers among four groups. Furthermore, the levels of oxidative stress (i.e. malondialdehyde, MDA) and antioxidant activity (i.e. catalase, CAT) were measured and compared among four groups.
RESULTS: Compared with the age-matched WKY groups, the insulin-induced vasorelaxation was significantly ($p < 0.05$) impaired in 24wk- and 48wk-SHR groups, respectively. In addition, it was significantly ($p < 0.05$) worse in the 48wk-SHR group compared with the 24wk-SHR group. After incubations of the inhibitors of nitric oxide synthase (NOS) and phosphoinositide 3-kinase (PI3K), the insulin-induced vasorelaxation was significantly ($p < 0.05$) reduced and not significantly different among four groups. The level of MDA was significantly ($p < 0.05$) higher in the 48wk-SHR group compared with the 48wk-WKY group, while the level of CAT was significantly ($p < 0.05$) reduced in the 48wk-SHR group compared with the 24wk-SHR group.
CONCLUSION: This study demonstrated that the older hypertensive rats had more severity in endothelium-dependent insulin-induced vasorelaxation together with the increased MDA level and impaired CAT activity. It suggested that aging could additively affect endothelial function in hypertension, which was partly through the oxidative status.

INTRODUCTION: Gene expression changes that occur acutely and chronically with resistance exercise (RE) training (RT) have substantial bearing on skeletal muscle adaptations. Exploratory methods can be used to investigate if known RE-modulated genes and new gene clusters are modulated acutely and chronically by RT. Thus, we investigated the effect of training status at rest and after acute RE on the global transcriptome of young men.
METHODS: Vastus lateralis muscle biopsies of nine young men (age: 26(2) y; BMI: 24(3) kg.m-2) who undertook lower limbs RT (six sets [three of 45° leg-press and three of leg extension exercises] of 9-12 maximum [to concentric failure] repetitions with 90s rest intervals) for 10-wk were collected pre- and 24h post-RE at the first (W1) and last (W10) weeks of training and analysed using microarray. Tests of differential expression were conducted for rested and after RE contrasts in both training states. To control for false discovery rate (FDR), multiple testing correction was performed at a cutoff of FDR < 0.05.
RESULTS: An unaccustomed RE bout (at W1) up-regulated muscle gene transcripts related to stress (e.g., heat shock proteins), inflammation, extracellular matrix and cytoskeleton remodelling, protein processing and turnover and ribossomal biogenesis. Trained muscles (at W10) became more metabolically efficient, favoring a more oxidative metabolism, showed refined response to stress, with better antioxidant and immune responses, and up-regulated gene transcripts related to extra-intra cellular signalling transmission, muscle scaffold organization, development and growth. In the rested condition, the 500 most expressed genes show inter-subject variability, which is increased after acute RE irrespective of training state.
CONCLUSION: Changes in gene transcripts reflected the high stress promoted by an unaccustomed RE, relating to muscle remodelling, inflammation, high protein metabolism and increased translational capacity. As RT progresses, muscles showed energy efficiency, promptness to respond effectively to stress, structural reinforcement, improved muscle contraction efficiency, and development of myofibrillar hypertrophy. Between-subject variability in the transcriptome response is increased with RE performance regardless of training state, which is in accordance with a large inter-subject variability in both the response to muscle damage/stress in an untrained state (1) and to muscle hypertrophy after an RT period (2). In conclusion, global gene expression analyses showed that chronic repetition of RE increases muscle efficiency to respond more focused and accurately to RE-induced stress; still, inter-individual variability is high regardless of training state, especially in response to RE.

REGULATORS OF THE ANGIOGENESIS PATHWAY AND RISK MODELS FOR ANTERIOR CRUCIATE LIGAMENT RUPTURES

RAHIM, M., LACERDA, M., COLLINS, M., POSTHUMUS, M., SEPTEMBER, A.V.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: Previous studies have identified independent and haplotype associations within the genes encoding vascular endothelial growth factor (VEGFA) and its receptor kinase insert-domain receptor (KDR) with risk of anterior cruciate ligament ruptures and Achilles tendinopathy. The aim of this study was to explore the angiogenesis signalling pathway within the context of the more complex matrix remodelling pathway, following a pathway-based approach. Evidence suggests that the interleukins (IL-1β and Il-6) may upregulate the angiogenic response. Statistical modelling tools were used to develop a preliminary polygenic risk assessment model for ACL ruptures, incorporating the angiogenesis genes (VEGFA and KDR) and cell signalling molecules (IL1B, IL6, IL6R) which also function to regulate angiogenesis.
METHODS: A total of 232 asymptomatic controls (CON) and 234 participants with surgically diagnosed anterior cruciate ligament (ACL) ruptures, of which 135 participants reported a non-contact mechanism of injury (NON subgroup), were previously genotyped for the selected polymorphisms. Multivariate logistic regression analysis was used to identify the most informative contributors to ACL rupture risk from a range of eleven potential intrinsic risk factors: age, sex, BMI and eight genetic polymorphisms within five genes, namely, IL1B rs16944 C/T, IL6 rs1800795 G/C, IL6R rs2228145 C/A, VEGFA rs699947 C/A, VEGFA rs1570360 G/A, VEGFA rs2010963C/G, KDR rs2071559 A/G and KDR rs1870377 T/A.
RESULTS: The polygenic risk model identified the VEGFA rs699947 CC genotype (p=0.024, odds ratio (OR): 3.35, 95% confidence interval (CI): 1.17 – 9.62), rs2010963 GC genotype (p=0.049, OR: 2.43, 95% CI: 1.00 – 5.87), age (p=0.009, OR: 1.09, 95% CI: 0.57 – 2.11) and BMI (p=0.011, OR: 0.97, 95% CI: 0.95 – 0.99) as the most significant predictors of ACL rupture risk from the data included.
CONCLUSION: The results of this study highlight VEGFA, age and BMI as biologically significant components of this network requiring further investigation in the context of musculoskeletal soft tissue injury risk.

CHANGES IN FREE- AND EXOSOME-ASSOCIATED CIRCULATING MIRNAS AND MYOKINE PROFILE IN PROFESSIONAL SKY-RACERS DURING THE GRAN SASSO D'ITALIA VERTICAL RUN

LOMBARDI, G., FARALDI, M., SANSONI, V., PEREGO, S., GOMARASCA, M., BANFI, G.

I.R.C.C.S. ISTITUTO ORTOPEDICO GALEAZZI

INTRODUCTION: A first step in the adaptation to exercise is the modification of the gene expression profile leading to changes in the level of those molecules associated with skeletal muscle activity and energy metabolism, e.g., myokines, as well as those molecules involved in their transcriptional regulation, e.g., microRNA (miRNA). Since little is known about the exercise-dependent modifications on their expression, this study was aimed at studying the influence of strenuous exercise on circulating miRNA and their possible association with the myokine response.
METHODS: Pre- and post-race plasma samples were collected from 14 male athletes participating in a vertical run (+1000m gain, 3500m length) held in summertime at Gran Sasso d'Italia. Free- (f-miRNA) and exosome-associated (e-miRNA) circulating miRNAs were extracted from pooled plasma. A panel of 179 miRNAs, the most expressed in circulation, was assayed in triplicate by real-time PCR and analyzed by Exiqon GenEx v6. Relative expression was calculated by the 2-ΔΔCT method and normalization was made on the averaged value of the whole analysis. miRNAs associated with skeletal muscle activity and metabolism (myo-miRNA, according to mirDB) whose level was ≥5-fold up- or down-regulated in both free and exosome fractions were analyzed in triplicate in each single. Samples were assayed for a panel of 11 myokines by a magnetic bead-based multiplex immunoassay (interleukin-6 [IL-6], IL-15, irisin, fatty acids-binding protein 3 [FABP3], fibroblast growth-factor 21 [FGF-21], oncostatin [OSM], leukemia inhibitory factor [LIF] follistatin-like 1 [FSTL1], myostatin).
RESULTS: 47 f-miRNA were up-regulated and 7 down-regulated while amongst the e-miRNA 24 were up-regulated and 14 down-regulated; of these only 11 miRNAs were changed in both fractions. Among these, f- and e-myo-miRNAs (miR-143-3p, miR-29a-3p, miR-30a-5p, miR-424-5p, miR-485-3p and let-7e-5p) were analyzed in each single sample. The analysis show that these miRNAs were differentially modulated within the two fractions by the effort. Strenuous exercise affects the expression of myokines involved in energy metabolism (IL-6, IL-15, FABP3, FGF-21) inflammation (IL-6, OSM, LIF) and muscle anabolism (FSTL1) while it did not affect irisin and myostatin. There were significant correlations between the circulating levels of myokines and miRNA: all f-miRNA, except miR-424-5p, correlated directly with IL-6, IL-15, FABP3, FSTL-1, and OSM; among e-miRNAs, miR-485-3p correlated directly with IL-6, IL-15, LIF, FSTL-1, OSM, and indirectly with FGF-12 while let-7e-5p correlated directly with OSM.
CONCLUSION: These results indicate that whole-body adaptation to exercise is tightly regulated by miRNAs, other than myokines.

THE PREVENTIVE EFFECT OF VOLUNTARY PHYSICAL EXERCISE ON MENTAL DISORDERS IN HIGH-FAT-DIET-MICE

OYANAGI, E., WATANABE, C., KOBIKI, N., UCHIDA, M., KREMENIK, M.J., YANO, H.

KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Obesity, which is a major social problem not only in industrialized countries but also in developing countries, is regarded as one of the risk factors of mental health. Recently, it has been reported that gut microbiota might be an inducer of mental disorders. On the other hand, exercise, which is effective for preventing the onset of obesity, also causes a change in the gut microbiota. In addition, exercise habits might be effective for the prevention of mental disorders. However, it remains unclear whether or not mental disorders can be prevented via exercise habits. Therefore, in this study, we examined the effect of voluntary physical exercise on mental disorders in response to a high-fat-diet using a mouse model.
METHODS: 4-week-old male C57BL/6 (n=27) mice were divided into two groups: control diet (CD) and high-fat-diet (HFD).Then, each group was treated with or without voluntary wheel running (W and control: C) for 10 weeks. After that, anxiety behavior tests (open field test, marble burying test, forced swim test, and sucrose preference test) were carried out. The animals were euthanized after these behavior tests, and the collected brain tissue was measured for mRNA expression of brain-derived neurotrophic factor (BDNF), neuropeptide Y (NPY), interleukin-1beta (IL-1β) and IL-6 by real-time RT-PCR.
RESULTS: Body weight in the HFD group was significantly higher than that in the CD group. And, in both groups, weight gain suppression by the W condition was observed. In the open field test, the staying time in the central part of the field was significantly longer under the W mice compared with C mice in both groups. Although, in the marble burying test, the anxiety behavior increased under the W condition in both groups, the floating time of the W mice in the forced swimming test was shorter than that of the C mice in both groups. The result of the sucrose preference test showed that a significant low value in the HFD group and no effect of exercise was observed. BDNF and

NPY gene expression of the brain in the HFD group were significantly lower than those in the CD group, but the effect of wheel running was no observed.
CONCLUSION: It might clarify the effect of voluntary wheel running on the anxiety behaviors of high-fat diet fed mice by using various anxiety behavior tests.

AEROBIC EXERCISE INHIBITS TAU HYPERPHOSPHORYLATION THROUGH ACTIVATION OF THE PI3K/AKT PATHWAY IN THE HIPPOCAMPUS OF APP/PS1 MICE

FANG, G.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Many studies suggest that regular physical exercise can reduce the risk of Alzheimer's disease and slow its onset and progression. However, the exact mechanism is still unclear. Clinically, Alzheimer's disease is characterized by the presence of extracellular amyloid plaques and intraneuronal neurofibrillary tangles, which are associated with amyloid-β and tau hyperphosphorylation respectively. The PI3K/Akt signaling pathway regulates tau phosphorylation and plays a pivotal role in the development of pathology in Alzheimer's disease. Here we investigated the effects of aerobic exercise on tau phosphorylation and examined whether these effects were mediated by the PI3K/Akt pathway in the hippocampus of APP/PS1 transgenic mice.
METHODS: 40 male APP/PS1 transgenic mice were randomly divided into four groups: sedentary group , exercise group , sedentary with GNE-317 treatment group and exercise with GNE-317 treatment group . GNE-317 is a potent and selective PI3K/Akt pathway inhibitor that can cross the blood-brain barrier and show effective suppression of Akt phosphorylation in the mice brain. The mice in the T-EX and T-EXG groups were given exercise training on a treadmill for 5 days/week for 8 weeks with 0% grade, and progressively ran from 30 min/day at 12 m/min, up to 60 min/day at 15 m/min. The mice in the T-SE and T-SEG groups were placed individually on another treadmill at 0 m/min for the same duration. 48 hours after the last exercise bout, all mice were intraperitoneally injected an anesthetic for inducing anesthesia, and the hippocampus were rapidly extracted. The protein and phosphorylation levels of tau, PI3K, Akt and GSK3β were assayed by Western blot and immunohistochemistry. The cognitive function were tested by morris water maze.
RESULTS: We found out that 8 weeks of aerobic exercise reduced tau phosphorylation at multiple sites including Ser202, Thr231 and Ser396, and increased phosphorylation of Akt at Thr308 and Ser473 and of GSK3β at Ser9. Furthermore, in the morris water maze test, the exercise group showed a reduced escape time and distance compared with those of the sedentary group, suggesting that aerobic exercise improved learning and cognitive ability. While the above-mentioned results were attenuated in the PI3K/Akt inhibitor GNE-317 treatment groups.
CONCLUSION: Our study demonstrated that aerobic exercise could inhibit tau hyperphosphorylation and improve cognitive funtion through activation of the PI3K/Akt pathway in the hippocampus of APP/PS1 mice.

ACUTE AND LONG-TERM EFFECTS OF BLOOD FLOW RESTRICTED TRAINING ON HEAT SHOCK PROTEINS: COMPARISON BETWEEN A FAILURE AND A NON-FAILURE PROTOCOL

HODY, S.1, CUMMING, K.T.2, WERNBOM, M.3, BJØRNSEN, T.4, PAULSEN, G.2,5, RAASTAD, T.2

1: ULG , 2: NSSS ; 3: GU , 4: AG , 5:NIF

INTRODUCTION: The stress imposed on muscle fibres during low-load blood flow restricted resistance exercise (BFRRE) performed to failure seems to preferentially stress type I fibres (Cumming et al., 2014). Therefore, the aim of this study was to compare the effect of a failure (FA) vs non-failure (NON-FA) BFRRE protocol on heat-shock protein responses in the exercising muscles.
METHODS: Sixteen untrained men (18-45yrs) completed 14 BFRRE sessions divided into 2 blocks of 7 sessions in 5 days, interspersed by 10 days of rest. Legs were randomly assigned to either FA (4 sets to voluntary failure) or NON-FA protocol (30-, 15-, 15-, 15 reps) using unilateral knee extensions at 20% of 1RM with 30s rest between sets. BFRRE was conducted with partial blood flow restriction (100 mmHg) induced by a 15cm wide pressure cuff. Muscle biopsies were collected before, during and post intervention and analysed for αB-crystallin (αBc), HSP70 and MHC by immunofluorescence.
RESULTS: Relative to pre-exercise, an increase in αBc staining intensity (reflecting cytoskeletal bound proteins) was observed 2h post-exercise in type I and type II fibres for both legs (FA: 261 ± 194 and 202 ± 118%, $p<0.01$, respectively; NON-FA: 181 ± 118 and 162 ± 88%, $p<0.05$, respectively). At the acute phase, HSP70 staining intensity also showed an increase in type I fibres for both legs (FA: 136 ± 64%; NON-FA: 132 ± 44; $p<0.05$), but only NON-FA legs displayed an increase in HSP70 staining intensity in type II fibres (FA: 123 ± 52%, NS; NON-FA: 148 ± 57%; $p<0.01$).
During the rest week (11 days after the first session), both legs showed an increase in αBc staining intensity in type I (FA: 140 ± 55%, $p<0.01$; NON-FA: 128± 63%, $p<0.05$), but not in type II (FA: 140 ± 92%; NON-FA: 119 ± 82; NS). At this timing, only FA legs showed an increase of HSP70 in both type I and type II fibres (FA: 218 ± 224% and 172 ±115%, $p<0.01$, respectively; NON-FA: 128 ± 40% and 134 ± 102%, NS, respectively). No significant differences were found ten days post intervention.
Interestingly, significant differences between legs were found in the acute and long-term HSP responses for type I fibres. These fibres showed higher staining intensity of αBc 2h after the first session and of HSP70 during rest period in the FA legs compared to NON-FA legs ($p<0.05$).
CONCLUSION: The immunostaining analyses indicate that cytoskeletal proteins are stressed in both fibre types after the first session of both BFRRE protocols, with a higher stress response in type I fibres after FA protocol than after NON-FA protocol.

EFFECTS OF 12 WEEKS AEROBIC EXERCISE, WITH OR WITHOUT CALORIC RESTRICTION, ON MITOCHONDRIAL FUNCTION, MITOPHAGY AND THE MTORC1 SIGNALING PATHWAY IN SKELETAL MUSCLE OF AGING RATS

WEN, L., ZHANG, J., LIN, X., ZHAO, Y.Q., YU, M.C., ZHANG, Y.

TIANJIN UNIVERSITY OF SPORT

INTRODUCTION: It has been reported that both aerobic exercise and caloric restriction has benefit effects on improvement of a decreased mitophagic capacity due to aging muscle. However, there is no report on whether that was regulated by the mTORC1 (mammalian target of rapamycin complex 1) signaling pathway. The aim of this study was to examine the effects of aerobic exercise, with or without caloric restriction, on the mitophagy and mitochondrial function and the expression of proteins involved in the mTORC1 signaling pathway in the skeletal muscle.

METHODS: 21-month SD rats were allocated into 4 groups (n=8 in each): control (C), calorie restriction (CR, 60% diet of C group), treadmill exercise (E), and calorie restriction and treadmill exercise (CR+E). During the entire protocol, treadmill parameters were set as the belt speed of 15m/min and the slope of 5◦. The exercise intensity was at approximately 64% VO2 max. The E and CR+E groups were given the corresponding exercise with 1 hour per session, 5 sessions per week, for 12 weeks. Under anaesthesia, soleus muscles were collected24 h after the last session. Mitochondria were isolated immediately from a part of muscles by differential centrifugation. Oxygen electrode method was used to detect mitochondrial oxygen consumption. The respiratory control rate (RCR) was the ratio of ST3 (oxygen consumption rate after ADP) to ST4 (ADP-free oxygen consumption rate). The left muscles were stored in -80°C for the analysis of protein expression (including AMPKα,p-AMPKα（T172）, mTOR, p-Raptor, ULK1, p-ULK1（S757）, p-ULK1（S555）, LC3, p62, Parkin and BNIP3) by western blotting later.
RESULTS: There was a significant decrease in both the mitochondrial ST3 and ST4 respiration rate in the CR and the mitochondrial ST4 respiration rate in the CR+E (both P<0.01, by one-way ANOVA), and a significant increase in the mitochondrial ST3 respiration rate in the E (P<0.05), the mitochondrial ST4 respiration rate, the RCR and the activity of mitochondrial ATP synthase in the E (all P<0.01), as compared to the C respectively. The mitochondrial ST3 and ST4 respiration rate were significantly reduced in the CR+E (P<0.01) as compared to that in the E. The mitochondrial ST3 respiration rate was significantly increased (P<0.01), while the mitochondrial ST4 respiration rate was significantly decreased in the CR+E (P<0.01) as compared with that in the CR. The CR had an increased p-AMPK α and p-Raptor, while a reduced ULK1-757 and p62, than the C respectively (all P<0.01). However, both the E and the CR+E had a higher p-Raptor, while a lower of both ULK1-757 and BNIP3 than the C. p-AMPK αwas significantly decreased, while ULK1-757 was significantly increased in the CR+E, as compared to that in the CR (P<0.01).
CONCLUSION: Both aerobic exercise and caloric restriction could lead to an increase of mitophagy, which is the essential process for the maintenance of mitochondrial structural integrity. That may have an effective effect on the prevention of reduced skeletal muscle mitochondrial function from aging. This study indicated that the mTORC1 signaling pathway may play an important role in the promoting mitophagy resulted from aerobic exercise or caloric restriction.

THE EFFECT OF ACUTE EXERCISE ON T CELL VITAMIN D RECEPTOR (VDR) EXPRESSION IN YOUNG AND OLDER MALES

LITHGOW, H., FLORIDA-JAMES, G., ROSS, M., BARLOW, P., LEGGATE, M.
EDINBURGH NAPIER UNIVERSITY

INTRODUCTION: A low vitamin D status has been identified as an association risk factor in the etiology of numerous chronic diseases, with older adults identified as generally more deficient than younger populations. Exercise has been shown to act as a direct and indirect stimulus on key vitamin D metabolites, specifically the vitamin D receptor (VDR) (1, 2), however investigations are limited to murine model studies.
METHODS: The primary aim of the study is to explore whether a single bout of exercise upregulates VDR expression in circulating systemic T cells. Healthy young (n=11, age: 27 ± 2 y, BMI: 26.2 ± 3.5 kg/m2), young-mid (n=10, age: 39 ± 6 y, BMI: 25.2 ± 1.9 kg/m2) and older (n=12, age: 67 ± 4 y, BMI: 25.9 ± 2.9 kg/m2) male adults performed three trials: a single bout of resistance exercise (repeated maximal voluntary isometric contractions), a bout of endurance exercise (60 min cycling at 55% work load max), or a control trial (no exercise –60 min rest). Intravenous blood samples were collected pre- and post-exercise (0, 1, 3 hours) and analysed for cell-surface and intracellular T cell (CD3, CD4, CD8 T cell subsets) VDR expression via flow cytometry analysis.
RESULTS: The results are pending following analysis of the completed data set.
CONCLUSION: The findings could support exercise as a strategy to improve the orchestration of vitamin D metabolism through its main mediator the VDR, particularly in older adults whom are more deficient. Upregulating VDR receptor expression can alter gene transcription and thus regulate protein synthesis (3), therefore playing a mediating role in the prevention, development and progression of chronic diseases.

MO-PM19 Thermoregulation

EFFECT OF ACUTE HEAT EXPOSURE ON INDOOR ROWING PERFORMANCE AND PACING IN AMATEUR ROWERS

OHAGAN, C., ORME-SMITH, M.
SHEFFIELD HALLAM UNIVERSITY

INTRODUCTION: Exercising in hot and humid environments presents a greater cardiovascular challenge than in temperate conditions. This can result in a decrease in performance, which is particularly likely in athletes unaccustomed to hot conditions. Previous research in cycling and running time trials has found that decreased performance is often accompanied by changes in pacing strategies, as afferent feedback from internal and environmental sensations affect conscious control of the athletes distribution of effort across the exercise bout. The aim of this study was to investigate the effect of acute exposure to high environmental temperature on performance and pacing of a 2000m indoor rowing trial in amateur rowers.
METHODS: Eighteen amateur club rowers (females: n = 14, age = 30 ± 14 years, stature 170 ± 5 cm, body mass 68 ± 7 kg; males: n = 4, age = 19 ± 1 years, stature = 184 ± 2 cm, body mass 84 ± 12 kg, (all values shown as mean ± standard deviation)) completed three 2000 m trials on an indoor rowing machine; two in moderate environmental conditions replicating a typical summer day in the United Kingdom (MOD) (20.5 ± 1.2 C, 34 ± 8 % relative humidity) and one in conditions replicating an unusually hot summer day in the United kingdom (HOT) (30.4 ± 0.6 C, 49 ± 2 % relative humidity). During the trials, participants received no feedback except verbal indication of distance remaining after 500m, 1000m and 1500m of the trial. Heart rate was recorded throughout the trial, ear canal temperature and blood lactate concentration were measured immediately after completion of the trial. Reliability of the performance test was assessed by calculation of the typical error (TE); the effect of environmental conditions on performance, pacing and physiological variables was assessed by paired t-tests
RESULTS: Performance (time to complete) was worse in the hot condition (MOD: 489 ± 48 s, HOT: 498 ± 46 s, $p < 0.01$); the mean difference between conditions (8.7 s) was greater than two times the typical error obtained from repeated trials in the moderate condition (TE: 4.3 s), suggesting that the observed difference was both statistically significant and real. Pacing pattern (percentage of total time used to complete each 500m segment of the trial) did not differ between conditions. End-trial ear canal temperature was higher in the hot condi-

tion (MOD: 36.5 ± 0.7) C, HOT: 37.1 ± 0.6 C, p = 0.02); there were no between-condition differences in average heart rate during the trial or end-trial blood lactate.
CONCLUSION: This study found that in amateur athletes, 2000m rowing performance was decreased in hot and humid conditions compared to moderate environmental conditions. As this was not accompanied by a change in pacing profile, it is likely that the decreased performance was due to cardiovascular limitations or a self-selected conservative effort throughout the trial rather than changes in pacing strategy.

EVALUATION OF A NOVEL SHORT TERM HEAT ACCLIMATION PROTOCOL USING FAN COOLING

YUTA, M.1, SADAYOSHI, S.1, KEI, N.2, NORIKAZU, H.3

WASEDA UNIVERSITY

INTRODUCTION: Heat acclimation(HA) lessens a risk of heat stroke during exercise in heat. As a protocol inducing HA, continuous exercise of which intensity is gradually increased from lower to higher level is recommended. However, when applying the protocol to training in heat, we could not give athletes high enough intensity of exercise due to a possible risk of heat stroke. The present study aimed to evaluate effect of fan cooling on the HA protocol. We hypothesized that the fan cooling during the HA protocol enables athletes to conduct high intensity exercise with successful HA.
METHODS: Seventeen adult males were divided into two group with or without fan-cooling (FAN and CON, respectively) during HA protocol. At least one wk before the HA protocol, heat tolerance test (HTT) was conducted: 120-min walking on a treadmill at 5km/h and 2% grade in an environment of 40℃ and 40% RH. Rectal temperature(Tre), heart rate(HR), local sweat rate (LSR), and Na+ concentration of sweat([Na+]) were measured. The HA protocol consisted of 5 exercise days and in between 4 resting days. On the exercise day, subjects were asked to perform 6 bouts of high intensity exercise which consist of 5s maximum sprints, jogging at 50% of VO2max for 105s, and 10s rest using ergometer. Tre and HR were monitored during the exercise period. Fan-cooling was applied during entire exercise period in the FAN group. The HTT was repeated within 3 days after the completion of the HA protocol. Exercise in the HA protocol and HTT were ceased when Tre reached 39 ℃.
RESULTS: In the FAN group, walking time in the HTT became longer after the HA protocol (from 102.7 ± 17.7 to 120.0 ± 0.0 min). However, the time remained unchanged in the CON group (from 108.8 ± 18.7 to 111.3 ± 16.2 min). In the FAN group, Tre at the end of the HTT was lower after the HA protocol(from 38.4 ± 0.3℃ to 38.0 ± 0.4℃); however, the Tre was unchanged. LSR increased and [Na+] decreased after the HA protocol only in the FAN group. The total duration of the HA protocol was greater in the FAN than in the CON group (286.0±22.8 and 187.8±53.9 min, respectively).
CONCLUSION: We found that the fan cooling increased the efficiency of the HA protocol. On the contrary, when the fan cooling was not utilized, no effect of the protocol was observed. We speculated that 3 factors of the fan cooling were associated with the efficiency: i) total duration of exercise, ii) coducted time of higher intensity of exercise, and iii) net period that higher Tc was maintained. The present study showed that fan cooling enables the efficiency of the short-term HA protocol. In addition, even in a hot environment on a field, the protocol could be conducted with minimizing the risk of heat stroke. We must further investigate physiological and psychological mechanisms involved in the prolonged exercise duration and obtaining HA.It was shown that HA occurs by using fan-cooling in the 5-day HA training with high intensity exercise.

EFFECTS OF A COOLING GLOVE AND JACKET ON REPEATED SPRINT PERFORMANCE AND MANUAL DEXTERITY IN THE HEAT

MARONI, T., WALLMAN, K., DAWSON, B., DENNIS, M., BRADE, C., NAYLOR, L.

UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Team-sport players often use cooling modalities during breaks in play to attenuate an elevated core temperature (Tc) and improve subsequent exercise performance. Hand cooling represents a simple and practical cooling method that is easily transported and applied in the sporting field for reducing Tc. However, the effect of hand cooling on subsequent repeat-sprint performance or in comparison to other cooling modalities commonly used in team sport is unknown. Therefore, this study aimed to assess the effectiveness of using a cooling glove (CG) and a cooling jacket (CJ), used separately and combination, compared to no cooling (NC) during a half-time break in reducing Tc in hyperthermic athletes and then to assess the effects of this cooling on subsequent repeated-sprint exercise and manual dexterity performance (Purdue Pegboard Test) in hot/humid conditions.
METHODS: Twelve, non-heat acclimatised, male team-sport athletes performed four experimental trials (within subjects, counterbalanced design) consisting of 2 x 30 min halves of repeated-sprint cycling bouts, separated by a 20 min half-time break, all performed in heat (35.0±1.2°C, 52.5±7.4% RH). During half-time, participants undertook 15 min of cooling using either: (1) the CG, (2) the CJ, (3) combination of CG and CJ (CG+J) and (4) a NC control. This half-time duration is similar to that used in Australian football, rugby union, soccer and hockey. Additionally, manual dexterity was assessed at baseline and immediately following both exercise bouts and the cooling period (all in the heat).
RESULTS: No differences were found between trials for gastrointestinal core temperature (Tg) (p)0.05), however, moderate to large effect sizes (d=0.53-0.74) were found for absolute change in Tg and cooling rates (°C/min) between CJ and NC at 5, 10 and 15 min of cooling. No significant differences were found for mean skin temperature (Tsk) cooling between trials however at the end of half-time participants reported a lower thermal sensation whereby they felt 'cooler' wearing CG+J compared to NC (p(0.05). The CG+J trial also resulted in reduced sweat loss compared to all other trials (p(0.05), however, there were no differences were seen between trials for power and work performance variables assessed in the second half of exercise (p)0.05). Additionally, manual dexterity performance was not impaired following cooling with the CG (p)0.05).
CONCLUSION: In conclusion, the use of the CG, CJ or CG+J during a 15 min half-time break of prolonged repeated-sprint cycling in heat did not significantly further decrease Tg compared to NC in team-sport athletes, nor did use of these cooling modalities result in improved subsequent exercise performance. Furthermore, manual dexterity was not impaired after 15 min of cooling using the CG.

WEARING A COOLING VEST DURING HALF-TIME IMPROVES INTERMITTENT EXERCISE PERFORMANCE IN THE HEAT

CHAEN, Y.

HIROSHIMA UNIVERSITY

INTRODUCTION: Endurance and intermittent exercise performance are impaired by high ambient temperatures. Various countermeasures are considered to prevent the decline in exercise performance in the heat, convenient and practical cooling strategies attracts attention. The purpose of this study was to investigate the effect of wearing a new type of cooling vest which coolded torso and neck during half-time on intermittent exercise performance that imitated intermittent athletic games.
METHODS: All measurements on the experiments were carried out with the bicycle ergometer. Eight male soccer players performed a familiarization session and two experimental trials of a 2 × 30 min intermittent cycling exercise protocol, which consisted of a 5s maximal power pedaling (body weight × 0.075 kp) every minutes separated by 25s unloaded pedaling (80 rpm) and rest (30s) in the heat (33.0°C; 50% relative humidity). The two trials included cooling-vest condition (VEST) and control condition (CON) ,and the difference is with or without wearing cooling vest imposed for 15 min at half-time (HT). Mean and peak power output, rectal (Tre) and skin temperature (neck, upper back, chest, right upper arm, thigh), heart rate (HR), deep thigh temperature, ratings of perceived exertion (RPE), and thermal comfort (TC) and thermal sensation (TS) were measured.
RESULTS: Mean power output at 2nd half was significantly greater ($p < 0.05$) in VEST (3rd trial: 589±58W, 4th trial: 584±58W) than in CON (3rd trial: 561±53W, 4th trial: 561±53W). HR were significantly lower in VEST during HT and higher in VEST at the last maximal pedaling ($p < 0.05$). At the end of HT, neck skin temperature and mean skin temperature were significantly lower in VEST (32.04±1.47°C, 33.76±1.08°C, respectively) than in CON (36.69±0.78°C, 36.14±0.67°C, respectively) ($p < 0.05$). During 2nd half, TS, TC and RPE were significantly lower in VEST than in CON ($p < 0.05$). There was no significant difference in Tre and deep thigh temperature throughout each conditions.
CONCLUSION: These results indicate that wearing a new type of cooling vest during HT significantly improves intermittent exercise performance in the heat with decreased neck and mean skin temperature and improved subjective responses.

COOLING DURING EXERCISE ENHANCES AEROBIC AND ANAEROBIC EXERCISE PERFORMANCES: WHICH BODY AREA SHOULD WE COOL? A SYSTEMATIC REVIEW WITH META-ANALYSES.

DOUZI, W.1, DUGUÉ, B.1, VINCHES, L.2, SAYED, C.2, HALLÉ, S.2, BOSQUET, L.1, DUPUY, O.1

1-LABORATOIRE MOVE, UNIVERSITÉ DE POITIERS, FRANCE. 2- ECOLE DE TECHNOLOGIE SUPÉRIEURE DE MONTRÉAL, CANADA.

INTRODUCTION: It is well known that hyperthermia during exercise is accompanied by a higher central and peripheral fatigue and conduct to impair aerobic and anaerobic physical performances (1, 2). To facilitate heat loss and optimize performance, athletes can implement cooling interventions to hasten body cooling and prevent heat illnesses. While most of the previous body cooling investigations have concentrated on different methods for pre-cooling, less attention has been paid to the use of cooling applications during exercise, which could be more practical in field of training (or even in competitions). However, it is not clear whether the effect of per-cooling on aerobic and anaerobic performance is of the same kind and whether the body area that is cooled has an importance.
METHODS: A literature search led to the identification of 1456 potential studies for inclusion in the analysis. Included studies should implement a physical exercise with sufficient details on the type, the duration, the intensity, and provide valid performance measures as well as a cooling intervention administered during exercise with sufficient details on the type and site of application.
RESULTS: 45 studies met our inclusion criteria. Per-cooling provided a performance benefit during aerobic (standardized mean difference (SMD) of 0.60, $Z=6.87$, $p<0.001$) and anaerobic exercises (SMD=0.27, $Z=2.34$, $p<0.02$). However, we observed a greater per-cooling benefit in performance during aerobic exercises than in anaerobic exercises ($Z = 2.54$, $p<0.01$). Air ventilation, cooling garments and ice vest are the most effective interventions to enhance aerobic performance with a large positive effect (0.92 CONCLUSION: Per-cooling improves aerobic and anaerobic exercise performance with a better benefit for aerobic exercises. The positive effect depends on the type and the site of cooling application.

INFLUENCE ON RENALASE BY ACUTE EXERCISE AND ITS REGULATORY MECHANISM

TOKINOYA, K., SHIROMOTO, J., SUGASAWA, T., YOSHIDA, Y., OHMORI, H., TAKEKOSHI, K.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Renalase is a novel flavin-adenine-dinucleotide - dependent monoamine oxidase that is predominantly expressed in the kidneys (1). It is also found in other tissues such as the skeletal muscles. Cell survival and protective effects of renalase have also been recently reported. Renalase expression in the kidneys and liver is regulated by NF-κB, Sp1, and HIF-1α.
In a previous study, we reported that the serum renalase increases with exercise despite a decrease in the kidney function (2). The dynamics of renalase expression in acute exercise and its mechanism are unclear. In this study, we aimed to clarify the effect of different exercise intensity on renalase expression, and to examine its mechanism.
METHODS: After habitual breeding for a week, 26 male Wistar rats ran for 30 min on a treadmill for 15 min after resting. The sedentary group rested on a treadmill (SED group), while the exercise group ran for 30 min at 10 m/min (LOW group), or 30 m/min (HIGH group). Soleus, plantaris, kidney, and blood samples were collected after exercise. Renalase protein expression and phosphate IkB-α were measured using Western blotting, while HIF-1α and Sp1 were measured using real-time RT-PCR in the skeletal muscle.
RESULTS: For the first time, we observed that 1) protein expression of renalase in skeletal muscles was increased after acute exercise, but 2) the expression in the kidneys decreased, 3) NF-κB regulated renalase expression in the plantaris muscle and HIF-1α in the soleus muscle, 4) Sp1 mRNA expression did not change.

CONCLUSION: In this study, we found that protein expression of renalase in skeletal muscles is increased after acute exercise, but its expression declines in the kidneys. In addition, its expression may be increased in response to exercise-induced oxidative stress. Furthermore, NF-κB in the plantaris muscle and HIF-1α in the soleus muscle may mainly regulate the expression of renalase, and different expression regulatory mechanisms may exist depending on the type of myofibers. Since mRNA expression of Sp1 did not change, the contribution of cytoprotective effect may be greater than the metabolic function of catecholamine.

SPARASSIS CRISPA INTAKE IS ATTENUATED THE REDUCTION OF LPS-INDUCED TNF-A PRODUCTION BY EXHAUSTIVE EXERCISE IN MICE.

UCHIDA, M.1, HORII, N.1, IEMITSU, M.1

1: RITSUMEIKAN UNIVERSITY

INTRODUCTION: In general, severe exercise induces immunosuppression. We have shown that lipopolysacchride (LPS)-induced tumor necrosis factor (TNF)-α production, as a bacterial infection model which induces immune response, was inhibited by exhaustive exercise in mice (Tanaka et al., 2010). Sparassis crispa (SC), which is one of the edible mushroom, has an immunopotentiative action such as enhancement of natural killer cell activity (Hasegawa et al., 2004). However, the effects of SC on the exhaustive exercise-induced immunosuppression remains unclear. The aim of this study was to investigate the effects of SC intake on reduction of LPS-induced TNF-α production by exhaustive exercise in mice.
METHODS: Male 4-week-old C3H/HeN mice were randomly divided into three groups: normal chow intake + sedentary (ND+S), normal chow intake + exhaustive exercise (ND+Ex), and SC intake (chow containing 5% SC powder) + exhaustive exercise (SD+Ex) groups. After 8-week interventions, all mice in two exercise groups ran on the treadmill until exhaustion, and, mice in the sedentary group were rested for 70 min. Each group was injected LPS (1mg/kg) immediately after exhaustion exercise or rest. At 1 hour after LPS injection, blood samples and tissues (liver, spleen, lung, large and small intestine and adipose tissue) were collected from each mouse, to measure plasma TNF-α concentrations using ELISA kits.
RESULTS: Plasma TNF-α levels in ND+Ex and SD+Ex groups were significantly lower than that in ND+S group at 1 hour after LPS injection. However, exhaustive exercise-induced reduction of plasma TNF-α level was partially attenuated by SC intake. Moreover, in the ND+Ex and SD+Ex groups, TNF-α concentrations in liver, spleen, lung, small intestine and adipose tissues significantly decreased as compared with ND+S group. Exhaustive exercise-induced reduction of TNF-α levels in small intestine and adipose tissues was partially attenuated by SC intake.
CONCLUSION: These results suggest that SC intake attenuates exhaustive exercise-induced reduction of TNF-α production in small intestine and adipose tissues, thereby SC intake may improve exhaustive exercise-induced immunosuppression.

IMMUNE RESPONSE IN WOMEN DURING EXERCISE IN THE HEAT: A SPOTLIGHT ON ORAL CONTRACEPTION

MINAHAN, C., LARSEN, B., COX, A., QUINN, K.

GRIFFITH UNIVERSITY

INTRODUCTION: Sex hormones modulate the immune system[1], and it is well established that oral contraceptives (OC) change the hormonal milieu[2]. Given the relationship between sex hormones and immunity, it is surprising that relatively little research has investigated the role of exogenous female sex steroids on the modulation of immune function. Furthermore, OC are associated with an elevated core body temperature[3] and there is some evidence to suggest that exercising in the heat can exacerbate the immune response[4]. Exercising in the heat can also stimulate the production of the stress hormone cortisol[5], and women using OC have a different cortisol response to exercise when compared to naturally-cycling women[6]. Therefore, women using OC might display an altered immunoendocrine response compared to naturally-cycling women, particularly when exercising in the heat. This study compared the immune and stress response of women using OC to naturally-cycling women at rest and during exercise in temperate (TEMP; 22°C) and hot (HEAT; 35°C) conditions.
METHODS: Sixteen recreationally-active women participated in this study. Eight of the women were naturally-cycling (WomenNC) and the remaining eight women were taking a low-dose combined monophasic OC (WomenOC). Participants performed a 3-stage cycling trial in each condition at 90% (Stage 1), 135% (Stage 2), and 180% (Stage 3) of their pre-determined lactate threshold 1 (total = 52.5 min). C-reactive protein (CRP), serum cytokines (IL-1β, IL-1RA, IL-6, IL-8, IL-10, and TNF-α), and salivary cortisol were evaluated before and after exercise in both the TEMP and HEAT conditions.
RESULTS: Serum 17β-estradiol (75.74±57.21 pmol/L v 18.13±20.18 pmol/L, $p<0.01$) and progesterone (0.24±0.15 pmol/L v 0.12±0.06 pmol/L, $p<0.01$) were significantly higher in WomenNC compared to WomenOC, respectively. In both the TEMP and HEAT trials, core body temperature (Tc) was higher in WomenOC than WomenNC at baseline ($p<0.01$) and pre-exercise ($p<0.01$) but not post-exercise ($p=0.23$). There were no differences in cortisol or any of the pro- or anti-inflammatory cytokines measured at rest or after completion of the exercise trials ($p>0.05$). However, a trend ($p=0.07$) for higher C-reactive protein concentrations was noted for WomenOC (1.102±1.182), being more than three-fold higher than that observed in WomenNC (0.326±0.228).
CONCLUSION: The results obtained in the current study indicate similar immunoendocrine function in recreationally-active WomenOC and WomenNC both at rest and after exercise in temperate and hot environments.

EFFECT OF THE DIFFERENT IN STEP LENGTH DURING A STEP-DOWN EXERCISE WITH THE LOAD ON THE DELAYED-ONSET MUSCLE SORENESS IN THE LOWER LIMBS

TAMARI, Y.1, WADA, T.1, YOSHIDA, N.2, HAMADA, H.2, ONODERA, S.1

1: KAWASAKI UNIVERSITY OF MEDICAL WELFARE , 2: GRADUATE SCHOOL, KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: Walking speed is determined by the multiplication of cadence and step length. We revealed that delayed-onset muscle soreness (DOMS) was suppressed during the stair-descending exercise with a cadence of 110 steps/min (Tamari et al., 2017). However,

the influence of difference in step length during the step-down exercise on DOMS has not been elucidated. This study aimed to clarify the effect of difference in step length during the step-down exercise with the load placed on DOMS muscles in the lower limbs.
METHODS: Eight healthy Japanese males volunteered to participate in this study. Their ages, heights, body weight, and body mass index were 22±1 years, 169.6±5.1 cm, 60.2±5.4 kg, and 21.0±2.1, respectively (mean±SD). All subjects were issued informed consent forms prior to participation in this study. The exercise task was a step-down exercise (rise; 15 cm). The subjects raised their right leg to the same height as the left leg after landing their left leg on the step, then the right leg landed on the floor. The subjects repeated this motion for 15 minutes. Step lengths during the step-down exercise were 30 cm (30-condition) and 60 cm (60-condition). The experimental conditions were implemented in a random order. The cadence was 90 steps/min. The subjects had a load of about 10% of the body weight. Measurements included heart rate, oxygen uptake, blood pressure (systolic blood pressure, diastolic blood pressure), rating of perceived exertion (RPE), muscle soreness, and maximal isometric strength (muscle damage indices). Muscle soreness was determined based on the visual analog scale. Muscle soreness was assessed before exercise, immediately post exercise, and on post-exercise days 1–7. Maximal isometric strength was recorded before exercise, immediately post exercise, and on post-exercise days 1–4.
RESULTS: There was no significant changes in heart rate, oxygen uptake, systolic blood pressure, diastolic blood pressure, and RPE in the 30- and 60-conditions (each; n.s.). Maximal isometric strength 24 h after exercise was significantly lower in the 30-condition than in the 60-condition ($p<0.05$). The disappearance of DOMS was more delayed in the 30-condition than in the 60-condition. DOMS 24 h after exercise was significantly higher in the 30-condition than in the 60-condition ($p<0.05$). These results suggest that the step-down exercise with a step length of 30 cm has a higher percentage of muscle damage compared to 60 cm and causes severe DOMS.
CONCLUSION: This study revealed that the step-down exercise burden on the lower limbs increases when the step length is 30 cm compared to 60 cm.

EFFECT OF ULTRA-MARATHON ON MEDIATORS OF INFLAMATION AND ENDOTHELIUM IN EXERCISE-INDUCED HYPERTENSION ATHLETES

KIM, C.H., KIM, H., KIM, Y.J.

SOONCHUNHYANG UNIVERSITY, KOREAN NATIONAL UNIVERSITY OF EDUCATION, SUNGSHIN UNIVERSITY

INTRODUCTION: The purpose of this study is to exam the responses of anti-inflammatory, inflammatory, and endothelial regulation factors to 100KM ulatromaraton of athletes who have exercise-induced hypertension. For this study, we obtain and analysis IL6, TNF-alpha, IL-10, MCP-1, and NO from 100KM ultramarathoners before and right after the 100KM race.
METHODS: There were 40 volunteers who had ever won the 100KM marathon race before more than one time. They had the graded exercise test with measurement of blood pressure for assessing exercise-induced hypertension. Among them, eight athletes were categorized to normal control group (NRM) and 10 athletes were assessed by exercise-induced hypertension(EIH).
The graded exercise test with treadmill was performed for the maximal strenuous exercise and blood pressure. Exercise-induced hypertension was diagnosed as >140/90mmHg in normal and >=210mmHg in maximal exercise. Marathoners including EIH=10 and NRM=8 participated in 100KM ultra-marathon race and blood extracted from them before the race and right after the race. Blood samples of EIH and NRM were analyzed for TNF-alpha, IL-6, IL-10, MCP-1, CK, and NO as the makers of anti-inflammatory, inflammatory and endothelial regulation factors.
RESULTS: EIH had lower IL-10 than NRM during resting states and after the 100KM race EIM had significantly lower NO concentration than NRM. Therefore, the nitric oxide (NO) in the endothelial is inhibited during strenuous endurance exercise, resulting in vasoconstriction with increasing the blood pressure.
CONCLUSION: This study found out for the first time that the nitric oxide in the endothelial cell in blood vessels can not increase in exercise-induced hypertension athletes during strenous exercise; EIH inhibits the NO leading to the vasoconstriction of vassels with increasing the peripheral blood pressure. This result can indicate the mechanism of EIH and can be undersood. This NO inhibition in EIH can be used in treatment and prevention of EIH.

EFFECTS OF RESPIRATORY MUSCLES TRAINING ON DIAPHRAGM THICKNESS, RESPIRATORY FUNCTION AND EXERCISE CAPACITY OF MALE CYCLISTS

BAI, J.

BEIJING RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: The respiratory system directly affects athletic performance, especially in the aerobic endurance performance. There is a close relationship between aerobic metabolism ability and performance of road cyclists. The athletes respiratory function is closely linked with aerobic endurance, respiratory muscles fatigue directly affect the ability to exercise. Therefore, it is necessary to improve the strength, endurance and anti-fatigue ability of respiratory muscles through breathing training. Respiratory muscle training at the same time can improve lung ventilation
Respiratory muscle and lower extremity muscle competition for blood, feeling of difficulty breathing and respiratory muscle fatigue these factors limit the exercise capacity. Diaphragm is the main respiratory muscle, although only about 0.5% of body weight, but its role in the inspiratory process of respiratory muscles accounted for 60% -80%. Diaphragm thickness is an important factor in measuring its function.
This study aims to improve respiratory performance by training the respiration muscle strength, thereby enhancing aerobic capacity, and ultimately improve performance, and compare related functions before and after training, so as to evaluate training effect.
METHODS: We included 10 healthy Long-distance male cyclists in this study (age: 18.5.5±1.51 height: 181.8±3.45cm, weight: 72.1±4.64kg). Subjects were trained for 6 weeks with the "PowerBreathe" respiratory muscle trainer and practiced for 10 minutes every day. Each set of 30 breaths, three sets a day and a day off every week. Keep the training load in 30rm.
Before and after breathing training, athletes were tested lung ventilation (vital capacity, forced vital capacity, maximum ventilation per minute) (CHESTGRAPHHI-101 breath tester); diaphragmatic thickness measurements (calm, end-inspiration, end-expiratory) (PHILPS HD7 XE type B ultrasonic instrument).

Before and after 6 weeks of training, the subjects were tested in the cycle ergometer performing for VO2max test (maximum oxygen uptake, maximum power, maximum ventilation, heart rate). (Speed : 95-100rev/min, 60W at the beginning, 20W was increased every 1 minutes till exhaustion).
Paired t-test was used to compare the two sets of data before and after respiratory muscles training.
RESULTS: After 6 weeks of respiratory muscles training, the athletes diaphragm thickness increased significantly by 9.5% (from 2.73±0.27 to 2.99±0.35mm) at the end of inspiration (P<0.05). Diaphragm thickness had no significant changes at the calm and end of expiratory (P>0.05).
After 6 weeks training, the MVV(maximal voluntary ventilation) was significantly increased than before (from 184.38±30.45 to 196.24±22.61 L/min, P<0.05). There was no difference in VC(Vital Capacity), FVC (Forced Vital Capacity), and FEV1%(Forced Expiratory Volume) when comparing six weeks ago(P>0.05), respectively.
10 subjects performed incremental cycling test. There was a significant increase in maximum power which improved 5.77% (417.13±14.02 to 441.28±27.96 watt) (P<0.05) and maximum ventilation/weight increased by 8.56% (from 2.57±0.24 to 2.79±0.28 L/min/kg) (P<0.05). After training the VO2max and maximum heart rate increased slightly, but there was no significant difference.
CONCLUSION: Six weeks of respiratory muscle training increases diaphragm thickness at end-inspiratory and increases maximal voluntary ventilation in male cyclists.
Six weeks of respiratory muscle training can effectively improve the maximum power and maximum ventilation of aerobic endurance test of male cyclists, but no effect on the VO2max was found.
Respiratory muscle training can increase the diaphragm thickness to enhance respiratory function, and thus improve the athletic performance.

USING POLYNOMIAL REGRESSION TO AUTOMATICALLY DETECT VENTILATORY INDICES IN PARACELSUS 10.000 PARTICIPANTS

PUEHRINGER, M., RING-DIMITRIOU, S., IGLSEDER, B., PAULWEBER, B.

UNIVERSITY OF SALZBURG

INTRODUCTION: Ventilatory indices (e.g. anaerobic threshold, VI-1; and respiratory compensation point, VI-2) have been shown to be useful in assessing the efficiency of training, and in classifying performance in various populations (Meyer & Lucía, 2005). Accordingly, precise identification of VI is essential in cardio-pulmonary exercise testing. Thus we compared different automatic detection methods, based on polynomial regression, with visually detected VI-1 and VI-2.
METHODS: Gas exchange measurements from incremental cycling (Master Screen CPX, Jaeger) of 50 females (55±3 y, 25.0±4.2 kg/m2 BMI, 24.0±6.6 ml/kg/min VO2peak) and 50 males (55±3 y, 26.5±4.3 kg/m2 BMI, 29.9±9.2 ml/kg/min VO2peak) served to determine VI-1 and VI-2 with three different methods. (1) visual, (2) automatic detection by polynomial regression using the time series data of ventilatory equivalents and end tidal pressures of oxygen (EQO2 and PETO2) and carbon dioxide (EQCO2 and PETCO2) and calculating their local minima, maxima, and maximum curvatures (Sherrill, Anderson, & Swanson, 1990), (3) semiautomatic detection by using methods (2) with a final visual selection of VI-1 and VI-2 (Meyer & Lucía, 2005). Mean differences and agreement between the methods were assessed separately for VI-1 and VI-2 using analysis of variance (ANOVA) with $p<0.05$, mean biases ± 95% limits of agreement (LOA), and intraclass correlation coefficients (ICC). The study was approved by the Salzburg Ethics Committee.
RESULTS: Overall, ANOVA revealed significant differences between the methods for VI-1 ($F(5, 225) = 24.7$, $p < .001$) and VI-2 ($F(5, 325) = 15.1$, $p < .001$), respectively. The highest level of agreement was found between visual and semiautomatic method (for VI-1: LOA=108±289 ml/min, ICC=0.86 [0.61, 0.94], and for VI-2: LOA=160±509 ml/min, ICC = 0.86 [0.68, 0.93]), and the semiautomatic method also resulted in the lowest number of indeterminable cases.
CONCLUSION: The automatic determination using local minimum of EQO2 and PETO2 time series showed higher agreement with the visual method than using the maximum curvature for VI-1, while it was the other way around for VI-2. As described by Meyer & Lucía (2005), the EQO2 time series occur with an inflection point at VI-1 and a second at VI-2. Because of intense hyperventilation the second point could be identified as VI-1. The results of this study demonstrate that automatic methods are useful to detect VI. However, different patterns in gas exchange response due to incremental testing require a systematic approach combining automatic and visual methods.

EVIDENCE OF THE EQUIVALENCE IN METABOLIC RATE AT RCP, [HHB]BP AND MLSS

INGLIS, E.C., IANNETTA, D., MURIAS, J.M.

UNIVERSITY OF CALGARY

INTRODUCTION: A correspondence between exercise intensity thresholds, such as the respiratory compensation point (RCP), the maximal lactate steady state (MLSS), and the near-infrared spectroscopy (NIRS) derived break point (BP) in the deoxyhemoglobin ([HHb]) signal (i.e., the [HHb]BP) have been shown to exist, suggesting that these demarcation points share similar physiological bases(1). However, others have proposed that this correspondence is rather coincidental(2). Therefore, current conclusions state both that the metabolic rate (VO2) associated to the RCP and the MLSS are(1) and are not(2) equivalent to the [HHb]BP. An approach to determine if the RCP, MLSS, and the [HHb]BP are all a representation of similar physiological events would be to study these responses before and after an exercise training intervention that is expected to result in changes in the VO2 associated to these boundaries. Thus, this study evaluated the interplay of these indices with regards to VO2, in a longitudinal manner.
METHODS: Nine amateur male cyclists reported to the lab for testing in 3 separate phases (PRE, MID and POST) over the course of a 7-month competitive cycling season, during which, although training was not controlled by the investigators, the participants aimed to improved and sustain their fitness level. Testing included a ramp incremental test to exhaustion (30W/min) to determined VO2max, RCP, and the [HHb]BP. Additionally, 2 30-min rides were performed at both PRE and POST for determination of MLSS. Expired gases and NIRS measurement were continuously measured throughout all testing sessions.
RESULTS: VO2 at both RCP and [HHb]BP were significantly higher at MID (RCP, 3.92 L/min; [HHb]BP, 3.92 L/min) and POST (RCP, 3.89 L/min; [HHb]BP, 3.90 L/min), compared to PRE (RCP, 3.69 L/min; [HHb]BP, 3.65 L/min) ($p<0.05$). In all phases no differences were found in VO2 at RCP (PRE, 3.69 L/min; MID, 3.92 L/min; POST, 3.89 L/min), MLSS (PRE, 3.72 L/min; POST, 3.81 L/min), and [HHb]BP (PRE, 3.65 L/min; MID, 3.92 L/min; POST, 3.90 L/min) ($p>0.05$). Significant correlations in VO2 existed between RCP and [HHb]BP ($r=0.89$ PRE, 0.94 MID, 0.84 POST), RCP and MLSS ($r=0.91$ PRE, 0.91 POST), and between [HHb]BP and MLSS ($r=0.73$ PRE, 0.75 POST) in all phases ($p<0.01$). Bland-

Altman plots comparing the VO2 values at RCP and [HHb]BP revealed no significant biases in any of the 3 phases (PRE, 0.03 L/min; MID, -0.01 L/min; POST, 0.00 L/min).
CONCLUSION: This study demonstrated that the VO2 associated with RCP, [HHb]BP and MLSS remained equal at each point where these were evaluated. Importantly, these similarities remained consistent even when the VO2 associated with RCP, [HHb]BP, or MLSS changed. This study demonstrated that the agreement among RCP, [HHb]BP and MLSS remained constant throughout the different phases, which provides a strong argument that they represent the expression of similar physiological response.

THE DURATION-SPECIFIC PEAK RUNNING DEMANDS OF ACADEMY LEVEL RUGBY LEAGUE MATCH-PLAY

WHITEHEAD, S., TILL, K., DALTON-BARRON, N., IRETON, M., WEAVING, D., JONES, B.
LEEDS BECKETT

INTRODUCTION: Quantifying the peak distances that players cover across specific durations of time is important to enhance training prescription and appropriately prepare players for rugby league match play. This study aimed to quantify, and compare, the peak running demands of different positional groups during professional academy rugby league match play.
METHODS: Following institutional ethics approval, 10-Hz Global Positioning System (GPS) (Optimeye S5, Catapult Innovations) data were collected from one hundred and forty-nine players competing across nine teams during 21 professional Academy (under-19) matches. Players were split into six positional groups for analysis: hookers (Ho; no. = 40), fullbacks (Fb; n = 24), halves (Ha; n = 47), outside backs (OB; n = 104), middles (Mid; n = 118) and back rows (BR; n = 104). Players who played less than 10 minutes were excluded from analyses. Data were extracted using propriety software Openfield. 10-Hz velocity files were exported with the duration-specific peak running demands determined via moving averages of relative distance (m·min-1) for 10- and 30-seconds, and 1- to 5- and 10-minute durations. Data were log-transformed and differences between positional groups were analysed using linear mixed effect models to account for repeated observations on players and teams, followed by magnitude based inferences, with the threshold of the smallest worthwhile difference set at 0.2 x between-subject standard deviation.
RESULTS: The highest peak running demands for 10-seconds, 1- and 10- minutes were 368 ± 39, 178 ± 16, and 106 ± 9 m·min-1. Fb most likely had greater peak running demands compared to Mid, Ho and BR over 10- and 30-second, and 1- and 5-minute durations (% difference: 6.3 – 18.9, effect size [ES]: 2.1 – 6.0), and compared to OB over all durations except 10-seconds and 2-minutes (% difference: 6.1 – 11.4, ES: 2.9 – 6.4). Ho had most likely and very likely decreased peak running demands compared to OB at 10- and 30-seconds respectively (% difference: 5.1– 13.0, ES: 2.6 – 5.4), but most likely increased demands at 4-, 5- and 10-minute durations (% difference: 4.2 – 6.1, ES: 2.5 – 3.8). Similarly, compared to OB, the Mid and BR had most likely decreased relative distance at 10-seconds (% difference: 9.4 – 14.6, ES: 4.5 – 8.5), but very likely increased at 10-minutes (% difference: 2.9 – 3.4, ES: 2.5).
CONCLUSION: This study provides 'league-wide' peak running demands of Academy level rugby league match-play across varying durations that can be used by practitioners to prescribe conditioning drills and monitor the intensity of coach-led drills. Differences in the peak running demands are present between positional groups; Fb exhibit the greatest running intensities across all durations and OB have greater short duration, but lower long duration peak running demands compared to Ho, Mid and BR. Therefore position-specific prescription should be considered when prescribing velocity-based training intensities across short and longer durations.

AN ANALYSIS OF GAME MOVEMENT DEMANDS OF INTERPROVINCIAL WOMENS RUGBY UNION

CALLANAN, D., FITZPATRICK, P., RANKIN, P.
INSTITUTE OF TECHNOLOGY CARLOW, IRELAND

INTRODUCTION: The growth in womens Rugby Union (RU) has led to an increase in its professionalism, competitiveness and intensity. This warrants the need to identify the physiological demands to ensure practitioners can develop accurate planning and periodisation of training sessions for both individuals and positional groups (Ziv and Lidor, 2016). Despite the growth of female participation rates in RU, there is a dearth in the research examining women RU players.
METHODS: The members of two Interprovincial womens rugby union squads (n=34, age, weight 78.1 ± 9.0 kg, height 169.4 ± 6.1 cm and CMJ 29.0 ± 4.3 cm) volunteered to participate in this study. The number of data files collected for each position was as follows, forwards (n=46) and backs (n=38). Game movement demands were recorded using a 10 Hz global position series integrated (PLAYERTEK , Dundalk, Ireland). The locomotor variables that were analysed include the following: total distance (TD) (m), relative distance (RD) (m.min-1), max velocity (m.s-1) and sprint distance (SD) (>5.5 m/s) (m).
RESULTS: Backs covered significantly greater TD than forwards in the first half (3117 ± 289 v 2864 ± 207 m), second half (2987 ± 576 v 2605 ± 679 m) and total game (6104 ± 720 v 5469 ± 761 m) ($p<0.01$). There were significant differences observed in RD, with backs reporting a higher intensity across the first half (71 ± 6.2 v 65.6 ± 4.0 m.min-1), second half (67.7 ± 8.2 v 63.2 ± 6.9 m.min-1) and total game (69.4 ± 6.5 V 64.6 ± 4.8 m.min-1) ($p<0.01$). Backs had significantly greater max velocity speeds across the first half (6.68 ± 0.50 v 5.88 ± 0.53 m.s-1), the second half (6.66 ± 0.56 v 5.89 ± 0.67 m.s-1) and total game (6.91 ± 0.43 v 6.15 ± 0.62 m.s-1). ($p<0.01$). Backs also covered greater SD than forwards in the first half (158.9 ± 76.6 v 65.2 ± 50.9 m), the second half (146.5 ± 86.0 v 65 ± 51 m) and total game (305.4 ± 142.8 v 130.2 ± 85.2 m) ($p<0.01$).
CONCLUSION: These results highlight the various differences in game movement demands between backs and forwards across various time points and variables. These findings are similar to those reported by Suarez-Arrones et al. (2013). This information is pivotal for both coaches and sport science practitioners. The ability to quantify the games movement demands can allow conditioning staff to periodise individual training sessions to elicit the required physiological adaptations. Furthermore, it may provide additional information on the demands on the game for specific positional groups which may have an impact on the subsequent recovery process.

IS THE KINETIC ENERGY EFFECTIVE AS ASSESSMENT OF THE RUGBY PERFORMANCE WITH BODY CONTACT?

KURITA, K.

UNIVERSITY OF EAST ASIA

INTRODUCTION: The physical fitness of rugby players is often evaluated by sprinting or strength. However, a characteristic of rugby performance is to combine running with body contact. We propose that kinetic energy that calculated from body weight (kg) and sprinting (m/s) is a good assessment of rugby performance play with body contact.
PURPOSE
To investigate whether Kinetic energy is effective as an assessment of rugby performance with body contact.
METHODS: For three years the top team of college rugby in Japan was investigated (the number of players totaled 332 between 2014-16). Body weight (kg), 10m&30m sprint time (seconds), momentum of 10m&30m sprints(kg・m/s), kinetic energy of 10m&30m sprints(kg・m2/s2), bench press 1RM(kg), and squat 1RM(kg) were measured as fitness characteristics.
Every season, the number of official match players and reserve players (performance level of each player) were included in the high level group of each measurement item . The effectiveness of each measured item was showed by comparing the relationship between the number of members (Forwards & Backs) participating in the official match and the number of people of top group that exceeded the reference value of each measurement item using "specificity". The reference value of each measured item was adjusted to the value of the player of the same rank as the number of official game participants in each year and position.
RESULTS: With forwards, specificity of kinetic energy of the 10m sprint was the highest (0.827), followed momentum by 30m sprint (0.813), and body weight (0.813). With backs, specificity of kinetic energy of the 30m sprint was the highest (0.846), followed by momentum of the 10m sprint (0.837), the momentum of the 30m sprint (0.827), in order respectively.
CONCLUSION: It was suggested that kinetic energy of the 10m sprint in FW and kinetic energy of the 30m sprint in BK had the highest specificity and therefore these are the most effective assessments of rugby performance with body contact.

TACKLE TECHNIQUE IN AMATEUR AND PROFESSIONAL RUGBY UNION PLAYERS

BARNES, A.

SHEFFIELD HALLAM UNIVERSITY

INTRODUCTION: Contact injuries during the tackle pose a serious threat to player welfare with concussions accounting for a significant proportion. Concussion rates in amateur rugby have been found to be significantly elevated compared to the professional game (Gardner et al., 2014), which may result from differences in tackle behaviours. This study sought to compare the tackle characteristics between amateur and professional rugby union players.
METHODS: Video analysis was conducted of 24 rugby games (12 amateur and 12 professional) from the English RFU league (2015-16 season) comprising 14 amateur (levels 5 and 6) and 22 professional teams (Level 1 and 2). Tackle incidences were coded using technical proficiency criteria (Burger et al., 2016) focussing on pre contact, contact and post contact phases. Normalised incidences of tackle behaviours were compared using independent t-tests and Cohens d effect size.
RESULTS: The total number of tackles in professional games was higher than in amateurs (professional: 154± 23 vs amateur: 128 ±11). Amateurs displayed a head down position more in the pre-contact phase (amateur 22± 8%; professional 11 ±5%, $p<0.01$, $d=1.73$) and made a higher percentage of their tackles with their head in front of the ball carrier compared to professionals (amateur 23± 3%; professional 13 ±4%, $p<0.01$, $d=2.95$). Professionals made a greater proportion of their tackles on the mid-torso of the ball carrier (professional 43 ±7%, amateur 32± 5%, $p<0.01$, $d=1.82$) and made a greater proportion of double (2vs1) tackles compared to amateurs (professional 33 ±4%, amateur 24± 5%, $p<0.01$, $d=1.68$)
CONCLUSION: Amateur players were more likely to display techniques which may increase the risk of injuries such as concussions, particularly related to the position of the head in the pre- and contact phases of the tackle (Burger et al., 2016). Research supports a reduced injury risk when tackling the ball carrier between he hips and sternum (Burger et al., 2016) compared to the shoulders or below the waist, a characteristic that was seen more in professional players in our results. Findings point towards the need for tackle education at the amateur level to help reduce injuries in this group of players. Despite an increased cumulative tackle load in professionals potentially putting them at greater risk of chronic injury, both physical conditioning and tackle skill have been suggested to contribute to injury risk (Hendricks et al., 2014), therefore future research should focus on the interaction of these factors at all levels of the game.

TRANSITION FROM PREPARATION PERIOD TO COMPETITIVE PHASE IN PROFESSIONAL FEMALE BASKETBALL: RELATIONSHIP BETWEEN TRAINING LOAD AND RECOVERY

SANSONE, P., TSCHAN, H., CONFESSORE, E., TESSITORE, A.

UNIVERSITY OF ROME FORO ITALICO

INTRODUCTION: The preparation phase is crucial to set up the athlete for the demands of competition. Considering the high demands of professional sports, training and recovery have to be carefully monitored in order to ensure the athletes' fitness and health. Therefore, this observational study monitored training load (TL) and recovery of professional female basketball players during the season's preparation and initial competitive phases.
METHODS: 13 female basketball players (age: 21 ± 3 years) from an Italian Serie A1 team were recruited. Training and recovery were monitored with the session-Rating of Perceived Exertion (sRPE) method by Foster et al. (2001) and Total Quality Recovery (TQR) scale (Kentta & Hassmen 1998), respectively. Data were collected over the preparation (M1: weeks 1-4) and the following two competitive (M2: weeks 5-8; M3: weeks 9-12) mesocycles. Weekly team parameters calculated were: training volume (V, sum of training hours); RPEm (mean of RPE values, in arbitrary units (AU); TL (sum of daily TLs, calculated in AU by multiplying each sessions RPE value for its duration in minutes);

TQRd (mean of daily TQRs, in AU); TQRfw (TQR at the start of the following week, in AU). Comparison between mesocycles was evaluated via one-way ANOVA (Bonferroni post-hoc). TL-TQRd correlations (Pearson's r) were calculated within mesocycles.
RESULTS: V was greater in M1 (14.6 ± 2 hrs), compared to M2 (11 ± .6 hrs) and M3 (10.1 ± .9 hrs) (p= .002, ES: .750). TL was higher in M1 (4018 ± 624 AU) compared to M3 (2867 ± 430 AU), but not different to M2 (3277 ± 221 AU) (p= .015, ES: .608). TQRfw was greater in M1 (5.5 ± .2 AU) compared to both M2 (4.8 ± .1 AU) and M3 (4.9 ± .2 AU) (p= .011, ES: .636). No effects were found for RPEm (M1: 5.0 ± .4 AU; M2: 5.5 ± .3 AU; M3: 4.6 ± .7 AU) (p= .085) and TQRd (M1: 5.0 ± .5 AU; M2: 4.7 ± .3 AU; M3: 4.7 ± .1 AU) (p= .464). TL-TQRd correlations were as follows: M1: r= -.314 (p= .684); M2: r= -.902 (p= .098); M3: r= -.312 (p= .688).
CONCLUSION: The main finding of this study is that the teams recovery (TQRfw) was higher during preparation compared to competition phases, suggesting a potential negative effect attributable to training design. In fact, the concurrent increase of training intensity (RPEm) (+12.2%) and decrease of volume (V) (-24.7%) from M1 to M2, planned to meet the demands of competition, may have been insufficient to optimize players' recovery; indeed, TL was not different between M1 and M2. Moreover, seen the negative moderate TL-TQRd correlations in M1 and M3, the nearly perfect one found in M2 highlights the athletes' vulnerability to TL in this transitional phase. Thus, this study suggests the importance of designing training and recovery in the transition from the preparation to the competitive phase.

THE EFFECT OF A PERIODISED SMALL-SIDED GAMES INTERVENTION ON PHYSICAL AND PHYSIOLIOGICAL MEASURES IN HURLING PLAYERS

MALONE, S.1,2, OWEN, A.3, COLLINS, D.K.1
GAELIC SPORTS RESEARCH CENTRE, INSTITUTE OF TECHNOLOGY TALLAGHT

INTRODUCTION: Small-sided games (SSG) allow coaches to develop both technical and tactical proficiency within players while furthermore allowing the development of aerobic and anaerobic fitness characteristics simultaneously (Malone, Hughes, Collins, 2017). The current investigation examined the effect of a periodzed small-sided games intervention across a six-week (two test weeks and four intervention weeks) pre-season period on physical (Yo-YoIR1, RSAb, and 5-,10-,20-m Speed) and physiological performance measures (VO2max, vVO2max, vOBLA, vLT and RE) within hurling players.
METHODS: Twenty-five (n=25) hurling players were observed across a 6-week training intervention with GPS and HR technologies, these players participated in 12 sessions of exclusive 4 min SSG bouts (4v4) across differing pitch dimensions from 100-200-m2 with the number of bouts of SSG increasing across the intervention period. Pre- and post-intervention tests included physiological (VO2max (mL·kg-1·min-1), vVO2max (mL·kg-1·min-1), PTV(km·h-1), RE (mL·kg-1·min-1), vLT (mmol·L-1), vOBLA (mmol·L-1) and physical testing (5-, 10-, 20-m speed (s), YoYoIR1 (m), RSAb (s)) methodologies.
RESULTS: Across the period, improvements in physiological qualities were observed. Large improvements in VO2max (mL·kg-1·min-1) were reported (ES: 1.79; 95%CI: 1.02 – 2.01) and vLT (ES: 1.56; 95%CI: 1.12 – 1.78) with moderate improvements in vVO2max (km·h-1) (ES: 0.93; 95%CI: 0.77 – 1.11) and vOBLA (ES: 0.89; 95%CI: 0.34 – 0.99). Moderate improvements in Yo-YoIR1(ES: 0.65; 95%CI: 0.33 – 0.78) and RSAb (ES: 0.41; 95% CI: 0.21 – 0.66) were also observed across the period with trivial differences observed for speed across 5-,10- and 20-m. Furthermore, the SSGs also led to an improvement in RE as indicated through significantly reduced VO2 and heart rate at running speed 8, 10, 12, 14 and 16 km·h-1 (ES: 0.99-1.78).
CONCLUSION: The present study supports previous studies (Owen et al., 2012; Malone, Hughes, Collins, 2017) that demonstrate the capacity of SSG to improve fitness in team sport players. Coaches should be aware that SSG represent an important concomitant training methodology that develops physiological characteristics in conjunction with technical and tactical capacities of players within simulated game environments. In conclusion, SSG have been shown to evoke improvements in physical and physiological fitness capacities within a relatively short period, making SSGs an appealing proposition for fitness coaches, players, and skills coaches within the hurling training process.

QUANTIFYING THE MATCH TO MATCH DEMANDS OF NBA BASKETBALL

DAMELIO, K., WARD, P., COUTTS, A.
UNIVERSITY OF TECHNOLOGY, SYDNEY

INTRODUCTION: Our current understanding of the match activity demands in the elite professional basketball is limited. In particular, our understanding of the detailed activity demands and their variation is limited. The aim of the present study was to determine the match to match variation of physical performance demands in the National Association of Basketball (NBA).
METHODS: Player optical tracking data (SportVU, Chicago, IL) was collected in competition during two seasons, 2015-16 (n = 379) & 2016-17 (n = 464) on the NBA. A total of 44,382 individual player observations were recorded in 2015-2016 (n = 21483) and 2016-2017 (n=22899) seasons. The physical activity data were categorized into total distance covered, high intensity running, high intensity running efforts, total accelerations, and high acceleration efforts. Between-match coefficients of variations (CV) were calculated for each player, across all games. The CV was then compared between home and away competitions, wins and losses, and by playing position (Center, Forward, Guard). A mixed effects linear model, with random intercepts, was used to estimate the within-and between-player variability. Variability was expressed using the CV (%) and CVs were presented with 95% CL as markers of uncertainty of the estimates.
RESULTS: Higher variability was observed for high-intensity activities, high intensity running efforts (16.2%) and number of high accelerations (15%.). In contrast, there was lower variability in global physical activity measures, total distance (3.6%), average speed (1.6%), and maximum speed (1.6%). Match-to-match variability in activity profile was not influenced by match outcome (win/loss) or match location (home/away). The between-match variability was relativity stable for all measures between and within NBA seasons (2015-16 & 2016-17).
CONCLUSION: While global physical activity measures are relatively stable, higher-intensity activities exhibit a large degree of between-match variability in NBA basketball. However, these measures remain relatively stable between positions, within and between NBA seasons. Enhanced understanding of the variation in the physical activity demands will allow practitioners to determine meaningful changes and can be used to inform athlete preparation.

WELLNESS, TRAINING LOAD AND RUNNING PERFORMANCE DURING AN IN-SEASON HIGH INTENSITY PERIOD IN ELITE FEMALE FIELD HOCKEY PLAYERS

MCGUINNESS, A., MALONE, S., KENNA, D., MCMAHON, G., PASSMORE, D., COLLINS, K.

INSTITUTE OF TECHNOLOGY TALLAGHT

INTRODUCTION: The aim of the current observational study was to quantify the global variation in players activity profiles during a high-intensity period and determine whether an association is apparent between wellness measures and running performance.
METHODS: Sixteen elite female field hockey players (23 ± 3years; 162.6 ± 13cm; 66 ± 6kg) participated in the current study. Participants were monitored with GPS technology and activity was categorised into total distance (m), relative total distance (m·min-1), and high intensity distance (m·min-1), max velocity (km·h-1), and relative maximal velocity (%) (3). The intensity of match-play was determined using the modified Borg CR-10 rate of perceived exertion scale(2). Wellbeing was monitored and players were asked to rank mood and sleep quality on a 10-point scale ranging from 1 (Worst) to 10 (Best) with muscle soreness ranging from 1 (A little) to 10 (A lot) daily (1).
RESULTS: Total distance (m) was likely higher when compared to game one (5135 ± 646m) in game 2 (5566 ± 920m). Relative distance (m·min-1) was likely lower when compared to game one (115.8 ± 11.5m·min-1) in game 7 (106.1 ± 9.8m·min-1). Relative high-speed (m·min-1 >16 km·h-1) was likely lower in games 5,6,7 (14.9 ± 4.1m·min-1, 14.9 ± 4.4m·min-1, 15.0 ± 5.8m·min-1). Max velocity (km·h-1) was possibly higher when compared to game 1 (23.8 ± 1.5km·h-1) in game 2 (25.1 ± 1.2km·h-1) and unlikely in game 6 (24.5 ± 1.1km·h-1). Session load was very likely higher when compared to game 1 (348 ± 61AU) in game 2 (436 ± 85AU) and very likely lower in game 3 (295 ± 52AU). Mood (8 ± 1.1AU) and sleep quality (8.2 ± 0.8AU) were likely lower in game one when compared to game 4 (7.2 ± 1.6AU) and game 7 (7.6 ± 1.0AU). Muscle soreness was likely higher when compared to game one (2.8 ± 1.1AU) in game 7 (3.6 ± 0.9AU). During these high intensity periods it was observed that a decrease in daily psychometric questionnaire was accompanied by changes in running performance.
CONCLUSION: The result of the current study suggest that changes to players muscle soreness and sleep quality decreases players running performance. However, decrements in running performance seen between games may be linked to the changes in team-tactics. Therefore, to prevent the effects of fatigue coaches should adapt strategies to enhance sleep quality and incorporate ways to reduce muscle soreness.

MAX INTENSITY PERIOD COMPARISON OF CLUB LEVEL AND INTERNATIONAL LEVEL FIELD HOCKEY - CUNNIFFE E,.DELAHUNT E, MCCARTHY-PERSSON,U, BOREHAM C, BLAKE C. SCHOOL OF PUBLIC HEALTH, PHYSIOTHERAPY AND SPORTS

CUNNIFFE, E.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Many studies have been published in Field Hockey outlining the physical demands of the game (1). These studies highlight the average demands of the game as a team or a positional group however they fail to identify the peak demands of game play where maximal output is required from each individual. Therefore, it is difficult for coaches to prepare athletes for the "peak" demands of the game. The max intensity period (MIP) is an output that is the 3-minute period of a match where physical output is at its greatest. This study explored the Max Intensity Period in elite hockey players, contrasting national (club) and international athletes.
METHODS: 18 Male national level and 21 international athletes were tracked utilising a 10 Hz GPS Unit (APEX, STATSport) and 100Hz Accelerometer for 11 games and 7 games respectively. The MIP was calculated post games in the APEX software (STATSport) based off total distance. Each unit was turned on at least 15 minutes pre-use to ensure satellite connectivity.
RESULTS: Mean total distance covered was greatest at international level for all positions, ranking in descending order from forwards to midfielders, outside backs and finally centre backs; range 510m - 462m. This same positional order was maintained at club level hockey; range 507m – 434m, marginally lower than the international players. In relation to peak output, positional ranking remained the same at both levels, with international players demonstrating greater output in all positions, except forward, with a range of 598m – 541m. Forwards were matched at both levels exhibiting 598m.Club players produce a range of 507 to 598m.
For metres per minute, mean output ranged 170 – 154 m/min at international level and 169-145m/min at club level, with the same positional ranking observed across levels and consistently higher output recorded by internationals. Internationals recorded higher peak m/min for all positions, except for forwards who demonstrated 199m/min at both club and international level.
On average international games demand 3 sprints more than club level during the Max Intensity Period per position. The greatest disparity in terms of max sprint demands is represented by international centre backs who were required in the max period to complete an extra 4 sprints.
CONCLUSION: There is a minimal difference in the average output during the MIP at both levels. However, there is an evident divergence between the peak sprint demands of each position with the peak demand being greater at international level.

LEVEL OF AGREEMENT BETWEEN CATAPULT AND SPORT PERFORMANCE TRACKING GPS DEVICES DURING TEAM SPORT MATCH PLAY

ELSWORTHY, N., KITTEL, A., SPITTLE, M.

CQUNIVERSITY

INTRODUCTION: Global positioning system devices are widely available to team sport participants of all levels, with a number of different manufacturers developing this technology. Catapult GPS devices are used extensively within elite sport and previous research has outlined the level of validity and reliability of these. Other units are available , however the accuracy of these units during team sport match

play is yet to be determined. The aims of this study, therefore, were to determine the level of agreement between Catapult and SPT units during team sport match play.
METHODS: Two GPS devices were worn by Australian football umpires during games and training . Various GPS metrics were analysed 6 m/s>, relative distance, Player LoadTM, and SPT Intensity Rating>. To determine the level of agreement, the mean difference, % bias, Pearson product moment correlation and effect sizes were calculated, with measures from Catapult devices regarded as the criterion measure.
RESULTS: Overall, data for the TD , sprint distance and relative distance were highly related, with near perfect correlations and small-trivial effect sizes reported. Bland-Altman plots identified that there was no trend to over or under-estimate TD, however as sprint distance increased, SPT devices over-estimated when compared to Catapult devices. Average Catapult PlayerLoadTM was 827 ± 442 AU, while SPT Intensity rating was 60.5 ± 27.4 AU, with a very large correlation between these measures .
CONCLUSION: Overall, results suggest that there is a relatively high level of agreement between the two GPS devices. While there is some over-estimation for sprint distance within the SPT units, most external load variables were highly correlated, when compared to the Catapult devices. Typically, GPS technology over estimates distances at higher running speeds , with lower frequency units . The overall findings for these data, however, were similar between devices, despite differences in the recording rate. These results suggest that SPT units may provide an acceptable level of agreement compared to Catapult GPS devices, with no trend to over or under estimate in various external load measures. The SPT Intensity Rating also shows acceptable agreement with Catapult's PlayerLoadTM calculation. Lower level athletes and coaching staff may find these units a suitable and more affordable alternative to the industry standard of external load monitoring within team sport participants.

THE EFFECT OF PHYSICAL FATIGUE ON TACKLE TECHNIQUE IN RUGBY UNION PLAYERS

DAVIDOW, D.1, REDMAN, M.1, LAMBERT, M.1, BURGER, N.1, DEN HOLLANDER, S.1, JONES, B.2, SMITH, M.3, HENDRICKS, S.1,2
1: UNIVERSITY OF CAPE TOWN, SOUTH AFRICA 2: LEEDS BECKETT UNIVERSITY, UNITED KINGDOM 3: NEWCASTLE UNIVERSITY, AUSTRALIA

INTRODUCTION: Proficient tackle technique in rugby union has been associated with a reduced risk of injury and higher likelihood of tackle success. Tackle technique proficiency has been shown to decrease in the second half of matches. These findings suggest that physical fatigue may influence tackle technique. However, no study has tested the effect of physical fatigue on tackling technique in rugby union players. To improve training for safe and effective tackles, a better understanding of the effect of fatigue on tackle technique is required. Therefore, the purpose of this study was to determine the effect of physical fatigue on tackle technique in rugby union players.
METHODS: Nineteen rugby union players participated in a randomised cross-over study design with a physical fatigue condition and non-physical fatigue condition (control). During each condition, each player performed four sets of 6 tackles (set 1=baseline; 3 tackles on each shoulder) on a contact simulator (total of 24 tackles). Between each set of tackles in the physical fatigue condition, players performed the prolonged high-intensity intermittent running ability test, which lasted 8 minutes. Between each set of tackles in the control condition, players passively rested for 8 minutes. Each condition was separated by at least 72 hours. Each tackle was video recorded and analysed using a standardised list of tackling technical criteria. The technical criteria outlines a list of observable actions, and a player is awarded either one point or zero depending on whether a particular action is performed or not. The sum of these points is subsequently used to represent the technical proficiency score of the player.
RESULTS: For dominant and non-dominant shoulders combined, physical fatigue did have an effect on tackling technique. The difference between conditions were significant (p=0.007) at set 3 (fatigue mean 7.28, 95%CI 7.12-7.45 vs. control 7.53, 95%CI 7.387.69, out of a total score of 9). For the non- dominant shoulder, there was a difference between the fatigue and control at set 2 (fatigue mean 7.34 95%CI, 7.09-7.59 vs. control mean 7.60, 95%CI 7.41-7.85, p=0.06) and at set 3 (fatigue mean 7.29, 95%CI 7.04-7.53 vs. 7.72 95%CI 7.50-7.94, p=0.006). In the non-dominant shoulder control condition, players tackling technique scores improved over the sets (baseline mean 7.40 95%CI 7.19-7.62 vs. set 3 7.72 95%CI 7.50-7.94, p=0.05).
CONCLUSION: This study showed that physical fatigue had an effect on tackle technique in rugby union players. The effect of fatigue on tackling technique seemed to be more influential when tackling with the non-dominant shoulder. Also, in the control condition, players tackling technique improved as the session progressed. The findings of this study can be used to design and develop tackle training programmes to better prepare players for match tackle demands, with the ultimate goal of reducing the risk of injury while improving tackling performance.

INFLUENCE OF A PROPRIOCEPTIVE SESSION ON SHOOTING TECHNIQUE IN BASE-CLASS BASKETBALL PLAYERS

NIETO, A., SOLANA TRAMUNT, M., MORALES, J.
FPCEE BLANQUERNA RAMÓN LLULL UNIVERSITY

INTRODUCTION: One of the qualities considered most important for the proper technical execution of athletes is proprioception, which is measured the degrees of error between the requested position and the one made, i.e., repositioning error . Few studies have tried to apply analytical proprioceptive training to improve the awareness of joint position; therefore, the aim of this article was to investigate how a proprioceptive training session affected the ER of the elbow and knee in a basketball shot.
METHODS: This quasi-experimental study of pre- and post-intervention measures included 40 basketball players, aged from 8–14 years, who volunteered to participate in the study. The proprioception in the knee and elbow was evaluated before and after a proprioceptive session that focused on the shooting technique or a conventional basketball training technique .
RESULTS: We found significant differences between the ER obtained before and after the test , with the following average for each group: infantile experimental -4 vs. -0.8 , -11.9 vs. 2.9 ; fry experimental -4 vs. -0.5 , -4.4 vs. 2.8 ; prebenjamin experimental -1.7 vs. -0.2 , -2 vs. 4.6 ; and control -3.3 vs. 0.1 , -0.7 vs. 4.6 .There were no differences between the groups measured, except between the experimental infantile group and the control that obtained significant differences in the elbow .

CONCLUSION: No correlations were found between the high success rate in a shot and the position of the segments in space. Nevertheless, it is suggested that the variability and control of movement in the shot, to a certain extent, is determined by afferent proprioceptive processes. This study is an example of how afferent stimulation on a specific joint position has led to improvements in the perception of the position of the elbow and knee joints.

INTERRELATIONSHIP BETWEEN KOREAS SHOTGUN SHOOTING ATHLETES' HIGH HEAVY METAL BLOOD CONTENT AND THE STATUS OF SELF-RATED HEALTH AND HYGIENE EVALUATION

NAM, S., CHUN, H., PARK, N., CHO, I.

KOREA NATIONAL SPORT UNIVERSITY

INTRODUCTION: Athletes training environment is the utmost priority for the best health and safety conditions for the players. Shotgun shooting uses the shotgun to aim at the clay pigeon which emits detrimental and hazardous chemical dust particles transmitted through the players breathing, skin, and hair. However, very little scientific research is conducted and the available source for improvement is very scarce.
METHODS: For this research, based on the training environment of 33 shotgun shooting players officially registered in the 2017 Korea Shooting Federation, high metal level content(ICP-MS) and index of liver damage(AST(aspartate aminotransferase), ALT(alanine aminotransferase), γ-GT(γ-glutamyl transferase)) were conducted through modified IFCC UV and enzymatic colorimetric assay measurement from the 10ml of blood collected from the brachial vein of all 33 players at stable conditions. The blood samples were taken after the players had given written informed consent.
High metal content in open air was measured by using the portable air sampler to collect the bullet dust(air flow-0.78l/min) and ICP-MS and SEM-EDS for other collective data. In addition, shotgun shooting players completed a questionnaire assessing demographics, self-rated health status(Todai Health Index), personal hygiene behaviors, preventive awareness and education.
RESULTS: The research study showed that the shotgun fume emitted relatively higher level of Antimony(Sb) and Lead(Pb) thereby making the athletes heavy metal blood content also above upper limit(3.27mg/dl, which is 97.5%ile value of 306 normal Korean). Furthermore, shotgun shooting players heavy metal blood content positively correlated with the number of training, training hours, smoking, and more specifically, the average number of training per week and daily training hours were the crucial deciphering factors. In addition, AST, ALT and γ-GT showed a tendency to increase depending on higher heavy metal blood content and longer years of training.
Through self-rated health status evaluation overall feeling of sluggish arm, leg and neck was more apparent among the younger players and players with less years of training and no relevance was found between the average weekly hours of training. Examining the state of hygiene, sex and gender was not a significant factor whereas blood high metal content was relative to the players consumption of snacks without washing their hands and failure to use individual utensils.
The most important area of hygiene awareness needed was maintaining clean and sanitary hand, hair after the training. Higher heavy metal blood content level was proportional to the less experience of education and deteriorated willingness to participate in education about their training environment and personal hygiene. Contrastingly, players with longer years of training experience manifested notably higher blood heavy metal content level, but also showed higher level of preventive awareness and experience of education for their training environment and personal hygiene.
CONCLUSION: In summation, Koreas shotgun shooting players heavy metal blood content is relatively above upper limit which is the direct result of their overall training environment. The level of heavy metal blood content but no relevance to the awareness of their personal health and hygiene. The need for significant improvement and enhancement of players training environment, continuous medical examinations and health and hygiene awareness is vital.

THE ANALYSIS OF PENALTY SITUATIONS IN SOCCER WHERE THE REFEREE MAKES AN INCORRECT DECISION

JOHANSEN, B.T.

UNIVERSITY OF AGDER

THE ANALYSIS OF PENALTY SITUATIONS IN SOCCER WHERE THE REFEREE MAKES AN INCORRECT DECISION
Bjørn Tore Johansen & Martin Kjeøen Erikstad, University of Agder, Norway
Introduction: The psychological demands for excellent performance among soccer referees are substantially increasing (Slack et al., 2013). However, referees can and do make mistakes (Mascarenhas et al., 2009), and sometimes that may influence the match result (e.g., penalty situations). The aim of this study was to investigate characteristics of penalty situations where top referees in soccer make an incorrect decision.
Methods: Two expert panels, consisting of four top-class referees and four top-class players respectively, assessed 98 potential penalty situations in Norwegian premier league. The situations in which both expert panels considered that the match referee made an incorrect decision (N = 14) were then analyzed based on recommended technical refereeing criteria and guidelines (i.e., the referees distance to, angle to, and insight into these penalties situation; UEFA, 2017),
Results: The results indicated that the referee had an extended distance to the penalty situation than recommended in 12 of the 14 situations. Furthermore, results revealed that the referee had a good angle in three situations and good insight into three situations. Teams of high status playing at home ground received all three penalties that were awarded, while teams of low status were the attacking team in seven of the remaining 11 situations where no penalty were awarded.
Discussion: The match referee had a poor starting position (Mallo et al., 2012) to assess the penalty situations where they landed on a wrong decision. The referees' positioning in the field of play may have caused uncertainty, and in their fear of failure they have landed on a "no penalty" decision (Haselton & Nettle, 2006). Discussed in the framework of error management theory and social impact theory, we argue that referees may have been influenced by social pressure, as teams of high status derived advantage of mistakes in 10 of the 14 situations. Findings may be considered as an argument in favour of the introduction of Video Assistant Referee system, as referees error are not distributed equal across distinct teams. Apropriate positioning combined with improved self-confidence seems warranted for referees to correctly award a penalty kick in soccer.

INCIDENCE AND RISK FACTORS OF LATERAL ANKLE SPRAIN IN MALE YOUTH SOCCER PLAYERS –PROSPECTIVE STUDY–

MURATA, K.

WASEDA UNIVERSITY

INTRODUCTION: Lateral ankle sprain (LAS) is a trauma with high occurrence frequency and recurrence rate in soccer [1]. Previously, epidemiological studies and prospective investigation of risk factor in LAS have been mostly conducted with adult players [2,3]. Thus, the risk factors of LAS in youth soccer players is still unclear. Based on this background, this study aims to investigate prospectively risk factor of initial LAS for youth soccer players.
METHODS: The chronological age, height, weight, competition history, history of LAS, and the incidence of the initial and recurrent LAS were recorded for 195 male youth soccer players (ages 10 to 15 years old). The peak height velocity age (PHVA) was estimated using Auxal (Scientific Software International, Inc.). The subjects were then divided into three groups with the following criteria; Pre (< PHVA-1yr.), Average (PHVA±1yr.), and Post (> PHVA+1yr.). Measurements included: arch height ratio, leg heel angle (LHA), forefoot angle (vs. rearfoot), ankle dorsi / plantar flexion, foot internal rotation in ankle plantar flexion, weight-bearing dorsi flexion, navicular-medial malleolus distance, lateral side hop distance, side hop test time, and Y-balance test results. Then, a logistic regression analysis was performed for analyzing risk factor of LAS using all measurements as independent variables. One-way ANOVA was conducted between the three groups [Sprain Foot (SF) group, No Sprain Foot (NSF) group and the control (C) group]. The statistical significance level was set at 0.05.
RESULTS: The incidence of initial and recurrence LAS was 7.4% and 17.6%, respectively. The incidence rate was higher in Post (11.1%) than that of Pre (8.6%) and Average (4.8%). Risk factors of the initial LAS group were short competition history [odds ratio (OR) 0.95 (95% CI: 0.92-0.99)] and the lack of ankle dorsiflexion ROM [OR 0.91 (95% CI: 0.84-0.99)]. In comparison among the three groups, LHA was significantly eversion in the NSF group compared with C and SF group ($p < 0.05$). Forefoot angle was significantly inversion in the NSF group compared with the C group ($p < 0.01$). Ankle dorsiflexion was significantly smaller in the NSF group compared with the C group ($p < 0.05$).
CONCLUSION: The recurrence rate of LAS in youth soccer players was higher than that of adult players [3]. These results imply that youth soccer players need more appropriate rehabilitation for preventing recurrent LAS. In addition to the internal risk factors such as lack of ankle dorsiflexion ROM and the relative inversion alignment of ankle, short competitive history was the possible risk factor. These results may imply that players with inadequate skills are vulnerable to LAS. Thus, developing specific soccer skills as well as improving ROM and alignment of ankle are warranted for preventing LAS of youth soccer players.

CONCUSSION REPORTING BEHAVIOURS AND ATTITUDES IN IRISH AMATEUR AND PROFESSIONAL JOCKEYS

CULLEN, S.1, WARRINGTON, G.2, WHELAN, G.3, MCGOLDRICK, A.3, O'CONNOR, S.4

1: WATERFORD INSTITUTE OF TECHNOLOGY, IRELAND 2: UNIVERSITY OF LIMERICK, IRELAND 3: THE TURF CLUB, KILDARE 4: DUBLIN CITY UNIVERSITY, IRELAND

INTRODUCTION: Under-reporting of concussions is a serious concern in sport, with concussion understanding and attitudes potentially impacting on reporting (Kroshus et al., 2010). Concussions are frequent in both professional and amateur horse racing (O'Connor et al., 2017), however concussion reporting behaviours and attitudes in these athletes have not yet been investigated. This study aimed to investigate concussion reporting behaviours and attitudes among Irish professional and amateur jockeys.
METHODS: Licensed amateur and professional jockeys (n=119) were recruited to complete an anonymous questionnaire which was distributed through emails sent to jockeys, over social media and during professional and amateur race meetings. Questions were included on basic demographics, past personal concussion history and attitudes towards concussion.
RESULTS: Despite not being medically diagnosed, amateur (32.4%) and professional (19.6%) jockeys suspected that they did sustain a concussion. This was not apparent in professional flat jockeys. If a concussion occurred during riding out or if an important race was coming up within the following week, 52.8% and 63.8% of jockeys would not report a suspected concussion respectively. However, if they felt they were unable to ride the next horse to the best of their ability, three quarters of jockeys would report a suspected concussion. Reasons for not reporting a suspected concussion and continuing to ride included not considering it serious (85.7%); under pressure at risk of losing the ride (84.0%); not wanting to let owner down (77.8%); considered as a sign of weakness (74.1%); unsure if a concussion was present (60.0%); needed money (48.1%) and an important race (44.0%).
CONCLUSION: Attempts have been made in the Irish horse racing industry to improve jockey knowledge and understanding of concussion through the distribution of factsheets to each license holder annually as well as displaying these at all race tracks. In addition, a mandatory medical assessment by a Turf club approved medical doctor is required following any fall at a race-track in the attempt to deter under-reporting. Despite this, under-reporting of concussions does still occur. The reasons provided by jockeys for under-reporting suggest there is a need to educate the wider racing community and jockey support network on the adverse health implications of concussion as well as appropriate management to encourage reporting of suspected concussions by jockeys.

NO ADAPTATIONS IN MUSCLE ARCHITECTURE AFTER 12 WEEKS OF STATIC STRETCHING IN YOUNG HEALTHY PARTICIPANTS

LONGO, S., CÈ, E., BISCONTI, A.V., LIMONTA, E., RAMPICHINI, S., SHOKOHYAR, S., CORATELLA, G., ESPOSITO, F.

UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Muscle architecture is one of the main determinant of muscle function and performance. Adequate mechanical stimuli (e.g., strength training) can induce modifications in muscle architecture. However, whether long-term stretching provides a sufficient stimulus for bringing architectural changes is still controversial. Therefore, the aim of the present study was to assess possible changes in muscle architecture after 12 weeks of static stretching (SS) in young healthy participants.
METHODS: Twenty-eight participants were randomly divided into two groups: stretching (STR, n=16, 7 females and 9 males; mean±SD: age=23.5±1.0 yrs; stature=1.75±0.08 m; body mass=69.8±8.9 kg) and controls (CTR, n=12, 6 females and 6 males; mean±SD: age=24.2±2.4 yrs; stature=1.70±0.06 m; body mass=65.5±7.2 kg). STR underwent 12 weeks of SS for both pantarflexors (PF) and knee extensors (KE) muscles. CTR did not undergo any training intervention. SS was performed five times per week. One session consisted in 5

sets of 45-s SS each (15-s rest in-between). A total of four exercises were executed: two for PF and two for KE of the right lower limb. All participants kept a file record of the training sessions performed. Ultrasound images of the medial head of the right gastrocnemius (GM) and vastus lateralis (VL) muscles were obtained at 50% muscle length before, at six weeks, and the end of the 12 weeks in both groups. Fascicle length (Lf), pennation angle (PA) and muscle thickness (MT) were measured offline by using an open source software. A 3x2 mixed-model ANOVA was used to assess possible differences over time and between groups in all architectural parameters for each muscle group. Significance was set with $p<0.05$.
RESULTS: Lf, PA and MT did not change significantly in STR over time ($p>0.05$ for all parameters) in both PF and KE. No significant differences were found between STR and CTR over time ($p>0.05$ for all parameters at any time point) in both PF and KE. No time x group interactions were found ($p>0.05$ for all parameters) in both PF and KE.
CONCLUSION: 12 weeks of SS did not induce architectural changes in the mid portion of the GM and VL muscles. These results suggest that common SS exercises for the PF and KE do not provide a sufficient mechanical stimulus for structural adaptations of GM and VL, respectively, despite the protocol duration (12 weeks). However, regional adaptations cannot be excluded.

TRAINING EFFECTS OF ALTERNATED AND PULSED CURRENTS ON FAT MASS OF COMPETITIVE ATHLETES

OLIVEIRA, P., MODESTO, K., BOTTARO, M., BABAULT, N., DURIGAN, J.

UNIVERSITY OF BRASÍLIA/FEDERAL INSTITUTE OF BRASÍLIA

INTRODUCTION: Neuromuscular electrical stimulation (NMES) is widely used for strength training in healthy individuals and athletes. Previous studies have shown that alternated mid-frequency currents (MF) and low-frequency pulsed currents (PC) have similar effects on quadriceps evoked strength and level of discomfort in this population. However, little is known about the effects and best parameters of NMES to induce fat mass loss. The aim of the study was to evaluate the effects of 6 weeks training with different neuromuscular electrical stimulation (NMES) currents (medium alternated and low frequency pulsed current) on fat mass of competitive athletes.
METHODS: A double-blind controlled and randomized experimental study was carried out with 33 athletes (22.2 ± 2.6 yrs, 74.7 ± 9.8 kg, 176.8 ± 6.0 cm), divided into 3 groups: mid-frequency current (MF, n=12), pulsed current (PC, n=11) and control group (CG, n=10). Fat mass percentage was assessed before and after the interventions through a body composition bio-impedance scale (BC-418 Segmental Body Compostion Analyzer, Tanita Corporation of America Inc., Illinois, USA). NMES training was performed 3 times per week and consisted of 18 sessions, 15 min/session (36 involuntary isometric contractions per session), 6s duration in each contraction interspersed with 18s rest. Data were expressed as means ± standard deviation (SD) and normality was checked using the Shapiro-Wilk test. A two-way analysis of variance (ANOVA) with repeated-measures and Tukey post-hoc test were used to analyze data (group and time effects). Statistical significance was accepted with $p < 0.05$.
RESULTS: After the training period, fat mass percentage did not change in any group (PRE: PC = 14.2 ± 3.5 %, MF = 15.4 ± 3.8 %, CG = 15.0 ± 5.1 %; POST: PC = 14.3 ± 3.5 %, MF = 15.0 ± 4.1 %, CG = 14.7 ± 3.9 %; $p > 0.05$). All currents produced similar evoked torque and levels of discomfort ($p > 0.05$).
CONCLUSION: Quadriceps NMES training applied through alternated or pulsed currents produced similar effects and did not change fat mass composition in competitive athletes.

CORTICAL AND MOTOR NEURONE EXCITABILITIES VARY WITH THE RATE OF FORCE DEVELOPMENT OF THE SUBSEQUENT CONTRACTION

GOUVERNEUR, Y., BAUDRY, S., DUCHATEAU, J.

UNIVERSITÉ LIBRE DE BRUXELLES

INTRODUCTION: Previous work indicates that, in leg muscles, the increase in corticospinal excitability prior to ballistic (BAL) contractions (high rate of force development) was delayed compared with ramp (RAMP) contractions (low rate of force development) (1), suggesting that corticospinal excitability during the preparatory period of a contraction may be specifically tuned depending on the rate at which force is developed during the subsequent contraction (2). To further document this possibility, this study investigated the modulation of cortical and spinal excitability during the preparatory period of BAL and RAMP contractions.
METHODS: Seventeen young adults performed isometric contractions with the right ankle dorsal flexor muscles. Subjects had to match a template displayed on a monitor with the force of the ankle dorsiflexor muscles. The template represented a RAMP (1500-ms duration) or a BAL (150-ms duration) contraction developing the same level of force (force associated with the maximal rate of force development during BAL contraction). Transcranial magnetic stimulation was applied over the left motor cortex to induce motor evoked potential (MEP) in the tibialis anterior, in a 500-ms window preceding the onset of the contractions (n=17). In 6 subjects, paired-pulse stimulations (2-ms interval) were used to assess short-interval intracortical inhibition (SICI, %). Peripheral nerve stimulation was used to assess motoneurone excitability by recording the occurrence of F wave (n=8).
RESULTS: MEP amplitude increased significantly ($p<0.05$) between each 100-ms window (+18.7%, +25.58%, +48.7%) from 500ms to the onset of the ramp contraction, whereas it increased (+85%) only in the last 200-ms prior to BAL contractions ($p<0.001$). In contrast, SICI (-50.8±23.4% prior to BAL and -46.4±19.5% prior to RAMP) did not change within the preparatory period, regardless of the contraction type ($p>0.05$). The F-wave occurrence increased progressively ($p<0.05$) from 500ms (18%) to 100ms (34%) prior to the onset of the RAMP contraction, whereas it did not change significantly over the same epoch preceding the BAL contraction (~20%; $p>0.05$).
CONCLUSION: These data suggest that prior to a BAL contraction, the motor neurones excitability is depressed up to the onset of the contraction to achieve a non-refractory state leading to greater motor units discharge rate during the subsequent contraction (3).

MO-BN04 Rehabilitation and prevention

IDENTIFICATION OF INTRAMUSCULAR TISSUE OEDEMA AND CHANGES IN MUSCLE CONTRACTILE PROPERTIES INDUCED BY DRY NEEDLING

MARTÍN RODRÍGUEZ, S.1, PIQUERAS-SANCHIZ, P.2, BAUTISTA, I.J.3, BARAJA-VEGAS, L.4

1. UNIVERSITY OF VERONA, ITALY; 2. SPORT PLUS CENTER, SEVILLA, SPAIN; 3. FISIOSALUD ELITE, HEALTH, TRAINING & INNOVATION, UNIVERSITY OF GRANADA, GRANADA; 4. CATHOLIC UNIVERSITY OF VALENCIA, VALENCIA

INTRODUCTION: Myofascial trigger points are a common cause of clinically observed local muscle pain and tenderness. The improvement associated with the muscle relaxing effect (reduction of muscle stiffness) produced by dry needling (DN) is still not well understood. In this regard, it is believed that the regeneration of tissue destroyed by dry needling through the inflammatory process should do with the return to normality of muscle contractility. A contractility marker (muscle belly displacement, Dm) has been associated with changes in muscle stiffness (increase in Dm = decrease in stiffness and vice versa). The aim of this study was to identify via magnetic resonance imaging (MRI) if the local inflammatory response is immediately induced by DN as well as changes in Dm of asymptomatic patients.
METHODS: 18 asymptomatic patients participated in the study. We used an inter-group research design to investigate the regional-signal differences of MRI measurements in the gastrocnemious medialis (GM), before and after 1h DN. The research unit of analysis was the GM. The GM that presented more pain to pressure and reported by visual analogue scale was used for further analysis. The contralateral GM was used as a control group (CG) while the other one was considered the experimental group (EG). MRI Short tau inversion recovery (STIR, signal intensity) was used to identify signal changes due to by local inflammation. Changes in contractile muscle properties were assessed by tensiomyography using the key parameter: Dm (mm). An ANOVA was performed to analyse the influence of DN on the STIR variable and a t-test for dependent samples was performed to compare the pain perception after the DN.
RESULTS: The STIR (signal intensity) increased 128.97 % after the DN. The interaction effect showed significant differences (F(1,34) =235, p =0.0001, r =0.93). Bonferronis post hoc tests showed significant differences [mean differences and 95% confidence interval (95% CI) =198 (172 – 224)] signal intensity (F (1,34) =236, p =0.001; r =0.93; d =5.03). The difference between the CG vs. EG in Dm variable was 24.04 % after the DN. In addition, there was a significant effect of the group variable (i.e., CG vs. EG) after controlling the effects with the pre- variable (F(1,33) = 9.95, p =0.003, r =0.48, d =1.10. In relation to pain perception, a significant reduction (t(17) = 12.40, p =0.001, r =0.65, d =1.71) were found. Pearsons correlation did not show correlation between any variable.
CONCLUSION: Intramuscular oedema appears immediately after (1h) of the application of DN, therefore indicating an inflammatory process with unexpected reduction in the pain perception. A loss of muscle contractility measured by Dm did not correlate with changes in the STIR. Our results are in line with others found in mice showing signs of an inflammatory response after DN. Our research was limited for the lack of subsequent measurements of MRI to detect when the edema was removed.

THE EFFECTIVENESS OF ANTI-PRONATION TAPING IN LOWER EXTREMITIES STIFFNESS TO LOW MEDIAL LONGITUDINAL ARCH PEOPLE DURING LANDING PHASE

LIN, C.F., CHIOU, C.W.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Flat foot is one of the most common foot deformities. Possible risks factors for the development of flat foot include obesity, muscle unbalance or foot structure deformity. The low-dye taping (LDT) was first used to help athletes with flat foot to improve their performance. Furthermore, some studies used it on flat foot patients and showed improvement in pain and walking ability. However this study showed the short term effect in ankle joint with LDT. Furthermore, according to the kinematic chain, the flat foot may also affect upper joint by rotating the tibia & hip. Those changes will lead hip and knee joint suffer more stress. Therefore, this study aims to find out if the LDT taping would affect landing impact through LE joint.
METHODS: Fourteen participants between 20 to 30 years old were recruited from Tainan area. Low longitudinal arch (low arch) subjects were randomly assigned to 2 groups, intervention group or placebo group. All participants met the inclusion criteria of having a low foot arch- the Navicular drop test over 8mm, Visual Analog Scale below 6. Participants are free of substantial lower limbs injury in the 6 months before the study, such as a sprain and other symptoms that would affect landing tasks.
Navicular drop test (NDT) was using the navicular drop height to evaluate the severity of flat foot. The 3D motion data and vertical ground reaction force (vGRF) collection were conducted before and after intervention using 8 infrared cameras (Eagle camera system, Motion Analysis Corporation, USA) and two kistler force plates. The whole body marker set was used for COM calculation. There were 3 different jump tasks that including double legs forward landing (DLL), single leg forward landing (FL), and single leg side landing (SL). Those single leg landing tasks mentioned above concluded both right and left jump landing tasks. These tasks were performed in a random order. The outcome measure is lower extremity stiffness, calculated as (maximum vGRF)/range of center of mass (COM). The higher lower extremity stiffness (LES) means body landing with a stiffer way.
RESULTS: The LES in intervention group showed a decreasing trend. LES during double leg landing before and after taping are 0.298/0.265. LES during forward single leg landing before and after taping are 0.354/0.195. LES during sideward single leg landing before and after taping are 0.329/0.224. In the placebo group, the LES values in two conditions are similar. The decreased lower extremity stiffness may show that the anti-pronation taping skill could improve support ability in flat foot population. Furthermore, the lesser stiffness means lower extremity joints can suffer from lesser force during landing.
CONCLUSION: The changes in lower extremity stiffness shows that there must be landing mechanism differences during these tasks. However, the relationship between kinematic data and kinetic data in this study need further study to explain the mechanism behind.

IMPACT OF A STRENGTH INTERVENTION PROGRAM ON CHANGE IN HAMSTRING:QUADRICEPS RATIO

HAMMEROVA, T., KRALOVA, T., CACEK, J., KALINA, T., HLAVONOVA, Z., ONDRACEK, J.

MASARYK UNIVERSITY

INTRODUCTION: The most common knee joint injury is the rupture of the anterior cruciate ligament (ACL). When the H:Q (hamstrings:quadriceps) ratio is too low, the risk of ACL injury increases (Holcomb et al, 2007). The H:Q ratio can be expressed based on mus-

cle contraction. The conventional HCON:QCON ratio compares maximal hamstrings strength to maximal quadriceps strength during concentric contraction. The functional HECC:QCON ratio expresses maximal hamstrings strength at eccentric muscle contraction and maximum quadriceps strength at concentric contraction (Delextrat et al., 2010). The purpose of this study is to assess the impact of a strength intervention program on the conventional H:Q ratio, which is one of many factors related to ACL injuries.
METHODS: The work was achieved using the inter-individual research strategy of experimental character. Fifty male participants were randomized into 5 groups (4 experimental, 1 control): for EX1: high-bar back squats with 90% of 1RM (one-repeatition maximum); EX2: squat jumps with 30% of 1RM; EX3: high-bar back half squats with 90% of 1RM, EX4: half squat jumps with 30% 1RM. The intervention took place twice per week for 2 months. The control group did not participate in any exercises. Subjects were tested using a method of isokinetic dynamometry (Humac Norm, CSMI, Stoughton, USA) at an angular rate of 60°/s and then 300°/s. Two-way ANOVA with repeated measures was used for statistical analysis.
RESULTS: Pre-test and post-test comparison did not showed a significant improvement of H:Q ratio ($p>0.05$) for EX1, EX2, EX3 and EX4.
CONCLUSION: The results show that strength intervention involving various modifications of the squat and half squat does not affect the H:Q ratio. This may be because the intervention increases both quadriceps and hamstrings strength. It is important to note that squatting does not decrease the H:Q ratio, so squats can be safely included in exercise programs, where emphasis should be placed on correct execution of the squat and on the individual needs of trainees.

WILL DYNAMIC STRETCHING OF HAMSTRING ON FEMALE ATHLETES CHANGE KNEE JOINT BIOMECHANICAL CHARACTERS DURING SIDE-CUTTING TASK?

CHEN, B.Y., LEE, H.J.
NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Anterior cruciate ligament injuy was one of the common sport-related injuries. Athletes were prone to injury during side-cutting task and the incidence of ACL tear. Female athletes were 3 times higher than male athletes suffering ACL injury. Hamstring has been known could help to stabilize the knee joint. Dynamic stretching could enhance joint range of motion and muscle activations . The purpose of this study was to investigate the influence of dynamic stretching of hamstring on knee joint biomechanical characters during side-cutting tasks .
METHODS: There were 10 female collegiate athletes with no lower extremity injury within 6 months volunteered for this study. During the experiment, participants were asked to perform SC as the pretest and then perform HDS as the intervention, finally perform SC for post-test. Kinematics, kinetics and EMG data were collected by 8 VICON cameras at 250Hz, 1 Kistler force plate at 1000Hz and 2 Delsys wireless EMG sensors at 2000Hz placed on semitendinosus and biceps femoris during SC. One-way Anova was used for statistical analysis.
RESULTS: Subjects demonstrated significantly greater hamstring activation <9%> and lesser knee varus angle at initial contact after HDS intervention in pre-contact phase. Subjects showed significantly greater hamstring activation <12%> and a significant lesser peak knee valgus moment <0.023N·m/BW> after HDS intervention in deceleration phase. During SC, knee varus angle was significantly lesser after HDS intervention .
CONCLUSION: The knee valgus moment were predictors of ACL injury . Therefore, decreasing knee valgus moment during SC could reduce possibility of ACL injury. The current study found that HDS could increase hamstring activation in pre-contact phase, which may help knee joint to land at less knee varus angle during SC. In the deceleration phase, HDS could also increase hamstring activation, which may help knee joint to decrease knee valgus moment. These findings suggest that dynamic stretching of hamstring might be a good method to cooperate in warm-up which could prevent occurrence of ACL injury.

RESPONSIVENESS OF THE IDFAI-BRAZIL QUESTIONNAIRE IN SUBJECTS WITH FUNCTIONAL ANKLE INSTABILITY

MARTINEZ, B.R.1, SAUERS, A.D.L.2, SOUZA, V.T.O.C.1, OLIVEIRA, J.C.1, SILVA, J.B.1, DOCHERTY, C.L.3, YI, L.C.1
1: FEDERAL UNIVERSITY OF SÃO PAULO , 2: A.T STILL UNIVERSITY , 3: INDIANA UNIVERSITY .

INTRODUCTION: The Identification of Functional Ankle Instability (IdFAI) Questionnaire has been recommended as the best self-reported instrument to use when identifying a patients ankle stability status. Recently, the IdFAI was translated to Brazilian-Portuguese language and has shown to be a valid and reliable tool to evaluate functional ankle instability (FAI). Therefore, the aim of this study was determine the responsiveness of the IdFAI-Brazil in patients with FAI.
METHODS: Twenty-five college students (23,12 ± 2,80 years) with FAI were enrolled in the study. For responsiveness measurement, the IdFAI-Brazil and 11 anchor-based approaches were used before and after an eight-week treatment period. The assessments were: Visual Analog Scale for instability; Cumberland Ankle Instability Tool; Strength of dorsiflexors, plantarflexors, inverters and everters; Star Excursion Balance Test; Lunge test; Single Hop test; Triple Crossover Hop test and Side Hop test. The internal responsiveness was tested with the paired t-test, effect size and standardized response mean.
RESULTS: When analyzing the clinical changes in volunteers with FAI after a physiotherapeutic intervention, the IdFAI-Brazil showed high responsiveness ($p< 0,001$) with values of 1.34 for effect size and 1.28 for standardized response mean (values ≥0.80 = high responsiveness).
CONCLUSION: The translation and cultural adaptation of the IdFAI to other languages and different countries helps to improve the diagnosis and to standardize the definition of FAI. This was the first study of responsiveness analysis of the IdFAI questionnaire and from the anchor-based approaches, it was possible to identify clinical consistent changes in the IdFAI score. The Brazilian version of the IdFAI questionnaire has been shown to be responsive in identifying clinical changes in patients with ankle functional instability undergoing physiotherapeutic intervention and it may be used in clinical and scientific fields.

EFFECTS OF MYOFASCIAL RELEASE OF THE ANKLE PLANTAR FLEXORS ON STATIC POSTURAL BALANCE OF YOUNG MEN

MEDEIROS, F., BOTTARO, M.1, LAURENÇO, D.F.R.1, MARINHO, E.B.A.1, PIMENTEL, M.O.C.1, GONÇALVES, M.S.1, FERREIRA-JUNIOR, J.B.2, CARVALHO, J.C.1

UNIVERSIDADE DE BRASILIA

INTRODUCTION: Myofascial release (MR) is a type of massage that consists in compression of myofascial tissue. It has been hypothesized that MR stimulate the somatosensory and proprioceptive system leading to improvement on postural balance (Kumka et al., 2012). However, MR has been performed on the plantar fascia, despite it is known that the ankle flexor muscles are the main responsible for the control of static postural balance (Noda et al., 2006). Furthermore, controlled studies on the effects of MR on postural balance are lacking. Therefore, the aim of this study was to investigate the effect of MR of the ankle plantar flexor muscles on static postural balance of healthy young men.
METHODS: Fifty young men were randomly exposed to two different manipulation techniques on ankle plantar flexors: 1) MR group (n = 25), the MR was administered by using a roller massager with a controlled force of 8.5±5.0 kgf, and perceived muscle soreness of 5), and 2) Sham group (n = 25), the sham was performed with a turned off ultrasound probe using light slip movements. Both techniques were applied bilaterally at 60bpm frequency during 5 min. The bipodal static postural balance test was performed before and 2 min post both interventions on a force plate with eyes closed during the test. Subjects performed 3 sets of 30-s with 1 min of rest. Mean values of displacement area (area95) and center of pressure velocity (COPvel) was used for analysis.
RESULTS: The Sham group obtained 21.4±8.2 cm2 in the pre-test and 20.3±7.3cm2 in the post-test for area95 and 5.3±1.0 cm.s-1 and 4.9±1.2 cm.s-1 in the pre-test and post-test, respectively, for COPvel. The MR obtained 20.6±6.4 cm2 and 19.5±6.7 cm2 in the pre- and post-test, respectively, for area95 and 5.0±0.8 cm.s-1 in the pre-test and 4.5±0.6cm.s-1 in the post-test for COPvel. Area95 did not differ between groups or between pre- and post-test ($p>0.05$). COPvel decreased on post-test in both MR and sham group ($p<0.05$), but there was no difference between them ($p>0.05$).
CONCLUSION: There was no difference between MR and Sham intervention on the variables investigated. However, both techniques acutely improved the static postural balance. This improvement may be related to mechanical and positive effects on somatosensory system induced by massage (Kumka et al., 2012). Previous studies reported that COPvel is more sensible than area95 to assess postural balance (Raymakrs et al., 2005), this would explain significant COPvel decreased on post-test observed in the present study.

ASSOCIATION BETWEEN GLENOHUMERAL AND HIP ROTATIONAL RANGE OF MOTION IN TWO DIFFERENT HIP POSITIONS: A CROSS-SECTIONAL STUDY IN HEALTHY MIDDLE-SCHOOL BASEBALL PLAYERS

YUSUKE, S.

HOSEI UNIVERSITY

INTRODUCTION: Every joint in the body contributes to the completion of the throwing motion. The glenohumeral joint (GHJ) and hip joint rotational range of motion (ROM) are large and are essential for proper throwing mechanics. Previous studies showed an association between GHJ and hip ROM in adult baseball players. The throwing mechanics are different at each age level; however, these associations have not been investigated in younger individuals. In addition, hip rotational ROM, which was used in these studies, was examined in only one measurement position. The purpose of this study was to investigate the association between glenohumeral and hip rotational ROM at two different hip positions in healthy middle-school baseball players.
METHODS: Out of 33 middle-school baseball players, 23 were included (10 players with hip or GHJ injuries were excluded). Rotational ROM was measured using a goniometer. ROM for the GHJ internal rotation (IR) and external rotation (ER) in the dominant side was assessed with the arm abducted at 90-degree angle. Hip rotational ROM was measured in two hip positions: 0 and 90 degrees of hip flexion. The Pearsons correlation was used for statistical analysis; the level of significance was set at 0.05.
RESULTS: An association between GHJ IR and hip joint rotational ROM was not found. A moderate positive correlation was found between GHJ ER and the non-throwing-side hip joint ER ($r=0.53$ $p<0.001$) and the throwing-side hip joint IR ($r=0.51$ $p=0.013$) at 90 degrees of hip flexion. Although there was no significant difference, throwing-side hip joint ER and non-throwing-side hip joint IR also showed a low to moderate correlation with GHJ ER ROM. The association between GHJ ER and hip joint rotational ROM at 0 degrees of hip flexion was not found.
CONCLUSION: There was no relationship between GHJ IR and hip rotational ROM. Hip rotational ROM was related to GHJ ER not at 0 degrees of hip flexion, but at 90 degrees of hip flexion in healthy middle-school baseball players.

EFFECT OF A TWENTY-FOUR-WEEKS STRENGTH TRAINING PROGRAM ABOUT PAIN INTENSITY AND INTERFERENCE WITH DAILY ACTIVITIES IN TWO DIFFERENT GROUPS OF WOMEN DIAGNOSED WITH FIBROMYALGIA.

MAESTRE-CASCALES, C.1, PASTOR, D.2, ROJO-GONZÁLEZ, J.J.1

1. LFE RESEARCH GROUP ; 2. SPORT RESEARCH CENTER – MIGUEL HERNÁNDEZ UNIVERSITY

Introduction: Fibromyalgia (FM) is a chronic disease characterized by widespread pain and other associated symptoms. It has a relevant impact on physical fitness and the ability to perform daily living tasks. Among the physical impairments of FM patients, we found the low levels of strength, endurance, and loss of handgrip strength (1,2). The objective of the study was to compare the effect of a strength training program in women ≤ 55 years, and woman ≥56 years, and how it affects in the pain intensity and interference daily life.
Methods: A total of forty-one women diagnosed of FM participated in the study. Participants were divided into 2 groups taking into account the age, the first (n=17;≤55yrs)(47.54±7.99yrs; 64.69±15.46kg;161.66±6.09cm) and the second (n=24;>55yrs)(61.81±5.68yrs; 70.54±12.72kg; 158.72±5.24cm). The physical condition was measured with Senior Fitness Test battery (SFT) and the handgrip strength was assessed by manual dynamometry (T.K.K.5101). All participants completed the Brief Pain Inventory. We used Student's t-test to analyze the differences pre-post training program and the clinic effect size was interpreted according to Cohen (1988).

Results: In the first group (≤55yrs) we obtained statistically and clinical differences in pain intensity (p=0.01;d=0.93) and with the interference activities daily we found a high clinic effect (p=0.058;d=0.68). To the contrary, we found in the second group a clinic effect higher in interference activities daily (d=1.00) than pain intensity (d=0.76). In relation to the physical condition, we found statistically and clinical differences in all test of both groups (p<0.01;d>1.0) being the highest effect in the second group, as to AC (d=2.43) and 30" CST (d=1.54).
Discussion: The evolution of the levels of strength in the upper and lower limbs was significant in both groups producing a series of changes. In elderly women diagnosed FM affected to a greater extent the ability to perform the activities of daily life compared with early ages, where the effect was smaller. Therefore, supporting authors (1), new patients with this condition tend to age before if we did not stop the loss of physical condition. On the other hand, the intensity of pain decreased at the end of the program in both groups, producing a greater effect in the group of older women. In conclusion, the decrease in pain produces greater benefits in physical capacity in older women when it comes to daily activities than in more early ages.

MENTAL FATIGUE INCREASES GAIT VARIABILITY DURING DUAL-TASK WALKING IN OLD ADULTS

BEHRENS, M.1, MAU-MOELLER, A.1, LISCHKE, A.2, KATLUN, F.1, GUBE, M.1, ZSCHORLICH, V.1, SKRIPITZ, R.3, WEIPPERT, M.1
1: INSTITUTE OF SPORT SCIENCE, UNIVERSITY OF ROSTOCK, 2: DEPARTMENT OF PSYCHOLOGY, UNIVERSITY OF GREIFSWALD, 3: ROLAND-KLINIK AM WERDERSEE, BREMEN

INTRODUCTION: Mental fatigue is a psychobiological state induced by sustained periods of demanding cognitive activity and is characterized by feelings of tiredness which are common in everyday life. Recently, it has been hypothesized that mental fatigue might have an impact on gait performance in old adults. Therefore, the effect of mental fatigue on gait performance under single- and dual-task conditions was investigated in young and old participants.
METHODS: Spatio-temporal gait parameters of 16 young and 16 old healthy participants were measured using a photoelectric system during single- and dual-task walking (motor + cognitive interference task) before and after a randomly assigned mental fatigue (performing a stop-signal task for 90 min) and control intervention (watching a video for 90 min), respectively. Changes in subjective fatigue, wakefulness, mood, arousal and psychophysiological workload (heart rate variability (HRV) indices) were assessed.
RESULTS: Psychometric measures indicated increased subjective fatigue and arousal as well as decreased mood and wakefulness after the mental fatigue task. HRV indices revealed a higher psychophysiological workload during the mental fatigue intervention in old compared to young participants. Gait measures (coefficient of variation of speed, stride length and stance time) indicated impaired dual-task walking performance following the mental fatigue intervention only in old participants.
CONCLUSION: Data indicate that mental fatigue, induced by sustained cognitive activity, can impair gait performance during dual-task walking in old adults. Structural alterations of the brain, e.g. in the prefrontal areas, have been observed with aging. This factor has been identified as a contributor to decreased gait performance under dual-task conditions in older people. Challenging these brain areas by means of a mental fatiguing task seems to increase gait variability during dual-task walking in the old age. This effect of mental fatigue on gait variability during dual-task walking was not observed in young participants. These results indicate that young adults can cope with the cognitive interference task in a mental fatigued state without attenuating (i) processing capacity for the motor task (central capacity sharing model) and/or (ii) sequential neural processing of the motor and cognitive interference task (bottleneck model). The susceptibility to mental fatigue could be a new intrinsic risk factor for falls in older people and should be taken into account when dual-task gait analyses are performed.

SPECIFICITY OF BALANCE TRAINING EFFECTS AFTER SIX WEEKS OF SLACKLINE TRAINING

RINGHOF, S., ZEEB, N., ALTMANN, S., NEUMANN, R., WOLL, A., STEIN, T.
KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: Balance is vitally important for most sports and activities of daily living. Therefore, balance training is commonly employed to improve postural control as well as to prevent injuries or falls . A special and challenging type of balance training is slacklining, which has been suggested to improve proxies of balance and neuromuscular performance . However, recent studies have provided evidence for the task-specificity principle of balance . Therefore, this study aimed to investigate the generalizability of slackline training effects. In particular, we studied whether six weeks of slackline training can elicit transfer effects to either more or less similar balance tasks as well as to neuromuscular performance tests.
METHODS: Participants were 21 female handball players who were matched to a slackline training or a control group based on their initial slackline performance. The intervention comprised twelve sessions of slackline training <~10 min> on single and double slacklines. Pre and post intervention, dynamic balance tests and static balance tests were performed using biomechanical motion analyses. In addition, neuromuscular performance parameters time> were assessed.
RESULTS: Two-way ANOVAs revealed a significant group × time interaction for slackline standing time with larger training effects in SLT than in CON. For the remaining dynamic and static balance tests, no significant interaction effects were apparent. With regard to neuromuscular performance tests, a significant group × time interaction in favor of SLT was found only for CoD time .
CONCLUSION: The study showed that slackline training induced large performance enhancements in the trained slackline task. However, slackline training did not improve balance in a general way, as was evident by lack of transfer effects. This adds further evidence to the task-specificity principle of balance, suggesting that generalizability and transfer effects – even between very similar balance tasks – are limited. Besides, the addition of slackline training to the usual handball training seems to contribute to improve CoD performance. These findings contain practical implications for future balance training studies, highlighting the significance of selecting appropriate training protocols and balance tests.

COMPARISON OF THE EFFECTS OF A SHORT-TERM VIRTUAL REALITY-BASED AND CONVENTIONAL BALANCE TRAINING ON BALANCE IN HEALTHY WOMEN

KIM, A.R.1, YOO, K.T.1, LEE, S.A.2, LEE, H.S.2

1. NAMSEOUL UNIVERSITY 2. DANKOOK UNIVERSITY

INTRODUCTION: Virtual reality (VR) can be defined as an approach to user-computer interface that involves real-time simulation of an environment, scenario or activity that allows for user interaction via multiple sensory channels (Burdea, 2003). Many disciplines of healthcare now rely on VR, such as for training surgeons, delivery of cognitive therapy, and delivery of post-traumatic stress disorder therapy. The use of VR for sensorimotor training is a promising addition to its already broad utility in healthcare (Adamovich et al., 2009). However, rigorous randomized studies regarding its efficacy, safety, and applicability with individuals are lacking. In this study, we aimed to investigate the comparison of the effects of a short-term virtual reality (VR)-based balance training and conventional exercises on balance ability in healthy woman.
METHODS: Twenty healthy women were divided to VR-based balance training group (VRG, n = 10), and conventional balance exercise group (CON, n = 10). The VR-based balance exercise that challenged balance (eg, rope crossing adventure, tunnel race) performed while standing. The conventional balance exercise performed one leg standing and threw and catch ball with unstable surfaces. The training consisted of 30 minute/day, three times a week for a 4-week period. Objective outcome measures of static and dynamic balance were assessed before, and 4-week after training each group.
RESULTS: According to the static and dynamic balance test conducted to examine the effects of the training, both the area covered by the bodys center of pressure movement, and movement distances per unit area of the bodys center of pressure envelope significantly improved in the VRG and CON ($p < .05$, respectively). Although there were no significant differences between the two groups after the intervention.
CONCLUSION: Similar improvements were found in static and dynamic balance with VR-based balance training and conventional balance training in the healthy women. Results from the current study will provide important evidence for the use of low-cost, accessible VR-based balance training as an adjunct intervention to increase balance ability. The motivating and enjoyable attributes of VRT may increase exercise dosage, leading to improved function and optimal results from increase of balance ability.

THE INFLUENCE OF THE 3D SOUND IMAGE MOVEMENT ON THE MOVEMENT OF THE CENTER OF PLANTAR PRESSURE OF THE STANDING POSTURE

INOUE, Y., TANAKA, R.

OSAKA INSTITUTE OF TECHNOLOGY

INTRODUCTION: It is known that visual information influences controlling the standing posture. However, there are not many studies on how the auditory stimulus affects the center of plantar pressure (COP) when the eyes are closed, that is, when there is no visual information. Some previous studies have reported that the traveling distance of the COP movement with sound image movement tends to be longer than with no sound (Miura et al., 1991, Nara et al., 2000). Auditory stimulation has two types: dynamic sound source and static sound source. The speakers are fixed in a position, but in the former the source is virtually moving (it sounds as if it is moving) and in the latter it actually sounds still. This research examines how the speed and direction of the 3D sound image movement affect the COP movement of the standing posture.
METHODS: 16 male college students were participated in the experiment on two cross-cutting dimensions. One dimension was four conditions for changing the direction of sound image movement: front to rear (F-R), rear to front (R-F), left to right (L-R), right to left (R-L). The other was four conditions for changing the speed of sound image movement: 0, 10, 15 and 20m/s. The participants were made to hear a one-second pure tone on 16 conditions and control condition (no sound condition) twice. A 3D sound image was presented through 5.1 channel virtual surround speakers. They were instructed to stand on the plantar pressure measurement plate (Footscan 2D, RS International) with their eyes closed.
RESULTS: The total distance of the COP movement was shown to be significantly longer in the R-F, L-R, and R-L conditions than in the control condition ($P<0.05$). Regardless of the direction in which the sound image was moving, the COP tended to move forward as the sound approached. Compared on the four speed conditions and the control condition, the total distance of the COP movement on the control condition tended to be the shortest.
CONCLUSION: From the results, we could conceive two factors. First, it is difficult to lean back due to the structure of the body. Second, as the sound image passes by, there is a tendency to move the COP forward to get rid of the object. Therefore, the direction of sound image movement does not matter when the COP moves forward. In other words, the COP normally moves forward even though the sound comes in any direction.

TOWARDS A BALANCE ALGORITHM TO DETERMINE FORWARD AND BACKWARD LEANS IN SKIING

VENEK, V.1, BRUNAUER, R.1, BUCHECKER, M.2, JAHNEL, R.2, STÖGGL, T.2

1: SALZBURG RESEARCH, 2: PARIS LODRON UNIVERSITY SALZBURG

INTRODUCTION: Keeping balance is a crucial skill of alpine skiing (Lesnik et al., 2017; Hrysomallis, 2011). Skiers are advised to prepare with balance exercises to prevent self-inflicted falls and injury (Cigrovski et al., 2017). To assess tendencies towards unwanted backward and

forward leans, the influence of the ski boot on balance performance must be considered (Mildner et al., 2010). We present a study on a novel concept for balance assessment by comparing pressure sensors integrated into ski boots towards a force plate system. We aimed at developing a balance algorithm displaying back and forward leans based on pressure distribution over the feet to provide a proof-of-concept for in-store application and a pre-study for balance on-ski.
METHODS: Readings from two pressure sensors positioned at the ski boots' forefoot and heel were weighted to result in balance values ranging –1 and +1 reflecting maximal backward and forward lean. To determine reference data, two expert skiers performed a sequence of alternating forward and backward leans according to the natural range of motion during skiing on a force plate (AMTI) with boots clipped on skis. By placing markers onto each ski boot and the force plate edges, the center position of the ski boots on the plate was obtained. The center of pressure (CoP) course in anterior-posterior axis from the force plate was adapted to the center position of the boots. Then the maximal values of the forward and the backward lean were determined to normalize the CoP signal to the range of –1 and +1. Finally, the sensor-based balance results were optimized using the reference data to align the weights of the pressure sensors to detect the leans.
RESULTS: The comparison of the sensor-based balance values with the reference data revealed that there are not common weights to map the pressure sensor values to the whole balance range since there are two ways for how to perform forward and backward leans. One subject performed as expected; the extreme leaning positions coincided with the maximal pressure on the corresponding feet area, i.e. forward lean was produced by maximal pressure on the forefoot and backward lean vice versa. The other subject applied a torque in the opposite direction, i.e. the maximal pressure was applied over the heel during forward leans instead of over the forefoot and during backward leans vice versa.
CONCLUSION: During the study, an unexpected result occurred because there are at least two patterns for extreme forward and backward lean performances. This already overexerted the sensor-based balance algorithm. The identification of subtypes of forward and backward lean in skiing supports the further development of the algorithm and the application on more subjects to confirm these two types. Simultaneously, a further development of the reference data generation (e.g. force binding system) and balance understanding for on-piste conditions is warranted to monitor the CoP during skiing and compare to the pressure distribution over the feet.

THE INFLUENCE OF IMPROVED COGNITIVE CONTROL AFTER NON-PHYSICAL TRAINING ON MOBILITY-RELATED OUTCOMES IN HEALTHY AND PHYSICALLY ACTIVE ELDERLY: A RANDOMIZED CONTROLLED TRIAL

MARUSIC, U.1,2,3, PISOT, R.1, MAHONEY, J.4

1-SCIENCE AND RESEARCH CENTRE KOPER; 2-ALMA MATER EUROPAEA-ECM; 3-UNIVERSITY OF PRIMORSKA; 4-ALBERT EINSTEIN COLLEGE OF MEDICINE

INTRODUCTION: Gait and cognition have shown to be interrelated, especially in late life (Montero-Odasso et al., 2012). Our recent research revealed a positive influence of non-physical intervention on several complex functional outcomes (e.g., walking while talking) in frail older adults (Marusic, Verghese & Mahoney, 2018). The aim of the current study was to determine the efficacy of the same computerized cognitive training (CCT) intervention on healthy, active and independently living older adults.
METHODS: Forty members (mean age = 66 years, mean MoCA score = 27) of the Center for Daily Activity Koper (Slovenia) were carefully selected and randomized into one of two groups: Experimental group (EXP) receiving 24 sessions of CCT in 2 months or control group (CON) receiving only pre- and post-measurements. Primary outcomes were self-selected gait speed in normal and dual-task conditions, and fast-paced gait speed in the normal condition. The 2x2 ANOVA was used to assess the interactions at $p<0.05$.
RESULTS: Our preliminary results reveal that at post-measurements, EXP manifested significant improvements in both the fast-paced walking condition ($p=0.021$) and the self-selected dual-task walking condition ($p=0.009$) compared to the CON. However, no significant interaction was found for self-selected walking condition ($p=0.148$).
CONCLUSION: Our results suggest that CCT can improve mobility outcomes also in a population of active, healthy and independently living older adults and as such represents a novel tool for cognitive and motor decline prevention. Future studies should examine the CCT-related neural adaptations as well as long-term retention effect.

EFFECTS OF 4 WEEKS SLACKLINE TRAINING ON ANKLE JOINT KINEMATICS.

SCHAEFER, T., DEBOECK, G., SOBCZAK, S., FAORO, V.

FACULTY OF MOTRICITY SCIENCE

INTRODUCTION: Balance training takes more and more place in athletic preparation in order to increase performances and reduce injuries risks. Balance exercise on slackline have been shown to improve postural control even if transfer to other conditions is limited in agreement with "task-specificity principle". Previous studies showed positive slacklining effects on muscular strength, muscular activation and preactivation, on spinal reflex and supraspinal control. Although ankle is one of the most injured joints, the effects of slackline on ankle joint kinematics remain unclear.
METHODS: Twenty-two healthy young subjects were randomly devided in two groups; training group (n = 11, 24 ± 1 years; 4 females) and control group (n = 11, 24 ± 2 years; 1 female). Training consisted in 2 slackline sessions of 45min a week during 4 weeks. The control group did not follow any balance training. Ankle joint angular velocity (AV) and angular acceleration (AA) of the dominant leg were measured during a unipodal standing 30s test before and after intervention in all subjects.
RESULTS: Slackline training improved ($p<0,05$):
- Angular velocity of pronation (pre: 13,9 5,1 deg/s ; post: 9,9 3,3 deg/s), supination (pre: 9,8 5,1 deg/s ; post: 5,8 3,6 deg/s), plantar flexion (pre: 7,8 2,4 deg/s ; post: 5,8 1,8 deg/s) and dorsal flexion (pre: 3,7 2,5 deg/s ; post: 1,9 1,7 deg/s).
- Angular acceleration of pronation (pre: 206,7 93,7 deg/s2 ; post: 126,0 54,2 deg/s2), supination (pre: 214,6 106,2 deg/s2 ; post: 125,7 53,3 deg/s2), plantar flexion (pre: 90,9 30,9 deg/s2 ; post: 65,7 25,5 deg/s2) and dorsal flexion (pre: 86,7 33,9 deg/s2 ; post: 60,6 24,9 deg/s2)
No change has been observed on control groups kinematics parameters between pre and post-test.
The decreased ankle kinematics parameters suggest a better ankle stability after slackline balance training.
CONCLUSION: A decreased ankle angular velocity and acceleration of the pro/supination and plantar/dorsal flexion motion following slackline training reflecting increased joint stability highlights the interest of this type of training to prevent risks of ankle injury.

ALPINE SKIINGS ENVIRONMENT, AND THE EFFECTS ON THE POSTURAL STABILITY: STRATEGIES TO IMPROVE THE BALANCE PERFORMANCE

BRIGHENTI, A., SCHENA, F., MOUROT, L.
UNIVERSITÉ BOURGOGNE FRANCHE-COMTÉ

INTRODUCTION: Alpine skiing is a popular activity practiced either for leisure or competition. The postural control, in particular the management of the balance despite of all the forces that act on the skier, is widely considered as one of the factors that limit the race performance in this sport. Alpine skiing is characterized by the environment where is practiced: high mountain on the snow i.e. lack availability of oxygen and cold.
METHODS: Our literature search included the electronic databases Pubmed and Google Scholar (1987-March 2018). In total, 59 studies met the inclusionary criteria for review
RESULTS: Findings from our literature review shows that, the hypoxic (hypobaric and normobaric) and hypothermic nature of alpine skiing, cause an impairment of the postural control during static and dynamic tasks.
CONCLUSION: Perform high intensity resistance exercises, is a well investigated method to insert into the warm-up tool in order to stimulate the postactivation potentation (PAP) that, it has been demonstrated, increase the strengths level, the power, the speed and improve the performance in several sports. The two main effects on the contractile muscular performance of the PAP are an increase of the rate of force development and the facilitation of the Hoffmans reflex.
These two above cited effect, could lead an enhancement of the balance performance and consequently the race performance, making the muscles more responsiveness to maintain the stability despite the perturbation that the skier suffers.

THE INFLUENCE OF ACTIVITY-DEPENDENT STIMULATION DURING GAIT RETRAINING ON DUAL-TASK COST IN CHRONIC STROKE SURVIVORS: A PILOT STUDY.

WATSON, J., WELMAN, K., SEHM, B.
STELLENBOSCH UNIVERSITY

INTRODUCTION: Walking is recognised as a complex skill, involving dual-tasking. Dual-task paradigms have been used to assess the real-world effects of cognitive-motor interference; dual-task cost (DTC) is particularly sensitive in the swing and stance kinematics of gait in chronic stroke survivors. Additionally, there is emerging research for the benefits of transcranial direct current stimulation (tDCS) for gross motor skill learning post-stroke. It is hypothesized that a combination of gait re-training and tDCS may yield benefits for cognitive-motor interference on certain gait kinematics. Consequently, this study endeavoured to compare the efficacy of gait re-training during real and sham stimulation on swing and stance asymmetry in chronic stroke survivors.
METHODS: A randomized double-blinded case study, whereby 10 chronic stroke survivors (≥6 months) were divided into either an attention-matched control group (n=4), or an 8-week task-specific gait re-training program with concurrent tDCS over the primary motor cortex (1mA; 20 minutes; n=2) or with Sham stimulation (20 minutes; n=3), was implemented.
Gait kinematics were measured pre- and post-intervention by using the two-minute walk test and the APDM mobility lab™.
RESULTS: Dual-task cost decreased for swing (M= 0.73; IQR= 0.46) and stance (M= 0.82; IQR= 0.37) assymetry in participants who received real stimulation, compared to participants who received sham stimulation; where DTC increased for swing (M=-4.45, IQR= 6.79), and stance (M=-10.98, IQR= 14.15) assymetry. Additionally, DTC for swing (M= -0.70, IQR= 0.53), and stance (M= -0.77, IQ = 0.38) assymetry increased in the attention-matched control group.
CONCLUSION: These preliminary data show the potential benefits of an 8-week task-specific gait re-training program with concurrent tDCS, on DTC in gait symmetry in chronic stroke survivors.

ASSOCIATION OF EARLY SLEEP-WAKE LIFESTYLE WITH INCREASED BODY FATNESS INSTEAD OF DAILY TOTAL PHYSICAL ACTIVITY IN JAPANESE OLDER MEN

MURATA, H.1, ZHANG, Q.1, NAGANUMA, S.1, ITO, T.1, KAWAKAMI, R.1, SAKAMOTO, S.1, TORII, S.1, SHIBATA, S.2, HIGUCHI, M.1
WASEDA UNIVERSITY

INTRODUCTION: Evening chronotype has been reported to be associated with body fatness and metabolic disorders in middle-aged adults. However, little information is available on the relationship between circadian phenotype and body fatness in older people. This study aimed to clarify characteristics of circadian phenotype and to examine the relationship between these phenotypes and body fatness in older people.
METHODS: We performed a cross-sectional study consisting of 200 older adults (men: n=84; women: n=114; age: 60–79 yrs) who were classified into chronotype groups based on their scores on the morningness - eveningness questionnaire (MEQ) as follows: "definitely morning type (DMT)," "moderately morning type (MMT)," "neither type (NET)." The participants were asked to report their daily rhythms of behavior such as meal time and sleep-wake cycle. Additionally, their physical activity was measured using a uniaxial accelerometer (Kenz Lifecorder EX, SUZUKEN, Nagoya, Japan). Energy intake was assessed using a brief self-administered diet-history questionnaire.
RESULTS: Among men, BMI in the DMT group (25.2±2.7 kg/m2) was significantly higher than in the MMT group (23.2±2.5 kg/m2) and in the NET group (22.6±2.1 kg/m2), respectively (P<0.05), whereas no significant differences were found among the three groups in women. Breakfast time in the DMT group (6:00 am) was earlier than in other groups (median MMT: 7:00 am, NET: 8:00 am); however, lunch time (median DMT: 12:00 noon, MMT and NET: 0:15 pm) and dinner time (median all groups: 7:00 pm) were similar in all groups. The DMT group had a significantly shorter interval between dinner and bedtime than the other two groups (median DMT: 2h 00 min, MMT: 3h 30 min, NET: 4h 00 min in men, DMT: 3h 30 min, MMT: 4h 00 min, NET: 4h 30 min in women, respectively, P<0.01). Total energy intake did not indicate significant differences between the three groups for men and women respectively. The interval duration between dinner and bedtime for the DMT group was shorter than for the other two groups and physical activity between dinner and bedtime for this group

was smaller than in the other two groups (mean DMT: 4.2±2.1 METs*h, MMT: 5.5±1.8 METs*h, NET: 7.2±2.1 METs*h, P<0.01). According to Pearson's correlation coefficients, BMI in men was negatively correlated (r = -0.405, P<0.01); however, BMI in women was positively correlated (r=0.196, P<0.05) with physical activity from dinner to bedtime.
CONCLUSION: In conclusion, this study demonstrated that the DMT group with early sleep-wake lifestyle had higher BMI and that a shorter interval duration from dinner to bedtime was associated with increased body fatness in older men, but not in women. Elderly men with DMT should eat dinner earlier and have a longer interval between dinner and bedtime, and old women with NET should have a shorter interval between dinner and bedtime to prevent obesity.

AN EXPERIMENTAL STUDY OF SLEEP QUALITY IN UNIVERSITY ATHLETES - THE EFFECT OF A RELAXATION TRAINING

KOTYSKO, M.1, LITWIC-KAMINSKA, K.2

1: UNIVERSITY OF WARMIA AND MAZURY , 2: KAZIMIERZ WIELKI UNIVERSITY

Introduction: Autogenic training (AT) involves suggestions based on passive concentration of bodily perceptions of heaviness and warmth, which are supposed to induce a state of relaxation. According to Stetter and Kupper's (2002) meta-analysis, it can be stated that AT is an effective method of solving problems with sleep. However, there is a lack of reports related to sportspeople. Thus, the main aim of this research was to evaluate the effect of the AT on sleep quality in a group of university athletes.
Methods: The experiment included 31 university athletes from different sport disciplines (students of physical education who were involved in sport: trained in a sport clubs, under academic sport association or had an individual training routine) with lower sleep quality measured with the Pittsburg Sleep Quality Index - PSQI. The participants were divided into an experimental (EG, n = 16) and a control group (CG, n = 15). The study used the Ecological Momentary Assessment (EMA). During two weeks the actigraphic measurements (with Actiwatch 2) and electronic daily logs (by Android application) were gathered to check the sleep parameters and athletes' daily activity. The EG was supposed to perform a relaxation training every day (based on the AT method), in a form of an audio recording implemented in the Android application. In contrast, the recording used in the CG contained only background music without suggestions. Additionally, two measurements, before and after carrying out relaxation trainings, were made using the PSQI.
Results: Both groups presented similar sleep length measured with actigraphy (EG, *M* = 403.5; CG, *M* = 401.09; *t* = .118, *p* = .907), and mean sleep quality measured by daily log (EG, *M* = 3.57; CG, *M* = 3.63; *t* = -.277, *p* = .784). The significant difference in Pre and Post PSQI results were noted only in the EG (Pre, *M* = 5.56; Post, *M* = 4.56; *t* = 2.74, *p* = .015; *d* = .68).
Discussion: AT is considered effective in improving the subjective quality of sleep, the time needed to fall asleep or the sleep duration (Robinson, Bowden, & Lorenc, 2010). Our study only partially confirms these reports. Athletes after AT declare generally higher sleep quality, but there is no effect on sleep habits. Reasons can be traced in the duration of the training. AT is a long-term process requiring regularity to automate the reactions being practiced. After two weeks only the first effects of the exercises may have occurred.

EFFECT OF EXERCISE INTENSITY ON SUBSEQUENT NIGHTS SLEEP IN WELL-TRAINED RUNNERS

THOMAS, C., JONES, H., WHITWORTH-TURNER, C., LOUIS, J.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Observational studies have shown sleep quality in athletes is reduced after training and competition. As such, this period is considered a big obstacle to athletes' recovery, which could hinder future performances. Exercise intensity is one of several factors that may explain this phenomenon. Yet, no research has studied the impact of a single bout of exercise on sleep within a well-trained cohort, making it impossible to discern whether exercise intensity has a positive or negative effect on sleep. This study investigated the effect of exercise intensity on subsequent night's sleep in well-trained runners. We hypothesised high intensity interval running would elicit a greater percentage of slow wave sleep (recovery sleep) compared to a no exercise condition.
METHODS: Two well-trained male runners (age: 25.5±6.4yrs; height: 176.4±2.1cm; weight: 70±5.6kg and VO2 max: 58.5±2.8ml.kg-1.min-1) completed three experimental trials in a randomised, crossover design. Following a standardised afternoon meal (2g CHO.kg-1BM) participants either performed: i) a 1h high intensity interval running session (6x5 min @60% VO2 max interspersed with 6x5 min @90% VO2 max); ii) a 1h low intensity running session (45% VO2 max); iii) no exercise. Exercise sessions were performed at 18.00h prior to a fixed bedtime of 22:30h. Sleep stages were assessed in a temperature controlled laboratory using overnight polysomnography.
RESULTS: The percentage of slow wave sleep was higher ($p < 0.05$) and the percentage of rapid eye movement sleep was lower ($p < 0.05$) than the no exercise condition after high intensity interval running. In addition, total sleep time was increased ($p < 0.05$) and total wake time was reduced ($p < 0.05$) after the high intensity interval running session compared to no exercise. There were no changes in sleep following the low intensity running session.
CONCLUSION: 1h high intensity interval running improves sleep duration and sleep quality over no exercise in well trained runners. It should be considered that poor sleep on the night following a single training session or competition day is not caused by exercise intensity. Future research is warranted to determine if multiple exercise sessions per day, a regime used by many athletes to induce physiological adaptation, leads to sleep disruption.

AN INVESTIGATION OF THE SLEEP AND RECOVERY PRACTICES OF ATHLETES.

DOHERTY, R., MADIGAN, S., WARRINGTON, G., ELLIS, J.

SPORT IRELAND INSTITUTE/LETTERKENNY INSTITUTE OF TECHNOLOGY

INTRODUCTION: Athletes train at high intensity to maintain or improve sport specific physical qualities such as speed, strength, power and technique. Training followed by optimum recovery strategies can induce favourable physiological and psychological adaptations resulting in improved performance. The repetitive demanding nature of a competitive season can test athletes physiological and psychological capacity. Athletes must maintain a balance between stress and recovery and adopt recovery modalities that manage fatigue and enhance recovery. Sleep has been accepted as a primary mode of recovery following both training and competition. Post-exercise recovery is vital for all athletes, the balance between training stress and physical recovery must be managed to maximise the adaptation from, and performance in subsequent training sessions or competition. Sleep has a restorative effect on the immune system and the endocrine system, facilitates the recovery of the nervous and metabolic cost of the waking state and has an integral role in learning,

memory and synaptic plasticity. The classic view of sleep is as a recovery process of both body and brain. It has been hypothesised that sleep, especially slow wave sleep (stages 3-4 of Non Rapid Eye Movement (NREM) sleep) are vital for recovery, due to the relationship between growth hormone release and slow wave sleep.
METHODS: A convenience sample of comprising of athletes (n=338; elite n=115 [male n=74; female n=41] and sub-elite n=223 [male n=129; female n=94]) were recruited from both Ireland and the United Kingdom. The data was collected using an online questionnaire included questions relating to age, gender, sport, phase of season, normal training time and number of hours trained per week and a battery of reliable and valid questionnaires:
• EuroQOL (5-level version): assessment of health state.
• Pittsburgh Sleep Quality Index (PSQI): Subjective sleep quality, sleep latency, sleep duration and habitual sleep efficiency.
• Epworth Sleepiness Scale (ESS): daytime sleepiness.
• Recovery Stress Questionnaire (REST-Q Sport): measured general stress and recovery scales along with sport-specific stress and recovery scales.
• Athlete Morningness/Eveningness Questionnaire (AMES): classification of chronotype.
• Consensus Sleep Dairy – Core (CSD-C): sleep diary.
Participants also completed a three-day food diary (two training/competition days and one rest day). Participants were instructed to record all meals, snacks, supplements and beverages consumed each day.
RESULTS: The data collection period was completed on 31/12/17, preliminary results are currently available and data analysis will be completed prior to the conference. The athletes were at different phases of their season; Preseason (n=88), Competition (n= 180) and Off-Season (n=70). Phase of the season affected sleep duration, quality and recovery-stress balance. Both groups reported poorer sleep quality on competition days compared to rest days. While longer sleep durations were reported on, 'Rest Days' compared to 'Competition Days.' Preliminary analysis has shown training before 8am was associated with a reduction in total sleep time and poorer sleep quality (higher PSQI score). While training during the day (8am-5pm) was associated with better sleep quality.
CONCLUSION: Improving athletes' sleep would enhance the recovery process, which could improve athletic performance and both mental and physical health. The results of this study indicate that there is scope for investigation of functional food based interventions designed to enhance sleep quality and quantity or promote sleep health, training adaptations and/or recovery.

A CROSS-SECTIONAL STUDY TO EXAMINE THE ASSOCIATION BETWEEN SELF-REPORTED SLEEP AND THE FREQUENCY, DURATION AND INTENSITY OF EXERCISE

LITLESKARE, S., VAKTSKJOLD, A., BARENE, S.
INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Insufficient sleep is associated with increased risk of several health concerns. Although physical activity is generally considered to improve sleep, the influence of different levels of exercise frequency, duration and intensity respectively, has not been sufficiently examined to allow specific recommendations to the general population. Therefore, our aim was to evaluate the association between different levels of the three cardinal characteristics of exercise and sleep disturbance.
METHODS: Data were collected through a Norwegian comprehensive self-report survey. A total of 3763 respondents (46 % males) with an average age of 47.9 years (range 15-93) completed the questionnaire. The exercise characteristics were measured on a 6 to 8-item Likert scale. Sleep disturbance was measured on a 4-item Likert scale and then merged into a dichotomous variable ("good sleepers" and "poor sleepers"). Binominal logistic regression was used to calculate odds ratios (OR). Respondents reporting an exercise frequency of "never" were considered sedentary and were used as the reference category. ORs were adjusted for age, gender, alcohol consumption and nicotine use.
RESULTS: Respondents reporting intermediate levels of exercise frequency, duration and intensity, respectively, had a significantly lower occurrence of sleep disturbance compared to respondents with a sedentary lifestyle. No statistical difference in sleep disturbance was observed between respondents performing exercise corresponding to the lowest and highest levels of the three exercise characteristics and those who were sedentary.
CONCLUSION: The lack of positive association between the lowest and highest levels of the cardinal exercise characteristic and reduction in sleep disturbance in the present study support a recommendation of intermediate levels of exercise frequency, duration and intensity for preventing sleep disturbance in the general population.

MIGRAINES IN UNIVERSITY STUDENTS: PREVALENCE, TRIGGERS AND SELF-REPORTED EFFECTS ON EXERCISE

TAMULEVICIUS, N., SHAH, D.M., WADHI, T., AGUADO LOI, C.X., MARTINASEK, M.P.
THE UNIVERSITY OF TAMPA

INTRODUCTION: Migraines, or migraine headaches are a primary headache disorder. The prevalence of migraines in university students globally is approximately 16% <1>. The most common triggers of migraines are stress, lack of sleep, fasting, alcohol or excessive caffeine consumption, cigarette smoking, and hormonal changes in women <2,3>. Of these, stress is one of the highly-observed triggers among migraine sufferers <3>. The aim of this study was to investigate migraine prevalence, triggers and self-report of effects on exercise in university students.
METHODS: 439 university students <20.7 +/- 4.6 y.o.> participated in a cross sectional online survey. The instrument was a 26-close ended questionnaire composed of questions to identify migraine prevalence, trigger factors, impact of migraine in students exercise or daily life, and exercise profile. Headache Impact Test , a validated questionnaire, measured the impact of migraine headaches on functional abilities and daily lifestyle and activities.
RESULTS: Of the participants, 84.7% had self-reported migraine headaches, with stress being the most common trigger factor, followed by lack of sleep, and skipping meals. The mean HIT-6 score was 3.1 +/- 1.2 . About 57.2% of the participants rated a 4 on the impact of daily living, implicating a severe impact according to HIT-6 scoring.
Interestingly, although the majority of participants reported that exercise did not reduce migraine occurrence, 52.9% reported not having migraines within 24 hours post exercise. Our study also found that there was no significant correlation between the type of exercise , physical activity and the prevalence of self-reported migraines which is in line with multiple previous studies <4>.
CONCLUSION: Our study found that migraine headaches are prevalent in university students with stress, lack of sleep and skipping meals as the most common triggers. While most do not believe exercise would reduce the frequency of their migraines, our data suggests that more than half of the students report not having migraines within 24 hours post exercise. Further research is required to directly measure the impact of exercise on migraine through intervention studies for more conclusive evidence.

MO-PM23 Children and Youth

RELATINOSHIP BETWEEN MATERNAL HEALTH AND PHYSICAL FITNESS OF THEIR PRESCHOOL CHILDREN

KUNO-MIZUMURA, M., KAWANO, Y., SHIONOYA, Y., YOSHIDA, M.

OCHANOMIZU UNIVERSITY

INTRODUCTION: It is indicated that maternal health would influence children`s health, since previous studies reported that maternal obesity would be associated with their children`s obesity. However, little is known about the relationship between maternal health as an environmental factors for physical fitness of their children especially for preschool children. So the purpose of this study was to investigate maternal both physical and mental symptoms including perceived stress and their relationship with their children`s physical fitness level.
METHODS: Forty-nine mothers and their children aged five-to-six years old participated in this study. All participants lived in urban area of Tokyo, Japan. All mothers completed questionnaire asking their demographics, both physical/mental symptoms and perceived stress scale (PSS) (Cohen et al., 1986) by Japanese version of PSS-10 (Washimi, 2006). For preschool children, physical fitness measures were evaluated by the battery test for preschool children in Japan such as the performance of standing long jump, 25-m run, throwing the soft ball, ball-catching task, repetitive small jumps, sustaining the balance with their arms and sit-and-reach test. Person correlation was used to evaluate the relationship between maternal general symptoms or PSS-10 and physical fitness measures of their children.
RESULTS: Significant and the highest positive correlation between maternal general symptoms and PSS scores (r=0.91) was obtained. Significant positive correlation between maternal general symptoms and only one physical fitness measure of their children that is catching performance. Significant positive correlation was also obtained between maternal PSS-10 and the catching performance of their children. There was no significant correlation between maternal health and maternal age or the number of children they were taking care of.
CONCLUSION: From the results of our study, there was close relationship between general symptoms and perceived stress scale in mother. Previous study had reported that perceived stress would be influence by age for older females aged up to 65 (Osmanovic-Thunstrom et al, 2015). However, for the age group in this study, perceived stress would not relate closely to their age. Significant positive correlation between general symptoms or PSS in mother and the catching performance of their children was only obtained. If mother who suffer from higher general negative symptoms or perceived stress, it would not be easy for them to play with their children for long time or go out during weekends or after kindergarten. To improve catching performance, children need somebody to play a ball with or some places to play with a ball. Maternal health would be one of effective factors for preschool children to improve their motor development such as catching performance.

MOVING WELL-BEING WELL

PEERS, C., BEHAN, S., BELTON, S., ISSARTEL, J.

DUBLIN CITY UNIVERSITY

INTRODUCTION: As appropriate to each individual, physical literacy can be described as a disposition to capitalise on our human capability, wherein the individual has: the motivation, confidence, physical competence, knowledge and understanding to value and take responsibility for maintaining purposeful physical activities throughout life. Recent research suggests that Irish adolescents are not displaying the attributes of physical literacy that would see them adopt purposeful physical pursuits as an integral part of their lifestyle (Belton et al, 2014). The objective of this research was to build on previous work by assessing the current level of physical literacy in Irish primary school children (5-13 years).
METHODS: Cross-sectional data on physical literacy constructs (Whitehead, 2010), perception of body figure (Collins, 1990), well-being (KIDSCREEN-27, 2006), and fundamental movement skill proficiency (TGMD-2, Ulrich, 2000) of 958 children (50.6% male, 9.17 ± 2.04 years) were collected. Additionally, physical activity levels (using self and proxy reports, and accelerometers) and anthropometric characteristics were acquired to supplement.
RESULTS: Findings indicate that the majority of children (85%) were not accumulating the minimum 60 minutes of physical activity recommended daily for health, with 77.5% classed as below average or very poor for fundamental movement skill proficiency.
Findings highlight that self-efficacy, intrinsic motivation, and physical ($p < 0.01$) and relational ($p < 0.05$) wellbeing scores were significantly different between low (0-3 days), moderate (3-5 days) and high (5+ days) active participants. Comparison of body image discrepancy scores (Ideal - Self) revealed that children, both male and female, selected figures for Ideal that were significantly thinner than selections for Self ($p < .05$).
CONCLUSION: According to a physical literacy framework the earlier we learn to move competently and confidently, the more likely we are to be motivated to be physically active for life (Whitehead, 2010). Results of this study highlight that a large number of Irish children are insufficiently active to benefit their current and future health (only 15% meeting PA guideline for health). Worryingly this is lower than a slightly older age group (Belton et al, 2014). Given the consistently reported decline in activity with age the need for intervention to address these low levels reported for children is evident.
Consistent with physical activity reviews (Biddle et al 2005; Bauman et al, 2012), analysis of psychological physical literacy constructs reveals an association with physical activity level, this was evident for self-efficacy and motivation. Meanwhile, both active and inactive children had a poor knowledge and understanding of why it is important to value and take responsibility for engagement in physical activities for life. Considering the results, the Moving Well-Being Well physical literacy intervention will target the psychological constructs of physical literacy.

SIX MINUTE WALK DISTANCE: REFERENCE VALUES IN HEALTHY ITALIAN CHILDREN.

CORREALE, L.1, VANDONI, M.1, PUCI, M.1, GALVANI, C.2, CODELLA, R.3, TOGNI, F.4, LA TORRE, A.3, CASOLO, F.2, PASSI, A.5, ORIZIO, C.4, MONTOMOLI, C.1

1UNIVERSITÀ DI PAVIA, 2UNIVERSITÀ CATTOLICA DEL SACRO CUORE DI MILANO, 3UNIVERSITÀ DEGLI STUDI DI MILANO, 4UNIVERSITÀ DI BRESCIA, 5UNIVERSITÀ DELLINSUBRIA.

INTRODUCTION: The 6-minute walk test (6MWT) is a simple assessment tool to evaluate exercise capacity. The result of the test is the distance that a subject can walk at a constant and normal pace within 6 minutes (6MWD) and reflects walking function at a submaximal level (Crapo RO et al., 2002). Use of 6MWT on healthy children has been relevant to assess exercise tolerance (Rostagno C., 2003) and to compare it to pathological conditions (Paridon SM et al.,2006). Our aim was to find reference values for the 6MWT in healthy Italian children.
METHODS: The 6MWT was performed by 5614 children between 6 and 11 years, following the instructions outlined in the ATS guidelines (Crapo RO et al., 2002). Summary statistics are expressed as means and standard deviations or percentages, as appropriate. Age-related percentiles (mean±SD of 3rd, 10th, 25th, 50th, 75th, 90th and 97th centiles) of the 6MWD were developed for males and females. Pearsons correlation coefficients were calculated between 6MWD and demographic data. A multiple linear regression model was assessed to predict expected 6MWT performance. All analyses were conducted using STATA/SE, a p-value of less than 0.05 was considered significant.
RESULTS: Males walked longer distances than females, respectively 598.8±83.9 m vs 592.1±77.6 m (p=0.0016). Values ranged between 513.3±60.4 m for 6 years old children to 656.1±71.6 m for 11. The 50th percentile values resulted in 511 m, 554 m, 603 m, 624 m, 649 m and 670.8 m for boys aged 6 to 11 years old, respectively. Differently, the 50th percentile values resulted in 512 m, 543 m, 597 m, 620 m, 643 m and 655 m for girls aged 6 to 11 years old. A moderate correlation was found between 6MWD and age, weight and height (respectively rho=0.58; 0.32; 0.52; p<0.0001). In regression analysis, we found that age, gender and height were positively related to 6MWD, while weight was negatively related with 6MWD [6MWD=107.91 + 25.02× age (years) +7.52× gender (M) +2.62× height (cm) −2.25× weight (Kg)].
CONCLUSION: Reference values were established for the 6MWT in Italian healthy children. The 6MWD percentiles according to age provided a useful tool in the assessment of capacity in children aged 6-11 years.

EFFECTS OF A CONGESTED FIXTURE SCHEDULE ON MUCOSAL IMMUNITY AND INTERNAL LOAD IN YOUTH SOCCER PLAYERS

MORTATTI, A., OLIVEIRA, R., PINTO, J., GALVÃO, N., MOREIRA, A.

FEDERAL UNIVERSITY OF RIO GRANDE DO NORTE

INTRODUCTION: The effects of congested fixture schedules on immune and match load markers of youth players are still relatively unclear (Moreira et al., 2016). Given the importance of extending current knowledge, the aim of this study was to analyse the effects of a congested match schedule on mucosal immunity and internal match load in youth soccer players.
METHODS: Twelve male soccer players (16.6 ± 0.5 yr.; 175 ± 8cm; 65 ± 8kg) volunteered for this study. They completed 4 official matches within a 4 day-period with a 24h recovery interval between the matches. All assessed matches begun at 3:00 p.m. Saliva samples were collected 30 min before the first match (pre-match 1) and 22h post-match four (post-match 4), and tested for salivary immunoglobulin A (SIgA) and salivary flow rate. Internal match load (IML) was determined using the session-RPE method. The players completed the CR-10 scale, 20-25 min after each match; the match strain (MS) and monotony index (MI) were also analyzed. An ANOVA with repeated measures was used to compare the session-RPE and IML for the assessed matches. Bonferronis post hoc was used to locate the differences. Student's t-test was used to compare SIgA concentration and salivary flow rate at the pre-match 1 and post-match 4. Cohens "d" or partial eta squared (η^2) was used to estimate magnitudes of differences. Spearmans correlation coefficient was used to analyze the association between the IML and the MI with the percentage changes in SIgA (ΔSIgA).
RESULTS: There were significant differences in IML across the matches ($F(4.33) = 6.299$, $p < 0.000$, $\eta^2 = 0.66$). A higher IML was observed for match 3 (312±182 AU) compared to match 2 (463±239 AU) and 4 (496±175 AU). SIgA concentration decreased from pre-match 1 (67.88 ± 45.2 pg/ml/min) to post-match 4 (46.18± 34.7 pg/ml/min) ($t(11) = 2.744$ $p = 0.01$, $d = 0.84$), while no change was observed for salivary flow rate (pre and post) ($t(11) = 0.1010$, $p = 0.921$, $d = 0.03$). There was large within-individual correlations between ΔSIgA and MI and MIL ($r = 0.68$: $p<0.05$ and $r = 0.67$: $p<0.05$, respectively).
CONCLUSION: The current findings suggest that young players participating in a congested match schedule may present a decrease in mucosal immunity function that might lead to increased risk of upper respiratory tract infections. In addition, the identification of the internal load variability (MI) as well as the global stress given by the IML may be used as valuable markers for monitoring competition load during congested fixture schedules.

HEART RATE RECOVERY IN YOUNG ATHLETES AFTER MAXIMAL AEROBIC AND ANAEROBIC TESTS

RODRIGUES-FERREIRA, M.A.1,2,3, VENCESBRITO, A.M.1,2,3

1: SPORT SCIENCES SCHOOL OF RIO MAIOR, POLYTECHNIC INSTITUTE OF SANTARÉM , PORTUGAL; 2: LIFE QUALITY RESEARCH CENTRE , PORTUGAL; 3: UIIPS, PORTUGAL

INTRODUCTION: Young athletes regularly perform maximal aerobic and anaerobic efforts during training and competition and it is important to understand how they recover. Heart rate recovery (HRR) is characterized by the parasympathetic reactivation and sympathetic withdrawal by the autonomic nervous system. The aim of this study was to investigate HRR in young athletes after maximal aerobic and anaerobic tests.

METHODS: Twenty-eight pubertal male participated in this study and were divided into 3 groups according to sport practice: 10 footballers (age 14±0.94 yrs., height 171±9.08 cm, weight 62±8.97 kg), 10 swimmers (13.9±1.10 yrs., 168±6.18 cm, 56±10.22 kg), and 8 participants not involved in any regular sport practice but physically active (13.9±1.13 yrs., 168±13.25 cm, 68±16.18 kg). All participants completed two maximal tests: a continuous progressive treadmill protocol where the participants ran until exhaustion (Technogym Runrace Treadmill HC1200, Italy), and the Wingate anaerobic test (Monark 839E, Vansbro, Sweden). The active recovery in the treadmill was set at 3 km·h-1 during 3 min and in the cycloergometer was between 40 to 50 rpm during 3 min. Heart rate (HR) was assessed, during the tests and the recovery phase, using the Polar S 610ws (Finland). HRR was calculated as the rate of decline of HR from end of exercise to rates 1, 2 and 3 min after cessation of maximal aerobic and anaerobic tests (HRR1, HRR2 and HRR3). Normality (Shapiro-Wilks test) and homogeneity (Levene's test) were assumed. A one-way analysis of variance (ANOVA) was used with significant level of $p<0.05$ (SPSS 17.0).
RESULTS: The footballers showed a significantly higher HRR2 (60.6±9.61 vs. 45.9±11.27 b·min-1; p=0.005) and HRR3 (71.7±9.61 vs. 53.4±13.09 b·min-1; p=0.001) after the maximal aerobic test compared with the control group. Swimmers presented a higher HRR3 (63.8±5.98) than the control group, but failed to reach the significant level (p=0.055). During the recovery after the maximal anaerobic test, it was observed a significantly higher HRR3 in swimmers (63.2±7.60 vs. 50.63±11.22 b·min-1; p=0.035) than control group.
CONCLUSION: Maximal HR and HRR1 were not significantly different between groups showing similar recovery between young athletes and pubertal male not involved in any sport practice in the first minute of post-maximal aerobic and anaerobic tests. Although, significantly differences were found between young athletes and control group during the second and third minutes of recovery after maximal aerobic test in footballers and during the third minute after maximal anaerobic test in swimmers. Additionally, the footballers and swimmers tended to present lowest values of HR during the recovery phase showing adaptations of cardiovascular system to aerobic and anaerobic efforts. Further research is needed to assess the HRR in larger samples and in other sports, trying to understand training adaptations in young athletes.

PECULIARITIES OF ADAPTATION TO EXERCISE LOADS IN YOUNG SOCCER PLAYERS

BERDNIKOVA, A.N., TIMOKHINA, V.E., MEKHDIEVA, K.R., ZAKHAROVA, A.V., BLYAKHMAN, F.A.
URAL FEDERAL UNIVERSITY

INTRODUCTION: Taking into consideration multifactor nature of soccer it is affected by various physiological factors. In terms of intensive training schedule it is important to prevent functional reserves reduction and development of sports related pathologies (Urbina E. et al., 2010). The study was focused on investigation of young soccer players' adaptation to exercise loads.
METHODS: Thirty young soccer players born in 2004 (height 158.14±7.87m, weight 46.06±7.40kg), with more than 6 years soccer experience were recruited for the study. Hemodynamics measurements with the use of MARG10-01 ("Microlux", Russia) and exercise testing with gas exchange measurements (RAMP-protocol) with the use of cycle ergometer (Schiller, Switzerland) and metabolic analyzer FitMatePro (COSMED, Italy) (Zakharova A. et al., 2016) were conducted.
RESULTS: All subjects were players of the same team and performed the uniform of the sports training. However, 33% (n=10) of athletes had lowered heart volume (end-diastolic index 89.5±6.92 ml/m2, N>100, stroke volume index 56.1±4.36 ml/m2, N>70). Moreover, in comparison with the main group (n=20), these athletes had significantly higher heart rate at rest (p=0.00003), lower peripheral vascular resistance (p=0.0005), higher resting systolic blood pressure (p=0.03) and resting pulse pressure (p=0.02). Notably, the external parameters of exercise performance had no significant differences with the parameters of the main group. In particular, measured parameters during stress test were as follows: VO2max – 56.3±7.21 ml/kg/min, maximal relative attained power during stress-test – 4.7±0.37 W/kg, maximum heart rate – 186.5±7.37 bpm.
CONCLUSION: Peculiarities of adaptation to physical loads found in some athletes may both serve as a risk factor for the development of cardiovascular pathologies, as well as limit physical working capacity. To prevent adverse consequences, an individual approach to the training process is essential, taking into account age-related features of the development of cardiovascular system and focus on increasing the efficiency of adaptation. Analysis of hemodynamics indices allowed to reveal the internal physiologic features of cardiovascular system of these athletes.

THE IMPACT OF BIOLOGICAL MATURATION IN THE SELECTION OF YOUNG ATHLETES IN DIFFERENT SPORTS

UTCZÁS, K., TRÓZNAI, ZS., SZABÓ, T.
UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: Biological age is an important aspect in the selection of athletes in youth teams and academies. The relationship between biological and chronological age provides information on the rate of maturation or tempo of growth. Starting from early childhood, the more mature children usually have higher chances for selection than the less mature children of the same age. Two of the methods to assess maturity status are the estimation of the morphological age and of the bone age. The former describes the development of several body dimensions, whereas the latter describes the development of the skeleton system. Our aim was to examine the impact of these two methods in the selection pattern of young athletes in different sports.
METHODS: 254 Hungarian boys were measured, aged from 13 to 15 years. The athletes participated in three different sports at an elite level in their respective age group: soccer (N:46), handball (N:59) and basketball (N:49). Morphological age was estimated based on the Mészáros-Mohácsi method (1983). This method estimates the morphological age based on growth charts from body size measures (body weight and body height), and from the body structure indicator (plastic index) by comparing the athlete's maturity to the developmental status of the Hungarian children of the same age. Bone age was determined using a Sunlight BoneAge ultrasonic instrument. Descriptive statistics were analyzed in Statistica 13.2 software.
RESULTS: Both skeletally and morphologically retarded athletes showed the highest frequency among soccer players (on average 10-12 percent). The proportion of skeletally accelerated children increases with age in soccer (from 29 to 53 percent), but their percentage is still lower compared to the other two sports. Besides the highest frequency in morphological maturation in all examined age groups, handball players also demonstrated high frequency (>80 percent) in skeletal maturation as well. Among basketball players, the proportion of

skeletally-developed children increases (from 44 to 90 percent), while the proportion of the morphologically more mature decreases with age (from 28 to 10 percent).
CONCLUSION: The impact of skeletal maturity in the selection of young athletes was more evident in handball and in basketball at the age of 13 years as this was revealed by their high frequencies in both sports. In soccer the effect of skeletal maturity in the selection is demonstrated only after the age of 15 years. Among the three sports, in handball, along the bone development, the morphological development seems also to be an important aspect in the selection. Our results suggest that, although at different ages, but for all three sports, skeletal development has a significant effect in the selection.

MO-BN03 Biomechanics of jumping and squatting

THE INFLUENCE OF GLUTEAL ACTIVATION IN LOWER LIMB BIOMECHANICS DURING SINGLE LEG LANDING

LOU, C.W., LEE, H.J.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: The injury of lower extremity always occurred in the sports competitions which required the athletes to perform jumping and landing. The gluteal muscle was a key character in sports injury prevention. Therefore, the aim of this study was to investigate if the gluteal activation exercise can improve the landing strategy during single-leg drop landing in females.
METHODS: Three female collegiate recreational athletes have participated in this study. All the participants needed to perform 5 successful trials of 30-cm single leg drop landing before and after five gluteal activation exercises (Bridge, Side-lying hip abduction, Quadruped with contralateral arm/leg lift, Single limb squat, Lateral band walks). One set of 10 repetitions was performed for each exercise. 8 VICON cameras were used to capture the dthree-dimensional motion and surface EMG was used to capture the gluteal maximus and medius muscle activity 100ms before and after the initial contact during each trial. The kinematic data of hip and knee were sampled at 250Hz. EMG signals were sampled at 2000Hz. A two-way mixed-design ANOVA was performed on selected variables.
RESULTS: There were significant differences in muscle activities and the hip and knee ROMs. After gluteal activation exercise, gluteal maximus and medius increased significantly in muscle activity 100ms before and after the initial contact. Biceps femoris and semitendinosis increased significantly in muscle activity only at the time of 100ms before the initial contact. Hip flexion and knee flexion angle were significantly increased at initial contact and at the moment of peak knee flexion. Hip adduction angles were significantly reduced at initial contact and at the moment of peak knee flexion.
CONCLUSION: At the time of 100ms before the initial contact, the gluteal maximus, medius, biceps femoris and semitendinosis had increased their muscle activities. Studies have demonstrated that pre-contraction of lower limb muscle could help to absorb ground impacts and prevent excessive joint ROMs. Gluteal maximus and medius could control the hip flexion, adduction, and internal rotation eccentrically. The increasing of muscle activity indicated that they might improve the neuromuscular control so that it could increase the range of motion during landing. Due to the mechanism of non-contact ACL injury was lesser hip flexion, excessive hip adduction and internal rotation angle during landing, we observed that gluteal activation had increased hip and knee flexion, reduce hip adduction angle during landing, which meant they could utilize more on the muscle instead of the non-contractile soft tissue to absorb the force, so as to reduce the probability of soft tissue injury.

THE EFFECTS OF SHOE WEIGHTS ON LOWER EXTRIMITY LOADINGS DURING LANDINGS

GU, C.

NATIONAL DONG HWA UNIVERSITY

INTRODUCTION: During landing, shoes act as a buffer between feet and contact surfaces to reduce impact forces. Shoe weights have been deemed an important factor (Steinberg, Waddington, Adams, Karin, & Tirosh, 2016). Studies focus mainly on running and confirm a corelation between shoe types and running-related biomechanics and injuries (Cauthon, Langer, & Coniglione, 2013; Miller et al., 2014). Landing,were not discussed as much; this study aims at exploring the relationship between shoe weights and impact forces.
METHODS: Prior to the experiment, participants were notified of the detail of the experiment and signed a consent form.20 minutes before the experiment, participants arrived at the laboratory, put on shoes, and ran on the treadmill for 5 minutes to warm up.After the warm-up drill, participants practiced 5 times to familiarize themselves with the required movements. Ground reaction forces were recorded using Two AMTI force plates and standardized by participants' weights.Platforms of different heights (30cm、40cm、50cm) and shoes of different weights (255g、335g、415g) were selected; therefore, the experiments were conducted under 9 combinations.The analysis was based on two-way ANOVA (α=.05) using data collected from 3 successful jumps for each comnination.
RESULTS: The interaction effects from (platform heights*shoe weights) for dominant and non-dominant legs are insignificant ($p>0.05$). The main effect of platform heights is significant ($p<0.05$) with H30 The interaction effects from (platform heights*shoe weights) for dominant and non-dominant legs are insignificant ($p>0.05$). The main effect of platform heights is significant ($p<0.05$) with H30>H40>H50 (dominant legs H30: 94.04 ± 13.30 ms, H40: 71.32±6.75 ms, H50: 61.12±3.62 ms; non-dominant legs,H30: 93.48±13.14ms, H40:73.37 ±6.25 ms, H50: 63.60±3.80 ms).
CONCLUSION: Lower extrimity loading and injuries have been found linked to platform heights. As the platform heights increase, so do the vertical reaction forces; the higher the platforms the sooner the peak values appear (Wang, Liang, & Wang ,2011) . Our analysis corresponds with conventional wisdom. Furthermore, we have discovered that heavier shoes on non-dominant legs cause peak impact forces to appear sooner, which increase the tension in ACL (Bates et al., 2013). This implies that the risk of injury for non-dominant legs increases with heavier shoes. Non-dominant legs are in nature weaker, which may cause irregular patellar tilt (Kernozek et al., 2005).

THE EFFECTS OF SKIPPING WITH A ROPE AND HOPPING FREQUENCY ON LEG STIFFNESS OF EXPERIENCED ROPE-SKIPPERS AND UNTRAINED SCHOOL CHILDREN

CHENG, K.C.1, LAU, Y.P.1, HA, A.S.1, NG, J.Y.Y.1, KONG, P.W.2

1: THE CHINESE UNIVERSITY OF HONG KONG , 2: NANYANG TECHNOLOGICAL UNIVERSITY,

INTRODUCTION: Rope-skipping as a form of physical activity has shown much health benefits. Previous works on the biomechanics of hopping and jumping has shown that leg stiffness tends to increase with the demands of the jumping task due to increased co-contraction of knee and ankle muscles (Hobara et al. 2007). With higher leg stiffness, individuals can resist the collapse of the lower extremity upon landing and enable the muscles to develop higher force and power at takeoff (Arampatzis et al. 2001). However, having an optimal amount of leg stiffness in various jumping tasks is important because excessive or insufficient leg stiffness may lead to increased risk of developing bony or soft tissue injuries, respectively (Butler et al. 2003). Although hopping-in-place and rope-skipping both involve similar jumping mechanism, it is possible that the presence of a skipping-rope would alter the control of leg muscles, especially for untrained individuals. Therefore, the objective of this study is to investigate how the presence of a skipping rope would alter the control of leg stiffness in experienced rope-skippers and untrained school children.
METHODS: Experienced rope-skippers (>5 years of training and competition experience) and untrained grade 7 to 9 school children aged 11 to 15 were recruited from local schools to participate in this study. All participants were asked to jump two-legged at two different frequencies (1.5Hz and 2.2Hz) with and without a skipping rope on a force plate. Participants were asked to perform 2 trials of 15 jumps for each condition (frequency: fast vs. slow; rope: with vs. without). Using peak vertical ground reaction force measured by the force plate and center of mass displacement measured by a 3D motion capture system, leg stiffness normalized relative to body mass was calculated with the spring-mass model (Hobara et al. 2007). The middle five consecutive hops (6th to 10th hop) were used for data analysis.
RESULTS: Preliminary results with 10 experienced rope-skippers and 10 untrained school children have shown that the presence of rope (rope: 0.304 (0.028) vs. no rope: 0.258 (0.015) kN/m/kg; $p=0.029$) and jumping frequency (fast: 0.332 (0.022) vs. slow: 0.230 (0.020) kN/m/kg; $p<0.001$) had significant main effects on leg stiffness. Moreover, significant group*frequency interaction revealed that experienced rope-skippers were better at maintaining their leg stiffness at different jumping frequency.
CONCLUSION: Experienced rope-skippers may be trained to optimize their leg stiffness to enhance their jumping performance and reduce injury risk.

EFFECT OF COUNTERMOVEMENT DEPTH AT DIFFERENT GROUPS ON MAXIMUM JUMP HEIGHT IN VERTICAL JUMPS

SUZOVIC, D.1, BORISAVLJEVIC, A.1, JARIC, S.1,2

1 FACULTYOF SPORT AND PHYSICAL EDUCATION, 2 DEPARTMENT OF KINESIOLOGY AND APPLIED PHYSIOLOGY AND BIOMECHANICS AND MOVEMENT SCIENCE GRADUATE PROGRAMUNIVERSITY OF DELAWARENEWARKUSA,

INTRODUCTION: When testing maximum vertical jumps, it is typically presumed that the subjects are able to select the movement pattern that maximizes the height of the maximum vertical jump, and to reproduce it over a series of consecutive trials. As a consequence, a possible effect of the countermovement depth (Hdep) on the jump height can be seen by various mechanisms. Some studies have shown that there is a stable form of muscular activation during jump performance, although there are somewhat sensitive to changes in the height depth (Bobbert & van Soest, 2001). Note that muscle length also changes with Hdep and the same applies to the muscle stretch-shortening cycle. All of that can considerably influence the tested muscle power. Namely, when performing CMJ, subjects descend more than at the SJ (Kirby, et al., 2011). The aim of this study was to analyze the relative contributions of the spontaneous Hdep on the jump height.
METHODS: The research involved forty subjects divided into four groups. Two groups consisted of male and female basketball players, while the other two groups consisted of age matched college students and sedentary subjects. All of them performed a set of 12 countermovement jumps without arm swing on a force plate. The sole task was to try to achieve a higher jump height than in the previous attempt. The value of the achieved jump was reported as a feedback to the subjects immediately after each attempt.
RESULTS: Obtained results revealed consistent Hdep and jump height at the basketball male and female groups (31.97±0.72 cm; 57.83±1.82 cm and 40.33±0.70 cm; 23.33±0.66 cm respectively), while other two groups gradually increased Hdep during the set of jumps (from 34.51 to 38.63 and from 30.81 to 35.47 cm; $p\leq0.05$) trying to achieve higher jump height at the next attempt.
CONCLUSION: A regression models revealed a presence of optimum Hdep for maximizing jump height, for basketball players with only small changes of Hdep. The preferred Hdep proved to be optimal for achieving the maximum jump height along the set of attempts. Therefore, it was concluded that although the optimum Hdep should exists, the magnitude of its effect on maximum jump height should be only weak for experienced athletes who use this type of jumps on a daily basis. The less experienced subjects try to achieve a higher jump height by increasing the Hdep. The locomotor apparatus is best shown in everyday activities in the conditions that the person is exposed to for a long period of time and according to which has been adapted (Jaric & Markovic, 2009).

LONGITUDINAL CHANGES IN THE QUADRICEPS FEMORIS MUSCLE AND JUMP PERFORMANCE IN JAPANESE ADOLESCENT BOYS

SEKINE, Y.1,2, HOSHIKAWA, S.3, HIROSE, N.2

1: TEIKYO HEISEI UNIVERSITY, 2: WASEDA UNIVERSITY, 3: EDOGAWA UNIVERSITY

INTRODUCTION: The quadriceps femoris muscle (QF) is an important muscle for athletes, because the power generated in the lower extremity is an important factor in athletic performance. The QF head shows varying growth rates related to differing roles or functions in each muscle heads (Sekine and Hirose, 2017). However, it is unclear how to increase the QF and develop jump performance in an individual. This study aimed to examine the longitudinal changes in the QF and jump performance in Japanese adolescent boys based on the age at peak height velocity (APHV).
METHODS: Twenty-five Japanese male adolescent male basketball players (aged 12-15 years) volunteered to participate in this study and were divided into Before PHV (<1 year from PHV, n=6), APHV (within 1 year from PHV, n=7) and After PHV (>1 year from PHV, n=12) according to the predicted APHV calculated with the BTT model (Auxal 3.1). The muscle thicknesses (MTs) of the vastus medialis (VM), rectus femoris (RF), vastus intermedialis (VI), and vastus lateralis (VL) were measured in the dominant leg using real-time ultrasonography. Cross-sectional images were obtained and analysed using a software. The countermovement jump (CMJ) measurement was performed with Vertec equipment. These measurements were performed again at 12 months after the first measurement. The MTs and CMJ were compared among groups and time using the repeated two-way (groups × times) analysis of variance followed by the Bonferroni post hoc test.
RESULTS: Significant interaction was observed for the CMJ ($p=0.002$), and significant increases were recognized in the Before PHV ($p<0.001$) and APHV ($p<0.001$) groups. Significantly increased main effects (time) were recognized for all subdivided QF muscles ($p= 0.05$-0.001). In the Before PHV group, the MT of VM ($p=0.005$), RF ($p=0.02$), and VL ($p=0.02$) increased significantly, which was not seen in the APHV and After PHV groups except for the MT of VM (APHV: $p<0.001$; After PHV: $p=0.01$).
CONCLUSION: The result of notable improvement in jump performance between the Before PHV and APHV groups and the age corresponds with those of a previous study (Philippaerts et al., 2006). The QF may increase in the Before PHV group; however, VM (activated during weight-bearing) was increased in the APHV and After PHV groups. Our results showed that the increasing QF and improvement of jump performance occurs during the moment of peak height velocity.

KNEE KINEMATICS AND KINETICS IN DIFFERENT LANDING TASKS AND SINGLE-LEGGED SQUATS

KAGAYA, Y.1,2, TSURUIKE, M.2, WATSON, M.M.2

1:SHOWA UNIVERSITY , 2: SAN JOSE STATE UNIVERSITY

INTRODUCTION: Anterior cruciate ligament (ACL) injury is one of the major concerns in women's basketball players. Many researchers have conducted the screening test for ACL injury prevention using double-legged jump tests. We have developed a two-dimensional (2D) screening test using single-legged tasks (Kagaya, 2015). It has yet to identify differences in kinematics and kinetics between the double-legged and the single-legged tasks. The purpose of this study was to investigate the differences between these two tasks.
METHODS: Twelve National Collegiate Athletic Association Division I women's basketball players (age: 18.9 ± 1.4 years, height: 177.2 ± 6.6 cm, weight: 72.1 ± 9.9 kg) agreed to participate in this study. All subjects performed single-legged squats (SLSQ) and three different landing tasks: 1) single-legged drop landings (SLDL), 2) double-legged drop landings (DLDL), 3) double-legged jump-landing for the Landing Error Scoring System (LESS). The SLSQ was performed by bending the knee of the supporting leg to 60 degrees. All the landing tasks were landed on a force plate from a 31-cm height box. In the LESS, the subjects jumped vertically as high as possible immediately after landing on ground. All procedures were recorded using two digital video cameras in the frontal and sagittal plane. Knee flexion and valgus angles were analyzed using 2D video image. Knee joint angles and ground reaction force in each task were compared using repeated-measures analysis of variance and Tukey's test at an alpha level of 5 % ($p < 0.05$).
RESULTS: The mean values of maximum knee valgus angle in DLDL, LESS, SLDL, and SLS were -6.9 ± 6.3, 1.1 ± 7.7, 6.6 ± 5.6, and 11.3 ± 7.6 degrees, respectively. The means of maximum knee flexion angle in each task were 76.2 ± 4.2, 80.1 ± 6.6, 63.1 ± 4.7, and 69.1 ± 3.8 degrees, respectively. The mean values of peak vertical force normalized by body mass in DLDL, LESS and SLDL were 25.3 ± 7.0, 25.3 ± 6.8, 43.2 ± 6.3 N/kg, respectively. No difference in the maximum knee flexion angle and the peak vertical force were observed between DLDL and LESS. However, we observed a significant difference across each of the double-legged tasks and single-legged tasks.
CONCLUSION: This study demonstrated that the single-legged task was larger knee valgus angle and vertical ground reaction force than the double-legged task, although the SLDL produced knee flexion angle smaller than the double-legged task. The results of this study were consistent with the previous report using a three-dimensional motion analysis (Heebner, 2017). It is plausible to suggest that clinicians and researchers consider kinematic and kinetic differences between the double-legged and single-legged tasks when they conduct a screening tests for ACL injury prevention.

THE EFFECTS OF GENDER AND APPROACH SPEED ON LOWER LIMB BIOMECHANICS DURING 90° SIDE CUTTING

XU, Y.L.1, YUAN, P.1, WANG, D.2, CHEN, W.1

1. JIANGSU RESEARCH INSTITUTE OF SPORTS SCIENCE; 2.NANJING UNIVERSITY OF CHINESE MEDICINE

INTRODUCTION: ACL injury often occurs in sports involving deceleration movements such as cutting. Female athletes suffer ACL injury at a 4-6 fold greater injury rate than their male counterparts. Although several mechanisms have been proposed to explain gender disparity in ACL injury rate, biomechanical mechanism has received more attention than the others. It may be attributed to the modifiable nature of this mechanism compared to the others. Previous studies found that gender may affect biomechanical mechanism. Further, biomechanics needed in cutting was also affected by approach speed. Therefore, the purpose of this study was to investigate the effects of gender and approach speed on lower limb biomechanics during cutting.

METHODS: Eleven female (17.45±1.25yrs; 1.79±0.08m; 74±7.40kg) and 12 male (17.33±2.15yrs; 1.91±0.06m; 80.08±6.63kg) young basketball players were recruited to perform 90°side cutting at approach speeds of 3, 4 and 5ms-1. 3D kinematical trajectories were collected using eight-camera motion capture system (Qualisys, Switzerland) at 200Hz. 3D kinetic data were synchronously collected using force platform (Kistler, Switzerland) at 1000Hz. Visual 3D was used to process 3D kinematic and kinetic data. Kinematical trajectories and kinetic data were low pass filtered using 4th order Butterworth filter with cutoff frequency of 12 and 50 Hz, respectively. The repeated measures ANOVA followed by LSD post hoc test was performed for statistical analysis (α=0.05).
RESULTS: Gender significantly affected knee flexion angle at initial contact (p=0.001), peak knee flexion angle (p=0.005) and moment (p=0.002). Specifically, knee flexion angle at initial contact (p<0.05) and peak knee flexion angles (p<0.05) in females were less than males at 3, 4 and 5ms-1, respectively. However, peak knee flexion moments (p<0.05) in females were greater than males at 3, 4 and 5ms-1, respectively.
Approach speed significantly affected peak VGRF (p<0.001), peak knee flexion (p<0.001) and abduction (p<0.001) moments. Specifically, peak VGRF and at 5ms-1 was significantly greater than that at 3ms-1 in females (p=0.011), and peak knee flexion moment at 5ms-1 was significantly greater than that at 3ms-1 in males (p=0.007). Furthermore, peak knee abduction moment at 5ms-1 was significantly greater than the moments at 3 (p<0.001) and 4ms-1 (p=0.001) in males.
CONCLUSION: Gender differences in lower limb kinematics and kinetics might help explain gender disparity in ACL injury rate. Furthermore, ACL injury risk might increase with increasing approach speed. These findings implicated that neuromuscular prevention program should consider the specific effect of gender and movement intensity on lower limb biomechanics.

AN ALTERNATIVE ANALYTICAL APPROACH FOR UNDERSTANDING LANDING STRATEGIES DURING ACL REHABILITATION

STEPHENS, J.M., CHAPMAN, D.W., TATE, K., WARMENHOVEN, J.

AUSTRALIAN CAPITAL TERRITORY ACADEMY OF SPORT

INTRODUCTION: Anterior cruciate ligament (ACL) injuries are a common traumatic athletic injury leading to a lengthy rehabilitation and reducing an athlete's dynamic postural stability. Discrete variables such as time to stabilisation (TTS) following drop landings have been proposed as useful functional measurements for athlete monitoring during the rehabilitation process (DuPrey, 2016). However, it is unclear whether this approach is informative for monitoring and evaluating the complete landing strategy before an athlete returns to competition. The present study sought to explore the possibility of using functional principal components analysis (fPCA) of the vertical ground reaction force (vGRF) during landing as an athlete monitoring tool with the intent of assessing changes representative of the landing strategy of a single athlete post ACL injury.
METHODS: Data from one female netball athlete was used in this case study. This athlete was tested on single left leg drop landing (3 per session) over 6 sessions pre-injury and 3 sessions post-ACL injury, leading to a total of 27 landings. Landings were performed using a step off from a 0.3 m box. vGRF was collected during each landing and cropped to 0.5 s post maximum vGRF. Each vGRF time-series was fitted (n=27) using B-Splines prior to application of fPCA. Each fPC score was further compared to identify differences in landing strategy pre- and post-ACL injury.
RESULTS: Five functional principal components (fPCs) explained 86% of all variation in the original 27 landings, with each fPC describing a different pattern of variation in the landing vGRF. fPC scores for all healthy landings (n=18) were used to build a regression model for healthy landing behaviour. fPC scores for all post-surgery landings (n=9) were tested for deviations from this regression model using concepts taken from magnitude-based inferences (Hopkins, 2017).
CONCLUSION: A modified landing strategy after ACL surgery was identified by fPC4, indicating the presence of higher force following the initial contact peak force and shock absorption phase of the landing. This demonstrated that further evaluation of this athlete was warranted before a return to competition. The use fPCA has the potential to highlight changes in movement strategies that may have occurred post-injury, which conventional discrete variables will not detect.

A SYSTEMATIC AND META-ANALYSIS ON THE EFFECT OF NOVEL KNEE REHABILITATION TECHNIQUES DURING SQUATTING ON ACUTE VASTUS MEDIALIS MUSCLE ACTIVITY IN HEALTHY INDIVIDUALS: IMPLICATIONS FOR PATELLA FEMORAL

ALQASEER, D.1 VALENTIN, S.1 BAKER, J.1 SANDERSON, M.1

UNIVERSITY OF THE WEST OF SCOTLAND .

INTRODUCTION: The imbalance between Vastus Medialis (VM) and Vastus Lateralis (VL) muscle activity is a major cause of PFPS which leads to patellar maltracking by placing anatomical components of the knee joint under strain (Ryan & Rowe, 2006). This imbalance can be addressed by using selective exercises that aim to increase VM muscle activation relative to VL activation. To date there is a lack of evidence relating to novel treatments performed during squatting on VM muscle activation as no extensive meta-analysis has been completed on this topic. The aim of this review was to evaluate which novel rehabilitation techniques increase acute VM muscle activation during squatting. The findings of this review will have fundamental implications for future research and rehabilitation strategies in PFPS patients.
METHODS: This review followed evidence-based PRISMA guidelines. The following electronic databases were searched; CINAHL, PubMed, Science Direct, Web of Science and Medline for; Vastus Medialis, muscle activation and PFPS. Risk of Bias (RoB) was assessed.
RESULTS: A total of 11 repeated measures studies with 16 different novel exercises and a total of 234 participants were included. Whole body vibration (WBV) stimuli showed a positive effect on VM activation in healthy individuals; standard mean effect size (d)=2.50, 95% confidence interval [CI] ([0.72 to 4.28]; p<0.05). Hip adduction and elastic band exercises appeared to have a positive effect on VM activation in PFPS but not healthy populations (d=0.52, 95% CI [0.07 to 0.97]; p<0.05). Squatting on unstable surfaces appears ineffective for VM activation (d=0.24, 95% CI [-0.12 to 0.60]; p>0.05).
CONCLUSION: WBV stimuli appears to have a positive impact on VM muscle activation which is supported by the finding of higher VM activation during rubber platform squatting versus harder surface (Hyong & Ho, 2013). Although VM activation in PFPS patients appears to be higher during combined squat with hip adduction and resistance exercise; these interventions need to be re-evaluated by further research using more robust study designs. In addition, combined interventions appears to be a new recommended approach in PFPS management (Crossley et al., 2016).

This systematic review and meta-analysis provides an insight into novel rehabilitation techniques which aim to increase VM activation during squatting in healthy and PFPS populations. Evaluation of these novel interventions is essential to provide evidence based practice in a clinical setting.

RESEARCH ON COMMUNITY SPORT DEVELOPMENT IN CHINA

WANG, Y.

CHINA SPORT INFORMATION CENTER

Introduction: China has entered the decisive stage in building a moderately prosperous society in all respects. Community sport plays an important role in promoting well-rounded human development and all-round social progress in China.
Methods: This paper tries to summarize and analyze the status quo of community sport in China, and come up with some suggestions accordingly. The methods of literature research, expert interviews and comparative analysis are applied in this paper.
Results: The past decades have witnessed huge improvement in community sport development in China. However, there still exist some problems. For example, the development levels among different regions are unbalanced; there is still a lack of fitness building facilities in most communities; the number of professional instructors can't meet the need of community residents, etc.
Discussion: A few suggestions for further enhancing the participation level of community sport in China have been proposed. Firstly, it is better to apply differentiated development strategies to different groups of community residents. Secondly, while the construction of more community sport facilities is needed, the focus of government should be on the provision of comprehensive public services. Thirdly, the role of various levels of social organizations should be given full play. Fourthly, the training of specialized talents should be accelerated to organize more creative community sport events and instruct more community residents.

ANALYSIS OF THE DOPING CONTROL TEST RESULTS IN INDIVIDUAL AND TEAM SPORTS FROM 2003 TO 2016

AGUILAR-NAVARRO, M., MUÑOZ-GUERRA, J., PLATA, M., DEL COSO, J.

CAMILO JOSE CELA UNIVERSITY AND FRANCISCO DE VITORIA UNIVERSITY

INTRODUCTION: Since the creation of the World Anti-Doping Agency (WADA) in 1999, one of the main objectives of the international anti-doping community has been to reduce the gap between the "forces" that act in favour of doping in sports and the procedures employed by the anti-doping authorities to assess the use of prohibited substances and methods.
The prevalence of doping has been assessed in several sports but the information is scarce and the athletes' samples and the methodologies employed to assess the prevalence of doping in each sport preclude an objective comparison among sports disciplines. The aim of the present investigation was to assess the differences in the prevalence of doping among sports by analysing the frequency of adverse/atypical findings reported by WADA accredited laboratories over the course of 14 years.
METHODS: The data included in this investigation have been gathered from the Testing Figures Reports made available annually from 2003 to 2016 by WADA. These Testing Figures Reports can be accessed from the WADA website and they contain information about the number of samples analysed, the percentage of adverse and atypical findings and the most commonly found drugs in urine and blood samples, among other analyses.
RESULTS: A total of 1,132,143 samples were analysed from the individual sports selected for this investigation from 2003 to 2016 with an overall frequency of adverse/atypical findings of 2.0 ± 1.0%. In the team sports examined, the number of samples analysed was 757,011 while the frequency of adverse/atypical findings was significantly lower than in individual sports (1.6 ± 0.6%). Specifically, athletics was the sport with the highest number of samples analysed per year, followed by cycling, aquatics and weightlifting. Cycling, weightlifting, and boxing were the sports with the highest proportion of adverse/ atypical findings.
Football was the team sport with the highest number of samples analysed per year, followed by rugby and basketball. Regarding the percentage of adverse/atypical findings, ice hockey, rugby, and basketball presented a higher proportion.
CONCLUSION: The prevalence in the use of doping substances was not uniform in all sports disciplines from 2003 to 2016 with a higher overall proportion of banned substances found in individual vs. team sports. Furthermore, some specific sports had higher proportions of adverse/atypical findings that suggests a greater prevalence of doping related to their idiosyncrasy rather than other physiological explanations. This information may be valuable for national and international anti-doping organisations to improve the policies used to reduce the prevalence of doping in sports and to detect specific sports with a higher risk of doping misconduct. Specifically, this information could aid in obtaining a more informed athlete population and the implementation of test distribution plans adapted to the sport disciplines that will lead to the establishment of muchmore "intelligent" testing policies.

CLASSIFICATION OF THE NATIONAL FEDERATIONS BY FOCUSING ON THE RELATIONSHIPS WITH THE NATIONAL DISABILITY SPORT ORGANIZATIONS IN JAPAN

AOYAMA, M.1, YAMAGUCHI, Y.2

1: RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE, KOBE UNIVERSITY , 2: KOBE UNIVERSITY

Introduction: In recent years, the integration between the National Federations (NFs) and the National Disablity Sport Organizations (NDSOs) has been progressing internationally. In Japan, NFs joining both committees of National Olympic Committee (NOC) and National Paralympic Committee (NPC) are only 2 NFs of "All Japan Taekwondo Association" and "Japan Triathlon Union". Besides, the relationships between the rest of NFs and NDSOs are unclear. The purpose of this study was to classify the National Federations by focusing on the relationships with the National Disability Sport Organizations in Japan .

Methods: Data were collected from the archival materials, documents and interviews with the staff members of the eight NFs. Comprehensive content analysis with a triangulation method by two researchers was undertaken.
Results: The main results of this study were as follows. The NFs in Japan were classified into four groups. The first group (28 out of 54 NFs) did not have any corresponding NDSOs on their sports. The second group (22 out of 54 NFs) had corresponding NDSOs. For nine of those, multiple NDSOs (e.g., intellectual, mental and physical disability) were existed. Also, there were 13 NFs with only one NDSOs. The third group (two out of 54 NFs) had intermediate organizations between NFs and multiple NDSOs. "Japan Football Association" and "Japan Swimming Federation" were included in this group. The last group (two out of 54 NFs) consisted of NFs that had already integrated as mentioned above.
Discussion: In Japan, there were many cases that NDSOs were divided by disability types. Before the integration of NFs and NCSOs, it is first required to integrate multiple NCSOs, or it is necessary to place intermediate organizations between NFs and multiple NDSOs. As a result of the interviews, it became clear that the necessity of integration was influenced by the relationship between International Federations (IFs) and International Paralympic Sport Federations (IPSFs). When IFs coexisted with IPSFs, it mattered little if they were divided at NF level. When the IFs had been integrated with IPSFs, several problems occurred at the administrative level. In this case, it may be required to consider the integration with NDSOs even at the NF level. In addition, the Disability Discrimination Act was not enacted in Japan. Prior to hosting the Paralympic Games in UK, Canada and Australia, it was already enacted in those countries (Sasakawa Sports Foundation, 2017). In order to promote the integration and inclusion of the disability sport, enactment of the Disability Discrimination Act is urgently required.

THE UNEVEN PROFESSIONALIZATION OF TEAM SPORTS

LÄMSÄ, J.

KIHU - RESEARCH INSTITUTE FOR OLYMPIC SPORTS

Introduction: Modern sport is claimed to reflect the ideas of professionalization, commercialization and commodification, which are in turn reinforced by pressure from mass media. To be professional means both state of art knowledge or skills as well as rational and efficient model of organization. However, professionalization is an uneven process. Not all sports are able to attract resources outside their own participant base needed to even start the professionalization process. Therefore, the aim of this study is to analyze the differences of professionalization processes of four team sports (ice-hockey, football, Finnish baseball, floorball) in Finland.
Methods: The data of this study were gathered by doing structured interviews with five team sport experts and by studying official and unofficial documents from both local level (elite clubs) and national level (national governing Bodies) organizations. The different data sources were not used for triangulation but to gain a more detailed interpretation.
The level professionalization is dependent heavily on the overall resources of the sport. Therefore, the number of professional athletes and coaches, number of paid staff both at the local and at the national were analyzed between year 2001-2017. Secondly, financial resources of different sports and existence of the professional league, and its relation to the broader structure of sport was, studied.
Results: Ice-hockey, with 700 professional players and 260 coaches, is clearly the only advanced professional sport in Finnish context. The annual turnover of 15 league teams was altogether 93 m compared to 17 m of 12 teams in the football league. Finnish baseball has been able to professionalize by being popular on smaller municipalities and not competing directly with the bigger sports.
Conclusion
These results show that the nature of the professionalization processes of four different Finnish team sports is uneven and asynchronous. Only one sport, ice-hockey, is fully professional and have adopted a mixture of the European and American models of organizing professional sport.

HOW DID THE PARALYMPIC GAMES BE IMAGINED IN JAPAN? FROM DISCOURSE ANALYSIS FOCUSING ON MEDIA COVERAGE

WATARI, T.

JUNTENDO UNIVERSITY

1. Background and purpose
In Japan, a lot of people are paying attention to the Paralympic Games in 1964 . So, how did we talk about the Paralympic Games in Japan from the Paralympic Games in 1964 to the present?
In this research, by analyzing text data mainly of newspapers, we will examine how the Paralympic Games have been imagined in Japan. Especially, from the comparison of the social image towards the disability sports at the time and the current, we argue that how Japanese society changed to see the disability sport and the disabled people. And we would like to think about the continuity / disconnection of Japanese history of the disability sport.
2. Method
To analyze the article, we use the KH Coder which is a free software for statistically analyzing text type data. We prepared code for classifying article content and note the collocation (co-occurrence relation) of articles related to the code and words. The target newspapers are the Asahi Shimbun, the Yomiuri Shimbun, the Mainichi Shimbun and other various discourse materials. From the search results of the database, we selected articles related to the disability sports and paralympics. Although the word of Paralympic Games is included in the article, the content itself is not directly related to sports, disability sports and Paralympic Games, excepted from the Analysis.
3. Results: Here we show only what is relevant to the 1964 articles. Around 1964, almost articles are not related to the result of the competition, but the announcement and explanation of the event itself occupies the center. In particular, some articles of disability sports since 1965 tended to be reported in relation to the Imperial family.
Meanwhile, articles of the Paralympic Games in recent years tends to be clearly reported in association with the results of individual players. As a whole, there is also a tendency to be reported in relation to the athletes competitive results, and it can be said that the appearance of other phrases such as the social problem for the athletes with impairments are decreasing.

4. Discussion: Media coverages of the 1964 Tokyo Paralympic Games focused the announcement of the event rather than the competition result. In some articles, it was pointed out that Japans disability welfare efforts were delayed by referring to the situation of foreign players. In around 1964, the articles mainly visualized the existence of Sports event for the disabled. Also, especially during the period from 1965 to the 1980s, articles of disability sports were reported only in relation to the Imperial family.
Recent coverages of the Paralympic Games, for example the coverages of the Rio Paralympic Games in 2016, tend to be focused on the achievement of individual players. On the other hand, social problems such as inclusive society are rarely reported. In other words, it turns out that the Paralympics was understood as an event with news value completely independent from other social phenomena.

MO-SH05 Effects of exercise of stress, cognition and health

AN ACUTE BOUT OF EXERCISE DIMINISHES SYSTOLIC BLOOD PRESSURE RESPONSES TO STRESS, BUT INCREASES FEELINGS OF THREAT AND STRESSFULNESS.

GINTY, A.T., TROTMAN, G.P., VELDHUIJZEN VAN ZANTEN, J.J.C.S., WILLIAMS, S.E.

BAYLOR UNIVERSITY; UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Exercise is beneficial for cardiovascular health and managing stress. Research examining the impact of exercise on subsequent cardiovascular and psychological responses to acute psychological stress has produced mixed results. Few studies have simultaneously examined the effects of exercise on both the cardiovascular and psychological responses to the same stress task. The aim of this study was to examine whether exercise prior to acute psychological stress could attenuate blood pressure and negative appraisals of stress.
METHODS: Forty participants (50% female, Mean age = 19.95, SD = 1.93 years) completed three laboratory visits. The first visit assessed participants' VO2 max with an incremental exercise test. The second and third visits were counterbalanced and consisted of either mental stress or exercise and mental stress. The stress only condition consisted of a resting baseline period and standardized mental stress task. During the exercise and stress condition, participants undertook 10 minutes of cycling at 70% of VO2 max, a baseline period followed by the same stress task. Participants' systolic blood pressure was measured at baseline and during the stress task. In each condition, participants also rated how threatening and stressful they found the stress task.
RESULTS: A 2 condition (stress only, stress following exercise) x 2 time (baseline, stress) ANOVA demonstrated that there was a significant main effect for time $F(1, 37) = 48.74$, $p < .001$, $eta2 = .568$, and a significant visit × time interaction for systolic blood pressure, $F(1, 37) = 6.26$, $p = .017$, $eta2 = .145$. Although the mental stress task significantly increased systolic blood pressure in both conditions, the systolic blood pressure response was attenuated in the stress following exercise condition compared to the stress only condition. Paired samples t-tests (stress only, stress following exercise) indicated participants found the stress following exercise condition to be significantly more threatening ($t(39) = -3.63$, $p = .001$) and stressful ($t(39) = -2.89$, $p = .006$) compared to the stress only condition.
CONCLUSION: Exercise prior to stress may be effective in reducing blood pressure responses to stress which may have cardiovascular health benefits. However, exercise prior to stress may be detrimental to the psychological interpretations of the stressor.

TASK DIFFICULTY OF COMPLEX FULL-BODY EXERCISE AFFECTS ON A PATTERN OF COGNITIVE NEURAL ACTIVATION

KIMURA, K., OKA, F.

TOKYO DENKI UNIVERSITY

INTRODUCTION: Recently, physical exercise has been focused on as being beneficial for maintaining and improving cognitive function. These reports suggested that the unique aspects of task complexity with regard to sports such as dance, tai-chi, ball sports, etc., effectively facilitate neuronal networks responsible for cognitive behavior. The present study was conducted to demonstrate the correlation between task difficulty of a full-body action and neuro-cognitive activation by having participants observe and mentally rehearse a full-body dance performance.
METHODS: Functional magnetic resonance imaging (fMRI) was employed to identify the cognitive neural activation while participants were observing a pre-recorded movie of a dance performance. The participants were asked to observe and mentally rehearse the instructors full-body dance choreographs while watching the video. Immediately after the MRI assessments, participants took part in the dance performance to test if they could correctly follow the instructor's performance. Thus, to determine the task difficulty of each participant's body movements, temporal or special errors of dance steps were counted during the sequence of the dance performance, which was the same dance they while undergoing MRI scanning. We concluded that the lower the difficulty of the dance choreographs, the fewer was number of errors occurred in step sequence, and vice versa. The present study demonstrated that neuro-cognitive activation from mental rehearsing of dance could be accentuated according to the difficulty of the dance task.
RESULTS: In the results, the following areas were activated during observation of the dance: the premotor and supplementary motor cortices, the cingulate gyrus, and the inferior parietal cortices. However, unique correlations were detected between neural activation and task difficulty in those brain regions. Positive correlations were recognized in prefrontal area and anterior cingulate gyrus. While, negative correlations were detected in parietal and temporal areas.
CONCLUSION: The results showed that observing dance performance activated the executive-cognitive network associated with complex dance movements. Moreover, individual difficulty of the dance task might affect the pattern of the neuronal activation within those areas. Notably, the frontal network was utilized more by decreasing the difficulty of the dance task, suggesting that the neural resources could be available for creation/preparation of motor actions. Because the parietal and temporal networks were utilized more for increased dance difficulty, this may suggest that the neural resources would be supplied more with analysis/understanding of dance contents.

TIMING OF ACUTE MODERATE INTENSITY EXERCISE EFFECTS CORRECT BUT NOT FALSE REMEMBERING

MARCHANT, D.1, ELLISON, P.1, CRONIN, L.1, THORLEY, C.2

1: EDGE HILL UNIVERSITY , 2: JAMES COOK UNIVERSITY

INTRODUCTION: Physical exercise can benefit cognitive function, yet research assessing the effects of acute exercise on memory processes is inconsistent. The present study examined how the timing of acute moderate intensity aerobic exercise impacts delayed recall.

The Deese-Roediger-McDermott (DRM) paradigm was used, which examines veridical and false memory through encoding lists of semantically related words associated with a non-presented 'critical lure'. These lures are typically later remembered as frequently as studied words. The aim of this study was to assess the effects of a single bout of moderate intensity exercise performed prior to or after information encoding on long term memory.
METHODS: In a between-subjects design, sixty healthy and regularly active young adults (mean age =19.4 ± 1.1 years; weight = 71.2 ± 11kg; height = 173±8cm; resting HR = 74±10.5bpm-1) were randomly allocated to one of three conditions: Quiet rest prior to encoding (Rest), Exercise pre encoding (ExPre), and Exercise post encoding (ExPost). Exercise was 30 minutes of self-regulated moderate intensity stationary cycling (RPE = 13-15, HRR = 50-60%), whilst quiet rest involved seated reading. Participants studied six neutral DRM word lists. Retention was assessed using free recall and recognition tests one week later. Encoding was completed immediately prior to (ExPre) or post (ExProst) exercise or rest (Rest). Ratings of perceived exertion (RPE), affect and heart rate were measured at 2 minute intervals.
RESULTS: HR and RPE data indicated exercise was undertaken at the intended intensity. Affective valance was positive during exercise. No significant differences were observed in any immediate recall variables. At one-week delayed recall, total correct words recalled was significantly ($p<0.05$) greater for ExPre compared to ExPost and Rest. No differences were found in total critical lures and total errors recalled between each condition. No differences in recognition rates were observed one week later.
CONCLUSION: Performing moderate intensity cycling prior to encoding facilitated encoding processes, by improving the volume of studied information correctly recalled. There were no differences in false memory generation across conditions, suggesting that exercise induced arousal facilitated verbatim memory traces rather than gist-based processing that would promote misinformation effects. This beneficial effect may be associated with the effects of acute exercise on supporting attentional processes and allocation.

THE RELATIONSHIP BETWEEN THE DIFFERENCE OF PLAYING STYLES AND THE COGNITIVE FUNCTIONS IN TENNIS PLAYERS

TOCHIGI, Y., SUGAWARA, Y., HAMASAKI, A., SATO, T., MOMMA, R., PARK, J.Y., TANAHASHI, K., TAKAHASHI, A., MAEDA, S.
UNIVERSITY OF TSUKUBA

INTRODUCTION: Cognitive functions are very important for tennis players as well as technique, physical strength, and so on (Ishihara T. et al, 2016). Several studies showed that the levels of tennis involve in the cognitive functions (Mosoi A.A. et al, 2014). However, the relationship between playing styles of tennis and cognitive functions remains unclear. We classified playing styles into the three groups: baseline-style, net-style, and combination-style, and into the two ones: offensive-style and defensive-style. Then, we investigated whether the differences of the playing styles are related to the cognitive functions.
METHODS: Subjects were collegiate athletes (male=20, female=15), who practiced tennis more than five days a week. The cognitive functions evaluated the reaction time and the interference time to problems using the Stroop test (Samuel J.E.L. et al, 2012), the Spatial Working memory task (Aoki R. et al, 2011), and the Trail Making Test (Tom N.T., 2004). The Stroop test was consisted by four difficulty levels and employed to evaluate attention and information processing speed (MacLeod C.M. et al, 2000). Working memory was important for reasoning and the guidance of decision-making and behavior. The Trail Making Test provides information on visual search, scanning, speed of processing, mental flexibility, and executive functions (Tom N.T., 2004). Subjects answered each problem as fast as possible after they practiced to answer the problems enough. The playing styles of tennis classified using the questionnaire (Yamada Y. et al, 1989).
RESULTS: In the groups of net-style and combination-style, the reaction time of the Spatial Working memory task was significantly faster than in the baseline-style group ($P < 0.05$). When we classified playing styles into the groups of offensive-style and defensive-style, the reaction times of the Spatial Working memory task and the Stroop task relating to the offensive-style were faster than the other one ($P < 0.05$). In the reaction time of the Trail Making Test, there was no significantly difference among all groups.
CONCLUSION: We found that the difference of net-baseline styles and offensive-defensive styles are related to the cognitive function. The result of this study suggests that the tennis players of net-style and combination-style are superior in reasoning and the guidance of decision-making and behavior. Furthermore, we suggest that the offensive-style tennis players are superior in attention and information processing speed, reasoning and the guidance of decision-making, and behavior.

DOES THE SPEEDCOURT REALLY ASSESS REACTIVE AGILITY? RELATIONSHIP BETWEEN OPEN AND CLOSED SKILL MOVEMENTS

RAEDER, C., PRAETORIUS, A., OHMANN, T., SCHOEPP, C.
BG KLINIKUM DUISBURG

INTRODUCTION: The SpeedCourt (SC) has been introduced as a tool for assessing reactive agility since it is composed of change of direction (COD) movements in response to a visual stimulus. Due to the perceptual-cognitive processes during the unplanned COD actions, which can be considered an open skill, one would generally not expect strong associations of these SC agility variables with closed skill performance measures such as jumping or sprinting (preplanned movements). To test this assumption, this study investigated the relationship between SC performance variables and several markers of jump, sprint and COD ability.
METHODS: Using a cross-sectional design, 24 male junior and senior handball players of the 3rd German division (mean±SD; age: 21.1±4.5 yrs) volunteered to participate in this study. The players first conducted two linear sprints followed by two 180° COD sprints turning with either the right or left leg, using a modified version of the 505 test (mod505). The 5m sprint (SP5), 10m sprint (SP10) and mod505 times as well as the COD deficit (mod505-SP5) were collected. Due to organizational constraints, the subjects were then split into two groups. One group performed jump tests including three countermovement jumps (CMJ [height]), 15s multiple rebound jumps (MRJ) using ground contact time (MRJ-GCT) and jump height (MRJ-JH) of the five best reactive strength indices (MRJ-RSI), as well as three bilateral horizontal hops (HOP [distance]). The other group conducted nine consecutive SC protocols with a work-to-rest ratio of approximately 1:3 (~12-15:45s) consisting of about ten multidirectional CODs over a distance of 30m in random fashion. The SC performance variables measured included total time (SC-TT) and time to change direction (SC-TCD). Thereafter, the tests were changed for both groups. For all measurements, the mean was taken for analysis. In mod505, the data were pooled for the right and left leg. All measurements were preceded by a standardized dynamic warm-up followed by sufficient familiarization trials.
RESULTS: The Pearson correlation revealed small to large relationships of SC-TT with CMJ (-.39; 90% CI: -.66, -.03), MRJ-JH (-.41; -.68, -.08), MRJ-GCT (.18; -.20, .51), MRJ-RSI (-.43; -.68, -.08), HOP (-.36; -.64, .00), SP5 (.59; .29, .78), SP10 (.58; .28, .78), mod505 (.29; -.08, .59), and COD deficit (-.26; -.57, .11). There were moderate correlations of SC-TCD with mod505 (.35; -.02, .63) and COD deficit (.32; -.05, .61), while the other measures showed trivial to small associations with SC-TCD (-.19–.20).

CONCLUSION: Most of the closed skill measures showed a small to moderate relationship with SC performance variables. This may indicate the presence of additional required qualities like cognitive stimulus processing probably affecting SC performance. However, linear sprinting seems to have a large contribution to SC performance which may be related to the slight technical delay of the visual stimulus that likely impair the proper assessment of reactive agility.

EFFECT OF COMBINED AEROBIC AND ANAEROBIC EXERCISE TRAINING ON PSYCHO-BEHAVIORAL CHARACTERISTICS IN BINGE EATING DISORDER

GALASSO, L.1, MONTARULI, A.1,2, BRUNO, E.1,3, CALOGIURI, G.4, MULÈ, A.1, CASTELLI, L.1, CAUMO, A.1, ROVEDA, E.1,2, ESPOSITO, F.1,2

1:UNIVERSITY OF MILAN, MILAN, ITALY; 4: INN UNIVERSITY, ELVERUM, NORWAY

INTRODUCTION: Eating disorders are the most common psychological and physical diseases for young women (Hudson et al., 2007). According to the DSM-5, Binge Eating Disorder (BED) is characterized by frequent and persistent episodes of binge eating followed by a loss of control and marked distress in the absence of regular compensatory behaviors (Galasso et al., 2017).
The aim of this study was to investigate the effects of an exercise training intervention on anthropometric and psychological characteristics, aerobic capacity, and muscle strength in BED patients compared to traditional treatment alone.
METHODS: Twenty participants with diagnosis of BED were recruited from the Department of Clinical Neurosciences at IRCCS San Raffaele Turro in Milan, Italy, and were randomized into a treatment and a control groups. All patients kept their individual weekly multidisciplinary therapy during the study, consisting in traditional BED treatment and nutritional program. Psycho-behavioral characteristics (i.e. amount of binges), anthropometric parameters (body mass and BMI), and exercise capacity (6MWT and Squat Test) were assessed before (PRE) and after (POST) six months of intervention, consisting in a combination of aerobic and anaerobic exercises (CAAET) in addition to the traditional therapy (CAAET group), or a same period with only traditional therapy (CTRL group).
RESULTS: In PRE, the groups resulted homogeneous and there were no statistically significant differences for all variables analyzed. In POST, the CAAET group obtained a significant decrease in the amount of binges, in body mass and BMI, accompanied by an increase in 6MWT and Squat Test. A delta analysis showed that these changes in women of CAAET group were significantly larger than the one observed in the CTRL group, except for the exercise capacity.
CONCLUSION: Our study shows that patients attending a CAAET treatment, in addition to a traditional therapy only, obtain higher improvements in psycho-behavioral sphere. This suggests that the addition of combined exercise training to the traditional BED treatment can generate beneficial effects in obese individuals with BED. The incorporation of exercise training intervention is proposed to be a valuable addition for effective treatment in BED.

A META-ANALYSIS ON NEUROMUSCULAR VS. AEROBIC EXERCISE TRAINING ON DEPRESSIVE SYMPTOMS

NEBIKER, L., LICHTENSTEIN, E., MINGHETTI, A., ZAHNER, L., GERBER, M., FAUDE, O., DONATH, L.

UNIVERSITY OF BASLE

INTRODUCTION: The NICE guidelines recommend exercise training as a beneficial treatment strategy for depression (NICE, 2013). Previous meta-analytical reviews mainly examined the effect of aerobic exercise on depressive symptoms. Our meta- analysis aimed to a) compare aerobic exercise with neuromuscular exercise training, b) conduct sensitivity analyses reflecting on study quality and c) investigate the influence of relevant training prescriptors such as exercise duration, frequency, intensity and number of exercise sessions (volume) in a meta-regression analysis.
METHODS: A structured literature search along the PRISMA guidelines was conducted in biomedical and psychological databases with a selected search term related to exercise and depression. (Randomized) controlled trials that compared supervised neuromuscular or endurance exercise interventions with an inactive control group (CON) in clinically depressed adults over 18 years were included.
Study quality was evaluated with PEDro scale and standardised mean differences (SMD) were calculated with the adjusted Hedges'g equation as main outcome for the comparison of endurance and neuromuscular exercise interventions vs. CON. Statistical analyses were conducted using random effects inverse-variance model. Multivariate meta-regression analysis was performed in order to examine the modulating effects of exercise training prescriptors on effect sizes.
RESULTS: In total, 25 trials of good study quality (mean PEDro score 6.6) comprising 1'340 participants were analysed. Irrespective of the exercise mode and study quality, large effects in favor of exercise compared to CON were found (SMD: -0.97 (90% CI: -1.26, -0.67); $p < 0.001$, $I2 = 83\%$). Compared to CON, sensitivity analyses revealed a large effect in favor of endurance exercise (SMD: -0.83 (90% CI: -1.24, -0.42; $p < 0.001$, $I2 = 85\%$) and a very large effect size in favor of neuromuscular exercise (SMD: -1.14 (90 CI: -1.57, -0.72); $p < 0.001$, $I2 = 80\%$). These effects decreased to moderate effects for endurance (SMD: -0.52 (90% CI: -0,85 -0.19) and remained large for neuromuscular trial (SMD: -1.19 (90% CI: -1.13, -0.52) when considering studies of high quality (PEDro-score: •6), indicating a significant difference (p=0.03). Multivariate meta- regression revealed that exercise duration in endurance trials and exercise intensity in neuromuscular trials had a significantly moderating effect on the effect sizes.
CONCLUSION: Physical exercise interventions are generally a very effective treatment for depression. Neuromuscular exercise interventions seem to be more effective than endurance exercise interventions, particularly in studies with higher study quality. Interestingly, exercise duration and exercise intensity moderated the effect size meaningfully. This result might be used on exercise in depression to increase efficacy.

BIGOREXIA SYMPTOMS AFFECT SELECTION OF MEAL PARTNER

DEVRIM, A., BILGIC, P.

ISTANBUL MEDENIYET UNIVERSITY

INTRODUCTION: Bigorexia (muscle dysmorphia) is a psychologic disorder that primarily effects male bodybuilders (Mosley, 2009). Some studies have found that bodybuilders with bigorexia have strict eating rules to gain more muscle (Murray & Touyz, 2013; Strother, Lemberg, Stanford, & Turberville, 2012; Suffolk, Dovey, Goodwin, & Meyer, 2013). Therefore, this strict rules have a negative impact on eating

habits and caused disordered eating behaviors (Jones & Morgan, 2010). This study aimed to determine whether bigorexia symptoms affects selection of meal partner.
METHODS: One hundred twenty bodybuilders (mean age 31.05 ± 10.60) included in this study. Muscle Dysmorphia Disorder Inventory (MDDI) was used to detect bigorexia symptoms. >39.0 of the MDDI scores mean that the bodybuilders have bigorexia symptoms. Self-administered questionnaire was applied to determine selection of eating partner. Questions concerning their selection of meal partner is included to determine if they prefer eating with friends, or eating with all family, or eating with only their partner, or eating with only children, or eating alone. Data taken the study was evaluated by IBM SPSS 23.0.
RESULTS: In this study it was found that % 58.3 of the bodybuilders have bigorexia symptoms (mean MDDI scores 41.0 ± 2.9). Bodybuilders with bigorexia commonly preferred to eat alone (%65.7), while the others commonly preferred to eat with all family together (%42.0). The differences between selected meal partner according to the presence of bigorexia were statistically significant ($p<0.05$). %78.2 of the bodybuilders with bigorexia stated that they prepared their own meals when they asked why they prefer eating alone.
CONCLUSION: Bigorexia causes some disordered eating habits (Jones & Morgan, 2010). Therefore, selection of meal partner were affected by bigorexia symptoms. Both in eating disorders and bigorexia, patients having one of the disorders chose to eat alone and prefer social isolation. Determining whom they eat with could be a diagnostic tool for both in bigorexia and eating disorders.

RELATIONSHIP BETWEEN LIFESTYLE AND SELF-PERCEPTION OF PHYSICAL FITNESS IN RUGBY PLAYERS IN COLOMBIA: FINAL RESULTS.

MARTÍNEZ-RUEDA, R., GUTÍERREZ-GALVIS, A., HERNÁNDEZ CUBILLOS, V., SÁNCHEZ MENDOZA, N., LOZADA BELTRÁN, N.
UNIVERSIDAD MANUELA BELTRAN

INTRODUCTION: Self-perception and lifestyle may be considered as a significant determinant on athletes´ performance. The last years we have focused on study these aspects in Colombian Rugby players, final results are finally presented. The aim of this study was to identifiy the relationship between lifestyle and self-perception of phyisical fitness in Rugby players in Colombia.
METHODS: The FANTASTIC questionnaire (Ramírez-Vélez, R. & Agredo, R., 2012) and the International Fitness Scale, IFIS (Español-Moya, M. & Ramírez-Vélez, R., 2014) were applied to assess lifestyle and self-perception of physical fitness to Rugby players in 7 cities in Colombia. Statistical analysis was performed through central tendency measures, standard deviation, t-student and Chi- Square.
RESULTS: 479 players were surveyed. The age average was 25 (±4,4) years. According to the position on the field, 54% were Backs and 46% Forwards; 68% of the athletes were men. In relation to Lifestyle, the mean of total score was 75.3 (±10,2) classifiying it as "Good"; significant differences were found by position in Nutricion (p= 0,000), Alcohol (0,045), Tobacco toxis (0,033) and the total score of the questionnaire (0,004). Regarding to self-pereception, most of the players perceived their physical fitness and its components as "Good", except Flexibility, which was perceived as "Average". Differences between position were found in Cardiorresspiratory endurance (p=0,015), Strength (p=0,000) and Speed (p=0,001). Differences by sex were also found in Cardiorrespiratory endurance (p=0,001). When total scores of FANTASTIC were contrasted with the IFIS results´, a significant relationship between higher scores of lifestyle and better self-perception of cardiorrespiratory endurance (p=0,000) was found.
CONCLUSION: Our results are consistent with previous studies (F. Chague et al., 2017; Martínez Rueda et al. 2016). It highlights the fact of finding a relationship between better scores of the FANTASTIC and self-perception of Cardiorespiratory Fitness. The differences by position might be explained by the particular characteristics of each pack. Further studies that allow associating these results with the assessment of physical fitness of the players are recommended.

AEROBIC FITNESS LEVELS AND MOVEMENT CHARACTERISTICS IN ELITE GAELIC FOOTBALL AND HURLING REFEREES

BRADY, A.J., DURKAN, E., MCDERMOTT, C.M., HURLEY, N., HAYES, C., MOYNA, N.M.
DUBLIN CITY UNIVERSITY

INTRODUCTION: Field-based testing has consistently been incorporated as part of the referee match selection criteria by governing bodies of sport. Numerous field-based tests have been developed with The Yo-Yo Intermittent Recovery Test Level 1 (YIRT1) being the most extensively researched due to its specificity and practicality. The YIRT1 is also the most commonly used test to assess cardiovascular fitness in invasion team sports. No published studies have examined the effectiveness of the YIRT1 as a measure of aerobic capacity in elite Gaelic Football referees (GFR) or hurling referees (HLR) despite it being a part of the GAA selection criteria. The purpose of this study was to investigate the relation between performance in the YIRT1 and both VO2 max and selected movement characteristics during competitive match-play in elite GF and HL referees.
METHODS: A total of 17 elite GFR and 13 elite HLR with a mean (± SD) age of 40.6 ± 4.1 and 40.7 ± 3.8 years respectively, participated in the study. Each participant completed a VO2 max test and the YIRT1 prior to the commencement of the 2016/2017 senior All-Ireland Gaelic Football and Hurling championships. Participants wore a 10-Hz GPS unit (STATSportsTM) during each game they officiated. A total of 52 full game data sets (36 GF and 16 HL) were recorded. The movement variables measured were total distance (TD) in metres, relative distance (RD) in m.min-1, walking (0.0–6.5 km.h-1), jogging (6.6–12.0 km.h-1), low intensity running (LIR; 12.1–15.0 km.h-1), moderate intensity running (MIR; 15.1–18.0 km.h-1), high intensity running (HIR>18 km.h-1), sprints (>18km.h-1 for ≥1 s) and maximum speed (MS) in km.h-1.
RESULTS: There was no significant difference in VO2 max between GFR (57.4 ± 6.3 ml.kg.min-1) and HLR (54.2 ± 5.7 ml.kg.min-1). Distance covered in the YIRT1 was not significantly different between GFR (1675.3 ± 215.4 m) and HLR (1590.8 ± 243.4 m). There was a significant

correlation between the YIRT1 distance and VO2 max in HLR ($r = 0.81$, $p < 0.001$) and GFR ($r = 0.71$, $p < 0.001$). There was no significant correlation between performance in the YIRT1 or the VO2 max and TD for GFR or HLR. Performance in the YIRT1 was significantly related to HIR in HLR ($r = 0.62$, $p < 0.01$) and GFR ($r = 0.41$, $p < 0.01$). There was also a significant correlation between performance in the YIRT1 and sprints in HLR ($r = 0.66$, $p < 0.01$) and GFR ($r = 0.50$, $p < 0.001$). VO2 max was significantly related to HIR ($r = 0.45$, $p < 0.01$) and sprints ($r = 0.50$, $p = 0.001$) in GFR. There was no significant relation between VO2 max and any of the measured movement characteristics in HLR.
CONCLUSION: Elite GFR and HLR have above average aerobic capacity. YIRT1 distance is related to VO2max and to HIR and sprint performance but not TD in elite GFR and HLR.

ISOMETRIC STRENGTH OF KNEE FLEXORS AND EXTENSORS WITH RELATION TO SOMATIC PARAMETERS OF MALE FOOTBALL PLAYERS UNDER 15 YEARS OLD.

PELLA, M.

PALACKY UNIVERSITY OLOMOUC

INTRODUCTION: Panteleimon (2012) proved strong correlation between age, body size and isometric strength (IS) for young male footballers. Thus, the body size and age could be predictors of isometric strength. McGuigan and Winchester (2008) verify that some type of isometric contraction is an efficient method for dynamic strength indication. But Thomas et al. (2015) proved there are no correlation in jump height and isometric strength. Nevertheless, none of them provided tests unilaterally for main flexors and extensors of knee in the same group in relation to their body composition change after a period and in relation to CMJ and SJ parameters. The aim of the study was to compare one sample of footballers after a half year of their active lives and to trace how isometric (unilateral knee flexion and extension) and dynamic (counter-movement jump CMJ, and squat jump SJ) strength of knee react to somatic parameters changes in time. The study has a long-term character.
METHODS: A total of 15 male footballer (13,9±1 y) performed unilateral IS test with 5530 leg extension/curl rehab machine and dynamometer Performance Recorder unit. Dynamic contraction was recorded by Force Platform (all HUR, Finland). However, firstly lower limb dominance was tested using three standard functional limb dominancy tests (step up, step after pushing of the body, and ball kick test). A dominant limb scored in at least 2 tests. Software Statistica 13 and its tests was used (Shapiro-Wilk test for normality verification, paired t-test for normal distributed data and Wilcoxon signed ranks test for other data. The variables comparison was performed by the Spearman´s test and Pearsons test for found correlations). Retesting was performed after 6 months later. Preset significance level was used.
RESULTS: Significant increases during the 6 months were expressed for IS of hamstring (0.23±0.32), weight (3±1.17), height (2.94±1.43), fat free mass (2.67±1.36), skeletal muscle mass (1.62±0.83), fat free mass of dominant lower limb (0.63±0.25) and of non-dominant (0.61±0.28), SJ (2.58±3.12), max power SJ (241.42±244.20), CMJ (2.50±8.67).
CONCLUSION: The process of growing up and getting massive (especially muscle gaining) was the main reason (strong correlation) of an increase in the IS, maximum power for the CMJ, SJ and height of CMJ and SJ. However, the correlation between IS and height of CMJ and SJ were not proved. The limit of the study is absence of bilateral hamstring and quadriceps isometric strength data for statistics. The sums of the unilateral measures could not be used due to bilateral strength deficit (Teixeira et al., 2013).

PLAYERS' TECHNICAL PERFORMANCE PROFILES AND TECHNICAL VARIATION IN THE CHINESE FOOTBALL SUPER LEAGUE DURING 2015 TO 2017 SEASON

YI, Q., GÓMEZ, M.A., GONG, B.N., GAI, Y., CUI, Y.X.

FACULTY OF PHYSICAL ACTIVITY AND SPORT SCIENCES, POLYTECHNIC UNIVERSITY OF MADRID, MADRID, SPAIN

The aims of this study were: (1) to establish technical performance profiles of football players and (2) to identify the differences of variation in technical match performance according to 5 playing positions under 5 situational variables in the Chinese Football Super League within 3 seasons. Technical match data of players from season 2015 to 2017 (N=720) were collected by Shanghai Champion Technology Co. Ltd, who owns a validated notational system in collecting and providing football performance statistics. Twenty-two technical performance related match actions or events were chosen as variables in current study and were divided into the following four groups: variables related to goal scoring, variables related to attacking, variables related to defending, variables related to passing and organizing. Technical performance profiles were established by profiling techniques and presented by radar charts, while the coefficient of variation (CV) of each variable within a player was calculated to present the technical variation. Differences of player's match performance and variability of match performance across different positions and different contexts were identified by magnitude-based inferences. Results showed that situational variables had obvious effects on players' match performance and variability of match performance. The match performances and their corresponding variability for players were different among distinct positions and contexts. The differences were mainly in variables related to attacking and variables related to passing and organizing when controlling for different situational variables. The differences of match performance and variability of match performance between wide midfielders and forwards were greater than those among central backs, full backs and central midfielders.

ALTERATIONS IN BIOCHEMICAL MARKERS OF RECOVERY DURING A TYPICAL TRAINING WEEK IN ELITE YOUTH SOCCER

HUGHES, J.D.1, RITSON, D.C.1, LEKUE, J.2, MARTIN GARECHANA, I.2, CALLEJA-GONZALEZ, J.2,3, MOSQUEIRA, M.2, O'DOHERTY, P.4, DE STE CROIX, M.B.A.1

1 UNIVERSITY OF GLOUCESTERSHIRE; 2 ATHLETIC CLUB BILBAO, BILBAO, SPAIN 3 UNIVERSITY OF THE BASQUE COUNTRY, BILBAO, SPAIN 4 STAT SPORTS, DUBLIN, IRELAND

INTRODUCTION: Soccer matches can elicit exercise induced muscle damage (EIMD) which can be attributed to the high magnitude eccentric muscle loading experienced in landing and decelerating to change direction. It has been shown that various potential fatigue measures do not return to baseline levels up to 72 h post-match. With the pressure to re-perform on a weekly basis in soccer, recovery durations may shorter than 72 h due to the need to train during the week leading to subsequent matches. The congested nature of

training and matches may increase the risk of injury incidence in maturing players. Increased incidence of injury has been reported during the later stages of training and competition when fatigue is evidenced. Biochemical markers of EIMD, if collected at time sensitive periods during a typical training week can allow for mitigation of risk and allow to reduce non-contact injuries. Therefore, this study sought to explore the potential time frame for biochemical variables to return to pre-game levels in elite youth players following competitive match-play and during a typical training week.
METHODS: 44 elite male soccer players were split into three age groups according to chronological age (U13 n = 16; U15 = 13; and U17 n = 15). Creatine kinase (CK) and urea were taken pre-, immediately post competitive match-play and pre-training on 3 occasions (48 h, 72 h and 120 h) during the training week and pre- a 2nd match (168 h). Match and training activities were collected using global positioning system (GPS).
RESULTS: Significant time effects were reported for CK ($P < 0.01$). All age groups reported significant increases in CK immediately post-match. There were no significant differences in CK activity in the two pre-match measures for any age group ($P > 0.05$). Significant differences were reported between the U17 and U13 age groups at all time points with U17 reporting greater CK activity at all time points. CK values from post-match 1 and across the training week were all significantly correlated to the number of accelerations and decelerations performed ($P < 0.05$). Significant time effects were reported for urea ($P < 0.01$). Significant differences between pre- and post-match, with further increases at 120 h post-match ($P < 0.01$) were evidenced, there were no significant differences between age groups. There were significantly higher levels of urea reported at pre-match 2 compared to pre-match 1 ($P < 0.05$). CK activity returned to baseline in all age groups but increased urea was evident for all age groups at 168h.
CONCLUSION: In conclusion 7 days may be insufficient for biochemical recovery in youth male soccer players. Therefore, specific monitoring strategies to assess biochemical markers of EIMD between match-play and subsequent training sessions should be considered to track recovery and potentially reduce muscular injury risk.

RPE-LOAD CAN BE USED TO QUANTIFY SOCCER PLAYER ACUTE:CHRONIC WORKLOAD RATIOS ACROSS A SEASON

BACON, C., PETERSEN, C.

UNIVERSITY OF CANTERBURY

INTRODUCTION: Ensuring players optimize their training/match workload is a challenge for soccer club fitness and medical support staff. Commonly global positioning system (GPS) units are used to closely track running volume and intensity of training/matches to determine individual workloads. These workloads can be converted to injury risk probability for each player via the acute:chronic workload ratio (ACWR) calculation. Expensive GPS systems necessitate more financially confined clubs finding more cost-effective solutions to monitor ACWRs. One possibility is using rate of perceived exertion (RPE) load quantified by Impellizzeri et al. (2004). Therefore, the present study investigates the relationship between RPE load and GPS load and hypothesizes that both workload tracking methods will positively correlate.
METHODS: Over 6 months, 24 semi-professional soccer players, (Age: 23.6 ± 4.5 yrs, yoyo IRT L1: 19.7 ± 1.3 laps) were monitored providing a total of 1012 training and 219 match cases. Players wore STATSports Viper Pod v1.0 (10Hz) GPS units in each training session and match and provided a post session Borg-RPE. GPS metrics assessed included; total distance, high speed running, explosive distance and dynamic stress load. ACWR was calculated per individual and GPS metric using Gabbett's (2016) ACWR formula with RPE-load calculated via Impellizzeri et al. (2004) method. A Pearson's correlation test (2-tailed) was conducted on the metrics.
RESULTS: Overall, RPE-load had a large to very large correlation to 75% of the GPS metrics ACWR assessed; $P<0.001$ for total distance ($R = 0.704$), high speed running ($R = 0.586$) and explosive distance ($R = 0.295$). It should be noted that dynamic stress load ACWR did largely correlate with RPE-load for central defenders and central midfielders ($P < 0.05$, $R = 0.692$ and $R = 0.588$ respectively).
CONCLUSION: This research demonstrates that clubs with limited financial resources for GPS monitoring systems can instead effective improvise using the RPE-load to effectively assess player workload across a season. A word of caution, across a macro/meso cycle the RPE-load method standardizes out to give a strong interpretation of player workload, however this RPE scale based method is also highly subjective and sensitive to multiple external factors so interpretation over the smaller micro-cycle period is less precise. Sports scientists can apply these findings to their own players to closely monitor ACWR and minimize injury risk.

THE EFFECT OF MATURATION ON MOTION CAPTURE MOVEMENT SCREENING SCORES IN YOUNG SOCCER PLAYERS

LAAS, M., SPEARS, I., PARKIN, G., PORTAS, M.

TEESSIDE UNIVERSITY

INTRODUCTION: Movement screens have been previously suggested as important tools for athlete injury prevention and performance monitoring. When testing with young athletes it is important to select tests and devices to distinguish whether the improvements in scores are not down to maturation. Some screening tools have been linked with a maturation effect previously. There could also be a concern about the accuracy of the manual scoring of movement quality by the tester, especially if the scoring system does not have many options. The aim of this study was to assess the movement capabilities of young athletes using an objective measuring device. A new product using the Kinect camera was designed to analyse fundamental adolescent athletic movements (AMAT Performance, AMAT Performance).
METHODS: Forty six youth male soccer players (age=13.7 ± 1.5 years; maturity offset =0.0 ±1.5 years) across five age groups (U12s, U13s, U14s, U15s, U16s) belonging to an English soccer academy participated in this study. All players were free from injury and medically cleared to participate in training. Written informed consent was obtained from the parents or guardians of the participants. The players undertook their preseason movement screening on the AMAT Performance system. The players had one trial per test and performed a single alternate leg hop for control and maximal distance as well as the back squat. They were also categorised from Peak Height Velocity (PHV) as being pre -PHV [n=17] at-PHV [12] and post-PHV [17] from the maturity offset. The data was analysed looking at the change in the group mean scores on the Hopkins custom-made spreadsheet. Later the probability that a change in the testing scores was beneficial, harmful or trivial, was identified according to the magnitude-based inferences approach. Confidence intervals were set at 90%.

RESULTS: The mean maximum hopping distance (cm) between pre-PHV, at-PHV, post-PHV was from left to right leg (198.9 ± 18.0, 203.6 ± 12.3, 206.5 ± 14.9) and right to left leg (193.4 ± 11.6, 192.5 ± 12.7, 201.7 ± 14.9). The mean hop (cm) for control left to right leg was (163.9 ± 16.9, 171.6 ± 17.3, 171.3 ± 22.8) and right to left leg (171.4 ± 17.1, 169.4 ± 14.8, 171.1 ± 22.5). The mean squat depth (cm) was as follows (39.5 ± 6.5, 45.7 ± 10.8, 39.2 ± 12.2). The comparison data among the means of the maturation groups will be presented in 90% CI. The post-PHV group had small likely higher scores compared to the pre-PHV and at-PHV groups on the maximal distance hop right to left leg 5.8 (2.6-14.1) and 7.9 (1.3-17.1). The post-PHV group had also small likely increments in maximal hop for distance left to right leg against pre-PHV 5.5 (2.1-13.2), the other side was unclear. The data for hopping with control was either unclear or most likely unbeneficial. Regarding the squat comparison, the at-PHV group showed likely small increase in back squat depth distance against the pre-PHV 7.5 (-1.3-13.7).
CONCLUSION: The more mature boys performed better on the single leg maximum hop tests. The hop distance for control did not seem to have any influence from the maturation status. The latter might have been because of the players not estimating their distance to control very well and having only one trial. The depth the players squatted was not clearly influenced by maturation either with the at-PHV group showing the best scores. Maturation had an effect on tests where maximum power effort was needed and not a clear influence on tests where more movement control was necessary. More than one trial is recommended to overcome potential learning effects in tests were controlled movement is required.

THE EFFECTS OF A PROGRAMME-BASED FOOTBALL TRAINING SCHEDULE ON BOYS IN HONG KONG S.A.R., CHINA

OREILLY, J., LU, S.Y.J., HUI, S.S.C.
THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: In keeping with a current global trend, Hong Kong is facing the public health concern of childhood obesity (Hui et al., 2008). Involvement in team sports promotes a more active lifestyle, enhances physical fitness and improves clinical health markers in children and adolescents (Hills et al., 2015). Unfortunately, very few studies in China and Hong Kong have placed emphasis on the use of team sports, such as soccer, among "at-risk" youth groups as an intervention strategy to increase physical activity levels, as well as physical and psychosocial status.
METHODS: Male participants from a 10-month, Hong Kong Football Association (HKFA) Summer Scheme development programme, based in different districts in Hong Kong, were recruited to participate in this study. Classes and age groups from each district were selected at random for the data collection. Each weekly 60 min football training session was administered by a qualified HKFA coach. The Life Satisfaction Ladder; the Physical Activity Questionnaire for Children (PAQ-C); the Physical Activity Rating for Children and Youth (PARCY); Stage of Change, with 5-level statements, and Sport & Physical Activity Questionnaire were all measured to assess the effectiveness of soccer as a tool to enhance various health-related measures. In addition, questionnaires relating to health behavior change, self-perceived football skills, interest and attitude towards sports were adopted and implemented during this study. Data collection took place during the midpoint and end of the programme to assess and observe changes in responses throughout the programme. At least 1 researcher was present for each class, to supervise the questionnaire completion and answer any questions from the participants. All questionnaires were prepared in bi-lingual format.
RESULTS: In total, 194 boys completed both tests, with a mean age of 12.7 years. Results showed improvement in the self-perceived level of football skills (pre: 3.19, post: 3.26), life satisfaction (pre: 7.33, post: 7.44), interest in sports due to the football training (pre: 2.77, post: 2.80), and level of Stage of Change (pre: 3.49, post: 3.54), though not significant. Total football playing time in mins (pre: 298, post: 296), self-reported level of health status (pre: 4.09, post: 4.08), the anticipation levels for the next training (pre: 4.25, post: 4.21), and PARCY score (pre: 7.48, post: 7.47) were all similar between the two time points. A slight reduction in the current level of interest in sports (pre: 5.55, post: 5.31, $p<0.05$) and opinions on the importance of sports (pre: 5.48, post: 5.31, $p<0.05$) were observed.
CONCLUSION: These preliminary results suggest that beneficial effects can be gained from a football training programme in relation to improvement of skill levels, interest in sports and maintenance of health-status among boys in Hong Kong. In addition, playing time and physical activity levels were maintained throughout the study. Limiting factors surrounding the collection of such data in a local context included an overlap with school exam periods. Further analysis of these results and additional investigations into the reasons for playing soccer can serve as a potential indicator for the strategic application of sports-programme promotion among children and adolescents.

GENDER DIFFERENCES IN LANDING AND JUMPING MOVEMENTS USING PRINCIPAL COMPONENT ANALYSIS OF KINEMATIC DATA

WERNER, I., PEER-KRATZER, M., FEDEROLF, P.
INSTITUTE OF SPORT SCIENCE

INTRODUCTION: The observation of several local movement parameters like the amount of the knee valgus during landing and jumping is used for information about the athletes´ knee injury risk. Using the Principal Component Analysis (PCA) to check for differences in movement patterns provides the possibility taking the whole body movement into account at once and might be a good tool for finding more complex injury risk factors. This study investigates gender differences in bipedal landing and jumping movements using PCA in order to evaluate excessiveness of this approach.
METHODS: 16 young well trained athletes (mean age 15.9y, SD 0.5y, 9 male, 7 female) jumped from a 40cm platform with a smooth landing and subsequent jumping movement to submaximal jumping height. They were all free of knee injuries. To analyze the movement a Vicon system with 8 cameras was used. Participants were equipped with 41 markers on all body segments. Starting from the first ground contact untill leaving the force plate marker positions were centered and normalized to body height. PCA was calculated, scores and score differences over time (principal velocities) as well as velocity differences over time (principal accelerations) (Federolf 2016) were proved for gender differences using t-tests for independent samples.
RESULTS: The PCA revealed an explanation of variance of 98.3% within the first 10 components. Gender differences were seen on the 3rd component ($p=0.004$) which can be characterized by variation in the medio lateral direction (arm swing, trunk position, knee axis). Also principal velocities differ significantly ($p=0.012$) in this component between male and female athletes, additionally in PC2, PC5 and PC6. Only in the latter principal accelerations showed a significant difference, identifying the control of head and leg (knee) position.

CONCLUSION: Results show well known gender differences (e.g. knee valgus, Alenezi et al. 2017) added by combined movement patterns (e.g. dissymmetric arm swing) and offer information about the movement dynamics (e.g. lower score acceleration in male athletes). Bipedal landing and jumping bear a low risk of injury while providing important information about landing patterns and dynamics. For a next step this approach will be used for checking injury risk factors in athletes.

BIOMECHANICAL ANALYSIS OF VOLLEYBALL PLAYERS DURING SPIKE LANDING

HUANG, C.
NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Volleyball competition is a non-contact sport, but it had a high musculoskeletal injury rate after landing. The spike is an offensive skill that results in a higher injury rate than other skills in volleyball game (Ferretti A et al. 1992). Previous studies (Ferretti A et al. 1992, Arendt E, et al. 1995) reported that the females possessed a non-contact ACL injury rate four to eight times greater than males in the same competitions such as basketball, handball, and volleyball. The purpose of this study was to investigate the biomechanical differences between male and female players after a volleyball spike landing.
METHODS: Sixteen university volleyball players, 8 females (age = 21.8 ± 1.0 yrs, height = 171.1 ± 2.7 cm, weight = 60.8 ± 3.8 kg) and 8 males (age = 20.1 ± 0.9 yrs, height = 185.9 ± 4.2 cm, weight = 79 ± 6.2 kg), participated in this study. Two force plates embedded into the floor sampling at 1500 Hz and a 10-camera Vicon system, sampling at 300 Hz were synchronized to collect kinematic and kinetic data.
The standard net was set up at 2.43 and 2.24m for the male and female players. The players were asked to hit the ball with maximal effort from NO. 3 position in the area (4.5×9 m2). The landing was defined from the initial contact with the force plate to the minimal height of the center of mass achieved. The Visual3D software was used to calculate kinematic and kinetic parameters. Frontal and sagittal plane lower extremity joint angles were calculated for the hip, knee, and ankle during the landing phase. A t-test was used to test the biomechanical variables between male and female volleyball players.
RESULTS: The males had a greater jump height 0.71 ± 0.06 m than females 0.51± 0.02 m during the spike action. No difference for the VGRF force for male 4.79 ± 0.94 and female 4.47± 1.1 N/BW players. In the sagittal plane, males showed greater hip flexion angle at peak VGRF 17 ± 8.3 and maximum joint angle 57.9± 16.9 than females 9.5 ± 8, 34.6± 9.8 deg. Also, the female players exhibited greater maximum ankle dorsiflexion 26.9±3.7 than males' 17.9±4.2 deg. In the frontal plane, females have greater knee valgus angle than males at initial contact (M -6.4 ± 2.2, F -9.9 ± 2.2), peak VGRF (M -12.6 ± 4.4, F -17.0 ± 3.4) and max angle (M -18.4 ± 4.3, F -24.5± 4.5 deg).
CONCLUSION: The males have greater hip flexion angle than females at initial contact, time of peak GRF, and at max hip flexion. The females have greater knee valgus angle than males at initial contact, time of peak GRF, and at max knee valgus. These showed that males and females have different strategies for volleyball spike landing. Females showed a less hip flexion and a greater knee valgus angle than males during the spike landing, it may increase the risk of ACL injury. These differences may explain the higher ACL injury rate in female playing volleyball.

KNEE EXTENSION TORQUE IS A SIGNIFICANT DETERMINANT OF JUMP HEIGHT OF LAYUP SHOT IN BASKETBALL

FUKUDA, S., UEDA, A., NAKAMURA, Y., KAMIBAYASHI, K., WAKAHARA, T.
DOSHISHA UNIVERSITY

INTRODUCTION: In basketball, layup shot is frequently used in the games. A high jump of the layup shot makes it difficult for the defenders to block the shot. Hence, it is important for players to achieve a high jump height in the layup shot. Sugiyama et al. (2014) examined kinematics of the lower limb during a jump of layup, and reported that a side-to-side difference in the jump height could be attributed to the angle and the angular velocity of the ankle joint during the takeoff phase. Stefanyshyn and Nigg (1998) demonstrated that the ankle joint was the largest energy generator for a jump of the layup among the lower limb joints. However, no studies investigated the biomechanical factors determining the inter-individual differences in the jump height of layup. Therefore, the aim of this study was to investigate determinants of jump height in layup from the viewpoint of kinematics and kinetics of the lower limb.
METHODS: Thirty male collegiate basketball players performed layup with a 4 m approach using a ball. Thirty-four reflective markers were placed on anatomical landmarks of the body. Three-dimensional positions of the markers and ground reaction force (GRF) of the takeoff leg were recorded by a motion capture system and a force platform, respectively. Jump height was defined as the vertical height traveled by the marker attached to the sacral bone from standing position (Sugiyama et al., 2014). Each torque of hip, knee and ankle joints of the takeoff leg was calculated by inverse dynamics during push-off phase [from the instant of lowest center of mass (COM) position to toe-off].
RESULTS: There were significant correlations between jump height in the layup and the vertical velocity of COM at toe-off ($r = 0.786$, $P < 0.01$), and between the velocity of COM and the vertical impulse of GRF during push-off phase ($r = 0.780$, $P < 0.01$). The vertical impulse of GRF was significantly correlated with the peak value of vertical GRF ($r = 0.574$, $P < 0.01$), but not with the duration of push-off phase. The peak value of GRF was significantly correlated with the knee extension torque at instant of peal vertical GRF($r = 0.404$, $P < 0.05$), but not with the hip extension torque or ankle planter flexion torque. The significant correlation between the peak vertical GRF and the knee extension torque may be related to the facts that, at the instant of peak GRF, the knee extension torque was significantly correlated with the moment arm of the GRF at the knee joint ($r = 0.585$, $P < 0.01$), and the moment arm at the knee joint was significantly longer than that of hip and ankle joints ($P < 0.05$). On the other hand, no significant correlations were found between the peak vertical GRF and each of the angle or the angular velocity of hip, knee or ankle joints.
CONCLUSION: The results suggest that the knee extension torque during push-off phase is a significant determinant of jump height of layup in basketball players.

RECTUS ABDOMINIS AND ILIACUS MUSCLE SIZE ARE ASSOCIATED WITH LONG JUMP PERFORMANCE INDEPENDENTLY OF SPRINT RUNNING CAPACITY

TAKAHASHI, K., WAKAHARA, T.

DOSHISHA UNIVERSITY

INTRODUCTION: Long jump performance is primarily determined by the takeoff speed (Hay et al. 1986). To obtain a high takeoff speed, the hip extensors and flexors were suggested to be important (Muraki et al. 2008). On the other hand, it is possible that the trunk muscles also contribute to the attainment of a high takeoff speed by increasing the trunk stability to resist the huge impact force on the trunk during takeoff phase (Luhtanen & Komi 1979). However, less information is available about the association between the size of these muscles and the long jump performance. The purpose of this study was to elucidate the association between the sizes of the trunk and gluteus muscles and the long jump performance.
METHODS: Twenty-three male long jumpers participated in the present study. Their personal best records in the long jump and the 100-m sprint (t100) ranged from 653 to 788 cm (721.6 ± 46.3 cm), and 10.41 to 11.94 s (11.15 ± 0.39 s), respectively. T1-weighted magnetic resonance images of the trunk and hip were obtained to determine the maximal anatomical cross-sectional areas (CSAs) of the rectus abdominis (RA), internal and external obliques and transversus abdominis, psoas major, quadratus lumborum, erector spinae and multifidus, iliacus (IL), gluteus maximus, and gluteus medius and minimus.
RESULTS: The absolute CSA (cm^2) of RA of the takeoff leg side ($r = 0.505$, $P = 0.014$) and the relative CSAs (cm^2/kg^(2/3)) of RA and IL to the body mass of takeoff leg ($r = 0.674$, $P < 0.001$, $r = 0.478$, $P = 0.021$, respectively) and free leg sides ($r = 0.490$, $P = 0.018$, $r = 0.434$, $P = 0.038$, respectively) were significantly correlated with their personal best records for the long jump, whereas the other muscle CSAs were not. Stepwise multiple regression analysis selected relative CSAs of RA and IL of the takeoff leg side and t100 to predict the personal best record for the long jump (SEE = 22.6 cm, adjusted R^2 = 0.763).
CONCLUSION: The results demonstrated that the size of RA and IL was associated with long jump performance independently of sprint running capacity. As RA has a long moment arm of the lumbar spine flexion, it could contribute to the maintenance of trunk posture by resisting the impact force that causes the excessive lordosis during the takeoff phase. The IL may contribute to the generation of the hip flexion torque of the takeoff leg in the later phase of takeoff. The present results suggest that resistance training for hypertrophy of RA and IL may be beneficial to achieve a high performance of long jump.

DETERMINANT FACTORS OF LATERAL CUTTING PERFORMANCE IN BASKETBALL PLAYERS

KAMEDA, M., KIBA, K., MAEDA, A.

NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: In a basketball game, a defensive player is often outrun by an offensive player, because the defensive player loses balance when the offensive player changes running direction. Thus, it will be important to clarify the strategy for performing lateral cutting maneuvers under the unanticipated condition for improving performance of the defensive player. This study aimed to investigate the kinematics and kinetics indicators related to performing lateral cutting maneuvers in defensive basketball players.
METHODS: The participants were 14 college basketball players. In the experiment, participants were provided the sigh of an arrow directing either the right or left on a monitor in front of them while moving with side steps toward the right. When the right directed arrow was provided, they moved for 3 m by side steps to the right. Conversely, when the left directed arrow was provided, participants moved for 3 m to the right, performed lateral cutting to the left, and moved back to the starting spot with side step. Participants responded to randomly provided direction of the arrow signal. Coordinates of markers affixed to participant's body were collected using a motion capture system (300 Hz). Moreover, ground reaction force (GRF) data were collected using a force plate at 1500 Hz. The data only in lateral cutting trials were analyzed from the instant of the foot strike on the ground to the instant of the toe-off during lateral cutting. Contact time (CT) was calculated from the GRF. Moreover, impulse was computed by time integration of lateral GRF. To evaluate the lateral cutting maneuvers, mean lateral GRF was obtained by dividing the impulse by the CT. We investigated the relationship between the mean lateral GRF and other variables.
RESULTS: The results showed that negative correlations were found between the mean GRF and the CT during lateral cutting. Moreover, negative correlations were found between the mean GRF and the center of gravity (CG) position, distance from the right foot position to the CG position at the lateral CG velocity when it was zero during lateral cutting. By contrast, at the instant of the foot strike during lateral cutting, negative correlations were not found between the mean GRF and the CG position, distance from the right foot position to the CG position. In addition, the propulsive mean GRF was stronger correlation than that of braking mean GRF.
CONCLUSION: The current results show that, the lower limbs seem to affect the position of CG at the lateral CG velocity when it was zero during lateral cutting and could be important factor for better lateral cutting maneuvers. Moreover, to enhance the propulsive mean force could lead to an improvement performing lateral cutting maneuvers.

BIOMECHANICAL DIFFERENCES DURING DROP JUMPS ON RIGID AND SAND SURFACE

WIRTZ, S., SZWAJCA, S., STELZER, L., ZENTGRAF, K., EILS, E.

WESTFÄLISCHE-WILHELMS UNIVERSITÄT MÜNSTER

INTRODUCTION: A rising number of athletes participate and compete in beach sport. An important performance indictor is vertical jump performance as it is crucial for several athletic situations (Bobbert, 1986). Most beach sports such as Beach Handball and Beach Volleyball highly rely on jumps, resulting in a need for specialized training programs and adequate diagnostics. Therefore, the aim of the study was to detect differences in drop jump performance on rigid and sand surface using a sandbox under laboratory conditions.
METHODS: Eighteen subjects (23.7 ± 3.5 years; 178.3 ± 9.5 cm; 78.9 ± 11.9 kg; mean ± SD, respectively) conducted three consecutive drop jumps from a 40cm box on rigid and sand surface in randomized, counterbalanced order. EMG activity of five muscles of the right leg was recorded with Noraxon electrodes. Force data was collected by using Kistler force plates. Qualysis motion system was used to

obtain data about the jumping height using a marker that was attached to the lower back. Data analysis was conducted with MATLAB and SPSS. Dependent variables were jumping height, ground contact time, force impulse, concentric and eccentric muscle activity which were compared among the conditions.
RESULTS: Jumping height on rigid surface (M= 34.4cm; SD= 5.9cm) was significantly higher (F(1,38)= 7.091, p=.011, η2=.157) than jumping height on sand surface (M= 30.0cm; SD= 5.5cm). There was no significant difference (F(1,38)= 1.56, p=.695, η2= .004) detected in ground contact time between rigid (M= 0.249s; SD= 0.051s) and sand (M= 0.246s; SD=0.067s) condition. However, the force impulse was significantly higher on rigid compared to sand surface. There were no significant differences in muscle activation.
CONCLUSION: Reduced jumping height on sand surface can be explained by the reduced force impulse. The produced muscle energy is stored in the sand and not returned as good as on rigid surfaces (Bishop, 2003).
Training should aim to improve an athletes power output (Giatsis et al., 2004). Implementing plyometric exercises seems beneficial to improve explosiveness (Stojanovic et al., 2016).

KINEMATICS OF MAXIMUM SPEED RUNNING ON TRACKS OF DIFFERENT STIFFNESS

NEMTSEV, O., NEMTSEVA, N.
ADYGHE STATE UNIVERSITY

INTRODUCTION: One of the crucial conditions for successful performance in pole vaulting is training with a large amount of jumping done at maximal effort. At the same time, this is not always possible in the periods of intensive strength training (Verkhoshansky, 1991). A solution to this problem may be to use more elastic tracks during such periods to enhance run-up economy (Kerdok et al., 2002). However, the features of high speed running on such tracks are still poorly understood. So, the aim of this study was to compare the kinematics of maximal speed running on Mondo and on a less stiff track.
METHODS: Eleven pole volte jumpers took part in the study (eight males: age 20.8±5.8, height 1.86±0.08 m, weight 74.8±8.4 kg, personal best 5.00±0,74 m; and three females: age 17.0±3.6, height 1.69±0.07 m, weight 54.7±10.6 kg, personal best 3.36±1.51 m). Each athlete performed 30-meter maximum speed running on Mondo track and, after 15 minutes of rest, on a fiberglass track. The fiberglass track was made up of several blocks each of which was a rectangular parallelepiped with three arcs of fiberglass rods coming from above and fastened together, covered with plywood and a Regupol roll. Casio EX-ZR700 camera (240 Hz) was located 23 meters away in a perpendicular direction from the sprinting lane at the 25 meter mark from the start. SkillSpector software was used for 2D analysis. Paired sample t-test was used to estimate differences in the kinematic data.
RESULTS: Horizontal center of gravity (CG) velocity at touchdown (8.08±0.74 and 8.05±0.71 m/s) and takeoff (8.52±0.76 and 8.48±0.70 m/s), step length (2.03±0.12 and 2.05±0.10 m), flight (0.129±0.011 and 0.128±0.006 s) and support times (0.121±0.014 and 0.122±0.015 s), CG takeoff angle, CG support displacement, leg angle at touchdown, knee angle at touchdown and midstance, mean angular velocity of support leg knee flexion differed non-significantly (p>0.05) during maximum speed running on Mondo and fiberglass tracks. Horizontal CG velocity at midstance was significantly smaller (7.80±0.78 and 8.01±0.71 m/s, p=0.016) while mean angular velocity of support leg knee extension (380±113 and 333±117 deg/s, p=0.020) and support leg knee angle at takeoff (169±6 and 167±7 deg, p=0,022) were significantly larger when running on Mondo track.
CONCLUSION: The external spring element when running on fiberglass track allows pole volte jumpers to run as quickly as on Mondo track, to lose less horizontal velocity of CG at landing phase and leads to a slower and smaller extension of the support leg knee in takeoff phase. It is necessary to study the impact of training on Fiberglass track on the jumpers condition within different periods.

A COMPARISON OF FORCE PRODUCTION AND NEURAL DRIVE BETWEEN EXPLOSIVE ISOMETRIC AND ISOINERTIAL CONTRACTIONS AT DIFFERENT LOADS.

LANZA, M.B., BALSHAW, T.G., FOLLAND, J.P.
LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Whilst explosive strength and its determinants (primarily agonist neural drive) have been investigated extensively little is known about the neuromechanics of ballistic isoinertial contractions (BC) performed across the load range. A comparison of force production and neural drive between contraction modes [i.e. explosive isometric (ECi) vs. BC] and across isoinertial loads may inform both strength assessment selection and exercise prescription. Therefore, the aim of the study was to compare knee extension force production and neural drive across the first 200 ms of contraction between ECi and BC at different loads.
METHODS: 11 healthy males (28±3 years; 1.78±0.08 m; 85±12 kg) who were participating in systematic strength training for ≥12 months participated in the study. Participants attended 5 laboratory sessions (familiarisation and 4 measurement sessions). In the first and second measurement sessions, following a warm-up, ECi, maximum isometric voluntary contractions (MVCs) and evoked twitch contractions were performed. During sessions three and four, MVC, evoked twitch contractions; BC at percentages of 1 repetition maximum (1RM) (80%, 60%, 40% and 20%) and at 1RM were performed. All tasks were executed unilaterally and superficial quadriceps EMG (QEMG) were recorded. Force was measured at 25-50 ms intervals from contraction onset, until 200 ms (F25, 50, 75, 100, 150 and 200) and QEMG was measured during consecutive 25-50 ms time periods after EMG onset (QEMG0-25, 25-50, 50-75, 75-100, 100-150 and 150-200) and normalized by maximal m-wave.
RESULTS: From F25 to F100 and also at F200 ECi present higher force than all isoinertial contractions (P<0.001) except for F25 where ECd60 did not differ from ECi and at F150 where ECi was higher than ECd60, ECd40 and ECd20 (P<0.001). 1RM was lower than the other isoinertial loads (P≤0.037) except ECd20 (P=0.444) at F50 and F75. ECd20 was also lower than ECd80 and ECd40 at F75 and lower than ECd40

(P≤0.023) at T100. During F150 and F200, ECd20 was lower than the other contractions (P≤0.003) and ECd40 also was lower than ECd80 and ECd60 (P<0.001). EMG0-25 was lower at 1RM than ECd20 (P=0.032). For EMG25-50 1RM and ECd60 were lower than ECd80 and ECd20 (P≤0.021). During EMG50-75, 1RM was lower than ECd80 and ECi but higher than ECd20 (P≤0.006). ECi also was higher than ECd60 (P=0.007) which was lower than ECd20 (P=0.009) at EMG50-75. EMG75-100 and EMG100-150 showed that 1RM was lower than ECd80 (P≤0.004). Finally, 1RM at EMG150-200 was lower than the other contractions (P≤0.046) except for ECi which was only lower than ECd80 (P=0.002).
CONCLUSION: Explosive force was generally higher during ECi vs. BC but showed no clear progression with increasing load. Neural activation varied across different loads showing 1RM generally lower than the other contractions specially at the latter phases of the explosive force.

RELATIONSHIP BETWEEN MAXIMAL VOLUNTARY CONTRACTION AND THE IMPULSE ABOVE END-TEST TORQUE IN INDIVIDUALS WITH DIFFERENT MUSCLE STRENGTH LEVELS

BASSAN, N.M.1, ABDALLA, L.H.P.1, CARITÁ, R.A.C.1,2, DE LIMA, L.C.R.1,3,4, DENADAI, B.S.1, GRECO, C.C.1

1: SÃO PAULO STATE UNIVERSITY, RIO CLARO, BRAZIL, 2: FACULDADE DE AMERICANA, 3: CENTRO UNIVERSITÁRIO HERMÍNIO OMETTO, ARARAS, BRAZIL, 4: CENTRO UNIVERSITÁRIO SALESIANO DE SÃO PAULO, CAMPINAS,

INTRODUCTION: The critical power model is utilized in both whole-body and small muscle mass exercises to estimate the critical power/critical torque asymptote (CP/CT, respectively) and the curvature constant of this hyperbola (W'). Specifically, the 5-min all-out intermittent isometric test has been used during resistive exercises to estimate end-test torque (ET) and impulse above the ET (IET) (Burnley, 2009). Cross-sectional and longitudinal studies suggest that neuromuscular characteristics influence W' (Miura et al., 2002; Sawyer et al., 2014). Thus, the aim of this study was to analyze the relationship between maximal voluntary contraction (MVC) and IET in individuals with different muscle strength levels.
METHODS: Thirty active males (25 ± 4.1 years, 175 ± 6.8 cm, 74.2 ± 16.1 kg) performed a maximal isometric test to determine MVC and a 5-min all-out intermittent isometric test to determine ET and IET. The tests were performed for knee extensors muscles. Participants were ranked according to their MVC values. The median third was excluded to form a high MVC group (HIGH) and a low MVC group (LOW). The comparison of the variables between groups was performed using the Student t test. The association between the variables was assessed using Pearsons product moment correlation coefficient.
RESULTS: The MVC (357.0 ± 52.0 N.m and 225.0 ± 26.6 N.m) and IET (8346.7 ± 1666.6 N.m.s and 4334.2 ± 2376.0 N.m.s) were significantly different between HIGH group and LOW group, respectively. There was significant correlation between MVC and IET in both groups (r = 0.76 and 0.72 for HIGH and LOW, respectively).
CONCLUSION: Thus, it can be concluded that MVC and IET are moderately associated in individuals with different muscle strength levels.

THE RELATIONSHIP BETWEEN STRENGTH AND MUSCLE THICKNESS IN UNTRAINED PARTICIPANTS

RYAN-STEWART, H., FAULKNER, J., JOBSON, S.

UNIVERSITY OF WINCHESTER

INTRODUCTION: Larger muscles are often able to produce larger strength outputs (Lauchbach and McConville, 1969, Medicine and Science in Sports and Exercise, 1, 189-94). The relationship between muscle thickness has been established in elderly (Strasser et al., Age, 35, 2377-88) and trained (Abe et al., 2000, European Journal of Applied Physiology, 81, 174-80) populations, but it is unclear how prior activity may have contributed to this. The aim of this study was to establish the relationship of muscle thickness with strength at select locations in both the upper and lower body.
METHODS: Thirty-nine untrained male participants (mean ± standard deviation age 23 ± 5 years; height 1.81 ± 0.07 m; body mass 76.5 ± 18.7 kg) volunteered to take part in this study, which was approved by the local University ethics committee. The ultrasound measurement location was determined using anatomical landmarks to identify the middle of the muscle bulk (Takai et al., 2014, The Journal of Nutrition, Health and Aging, 18, 579-585). Three separate transverse ultrasound images were recorded using B-wave ultrasound (Terason) at the biceps brachii (BB), triceps brachii (TB), quadriceps (rectus femoris; RF), hamstring (biceps femoris; BF) and calf (gastrocnemius; G and soleus; S). Muscle thickness (MT) was determined using the inbuilt calipers on the Terason software, and an average calculated for the three images. Predicted one repetition maximum (1RM) was determined with free weights for bench press (BP), unilateral bicep curl (BC) and back squat (BS) following the ACSM (2001) protocol for RM determination, but allowing participants to reach a RM between 3-10 repetitions. Predicted 1RM was then calculated using the conversion table from Sheppard and Triplett (2016). Pearson correlation analysis was performed to compare the upper body muscle thickness values to the predicted RM for bench press and bicep curl, and the lower body muscle thickness values to predicted RM for back squat.
RESULTS: There was a significant weak positive correlation between BB MT and BP ($r = 0.388$ $p < 0.05$), and BB MT and BC ($r = 0.390$, $p < 0.05$). There was a significant moderate positive correlation between TB MT and BP ($r = 0.452$, $p < 0.05$), and TB MT and BC ($r = 0.567$, $p < 0.01$). There was a non-significant weak positive correlation between G MT and BS ($r = 0.249$, $p > 0.05$). There was a significant weak positive correlation between RF MT and BS ($r = 0.386$, $p < 0.05$), and between S MT and BS ($r = 0.388$, $p < 0.05$). There was a significant moderate correlation between BF MT and BS ($r = 0.584$, $p < 0.01$).
CONCLUSION: In untrained participants there was some relation between the thickness of the major contributing muscles and strength performance. This relationship appears to be strongest with those muscles that act as antagonists (TB and BF). Whilst the size of the muscle does appear to influence strength performance, other factors such as muscle fibre type and neurological activity also likely contribute to a person's strength

COMPARISONS BETWEEN SYSTEMS TO MEASURE CONTACT AND FLIGHT TIMES IN ELITE RACE WALKING

HANLEY, B., TUCKER, C.B.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Race walking is an Olympic event dictated by a rule that states that no visible loss of contact with the ground should occur and that the leg must be straightened from first contact with the ground until the 'vertical upright position' . The measurement of flight times during race walking is therefore of great interest to coaches, athletes and judges. The aim of the study was to compare different methodologies used to measure contact and flight time in race walking.
METHODS: Ten male race walkers , mass: 64.4 kg <± 4.9>> and seven female race walkers , mass: 56.7 kg <± 11.0>> participated. Fourteen of the athletes had competed at the 2016 Olympic Games or 2017 World Championships. The men race walked down an indoor track at 11, 12, 13, 14 and 15 km/h , whereas the women's trials were at 10, 11, 12, 13 and 14 km/h. Contact and flight times were measured for the midsection of each trial using three adjacent 900 x 600 mm Kistler force plates <1000 Hz>, 5 x 1 m strips of an OptoJump Next system <1000 Hz> and a Fastec high-speed camera <500 Hz>. Results from the OptoJump Next system were extracted using five settings based on the number of LEDs that needed activating , and were annotated as 0_0, 1_1, 2_2, 3_3 and 4_4. The force plate values were considered the criterion values and measurements were assessed for reliability using Intraclass Correlation Coefficients and 95% limits of agreement .
RESULTS: For flight time, the ICCs between the force plate and OptoJump Next were 0.846 for the 0_0 condition , 0.901 <1_1> , 0.983 <2_2> , 0.844 <3_3> , and 0.563 <4_4> . The ICC between the force plate and the high-speed video for flight time was 0.975 . For contact time, the ICCs between the force plate and OptoJump Next were 0.967 for the 0_0 condition , 0.982 <1_1> , 0.995 <2_2> , 0.960 <3_3> , and 0.874 <4_4> . The ICC between the force plate and the high-speed video condition for contact time was 0.991 .
CONCLUSION: The OptoJump Next system provided results similar to those of the gold standard force plates, with the 2_2 setting the most reliable. Users of the OptoJump Next system should therefore note that adjusting the settings of the device might be necessary to achieve the most accurate results. The high-speed video recordings also provided very good reliability although the time-consuming nature of video analysis means the OptoJump Next system is better suited to providing immediate results.

EFFECTS OF PROSTHETIC ARM ON SPRINT PERFORMANCE AND KINEMATICS IN UNILATERAL BELOW-ELBOW AMPUTEES

HIRANO, T.1, KASHIWAGI, Y.1, SOMA, M.1,2, MIZUNO, Y.1, MIZUNO, M.1, FUNATO, K.1

1: NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: The relative advantages and disadvantages of using a prosthetic arm for the T47 class Paralympic Sprinter (PS) form an important question for athletes and coaches. In 2016 in the Rio Paralympics men's and women's T47 class 100m finals, three of the nine below-elbow amputees were using a prosthetic arm [1, 2]. This trend may be related to the fact that the role of the prosthetic arm in running sprints is not clear. Therefore, the goal of this study is to clarify the influences of wearing a prosthetic arm on PS sprint performance and other kinematic variables when sprinting.
METHODS: In this study, two Japanese female PSs (PS.A: missing right forearm; 100m personal record (PR): 12.86 sec; PS.B: missing right forearm; 100m PR: 13.11 sec) performed 40m sprints each with and without their prosthetic arms. Three-dimensional coordinate data of a reflective marker attached to the participants' bodies were captured by 20 infrared cameras (VICON MX, Oxford Metrics Ltd, UK) sampled at 250 Hz. Sprint velocity, spatio-temporal variables, and angular kinematics of segments and joints were calculated.
RESULTS: From these trials, it appears that PS running speed did not change significantly as a result of wearing a prosthetic arm (with vs. without; PS.A: 7.82 m/s vs. 7.71 m/s; PS.B: 7.80 m/s vs. 7.80 m/s), although there was a difference in thorax and pelvic rotation. According to previous studies, the ratio of the forearm and hand segment masses of the Japanese female athletes to their body mass is 1.5% for the forearm and 0.6% for the hand segments [3]. Therefore, together, the forearm and hand are a relatively small amount of the overall body mass compared with the trunk, thigh, and leg segments. Based on this data, the conclusion is that the prosthetic arm had no influence on sprint performance. On the other hand, it was thought that the factors of increased thorax and trunk rotation angles and angular velocities when wearing the prosthetic during sprints are augmented with the change of the arm swing motion caused by the additional mass of the prosthesis.
CONCLUSION: These results suggest that wearing a prosthetic arm does not improve a PSs running performance but may be effective to improve balance in trunk rotation.

RELATIONSHIP AMONG RUNNING VELOCITY, CADENCE, AND STEP LENGTH IN RUNNERS AND NON-RUNNERS

GOTO, Y.1, OGAWA, T.2,3, ISO, S.3, KANOSUE, K.3

1GRADUATE SCHOOL OF SPORT SCIENCES, WASEDA UNIVERSITY, SAITAMA, JAPAN. 2FACULTY OF SPORT SCIENCES, WASEDA UNIVERSITY, SAITAMA, JAPAN. 3DEPARTMENT OF LIFE SCIENCE, GRADUATE SCHOOL OF ARTS AND SCIENCES,

INTRODUCTION: As the determinant of the velocity of human running, the relationship between temporal and spatial components have been studied extensively. The relative contribution of each component in accordance with changing running velocity differs to a great extent and is highly dependent on the velocity ranges. While in the lower velocity range there is a greater change in the step length (thus more contribution of the spatial component), the cadence (temporal component) showed the greater changes in the higher velocity range (Hay,2002; Yanai & Hay, 2004). However, it is still unclear whether the optimization of the spatiotemporal characteristics is innate or reflect functional modification due to training. The present study, therefore, focused on a wide variety of populations with different back-

ground of engagement in running training, and compared the relationship among running velocity, the step length, and cadence over a wide range of running velocity.
METHODS: The subjects were eighteen sprinters, twenty long distance runners, twenty well trained athletes with no expertise in running, and seventeen non-athletes without history of any regular participation in sports events. The participants were asked to run along the 30 m or 20 m straight path at a variety of velocities, which varied from the slowest to the fastest. Then, the velocity (m/s), step length (m) and cadence (steps sec-1) were calculated using a video camera. The running velocity lower than 5 m s-1 was defined as the "low velocity" range. From the step length and cadence data, the slope of the linear regression line was obtained using a least squares method. To test the influence of body height, the slope was normalized with the height of each subject.
RESULTS: Mean values of the slope were significantly larger in the sprinters, long distance runners, and well-trained athletes than the non-athletes. After normalization with height to eliminate its influence on the spatial aspect (step length), the slope in the three groups were still significantly larger than the non-athletes.
CONCLUSION: It was indicated that in the low velocity range the non-athletes have greater contribution of cadence increase to increase in the running velocity as compared to the sprinters, long distance runners, and well-trained athletes. In other words, the profiles among running velocity, step length, and cadence reported in previous studies would not be innate but be acquired with some training that the individuals had underwent. However, it is difficult to clarify only from the present data what type of training caused the profiles specific to each group.

LONG-TERM EFFECTS OF MEDIALLY POSTED INSOLES ON RUNNING KINEMATICS, KINETICS AND ECONOMY

AVELA, J., HÄMÄLÄINEN, H., KULMALA, J.P.

UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: Foot orthotics represents a popular technique to alter lower extremity movement. Many orthotics, like medially posted insoles (MPI), are designed to reduce excessive foot pronation (e.g. Kosonen et al. 2017). Excessive foot pronation is potentially harmful and is associated with development of running related lower limb injuries. Biomechanical mechanisms of clinical relevance of the foot orthoses are not well known, even though a number of studies have reported their acute effects on lower extremity kinematics, kinetics and muscle activities during running. Primary aim of this study was to examine long-term effects of MPI (Footbalance Systems LTd.) on running kinematics and kinetics in subjects with over-pronation. Secondary aim was to investigate whether this has an effect on running economy.
METHODS: Recreational female runners (n=13; 27 ± 6.2 years) with excessive over-pronation were recruited for the study. Dynamic running (4.0 ± 0.3 m/s) analysis was conducted before and after a 4-week MPI intervention with MPI and normal insoles. Data was collected using an eight-camera system (Vicon T40) and five force platforms (AMTI). For motion analysis a Plug-in gait and Oxford foot models were utilized (28 markers). Running economy analysis was conducted after the 4-week MPI intervention using a portable telemetric O2 analyser (Oxycon Mobile) at a 200 m indoor running track with MPI and normal insoles in a randomized order.
RESULTS: A reduction in peak rearfoot eversion for MPI (4.7°, $p<0.05$) as well as for normal insole (4.4°, $p<0.05$) was found after the 4-week MPI intervention. A significant reduction in tibial rotation in respect to rearfoot was also found for both MPI (-4.8°, $p<0.05$) and normal insole (-5.6°, $p<0.05$). MPI decreased peak forefoot pronation in relation to rearfoot (-1.9°, $p<0.05$) and increased forefoot-rearfoot dorsiflexion throughout the stance phase. No significant effects were found for any frontal or transversal plane kinetics between sessions or between insole conditions, however, there was a tendency for decreased internal knee abductor moment for MPI (0.20 Nm/kg, $p=0.10$) and for normal insole (0.20 Nm/kg, $p=0.10$) after the intervention. There were no differences in the oxygen cost of submaximal running between the insoles after the intervention.
CONCLUSION: Current results suggest that there is an accommodation period, which is needed for full effects of MPI on foot kinematics. There also seems to be a "carry-over" effect, in which similar kinematic changes can be seen even with normal insoles after the intervention. This was most likely the reason that no differences were found in the running economy between MPI and normal insoles after the intervention. Thus, MPI's used in this study can be utilized in clinical settings to manage various lower extremity injuries without negatively affecting running economy.

RELATIONSHIP BETWEEN FOOT STRIKE PATTERNS AND BODY ACCELERATION IN MODERATE SPEED RUNNING.

KOJI, T.1, GAKU, K.1, YUTA, G.1, TERUKAZU, K.2, KAZUYUKI, K.1

[1]WASEDA UNIVERSITY, [2]FUJITSU SSL

INTRODUCTION: A good running form is essential to run fast and to run without injury. Recently, the foot strike pattern (FSP) attracts widespread interest and it is considered to be related to running forms. FSPs are roughly divided into two types: rear-foot strike (RFS), in which the heel first lands the ground, and non-rear-foot strike (NRFS), in which any sole part other than heel first lands the ground (Willson et al., 2014). The motion analysis of video images is widely used for the evaluation of running form. But it is time consuming. So it would be useful if wearable devices could be utilized to get real-time feedbacks concerning running form during running. To this end, we tried to clarify the relationships between FSP and acceleration of body parts.
METHODS: Subjects were 20 male students who had no orthopedic disease in the lower limb. Accelerometers were attached to the lateral gastrocnemius (LG), tibialis anterior (TA), and the waist on the Jacoby line. Nine reflective markers were also attached to the right half of the body in order to determine joint angles. After warming up, subjects were told to run on an electric treadmill at several speeds of 2.3m/s-4.2m/s. All subjects wore their own shoes. The FSP was determined from 240Hz high-speed video images. Acceleration magnitudes were calculated from the maximum and minimum values of acceleration during the stance phase.
RESULTS: Out of 20 subjects, 11 and 9 showed the RFS and the NRFS, respectively. And the subjects with the RFS had larger vertical LG acceleration magnitude compared to those with the NRFS ($p<0.001$). Similarly, the subjects with the RFS had larger acceleration of the waist in the negative direction compared to those with the NRFS ($p<0.05$).
CONCLUSION: In a previous study, RFS runners have greater collision forces compared to fore-foot strike (FFS) runners (Liberman et al., 2010). The RFS generates impacts 3-times as great as the body mass, which is much greater than the FFS. This suggests that the RFS requires much energy in landing to absorb the shock against the ground. This could be the reason why the RFS subjects of the present study had larger vertical acceleration magnitude of LG and negative direction acceleration of the waist compared to the NRFS subjects. Thus, it could be possible to distinguish FSP from the acceleration.

EFFECT OF BODY WEIGHT UNLOADING ON MUSCLE ACTIVITY AND KINEMATICS DURING WALKING

KAMIBAYASHI, K., NISHIYAMA, S., ARAKI, K., TSUJIUCHI, N., OHIRA, Y.

DOSHISHA UNIVERSITY

INTRODUCTION: Somatosensory inputs from load receptors and hip joints are considered to play an important role in muscle activities during walking (Dietz and Duysens 2000, Kamibayashi et al. 2009). To clarify the effect of decreased sensory input from load receptors during walking, changes in lower limb kinematics, kinetics and muscle activity while walking on a treadmill with different levels of body weight support were investigated.
METHODS: Eight adult subjects walked at a speed of 3.5 km/h on a lower body positive pressure treadmill under five conditions of body weight unloading (100%, 80%, 60%, 40%, and 20% of their body weights). The level of body weight unloading was computer-regulated by changing the air pressure in the chamber of the treadmill. The body weight unloading conditions were randomly changed. To investigate the muscle activity of the lower limb during walking, a wireless surface electromyographic (EMG) measurement system was used. A wearable three-dimensional motion measurement system that consisted of mobile force plates with shoes and five motion sensors (the lower back and both sides of the upper and lower legs) was used to record foot pressure and joint movements of the lower limbs. The measurements were also performed in a standing posture with five different body unloading levels.
RESULTS: The EMG activities in the vastus medialis and soleus muscles during walking were decreased by increased body weight unloading, whereas those in the biceps femoris and tibialis anterior muscles were unchanged with all five different levels of body weight unloading. The percentages of the stance phase in gait cycle at 20% and 40% body weight conditions were less than those at the other body weight conditions. The extents of hip joint extension at the late stance phase in 20% and 40% body weight conditions were less than those under the other body weight conditions. The knee flexion during the stance phase was initiated earlier under the 20% and 40% body weight conditions.
CONCLUSION: Dramatic changes in the joint kinematics of the hip and knee during walking were seen in 20% and 40% body weight conditions. With increased body weight unloading, earlier transition from the stance to the swing phase in gait cycle was observed. Therefore, the sensory inputs from load receptors might be a key factor for the transition from the stance to the swing phase of walking.

AN ANALYSIS OF LOWER BODY KINEMATICS IN RESPONSE TO CHANGES IN SPEED IN WORLD-CLASS RACE WALKERS

GRAVESTOCK, H., TUCKER, C.B., HANLEY, B., BISSAS, A.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Race walking is a competitive athletic discipline that requires competitors to comply with rules that influence the gait used. Specifically, no visible (to the human eye) loss of contact with the ground should occur, and the knee must be fully extended from first contact with the ground until the vertical upright position (IAAF rule 230.2). This rule applies to all competitive distances of race walking and is a key part of a race walker's training. Biomechanical analysis of race walking technique, and changes in this technique with speed, is of interest to coaches, athletes and the scientific community. Therefore, the aim of this study was to evaluate lower limb kinematic changes in race walking gait with speeds that are adopted in competition and training for Olympic athletes.
METHODS: Two male and two female Olympic race walkers (age: 29 ± 3 yrs; height: 1.75 ± 0.07 m; mass: 65.1 ± 8.2 kg) volunteered to participate in the study. Participants race walked at three speeds down the 40 m walkway. Speeds were relative to individual 10 km, 20 km and training paces and measured using timing gates. Twelve optoelectronic cameras (Oqus 7, Qualisys) were used to collect kinematic data from 62 retroreflective markers on body landmarks. Kinematic data were processed in Qualisys Track Manager and exported to Visual 3D for analysis. Repeated measures ANOVA and post-hoc paired samples t-tests were conducted in SPSS to compare spatio-temporal variables. Statistical parametric mapping (SPM) was used to compare lower body joint kinematics. All SPM analyses were implemented using the open-source spm1d code in Matlab (The Mathworks Inc).
RESULTS: Mean ± SD paces for 10 km, 20 km, and training were 4.03 ± 0.28, 3.78 ± 0.26, and 3.40 ± 0.15 m/s, respectively. There was an overall effect for step length ($p = 0.007$). Post-hoc tests revealed step length was greater at 10 km speeds compared with training pace ($p = 0.011$). Despite this, no differences were observed for flexion or extension at the knee and ankle for any point of the gait cycle. Additionally, no differences were observed in the hip angle in any plane of movement at any point of the gait cycle.
CONCLUSION: Despite changes in speed and step length, there were no differences in the lower body joint angles investigated. This shows that similar ranges of motion were utilised between speeds that are representative of 10 km, 20 km and training paces. The rule that constrains race walking gait, and the training requirement to develop and maintain such a technique throughout competition, potentially explain the similarities observed in lower body kinematics of Olympic race walkers.

INFLUENCE OF DIFFERENT CONCURRENT COGNITIVE TASKS ON GAIT VARIABILITY BEFORE AND AFTER SUSTAINED COGNITIVE ACTIVITY IN YOUNG ADULTS

GUBE, M., WEIPPERT, M., KNAACK, F., BRUHN, S., BEHRENS, M.

UNIVERSITY OF ROSTOCK

INTRODUCTION: Several findings of changes in gait patterns due to simultaneously performed cognitive tasks and their association with an increased risk of falling among older adults have been reported [1]. Nevertheless little systematic evidence exists for the effect of the type of concurrent attention demanding cognitive interference task on gait variability (GV) in young adults. In addition, associations between poor cognitive abilities, especially executive functions, and increased GV [2] imply an important contribution of cognitive functioning to dual-task (DT) gait performance. Thus, the aim of the study is/was to investigate the effect of single- vs. different DT walking trials with and without previous sustained cognitive activity (SCA) on GV in young adults.
METHODS: Twenty-eight healthy young adults (11 females, 17 males; 27.0 ± 4.1 years) completed single- and DT walking trials on a treadmill before and after a control and SCA intervention in a randomized order. Spatio-temporal gait parameters, i. a. step length (SL) and step width (SW) were measured at fixed, self-selected walking-speed using the Gait Realtime Analysis Interactive Lab (GRAIL). The SCA consisted of a digital version of the Stroop-Test (color-word-interference test) for 30 min. Reading in a magazine for 30 min served as control condition. To investigate the effect of the type of the DT on the gait performance, three different cognitive tasks (mental tracking, verbal fluency, inhibitory control and selective attention task) had to be completed during the DT walking trials. Coefficient of variation (CV) of SL and SW were calculated for 50 consecutive steps to quantify GV.
RESULTS: Preliminary analyses indicated significant differences between single- and DT walking, for GV (CV SL: +7.29 % ($p < 0.01$); CV SW: +6.49 % ($p < 0.01$)). Individual response patterns after SCA as well as the effects of task type will be presented.

CONCLUSION: In accordance with previous findings for shorter distances, we observed increases in GV (CV of SL and SW) during dual- compared to single-task walking in young adults. It was further demonstrated that all types of the simultaneously performed cognitive tasks disturb gait performance during DT walking in terms of increased GV. We assume that concurrently performed attention demanding tasks compete with cognitive resources contributing to stable gait pattern. This competitive interaction could explain the significant differences in single and DT gait performance. The impact of transient impairments of cognitive functioning, i. a. mental fatigue after SCA, on DT walking will be discussed in detail.

THE EFFECT OF 200 AND 400M TREADMILL GEOMETRY ON MUSCLE FATIGUE

MASTALERZ, A., URBANIK, C., IWANSKA, D., TABOR, P., KARCZEWSKA, M., GRABOWSKA, O.
UNIVERSITY OF PHYSICAL EDUCATION IN WARSAW

INTRODUCTION: Previous studies of different muscles fatigue were focused on muscles co-activation and dependence on the speed. (Thelen et al., 2005; Yu et al., 2008, Mastalerz et al. 2012). The influence of geometry of the treadmill (radius of curved path) on muscle fatigue has not been studied enough.
METHODS: Four professional male athletes that have an international master class in mens 400m took part in that research. The athletes aged 24±1 were 177±3 cm high and 66±3 kg weight. Subjects gave their informed consent before participating in this study. Surface Electromyographic readings were recorded using a sixteen channel Delsys TrignoTM Mobile system (Delsys, Boston, MA) at a sampling rate of 2000Hz. EMG signals were obtained by attaching eight Trigno sensors, with fixed centre to centre spacing of 1cm over various lower limb muscles bilaterally: the belly of Rectus Femoris (RF), Bicesps Femoris (BF), Tibialis Anterior (TA), and Gastrocnemius (GA) muscles, aligned parallel to the direction of the muscle fibres, all made in accordance with the SENIAM recommendations (Hermens et al., 1999). The RAW signals were first demeaned, full wave rectified and then filtered using an eighth-order Butterworth digital filter with a bandpass filter of 40-400Hz. The mean power frequency (MPF) was then calculated as fatigue indicator.
RESULTS: Muscle fatigue was evaluated by the slope of regression line. It characterizes the rate of changes in mean power of EMG signal spectrum (MPF) during the test exercise. The fatigue was different in the inside leg and outside leg and was related to the radius of the treadmill. Results indicate that the muscle fatigue was greater for the outside (right) leg (BF – 12%, TA –3%, GA -10%), excluding RF and during running on indoor treadmill (RF – 8%, BF -12%,TA – 6%, GA – 10%).
CONCLUSION: The results proved asymmetrical biomechanics of sprinting on curved path. The higher slope coefficients of the regression line shows that the right (outside) leg is exposed to greater fatigue. It is consistent with the research of Chang and Kram (2007) in which the inside leg, during sprinting on curved path, consistently generated smaller peak forces compared to the outside leg. Higher fatigue was observed during running on an indoor treadmill for all muscles. Shorter curved radius of indoor treadmill, can involve higher joint stabilization forces and it can increase the fatigue of muscle groups. Additionally, shorter radius of curved path can influenced on more muscle fatigue because the sprinter must generate centripetal forces by applying higher lateral force on the ground with each step.

CONTROLLING NEUROMUSCULAR PERFORMANCE: DOES CENTRAL MOTOR BEHAVIOUR DIFFER IN PRECEDING CONSECUTIVE CONTRACTIONS VS. RELAXATIONS OF ONE MOTOR SEQUENCE AT DISTINCT TORQUES?

VOGT, T.1, KATO, K.2, FLÜTHMANN, N.1, BLOCH, O.3, NAKATA, H.4, KANOSUE, K.2
1GERMAN SPORT UNIVERSITY, 2WASEDA UNIVERSITY, 3OLYMPIC TRAINING CENTRE RHINELAND, 4NARA WOMENS UNIVERSITY

INTRODUCTION: Muscle contractions and relaxations involve different activation strategies that result, at least in part, from central sensorimotor modulations. However, motor-related cortical potentials (MRCP) remain to be elucidated preceding combined contraction onsets and relaxation offsets in one consecutive motor task.
METHODS: Voluntarily, 12 healthy male participants (28±4 years, 182±7 cm, 85±7 kg) performed submaximal isometric 4 sets of 10 motor sequences (i.e. right-limb wrist flexions with 20 seconds of rest between sets), embedded in 2 initial (pre) and 2 closing (post) maximum voluntary contractions (MVC). Targeting distinct torque levels, each motor sequence comprised consecutive contractions to 20% and 40% MVC followed by relaxations from 40% and 20% MVC aiming to remain at each torque level for 3 seconds. According to the 10/20-system, 32 Ag/AgCl-channels were mounted over electrode sites representing motor-relevant cortical areas. Continuous EEG synchronized with EMG recordings (i.e. flexor carpi radialis, FCR) served to detect torque level on- and offsets for MRCP analyses, in particular the readiness potential.
RESULTS: Participants accurately maintained the motor sequences with mean values of FCR muscle activity revealing no signs of fatigue ($p>0.05$). MRCP main findings were larger amplitudes over centro-parietal electrode sites ($p<0.05$) preceding 40% compared to 20% MVC, whereas amplitudes were larger over frontal electrode sites ($p<0.05$) preceding contractions compared to relaxations.
CONCLUSION: Irrespective of the muscle activation type (i.e. contraction or relaxation), producing as well as releasing lower forces (i.e. 20% or 40%) may require similar proprioceptive and visuo-motor processing preceding consecutive motor sequences.

INFLUENCE OF NEUROMUSCULAR CAPACITY AND VO2PEAK ON RIGHT HEART STRUCTURE AND FUNCTION IN BODYBUILDERS AND ENDURANCE ATHLETES

1: PHD PROGRAM IN CARDIOLOGY, HEART INTITUTE, FACULDADE DE MEDICINA, UNIVERSIDADE DE SAO PAULO, , 2: FUNDACAO PIO XII, HOSPITAL DE CANCER DE BARRETOS

INTRODUCTION: Both endurance training and strength training promote morphological and functional adaptations in the heart, however, these adaptations have not been fully elucidated, especially when dealing with the right atrium and right ventricle. The objective of this study was to evaluate the influence of neuromuscular capacity and VO2peak on the structure and function of the right heart of endurance athletes and bodybuilders.
METHODS: We evaluated 19 athletes aged 20 to 51 years (33.1 ± 9.2 years) being 6 endurance athletes (1 woman) and 13 bodybuilders (2 women). Right atrium (RA) and right ventricle (RV) morphology and systolic and diastolic functions were evaluated using color Doppler two-dimensional echocardiography. Radioisotopic ventriculography was used to evaluate RV ejection fraction (RVEF), time to peak filling rate of the RV (RVTPFR) and the time to emptying rate of the RV (RVTER). The VO2peak was evaluated by means of cardiopulmonary test and muscle strength by means of one repetition maximum test (1RM) in the bench press and leg press exercises. The correlation between the cardiological variables and the physical performance was verified by Spearman's correlation coefficient.
RESULTS: The largest diameter of the RA was 4.6 ± 0.7 mm, the longitudinal diameter of the RV was 8.0 ± 1.1 mm, the RVEF was 45.1 ± 6.3%, the RVTPFR was 124.3 ± 57.4 ms and the RVTER was 146.2 ± 20.5 ms. The load of 1RM in the bench press was 94.5 ± 38.4 kg and in the leg press was 321.7 ± 99.1 kg, the VO2peak was 53.4 ± 9.6 ml.kg.min. There was a high correlation between greater diameter of RA and VO2peak (r = 0.890 p = 0.001) and moderate negative correlation between RVTER and 1RM in the bench press (r = -0.639 p = 0.025) and 1RM in the leg press (r = -0.703 p = 0.011).
CONCLUSION: These data show that cardiac adaptations to training, especially of the right heart are related with neuromuscular capacity and VO2peak, and it is also related to the type of exercise predominantly performed by the athlete.

CAN AN ACUTE BOUT OF BAREFOOT RUNNING ALTER LOWER LIMB MUSCLE CONTRACTILE PROPERTIRES?

ODDY, C., KOLODZIEJCZYK, K., DUXBURY, K., FRANCIS, P.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Kinematic changes following an acute bout of barefoot running have previously been reported. Concurrent EMG readings indicate a higher pre-activation of ankle plantar flexors prior to ground contact suggesting an acute change in muscle activity when running barefoot. At present, it is not known whether changes in muscle activity are transient (occur only during measurement) or are maintained after an acute bout of barefoot running. Understanding alterations in muscle contractile properties post-activity may be the first step toward understanding the longer term adaptive responses of skeletal muscle to barefoot running. The aim of this study was to measure lower limb muscle contractile properties (Tensiomyography; TMG) prior to and after an acute bout of barefoot running.
METHODS: Following ethical approval by the Leeds Beckett University research ethics committee, 29 recreational runners, (age=28±6 years, height=173.15±10.04cm, weight=69.83±13.27 kg), free from injury and without prior exposure to prolonged periods of barefoot running provided written informed consent to participate in this study. Each participant had a measure of lower limb (Gastrocnemius Lateralis and Medialis, GL, GM; Gluteus Maximus; GT) maximal muscle displacement (Dm) and contraction speed (Tc) assessed at baseline using TMG. Following baseline assessments, all participants carried out 5-minutes of running in their normal running shoes at a pace akin to their normal warm-up intensity. Subsequently, participants were randomised to perform 10-15 minutes of running shod (n=15) or barefoot (n=14). Muscle contractile properties (Dm, Tc) were immediately re-assessed post-running. The dependent variable, change in muscle contractile properties, was calculated for both groups and a one-way ANOVA was used to compare the mean difference between groups.
RESULTS: The change in lower limb (GM, GL, GT) Dm was not different between groups (P>0.05). Those in the barefoot group had a faster speed of contraction (Tc) in the GM muscle relative to their shod counterparts post running (P=0.05). The change in Tc was not different between groups for any other muscle (P>0.05).
CONCLUSION: The results of this study demonstrate a shorter contraction time for the medial portion of the gastrocnemius after an acute bout of barefoot running. The increased speed of contraction, after barefoot running, may suggest a post-activation potentiation of the muscle. These findings are inline with the increased pre-activation of the plantar flexor muscles observed during barefoot running when measured by EMG activity.

THE EFFECT OF MUSCLE RELAXATION ON SUSTAINED CONTRACTION FORCE OF OTHER MUSCLES IN THE LIMB.

KOJI, T., KOUKI, K., KAZUYUKI, K.

WASEDA UNIVERSITY

INTRODUCTION: Many sports movements consist of contracting and relaxing multiple muscles at different strengths at the same time. Previous study suggest that novice badminton player showed excessive muscle activity compared to that of experts (Sakurai and Ohtsuki, 2000). Furthermore, many studies investigated that both of muscle contraction and relaxation of one limb affect muscles activity of the other limb (Tazoe et al.,2007; Kato et al., 2015). However, the effect of muscle contraction and relaxation on the other muscles within the same limb has not well understood. We previously demonstrated that relaxation from 50% MVC affected muscle activity in other muscle within the same limb. The purpose of the present study is to clarify the effect of muscle relaxation from relatively weak intensity (5% MVC).
METHODS: Subjects were asked to volitionally relax or contract the other muscle while simultaneous contraction of one muscle in response to an auditory stimulus. It was combined by flexor of the finger and flexor of elbow(Exp.1) or flexor of the finger and abduction of the shoulder (Exp.2). Force magnitude of finger flexor was targeted 5% MVC, force magnitude of elbow flexior and shoulder abductor were targeted to 50% MVC. Electromyography (EMG) were recorded from the right first dorsal interosseous (FDI), extensor digital muscle (ED), deltoid muscle(DM) and pectoralis major muscle(PMM).
RESULTS: In Exp.1, force magnitude of sustained contraction for elbow flexor was decreased temporally by relaxing finger flexor muscle of contraction. Force magnitude of sustained contraction for finger flexor was decreased by relaxing elbow flexor muscle of contraction.
In Exp.2, force magnitude of sustained contraction for shoulder abductor was decreased temporally by relaxing finger flexor muscle of contraction. Force magnitude of sustained contraction for finger flexor was increased by contracting shoulder abductor muscle.

CONCLUSION: In this study, it was clarified that relatively small muscle activity (5% MVC) affects the sustained force of other muscles in the same limb. Therefore, the muscle activity of 50% MVC affects within the limb, as well as 5% MVC. In sports movements, experts control multiple muscles at an appropriate timing and strength than novice. In this study it became clear that small force contraction and relaxation affect other muscle activity. From this, it is considered important to appropriate control not only large muscle activity like agonist muscle, but also small activity like accessory muscles related to the movement in order to do efficient sports movements.

EFFECTS OF HIGH- AND LOW-FORCE ISOMETRIC EXERCISE ON CERVICOMEDULLARY MOTOR EVOKED POTENTIALS

NUZZO, J.L., BARRY, B.K., GANDEVIA, S.C., TAYLOR, J.L.

NEUROSCIENCE RESEARCH AUSTRALIA

INTRODUCTION: Acute isometric resistance exercise of the elbow flexors can facilitate cervicomedullary motor evoked potentials (CMEPs) in resting biceps brachii (Nuzzo et al. 2016; Nuzzo et al. in press). The purposes of this study were to determine if (a) this facilitation is due to increased motoneuron excitability or enhanced corticospinal transmission and (b) the intensity of exercise influences any effect.
METHODS: Ten participants completed 12 sets of 8 high-force (75% maximal voluntary contraction, MVC) isometric contractions of the elbow flexors in one session. In another session, they completed 12 sets of low-force isometric contractions (15% MVC). Electrical stimulation at the cervicomedullary junction was used to evoke CMEPs in resting biceps before and then at 5, 15, and 25 minutes after exercise. To "clamp" motoneuron excitability and examine the role of corticospinal transmission, CMEPs were also acquired during weak contractions of the elbow flexors (~10% biceps maximal EMG). All CMEPs were normalised to the maximal compound muscle action potential (Mmax). During the exercise and measurement procedures, the shoulder was flexed at 90 degrees, the elbow was flexed at 90 degrees, and the forearm was supinated. A two-way ANOVA was used to test for main effects of Time and Exercise Intensity and an interaction.
RESULTS: There were no main effects for Time or Exercise Intensity for biceps CMEPs at rest or during weak contraction (all $p > 0.05$). There was also no Time x Exercise Intensity interaction. On the day that involved high-force exercise, CMEPs in resting biceps were (mean ± SD): 10.2 ± 4% of Mmax at baseline; 10.9 ± 5.8% of Mmax at 5 min post-exercise; 11.2 ± 7.6% of Mmax at 15 min post-exercise; and 9.9 ± 6.6% of Mmax at 25 min post-exercise. On the day that involved low-force exercise, CMEPs in resting biceps were: 13.1 ± 4.7% of Mmax at baseline; 11.7 ± 5.8% of Mmax at 5 min post-exercise; 12.1 ± 4.4% of Mmax at 15 min post-exercise; and 10.9 ± 3.8% of Mmax at 25 min post-exercise.
CONCLUSION: When low- or high-force isometric exercise of the elbow flexors is performed with the elbow flexed and forearm supinated, the exercise does not alter motoneuron excitability or corticospinal transmission (i.e., CMEPs). Previous studies have observed facilitation of CMEPs after acute isometric exercise of the elbow flexors (Nuzzo et al. 2016; Nuzzo et al. in press). Thus, the cause of the inconsistent results requires clarification. At present, the upper-limb posture used in the current study does not appear to be useful for studying changes in the spinal cord with acute resistance exercise.

CROSS-SECTIONAL AREA OF QUADRICEPS FEMORIS NEGATIVELY RELATES TO 100-M SPRINT TIME IN LONG DISTANCE RUNNERS

ANDO, R.1, TANJI, F.1, OHNUMA, H.1, CHINO, K.1, IKEDA, T.1, YAMANAKA, R.2, SUZUKI, Y.1

1: JAPAN INSTITUTE OF SPORTS SCIENCES , 2: TEIKYO HEISEI UNIVERSITY

INTRODUCTION: It is generally known that sprint ability would be very important to win the long distance race (e.g., 5000-m or 10000-m). One of determinant factors of sprint ability is lower limbs muscularity because it was recently indicated a possibility that muscle volume of quadriceps femoris negatively related to sprint performance in sprinters (Sugisaki et al. 2017). However, it is never demonstrated if this relationship exists in long distance runners as well. The purpose of this study therefore was to examine the relationship between muscle volume in the thigh and sprint performance in long distance runners.
METHODS: Twenty Japanese male long distance runners (Age: 25.8 ± 3.3 yr, height: 171.6 ± 5.2 cm, Body weight: 57.4 ± 3.7 kg, VO2max: 70.9 ± 3.3 ml/kg/min) participated in the study. T1-weighted spin-echo transaxial images of the right thigh were collected from the greater trochanter to the lateral epicondyle using a 3.0-T magnetic resonance (MR> imaging. The cross-sectional areas (CSAs> of quadriceps femoris, hamstrings and adductor were calculated from MR image which corresponded to 50% of femur length. We then measured 100-m sprint time and requested an official personal record of 10000-m race time. Relationships between 100-m sprint time and 10000-m race time, and each muscle group CSA and 100-m sprint time were examined using a Pearson product moment correlation.
RESULTS: 100-m sprint and 10000-m race times were 13.44 ± 0.61 (12.42–14.34> and 28:26.98 ± 00:31.92 (27:29.69–29:06.64>, respectively. CSAs of quadriceps femoris, hamstrings and adductor were respectively 69.2 ± 5.4 cm2, 32.1 ± 2.8 cm2 and 28.0 ± 4.5 cm2. There was a significant correlation between 100-m sprint time and 10000-m race time ($r = 0.491$, $P < 0.05$). CSA of quadriceps femoris significantly correlated to 100-m sprint time ($r = 0.613$, $P < 0.05$), whilst those of hamstrings and adductor were not significantly correlated ($P > 0.05$).
CONCLUSION: First of all, we confirmed that sprint ability was also important to win in the long distance race in the present study. Furthermore, association between CSA of quadriceps femoris and 100-m sprint time was demonstrated in long distance runners as previously shown in sprinters (Sugisaki et al. 2017). These results may suggest that greater volume of quadriceps femoris would be negative factor for the sprint ability, which also affects to long distance running performance.

DISTRIBUTION OF DISPLACEMENT IN THE QUADRICEPS MUSCLES DURING ISOMETRIC CONTRACTIONS REVEALED BY VELOCITY ENCODING PHASE CONTRAST MR

ODA, T., MALIS, V., FINNI, T., SINHA, S.

HYOGO UNIVERSITY OF TEACHER EDUCATION, UNIVERSITY OF CALIFORNIA SAN DIEGO, UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: The quadriceps muscles contribute to functional ability and have important roles in many human movements such as jumping. Relative contribution of different muscles have been studied using surface electromyography but MR provides means for investigation of displacement of synergistic muscles. This may provide essential information on mechanical work which is determined as the product of force and displacement. The purpose of the present study was to investigate distribution of displacement between vastus medialis (VM), vastus lateralis (VL), vastus intermedius (VI), and rectus femoris (RF).
METHODS: Seven healthy male subjects were asked to isometrically contract and relax knee extensor muscles at 40% of maximal voluntary contraction in an MR setting. Muscle tissue velocities across entire cross-sectional area of thigh was assessed during the contractions using gated, velocity-encoded phase contrast MR images with specially designed MR compatible torque measurement system.

Subsequently, tracking algorithms applied at three different cross sectional slices along the longitudinal axis (proximal, middle and distal thigh) yielded the spatial distribution of displacement.
RESULTS: The distribution of displacements showed remarkably large variation even within each muscle in each plane. The highest proximal-distal displacement tended to concentrate around the aponeurosis (central aponeurosis) separating VI from other muscles surrounding it. The amplitudes of displacements of muscle tissues on one side of the central aponeurosis demonstrated almost similar values to those from the opposite direction. These results give rise to the possibility of synchronized length changes at these junctions. In the middle thigh, total displacement of VM was significantly larger than that of VL (p=0.005). In the distal thigh, the total displacement of VI was significantly larger than VL (p=0.004) and RF (p=0.002). In comparison of proximal-distal displacement corresponding approximately to the line of action, VI tended to show larger displacement than all the other muscles in all the sections. This large displacement of VI might imply high contribution of work generation along the length of the muscle. VM and VL demonstrated large in-plane movement in proximal section.
CONCLUSION: The results of the present work suggests that different quadriceps muscles act synchronously to produce force and displacement along the direction of line of action through the central aponeurosis, with different contribution of each muscle, which would result from architectural, morphological and physiological variations in four muscles.

ASSOCIATION OF MUSCLE SIZE AND FUNCTION WITH FORCE-VELOCITY PROFILE IN BALLISTIC ELBOW FLEXION.

NAKATANI, M., OYAMADA, K., MURATA, K., KANEHISA, H., TAKAI, Y.

NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: Inverse force-velocity (F-v) relationship during ballistic movements have been investigated to understand muscle mechanical properties of limbs (e.g. Samozino et al., 2012). The steeper slope obtained from F-v relationships means the higher the force capabilities compared with velocity ones. Muscle size is the main determinant of muscle function. On the other hand, the well-trained men have the lower muscle quality during isometric contraction (e.g. muscle force per cross-sectional area) (Sale et al., 1987), resulting from fiber type distribution, large pennation angle, and neuromuscular activities. However, it is unclear concerning association of F-v profile with each of muscle size and function. The purpose of this study aimed to clarify the relationships between F-v profile and muscle size and function.
METHODS: Forty men (bodybuilder, gymnasts, judo athletes and active men) performed ballistic elbow flexion at an intensity of 0, 15, 30, 45, 60 and 75% of maximal voluntary contraction (MVC) load. MVC was measured at 40 deg flexed elbow joint. The subjects were asked to flex the elbow as strongly and quickly as possible against 6 different loads. The upper arm was securely fastened to a plate of a custom-made dynamometer and the forearm was secured to a lever arm which rotated around the axis of the dynamometer. Force was measured with a load cell attached to the wrist. Velocity of elbow flexion was calculated from the angle of the lever arm measured with a potentiometer. F-v profile was defined as the slope obtained from the relationship between force and velocity. The muscle thickness (MT) of biceps brachii at 60% of upper arm length was measured with a brightness-mode ultrasound. Muscle cross-sectional area index (CSAindex) was calculated from the equation (MT/2)2 x pi.
RESULTS: F-v profile was 143.8 ± 47.8 N/m/s. MVC and CSAindex were not significantly related to the F-v profile in ballistic elbow flexion. MVC per CSAindex was negatively associated with the F-v profile ($r = -0.431$, $P < 0.05$), indicating that a man with lower MVC per CSAindex have the higher force capabilities.
CONCLUSION: In ballistic elbow flexion movement, F-v profile may depend on muscle function per muscle size.

CONTRIBUTION OF EACH HEAD OF QUADRICEPS FEMORIS MUSCLE DURING SINUSOIDAL FORCE EXERTION

TOMITA, A.1, AKIMA, H.1, MASANI, K.2

1: NAGOYA UNIVERSITY , 2: UNIVERSITY OF TORONTO

INTRODUCTION: The quadriceps femoris muscle (QF) plays a critical role in various lower limb movements, such as standing and walking. The quadriceps femoris muscle consists of four muscles heads, i.e., vastus lateralis (VL), vastus intermedius (VI), vastus medialis (VM), and rectus femoris (RF). While their anatomical structures are different among these four muscle heads, it is unknown how each muscle head contributes to controlling the knee joint torque. Here we investigated the contribution of each muscle head during sinusoidal force matching tasks, by focusing on the force fluctuation using a muscle model under isometric condition and an optimization technique.
METHODS: Thirteen healthy men and women (23 ± 4 years) performed force controlled, isometric knee extension tasks at knee joint angle of 90°. The force controlled task consisted of 30-sec sinusoidal force exertion with a frequency of 0.25 Hz, and at 30-50% (Hi) and 4-8% (Lo) of the maximal voluntary contraction. The participants matched the exerted force to the target sinusoidal wave on a computer monitor. Surface electromyograms (EMGs) were recorded from the four muscle heads in the QF muscle. We used a critically-damped 2nd order system as he muscle model whose input was a rectified EMG signal from each muscle head and whose output was the estimated muscle torque was fit with the measured knee joint torque, by optimizing the parameters of the four 2nd order systems using Direct optimization method. To prioritize fitting force fluctuations along the target sinusoidal wave, the cost function was set to the root square error in the derivative of joint torque. The contribution of each muscle was calculated as the percentage of the standard deviation of each muscle output divided by the standard deviation of estimated total torque output.
RESULTS: The contribution of each muscle head was as follows; Hi: VI 12.1 ± 11.1 %, VL 25.0 ± 15.3 %, VM 39.4 ± 24.4 %, RF 23.9 ± 13.9 %, and Lo: VI 21.3 ± 13.7 %, VL 38.5 ± 18.2 %, VM 20.0 ± 6.7 %, RF 20.5 ± 16.3 %. Bonferroni multiple comparison test revealed that VM was significantly higher than VI ($p = 0.038$) and VL ($p = 0.007$) in Hi contraction, and that VL was significantly higher than VM ($p = 0.038$) in Lo contraction.
CONCLUSION: During the sinusoidal force-matching task, VM has the highest contribution in Hi contraction, whereas VL has the highest contribution in Lo contraction. The result suggests that the contribution of each muscle head depends on the amount of joint torque. The proposed method relies on assumptions that the measured EMG represents the entire muscle activity and the critically-damped 2nd order system accurately represents the muscle torque exertion, whereas this method can be a useful tool in investigating the force contribution of synergistic muscles.

INFLUENCE OF KNEE JOINT ANGLE ON MECHANICAL ACTIVITY OF KNEE EXTENSOR MUSCLES AND PATELLAR TENDON UNDER ISOMETRIC CONTRACTION

TANAKA, S.1, IMAWAKA, T.1, YOKOZAWA, S.1, SRDJAN, D.2, TSUNODA, N.1

1: KOKUSHIKAN UNIVERSITY , 2: TMG-BMC CO.

INTRODUCTION: It is well known that the generation of muscle force depend on muscle length. Tension generated by muscle contraction causes articulation through the tendon. The mechanical activity of the muscle-tendon complex is an important factor for producing muscle force during exercises. The muscle contraction (MC) sensor is possible to evaluate the mechanical activity during muscle contraction (Srdjan et al., 2011, 2014). However, there are not many report on the mechanical activity of muscle-tendon complex during force output using the MC sensor. Therefore, the purpose of this study was to investigate the mechanical activities on knee extensor muscles and patellar tendon under the isometric contraction with different knee joint angle by MC sensor.
METHODS: The subjects were 11 healthy males. Morphological parameters of vastus medialis (VM), rectus femoris (RF), vastus lateralis (VL) and patellar tendon (PT) were measured by ultrasound method. Knee extensor torque under the isometric contraction with knee joint angle of 30 (K30), 60 (K60) and 90 (K90) degrees were measured using a dynamometer. At the same time, deformation amount as an index of mechanical activity on VM (MC_VM), RF, VL and PT (MC_PT) were measured by method of MC sensor (TMG-BMC co.). The MC signal indicate deformation amount of muscle and tendon by contraction.
RESULTS: The deflection of PT in K30 was greater than that of K90 and K60. The peak torque of K90 and K60 were significantly higher than that of K30. Significant correlation was observed between torque and deformation amount of knee extensor muscles in all condition. At the extended position, MC_VM with increase torque was higher than that of flexion position. On the other hand, MC_PT indicated a peak value at 20% torque, and K30 showed a significantly lower than that of K90 and K60.
CONCLUSION: A High linearity and good dynamic properties were showed between torque and deformation amount of knee extensor muscles under isometric contraction with any joint angle. MC_VM changed by knee joint angle. VM has role of stabilizing the patella in knee extension (Belli G et al., 2015). In more extended position, it was considered that VM was influenced by the remarkable activity. Also, MC_PT depended on knee joint angle. From these results, it was suggested that the flexion position increases the mechanical activity of muscle-tendon complex, whereas in the extended position it reduction the mechanical activity of PT.

FATIGUE-INDUCED CHANGES IN KNEE EXTENSOR TORQUE COMPLEXITY AND MUSCLE METABOLIC RATE ARE JOINT ANGLE DEPENDENT

BURNLEY, M.

UNIVERSITY OF KENT

INTRODUCTION: The temporal structure, or complexity, of muscle torque output is an important index of neuromuscular function, reflecting the ability to control and adapt motor output in response to task demands. It has been demonstrated that neuromuscular fatigue reduces the complexity of muscle torque output during contractions performed above the critical torque (Pethick et al., 2016). At these contractile intensities, a metabolic steady state is not attainable. It is therefore of interest that it has been proposed that system metabolic rate and complexity are inversely related: as system metabolic rate increases, physiological complexity should decrease (Seely and Macklem, 2012). During isometric contractions at short muscle lengths, muscle oxygen consumption is reduced and endurance increased (de Ruiter et al., 2005). This study tested the hypothesis that there would be an inverse relationship between knee extensor torque output complexity and vastus lateralis metabolic rate (mt Ό2) that would be conserved at different muscle lengths.
METHODS: Ten healthy participants performed intermittent isometric contractions of the knee extensors at 50% MVC for 30 minutes or until task failure (whichever occurred sooner) at 30, 60 and 90° of knee flexion (with 0° being full extension). The duty factor for the contractions was 60%, i.e. 6 seconds contraction, 4 seconds rest. Torque and surface EMG were sampled continuously. The mt Ό2 was determined using near-infrared spectroscopy and arterial occlusion. Complexity and fractal scaling of torque were quantified using approximate entropy (ApEn) and the detrended fluctuation analysis (DFA) α scaling exponent. Results are presented as means ± SEM.
RESULTS: Complexity significantly decreased during contractions at 90° and 60° (decreased ApEn, increased DFA α, both $P < 0.001$), but not at 30°. The mnΌ2 significantly increased at 90°, 60° and 30° (all $P < 0.001$), but the magnitude of this change was significantly lower at 30° compared to 60° ($P = 0.001$) and 90° ($P = 0.007$). There were significant correlations between complexity and m(Ό2 at 90° (ApEn, $r = –0.588$, $P = 0.037$), 60° (ApEn, $r = –0.657$, $P = 0.019$; DFA α, $r = 0.774$, $P = 0.004$) and 30 ° (ApEn, $r = –0.666$, $P = 0.018$; DFA α, $r = 0.940$, $P < 0.001$).
CONCLUSION: These results suggest that muscle metabolic rate and torque output complexity are correlated, and that these correlations are conserved with changes in muscle length. These results support the hypothesis of Seely and Macklem (2012) that physiological complexity and system metabolic rate are inversely related.

CP-BN04 Skill acquisition and motor learning

TALENT IDENTIFICATION BASED ON THE SOCCER-SIMULATOR SKILLS.LAB

QUEDER, T., KONRAD, A.

KARL-FRANZENS UNIVERSITÄT GRAZ

INTRODUCTION: Additional to physical requirements, technical and tactical skills are of great importance in soccer. Therefore, the process of scouting youth soccer players could be very complex (Larkin & O'Connor ,2017). Hence, the purpose of this study was to investigate if

the soccer-simulator skills.lab could distinguish between youth professional players (YPP) and youth recreational players (YRP) in the same age.
METHODS: 21 male YPP from SK Sturm Graz Academy (mean±SD, 13.2±0.31 years, 157.8±8.3cm, 44.3±7.6kg) and 16 male YRP from recreational clubs (mean±SD, 13.4±0.33 years, 161.4±8.0cm, 46±6.4kg) volunteered in this study. In total the subjects went through three selected exercises in skills.lab, namely "trapping and passing", "dribbling and passing", and "trapping and shooting" with the dominant leg, with the non-dominant leg, respectively. Every exercise consisted of two parameters, "handling time" and "distance to target". Skills.lab is able to automatically measure those parameters. To calculate an overall score of an exercise (including handling time and distance to target) all parameters were standardized and summarized. A t–test was performed to verify if the mean values of the groups in the overall score, in the parameters were different, respectively.
RESULTS: We found a significant better performance (i.e. overall score) in the YPP in all exercises ("trapping and passing", "dribbling and passing", "trapping and shooting") compared to the YRP in the dominant and non-dominant leg. Concerning the parameter "handling time" YPP showed a significantly quicker performance compared to YRP in all three exercises and both legs. Regarding the parameter "distance to target" YPP showed higher passing accuracy compared to YRP in the exercise "trapping and passing" only.
CONCLUSION: The outcomes of this study are in accordance with Huijgen et. al (2014), who showed that YPP had better physical, technical, and tactical skills compared to YRP. In our study YPP showed quicker ball processing and treatment compared to YRP in all exercises. Moreover, in the exercise "trapping and passing" YPP reached a higher passing accuracy in the soccer-simulator skills.lab. Therefore, we can conclude that skills.lab is able to distinguish between YPP and YRP and might be a useful tool in the process of scouting.

THE ASSOCIATION BETWEEN SELF-PERCEIVED MOTOR COMPETENCE AND ACTUAL MOTOR COMPETENCE IN BRITISH CHILDREN FROM EARLY AND MIDDLE CHILDHOOD.

LAWSON, C., DOBELL, A., EYRE, E.L.J., NOON, M.R., DUNCAN, M.J.
COVENTRY UNIVERSITY

INTRODUCTION: The role of motor competence (MC) in providing children with the skills to be physically active is well known (Barnett et al., 2015). Recently perceived motor competence (PMC) has been shown to be a strong correlate of actual MC in adolescents (Babic et al. 2014). Few studies have examined the association between MC and PMC in younger children and some authors suggest that PMC in younger children does not match actual MC (Harter and Pike, 1984). Others have suggested that middle childhood marks the point in which children become accurate in self-perception (Barnett et al. 2015). This study addresses this issue by examining if actual MC differed in children who were high and low for PMC or from different developmental stages in childhood.
METHODS: Following ethics approval and parental consent, 118 children (64 Boys, 52 Girls, 6-11 years old) from two primary schools in England participated in this study. Children were categorised as early childhood (ages 6-7, n=64) and middle childhood (ages 10-11, n=52). MC (run, jump, throw, catch) was assessed using the Test of Gross Motor Development-2 (Ulrich, 2000) from which measures of total MC (0-30) object control (OC, 0-14) and locomotor skill (LM, 0-16). PMC was assessed using the Pictorial Scale for Perceived Movement Skill Competence (Barnett et al., 2015). A median split was then used to classify children as high or low for PMC. A series of ANOVAs were used to examine any differences in actual MC, OC and LM between boys and girls, early and middle childhood and high and low PMC.
RESULTS: Results indication no significant higher order interactions for actual MC, OC or LM (all P>0.05). Children high for PMC had significantly higher actual MC than children who were low for PMC (P = 0.05). For actual MC, boys had significantly higher scores than girls (P = 0.20), actual MC was significantly higher for children in middle compared to early childhood (P = 0.00) and children high for PMC had significantly higher actual MC than children who were low for PMC (P = 0.26). When LM was examined, there were no significant main effects for gender or PMC, however, LM scores were higher for children in middle compared to early childhood (P = 0.00). Conversely, for OC boys had significantly higher scores than girls (P =0.02), actual MC was significantly higher for children in middle compared to early childhood (P = 0.00).
CONCLUSION: The results of this study identify two important aspects that have not been documented in the literature previously. Firstly, the perception of MC in children in both early and middle childhood matches their actual MC. Secondly, OC skills may be more important for children in formulating their self-perception of their own competence compared to locomotor skills. Such findings underline the importance of PMC for children actual MC and are contrary to prior suggestions that young children's perceptions of their own competence may not be aligned to their actual MC.

THE ASSOCIATION BETWEEN PERCEIVED COMPETENCE AND ACTUAL MOTOR COMPETENCE IN 4-7 YEAR OLD BRITISH CHILDREN

NOON, M.R., EYRE, E.J., LAWSON, C.A., DOBELL, A.P., DUNCAN, M.J.
COVENTRY UNIVERSITY

INTRODUCTION: Regular physical activity in children is associated with short and long-term psychological and physiological health benefits. Motor skill development has an important role in promoting lifelong physical activity (PA). While research has identified a relationship between perceived motor competence, physical activity and actual motor competence (Babic et al. 2014), this has focused on older children or has been assessed linearly. Subgrouping younger children using tertiles may provide a better understanding of how perceived competence relates to actual motor competence since younger children are presupposed to form less accurate perceptions of their competence compared to actual competence (Harter and Pike, 1984). This study sought to address this issue by examining whether actual motor competence differs between children who perceive themselves to have differing level of perceived motor competence.
METHODS: Following ethics approval and parental informed consent, 290 children (158 boys; 132 girls aged 6 ± 1 years) from 4 primary schools, participated in this observational study. Weight status was assessed using BMI. Product measures of motor skills were assessed using 10m sprint speed using smart speed pro light gates (Fusion Sport Coopers Plains, Australia), 1kg seated medicine ball throw and standing broad jump measured using a tape measure. Product scores were combined to create a Z score. Perception of motor skills was

assessed using the Pictorial Scale of Motor Competence (Barnett et al., 2016) for run, jump, throw and catch (0-16). For analysis, perceptions of motor competence were subgrouped using tertiles. A 2 (Sex) by 3 (high, medium or low perception score) factor ANCOVA, controlling for BMI assessed differences in perceived motor competence and product assessed motor skills.
RESULTS: Results identified no significant sex X perception interaction for motor competence (P = 0.33). However, a main effect for perception was found (P= 0.001), where children in the high perception group (mean ± SD: 0.46 ± 2.59 AU) had better motor skills and those with low perception (mean ± SD: -0.84 ± 2.10 AU) observing lower motor skill performance. BMI was a significant covariate (P=0.04; ß= -0.15).
CONCLUSION: The results of this study suggest further support for the link between perception of motor skill development and actual motor skills. Although establishing cause and effect is challenging, the findings suggest that developing a high perceived motor skill competence in children may be determinant of actual motor development and vice versa. The work highlights the role of motor skill interventions to improve perception of motor competence in children, which may impact on lifelong physical activity although further research is needed to confirm this.

ASSOCIATIONS OF MOTOR ABILITY AND NEUROELECTRIC AND BEHAVIORAL INDICES ON TASK SWITCHING IN CHILDREN WITH ATTENTION-DEfiCIT/HYPERACTIVITY DISORDER

HUNG, C.L., HUANG, C.J., TSAI, Y.J., HUNG, T.M.

DEPARTMENT OF ATHLETIC

INTRODUCTION: The purpose of the current study was to examine the relationship between motor ability and task switching using behavioral and electrophysiological indices in children with ADHD.
METHODS: A total of 30 participants were recruited and underwent a motor ability assessment by administering the Movement ABC as well as the task switching and event-related potential (ERP) measurements at the same time.
RESULTS: Methods: A total of 30 participants were recruited and underwent a motor ability assessment by administering the Movement ABC as well as the task switching and event-related potential (ERP) measurements at the same time.
The results indicated that the MABC scores were positively associated with the response accuracy and ERP P3 amplitude. Specifically, the MABC average score was associated with higher accuracy and lager P3 amplitude. Furthermore, higher MABC scores predicted a larger P3 amplitude in the mixed, non-switching and switching trials.
CONCLUSION: Our findings suggest that motor abilities may play roles that benefit the cognitive performance of switching in children with ADHD.

THE EFFECTS OF TWO DIFFERENT FREQUENCIES OF FEEDBACK DURING THE PROCESS OF LEARNING A COMPLEX GYMNASTIC SKILL

NIZNIKOWSKI, T., MASTALERZ, A., BUSZTA, M., BIEGAJLO, M., NOGAL, M.

JOZEF PILSUDSKI UNIVERSITY OF PHYSICAL EDUCATION IN WARSAW, FACULTY OF PHYSICAL EDUCATION AND SPORT IN BIALA PODLASKA, POLAND

INTRODUCTION: Gymnasts demonstrate stability in the performance of complex and difficult elements, routines and individual styles of sports techniques. The most characteristic peculiarities are the precise postures and body positions which change dynamically during the phases and key elements of a gymnastic exercise. However, the analysis of the phase structure of an executed gymnastic exercise and routine (both basic and competitive of various complexity) shows rather significant andeven gross technical errors in exercises of many athletes (Niznikowski et al. 2007). This is especially peculiar to the key elements of preparatory and final actions of a gymnastic exercise and routines (Sadowski et al. 2013). The aim of this study was to gain knowledge about the effects of two different frequencies of feedback during the process of learning a complex gymnastic skill, the salto backward stretched, performed after the round-off flick-flack on the balance beam.
METHODS: Twenty-eight top-level female gymnasts participated in the study. Mean values of body height, mass and age were as follows: 162 cm ± 3.2 cm, 52.4 kg ± 2.3 kg, 20 ± 3.3 years, respectively. The gymnasts were randomly assigned to one of the two groups: group A - with feedback about key elements (n=14) or group B - with 100% feedback (n=14). Group A was provided with error information regarding the key elements of movement techniques only. Group B received feedback on all errors that occurred. Technical performance (performance of particular routines) was evaluated by experts (3 judges).
RESULTS: At the beginning of the experiment (pre-test), the differences between the key elements and the mean values obtained by groups A and B for performing the the salto backward stretched, performed after the round-off flick-flack on the balance beam, were not significant ($p>0.05$). The experiment effect was analysed using ANOVA with repeated measures (Group x Test Time). The post hoc comparison indicated significant differences between the feedback applied in both groups during the retention test ($p<0.05$) and the delayed retention test ($p<0.05$) in favour of group A.
CONCLUSION: Providing too much verbal feedback during the learning of a complex gymnastic skill, the salto backward stretched, performed after the round-off flick-flack on the balance beam proved to be less effective than limited verbal feedback about the key elements of movement techniques.
Verbal feedback on errors about the key elements of movement techniques was more effective than 100% feedback of the movement performance.

STRATEGIES OF SELF-CONTROLLED TASK DIFFICULTY MOTOR LEARNING EFFECT
Chung-Yin, WANG & Hank Junling, JWO (National Taiwan Normal University, Taipei, Taiwan)

Introduction: Self-controlled practice refers to the learner has autonomy of choice and can use strategies to acquire the best motor learning benefit during practice phase. Few previous studies of self-controlled practice investigated what the strategies were used by learners. Thus in this study, we focus on learners' strategy of self-controlled task difficulty to explore how the strategy to affect motor learning effect. Four questions were asked as follows: (1) Whether self-controlled learners' motor performance is better than the yorked and was self-efficacy higher than the yorked in acquisition phase? (2) Does motor performance correlate with self-efficacy during acquisition phase? (3) Does self-controlled practice benefit learners' motor learning? and (4) Whether self-controlled practice learners chose relatively medium task difficulty level and cause motor learning better than the chose outlier task difficulty levels?
Method
Fifty participants (mean age=23±4.1 yr.) were recruited, who were randomly assigned to either self-controlled group or yorked group. Puck-shuffling was used as experimental task. All participants completed 60 trails during acquisition. The self-controlled group was allowed to choose task difficulty level before each trial, then, self-efficacy was assessed after these choices. In contrast, yoeked groups' task difficulty level was transferred accord with the self-controlled group. After 24 hours, twelve trials were completed to examine motor learning effect through retention test.
Results: The results showed that a significant negative correlation was found between two groups' self-efficacy and absolute error. Self-controlled group's absolute error was significantly lower than that of yorked group, and self-efficacy was higher than yorked group during acquisition phase. In retention test, self-controlled group's absolute error was significantly lower than yorked group. In comparison with the learners chose outlier task difficulty level, learners chose medium task difficulty level were found a significantly lower absolute error.
Conclusion
Thus, it is suggested that (1) self-controlled practice leads to higher self-efficacy and better motor performance, (2) self-efficacy correlates with motor performance, (3) self-controlled practice promotes motor learning effect, and (4) in self-controlled task difficulty, the learners choose relatively medium level of difficulty facilitates motor learning effect.

DETERMINANTS OF SELF-CONTROLLED FEEDBACK BEHAVIOR: EXAMINATION OF DECISION TIMING AND PREVIOUS MOVEMENT PERFORMANCE

JWO, H., TSAI, M.J., WU, S.W., WANG, C.Y.
NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Previous researches suggested self-control is a motor learning variable based on the fundamental concept of self-determination. Besides psychological factors, as for learning strategies, it is feasible for learners to initiate self-regulation on the decision of practice or feedback to shape individualized practice schedules while being in the condition with autonomy. The findings of self-controlled feedback researches indicated that learners' feedback request pattern was affected by perceived and actual motor performance, and involved with perceived competence and outcome expectation. Thus, the present study was designed to examine the determinants of feedback requesting in the course of motor learning acquisition. The effect of performance of previous trial on motor performance and learning were examined by manipulating feedback decision timing and opportunity of self-controlled feedback.
METHODS: Thirty-six adults were recruited 36 as participants who were randomly assigned to Pre-self-controlled feedback, Pre-self-controlled feedback yoked, or Self-controlled yoked groups. Golf- putting precision was adopted as experimental task. The experiment consisted of 60 practice trials and 24hr delay retention test of 12 trials.
RESULTS: Results revealed that the accuracy of the previous trials that learners requested feedback were significantly higher than the trials that they did not request feedback in Pre-self-controlled group during acquisition phase. Pre-self-controlled group exhibited significant higher accuracy than that of Pre-self-controlled yoked group and Self-controlled group in retention test.
CONCLUSION: Present study indicated that making decision of feedback provision prior to motor performance benefits motor performance and learning under a self-controlled circumstance. Also, feedback requesting prior to motor performance depends on the experience of the previous motor performance. Thus, self-controlled feedback prior motor execution is a variable of motor performance and motor learning

APPROACHING CENTRAL MOTOR BEHAVIOUR DURING BADMINTON-SPECIFIC MOVEMENT PERFORMANCES IN DIFFERENT MATCH SITUATIONS

SKRZEBA, C., VOGT, T.
PROFESSIONAL SPORT EDUCATION AND SPORT QUALIFICATIONS

INTRODUCTION: Cortical activation indicative for motor behavioural processes involves central neuronal modulations that have been detected by analysing EEG frequencies. Dominant frequencies (e.g. alpha, beta) over relevant cortical lobes (i.e. frontal, central, parietal, occipital) are suggested to reflect e.g. a requested attentional focus of e.g. a sport-specific movement performance or match situation. However, previous investigations were mainly examined in laboratory setups. Therefore, the present study aimed to examine cortical activation during sport-specific movement performances in realistic match situations, i.e. comparing the short backhand badminton serve to the smash defence.
METHODS: Voluntarily 26 healthy right-handed male players (20.3±7.7 years; 175.5±8.2 cm; 67.1±10.5 kg; 12.5±7.4 years' experience in playing Badminton) participated in this study. After familiarization, each participant performed 60 badminton-specific movement performances, randomly assigned into 30 badminton serve match situations (serve) and 30 badminton smash defence match situations (smash) with approximately 30 seconds rest between each serve and smash. 32 Ag/AgCl EEG channels recorded continuous and real-time triggered cortical activation covering frontal, central, parietal and occipital electrode sites in accordance to the standard 10:20 system. Mean cortical activation (i.e. alpha: 7-13 Hz, beta: 13-30 Hz) for baseline as well as averaged serve and smash match situations were exported for statistical analysis.
RESULTS: Results revealed interactions between match situations and relevant cortical lobes in both alpha ($p<0.001$) and beta ($p<0.001$) activation. Main findings were an increase of cortical activation during the serve (alpha: $p=0.05$, beta: $p<0.01$) that was even more distinguished during the smash match situation (alpha: $p<0.001$, beta: 0.001) compared to baseline, most pronounced over frontal and occipital electrode sites.
CONCLUSION: The present preliminary findings are in line with previous reports from laboratory-based motor task performances. However, the present findings on cortical activation indicative for motor behavioural processes (e.g. planning of a movement performance,

visuo-motor perception of a match situation) with respect to sport-specific movement performances in realistic match situations may serve applied and practical approaches as well as knowledge transfer.

RELATIONSHIP BETWEEN UNILATERAL JUMPING IN THE VERTICAL, LATERAL AND HORIZONTAL DIRECTION AND CHANGE OF DIRECTION PERFORMANCE IN YOUNG ELITE FEMALE BASKETBALL PLAYERS

ARBOIX-ALIÓ, J., AGUILERA-CASTELLS, J., BUSCÀ, B., BENET, A., MONTALVO, A., FORT-VANMEERHAEGHE, A.

1FPCEE BLANQUERNA RAMON LLULL UNIVERSITY-BARCELONA, SPAIN,2FCS BLANQUERNA RAMON LLULL UNIVERSITY-BARCELONA, SPAIN3:FLORIDA INTERNATIONAL UNIVERSITY, COLLEGE OF NURSING AND HEALTH SCIENCES (MIAMI-USA)

INTRODUCTION: Recently, some authors suggested that many unilateral actions a team sport player is required to perform in practice or match occur not only in the vertical direction but also in horizontal and lateral direction . Therefore, when assessing unilateral tasks it's important to consider different directions to create an accurate profile player. The aim of this study was to explore the relationship between tests pertaining to unilateral jumps in the vertical, lateral and horizontal direction and change of direction performance.
METHODS: Twenty-nine young elite female basketball players were included in this study: age <15.66 ± 1.34 y>, body mass <69.69 ± 10.18 kg>, height <1.82 ± 0.07 m>, sport experience <6.31 ± 1.73 y>. Single Leg Countermovement Jump in vertical , horizontal and lateral direction were tested in both legs, as well as a sprint test with a 180 º change of direction . The relationship between jumps and COD was analyzed using Pearson coefficient correlation with respect the more skillful or the less skillful leg. The more skillful leg was determined to be the leg with higher performance averages on each respective task.
RESULTS: Comparing the skillful leg, and also the less skillful leg, COD and jumping values correlated significantly between all their subvariables.
CONCLUSION: The main finding of this study was the significant relationships between unilateral jumping in the anterior, lateral and vertical direction and COD performance. However, Meylan et al <2009> obtained a limited correlation between jumping and COD with the dominant leg in women physical education students. The diferent level of training of the samples could explain this fact. The results of our study suggest that elastic and reactive strength components, assessed by jumping in all three axes correlated to a 180º COD. Many of the findings in this study have interesting assessment and training implications for the strength and conditioning coaches of young female basketball players.

LOWER EXTREMITY KINEMATICS FOR DIVISION II FEMALE SOCCER ATHLETES EXECUTING A -LANDING TASK: A COMPARISON BETWEEN LANDING ON STABLE AND UNSTABLE SURFACES

TERRELL, S., ALLEN, C., NORRSTROM, H., GRIESSLER, A., SVOPA, K., BUTLER, B., LYNCH, J.

FLORIDA SOUTHERN COLLEGE

INTRODUCTION: Female athletes in high-risk sports like soccer suffer anterior cruciate ligament (ACL) injuries 4-6 times more than male athletes. Controlling loads in lower extremity sports is best accomplished by attenuating forces and resisting perturbations through appropriate joint flexion range of motion. Our aim was to compare ankle, hip and knee kinematics during single-leg drop-landing tasks onto stable and unstable surfaces, with particular attention at the knee, to identify strategies to reduce ACL injury risk.
METHODS: Sixteen (n=16) Division II female soccer players (19.00±1.3 years; 62.32±6.6 kg; 163.81±6.4cm; 23.26±1.44 BMI) performed three single leg drop landings from 30.48 cm onto the floor, an Airex pad, and a Shuttle Balance™ device. Kinematic measures at the left and right ankle, knee and hip were assessed with Dartfish™ video analysis for the initial and the lowest landing positions. Data was analyzed using repeated measures ANOVA and paired t-tests (IBM SPSS software, 25.0) with α <0.05 a priori.
RESULTS: Total joint angle changes (Δ) at the left and right ankle, knee, and hip from initial contact to lowest landing point, indicate athletes demonstrated greater joint flexion when landing on the floor (Δ-201.85°), compared to the Airex (Δ-196.43°) and to the Shuttle Balance™ (Δ-178.93°).
At initial contact, joint angles at the knee were most reduced on the Shuttle Balance™ (Δ-72.02°) compared to the floor (Δ-83.46°), and Airex pad (Δ-85.60°). There was significantly larger total knee flexion on the floor compared to the Shuttle Balance™ (p<.001).
CONCLUSION: Proper landing strategies require an ability to absorb forces through ankle, knee and hip flexion. Landing on unstable surfaces mimics perturbations in sports like soccer. The knee flexion angle at initial contact was reduced as the instability of the landing surfaces increased, indicating landing kinematics associated with injury risk. The total knee flexion range of motion also decreased as the instability rose which paralleled similar research using a BOSU™ ball (Schultz et al., 2015). Results suggest that proper preventative training progressions which master landing on stable surfaces are needed before instability challenges are presented. Future research should compare other high ACL risk sports such as basketball or volleyball to soccer athletes to determine if similar landing strategies are utilized in the presence of stable and unstable challenges.

THE COMPENSATORY RELATIONSHIP BETWEEN THE MUSCLE TENSION OF THE ILIACUS MUSCLE AND OTHER HIP FLEXORS IN HEALTHY SUBJECTS.

YAGI, M., TATEUCHI, H., SAEKI, J., UMEHARA, J., HIRONO, T., MOTOMURA, Y., ICHIHASHI, N.
KYOTO UNIVERSITY

INTRODUCTION: Excessive joint force leads to joint deformity and pain (Felson, 2013). The muscle tension of the hip joint muscles generated most of the hip joint forces during movement (Correa et al., 2010), and the change in muscle tension balance of the hip muscle increased the hip joint force (Lewis et al., 2007). In particular at hip extension position, the hip joint force increased with a change in muscle tension balance, which meant decreased muscle tension of the iliacus muscle and increased compensatory muscle tension of other hip flexors such as the adductor longus muscle and the tensor fasciae latae in a simulation study (Lewis et al., 2007). However, it has not been clarified which of the hip flexors compensated for the muscle tension of the iliacus muscle in vivo. Therefore, this study aimed to show the compensatory relationship between the muscle tension of the iliacus muscle and other hip flexors at hip extension position in healthy subjects.
METHODS: Eighteen healthy subjects participated in this study. Subjects stayed in a supine position, and the muscle thickness was measured by B-mode ultrasound at the iliacus muscle, the adductor longus muscle, the tensor fasie latea, and the rectus femoris muscle. After then, their pelvis was fixed on a bed with a non-elastic belt, and subjects held their right lower limb at 0° knee flexion and 15° hip extension. During the task, we measured the shear modulus of the iliacus muscle, the adductor longus muscle, the tensor fasie latea, and the rectus femoris muscle by shear wave elastography. The shear modulus represents the magnitude of tension per unit area. In order to estimate the actual tension of each muscle, the muscle tension index was calculated by multiplying the muscle thickness and the shear modulus of each muscle. For the muscle tension index, Spearman rank correlation coefficient between the iliacus muscle and each flexor was calculated. Statistical significance was set at 0.05.
RESULTS: In the muscle tension index, a significant negative correlation was found between the iliacus muscle and the adductor longus muscle ($r = -0.624$), but no between the iliacus muscle and the tensor fasie latea or the rectus femoris muscle ($r = 0.195$, 0.420, respectively).
CONCLUSION: By using the muscle tension index, which was calculated by multiplying the muscle thickness and the shear modulus, a negative relationship was found between the iliacus muscle and the adductor longus muscle. This result suggested that the muscle tension of the adductor longus muscle compensated for the muscle tension of the iliacus muscle.

ARM COORDINATION SYMMETRY OF OPEN-WATER SWIMMING STROKES IN EXPERT SWIMMER AND UNSKILLED SWIMMER: A PILOT STUDY ON SENSOR AVAILABILITY

BABA, Y.1, ICHIKAWA, H.1, SHIMOJO, H.1, SATO, D.1, NARA, R.1, IKEDA, Y.1, HARA, R.2, SHIMOYAMA, Y.1
1: NIIGATA UNIVERSITY OF HEALTH AND WELFARE, 2: UNIVERSITY OF NIHON

INTRODUCTION: An inertial motion sensor device is a highly transportable instrument for measuring swimming motion validated by numerous researchers. Open-water swimming motion includes sighting the next buoy or other targets, and breathing while maintaining a front-crawl. Breathing to the preferential side leads to asymmetrical coordination of the upper limb (Seifert et al., 2008), indicating these tasks can affect arm coordination symmetry. This study examined arm coordination symmetry using three inertial sensors to compare the expert swimmer and unskilled swimmer.
METHODS: Three inertial sensors were attached to both wrists and the lower back of two male swimmers. The expert swimmer had participated in the FINA/HOSA 10-km Marathon Swimming World Cup. The unskilled swimmer was inexperienced in open water swimming. Trials were performed that involved three tests in a 25-m indoor pool; a normal front crawl in apnea (Apnea), a front crawl with breathing (CrB), and ocean swimming with breathing (OSB). Every lateral breathing motion took place on the preferential side. The sampling frequency of the waterproof sensors was 1 kHz. The swimmer's stroke rate (SR) was controlled with swimming beepers (Tempo Trainer Pro, Finis®). We used inertial sensors to detect the beginning and end of each pull phase, based upon the transverse (radioulnar) axis angular velocity of double wrists, and then estimated the Index of Coordination (IdC; Chollet et al., 2000), and the Symmetry Index (SI; Seifert et al., 2008). Seifert et al. (2008) described how the coordination on the preferential breathing side (IdCP) comprises the time between the end of propulsion on the preferential side and the beginning of propulsion on the non-preferential side. The opposite side of coordination is named the non-preferential breathing side (IdCNP). Coordination symmetry was assessed by calculating the SI. SI = IdCP - IdCNP.
RESULTS: The results of the expert swimmer vs the unskilled swimmer are shown below. The time of 25-m was Apnea; 14.8 vs 15.6 s, CrB;14.9 vs 16.6 s, OSB; 15.2 vs 16.7 s. SR was Apnea; 0.61 vs 0.61 cycles/min, CrB; 0.60 vs 0.61 cycles/min, OSB; 0.60 vs 0.63 cycles/min. IdC was Apnea; 5.8 vs 1.1%, CrB; 4.3 vs 1.5%, OSB; 8.5 vs 3.4%. IdCP was Apnea; 5.1 vs -1.0%, CrB; 5.2 vs -1.5%, OSB; 6.1 vs 11.6%. IdCNP was Apnea; 7.2 vs 3.2%, CrB; 4.3 vs 4.9%, OSB; 10.8 vs -4.2%. SI was Apnea; -2.2 vs -4.1%, CrB; 0.9 vs -6.4%, OSB; -4.7 vs 15.8%. In Seifert et al. (2008) expressed, $-10\ \% < SI < 10\ \%$ revealed symmetrical coordination, $SI < -10\%$ and $SI > 10\%$ indicated asymmetrical coordination. The unskilled swimmer used asymmetrical arm coordination in OSB, whereas the expert swimmer demonstrated symmetrical coordination.
CONCLUSION: The unskilled swimmer used asymmetrical coordination in OSB. This indicates that needing to use sight to track targets during open water swimming may change arm coordination techniques, and unskilled swimmer lead to asymmetrical coordination as breathing action.

RELATION BETWEEN UPRIGHT POSTURAL STABILITY AFTER RAPID FORWARD STEPPING AND RATE OF FORCE DEVELOPMENT OF THE ANKLE PLANTAR FLEXORS AND DORSIFLEXORS

KATO, T.

KYOTO UNIVERSITY

INTRODUCTION: The ability to take a rapid forward step is important for fall prevention in the elderly population. It has been reported that the time to reacquire a stable upright posture after taking a forward rapid step (time to stabilization, TTS) is longer in elderly people in comparison to young adults (Johnson, 2003). Explosive muscle power of ankle plantar flexors and dorsiflexors is one of the contributors to a successful recovery from a rapid step. However, few studies have examined the relation between postural stability after rapid stepping and the rate of force development (RFD) of the ankle plantar flexors and dorsiflexors. The purpose of this study was to investigate the influence of plantar flexion (PF) and dorsiflexion (DF) RFD on TTS in young women.
METHODS: Nineteen healthy young women (21.7±1.7 years) took part in the study. After measurements of static upright posture on a force plate, the forward rapid stepping task was performed. Subjects were instructed to step their right foot onto the force plate as quickly as possible after being cued by light, and keeping an upright position for 15 seconds. Reaction time (RT), defined as the time from the cue to right foot-off, and the center of foot pressure (COP) velocity after landing on the force plate were measured. TTS was calculated using the following equation: (time at decreasing COP velocity to less than 2 SDs for reference COP velocity during static standing) − (time at landing of right foot). Maximum isometric strength (MVIC) and RFD of ankle PF and DF at 0° of ankle motion were measured using a dynamometer. RFD was defined as the slope of the force-time curve from the onset of contraction, defined at 2.5% of peak torque. Subjects were asked to exert force as fast as they could. 50 ms and 200 ms RFDs were calculated as the time intervals from the onset to 50 ms and 200 ms, respectively.
Stepwise regression analysis was performed with TTS as the dependent variable, and RT, MVIC, 50msRFD and 200msRFD of PF and DF as independent variables.
RESULTS: The TTS was 2.96±1.86 s. The MVICs were 1.06±0.48 Nm/kg (PF) and 0.52±0.87 Nm/kg (DF). The RFDs were as follows: 50msRFD 3.15±1.86 Nm/s・kg(PF), 2.35±1.04 Nm/s・kg (DF); 200msRFD 3.22±1.54 Nm/s・kg(PF), 2.03±0.46 Nm/s・kg(DF). The RT was 0.57±0.62 s.
Stepwise regression analysis revealed that 50msRFD of PF (β= −0.478) was a significant and independent determinant of TTS. MVIC and 200msRFD of PF, MVIC and RFD of DF, and RT were not identified as significant determinants of TTS.
CONCLUSION: This study showed that only 50msRFD of PF was associated with TTS. Our results suggest that rapid force production capacity during the early phase of plantar flexion may be more important for upright postural stability after taking a rapid forward step than MVIC.

A STUDY OF THE VARIABILITY IN ADDRESS POSITION FOR AMATEUR GOLFERS

JONES, K.

ULSTER UNIVERSITY

INTRODUCTION: Highly skilled golfers have consistently demonstrated higher outcome consistency compared to lower skilled golfers (Bradshaw et al. 2009; Betzler et al. 2012). It has been postulated that a golfer's ability to achieve a consistent outcome is guided by their consistency at address, yet the evidence is inconclusive (Bradshaw et al. 2009; Glazier, 2011; Langdown, Bridge and Li, 2013). The aim of this study was to examine the variability of amateur golfers at address and shot outcome.
METHODS: Ninety-four mixed ability amateur golfers completed 10 driver and 10 5-iron shots toward a 250 yd target. Feet kinematics and ball position were captured using an 11-camera motion capture system (Qualisys Oqus 300+). Clubhead presentation and ball launch variables were captured using previously reported methods (Betzler et al. 2014). Ball position in stance, stance width and stance depth, left foot-right foot angle and feet-target line angle characterised the golfer's position at address. These variables were calculated at takeaway for each shot. Intra-individual variability was calculated using median absolute deviation.
RESULTS: Multiple linear regressions, with variability in address variables as predictors and variability in estimated total carry distance, variability in final shot angle and variability in clubhead speed as outcome variables were not significantly better predictors than a constant model for either the driver ($p = 0.73$, $p = 0.67$ and $p = 0.14$ respectively) or the 5 iron ($p = 0.07$, $p = 0.29$ and $p = 0.28$ respectively).
CONCLUSION: Bradshaw et al. (2009) reported a relationship between address variability and shot outcome variability with two groups of differently skilled golfers with a 5-iron, but these results were not replicated by subsequent research (Langdown, Bridge and Li, 2013). The present study found no clear relationship between consistency in the address variables studied and consistency in shot outcome. Rather some golfers who were consistent in shot outcome were also consistent in address whilst others were not. This suggests multiple strategies exist by which outcome consistency can be achieved and that whilst consistency in address might be one possible technique for achieving consistency in outcome, it is not necessary.

ANTICIPATORY POSTURAL ADJUSTMENTS UTILIZED BY THE DYSVASCULAR TRANSTIBIAL AMPUTEE

ROBERTS, M.1,2, PRINCE, F.1

1: UDEM , 2: SKIDMORE COLLEGE .

INTRODUCTION: Anticipatory postural adjustments (APA) allow for total center of mass to be transferred from bipedal stance in quiet standing to single limb stance, enabling gait initiation. The APA strategy employed by the healthy adult take place in both antero-posterior (A/P) and medio-lateral (M/L) directions in sequential phases (Jian et al., 1993). Few studies have investigated the APA pattern in the unilateral transtibial amputee (TTA) and no studies have yet investigated the APA strategy employed by the specific dysvascular TTA (DTTA) population. The purpose of the current study is therefore to compare the APA strategy in gait initiation employed by DTTA with that of age-matched healthy adults.
METHODS: On a walkway embedded with three force plates, standing with both feet on either side-by-side force plates, 10 DTTA and 10 control participants were asked to self-initiate gait, stepping onto the third force plate, completing five trials with each limb leading. Parameters for phases 1-3 and total APA net center of pressure displacement (dCoPnet) were calculated in A/P and M/L directions. Analyses were carried out using a Matlab program (The Mathworks Inc., MA) and SPSS 24 (IBM Corp., NY) ($p < 0.05$).

RESULTS: A significant reduction in phase 3 M/L dCoPnet was observed in the intact limb (3.59<2.9) cm) when compared to control (7.03<2.0) cm) and prosthetic (7.11<4.0) cm) limbs. An anterior total dCoPnet was observed in the prosthetic limb (3.2<3.0) cm) when compared to a posterior total dCoPnet observed in controls (-3.57<1.9) cm).
CONCLUSION: The reduction in intact limb M/L dCoPnet observed in phase 3 can be explained by limb load asymmetry observed during quiet standing in the DTTA (Hermodsson et al., 1994). The anterior total dCoPnet observed beneath the prosthetic limb is an important result in the DTTA. Previous studies have found both anterior and reduced posterior total dCoPnet, prior studies investigating APA in both traumatic and dysvascular TTA (Vrieling et al., 2008). When compared, the DTTA are deconditioned and inactive (Hermodsson et al., 1994). The total anterior dCoPnet observed would appear to be related to further reductions in stability caused by reduced fitness levels, sensory loss, peripheral dysvascularity in the intact limb, etc. associated with dysvascular amputation.

THE EFFECTS OF A PROLONGED HIGH INTENSITY INTERMITTENT RUNNING PROTOCOL ON BALANCE PERFORMANCE AS MEASURED BY THE MODIFIED BALANCE ERROR SCORING SYSTEM

O MEARA, D., LODGE, C., CAREY, M., HUNT, B.
INSTITUTE OF TECHNOLOGY, CARLOW

INTRODUCTION: The Modified Balance Error Scoring System (MBESS) is an objective tool for assessing deficits in static postural stability in adults (Guskiewicz, 2003). This measure is included as part of the Sports Concussion Assessment Tool 5 (SCAT5) (McCrory, et al., 2017). Various types of exercise have been shown to have a short term negative effect on static postural stability in adults (Hill, et al., 2016; Petry, et al., 2016). A Prolonged High Intensity Intermittent Running (PHIIR) protocol has been shown to closely replicate field sports in many physiological and performance based parameters (Sirotic & Coutts, 2007). Despite being designed to be used in a pitch-side setting, the short-term effects of sports related fatigue on MBESS scores remains unknown. Therefore, the aim of this study was to analyse the effect of a PHIIR protocol on MBESS performance.
METHODS: 20 participants were divided into two groups, experimental (n=11) and (n=9). The experimental group was administered the MBESS prior to (pre-test), and twice after (5 minutes post-test and 10-minutes post-test) completion of the PHIIR protocol in a controlled laboratory setting. The control group was administered the MBESS prior to, and twice following, a period of rest. The timeline of administration of the measures exactly replicated that of the experimental group. Data was analyses using IBM SPSS statistics package version 23.
RESULTS: A 3 by 2 mixed within-between analysis of variance revealed there was a significant group by time interaction present. Post-hoc analysis using Wilcoxon Signed-Rank tests revealed a statistically significant increase in total errors from pre-test (1.64 +/- 1.362) to 5 minutes post-test (4.73 +/- 3.636) (z=-2.527, P=0.012) and a statistically significant decrease in total errors from 5 minutes post-test (4.73 +/- 3.636) to 10 minutes post-test (2.55 +/- 2.544) (z=-2.196, P=0.028) in the experimental group. Analysis of group differences using Mann Whitney U tests revealed a statistically significant difference between groups at 5 minutes post-test (U=15.5, z=-2.650, P=0.007)
CONCLUSION: The results show that performance on the MBESS was significantly negatively affected following a PHIIR protocol. This indicates that performances on the MBESS may be affected by sports related fatigue. this may impair the validity of the MBESS as a pitch-side tool for assessing concussion as any deficits detected cannot be conclusively attributed to a mild traumatic brain injury in the presence of fatigue.

OPERATING FACTORS THAT DETERMINE THE ACCURACY OF THROWING TO SECOND BASE IN THE BASEBALL CATCHER

SUZUKI, C., FUJII, M., MURAKAMI, K., NAKAMOTO, H., MAEDA, A.
NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: In baseball game, the catcher plays an important role for checking the steal base. In order to achieve successful checking, there are three important conditions: Ⅰ. quick throwing action, Ⅱ. high ball speed, Ⅲ. accurate throwing. Previous studies have been identified key kinematic factors to satisfy the condition Ⅰ. Also, other researcher has been investigated the strategies that to achieve conditions Ⅱ. No research, however, about catchers "Accurate throwing" has been found. That is, it is unclear what kind of factor is affecting for successful performance and, how to improve the performance. Therefore, the purpose of this study was to clarify the determinant factors that enhance the accuracy of the catchers throwing to second base.
METHODS: The subjects were 15 mens baseball players who specialized for catchers (age: 21.0 ± 2.5 years old, height: 172.4 ± 5.5 cm, body weight: 75.7 ± 5.8 kg, competition history: 11.6 ± 3.0 years, catchers experience: 8.0 ± 3.3 years). The subjects caught a ball that is thrown from midway between the mound and home plate, and they required to throw 15 to 20 balls to a fielder in second base. We measured throwing kinematics and kinetics by using optical 3 dimensional motion analysis system Mac3D (500 fps) and by using multi analytical force plate (2 kHz). In addition, we measured ball velocity by using "TRACKMAN". To evaluate the accuracy of the thrown ball, distance from the position where the fielder on the second base catches the ball to the origin (an arbitrary point in the vicinity of the second base) was calculated using image analysis software. The throwing motion was divided into four phases; 1) catching ball (Catch), 2) pivot foot's contact to the ground (PFC), 3) stride foot's contact to the ground (SFC), 4) ball releasing (Release). We carried out multiple regression analysis by stepwise method with the accuracy of throwing (throwing position) as dependent variable and each analysis item as independent variable.

RESULTS: Different independent variables were chosen for each phase. In the entire operation phase, the moving distance of the pivot foot in the x direction from the Catch to the PFC, the forward trunk angle at the time of Release, and the inner and external rotation angular velocities of the axial leg knee joint at the time of Catch were selected The contribution rate was 83.5%.
CONCLUSION: It was suggested that the accuracy of the catchers throw can be explained from the operating factors of the lower extremity and trunk.

COMPARISON OF FINGER DWELL AND OVERLAP TIMES IN PIANISTS

LIPKE-PERRY, T.1, DUTTO, D.J.2, LEVY, M.1

1: UNIVERSITY OF MINNESOTA DULUTH, 2: EASTERN OREGON UNIVERSITY

INTRODUCTION: Musicians and scientists study pianism to better understand the mechanics of underlying technique. Movement control both within and across pianos is essential for optimal performance. Pianists often refer to the "feel" of a particular instrument: its responsiveness and sensitivity; key resistance; and the evenness and predictability of the instrument.
The purpose of this study was to compare duration of vertical key depression (dwell time) and overlap time of subsequent keystrokes on three piano keyboards during a common scale exercise. Dwell time was defined as the length of time the key was completely depressed, while overlap time was length of time that 2 subsequent fingers are down at the same time on a given hand.
METHODS: Seven (7) pianists with a minimum of 6 yrs of experience performed C-Major scales on three keyboards. Three keyboards were used: Kawai MP11, Kurzweil PC2, and a Yamaha upright piano. Both the Kawaii and the Yamaha had fully weighted keys. Participants were fitted with 22 retro-reflective markers to create a hand/finger model. Markers were tracked with a 240-Hz Optitrack motion capture system (Corvallis, Oregon, USA). Subjects performed 10 subsequent two-octave ascending/descending C-Major scales using both hands (right hand beginning on Middle C, left hand one octave below). Scales were performed at 60 bpm with 4 notes/beat. Fingers were identified by side (left/right) and given a number 1-5 (thumb = 1; fifth digit = 5). Position-time fingertip data were tracked and processed using a 12-Hz low-pass filter from which dwell and overlap times were extracted for all fingers. Comparisons of dwell and overlap time for each finger and keyboard were done using repeated measures ANOVA.
RESULTS: During the performance of the scale, transitions occur when fingers crossover. It is during these events that obvious time differences emerged when playing scale, but these differences were similar across keyboards. In particular, the R3-L3 to R1-L2 transition (occurring twice during the ascending scale), dwell time substantially increases for the right (**Δ**:0.07 ± 0.03s) and decreases for the left (**Δ**:-0.03 ± 0.03s), while during the descending scale (R3-L3 to R2-L1) it does the opposite (R:-0.06 ± 0.03s vs L:0.08 ± 0.02s). Differences in dwell time coincide with significant decreases observed in the overlap time in fingering transitions. The overlap times in transition were significantly smaller (0.05 ± 0.01s in transition, vs 0.10 ± 0.02s between transitions).
CONCLUSION: The scale performance was produced at 60 bpm with 4 notes/beat. Theoretically, a dwell time would be expected to be 0.25s and observed dwell times were around 0.35s. Similarity of respective overlap times across keyboards suggest that pianists adapt to different instruments. In addition, dwell times greater than 0.25s and variability of dwell times suggest that performance of a scale is not quantified simply and that a relationship among keystrokes is essential though not intuitive.

CORE MUSCLE EMG CHARACTERISTICS OF STAND UP PADDLE BOARDING YOGA

CHEN, C.Y., LIANG, J.M., LIAW, L.J., HSU, H.T., TSAI, F.H., WU, W.L.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Stand Up Paddle Board Yoga (SUP Yoga) is the exercise combine core muscle training and stand up paddle surfing (SUP) on calm water. Because of SUP provide the instability, therefore, it is an exercise for core muscle training, muscle endurance, and balance control to enhance core muscle strength and endurance and improve exercise performance. The muscle activation patterns adopted during specific yoga poses on SUP have not yet been confirmed, for this reason, our research hypothesis is that the effect of training could improve by unstable surface. The aim of this study is to assess the core muscle activation in specific Yoga pose when using SUP, and compared with stable surface (land).
METHODS: 20 people with SUP YOGA experience were recruited into this study that completed on calm water training at swimming pool, and the individual must have practiced yoga at least over a year. In this study, subjects were use Stand Up Paddle and Delsys Trigno (Trigno TM Wireless system, Delsys Inc., USA). The dominant side of the core muscle as the main measurement, include: m. rectus abdominis (RA), m. obliquus externus (OE), m. multifidus (MF), m. erector spinae (ES) and m. rectus femoris (RF). Each subject was instructed to perform the same Yoga pose (High Lunge with hands on SUP/land, Plank, Upward Facing dog) on land and on SUP. Paired t-test was used to compare iEMG value among these two conditions.
RESULTS: SUP Yoga yielded the higher iEMG value for RA, ES and RF, when compared with land condition in High Lunge with hands on SUP/land. In the Plank pose, the ES, MF, EO and RF produced higher activities level on SUP Yoga than on land. Finally, during the Upward Facing dog pose, the RA, ES and MF show higher muscle activity than on land.
CONCLUSION: The higher level of activity in core muscles were achieve during specific Yoga pose on the SUP. Previous literature, when performing movements on unstable surface, muscle could produce higher activities to maintain the balance and stability (Imai et al., 2010; Feldwieser et al., 2012). In this study, we found Yoga combined unstable-base, such as SUP, could be a more effective strategy for core stability training.

HOW DOES THE METHOD AND PITCH LOCATION OF GAINING POSSESSION INFLUENCE POSSESSION OUTCOME IN CLUB LEVEL GAELIC FOOTBALL?

MCGUIGAN, K.

SPORT NORTHERN IRELAND SPORTS INSTITUTE

This study aimed to investigate the influence both pitch location and method of gaining possession have on the outcome of any given possession in club level Gaelic football (GF). Possessions (n=2203) from 25 games across all three tiers (senior = 10, intermediate = 8,

junior = 7) of the Ulster club football championship of 2015 and 2016 were analysed using validated operational definitions for Gaelic football. Pitch location was defined as defensive third, middle third or attacking third and was based on where a team gained first gained full control of the ball. Methods of gaining possession were defined as opposition kick out, own kick out, turnover, throw up, regained and 45m kick. Possessions were measured retrospectively, using Dartfish TeamPro version 7 video analysis software (Dartfish Limited, Switzerland), for both teams participating in each of the analysed games.
Of the 2203 possessions analysed, 962 were gained in the defensive zone, 1019 in the middle third and 222 in the attacking zone. A total of 398 shots were generated from 962 (41.4%) possessions gained in the defensive zone. Possessions gained in the middle zone (1019) resulted in 543 (53.3%) shots, while attacking zone possessions proved most prolific with 178 shots generated from 222 possessions (80.2%).
The most prominent of the six methods of gaining possession were 'own kickout', 'opposition kickout' and 'turnover'. Winning an 'opposition kickout' resulted in a shot 192 times from 314 possessions analysed (61.4%), while possession from 'own kickout' was less effective at generating shots, with 259 shots from 577 possessions analysed (44.9%). The most common method of gaining possession was through 'turnovers' (1113), but only 533 (47.9%) of 'turnover' possessions resulted in a shot. When area of the pitch is factored in, possessions beginning from a turnover in the attacking zone are most likely to result in a shot (80.5%), when compared to those in the middle third (56.9%) and the defensive third (40.4%).
While basic, the data presented provides, for the first time, evidence upon which to base tactical approach of teams participating in GF. There are important factors to consider relating to kickout strategy, both defensively (opposition kickout) and offensively (own kickout), and the potential influence winning each may have on the eventual outcome of a possession. Another key strand of the data relates to the potential impact pitch location has on possessions won via a turnover, with valuable evidence provided for consideration when determining team defensive strategy. In summary, this is the first study that has examined tactical factors relating to Gaelic football at club level, and as such provides useful information for coaches throughout the GAA world upon which to consider and apply various tactical approaches.

DOES A DECADE OF THE RALLY-POINT-SYSTEM IMPACT MATCH CHARACTERISTICS IN ELITE BADMINTON?

HOFFMANN, D., VOGT, T.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Numerous studies have investigated match characteristics (e.g. 'rally time') in elite Badminton, addressing an impact of different scoring systems (e.g. the the 'old' scoring system before 2006 and the Rally-Point-System since 2006) and the Rally-Point-System (e.g. from Olympic Games 2008 and 2012). Previous research mainly focused on the men's finals at Olympic Games between 1992 until 2012; however, a comprehensive approach covering the entire period in which the Rally-Point-System has been practiced is lacking.
Therefore, the purpose of this study was to investigate match characteristics in elite Badminton over the entire period of the Rally-Point-System with a particular focus on changes in match duration.
METHODS: Based on video recordings of the Badminton World Federation's (BWF) World Championship tournaments from 2006 to 2017, the focus has been on men´s singles quarter-finals, semi-finals and finals (i.e. 7 matches per tournament) to cover elite Badminton matches. Videos were accessed via the BWF BadmintonWorld.TV archives and, wherever applicable, via open-to-public YouTube® channels to collect a total data set of 56 matches. Herein, the following temporal and notational parameters have been subject to a preliminary analysis: official match duration (stated on BWFs result sites); rally time (the time from the service until the shuttlecock touched the ground on each point); rest time (the time that elapsed from when the shuttlecock touched the ground until the next service was performed).
RESULTS: While an increase in 'official match duration' by 20.36% failed significance (p=0.101) from 47.00 minutes (± 9.90) in 2006 compared to 56.57 minutes (± 11.22) in 2017, 'rally time' increased (p=0.002) by 64.43% with 7.45 (± 1.60) seconds in 2006 compared to 12.25 (± 2.85) seconds in 2017. In addition, 'rest time' increased (p=0.001) by 45.64% with 20.40 (± 0.91) seconds in 2006 compared to 29.71 (± 3.27) seconds in 2017.
CONCLUSION: The present preliminary findings reveal an impact of a decade of the Rally-Point-System on the rally time and the rest time. It seems reasonable that further (planned) analyses support this impact on e.g. the 'real time played', 'total points played', 'work density', 'shots per rally' and 'shot frequency'. Annual developments are further hypothesized also have an impact. The present preliminary findings in support of the hypothesized impact may serve the on-going discussion to change the scoring system (again) to a Best-of-Five (until 11 points).
This study is funded by the Badminton World Federation (BWF).

MEASURING JUMPING PERFORMANCE IN A CONTROLLED SETTING ON SAND AND RIGID SURFACES WITH TWO DIFFERENT DEVICES

HENDKER, A., SZWAJCA, S., EILS, E.

HUMAN PERFORMANCE & TRAINING IN SPORTS

INTRODUCTION: In the last decade, beach sports such as -volleyball, -handball, and -soccer have become increasingly popular which demand specific attributes for the athletes. Sport-specific diagnostic, e.g. jumping performance on sand surfaces need valid measurements to evaluate training interventions. Jump performance diagnostics mainly takes place under controlled conditions e.g. in a lab on rigid surfaces questioning ecologic validity in sand sports. It is necessary to facilitate the "in field" diagnostic to make results feasible for athletes and the trainer. Therefore, the aim of the present investigation was to measure jumping performance in a controlled setting on sand and rigid surfaces with two different devices. One reliably method was set to as the gold standard (3D motion analysis with markers) and compared with a system that is easy to use in the field.
METHODS: A sandbox (1.25x1.25mx30cm) was constructed to measure counter-movement (CMJ) and drop- jumps (DJ) on a sand surface in the lab. Seventeen healthy novices (28.4±4.7 years, 181±8.4cm, and 76±11.2kg) perform CMJ and DJ on sand and rigid surface in a balanced order. Jumping height was measured using a 3D motion capture system (Q) (Qualisys, Göteborg, Sweden) and compared with an accelerometer-based system (H) (Humotion SmarTracks Diagnostics, Muenster, Germany). Validity of the in-field system was calculated using differences of the measured jumping performance compared to Q. Furthermore, 95% confidence intervals (CI) and Bland-Altman-Plots were used to assess validity.
RESULTS: Mean vertical jump results were 37.8±6.7cm (95%CI: 34.6-40.9) (Q) and 35.8±6.9cm (32.5-39.1) (H) for CMJ on sand, 39.4±6.9cm (36.1-42.7) (Q) and 38±8.2cm (34.1-41.9) (H) for CMJ on rigid surface, 28.4±8.2cm (24.5-32.3) (Q) and 27.5±7.6cm (23.9-31.1)

(H) for DJ on sand, 31.3±7.1cm (28.0-34.7) (Q) and 30.4±7.6cm (26.8-34.1) (H) for DJ on rigid surface. Mean differences between Q and H were 1.9±2.4cm for CMJ on sand, 1.4±2.8cm for CMJ on floor, 0.9±2.5cm for DJ on sand, 0.9±1.8cm for DJ on floor, respectively.
CONCLUSION: Although mean values and differences appear to be comparable with a systematic error between systems, high standard deviations and large confidence intervals suggest that individual results deviate greatly from the mean (Humotion does not constantly underestimate the gold standard). Bland-Altman-plot evaluation strongly suggests that results spread in an unsystematic manner out of the range of confidence intervals on either side. Single deviations up to 9.3cm were found between systems, and 15% of all jumps had to be repeated due to wrong automatic or non-detection of jumps via H especially on sand surfaces. Therefore, the validity of the accelerometer based system for the assessment of vertical jump performance is questionable on rigid as well as on sand surfaces. This is of particular importance when focusing on elite athletes´ performance.

COMPARISONS BETWEEN SYSTEMS TO MEASURE CONTACT AND FLIGHT TIMES IN DURING TREADMILL RACE WALKING

TUCKER, C.B., HANLEY, B.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Race walking is an event dictated by a rule that states that no visible loss of contact with the ground should occur and that the leg must be straightened from first contact with the ground until the 'vertical upright position' (IAAF Rule 230.2). The measurement of flight times during race walking is therefore of great interest to coaches, athletes and judges. The aim of the study was to compare different methodologies used to measure contact and flight time in race walking on a treadmill.
METHODS: Seven male race walkers (stature: 1.79 m (± 0.05), mass: 66.6 kg (± 3.3)) and six female race walkers (stature: 1.68 m (± 0.11), mass: 58.0 kg (± 11.5)) participated. The men race walked on an instrumented treadmill (Gaitway) at 11, 12, 13, 14 and 15 km/h (in a randomised order), whereas the women's trials were at 10, 11, 12, 13 and 14 km/h. Contact and flight times were measured for each trial using two in-dwelling Kistler force plates on the treadmill that recorded vertical ground reaction forces (1000 Hz) from both feet and temporal data, a 1 m strip of an OptoJump Next system (1000 Hz) placed on the treadmill and a Fastec high-speed camera (500 Hz). Results from the OptoJump Next system were extracted using five settings based on the number of LEDs that needed activating (contact begins after_contact ends when), and were thus annotated as 0_0, 1_1, 2_2, 3_3 and 4_4. The force plate values were considered the criterion values and measurements were assessed for reliability using Intraclass Correlation Coefficient (ICC) and 95% limits of agreement (LOA: bias ± random error).
RESULTS: For flight time, the ICCs between the force plate and OptoJump Next were 0.946 for the 0_0 condition (LOA: .003 ± .016 s), 0.889 (1_1) (LOA: −.009 ± .017 s), .648 (2_2) (LOA: −.021 ± .021 s), 0.446 (3_3) (LOA: −.032 ± .025 s), and 0.304 (4_4) (LOA: −.043 ± .021 s). The ICC between the force plate and the high-speed video for flight time was 0.912 (LOA: .002 ± .022 s). For contact time, the ICCs between the force plate and OptoJump Next were 0.983 for the 0_0 condition (LOA: −.003 ± .019 s), 0.982 (1_1) (LOA: .008 ± .009 s), 0.898 (2_2) (LOA: .020 ± .025 s), 0.799 (3_3) (LOA: .031 ± .030 s), and 0.688 (4_4) (LOA: .041 ± .034 s). The ICC between the force plate and the high-speed video condition for contact time was 0.978 (LOA: −.003 ± .022 s).
CONCLUSION: The OptoJump Next system provided results similar to those of the gold standard force plates, with the 0_0 setting the most reliable. Users of the OptoJump Next system should therefore consider this setting (which is the default setting) along others such as minimum flight time and contact time (typically the default is 10 ms) to achieve the most accurate results when using a treadmill. The high-speed video recordings also provided very good reliability but it was occasionally difficult to subjectively identify contacts with this method. Therefore, the Optojump Next system is better suited to provide more immediate results when collecting treadmill data.

HOW CHANGES IN BLOCK DESIGN AFFECT RELAY START PERFORMANCE IN SWIMMING

TOWNSEND, N., HALL, S., MCLEAN, S.P., SMITH, J.

SOUTHWESTERN UNIVERSITY

INTRODUCTION: Starting blocks used in competitive swimming often incorporate a wedge for the rear foot to push against when performing flat starts. In most competitions, this wedge cannot be removed so relay starts must be performed with the wedge in place despite the common addition of an approach step during a relay starts. The presence of the wedge constrains the length of the approach step but does provide an inclined surface from which to push which may improve propulsive force development. The purpose of this study was to evaluate the effect of using a wedge in relay start performance.
METHODS: Eight collegiate swimmers (177.69 + 8.73 cm, 74.7 + 9.11 kg, 19.59 + 0.59 years) provided informed consent and completed eight maximal effort relay starts, four with the wedge in place and four without. For all starts, participants were instructed to maintain a streamline position upon entering the water and to glide as far as possible. A relay judging platform was installed on the block and used with an in-water touch pad to measure the exchange time for the relay start. Two synchronized cameras captured movements at 60 Hz above and below water. A 16-point model of the body was used to compute center of mass position for above water movements. Takeoff velocity and angle were defined using the horizontal and vertical velocity of the whole body center of mass. Time to 7m was measured as the time needed for the wrist to reach a point 7m from the pool wall. Paired t-tests were used to compare dependent measures between start conditions.
RESULTS: Exchange time ($t(7) = 0.11$, $p = 0.99$), takeoff angle ($t(7) = 0.60$, $p = 0.57$), time to 7 m ($t(7) = 0.69$, $p = 0.51$), and max depth ($t(7) = 1.10$, $p = 0.31$) were not different when using the wedge as compared to not using the wedge (Table 1). However, takeoff velocity without the wedge was 2.4% faster ($t(7) = 2.48$, $p = 0.04$) than with the wedge on the block ($p<0.05$). This difference was characterized by a moderate effect size (Cohen $d = 0.46$).
CONCLUSION: Presence of the wedge on the block had a minimal effect on relay start performance. It adversely affected start performance by decreasing takeoff velocity however no other kinematic variables were affected. Having the wedge on the block may constrain the step length of the swimmer during the relay start, which might explain the decrease in velocity.

THE RELIABILITY OF LOWER-LIMB STIFFNESS MEASURES DURING HOPPING WITHIN A SLED-BASED SYSTEM

DIGGIN, D., ANDERSON, R., HARRISON, A.J.

ITHACA COLLEGE

INTRODUCTION: Stretch-shorten cycle (SSC) tasks are those where eccentric muscle actions are immediately followed by concentric shortening (Komi and Nicol 2011). Sled-based systems (SBS) are often used to study aspects of SSC operation (Flanagan and Harrison 2007).

Stiffness (k) is a characteristic that influences SSC function. Studies show that measures of leg (kleg) and ankle joint (kankle) stiffness exhibit strong reliability during overground hopping (Diggin et al. 2016). In contrast, knee (kknee) and hip joint (khip) stiffness measures exhibit weak-to-moderate reliability (Diggin et al. 2016). The reliability of kknee and khip may be confounded by variation in upper body movement and by participants' ability to control centre-of-mass position. Reliability during hopping may be improved by employing a SBS. The aim of this study was to examine the reliability of k measures during hopping within a SBS.
METHODS: Kinematic and kinetic data were collected at the same time of day on three separate days spaced five-to-seven days apart. Participants completed two trials of single-legged hopping at three different frequencies (1.5, 2.2 and 3.0 Hz) while attached to a SBS (Flanagan and Harrison 2007). Stiffness was calculated using models previously outlined (Diggin et al. 2016). Statistical analysis identified absolute and relative measures of reliability. Participants were familiarized with testing procedures seven days prior to initial data collection.
RESULTS: Data illustrated that kleg measures exhibited weak-to-moderate consistency (ICC = 0.71 → 0.89) between testing bouts at all hopping frequencies. kankle exhibited strong reliability at 1.5 Hz (ICC = 0.94) with weak and moderate consistency evident at 2.2 and 3.0 Hz respectively (ICC = 0.88 → 0.91). kknee and khip measures exhibited weak consistency throughout (ICC = 0.62 → 0.84).
CONCLUSION: Results showed that reducing task complexity by restricting upper body movement within a SBS did not alter the consistency of kknee and khip measures. In previous works, kleg and kankle exhibited strong reliability during hopping (Diggin et al. 2016). The use of a SBS in the present work caused deterioration in hopping consistency. Thus despite having been familiarized with procedures prior to testing, hopping within a SBS represented a novel task for the current participants. This point is supported by higher levels of variability than associated with overground hopping. Researchers should consider these findings prior to associating data collected within SBS to natural SSC actions.

DEVELOPMENT OF A COMBINED BENDING STIFFNESS INDEX FOR CYCLING AND OUTDOOR FOOTWEAR

MICHEL, F.I.1, RAUNER, K.2, KORDEN, O.1, SENNER, V.2

1: VAUDE , 2: TECHNICAL UNIVERSITY OF MUNICH TUM

INTRODUCTION: Footwear bending stiffness represents one of the most important functional properties in athletic footwear . During walking the shoe should provide an appropriate dorsiextension around the MTP-joints to ensure a smooth ride. Contrary, cycling shoes should be stiff to allow a direct power transmission. However, there are specialty shoes, such as for cycle touring, which should offer both a smooth ride during walking and adequate power transmission during cycling. Thus, the aim of this study was to develop a combined bending stiffness index to evaluated cycling and outdoor footwear according to activity and its functional requirements.
METHODS: To investigate the longitudinal bending stiffness a mechanical testing device was used . The device measures forefoot and midfoot flexibility regarding both DF and plantarflexion movement. Different loading condition were applied and the resultant bending angle was measured. Ten outdoor shoes and 8 cycling shoes were tested differing in functional requirements based on their field of use.
RESULTS: For outdoor footwear, the stiffness bending index consists of 4 values measured during DF. For cycling shoes one additional value during PF is considered. Depending on the field of use the tested footwear exhibit different bending stiffness properties. Within outdoor footwear, shoes belonging to the category "Approach" indicate much stiffer bending characteristics compared to "Urban Life". In cycling, the tested shoes of the "Cross Country"-category exhibit clearly stiffer PF bending characteristics compared to "Cycle Touring". Besides, tested footwear for "Cycle Touring" show a similar DF forefoot flexibility like "Urban Life".
CONCLUSION: Data recorded with the TrakTester allow the development of a combined bending stiffness index for outdoor and cycling footwear. The informative value of the mechanical testing is confirmed by several subjective test reports published in consumer magazines . However, a comparison with other studies is not possible since the method to determine the bending stiffness vary strongly . Based on the index, the longitudinal bending characteristics can be evaluated and improved according to field of use and its requirements. Moreover, the index may support the athlete to find the right shoe for its preferred activity.

FUNCTIONAL INSPIRATORY MUSCLE TRAINING, RESPIRATORY MUSCLE FATIGUE AND LOAD CARRIAGE

HINDE, K.1, LOW, C.1, LLOYD, R.2, COOKE, C.2

1-LEEDS BECKETT UNIVERSITY, UK, 2-LEEDS TRINITY UNIVERSITY, UK

INTRODUCTION: When load carriage exceeds 20 kg, respiratory muscle fatigue is induced . Performing in hypoxic-cold conditions increases the likelihood of RMF. Inspiratory muscle training can increase inspiratory muscle strength and attenuate RMF, but when combined with LC, IMT has failed to reduce RMF . Exercise involving LC alongside IMT may activate non-respiratory roles of the diaphragm and respiratory muscles and provoke adaptations beyond that of static IMT.
METHODS: Participants performed a loaded <18.2 kg> 6 km walk at 50%VO2max, at 4300m in -10°C, pre, mid and post training . The walk comprised 4 stages of 0.5 km at 0, 5 and 10% gradient. After trial 1, participants were randomly assigned to CON or EXP to undertake 4 weeks of foundation IMT using a Powerbreathe device. CON performed 60 daily breaths at 15% maximal inspiratory pressure whereas EXP performed 2 x 30 breaths daily at 50%Pimax. An additional 4 weeks of functional IMT 3 times weekly followed, which included 5 exercises designed to develop core strength. Three of the 5 exercises required LC <18.2 kg> and all were performed at ~50%Pimax and 15%Pimax .
RESULTS: Relative to baseline <126.9 ± 15.7 cmH2O> trends were identified for greater Pimax in the EXP group post-IMT <145.5 ± 20.5 cmH2O, p = 0.066, likely increase> and post FIMT <155.3 ± 30.8 cmH2O, p = 0.104, likely increase>. Pimax in CON remained unchanged. The reduction in Pimax post-6 km was unchanged by IMT or FIMT. There was no effect of IMT or FIMT on Ve, HR, VO2, BF or SpO2. Following FIMT, there was a significant 4-way interaction for whole-body RPE suggesting a greater reduction in RPE in EXP following FIMT.

CONCLUSION: Whilst IMT and FIMT produced an increase in the absolute strength of the inspiratory muscles, this failed to translate into any meaningful benefits and did not attenuate the reduction in Pimax post exercise. This may be because training load did not progress as time elapsed. Due to the prolonged, low intensity nature of LC activity, respiratory muscle endurance may be more influential than strength. Future research should focus on the effect of LC in cold-hypoxia on RME and employ a progressive overload IMT protocol that aims to improve Pimax and RME.

DECELERATION DEFICIT: A NOVEL METHOD OF MEASURING DECELERATION ABILITY DURING CHANGE OF DIRECTION PERFORMANCE

CLARKE, R., HUGHES, J.D., DE STE CROIX, M.
UNIVERSITY OF GLOUCESTERSHIRE

INTRODUCTION: Recently, the use of a change of direction deficit (CDD) has been proposed in order to quantify change of direction (COD) performance while controlling for linear speed ability. However, the CDD is still a composite of different skills (deceleration, reacceleration and turning technique). Due to the effect of momentum on joint loading and injury risk during COD performance, it would be beneficial to isolate the athletes deceleration capability during testing. This study utilised a novel method of measuring deceleration ability, termed the deceleration deficit (DD), during a 180° COD task and investigated its relationship with CDD, COD task completion and sprint speed.
METHODS: Sixteen recreationally trained athletes (21.5 +/- 6.2y; 84.5 +/1 19.7kg; 176.2 +/- 7.2cm) performed a 15m sprint (with a 10m split) and a 180° COD task with time measured (Smart Speed and Smart Jump, Fusion Sport) at 0m, 10m, the turn line (15m) and after a 5m re-acceleration (return past the 10m line). The CDD was calculated as the difference between the best 10m sprint time and the 10m portion of the COD task including the 180° turn (505 time). The DD was calculated as the difference between the best 15m sprint time and the time to reach the 15m turn line during the COD task. All variables were calculated from dominant side COD attempts. Correlations and partial correlations (P 0.05) were calculated between variables to compare their relationship with and without controlling for linear speed (15m sprint time). Z-scores were calculated to compare the difference between CDD and DD.
RESULTS: The CDD was significantly correlated to 505 time ($r = 0.531$; $P = 0.03$) while the DD was not significantly correlated to any other variable. The partial correlation reported significant relationships between CDD and 15m COD approach ($r = 0.743$; $P = 0.00$), total COD ($r = 0.748$; $P = 0.00$), re-acceleration ($r = 0.821$; $P = 0.00$) and 505 ($r = 0.964$; $P = 0.00$); and between DD and 15m COD approach ($r = 0.568$; $P = 0.02$), total COD ($r = 0.822$; $P = 0.00$) and 505 ($r = 0.525$; $P = 0.04$). 94% of participants showed a difference greater than the SWC between CD and DD z-scores.
CONCLUSION: It maybe concluded that the DD provides a practical tool to isolate an athletes deceleration capability and identify athletes whose COD performance is or is not hindered by their deceleration capability. This will allow coaches and researchers to measure the effect of training interventions, helping to mitigate potential injury risk and improve performance.

GAME PHYSICAL PERFORMANCE OF JAPANESE TOP-LEVEL FUTSAL PLAYERS IN DIFFERENT CATEGORIES

OHMURO, T.1, ISO, Y.2, TOBITA, A.1, HIROSE, S.1, SAKAUE, K.2, ISHIZAKI, S.2, YASUMATSU, M.1
1: RIKKYO UNIVERSITY , 2: SHIBAURA INSTITUTE OF TECHNOLOGY

INTRODUCTION: Several research on the game physical performance of futsal players in different competition levels have been reported (Dogramaci et al., 2011, Makaje et al., 2012). However, these studies neither comprised data of official matches, nor did they include male youth and female players. Therefore, the aim of this study was to compare the game physical performance of male, male youth and female Japanese top-level futsal players in official matches.
METHODS: The subjects were 79 top-level male players (age: 28.4 ± 4.6yrs), 59 top-level youth players (age: 17.1 ± 0.7yrs) and 87 top-level female players (age: 25.6 ± 6.9yrs). The game physical performance was assessed by active profiles of the matches using the automatic tracking system (Iseyama et al., 2016). All values are presented as means ± SD. Differences in the game physical performance between the different categories were determined by the analysis method one-way ANOVA, and in the case of significant differences, the Bonferroni˜s post hoc test was used to identify the point of difference. Statistical significance was set at $p < 0.05$.
RESULTS: The average of the total distance covered during matches of the male futsal players (141 ± 11 m/min) was significantly higher than those of youth (131 ± 10 m/min) and female players (134 ± 11 m/min; $p < 0.05$). In addition, the percentage of high intensity exercise (15.5 km/h～) during matches of youth and female futsal players was significantly lower than that of the male players ($p<0.05$).
CONCLUSION: This is the first study that has examined the game physical performance during official matches of youth and female futsal players, and these data may be useful for designing training programs of these groups. As a result of this study, the total and the high-intensity distance of the male futsal players was higher compared to Brazilian players (Murilo et al., 2014) and this game physical performance can be suggested to be the strength of the Japanese. These results also show that male futsal players have higher physiological demands than youth and female players, and it could be a help for physical coaches of youth and female futsal players in the future.

3X3 BASKETBALL: INERTIAL MOVEMENT AND PHYSIOLOGICAL DEMANDS DURING ELITE GAMES

MONTGOMERY, P., MALONEY, B.

ASPETAR

INTRODUCTION: 3x3 basketball has had an exponential increase in popularity in recent years and has now been included in into the 2020 Olympic Games. Given that 3x3 basketball is a relatively new sport, little is known regarding the game demands, or the physical and physiological responses of players during these games. The aim of this study was to determine changes in game demands and physical performance during international tournament match-play of elite 3x3 basketball.
METHODS: 361 males and 208 females competing in the under 18 World Championships, Senior European and World Championships, and Professional World Tour Final had game demands assessed by wearable technology (GPS, inertial measurement, heart rate) along with post game blood lactate and perceived responses. The total number of GPS and accelerometer game files collected for data analysis were 820 over 252 games, and 635 over 85 games for males and females respectively. Differences in the means were compared using magnitude based inferences and reported with Effect Size and associated 90% confidence limits, along with the percentage difference (ES; ±90%CL, % difference) of log-transformed data.
RESULTS: PlayerLoad™ and PlayerLoad™·min-1 during play was 127.5 ± 31.1 and 6.7 ± 1.5, and 128.5 ± 32.0 and 6.5 ± 1.4 for males and females respectively. For males, clear trivial differences were shown in PlayerLoad™ responses between under 18 (0.05; ±0.23, 1.2%), and World (0.17; ±0.21, 4.4%) championship levels compared to the professional level only. For females, a small difference was seen between European (0.28; ±0.22, 9.4%) and under 18 level. For PlayerLoad™·min-1, a trivial, and small clear difference was seen between the European and under 18 level for males (0.14; ±0.19, 3.3%), and females (0.20; ±0.22, 6.2%) respectively. There were small differences in accelerations >3.5m·s between competition levels up to 0.31; ±0.20, 22.2% for males, and 0.29; ±0.19, 20.3% for females, and for decelerations >3.5m·s; 0.29; ±0.19, 19.3% for males and 0.26; ±0.19, 17.2% for females, with European championships generally greater than other tournament levels. Average game heart rate was 165 ± 18 and 164 ± 12 bpm for males and females, with no difference between levels. Average RPE was 5.7 ± 2.1 and 5.4 ± 2.0 for males and females. Average game lactate for males and females was 6.33 ± 2.43 and 6.09 ± 2.24 mmol·L -1 respectively.
CONCLUSION: 3x3 basketball games require frequent high speed inertial movements in a limited volume of distance creating a relatively high physiological response. Practitioners working with 3x3 players at this level should endeavour to focus on the attributes that will improve these player characteristics for greater success.

CAN THE TIME-SERIES ANALYSIS OF BENCH PRESS FORM BY THREE-DIMENSIONAL MOTION ANALYSIS CONTRIBUTE TO THE PROBABILITY OF AN APPROPRIATE FORM IN PARA POWERLIFTING?

ISHIDA, N.

AICHI GAKUIN UNIVERSITY

INTRODUCTION: As targeting the athletes participated in Para Powerlifting of Paralympic, the author has already confirmed the influence from tiredness due to the subtle form disturbance and the repeated motion on its form by measuring the electromyogram at the bench press lifting, the joint angle of the elbow, the palmar force of holding position of the barbell shaft, and the floor reaction force at the position where shoulder blade attaches floor. In addition, the time-series analysis of bench press form by three-dimensional motion analysis were carried out to measure in this research. The subject is an able-bodied person and the experiment was conducted by aiming to establish an appropriate measuring method. After considering its practicality, the same measurement was carried out on the Para Powerlifting athletes with the aim to verify its effectiveness.
METHODS: The subject was the former Japan Masters Champion , one athlete aimed to participate in Paralympic as specializing for Para Powerlifting competition, and one athlete already participated in Paralympic 3 times. For the measurement, the bench press maximum weight of the subject was checked. As for the measuring condition, weight of 70% and 50% of 1RM was determined and 5 times of repeated lifting were carried out. The measurement was conducted by motion analysis with 9 Vantage/Vero cameras by VICON.
RESULTS: The difference in movement of left and right shoulders and elbows and the inclination of the shaft were detected from the change of segment position in left and right direction during continuous lifting motion. In addition, the difference between left and right of shaft movement while lifting was detected. Furthermore, in addition to the difference in left and right movement of the elbow joint and the shoulder joint, the angle at which the trunk and the shoulder joint open was able to be detected with high accuracy.
CONCLUSION: The subtle difference between the left and right movements revealed by the measurement is small, not able to be found from the visual observation. However, if these movements are continued in daily training, there is a possibility that it may lead to injury to the elbow or shoulder, and that is undesirable even if it's just subtle difference between the left and right from the viewpoint of strengthening. From the measurement of motion analysis at bench pressing with the normal training form conducted, it was found that it is possible to evaluate detailed motion. This result seems to be able to effectively contribute to obtain an appropriate and effective form for Para Powerlifting athletes.

BIOMECHANICAL ANALYSIS FOR SIMULATING THE WHEELCHAIR 100M AND 400M RACINGS USING MOTOR RESISTED ERGOMETER SYSTEM.

KASHIWAGI, Y.1, HIRANO, T.2, SOMA, M.3, HAKAMADA, N.4, FUNATO, K.2

1:SENSHU UNIVERSITY, 2:NIPPON SPORT SCIENCE UNIVERSITY, 3:JUMONJI UNIVERSITY, 4:JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: Wheelchair race of the Paralympic games have become increasingly popular in the last few years. Development of a wheelchair is record improve very it being important of an athlete. However, there are little quantification of mechanical output of an athlete playing a game and kinematic information while development and study of a wheelchair advance. In addition, pattern of wheelchair racing speed indicated that is different from compared with the Olympics 100m racing speed pattern. Wheelchair athletes have a case to participate in from a short distance to a long range races, and a document choosing a physical strength element specialized in a competition is poor. The purpose of this study was to biomechanics analysis of wheelchair sprint racing the 100m and 400m race simulations using wheelchair ergometer.
METHODS: The six wheelchair athletes（age:40.5±7.2yrs. BH:165.5±7.6cm, BW:55.5±8.7kg, Class: T53,54, 100m time:16.08±1.03s, 400m time:53.79±2.61s） were participated in this study. Subjects were performed 100m and 400m race simulation each wheelchair racer attach on wheelchair ergometer system (1kHz, KEKU,Canada). Reflective marker was attached to the upper limb anatomical point: acromion, humeral lateral epicondyle, ulnar styloid, Finger the second metatarsal. Upper limb extremity kinematics data was analysed using

the motion capture system (250fps, BTS, Italy). During race simulate mechanical model was applied form primary research. One stroke wheelchair power output was calculated from push force and disk velocity. One cycle time of spatio-temporal parameters were determined by power curve, stroke frequency (SF) was calculated from the reciprocal number. Stroke length was divide average of one cycle velocity by frequency (SF). Mechanical power output and spatio-temporal parameters of race simulations were indicated mean±SD each 10m or 50m phase.
RESULTS: In 100m race simulation, maximum speed was appeared just before 100m, but the 400m race simulation was indicated between 100m and 150m phases. Stroke frequency was not difference between 100m and 400m race simulations. As for the velocity of both races, what SL influenced than SF was accepted. As for the force, decrease was present, but the power display was steady in 100m race simulation. On the other hand, in 400m race simulation was indicated that decrease both force and power output. Maximum velocity was not significant difference between 100m(8.4±0.3m/s) and 400m(8.5±0.4m/s) race simulations.
CONCLUSION: Maximum velocity was not significant difference between both race conditions. It is suggested that rate of velocity not maximum velocity important for 100m and 400m race performance. Furthermore, it was indicated that ability for maintenance of power output important for 400m race. This study is suggested that upper limb strength to overcome frictional resistance of a wheel of early period of race is important in wheelchair racers.

PREDICTORS OF WALKING EFFICIENCY IN ADOLSCENTS WITH CEREBRAL PALSY

THEIS, N., RYAN, J., LAVELLE, G., NOORKOIV, M.
UNIVERSITY OF GLOUCESTERSHIRE

INTRODUCTION: Children with cerebral palsy (CP) have increased muscle stiffness and reduced muscle strength, which may contribute to a high metabolic cost of walking. In typically developing children, efficient gait is achieved by substantial force generation of the calf muscles, coupled with an optimum stiffness ratio between muscle and tendon to allow low muscle fibre shortening velocities (Lichtwark and Wilson, 2008). In children with CP, a greater stiffness ratio between muscle and tendon (Theis et al., 2016) and reduced muscle strength and size (Wren et al., 2010) may explain the high mechanical energy cost during walking. Understanding if these variables can predict walking efficiency may support the development of effective therapeutic strategies.
METHODS: Regression analysis of cross-sectional data from 30 adolescents with CP (age 13.0 ± 2.3 y; GMFCS levels I-III) was used to investigate if medial gastrocnemius muscle volume, plantarflexor muscle strength and stiffness and Achilles tendon stiffness would predict walking efficiency, measured from net non-dimensional energy cost during a 6-minute walk test. Simultaneous recording of ultrasonography and motion analysis during a maximal plantarflexion contraction manoeuvre was used to derive strength and stiffness. Muscle volume was assessed with a 3D-freehand ultrasound method.
RESULTS: All variables were significant and independent predictors of walking efficiency. Muscle volume alone explained 46% of the variance and when plantarflexor strength was also included in the model, the explained variance increased to 52%. Higher plantarflexor muscle stiffness and lower Achilles tendon stiffness were associated with lower walking efficiencies. When muscle and tendon stiffness were added to the model, the explained variance in walking efficiency was 67%.
CONCLUSION: Walking efficiency in adolescents with CP may be influenced predominantly by muscle weakness, which can be attributed to both reduced muscle volumes and strength. High plantarflexor muscle stiffness coupled with low Achilles tendon stiffness may prevent muscle fibres from operating at an optimal length. Therapeutic efforts for adolescents with CP should be aimed at increasing muscle size and strength, and optimising stiffness of the calf muscles and Achilles tendon.

MOVEMENT CHARACTERISTICS AND GREATER LEVER ARMS AS BIOMECHANICAL RISK FACTORS OF KNEES VALGUS DEFORMITY IN SEPAK TAKRAW ATHLETES

CHANG, C.C., JIANG, Y.S., CHANG, S.Y., ADEEL, M., HSIEH, Z.R., AHMED, M.I., HSU, W.C.
NATIONAL TAIWAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Increased risk of lower limb osteoarthritis (OA) has been found to be associated with repetitive, high impact sports (Conaghan 2002). For an athlete, a major knee injury will often have severe short-term consequences such as an interrupted sports career (Lohmander et al. 2004). Nowadays, the diagnosis of OA has most often been based on radiographic appearance. However, if we can relate the cause of knee OA during dynamic motion to sports mode or training method, athletes can adjust their strategy to prevent injury. Therefore, the aim of this study is to see the feature of knee OA in dynamic trial when performing different landing types.
METHODS: Two Sepak Takraw athletes participated in this study and one of them has been diagnosed with valgus knee, especially at the left side. Subjects were instructed to do three types of jumping, which were double-leg landing from 40cm platform, single-leg jumping forward with left leg as single propulsive leg and right non-weight bearing from 40cm platform, and single-leg jumping forward. The data was collected by motion capture system (Qualisys) and force plates (AMTI). Kinetic and kinematic parameters were analyzed using MATLAB including lever arm of knee joint, joint angle and joint moment of hip, knee, and ankle. Lever arm definition (3D). Positive value of lever arm indicating the GRF is lateral to the center of rotation at the knee joint while the negative value of lever indicating the GRF is medial to the center of rotation at the knee joint.
RESULTS: During single-leg jumping forward with left leg as single propulsive leg and right non-weight bearing, the greater knee adductor moment at the left limb compared to that at the right limb was only observed in the subject with more severe valgus left knee. If the subject keep performing this asymmetric task with already asymmetrically deformed valgus alignment at the propulsive side, the deformity may aggravate fast due to the found biomechanics repeated injured mechanism, in terms of greater lever arm and its corresponding adductor moment, reported in current study.
CONCLUSION: Research have showed that asymmetry of the movement characteristics may increase risk of deformity in Sepak Takraw athletes and that this biomechanical risk factor may become more pronounced for athletes with knees valgus deformity due to greater peak knee adductor moments and lever arms in the frontal plane.

REAL-TIME RECORDING OF PROPULSIVE PARAMETERS OF PADDLE-BOARDER ELITE SWIMMERS DURING CROSSING OF THE ATLANTIC

JOFFROY, S., GARNIER, S., OUAKNINE, M., AUTET, B., MAURIÈGE, P.

UNIVERSITÉ PAUL SABATIER

INTRODUCTION: Three elite women athletes (27 ± 5.8 yr-old) specialized in coastal rescue have related the islands of Cape-Breton in Canada to Capbreton in France (5000 km) on "Paddle-Board". They have taken turns day and night to travel 100 km on average a day. Postural adaptation of the locomotion of the swimmers was measured during all the crossing: their performances and spatio-temporo-frequential parameters of swimming in athletes of very high level under extreme conditions and constraints were analyzed.
The analysis of the driving forces is based on the measurement of the traction and propulsion forces exerted by the ventral side of the hand resting on the water (Silva and al. 2005). The sensors developed in our service were attached on the palm and / or the pulp of the finger (major or index) of the hand. They consisted of membranes or blades whose deformation is retranscribed as an electrical signal by means of strain gauges.
METHODS: To evaluate the swimming technique, our objective was to create a system for acquiring paddle board propulsion forces in real time, by measuring the swimmers hand thrusts on the mass of the paddle board water. The sensors had to be waterproof, miniaturized and placed not to hinder the locomotion of the swimmers. The sensors are connected to a box attached to swimmers'arms in the emerged part of the body. The electronic interface is responsible for shaping the force signals, performing a digital conversion at a rate of 20 Hz and sending the digitized sequences over the air (2.4 GHz). All in a waterproof conditions. The data are immediately recorded and transformed on board the logistic boat in the form of graphs giving the real time evolution of the locomotive pressures. The power supply of the boxes is ensured by accumulators of 3.6 volts. Swimmers row continuously with an active period of 2:30 h and a rest period of 5 h. The software, "SWIMMEX" acquisition, records the name of the current swimmer, the type of sensor, the start and end dates of the recording as well as various notes in progress exercise.
RESULTS: Our results allowed to establish the profile of a motor cycle, from which it is possible to extricate, its period, its spectral composition, the forces, speeds, accelerations under hostile environmental condition. Indeed, the results showed that the three women have adopted the same tactical swimming by alterning elongated and kneeling positions. The elongated position is fluid and controlled while the kneeling position is impulsed.
CONCLUSION: Swimmers have adopted the same swim-start tactics, probably for energy saving, exercise management and ergonomics considerations for the posture adopted on the paddle-board (Zamparo and al. 2005). This is the first time that such measurements were performed during a major sports event.

VARIABLES RELATED TO FATIGUE DURING A 2 X 40 MIN GAME SIMULATION IN MALE YOUTH SOCCER PLAYERS.

KUNZ, P.1, ZINNER, C.2, SPERLICH, B.1

1 UNIVERSITY OF WÜRZBURG, 2 UNIVERSITY OF APPLIED SCIENCES FOR POLICE AND ADMINISTRATION OF HESSE

INTRODUCTION: Soccer performance is, although not exclusively, determined by the players' endurance, addressing both the aerobic and anaerobic system and various neuromuscular demands like jumping and sprinting. Therefore, counteracting fatigue represents one major aim in planning and training of soccer players. Besides having an adverse effect on the probability of injuries and other health risks like overtraining, fatigue directly influences variables affecting acute match performance and should therefore be prevented. Especially short activities like sprinting, jumping or change-of-direction (CoD), frequently applied in a soccer game, often decide upon success and should be investigated in detail. Therefore, the aim of this study was to examine performance in sprinting, jumping and agility of male youth soccer players during a 2 x 40min soccer game simulation to investigate the time course of variables related to fatigue.
METHODS: Eleven highly trained male youth soccer players (16 ± 1 yrs; 178 ± 7 cm; 67 ± 7 kg) completed a 2 x 40-minute soccer match simulation in the lab, with a 10-minute half-time to recover. One half consisted of walking, jogging, linear sprinting, jumping and CoD in reaction to an extern stimulus. The percentages of these diverse physiological demands where set in accordance with youth soccer match analyses. The CoD were performed on the SpeedCourt (Globalspeed GmbH, Hemsbach, Germany). To complete one 40-min simulation, the player had to finish 15 equal rounds in 2 min 40 s, including all given intensities. To determine the cardio-respiratory load during the simulation in relation to maximum values, all players underwent an incremental test to receive VO2max (MetaMax3B_R2, Cortex, Leipzig, GER) and HRmax (H10, Polar Electro OY, Kempele, FIN). Lactate was measured after every five rounds and RPE was determined using Borg's 6-20 scale (Borg 1970) every round.
RESULTS: Within both halves, RPE increased significantly over time to 17.6 in the last round ($p<0.05$). VO2max and HRmax averaged 71% and 86%, respectively. When comparing the average 20m linear sprinting time of rounds 1-5 (3.2 ± 0.17 sec) with rounds 25-30 (3.21 ± 0.14 sec), no significant difference could be detected ($p = 0.92$). Similary, no difference were detected for jumping (CMJ) between rounds 1-5 (38.7 ± 5.3 cm) and rounds 25-30 (40.0 ± 5.7 cm) ($p= 0.27$). CoD performance was greater in rounds 25-30 (16.74 ± 1.48 sec) compared to round 1-5 (17.95 ± 1.97 sec).
CONCLUSION: In our study, we found signs of increasing intensity and high physical strain during a simulated 2 x 40 min soccer match as indicated by the increase in HR and VO2 and additionally by the players' perceived high exertion. Conversely, no decrease in neuromuscular performance, expressed in linear sprinting, jumping and CoD, were detected. These findings may provide indications that fatigue in this laboratory simulation was mainly of central origin, without affecting neuromuscular performance.

THE EFFECTS OF AUDIBLE STIMULUS ON GOLF COACHING PEDAGOGY BASED ON KINEMATICS

YOO, K., WU, X., ZHUANG, W., XIA, Z., LIU, Y.

KEY LABORATORY OF EXERCISE AND HEALTH SCIENCE OF MINISTRY OF EDUCATION, SCHOOL OF KINESIOLOGY, SHANGHAI UNIVERSITY OF SPORT, YANGPU, SHANGHAI 200438

INTRODUCTION: Golf coaching methodology has taken an important position in golf categories for improving mechanical respects with enhancing performance and injury prevention. However, the traditional golf pedagogy which has been depended on empirical and individualized method with insufficient scientific based verification are required to develop for the new forms of golf coaching methodology. Therefore, the purpose of the current study is to verify the efficacy of audible stimulation as a golf coaching strategy for novice golfers through the well-established kinematical variables after 5 weeks golf lesson.
METHODS: Twenty four male right handed novice participants who had no experience in golf and musculoskeletal injury participated in the study and randomly separated into two groups TG (tagger group / n=13) and NG (non-tagger group / n=11). The golf coaching pro-

cess was conducted on three times a week for 5 weeks. Only different coaching treatment between two groups was tagger using during the lesson procedure. To measure kinematical variables, 10 infrared cameras used and the resulting data was evaluated with kinematic analysis in the study. Also, Trackman radar device used to measure ball and club variables coincidently in the experiment.
RESULTS: The significant superiority of kinematical characteristics of club head and pelvic rotation in TG has found to compare with NG. Also, the COM (Center of Mass) alteration during the acceleration phase from backswing top to follow throw found the less COM displacement on X, Y, Z axis in TG at 5 week. Moreover, the golf performance parameters (club speed, face angle, ball speed, flight time, carry distance) except smash factor in TG have presented on significant improvement.
CONCLUSION: The efficacy of audible stimulus as a golf coaching strategy has proven by all kinematical parameters in the current study. The variation of velocity and acceleration in club head and pelvis have fully support the main idea, and the COM variation have shown comparatively better motor control ability in TG to compare with NG. Most of all, the golf performance parameters have revealed credible superiority in TG. Besides, the author as a researcher and professional golf coach has found the efficacy of audible stimulus in the process of golf lesson. So, we are able to acknowledge the effect of audible stimulus in golf coaching pedagogy based on the results in the study respectively. As a new golf coaching pedagogy trial, immediate audible stimulus feedback method would be utilized to lesson golf for novice golfers. Furthermore, it could be expected to provide a better motor learning process for golfers with all skill level, age, and gender.

QUANTIFICATION OF VISUAL BEHAVIOR AND PREPARATORY ACTION IN VOLLEYBALL BLOCKING

UMEZAKI, S., YAMAMOTO, D., KIDA, N., NOMURA, T.

TENRI UNIVERSITY

INTRODUCTION: In modern volleyball, it is a critical moment for the blocker to quickly judge the direction of opponent attackers in order to block their shots. The purpose of this study was to investigate the effective preparation of blocker from the point of visual behavior, and step motion. We hypothesize that the high-level blockers can read the direction of attacks by collecting the opponent setter and other behavior.
METHODS: We set up two groups by skill: i.e. Expert professional player (female, n=4), College player (female, n=4), and made players block balls from unexpected three directions (i.e. left, middle, right) at random. Eye movements of blockers while seeing a setter and their initial response towards take-off were both recorded using a lightweight binocularly eye mark recorder (EMR-9, 60 Hz) and video-camera (60 Hz), respectively. We measured the three sequential starting time points of preparation step, main step, and take-off, and analyzed the duration between them. We extracted 10 blocks per each player from the right and left directions, not middle one.
RESULTS: The expert players paid longer attention to setter's face while college ones to setter's hands (i.e. expected toss-impact). The means percentage of the viewing duration of the expert group on the setter's face was higher than the experienced group. During the starting time of preparation step and main one (i.e. preparation-step phase), 5 different type of steps were defined (i.e. the side-thrust, jab-step, kick-back, split-step, and double-step). During the starting time of main step and take-off (i.e. main-step phase), we defined cross-step, side cross-step and running-step. The experts stayed longer until the toss-impact in the preparation-step phase while the college players started moving with their assumption.
CONCLUSION: These finding showed that the expert players waited to start the preparatory motion until just before toss impact, and quickly executed that motion after precisely reading the direction of toss. Results suggested that experts give priority to perceptions when judging the direction of a toss, whereas experienced college players might give priority to motions for starting a move.

THE RELATION OF REGULAR PHYSICAL ACTIVITY WITH LIVING BEHAVIOR AND MENTAL HEALTH IN KOREAN ADOLESCENTS

GWAK, H., KIM, S.

KOREA UNIVERSITY

INTRODUCTION: According to the Organization for Economic Cooperation and Development , Korean adolescents resulted in 82 points in 2016 their self-reported sense of happiness as measured. The scores were the lowest rank among the members of the OECD. Also, Korean adolescents ranked high in the lack of physical activity. The severe problem is that level of stress and depression are increasing in Korean adolescents. This study examines the relation of regular physical activity with living behavior and mental health factors in Korean adolescents using Korea Youth Risk Behavior Web-based Survey data.
METHODS: Complex sampling design data was obtained from the 12th KYRBWS. The subjects, total 65,212 middle and high school students, were classified into two groups based on regular physical activity, depending on gender. We included economic status, academic achievement, breakfast, time sitting down, sleep duration, sleep satisfaction, smoking, drinking, self-rated health, self-perception of body image and BMI category in living behavior factor, and stress, depression, suicidal ideation and subjective well-being in mental health factor. Data were analyzed by complex sample linear model, chi-squared analysis, and logistic regression.
RESULTS: Regular physical activity did not differ by height and BMI in boys and girls from a little physical activity. Regular physical activity was more weight than little physical activity in boys, but girls were not a significant difference. Boys and girls containing regular physical activity were a higher academic achievement, eating breakfast ratio, normal sleep , sleep satisfaction and healthiness in self-rated health than other. Also, both genders included regular physical activity had less sedentary time than little physical activity. However, all adolescents of regular physical activity were higher ratios in smoking and drinking than little physical activity. Boys and girls who had little physical activity appeared to have a significantly higher than regular physical activity in to get stress. Boys and girls had OR values of 1.274<95% CI from 1.206 to 1.346> and 1.138<95% CI from 1.077 to 1.202>. In depression, boys and girls who had little physical activity were significantly lower than regular physical activity. Boys and girls had .820<95% CI from .771 to .873> and .939<95% CI from .883 to .998>. Also, suicidal ideation showed differences between boys and girls students. Boys had little physical activity were significantly higher than regular. Girls had little physical activity were significantly lower than regular. Boys had 1.152<95% CI from 1.051 to 1.263>, but girls had .783<95% CI from .728 to .843>.

CONCLUSION: In this study, Korea adolescents who had regular physical activity show positive in living behavior. Stress and suicidal ideation were associated with a regular physical activity. Stress was an association with regular physical activity in girls. This study provides a relation of regular physical activity mental health and factors related student living behavior in Korea.

A FUNCTIONAL NIRS EVALUATING TRIAL OF MOTOR IMAGERY AND PHYSICAL EXERCISE TASKS FOR A KARATE EXPERT

FUJIEDA, Y., KOBAYASHI, Y., TAKESHITA, K.

FUKUI HEALTH SCIENCE UNIVERSITY

INTRODUCTION: It has been taught that Karate katas, traditional self-learning method of form exercise must be executed against imagined opponent(s). A legendary karate adept had told his a disciple "Curiously enough, I am now perspiring due to only performing kata in my mind despite of no actual body movement". This open-skill learning strategy of solo performance can correspond to motor imagery and/or mental rehearsal of modern sport methodology. Recent neuroimaging studies have shown that skill acquisition or improved performance induces economical changes in brain areas demanded by the practiced task. In this study, we investigated the similarity and difference of cerebral activity between motor imagery and executing physical performance of karate kata in the way of an expert case study.
METHODS: A well-trained male karate ascetic (56 year-old, 8th degree of dan) was asked to mentally rehearse a traditional kata of Pinnan-shodan from a first person-perspective in sitting posture, a standing rest for 30 seconds, and to perform the same kata with actual physical actions. Through this brock-designed task, oxy-hemoglobin changes in the prefrontal lobe and motor areas of the subject were evaluated by using a wearable functional NIRS device （SMARTNIRS, SHIMADZU）. The oxy-hemoglobin data was analyzed to identify and map brain areas by using a software (Statistical Parametric Mapping for Near Infrared Spectroscopy : NIRS-SPM). The participant was right-handed with no clinical history of cerebral or neurological diseases.
RESULTS: During motor imagery of Pinnan-shodan, brain activations at bilateral frontal lobes and motor cortex were observed. On the other hand, similar brain activations at frontal lobes and reduced activations at motor related areas were revealed while the karate expert was executing the same Kata with actual physical movements. It could be considered that this economically activated motor cortex during performing Kata exercise was derived from the automation effects of physical skill that had been acquired by the expert.
CONCLUSION: Economically reduced activation at motor related area of a karate expert during physical performing karate kata than mental rehearsal can be detected by functional NIRS.

TRANSCRANIAL DIRECT CURRENT STIMULATION SUPPRESSES THE CONTRALESIONAL HEMISPHERE: A SYSTEMATIC REVIEW AND META-ANALYSIS

KANG, N., WEINGART, A., KIM, M., CAURAUGH, J.H.

INCHEON NATIONAL UNIVERSITY; UNIVERSITY OF FLORIDA

INTRODUCTION: The conventional perspective on the contralesional primary motor cortex (cM1) has changed because of the potential supportive role of the cM1 for a subset of stroke patients. Despite increased cM1 activity patterns post stroke interfering with paretic motor function, in some cases the hyperactive cM1 may contribute to improving paretic arm function. Thus, this comprehensive meta-analysis examined the beneficial effects of cathodal transcranial direct current stimulation (ctDCS) that suppresses the cM1 activity on motor rehabilitation for stroke individuals in different recovery phases.
METHODS: Fifteen studies that applied ctDCS on the cM1 for stroke motor rehabilitation were included. We identified 20 total comparisons from the qualified studies indicating motor function changes between ctDCS and sham stimulation protocols. For moderator variable analysis, we compared effect sizes between two different recovery stages: (a) acute and subacute phases (time since stroke = 6 months): eight comparisons and (b) chronic phase (time since stroke > 6 months): 12 comparisons.
RESULTS: A random effects meta-analysis model showed significant improvement in paretic motor function after applying ctDCS on the cM1: standardized mean difference effect = 0.61; SE = 0.15; 95%CI = 0.31-0.92; $P < 0.001$. Interestingly, the moderator variable analysis revealed that effect size for acute and subacute stroke patients was not significant (effect size = 0.46; $P = 0.07$), whereas the ctDCS protocol for chronic stroke patients showed significant effect size (effect size = 0.71; $P < 0.001$).
CONCLUSION: The current meta-analysis indicates that the treatment effects of ctDCS on the cM1 for stroke motor recovery are different between acute and subacute stroke patients and chronic stroke patients.

EFFECTS OF HALO SPORT ON COGNITIVE PERFORMANCE

ZHENG, X., HUANG, L.Y., WANG, Y.N., BIAN, X.L., LIU, Y.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: Recently, athletes use electrical stimulation to improve exercise performance or make the training more efficient. Halo Sport is a non-invasive brain stimulation headphone, and it has been shown to improve the height of jump (Hornyak, 2017). The ergogenic effect of Halo Sport may be due to deliver a constant, mild electrical pulses to the scalp and the brain, supposedly allowing motor-cortex neurons to build neural connections more easily. However, the effect of Halo Sport on the brain remains unclear. The cognitive function, specifically executive function, has been show related to the brain activation (Huppert et al., 2017). Therefore, the purpose of the present study was to investigate effects of Halo Sport on the performance of executive function.
METHODS: A within-subjects design with a counterbalanced order was employed. Six male participants in randomized order received a placebo Halo Sport stimulation (SHAM) or real Halo Sport stimulation (Halo). Each condition lasted 20 min and current was set at 0 mA or 2 mA. The executive function generally consists of metal set shifting, information updating, and inhibition of prepotent responses. To observe the changes of executive function, the Stroop Test and the N-back task were performed before and after Halo Sport for inhibition of prepotent responses and measuring information updating. The Stroop Test consisted Stroop Color and Stroop Color-Word conditions. The N-back task applied in this study, designed using E-prime software, consisted 1-back, 2-back and 3-back conditions.
RESULTS: Participants exhibited a decrease of reaction time in Stroop Test from pre- to post-stimulation after Halo Sport, but not after sham stimulation. Halo Sport induced a trend towards significant improvement of 2-back reaction time, but did not affect 1-back and 3-back conditions.
CONCLUSION: Halo sport is designed similar as transcranial direct current stimulation (tDCS) applied to the primary motor cortex. Using the same stimulate session and current intensity, tDCS has been showed to improve exercise performance and cognition, these effects of

tDCS may be due to the improvement of cortical excitability (Angius et al., 2018). In the present study, we firstly evidenced that Halo Sport could improve cognitive function, and these results indirectly indicate that the ergogenic effect of Halo Sport may be due to enhance brain function.

A CONCEPTUAL FRAMEWORK FOR THE MECHANISTIC EFFECTS OF PHYSICAL ACTIVITY ON IMPROVING COGNITIVE FUNCTION AND REDUCING THE RISK OF NEURODEGENERATION

PARMAR, V., BAIN, P.B.

IMPERIAL COLLEGE

INTRODUCTION: There is considerable interest concerning the effects of maintaining higher levels of physical activity throughout the lifespan with regards to improving cognitive abilities and reducing the risk of developing neurodegenerative diseases. Here we provide a conceptual framework for the likely mechanisms underlying these processes.
METHODS: We assembled information about the mechanisms concerning physical activity and improved cognitive function and decreased risk of neurodegenerative diseases from a scoping review of the literature.
RESULTS: Conceptually, the effects of physical activity can be perceived as having two component processes, either building a 'cognitive reserve' or providing active 'neuroprotection', each of which is likely to have a greater or lesser degree of influence on cognitive function depending on the individual's age.
Cognitive reserve itself has two sub-processes, one involving simply increasing the quantity of available neurons and the other involving increased neuronal connectivity; improving the way that the nerves interact and connect with each other, having more parallel circuitry in place.
Neuroprotection on the other hand is a more defensive process involving the prevention of damage to neuronal cells by upregulation of mechanisms which deal with oxidative stress; a significant factor in the pathophysiology of neurodegenerative diseases.
Physical activity contributes to these two component processes by intrinsic changes to the brain and also via systemic changes. Intrinsic factors include the production of neurotrophic factors such as BDNF, directly causing neurogenesis and dendritic formation. Systemic changes involve an increased aerobic capacity which will improve cerebral perfusion, thereby facilitating both neurogenesis and neuroprotection (improved delivery of nutrients and removal of wastes including reactive oxygen species). Additionally, in adulthood, IGF-1 synthesis shifts from cerebral production predominantly to production in metabolically active tissues elsewhere in the body. This production contributes directly to neurogenesis, but also to increasing cerebral perfusion via angiogenesis and directly modulating protein clearance adding to its neuroprotective qualities. Hence IGF-1 promotes an activity feedback loop with the brain.
CONCLUSION: We provide a conceptual framework for the main evidence gathered from animal and human studies on the effects of physical activity on improving cognitive function and modifying the risks of neurodegeneration. Understanding these concepts not only provides potential avenues for therapeutic interventions, which will help to tackle the ever-burgeoning problems of cognitive decline but helps to provide an insight into how these diseases arise.

COGNITIVE TRAINING TO IMPROVE ON FIELD PERFORMANCES IN RUGBY PLAYERS: A PILOT STUDY

DAVIAUX, Y.1, LEPAGNOT, M., DUMONT, J., LALANNE, R.2, LINI, S.1

<1> AKIANI FLOWTIDE, FRANCE / <2> UNIV BORDEAUX, FRANCE

INTRODUCTION: Team sport players have to divide cognitive resources when in multi-task situations: for example, when motor (driving a ball) and perceptual (gathering visual information on opponents) tasks are performed in the same time. Interestingly, training of perceptual process using Multiple Object Tracking task (3D-MOT) benefits to sports with dribbling skill while swift decision has to me made (e.g., ice hockey, Duchêne et al. 2016). Better on field game statistics are assumed to be the consequence of a reallocation of cognitive resources, from perceptual task to highly resource demanding task of fundamental (dribbling) skills.
We were interested in verify if such improvement was also verified in rugby, where ball manipulation is not as much demanding (ball holding but not dribbling). We hypothesized cognitive training to improve on field performances in rugby players. Cognitive training should benefit to global performance also because of others global processes involves in motor command (decision making).
METHODS: Twelve rugby women (age 19.6±1.1 y/o) were randomly separated into 2 groups of 6 players: trained group (TRN) vs. control group (CTL). TRN was assigned to 2 sessions x 3 weeks of cognitive 3D-MOT training. It consisted in 3 blocks of 20 trials: for one trial, participant was asked to visually track 4 targets mixed with 4 distractors for 8 seconds. Depending on tracking success or failure, speed was increased or decreased for the next trial.
Same procedure was used one week before (PRE) and after (POST) the training period, to track changes in groups performance. Averaged speed of the last 3 trials was computed for each blocks, with highest speed (Speed) taken as marker of the cognitive performance.
A dual-task reaction time (RT) of ball pass in reaction to visual trigger was also performed while rugby women performed 3D-MOT at 50% of Speed.
Rate of ball pass failures (RATE) was computed for PRE and POST in a rugby opposition game, for 20 sequences of 2 vs. 2 + 1 players. Counting was video-based, using a dedicated evaluation grid.
RESULTS: Two rugby women has been injured: inferential statistics were not applied because of sample size. TRN group shows however promising trends for larger improvement than CTL for cognitive performance (Speed +32% vs. 18%, respectively), dual-task performance (RT -21.1% vs. +10.4%, respectively), and on-field marker of rugby performance (RATE -26.0% vs. +21.2%, respectively).
CONCLUSION: Trends need a larger sample to be confirmed. Maker of cognitive improvement in 3D-MOT task has to be correlated with on-field marker of performance, to better understand how it profits to the on-field multifactorial performance in team sport.
Meanwhile, cognitive training in rugby can be carefully considered to take players to the next step of performance alongside with physiological and technical trainings.

THE INFLUENCE OF SLEEP DEPRIVATION ON RECOVERY FROM FATIGUE FOLLOWING ECCENTRIC STRENGTH EXERCISE

SHIODA, K.1, HONMA, T.1, HAYASHI, T.1, SUGIMURA, H.2

1: KANAGAWA UNIVERSITY, 2: KOHOKU FAMILY CLINIC

INTRODUCTION: Sleep is important for restoring the physiological processes that keep the body and brain properly functioning. However, it is unclear that the relationship between sleep duration and recovery in terms of central or peripheral fatigue resulting from muscle contraction.
The interpolated twitch technique (ITT) is used to assess voluntary activation (VA) of skeletal muscles (Kooistra et al., 2007). Additionally, the decline of VA in maximal efforts and resting twitch (RT) is the sign of central fatigue and peripheral fatigue, respectively (Gandevia, 2001). The critical flicker fusion frequency (CFFF) test is useful for assessing the arousal level, and the value of CFFF decreases with fatigue (Curran et al., 1990). The purpose of this study, therefore, is to investigate the effect of sleep duration on recovery from fatigue following eccentric strength exercise using ITT and CFFF.
METHODS: Healthy young adults who did not have sleep problem were recruited. To cause fatigue, they performed 3 sets of biceps curl with 75% of 1 repetition maximum until exhaustion before sleep. The quality of sleep was evaluated by polysomnogram (electroencephalogram, electro-oculogram, electromyogram, and heart rate) and rectal temperature during the nocturnal sleep. They participated in three experimental conditions in random order: sleep (0%: SL), partial sleep deprivation (50%: SD50) and total sleep deprivation (100%: SD) conditions. They performed isometric maximum voluntary contraction (MVC) of elbow flexor muscles for assessing VA using ITT before and after condition. In addition to ITT and CFFF, subjective fatigue and sleep index were measured using visual analogue scale and Stanford Sleepiness Scale.
RESULTS: In SD condition, RT which is index of peripheral fatigue shows lower than other conditions. Furthermore, the results show that there were certain differences VA and CFFF.
CONCLUSION: In conclusion, the present study revealed that sleep duration has a difference influence on the recovery from central or peripheral fatigue following eccentric exercise.

NEUROMUSCULAR FUNCTION AND FATIGABILITY IN PEOPLE EXPERIENCING HIGH LEVELS OF MULTIPLE SCLEROSIS FATIGUE

ELLISON, P., GOODALL, S., KENNEDY, N., HOWATSON, G., SAXTON, G.M.

NORTHUMBRIA UNIVERSITY

INTRODUCTION: Multiple sclerosis (MS) fatigue is multifactorial, directly linked to the disease itself (demyelination, inflammation) and other factors (depression, sleep quality). Defining and measuring fatigue in MS is challenging and the underlying neuromuscular mechanisms of motor performance are not fully understood. The aim of this study was to compare lower-limb neuromuscular function and fatiguability between people experiencing high and low levels of MS fatigue and healthy age-matched controls.
METHODS: 30 patients with definite MS were grouped, 15 fatigued (MS-F), 15 less-fatigued (MS-LF) and 15 healthy controls (HC). Fatigue was characterised using the Fatigue Severity Scale (FSS; fatigued ≥5 and less-fatigued <5). The Hospital Anxiety and Depression Scale (HADS) was used to measure anxiety (HADS-A) and depression (HADS-D). Muscle strength and voluntary activation were determined using twitch interpolation of the right quadriceps muscle during a maximal voluntary contraction (MVC). Fatigability was assessed during intermittent submaximal contractions. Comparisons between groups were made using one-way ANOVA. Associations between outcomes were determined by Pearsons coefficient correlation.
RESULTS: Group differences were observed in MVC at baseline (p=0.025) and post intermittent task (p=0.026). No differences in potentiated twitch force at baseline (p=0.490) and post fatigue task (p=0.621) between groups. VA differed at baseline (p=0.033), with reduced voluntary drive in HF-MS (p=0.035). People with MS fatigued more quickly than healthy controls (F-MS: 21 ± 9 min; N-FMS: 24 ± 15 min; HC: 30 ± 20 min, respectively). Subjective fatigue was significantly greater in HF-MS compared to LF-MS (p=0.000) with HC (P=0.000), with similar fatigue severity between LF-MS and HC (p=0.233). Fatigue severity significantly correlated with anxiety (r=0.64, p=0.010) and depression (r=0.54 p=0.036) in F-MS, but not for LF-MS and HC.
CONCLUSION: The impairment in voluntary activation associated with fatigue severity between MS-F and MS-LF are consistent with evidence of impairment of central motor drive to the muscle. People with MS tend to exhibit higher subjective fatigue scores and anxiety/depressive emotions when compared to their less-fatigued counterparts and healthy controls. Proposing central fatigue is mostly responsible for persons with MS, especially in MS-F.

RELATIONSHIP BETWEEN FRAILTY AND DUAL-TASK PERFORMANCE IN LONG-TERM NURSING HOME RESIDENTS

REZOLA-PARDO, C.1, GIL, S.1, IRAZUSTA, J.1, ARRIETA, H.1, ITURBURU, M.2, YANGUAS, J.3, RODRIGUEZ-LARRAD, A.1

1: UNIVERSITY OF THE BASQUE COUNTRY , 2: MATIA INSTITUTO, 3: FUNDACIÓN BANCARIA

INTRODUCTION: Despite frailty has been described as a purely physical syndrome, increasing evidence advocates that physical frailty and cognitive impairment interact together (Robertson et al. 2013) and suggest that an impaired capacity to perform two tasks simultaneously or dual-task (DT) could be a novel marker of frailty. Nevertheless, little attention has been given to the associations between frailty and DT in long-term nursing home (LTNH) residents. Therefore, the aim of this study was to assess the relationship between frailty and DT performance in LTNH residents.
METHODS: 64 participants from 4 LTNHs were included (inclusion criteria: age ≥ 70 years old, ≥ 50 on the Barthel Index, ≥ 20 on MEC Test (an Spanish validated version of MMSE) and capable to walk independently for 10m. Participants performed a Timed Up and Go (TUG) as a single task, and also a TUG while performing different cognitive tasks such as calculus, semantic fluency and inhibition (TUG-DT). The duration difference between the TUG and TUG-DT was calculated (dual-task cost, DTC). Moreover, frailty according to the Fried frailty Index, Rockwood frailty score, Tilburg frailty indicator, gait speed, short physical performance test (SPPB) and the Berg balance scale (BBS); and cognition, using the Montreal Cognitive Assessment (MoCa) test.
RESULTS: A significant correlation was observed between DTC under the inhibition task and Fried (r=0.477; p<0.001), Rockwood (r=0.691; p<0.001), gait speed (r=-0.703; p<0.001), SPPB (r=-0.751; p<0.001) and BBS (r=-0.672; p<0.001). In addition, there was a significant association between DTC under the calculus task and Rockwood (r= -0.277; p<0.05), SPPB (r=0.315; p<0.05) and BBS (r=0.347; p<0.05). Finally,

the BBS also showed significant correlations with DTC under the semantic fluency task (r=0.266; p<0.05). No correlations were found between DTC and the MoCa or Tilburg frailty Index tests.
CONCLUSION: The present study confirms the relationship between frailty and DT performance (Guedes et al. 2014). Additionally, DTC under an inhibition task is more related to frailty than the calculus or semantic memory tasks. Interestingly, the MoCa test failed to show correlations with any of the DTCs. Although DT performance has been associated with cognitive impairment in community-dwelling older adults (Plummer et al. 2012), in institutionalized older adults DTC seems to be independent of the cognitive and frailty status (Cadore et al. 2015). Future studies should further explore the relationship between frailty, cognitive impairment and DT in a highly deconditioned population like LTNH residents.

A FIRST TEST OF THE CLOUD-BASED IMPLICIT RELATIONAL ASSESSMENT PROCEDURE AS A MEASURE OF SELF-ESTEEM IN TAIWANESE ATHLETES

CHAN, W., CHI, L.K., CHIU, C.Y., HUANG, Y.C., CHAN, C.A.
NATIONAL TAIWAN NORMAL UNIVERSITY

A FIRST TEST OF THE CLOUD-BASED IMPLICIT RELATIONAL ASSESSMENT PROCEDURE AS A MEASURE OF SELF-ESTEEM IN TAIWANESE ATHLETES
CHAN, WEN-YU1 (TAIPEI, TAIWAN), CHI, LI-KANG1 (TAIPEI, TAIWAN), CHIU, CHUANG-YUAN1 (SHEFFIELD, UK), HUANG, YAO-CHUNG2 (TAIPEI, TAIWAN), CHAN, CHIH-AN3 (TAICHUNG, TAIWAN)
Introduction: Studies reported paper-based self-esteem measures typically register non-automatic evaluations of the self (Barnes-Holmes et al., 2006, Zentner and Renaud, 2007); by contrast, implicit self-esteem measures, such as Implicit Relational Assessment Procedure (IRAP), are designed to capture more automatic evaluations of the self (De Houwer et al., 2009). It might be not easy for evaluating athletes' mental status when they are in outdoors; therefore, it is an important issue to be considered. The aim of this study is to validate the cloud-based Implicit Relational Assessment Procedure (CBIRAP) with Rosenberg Self-Esteem Scale.
Method
Forty-seven participants who are athletes (aged 21.3±1.3 years old) in the university or college in Taiwan were recruited. Participants were requested to take the paper-based self-esteem questionnaire (Rosenberg Global Self-Esteem Scale) and the cloud-based questionnaire while they were in the training session or in outdoors. Criterion Related Validity is used, and the association between paper-based questionnaire scores and D-algorithm (CBIRAP) was assessed by using linear regression as the first step of calculations and Pearson correlation coefficient as the second step. All values were presented as mean and standard deviation, and the level of significance was set at $P < 0.05$.
Results: There was a small connection between the total self-esteem score and the total IRAP score (r=0.21, P=0.151). The CBIRAP questions with positive words has a medium association with the self-esteem scores for positive words (r=0.31, P=0.037); identically, the CBIRAP questions with negative words has a medium relation to the self-esteem scores for reversed words (r=0.40, P=0.005).
Conclusion
This study is the first research to evaluate the self-esteem level by web-based Implicit Relational Assessment Procedure in Taiwanese athletes, and it can be regarded as the antetype for the CBIRAP used in outdoors.

PRELIMINARY ANALYSIS OF THE PSYCHOMETRIC PROPERTIES OF THE MEXICAN VERSION OF THE PASSION SCALE IN SPORTS

MARTINEZ-ALVARADO, J.1, MONTOYA, G.1, AGUIAR, L.1, REYNAGA-ESTRADA, P.2, MAGALLANES, A.1, ASADI, A.1
1: UNIVERSIDAD AUTONOMA DE BAJA CALIFORNIA; 2: UNIVERSIDAD DE GUADALAJARA

INTRODUCTION: Vallerand & Houlfort (2003) define passion as a strong inclination toward a self-defining activity that one likes (or even loves), finds important, and in which one invests time and energy on a regular basis. Passion is of two types, which according to Vallerand et al., (2003) are the harmonious and obsessive passion. Harmonious passion refers to an autonomous internalization in the activity within the individual identity. Internalization occurs when the individual chooses freely and for pleasure the activity he wants to perform, this means that the personality of the individual is flexible (Decy, & Ryan, 2000). The obsessive passion is related to the complete control that the activity has over the individual identity, even there is the same desire for commitment that in the harmonious passion, in the obsessive passion this desire is not under the control of the person. The objective of this research is to analyze the psychometric properties of the Mexican version of the Passion Scale in Sports (Vallerand et al., 2003)
METHOD
The sample consisted of 468 Mexican athletes of both sexes and ages between 12 and 18 years (M = 16.3, SD = 1.65). The athletes reported an average of 3.62 years practicing their sport (SD = 2.54), as well as an average of 2.35 hours of training (SD = .79) distributed in

3 days a week. The Passion Scale consists of 14 items that evaluate obsessive passion and harmonious passion, each factor represented by 7 items using a Likert scale of five points.
To analyze the construct validity we used Exploratory and Confirmatory Factor Analysis and Cronbachs alpha coefficient for reliability.
RESULTS: The results of the EFA indicate two dimensions, each represented by 7 items obtaining a factorial weight between .77 and .88 and explaining 67.8% of the variance. As for the AFC, we found acceptable adjustment indices (X2 = 334.71; X2 /gl = 4.65; p < .01; TLI = .91, IFI = .94, CFI = .94 and RMSEA = .08) sustaining the model of 2 factors.
Regarding to the reliability of the two factors of the scale, we have found acceptable scores in the Cronbach alpha coefficient to evaluate the internal consistency (Obsessive Passion = .90, Harmonious Passion = .92).
DISCUSSION: The results of the different analyzes performed in this study indicate adequate psychometric properties of the Passion for Sport Scale in terms of construct validity and internal consistency. This allows an adequate use of the scale in young Mexican athletes of both sexes.

IMPACT OF RESTORATIVE FLOW MOVEMENT PATTERNS ON MENTAL HEALTH AND RESILIENCY IN NCAA DIVISION II BASKETBALL ATHLETES

GEIJER, J., METTILLE, C., GEISLINGER, A.

WINONA STATE UNIVERSITY

INTRODUCTION: The National Collegiate Athletic Association (NCAA) has identified mental health as a primary health concern for student-athletes. In an effort to address physical and mental health concerns of student-athletes, the authors developed the Restorative Flow Movement Patterns (RoFlow). RoFlow is a combination of yoga principles, functional movements, and various other training principles. The traditional yoga movements are essentially modified to improve function, recovery, mobility, and stability. Additionally, the RoFlow program is based on an incorporation of many of the same breathing and relaxation techniques as traditional yoga movements from which much of the program is based. RoFlow sessions were designed to combine the physical and mental training aspects of functional movements and yoga in an effort to improve the athletes abilities to withstand the physical and mental stresses associated with sport participation at the collegiate level. The purpose of this investigation was to determine program efficacy in improving not only the physical aspects of competing at the collegiate level, but also the mental aspects, as measured by survey responses.
METHODS: Thirty one (17 female) NCAA Division II mens and womens basketball athletes were surveyed before and after the 2016-2017 competition season. The survey contained 35 questions, which were selected from the College Student Health Survey (Boynton Health, University of Minnesota, Minneapolis, MN). The survey addressed aspects of physical health, drug and alcohol use, screen time, relationships, sleep, stress management, and resiliency. Between survey responses, athletes participated in weekly flows (RoFlow) as part of their in-season training regimen. RoFlow combined progressive functional movement patterns with yoga principles, once per week for the duration of the competitive season.
RESULTS: Athletes reported an 8% increase in the number of days their mental health has been negatively impacted (5.12 6.5 vs. 5.23 6.8; p=0.835). Additionally a 289% increase in the number of days their usual daily activities have been interrupted by physical or mental health concerns (1.06 1.6 vs. 4.14 9.2; p=0.146). Despite evidence of increased stress over the course of the competitive season, athletes reported significantly improved resilience between pre- and post-testing sessions (2.42 1.02 vs. 1.90 0.70; p=0.036).
CONCLUSION: The implementation of the RoFlow practice to the in-season training of NCAA Division II mens and womens basketball players may have improved the athletes ability to be resilient during stressful times. While not all statistically significant, the athletes reported improved resiliency across all six survey questions which centered on their abilities to appropriately manage stressful events. The combination of RoFlow practice and sports-specific training may improve the mental strength and resiliency of NCAA Division II collegiate basketball student-athletes.

THE EFFECT OF PARENTAL PSYCHOLOGICAL CONTROL ON MORAL DEVELOPMENT OF HIGH SCHOOL STUDENT ATHLETES

TENG, H., LIAO, C.

NATIONAL TAIWAN SPORT UNIVERSITY

The effect of parental psychological control on moral development of high school student athletes
Hsiu-Chiung Teng and Chu-Min Liao
National Taiwan Sport University
Introduction: Research has showed that teenagers who perceived higher levels of parental psychological control tended to experience negative emotions more often and showed more physical violence and disruptive behaviors (May, 2012; Cui, Morris, Criss, Houltbetg, & Silk, 2014). Parental psychological control refers to the behaviors by which parents manipulate parent-child relationship and make their children feel guilt and shame to control their children. In this study, we examined the effect of parental psychological control on high school student athletes' moral development based on Kohlberg's (1969) moral development theory.
Methods: 177 high school student athletes (M=113, F=64, mean age = 16.51) from 9 sports participated and filled in the Parental Psychological Control Scale (PPCS) and the Sport Moral Development Questionnaires (SMDQ). PPCS measured participants' perceived parental psychological control. SMDQ examined participants' stage of moral development by answering questions regarding a moral dilemma scenario in sport and provided reasons of their decisions.
Results: Participants were categorized into Kohlberg's five moral development stages with n=47, 44, 8, 19, 28, and 31, respectively. ANOVA and post-hoc comparisons showed that participants at both the "Obedience and punishment orientation" stage (M =1.78, SD = 0.60) and the "Interpersonal accord and conformity" stage (M = 2.05, SD = 0.47) had a significant higher score in perceived parental psychological control (p = .008 and p = .049, respectively) than those at the "Social contract orientation" stage (M = 1.38, SD = 0.37). No other between group differences was found.
Discussion: The results provided preliminary support for our notion that parental psychological control might affect young athletes' moral development. It seems that for young athletes from a family in which parents are more psychological controlling, avoiding punishment

and being a good boy/girl rather than the general welfare for most people are their major concerns when making a moral decision in sport. This study is correctional in nature, however, and more studies are certainly warranted.

ON THE SYMBOLIC AND THERAPEUTIC MEANINGS OF "DISORDERED MOVEMENT AND BODY PROBLEMS" MENTIONED BY ATHLETES IN PSYCHOTHERAPY

NAKAGOMI, S., AKIBA, S.
KOKUSHIKAN UNIVERSITY

On the symbolic and therapeutic meanings of "disordered movement and body problems"
mentioned by athletes in psychotherapy
Shiro Nakagomi and Shigeki Akiba
Introduction: The authors have found that athletes often talk about their disordered movement and physical problems during psychotherapy. The symbolic implications of their narratives help deepen our understanding of their inner experiences. Some of the athletes are able to arrive at therapeutic turning points because of these clues to the roots of their problems embedded in their narratives . The purpose of this presentation is to provide some case material on athletes in psychotherapy and describe the significance of their descriptions of disordered movement and physical problems.
Method
Based on the interview records of three clients, we retrospectively analyzed the overlap of therapeutic meanings between the clients' psychological tasks for resolving their main complaint and their descriptions of movement and their own bodies during therapy sessions. One case was that of a female gymnast who complained of feeling constrained and of a decline in performance. The other two cases were a female swimmer and a male track and field athlete whose talk of disordered movement coincided with their psychological tasks.
Results and Discussion: In case 1 , her description of her daily life , as well as her Landscape Montage Technique drawings showed a clear connection to her feelings of constraint in athletic performance. And while we never pointed out these connections to the client over the course of her therapy , she often spoke of her daily life and eventually came to understand the connections on her own. In that way her performance problems were resolved. Clients' descriptions of disordered movement and physical problems are uniquely significant in psychotherapy for athletes. They are richly symbolic and therapeutically significant – windows to an athlete's inner experience.
In our poster session we will present 2 additional cases.

EFFECTS OF FREE CLIMBING TRAINING TO PROMOTE THE INTERPERSONAL COMMUNICATION SKILLS —EXAMINATION OF AN EDUCATIONAL INTERVENTION PROGRAM TO SUPPORT PARENT-CHILDREN RELATIONSHIPS IN JAPAN—

TAKANASHI, M.
INTERNATIONAL CHRISTIAN UNIVERSITY

【Introduction】
Communication between parents and children is changing due to a rapidly declining birthrate and technological changes. In countries like Japan it is more difficult for fathers to spend recreational time with their children on weekdays due to work pressures. The number of working mothers is also growing in Japan further straining relations and communication between parents and children. This research aimed to analyze the effects of family sports participation on parent-child communication.
【Methods】
Participants included twelve children（4 males, 8 females, average age: 11.17 years old, and SD: 1.75） and eight parents （2 males, 6 females, average age: 43.25 years old, and SD: 3.45）. They participated in two, 2.5hour indoor climbing lessons that were designed to facilitate social interaction and trust. Validated questionnaires were administered to participants. Children answered the "Resilience Evaluation Scale for Children" （RESC） and the "Childrens Commitment Evaluation Scale for Parents" （CCESP）, while the parents answered "Child-Rearing Attitude Evaluation Scale for Parents" （CRAESP） and "Childrens Resilience Evaluation Scale for Parents" （CRESP）. Both parents and children were also asked to write their subjective impressions about the lessons and their relationship. Questionnaires were administered before the first lesson (Pre-test) after the final lesson (Post-test) and one month after the lesson completion (Follow-up test). Analyses included calculation of Cronbach's alpha scores for each scale, mean values and standard deviations, correlations between each scale for children and parents, and one-way repeated measures ANOVA to compare the results at pre-test, post-test and follow-up.
【Results】
The analyses of variance revealed that, with regards to "CCESP", 1） "Dependence on Parents" showed positive change immediately after and one month following the lessons. In relation to"CRAESP" 2） "Parents' Respect for Autonomy of Children," "Parents' Behavior Limits Children" and "Behavior Limitation Setting to Children" (subscales of CRAESP) showed positive changes immediately after and one month following the lessons.
【Discussion】
This research found that the climbing lessons became the opportunities to reconsider how parents' approached interactions with their children, and had positive effects on communication between participants, especially for parents. Usually, Japanese parents watch their children during sports practice, but have little direct recreational connection. By trying new sports activities together, such as climbing,

sharing experiences created an opportunity to change views about each other and influence parents' attitudes to child rearing. Sport climbing will be an official event from the Tokyo Olympic Games in 2020 and facilities will increase in Japan in the future. This preliminary research suggests that free climbing may have efficacy as a means to build relationships between parents and children.

DOES A BRISK WALKING PROGRAM IN POSTMENOPAUSAL WOMEN GENERATE SOCIAL HEALTH INEQUITIES?

GARNIER, S.1,2, JOFFROY, S.1,3, THON, B.1, AUNEAU, G.1, MAURIEGE, P.4

1 UPS, F2SMH, TOULOUSE - CRESCO FRANCE ; 2 GRAPA, MONTRÉAL, CANADA ; 3 ITO, TOULOUSE, FRANCE ; 4 UNIVERSITÉ LAVAL, DÉPARTEMENT DE KINÉSIOLOGIE, QUÉBEC, CANADA

Introduction: Reducing health inequalities is a major public health issue (WHO 2000). In France, the difference in life expectancy at age 35 is 7.5 years for men and 4 years for women between graduates of higher education and non-graduates (INSEE, 2016). Follow-up of an aerobic training program is a factor of health improvement in moderately obese postmenopausal women. Indeed, preferences for sport are part of the dispositions that constitute the habitus (Bourdieu, 1984). However, is this type of program more effective for the highest social classes women? Will it not increase social inequalities in health ?
The aim of this study is to evaluate the impact of a brisk walking program on physical cardiorespiratory fitness (CRF), body composition, perceived health, and adherence to the program of women, once social classes and educational levels are considered.
Methods: 168 sedentary and overweight-to-obese (mean body mass index, BMI = 30± 4 kg/m2) postmenopausal women (60±5 yr-old) were subjected to a 4-month endurance-training program (3 sessions of 45 min walking/week at 60 % of their heart rate reserve).
Following measurements were performed before and after the 4-month walking program:
. CRF assessed by the 2-km walking test (Roussel et al., 2009; Garnier et al., 2013),
. Body weight, height (BMI calculated) and waist circumference measured using standardized procedures (Roussel et al., 2009; Garnier et al., 2013),
. Fat mass and fat-free mass determined by bioelectrical impedance (Roussel et al., 2009; Garnier et al., 2013)
. Perceived health estimated by a visual analogue scale (six questions) (Garnier et al., 2013)
. Subjects' assiduity registered in an exercise logbook (Garnier et al., APRM 2015)
Results: Four months later, the decrease in body weight, BMI, fat mass, as well as the increase in CRF ($p<.001$) were not significantly different once social classes and educational levels were considered. However women with the highest education level showed the greatest reduction in waist circumference. Changes in perceived health ($p<.01$) and adherence to the program did not differ.
Discussion: It seems that our program does not increase health inequalities probably as brisk walking is also considered the most common feasible form of aerobic exercise for middle-aged women because of its safety (low risk of injuries), popularity (low cost) and accessibility to all publics and because the place of walking training was close to the subjects' residency.

INVESTIGATING THE RELATIONSHIP BETWEEN PHYSICAL ACTIVITIES AND MOTHERS' SUPPORT WITH RATE OF PHYSICAL ACTIVITIES IN YOUNG FEMALE STUDENTS

OSTOVAR, S., ASADOLAHI, M., NEZAMI, N., MIRAHMADI, M.

ISLAMIC AZAD UNIVERSITY CENTRAL TEHRAN BRANCH

Introduction: Physical activities positively influence on the humans' health, and it has particularly been found more essential for children. Numerous studies and researches have been conducted on supporting families to carry out such activities and they showed the impacts of parents' physical activities, particularly mothers, as an effective variable in increasing their daughters' physical activities (Hesketh et all., 2014)
Methodology:
The sample of the research included 121 female students at the age of 10 to 12 and their mothers which were selected by random cluster sampling method. The research instrument was a questionnaire on Sharki physical activities for assessment and evaluating the rate of physical activities of mothers and their daughters and a questionnaire of parents' support on physical activities. The research methodology was applicable and it was descriptive in correlation way, based on the data.
Pearson tests were performed to evaluate the correlation and linear regression models were used to describe the mathematical relation between variables and to calculate the determination coefficients. Also, ANOVA analysis helped to check for significance of regression coefficients
Research RESULTS: The results showed that the rate of daughters' physical activities is higher than their mothers and mothers; physical activities influence on their daughters physical activities(p= 0.00). Also there is a positive significant relationship between mothers' support and their daughters' physical activities(p= 0.00)
Discussion:
The rate of mothers' physical activities and amount of their support positively influence on the rate of their daughters' physical activities. The current research is eligible to be used in curriculum of schools in order to increase the rate of young female students and also in mothers' training and getting them involved in such physical activities curriculums.

EFFECTS OF ATTENTIONAL FOCUS AND PERSONALITY ON AFFECTIVE EXPERIENCE AND EXERTION AFTER ACUTE PHYSICAL ACTIVITY

MEIXNER, F., HERBERT, C.

INSTITUTE OF PSYCHOLOGY AND EDUCATION, ULM UNIVERSITY

INTRODUCTION: Long-term physical activity leads to a magnitude of positive health outcomes, benefitting not only physical health, but also psychological health (Petruzzello, Landers, Hatfield, Kubitz, & Salazar, 1991; Woll & Bös, 2004). In the short term, however, acute physical activity may have various consequences. While leaving some people active and energized, it can also lead to feelings of exertion, fatigue and negative mood in others. According to recent research literature, attentional focus during the activity (e.g., associative/dissociative strategies; Brick, MacIntyre, & Campbell, 2014; Lind, Welch, & Ekkekakis, 2009) and personality factors (e.g., Behavioral Inhibition / Behavioral Activation System (Hall, Ekkekakis, & Petruzzello, 2005; Schneider & Graham, 2009) according to the revised Reinforcement Sensitivity Theory (r-RST; Carver & White, 1994; Corr & Cooper, 2016; Gray, 1970) might prove to be potentially moderating variables.
METHODS: An experimental study (N = 15 female participants; repeated-measures design, 4 points of measurement for each participant) was conducted. Participants were asked to cycle on a stationary bicycle ergometer at moderate intensity (60-70% of HRmax), which was ensured by heart rate monitoring. During activity, the attentional focus of the participants (external/internal/no focus) was experimentally manipulated. A control condition without physical activity was included. Personality variables (e.g., r-RST) were assessed in an online questionnaire beforehand. At multiple times during the experiment, positive and negative affect, exercise experience and perceived exertion were recorded to measure the experience before, during, and after the activity.
RESULTS: Instructing an external focus or no specific focus resulted in an increased positive affect immediately after the physical activity, while an internal focus had no effects on positive affect, the inactive control condition displayed a decline in positive affect. Perceived exertion was generally higher after physical activity, but did not interact with attentional focus. Behavioral Inhibition (BIS) was negatively correlated with positive exercise experience during the internal focus condition. Behavioral Activation (BAS) was positively associated with favorable exercise experience during and immediately after the activity, but only when no specific or an internal focus was instructed.
CONCLUSION: The results obtained in this study suggest that instructing specific types of attentional focus might interact with personality variables to determine exercise experience and positive/negative affect during and following physical activity. This might help in understanding the link between certain personality traits and aversion towards physical activity, which consequently might lead to sedentary behavior (Schneider & Graham, 2009; Voigt et al., 2009). Manipulating attentional focus as a means to optimize exercise experience for people with certain personality traits is discussed.

BARRIERS TO PHYSICAL ACTIVITY FOR SEXUAL MINORITY WOMEN IN THE UNITED KINGDOM

WESTON, M., MULCAHY, A.

KINGS COLLEGE LONDON

Previous research suggests that sexual minority women (SMW) face specific barriers to physical activity in addition to those reported by other populations of women (Brittain et al, 2006, Women & Health, 43, 75-92). Research in this area is limited to the experiences of homosexual women, rather than women identifying as other minority sexualities, and findings are predominantly from the United States. Therefore the purpose of this study was to identify the factors affecting participation in physical activity, and how they are of influence, for SMW aged 18-25 living in the United Kingdom. A mixed methods explanatory design was adopted, comprising a 16-item questionnaire followed by semi-structured interviews. With institutional ethics approval, self-identifying SMW completed the questionnaire (N=100) and individuals were selected from the pool of respondents to participate in semi-structured interviews (N=10). Using Likert-type scales to investigate general and SMW-specific barriers, questionnaire respondents reported their physical activity levels and perceptions of how various factors influenced it. The interviews were audio-recorded and analysed using grounded theory analysis, grouping data into themes. When considered as a whole cohort, SMWs reported the most influential factors to be time, motivation, and tiredness. However, when considering those who had experienced homophobia in isolation, 'methods of addressing homophobia and sexism in physical education and sport' was reported as the most influential barrier. 47.0% of participants (N=47) indicated that they had experienced homophobia whilst participating in physical activity and, of that number, 68.09% (N=32) stated that this had affected their future participation. The latter group reported a lower average hours of physical activity, excluding walking, in the past week (2.6 hours) compared to 3.54 hours in the rest of the cohort. This was statistically significant (P = 0.048). Some of the common barriers identified following interview data analysis include: 1) navigating the intersecting identities of being both a woman and non-heterosexual; 2) discomfort in same-sex changing rooms due to sexual minority status; 3) the isolation associated with a 'masculine' appearance and subsequent assumptions about the individual's sexuality; 3) and 4) discomfort within a physical activity setting with men. One participant commented that "The locker rooms can be a hostile place for a gay person … I've experienced the worst homophobia in football". In conclusion, these results suggest an oversight when assessing the needs of SMW in sport and physical activity settings, associated with their experiences as a minority group, and this should be a focus for future research.

CHARACTERISTICS OF TWIN ATHLETES' INTERNAL EXPERIENCES BASED ON AUTOBIOGRAPHICAL MEMORIES

OKUDA, A., NAKAGOMI, S.

BIWAKO-GAKUIN UNIVEWRSITY, KOKUSHIKAN UNIVERSITY

INTRODUCTION: The motivation of athletes to perform over the long term is influenced by various psychosocial factors. Investigating these factors may contribute to a better understanding of their motivation to continue playing and striving for performance improvement. Based on autobiographical memories of monozygotic twins athletes who had continued to play the same sports over an extended period of time, this study explored some of the characteristics of these internal experiences.
METHODS: Study participants are 12 monozygotic twins athletes (6 pairs: 3 male and 3 female) who had played on college or corporate sports teams. Participant's identical twin status was verified by medical questionnaires. Individual interviews were conducted with each

athlete, asking questions about their autobiographical memories. Questions were asked about proto-scenery from their childhood (i.e., memories of various types of scene), proto-experiences in sport (i.e., memories of play and physical activities), the twin sibling relationship at the time their life-path decision-making, their continued involvement in their sport of choice, and the significance of each other's existence.
RESULTS: Results of qualitative analysis of the interviews demonstrated that their memories of their proto-scenery appeared to be highly dynamic with many sport-related elements mentioned. Both twins in 4 out of the 6 pairs mentioned each other's existence in their proto-scenery. In addition, 10 participants described proto-experiences in sport and stories of successful sport activities from memories of their earliest developmental stage. With respect to twin sibling relationships at the time of life-path decision-making, results suggest that the joint existence of each twin as a role model for the other played a part in career path selection and continued involvement in sports. The complementary nature of these relationships was often mentioned: "We have always played together," and "I am always encouraged by being in this together."
CONCLUSION: The subjects of this study were monozygotic twins that closely resemble genetically and environmentally.Characteristics of the internal experiences of these participants may help us understand the psychosocial factors involved in the continued involvement in sports of other athletes as well. In particular, the twin sibling relationship explored in this study could be considered as a potential role model for relationships between athletes and their significant others, including the important relationship between athletes and their coaches.

THE EFFECT OF STATUS AND POWER ON DISTRIBUTIVE JUSTICE

HUANG, L.W., LIAO, C.M., SHEN, W.C.
NATIONAL TAIWAN SPORT UNIVERSITY

Introduction: In an organization, authority's hierarchy has been the significant dominant of fairness owing to its demonstrated relation to resource allocation and subordinate's justice perception (Fast, Halevy, & Galinsky, 2012). It is considered, subordinates perceive differences in outcomes as fair depending on the different level of authority's concern on hierarchy (Blader & chen, 2012). In particularly, status (i.e., the prestige, esteem, respect and admiration from others) and power (i.e., control over critical resource), the 2 major components of hierarchy, represented different concerns of authority and different way in resource allocation, consequently, might lead to different impacts on subordinate's justice perception. However, systematic research attempt to compare the effect on fairness from different components of authority's hierarchy is relative scarce. The present study aimed to exam the effect of coach's status and power on athlete's distributive justice in sport team.
Methods: In the first stage, 34 recruited physical education teachers and coaches were randomly assigned to either status or power group. They were asked to play a role of a head coach and make allocations on champion prize ($75,000) to head coach, assistant coach and six athletes (including five finalist and one preliminary), and then complete questionnaire for manipulation check. 3 categories (baseline, status and power condition) of allocation patterns were conducted after allocation decision. In the second stage, we recruited 64 athletes (Mage=18.13, SD=2.71) to play the role of the athletes of the champion team and rank the fairness of the 3 different allocation decisions with 11-point scale, 0 (very unfairly) to 10 (very fairly).
Results: A series of independent t-test confirmed the success of manipulations. Participants in the status condition ($M = 5.81$, $SD = 1.31$) indicated that they had significantly more status than those in the power condition ($M = 4.73$, $SD = 1.39$), $t = -2.43$, $p = .02$, $\eta 2 = .16$. Similarly, participants in the power condition($M = 4.58$, $SD = 1.39$) had more power than those in the status condition($M = 3.30$, $SD = 1.22$), $t = 2.72$, $p = .01$, $\eta 2 = .19$. A one-way repeated measure ANCOVA was conducted to test the difference of justice perception between status and power. The result revealed that athlete's distributive justice in status condition ($M = 5.47$, $SD = 1.67$) is greater than in power condition ($M = 4.03$, $SD = 1.82$), $F = 20.12$, $p < .001$, $\eta 2 = .14$.
Discussion: Our study showed strong support that athletes' distributive justice perceptions were influenced by different dimensions of hierarchy. Compared the decision made by a coach who highlighted dominant critical resourced, the decision made by a coach highlihighlighted esteem and reputation was perceived more distributive justice by athletes. Further researches are warranted to explore the different effect status and power on other justice dimensions.

FOREIGN PLAYERS ARE GAME-CHANGERS IN CHINA FOOTBALL SUPER LEAGUE? — AN ANALYSIS OF PLAYERS' ROLES INSIDE PASSING NETWORK

GAI, Y., CUI, Y., GONG, B., YI, Q., GÓMEZ, M.A.
FACULTAD DE LA CIENCIAS ACTIVIDAD DE FÍSICA Y DEL DEPORTE

Introduction: Computer-based approaches have been applied to collect and analyse technical, tactical and physical aspects in team sport, especially in football. Recently, the general structure of football teams and connections among players during match-play were investigated using social network analysis. This body of research helped to understand the most prominent players' positions that best contributed to the build of attack in football and investigated the number of passes per minute and the clustering coefficient of teams during the FIFA World Cup. However, given the fact that many foreign elite players were transferred into Asian clubs, the research knowledge about the influence of foreign players on passing network in Asian professional football leagues is unknown. Therefore, the study was aimed to investigate the passing network features of teams from China Football Super League (CSL).
Method
Detailed inter-player passing statistics of a total of 211 matches from the China Football Super League (first division) 2017 season were tracked and provided by Champion Sports Information Technology Co., Ltd. through a validated data collection system. The data included 64,221 passes of 374 players (286 domestic and 88 foreign) from all 16 teams in the league. The inter-player's passing count less than 5 passes was excluded. Afterwards, thirteen passing network related variables that measure player's prominence inside a team's network were calculated and were compared between domestic and foreign players via standardized (Cohen) mean differences, computed with pooled variance and respective 90% confidence intervals (CL). Uncertainty in the true differences of the comparisons was assessed using non-clinical magnitude-based inferences.
Results: Foreign players presented higher values than domestic players in closeness (difference in means: 0.06; ± 90% CL: ± 0.03; inference: possibly), stress centrality (1.96; ± 0.94; possibly), directed edges (0.68; ± 0.23; likely), in-degree (0.35; ± 0.13; likely), out-degree (0.33; ± 0.14; possibly), betweenness (0.04; ± 0.01; likely) and number of passes received per match (2.46; ± 1.07; possibly). While domes-

tic players had a higher value of neighborhood connectivity than foreign players (0.29; ± 0.12; possibly). There were trivial differences between two groups of players in the other variables.
Conclusion
Using social network related metrics is helpful to identify how players connect with each other and compare the strength of the connection between domestic and foreign players. Foreign players played a prominent role in the offensive play of CSL teams and contributed to the build of attack. However, cautions should be taken for stake-holders of the league and clubs, given that an over-relying on foreign players would probably hinder the development of domestic players. This study provided useful information for coaching staffs in training and preparing the appropriate strategies during the matches.

AN ANALYSIS OF THE KEY FACTORS IMPACTING UPON THE COMPETITIVENESS OF CHINESE SUMMER OLYMPIC SPORTS

WANG, J.
TIANJIN UNIVERSITY OF SPORT

An Analysis of the Key Factors Impacting upon the Competitiveness of Chinese Summer Olympic Sports
Jian WANG et al
Introduction: China, since it rejoined the Olympic Games in Los Angeles 1984 has, with the exception of Seoul 1988, consistently ranked in the top 4 medal positions in the summer Olympic Games. Consequently, planning a sustainable development of Olympic sports in China has become an important task . However, China's Summer Olympic medals have been confined to a limited number of events most of which are not core Olympic sports such as athletics. This suggests that any sustainable success requires a restructuring of the Chinese Olympic sports development strategy in order to broaden the base of Olympic sports thereby facilitating the achievement of medal in sports previously considered unworthy of investment whilst increasing the overall medal count.
This research project employed survey research design techniques to critically analyse the current strategy for the development of Chinese Olympic sport and subsequently to identify the key factors impacting its effectiveness at the Olympic Games.
The research objectives were to identify:
1. the key impact factors determining China's medal count at the 27th & 31st Olympic games;
2. the barriers hindering the sustainable development of Chinese Olympic sports;
3. the sports events to be prioritized which could ensure an increase in medals at the next Olympic games.
Method
1. Documentary evidence regarding the top 8 of every event in 25th -31st summer Olympic Games. Relevant data were collected.
2. A questionnaire survey was distributed to 51 randomly selected experts in the field of Olympic sports in China.
3. The questionnaire consisted of 24 opened questions.
Results: The key findings:
1. The medal count in the 25th -31st summer Olympic Games evidenced as flat &/or declining.
2. The medals were concentrated in a minor of sports e.g. Table Tennis, Badminton, Gymnastic , Shooting, women's Judo and women's Weightlifting.
3. The medal count was equally distributed between men and women athletes.
There are barriers impacting the sustainable development of summer Olympic sports in China:
1. Shortage of talent pools;
2. The coaching knowledge and techniques are dated;
3. The Athletics events are remaining disadvanced position in the competition.
Discussion and suggestions
The strategic planning of Olympic sports development in China is a big project . This research was limited, however, on Olympic sport events analysis, the results only reflect issues directly impacting sport events development. The research made the following suggestions:
1. To prioritize women's events, e.g. team events which will be more effective in achieving medal success.
2. Preparation should focus on:Diving, Gymnastics, Table Tennis, Weightlifting, Shooting and Judo,Swimming, Athletics et

CP-SH02 Stress process and imagery in sport

PERFORMANCE AT A COST: AN EXAMINATION OF CONTINUOUS PERFORMANCE UNDER PRESSURE PUTTING HEALTH AT RISK PARTICULARLY FOR THOSE HIGH IN NARCISSISM

BARWOOD, C.
BANGOR UNIVERSITY

In most life domains excelling under pressure is seen as an advantage. However, high performance requires chronic engagement with stressors, and it is not clear whether this sustained performance may harm one's health. Individuals with extreme reactions to stress may be more susceptible to health problems that stem from high performance(Cheng, Tracy, & Miller, 2013). We examined whether narcissism moderated the performance-health relationship. We hypothesised those with high trait narcissism would be more susceptible to health problems due to their extreme stress reactions and increased effort when performing under pressure.
We used the openly available Addhealth database, (Harris et al., 2009), a longitudinal study of Americans. We measured performance via education and earnings, trait narcissism with the Addhealth narcissism scale (Davis & Brunell, 2012) and health in two ways; Diabetes was a dichotomous variable (diabetic or not) calculated by combining serum glucose and Haemoglobin A1C%, self-report history of diabetes, and anti-diabetic medication use. High cholesterol risk (HCR) was calculated from a range of serum lipid measures which were combined and dichotomised (high or low risk).
Significant moderating effects of trait narcissism were found when using education as the performance measure for both diabetes and HCR. Overall the models were significant (Hosmer & Lemeshow X2 =9.37,2.18 p=.31,.96 respectively). The regression analysis had significant effects for trait narcissism LLCI=.30, ULCI.50 and the interaction (educ*narc) LLCI=-.50, ULCI=-.06. Simple slopes analysis of the moderation showed no significant effects however Johnson-Neyman follow-up showed two regions of significance. The first region was ≥ -

1.62SD below the mean of narcissism; a significant positive moderation increasing the relationship between education and HCR, LLCI=.00,ULCI.=.88. The second region was ≥ 1.02SD above the mean of narcissism; a significant negative moderation decreasing the relationship between education and HCR, LLCI=-.61,ULCI=.00. When substituting trait narcissism descriptive statistics back in a score of ≤29 increases the positive relationship between education and HCR and a score ≥43 negatively decreases the relationship between education and HCR. The earnings model moderating effects were consistent with those of the education model. Similar results were seen for diabetes, simple slope analysis of the interaction showed significant moderation at low and average levels of narcissism LLCI= .05 and .01 respectively and ULCI= .83 and .52 respectively.
Results suggest those who are high performers are more at risk of diabetes and high cholesterol if they are low in trait narcissism. However, individuals high in trait narcissism don't have a increase in diabetes or risk of high cholesterol as education or earnings increases. This suggests there is a performance health trade-off and that narcissism has a protective role narcissism in this relationship.

PERFECTIONISM MEDIATES THE RELATIONSHIP BETWEEN INTOLERANCE OF UNCERTAINTY AND FEAR OF FAILURE

NIETO, M., JONES, E., VOSLOO, J., HARENBERG, S.

ITHACA COLLEGE

Introduction: The outcome of sport competitions is inherently uncertain. Athletes have to manage the perceived outcome uncertainty regularly. However, athletes, who are intolerant of uncertainty, may experience heightened maladaptive emotions (e.g., fear of failure, anxiety; Robinson & Freeston, 2015). It is very likely that various personality characteristics (e.g., perfectionism) may influence this relationship, however, empirical evidence on this topic is sparse in the current literature. Hence, the purpose of the present study was to examine if perfectionism mediates the relationship between intolerance of uncertainty and fear of failure.
Methods: Two hundred and forty-two NCAA Division III athletes (female n=131; Mage = 19.37±1.13; MYear of Study = 2.13±1.04) from track and field (n=60), swimming and diving (n=46), soccer (n=43), crew (n=40), lacrosse (n=33), gymnastics (n=20) teams participated in the study. The participants completed the Sport Multidimensional Perfectionism Scale-2 (Gotwals & Dunn, 2009), the Intolerance of Uncertainty Scale (Carleton et al., 2007), and the Performance Failure Appraisal Inventory (Conroy, 2001). Structural Equation Modeling (SEM) with Test of Joint Significance (TJS) was used to analyze the data.
Results: SEM revealed that intolerance of uncertainty predicted 29% of the variance of fear of failure (=.54, p<.001). TJS showed a full mediation of this relationship by perfectionism. The mediated model showed an acceptable fit (2/df = 3.40, CFI = .91, TLI = .86, RMSEA =.10, CI90%=.08-.12) and explained 60% of the variance of fear of failure (s=.60-.69, p<.001).
Discussion: The present study provides further evidence that personality factors may influence maladaptive emotions (i.e., fear of failure) towards the uncertainty of athletic competitions. In particular, perfectionism seems to play a central role in this relationship. The evidence from this study may inform counseling methods to target intolerance of uncertainty and perfectionism in order to optimize athletes preparation for competitions. Further reserach could examine the effectiveness of such interventions. In addition, future research should explore other personality factors that may influence athletes emotions towards competition. Limitations of the present research are discussed.

THE EFFECTS OF DIVING EXPERIENCE AND PERSONAL ANXIETY STATE IN SCUBA DIVERS

CHEN, C.Y., TSAI, F.H., CHEN, T.Y., LIANG, J.M., HSU, H.T., WU, W.L.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Scuba diving has become increasingly popular in recent years. There were some dangers and risks are presented by factors such as hydraulic pressure, water temperature, experience or personal anxiety level. Previous researches have reported that experience and anxiety would be related to underwater performance (Kneller et al., 2012; Morgan, 1995; Paulsen & Trevor, 2017; Steinberg & Doppelmayr, 2015). However, there were some inconsistent results due to different participant's age ranges, test environments, and testing tools. Therefore, this study involved using the same age group, test environment, and test methods to explore how diving experience and individual anxiety levels affect diving performance.
METHODS: 34 novice divers (23 male and 11 female, mean age = 23.5 ± 5.4 yr with 5.26 ± 3.56 logged dives) and 21 experienced divers (18 male and 3 female, mean age = 23.2 ± 4.1 yr with 418.76 ± 940.51 logged dives) were enrolled in this study and scuba diving performance was measured in a pool (2 m depth). The standardized scuba diving skills in the Scuba Schools International (SSI) dive guide involved mask clearing, buddy breathing, regulator recovery, and buoyancy control. The completion time of each skill and the total time were recorded by a diving instructor. Participants had to complete a trait-anxiety questionnaire and were subdivided into two groups on the basis of having trait anxiety scores either above or below 39. Two-way ANOVA was conducted using the two factors, diving experience and trait anxiety, and the score was used to analyze the difference in scuba performance. Statistical significance was set at p values < 0.05.
RESULTS: The two-way ANOVA analysis indicated that dive experience significantly affected the buddy breathing ($p < 0.01$) and total time ($p < 0.01$), and trait anxiety level significantly affected the completing time of mask clearing ($p = 0.02$) and regulator recovery tests ($p < 0.01$).
CONCLUSION: The results of the present study suggest that diving experience and personal anxiety level both affect recreational scuba diving performance. Emergency situations such as choking on inhaling water during mask clearing or losing a regulator may increase psychological stress and negatively affect underwater performance for individuals with higher trait anxiety scores. In addition, continuous practice is necessary to retain diving skills and is particularly valuable when divers are beginners.

THE VALIDATION OF THE CHINESE VERSION OF SPORT COURAGE SCALE

HSU, C.H., PENG, Y.C., LIAO, C.M.

1: CARDINAL TIEN JUNIOR COLLEGE OF HEALTHCARE AND MANAGEMENT 2: NATIONAL TAIWAN UNIVERSITY OF ARTS 3: NATIONAL TAIWAN SPORT UNIVERSITY

The Validation of the Chinese Version of Sport Courage Scale

Chih-Hao Hsu,1 Yi-Chen Peng,2 and Chu-Min Liao3
1: Cardinal Tien Junior College of Healthcare and Management (Taiwan)
2: National Taiwan University of Art (Taiwan)
3: National Taiwan Sport University (Taiwan)
Abstract
Introduction: Sport is a highly competitive environment and it takes great courage for athletes to overcome numerous setbacks before achieving the highest achievement. Courage refers to the voluntary willingness to act in response to a threat to achieve an important goal (Pury, & Lopez, 2011). This great virtue of a champion, however, has not been systematically and thoroughly studied in sport. So far, only Konter and Ng (2012) have attempted to explore the nature of courage of athletes and developed a Sport Courage Scale (SCS). SCS comprised five sub-scales labelled "determination", "mastery", "assertiveness", "venturesome", and "sacrifice behaviors". This study was an exploratory validation of a Chinese version of SCS with a sample of Taiwanese athletes.
Method
Items of SCS (English language) were translated into Chinese language (traditional font) with a back-translation procedure and administrated to 207 Taiwanese collegiate athletes (male=148, female=59; mean age=20.29, SD=1.73) of an average of 8.6 years of sports experiences (SD=2.92) from 10 sport teams. Exploratory factor analysis and item analysis were conducted given that this was a cross-cultural validation and changes in factor structure were possible.
Results: Results revealed a 4-factor structure with a total of 54.78% variance accounted and sub-scale internal consistency coefficient ranged from .66~.82. The four factors were "determination", "mastery", "assertiveness", and "venturesome" and were in line with four of the five sub-scales in the original SCS. All the four items from "sacrifice behaviors" of the original SCS were contained in either the "determination" or "venturesome" sub-scale.
Conclusion
The results provided preliminary support for the validity and reliability of the 4-factor, 18-item Chinese version of Sport Courage Scale (CSCS). The drop of the "sacrifice behaviors" sub-scale from the original SCS may due to the inadequate internal consistency of the original sub-scale (α = .61) and/or the possible cultural differences between the sample of Konter and Ng's work and our study. Further examination of criterion-related validity and cross-validation on more samples from various backgrounds are warranted.

THE RELATION BETWEEN ACTION ORIENTATION AND RUMINATION IN COMPETITIVE SPORTS

KRÖHLER, A., BERTI, S.

JOHANNES GUTENBERG-UNIVERSITY MAINZ

INTRODUCTION: Frequently athletes report that their thoughts revolve around the future or past and not around the here and now during competitions. Here the question arises whether there is a relation between the distraction of thoughts and other personality traits. The theory of action control (Kuhl, 1983) distinguished between action and state orientation, two action intentions that promise a further starting point. State orientation is described as ruminative cognitions about past, present and future states that inhibit the individual action readiness and implementation (Dibbelt & Kuhl, 1994). So far, there are little empirical results of this postulated relation. In the present study, we investigated the direct relationship between failure-related action orientation (HOSP: Beckmann & Wenhold, 2009) and rumination in competitive sports assessed by three rumination questionnaires, a general (PTQ, Ehring et al., 2011), a clinical (RRQ, König, 2012) and a competition-related one (modified from Krys et al., in prep.).
METHODS: Within a period of three months (October – December 2016) 157 athletes from different sports (77 males and 80 females) participated in an online-study. Mean age was 21.57 years (range 15-30 years, SD = 3.63). Overall 120 of the participants were squad athletes or did their sports on a comparable level. The athletes averaged 13.40 of competitions (SD = 8.02) per year.
RESULTS: Results of the (robust) regression analysis confirmed that action orientation is a significant predictor for rumination (PTQ: R^2adj. = .23, β = -.46, $p < .001$; RRQ: R^2adj. = .22, β = -.48, $p < .001$; competition-related rumination: R^2adj. = .24, β = -.50, $p < .001$).
CONCLUSION: Results confirm the assumption that failure-related action orientation is associated to rumination in general as well as in a specific competition context. Our results complement studies that report relations between action orientation and differences in athletic behavior. Moreover, the results support the assumption that rumination might be a relevant factor in competitive sports.

PREDICTORS OF PRECOMPETITIVE ANXIETY IN DOG AGILITY HANDLERS

STONE, S.1, HARENBERG, S.1, VOSLOO, J.1, WOLF, S.2

1ITHACA COLLEGE; 2UNIVERSITY OF AMSTERDAM

Introduction: Dog agility is a growing sport that requires directive human-dog interaction under competitive pressure. To date, the sport has been largely ignored by sport psychology research even though the dyadic relationship between the dog agility handler and the canine is complex and may provide unique psychological challenges in the preparation for competition. The purpose of the present study was to examine whether precompetitive appraisal, personality traits (i.e., trait anxiety, intolerance of uncertainty) and situational characteristics (i.e., canine precompetitive emotions) predict precompetitive anxiety in dog agility handlers.
Methods: Eighty-one dog handlers (female n=76; MAge=44.63±14.29; MExperience=13.62±6.57) completed the Precompetitive Appraisal Measure (Wolf et al., 2015), the anxiety subscale of the Sport Emotion Questionnaire (Jones et al., 2005) for the handler and canine, the Three Factor Anxiety Inventory (Cheng et al., 2009), and the Intolerance of Uncertainty Scale (Carleton et al., 2007) immediately (i.e., under 2 hours) prior to performing in a regional championship.
Results: A multiple regression model with handlers precompetitive anxiety as the criterion and precompetitive appraisal, personality characteristics, and situational characteristics as predictors accounted for 50.6% of the variance in precompetitive anxiety ($F(8,70)=8.96$, $p<.001$). The significant predictors included cognitive competitive trait anxiety (=.39, p=.002), inhibitory intolerance of uncertainty (=.23, p=.029), and the dogs precompetitive anxiety (=.20, p=.032).
Discussion: The tested model predicted half of the variance in dog handlers precompetitive anxiety. The individual predictors imply that both stable factors of the handlers personality and dynamic situational characteristics need to be considered in the precompetitive preparation of the dyadic pair. From an applied perspective, the findings suggest that interventions should target dog agility handlers pre-

competitive emotion regulation to optimize preparation for performance. Future research could explore further psychological processes in order to optimize the performance interaction between handler and canine.

TRAIT EMOTIONAL INTELLIGENCE, MOOD STATES & CORTISOL RESPONSE TO A TREADMILL ULTRAMARATHON.

HOWE, C.C.F.1, PUMMELL, E.1, PANG, S.2, SPENDIFF, O.1, MOIR, H.J.1

1: KINGSTON UNIVERSITY, , 2: LGC,

INTRODUCTION: Ultramarathon competitors experience & have to manage & overcome a complexity of physiological & psychological stresses. Trait emotional intelligence (TEI) is an individual's perception & understanding of how their emotions impact their thoughts & behaviours during competition & plays an important role in their ability to employ strategies to regulate them. The aim of this study was to investigate TEI & its effect on performance, mood states & serum cortisol levels over an 80.5km treadmill ultramarathon.
METHODS: Twelve ultramarathon runners completed an 80.5km time-trial on a treadmill & were instructed to cover the distance in the fastest possible time. Runner TEI was measured using the 33-item emotional intelligence scale (Schutte et al., 1998) prior to the trial. A mood state questionnaire (BRUMS: Terry et al., 2003) was completed prior (baseline), immediately before (pre), at 40.25km (halfway) & on completion of 80.5km (post), as were serum cortisol concentrations, measured by competitive ELISA-type electrochemiluminescence assay.
RESULTS: Average completion time was 09:00:18±01:14:07 (hh:mm:ss), at a running velocity of 9.8±1.3km.h-1. Increases in serum cortisol were observed between pre & halfway, & between halfway & post time points ($p=0.001$ & $p=0.003$, respectively). Significant decreases were observed between both baseline & pre time points compared to the post time point for 'Vigor' ($p=0.015$ & $p=0.01$, respectively). Significant increases were also identified for 'Fatigue' between pre & halfway, &, pre & post ($p=0.05$ & $p<0.01$ respectively), along with halfway to post ($p=0.02$). Runners with higher TEI displayed greater post serum cortisol levels ($r=0.78$, $p>0.001$). Significantly higher total mood disturbance (TMD) was also observed between baseline & post, as well as between pre & post time points ($p=0.001$).
CONCLUSION: The findings of the current study highlight the complex interactions of both physiological & psychological stresses imposed by an ultramarathon, demonstrated by the expected increase in fatigue & decrease in vigor over the course of the ultramarathon. Participants with a higher TEI displayed greater post-trial cortisol responses which may suggest that they are more aware of their emotions during an ultramarathon. These findings may give insight into what draws individuals to the sport of ultramarathon running, help to identify the stressors they face & further help develop strategies to aid both completion & performance in ultramarathon events.

THE EFFECT OF THE MENTAL IMAGE OF CLIMBING HOLDS IN MOTOR PREPARATORY INFORMATION PROCESSING

SUGI, T., ISHIHARA, M.

TOKYO METROPOLITAN UNIVERSITY, GRADUATE SCHOOL OF HUMANITIES .

Introduction: The mental image of an action has an effect on motor performance. In free-climbing, the image of climbing holds to grasp is important for a climber's performance(e. g., Bläsing et al., 2014). In the present study, we investigated whether such an imagery would facilitate the motor preparation of the action.
Method
Nine climbers participated in the experiment. The task was to react, by pressing the response button, to a visual stimulus presented on a computer display. The visual stimuli were composed of climbing holds (serving as a prime stimulus) and left or right arrow (serving as a target). The climbing holds as the prime were one (i.e., baseline block) or two (i.e., experimental block). The orientation of the hold was experimentally manipulated, these were either the up, down, left or right orientation (randomly presented). The participants were instructed to imagine themselves grasping the prime holds. There was another experimental condition about the "touch", participants were asked to touch a real climbing hold (i.e., touch condition) or just simply no-touch (just watching the hold, i.e., no-touch condition) in each trial of the experiment. The order of the touch/no-touch conditions was counterbalanced in two different days. The reaction times (RTs) were measured in each individual as the time from the target onset to the button pressing. In the experiment, participants were asked to stand in front of the computer display and press one of two buttons (left or right) to the given target as quickly and accurately as possible. After finishing the trial block, participants were asked to answer questions about the task. The RTs obtained from each participant were fed into the analyses of variance.
Results: The difference of the mean RT (dRT) between the experimental block and the baseline showed a congruency effect. The dRTs for the congruent condition appeared to be faster than that for the incongruent condition [$F(1, 8) = 3.61$, $p = .094$]. The facilitatory effect may be due to the influence of the mental image on the appropriate motor preparation to grasp the holds. There was no significant main effect or related interaction for the touch condition (i.e., touch vs. no-touch).
Conclusion
The results suggested that the climbers' mental image of a given action would be mediated by the holds' orientation and/or distribution. The congruity effect observed in the dRTs can be thought to reflect the mental action-related facilitation of the preparation for the appropriate action. The image of the climbing hold's orientation on the climbing wall may contribute to the improvement of the climbing action, such as grasping.

CHANGES IN MOVEMENT IMAGERY DURING THE TRAINING OF AN ELITE PLAYER WITH CONGENITAL BLINDNESS

MOMOSE, Y.

TOKOHA UNIVERSITY

Changes in movement imagery during the training of an elite player with congenital blindness
Momose, Y.1, Ito, H.1, 1: Tokoha University (Shizuoka, Japan)
Introduction: How does a soccer player with congenital blindness, who does not have any visual information, visualize while playing the sport? Is imagery training effective for a person with visual impairment? This study investigates the changes in movement imagery during the training of a Japanese elite soccer player with congenital blindness.
Methods: The subject was a Japanese elite soccer player who was diagnosed with early stage congenital blindness at age two. The measurements were carried out twice: once during the novice period and once at the competitive stage. We also conducted an interview using Personal Attitude Construct analysis to understand the imagery of the player in aggressive situations in the game. The first eight months, where the soccer player participated in only two games, was termed as the novice period. The competitive period was the time when the subject was elected as an all-Japan upbringing reinforcement player a year later.
Results: The main results were as follows: During the novice period, the player was able to receive a pass by only following auditory directions from a guide and callers. On the other hand, during the competitive period, he gathered essential information for an attack by relying on the sound of the ball and the sign-in-action of his supporters and opponents.
Discussion: These results suggest that the imaging of a Japanese elite soccer player with congenital blindness depends on the following: (1) only listening to auditory direction, using which three passes were made—one spatial, one detailed, and one spontaneous—and one shot was attempted to score a goal, and (2) effective use of external imagery, internal imagery and spatial imagery (Momose and Ito, 2017).

DEVELOPMENT OF CHINESE VERSION OF "MOVEMENT IMAGERY QUESTIONNAIRE-3"

CHEN, J.Y., CHI, L.K.

NATIONAL TAIWAN NORMAL UNIVERSITY

Development of Chinese Version of "Movement Imagery Questionnaire-3"
Jo-Yun, Chen., Li-Kang, Chi
NTNU (Taipei, Taiwan)
Introduction: Previous studies have proved that imagery can facilitate motor skill learning and performance (Cumming & Williams, 2012; Koehn, Morris, & Watt, 2014). Moreover, imagery ability is essential to ensure the effect of imagery. Therefore, a valid and reliable inventory to measure the movement imagery ability is critical. In order to assess Taiwanese athletes' ability of movement imagery, Movement Imagery Questionnaire-Revision (Hall & Martin, 1997) has been frequently used. However, Movement Imagery Questionnaire-3 (Williams, et al., 2012) has indicated as a better instrument to measure movement imagery ability. The purpose of the present study was to develop a Chinese-Version Movement Imagery Questionnaire-3 (CMIQ-3), and to examine its reliability and validity.
Methods: Participants were 190 college student-athletes (male= 107, female=83) recruited from 7 colleges in Northern Taiwan. After receiving the informed consent, all participants were asked to complete Chinese-Version Movement Imagery Questionnaire-3.
Results: The confirmatory factor analysis was conducted to examine the factorial validity and reliability of the CMIQ-3. The results indicated that the three-factor measurement model of CMIQ-3 (kinesthetic imagery, internal imagery and external imagery) has shown acceptable goodness-of-fit indices ($\chi 2$=45.59 df=32, CFI=.97, NFI=.91, TLI=.96, RMSEA=.047). Regarding the reliability of CMIQ-3, the composite reliability for the subscale of kinesthetic imagery, internal imagery, and external imagery are .76, .69, and .66 respectively.
Discussion: Our findings concluded that CMIQ-3 is a valid and reliable inventory which can be used to measure Taiwanese student-athletes' movement imagery ability.

RELATIONSHIPS BETWEEN FORMS OF MOTIVATION AND TEAM COHESION AS A FUNCTION OF COMPETITION LEVELS IN YOUNG SOCCER PLAYERS

RÓDENAS, L.

AUTONOMOUS UNIVERSITY OF NUEVO LEON

RELATIONSHIPS BETWEEN FORMS OF MOTIVATION AND TEAM COHESION AS A FUNCTION OF COMPETITION LEVELS IN YOUNG SOCCER PLAYERS

Ródenas, L.1, Castillo, I.2, Galilea, G.3, Soler, M.J.2, Duda, J.L.4, & Balaguer, I.2

1: Autonomous University of Nuevo Leon (Mexico), 2: University of Valencia (Spain), 3: Catalan Sports Council, Barcelona (Spain), 4: University of Birmingham (United Kingdom)

Introduction: Researches have consistently found significant correlations between forms of motivation and types of cohesion in the sport domain. However, little evidence exists about the role of different competitive levels in these relationships. The purpose of this study was to examine whether the relationships between forms of motivation (autonomous, controlled and amotivation), and perceptions of team cohesion (task and social) would vary as a function of two different competition levels: 'alevin' (under 11) and 'infantil' (under 13) or remains invariant despite the competition level.

Methods: Participants were 809 young soccer players (391 alevin and 481 infantil) ranged in age from 9 to 13 years old (M=11.49, SD=1.16) represented 12 different Spanish soccer schools, who completed a questionnaire package tapping the variables of interest.

Results: The results obtained using moderated regression analysis (PROCESS macro for SPSS) showed that competitive level did not significantly moderate the relationship between each of three forms of motivation and task cohesion; and between autonomous motivation and social cohesion. The model showed that autonomous motivation positively predicted task and social cohesion, despite the level of competition.

With respect to the relationship of the other forms of motivation (controlled motivation and amotivation) and social cohesion, competition levels significantly moderate these relationships. Concretely, in 'alevin' category, controlled motivation was positively related to social cohesion, whereas in 'infantil' category this relationship was non-significant. In addition, in 'infantil' category, amotivation was negatively related to social cohesion, whereas in 'alevin' category, this relationship was non-significant.

Discussion: The effect of autonomous motivation on task and social cohesion remain invariant despite the competition level. However, for social cohesion a moderating effect was produced, indicating that controlled motivation (in a positive sense) and amotivation (in a negative sense) have an impact on predicting social cohesion for 'alevin' and 'infantil' categories. Overall, our findings are suggestive of the importance of fostering autonomous motivation, despite categories, as may contribute to more positive social and task cohesion in sport teams.

TEAM DYNAMICS, EMOTIONAL INTELLIGENCE AND THE COHESION LEVEL GENERATED BY THE COACHES

REYES HERNÁNDEZ, O.1, TRONCOSO AVALOS, S.1, GARCIA-MAS, A.2, LÓPEZ-WALLE, J.1

1.UNIVERSIDAD AUTÓNOMA DE NUEVO LEÓN 2.UNIVERSITY OF THE BALEARIC ISLANDS

The present investigation examines how the trait emotional intelligence coachs and cohesion level (group environment) generated by a coach directly predicts the psychological dynamics of their teams. For this study, the sample was of 33 coaches (Mage = 39.42, SD = 9.81) and 370 athletes (Mage = 20.99, SD = 2.14) from 33 teams of sports teams. The coaches have an average of 8 years of experience (SD = 5.19). The instruments used were the Group Environment Questionnaire (GEQ, Carron, Wildmeyer and Brawley, 1985), the Trait Emotional Intelligence Questionnaire - short form (TEIQue-sf; Petrides and Furnham, 2006) and the Cooperative Workteam Questionnaire (CWQ; Olmedilla, García-Mas, Luo, Llaneras, Ruiz Barquín and Fuster-Parra, 2016). The obtained results show that the Emotional Intelligence in its subscale of Autocontrol positively predicts the Global Cooperation in its "As a player" form (B = .41, p <.05) and in the group environment subscales of task group attraction (B = .46, p <.05) and task group integration (B = .42, p <.05). While the Global Cooperation in its "As if was Coach" form positively predicts the task group Attraction (B = .45, p <.05). On the other hand, Personal Growth in its "As a Player" form positively predicts the task group Integration (B = .38, p <.05) and in its "As if was Coach" form with the task group Attraction (B =. 37, p <.05). Finally, the Emotional Intelligence in its subscale of Self-control positively predicts the Conditional Cooperation from the perspective "As a player" (B = .39, p <.05). According to the results, it can be concluded that when an athlete is trained by a coach who has control over their emotions and impulses, they will value the cooperation that their teammates have with the team. Likewise, it will tend to generate a greater task cohesion and will be willing to cooperate in group activities when their teammates are involved in participation. Finally, the fact that a player perceives personal growth in his group (both from the perspective of player and coach) predicts the cohesion towards the task.

RELATIONSHIPS BETWEEN PROACTIVE PERSONALITY AND 2X2 ACHIEVEMENT GOALS AMONG WOMEN'S BASKETBALL PLAYERS

CHIA-YU, H., LI-KANG, C.

NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction: Proactivity is about drawing and setting plans to pursue a different future. Parker et al. (2010) identified that proactivity requires a goal-driven process involving goal processes and motivational states. According to Achievement Goal Theory (Elliot, 1999), competence was defined and valenced as mastery/performance and approach/avoidance. However, few studies were conducted to develop the relationship between proactive personality and proactive goal process in the sports domain. The aim of this study was to take this perspective to examine the proactivity in the connection with the 2x2 achievement goals for sport.

Methods: In this study, we recruited 136 women's basketball players (Mage=20.10, SD=1.76) from 12 universities in Taiwan. Participants were requested to complete measures consisting of Proactive Personality Scale (Huang, 2009) and 2x2 Achievement Goal Questionnaire of Sport (Li et al., 2005). Data analysis and interpretation were based on Pearson correlation and linear regression analysis.
Results: The correlation analysis revealed that proactive personality is positively correlated with the mastery-approach goal (r=.50, p<0.01), mastery-avoidance goal (r=.27, p<0.01), and the performance-approach goal (r=.48, p<0.01). Otherwise, there was no correlation between proactivity and performance-avoidance goal (r=.10, p>0.05). The results of linear regressions analysis showed that proactivity positively predicted mastery-approach goal (β=.50, p<0.001), mastery-avoidance goal (β=.27, p=0.003) and performance-approach goal (β=.48, p<0.001).
Discussion: The results of this study showed that athletes with higher scores in proactive personality have the association with the mastery-approach goal, performance-approach goal, and the mastery-avoidance goal. No correlation was found between proactivity and performance-avoidance goal. Moreover, proactivity can predict mastery-approach goal and performance-approach goal. In other words, athletes with high proactivity tend to have a higher mastery-approach goal, performance-approach goal, and mastery-avoidance goal. Previous studies from achievement goal theory have found that mastery-approach goal, performance-approach goal, and mastery-avoidance goal are related to adaptive achievement behaviors. Based on the results of this study, proactive personality might be the important antecedent related to achievement goals. More studies in terms of examining the relationship between proactive personality and achievement goal are warranted.

INTERACTION BETWEEN THE PLAYERS' PERCEPTIONS OF THE COACHES' INTERPERSONAL STYLES AND ITS IMPLICATIONS FOR FEMALE BASKETBALLERS' DEVELOPMENT

BALAGUER, I.1, CASTILLO, I.1, ATIENZAR, M.A.1, TOMÁS, I.1, CONDE, C.2, IBAÑEZ, S.3

1 UNIVERSITY OF VALENCIA, SPAIN; 2 UNIVERSITY OF HUELVA, SPAIN; 3 UNIVERSITY OF CÁCERES, SPAIN.

INTERACTION BETWEEN THE PLAYERS' PERCEPTIONS OF THE COACHES' INTERPERSONAL STYLES AND ITS IMPLICATIONS FOR FEMALE BASKETBALLERS' DEVELOPMENT
Isabel Balaguer1, Isabel Castillo1, Mª Ángeles Atienzar1, Inés Tomás1, Cristina Conde2, & Sergio Ibañez3
1 Faculty of Psychology. University of Valencia, Spain
2 Faculty of Education. University of Huelva, Spain
3 Faculty of Sport Sciences, University of Caceres, Spain
Introduction: In this study the relationships between players' perceptions of the coach-created empowering climate and athletes reported personal and interpersonal development were examined, testing the moderating role of players' perceptions of the coach-created disempowering climate in those relationships.
Method
Participants were 399 Spanish young female basketball players aged between 11 and 18 years (M=14.10; SD=1.61), who completed a questionnaire package tapping the variables of interest. On average, athletes had a mean of 6.12 years of experience (SD=2.68), and practiced sport 6.14 hours a week (SD=1.62).
Results: The results obtained using moderated regression analysis showed that the perceived disempowering climate moderated the relationships between the perceived empowering climate and athletes' personal and interpersonal development. When empowering coaching increased, athletes reported higher personal and interpersonal development. However, this positive relationship was stronger when perceived disempowering coaching was low (1 SD below the mean; 1.80 on the 1-5 scale), than when it was high (1 SD above the mean; 3.21 on the 1-5 scale) for personal development, turning out to be non-statistically significant for high values of disempowering (1 SD above the mean; 3.21 on the 1-5 scale) in the case of interpersonal development. More concretely, the relationship between empowering climate and personal development would be positive and significant for any value of disempowering climate lower than 3.26 (on the 1-5 scale); additionally, the relationship between empowering climate and interpersonal development would be positive and significant for any value of disempowering climate lower than 3.13 (on the 1-5 scale).
Discussion: Potential beneficial effects that empowering climate could have on personal and interpersonal development, are diminished, and even blocked when the social environment is highly disempowering. The negative implications of disempowering climates for female athletes´ development and the convenience to create empowering climates in the sport domain are emphasized.

PLAYERS PERCEPTIONS OF COACHES CORRECTIVE FEEDBACK AND IMPLICATIONS FOR ATHLETES ILL-BEING

TRISTAN, J.1, LOPEZ-WALLE, J.1, BALAGUER, I.2, VALDEZ, H.3, DUDA, J.4

1: UANL , 2: UV , 3: UES , 4: UB .

Introduction: The way in which corrective feedback is communicated can have differential effects depending on how it is perceived by athletes; these perceptions can lead to differential motivational states and diverse emotional and cognitive outcomes in athletes within the sporting context (Mouratidis, Lens, & Vansteenkiste, 2010). This study examined the relationships between players perceptions of coaches corrective feedback (CF), the legitimacy of this CF and the opportunity to learn from CF to indicators of ill-being (burnout). The hypothesized moderating role of players autonomous motivation in these relationships was also tested.
Methods: Participants were 322 Mexican university athletes, aged 17-28 years (M = 18.82, SD = 2.42). They respond to a set of Spanish versions of the following questionnaires: Corrective Feedback Scale (CFS); Sport Motivation Scale (SMS-II) and the Athlete Burnout Questionnaire (ABQ). For the analyses of the data, the macro PROCESS for SPSS was used.
Results: Corrective Feedback was a positive predictor and explained 36% of reported Burnout. Change in the R2 with the addition of the moderating effect of Autonomous Motivation (AM) was low but significant ($F = 5.64$, $p < .05$). The relationship between corrective feedback (CF) and burnout was significant with athletes of low and medium AM only. The perceived Legitimacy of the CF was a negative predictor and captured 35% of reported Burnout. The observed change in R2 with the inclusion of the moderating effect of AM was low but significant ($F = 4.89$, $p < .05$). The relationship between perceptions of the legitimacy of CF and Burnout was significant only in the case of athletes exhibiting high AM. The Opportunity to Learn from CF negatively predicted and explained 35% of Burnout symptoms ($R2 = .35$). In addition, changes in R2 with the addition of the moderating effect of AM was low but significant ($F = 5.98$, $p < .05$). The relationship between the perceived opportunity to learn from CF and Burnout was significant with athletes of high AM only.
Discussion: Amongst university athletes who are moderate to low in autonomous motivation, corrective feedback corresponds to heightened burnout. In university athletes with high autonomous motivation, perceiving the CF to be legitimate and as an opportunity to learn could reduce the symptoms of burnout. These findings suggest that coaches might be best advised to ensure that their athletes accept

CF, by having it couched in a manner that suggests that learning and improvement can follow, and communicated in an autonomy-supporting way.

Mouratidis, A., Lens, W., & Vansteenkiste, M. (2010). How you provide corrective feedback makes a difference: the motivating role of communicating in an autonomy-supporting way. Journal of Sport & Exercise Psychology, 32, 619-637.

SELF-COMPASSION AND SELF-DETERMINED MOTIVATION TOWARDS EXERCISE: AN EXPLORATION OR GENDER AND AGE DIFFERENCES OF REGULAR EXERCISERS

LOWRY, R.G., WALLER, K.

UNIVERSITY OF CHICHESTER

Introduction: Self-compassion occurs when an individual displays kindness and understanding rather than criticism in the face of set-backs and failures. A greater capacity for self-compassion is associated with the intention to engage in health promoting activities including exercise and exercise related outcomes. The purpose of this study was to explore, using a cross-sectional design, the concept of self-compassion for regular exercisers whilst accounting for potential age and gender differences. More specifically how self-compassion relates to self-determined motivation towards exercise involvement.
Methods: Participants (n=172), recruited through social media sites aimed at recreational runners were regular exercisers (M = 40, SD = 9; males = 26; females = 146). An online survey containing the Self-Compassion Scale (Neff, 2003), the Behavioural Regulations in Exercise Questionnaire-2 (Markland & Tobin, 2004) and the International Physical Activity Questionnaire Long Form (Craig et al., 2003) was completed.
Results: Total self-compassion was related to higher intrinsic motivation and lower external and introjected regulation. Older exercisers experienced lower levels of negative self-compassion, namely self-judgement, isolation and over-identification than younger adult exercisers. Similarly males, greater total self-compassion and specifically lower negative self-compassion to female exercisers. No relationship was observed between self-compassion sub-scales and the amount of physical activity self-reported by exercisers.
Conclusion: Motivation to exercise is concerned with regulated self-determination such as health and appearance related pressures. Self-compassion was positively, linearly associated with self-determination to exercise however this the concept was not associated with the amount of physical activity completed. Older adults and men involved in exercise appear display greater self-compassion than women and younger exercisers.

THE EFFECT OF AUTHENTIC AND TRANSFORMATIONAL LEADERSHIP OF KOREAN GOLF COACHES ON LEADER-MEMBER EXCHANGE AND GOLFERS' PERFORMANCE

KIM, I., KIM, J., PARK, J.

1: KOREA NATIONAL SPORT UNIVERSITY , 2: GERMAN SPORT UNIVERSITY COLOGNE

Introduction: In 2017, South Korean golfers won 15 times in the LPGA Tour, and 18 Koreans were ranked the top 100 on the LPGA money list (LPGA, 2017). A coach's leadership is considered one of the main factors to determine the performance. The leadership of the coaches have traditionally been described by transformational, servant and transactional leadership. In particular, transformational leadership was regarded as a prerequisite for success or winning in that it allows athletes to have clear objectives and strategies through mutual interaction. However, authentic leadership has recently emerged because authenticity leads to a voluntary devotion and trust, resulting in high performance. As such, the leadership tends to entail dyadic interaction controlling the performance, which is closely related to leader-member exchange (LMX) (Truckenbrodt, 2000). Therefore, the purpose of this study is to investigate the effect of authentic and transformational leadership of Korean golf coaches on LMX and golfers' performance.
Methods: Data were collected from 250 prospective golfers who belonged to golf academies in 2016 by using convenient sampling method. After removing 45 cases of incomplete questionnaires, 205 were used for data analysis. For the study, reliability analysis, Confirmatory Factor Analysis (CFA), correlation analysis and Structural Equation Model (SEM) were conducted by using SPSS 20.0 and AMOS 20.0.
Results: The overall validity and fit did not seem acceptable, $\chi 2(df) = 356.869$ (203, $p<.001$). Nevertheless, CFI = .931, TLI = .922, RMSEA = .061 and RMR = .037 exceeded fit index recommended by Bagozzi & Dholakia (2002), and therefore overall validity and fit can be considered a good model for the study. As a result, authentic and transformational leadership positively affected LMX, respectively, β=.425, t=3.654 and β=.510, t=4.194. Authentic leadership significantly influenced performance, β=.387, t=2.459. However, LMX and transformational leadership were not significant for performance, respectively, β=.315, t=1.742 and β=.072, t=.466.
Conclusion
The findings found that transformational leadership relatively had a higher influence on LMX than authentic leadership, and golfers' performance was positively affected by authentic leadership. It can be inferred that each leadership is effective, but transformational leadership seems more important to LMX as the leaders enthusiastically motivate their golfers to have an inspiration and confidence toward their goals. Also, golf performance is largely dependent upon psychological and emotional aspects, and therefore authentic leadership with rational transparency could positively induce golfers' state of mine and commitment for the high performance.

PL-PS04 PHYSICAL ACTIVITY AND HUMAN ENHANCEMENT DRUGS: A HEALTH HAZARD OR A USEFUL BEHAVIOUR CHANGE TECHNIQUE?

PHYSICAL ACTIVITY AND HUMAN ENHANCEMENT DRUGS: A PUBLIC HEALTH CONCERN?

BACKHOUSE, S.H.

LEEDS BECKETT UNIVERSITY

Superfoods, clean eating and dietary supplements are just a few examples of contemporary diet and lifestyle practices embedding in popular culture as we turn to an expanding list of produce and products that promise to enhance our bodies, performance and well-being. At the same time the widespread availability of human enhancement drugs has enabled growth in their non-medical use for muscularity , weight-loss , endurance and cognitive function . Despite this emerging threat to public health, efforts to prevent, detect and deter HED use are still defined by - and situated within - competitive sport. This context will be discussed in light of the extant evidence base on the psychosocial correlates and determinants of HED use, as well as their potential to cause harm. By acknowledging that the root causes of HED use are incredibly complex, and that short-term solutions will only address the symptoms of use, this paper will call for a systems-based approach to assist in preventing and managing HEDs in physical activity contexts.

TITLE: PHARMACOLOGICAL FACILITATION OF PHYSICAL ACTIVITY BEHAVIOUR

MARCORA, S.

UNIVERSITY OF KENT

Psychoactive drugs that reduce perception of effort and improve endurance are used legally (caffeine) and illegally (e.g., modafinil and ritalin) by many athletes. We argue here that pharmacological reduction of perception of effort may also be used to facilitate physical activity behaviour in the general population and, by doing so, improve many health outcomes. Avoidance of unnecessary effort is one of the main mechanisms that evolved to maintain the relatively high body fat humans with large brains needed to survive in an environment where food was scarce and physical activity mandatory. This inherent laziness motivated humans to create the current hypokinetic environment and is one of the main barriers to regular physical activity in the general population. After describing the psychobiology of how perception of effort interacts with motivational factors to determine physical activity, we present initial experimental evidence that pharmacological reduction of perception of effort using caffeine can positively affect physical activity behaviour. Finally, we will discuss directions for future research and the potential ethical issues related to this proposal.

KINETIC ANALYSIS OF CRUTCH RUNNING FOR AMPUTEE SOCCER

NAKASHIMA, D.1, KIMURA, H.2, SAKAMITSU, T.1, HIRATA, K.1, MIKAMI, Y.2, ADACHI, N.3

1,2: HIROSHIMA UNIVERSITY HOSPITAL, 3: HIROSHIMA UNIVERSITY

INTRODUCTION: Amputee soccer is a sport performed by using crutches. Lower limb injuries such as muscle tears of the leg and shin splint during amputee soccer have been reported. However, there are no report on biomechanics of crutch running. The purpose of this study was to clarify the kinetic load of the crutch running and compare it with normal running.
METHODS: Eight healthy young males participated in this study. Sixteen camera Vicon optical motion analysis system, and eight AMTI force plates were used to track and analyze the participants one-leg crutch running motion by using the two Lofstrand crutches and normal running motion. The crutch running method involved two steps of the foot and one step of the crutches. The center of mass (COM) coordinates, ground reaction forces, and kinetics data of the lumbar and lower limb joints were compared between the two conditions.
RESULTS: There was no significant difference in COM forward velocity between the two conditions. The amount of change in COM vertical direction was significantly larger for clutch running (10.9±3.2 %Body Height; BH) than for normal running (5.4±0.8 %BH). Under the crutch running condition, the ground reaction force, vertical (Fz: 3.02±0.29 N/kg), front, and rear components, and the internal lumbar, hip, knee, and ankle joint extension moment peaks (lumbar: 0.12±0.02, hip: 0.13±0.02, knee: 0.31±0.07 at foot contact to loading response phase, ankle: 0.29±0.02 Nm/kg at the push-off phase) increased significantly compared to those under the normal running condition (Fz: 2.52±0.20 N/kg, lumbar: 0.04±0.01, hip: 0.07±0.01, knee: 0.20±0.03, ankle: 0.26±0.03 Nm/kg). In the crutch running condition (0.072±0.036 Nm/kg), the sum of the bilateral hip joints flexion and extension moments calculated as a result of the scissors motion at the foot contact increased significantly compared with normal running condition (-0.003±0.012 Nm/kg, $p<0.01$).
CONCLUSION: The results of the present study show that crutch running was greater kinetic load for lumbar, hip, knee, ankle joint than normal running. Since the crutch running used only one leg, it may be difficult to use the scissors motion. The lack of offsetting of the bilateral hip joints flexion and extension moments increases the mechanical load on the lumbar. The scissors motion may reduce the load on the lower limb joints after foot contact. Therefore, training that reduces the COM vertical variation and increases the flexion moment of the swing leg side may lead to the reduction of the mechanical load of the lumbar and lower limb joints.

EFFECTS OF RHYTHMIC EXERCISE ON CARDIOVASCULAR FACTORS, BLOOD INFLAMMATORY MARKERS AND PHYSICAL FITNESS IN PSYCHOTIC PATIENTS

PARK, H.1, HWANG, Y.H.1, CHO, S.C.2, KIM, S.H.3, LEE, K.H.3, KIM, J.1, KIM, D.H.1

1: CHONNAM NATIONAL UNIVERSITY.(GWANGJU, KOREA), 2: MOKPO NATIONAL MARITIME UNIVERSITY.(MOKPO, KOREA) 3: CENTER FOR SPORT SCIENCE IN GWANGJU. (GWANGJU, KOREA)

INTRODUCTION: Currently, numbers of psychotic patients are getting increased, and it is socially or economically issued. The patients have to take atypical antipsychotic medications for managing their mental problems, but taking these medications leads to health issues such as decreasing level of physical activity and increasing appetite, thus it results in the patients to be obese. Thus this study is to examine effects of rhythmic exercise on cardiovascular factors, blood inflammatory markers and physical fitness in psychotic patients.
METHODS: This study shows the rhythmic exercise program to prevent cardiovascular diseases of psychotic patients and to improve their physical fitness. After the program was used on patients for 12 weeks, examined closely effects of cardiovascular factors (TC, TG, HDL-C, LDL-C, Insulin, Blood glucose, VEGF, NO), blood inflammatory markers (hs-CRP), and physical fitness(muscular strength, muscular endurance, cardiorespiratory endurance, flexibility, body composition). To achieve this aim, 18 psychotic patients were randomly assigned the two groups; one with 9 called exercise group (EX, n = 9) did rhythmic exercise 3 times a week, 60 minutes at a time and the other with 9 called regulation group (CON, n = 9) those who were in daily lives as usual.
RESULTS: The result of this study suggested that a decrease of TG and an increase of VEGF which are cardiovascular factors had positive effects on preventing cardiovascular diseases in EX group. Furthermore, physical fitness could be enhanced by an increase of flexibility and a decrease of BMI which are physical fitness factors in EX group, but not CON group.
CONCLUSION: If rhythmic exercise modified and supplemented is constantly used to psychotic patients, the danger of their potential cardiovascular diseases will be prevented and the quality of lives improved by keeping their body healthy. Rhythmic exercise program, which is neither the limit of places nor the risk of tools, is particularly considered to be used in hospitals and psychotic health care centers.

STUDY OF PARA SPORTS INSTRUCTOR TRAINING PROGRAM AT UNIVERSITY OF PHYSICAL EDUCATION: BASED ON AMPUTEE SOCCER COACHING PRACTICE

WATANABE, T., MAEHANA, H., WATARI, T., SUZUKI, K.

JUNTENDO UNIVERSITY

Study of Para sports Instructor Training Program at University of Physical Education: Based on Amputee Soccer Coaching Practice
Watanabe, T., Maehana, H., Watari, T., Suzuki, K.,
1. Juntendo University, Japan

Introduction: With the Tokyo Paralympic Games scheduled for 2020, various policies related to para sports have been proposed in Japan. One of them is instructor training. In particular, universities of physical education that have instructor training courses are playing a crucial role in promoting para sports. In instructor education, it is important to establish courses to provide basic knowledge regarding special education, the principles of inclusive physical education, the practice and understanding of para sports, and the education, in this regard, of students aspiring to become educators. In this study, we examined sports-instructor training programs at universities of physical education using a case study.
Methods: We conducted a practical study on instructor training courses at departments of health and physical education. We included para sports among the practical courses that students enrolled in. We created an amputee-soccer program based on partial and total learning. The participants were freshmen university students who were taking soccer courses, and several of them were asked to participate in semi-structured interviews. The data obtained from the interviews were analyzed by two specialists.
Results: As a result, we were able to divide the data into four categories:
1) Understanding of para sports: e.g., The interviewee knew about the existence of soccer for amputees.
2) Enjoying the game: e.g., Amputee soccer is just as enjoyable as soccer played by people without physical disabilities.
3) Application in regular soccer practice: e.g., Positioning the ball so that you can pass it off to another player at any time is important even in regular soccer.
4) Expertise as an instructor: e.g., The interviewee would like to introduce it to their own students in the future.
Discussion: Having students, who aim to join the ranks of the teaching staff at a department of health and physical education, experience para sports was effective not only in terms of sparking their interest in para sports but also in terms of deepening their knowledge of existing sports. Furthermore, it became an opportunity for them to contemplate how they would accept a student with disabilities and how they would conduct their classes. We will continue studying how this kind of learning through experience will affect further learning and student life.

CURRENT STATE AND ISSUES OF PARALYMPIC EDUCATION IN JAPAN: RESEARCH FROM THE PERSPECTIVE OF PRACTICAL SESSIONS OF PARA SPORTS

NAGATA, Y., MAEHANA, H., WATARI, T., SUZUKI, K., WATANABE, T.
JUNTENDO UNIVERSITY

Current State and Issues of Paralympic Education in Japan: Research from the Perspective of Practical Sessions of Para sports
Nagata,Y., 1 Maehana, H., 1 Watari, T., 1 Suzuki, K., 1 Watanabe, T., 1
1. Juntendo University, Japan
Introduction: Various policies are being proposed as Japan prepares for the 2020 Olympic and Paralympic Games that will be hosted in Tokyo. One of them is Olympic and Paralympic education. Recently, practical sessions of Paralympic sports (hereafter referred to as para sports) have been conducted at schools and other educational settings as part of Olympic and Paralympic education. However, the concept of Paralympic education itself is not clear, and the effects of practical para sports sessions on the participating students have not been elucidated. In this study, we summarize the concept of Paralympic education and examine the significance of practical para sports sessions.
Methods: We summarized the concept of Paralympic education based on literature obtained using the search engine on the National Institute of Informatics website. In addition, we conducted practical sessions of para sports for elementary and middle school students who were also asked to participate in a questionnaire-based survey, and several of them were asked to participate in semi-structured interviews.
Results: We were able to summarize the concept of Paralympic education based on the following 4 categories: awareness of Paralympic sports, understanding what a sporting event is, understanding what a disability is, and understanding what inclusive society is. Through practical sessions of para sports, the participants were able to experience the highly difficult and competitive, yet interesting, nature of para sports. However, their understanding of disabilities and inclusive society was limited.
Discussion: The effectiveness of using practical sessions of para sports as a means of providing Paralympic education was confirmed even by participants' opinions. However, many of the practical sessions currently conducted in Japan are limited to sports experience, which is similar to the practical sessions conducted in this study. In particular, an understanding of disabilities is also important in order to become an inclusive society. Further research on the content of the program is required to further improve Paralympic education.

TEMPORAL PARAMETERS OF RUNNING ON CRUTCHES OF THE ITALIAN AMPUTEE SOCCER TEAM

NIGRO, F.1, BARTOLOMEI, S.1, CORTESI, M.2, MERNI, F.1, DI MICHELE, R.1, CIACCI, S.1, FANTOZZI, S.3
UNIVERSITY OF BOLOGNA

INTRODUCTION: Amputee soccer (AS) is a relatively recent discipline, where six lower limb amputees play soccer in the field using crutches (CR). CR can be used for assisting the player in moving only. Biomechanical investigations focused on ambulation on CR has been previously examined from a biomechanical point of view but researches were focused on daily life activities (Opila 1987, Goh 1986). Sprinting on CR represents one of the most important motor task characterizing AS. The purpose of the present study was to assess the temporal parameters of running on CR using wearable inertial sensors (IS).
METHODS: 8 male AS players of the National Italian Amputee Football Team performed 3 trials of a 40 meters sprint wearing three IS. One was placed on L5 vertebra and the other two on one CR. Contact time and flight time of the athletes feet and CR were recorded by the IS and collected using Motion Studio software. Data recorded by the L5 IS were processed by MatLab using the algorithms proposed by Bergamini (2011). A specifically developed algorithm was used for the IS on the CR.
RESULTS: Running steps sequence differed depending on whether the athlete was or not already in motion. After some initial cycles, the step became regular and showed a common dynamic in all AS analysed. While the CR alternated between a single flight (mean value 66.7%) and a single support phase (mean value 33.3%), the foot made two support phases (23.6% and 23.5%) alternated with two flight phases (mean values 23.0% and 29.8%). The temporal phases identified during running on CR were explained as follow. The first foot contact with the ground was performed for balance recovery, while the second foot contact for the push. The first foot flight was short and was designed to allow the AS a better push on the ground during the second support phase. This strategy allows performing a second longer flight, that looks like a long-jump on CR. Similar to able bodied athletes, AS players searched for a double support and a double flight phases during the sprints, as if they wanted to keep the rhythm of a two legs runner. All athletes analysed chose the same synchronous running with CR pattern during sprint.

CONCLUSION: The main characteristics of this unique sport gesture is the alternation between the double flight and the double support phases. The development of a CR running model of performance could provide a useful tool for coaches and researchers.

DEVELOPING AN ASSESSMENT BASED ON PHYSICAL FITNESS AGE TO EVALUATE MOTOR FUNCTION IN ELDERLY INDIVIDUALS

NAKAGAICHI, M.

SCHOOL OF HEALTH SCIENCES

INTRODUCTION: the purpose of this study was to identify a method for assessing physical fitness age that is easy to use with elderly women and to examine its validity.
METHODS: Principal component analysis was used to develop a formula of physical fitness age from four motor function variables. The subjects comprised 688 (75.7±6.0 years) elderly women, in order to develop a physical fitness scale. The formula for calculating physical fitness age was expressed as physical fitness age =−0.419× grip strength −0.096× balancing on one leg with eyes open −0.737×30 s chair stand +0.503× figure-of-8 walking test +0.47× chronological age +52.68.
RESULTS: Measures obtained from subjects in the frail elderly (n=11, 73.0±2.3 years) and exercise (n=10, 70.8±3.1 years) groups were used to examine the validity of the assessment. The mean physical fitness age of the frail elderly group (79.0±3.7 years) was significantly higher than its mean chronological age (73.0±2.3 years, p,0.05). The mean physical fitness age of the exercise group (65.6±3.1 years) was significantly lower than the chronological age (70.8±3.1 years, p,0.05).
CONCLUSION: These findings confirm that physical fitness age scores are applicable to frail and healthy elderly women. Physical fitness age is a valid measure of motor function in elderly women.

CORRELATES OF PHYSICAL ACTIVITY AMONG PRIMARY-SCHOOL BOYS DIAGNOSED WITH AUTISM SPECTRUM DISORDER

PAN, C.Y.1, SUNG, M.C.1, MA, W.Y.2, HUANG, C.Y.1, CHEN, P.L.1, CHU, C.H.1

NATIONAL KAOHSIUNG NORMAL UNIVERSITY

Introduction: Children with autism spectrum disorder (ASD) might be at particular risk for inactivity due to social and behavioral impairments associated with the condition. Low levels of physical activity (PA) may contribute to harmful health outcomes. To date, there is no clear evidence documenting the correlates of PA in children with ASD. The personal and social and/or family environment are important to facilitate healthy behaviors in these children. Therefore, the International Classification of Functioning Model (ICF) was used for the current study as the guiding conceptual framework (WHO, 2002).
Methods: Thirty-six families of children with ASD, aged 6-12, participated. Parents (n=36), siblings of children with ASD (n=19), and children with ASD (n=36) wore an accelerometer for 7 days and parents completed a PA support questionnaire. Two primary PA outcome variables were the daily overall PA and average time spent in moderate-to-vigorous PA (MVPA). Fundamental movement skills of children with ASD were assessed by using the Test of Gross Motor Development-2 (Ulrich, 2000). Pearson product-moment correlation coefficients were calculated to evaluate the relationships between each explanatory variable and childrens PA. When a variable was significant in the correlations, it was entered into the hierarchical multiple regression analysis. The probability level was set at $p < .05$.
Results: Findings of bivariate correlations indicate that (a) age ($r = -0.70$, $p < .01$) and fundamental movement skills ($r = 0.38$, $p < .05$) of children with ASD were correlated with time spent in MVPA, (b) sibling overall PA ($r = 0.58$, $p < .01$) and support ($r = 0.40$, $p < .05$) were positively associated with overall PA of children with ASD, and (c) parent PA and support, after-school sedentary pursuits of children with ASD, and peer support were not correlated with PA of children with ASD. Results of the hierarchical multiple regression analyses revealed that (a) childrens age explaining 47% of the variance in time spent in MVPA, and (b) siblings overall PA explaining 30% of the variance in overall PA of children with ASD.
Discussion: Consistent with findings in children with and without disabilities, child age was significant factors affecting PA of children with ASD. As expected, sibling PA was a significant predictor of PA in children with ASD. It was surprising that neither parent modeling nor support were strongly related to or predictive of children with ASD PA. Resources to promote PA based on personal and family environmental factors are needed for this population.

DEVELOPMENT OF NEW ESTIMATION FORMULA BASED ON ASTRAND-RYHMING STEP TEST PROTOCOL FOR VO2MAX EVALUATION OF ADOLESCENTS (13-18 YEARS)

SONG, J.R., LEE, S.H., KIM, Y.J., KIM, S.J., KWAK, H.B., KIM, C.S., SHIN, Y.A., PARK, D.H.

INHA UNIVERSITY, DONGDUCK WOMEN'S UNIVERSITY, GRADUATE SCHOOL DANKOOK UNIVERSITY

INTRODUCTION: Validity and reliability of the Step test have been examined in several studies (Beutner et al., 2015; Hansen et al., 2016; Astrand and Ryhming, 1954), but mainly in Westerners. To date, the Step test has not been validated using Korean population. The purpose of this study was to develop and validate regression models to estimate maximal oxygen uptake (VO2max) from the new estimation formula based on Astrand-Ryhming step test protocol (AR protocol) in Korean male and female youths aged 13-18 years.
METHODS: One hundred twenty participants performed maximal graded exercise test (GXT) on a treadmill and Astrand-Ryhming step test (AR test) to measure VO2max and VO2max estimates, respectively. Participants in the validation study performed the GXT with the stationary metabolic cart and the Astrand-Ryhming step test twice for test-retest reliability. All tests were conducted at least three days apart and in a random order.

RESULTS: Mean calculated VO2max (40.43±11.57 mL/kg/min) from the Astrand-Ryhming step test equation was significantly low from that measured during the GXT from stationary metabolic cart (47.32±8.75 mL/kg/min, p<.01). New regression equations were developed from present data to predict VO2max for male and female youths: y = (-13.963 × sex) – (0.216 × W) – (0.072 × HR) + 91.296 (r=.772, SEE=5.64 mL/kg/min). The VO2max (47.22±6.76 mL/kg/min) of modified Astrand-Ryhming step test equation showed no significant difference from the VO2max measured through GXT.
CONCLUSION: It is concluded that this equation developed in this study provides valid estimates of VO2max of Korean male and female youths aged 13-18 years. A further study needs to develop a step test estimation equation targeting adults and elderly people in which validity and reliability are secured.

Biomechanics

FATIGUE EFFECT ON BIOMECHANICAL PARAMETERS OF TRAIL RUNNING.

CIACCI, S.1, TOTTI, V.1, BARTOLOMEI, S.1, STELLA, F.1, NIGRO, F.1, FANTOZZI, S.2

UNIVERSITY OF BOLOGNA

INTRODUCTION: Fundamental biomechanical parameters in trail running are step length (SL) and frequency (SR), contact (CT) and flight time (FT), and shock attenuation (SA) (Derrick et al., 1998). SA is considered a significant indicator for injury prevention (Mizrahi et al. 2000) and is influenced by several factors such as fatigue and foot strike pattern (Giandolini et al. 2014). The aim of the present study was to investigate the effect of fatigue on the kinematic parameters of step and SA during downhill trial running.
METHODS: Eleven well trained participants (10 men and 2 women, age: 31.5±11.4 years, height: 173.9±5.6 cm, mass: 34.1±6.5 Kg) were enrolled. Four inertial sensors (EXLs3, 200 Hz) were attached to the pelvis, tibia, heel and second metatarsal head of the foot (Giandolini et al., 2014). Data were collected during a 290m downhill running (mean inclination 13°). The task was performed before and after an 18km trail running and filmed by a videocamera (Panasonic HC-V700, 50hz). The self-selected running speed was similar in both pre- and post-trial acquisitions. 854 steps were analyzed. For each step, the following parameters were estimated SL, SR, step time (ST), CT, FT, SA, center of mass acceleration (CA), tibial acceleration (TA) and foot strike pattern (Giandolini et al. 2014).
RESULTS: Reduced FT (p<0.009) and CA (p<0.047) were found comparing pre- and post- trial acquisitions. TA and FT (r=-0.664) and TA and SA (r=0.818) were found to be correlated. Considering foot strike pattern, forefoot strike decreased both TA and CA with respect to midfoot (p=0.013 and 0.013, respectively) and rearfoot strike (p=0.015 and 0.013, respectively). Comparing post- with respect to pre-trial acquisition, athletes used more the forefoot strike pattern (+7.38%).
CONCLUSION: According to Mercer et al. (2002), the reduced SL, enhanced by a lower FT with similar SR and velocity, leaded to a lower TA. This result is confirmed by the negative correlation between FT and TA and by the positive correlation between TA and SA. Forefoot strike sustained the significant reduction of TA, according to DeWit et al. (2000). In the fatigued condition, the athletes tended to diminish FT and to use a forefoot strike pattern with the aim of reducing the impact of the tibia to the ground.

RELATIONSHIP OF RESISTED SLED SPRINTING, BODY MASS AND MAXIMUM STRENGTH

SMIRNIOTOU, A., KESOGLOU, I., PANTELI, F., THEODOROU, A.

KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Research studies and track coaches indicate the importance of the resisted sled sprinting as a crucial training aid for sprinters' work outs. Various sled loads as a percentage of athlete's body mass(BM) have been under investigation, based on the fact that the larger muscle mass can produce greater muscle output. This study aims to identify the relationship of sprinting acceleration(SA) and maximum velocity(MV) phases with different sled loads to the BM and the maximum strength(MS).
METHODS: Eight 400m male track athletes (20-27yrs), with 5 years' experience of training/ competition, participated. They were tested on 2 separate days. The 1st day an anthropometric assessment (height 1.78±0.6m, BM: 76.8 ± 3.8kg) and an MS test (half-squat 1RM:172.5 ± 10.84kg) were carried out. 2nd day athletes were randomly assigned to complete unloaded and loaded (10%,15% & 20% of BM) 50m sprints. EMG activity of gastrocnemius, bicep femoris, rectus femoris, lateral femoris & max gluteus was recorded. 0-30m set as the SA and 30m to 50m as the MV phase. The repeated-measures analysis used to determine if any significant differences existed between conditions and Pearson (r) used for bivariate analysis.
RESULTS: The loaded conditions significantly affect both the SA (F=120.14, p<.001) and the MV phase, (F=44.16, p<.001). BM is positively related(r=.66) to MS as well as BM shows significant and negative correlation to the unloaded SA phase (r=-.867, p=.025). MS also indicates moderate to weak correlations to SA for all conditions. Finally, the MS is related positively but no significantly to the MV of 15%BM(r=.52) and 20%BM(r=.53) conditions.
CONCLUSION: Squat 1RM correlated with MV when loads more than 10%BM were applied, thus, stronger athletes tend to sprint faster under loaded conditions. But as the BM increases the unloaded acceleration time gets slower. The EMG activity is differentiated depending on the sprinting phases and the load of the weighted sled.

COMPARISON OF LOWER LIMB SEGMENTS KINEMATICS IN A TAEKWONDO KICK ON DIFFERENT ANGLE OF ELECTRONIC BODY PROTECTOR

TSUN-TE LIU.1.2, JUNG- SAN CHANG.1, YI-CHUN LIN.1, WEN-TZU TANG.1

NATIONAL TAIWAN SPORT UNIVERSITY / TAMKANG UNIVERSITY

INTRODUCTION: The most used technique to score in taekwondo competition.is the roundhouse kick directed to the thorax . In combat, the actions of opponents are.unpredictable,.Velocity and accuracy of kick are important factors that help in achieving victory . Additionally, to generate enough impact energy to score points on electronic protectors, a high linear velocity of leg segments is required . Therefore, the aim of this study was to analyze the peak velocity of lower limb segments by roundhouse kicking in three different angle of EBP.
METHODS: An EBP (Daedo) was used for the experiment. Eleven TKD male athletes were asked to perform the roundhouse kick five times within three different impact angle in the thorax area . The linear velocity of the pelvis (anterior superior iliac spine), knee (lateralcondyle of femur), ankle (lateral malleolus) and CG foot (Center of Gravity of foot) during the kicking phase were recorded for comparisons.
RESULTS: The results revealed a significant difference in pelvis. Comparative analysis within three different impact angle for the pelvis segment. In 90◦ impact angle demonstrated greater linear velocity than 30◦impact angle.
CONCLUSION: Previous research suggest that during the roundhouse kick in taekwondo inter-segment motion seems to be based on a proximo-distal pattern.. In the present study, we analyzed the peak velocity of lower limb segments by roundhouse kicking in three different angle of EBP , with the evidence showing that the pelvis, plays a main role increased the foot segment reaching the highest peak velocity of kicking leg. In order to generate enough impact energy to score points on electronic protectors, a high linear velocity of pelvis segments is required.

THE COMBINED EFFECT OF THIGH MUSCLES STRENGTH ASYMMETRY AND FMS SCORE LEVEL TO CYCLISTS POSTURAL STABILITY AND PERFORMANCE DURING SPRINT CYCLING

RANNAMA, I., PEDAK, K., REINPÕLD, K., PORT, K.

TALLINN UNIVERSITY

INTRODUCTION: The core muscles state affects cycling kinematics (Abt et al, 2010), but relationships with the performance are unclear. It is found that knee extensors and upper-body movement asymmetry affects negatively sprint cycling performance (Rannama et al, 2015), but is the effect of asymmetry depending also on cyclists body functional state? The aim of the present study was to investigate combined effect of cyclists Functional Movement Screen (FMS) score level and existence of thigh muscles asymmetry (ASY) to postural stability and performance during 30 sec sprint cycling.
METHODS: 33 competitive road cyclists (18.5±2.0 y.; 1.82±0.07 m; 74.1±7.4 kg) were categorized based on FMS test (Cook et al, 2006) results in low (LS, n=17; FMS≤14) and high (HS, n=15; FMS>14) score group and based on thigh muscles bilateral isokinetic testing in symmetry (SYG, n=21; ASI<10%) and asymmetry (ASG, n=12; ASI>10%) group. The pedalling power (POW in W/kg) was captured during 30s isokinetic (100 rpm) seated sprint cycling test. The Cyclus2 ergometer was mounted on Kistler force plates and cyclists' postural stability (PS) indexes were computed by normalizing the standard deviation of GRF (Ground Reaction Force) with produced POW measured during 30 sec. The two-way MANOVA was performed to measure the combined effect of FMS score level and ASY existence to linear combination of PS and POW. Significance level was set to $p<0.05$.
RESULTS: The FMS level did not had ($p=0.79$) main effect to combination of PS and POW, but asymmetry existence had main and also existed combined effect of 2 factors to cycling performance. The Cyclist in LS had significantly higher POW in SYG (10.7±0.8 W/kg) than in ASY (9.7±0.8) group, but no differences were in HS (10.4±0.9 v 10.0±0.3). Also there was different direction effect of asymmetry to LS and HS. The cyclists' in LS group improved PS with asymmetry existence but in HS the existence of asymmetry caused more postural swaying.
CONCLUSION: The results of present study indicate that the effect of thigh muscles strength asymmetry to sprint cycling performance is depending on cyclist's upper body functional state. Low FMS level with combination of thigh muscles asymmetry reduce sprint cycling performance, but for cyclists with high FMS score it will cause more swaying on the bicycle. This supports our previous findings between 5 sec. sprint performance and knee extensors and upper body kinematics asymmetry (Rannama et al, 2015).

EFFECTS OF WHOLE-BODY VIBRATION TRAINING ON DYNAMIC BALANCE IN OLDER PERSONS WITH LOCOMOTIVE SYNDROME: A RANDOMISED CONTROLLED TRIAL

FUJITA, K.1, OGASAWARA, I.2, HASHIZUME, K.2, SHIMAMOTO, H.1, NAKATA, K.2

OSAKA UNIVERSITY

INTRODUCTION: Locomotive syndrome (LS) is defined by the Japanese Orthopaedic Association as a functional disorder of movement. Whole-body vibration (WBV) training has been used to improve dynamic balance in older persons with LS. However, prior studies did not adequately document the training effects of WBV on dynamic balance (Bogaerts et al., 2007, 2011). We previously reported that dynamic balance measurement of average and peak centre of pressure (COP) velocity in the two-step forward test (2ST) might be useful for predicting the risk of LS in older persons (Fujita et al., 2016). This study examined the effects of a 12-week WBV intervention on dynamic balance measured using COP parameters in the 2ST in community-dwelling older persons with LS in Japan.
METHODS: After baseline measurement, we randomly assigned 31 older persons with LS (12 men, 19 women; 74.3±6.7 years) to an intervention (WBV; n = 15) or control (CON; n = 16) group. The WBV group received 27 training sessions using a vibration platform (Power Plate®) over 12 weeks. The outcome measures in this study were the length, and average and peak velocities of COP after the second-step landing in the 2ST. These parameters were analysed for 3 intervals separated by 100 and 200 ms. Analysis of covariance adjusted for age, sex, and body mass index was used to assess between- and within-group differences.
RESULTS: The length of the COP in the second step of the 2ST tended to decrease in the WBV group but increased significantly in the CON group ($p < 0.01$), with a significant between-group difference ($p < 0.05$). A similar tendency was observed in the width of the COP in the sagittal direction. The mean COP velocity in the second step of the 2ST decreased significantly in the WBV group ($p < 0.05$) but tended to increase in the CON group, with a significant between-group difference ($p < 0.01$). The most significant change in mean COP velocity in the WBV group was found after 201 ms ($p < 0.05$). A similar tendency was observed in the mean COP velocity in the sagittal direction.

Peak COP velocity tended to increase during the 20–100 ms and 101-200 ms intervals, and showed a decreasing tendency after 201 ms in the WBV group, but an increasing tendency during all intervals in the CON group.
CONCLUSION: This is the first report of the effects of WBV training on dynamic balance using measurement of COP parameters during the 2ST in older persons. In the WBV group, some COP parameters improved after landing in the 2ST. These findings suggest that WBV training has the potential to enhance dynamic balance in older persons with LS.

INFLUENCE OF KNEE HYPEREXTENSION ON UNDERWATER DOLPHIN KICK PERFORMANCE

IIZUKA, S., TORII, S., KANEOKA, K.

WASEDA UNIVERSITY

INTRODUCTION: Hyperextension of the knee joint is observed in swimmers with increased joint laxity. Knee hyperextension is thought to enhance performance, but this has not been verified. Therefore, this study investigated the effect of knee joint laxity on underwater dolphin kick performance.
METHODS: This study included 17 elite male college competitive swimmers. All subjects performed an underwater dolphin kick at a maximum speed from the swimming pool wall. LED markers were placed on the greater trochanter, popliteal fissure, lateral malleolus, and toe. A high-speed camera was placed in the water. Knee and ankle angles were measured, and swimming speed was calculated using movement analysis. Joint angles and swimming speed were examined using Pearsons product-moment analysis.
RESULTS: Knee hyperextension (r=0.43, p=0.09) and ankle plantar flexion had significant positive effects on swimming speed (r=0.43, p=0.08). The smallest knee angle (r=0.54, p=0.03) showed a significant positive correlation with swimming speed. During swimming, an increase in resistance leads to a decrease in swimming speed. It is thought that resistance is produced in the femoral region, and increased knee flexion causes deceleration. Both the knee and ankle are necessary to achieve high propulsive force. Articular flexibility is necessary to transmit energy from the trunk to lower extremity efficiently when the whip-like underwater dolphin kick is performed.
CONCLUSION: Knee hyperextension, the smallest knee angle, and ankle plantar flexion were correlated with the speed of the underwater dolphin kick.

NEUROMUSCULAR CHARACTERISTICS DURING DOLPHIN-KICK SWIMMING AND ITS FUNCTIONAL IMPLICATION OF ELASTIC UTILIZATION.

SANO, K.1, DANNO, Y.2, ISHIKAWA, M.2

1: RITSUMEIKAN UNIVERSITY, 2: OSAKA UNIVERSITY OF HEALTH & SPORT SCIENCES

INTRODUCTION: The joint flexibility and long muscle fascicles are characteristics by competitive swimmers. Therefore, it is expected that their muscle behavior can specifically play important roles during swimming. On land, impact force can be utilized as the storage and release of elastic energy during terrestrial gait. The specific muscle-tendon interaction has been examined during human running and jumping (e.g. Ishikawa & Komi 2008). In swimming, however, it remains questionable how swimmer can enhance the swimming efficiency and whether elastic strain energy is utilized during swimming. Without impact forces, it is not clear how human can utilize the muscle and tendon elasticity during swimming. Therefore, the purpose of the present study was to examine the muscle-tendon behavior together with EMG activities of vastus lateralis muscles (VL) during the human dolphin-kick of swimming.
METHODS: In the swimming pool, each subject (n=8) performed the 25 m dolphin-kick swimming with two different speeds (normal (NORMAL) and maximal effort (FAST) conditions). Surface EMGs in the VL and biceps femoris (BF) muscles as well as the knee joint angular data by goniometer were measured. In addition, fascicle lengths of VL were measured by using ultrasonography. Instantaneous muscle-tendon unit (MTU) length of VL during swimming were estimated by knee joint angular data. The tendinous length of VL was calculated by subtracting the horizontal part of fascicle length in the direction to the aponeurosis from the MTU length.
RESULTS: In the dolphin–kick swimming, stretching and shortening amplitudes of the VL MTU length did not show any differences for both NORMAL and FAST. The VL EMG was activated from the late MTU stretching (up-beat phase) and the early MTU shortening phases (down-beat phase). The stretching and shortening amplitudes of the VL tendinous length were increased significantly in FAST than in NORMAL. Instead, the amplitudes of the VL fascicle length were smaller in FAST than in NORMAL.
CONCLUSION: During dolphin-kick swimming, the VL fascicles and tendinous tissues can perform a stretching-shortening action (Komi 1992). Therefore, the tendinous elasticity can play important roles not only on land but also under water.

COMPARISON OF CONTRACTILE PROPERTIES ON RECTUS FEMORIS AND BICEPS FEMORIS MUSCLES AMONG TRACK AND FIELD ATHLETES.

TSUNODA, N.1, HIRATSUKA, K.1, MIYAZAKI, D.1, SIMUNIC, B.2, DJORDJEVIC, S.2

1: KOKUSHIKAN UNIVERSITY , 2: UNIVERSITY OF PRIMORSKA

INTRODUCTION: The Tensiomyography (TMG) method as non-invasive technique was developed to evaluate the contractile properties of selective muscle (Dahmane et al., 2006). Measurements of muscle belly responses to electrical stimuli (TMG method) have revealed differences among athlete (Loturco et al., 2015). However, characteristics of contractile properties in Track and field athletes are not clear by TMG method. Therefore, in this study, it is to clarify the contractile properties of thigh muscles in sprinters, long distance runners and throwers.
METHODS: Seventy male collegiate athletes of sprinters (SP; n=19; mean ± SD age, height and weight were 20.0±1.8years; 173.2±4.4cm and 64.8±5.1kg), long distance runners (LDR; n=24; mean ± SD age, height and weight were 19.6±1.0years; 170.8±5.7cm and 55.5±4.2kg) and throwers (TH; n=27; mean ± SD age, height and weight were 20.4±1.9years; 177.9±5.7cm and 89.7±12.9kg). The contractile properties of rectus femoris (RF) and biceps femoris (BF) in thigh were assessed by TMG method. Contractile properties of contraction time (Tc), maximal displacement of the muscle belly (Dm) and normalized velocity (Vrn) were analyzed in each groups.

RESULTS: In TH, Dm of RF obtained lowest value among the each groups. Tc of RF in LDR was observed long contraction time. Whereas, Tc for RF in SP and TH were significant shorter contraction times than LDR. And also, same values of Vrn were observed on SP and TH. In LDR, Dm of BF obtained highest value among the each groups. Tc for BF in LDR were significant longer contraction times than SP and TH. Dm of RF/BF ratio in SP and TH were significantly higher value than LDR. Tc of RF/BF ratio in LDR were significantly lower value than LDR. And Tc of RF/BF ratio in SP and TH were showed same values.
CONCLUSION: In this study, contraction properties for rectus and biceps femoris in throwers were significantly different to the long distance runners. Also, the ratio of RF per BF on Tc and Dm in throwers and sprinters were showed significantly higher values to the long distance runners. From these results, it was considered that Tc as a contractile properties on knee extensor and flexor muscles in thigh may reflect to the muscle fiber composition in athletic events.

THE EFFECT OF BALL TEMPERATURE ON BALL SPEED AND CARRY DISTANCE IN GOLF DRIVES

CARLSSON, T.1, NILSSON, J.1,2, HELLSTRÖM, J.3, TINMARK, F.2, CARLSSON, M.1

DALARNA UNIVERSITY

INTRODUCTION: Previously it was reported that golf-ball temperature has influence on the golf balls' coefficient of restitution, impact duration, and maximal deformation (Allen et al., 2012). They concluded that their research was the first step in a process for determining the effect of temperature on a golf drive. However, how large influence the golf-ball temperature has on golf drives remains to be investigated. The purpose was to investigate the effect of ball temperature on impact ball speed and carry distance during golf drives in a blind randomized test design.
METHODS: The balls were exposed to a temperature-controlled environment (4°C, 18°C, 32°C, and 46°C) for twenty-four hours prior to the test, and each of the four different ball-temperature groups consisted of 30 balls. The 120 drives were performed by an elite male golfer (handicap: 0.0) in an indoor driving range. All drives were measured by a Doppler-radar system to determine club-head speed, launch angle, spin rate, ball speed, and carry distance. Differences between the four ball-temperature groups were investigate using a one-way analysis of variance.
RESULTS: The results indicate that there are ball-speed and carry-distance differences within the four ball-temperature groups ($P < 0.001$ and $P < 0.01$, respectively). The post-hoc analyses showed that the ball temperatures 18°C and 32°C had both greater ball speeds and carry distances compared to the balls in the ball-temperature groups 4°C and 46°C (all $P < 0.05$); the intervals for the between-group differences were 2.0 to 2.4 km/h and 2.9 to 3.9 m for ball speed and carry distance, respectively.
CONCLUSION: The novel results of the current study show that the ball's temperature has a significant effect on the ball speed after club-head impact and carry distance for drives performed by an elite golfer. The ball temperatures 18°C and 32°C gave significantly increased ball speeds and carry distances compared to the ball-temperature groups 4°C and 46°C. This knowledge could be used to maximise the carry distance and/or to minimise the carry-distance variability related to ball temperature.

CROSS-SECTIONAL INVESTIGATION OF AGE-RELATED DEVELOPMENT OF SKATING MOTION IN JAPANESE SPEED SKATERS

YUDA, J.1, YOKOZAWA, T.2

1: JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION, 2: JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: Skating velocity is affected by external power output of a skater, as well as air and ice resistances. In addition, skaters can attain skating speed by propulsive support leg extension in a crouched skating posture with a small knee and trunk angle. Therefore, both power output and lower limb technique are important for speed skaters. This study identified the characteristics of age-related development of skating motion in speed skaters.
METHODS: In total, 118 skaters <67 men and 51 women> provided informed consent and served as study subjects. The skaters participated in a 500-m speed skating competition in Japan or a time trial. The subjects were divided into 6 groups based on their age for each sex. However, senior skaters were divided into 2 groups based on the average 500-m race time. The age groups for men were as follows: 9.8 ± 0.4 y, 11.6 ± 0.5 y, 14.1 ± 0.7 y, 16.8 ± 0.9 y, 20.1 ± 1.4 y, 23.4 ± 3.8 y; the groups for women were 9.4 ± 0.5 y, 11.8 ± 0.4 y, 13.9 ± 0.8 y, 16.8 ± 0.9 y, 21.3 ± 4.4 y, and 24.0 ± 3.9 y. Skaters were videotaped with 3 synchronized high-speed video cameras <300 fps> positioned at the middle of the home straight <~50 m from the start line>; the recorded images were analyzed using a panning direct linear transformation technique. The three-dimensional coordinates of the segment endpoints and blades were determined to calculate the kinematic variables during the right stroke.
RESULTS: Tilt angles of the body and shank of the right support leg increased gradually during the right stroke in both men and women. These findings indicate that skaters push the ice sideward, with the body and shank tilting in a medial direction. From the middle to the end of the stroke, the tilt angles gradually increased with growth in both men and women.
CONCLUSION: Greater tilt angles of the body and shank from the middle to the end of the stroke are important in the development of skating performance in the straight phase. It was found that this technical ability gradually increased with growth.

ANTHROPOMETRIC CHARACTERISTICS AND VERTICAL JUMP HEIGHT IN CLASSICAL BALLET DANCERS

RAKOVAC, M.1, SAJKOVIC, D.1,2

1: UNIVERSITY OF ZAGREB, FACULTY OF KINESIOLOGY , 2: UNIVERSITY CLINIC OF TRAUMATOLOGY

INTRODUCTION: Vertical jump ability is an indicator of lower limb power, important for performance in many sports activities (Caia et al., 2016). Vertical jumping is also an integral element in classical ballet performance (Wyon et al., 2006). Many factors possibly influencing vertical jump height in classical dancers have been previously studied (Wyon et al., 2006). However, the influence of different anthropometric measures has not yet been thoroughly explained. The aim of the study was to investigate the relationship between the selected lower limb anthropometric characteristics and vertical jump height in professional ballet dancers.
METHODS: The participants were professional classical ballet dancers, members of the ensemble of the Croatian National Theatre in Zagreb (n=37, 24 females; age (mean±SD) 31.8±7.8 yrs; height 170.2±7.5 cm; body mass 58.6±10.3 kg). Pelvic width, thigh length, lower leg length, foot length, thigh girth, calf girth and Q-angle were measured. Vertical jump ability was tested by Sargent jump test. A multiple

regression analysis with vertical jump height as criterion and anthropometric parameters as independent variables was performed using a forward stepwise procedure.
RESULTS: The average vertical jump height was 43.6±9.9 cm. The results of the regression analysis indicated four predictors explaining 51% of the variance in vertical jump height (R2=0.51, F(4,32)=8.22, p<0.0001). The anthropometric characteristics significantly predicting vertical jump ability were foot length (beta=0.33, p=0.028), calf girth (beta=0.66, p=0.001), thigh girth (beta=-0.49, p=0.012), and Q-angle (beta=-0.27, p=0.048).
CONCLUSION: Expectedly, foot length was positively related with vertical jump height, but the previously determined relationship between other longitudinal leg dimensions with jump height was not confirmed. While larger lower leg muscle mass, indicated by a larger calf girth, was positively related with jump height, there was a significant negative relationship between thigh girth and jump height, a result discordant with previous studies (Wyon et al., 2006). This result could possibly be attributed to a positive relationship between thigh girth and body fat percentage, previously indicated as a negative predictor of jump height (Caia et al., 2016). Increased Q-angle can be related with both decreased jumping performance and increased risk of knee injuries (Russell, 2013).

A NEW CALIBRATION METHOD FOR ESTIMATING SCAPULAR POSTURE DURING SHOULDER MOVEMENTS

MATSUMURA, A., UEDA, A., NAKAMURA, Y.

GRADUATE SCHOOL OF HEALTH AND SPORTS SCIENCE

INTRODUCTION: The acromion marker cluster is a standard technique used for the measurement of scapular posture. The AMC was attached to the skin overlying the flat portion of the acromion. A motion capture system was used to locate the AMC and to estimate scapular posture. When the arm elevation angle exceeded 120°, the estimation error for scapular posture increased. Therefore, this conventional method cannot adequately represent complex shoulder movements, including activities of daily life and sporting motions. The aim of this study was to develop a new calibration method using scapular posture measurements during shoulder movements. This enabled scapular posture for shoulder movements in ADL to be estimated.
METHODS: Ten healthy males were recruited. A motion capture system recorded the location of the AMC and the position of anatomical landmarks on the scapula, humerus, and thorax. To estimate scapular posture, the positional relationship between the AMC and the landmarks was calibrated. To derive calibration tables, the AMC and the landmarks were measured in 10 positions including 0° and 180° of arm elevation, and 90° and 150° of arm elevation in each elevation plane. The calibration tables used spline interpolation. The location of the AMC, the arm elevation angles, and the elevation plane angles were inputted into the calibration tables. The conventional method , was used as the reference; with a fixed relationship between the AMC and the landmarks at an arm elevation angle of 0°.
To evaluate the accuracy of the new and conventional methods, four tasks , were applied. The International society of biomechanics recommendations were used to calculate scapular angles. To determine the differences between our method and the conventional method, the root mean square error was calculated for each task.
RESULTS: Our new method decreased the RMSE of all the scapular angles, as compared with the conventional method. The RMSE for our method was approximately 5° . For tasks requiring greater arm elevation angles , the RMSE of our new method was less than that of the conventional method.
CONCLUSION: The positional relationship between the AMC and the landmarks was not constant across shoulder positions due to soft tissue artifacts, particularly when the arm was elevated above 120°. Therefore, the error associated with the conventional method increased. Our new calibration method could improve this estimation error, since it considered the positional relationship between the AMC and the scapular landmarks using several shoulder movements with >120° of arm elevation in each elevation plane.

DETERMINE UPSTAIRS AND DOWNSTAIRS MOTION WITH IMU SENSOR

SHIANG, T.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Researchers can estimate people's daily physical activity and energy expenditure by counting their total number of steps in a day. However, for a single step, energy expenditure can differ considerably during upstairs and downstairs walking. In addition to level walking, common walking patterns include stairs walking. Previous studies have shown that the motion characteristics among the aforementioned walking types differ considerably regarding the angle of the trunk and limbs, ground reaction force, landing strategy, stride frequency, and step length, despite identical motion phases. This is because different motions and strength can have distinct effects on muscle stimulation and energy expenditure. Therefore, the purpose of this study was to identify differences of upstairs and downstairs walking by using an inertial measurement unit (IMU) to improve the accuracy of daily physical activity assessment.
METHODS: Thirty healthy participants were recruited for this study. The IMU was stabilized on the exterior of the left shoe. Participants were asked to perform normal walking under 3 distinct conditions: level walking, upstairs walking, and downstairs walking. The IMU chip used in this study was an MPU6050 (InvenSense, CA, USA), the sampling frequency was set at 100 Hz. Repeated measures one-way ANOVA was used to determine the differences of signal features among the three conditions.
RESULTS: The results revealed significant differences in most axial directions of the three walking conditions except for the angular velocity of inversion–eversion (G–X) during the HS phase and the angular velocity of internal–external rotation (G–Y) during the TO phase. Specifically, the results of the angular velocity of dorsi–plantar flexion (G–Z) in the HS phase completely conformed to our expectations ($p < .01$). Combining the results of the angular velocity of dorsi–plantar flexion in the HS and toe-off phases or the results of the angular velocity of dorsi–plantar flexion and anteroposterior acceleration in the HS phase can facilitate more precisely determining the differences among the three conditions.
CONCLUSION: The signal feature of the IMU can be used to identify walking patterns under different conditions such as up and downstairs. A dual-index approach such as the angular velocity of dorsi–plantar flexion in the ankle joint during the HS phase combined with the acceleration of anteroposterior direction, or with the angular velocity of dorsi–plantar flexion in the TO phase can facilitate a more accurate differentiation of similar patterns under different conditions. The techniques designed for identifying movements in different

terrains can more accurately calculate physical activity levels and can be utilized in the fields of sports medicine and rehabilitation for recording the daily activities.

Coaching

THE EFFECT OF CHANGE IN THE DIRECTION OF A MALE SWIMMER'S FACE DURING THE SETTING BEFORE THE START SIGNAL ON HIS START PERFORMANCE IN COMPETITIVE SWIMMING

TAKASHI, K.

NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA

INTRODUCTION: In the swimming start phase, it is reported that the head of swimmer reaches 15m distance point early if the swimmer increases the horizontal velocity at the front foot-off and approaches the take-off angle forwards horizontal (Takeda et al., 2006; Yoshida and Saito, 1981). Regarding the start action, various improvement methods are founded. However, few of them are unclear. This study focused on a posture with the swimmers face turning in an anterior direction before the start signal. Hence, the purpose of this study was to clarify the effect of change in the direction of a male swimmer's face during the setting before the start signal on his start performance in competitive swimming.
METHODS: Six Japanese male college swimmers participated in this study. The subjects performed 6 trials of the competitive start. The first half is their usual start (US). The second half is the start with their faces turning forward during setting before the start signal (FS). The subjects were instructed to perform each start with maximum effort, followed by a 15 m freestyle swim. Trials were recorded at 250 fps using two synchronized high-speed cameras (MEMRECAM FX-K5, nac, Japan) equipped.
RESULTS: The results of 15-m time were 7.09 ± 0.18 s (FS), 6.97 ± 0.30 s (US) respectively. No significant difference was recognized between FS and US, but the time of US tended to be shorter than FS. In the experiment, only subject B reached 15 m distance point in FS faster than US. Those results were 7.28 s (FS), 7.46 s (US) respectively.
A decrease in subject B's take-off angle brought about the outcome. The other subjects tended to take off downward in both FS and US. However, subject B had a tendency to take off obliquely upward in US. On the other hand, he was inclined to take off linearly in FS. Additionally, his flight distances in FS and US were almost the same. Thus, it is indicated that 15-m time became shorter in FS because the distance was shorter from his start position to his entry position due to his face which was turned upward. Consequently, FS can be effective for competitive swimmers like subject B who have a tendency to take off upward.
CONCLUSION: It was clarified that the change in the direction of a male swimmer's face during the setting before the start signal don't always have an effect on his start performance.

BIOMECHANICAL ANALYSIS OF VOLLEYBALL OVERHEAD PASS WITH DIFFERENT DISTANCES

OZAWA, Y.

WASEDA UNIV.

INTRODUCTION: Volleyball overhead pass is an important skill for setting a ball to attackers. The higher the performance of setters, the higher the performance of attackers (Nikolaos et al. 2009). However, there is no biomechanical investigation of the overhead pass. In this research, we investigated the difference in movements of the elbows and wrists, and in activities of the muscles responsible for these joint movements during overhead passes of three different distances.
METHODS: Four male subjects participated in this study. All of them were top level university volleyball players. Subjects were told to pass a ball with overhead pass into a ring (diameter: 1 m, height: 2.43 m) set at 3, 6 or 9 meters ahead from a subject. They repeated trials at each distance until they times. Forty-one reflective markers were placed on the ball and the subject's body to obtain joint centers and joint angles. EMG activities were recorded from the Triceps Brachii (TB), Biceps Brachii (BB), Extensor Carpi Ulnalis, and Flexor Carpi Radialis (FCR).
RESULTS: The contact time the duration from ball touch to ball release, did not differ among 3 m, 6 m and 9 m. And there was no common tendency in the contact time among subjects. While a subject had the longest contact time in the 3 m trials, another subject had the longest contact time in the 9 m test. The elbow angular velocity had also no common tendency. In the TB, all subjects had lower activity for the 3 m trials than the other distances. In the 3 m trials, the angular velocity of the wrist tended to be lower than the other distance in three subjects. In all tests, the onset time of FCR activity occurred tens of milliseconds before the ball touch in all subjects. The rise in FCR activity was slowest in the 3 m trials, and fastest in the 9 m trials.
CONCLUSION: There was no clearly difference in the contact time among three different target distances. However, the longer the target, the higher the TB activity. In addition, the longer the target, the steeper the FCR activity was. The subjects controlled the distance of overhead pass not by controlling the contact time but muscle outputs, especially that of the FCR, just after ball touch when the wrist pull the ball, and the adjust the activity of the TB during the contact of the hands and the ball.

Health and Fitness

MODERATE AEROBIC EXERCISE OR HIGH INTENSITY INTERVAL PROGRAMS: WHAT'S BETHER TO THERAPEUTIC IN OBESE BOYS?

LEITE, N., PIZZI, J., MILANO-GAI, G.E., SCHIAVONI, D., RADOMINSKI, R.B., MOTA, J.

FEDERAL UNIVERSITY OF PARANÁ AND UNIVERSITY OF PORTO

INTRODUCTION: Physical activity was used as preventive and therapeutic actions to obese and comorbidities in pediatric population. The aim of this study was to compare the effect of 12-week intervention using two aerobics programs on anthropometrics, body composition and cardiometabolic parameters in obese adolescents.
METHODS: Fifty-six boys, aged 10 to 16 years, with body mass index Zscore ≥2 were evaluated. Weight, height, systolic blood pressure and diastolic , waist circumference , waist-to-height ratio , body composition, direct maximal oxygen uptake relative and absolute , heart rate at rest , glucose, insulin, triacilglycerol , total cholesterol and fractions HDL-c and LDL-c were assessed at the beginning and after 12 weeks. Homeostasis Metabolic Assessment and Quantitative Insulin Sensitivity Check Index were determinated. Participants were divided into three groups: aerobic moderate , high intensity interval training and control group . AMG bout session consisted of 45-minute indoor cycling and 45-minute walking, starting first weeks with 35-45% of heart rate reserve and progressive increasing up to 50-60%. HIITG bout session consisted of 45-minute with exercises of heating, HIIT in the form of race/walk indoor, with interval intensities of 100% and

50% of HRreserve, and the cooling phase at the end. Exercise groups performed three times a week, totalizing 36 sessions. Control group was only engaged in physical education at school. All participants were followed for 12 weeks and took part in nutritional guidance. ANOVA was used for comparisons at baseline and after 12 weeks and the effect size was calculated for each group, to compare the magnitude of each type of physical exercise.
RESULTS: No statistical significant differences were found between groups at baseline, except for BMI-Zscore and WHtR higher in HIITG and fat mass lower in AMG . After 12-weeks, exercises groups presented a significant reduction in HRrest and, respectively AMG and HIITG, the EF <0.77 vs 0.40>, and increase in height <0.33 vs 0.07>, VO2ml/kgmin <0.88 vs 0.15> and VO2l/min <0.33 vs 0.12>. Only AMG showed a significant reduction in BMI , BMI-Zscore , WC , WHtR , FM in % and kg , TG and an increase in HDL-c . HIITG presented a significant reduction in TC and DBP and an increase in LDL-c . CG increase only height .
CONCLUSION: Regular PA such as aerobic or HIIT provides health benefits in cardiorespiratory fitness. The HIITG presented some clinical improvements, but the AMG was able to improve modifications in anthropometric, body composition and cardiometabolic parameters, and higher ES. We concluded that moderate aerobic exercise presented better therapeutic response in obese boys.

INHIBITORY CONTROL PERFORMANCE AND LEPTIN RESPONSE TO ACUTE MODERATE-INTENSITY INTERVAL EXERCISE IN OBESE SEDENTARY FEMALE ADULTS

WEN, H.J., ANG, B.S.

1:TZU-CHI UNIVERSITY, 2:UNIVERSITI SAINS MALAYSIA

INTRODUCTION: Obesity is a concerned public health problem and contributes to huge medical expenses . It is frequently accompanied by a subclinical systemic inflammation which is marked by the increase in circulating levels of leptin . It's also associated to adverse neurocognitive outcomes and reduced brain volume. Currently, moderate-intensity interval exercise is a popular exercise modes that combine aerobic exercise and resistance training, which was effectively reduced body weight and percentage of body fat in a shorter time . The purpose of this study was to explore the acute effect of MIIE on inhibitory control performance and leptin response in obese sedentary female adults.
METHODS: Nineteen age-matched obese and normal weight female adults were recruited for this study. Both groups were required to attend a single bout specifically designed 30 minutes supervised MIIE. Percentages of body fat and cardiovascular endurance were determined within one week before the MIIE. Blood samples and behavioral performance were obtained before and 2-hour after the 30 minutes supervised MIIE. The MIIE program consists of 5 minutes warm-up, 30 minutes interval training at 55% of heart rate reserve and 5 minutes cool down. There were 4 cycles in a session, and six sets per cycle, 1 minute per set, 15 seconds break between each set. The exercise intensity was monitored to ensure the participants reached the target HR.
RESULTS: The results showed that at baseline, the OG was significant higher in percentage body fat and leptin levels than CG, but no difference in cardiovascular endurance . On the inhibitory control performance, both groups have a similar high accuracy rate in both condition, and the accuracy rates were sustained after the 30 minutes of MIIE. However, the reaction time in OG was significantly improved after the 30 minutes of MIIE , but no change in CG . The serum concentration of leptin in both groups were significantly decreased after the MIIE session , and no change in C-reactive protein concentrations.
CONCLUSION: The leptin in obese females were significantly higher than that in normal weight. The effect of a single bout of 30 min MIIE showed an acute effects on the inhibitory control, which improved the reaction time, and reduced leptin levels. The long-term effects of MIIE were recommended for further study.

LIPID AND GLYCEMIC PROFILE OF EUTROPHIC, OVERWEIGHT AND OBESE SCHOOL ADOLESCENTS

RIBEIRO DA SILVA, A., LURDES CENCI TSUKUDA, V., MARIA BACELAR SANTOS, L., EMANOELLA SILVA MARTINS DE SOUZA, S., LEÔNIDAS SOARES, J., LINS DE MAGALHÃES, G., DE FRANÇA BARROS, J.

UNIVERSIDADE DE BRASÍLIA

INTRODUCTION: Objective: of this work was to evaluate the changes on the lipidic and glicemic profile in adolescents with overweigh and obesity compared to eutrofic group.
METHODS: The criterion for the diagnose was the body mass index suggested by Cole et al., <2000>. The association between waist circumference. The first part of the study 769 students were evaluated and from wich were selected 133 adolescents, aged 12 to 18 years old, of both sex, distributed in eutrofic , overweight and obese . In these groups were measured lipoproteins, glucose, body mass index, triceps and subscapular skinfold waist circumference.
RESULTS: Showed that overweigh and obesity leads to an increase in blood levels of total cholesterol, LDL cholesterol, and triglycerids and a decrease in HDL cholesterol levels. Glucose level increased only in the femmale group. The waist circumference, a visceral fat indicator, was also associated with an abnormal lipid profile but not with increase in glucose level.
CONCLUSION: This work emphasyses the needs to inget public health measures to control overweigh and obesity among adolescentes.

EFFECT OF EIGHT WEEKS MODIFIED HIGH-INTENSITY CIRCUIT TRAINING USING BODY WEIGHT ON BODY COMPOSITION IN SEDENTARY OBESE WOMAN

AJJIMAPORN, A., WIDJAJA, W., KHEMTONG, C.

COLLEGE OF SPORTS SCIENCE AND TECHNOLOGY, MAHIDOL UNVERSITY, SALAYA CAMPUS, NAKHON PATHOM

INTRODUCTION: It is well documented that a sedentary lifestyle along with poor eating behavior is directly associated with obesity. Exercise prescription is one of the powerful treatments for this population offered by healthcare providers. However, physical training for obese people should consider safe movements without pain or risk for injury but with an intensity and duration aimed to improve body composition. Positive effects of high-intensity circuit training design using body weight (BW) as the only form of resistance (HICTBW) on health-related fitness conditions have been observed in recreationally active men and women (Schmidt et al., 2016). The aim of the present study was to examine the effects of 8 weeks modified HICTBW program on body composition parameters in sedentary obese women.
METHODS: Twenty-four sedentary obese females (age = 34±4 years, BMI = 27±7 kg·m-2) were randomly assigned into 2 groups: a HICTBW group (n=12) and a control group with no training (n=12: CG). Participants in the HICTBW group performed 8-weeks, 3 times weekly, a modified HICTBW training which consisted of 30-sec work and 10-sec rest for 12 exercise positions per 1 round, continuously increased by 1 round every 2 weeks. Whereas CG group performed the usual physical activity for 8 weeks. Both groups were advised not

to change their dietary habit throughout the program. Body composition including BW, fat mass (FM), skeletal muscle mass (MM), visceral fat area (VF), and percent body fat (%BF) was measured before and after the 8-week training program.
RESULTS: At baseline, no differences for all parameters were observed between the two groups. Post-training, improvements for the HICTBW group were observed for FM, MM, VF and %BF ($p<0.05$) but not BW ($p>0.05$) compared to baseline values. No changes were observed for the CG group from baseline to week 8.
CONCLUSION: This study showed an improvement in body composition and prevention of weight gain from 8 weeks of a modified HICTBW program in previously sedentary obese women. A HICTBW program seems to provide benefits for sedentary obese women and the exercises may be performed daily as the program is simple, inexpensive, practical, and seemingly low risk for injury.

COMPARISON OF DAILY SEDENTARY TIME BETWEEN CHILDREN ENGAGING IN MORE AND LESS THAN 2-HOUR SCREEN TIME

OKAZAKI, K.1, KOYAMA, Y.2, OHKAWARA, K.3

1: TOHOKU-GAKUIN UNIV. , 2: SEIKEI SENIOR HIGH SCHOOL , 3: UNIV. OF ELECTRO-COMMUNICATIONS

INTRODUCTION: The questionnaire of the Health Behaviour in School-aged Children (HBSC) is one of the commonly and widely used questionnaires to evaluate sedentary behaviour (SB). This study aimed to objectively measure and compare SB assessed via the HBSC questionnaire in Japanese children.
METHODS: A total of 94 children (boys=46 and girls=48) from the fourth to the sixth grade were asked to complete the questionnaire and wear a traxial accelerometer for more than seven consecutive days. The HBSC questions (Morgan et al, 2016; Booth et al., 2001) asked children to report three type of screen-based SB patterns on weekdays and weekends. Responses to these types of SB were summed separately for weekdays and weekends to calculate average daily screen time. Following this, children were classified into the low sedentary group (LS; ≤2 hrs per day) and high sedentary group (HS; >2 hrs per day). The minimal amount of objective data on SB that was considered acceptable was 4 days of wearing time with at least 10 waking-hours per day, including at least one weekend day. Children's mean time spent in objective SB was calculated for weekdays and weekends.
RESULTS: Among the children who completed the study on week days (N=87), there was no significant difference in the mean time spent on SB per day between LS (429 min) and HS (429 min) in the independent t-test. Similarly, the mean time spent in SB on weekends (N=71) did not differ significantly between LS (476 min) and HS (462 min).
CONCLUSION: Our findings suggested that the amount of SB per day between LS and HS on weekdays and weekends did not differ among Japanese children. One possible explanation for this finding is that the HBSC questionnaire evaluated screen-based patterns focusing on media use only. Therefore, whether SB assessed via the HBSC questionnaire can reflect objectively measured SB per day needs further discussion. Although screen-based SB, including watching TV, using a computer, and playing video games, is becoming a central component of the daily lives of children (Tremblay et al, 2011), it is possible that there are no differences in the amount of daily SB among children who are classified as 2 h cut-off value's recommendation (Barlow, 2007).

ASSESSMENT OF A SHORT-FORM FALL RISK QUESTIONNAIRE FOR COMMUNITY-DWELLING ELDERLY PEOPLE

SONG, C.Y., TSAUO, J.Y., FANG, P.H., FANG, I.Y., CHANG, S.S.

NATIONAL TAIPEI UNIVERSITY OF NURSING AND HEALTH SCIENCES

INTRODUCTION: The worlds population is ageing. Fall prevention is an important global health issue in long-term care. This study aimed to develop a practical fall risk assessment questionnaire for identifying high-risk fallers in the community.
METHODS: Three hundred and forty-four community-dwelling individuals (73 men and 271women) aged 65 years or older who voluntarily participated in a community- and exercise-based fall-prevention program were assessed with a 12-item fall risk questionnaire (FRQ) (Rubenstein et al., 2011) to evaluate risk factors associated with falls.
RESULTS: Of the participants, 136 (39.5%) experienced at least one fall in the previous year (average fall= 1.7 times). The FRQ scores were higher in fallers than in non-fallers (5.7 and 2.3, $p<0.005$). The item score of gait/balance problems, muscle weakness, fear of falling, and incontinence was significantly different between fallers and non-fallers (all $p<0.05$). The area under the receiver operating characteristic curve for the simple sum of the 6 significant items was 0.65 ($p<0.05$). The best cutoff point was 2, with sensitivity and specificity of 62.9% and 61.1%, respectively. Logistic regression analysis showed the odds ratio= 2.68 ($p<0.001$).
CONCLUSION: This study found the risk factors associated with falls for community-dwelling elderly people which contribute to development of early preventive exercise interventions in community settings. Future research may explore psychometric properties of the 6-item short-form of the FRQ for assessing risk of falling.

EFFECT OF RESPIRATORY STRETCH GYMNASTICS FOR SENIOR CITIZEN PEOPLE.

AKAE, K.

TOKYO ARIAKE UNIVERSITY OF MEDICAL AND HEALTH SCIENCES

INTRODUCTION: Respiratory patterns are influenced and altered by various emotional changes. In the present study, that we investigated how respiratory patterns differ from individual to individual during quiet breathing.

METHODS: We examined the State-Trait Anxiety Inventory (STAI) and various respiratory parameters in 13 healthy male subjects. Subjects sat on a chair wearing a facemask with a transducer connected to a respiratory monitor for measuring respiratory pattern and metabolism in a quiet room. All statistical analyses were performed with commercially available statistical package (SPSS). A P value of <0.05 was considered statistically significant. Pearson's correlation coefficient (r) was used to study the relationships between trait anxiety and state anxiety or various respiratory parameters.
RESULTS: Tidal volume was significantly larger and respiratory rate (RR) was significantly higher in both the higher trait (HT) and higher state (HS) anxiety groups compared to the lower trait (LT) and lower state (LS) anxiety groups. There was no significant difference in minute ventilation (VE) between these two groups. End-tidal CO2%, heart rate (HR) and oxygen uptake (VO2/W) also showed no significant differences.
CONCLUSION: These results suggest that the respiratory rhythm reflected by RR is affected by the activity generated in the higher center in accordance with the level of trait and anxiety during quiet breathing in awake humans. The study showed that respiratory rate and anxiety score has an undivided relationship. Second, we examined how respiratory stretch gymnastics affect on RR and anxiety score. 70 senior citizen in Kawaguchi city were participated in this study. RR and state anxiety score were decrease after performing the respiratory stretch gymnastics. The results suggest that the respiratory stretch gymnastics is an useful gymnastics for senior citizen people to decrease anxiety.

FATS ARE HIDING UNDER CLOTHES! ~STUDY ON THE BODY COMPOSITION OF ELDERLY WOMEN IN THE EXERCISE CLASS~

NISHIZAWA, T.

SIGAKKAN UNIVERSITY OF JUNIOR COLLEGE

INTRODUCTION: We measured the fat balance (abdomen, upper limb and lower limb) of the elderly women participating in the exercise class. Aims To verify relationships between physical activity (steps per day) and obesity (components of body composition) among postmenopausal women.
METHODS: Obesity were assessed among 23 healthy postmenopausal women (54-85years). With regard to the body build, obesity was diagnosed based on weight, BMI (the body mass to the square of the body height), and waist-hip ratio (WHR, i.e. the circumference of the waist to hips; ratio above 0.85 means abdominal obesity). We measured the fat balance (abdomen, upper limb, lower limb) of the elderly women, using the body composition analyzer InBody 430 (Biospace Co.). The amount of physical activity was measured using a Lifecoder (suzuken Co.)for 2 months. Physical test was measured for elderly women at the first and 2 months after exercise class. Items were sit up, balance, walking for 6 minutes(endurance), walking with obstacles and grip strength.
The exercise classroom was held for 2 months. The program content was a 30-minute aerobics and resistance circuit. On the circuit training, I made three laps of sit-up, push-up, side raise, arm curl and rat pull-down. Exercise time was 1 minute exercise and 30 seconds rest.
RESULTS: The results of WHR showed 40% above 0.85. The BMI result was obesity 18%, standard 82%. The fat balance for each part by number of people was abdominal fat percentage high 57%, standard was 43%, low value was 0%. The results of upper limbs and lower limbs were standards for everyone. The value after 2 months was 57% for high, 40% for standard and 3% for low value. The average number of steps per day was 75**%** with more than 5,900 steps and 25**%** with less than 5,900 steps. As a result of the physical fitness test after 2 months, 6 minutes walking (endurance) and walking of obstacles improved. Sit up could not be done by six people. There was no change even after two months.
CONCLUSION: There was no significant change in body composition in the exercise class for 2 months. The results showed that while BMI was normal and fat percentages in upper limbs and lower limbs were standard, there were many people with abdominal fat. In addition, the amount of physical activity was not low. Therefore, degree of obesity should not be judged by BMI or the body composition of the whole body, and fat percentage by body part must be emphasized. Fats are hiding under clothes. One of the reasons why fat in the lower abdomen of elderly women is large is considered to be a decrease in female hormone associated with menopause. Also, it may be one of the causes that sit up can not be done.

TRAINING INDUCED IMPROVEMENTS IN STRENGTH OF THE KNEE EXTENSORS IS ASSOCIATED WITH INCREASED PHYSICAL ACTIVITY LEVEL 4 YEARS AFTER TRAINING IN ELDERLY MEN

BERNTSEN, S.1, BJØRNSEN, T.1, LOHNE-SEILER, H.1, STEA, T.H.1, PAULSEN, G.2

1. UNIVERSITY OF AGDER, KRISTIANSAND, NORWAY, 2. NORWEGIAN OLYMPIC SPORT CENTER, OSLO, NORWAY

INTRODUCTION: Skeletal muscle power and strength are important determinants of physical function in older adults, and strength-training induced increases in the power and strength of the leg muscles is associated with increased walking speed. However, whether such training induced improvements in the legs translates into a more physically active lifestyle in the long run is unknown. The aim of the present study was to determine whether increases in leg muscle strength and -size during 12 weeks of strength training are correlated with objectively recorded physical activity level and sedentary time four years after training, in elderly men.
METHODS: Thirty-five elderly males (64 – 85 yrs old) participated in a supervised heavy-load strength training regime (2/wk with 8-10RM load and 1/wk with 3-5RM or 13-15RM) for 12 weeks, Muscle strength, -tickness, lean mass of the legs and objectively recorded physical activity were measured before and after the strength training period, as well as four years after the training period. Muscle size was assessed as changes in lean mass with Dual Energy X-ray absorptiometry and thickness of m. rectus femoris and m. vastus lateralis with ultrasound imaging. Strength was measured as 1-repetition maximum (1RM) in leg press and knee extension. Physical activity was recorded by the activity monitor SenseWear™ Mini (BodyMedia inc, US) for seven consecutive days. Data were analysed using Spearman rank correlation.
RESULTS: Percentage increase in knee extension during 12 weeks of strength training was significantly and positively correlated to moderate-to-vigorous intensity physical activity (ρ=0.49, p=0.003), but negatively correlated to sedentary time (ρ= -0.49, p=0.003), four years after training. Neither improvements in leg press, lean mass of the legs nor muscle thickness were correlated with moderate-to-vigorous intensity physical activity or sedentary time.
CONCLUSION: Improvements in knee extensor muscle strength during twelve weeks of strength training seems important for maintenance of a physically active lifestyle in older adults, suggesting that physical activity programmes may need to include strength exercises involving knee extensors. Our findings should be confirmed in a ranomized controlled setting with a control group not participating in strength training.

EFFECTS OF AQUATIC EXERCISE ON METABOLIC SYNDROME RISK FACTORS, CARDIOVASCULAR FITNESS, KNEE ISOKINETIC FUNCTION, AND WOMAC INDEX IN PATIENTS WITH OSTEOARTHRITIS WOMEN

YOON, J.R., HA, G.C., YOO, C.G.

KOREA NATIONAL SPORT UNIVERSITY

INTRODUCTION: Purpose: The purpose of this study was to investigate to effects of aquatic exercise on metabolic syndrome risk factors, cardiovascular fitness, knee isokinetic function, and WOMAC index in patients with osteoarthritis women.
Purpose: The purpose of this study was to investigate to effects of aquatic exercise on metabolic syndrome risk factors, cardiovascular fitness, knee isokinetic function, and WOMAC index in patients with osteoarthritis women.
METHODS: Method: The subjects were 19 women who were osteoarthritis. Aquatic exercise program has performed the 60min per day, 3days per week. The changes of body syndrome risk factors, cardiovascular fitness, knee isokinetic function, and WOMAC index were measured and analyzed at pre- and post- exercise program for verifying exercise effectiveness.
RESULTS: Result: The results were as follows; After 12 weeks of exercise program, % fat, fasting glucose, systolic blood pressure, and diastolic blood pressure were significantly decreased. Left and right extensor knee muscle function were significantly increased. In the WOMAC index, stiffness and physical activity were significantly decreased.
CONCLUSION: Discussion: In conclusions, aquatic exercise program showed beneficial effects on metabolic syndrome risk factor management, knee muscle function increase and WOMAC index improvement in osteoarthritis women.

FALLS IN ELDERLY PEOPLE PRACTICING PHYSICAL EXERCISE

FERNANDES, V.L.S., FREITAS, I.P., AUGUSTO, G., RODRIGUES, F.F., VENTO, D.A., TACON, K.C.B., MENEZES, R.L.

CENTRO UNIVERSITARIO DE ANÁPOLIS - UNIEVANGELICA

INTRODUCTION: Due to the repercussion on the health of the elderly, the fall is considered a limiting event, it is a public health issue, where there is a decrease in self-confidence which can lead to a lower level of physical activity, a reduction in muscle strength and, consequently, an increase in risk of falls. The aim of the study was to identify the incidence of falls and associated factors in active elderly participants of the Open University Project for Third Age - UniATI.
METHODS: Longitudinal study, approved CEP n. 1.456.257, the history of falls was evaluated with the following question: "Have you suffered a fall in the last 12 months?" The fall was recorded regardless of the severity of the injury. A questionnaire was applied to identify sociodemographic profile and health conditions. The Mini Mental State Examination (MMSE) served as a screening of cognitive function. Physical-functional tests, such as the Timed Up and Go (TUG) and Manual Hold Force (FMP) were used. Inferential analysis was performed with means, standard deviation, minimum, maximum, confidence interval, frequency and percentage. Comparison of the means of 'fallen" and "non-fallen" subgroups in the scalar variables (age, weight, height, BMI) using the Students T-test for the parametric variables and the Mann-Whitney test for the non-parametric variables.
RESULTS: A total of 146 subjects of both sexes, with cognitive preservation, participated in the study, most of them women (87%), mean age of 68 ± 2.90 years, BMI 27.37 ± 4.48. All subjects were active in practising physical exercise, at least twice a week, with an average duration of 40 minutes, being water gymnastics 60 (41%), bodybuilding 74 (51%) and zumba 12 (8%). The occurrence of falls in the last 12 months was present in 32.2% of the active elderly. Participants were classified into two subgroups, "fallen" (n = 47) and "non-fallen"(n = 99). The groups were homogeneous in relation to gender, age, and anthropometric variables, such as weight, height and BMI ($p > 0.05$). There was no significant difference for functional physical variables such as TUG and FPM between groups ($p > 0.05$). Variables that contributed to falls were personal / family income, living alone, and health conditions, such as diabetes, urinary incontinence, poor perception of health and vision, and hospitalization ($p<0.05$).
CONCLUSION: Falls are considered a public health problem, and even the healthy and physically active elderly are also vulnerable to falls, and the reasons can be associated with social and health issues. In the present study, one third of the elderly had a fall episode in the last 12 months, reinforcing data from the literature that states that the causes of falls are multifactorial and that the approach must involve a multiprofessional team.

INTEGRATED YOGA THERAPY ON QOL, HEALTH STATUS AND FITNESS OF LIFE IN SENILE PEOPLE

KIM, H.

DONG-EUI UNIVERSITY

INTRODUCTION: The purpose of this study was to investigate the effects of yoga therapy and integrated yoga program on the activities of daily living , muscle mass, mood state, physical fitness, and disease prevention in senile people. We also analyzed yoga program and yoga therapy through many experimental and review papers in terms of elderly exercise practices.
METHODS: In this purpose, we searched the Pubmed data base for the articles and review papers having the terms nonpharmacological therapy and yoga program in the elderly in the title, published from 2005 untill 2017. A total over 100 papers displayed, out of which almost 30 papers were closely relevant to this papers. All these data were selected and analyzed. Appropriated cross-references within the papers along with cochrane reviews were also examined.
RESULTS: In this paper, we analyzed and evaluated two main points such as the importance of yoga
therapy in the elderly and disease prevention of yoga program in the
elderly . This paper evaluated that yoga programs might be performed in the elderly people and elderly patients and also this program might help in the prevention of age-related degeneration by changing cardiovascular diseases, immunological disease, bone health, muscle function, autonomic function, brain function and even mental health.
CONCLUSION: These findings also indicate that yoga therapy improves many psychological outcomes, and enhance the QOL by improving their overall mental health status.This might be caused because the yoga practice resists the autonomic changes and celluar impairment in the elderly. Therefore, we have to consider adding yoga therapy to ongoing inpatient rehabilitation and participants recognized the benefits of having the yoga therapy. Further study about the disease treatment and the treatment mechanism of yoga program is needed in this area.

ASSOCIATION BETWEEN MUSCULOSKELETAL AMBULATION DISABILITY SYMPTOM COMPLEX (MADS) AND HABITUAL FISH AND SHELLFISH INTAKE IN COMMUNIY-DWELLING ELDERLY WOMEN

OHKI, K.

SUGIYAMA JOGAKUEN UNIVERSITY

INTRODUCTION: Regular physical activity is essential to better health and wellness. However, falls must be prevented, because they are prone to losing their balance during physical activities. Recent research has shown that older people who perform poorly on standardized tests of lower extremity strength and balance are at a higher risk of developing disabilities. It is well known that balance ability is one of the items of muscleskeletal ambulation disability symptom complex (MADS). Dietary habits also important factor in our heathy life. The purpose of this study is to clarify the association between MADS and dietary habits in Japanease community -dwelling elderly women.
METHODS: 94 local elderly women residents aged 65 yrs. or older were recruited. The subjects were divided into two groups: 1) one-leg standing time with eyes open for more than 15 sec. (high-level group; n=66, HG) , 2) one-leg standing time with eyes open for less than 15 sec. (low-level group: n=28, LG). Hand-grip strength, chair-stand test, functional reach test (FR), time up go test, 10-m maximal walking speed (MWS), mini-mental state examination (MMSE), trail making test (TMT), fall efficacy scale (FES), psychological functions and brief-type self-administered diet history questionnaire (BDHQ) were examined.
RESULTS: As the results, one-leg standing time with eyes open was 59.5+43.9 sec., and HG subjects, accounted for 70.7% of the total subjects. Significant differences ($p<0.05$) were observed in the age (HG;71.5+4.2, LG;74.3+4.4 yrs.), hand-grip strength (HG;29.6+6.2, LG;24.8+5.6 kg), FR (HG;79.6+8.2, LG;61.2+18.0 cm), MWS (HG;2.0+0.2, LG;1.8+0.2 m/sec.), MMSE (HG;28.5+1.9, LG;26.7+3.2 pts.) and FES (HG;37.6+3.9, LG;32.7+4.5 pts.) between the two groups. The results of BDHQ revealed that fish and shellfish intake (HG;60.1+43.3g, LG;10.6+3.5 g, $p<0.01$) were associated with physical function and MADS. When comparing the two groups after adjusting for age, a significant difference ($p<0.05$) was observed only in TMT (HG;92.2+22.0, LG;128.8+56.2 sec.).
CONCLUSION: It was suggested that the elderly women with lower level of balance ability and lower frequency of eating fish and shellfish were markedly influenced to their healthy life.

RELATIONSHIP BETWEEN ANTHROPOMETRIC VALUES, HEALTH AND PHYSICAL ACTIVITY PARAMETERS IN HEALTHY ADULTS AND ELDERLY PEOPLE

VIRGALA, J., ARIZAGA, N., ZARRAZQUIN, I., FERNÁNDEZ-ATUTXA, A., IZAGIRRE, A., MARTÍNEZ-LAGE, P., IRAZUSTA, A., KORTAJARENA, M.

UNIVERSIDAD DEL PAÍS VASCO

INTRODUCTION: Different authors have described the positive effect of the physical activity (PA) in cardiovascular disease (CVD) after doing PA interventions or observing population. The aim of this study was to observe PA patterns in a sample of adults and elderly individuals and health parameters related to CVD to determinate how does their everyday PA influence in the CVD risk.
METHODS: 374 people between 42 and 82 years participated in the study (Mage60.72 • 6.94). Blood samples were collected to measure the lipid profile (total cholesterol (TC), LDL-c, HDL-c,), glucose (GLU) and triglycerides (TG). Blood pressure (BP) was determined, anthropometry was measured (weight, height, waist circumference (WC)) and body fat percentage was measured by bioimpedanciometry. Body mass index (BMI) and waist-to-hip ratio were calculated and PA was assessed by accelerometers (Actigraph GT3X).
RESULTS: All the anthropometric parameters named before had negative correlation with HLD-c ($p<0.001$) and positive correlation with GLU, TG and BP ($P<0.001$).
When we analyzed PA, total counts, counts per minute (CPM) (MCPM 731.29±195.88), steps/day (Msteps/day 10150.62±3349.69) and moderate-to-vigorous PA (MVPA) min/day (MMVPAmin/day 53.84± 27.97) were negatively correlated with all the anthropometric parameters ($p<0.05$). Total counts, CPM and steps/day had positive correlation with HDL ($p<0.05$) and negative correlation with TG and GLU ($p<0.05$), except steps/day. Moderate PA (MPA) and MVPA min/day had negative correlation with GLU ($p<0.05$). BP only had negative correlation with vigorous PA (VPA) min/day ($p<0.05$).
CONCLUSION: Cigarette smoking, elevated BP, elevated TC and LDL-c, low HDL-c, Diabetes Mellitus and advancing age are described as the major independent Risk Factors for CVD. The American Heart Association describes obesity, abdominal obesity and physical inactivity as major predisposing risk factors (that worsen the independent ones). The correlations of our study between anthropometric and blood parameters also support some of the risk factors described before.
In our study, we have seen that people with lowers levels of PA had worse health parameters, which back the idea of the beneficial effect of the PA on obesity, and therefore in related disorders like hypertension and dyslipidemia.
Even though the risk of CVD decrease increasing PA, we have not almost found significant correlations between MVPA and the lipid profile and TG. That could be because not all the participants reach the recommended amount of steps/day or MVPA per week.

USING PHYSICAL ACTIVITY IN ACUTE PSYCHIATRIC INPATIENTS

CODRONS, E., BRONDINO, N., BARETELLA, G., BERGAMASCHI, G., DELFINO, F., PEZZULLO, M., FIZZOTTI, S., CORREALE, L., VANDONI, M.

UNIVERSITY OF PAVIA

INTRODUCTION: The benefits of physical activity for psychiatric patients are well known. However, there is a paucity of data regarding the use of exercise programs in inpatients, especially in patients admitted to a psychiatric ward for acute treatment. To the best of our knowledge, trials designed to test the effect of physical activity in inpatients involved patients hospitalized in residential facilities for minimum 6 weeks. To the best of our knowledge there is no evidence on the potential benefit of physical activity in acute psychiatric inpatients. We introduced physical activity in an open-label fashion in the routine of the psychiatric ward.
METHODS: For the first part of the trial (feasibility study), physical activity consisted in a one 1-h weekly session of supervised aerobic floor exercises. Patients participation during hospitalization was recorded. Mean hospitalization length, number of violent behaviors, necessity of seclusion, global clinical impression were recorded for both participants and patients who did not join the exercise program during

one year. We additionally measured the need for rescue medication in the night of the physical activity sessions was recorded for all patients.
RESULTS: From October to December 2017 80 patients were admitted in the psychiatric ward (75 had a single admission, while 5 had multiple admission)Patients who attended at least one session of physical activity did not differ significantly from those who did not participate in hospitalization length (15.75±9.37 vs 14.17±10.76, t=-0.64, p=0.52), severity of symptoms at baseline (CGI-S 4.80±0.95 vs 4.42±1.21, t=-1.15, p=0.26) or improvement (CGI-I 2.21±0.53 vs 2.33±0.70, t=0.63, p=0.53). We did not observe a significant correlation between the number of physical activity sessions and severity at baseline (r=0.09, p=0.54) or improvement (r=-0.02, p=0.88). Patients with comorbid substance abuse attended physical activity sessions more frequently than patients who did not abuse (Chi-square=5.25, p=0.02). No significant difference was observed between patients who attended physical activity sessions and patients who did not in the need of rescue medications for the night following the session (Chi-square=0.31, p=0.54).
Discussion:
These are the preliminary findings of an open-label study designed to test the effect of a physical activity program in an acute psychiatric ward. The study will continue for other six months and we will expect an improvement in patients symptoms and in the relationship between patients
and personnel.

EFFECTS OF TWO DIFFERENT TYPES OF EXERCISE ON PHYSICAL PERFORMANCE IN HEMODIALYSIS PATIENTS

BOGATAJ, S., PAJEK, J., BUTUROVIC PONIKVAR, J., BUCAR PAJEK, M.

UNIVERSITY MEDICAL CENTRE LJUBLJANA

INTRODUCTION: Systematic literature review shows that physical activity has many positive effects on the health of dialysis patients. Many previous studies report the effects of intradialytic training on a customized ergometer, which can currently be considered as the gold standard of the training type for dialysis patients. The aim of this study was to determine the effect of functional exercise guided by a kinesiologist in addition to the basic exercise program of cycling during dialysis on physical performance of dialysis patients.
METHODS: Twenty-nine dialysis patients participated in the study. We first tested their physical condition with selected motor tests. Our main outcome measurements were: 6-minutes walking test (6MWT), 10 repetitions sit-to-stand test (STS10 test) and sit-and-reach test (SRT). After baseline testing we randomized patients in two groups - one experimental and one active control group. The exercise program for both groups was performed three times per week over the course of eight weeks. The experimental group attended a guided functional exercise before the dialysis procedure and after that performed a cycling session during dialysis. The active control group participated in intradialytic exercise program only (intradialytic cycling equal to cycling program of experimental group). Intensity of exercise was determined by Borg scale of perceived exertion. After eight weeks we repeated the baseline tests.
RESULTS: Twenty-seven patients completed eight weeks of training. Statistical analysis revealed that both groups have a statistically significant increase in 6MWT (experimental group (baseline: 510,08±68,69 m; after 8 weeks: 561,62±94,98 m; p=0,002), active control group ((baseline: 456,86±78,86 m; after 8 weeks: 487,07±76,16 m p=0,000)) and in STS10 test (for both groups: p=0,000) compared with baseline values. In SRT there was a statistically significant difference in experimental group (p=0,000), with no statistically significant difference in active control group (p=0,407) when comparing with their baseline values. When comparing both groups, we can see a greater increase in experimental group in STS10 test (p=0,004) and in SRT (p=0,001) compared to the active control group. There were no statistically significant difference between groups in 6MWT (p=0,053).
CONCLUSION: Both types of exercise are effective in improving aerobic endurance and strength of lower limbs. However we believe that, if we want to improve various motor skills, cycling during dialysis alone is not enough. Our research showed us that functional training led by kinesiologist in dialysis centre is practical, feasible and effective in improving the physical function of hemodialysis patients.

THE RELATIONSHIP BETWEEN FIRE FIGHTER PERFORMANCE AND BODY COMPOSITION

WILLIFORD, H., ALLEGRO, D., REILLY, E., RUSSELL, A., ESCO, M., NICKERSON, B., SCHAEFER, G.

AUBURN UNIVERSITY MONTGOMERY

INTRODUCTION: Fire fighting is a demanding occupation that requires a high level of performance and physical fitness. Fire fighters must be able to perform carrying heavy loads, and the weight of their turn out gear and SCBA may exceed 25kg. Research in our laboratory has shown that body composition is an important variable to consider as it relates to both the fire fighters health and performance. The purpose of this investigation was to evaluate the relationship of body composition to a simulated fire fighter job performance test (FFJP).
METHODS: Eighty-two male fire fighters performed a maximal FFJP test, wearing turn-out gear and self-contained breathing apparatus (SCBA). The test consisted of the following: stair climb, hoist, forcible entry, hose drag, and dummy drag. The results were recorded in seconds. In addition the fire fighters were evaluated in the laboratory for body composition by Bod-Pod. The body composition analysis included height (m), weight (kg), percent body fat (%), and fat free mass (FFM).
RESULTS: The descriptive statistics included M and SD: age 34.9 ± 7.5 (yrs), height 1.81 ± .06 (m), weight 96.37 ± 10.05 (kg), percent fat 25.13 ± 6.09 (%), and FFM 71.81 ± 6.45 (kg). The total time to complete the FFJP test was 262.57 ± 48.61 (sec). Pearson correlation was performed between FFJP and each of the body composition variables including percent fat ($r = 0.42$, $p = .000$) and FFM ($r = -0.46$, $p = 0.00$). The multiple regression analysis produced two significant models. Model 1 included FFM and explained 21% of the variance ($R2 =.21$, $F(1,81)=21.33$, $p<.01$), ($\beta = -3.48$, $p<.001$). Model 2 included FFM and percent fat which explained 31% of the variance ($R2=.31$,$F(2,81)=17.68$, $p<.01$), ($\beta = -2.83$, $p<.001$, FFM), and ($\beta = 2.59$, $p<.001$).
CONCLUSION: The results of this investigation found significant a significant negative relationship between FFM and FFJP and a significant positive relationship between percent fat and FFJP. This indicates that FFM is a positive predictor of performance while body fat is a negative predictor of performance. The nature of fire fighting requires the fire fighter to perform at a high level while carrying a significant amount of weight in addition to the body fat that is stored in the body. Fire fighters should attempt to develop or maintain a high level of FFM with low percent body fat in order to perform at optimal levels.

INFLUENCE OF PILATES ON THE MENTAL AND PHYSICAL HEALTH BY EVALUATING AUTONOMIC NERVOUS FUNCTION

MURAKAMI, K.

KOKUGAKUIN UNIV

INTRODUCTION: "Pilates" is an exercise done by sleeping or sitting on the mat, aiming to develop a body that is easy to move with no distortion by balancing the whole body muscles while utilizing the breathing method. From the Pilates practitioner, there are voices saying that besides improving the physical function, it has effects on mental stability and relaxation. Although the effect of improving physical function is clear, there is no research that report an objective evaluation of "mental stability effect". Therefore, in this study, we aimed to observe the mental and physical influences due to Pilates by evaluating autonomic nervous function and to obtain objective data to prove that Pilates is an effective exercise for mental and physical health.
METHODS: 1. Subjects
We targeted 4 adult women who regularly participated in a 60 minute Pilates lesson from November 2016 to April 2017. A subject W, 26 years old, is diagnosed with autonomic imbalance. Regarding the subject, we decided the period when the subjective symptoms appeared, February - June 2016, was taken as the first half of W, and the symptoms improved, November 2016 - March 2017, was taken as the latter half of W. Three other subjects Y (31 years old), K (46 years old), N (55 years old) are healthy adult women.
2. Measurement items
Acceleration pulse wave measurement system Altet (made by Yumedika) was used for autonomic nerve function measurement, and acceleration pulse wave was recorded before and after the lesson was performed. LF and HF values were obtained by software in the system, LF / HF values were calculated and evaluated as "index of stress". In addition, the heart rate variation coefficient (CV %) was obtained and it was taken as "ability to respond to stress".
RESULTS: Table 1 and Table 2 show the average value and standard deviation of the LF / HF value and CV% before and after the lesson, and also show the t-test results. As shown in Table 1, as a result of comparing before and after the lesson, the subject W was evaluated as "a normal state" of the later value 2.1 from the evaluation of the "strong stress state" of the previous value 7.2. Subject N has significantly changed from 2.0 "normal condition" to 0.69 "very relaxed state" ($p < 0.05$), which can be inferred that Pilates caused a relaxation effect. As shown in Table 2, when comparing CV% as well, the values of CV% showed a tendency to rise in all the subjects after the lesson than before the lesson. There was a clear increase in subjects W and N in particular. Because CV% reflects the overall autonomic nervous activity and tends to rise at the time of mental health improvement and fatigue degree recovery, Pilates is presumed to have a beneficial effect on "mental and physical health ". Moreover, comparing the data of the first half and the second half of the subject W who continuously observed for one year, the autonomic nervous function improvement were found that the LF / HF value before the lesson decreased from 7.21 to 1.86 and the CV% increased from 2.89 to 3.76.
CONCLUSION: 1. If the LF / HF value shows a high value before the lesson, a tendency to show a low value after the lesson was confirmed.
2. In the heart rate variability coefficient (CV%), it increased after the lesson and the tendency that the autonomic nerve activity became active was confirmed.
From these results, we could obtain objective data that prove mental stability and relaxation effect by Pilates.

MASSAGE INTERVENTION USING MASSAGE CHAIR DECREASES BLOOD PRESSURE

YAMAMOTO, K.

TEIKYO HEISEI UNIVERSITY

INTRODUCTION: Massage is often used to facilitate recovery from fatigue in sports. On the other hand, a recent systematic review suggested that massage is useful for lowering blood pressure in hypertensive patients. The present study investigated whether a 4-week massage intervention by a massage chair decreases blood pressure or not.
METHODS: Systolic blood pressure (SBP), diastolic blood pressure (DBP) and heart rate (HR) were measured every week during the course of study in a massage group (n=6) and before and after the 4-week period in a control group. The massage group was massaged for 4 weeks, 3 days a week, and the duration of massage was 30 min. The massage chair is designed for a full body massage from neck, shoulders, and arms to feet, calves, and buttocks. This massage chair scans the whole body curve and makes adjustments, focusing on the lumbar, neck and shoulders. The control group led normal lives during the 4-week period.
RESULTS: The 4-week massage intervention decreased SBP from 138±5 (mean ± SE) to 129±6 mmHg ($P<0.01$) and DBP from 84±6 to 76±6 mmHg ($P<0.01$). SBP (132±6 mmHg) and DBP (79±6 mmHg) at 3rd week were not significantly lower than those measured before the massage intervention began in the massage group, suggesting that the massage intervention requires at least for 4 weeks to decrease blood pressure. HR did not change during the intervention period. There were no significant changes in SBP, DBP and HR in the control group during the 4-week period.
CONCLUSION: These results indicate that the massage intervention using massage chair decreased blood pressure. Hypertension is a global problem that typically presents as an asymptomatic, cardiovascular disease. Unfortunately, only 30% to 40% of patients currently taking antihypertensive drug treatments are meeting blood pressure goals in Japan. The present study suggests that massage, even using massage chair, has an important role in the management of blood pressure as complementary therapy.

STABILITY OF SEDENTARY BEHAVIOURS IN ADOLESCENTS: A 4-YEAR FOLLOW-UP STUDY

MISIGOJ DURAKOVIC, M., STEFAN, L., SORIC, M.

FACULTY OF KINESIOLOGY UNIVERSITY OF ZAGREB

INTRODUCTION: Recent studies have shown association of sedentary behavior, primarily screen time with increased risk for obesity and cardio-metabolic risks in adolescents. Moderate stability of this trait has been reported in previous studies. However, little is known about stability of other domain of sedentary behavior during late adolescence.
METHODS: In this longitudinal study, participants were 844 high-school students (mean age at the baseline 15.6 years, 49% of the girls). To assess different sedentary behaviours, School Health Action, Planning and Evaluation System (SHAPES) questionnaire was used. Four types of sedentary behaviours were: (1) total sedentary behaviour, (2) screen-time, (3) studying and (4) other sedentary behaviour activities. General estimating equations (GEE) were used to calculate stability coefficient, stratified by gender.
RESULTS: Over a 4-year of follow-up, stability coefficients for total sedentary behaviour, screen-time, studying and other sedentary behaviour were similar in both boys (0.63, 0.60, 0.66 and 0.72) and girls (0.60, 0.64, 0.70 and 0.63).

CONCLUSION: Our results show moderate tracking of sedentary behaviours over a 4-year of follow-up in high-school students. Thus, policies and strategies that promote higher levels of physical activity and decline the time spending in sedentary behaviours are warranted.

RELATIONSHIP BETWEEN NON-COGNITIVE FUNCTIONAL CHARACTERISTICS AT AGE 6 AND PHYSICAL FITNESS CHARACTERISTICS AT AGE 10

KASUGA, K., NAKANO, T., OGURI, K.

GIFU UNIVERSITY, NAGOYA GAKUIN UNIVERSITY, GIFU SHOTOKU GAKUEN UNIVERSITY

Introduction: Human non-cognitive functioning is developed mostly in early childhood. It is speculated that the characteristics of non-cognitive functions will influence various subsequent behaviors. It may be that physical characteristics during childhood affected by daily exercise behaviors are also affected by non-cognitive functional characteristics in the early childhood.
Purpose
The purpose of this study was to examine the relationship between non-cognitive functional characteristics at age 6 and the physical fitness characteristics at age 10.
Methods: Subjects included 223 children (110 boys and 113 girls) who performed the physical fitness test at 10 years of age. We administered physical fitness tests comprising eight exercises (grip strength, standing long jump, softball throw, 50-m run, side-step, sitting trunk flexion, sit-up, and 20-m shuttle run) to gauge the children's physical fitness status. In order to understand non-cognitive functional characteristics at 6 years of age, a questionnaire of 21 questions consisting of 8 items (self-recognition, motivation, perseverance, self-control, social appropriateness, resilience and coping ability, creativity, and personality) was used. Evaluation of non-cognitive function was carried out by three kindergarten teachers who had the experience of being their homeroom teacher. The mode of 3 evaluations was adopted to achieve a representative value of non-cognitive functional characteristics. When the evaluations were different, the median of the evaluation was used as a representative value.
From the evaluation obtained, grouping was performed with the upper group (UG), the middle group (MG), and the lower group (LG) based on the evaluation value of each non-cognitive function. We applied a principal component analysis on the test results and used the first principal component score as an indicator of overall physical fitness.
Statistical analysis of the data was conducted using a one-way ANOVA and multiple comparisons (Tukey's HSD test) to compare physical fitness among the groups. In the items with lower group samples less than 5, a t-test between the upper group and the middle-lower group (MLG) was applied.
Results: Results of the analysis revealed significant differences in physical fitness in all items except "nervous" among the 21 questions. UG of each item was significantly higher than LG. In particular, there was a very high effect size (ES) in "persistent efforts" (ES: 1.99), "ingenuity" (ES: 1.92), and "ability to pull out" (ES: 1.85).
Conclusion
It was suggested that children with increased non-cognitive functions such as condition judgment ability and tenacity in early childhood have a good effect on physical fitness at school age.
Supported by Grant-in-Aid for Scientific Research (B) (No.16H03271) from Ministry of Education, Culture, Sports, Science and Technology in Japan.

THE METABOLIC SYNDROME CAUSE ARTERIOSCLEROSIS IN JAPANESE CHILDREN

OGURI, K., KASUGA, K., NAKANO, T.

GIFU SHOTOKU GAKUEN UNIVERSITY

INTRODUCTION: Information on whether metabolic syndrome (MetS) is involved in development of arteriosclerosis in children is sparse. The ratio of high-density lipoprotein cholesterol (HDL-C) to low-density lipoprotein cholesterol (LDL-C) ratio (L/H ratio), adiponectin, remnant-like particle cholesterol (RLP-C), small dense LDL particle size (LDL size) and level of high sensitive C-reactive protein (hsCRP) are known to be novel markers characterizing the atherosclerotic process at an early stage. Therefore, this study compared the L/H ratio, adiponectin, RLP-C, LDL size and hsCRP level among obese children with MetS, normal and non-obese children without MetS. And this study compared the relationships between body fat percentage, visceral fat mass and subcutaneous fat mass with arteriosclerosis risk factors in obese and non-obese children.
METHODS: The subjects were 112 children (age: 7.5-12.6 years) who consented to participate in this study. They were divided into an obese group (68 children, age: 9.7±1.5 years) and a non-obese group (44 children, age: 9.6±1.4 years) with an obesity index score of 20% or higher the cutoff for determining obesity. The Bod Pod system was used to measure body density and body fat percentage was then calculated. MRI with 0.2T magnetic field strength was used to calculate visceral fat and subcutaneous fat cross-sectional areas in the horizontal plane between lumbar vertebrae 4 and 5. Fasting levels of adiponectin, LDL size, hsCRP, glucose, insulin, lipid profile and blood pressure were determined, and L/H ratio and the homeostatic model assessment (HOMA) index were calculated. Systolic and diastolic blood pressure was measured three times and the lowest values for each were used as data. MetS was determined upon abdominal obesity (waist circumference: ?75 cm) plus at least two other factors from elevated triglyceride (?120 mg/dl), HDL-C (<40 mg/dl), high systolic or diastolic blood pressure (?125 or ?70 mmHg), and fasting glucose (?100 mg/dl). Obese children were grouped into with (n=8) and without (n=60) MetS.
RESULTS: Obese children with MetS had significantly smaller LDL size and adiponectin than normal and obese children without MetS ($p<.05$). Obese children with MetS showed higher L/H ratio, RLP-C hsCRP and HOMA index than normal and obese children without MS ($p<.05$). No differences between normal and obese children without MetS were observed for all markers. Comparison of the correlation coefficients of test items with body fat percentage, subcutaneous fat area and visceral fat area in obese children indicated that the correlation coefficient of visceral fat area for LDL size (r=.513), RLP-C (r=.444), adiponectin (r=-.418), HOMA index (r=.491), L/H ratio (r=.478), LDL-C (r=.458), triglycerides (r=.594), systolic blood pressure (r=.564) was significantly higher than for the other two indices.
CONCLUSION: Our findings suggest that metabolic syndrome more than obesity per se may be involved in early arteriosclerosis in children.

NUTRITIONAL STATUS, PHYSICAL ACTIVITY AND EATING HABITS OF HUNGARIAN YOUTH

UVACSEK, M.1, NÉMETH, A.2

1.UNIVERSITY OF PHYSICAL EDUCATION, BUDAPEST 2.EÖTVÖS LORÁND UNIVERSITY, BUDAPEST

INTRODUCTION: The Health Behaviour in School-Aged Children (HBSC) study is a World Health Organization- (WHO) collaborative cross-national data collection initiative, in which Hungary has taken part for more than three decades. One of the aims of the study is to monitor the health and risk behaviour of youth, analyse sex/age group differences and trends based on the national representative samples.
METHODS: In the present study we analysed data regarding 8,096 and 6,153 11- to 18-year-old children, collected in 2010 and 2014, respectively. We aimed to compare the results of the last two representative sample's data concerning nutritional status, breakfast consumption, physical activity and daily fruit and vegetable consumption. The questionnaire results were categorized and the frequencies were compared with chi-square-tests using Statistica for Windows 13.2.
RESULTS: Young people's prevalence in different nutritional status groups was very similar in 2010 and 2014; less than 3% of them were obese, a bit more than 12% were overweight, 70% were of normal weight, and 15% were underweight. The prevalence of youth achieving the daily MVPA recommendation did not change significantly, at 17% versus 19%. The frequency of regular breakfast consumption is higher in boys, and comparing the last two results neither the boys' (51.5% vs. 53.6%) nor the girls' frequency (46.8% vs. 45.2%) changed significantly. Daily fruit consumption (31.1% vs. 32.6%) has also remained unchanged, while daily vegetable consumption (23.6% vs. 30.4%) increased in Hungary between 2010 and 2014. Though almost all tendencies are positive regarding physical activity and eating habits, the results are far from meeting the international dietary recommendations.
CONCLUSION: According to HBSC data, there are some positive changes in the health behaviour of Hungarian youth; however, considering protective factors like physical activity and regular breakfast consumption, the group lags far behind in terms of international recommendations.

PHYSICAL ACTIVITY, BODY STRUCTURE AND PSYCHOSOMATIC SYMPTOMS IN CHILDREN

SZMODIS, M., FARKAS, A., BOSNYÁK, E., PROTZNER, A., TRÁJER, E., ALMÁSI, G., RICHTER, R., SZOTS, G., TÓTH, M.

UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: The beneficial effects of regular physical activity on body structure seem evident. Anthropometric parameters of children differ by their activity levels. Somatic and mental well-being can be associated with each other. The main goal was to find and analyse the relationships between physical activity, anthropometric variables and psychosomatic symptoms in children.
METHODS: Participants were 7-19-year-old Hungarian children . The children came from twelve different schools in various regions, including the capital, other cities, small towns and villages. Anthropometric measurements were taken according to the suggestion of International Biological Program. Objective level of habitual physical activity was measured with accelerometer , the psychosomatic symptoms and health profile were examined by questionnaire. Differences of the subgroups and correlation patterns were analysed .
RESULTS: Two-third of the children reached the international recommendation of physical activity level, mainly the boys. Their daily activity in the MVPA zone was significantly more that for the girls' <138.3±49.8 vs. 117.4±44.5 min; p=0.003>. Psychosomatic symptoms were more common in girls <18.9±5.5 vs. 21.7±7.0; p=0.001> and as they get older, the symptoms get more frequent . The body image of boys was better <4.1±0.9 vs. 3.5±1.0; p=0.003>.
Physical activity had positive effects on health-image and body image , furthermore, those children who were more satisfied had less psychosomatic symptoms .
CONCLUSION: The results of this survey emphasize the necessity of physical activity, the data relative to nutrition and „the way you feel" comfort feeling can give a good perspective for the professionals, concerning healthy lifestyle. However, more examination is needed in order to reveal the more relationship.

RELATIONSHIPS BETWEEN AEROBIC FITNESS AND NOVEL RISK FACTORS FOR CARDIOVASCULAR DISEASE AND INFLAMMATORY MARKERS IN CHILDREN

DENCKER, M., THORSSON, O., KARLSSON, M.K., WOLLMER, P., ANDERSEN, L.B.

SKÅNE UNIVERSITY HOSPITAL

INTRODUCTION: Inflammation is present in a variety of diseases. Moreover, there is continuous emergence of novel risk factors for cardiovascular disease. However, limited information exists about possible relationships between novel risk factors for cardiovascular disease and inflammatory markers versus aerobic fitness in children.
METHODS: We performed a study in 166 <88 boys and 78 girls> healthy children aged 8-11 years. Maximal oxygen uptake was assessed by indirect calorimetry during a maximal exercise test and scaled to body mass . A total of 10 biomarkers for cardiovascular disease and inflammation were analyzed in frozen serum samples by the Proximity Extension Assay technique.
RESULTS: Partial correlations, with adjustment for sex, between VO2PEAK versus the different biomarkers indicated weak to moderate correlations in either positive or negative direction, all concordant with the hypothesized direction. Summary of the findings: Interleukin-1 receptor antagonist protein , Interleukin-6 , Galectin-3 , Chitinase-3-like protein 1 , TNF-related activation-induced cytokine , Tissue-type plasminogen activator , Furin , CUB domain-containing protein 1 , Interleukin-18 receptor 1 , Stem cell factor , $P<0.05$, for all.
CONCLUSION: This study shows that a weak to moderate relationship exist between aerobic and inflammatory markers and novel risk factors for cardiovascular and in children aged aged 8-11 years.

TIME SPENT IN PHYSICAL ACTIVITY BY PRESCHOOL CHILDREN - COMPARISON ACROSS ONE YEAR -

ISHIZAWA, J.1, SASAKI, R.2, YOSHITAKE, Y.3

1: SHIRAYURI UNIV. , 2: KEIO UNIV. , 3: NIFS IN KANOYA

INTRODUCTION: According to previous research, children's physical activity (PA) is associated with their health and movement ability (Harriet G. et al., 2008; Fisher et al., 2005). Some cross-sectional studies have examined the PA of preschool children in Japan (Tanaka et al. 2013). However, little is known about the longitudinal course of preschool children's daily PA levels. This study aimed to compare children's PA level variation in the first year of kindergarten with that one year later.

METHODS: Participants were 34 children in the first year of kindergarten (19 boys, mean age 4.9±0.3 years; 15 girls, mean age 5.0±0.3). Their PA was measured using a triaxial accelerometer (Active Style Pro, Omron) for eight consecutive days except during unavoidable circumstances, such as sleeping and bathing. We examined their PA by measuring the step counts and time spent in moderate and vigorous physical activity (MVPA). One year later, we examined their PA again in the second year of kindergarten. We compared their PA between the first and second year.
RESULTS: On weekdays, first year boys and girls engaged in MVPA for 81.7±20.1 mins/day and 75.3±13.7 mins/day respectively. Second year boys and girls engaged in MVPA for 93.0±20.4 mins/day and 81.1±14.9 mins/day respectively. Their total second year MVPA was significantly higher than in the first year ($p<0.01$). Analyzing classifications of movement showed that during the second year, their locomotive activity time during MVPA was higher than in the first year. On the other hand, there were no significant differences in the total MVPA and step counts on weekends. The children's first year total MVPA correlated with that of the second year on weekdays.
CONCLUSION: This result shows that compared to the first year, children's MVPA increased one year later in both boys and girls on weekdays. Furthermore, these findings suggest that the quantity of total MVPA in the first year tended to continue into the second year. Therefore, promotion of children's PA might commence before the first year of kindergarten.

EFFECT OF A CHILD HEALTH EDUCATIONAL PROGRAM ON THE PHYSICAL ACTIVITY LEVEL, DIETARY INTAKE AND PHYSICAL FITNESS OF OBESE CHILDREN

RIBEIRO, H.L., RAUBER, S.B., OLIVEIRA-SILVA, I., VENÂNIO, P.E.M., CAMPBELL, C.S.G.

UNIEVANGÉLICA

INTRODUCTION: Childhood obesity has increased exponentially, this factor is consider worrying and a big problem of this century. Sedentary behavior, poor diet have been affecting the population and increasing a lot of diseases. Innovative practices of intervention have been used with the goal of prevention and promotion of childrens health. The aim the study was to investigate the impact of a 5-day KIDS educational program and 12-week follow-up on Physical Activity Level (PAL), dietary intake (DI), and physical fitness (pre and post camp) of obese children.
METHODS: Twelve children participated in the HEPchild program, they were divided into two phases. Phase 1 of pre-assessments; and Phase 2 corresponded to 12 weeks of follow-up to assess PAL and FI over time with questionnaire use and pre and post camp to assess physical fitness variables (flexibility, muscle strength, explosive strength of upper and lower limbs, aerobic capacity). The Shapiro-Wilk test was used for data normality. The descriptive statistics used for mean, standard deviation (± SD) and 95% confidence interval. The t-test paired to identify the effect of the camp on the variables of physical fitness. The magnitude of the pre and post changes with the effect size Cohens D (ES). It was calculated for each variable the percentage of the change (% Δ). The significance level was set at $p <0.05$.
RESULTS: After all the follow-up, 25% of the children were active (> 1500 and <3000 METs per week). The number of sedentary children (<600 METs per week) decreased by 15% and insufficiently active (600 to 1500 METs per week) increased by 15%. The leisure time PAL increased significantly during the week (26.0%) and at the weekends (14.1%) after the follow-up compared to before the KIDS. Before KIDS, 91.6% of the children consumed soft drinks ≥ 3x / week and after HEPchild reduced to 50%. Fruit consumption (≥ 5 portions / day) increased 51% and vegetables (≥ 5 portions / day) increased from 8.4% to 66.7%. There was a significant improvement in body mass (~ 1.2kg), body mass index (~ 0.8kg/m2), waist circumference (~ 1.9cm), summation of skin fold (5.7mm) and flexibility (~ 4.58cm), horizontal jump (7.33cm). However, the effect size was low. The only result that besides significance had high effect size (i.e. .77) was the upper limb strength (~ 43cm).
CONCLUSION: Five days of camping and health education, with emphasis on promoting a healthy lifestyle, can be effective for improving physical fitness variables and increasing PAL of obese children.

TRACKING OF MOTOR SKILLS FROM CHILDHOOD TO ADOLESCENCE IN JAPANESE.

HIRANO, T.

NAGOYA COLLEGE

Introduction: Childhood is one of the most important times to develop healthy lifestyle habits. Several studies have reported that high levels of physical fitness and motor skills in childhood predict high-level adult physical fitness and exercise capacity. The aim of this study was to investigate the tracking of selected aspects of motor skills from childhood to adolescence in Japanese.
Methods: The subjects were about 400 boys and girls school students. A 50m sprint, a standing long jump, a soft ball throw, a grip strength, a flexibility of the lower back, and a repeated lateral jump were used to assess motor ability. These activities were measured every year, and the subjects were followed from 6 to 17 years old. The physical size and motor skills of the subjects didn't have significant differences to those in the nationwide survey. The subjects were asked about daily activities after school using a questionnaire.
Results: Correlation coefficients of the 50m sprint between 6 and 17 years old revealed statistically significant tracking among boys (0.36) and girls (0.33). The standing long jump and the soft ball throw between 6 and 17 years old were consistent with this tracking. Correlations for the repeated lateral jump are moderate between 10 and 17 years old. The longer of years to belong to athletic activities and sports clubs, the higher value at the 17 years old physical fitness score. Due to the habit of sports activities, there was a case where the relative exercise capacity increased from school childhood to adolescence.

EFFECTS OF AEROBIC EXERCISE ON MENTAL WORKLOAD OF FLIGHT SIMULATION BEHAVIOR

LIU, H.1, HU, H.H.2

NANJING UNIVERSITY OF AERONAUTICS AND ASTRONAUTICS

INTRODUCTION: This paper wants to explore the effect of long-term moderate-intensity aerobic exercise on improving the cognitive ability of the pilots and the possibility of mental load, to provide the basis for the importance of student pilots participation in physical activity, to provide effective design of the content and extracurricular exercise mode reference.

METHODS: The experimental groups were divided into three groups: experimental group <31 subjects> and control group <31 subjects>. The experimental group was treated with exercise bike and basketball during the morning exercises. The exercise intervention time was 11 weeks, 3 times a week, The duration of exercise was 45 minutes, the intensity of exercise was moderate <220-age> × <60% -70%>, and the change of mental load was simulated before and after the intervention.
RESULTS: The multiple linear regression equation showed that there was significant difference in the mental workload between different groups of flight simulation driving. The weighted total load of the experimental group has a decreasing trend after exercise intervention（F（6,55）=2.216，p=0.055），and the time requirement of the experimental group after exercise intervention was significantly reduced（F（6,55）=2.606，p=0.027）.
CONCLUSION: Moderate-intensity aerobic exercise can relieve the mental workload stress of the the civil aviation student pilots flight simulation, and the pressure relief effect of the mental workload stress, which can be described as follows: Of the experimental group is higher than that of the control group.

THE IMPACT OF ACUTE PHYSICAL EXERCISE ON PERCEPTUAL-COGNITIVE PERFORMANCE IN SOCCER PLAYERS

OLM, T.1, BASKIN, K.2, HERDE, K.2

TALLINN UNIVERSITY

INTRODUCTION: The aim of this study is to examine the influence of acute physical exercise on the simple and the choice reaction times in soccer players of different ages.
METHODS: Professional soccer players of the best clubs of Estonia (n=236) aged 17 to 31 years were examined. The athletes were divided into 3 age groups. The test battery included anthropometrics, ECHO and ECG, and BLa concentration, VO2max and the anaerobic threshold were recorded. The simple and choice reaction times were measured before and after incremental treadmill test to volitional exhaustion, using the software Win Psycho Test (K.Thomson).The ANOVA-test was used. Statistical significance was assumed at $p<0.05$. Pearson product moment correlation coefficients were calculated.
RESULTS: Before the acute exercise the average simple reaction time was the shortest in the oldest athletes group. The same can be said about their mean choice reaction time. The best response accuracy (the error rate) was the smallest in the youngster group. After the acute physical exercise the averages of the simple reaction time didn't change in any age group. However, the averages of the choice reaction time shortened significantly, especially in older players. The error rate increased in all groups. The smallest change was in the oldest athletes' group. Correlation analysis shows that all four averages of the reaction times have strong positive correlation between themselves and a moderate one with the error rates and with anaerobic metabolic indices.
CONCLUSION: Soccer requires fast reaction and accurate decisions from players. Perceptual-cognitive performance of athletes must stay on as good level as possible. There are many contradictory investigations about the influence of acute physical load on the nervous system. Basing on results this study, we can agree with researchers who suggested that athletes´ perceptual-cognitive performances in speed-related tasks are improved by moderate and high intensivity physical exercise (McMorris et al., 2012) and the results of accuracy are deteriorated (Casanova et al., 2013). In our previous study and this one we are finding many strong relationships between the characteristics of different organic systems but the relationships between the nervous system characteristics and the characteristics of other systems was surprisingly rare. We can conclude. a)Older, experienced players with high anaerobic working capacity were more positively influenced by acute physical exercise than the younger ones. b)To correctly evaluate the functional state of athletes without assessing the nervous system characteristics is impossible.

CHRONIC NONCOMMUNICABLE DISEASES: FAMILY HISTORY, EATING HABITS AND SEDENTARY

BANKOFF, A.D.P., ZAMAI, C.A., BISPO, I.M.G.P., RODRIGUES, M.D.

UNIVERSIDADE FEDERAL DE MATO GROSSO DO SUL E UNIVERSIDADE ESTADUAL DE CAMPINAS

INTRODUCTION: Chronic non-communicable diseases (NCD) currently are the ones that cause the most deaths in Brazil and worldwide. Every human being is subject to the daily routines of life, regardless of age and socioeconomic status. It is within our home and within the family that we learn our daily habits of life, which accompany us (Bankoff, Zamai, 2012,2013). As for college students, when they enter, most of them become sedentary, and also because of the circumstances they acquire not very healthy eating habits, making them more vulnerable to chronic noncommunicable diseases early (Bankoff et al, 2013, 2012).
METHODS: Were assessed using a questionnaire developed itself to the project, students of both sexes and 140 men aged 23.6 years and Standard Deviation 4,591; 140 women aged 22.5 years and Standard Deviation 4,007. The questionnaire-prioritized questions relating to eating habits, sedentary, lifestyle, chronic noncommunicable diseases and family history. For better understanding, the questionnaire was applied in the classroom using Power Point presentation to students. The research coordinator remained in the classroom while the questionnaire was answered to answer questions when necessary.
RESULTS: For women the family history of chronic noncommunicable diseases: Obesity 67.85%, Hypertension 62.14%, Diabetes 54.28% and Cardiovascular Diseases 24.38%. For men, the family history of chronic noncommunicable diseases: Obesity 56.12%, Hypertension 48.34%, Diabetes 43.79% and Cardiovascular Diseases 45.26%. The authors concluded from the statistical results that these students are strong early candidates for family history to be afflicted by chronic noncommunicable diseases. In relation to the habits of life, the following results were found for women: Consumption of red meat twice daily 98.12%, Alcoholic beverage 84.43%, Consumption of daily soda 92.47% and Sedentarism 97.67%. For men: Red meat consumption twice a day 96.83%, Alcoholic beverage 97.24%, Consumption of daily soda 92.37% and Sedentarism 67.71%. The Body Mass Index found for men was 26.02 and for women 25.54. When we analyze the results by BioEstat 5.3 program using the Contingency Correlation Coefficient C the results for both sexes were significant (p) = <0.0001. This shows very high degree of correlation between family history and early onset of chronic diseases in the research participants.
CONCLUSION: It is within the family that starts the history of chronic diseases considering the eating habits and lifestyles. Through the results in percentage, there was strong relationships for both sexes, research participants and family heritage in relation to chronic diseases.

THE ASSOCIATIONS BETWEEN CHRONOTYPE, DIETARY INTAKE, AND PHYSICAL FITNESS IN YOUNG JAPANESE WOMEN.

USUI, C.
WASEDA UNIVERSITY

INTRODUCTION: An individuals chronotype is a trait which reflects differences in their timing of sleep (e.g., bedtimes, rise times) and in their preferences for the times of rest and activities. Several studies have reported that eveningness tends to be associated with an unhealthy lifestyle. However, no study has examined the relationship between chronotype and physical fitness. In this study, I examined the associations between chronotype, dietary intake, and physical fitness in young Japanese women.
METHODS: The subjects were 124 female university students aged 18-20 years in Japan. Body weight, height, and body fat percentage were measured, and body mass index (BMI) were calculated. Chronotype was assessed using a Japanese version of Horne and Östberg's morningness–eveningness questionnaire (MEQ). The MEQ score was divided into tertiles of which the lowest tertile demonstrated eveningness and the highest tertile demonstrated morningness. The dietary intake was assessed by a brief, self-administered diet history questionnaire (BDHQ). Grip strength, sit-ups, sit & reach, side step (100 cm), standing long jump, vertical jump, 20 m shuttle run, and 5 minute run were measured as physical fitness.
RESULTS: The MEQ score was significantly negatively associated with the percentage of body fat (coefficient = −0.19; p = 0.04), BMI (coefficient = −0.20, p = 0.03), salt intake (coefficient = −0.18; p = 0.05), and noodles intake (coefficient = −0.20; p = 0.03). In addition, it was also significantly positivity associated with soy intake (coefficient = 0.18, p = 0.05) and vertical jump score (coefficient = 0.25, p = 0.01). Furthermore, subjects in the highest tertile (morningness) had significantly higher score in standing long jump compared to the lowest tertile (eveningness), even though no correlation between scores of these.
CONCLUSION: This study revealed that the chronotype is associated with dietary intake of certain nutrients and foods and physical fitness (particularly, muscle power of legs) in young Japanese women.

RELATIONSHIP BETWEEN ANTHROPOMETRIC VALUES, HEALTH AND PHYSICAL FITNESS PARAMETERS IN HEALTHY ADULT AND ELDERLY PEOPLE

ARIZAGA, N., VIRGALA, J., ZARRAZQUIN, I., CEPEDA, S., IZAGIRRE, A., MARTÍNEZ-LAGE, P., IRAZUSTA, A., KORTAJARENA, M.
UNIVERSIDAD DEL PAÍS VASCO-EUSKAL HERRIKO UNIBERTSITATEA

INTRODUCTION: Physical activity reduce the risk of morbidity and mortality and is associated with healthy aging. The aim of this study was to know the relationship between anthropometric values, health parameters and physical fitness of healthy adults with a family history of Alzheimer´s disease (AD).
METHODS: This study was carried out with 374 participants, between 42 and 82 years old (Mage60.72 • 6.94), (Myearsofeducation14.02 • 3.72), in the CITA-Alzheimer foundation in San Sebastian (Spain). The inclusion criteria were: no diagnosis of dementia and age between 40 and 82 years. Anthropometric values, health parameters and physical fitness were measured. Dynamometry tests, Senior Fitness Test (SFT) and Short Physical Perfomance Battery (SPPB) were used to measure the physical fitness of the participants.
RESULTS: It has been found that a positive ($p<0.05$) correlation was established between LDL cholesterol and lower-body flexibility in men, although not in women ($p>0.05$). On the other hand, HDL cholesterol was positively related with lower body strength and 6 minutes walk in men ($p<0.05$).
When we analyzed the relationship between anthropometry and physical fitness we observed a positive correlation between the strength of both hands and, fat-free mass and muscle mass, both in men and women ($p<0.05$). There was a negative relation between 6-minutes-walk and body fat, in both sexes ($p<0.05$).
CONCLUSION: Other studies, also presented a correlation between physical fitness and cardiovascular health and cholesterol, and those health parameters are associated with more cardiovascular diseases. The results of this study are in line with other studies, regarding the relationship between physical fitness (more specifically the aerobic resistance), weight and percentage of body fat. Over weight is associated with worse aerobic resistance. Although, there are some studies that predict future physical capacity in elderly people, further studies are needed to assess the relation between cardiovascular health parameters and physical fitness in adult and elderly people.

EFFECT OF HIGH INTENSITY INTERMITTENT TRAINING COMBINED WITH DIET CONTROL ON BODY COMPOSITION

HOU, X., SONG, B., MO, K.
GUANGZHOU SPORT UNIVERSITY

INTRODUCTION: In recent years, high-intensity intermittent training has been gradually extended to the health management field of the general population for the training of professional athletes. However, there are few studies on the influence of high-intensity intermittent training on body composition, especially high-intensity intermittent training and diet control. The purpose of this study is to explore the effects of high intensity intermittent training combined with dietary control on body composition.
METHODS: A total of 152 clients who participated in the Reducing Training Camp at the Sports Medicine Rehabilitation Center were enrolled in the intensive (15 days) intensive intermittent training and controlled by diet. Training content arrangements: warm-up 13 minutes, high-intensity intermittent training for 30 minutes, relax and stretch for 17 minutes. Training duration and frequency: 60 minutes / time, 7 days / week. Dietary requirements: Reduce the period, the need for intake of double low food, that is, low calorie calorie (GL) food, low glycemic index (GI) food. The first five days of dinner (fruit salad) to participate in the slimming training camp are provided by the researchers. Other diet reference diet recommendations. The body mass index, body fat percentage, waist - to - hip ratio, skeletal muscle, muscle mass and basal metabolic rate were analyzed before and after the experiment.
RESULTS: The body mass index of the subjects was significantly lower than that before the experiment (Before,22.49 ± 3.36, then 22.35 ± 3.21, $P<0.05$). The percentage of body fat was significantly lower than that before the experiment （Before, 27.85±6.23 , then 26.45±5.86, $P<0.01$）; the skeletal muscle WHR was significantly lower than that before the experiment (Before, 0.84 ± 0.06, then 0.82 ± 0.05, $P<0.01$). The skeletal muscle was significantly increased before the experiment (Before, 24.01±5.84 , then

24.31±5.62, P<0.01) . The number of muscle was significantly higher than that before the experiment (before, 41.32 ± 9.09, 41.79 ± 8.77, P <0.01) The basal metabolic rate was significantly higher than before the experiment (before 1319 ± 207.86, after 1330 ± 200.48, P <0.01).
CONCLUSION: 15 days of high intensity intermittent training with diet control can effectively reduce the body mass index, body fat percentage, waist to hip ratio, increase skeletal muscle, muscle mass and basal metabolic rate.

CHALLENGING THE MONT VENTOUX WITH MULTIPLE SCLEROSIS: A HOME-BASED RANDOMIZED CONTROLLED CYCLING AND AWARENESS PROJECT.

KEYTSMAN, C., VAN NOTEN, P., SPAAS, J., NIESTE, I., VAN ASCH, P., O EIJNDE, B.

RESEARCH REHABILITATION CENTER HASSELT UNIVERSITY - BELGIUM

INTRODUCTION: Despite substantial clinical effects (e.g. +22% exercise capacity, 12w) of high intensity training (HIT) in MS, implementation of such interventions in actual rehabilitation programs is not common yet. Possibly, rehabilitation regimens consisting of HIT only are too demanding (1-5 exercise bouts 6s- 4min, recovery periods of 30s–4min, 90-100% maximum heart rate) and require self-guidance and external motivational factors to adhere longer term. Therefore any exercise therapy strategy in MS that includes HIT but ensures longer term training adherence is worthwhile investigating. Possible strategies to achieve this are common in the exercise/sports community and include training periodization, ergogenic supplementation (e.g. β-alanine supplementation), home-based exercise and goal setting. In keeping with the above line of reasoning, we investigated the feasibility and effects on exercise performance of a periodized (low and high intensity exercise and recovery), long-term (6m), home-based cycling exercise program in
METHODS: In this double-blind, randomized, placebo-controlled trial, exercise capacity (maximal graded exercise test) and body composition (DEXA) were assessed at baseline (PRE). Following baseline screening, persons with MS and HC were randomized into a β-alanine supplementation (β-alanine supplements: MSβ, HCβ), or a placebo (placebo tablets identical in taste and appearance: MSpla, HCpla) group. Next, all participants received an activity tracker (Polar® M200) and were enrolled in a 6m home-based exercise program. Training involved cycling on their personal bicycle. Subjects were supervised remotely using the Polar® Coach module. Following 8 training cycles POST measurements were performed similar to baseline. Hereafter, subjects climbed the Mont Ventoux.
RESULTS: Six months of home-based training induced main time effects for body weight (-1.4%, p=0.004), BMI (-2%, p=0.02), total mass (-1.2%, p=0.021), VO2max (+5,4%, p=0.001), workload (+10.8%, p<0.0001), time until exhaustion (+11,2%, p<0.0001), recovery heart rate (+1.8%, 0.0017) and lactate max (+35,4%, 0.002). Furthermore, all persons with MS safely reached the top of the Mont Ventoux, except for two (ceased at 2km and 1km from the top because of exhaustion). No injuries or adverse events occurred during the challenge.
CONCLUSION: The 6m home-based, periodized and HIT oriented cycling program appeared to be feasible and provided good adherence, showed significant improvements in exercise capacity and body composition, and trained persons with MS sufficiently to climb the Mont Ventoux safely. Supplementation of β-alanine showed no additional effects.

THE EFFECT OF EXERCISE TRAINING ON FUSOBACTERIUM AND CORAL RECTAL CANCER RISK FACTORS IN SEDENTARY YOUNG ADULTS

WU, C., CHEN, W., CHIU, C., HUANG, Y., CHANG, C., WU, S.

NATIONAL CHUNG HSING UNIVERSITY

INTRODUCTION: The influence of exercise on human microbiota in literature was very limited. Recent findings showed the strong link between Fusobacterium and Colorectal cancer (CRC). Exercise has been proposed one of the major factors of reducing colorectal cancer (CRC) risks. However, the underlying mechanism is still unclear. We hypothesize exercise may influence anaerobe - Fusobacterium, and butyrate concentration to reduce CRC risks.
METHODS: Twenty-seven healthy, inactive subjects participated in either high intensity exercise group (HEX) (13) or low intensity exercise group (LEX) (14). HEX was instructed to perform walking exercise at 70% predicted heart rate max (HRmax), while LEX at 50%HRmax, for 30 min, 3 times/week for 6 weeks after 4 weeks original inactive life style. Samples collection time will be at week 0, week 4, and week 10. Blood samples were analyzed for cytokines (TNF-α, IL-1β, IL-6, and CRP), leucocyte counts (lymphocyte, neutrophil) and biochemistry markers (glucose, triglyceride, cholesterol, HDL-C). Stool samples were used to investigate the Fusobacterium using the qPCR technique.
RESULTS: Results showed that there both group were significantly decreased in wait and hip circumference and body fat after training. There were no significant difference in biochemistry markers (glucose, triglyceride, cholesterol) and leucocyte counts (lymphocyte, neutrophil). The HEX showed decreased in RBC, hemoglobin, hematocrit after training. The stool Fusobacterium concentrations showed no difference between two groups.
CONCLUSION: Exercise intervention improved anthropometric measurement and body fat in sedentary young adults. The different exercise training intensity did not affect the Fusobacterium concentrations and other CRC risk factors.

THE EFFECTS OF AN EXERCISE TRAINING PROGRAM OF 21 DAYS IN THE FACTORS OF METABOLIC SYNDROME IN ELDERLY WOMEN

SILVA, A.A., PRESTES, J., BATTAGLINI, C., SOUSA, P.F., FRANÇA, N.M., MELO, G.F.

CATHOLIC UNIVERSITY OF BRASILIA

INTRODUCTION: The metabolic syndrome (MS) is characterized by a group of metabolic risk factors such as abdominal obesity, hypertension, dyslipidemia (high triglycerides and low HDL) and insulin resistance or type 2 diabetes mellitus, reaching a prevalence of 43% in the elderly. How to evaluate the effects of a consecutive 21-day program combined exercise (aerobic and resistance training) and feed restriction on the MS risk factors in older women.
METHODS: The training program was held lasting 2 hours and 15minutes of stretching, resistance exercise 1 hour (bench press, leg press, table abductor, adductor table, crucifix, biceps, triceps and calf sitting) - 3 sets of 8 to 12 repetitions with rest of 130"; half hour walk intensity ranging from 65 to 75% of the heart rate and 15 minutes of stretching. Caloric restriction has 30% of the metabolic rate.
RESULTS: Therefore, part of the sample 22 women diagnosed with MS as criteria of NCEP / ATP III, mean age 66.32 ± 3.99 years. The results showed a significant reduction (p = 0.05) of all the factors of MS and improved body composition of elderly women. There was a 2.9% percent reduction in body fat, waist circumference 6.67%, 21.97% in triglycerides, LDL and 19.23% increase in HDL by 14.9%.
CONCLUSION: With these results we can conclude that 21 days combined in moderate exercise intensities in conjunction with a dietary restriction is able to change the MS risk factors in elderly women.

A PRACTICAL MODEL OF VERY LOW-VOLUME HIGH-INTENSITY INTERVAL TRAINING IMPROVES CARDIOMETABOLIC HEALTH IN OBESE INDIVIDUALS: PRELIMINARY RESULTS OF A RANDOMIZED-CONTROLLED STUDY

ZOPF, Y., RELJIC, D.

UNIVERSITY HOSPITAL ERLANGEN

INTRODUCTION: Obesity, particularly in conjunction with further cardiometabolic risk factors, such as hypertension, hyperglycaemia or hyperlipidemia, is associated with an increased risk for cardiovascular disease and mortality. Regular physical activity (PA) plays a central role for improving cardiometabolic risk factors. Guidelines recommend at least 150 min of PA/week to achieve relevant health benefits. However, many adults with obesity do not achieve these PA-levels and lack of time is among the reasons most commonly cited for insufficient PA. Recently, high-intensity interval training (HIIT) has emerged as a time-efficient exercise strategy for inducing physiological adaptations that are linked to improved health outcomes. However, evidence regarding the efficacy of particularly time-efficient "low-volume" HIIT is based mainly on "all-out" protocols that may not be practical and safe for obese individuals. Here, we present preliminary data from a randomized-controlled study examining the effects of a practical very low-volume "non-all-out" HIIT model (14 min/session and 28 min time-effort/week, respectively) on cardiometabolic health, as assessed by the Metabolic Syndrome Z-Score (MetS), in obese individuals.
METHODS: Thirteen obese subjects (55±19 yrs, BMI: 36.6±4.6, %body fat: 44.7±3.4) at increased risk for metabolic syndrome (≥2 cardiometabolic risk factors) were randomized to either a training group (HIIT-group, n=9, baseline MetS: 4.1±4.5) performing 5x1 min HIIT at 85-95% maximal heart rate on cycle ergometers (2x/week for 6 weeks) or an inactive control group (CON, n=4, baseline MetS: 0.2±3.2). Body mass/composition, MetS and insulin resistance, as determined by homeostatic model assessment (HOMA-IR), were assessed baseline and after 6 weeks. MetS was determined from fasting blood glucose, HDL-cholesterol, triglycerides, waist circumference and mean arterial blood pressure according to Johnson et al. (2007). HOMA-IR was calculated from fasting blood glucose and insulin.
RESULTS: HIIT was well tolerated and no adverse events occurred. There was 100% compliance to the exercise sessions. Body weight/composition remained relatively unchanged in both groups. In the HIIT-group, there was a significant reduction in MetS by 1.4 units ($P<0.05$). HOMA-IR tended to decrease by 4.2 units without reaching statistical significance ($P>0.05$). In CON, MetS and HOMA-IR remained unchanged.
CONCLUSION: The preliminary results of this study indicate that low-volume (non-all-out) HIIT that requires as little as 28 min/week may induce clinically relevant improvements in cardiometabolic health in obese individuals after only 6 weeks, even in the absence of weight loss. The final data of this still ongoing study will allow more definitive conclusions.

THE EFFECTS OF PHYSICAL ACTIVITY ON HEART RATE VARIABILITY IN TYPE 1 DIABETES. A CASE REPORT

PERINI, R., NICOLI, A.

UNIVERSITA DI BRESCIA

INTRODUCTION: Regular physical activity in type 1 diabetes reduces many cardiovascular risk factors and related co-morbidities. Less consistent are the data on the benefits on glycemic control. Nonetheless, exercise is considered an important part of type 1 diabetes management. Cardiac autonomic neuropathy (CAN) is a frequent manifestation of type 1 diabetes, being probably hyperglycemia its main determinant. An early sign of CAN is the reduction in Heart Rate Variability (HRV), especially in vagal indices. We report the case of a young man with long-lasting type 1 diabetes, who restarted physical activity after 3 years of inactivity due to an injury. HRV was evaluated to verify if cardiac autonomic function could benefit from regular exercising.
METHODS: A 24 yrs male cycled outdoors for 70-90 minutes at an intensity eliciting 50-60% of HRmax 3 times a week for 6 months. At the beginning (pre), after 3 months (middle) and at the end (post) of the period: a) body weight (BW), waist circumference (WC) and BMI were assessed; b) HbA1c was determined; c) HR was continuously recorded in supine and sitting position (10 min each) and HRV was analyzed in time (SDNN, rMSSD) and frequency domain (total power, LFnu, HFnu, LF/HF) and by Poincaré plots.
RESULTS: A decrease in anthropometric parameters occurred from pre to post (BW from 94 kg to 88.5 kg; BMI from 27.5 to 25.8; WC from 102 cm to 97 cm). HbA1c was 9.2% in pre, decreased to 8.1% at middle and further decreased to 7.5% at post. At pre, all HRV parameters were similar in the two body positions. At middle and post, an increase was found in SDNN and rMSSD (both 40% and 80% vs pre, respectively), in total power (3 times and 4.5 times vs pre, respectively) and in SD1 and SD2 (both doubled at post) in supine position. LFnu and HFnu powers remained almost stable during the 6 months in both positions, showing HFnu a tendency to be lower at post than at pre in sitting position. The difference in LF/HF between the two positions was negligible at pre and at middle and became positive at post (+1.9).
CONCLUSION: Performing regular physical activity induced a reduction in anthropometric parameters, so that after 6 months BMI attained a value only slightly beyond the upper limit of normality. At the same time, a progressive decrement in HbA1c was observed, suggesting that glycemic control was improved by the kind of exercise carried out by the subject. At pre, HRV parameters were very similar in supine and sitting position, possibly as a reflection of altered autonomic function. After 6 month of physical activity, assuming the sitting position induced a slight increase in LF/HF ratio, suggesting that a shift in autonomic interaction occurred. This together with the observed increment in HRV indices in supine position seems to indicate that physical activity could have a positive effect on autonomic control of HR in type 1 diabetes.

AEROBIC CAPACITY BUT NOT ENDOTHELIAL FUNCTION IS ASSOCIATED WITH PHYSICAL ACTIVITY IN HEALTHY POST-MENOPAUSAL WOMEN

HOPKINS, N., BRISLANE, A., HOLDER, S.M., JONES, H., LOW, D.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Aerobic capacity and endothelial function are important predictors of future cardiovascular morbidity and mortality. Both can be modified by physical activity (PA) and sedentary time (ST). Typically, post-menopausal women display reduced endothelial function and aerobic capacity, yet the roles of PA and ST in modulating these reductions are poorly defined. The aim of this study was therefore to examine the relationships between aerobic capacity and endothelial function with PA and ST in healthy post-menopausal women.

METHODS: Forty-seven healthy, post-menopausal females (58.6 ± 5.6 years old, time from menopause: 6.3 ± 4.1 years, BMI: 25 ± 4 kg/m2) were recruited. High-resolution ultrasound was used to assess brachial artery vasodilator response to 5 minutes distal limb occlusion, and VO2max was determined using a cycling ramp protocol to volitional exhaustion. ST and PA were measured over 7 days using an inclinometer (ActivPal) and an ActiGraph accelerometer, respectively. Relationships between daily ST and PA, and VO2max and endothelial function were evaluated using Spearmans rank correlation.
RESULTS: Endothelial function (3.99 ± 3.43%) was not associated with ST (488.7 ± 103.5 minutes; r=-0.25, P=0.17), total PA (334.3 ± 119.9 minutes; r=0.31, P=0.06) or any intensity of PA (light PA 283.7 ± 108.2 minutes, r=0.31; moderate PA 45.2 ± 24.6 minutes, r=0.11; vigorous PA 5.5 ± 6.7 minutes, r=-0.18; P>0.05). Aerobic capacity (25.0 ± 6.3 ml.kg-1.min-1) was associated with moderate PA (r=0.44, P<0.01), but was not associated with ST (r=0.18, P=0.92), total PA (r=0.17, P=0.28), light PA (r=0.06, P=0.71) or vigorous PA (r=0.22, P=0.16).
CONCLUSION: In healthy post-menopausal women there were no relationships between endothelial function and PA or ST, whilst aerobic capacity was related to moderate PA only.
Maintenance or improvement of moderate PA therefore appears important for post-menopausal women to prevent age-related decline in aerobic capacity and the associated mortality risk.

CARDIOVASCULAR RISK FACTORS ASSOCIATED WITH FOOD FREQUENCY OF SUBJECTS ASSISTED AT A SPORTS NUTRITION OUTPATIENT CLINIC

AMORIM, A.1, VIEIRA, E.1, GOMES, M.1, OLIVEIRA, K.1, ARAUJO, M.1, SILVA, T.1

<1> FEDERAL UNIVERSITY OF MARANHAO, SAO LUIS, BRAZIL

INTRODUCTION: Cardiovascular diseases are the main cause of morbidity and mortality in Brazil and worldwide. Nutrition and physical exercise are important risk components in this scenario. Therefore, the objective of this study was to evaluate cardiovascular risk according to anthropometric and food frequency indicators in patients attending Federal University of Maranhaos Sports Nutritional Care Project.
METHODS: A cross-sectional study was executed with 121 subjects, assisted at a sports nutrition outpatient clinic. The subjects were considered physically active according to the American College of Sports Medicine (ACSM). Weight, height, body-mass index (BMI) and waist circumference (WC) determinations were assessed according to International Society for the Advancement of Kinanthropometry (ISAK) guidelines. World Health Organization (WHO) parameters were utilized to classify cardiovascular risk. In addition, a food frequency questionnaire was used, which analysed the intake of adapted food pyramid's groups. Quantitative (average±standard deviation) and qualitative (%) data were analyzed through t test and qui-square, respectively, at a p<0,05 significance, by Epi InfoTM software.
RESULTS: The patients' age ranged form 17 to 67 years-old. From those, 68 (56.2%) were physically active (PA) and 53 (43.8%) were considered physically inactive (PI). It was verified that only 32.1% of the PI were eutrophic (p=0,001 vs PA group). With regard to waist circumference, it was observed that in the PI group 14.7% had a high cardiovascular risk and 29.4% had a very high cardiovascular risk. In the PA group, the values were 11.3% and 22.6% for high and very high cardiovascular risks, respectively. Concerning the food frequency questionnaire, the most common frequency of consumption for both PA and PI groups was "Daily". It was noticed that the most consumed groups on a daily basis were pasta and cereals, fats, sugars, meats/eggs and dairy products. The PA group appointed daily intake of vegetables at 36,8%.
CONCLUSION: Cardiovascular risk factors were more prevalent among physically inactive subjects. Overweight, obesity and large WC were more prevalent among the PI group. However, the PA group presented lower consumption of fruits and vegetables compared to the PI group. That's a worrisome data, since these food groups have higher caloric density than fruits and vegetables, which, in contrast, have high content in fiber, vitamins and minerals. A possible reason is that sedentary people are aware of the risks in their condition and try to compensate the lack of physical activity by eating more fruit and vegetables in their diet. In addition, it would be interesting to evaluate a 24-hour food recall to corroborate the information in the food frequency questionnaire. Finally, it's important to apply and amplify the range of intervention programs focused on lifestyle change.

ACUTE EFFECTS OF ENDURANCE EXERCISE ON INSULIN-INDUCED VASORELAXATION AND NITRIC OXIDE PRODUCTION IN AGING HYPERTENSION

LIU, J.L.1, YANG, A.L.1, SU, C.T.2

1: UNIVERSITY OF TAIPEI ; 2: FU JEN CATHOLIC UNIVERSITY

INTRODUCTION: Epidemiological studies claim that more than half of the elderly have hypertension. Advanced age is associated with the prevalence of hypertension. Moreover, the endothelial dysfunction and early atherosclerosis could be observed in aging individuals . Endurance exercise has been found to reduce several risk factors of cardiovascular disease in the elderly . However, whether acute endurance exercise positively influences the endothelium-dependent insulin-induced vasorelaxation, as well as its underlying mechanisms, in the aging population with hypertension remains unknown. Therefore, the purpose of this study was to investigate acute effects of endurance exercise on the insulin-induced vasorelaxation and nitric oxide production in aging hypertension.
METHODS: The 12-month-old spontaneously hypertensive rats and normotensive Wistar-Kyoto rats were used in this study. The SHR rats were divided into sedentary and acute exercise groups. The SHR-AEX group was conducted by running on a motor-driven treadmill at the moderate speed of 21 m/min <0% slope> for 60 min. After the single-bout exercise, thoracic aortas were immediately isolated for the evaluation of vascular function by organ bath system. Also, the NO production was measured immediately after the exercise. In contrast, no exercise intervention was conducted for the SHR-S and WKY groups.
RESULTS: After the single-bout exercise, we found that the insulin-induced vasorelaxation was significantly improved in the SHR-AEX groups compared with the SHR-S group. However, no significant changes were found in the denuded aortas among three groups. Moreover, the single-bout exercise acutely increased NO production in the SHR-AEX groups compared with the SHR-S group.
CONCLUSION: Our findings indicated that the endurance exercise acutely improved the insulin-induced vasorelaxation and NO production in 12-month-old hypertensive rats. It suggested that the single-bout endurance exercise would ameliorate the vascular function, which was associated with the increased NO production, in the aging population with hypertension.

RELIABILITY OF THREE PHYSICAL ACTIVITY QUESTIONNAIRES FOR ELDERLY PEOPLE: THE RESULTS FROM POLISH ADAPTATION

KRÓL-ZIELINSKA, M.1, KANTANISTA, A.1, CIEKOT-SOLTYSIAK, M.2, SZEKLICKI, R.3, OSINSKI, W.3, ZIELINSKI, J.2

POZNAN UNIVERSITY OF PHYSICAL EDUCATION

Introduction: There is lack of reliable and validated physical activity questionnaire adapted to Polish elderly population to improve research quality on physical activity. The aim of the study was to estimate reliability of three different physical activity questionnaires for older adults, adapted to Polish culture. The following questionnaires have been selected: Community Healthy Activities Model Program for Seniors - CHAMPS (Stewart et al. 2001), Physical Activity Questionnaire for the Elderly – PAQE (Voorrips et al. 1991) and Yale Physical Activity Survey – YPAS (DiPietro et al. 1993).
Methods: In order to assess the measurement reliability of the adapted version of each questionnaire in terms of the stability aspect, repeated measurements were performed. The reliability of the CHAMPS, PAQE and YPAS was assessed by test-retest within 1 week (1st examination) and after 3, 6, and 9 month. Of the 104 independently living elderly people (age 72.2 ± 5.7) who completed each questionnaire twice within 1 week, 73 older adults filled in again each questionnaire in next three examinations. Spearman's rank correlation coefficients were calculated.
Results: The one week test-retest reliability correlations for all physical activity measures ranged from 0.62 to 0.70 for the CHAMPS, from 0.49 to 0.78 for the PAQE and from 0.39 to 0.78 for the YPAS. Caloric expenditure of all physical activities assessed with the CHAMPS in 1st examination was correlated to the results obtained 3, 6 and 9 month later (coefficients: 0.58, 0.69, and 0.51, respectively). For the PAQE, the 3-month, 6-month and 9-month stability of activity score was 0.57, 0.45 and 0.32, respectively. Reliability coefficient for energy expenditure evaluated by the YPAS was 0.60 after 3 month, 0.66 after 6 month, and 0.62 after 9 month.
Conclusion
Polish adaptations of CHAMPS, PAQE and YPAS questionnaires have similar reliability to their original versions and are suitable for use among older Polish people.

OBJECTIVELY ASSESSED LEVELS OF PHYSICAL ACTIVITY OF ADOLESCENTS IN BEIJING, CHINA

WANG, C., HE, G., JI, G.

CAPITAL UNIVERSITY OF PHYSICAL EDUCATION AND SPORTS

INTRODUCTION: Objective data on adolescents' physical activity (PA) in China are rare. The aim of this study was to objectively assess the PA level of adolescents in Beijing, China using accelerometer.
METHODS: 1100 students were randomly recruited as participants from ten junior high schools located in ten Districts of Beijing, China. Age and sex were reported by participants. Body weight and height were measured by investigators, and body mass index (BMI) was then calculated. According to the standard developed by the Working Group on Obesity in China, participants were classified as overweight and non-overweight based on their BMI. Participants wore the ActiGraph GT3X+ accelerometer for seven consecutive days for objective assessment of PA. Time spent in light PA (LPA), moderate PA (MPA), vigorous PA (VPA), and moderate-to-vigorous PA (MVPA) were derived based on the cut-offs specifically developed for Chinese youth (Zhu et al., 2013). Independent sample T-test was performed to compare the differences of PA time between sexes and weight status. Paired sample T-test was used to examine the difference of PA time on weekdays and weekend days.
RESULTS: 673 participants who provided valid accelerometer data (number of boys = 262; mean age = 12.6 ± 0.6 years) are included in the data analysis. Of which, 20.5% were classified as overweight. Participants spend an average of 142.7 ± 36.7 min, 19.6 ± 7.2 min, 22.1 ± 11.5 min, and 41.8 ± 16.7 min daily on LPA, MPA, VPA, and MVPA, respectively. Only 13.2% of the overall sample meet the recommended 60min/d MVPA guideline. Participants are more active on weekdays than on weekend days (MVPA: 47.1 ± 18.4 min/d vs. 27.2 ± 20.9 min/d, $p < 0.05$). Boys spend more time on MVPA (48.3 ± 17.4 min/d vs. 35.9 ± 13.8 min/d, $p < 0.05$) and have a higher proportion that meet the PA guideline than girls (21.0% vs. 5.4 %). Daily LPA (136.7 ± 33.1 min/d vs. 150.3±36.1 min/d, $p < 0.05$) and MPA time (18.5 ± 6.8 min/d vs. 20.9 ± 7.3 min/d, $p < 0.05$) of non-overweight adolescents are lower than those of overweight counterparts.
CONCLUSION: PA levels of Chinese adolescents are extremely low. Intervention programs may take girls and weekend days as the targets for PA promotion.

THE EFFECT OF INACTIVITY ON THE FUNCTION OF SATELLITE CELLS

YUYA, O.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Muscle specific stem cells, termed satellite cells, play pivotal roles in postnatal growth, maintenance, repair, and regeneration of skeletal muscle. It is reported that exercise increases the number of satellite cell and improves its function. On the other hand, inactivity is reported to decrease the number of satellite cells, however it remains unclear the effects of the function of satellite cells like activation, proliferation or self-renewal. To investigate the effect of inactivity on the function of satellite cells, we adopted hindlimb suspension and reloading and single fiber immunostaining.
METHODS: 5 weeks of age male C57/BL6 mice were divided into two groups: CON (normal keeping) and HS-RL (1 week hindlimb suspension 2 weeks reloading). After 3 weeks keeping, mice were sacrificed and gastrocnemius, soleus and extensor digitorum longus (EDL) muscles were quickly dissected out from each mouse for subsequent analyses. Single fibers were obtained from EDL muscle. Single fibers were cultured in plate medium. After culture, each single fiber was fixed and immunostained to evaluate satellite cells function.

RESULTS: There are no changes in body weight and muscle wet weight between two groups. Immunostaining indicated the reduction of satellite cells proliferation number in HS-RL group mice EDL fiber cultured 48 hours.
CONCLUSION: Inactivity decrease the satellite cell number (Arentson-Lantz et al., 2016). However, its effect on satellite cells function is unclear. On the other hand, exercise improves its function (Fujimaki et al., 2016). In this study, we revealed that hindlimb suspension impairs satellite cell proliferation like aging (Zhang et al., 2016) even after 2 weeks hindlimb reloading. To conclude, inactivity depress the satellite cell function.

EFFECTS OF EXERCISE TRAINING ON ANTI-INFLAMMATION CYTOKINES OF THE MYOCARDIUM AND SKELETAL MUSCLE IN OBESE AGED RATS

AHN, N., KIM, K.

KEIMYUNG UNIVERSITY

INTRODUCTION: Depression of cardiac muscle function is the important factor of the increasing prevalence of metabolic syndrome through the increase of inflammatory cytokines. Especially, myocardium may drive the stimulation of the anti-inflammatory cytokine expression with different mechanism as compared to skeletal muscle. We should try to develop the effective exercise training program of cardiac function for the prevention of metabolic syndrome, and we can suggest the importance of combine exercise training for activation of anti-inflammatory function. Therefore the purpose of this study is the analysis of the anti-inflammation cytokines expression mechanism of cardiac muscle for improves cardiovascular function.
METHODS: 50 male, middle-aged Sprague-Dawley rats were induced to become obese with 8 weeks of a high-fat diet, and were randomly divided into four experimental groups: normal diet (ND), normal diet exercise (NDEx), high-fat diet (HFD), high-fat diet exercise (HFDEx). The exercising groups underwent high-intensity intermittent training using a ladder-climbing and weight exercise and treadmill-running exercises 3 days/week for a total of 12 weeks. Myocardium and skeletal muscle were analyzed the protein expressions of Heat shock protein (HSP) and interlukin 15 (IL-15) by western blotting.
RESULTS: The exercise group (NDEx and HFDEx) of the HSP protein levels significantly ($p<0.005$) increased than non-exercise group (ND and HFD) in myocardium. Also, high-fat diet exercise (HFDEx) of the IL-15 protein levels significantly ($p<0.005$) increased than non-exercise group (ND) in myocardium. However, there was no significant difference in skeletal muscle.
CONCLUSION: Exercise training confers a myriad of physiological benefits in aging and cardiovascular diseases through its antioxidant and anti-inflammatory actions. Heat shock proteins are highly conserved chaperone proteins that regulate the folding and processing of damaged proteins and therefore exert significant anti-inflammatory action (Walsh et al., 2001). Exercise increases nutritive blood supply to and removes waste from skeletal muscles, while also upregulating the expression of the anabolic myokine IL-15 (Nielsen et al., 2007). Therefore, exercise training can contribute to the prevention of aging- and obesity-associated decrease in cardiac function as a increase anti-inflammation cytokines expression of cardiac muscle for improves cardiovascular function.

EFFECTS OF EXERCISE ON BONE METABOLISM MEDIATED BY BMP-SMAD1 SIGNALING PATHWAY

JUN, Z., LINGLI, Z.

DEVELOPMENT AND PLANNING OFFICE

INTRODUCTION: The study tends to reveal how bone morphogenetic protein signaling pathways affects bone metabolism in the process of exercise training, via checking bone mineral density (BMD), biomechanics characteristics and blood and urine indices after injecting mice with Smad1 activating enzyme inhibitor, running a treadmill exercise or both.
METHODS: 72 six-week-old C57BL/6 male mice were divided into 4 groups as follows (18 mice for each group): control group (C group), exercise group (E group), LDN group (LDN+C group), exercise in combined with LDN group (LDN+E group). The mice were trained on a treadmill. The starting speed was 12 m/min, for 20 min per day, with 0° slope. In the firstly two weeks, the speed was increased by 3 m/min every other day, and the duration was increased by 10 min every other day. After a period of adaptation, from the third week to the end, the speed was 18 m/min, on a 5° slope, with the training duration of 50 min per day. Training was continued for 6 weeks, 6 days per week. The speed of exercise group was equivalent to 85 % maximal oxygen uptake (VO2max). Mice in the LDN groups were injected with LDN (LDN-193189HCL, Selleck chem) on Wednesday from the third week to sixth week. LDN (3mg/kg body weight) was mixed with DMSO and slowly added this DMSO liquor into physiological saline. LDN powder was completely dissolved using water bath ultrasonic and dissolved by 0.22 μm filter. Each mouse was weighed before injecting and the doses of LDN were adjusted. After intervention, we check mineral density of femoral bone, biomechanics characteristics (maximum load, yield stress and elastic modulus), and blood and urine indices (serum calcium level, serum phosphate level, urinary DPD/Ucr).
RESULTS: Firstly, the BMD of E group was greatly higher than C group ($P<0.01$) and the BMD of LDN + E group was higher than LDN + C group ($P<0.05$), but it sharply lower than LDN + C group ($P<0.01$). The serum calcium level of LDN + E group was higher than LDN + C group ($P<0.05$). Moreover, the serum calcium level of LDN + C group was greatly higher than C group ($P<0.01$), and LDN + E group was greatly higher than E group ($P<0.01$). In addition, serum phosphate level of LDN + C group was higher than C group ($P<0.05$) and LDN + E group was higher than E group ($P<0.05$). DPD of LDN + C group was higher than C group ($P<0.05$) and LDN + E group was higher than E group ($P<0.05$).
CONCLUSION: Exercise could improve BMD of growing mice, but injecting LDN-1931189HCL greatly inhibits the effect of exercise, which represents that BMP-Smad1 signaling pathway induces effects of exercise on bone resorption but it has no significant effect on bone biomechanics characteristics.

EFFECT OF EXERCISE TRAINING ON SKIN-GAS NITRIC OXIDE CONCENTRATIONS AND ANTIOXIDATIVE CAPACITY IN RATS

ITOH, H.1, UTSU, Y.1, KATO, H.1, MINAGAWA, A.1, TSUDA, T.1, MATSUMOTO, T.2

1: NAGOYA INSTITUTE OF TECHNOLOGY, 2: NAGOYA UNIVERSITY

INTRODUCTION: Exercise training increases the plasma nitrite and nitrate (NO_2^- + NO_3^-; NOx) as an index endogenous formation of NO (Xiao and Qian 2000). However, no one has confirmed the effect of exercise training on skin-gas NO concentrations. We have previously reported that exercise training reduced basal level of reactive oxygen species (ROS) by increasing antioxidative capacity (glutathione

redox system) (Itoh 1998). On the other hand, oxidative stress reduces the bioavailability of vascular NO (Förstermann 2010), there is no data concerning the relationship between skin-gas NO concentrations and antioxidative capacity. Therefore, the purpose of the present study was to examine the effect of exercise training on skin-gas NO concentrations emanating from rat tails and to confirm relationships among skin-gas NO, plasma NOx concentrations, and antioxidative capacity in rats.
METHODS: Wister male rats (5 weeks of age) were divided into sedentary (S) and training (T) group. Exercise training was carried out on treadmill (12-20 m/min, 30min, 4 days/wk, 10-15 wk). The skin-gas samples were obtained by covering the tail with a polyethylene bag in which pure nitrogen gas was introduced, and collected in a sampling bag at rest. The skin-gas NO concentration was measured by a chemiluminescence analyzer (Pico-Device Co., Ltd., Nagoya, Japan). At 16 weeks of age, rats were anesthetized and blood and liver was taken. The plasma NOx (BioAssay Systems, USA), aorta NOS activity analyzed with a kit (Oxford Biomedical Research). Reduced (GSH) and oxidized (GSSG) glutathione (HPLC), MDA (UV) in plasma and liver, furthermore, systolic blood pressure (SBP) and heart rates (HR) were also measured from the tail (KN-210; Natsume Co., Ltd.).
RESULTS: Significantly higher skin-gas NO, plasma NOx concentrations ($p<0.05$), and lower SBP, HR ($p<0.05$) were observed in T compared to S. On the other hand, no significant difference was found in aorta NOS activity, MDA in plasma and liver between S and T. A higher GSH/GSSG tendency was observed in T compared to S, however, no significant difference was found between T and S.
CONCLUSION: These results suggest that exercise training increased skin-gas NO and plasma NOx concentrations of rats. Increased eNOS content in leg muscles and eNOS expression in cardiac muscle (McAllister 2008) of trained rats might be reasons of increased NO production in the vascular endothelial cells, nevertheless no significant difference was found in aorta NOS activity. Moreover, a higher GSH/GSSG tendency observed in T and decreased plasma endothelin-1 concentrations (Maeda 2003) which was potent vasoconstrictor peptide produced by vascular endothelial cells might be the reasons of increased NO bioavailability in the blood. Therefore, exercise training in this study decreased SBP and HR in trained rats.

EFFECT OF BLACK TEA DERIVED POLYPHENOL FRACTION ON MUSCLE ATROPHY AND RECOVERY IN MICE

AOKI, Y.
UNIVERSITY OF TSUKUBA

INTRODUCTION: Recently, there are some reports that polyphenols have some good effects on muscle. Our laboratory originally purified high-molecular-weight polyphenols extracted from black tea. We named it Mitochondria Activation Factor (hereafter, MAF), because MAF enhanced mitochondrial membrane potential of ciliated protista Tetrahymena pyriformis (Fujihara et al.). We found MAF raises AMPK (regulator of PGC-1 alpha, which stimulates mitochondria biogenesis) phosphorylation level and improves endurance performance in mice (Eguchi et al.). Recently, we extracted crude MAF fraction with 80% ethanol, and named this fraction E80. In this study, we examined whether E80 prevented skeletal muscle of mice during tail suspension or promoted recovery from muscle atrophy.
METHODS: Adult mice (8 weeks of age) were fed on food containing 0.5% E80 during 2 weeks of tail suspension and 5 days or 10 days of recovery after 2 weeks of tail suspension. After these process, mice were euthanized by cervical dislocation and excised soleus muscle.
RESULTS: We measured muscle wet weight and molecules regulating muscle mass and some molecules regulating hypertrophy. Then, we found E80 may have potential for promoting recovery of muscle mass from atrophy by tail suspension.
CONCLUSION: Previously, we reported E80 promote muscles hypertrophy during functional overload in mice. In this study, we demonstrated E80 has potential for promoting recovery of muscle mass from atrophy.

BODY FAT, REDOX BALANCE AND TELOMERE LENGTH OF MIDDLE AGED UNTRAINED AND MASTER ATHLETES

AGUIAR, S.S., SOUSA, C.V., SANTOS, P.A., BARBOSA, L.P., DEUS, L.A., ROSA, T.S., ANDRADE, R.V., SIMÕES, H.G.
CATHOLIC UNIVERSITY OF BRASÍLIA

INTRODUCTION: Several evidences suggest that low body fat is associated with a lower oxidative stress and a longer telomere length (TL), however, these parameters have not yet been investigated in track and field master athletes. We compared and associated the % body fat, redox balance and TL of master athlete runners (MA) and untrained middle aged controls (CON).
METHODS: Both MA (n=21; 51.6±8.1yrs) and CON (n=11; 45.4±10.3yrs) had anthropometrics and blood samples collected for biochemical and molecular analyzes. Pro and antioxidant measures as well as DNA extraction were performed using commercial kits following the fabricant protocols. TL was measured through quantitative PCR analyses for relative TL determination (T/S).
RESULTS: The TL of MA group ($T/S = 1.10 \pm 0.84$) was longer than CON ($T/S = 0.56 \pm 0.56$; $p = 0.038$). A large effect-size between MA and CON (Cohen's $d = 0.849$) was also observed. The comparison of antioxidant/pro- oxidant ratios indicated a better redox balance for the MA in comparison to the studied middle aged CON, which showed lower values for SOD/TBARS and CAT/TBARS ($p < 0.05$). Furthermore, MA had lower body fat (12.21±4.1%) than CON (26.02±4.3; $p = 0.001$), with a significant positive correlation between TL and CAT/TBARS ($r = 0.380$; $p = 0.032$) and a negative correlation between TL and body fat ($r = -0.471$; $p = 0.007$).
CONCLUSION: In conclusion, master athletes have longer TL than untrained peers, what in turn seems to be related to their better body composition and redox balance.

ASSOCIATIONS OF PPARG AND PGC-1A GENE POLYMORPHISMS WITH BODY STRUCTURE

BOSNYÁK, E., TRÁJER, E., PROTZNER, A., GYÖRE, I., MÓRA, Á., TÓTH, M., SZMODIS, M.
UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: The PPARG gene codes a nuclear hormone receptor, and is involved in the regulation of several genes, and metabolism pathways. The activitation of the gene results the decrease of insuline resistency and the increase of the adiponectin's level, which is one of the fat cells' hormones. Through these mechanisms the gene enhances the insuline sensitivity. The rs1801282 polymorphism was associated with body weight, body mass index and waist circumference.
The biogenesis of the mitochondria goes through the activation of the PGC-1α . The PGC-1α takes part in the induction of the enzymes that are neccessary for carbohydrate and fatty acid consumption as well. The rs8192673 polymorphism of the PGC-1α gene was associated with insulin resistance, obesity indices in women, lipid metabolism and insulin secretion. The aim was to describe the PPARG and PGC-1α genotype frequencies and the possible connetions to body dimensions and obesity indices.
METHODS: 324 participants were involved to the study, both athletes and controls . Genotype analysis was carried out via a DNA chip, anthropometric measurements were taken according to the International Biological Program. The level of significance was 5%.

RESULTS: The PPARG genotype frequencies in the total sample were: Pro12Pro=62.04%, Pro12Ala=21.91%, Ala12Ala=16.05%, while that of the PGC-1α were: CC=10.63%, CT=45.85%, TT=43.52%. There was significant difference in the athletes' group in the values of the upper arm circumferences , and in the values of the upper arm circumference minus the biceps skinfold between the Pro and Ala homozygote genotypes. The difference in the triceps skinfold was significant between the genotypes in control group . Grouping the participants according to the WHO BMI categories the genotype frequencies differed in control group. There were no relations between PGC-1α genotypes and obesity indices in this sample.
CONCLUSION: The AlaAla genotype was associated with higher mid upper arm circumference and mid upper arm circumference minus biceps skinfold values among athletes, while the same polymorphism was connected to higher triceps skinfold in controls. These results suggest no clear connection between the PPARG variants and body dimensions, confirming the international results. This study have not found any relation between the PGC-1α rs8192673 polymorphism and obesity indices.

NOVEL USE OF UNTARGETTED METABOLOMIC PROFILING OF TREADMILL ULTRAMARATHON RUNNING

MOIR, H.J.1, HOWE, C.C.F.1, ALSHEHRI, A.2, MUGGERIDGE, D.2, MULLEN, A.B.2, BOYD, M.2, SPENDIFF, O.1, WATSON, D.G.2
1: KINGSTON UNIVERSITY LONDON , 2: UNIVERSITY OF STRATHCLYDE

INTRODUCTION: The rising popularity of ultramarathon running over the past few years has seen non-professional runners striving for bigger and tougher extreme physical challenges. Understanding the effects of ultramarathon events and the ultramarathon runners profile provides a unique model to investigate the physiological responses to prolonged physical exertion. The current study determined the metabolic changes induced by extreme exercise through ultra-marathon running in order gain an insight into how metabolism is adapted for endurance performance. Plasma samples were analysed for their metabolomic profiles to determine the metabolic changes. The aim of the current study was to analyse the change in metabolic profile of trained ultramarathon runners in response to an 80.5km simulated treadmill ultramarathon.
METHODS: Metabolomic profiling of nine trained male ultramarathon runners was performed in response to an 80.5km self-paced treadmill-based time trial performed in a controlled laboratory environment. Plasma samples were obtained from venous whole blood, collected at rest, half-way (40.25km) and on completion of 80.5km (post-80.5km). Samples were analysed by high resolution mass spectrometry in combination with both hydrophilic interaction (HILIC) and reversed phase (RP) chromatography. The extracted putatively identified features were modelled using Simca P 14.1 software.
RESULTS: The runners completed the distance in 09:00:18±01:14:07 (hh:mm:ss), at a running velocity of 9.8±1.3 km.h-1. The exercise induced a large number of metabolic changes with multiple amino acids decreasing in abundance while there were increases in the levels of a number of acylcarnitines, fatty acids and oxidised fatty acids. There were no significant differences observed between the halfway (40.25km) and post-80.5km samples (p>0.05). A large number of amino acids decreased and fatty acid metabolism was affected with an increase in the formation of medium-chain unsaturated and partially oxidised fatty acids and conjugates of fatty acids with carnitines.
CONCLUSION: A marked elevation in acylcarnitine levels suggests a source of energy for export into the musculoskeletal mitochondria. The fall in the amino acids used in protein biosynthesis may be due to an increase in protein biosynthesis during exercise. Elevation of oxidised fatty acids may be associated with potent effects on blood vessels promoting either vasodilation or vasoconstriction or as markers of oxidative stress. The pattern of fatty acids and carnitines observed in the current study suggests a large increase in peroxisomal metabolism providing acetyl carnitine as a fuel source. This is the first study to provide evidence of the metabolic profile in response to prolonged ultramarathon running using an untargeted approach. The findings provide an insight into the effects of ultramarathon running on the metabolic specificities and alterations that may demonstrate cardio-protective effects.

Motor Learning and Motor control

EFFECTS OF DIFFERENT PROTOCOLS OF PHYSICAL EXERCISE IN AQUATIC MEDIUM ON MOTOR-COGNITIVE PERFORMANCE AND COGNITIVE FUNCTION ON PHYSICALLY ACTIVE ELDERLY: A CROSSED STUDY

FRANÇA BARROS, J., ANDRÉ GOMES DA SILVA, R., BEZERRA PADILHA, K., RAFAELLY DA SILVA PERES, I., RIBEIRO DA SILVA, A., ANSELMO SILVA DE LIMA, F., ALBERTO VIEIRA BROWNE, R.
UNIVERSIDADE DE BRASÍLIA / UNIVERSIDADE FEDERAL DO RIO GRANDE DO NORTE

INTRODUCTION: The aging process is inevitable, but it varies from individual to individual the effects caused by it, it is known that active aging slows down the degenerative effects caused by advancing age, thus being dependent on the program of activities practiced over time will contemplate modifications different substances on the motor and cognitive performances compared to the elderly who do not have an active lifestyle. Objective: To analyze the acute effects of different sessions (automatic, dual task, cognitive and moment control) on gait performance and executive function in physically active elderly women.
METHODS: This is a randomized controlled trial with a cross-over design, where each subject will undergo two sessions of scientifically-based physical exercises (dual task and automatic session), a session with cognitive stimulation and a control momentum, as described The dual task session occurred through exercises with stimuli based on motor learning with new movements in the aquatic environment, the automatic session occurred through exercises with standardized movement in the aquatic environment, and the cognitive session occurred through cognitive (audiovisual) stimuli by In the midst of a video demonstrating aquatic physical exercises, the moment of control there was no type of motor and cognitive stimulation, in which the subjects remained lying on a mat. To analyze the effect on gait performance, the gait and gait test was used in different situations and to analyze the executive function, we used the gait tests A and the stroop test. The normality of the data was verified by the Shapiro-Wilk test. The data were expressed in median and 25th and 75th percentiles. Friedman test was applied to compare the absolute change values (? = post - pre) of each dependent variable between the exercise sessions. Wilcoxons test was used in the intra-condition comparison of each dependent variable. The size of the effect was calculated by the following formula: [z / v n]. The level of statistical significance was set at p <0.05. Statistical procedures were performed using SPSS for Win / v.22.0 (Statistical Package for Social Sciences, Chicago, IL, USA)
RESULTS: Regarding gait performance and executive function, no statistically significant difference was found between the sessions (dual task, automatic, cognitive and moment control), but a better motor-motor gait was observed after the automatic session (p = 0.015) and double task (p = 0.001) and motor-cognitive torque only after the dual task session (p = 0.032). We also observed an improvement in the Stroop test after automatic sessions (p = 0.003) and double task (p <0.001) 0.001) and cognitive (p <0.001). There was no effect on the control session variable (p> 0.05).

CONCLUSION: The results of the study demonstrated that the dual task protocol presented a potential positive effect on the improvement of motor-cognitive performance and cognitive functions in physically active elderly women, related to the aspect of mobility and cog

WATCH OUT FOR THE HAZARD! BLURRING PERIPHERAL VISION FACILITATES HAZARD PERCEPTION IN DRIVING

RYU, D., COOKE, A., WOODMAN, T.

BANGOR UNIVERSITY

INTRODUCTION: In dynamic and time-constrained environments, such as those we encounter when playing sport or driving a car, the rapid acquisition and comprehension of a wide range of visual information is essential for successful performance. To locate the most pertinent information in these environments (e.g., the player best positioned to receive a pass in team sport, or road hazards that occur during driving), a continuous interaction between the central and peripheral parts of the visual field is thought to be crucial. However, research has yet to directly examine the comparative roles of central and peripheral vision in hazard detection; a critical component of driving performance. In the present study, we examine the role of central and peripheral vision in perceiving and detecting hazards in driving. We also compare the hazard perception ability of experienced and novice drivers.
METHODS: The gaze-contingent display paradigm was used to selectively present information to central and peripheral parts of the visual field. Twelve experienced and twelve novice drivers watched 2 sets of hazard perception test video clips (60 trials in total) in three different viewing conditions: full vision (unrestricted vision), moving window (clear central and blurred peripheral vision), moving mask (blurred central and clear peripheral vision). Participants were required to locate hazardous situations by making a mouse click on each hazard as soon as it was detected.
RESULTS: The experienced drivers were more accurate at detecting hazards than the novices. Both groups showed more accurate and faster responses to hazards in the full vision and moving window conditions than the moving mask condition. Most Interestingly, response accuracy was highest in the moving window condition, especially for experienced drivers. Gaze behaviour analyses revealed a narrower search strategy in the moving window condition compared to the full vision and moving mask conditions. Finally, if participants fixated on a hazard, they were more likely to correctly identify it as a hazard in the moving window condition than in the other two conditions.
CONCLUSION: The findings indicate that central vision is important in driving regardless of skill level. More importantly, blurring peripheral vision facilitates the processing of prominent information (i.e., hazards) by removing less relevant information from the visual field, and leads to more accurate performance especially for experienced drivers. Our finding paves the way for future research to use blurred peripheral vision as a training tool to enhance hazard perception in any domain where this is a crucial component of performance, including car driving and sport.

VISUAL SEARCH STRATEGIES IN EXPERIENCED FEMALE SOCCER PENALTY TAKERS: RESPONSES TO FIVE GOALKEEPER TACTICS

ELLISON, P.

EDGE HILL UNIVERSITY

Introduction: Visual search strategies are used to identify key performance cues and are used by penalty takers to establish shot placement to improve chance of success (Wilson, Wood and Jordet, 2013). Three main strategies employed are: keeper-independent (ignore keeper and pick a spot); keeper dependent (wait for keeper to move); and opposite-independent (look one way and shoot the other). However, goalkeepers can employ techniques to influence or distract the player in order to be able to save the shot (Wood and Wilson, 2010). The aim of this study was to investigate differences in visual search strategies in experienced female soccer players and their responses to five different goalkeeper techniques.
Method
This study used a within-subjects research design. Thirteen experienced (≥ 5 years' experience) female soccer players (Mean age = 20.12, SD = 2.23 years.) took part. In order to establish preferences, they were asked which penalty taking strategy they preferred prior to participating in the study. They viewed 20 video clips of a simulated penalty scenario, and were instructed to watch and finally fixate their gaze in the section of the goal that they would shoot the penalty. Five randomly presented goalkeeper movement categories were evenly presented: stationary (ST), jockeying (JK), off centre (OC), crouching (CR) and focused arm movement (AM). Total of eye fixations (TF), duration of fixations (DF), number of fixations in areas of interest (FA), and location of last fixation (LF) were measured using a Tobii Pro X2-30 eye-tracker. ANOVA investigated differences between categories and the statistical significance level was set at $p < 0.05$.
Results: Significant differences were found between all goalkeeper movement categories ($p=0.024$). Bonferroni adjustments post-hoc found significant differences for TF between ST and JK ($p = 0.003$) and ST and CR ($p=0.043$) and JK and AM ($p=0.009$); DF between ST and CR ($p = 0.003$); and for FA between ST and JK ($p = 0.013$), and ST and OC ($p = 0.037$). LF identified comparable outcomes for all conditions.
Conclusion
Despite similarities in final fixations, goalkeeper movement categories affected visual search strategies and distracted the player viewing the penalty. Moving goalkeeper scenarios resulted in a higher numbers of fixations than those with stationary positions supporting the results of previous literature (Wood and Wilson, 2010).

MOTOR EXPERTISE MODULATES RESPONSE VARIABILITY AND BRAIN SIGNAL COMPLEXITY OF COGNITIVE CONTROL

WANG, C.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Motor expertise has been associated with differences in domain-general cognitive function. However, the neural mechanisms for such effect are still unclear. Brain signal complexity, an index of information processing capacity, has recently shown to increases with training experience, taken as evidence of experience-driven neural adaptability. Accordingly, this study aimed to explore whether individual difference associated with motor expertise in cognitive control performance is linked to differential brain signal complexity.
METHODS: We employed multiscale entropy analysis of electroencephalographic , a measure of brain signal complexity that calculates sample entropy at multiple time scales, to reveal the relation of motor expertise to neural adaptability and information processing capaci-

ty. A between-subjects design that included 18 open skill sport players and 18 age- and gender-matched closed skill sport players was conducted to examine differences related to motor expertise in performance and MSE of EEG signal during a flanker task which has varying levels of cognitive demand.
RESULTS: Results revealed that open skill players made more stable responses than closed skill players, regardless of levels of cognitive demand. In terms of EEG data, we observed that open skill players showed significant conflict-related modulation on MSE values at more coarse-grained temporal scales over frontal midline areas, while such effect was not found for closed skill sport players .05 FDR corrected>.
CONCLUSION: Taken together, our findings suggest that players trained in open skill sports showed greater domain-general cognitive control than those from closed skill sports, as revealed by lower behavioral variability but higher brain variability during cognitive control processes. We thus concluded that greater complexity occurring in response to the task involving higher cognitive demands appears to reflect brain networks of adaptation to the cognitive effort and opportunity provided by specific sport training.

EFFECTS OF ACUTE MODERATE-INTENSITY INTERVAL EXERCISE INTERVENTION ON FITNESS AND ERP INDICES OF INHIBITORY CONTROL IN SEDENTARY FEMALE ADULTS

JI, W.T., CHEN, K.H., ANG, B.S., WEN, H.J.

TZU CHI UNIVERSITY

INTRODUCTION: Greater aerobic fitness is associated with superior cognitive function (Kamijo & Masaki, 2016). People with low fitness level had smaller amplitude of the P3 wave, which indicated poor attention. Physical activity and aerobic exercise in particular, promotes health and effective cognitive function. The electrophysiological (event-related potential, [ERP]) in inhibitory control performance at different fitness level still not known. Currently, moderate-intensity interval exercise (MIIE) is a popular exercise modes that combine aerobic exercise and resistance training, and was a good choice for sedentary female adults (Chen, Wen, & Ang, 2017). This study was to investigate the effects of acute MIIE intervention on inhibitory control in different fitness female adults.
METHODS: Twenty healthy sedentary female adults (aged 20-45 years) were recruited from a larger pool of potential participants and were placed into high-fit group (HF, n=10, estimated VO2max= 33.26±1.31 ml/kg/min) and low-fit group (LF, n=10, estimated VO2max= 21.84±1.34 ml/kg/min). All participants accept an acute MIIE 30 min which including 4 cycles in a session, 6 sets in one cycle, 1 minute per set, and 15 seconds break between each set. During training, the HR was monitored using telemetry HR monitor to ensure they reached target HR. The inhibitory control performance data (accuracy rate [ACC] and reaction time [RT]) and electrophysiological (ERP) indices were simultaneously to record the amplitude and latency of N2 wave when participants performed a go/ nogo task before and after the acute MIIE.
RESULTS: The results showed that at baseline, the percentage body fat in LF (40.4±4.8%) was significant higher than HF (31.8±3.1%, $p<0.001$). ACC at baseline in go condition significantly higher in HF (100.0±0%) than in LF (99.8±0.26%, p=.025). however, ACC significantly decreased in HF (pre 100.0±0%, post 99.3±0.89%; p=.026) after the acute MIIE, whereas no change in LF (pre: 99.8±0.26%, post 99.3±1.42%, p=.221). N2 amplitudes revealed significant main effects of condition [$F(1,18) = 7.2$, $P=0.015$, $\eta p1 = 0.286$] and electrode [$F(2,36) = 5.78$, $P=0.007$, $\eta p2 = 0.24$], with the go condition exhibiting smaller than the nogo condition, and the N2 amplitude at the FCz significantly larger than those at the Cz and Fz sites. There were significant interactions among time × group [$F(1,18)=5.82$, $P=0.027$, $\eta p2=0.24$], after post hoc revealed that at HF after acute MIIE the N2 amplitude in go condition at Cz was higher than that in LF (pre adjust -1.99, post HF adjust -1.367 vs. LF adjust -3.04, p=.016).
CONCLUSION: A single bout of 30-min MIIE showed an acute effect on inhibitory control, which significantly enhanced the N2 amplitude at Cz in high-fit sedentary female adults than that in low-fit. Further work could investigate the long-term effects of MIIE on inhibitory control performance and ERP indices in sedentary female adults.

DOES COORDINATION PREDICT MAXIMAL STRENGTH AND STRENGTH GAINS IN YOUNG FEMALE ELITE BASKETBALL PLAYERS?

SEMPF, F., KÖNIG, B., GLAG, D., THIENES, G.

UNIVERSITY OF GÖTTINGEN

INTRODUCTION: Coordination is regarded as an important factor in the development of sport and condition skills (Meinel & Schnabel, 2015; Schnabel, 2014) and training of coordinative abilities such as balance can be linked to improvements in performance (Hrysomallis, 2011) and strength gains (Heitkamp, Horstmann, Mayer, Weller & Dickhuth, 2001). The purpose of this study was to examine if a basketball adjusted coordination level (CL) is related to maximal strength and predicts strength gains after a strength training intervention in young female elite basketball players.
METHODS: A convenience sample of 14 female elite basketball players (age = 15.21 ± 1.31 years, height = 174.89 ± 8.55 cm, weight = 60.07 ± 5.48 kg) was tested in four coordination tasks (dribbling course, free throw, jumping laterally, modified star excursion balance test) and subsequently for their maximal isometric upper body strength (MIUBS) using a Dr. Wolff Backcheck device (Dr. Wolff Sports & Prevention GmbH, Amsberg, Germany). After 8 strength training sessions consisting of lower and upper body movements MIUBS of the players was retested. A z-transformation was used to calculate CL from the four coordination tasks and the relationships were computed using Kendall's Tau. A paired t-test was conducted to assess differences between pre- and post-training MIUBS.
RESULTS: Significant changes in MIUBS were observed after the training intervention (+35.79 ± 18.02 kg; $p \leq .001$; $d = 1.99$), albeit no significant correlations ($p \geq .05$) could be found between CL and pre-/ post-test MIUBS or strength gains after the intervention.
CONCLUSION: While the importance of coordination is often presumed to be an important factor for physical abilities, coordination as evaluated in this study seems not to affect MIUBS or strength gains in young female elite basketball players. However, due to the small sample size the results should be regarded with caution. Further studies should include a dynamic strength test and investigate if these findings are similar in male athletes.

THE INFLUENCE OF LIGHT FINGERTIP TOUCH ON FEED-FORWARD AND FEED-BACK CONTROL IN POSTURE STABILITY

EDAMATSU, C.

KURASHIKI UNIVERSITY OF SCIENCE AND THE ARTS

INTRODUCTION: We propose a new method "stabilogram fan-shaped analysis (SFA)", which representing the COP fluctuation with one variable by calculating the area of the circular sector defined by the COP sway vectors. This concept is both similar to "stabilogram diffusion analysis (SDA)" (Collins et al., 1993) and Nagano's analysis (Nagano et al., 2010). These methods can analyze the dynamic characteristics of postural control. Meanwhile, light touch to stable object with a fingertip stabilizes standing posture because of it generates extra somatosensory information. While the effect of light touch has been studied, less attention has been given to the dynamic characteristics of postural control, particularly for feed-forward and feed-back control. The purpose of this study was to investigate the influences of light fingertip touch on feed-forward and feed-back control in posture stability.
METHODS: Nine healthy young subjects participated. Stabilographic examinations were performed during the trials with (LT) and without (NT) lightly touching a stable object. The time-series data for the COP were acquired at 100 Hz with a 30-s sampling time.
Using the SFA method, the area of the circular sector was defined by the velocity vector after a certain time interval (ΔT) was calculated. The area was then averaged over the number of time intervals that made up the COP time series. This process was repeated for increasing values of ΔT. A plot of the mean area of the circular sector versus ΔT was called SFA plot. The FFratio was defined as the ratio of the integrated value of SFA plot up to 0.10 s to that up to 3.0 s. Additionally, the FBratio was defined as the ratio of the integrated value of SFA plot from 0.20 s to 0.70 s to that up to 3.0 s.
RESULTS: The FFratio and the directional change of COP sway in the feed-forward phase was significantly larger for the LT condition. This implies that the COP sway for the LT condition displayed a random-like nature as one would expect from predictive postural control in the feed-forward phase. Meanwhile, there was no significant difference for any conditions with regard to the FBratio and the directional change of the COP sway in the feed-back phase.
CONCLUSION: These results suggest that light fingertip touch alters feed-forward control, but doesnt alter feed-back control in posture stability.

THE RELATIONSHIP BETWEEN TACTICAL SKILLS AND SHOOTING SKILLS OF BASKETBALL AMONG COLLEGE STUDENTS

KONNO, R.

J. F. OBERLIN UNIVERSITY

The purpose of this study is to assess the relationship between tactical skills and shooting skills, as one of individual skills, among college students taking a basketball class, considering their experience of playing sports in a club team and whether or not they take a teaching profession class in college of health and physical education.The participants were 55 college students taking a basketball class. They completed the Tactical Skills Inventory (Elferink-Gemser et al., 2004) at the beginning of the basketball course. Regarding the shooting skills, the number of shooting attempts within a limited time and their successes were recorded. Students had two types of shooting (i.e., shooting close from the basket and layups after dribbling) at the beginning of the course. They practiced those two types of shooting throughout the course, and then those two types of shooting were measured at the end of the course to assess their improvement. Various experience of playing in club sports were classified into 3 groups: the group of students who has experience playing basketball in a club, the group of students who have experience playing any ball sports except for basketball, and the group of students who have experience playing the other sports. Students were also separated into 2 groups: the group of students who were taking a teaching profession class and the group of students who were not. The exploratory factor analysis on the Tactical Skills Inventory produced 2 factors; their reliabilities and validities were assessed. Correlational coefficients were calculated, and all correlations between these two tactical skills and all 4 shooting skills were found moderate. After classifying students based on their experience of playing in club sports and their choice of taking a teaching profession class, all of those correlations were recalculated, and the analyses produced different results. The group of students who were not taking a teaching profession class had significant relationships between their tactical skills and all 4 shooting skills. However, the group of students who were taking that class did not have significant relationships between those two types of skills, except for the relationship related to one of the shooting skills at the end of the course. The results of the two-way ANOVA showed that the group of students who were taking a teaching profession class had significantly greater tactical skills. It might be considered that students who were taking a teaching profession class tend to assume their own tactical skills as very great but their results of shooting skills at the beginning of the course were not as great as their tactical skills. Students who were taking a teaching profession class might had taken many sports classes and had a great confidence in general sports; therefore, they might assume that they had a great knowledge about tactical skills even specific to basketball.

EFFECTS OF THE TIME OF DAY ON SPRINT START PERFORMANCE

KESOGLOU, I., SMIRNIOTOU, A., PILIANIDIS, T., PARADISIS, G.

NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Time of day is considered to influence physiological and neurological functions of exercise performance via circadian rhythms. Sprint start is a complex motor action which critically affects the sprint performance. Chronobiological studies suggest that short-term performance and psychomotor performance are improved during the early afternoon when core temperature is at its highest level. The purpose of the present study is to determine the time day effect on sprint start performance.
METHODS: 16 healthy males (age:18-21yrs, BM: 68-75kg) participated in this study. Prior to the experimental study, an extensive number of sprint start trials were performed to familiarize the participants and to determine the most comfortable crouch position on the starting blocks. During the experimental design, the participants completed three sprint trials in each session, morning session at 09:00, evening session at 17:00 and night session at 21:00. The best out of the three trials was used for further analysis. Time of 3m (3M), Reaction-Time(RT)and pre-Motor-Time(PMT) of gastrocnemius muscle of the rear leg used to assess the sprint starting performance. The repeated-measures analysis used to determine if any significant differences existed within the day with Bonferroni confidence interval adjustments.
RESULTS: RT differentiated significantly within a day, $F(1.939, 29.079)=5.54$, $p=.010$. Post hoc tests revealed that RT reduced by 0.15sec between morning and evening ($P<.05$). RT decreased 0.12sec between morning and night($P<.05$). PMT is not significantly affected by the time of the day $F(1.683,25.239)=0.99$,$p>.05$, and 3M time also $F(1.579,23.685)=0.253$, $p>.05$.
CONCLUSION: Starting action requires advanced physiological and psychological abilities and could be influenced by several factors. The time of day has a positive influence on reaction time indicating a better sprint start performance in the evening and at night than in the

morning. PMT of gastrocnemius and time of 3M showed repeatable results within a day. More research is required to assess the sprint start performance and the muscles involved as well within a day as between days.

Neuromuscular Physiology

ELECTROMECHANICAL RESPONSE TIMES IN THE KNEE MUSCLES IN YOUNG AND OLD WOMEN *

SZPALA, A., RUTKOWSKA-KUCHARSKA, A.

UNIVERSITY SCHOOL OF PHYSICAL EDUCATION IN WROCLAW

INTRODUCTION: The aim of the study was to compare electromechanical response times (total reaction time, TRT; pre-motor time, PMT; electromechanical delay) in the knee muscles in groups of young and older women during release of peak torque (PT), and to analyze the symmetry of the parameters measured. Muscles acting on the knee joint were selected for the study since the weaker stabilizing muscles of the joint increase the risk of falling among older people.
METHODS: Fifty women (one group approximately 20 years of age and the other approximately 60) participated in the study. PT and electromyographic activity were measured for flexors and extensors of the right and left knee in static conditions in response to a visual stimulus.
RESULTS: Significantly longer TRTs (p=0.05) and PMTs (p=0.05) were found in the group of older women compared to the younger participants. Asymmetry was found between the older and the younger group of women in PT of knee flexors.
CONCLUSION: Significantly longer TRT and PMT phases in the group of older women suggests a longer time for information processing in the central nervous system in older people. Electromechanical response parameters may be useful when assessing the risk of falls in older people.

EFFECT OF AGE ON MUSCLE STRENGTH OF LOWER LIMBS: A CROSS-SECTIONAL STUDY

IKEZOE, T., SATO, S., ICHIHASHI, N., TABARA, Y., NAKAYAMA, T., MATSUDA, F., TSUBOYAMA, T.

GRADUATE SCHOOL OF MEDICINE, KYOTO UNIVERSITY

INTRODUCTION: There have been many studies on age-related changes of muscle strength, and it is well known that age-related decline in the lower limbs strength such as knee extension strength is greater than that in the upper limbs strength such as hand grip strength. However, there have been few studies focusing on age-related changes in lower limbs strength, including those around the hip, knee and toe joint. We, therefore, investigated the effect of age on muscle strength constituting the lower limb muscles including those around the hip, knee and toe joint.
METHODS: The subjects comprised 2092 community-dwelling middle-aged and elderly people (744 men, 1348 women, aged 68.2±5.4 years) and 39 young people (19 men, 20 women, aged 22.6±2.7 years). Subjects with physical dysfunctions, which could potentially influence measurements such as acute neurological and severe musculoskeletal and cognitive impairments, were excluded. The subjects were divided into 5 groups according to age: young, 60-64, 65-69, 70-74, and 75 years and older.
Maximal isometric strength of the lower limbs were assessed including strength of hip flexion, hip extension, hip abduction, knee extension, quadriceps setting, and toe flexion. Muscle strength in the right leg was measured twice after a premeasurement trial, and the higher value of the two measurements was used for analysis.
We calculated the t-scores to take into account the variability in muscle strength between muscles in the young reference group. The t-score was calculated using the following equation: t-score = (muscle strength in the middle-aged and elderly − mean strength in the young) / (SD of strength in the young). Differences in the t-score between muscles were examined using a multiple comparison method (Tukey test).
RESULTS: For middle-aged and elderly men, the t-score in muscle strength was lowest for the toe flexion, followed by the quadriceps setting and hip abduction, whereas the t-score was highest for knee extension in all middle-aged and elderly groups. The multiple comparison test showed that the t-score of toe flexion has significantly smaller values than other muscles among the lower limb muscles.
For middle-aged and elderly women, the t-score in muscle strength was lowest for the quadriceps setting, followed by hip abduction and toe flexion, whereas the t-score was highest for hip extension in all middle-aged and elderly groups. The multiple comparison test showed that the t-score of quadriceps setting has significantly smaller values than other muscles.
CONCLUSION: We investigated the age-related change in muscle strength of lower limbs. Our findings showed that noticeable decreases of muscle strength were observed in the quadriceps setting, toe flexion and hip abduction in both middle-aged and elderly men and women. These results suggest that greater degree of age-related decline was seen in the quadriceps setting strength, which reflects both hip and knee extension strength, than in the knee extension strength alone.

THE RELATIONSHIPS OF SENSORY INTEGRATION TO MOTOR PERFORMANCE AND QUALITY OF LIFE IN CHILDREN WITH OBESITY

SU, C.T.1, FU, C.P.1, LU, C.I.2, YANG, A.L.3

1: FU JEN CATHOLIC UNIVERSITY, NEW TAIPEI CITY, TAIWAN 2: JIANG-TSUN UNITED CLINIC, TAIWAN 3: UNIVERSITY OF TAIPEI, TAIPEI, TAIWAN

INTRODUCTION: The global prevalence of childhood obesity has become around 30%, which is already one of the major issues of health. Previous studies have indicated inferior levels of motor performance and quality of life in children with obesity. Sensory integration is relevant of conducting many daily activities, including motor and psychosocial aspects. A few studies speculated that insufficient ability of processing sensory inputs may contribute to poorer motor skills in children with obesity , and a correlation may exist between sensory modulation ability and QOL . However, studies in children with obesity exploring either the relationships between motor performance and SI, or the relationships between QOL and SI remained limited. Thus, we examined these relationships.

METHODS: We recruited 12 children who were categorized as obesity based on the BMI norm of Taiwanese children. Their motor performance, QOL, and SI were measured by Bruininks-Oseretsky Test of Motor Proficiency , Kid-KINDL, and Sensory Profile , respectively.
RESULTS: Correlational analyses indicated that some significant relationships existed . Specifically, moderate correlations between better motor performance and more responses in SP were found in fine manual control and sensory seeking, and manual coordination and sensory avoidance. Less responses in sensory seeking were moderately correlated with better physical well-being scores. High correlations between less responses in SP and higher QOL scores were found in sensory sensitivity and family, sensory sensitivity and school, sensory avoidance and family, and low registration and school.
CONCLUSION: Some significant correlations were found between motor performance and SI, as well as QOL and SI. These results may support the influences of SI in motor performance and QOL in children with obesity. However, sample size was limited in this study. Recruiting a larger sample size were highly recommended in future studies.

EFFECT OF HEAT STIMULATION ON SKELETAL MUSCLE CONTRACTILE PROPERTIES.

HIRATSUKA, K.1, TSUNODA, N.1, SIMUNIC, B.2, DJORDJEVIC, S.2

1: KOKUSHIKAN UNIVERSITY , 2: UNIVERSITY OF PRIMORSKA

INTRODUCTION: It is many reported that skeletal muscle contractile properties by tensiomyography (TMG) method are informed to sports and rehabilitation fields (Simunic, 2012). For example, contractile properties of muscle effected by cooling with cold-water.However, effect of heat stimulation on skeletal muscle contractile properties by TMG method is not so reported. Therefore, this study was to clarify the effect of heat stimulation on muscle contractile properties.
METHODS: Recnosix-Red Coral was used for producing heat stimulation. Heat stimulation of 750KHz at 60W power output was generated in 15 minutes, after muscle contractile properties were measured. Skin temperature was monitored by a high-precision thermometer (LT-2). Muscle contractile properties on rectus femoris (RF) were assessed by a Tensiomyography (TMG method). A contraction time (Tc) and maximal displacement of the muscle belly (DM) were measured as parameters for the contractile properties (Dahmane et al., 2006). In addition, normalized velocity (Vrn) was also analyzed (Rodríguez-Ruiz et al., 2014). Muscle contractile properties and skin temperature were measured pre and post heat stimulation condition.
RESULTS: Skin temperature was significantly increased by heat stimulation. Dm showed significant higher values than pre, the values of Td and Tc were significant shorter than that of pre. And also the Vrn value showed significantly higher velocity than that of pre.
CONCLUSION: It was considered that heat stimulation may considerable alterations to muscle contractile properties. These alterations significantly affect the state of muscles and their response capacity, particularly in relation to muscle stiffness and muscle contraction velocity.

EFFECT OF EXHAUSTED TREADMILL RUNNING IN RATS ON THE STAINING OF PARVALBUMIN-POSITIVE NEURONS IN THE CORTICOSTRIATAL PATHWAY

CUI, S.

BEIJING RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Central nervous system alteration contribute to the exercise-induced fatigue. Corticostriatal systems are known to mediate motor behavior,but the changes of the corticostriatal circuits after exercise are unclear.Owing to parvalbumin-positive interneurons vital for feedback and feedforward inhibition and are critically involved in the generation of network oscillations and GluN2B-Containing NMDA Receptors in the shift choice behavior.The purpose of this study was to determine the role of Corticostriatal PV+ intherneurons in the regulation of exercise induced fatigue.
METHODS: All the 16 Wista rats were randomly divided into exhausted group; and control group, incremental of treadmill exercise was employed. The initial treadmill speed was 8.2m/min, after 15min the speed increased to 15m/min, 15min later the speed improved upto 20m/min until fatigue. Record exercise time and movement distance. The immunofluorescence method was used to observe the expression of PV+ interneurons and GluN2B-NMDAR.
RESULTS: The PV+ interneuron expression more prevalently distributed in the primary motor cortex and dorsolateral striatum of EG group. Compared to the control group, It was observed a higher number of PV-positive neurons in the primary motor cortex and dorsolateral striatum < p<0.01>. Moreover, we found that the coexpression of PV+ interneuron and GluN2B-NMDAR in the dorsolateral striatum of EG group significantly increased. These regional distribution of PV+ interneuron indicate activity of M1-DLS loops was enhanced after exercised-induced fatigue.
CONCLUSION: It is revealed that the PV+ interneuron of the M1-DLS pathway play an important role in neural modulation for the exercise-induced fatigue. Our results indicated that GluN2B-NMDAR may contribute for the mechanism of central fatigue.The present study might provides morphological basis for the research of central mechanism of exercise-induced fatigue.

EFFECT OF FATIGUE GENERATED BY LONG INTENSIVE EFFORT ON KINESTHETIC SENSE.

JASTRZEBSKA, A.D., BAKONSKA-PACON, E., WIERZBICKA-DAMSKA, I.

UNIVERSITY OF PHYSICAL EDUCATION IN WROCLAW

INTRODUCTION: In majority cases we are able to provide a precise estimation of force and movements. However, in fatigue conditions having problems with execution of skilled movements is well-known experience. The aim of presented study was to estimate the changes of kinesthetic sense (KS) in fatigue condition induced by long intensive effort performed on treadmill.
METHODS: 15 participants performed incremental test to volitional exhaust for fitness level and VO2max estimation. The 40-min effort with intensity of 80% VO2max was performed for fatigue elicitation. Respiratory parameters were measured breath-by-breath (K4b2, Cosmed, Italy). KS was measured before (pre-test) and follows the 5 min of recovery (post-test) for incremental and 40-min effort. Blood was collected for estimation of lactate concentration (Dr Lange Küvettentest, LKM 140, Germany) and venous blood was collected to determine the concentration of selected neurotransmitters (ELISA Test Demeditec Diagnostics GmbH Germany).

RESULTS: Lactate concentration in blood reach 3.92 ± 1,0 [mmol]. Concentration of neurotransmitters in plasma increased significantly. The generated force was on similar level in both pre- and post-test conditions in both incremental and 40-min efforts. Parameters describing force regulation (SD – standard deviation of mean force and CV – coefficient of variation [%]) significantly improved for right arm pushes after the effort and stayed on similar level for other limbs. We noticed significant reduction of time of force development and exhibition for right arm pushes ($p<0.05$), reduction tendency for left arm pushes and no difference for legs.
CONCLUSION: We expected worsening of KS after the 40-min effort. The increase of neurotransmitters indicates the development of fatigue, although not converted into a decline of KS directly after the efforts. It may be that 5 min after the effort the excitation of nervous system allows better muscle sense and a biochemical changes resulted by effort occur before fatigue appears in nervous system function.

A COMPARISON OF HIGH VELOCITY RESISTANT LOADING AND TRADITIONAL STRENGTH LOADING METHODS ON POST-ACTIVATION POTENTIATION

RICHARDS, B.J., KASHETSKY, N., GIFFORD, M., SEAMAN, K.

UNIVERSITY OF NEW BRUNSWICK

INTRODUCTION: The effect that Post-activation potentiation has on an athlete's ability to produce maximal power outputs has been an area of interest in recent years. According to this theory, contractile history has the ability to elicit potentiation of activated muscle fibre, which can be utilized by athletes to increase power output if fatigue can be mitigated prior to subsequent force applications[2]. The underlying mechanisms that may contribute to PAP are: 1> Phosphorylation of myosin regulatory light chains; 2> Increased recruitment of higher order motor units; 3> Muscle fiber pennation angle[1,3]. The purpose of this study was to investigate the utility of high velocity resistance loading in comparison to traditional strength loading (TS) on the fulfilment of PAP.
METHODS: Thirteen <7 male and 6 female> university varsity athletes volunteered to participate in the study. Participants were 19±2.1 years old with an average 1-RM of 113±29.5 kg and an average strength to weight ratio of 1.5±0.5. Participants completed a standardized warmup protocol. Upon completion, baseline vertical jump was measured. Participants then performed two sets of five repetitions of either HVR <65% of 1-RM> or TS <90% of 1-RM> in a randomized order. Participants returned one week later to complete the remaining condition (HVR or TS). Following a rest period of four and eight minutes, vertical jump was performed. Vertical jump heights were converted to power via the Sayer equation[2].
RESULTS: Following the HVR and TS interventions, significant improvements were observed between the HVR baseline and eight minute rest ($p=0.009$, ES 0.736), and between HVR and Maximal power regardless of time . No other differences were observed.
CONCLUSION: The main findings include: 1> HVR loading provided significant improvement from baseline in maximal power output demonstrating the utility of this method for stimulating PAP, 2> Rest period timing results demonstrate that optimized rest durations are an important consideration related to achieving PAP and vary between participants as some achieved peak power output at eight minutes and others are four.

OPEN VERSUS CLOSED KINETIC CHAIN EXERCISES FOR INDUCTION OF POST ACTIVATION POTENTIATION IN VERTICAL JUMP

DAL PUPO, J.1, GARCIA, T.1, KNIHS, D.1, RODRIGUES, O.A.F.1

1 - FEDERAL UNIVERSITY OF SANTA CATARINA

INTRODUCTION: Positive effects have been evidenced using strength exercises as post-activation potentiation (PAP) prior to the power activities such as vertical jump (Esformes and Bampouras, 2013; Fukutani et al., 2014). However, the influence of specificity regarding the type of kinetic chain in the conditioning exercises used in PAP induction has not been investigated yet. Thus, the objective of this study is to analyze the effects of PAP induced by isometric strength exercises of open and closed kinetic chain on squat jump (SJ) performance.
METHODS: Thirteen male weight training practitioners (age: 24.0±3.14 years; body mass: 80.72±3.14 kg) volunteered to participate in this study. Four experimental protocols were performed: P1 - SJ performed before and 3 min after performing the closed kinetic chain conditioning exercise (CKC); P2 - SJ performed before and 7 min after the CKC conditioning exercise; P3 - SJ performed before and 3 min after an open kinetic chain conditioning exercise (OKC); P4 - SJ performed before and 7 min after an OKC conditioning exercise. The protocols were performed on four days, in a randomized order. CKC consisted of a free squatting exercise performed with a barbell over the subject's shoulders attached to a chain on the ground and OKC was performed in a knee extensor chair. The squat jumps were performed on a force platform. Jump height (JH), mean power output (MPO), peak power output (PPO) and net impulse (NI) were obtained. Electromyographic (EMG) activity of vastus lateralis, vastus medialis, rectus femoris and biceps femoris muscles were analyzed in SJ pre and post-PAP. ANOVA was used for the comparison pre and post-potentiation, for all protocols.
RESULTS: Higher PPO was observed after PAP compared to the baseline condition for Protocol 1 ($p=0.04$). No effect was observed for the variables JH ($p=0.07$), MPO ($p=0.17$) and NI ($p=0.14$) in any of the protocols. No effect was also found for EMG activity when comparing pre vs. post-PAP, in any of the muscles analyzed ($p>0.05$).
CONCLUSION: The results of the present study indicate that CKC conditioning exercise, performed 3 minutes before the main task, is more effective than an OKC exercise to induce PAP in squat jump. These findings may be explained due to the greater specificity of CKC exercise with vertical jump task. A three minute interval seems to be more adequate to trigger the potentiation process and avoid the fatigue effects (Wilson et al., 2013).

MRCP INDUCED BY PUSHING BUTTON IN RESPOSE TO THE START SOUND OF ALPINE SKIING

SUDA, K.1, GOTO, A.1, FUMOTO, M.2, USUI, S.2, NISHIHIRA, Y.3

1:TOKYO INSTITUTE OF TECHNOLOGY 2:TOKYO INTERNATIONAL UNIVERSITY , 3: UNIVERSITY OF TSUKUBA

INTRODUCTION: The start of Alpine skiing is allowed within 10 seconds, and the start sound are consisted of 6 sounds from the first sound to the last sound. Fifth sound is highest and indicate the center of the start time. From the view point of neurophysiology, it is not clear whether skiers should start in response to the fifth sound or not. On the other hand, brain wave, especially event related potentials (ERPs) have been used for studying the activity of the brain at various human situations. MRCP (motor related cortical potentials) is one of the ERPs which can be recorded just before movement (Kornhuber, H. H., Deeke L., 1965). With this potential, readiness of movements can be compared. To compare start performance in Alpine skiing, reaction time is meaningless, so we compared the MRCP induced by pushing button in response to the fifth sound of Alpine skiing start, with the one at optional time.
METHODS: 12 persons participated in this study. They were asked to push button under three conditions. 1) in response to the fifth sound of Alpine skiing start sound as quickly as possible. 2) at optional time from the first sound to the last sound. 3) at optional time without start sound. MRCPs were analyzed from C3 and Cz electrodes according to the international 10-20 method. EMG was recorded from flexor pollicis brevis muscle of right hand. The EMG is used for analyzing MRCP. Data from 4 participant were rejected because of the artifact, ANOVA was used for the statistics.
RESULTS: We analyzed three components of MRCP, BP, NS' and MP. There were not significant differences in the amplitudes among the three conditions. On the other hand, the onset of BP was significantly early without sound compared to the with Alpine skiing start sound.
CONCLUSION: From the results following things are concluded. 1) We could not find clear difference in activation of motor related areas when the participant pushed button under the start sound and without start sound. This may imply that there are no clear differences in start timing from the view point of the activation of motor related areas. 2) Rhythmical sound like Alpine skiing start sound may shortens preparation time of the motor related area for an action.

MUSCLE ACTIVATION ON THE FLYWHEEL SQUAT ASSESSED BY FUNCTIONAL MAGNETIC RESONANCE IMAGING

ILLERA-DOMÍNGUEZ, V., NUELL, S., ALOMAR, X., CARMONA, G., PADULLÉS, J.M., PADULLÉS, X., LLORET, M., CUSSÓ, R., CADEFAU, J.A.

INEFC BARCELONA

INTRODUCTION: Resistance training results in a rapid activity-dependent influx of fluid and accumulation of osmolites (phosphate, lactate, sodium) in muscles. Based on this physiological phenomena, functional magnetic resonance imaging (MRI) is a non-invasive technique to assess increases on the transverse relaxation time (T2) of muscle water from pre-exercise to post-exercise as an index of muscle activation (1). The aim of this study was to examine thigh muscles activation on the squat exercise, performed on a flywheel device.
METHODS: 10 physically active students (age 23.4±4.1 years) performed 10 sets of 10 flywheel squats (Inertia 900 kg·cm-2). MRI scans were performed in basal conditions (Pre) and ≈ 5 min after finishing an acute bout of the exercise (Post), using a 3-T MRI scanner (Magnetom VERIO, Siemens, Germany). In each scan, twelve contiguous (each 31.5 mm) 3.5-mm cross-sectional images of the thigh of both limbs were obtained, starting at the iliac spine. A parametric image was generated from the T2 mapping sequence and T2 of muscles from both thighs were measured using OsiriX 8.5.2. (Pixmeo, Switzerland). A circular region of interest (ROI) was selected for the muscles gluteus maximus (GM), rectus femoris (RF), vastus intermedius (VI), vastus medialis (VM), vastus lateralis (VL), adductor magnus (AM), gracilis (GR), biceps femoris long head (BFL), biceps femoris short head (BFS), semitendinosus (ST) and semimembranosus (SM) using the similar size and anatomical location in each of the T2 mapping images where these muscles were visible. T2 values for each muscle were computed as the mean value of its different ROIs. T2 shift was then calculated by subtracting T2 basal values to T2 values post-exercise, expressed as a percentage of the basal value. Results are shown as the average T2 shift of right and left thighs.
RESULTS: There was a significant increase in GM (42.5±8.4%), AM (20.8±13.0%), RF (18.4±13%), VI (31.7±18.1%), VM (36.3±13.9%) and VL (45.9±18.4%) T2 signal. There was a significant decrease in GR (7.5±7.8%), BFL (4.2±4.8%), BFS (8.0±6.9%), ST (7.1±3.0%) and SM (6.5±5.9%) T2 signal.
CONCLUSION: The reported decrease in T2 signal of the hamstring muscles supports the results of previous electromyographic studies of the squat (2), which show a lower activation of hamstrings as compared to quadriceps. Given the significance of muscle activation and muscle swelling this study has potential implications for designing resistance training programs.

EFFECT OF HIP, KNEE AND ANKLE JOINT ANGLES ON ELECTROMYOGRAPHIC ACTIVITY IN HIP THRUST

NISHIOKA, T.1, YAMAGUCHI, S.1, OKADA, J.1

WASEDA UNIVERSITY

INTRODUCTION: Hip thrust is known as a very effective exercise for strengthening hip extensors like gluteus maximus. However, few studies have considered more effective technique of hip thrust. We examined the influence of hip thrust performed by changing angles of hip joint, knee joint and ankle joint on the muscle activity of lower limbs, and clarify the technique with the highest muscle activity of each muscle. It was aimed to verify the pros and cons of technique that have been regarded as effective.
METHODS: 9 healthy male college students who did not regularly practice hip thrust participated. The hip thrust trial methods were conducted by the eight kinds of various joint angle (10° or 30° hip abduction/90° or 80° knee flexion/ankle plantar or dorsal flexion). all trials of hip thrust were performed 1 set of 3 repetitions using 70%1RM estimated from the result of 3RM testing. The intervals between the sets were set to 3 minutes, and the order of each trial was set at random. EMG of each test muscle was measured. The test muscles were all in the right vastus lateralis (VL), biceps femoris (BF), upper and lower gluteus maximus (UGM and LGM). The EMG signals were normalized, and the RMS value in the 2nd repetition phase out of 3 repetitions of hip thrust trials was calculated.
RESULTS: Regarding the total RMS values of posterior chain (BF+UGM+LGM), 10/90/D was significantly lower than 10/80/D, 30/90/P, 30/90/D and 30/80/P (10/80/D: $p<0.01$, 30/90/P, 30/90/D, 30/80/P: $p<0.05$). 30/80/P was significantly greater than 10/90/P and 10/80/P (10/80/P: $p<0.05$, 10/90/P: $p<0.01$). Additionally, significant simple・simple main effect was observed in the hip abduction angle

and the knee flexion angle ($p<0.05$). They significantly increased at 30° hip abduction position than 10° hip abduction position, and significantly increased at 80° knee flexion position than 90° knee flexion position. However, no significant second interaction and simple interaction were observed
CONCLUSION: Although 10/90/P and 10/90/D have been regarded as effective (Contreras et al.,2011;Eckert and Snarr, 2014), according to the results, the most effective technique of hip thrust seems to be 30/80/P. This seems to be due to the fact that the muscle activity of BF increased in 80° knee flexion position and the muscle activity of UGM and LGM increased in 30° hip abduction position. Therefore, the muscle activity of gluteus maximus and biceps femoris in hip thrust is thought to be largely influenced by hip abduction angle and knee flexion angle.

EVALUATING REGIONAL DIFFERENCES OF METABOLIC RESPONSE BY 31P- CSI DURING INCREMENTAL ISOTONIC EXERCISE ON QUADRICEPS

KANEKO, Y.1,2, KIME, R.2, HONGO, Y.1, OHNO, Y.1, SAKAMOTO, A.1, KATSUMURA, T.2
KURETAKE COLLEGE OF MEDICAL ARTS & SCIENCES

INTRODUCTION: Imbalanced activity of vastus medialis and vastus lateralis has been found in patients with patellofemoral joint pain (PFP) by electromyography investigation and it is essential to facilitate these muscles adequately for rehabilitation and prevention (Souza and Gross 1991; Pal et al., 2011). Evaluating the activities of knee extensor muscles in various aspects can provide more information to confirm if appropriate intervention is provided for rehabilitation. The aim of this study was to detect the differences in muscle metabolic response of the quadriceps during incremental dynamic knee exercise by using regional 31Phosphorus Chemical Shift imaging (31P-CSI).
METHODS: Sixteen healthy male participated in this study. The experiments were carried out with a 1.5-T superconducting magnet with a 5-inch diameter circular surface coil. The subjects performed isometric unilateral knee extension for their maximum voluntary contraction (MVC) in the prone position. Then they performed dynamic unilateral knee extension of right leg at 10% to 30% of their MVC. The subjects pulled down a rope with the adjusted weight attached to the ankle at a frequency of 0.5 Hz for 380 sec for a one-pulse 31P-CSI acquisition. The peak areas of inorganic phosphate (Pi) and phosphocreatine (PCr), and the intracellular pH (pHi) were calculated in post processing. The changes in Pi/PCr and pHi of medial and lateral side of quadriceps were analyzed.
RESULTS: There was no significant difference in Pi/PCr between the medial and the lateral side of the quadriceps during the exercise at rest, 10%, 20%MVC (medial side: 0.16±0.03, 0.20±0.05, 0.23±0.05, lateral side: 0.16±0.05, 0.16±0.05, 0.22±0.06, respectively) . There was significant difference in Pi/PCr at 30%MVC (medial side: 0.34±0.12, lateral side: 0.27±0.09, $p < 0.05$). The pHi showed no significant difference.
CONCLUSION: These results suggest that there is a regional difference in metabolic responses on quadriceps during incremental isotonic exercise in healthy subjects. Present study supports previous study reported heterogenic muscle metabolism (Cannon DT et al., 2013) and another study showed the spatial heterogeneity of muscle blood flow, which revealed the greatest increase in vastus medialis compared to the other muscles during isometric exercise (Kalliokoski et al., 2000). Further study is required in PFP subjects with the same protocol.

ANGULAR VELOCITY-DEPENDENT POTENTIATION OF MAXIMAL CONCENTRIC PEAK TORQUE OF KNEE EXTENSION

MIYAMOTO, N.
NATIONAL INSTITUTE OF FITNESS AND SPORTS

INTRODUCTION: One bout of 5–6 s of maximal voluntary isometric contraction (MVIC) is known to enhance subsequent dynamic joint performance such as concentric peak torque and power with maximal voluntary effort (Baudry 2010; Miyamoto 2011, 2012, 2013). The presence of such potentiation is angular velocity-dependent (Fukutani et al. 2013). However, it remains unclear (1) what is the threshold of angular velocity for the potentiation of concentric peak torque is, and (2) whether the extent of potentiation increases with the increase in the angular velocity of concentric contractions. The present study aimed to clarify these questions.
METHODS: Thirteen healthy male subjects performed maximal voluntary concentric (isokinetic) contractions of knee extension at 30, 60, 120, 240, and 360 degrees/second before and 1-min after a 5-s conditioning MVIC of knee extension. Immediately before the measurements of concentric knee extension, measurements of evoked isometric twitch of knee extension were performed. Electromyographic (EMG) signals were obtained from the vastus medialis, vastus lateralis, rectus femoris, and biceps femoris. Measurements of each angular velocity condition were separately performed in a randomized order.
RESULTS: The twitch peak torque significantly increased after the conditioning MVIC in all velocity conditions ($P < 0.05$) whereas the extent of potentiation in isometric twitch torque was similar between the five conditions. EMG amplitudes (i.e., M-wave peak-to-peak value in twitch and root-mean-square value in concentric contraction) were unchanged before and after the conditioning MVIC in all conditions. The maximal voluntary concentric peak torque significantly increased in 240 and 360 degrees/second conditions (+3.6% and +8.6%, respectively; $P < 0.05$), but not in 30, 60, and 120 degrees/second conditions. Additionally, the extent of the increase in concentric peak torque was significantly higher in 360 degrees/second condition than in 240 degrees/second condition ($P < 0.05$).
CONCLUSION: These results indicate that the maximal voluntary concentric torque can be potentiated by the conditioning contraction when the concentric contraction is performed at an angular velocity higher than 240 degrees/second. Furthermore, the extent of the potentiation of concentric torque can increase with the increase in angular velocity of concentric contractions.

EXCITABILITY AND FIRING PROPERTIES OF MOTONEURONS ARE MODIFIED BY TRANS-SPINAL DIRECT CURRENT STIMULATION

KRUTKI, P., DRZYMALA-CELICHOWSKA, H., MROWCZYNSKI, W., BACZYK, M.
POZNAN UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: Polarization of neurons induced by externally applied constant current stimulation is a new neuromodulatory technique which has recently been introduced in rehabilitation of patients after neurological injuries to decrease spasticity (Lefaucheur et al. 2017) or as an addition to physical training in sport (Angius et al. 2017). However, physiological mechanisms and neuronal interactions within

spinal networks are poorly known. The aim of this study was to reveal changes in motoneuron membrane and firing properties in response to trans-spinal direct current stimulation (tsDCS).
METHODS: The study was performed in vivo on adult male rats under general anesthesia. The intracellular recordings of electrical potentials were made from motoneurons located in L4-L5 segments of the spinal cord, innervating hind limb muscles. Anodal or cathodal tsDCS was applied through a stainless steel electrode, located on the dorsal surface of the lumbar vertebra above the recording site. A current intensity varied from 0.1 mA to 0.4 mA. Electrophysiological parameters of motoneurons were measured before, during and after an application of tsDCS, lasting from 5 to 15 minutes.
RESULTS: Changes in electrophysiological parameters of motoneurons could be observed in all tested motoneurons immediately after the onset of polarization, the effects lasted throughout the whole session and were sustained after the end of polarization (measured up to 30 min.). Anodal tsDCS resulted in an elevation of the resting membrane potential, a decrease in the rheobase current and the threshold of rhythmic firing, and an increase of the maximum firing frequency. Reverse effects were observed after cathodal tsDCS: the hyperpolarized resting potential,an increase in the rheobase, an increase in the threshold of rhythmic firing (or its complete blocking).
CONCLUSION: tsDCS mimics the physiological polarization processes which occur within the spinal networks: it does not evoke action potentials in neurons, but puts them in a state of subthreshold depolarization or hyperpolarization, depending on a polarity of applied current (Weiss and Faber, 2010). The results of this study indicate that tsDCS immediately facilitates (anodal) or inhibits (cathodal) generation of action potentials in motoneurons, and these effects last longer than duration of polarization. This partly explains how tsDCS influences on the recruitment of motor units and the generated muscle force.

SPECIFIC DISTRIBUTION OF HAMSTRING MUSCLES FOR SPRINT RUNNERS AND ITS FUNCTIONAL IMPLICATION FOR PERFORMANCE IMPROVEMENT

KAMINO, K., KUNIMASA, Y., MAKINO, A., SANO, K., KIJIMA, K., KOMI, P.V., ISHIKAWA, M.
OSAKA UNIVERSITY OF HEALTH AND SPORT SCIENCES

INTRODUCTION: Bi-articular muscles show the spatial distribution of neural activation at different regions from proximal to distal parts. If bi-articular muscle function was different by region, the muscle longitudinal shape, such as CSA size at different regions, may be different by region. The purpose of the present study is to examine the characteristics of muscle anatomical cross sectional area (CSA) at different regions from proximal to distal parts of each muscle of the hamstring muscles in high level sprinters, and to examine the relationship with those and the sprint performance.
METHODS: The CSA of the semitendinosus muscle (ST), semimembranosus muscle (SM), biceps femoris long head (BFL) and biceps femoris short head (BFS) at the four different region of hamstring muscles for sprinters (SPRINT: n = 20, age: 21.5±1.5 yr, 100m season best record: 10.8±0.2 sec) and healthy male control subjects (CTRL: n = 20, age: 20.8±1.3 yr) were measured by using B-mode ultrasonography. The CSA of each region of each muscle was calculated by cross sectional musculoskeletal ultrasonographic images.
RESULTS: The measured regions were divided into four parts from proximal to distal parts (PRO1, POR2, DIS2, DIS1). The results clearly showed that the shaves of CSA from proximal to distal parts were similar across the four muscles between both groups but the size of the CSA for SPRINT was significantly greater at PRO2, DIS2 and DIS1 in ST, DIS2 and DIS1 in SM, DIS2 and DIS1 in BFL, DIS1 in BFS as compared with CTRL. In the relationships with sprint performance, the CSA of PRO1 and PRO2 in ST and PRO1 in SM was negatively related.
CONCLUSION: These results suggest that distal parts of hamstring muscles for SPRINT may be characteristics of movement specific. However, the proximal parts of ST and SM muscles may play important roles of the improvement of their sprint performance.

THE EFFECT OF KINESIO TAPING IN LEG RECOVERY AFTER DELAYED ONSET MUSCLE SORENESS

LIN, Y.J., LENG, Y.R., LIN, H.T.
KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Delayed onset muscle soreness (DOMS) is usually occurred in two to seven days after high-intensity exercise. DOMS may lead to swelling and painful muscles, decrease joint ROM and muscle strength, increase muscle stiffness and resting tension. In recent years, an increasing number of athletes had been using Kinesio taping® for better performance in many sports competition. Until now, the effect of Kinesio taping in DOMS and its possible mechanism was still unclear. Therefore, the purpose of this study was to investigate the effect of Kinesio taping in recovery of leg after DOMS.
METHODS: Fifteen healthy college students attained two different testing conditions, attached Kinesio taping and without Kinesio taping after DOMS, the testing order was randomized, and at least one month apart between testing conditions. Before test, the subject was asked to warm up five minutes by using a stationary bike first, and then went on the calf muscle eccentric exercise (Yanagisawa et al., 2011). The timing of evaluation were before eccentric exercise (T0), immediately after eccentric exercise (T1), 24 hours (T2), 48 hours (T3) and 72 hours (T4) after eccentric exercise. The participants attached Kinesio taping just after eccentric exercise. The evaluated parameters include ankle range of motion, muscle soreness, calf muscle tenderness, sarcous character measurement, muscle strength, and ankle proprioception. The repeated measure two-way ANOVA was used to test the effect of Kinesio taping and five evaluation times in analysis parameters.
RESULTS: When applied Kinesio taping, significant decreased in muscle stiffness, passive muscle tension, muscle soreness, leg circumference, and increased ankle range of motion, muscle elasticity, and ankle dorsiflexion maximum torque in subjects ($p < 0.05$). There were significantly differences between evaluated time in CK, lactate, sarcous character, muscle soreness, muscle tenderness, ankle proprioception, and ankle plantarflexion maximum torque ($p < 0.05$).
CONCLUSION: The occurrence of delayed onset muscle soreness depends on multiple potential physiological mechanisms and neuromuscular system. Results from this study found that the Kinesio taping has some positive improvement in some syndromes after DOMS that are similar to the previous study tested in Biceps (Lee et al., 2015). However, no significant difference results especially in blood biochemistry need further investigated. For the athletic trainer, the Kinesio taping may be helpful as an complimentary therapy for delayed onset muscle soreness.

NEW ZEALAND BLACKCURRANT EXTRACT ENHANCES FAT OXIDATION DURING PROLONGED CYCLING IN ENDURANCE-TRAINED FEMALES

STRAUSS, J.A.1, WILLEMS, M.E.T.2, SHEPHERD, S.O.1

1: LIVERPOOL JOHN MOORES UNIVERSITY, 2: INSTITUTE OF SPORT, UNIVERSITY OF CHICHESTER

INTRODUCTION: New Zealand blackcurrant (NZBC) extract has previously been shown to increase fat oxidation during prolonged exercise, but this observation is limited to males. We examined whether NZBC intake also increases fat oxidation during prolonged exercise in females, and whether this was related to greater concentrations of circulating fatty acids.
METHODS: In a randomised, crossover, double-blind design, 16 recreationally active females (age: 28±8 years, BMI: 21.3±2.1 kg·m-2, VO2max: 43.7±1.1 ml·kg-1·min-1) ingested 600 mg·day-1 NZBC extract (CurraNZ™) or placebo (600 mg·day-1 microcrystalline cellulose) for 7 days. On day 7, participants performed 120 min cycling at 65% VO2max, using on-line expired air sampling with blood samples collected at baseline and at 15 min intervals throughout exercise for analysis of glucose, NEFA and glycerol.
RESULTS: NZBC extract increased mean fat oxidation by 27% during 120 min moderate-intensity cycling compared to placebo (P=0.042), and mean carbohydrate oxidation tended to be lower (P=0.063). Pre-exercise, plasma NEFA (P=0.034) and glycerol (P=0.051) concentrations were greater following NZBC intake, although there was no difference between conditions in the exercise-induced increase in plasma NEFA and glycerol concentrations (P>0.05). Mean fat oxidation during exercise was moderately associated with pre-exercise plasma NEFA concentrations (r=0.45, P=0.016).
CONCLUSION: Intake of NZBC extract for 7 days elevated resting concentrations of plasma NEFA and glycerol, indicative of higher lipolytic rates, and this may underpin the observed increase in fat oxidation during prolonged cycling in endurance-trained females.

SPRINT, STRENGTH AND BODY MASS CHANGES FOLLOWING INGESTION OF A COMBINED SUPPLEMENT BY COMPETITIVE GAMES PLAYERS

ELLMORE, M.

UNIVERSITY OF LINCOLN

INTRODUCTION: From survey findings (Airstone et al. 2005), a significant proportion of players chose this supplement to improve muscle mass and performance. The purpose of this investigation is to determine whether the reasons for supplement choice were justified as the evidence available to support supplementation of this combination of ingredients is not sufficient.
METHODS: Fifteen trained male games players (mean body mass 80.4kg±7.7) ingested 1.2g/kg/day of a combined supplement or placebo for a period of 8 weeks, through randomised, double-blind, crossover administration. The effects of the powdered supplement (SUPPL) containing whey protein, carbohydrate, creatine monohydrate and glutamine or lactose placebo (PLA) were determined in ten, 6s cycle ergometer sprints with 24s active recovery in terms of peak power output (PPO), mean power output (MPO), fatigue index (FI) and peak pedal frequency (PPF). Measures of maximal strength during 1 repetition (1RM) of bench press (Max B) and squat (MaxS) exercises and changes in total body mass (TBM) and lean body mass (LBM) were also recorded. Differences between treatment, trial and performance data were established using repeated measures ANOVAs (F1,15) and interactions were determined using the Bonferroni correction (P≤0.0125).
RESULTS: After determining that activity (P=0.912) and dietary intake of protein (P=0.260) were consistent during placebo and supplement phases of the investigation and there were no crossover effects, significant interactions (P≤0.0125) between treatments (Placebo, Supplement) and trials (Pre, Post) were determined in terms of PPO (PLA:892W SUPPL:937W F(1,15)=27.000), FI (PLA:43% SUPPL:39% F(1,15)=47.221), PPF (PLA:83rpm SUPPL:90rpm F(1,15)=36.347), TBM (PLA:82kg SUPPL:83kg F(1,15)=54.255) and MaxS (PLA:86kg SUPPL:98kg F(1,15)=88.872).
CONCLUSION: These findings demonstrate that, to some extent, participants' reasons for choosing this supplement were justified. The mechanisms of effect can be attributed to participants' meeting daily requirements for calorie and protein intake, established for these athletes in a previous study (Ellmore, 2017) and a number of previously reported factors including enhanced pre-exercise phosphocreatine storage, adenosine triphosphate availability, a reduction in muscle relaxation time and muscle growth, which may alter protein turnover and enhance training capability. Further research incorporating appropriate dietary control and analysis of supplement content would highlight the impact of such supplement intake more effectively.

CARNOSINE IN MULTIPLE SCLEROSIS AND EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

SPAAS, J.

HASSELT UNIVERSITY

INTRODUCTION: Carnosine, a dipeptide composed of β-alanine and histidine, is present in many tissues throughout the body and ~99% of carnosine is found in skeletal muscle tissue. Here, it has several physiological functions (e.g. Ca2+ handling, intramyocellular buffering) that correspond with multiple sclerosis (MS)-related (muscular) dysfunctions. Due to its antioxidant properties, carnosine is also considered a neuroprotective and antisenescent compound. We present a series of three consecutive studies investigating the role of carnosine in MS and Experimental Autoimmune Encephalomyelitis (EAE), an animal MS model.
METHODS: Study 1 compared muscle carnosine content between MS patients (n=24) & healthy individuals (n=22, m. vastus lateralis), and between EAE & control animals (both n=40, m. tibialis anterior). Study 2 evaluated the effects of carnosine and β-alanine intake (24d) on muscle carnosine content and clinical disease course in a monophasic EAE rat model (n=39). Study 3 evaluated the effects of carnosine intake (35d) on clinical disease course in a chronic EAE mouse model (n=20).
RESULTS: Muscle carnosine content was reduced in EAE (-46 to -60%, p<0.001) and MS (-25%, p=0.03) (study 1). Carnosine and β-alanine intake restored muscle carnosine levels in EAE (p<0.01, study 2). Finally, carnosine appears to affect the disease course (delayed hind quarter paralysis onset, reduced peak and cumulative disease score) in monophasic and chronic EAE models (study 2 & 3).

CONCLUSION: Muscle carnosine is reduced in MS and EAE, and carnosine intake restores this in EAE. Carnosine intake appears to improve hind quarter paralysis in EAE. Future studies will further investigate the effects of carnosine (loading) in MS and EAE.

EFFECTS OF NITRATE SUPPLEMENTATION ON THE WINGATE TEST IN RUNNERS.

SANTANA, J., MADUREIRA, D., FRANÇA, E., CAPERUTO, E.C.

SÃO JUDAS UNIVERSITY

INTRODUCTION: During a 10km race, runners perform sprints (anaerobic exercise) in the beginning and the end of the event and keep continuous running (aerobic exercise) between these sprints. The literature shows that the improvement in the anaerobic phase of the runner increases running performance. Nitrate is a supplement that increases performance reducing O2 cost improving nutrients delivery to the muscles. Therefore, the aim of this study was to evaluate the effect of nitrate supplementation in the anaerobic phase of runners.
METHODS: Sixteen runners (age 30.2 ± 5.7 years old) received nitrate supplementation in a double-blind, randomized trial and were divided in two groups: Nitrate (N03) (750mg of Nitrate per day for thirty days) and Control (CON) (750mg of Resistant Starch per day for thirty days). All groups trained three times/week during four weeks. Anaerobic phases were evaluated through a 60sec Wingate test and blood lactate concentration before the test (BAS), fifteen days (DUR) and thirty days after (POS) the tests. After the normality test (Shapiro-Wilk), two way Anova test was made with Tukey Post-test with $p<0.05$.
RESULTS: There was no significant differences in the 60sec Wingate Test in both the groups (Nitrate: BAS 370.1±64.4; DUR 409.2±79.6; POS 421.2±71.5) (Control: BAS: 460.2±117.3; DUR 480.9±119.7; POS 500±123.9). Blood lactate showed significance decreases in Nitrate group and the Control group, but the nitrate group showed a significant decrease in the moment DUR and POS moment, when compared with BAS moment (Nitrate: BAS 13.4±1.7; DUR 9.7±2.7; 8.1±1.2). The Control group showed significant decrease only in the POS moment, when compared with BAS moment (Control: BAS 12.4±1.8; DUR 11±2; POS 9.5±2.8). The runners of both groups did not show significant improvement in the Wingate test due to their training being predominantly aerobic. The nitrate group showed significant decrease in blood lactate in 15 days due to the effect of nitrate supplementation, through vasodilation, reducing work during the test, thus producing less blood lactate.
CONCLUSION: We can conclude that in two weeks of supplementation, nitrate decreases the blood lactate concentration in anaerobic tests of runners.

EFFECTS OF OMEGA-3 FATTY ACIDS SUPPLEMENTATION ON VO2MAX, BLOOD LIPOPROTEINS AND HORMONE CONCENTRATION IN CYCLISTS

POPRZECKI, S.1, ZEBROWSKA, A.1, STANULA, A.1, MIKOLAJEC, K.1, BARON-KACZMAREK, D.1

ACADEMY OF PHYSICAL EDUCATION

INTRODUCTION: Several studies have demonstrated potential sport and health benefits from consumption fish oil derived omega-3 FA supplementation (Boss et al.2010, Peoples et al. 2008). Hence there is clear evidence that n-3 FA ingestion has the potential to modulate a wide range of physiological (VO2max) and biochemical (lipids, lipoproteins, hormone) processes that could, theoretically, enhance adaptation to exercise training (Ooi 2015). The aim of this research was to analyzed effects of cyclists supplementation with n-3 FA, combined with aerobic training on blood lipoproteins, hormone and VO2max.
METHODS: The 15 cyclists, aged 23,1±5,4 y were assigned to two groups: experimental (n=8) (E), supplementing the diet with n-3 FA (1,2 g/d for 3 weeks- 660 mg EPA and 440 mg DHA) and control group (C) (n=7) without changing of the diet. The mean individual training volume was 655±53 km/week. Before and after 3 weeks cyclists performed VO2 max test using cycloergometer Lode Excalibur Sport. Blood samples were taken before VO2max cycling test and after 3 weeks.
RESULTS: No significant effect was observed on VO2max (p=0,300) in response to n-3 PUFA supplementation. But it was significantly differentiated the value of Peak Power (PP) (p=0,000). We observed significant increase PP only in supplemented group (p=0,002). Modified diet not significantly differentiated PPLT (p=0,086), HRmax (p=0,117), HRLT (p=0,946), as well as Ve (p=0,976). Supplementation with omega-3 FA didn't significantly influenced on cortisol (p=0,234), hGH (p=0,561) and insulin (p=0,396) concentration. Serum glucose was significant differentiated (p=0,021). Then supplementation did not effect on TAS (p=0,323) and FRAP (p=0,312) concentration. Supplementing the diet with omega-3 FA did not affect significantly on FFA concentration (p=0,860) and TC (p=0,44), HDL-C (p=0,84), LDL-C (p=0,72), TG (p=0,74), also on atherogenic index, e.g. Castelli (p=0,98), LDL/HDL (p=0,47), and HOMA IR index (p= 0,154) and Quicki index (p=0,14).
CONCLUSION: The supplementation of cyclists diet with 1,2 g/d omega -3 PUFA during 3 weeks, combined with aerobic training, did not significant effect on respiratory parameters, as well as, serum hormone concentration, antioxidant status then lipids and lipoproteins profile. Only PP value was significantly differentiated by modified diet. In generally, the human data are inconclusive as to whether omega-3 PUFA diet supplementation at this dosage is effective, the potential synergism between n-3 supplementation and exercise provides an area for future research.

EFFECTS OF PHYSICAL FITNESS LEVEL AND NUTRIENT INTAKE ON VENOUS COMPLIANCE IN YOUNG HUMANS

OUE, A., SAITO, M., IIMURA, Y.

TOYO UNIVERSITY

INTRODUCTION: Ageing and/or the lower physical activity associate with the increased stiffness of veins (Hernandez et al. 2004, Monahan et al. 2001), causing the cardiovascular disease (e.g. hypertension) (Olsen and Lanne 1998, Safar and London 1987). In order to reduce the risk for cardiovascular disease, it is important to enhance the venous compliance at an early age. Some physical fitness (e.g. aerobic capacity) and nutrients (e.g. vitamin C and vitamin E) could offer health benefit to the arterial function, although it is not understood whether these factors influence venous compliance. Thus, the purpose of this study was to reveal the relationship between physical fitness and venous compliance, and between nutrients and venous compliance in young humans.
METHODS: In 81 health young subjects (male: n = 46, female: n = 35) who had no a habitual physical activity, fitness levels, diet survey and venous compliance were investigated. As fitness levels, muscle strength (grip strength), high power (standing broad jump), agility (jumping side to side), muscular endurance (sit-up), flexibility (long seat body anteflexion), and whole body endurance (multi-stage fitness

test) were measured. In addition, total fitness score was calculated from all fitness levels. BDHQ (brief-type self-administered diet history questionnaire) was used to assess diet survey. Venous compliance in the forearm was determined using the first derivation of the cuff pressure–venous volume relation obtained by venous occlusion plethysmography during cuff deflation protocol.
RESULTS: In both males and females, total fitness score had a significant positive relation with the venous compliance ($P < 0.05$). In each fitness level, venous compliance in males correlated with grip strength and standing broad jump ($P < 0.05$), and venous compliance in females correlated with grip strength, sit-up, long seat body anteflexion, and multi-stage fitness test ($P < 0.05$). There was a positive correlation between vitamin D or vitamin B12 and venous compliance in females ($P < 0.05$), although α- and β- carotene and vitamin K had significant negative correlation with venous compliance ($P < 0.05$).
CONCLUSION: Compared with females, venous compliance in males had a positive relation with fitness levels which depended on muscle mass, which might be due to the difference of body composition between sexes. In addition, the relationship between nutrition intake and venous compliance had also a sex difference, which might be attributed to the difference of dietary habit and eating behavior between females and males. In conclusion, these results suggest that some physical fitness and vitamins might be related to the venous compliance in young humans, which have a sex difference.

THE EFFECTS OF 10 WEEKS OF CHOCOLATE MILK CONSUMPTION AFTER BODY-WEIGHT RESISTANCE TRAINING ON BODY COMPOSITION IN FEMALE UNIVERSITY STUDENTS

CHEN, T.T., QIU, Y.H., LUO, P.F.
NATIONAL ILAN UNIVERSITY

INTRODUCTION: Adequate post-exercise nutrition regimen is essential for optimizing recovery and adaptations. Chocolate milk has become a favored recovery aid for exercise participants due to its desired carbohydrate: protein ratio (about 4:1) and its great accessibility. The purpose of this study was to investigate the effects of 10 weeks of body-weight resistance training combined with post-exercise chocolate milk consumption on body composition in female university students.
METHODS: Thirteen college-aged, sedentary females were recruited for this study. Subjects were randomly assigned to either control group (CON) or body-weight training group (BWT).The subjects (n=7) in BWT trained 3 days per week for 10 weeks and ingested 290 mL of chocolate milk immediately after body-weigh exercise training for whole major muscle groups while the subjects (n=6) in CON maintained the similar lifestyle without any intervention. The chocolate milk (180 kcal) contained 5.8 g of protein (23.2 kcal), 23.78 g of carbohydrate (95.1 kcal), and 6.96 g of fat (62.6 kcal). Body composition (lean body mass, fat mass, and total mass, and other measures) was assessed by bioelectrical impedance analysis (BIA) methods before and after intervention.
RESULTS: No significant differences existed between groups at baseline and after 10 weeks for any measure. The muscle mass (18.98 ± 3.68 kg vs. 19.58 ± 3.83) and lean body mass (35.48 ± 6.03 vs. 36.46 ± 6.33) of BWT increased significantly ($p < 0.05$). The body weight increased and fat mass tend to decreased in BWT, however, no significant differences were observed ($p > 0.05$).
CONCLUSION: Body-weight resistance training in combination with post-exercise chocolate milk ingestion could evoke favored changes in body composition in female university students.

COMBINED EFFECTS OF LACTOTRIPEPTIDE AND AEROBIC EXERCISE ON COGNITIVE FUNCTION AND ARTERIAL STIFFNESS IN MIDDLE-AGED AND OLDER ADULTS

HAMASAKI, A., AKAZAWA, N., YOSHIKAWA, T., MYOENZONO, K., TAKAHASHI, K., SAWANO, Y., NISHIMURA, M., MAEDA, S.
UNIVERSITY OF TSUKUBA

Background: Age-related declines in vascular function increase the risk of cognitive impairment and dementia (Waldstein et al. 2008; Tarumi et al. 2015). The aim of this study was to investigate the effects of lactotripeptide (LTP) ingestion and exercise training on cognitive function and arterial stiffness in middle-aged and older adults.
Methods: In a randomized, placebo-controlled, double-blind design, 64 healthy older adults were assigned to four groups: placebo without exercise (Placebo, n = 18), placebo with exercise (Exercise, n = 15), LTP without exercise (LTP; n = 15), and LTP with exercise (Combined; n = 16) groups. The participants ingested placebo or LTP every day and performed aerobic exercises 0 or 4–6 days/week for 8 weeks. Before and after the 8-week intervention, Stroop interference time and carotid artery β-stiffness were measured.
Results: After the intervention, the Stroop interference time was significantly shorter in the Combined group and β-stiffness was significantly decreased in the LTP and Combined groups. The changes in Stroop interference time and β-stiffness were significantly greater in the Combined group than in the Placebo group. In addition, there were significant correlations between changes in Stroop interference time and β-stiffness.
Conclusions: The 8-week intervention that involved both LTP ingestion and exercise combined training improved executive function and arterial stiffness in middle-aged and older adults. These results suggested that the intervention-induced improvements in cognitive function was mediated by vascular function.

SURVEY ON FLUID INTAKE HISTORY OF COLLEGE STUDENTS MAJORING IN SPORT AND WELLNESS

SUGIURA, K.
RIKKYO UNIVERSITY

INTRODUCTION: Proper hydration is very important both for improving sports performance and for promoting health by sports. However, there are few research studies on age at which proper hydration is started in Japan.
METHODS: In this study, a questionnaire survey on fluid intake history was conducted for 204 students (136 males and 68 females) majoring in sport and wellness. The contents of the survey were (1) according to the time of elementary school, junior high school, high school,

and college, what kind of drinks were prepared during sports, and who prepared drinks and taught the importance of hydration to subjects, (2) when subjects understood the significance of hydration.
RESULTS: In elementary school, parents instructed hydration and prepared drinks (mainly water and barley tea). In both junior high school and high school, coaches instructed the need for hydration and ordered team members to prepare drinks (mainly water and sports drinks). In college, team managers prepared drinks (mainly water and sports drinks), however, there was no guidance. The time when the students understood the significance of hydration was the highest in high school days.
CONCLUSION: Although it was a good thing to prepare drinks during sports even at elementary school, teaching hydration was still left to parents. In the education curriculum that trains childrens sports coaches, it will be a future task to focus on hydration.

THE CHANGE OF DIETARY HABITS INFLUENCING DEGREE OF SATISFACTION WITH DIETING IN CHILDHOOD AND YOUNG ADULTHOOD.

SAKAGUCHI, S.1, AOYAGI, O.2, SAKAGUCHI, H.3

1> FUKUOKA SEISHU-KAI HOSPITAL, 2> FUKUOKA UNIVERSITY, 3> JAPAN UNIVERSITY OF ECONOMICS

INTRODUCTION: It is thought that in order to be satisfied with one's dieting, various factors such as with whom, what foods, how much, and when people eat have an effect. Again, it is easily expected that the extent to which these factors cause an effect is different between children who have no choice about how to eat and young adults who are able to form their own dietary habits by themselves. Thus, this study aimed to compare the degree of satisfaction with dieting between children and young adults.
METHODS: A 13-item questionnaire survey concerning dietary habits in elementary school years and at the present day was conducted with 1204 N-university students in September 2017. In addition, respondents were questioned about their degree of satisfaction with dieting in elementary school years and the present day, using a 5-level scale from "very satisfied" to "not satisfied at all." Cross tables were tabulated between the degree of satisfaction and 13 dietary habit items in childhood and young adulthood respectively, and a chi-square test was conducted. When a significant difference was found, adjusted residuals were successively computed and tendencies found between childhood and young adulthood were examined.
RESULTS: In response to the question about with whom they ate breakfast or dinner, whereas children who ate breakfast alone felt quite a low degree of satisfaction, young adults responded with "neither" for eating alone. However, young adults felt a low degree of satisfaction eating dinner alone, as opposed to breakfast.
Concerning the time of day for eating breakfast or dinner, in both of childhood and young adulthood, those who were satisfied with their dieting ate early in the day, indicating that the range of eating times was wider in young adulthood than childhood. Although no remarkable tendency was detected in childhood, there was a tendency that those who were satisfied with their dieting ate dinner early in the evening.
As far as the contents of breakfast were concerned, although no relationship between the degree of satisfaction with dieting and the contents of breakfast was found, satisfied young adults ate only rice (e.g. a rice ball).
Although the frequency with which satisfied respondents bought pre-cooked food from a supermarket or a packed lunch from a convenient store was at the most in "once a week," children had a tendency to be equal to or less than equal to this and a tendency to be equal to or more than this was found in young adults.
CONCLUSION: It can be concluded that eating alone, a dependence on pre-cooked food from a supermarket or a packed lunch and eating breakfast regularly affect the degree of satisfaction with children's and young adults' dieting.

THE CONTINUITY OF DIETARY HABITS BETWEEN CHILDHOOD AND YOUNG ADULTHOOD

SAKAGUCHI, H.1, AOYAGI, O.2, SAKAGUCHI, S.3

1> JAPAN UNIVERSITY OF ECONOMICS, 2> FUKUOKA UNIVERSITY, 3> FUKUOKA SEISHU-KAI HOSPITAL

INTRODUCTION: If dietary habits acquired while young strongly affect those in adulthood or later and they are hard to change, then dietary education, e.g. in university, is limited in its ability to change this and the childhood dietary habits are concluded to be already important. On the contrary, if it is sufficiently possible to change this even after young adulthood, then effective dietary education in higher education institutes can be expected. Thus, this study aimed to investigate the continuity of dietary habits between childhood and young adulthood.
METHODS: A questionnaire survey consisting of 13 items concerning dietary habits during elementary school years and the present day was conducted with 1204 N-university students in September 2017. Cross tables were tabulated between elementary school years and the present day and then ratios choosing the same option ordinal correlation coefficient in the case of ordinal-scaled data and contingency coefficient in the case of nominal-scaled data were computed. At the same time, a chi-square test was conducted and when significant differences were found, adjusted residuals were computed, and their tendency was examined in terms of what cells in the cross table were significant.
RESULTS: "How many times did you adjust the amount of food you ate?" "Where was the most seasoning used, at home or other dining locations?" "How frequently did you eat your favorite food repeatedly?" "How frequently did you go on a diet?" "What did you eat for dinner?" and "How much did you eat?" in the order of the degree of continuity with higher than 50% of the degree of continuity and higher ordinal correlation coefficient of more than 0.5. However, others did not show a high degree of continuity and correlation coefficient. Except for "What did you eat for dinner?" the items showing a high degree of continuity and correlation coefficient were common to individual tastes and attitudes toward dietary habits. This is to say, it can be said that although it is hard to change individual tastes and attitudes toward dietary habits, there is a sufficient possibility to change other dietary habits.
CONCLUSION: Although it is hard for the effect of dietary education in university or other educational institutions to change individual dietary tastes and attitudes toward dietary habits, there is a possibility to correct improper dietary habits in other areas in young adulthood.

THE CHANGING POSSIBILITY OF DIETARY HABITS FROM CHILDHOOD TO YOUNG ADULTHOOD

AOYAGI, O.1, SAKAGUCHI, S.2, SAKAGUCHI, H.3

1> FUKUOKA UNIVERSITY,2> FUKUOKA SEISHU-KAI HOSPITAL, 3> JAPAN UNIVERSITY OF ECONOMICS

INTRODUCTION: Dietary habits in childhood are basically determined by parents. However, after becoming young adults, they are able to determine all their dietary habits. Yet, not all their dietary habits that they were familiar with during their childhood change although their options increase. Thus, this study investigated the discontinuity of dietary habits between childhood and young adulthood.
METHODS: A questionnaire survey consisting of 13 items concerning dietary habits in elementary school years and the present day was conducted with 1204 N-university students in September 2017. Cross tables were tabulated between elementary school years and the present day and a chi-square test was conducted. When a significant difference was found, adjusted residuals were computed and the tendency was investigated from what cells except for the same options in the cross table is significant.
RESULTS: Significant differences in the chi-square test and significant adjusted residuals, except for the same options between elementary school days and university years , were found in only the following 6 items: "With whom did you eat breakfast?" "What time did you eat breakfast?" "With whom did you eat dinner?" "What time did you eat dinner?" "How frequently did you go to a convenient store or supermarket for food?" and "How frequently did family members eat food different from the other members?" Those who responded that they ate with not all family members but with their parents at breakfast and dinner in elementary school years responded that they eat with people other than family members . Concerning the question of what time they ate breakfast and dinner, those who ate breakfast from 8 am to 9 am responded "10 am or later" in young adulthood and those who ate dinner from 8 pm to 9 pm during childhood responded "10 pm or later" during young adulthood. In response to the question of "How frequently did you go to a convenient store or supermarket for food?" those who bought pre-cooked food or packed lunches in supermarkets or convenience stores two to three times per week responded "four to six times a week" during young adulthood. Finally, also regarding the question of the frequency of family members eating food different from other members, significantly many people who responded "four to six times" during childhood responded "everyday" during young adulthood.
CONCLUSION: This fact that only 6 items showed significant differences indicated that basically dietary habits in childhood are retained in young adulthood, so desirable dietary habits would have already been formed in childhood.

EFFECTS OF PHYSICAL EXERCISE AND IRON SUPPLEMENTATION ON THE LOCOMOTOR ACTIVITY OF PREGNANT RATS.

DAUBIAN-NOSÉ, P., FRANCO, B., FORTE, L.D.M., DE FANTE, T., MANCHADO-GOBATTO, F.B., TORSONI, A.S., BEZERRA, R.M., ESTEVES, A.M.

UNIVERSIDADE ESTADUAL DE CAMPINAS

INTRODUCTION: Restless Legs Syndrome (RLS) is a sleep disorder characterized by an uncomfortable feeling and the desire to move the legs. Studies have shown this syndrome in several populations, including pregnant women, suggesting investigation of iron deficiency. Both intravenous and oral iron supplementation have been shown to be beneficial in treatment of the syndrome. Physical exercise in turn presents several benefits and has also been observed in the treatment of RLS. The present study aimed to evaluate the influence of physical exercise and iron supplementation on a sleep-related movement disorder (RLS) in pregnant (P) rats.
METHODS: The animals (60 days) were distributed into4 groups: Control diet standard (CTRL/NP - CTRL/P); Diet with iron supplementation (Sfe/P); Physical exercise+standard diet (EF/P); Exercise + diet with iron supplementation (Sfe+EF/P). A vaginal smear was performed to establish the estrus cycle of the rats and for subsequent use in the data collection. Locomotor activity was evaluated through the Open Field test. The animals were submitted to an aerobic exercise program (swimming) during the pregnancy period, 6 days per week, until the 20th day of pregnancy. For the iron supplementation groups, a 100ppm Fe diet was maintained during pregnancy. For the standard diet group, a diet of 52-57ppm Fe was maintained. At the end of the experiment, the animals were euthanized individually for extraction of the striatum for analysis of D2, dopamine transporter (DAT), and tyrosine hydroxylase (TH) receptor expression. To evaluate the proteins of interest, the Immunoblot technique was used.
RESULTS: The results regarding locomotor activity suggest that iron supplementation did not differ in relation to the control group in any variable. Physical exercise induced a reduction in the variables total ambulation and rearing, and an increase in the variable grooming. The combined treatment of iron supplementation and physical exercise precipitated a reduction in the variables total ambulation, rearing, and grooming, and an increase in total freezing time. Through the Imunoblot method we observed reductions in dopamine D2 receptor expression for the Sfe+EF/P group compared to the CTR/P group, the DAT did not demonstrate a second major statistic for any of the groups, while the TH was reduced in the Sfe+EF/P group in relation to the CTR/P.
CONCLUSION: Therefore, we can conclude that non-pharmacological treatments (supplementation of iron and physical exercise) in combination demonstrated a relation with the expression of proteins related to RLS and was effective in combating the syndrome in this animal model.

THE USE OF NUTRITIONAL SUPPLEMENTS IN JAPANESE TOP-LEVEL TRACK AND FIELD ATHLETES

TABATA, S.1,2, TAGUCHI, M.2, TAHARA, K.2, MANABE, T.2, MATSUMOTO, H.1, YAMASAWA, F.2

1: INSTITUTE FOR INTEGRATED SPORTS MEDICINE, KEIO UNIVERSITY, TOKYO, JAPAN 2: MEDICAL COMMITTEE, JAPAN ASSOCIATION OF ATHLETICS FEDERATIONS (JAAF), TOKYO, JAPAN

INTRODUCTION: The high use of nutritional supplements in professional athletes has become an important issue in sports medicine. The use of nutritional supplements increases not only the risk of having positive doping test because of contaminated prohibited substances but also serious health problems in athletes. Therefore, it is necessary to have a correct understanding of the use of nutritional supplements in athletes. The aim of this study was to elucidate the use of nutritional supplements in Japanese top-level track and field athletes.
METHODS: Subjects were 183 junior <101 males and 82 females> and 266 senior <144 males and 122 females> Japanese TF athletes who had participated in international competitions from 2013 to 2017. The discipline was divided to seven categories as follows: sprinting <≦400m>, middle-distance <800-1500m>, long-distance <≧3000m>, hurdle, jumping, throwing, and combined events. Medical questionnaire was performed to all entrants by Japan Association of Athletics Federations before participating in international competitions. The athletes were requested to report for any nutritional supplements that they were taking. Nutritional supplements were classified as follows: protein, carbohydrate, vitamins, minerals, amino acids, creatine, caffeine, fish oil , ubiquinone , herbal supplements, and others.
RESULTS: 292 athletes showed a total consumption of 666 nutritional supplements. The prevalence of supplements use in athletes was 65.0% and 2.3 products were reported per supplements user. One female athlete reported to have used 12 supplements. Amino acid

and vitamins, followed by minerals and protein were found most popular supplements. The prevalence of use of females <69.6%> was higher than in males <61.2%> but was not statistically significant. The senior athletes showed higher prevalence <69.2%> than junior athletes <59.0%> . The prevalence of use by discipline varied from 47.7% for jumping to 78.3% for long-distance. The long-distance athletes particularly reported higher use of vitamins, amino acid, and minerals than that in other disciplines.
CONCLUSION: 65% of Japanese top-level TF athletes reported the use of nutritional supplements. The prevalence of use was great in female, senior and long-distance athletes.

THE PERFORMANCE EFFECT OF SCHEDULED CARBOHYDRATE AND CAFFEINE INTAKE DURING HURLING MATCH-PLAY

KEANE, J.1, SHOVLIN, A.1, MANGAN, S.1, MALONE, S.1, COLLINS, K.1, SHORTALL, M.1
INSTITUTE OF TECHNOLOGY TALLAGHT

INTRODUCTION: Hurling is a stick and ball high intensity intermittent field sport. Hurling players can complete up to 14.8% of match-play at high intensity (>17 km·h-1) with high intensity work rates decreasing throughout match-play (Collins et al., 2017). Given that nutritional intervention studies completed in other intermittent field sports have shown performance benefits from co-ingestion of CHO+CAF, the current study investigated the effects of scheduled caffeine (CAF) and carbohydrate (CHO) supplementation on simulated hurling match-play performance.
METHODS: Eight (n=8) male hurling players completed three hurling match-play simulation protocols performed 7 days apart in a double-blind, randomized design. Treatments included PLA, CHO and CAF + CHO. Participants ingested in randomised order, either a 6% CHO solution (CHO), a placebo solution of similar taste (PLA) or a combined intake of 6% CHO solution + 200mg CAF capsule. At specific time points (Pre, HT, FT) participants completed a repeated sprint protocol (RAST; 12 x 20-m). Several physiological (%VO2max, %VO2mean, %HRmax, %HRmean, RER, and blood lactate; BLa) and performance (RSAbest, RSAmean and RPE) variables were monitored at multiple time points throughout each match simulation.
RESULTS: There was a non-significant difference reported between supplement trials (CHO, PLA & CHO + CAF) regarding BLa (ES: 0.030, small), %VO2max (ES: 0.018, small), %VO2mean (ES: 0.008, small), %HRmax (ES: 0.037, small), %HRmean (ES: 0.019, small), RER (ES: 0.018, small), RPE (ES: 0.027, small) and RSAbest (ES: 0.070, small). RSAmean performance significantly increased in CHO + CAF trials compared to PLA and was significantly different based on time condition (Pre, HT & FT) (ES: 0.124, small). A significant difference was observed in BLa between time points (Pre, HT & FT) (ES: 0.820, large), in %HRmean (ES: 0.477, large) and RER (ES: 0.553, large) across halves and in RPE from S1-S10 (ES: 0.614, large).
CONCLUSION: This study is the first to provide normative data regarding effects of CHO and CAF supplementation on simulated hurling match-play performance. Similar to previous research, performance benefits were observed following co-ingestion of CHO and CAF (Gant et al., 2010). Significant improvements in RSAmean performance at FT during the CHO + CAF treatment suggest that repeated running performance decrements may be limited as a result of nutritional supplementation during match-play.

EFFECTS OF CREATINE SUPPLEMENTATION ON MUSCULAR STRENGTH, POWER, AND ANAEROBIC CAPACITY AFTER UPPER-BODY COMPLEX TRAINING WITH OPTIMAL INDIVIDUAL POST-ACTIVATION POTENTIATION TIME IN KAYAKERS

YANG, M.T., LEE, Y.H., LIN, S.C., LEE, M.M., CHAN, K.H.
TAIPEI MEDICAL UNIVERSITY

INTRODUCTION: To investigate the effects of creatine supplementation on muscular strength, power, and anaerobic capacity after upper-body complex training with optimal individual post-activation potentiation time in canoeists.
METHODS: Sixteen male high school canoeist volunteers were recruited to participate in this study. The tests of prone row for one repetition maximum, distance of overhead medicine ball throw, 30 s Wingate power, and the individual postactivation potentiation (PAP) period were determined before the study. Subjects were divided into groups of creatine (CR) and control (CON) according to their maximal strength. In the initial 6 days of loading phase, subjects in CR group consumed 20 g creatine and 20 g glucose per day, and CON group consumed 20 g methylcellulose. Thereafter, subjects in CR group consumed 2 g creatine, 2 g glucose and CON group consumed 5 g methylcellulose and 2 g glucose per day until the end of study. Subjects then perform the complex training 3 times per week for 4 weeks after 2 days of loading phase. The training protocol consists 6 sets (2 min between sets) of 3-RM bench press/ 8 repetition medicine ball chest press and 3-RM bench pull/ 8 repetition medicine ball over head throw with the rest time of individual PAP period. After 4 weeks training, the same testing protocol with pre-training will also be proceed. Data was analyzed by two-way mixed-design ANOVA.
RESULTS: After supplementation and complex training with the rest time of optimal individual PAP time, the prone row for one repetition maximum, distance of overhead medicine ball throw, and 30 s Wingate power in both group were significantly higher than pre-test values. However, there were no significant differences between CR and CON.
CONCLUSION: Four weeks of upper-body complex training with optimal individual post-activation potentiation time can effectively enhance muscular strength, power, and anaerobic capacity. However, creatine supplementation had no additional benefits on muscular strength, power, and anaerobic capacity.

EFFECT OF CHRONIC DIETARY NITRATE SUPPLEMENTATION ON 100-M SWIM PERFORMANCE.

MARSTON, M., VARNHAM, R., RAMSBOTTOM, R.
OXFORD BROOKES UNIVERSITY

INTRODUCTION: Dietary inorganic nitrate (NO3-) has been shown to improve human leg extensor power (Coggan et al., 2014), time trial performance using the upper body (Peeling et al., 2015) and extend exercise capacity during cycle ergometry (Bailey et al., 2009). However, little is known with respect to swimming. The aim of the present study was to investigate the effect of NO3- supplementation, in the form of concentrated beetroot juice (BRJ), on 100-m swim performance.
METHODS: Ten University level swimmers, eight men, two women (age, 21.0±2.1 years; height, 1.80±0.06 m; body mass, 69.6±9.2 kg) (mean±SD) participated; and were treated in accordance with principles laid down in the Declaration of Helskinki. Volunteers attended

three time trials in a 25-m swimming pool (temperature 27±0.5 0C). A standardized warmup preceded each trial and trials were repeated at similar times of day (±1 hour). After familiarization volunteers (in random order) consumed either 70 mL 'Beet it' (0.04 mmol NO3- per 70 mL) twice a day for three days or the equivalent volume of orange juice (OJ) as placebo. The true nature of the study was disguised as volunteers were advised both beverages were isocaloric and high in antioxidants (Bond et al., 2014). Consumption of beverages was interspersed by a 7-10 day 'wash out' period. Differences between conditions were determined using Student's t-test (SPSS v.23).
RESULTS: There was a significant difference in systolic and diastolic blood pressure supplementing with NO3- compared with OJ, 128±8/72±6 vs.133±9/75±6 mmHg respectively, which was associated with a lower pre-exercise heart rate 71±11 (NO3-) vs. 75±14 b min-1 (OJ) (P<0.01). Volunteers recorded significantly faster 100-m swim times 67.3±7.8 BRJ vs. 69.1±6.7 s OJ (P<0.05), Cohen's ES = 0.27.
CONCLUSION: Swim performance was significantly improved in University level swimmers using BRJ supplementation, possibly due to increased oxygen availability.

DOES L-CARNITINE SUPPLEMENTATION IMPROVE PERFORMANCE OF DISTANCE ATHLETES?

GRIVAS, G.V., VAVRITSAS, S.

PHYSICAL EDUCATION AND SPORT SCIENCE

INTRODUCTION: Carnitine (L-3-hydroxytrimethylamminobutanoate) is an endogenous compound that can be synthesized in the liver and kidney from the essential amino acids lysine and methionine or ingested through diet (Bremer, 1983; Clarkson, 1992; Kraemer, 2005). L Carnitine plays a critical role in energy production and in fat metabolism through its function as a transporter of long-chain fatty acids into mitochondria for β-oxidation (Fritz, 1963). In cells, it helps transport fatty acids into the mitochondria, where they can be burned for energy. There is a debate about the effects of L-Carnitine supplementation on performance in endurance runners (Panjwani et al., 2007; Broad et al., 2005). Therefore, the aim of the present study is to investigate the effects of L-Carnitine on performance of distance athletes.
METHODS: The following databases were searched: Pubmed, SPORTDiscus, Medline and CINAHL (Cumulative Index to Nursing and Allied Health Literature). In each database the title, abstract and keywords search fields were searched. The following keywords, combined with Boolean operators (AND, OR), were used: "L-Carnitine", athletic performance", "distance runners", "sports performance", and "endurance runners".
RESULTS: There are only three studies in the literature showing beneficial effects of L-Carnitine on performance of distance athletes (Arenas et al., 1994; Gorostiaga et al., 1989; Marconi et al., 1985). On the contrary, four studies have shown no effects of L-Carnitine supplementation on performance of distance runners (Cooper et al., 1986; Colombani et al., 1996; Greg et al., 1987; Wachter et al., 2002).
CONCLUSION: These results indicate that there is uncertainty in regards to how L-Carnitine helps athletic performance. However, it is clear that L-Carnitine plays an important role on recovery from strenuous exercise (Ho et al., 2010; Kraemer et al., 2003; Spiering et al., 2007; Volek et al., 2002). The majority of studies suggested a dose of 2 g/d of L-Carnitine. Perhaps should be examined higher dose than 2 g/d of this supplementation to improve performance of distance runners.

AN INTERVENTION TO PROMOTE WALKING IN UNIVERSITY CAMPUS SETTING

LEUNG, E.F.L.1, SUM, R.K.W.2, YUEN, B.P.K.1

THE CHINESE UNIVERSITY OF HONG KONG

Purpose: Physical activity (PA) habits during young adult years may have long-term health influences on adult life. University campuses possess unrealized opportunities for PA promotion among young adults. The current study aimed to evaluate the effectiveness of an 8-week campus walking programme among university students.
Methods: A total of 1308 students from a university were recruited and participated in the current study. They were group-randomized by class and placed into two groups, i.e. the intervention group (I) and the control group (C). Participants of the I group were encouraged to walk on the campus trails instead of using campus shuttle bus for transportation. Participants were requested to record their walking frequency by using the reading devices installed along the trails. The "Green Walker" prize for students walked more than 40 times in the campaign period would be awarded. Participants of group C did not receive any intervention treatment. They were requested to maintain their present lifestyle for 2 months. The assessments of walking scores were conducted at baseline and two months after the commencement of the intervention.
Results: Increased in walking score was found in the I group, but they were not statistically significant ($p > 0.05$). Although the increase in walking was not significant, the significance level was close to 0.05 ($F [1, 1306] = 2.853$, $p < 0.091$). The walking score for C group was more or less the same after 2 months.
Conclusion: The results showed that the 8-week campus walking programme was not effective in promoting walking on campus. The lack of intervention effects might be attributed to the short intervention period and lack of reminding messages for intervention participants. The current study collected self-reported data, which could create a response bias. Objective PA could be assessed by using accelerometers which might also help to remind and motivate participants to exercise.

THE EXPERIENCES OF DAILY PHYSICAL EDUCATION IN HUNGARY

HAMAR, P.1, KARSAI, I.2, CSORDÁS-MAKSZIN, Á.1, SOÓS, I.3

1UNIVERSITY OF PHYSICAL EDUCATION, BUDAPEST, 2UNIVERSITY OF PÉCS, HU, 3UNIVERSITY OF SUNDERLAND, UK

Introduction: In Hungary, the regulation of public education requires delivering 5 PE lessons a week. The weakest link in daily PE is the insufficient availability of sports facilities and equipment. In order to teaching physical education to meet the challenges of the 21st centu-

ry's standards, effective education, teaching and training, one school - one gym - one swimming pool primary objectives are required. Creative and highly experienced physical education teachers can temporarily overcome the difficulties caused by incomplete material conditions, but this cannot be sustained in the long run. In our study, we investigated the opinion of physical educators regarding to whether or not the quality and quantity of material conditions (facilities/equipment) provided to physical education are adequate. Are the unacceptable conditions of existing sports facilities used in classrooms generic? We assumed that the answers would differ depending on the type of settlements and schools, ultimately the location where the respondent PE teachers teach physical education.
Methods: A cross-sectional questionnaire-based survey method was taken place in Hungary. The original version of the questionnaire translated into Hungarian was used by K. Hardman and J. Marshall in an international investigation (Hardman & Marshall, 2009). In the interest of the representativeness of the data, the stratified sampling procedure for groups was used (N=1161). In addition to descriptive statistics (frequencies) performed, chi-square test was employed to reveal the relationships between the dependent and independent variables.
Results and Discussion: 45.1% of the respondents consider the sports facilities used for teaching are unacceptable. However, 71.4% of the quality of the facilities and 77.3% of the quality of the equipment are judged good-adequate. In contrast, 52.1% of respondents reported the amount (quantity) of facilities, while 40.8% the quantity of equipment as average-inappropriate, The results of the chi-square test show significant differences between the quantitative and qualitative indicators for sports facilities and equipment according to the type of settlements and schools ($p < 0.05$). As for the question of Where, in what kind of settlement do you teach?, The least negative (34.5%) responses are manifested by the teachers from Budapest. Thus, the "capital centering" is also reflected in other areas, as in the financial situation of schools, such as related to school sports facilities and sports equipment. From the whole sample, vocational schools teaching staff agreed in the highest percentage (62%) with the unacceptable situation of sports infrastructure. This may be due to the fact of the content features of vocational training, as well as the maintainers of vocational training vary considerably from other school types.

THE EFFECTS OF CHARACTER PERFORMANCE IN TEACHING GAMES FOR UNDERSTANDING WITH TEACHING PERSONAL AND SOCIAL RESPONSIBILITY

YA-TZU, K., HUNG-SHIH, C., SHYH-CHING, C.
NATIONAL TAIWAN SPORT UNIVERSITY

Introduction: Teaching Games for Understanding has a lot of research in physical education teaching to prove its effectiveness. However, the method doesn't have any research results on the students' character performance. Therefore, the Teaching Personal and Social Responsibility might be an effective mode and it can enhance the performance of character under the Teaching Game for Understanding method.
Aim
The purpose of this study was to explore the influence of character performance in Teaching Games for Understanding with Teaching Personal and Social Responsibility.
Sample
Two of the classes including 49 ninth graders received the instruction lasted 8 weeks. The students were randomly assigned to one experimental condition. One group (N=24) worked on the Teaching Game for Understanding, and another (N=25) worked on the Teaching Game for Understanding with Teaching Personal and Social Responsibility.
Method
It takes "Measuring student responsibility in physical education" designed by Hsu, Pan, Chou, Lee and Lu (2014) for teenager students from 13 to 18 years old in Taiwan. The instrument is the measurement of students responsibility in PE classes. In order to examine the leaning effects between two groups, a t-test analysis was performed. Then, an ANCOVA was performed to examine the comparison of the character performance in the two groups.
Result
They showed that the students had a better performance in their character performance after they were received Teaching Game for Understanding with Teaching Personal and Social Responsibility.
Conclusion
It can be a reference for the study based on the Teaching Personal and Social Responsibility and Teaching Game for Understanding. Besides, it also may be beneficial for PE teachers and scholars to future study. The study suggests that researchers manipulate different the variables likes ages or athletic events. Teaching Games for Understanding can combine with other different teaching methods. Researchers implement the study in longitudinally or qualitatively study.

EFFECTS OF PERCEIVED PHYSICAL LITERACY ON PHYSICAL ACTIVITY ENJOYMENT AND SITUATIONAL INTRINSIC MOTIVATION IN PE CLASSES

SUM, K., WALLHEAD, T., HA, S.C.A., SIT, H.P.C.
THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: This study aims to examine the influence of student-athletes' perceived physical literacy in predicting physical activity enjoyment and situational intrinsic motivation in physical education classes among Hong Kong primary and secondary school students.
METHODS: A total of 2446 primary and secondary school students in Hong Kong were recruited into this cross-sectional study. Self-report scores from perceived physical literacy instrument , physical activity enjoyment scale and situational intrinsic motivational scale were recorded.
RESULTS: Three instruments were significantly correlated with the r between physical activity enjoyment and perceived physical literacy being highest . Regressions further revealed that students perceived physical literacy was the best predictor for physical activity enjoyment . While physical activity enjoyment was used to predict perceived literacy, physical activity enjoyment was the best predictor for

perceived physical literacy . In addition, knowledge and understanding , intrinsic motivation and amotivation were significant for predicting physical activity enjoyment in PE classes.
CONCLUSION: The results were useful in intervening in the perception of physical literacy and participation in physical education classes for primary and secondary school students in Hong Kong and other countries. Findings also provide a new perspective for teaching education institutions and professional development programmes by emphasizing the concept of physical literacy.

TEACHERS' ROLE MODEL IN PHYSICAL ACTIVITY: ARE PRE-SCHOOL CHILDREN MORE ACTIVE WHEN TEACHERS ARE ACTIVE?

CHEUNG, P.

THE EDUCATION UNIVERSITY OF HONG KONG

Introduction: In early childhood, children spend a large amount of time in pre-school. Teachers, with the opportunity to interact with children in every school day, are in a unique position to influence childrens behavior. The purposes of this study are: 1) to compare the activity level of pre-school children in a structured PE class led by an active or a less active teacher, and 2) to examine the interaction effect of school size, gender, and teacher activity level on the activity level of children.
Methods: Participants were 248 pre-school children (134 boys, 114 girls; mean age = 5.5) and teachers from twelve pre-schools. A 30-minutes structured PE class was conducted by trained teachers and the participants' physical activity level was measured by pedometers. Teachers' recorded steps counts were derived to classify if the children were led by active or less active teacher. Factorial analysis of variance (ANOVA) was used to determine if there was a significant difference in the pedometer-determined activity on gender and school size between the different classes.
Results: In the 30-minute PE class, significant difference between groups was observed as determined by ANOVA [F(1,246) = 149.81, p = .00], which revealed that the activity level of children was higher in the active teacher class (1,712 ± 501 steps) than that of the less active teacher class (951 ± 437steps). The main effects of gender on the PA level of children [F(1,247) = 6.20, p = .01] and of the teacher group [F(1,247) = 148.35, p = .00] were significant. The main effect of school size on children PA level was insignificant [F(1,247) = 3.44, p = .07].
Conclusion
The findings of this study confirmed that pre-school children were more physically active when the class was led by an active teacher. The understanding of this association would provide implication for pre-school teacher education training. Future study can explore different pedagogical approach for teachers to involve pre-school children to be more active during school hours.

EFFECT OF DRINKING WATER DURING SIMULATED HEAT WAVE CONDITIONS ON COGNITIVE PERFORMANCE IN CHILDREN

MEKJAVIC, V., MEKJAVIC, I.B.

JOZEF STEFAN INSTITUTE

INTRODUCTION: Due to global warming, summer heat waves have increased in frequency, magnitude and duration. Such heat waves place a burden on all individuals, increasing the risk of heat strain, and impairing performance. We evaluated the effect of children's hydration status during conditions simulating a heat wave on their cognitive performance.
METHODS: Nine girls (age: 14 yrs, body mass = 52.1 ± 9.7 kg, height = 149.5 ± 31.4 cm) participated in two trials, during which they sat for 90 minutes (two school hours) in a climatic chamber maintained at a temperature of 35°C and 50% relative humidity. The temperature and humidity were chosen to mimic the conditions during heat waves in June, which is the last month of school. On one occasion (Hydration trial), the subjects were requested to drink 500 ml of water (approximately 0.125 L every 20 minutes) during the 90 min exposure, and on the other occasion (Control trial) they refrained from drinking water. Before, and upon completion of the exposure in the climatic chamber, we measured their mass, tympanic temperature, heart rate, ratings of thermal comfort and temperature sensation, and also recorded their simple and choice reaction times, and their performance on two trail tracking tests; one tracking numbers only (Tracking Test A), and the other alternating tracking numbers and letters (Tracking Test B).
RESULTS: In the Control trial there was a significant ($p<0.05$) loss of body mass, and a significantly ($p<0.05$) greater increase in tympanic temperature and concomitantly heart rate than in the Hydration trial. The increase in thermal discomfort was similar in both trials, with subjects reporting a lower sensation of temperature during the Hydration trial. There was no effect of temperature or hydration on simple and choice reaction times. Lack of hydration (Control trial) significantly ($p<0.05$) increased the time required to complete the tracking tests.
CONCLUSION: During the heat waves that are anticipated to occur with greater frequency and intensity during the last month of the academic year (June), inappropriate hydration will cause a decrement in cognitive performance in children.

OXYGEN UPTAKE KINETICS DURING TREADMILL WALKING IN PRESCHOOL CHILDREN

STASIULIS, A., STASIULE, L., CAPKAUSKIENE, S.

LITHUANIAN SPORTS UNIVERSITY

INTRODUCTION: The pulmonary oxygen uptake (pVO2) kinetic response at the onset of exercise provides a non invasive method of evaluating aerobic metabolism in muscles during growth and maturation. However, to date only limited research has been devoted to investigating the pVO2 kinetics during exercise in children (Armstrong, 2017). Therefore, the aim of this study was to compare the pVO2 kinetics during six minutes walking on treadmill in preschool children of different gender.
METHODS: Preschool children (19 girls and 15 boys) participated in two consecutive treadmill exercises sessions separated be one hour. The mean age, height and body weight was 6.70 ± 0.38 and 6.79 ± 0.66 years, 1.23 ± 0.41 and 1.23 ± 0.50 m and 24.4 ± 3.6 and 24.3 ± 3.1 kg in girls and boys, respectively ($p>0.05$). During each session pVO2 data were collected at subjects rest and during walking (at 6 km/h and a 4% grade treadmill) for 6 minutes. The kinetics of pVO2 during exercise was analysed by applying mono exponential function.
RESULTS: Slow component of pVO2 was not observed in any group of children during this mode of exercise. For the girls and boys the pVO2 baseline value was 0.260 ± 0.042 and 0.274 ± 0.042 L/min, amplitude of pVO2 response was 0.564 ± 0.063 and 0.604 ± 0.053 L/min., time constant of pVO2 kinetics was 15.4 ± 2.2 and 15.9 ± 2.8 s, respectively (in all cases $p>0.05$). Absolute mean VO2 during third

minute of exercise was significantly higher in boys group (0.818 ± 0.081 and 0.881 ± 0.092 L/min in girls and boys, respectively; p=0.04). However, there was no significant difference of this measure between groups at fourth min of exercise (0,875 ± 0,076 and 0,824 ± 0,076 L/min; in boys and girls respectively, p=0.06). Absolute mean VO2 at fifth min of exercise was significantly higher in boys group than in girls (0,890 ± 0,075; 0,830 ± 0,070 L/min in girls and boys, respectively, p=0.02). However, there no significant difference between groups of that measure at sixth minute of exercise (0.843 ± 0.072 and 0.889 ± 0.078 L/min; girls and boys, respectively, p=0.09).
CONCLUSION: pVO2 kinetics estimated during two treadmill walking sessions is similar in preschool girls and boys but girls tend to demonstrate better walking economy during steady state of exercise.

IMPROVEMENT IN EXECUTIVE FUNCTION OF CHILDREN DURING A MONTH-LONG CAMPING TRIP

SHIMANO, A., NOI, S., TANAKA, R.

NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: In Japan, there is concern about poor development and performance of execution function in children. Therefore, we examined the influence of a long-duration camping trip on executive function. Results confirmed that long-duration camping activities may include elements that encourage the development of childrens executive function. However, the report was based only on the camp implementation group where control data had not yet been collected. Therefore, the aim of the present study is to reexamine the influence of a long-duration camping trip (31 nights and 30 days) on the executive function of children through comparison with a control group.
METHODS: Participants of this study were 203 children attending a long-duration camping trip (camp group: 9-14 years old) conducted in July and August from 2008 to 2017; 25 children formed the control group (control group: 9-12 years old) conducted in July and August 2017. Measurement of the camp group was carried out only in the morning, either on the 2nd day or the 3rd day (early stage) of the camp, 12th to 14th day (middle stage), or 30th day of the camp (final stage). Measurement of the control group was carried out according to the same schedule as the camping group. A go/no-go task was used to measure executive function. In the analysis, the number of commission errors (no-go errors) in the no-go trials, omission errors (go errors) in the go trials, and incorrect responses between stimuli (no-task errors) were calculated in both a differentiation experiment and a reverse differentiation experiment for the go/no-go task. Task results and their changes for both the camp and control groups were observed throughout the duration of the camping trip.
RESULTS: Results of a two-way analysis of variance examining group factors and period factors, no task errors in the differentiation experiment and no-go errors in the reverse differentiation experiment confirmed a significant interaction, and a significant difference was detected in the main effect of the time-period. As a result of subsequent multiple comparisons, it was confirmed that the no task errors in the differentiation experiment were significantly fewer in the final stage of the camp group than in the early stage. In addition, in the camp group, it was confirmed that the no-go errors in the reverse differentiation experiment decreased significantly from the early stage to the middle stage, and from the middle stage to the final stage. In recent years, several study findings suggesting that physical activity has a positive influence on executive function. It has been confirmed that during the long-duration camping trip examined in this study, the amount of physical activity is increased compared to before and afterward. Therefore, it can be inferred that physical activity contributed positively to executive function.
CONCLUSION: Long-duration camping trips may improve childrens executive function.
NOTE: This study was supported by commissioned research from Base Brain Work, Inc.

AN 8 WEEK STUDY ON YOGA STRETCHING AND CORE MUSCLES TRAINING AT A HIGH SCHOOL IN HONG KONG: TEACHER'S PERSPECTIVE

HON, S.

THE CHINESE UNIVERSITY OF HONG KONG

Introduction: The benefits of yoga stretching and core muscles exercises have been known, however, not too many school includes them in physical education classes. In addition, research in the area usually was done from the perspective of students and not from teacher. Therefore, the aim of this study was to explore the learning motivation and responses of a female high school teacher aged 40 when learning and implementing the new design exercise program for 40 female students aged between 12-14.
Methods: An in-service physical education teacher attended a 4-hour training by one certified yoga instructor and one certified fitness trainer on a new design exercise program including 32 yoga stretching postures and 18 core muscles exercises. After the training, the teacher implemented the new design program during physical education classes for 8 weeks at a chosen high school. The chosen class attended a 90 minutes physical education class once a week. In order to reflect the teaching and learning experience of the teacher, she completed a questionnaire after each class and attended interviews before and after the 8 week program. At the end, the teacher completed eight questionnaires and attended two 1-hour interviews. The questionnaires and interviews data were used for analysis in this study. Video recording was done in each physical class for analysis.
Results: The major reflections from the teacher were as follows: 1) an increase in teaching motivation in teaching new program and confidence in putting new elements in traditional physical education classes; 2) to combine the new program with other physical activities like ball games will make the class more fun; 3) the yoga elements in the new program improved the balance and stability of students; 4) students showed increased exercise intensity and motivation for the physical education classes while learning the new program. 5) the core training exercises can be used as warm up in every lesson and the yoga stretching exercises can be used as cool down in every lesson.
Conclusions
This study suggests that the new design program increased the teaching motivation and enhanced the teaching experiences of the teacher. In addition, the 8 week yoga stretching and core muscles exercises increased the exercise intensity of the students and increased the participation motivation of the students in the class.

Physiology

INFLUENCE OF LONG EXERCISE EFFORT ON ANTHROPOLOGICAL PARAMETERS.

WIERZBICKA-DAMSKA, I., BAKONSKA-PACON, E., JASTRZEBSKA, A.

UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: Every effort requires energy supply and causes fatigue. Symptoms of fatigue are evident in changes on inside body parameters (at all levels), but they can also easily be seen in the area of changes in muscle circumference and body composition.
The aim of the study was to show changes in anthropological parameters: circuits and body composition against changes of other internal markers resulting from fatigue caused by progressive and continuous running test.
METHODS: The study included a group of 30 people aged 27.9 ± 5.6, subjected to a progressive and continuous laboratory treadmill test. Arterialized blood parameters of acid-base balance (RapidLab 348 Siemens Germany), colorimetric lactate (Dr. Lange Küvettentest, LKM 140 Germany) were studied. Plasma concentrations were determined by immunoassay (ELISA Test Demeditec Diagnostics GmbH Germany): catecholamines (dopamine, noradrenaline adrenaline) and serotonin and tryptophan. Before and after exercise, body circumferences were measured: chest, waist, right and left forearm and arm, right and left leg and thigh and body composition (Biometrix, USA). The results were analyzed by Students t-test using Statistica 13.1.
The study was supported by a research grant from the National Science Centre in Poland (0022/RS4/2016/54).
RESULTS: Significant (statistically significant) changes in circumferences of the body and body composition were also observed in the background of statistically significant changes ($p \leq 0.001$) of biochemical fatigue markers.
The current circuit changes are always caused by a forced displacement. Their distribution is due to the nature and distinctness of the specific test, is determined by the size of the blood flow and thermoregulation and muscle micro-injury within the muscle cells. After the test attempts, the thigh and leg circumference increase while the waist circumference decreases. The composition of the body is visible changes in percentage of water content. These changes are particularly visible after 40 minutes continuous testing
CONCLUSION: Anthropological changes (changes in circumferences of the body and body composition) observed after exercise can be indicators of fatigue along with biochemical markers, especially since the direction of change is characteristic of the type of exercise stimulus.

CHRONIC TENDINOPATHIES AND PLATELET-RICH PLASMA TREATMENT: HOW TI IMPROVE THE EFFICENCY ?

KAUX, J.F., EMONDS-ALT, T.

UNIVERSITY OF LIÈGE

INTRODUCTION: Platelet-rich plasma is blood plasma with a high concentration of autologous platelets which constitute an immense reservoir of growth factors. Although highly popular with athletes, the use of PRP for the treatment of tendinopathies remains scientifically controversial, particularly due to the diversity of products that go by the name of "PRP".
METHODS: In a literature review, we take a closer look at eight parameters which may influence the quality of PRP: 1> anticoagulants used to preserve the best platelet function, 2> the speed of centrifugation used to extract the platelets, 3> the platelet concentrations obtained, 4> the impact of the concentration of red and while blood cells on PRP actions, 5> platelet activators encouraging platelet degranulation and, hence, the release of growth factors, and 6> the use or nonuse of local anesthetics when carrying out infiltration. In addition to these parameters, it may be interesting to analyze other variables such as 7> the use of ultrasound guidance during the injection with a view to determining the influence they have on potential recovery.
RESULTS: Analysis of the 59 studies shows that a majority use ACD-A as an anticoagulant during sampling. A platelet activator is only used in a few studies. However, the best results have been obtained in studies which use no platelet activator. In terms of the speed of centrifugation, analysis of all these studies appears to confirm the existence of a great number of protocols in the literature. It is difficult to draw any conclusions when these different variables are unknown . Currently, no studies have been carried out neither on the use of a "buffer" product to neutralize the acidity caused by the anticoagulant nor on the optimal volume of PRP to be injected. Although it would appear inadvisable to administer a local anesthetic because the anesthetic may reduce the local pH and lead to the inhibition, reduction, or absence of platelet degranulation, the literature shows that the majority use a local anesthetic. They do not, however, obtain better results than those not using a local anesthetic. Finally, it appears to be advisable to carry out infiltration under ultrasound guidance, even if PRP diffusion is observed after injection. This all aims to show that there is still a need for high quality studies, with standardized collection protocols and the use of PRP in the context of tendinopathies, in order to better scientifically understand the real effectiveness.
CONCLUSION: There is a lack of standardization in PRP preparation technique for chronic tendinopathies. However, our study helped identify features of PRP recommended a platelet concentration lower than 5 times the baseline , and avoiding leukocytes and erythrocytes. We recommend leveraging this information about PRP for future studies.

EVALUATION OF ION PROCESS AND QUALIFICATION IN VOLLEYBALL

BIRÓNÉ ILICS, K., MÁTRAI, ZS.

EÖTVÖS LORAND UNIVERSITY

Introduction: The purpose of the present research was to verify the results of our 2012-2013 research on the methods of selecting talented volleyball players. The scope of the initial research, based on measurements, covered the age group of children <12-13 years> and adolescents <14-15 years> . During our study, we applied selection methods – aimed at evaluating predictive validity – which best predicted the anticipated performance.
Methods: During the study, 7 types of data have been collected from the participating 141 children. To test the anthropometric parameters, we took 24 different body sizes of the players. The data also provided the expected adult height, the difference between the biological and calendar age, the athletes body type. We selected 6 motor tests: 18m running, 3kg medicine ball forward throw, long distance jump, 3kg two-handed medicine ball back throw, sit-up, jumping, flying sprint>. Ball control and performance were evaluated by coaches. They had to evaluate the players ball control skills on a scale of 1 to 5 during 50 individual training sessions. To analyze the environmental and personality factors, we compiled questionnaires for athletes and parents. Volleyball performance was evaluated by analyzing 3 matches for each player. We considered the best performers in the tests to be talented <5 girls and 8 boys>. We have tracked the career of the selected players so that we can verify their competence and qualification after 5 years.

Results: Of the 13 selected players <5 girls and 8 boys>, we considered qualified those who are currently at the forefront of Hungarian volleyball and whose performance is outstanding in Hungary. According to the study, 5 of the 13 talented players have met the expectations. It can be concluded that the selection process and the consequent qualification was successful for these 5 players.
Discussion: Our test results prove that our selection methods were correct. There is no doubt, however, that the research would only have been complete, if we had – besides sports sciences literature – included sports psychology literature too, as part of our selection procedures. The sport psychological aspect can determine the direction of possible research continuation.

EFFECTS OF INTERMITTENT COLD EXPOSURE ON MUSCLE STRUCTURE AND FUNCTION: IMPLICATIONS TO IMPROVE RECOVERY AFTER INJURIES

TORRELLA, J.R., LARA, S., SANTOCILDES, G., CABRERA-AGUILERA, I., RIZO-ROCA, D., PAGÈS, T., VISCOR, G.

UNIVERSITAT DE BARCELONA

INTRODUCTION: Cold acclimatization induces changes in resting metabolic rate and different biochemical markers. The increase in metabolic rate is reflected as an increase of oxygen consumption that could reflect the remodelling of structural tissues. The aim of this study was to investigate the effects of whole-body intermittent cold exposure on rat gastrocnemius muscle and its usefulness to improve recovery after muscle injury.
METHODS: After inducing injury in the rat gastrocnemius, two groups of animals (n=6) were considered: COLD, submitted to intermittent cold exposure at 4ºC for 21 days; and CTRL, maintained at 27°C. Histological slides were stained for demonstrating the oxidative and contractile properties of the fibres, classified as slow oxidative (SO), fast oxidative glycolytic (FOG), fast intermediate glycolytic (FIG) and fast glycolytic (FG). Capillary density (CD), fibre capillarization (CCA) and fibre cross-sectional area (FCSA) were measured after ATPase staining. Force properties of contralateral injured and healthy gastrocnemius were registered by electrical stimulation of sciatic nerve. Peak (PF in mN/g) and tetanic force (TF in mN/g), contraction (CT) and half relaxation times (HRT), and fatigue properties at low frequency (30 Hz) were measured.
RESULTS: Intermittently exposed animals to cold evidenced a significant shift from FOG fibres to a more anaerobic phenotype (FIG and FG), together with an increase in capillary supply (CD and CCA) and smaller FCSA. Injured leg from the CTRL group registered significant lower values than the healthy leg in PF (37±9 vs 44±5, p=0.048), TF (110±40 vs 148±22, p=0.016), and showed lower resistance to fatigue. Intermittent cold exposure recovered PF and TF (but with lower values for injured leg: 39±5 vs 44±4, p=0.082 and 156±21 vs 167±26, p=0.309) and resistance to fatigue. No alterations were registered neither for CT nor HRT in any group.
CONCLUSION: Intermittent cold exposure resulted in a significant decrease of FCSA and an increase of CD reducing diffusion distance and facilitating oxygen supply to the tissue. This would counteract the effects of peripheral vasoconstriction induced by cold exposure. Moreover, a shift from an oxidative phenotype of the muscle fibres to a more anaerobic one, would give a faster thermogenic response against cold. Although without reaching the same values that its contralateral healthy leg, the injured leg was partially recovered after intermittent cold exposure. As has been described for therapies applying local cold to injured muscles, recovery was probably favoured by increased capillarization, reducing the infiltration of macrophages, oedema and accelerating the recovery from fibrosis.

DIFFERENCES IN MUSCLE OXYGENATION BETWEEN YOUNG AND MIDDLE-AGED RECREATIONALLY ACTIVE MEN DURING HIGH-VOLUME RESISTANCE EXERCISE

GEPNER, Y., WELLS, A.J., GORDON, J.A., ARROYO, E., VARANOSKE, A.N., COKER, N.A., FUKUDA, D.H., STOUT, J.R., HOFFMAN, J.R.

UNIVERSITY OF CENTRAL FLORIDA

INTRODUCTION: Near-infrared spectroscopy (NIRS) is a noninvasive technique that provides information regarding changes in tissue oxygenation based on oxygen-dependent absorption characteristics of infrared light in the range of 600–900 nm. The benefit of NIRS is in its ability to measure the instantaneous oxygenation response in a less restricted environment, which is suitable for evaluating exercise tasks involving both static and dynamic exercise. Previous research has demonstrated no differences in muscle deoxygenation between high intensity versus high volume resistance training programs. However, the greater duration of high volume resistance training (15 repetitions at 60% of the participants' maximal strength) has been shown to result in a significant delay in muscle reoxygenation. Investigations examining differences in muscle oxygenation between younger and middle-aged adults performing resistance training are limited. Thus, the purpose of this study was to compare muscle oxygenation of the vastus lateralis during a high volume, isokinetic resistance exercise protocol (HVP) between young adult (YA) and middle-aged adult (MA) men
METHODS: Twenty recreationally trained men were assigned to either the YA (21.8±2.0 y, 90.7±11.6 kg, 179±4.7 cm) or MA (47.0±4.4 y, 96.1±21.6 kg, 177±7.7 cm) group. The HVP consisted of eight sets of 10 repetitions of unilateral isokinetic concentric knee extension and eccentric knee flexion at 60°·sec-1. Changes in tissue hemoglobin saturation index (TSI), tissue oxygenated hemoglobin concentration (O2Hb), deoxygenated hemoglobin (HHb), and muscle oxidation index (O2Hb-HHb) were measured during the exercise session using near-infrared spectroscopy (NIRS). Data were analyzed using two-way mix factorial analyses of variance.
RESULTS: Prior to exercise, TSI was significantly greater for YA compared to MA (73.2±3.4% vs. 68.6±4.8%, p=0.024). For both groups, significant decreases in O2Hb and O2Hb-HHb, and increases in HHb were observed during each of the eight sets relative to the rest periods (p<0.05). However, the average change during the eight sets of the HVP revealed a significantly higher (p=0.036) level of HHb (7.8 ± 0.5μM vs. 5.3 ± 3.1μM) and a lower (p=0.029) level of O2Hb-HHb (-11.3 ± 1.4μM vs. -7.1 ± 5.5μM) for MA compared to YA.
CONCLUSION: During a high volume, resistance exercise protocol, middle-aged adults experienced reduced muscle oxygen saturation levels compared to younger, recreationally active adults. These results suggest that age-related changes in muscle oxygenation appear to occur in middle-aged adults, regardless of recreational exercise training experience.

ISCHEMIC PRE-CONDITIONING FOR HUMAN PERFORMANCE IS NOT EXPLAINED BY PLACEBO EFFECTS DURING CYCLE ERGOMETRY

BURR, J.F., CHEUNG, C., SLYSZ, J.T.

UNIVERSITY OF GUELPH

INTRODUCTION: The efficacy of ischemic pre-conditioning (IPC) for the augmentation of human aerobic exercise performance remains debated. In particular, it is suggested that previously observed effects of IPC may be influenced by insufficient placebo/nocebo shams and inappropriate aerobic exercise performance tests (1). Thus, the purpose of this investigation was to compare the effects of IPC versus both a non-treatment and sham placebo control, for altering measures of exercise performance and efficiency during a staged test to exhaustion.
METHODS: Twelve recreationally active participants (6M/6F, 66.7±15 kg, 169±9 cm, 43±8 ml.kg.-1min-1) underwent three 40 min pre-exercise conditions on different days in a random order: 1) wakeful supine rest, 2) sham therapeutic ultrasound or 3)IPC. The exercise challenge consisted of 3 min submaximal cycling stages commencing 5W below measured lactate threshold, and increasing 5W/stage to failure. Following a short 2 min break a supramaximal test (5W above power at VO2max) was conducted to failure. Cycling performance, lactate production, and metabolic demand were measured, and subjects were asked about their perceptions of treatment efficacy using a visual analogue scale.
RESULTS: 72% of participants reported a pre-exercise expectation of the sham being more effective than IPC, confirming efficacy of the deception. Comparing the IPC and Sham treatments to the baseline performance observed following 40min of quiet rest, an improvement was observed in the IPC group for max power output (IPC: +2.5±4W, Sham: 0±3.5W) and thus incremental stages completed (IPC: +0.5±0.9, Sham: 0±0.3 stages), both $p \leq 0.05$. Alterations were also observed only for the IPC group comparing time to failure during the supramaximal bout (control: 1378±288s, sham: 1380±256s, and IPC 1493±299s). No meaningful differences were observed for submaximal oxygen consumption, maximal oxygen consumption or lactate across the varying exercise intensities.
CONCLUSION: The present study refutes the suggestion that the observed effects of IPC do not exceed the performance benefits of an effective sham control. Differences between this study, and those after which it was modelled may be explained by the use of cycle ergometry, which is dynamic and adjustable in comparison to treadmill exercise.

EFFECTS OF EXERCISE TRAINING INTERVENTION ON INTRINSIC HIGH- OR LOW-AEROBIC EXERCISE CAPACITY IN MICE

HSU, Y.J., HUANG, W.C., LEE, M.C., HUANG, C.C.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Current exercise research is focusing on the physical fitness, physical activity, health promotion, disease prevention and performance improvement for individuals and communities around the world. Response to exercise intervention is often highly variable among individuals, however, the researchers have indicated that response to exercise may be affected mainly by genetic variations. We aimed to investigate different type exercise training and relationship affecting congenital exercise performance in an animal model with physical activity challenge from physiological and biochemical perspectives.
METHODS: In this study, we selected high- and low- intrinsic exercise capacity mice by using exhaustive swimming test. We investigated the differential effects of aerobic exercise or isometric strength training on physiological performance and biochemical profiles in high aerobic swimming exercise capacity mice (HAEC) and low exercise capacity mice (LAEC) mice, a total of 24 HAEC and 24 LAEC male mice 6 weeks old were randomly divided into 6 groups: (1) HAEC with sedentary control (HAEC-SC), (2) HAEC with aerobic exercise training (HAEC-AE), (3) HAEC with isometric strength training (HAEC-ST), (4) LAEC with sedentary control (LAEC-SC), (5) LAEC with aerobic exercise training (LAEC-AE), (6) LAEC with isometric strength training (LAEC-ST). After 4 weeks, mice underwent exhaustive swimming test, forelimb grip strength test and maximum holding time, respectively. The blood biochemical markers and tissue damage markers were determined.
RESULTS: The exhaustive swimming time of the HAEC-AE group were significantly 7.01-, 6.64 -and 4.37- fold (all $P < 0.0001$) higher than those of the LAEC-SC, LAEC-AE and LAEC-ST groups, respectively. The forelimb grip strength test of HAEC-ST group were significantly higher, by 1.18- ($P = 0.0003$), 1.14- ($P = 0.0022$) and 1.11- ($P = 0.0169$) fold, respectively, as compared with LAEC-SC, LAEC-AE and LAEC-ST groups. The maximum holding time of the HAEC-ST group were significantly 9.97-, 4.01 -, 6.94-, 6.70- and 3.27- fold (all $P < 0.0001$) higher than those of the LAEC-SC, LAEC-AE and LAEC-ST groups, respectively. LAEC-AE group were significantly increase serum ammonia, BUN (blood urea nitrogen) and creatine kinase (CK) concentration after the 15-min swimming test. Liver glycogen of the HAEC-AE group were significantly 3.00- ($P = 0.0027$), 2.18- ($P = 0.0228$) and 8.09- ($P < 0.0001$) fold higher than those of the LAEC-SC, LAEC-AE and LAEC-ST groups, respectively.
CONCLUSION: Acquired training could elevate the exercise performance in both lines mice, especially the improvement of HAEC mice is better than LAEC group. Intrinsic aerobic capacity is associated with the effectiveness of exercise training.

ACUTE EFFECTS OF HIIT IN HYPEROXIA ON RED BLOOD CELL DEFORMABILITY AND DEEP TISSUE OXYGENATION

SCHUMANN, M., FREITAG, N., BÖTTRICH, T., MANFERDELLI, G., BIZJAK, D.A., GRAU, M., BLOCH, W.

GERMAN SPORT UNIVERSITY

INTRODUCTION: Increased inspired fractions of oxygen (hyperoxia; FiO2) are known to enhance exercise performance and recovery, while simultaneously reducing perceived exertion. It is suggested that this may be attributed to improved cellular oxygen kinetics (1) but research underlying these assumptions is sparse. Red blood cell deformability is considered as an important determinant of tissue oxygen supply and, therefore, associated with sports performance. Thus, this study aims to examine the effects of hyperoxia during high-intensity interval training (HIIT) on red blood cell deformability and deep tissue oxygenation.
METHODS: Thirteen recreationally endurance trained men (age, 24 ± 3 years; weight, 79 ± 9 kg) performed a HIIT session (5 x 3 minutes at 80% of Wmax, separated by 2 minutes at 40% Wmax) on a cycle ergometer, both in hyperoxia (FiO2 0.3, HYP) or ambient conditions (NORM) in a randomized and counterbalanced order. Red blood cell deformability (maximal deformability [EImax] and shear stress needed for 1/2 of EImax [SS1/2]) was assessed from capillary blood before and after both loadings by ektacytometry. Tissue oxygen saturation (SO2) as well as oxygenized (OxyHb) and deoxygenized (deOxyHb) hemoglobin of the m. rectus femoris were assessed

throughout both loadings by near-infrared spectroscopy. Blood lactate concentrations were assessed after each high- and low-intensity bout, respectively.
RESULTS: EImax and SS1/2 remained statistically unaltered in both HYP (EImax: -0.4 ± 1.2%, ES 0.3; SS1/2: -4.7 ± 8.8%, ES 0.6) and NORM (EImax: -1.2 ± 1.8%, ES 0.7; SS1/2: -6.8 ± 5.8%, ES 1.2). Similarly, SO2, OxyHb and deOxyHb remained statistically unchanged in both conditions during high- (ES: all ≤ 0.3) and low-intensity bouts (ES: all ≤ 0.3), respectively. No significant between-condition differences were observed for changes in blood lactate concentrations. Blood lactate significantly increased in both HYP and NORM during high- (both $p<0.01$, HYP: 72.9 ± 41.1%, ES 1.5; NORM: 76.6 ± 50.4%, ES 1.7) and low-intensity bouts (both $p<0.01$, HYP: 42.7 ± 30.3%, ES 1.3; NORM: 47.3 ± 24.0%, ES 1.9), respectively.
CONCLUSION: Our data did not show statistically significant differences in red blood cell deformability and deep tissue oxygenation when HIIT was performed in hyperoxia and normoxia, respectively. This might be at least partially related to the rather low FiO2 of 30%. Whether the somewhat lower effect sizes in red blood cell deformability and blood lactate concentrations during HIIT in hyperoxia are physiological meaningful, should be addressed in future investigations.

FEASIBILITY AND EFFICACY OF HIGH-INTENSITY INTERVAL TRAINING (HIIT) IN CANCER PATIENTS: A SYSTEMATIC REVIEW AND META-ANALYSIS

RELJIC, D., ZOPF, Y.

UNIVERSITY HOSPITAL ERLANGEN

INTRODUCTION: Many cancer patients decrease physical activity after their diagnosis, mainly due to fatigue and physical discomfort. However, it is well established that physical exercise during/after cancer treatment can positively influence fatigue and other disease outcomes. Moreover, higher levels in cardiorespiratory fitness (CRF) are associated with a lower risk of post-operative complications and mortality in cancer patients. Thus, regular exercise plays an important supportive role in cancer therapy. High-intensity interval training (HIIT) has emerged as a promising exercise strategy allowing significantly shorter training times for achieving relevant increases in CRF in chronic disease populations. However, data on the application of HIIT in cancer patients are sparse. The aim of this systematic review was, therefore, to provide first insights into the feasibility and efficacy of HIIT for improving CRF in cancer patients.
METHODS: Pubmed/MEDLINE was searched systematically for relevant articles published in peer-reviewed journals through January 2018. Studies included were required to (1)apply a structured HIIT-intervention in cancer patients, (2)report data on compliance and adverse events (AEs), (3)report changes in maximal oxygen uptake (VO2max).
RESULTS: The database search yielded 292 potentially relevant articles. After removal of duplicates and studies not meeting inclusion criteria, 7 studies (n=197 subjects with different cancer types, 57.2±6.9 yrs) were finally analyzed. Mean study duration was 8 weeks and on average, 3 sessions/week were implemented. Participants exercised with a mean intensity of 91±2.9% of maximal heart rate. Exercise sessions lasted on average 32±5 min. Overall, studies reported high compliance (92%) and low dropout rates (4%). No serious AEs were reported. In total, only 3 minor AEs were observed, including sciatica (n=1) and knee pain (n=2). After data pooling, VO2max increased by 3.5 ml/kg/min following HIIT.
CONCLUSION: The results indicate that HIIT can effectively improve VO2max within only a few weeks in cancer patients. An increase in VO2max by 3.5 ml/kg/min (=1 MET) can be considered highly clinically relevant, given that an each 1 MET increase in CRF is associated with a 12% reduction in mortality. HIIT was generally well tolerated and the risk of AEs was low even though exercise intensities were higher compared to traditional exercise programs commonly implemented in cancer patients. Thus, HIIT may be a promising exercise modality to improve CRF in a time-efficient manner during cancer treatment. However, given the limited number of available studies, further research is necessary to substantiate these initial data.

DISSIMILAR INFLAMMATORY AND BDNF RESPONSES TO A HIGH-FAT MEAL AFTER HIGH INTENSITY INTERVAL EXERCISE AND CONTINUOUS EXERCISE

LEE, C.L.1, CHENG, C.F.2

NATIONAL SUN YAT-SEN UNIVERSITY

INTRODUCTION: The continuous exercise (CE) is aiming to decrease the risks of atherosclerosis and cardiovascular disease. Recently, low-volume high-intensity interval exercise (HIIE) has been considered as a time-efficient approach to prevent these chronic diseases in adults. Postprandial lipemia is an established independent risk factor for cardiovascular disease; however, the effects of CE and HIIE on inflammatory and brain derived neurotrophic factor (BDNF) after postprandial lipemia is unclear. This study examines the effects of CE and HIIE on interleukin-6 (IL-6) and BDNF followed a high-fat meal (HFM).
METHODS: Thirty-six active males were randomly assigned to three exercise trials in the evening: HIIE (10 × 1-min sprints at 85% of maximal oxygen uptake with 2-min rest interval), CE (65% of maximal oxygen uptake for 50-min), and control group (CON). The next morning after exercise, participants consumed a HFM of 13 kcal/kg body mass [1] after a 12 hr overnight fast. Blood samples were drawn before and after exercise on day 1, before HFM and then hourly until 4 hr on day 2.
RESULTS: There were no differences among groups for IL-6 and BDNF levels ($P > 0.05$) before exercise. The IL-6 concentrations in HIIE ($P = 0.02$) and CE ($P = 0.00$) were significantly higher than that in CON after exercise, but no significant differences were observed at other time points among groups ($P > 0.05$). The area under curve (AUC) of IL-6 from pre- to post-exercise was significantly higher in CE than those in HIIE and CON ($P < 0.05$), and CE and HIIE had higher IL-6 AUC compared with CON from post-exercise to pre-meal ($P < 0.05$). BDNF after exercise in HIIE and CE were significantly higher than that in CON ($P = 0.01$), but no difference between HIIE and CE. No significant difference was revealed in BDNF after HFM among groups ($P > 0.05$). BDNF AUC from post-exercise to pre-meal in HIIE (+23%, $P < 0.05$) was significantly higher than that in CON, and the CE had a particular trend toward significance (+21%, $P = 0.08$).
CONCLUSION: The IL-6 and BDNF were significantly increased after 1.5 and 2.5 km run, but no significant difference between exercise regimes [2]. Our results, different IL-6 AUC and BDNF AUC responses to CE and HIIE, might provide support for that the duration and intensity of exercise should be the essential factors [3] to the increases in IL-6 AUC and BDNF AUC. HFM resulted in a decrease by 27% in BDNF [4], however, HIIE and CE did not attenuate BDNF levels after HFM in this study which was in line with previous research [5]. Overall, despite significant increases in IL-6 and BDNF following an acute exercise, HIIE and CE did not alter the inflammatory and BDNF responses to HFM.

EFFECTS OF INTERACTIVE VIDEO GAMES ON BRAIN FUNCTIONS BETWEEN YOUNG AND ELDERLY PEOPLE

WIDJAJA, W.1, THITIPHONGTAKAN, S.1, AJJIMAPORN, A.1, KHERDKARN, P.2, SIRIPORNPANICH, V.3

1: CSST ,2: IPE ,3: IMB

INTRODUCTION: With developments of computer and software technologies, interactive video games become one of popular physical activities among adults and adolescents. It is a virtual-reality based game in which body movement is used to control the game. This game can be developed to promote health, fitness and happiness. However, its effects on the brain functions has not been rigorously studied. The aim of this study was to investigate the effect of interactive video game on the brain functions between young and elderly people.
METHODS: Participants were divided into two groups; Groups I (YG), aged 18-25 years old (n = 10) and Group II (EG), aged 55-70 years old (n=10). They had a normal physical activity less than 150 min/week. Physical activity readiness questionnaire and the Edinburgh handedness inventory were used for screening subject prior to the experiment. On the experimental day, their brain wave activities were measured by EEG with closed-eye condition for 5 minutes at pre and post exercises. The participants played Wii games (Nintendo) at 50-70% of the maximum heart rate by warming up for 10 minutes and exercise for 20 minutes. All parameters data were analyzed by using two-way repeated measures ANOVA in SPSS.
RESULTS: The results showed that the amplitudes of theta, alpha, and beta waves before exercise in YG were 12.96, 17.52, 7.93 μV, respectively. In EG, the amplitudes of the three waves were 11.70, 14.24, 9.28 μV, respectively. After exercise, all three waves increased. In comparison between groups they were not significantly different. However, the alpha waves before and after exercise in YG were significantly different ($p<0.01$). The beta wave in EG was not significantly higher than those in YG.
CONCLUSION: The higher alpha wave in YG may be caused by cortical inhibition and brain-stem activation during exercise (Koriath et al.,1987). The effects of exercise on cortical activity in cerebral cortex caused the increase of the beta wave in EG more than that in YG after exercise. This is correlated with the arousal and increase in blood flows to the brain. Moreover, the increase of the beta wave amplitude was also related with the level of exercise intensity (Timinkul et al.,2010). Therefore, the interactive video game is useful for sedentary people who want to relax after work or as a program to cool down after intense exercises.

DEHYDROEPIANDROSTERONE SUPPLEMENTATION COMBINED WITH WEIGHT-LOADING WHOLE-BODY VIBRATION TRAINING (WWBV) AFFECTS EXERCISE PERFORMANCE AND MUSCLE GLYCOGEN STORAGE IN MIDDLE-AGED C57BL/6 MICE

CHEN, W.C., LEE, M.C., LI, H.Y., TSAI, B.H., HUANG, C.C.

CHANG GUNG UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Dehydroepiandrosterone (DHEA), one of the most abundant circulating steroids in humans and a precursor hormone, is primarily secreted by the adrenal gland and used by athletes for performance enhancement. Resistance training is known to be a strong stimulus for inducing muscle hypertrophy and preventing sarcopenia in the middle-aged or elderly. Towards this end, we investigate the effects of DHEA supplementation combined with WWBV training on exercise performance, physical fatigue-related biochemical responses and testosterone content in middle-aged 9 months old C57BL/6 mice.
METHODS: Male middle-aged C57BL/6 mice were divided into 3 groups (n = 8 per group) and treated for 4 weeks with the following: 1) Sedentary control (SC) with vehicle, 2) DHEA supplementation (DHEA, 10.2 mg/kg) and 3) DHEA supplementation with WWBV training (DHEA: 10.2 mg/kg; WBV: 5.6 Hz, 2 mm, 0.13 g). Exercise performance was evaluated by forelimb grip strength, time to exhaustion and anti-fatigue levels after a 15-min swimming exercise. In addition, the biochemical parameters and the testosterone levels were measured at the end of the experiment.
RESULTS: DHEA supplementation combined with WWBV training for 4 weeks significantly improved the grip strength was significantly higher by 1.15-fold ($p = 0.0006$) and 1.16-fold ($p = 0.0003$) in the DHEA group and WWBV + DHEA group. The swim time to exhaustion in the DHEA and WWBV+DHEA groups were significantly higher1.47-fold ($p = 0.0458$) and1.83-fold ($p = 0.0013$) than the SC group. The lactate level was lowered by 14.72% ($p = 0.0261$) for the DHEA treatment group and 32.31% ($p < 0.0001$) for the WWBV+DHEA treatment group when compared with the SC group. The BUN levels of the DHEA and WWBV + DHEA groups were significantly lower by 7.54% ($p = 0.0370$) and 29.20% ($p<0.0001$) than the SC group. In the DHEA and WWBV+ DHEA group, the testosterone levels were both significantly increased by 1.25-fold ($p = 0.0173$ and $p=0.0174$) compared with the SC group. The liver glycogen content of the WWBV + DHEA group was 1.4-fold higher ($p = 0.0307$) than the group with DHEA supplementation alone. SC group and DHEA group showed no significant difference in liver glycogen levels.
CONCLUSION: WWBV + DHEA group had increase anti-fatigue activity after acute exercise. Lactate and BUN levels decreased, all of which contribute to enhancing exercise performance in middle-aged mice. Taken together, our results suggest that combining the WWBV training program with DHEA supplementation could provide an anti-fatigue pharmacological effect in middle-aged males mice.

EFFECTS OF AGE ON DIVING BRADYCARDIA AND HEART RATE RECOVERY IN PEOPLE OLDER THAN 40 YEARS

KONISHI, M.1, TABATA, H.1,2, HIGUCHI, M.1, SAKAMOTO, S.1

1: WASEDA UNIVERSITY, 2: RESEARCH FELLOW OF THE JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE

INTRODUCTION: The autonomic nervous system plays an important role in the maintenance of cardiovascular homeostasis. The attenuation of parasympathetic regulation increases the risk of cardiovascular disease and mortality (Thayer and Lane 2007). Heart rate recovery immediately after exercise is an established measure of the parasympathetic regulation. The reduction in heart rate recovery is associated with elevated all-cause mortality (Cole et al., 1999). However, the measurement of heart rate recovery imposes a physical load on participants because of the strenuous exercise involved. The diving reflex test is short, simple, and relatively safe to perform and can be used to assess parasympathetic regulation (Heath and Downey 1990). Diving bradycardia has been observed to occur due to facial cooling and breath-holding. Although heart rate recovery declines with age, the effects of age on diving bradycardia have not been determined, especially in people aged over 40 years. Therefore, the purpose of this study was to examine the effects of age on diving bradycardia and heart rate recovery in people older than 40 years.
METHODS: The participants of the present study were 115 men and 58 women (age: 40-69 years) recruited from "Waseda Alumni's Sports, Exercise, Daily Activity, Sedentariness Health Study" from 2015 to 2018. The diving reflex test was performed for all participants in the sitting position, with their faces immersed in cold water (3-5 degrees centigrade) and with breath-holding for 30 seconds, before a graded exercise test. R-R intervals were recorded before and during the cold face test to determine maximal bradycardia. Heart rate recovery was determined by a graded exercise test on a cycle ergometer. After achieving the peak exercise level, all participants spent 3 minutes in the sitting position. Heart rate recovery was defined as the reduction in the heart rate from the rate at peak exercise to the rates 1, 2, and 3 minutes after the cessation of exercise.
RESULTS: Diving bradycardia was negatively correlated with age ($r = -0.235$, $P < 0.01$). Heart rate recovery at 1, 2, and 3 minutes after peak exercise was also negatively correlated with age ($r = -0.196$, $P < 0.01$; $r = -0.304$, $P < 0.01$; and $r = -0.327$, $P < 0.01$, respectively). Diving bradycardia was longer at the age of 40-49 years than at the age of 50-59 and 60-69 years ($P < 0.01$, all). Heart rate recovery at 2 and 3 minutes was slower at the age of 60-69 years than at the ages of 40-49 and 50-59 years ($P < 0.01$, all).
CONCLUSION: The present study suggests that diving bradycardia and heart rate recovery both deceased with increasing age. Aging appears to be related to an attenuation of diving bradycardia as an index of parasympathetic regulation in people aged over 40 years.

CHANGES OF BODY TEMPERATURE AFTER EXERCISE IN SPINAL CORD INJURY PERSON

HAYASHI, S.

FUKUYAMA CITY UNIVERSITY

INTRODUCTION: In spinal cord injured persons, in the dominant area below the injured level, the superior central command is not transmitted or incompletely transmitted, so that movement disorder not only occurs but also the thermoregulatory responses are slowed or inhibited. It is divided into a complete type in which the spinal cord is transected and an incomplete type which has some function but remaining function but the paralyzed part extends to the nerve and muscles which are dominated below the injury level. The SCI that damaged the spinal cord, the central nervous system, became sympathetic dysregulation dysfunction, and the thermoregulatory function below the injured area was paralyzed. The lack of thermoregulatory functions such as sweating and skin vasodilation, which is a mechanism of heat dissipation, causes excessive rise in core temperature in heat environment. The aim of this study was to clarify the changes of body temperature during exercise and post exercise in heat environment with SCI man.
METHODS: Six healthy Japanese males, as control group, and three spinal cord injury persons, as SCI group, volunteered to take part in this study. The present study was approved by the Ethics Committee of Fukuyama City University (Japan). The subjects remained seated in a chair for at least 10 min before the resting measurement in the sitting position was conducted for 5 minutes. After that the subjects performed the arm cranking exercise at an exercise intensity of 60 % VO2 peak using arm cranking ergometer (881E MONARK) for 30 minutes. The tests were conducted during last autumn when the subjects should have been naturally heat acclimated. HR, RPE and core temperature were monitored each 5 minutes. Measurement after exercise was followed up for 30 minutes per 5 minutes.
RESULTS: The core temperature of SCI during exercise was significantly higher than control group ($p<0.05$). In SCI group, core temperature kept higher until the post exercise phase, and showed that the reduction rate of the body temperature was significantly lower than control group for 30 min ($p<0.05$). There was reported that persons who had damage higher than T11 or T12 lacked the function of skin vasomotor in the sympathetic nervous system, the skin blood flow of the femoral area became invariable, and affected the rise of core temperature. The injury level of this subjects was T10. Therefore, it was suggested that the core temperature kept higher value compared to control group due to lack of thermoregulation.
CONCLUSION: It is necessary to implement cool body for the SCI during exercise and after excise, because of these lacks of thermoregulation in the SCI cause not only heat injury but also impaired exercise performance.

A STUDY ON THE PREVENTION OF HEAT STROKE AT SPORT SPECTATORS UNDER HEAT ENVIRONMENT

IIDA, T., SEKI, K., TAKAGI, Y., NISHIMURA, K., MIYASAKA, Y.

SHUJITSU UNIVERSITY

INTRODUCTION: Spectators of sport games as well as athletes are at the risk of heat stroke. However, a survey on thermophysiological response of the spectators, which are risk factors for heat stroke, has not been reported.
The National High School Baseball Championship in the summer is one of the most popular sport games in the education at schools. Heat stroke in the spectators of high school baseball has recently been recognized. We clarified that the spectators at the baseball game in summer lacked water intake depending on their thirst rating. Therefore, this study aims to clarify the influence of watching a high school baseball game under a hot environment on weight loss amount and urine component.
METHODS: Eight healthy young men (21±1 yrs, 173.0±8.3 cm, 70.0±13.1 kg) volunteered as subjects for this study. Subjects watched DVD of high school baseball game in the climate chamber. The drink condition was that subjects can freely drink the barley tea which is a com-

mon drink in Japan, during watching about 2 hour game. Water intake, weight loss, sweat loss and urinary electrolyte concentration in the subjects were measured.
RESULTS: Air temperatures of the climate chamber during watching games were 33.1±0.2 °C, the humidity were 57.6±1.3% and the WBGT (Wet-Bulb Glove Temperature) were 29.4±0.2 °C. The weight before the game was 70.3±13.1 kg, that of after the game was 69.8±12.9 kg. No significant differences were observed in the body weight between the before and after the game. Additionaly, the subjects drank 453.6±510.3 ml of barley tea and the amount of perspiration was 559.9±248.3 ml, which were almost equivalent values. In contrast, the Na of urinary electrolyte was 1.002±0.681 mEq/gCr before the game, 0.675±0.371 mEq/gCr after the game. Moreover, the Cl was 1.211±0.657 mEq/gCr before the game, 0.788±0.353 mEq/gCr after the game. Futhermore, the Ca was 0.090±0.044 mEq/gCr before the game, 0.048±0.025 mEq/gCr after the game. Three urine components after the game were significantly lower than the one before the game ($P < 0.05$). These results indicates that water intake of spectators drinking barley tea in heat environment are enough, but the electrolyte is insufficiency.
CONCLUSION: We concluded that spectators watching sport events in summer needs to drink sports-drinks to prevention heat stroke.

STRESS-RECOVERY DYNAMICS DURING MOUNT KILIMANJARO CLIMB

PEREIRA, S.1, TAMULEVICIUS, N.2, WADHI, T.2, TIEN, J.J.3, MOSS, S.J.4

1. R.G. SPORTS CENTER, KSA.; 2. THE UNIVERSITY OF TAMPA, U.S.A.; 3. RAHIMA MOOSA HOSPITAL, S. AFRICA; 4. NORTH-WEST UNIVERSITY, S. AFRICA

INTRODUCTION: It can be argued that an athlete's experience has a profound effect on their self-efficacy in physiologically and emotionally stressful situations. The probability of injury in any given situation is influenced by the perception of stress as demonstrated by Anderson and Williams' Stress-injury Model (1988). Stressors within the mountain climbing population include both physiological and emotional aspects; physiological stress is caused primarily by altitude and emotional stress is caused by lack of experience, failure to attain goals, etc. The greater the stress, the greater the vulnerability to injury via attentional or physiological changes (Andersen & Williams, 1988). The aim of this study was to evaluate perception of stress-recovery during a climb of Mt. Kilimanjaro.
METHODS: 84 trekkers (age 42.98 ± 11.62) participated in a cross-sectional survey while climbing Mt. Kilimanjaro (altitude 5895m). The instrument was a Recovery – Stress Questionnaire (RESTQ-76); a close ended questionnaire composed of questions to identify physical recovery, self-efficacy, general stress, emotional exhaustion among other self-reported parameters. Resting Heart rate (RHR) and Oxygen Saturation (SO2) was measured the same time as participants were completing the survey. The survey was administered during seven days of climbing, at rest camps (altitudes ranging from 835m to 4600m).
RESULTS: Experience had a significant impact on RHR ($r=-0.539$, $p<0.001$). Physical Recovery was significantly related to the participants perception of physical fitness and vitality ($r=0.7$, $p<0.001$) as well as their perception of being burnt-out and/or wanting to quit ($r=-0.535$, $p<0.001$). Unpleasant thoughts or actions and/or not achieving goals were related to over-fatigue and lack of proper sleep ($r=0.629$, $p<0.001$). Self-perception of optimal training and preparation was related to the participant's perception of physical fitness ($r=0.696$, $p<0.001$) and also personal accomplishment and enjoyment ($r=0.617$, $p<0.001$). Higher injury rates were related to participants burning out and wanting to quit ($r=0.641$, $p<0.001$). Interrupted breaks or under-recovery showed an increase in general stress levels. ($r=0.588$, $p<0.001$).
CONCLUSION: The survey showed correlations between stress and recovery factors for trekkers in high altitudes. While altitude is known to have impact on RHR (O'Connor et al., 2004), trekkers with experience in higher altitudes had a lower RHR. Interestingly, physically active participants (as per ACSM) did not show any significant relationship with vulnerability to injury or perception of being in shape. As per our knowledge, this was the first study to record self-perceived recovery and stress factors among trekkers in mountains, and while the data is limited to a cross-sectional self-reported survey with a small sample group, it gives us insight into what factors to consider for future research.

THE IMMUNE, INFLAMMATION AND AEROBIC CAPACITY RESPONSE TO LIVING HIGH-TRAINING HIGH-TRAINING LOW UNDER SIMULATED 3200M NORMOBARIC HYPOXIA

GAO, H.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Altitide training has been used by lots of endurance athletes to improve exercise performance. It success belongs to the erythropoietic effect of chronic hypoxia initiated by continuously residing at natural or simulated altitude. Hypoxic dose was an important factor and could influence the altitude training effects. However, several researches reported that the immune system was sensitive to hypoxia. This study was to explore the characteristics of immune response to living high-training high-training low (HiHiLo) during 3-week simulated 3200m hypoxia.
METHODS: Twelve female rowers slept in simulated 3200m normbaric hypoxia at least eight hours a day and trained under 3200m hypoxia two times per week for three weeks. The target heart rate of hypoxic training was 140-160bpm. After 1 day rest every week, blood was taken from cubital veins to measure different kinds of variables. Repeated measures analysis of variance was used to test differences in different time point. Paired T test was employed to compare the difference between two weeks.
RESULTS: (1) During HiHiLo period, WBC count show a significant time effect($P=0.01$). Compared with pre-HiHiLo, WBC count decreased significantly in the 1st week of HiHiLo. GR%, LY% and MO% had no obvious change. (2) There were a significant time effect both in T% and NK%（$P=0.046$、0.048）. In the 1st week of HiHiLo, T% elevated and NK% decreased significantly compared with pre-HiHiLo. (3) No significant time effect was observed in the count and percentage of CD4+ and CD8+. But the ratio of CD4+ to CD8+ decreased obviously in the 1st week after 3-week HiHiLo. (4) No significant time effects were observed in B%, IgA, IgM and IgG during HiHiLo period. (5) Plasma CRP kept in a normal range and show an obvious time effect. Compared with the 1st , 2nd and post-1st week of HiHiLo , plasma CRP of the 3rd week was obviously lower. No significant time effect of plasma IL-6 and TNF-α existed. (6) After 3-week HiHiLo, the blood lactate reduced significantly in 120W and 160W （$P=0.001$, 0.047）and the heart rate decreased significantly in all three steps（all $P<0.01$）.
CONCLUSION: 3-week living high-training high-training low under simulated 3200m normobaric hypoxia in low to middle aerobic intensity training period could improve aerobic capacity of female rowers. But it may lead to immunological stress in the first week. This stress will be alleviated gradually in the next two weeks. During HiHiLo, the inflammation response didn't show significant change. In the first week after HiHiLo completed, the immune function may shift toward suppression.

HEART RATE VARIABILITY CHANGES DURING PACED BREATHING MANEUVER PRE- AND POST-CONCUSSION

NEARY, J.P.1, SINGH, J.1, PISKORSKI, J.2, SIRANT, L.W.1, DECH, R.T.1, GUZIK, P.3

1:UNIVERSITY OF REGINA ; 2:INSTITUTE OF PHYSICS, UNIVERSITY OF ZIELONA GORA ; 3:CARDIOLOGY-INTENSIVE THERAPY, POZNAN UNIVERSITY OF MEDICAL SCIENCES

INTRODUCTION: Slow paced breathing at a rate of 6 breaths per minute (6-bpm) may force different cardiovascular oscillations to subdue to its rhythm, and it also modifies the autonomic function. The 6-bpm breathing augments the heart rate variability (HRV), i.e., an indirect and non-invasive marker of the autonomic control of the duration of cardiac cycles (RR intervals). Each pair of consecutive RR intervals is represented as one point in the Poincare plot of RR intervals, and all points in this plot contribute to both short- (SD1) and long-term (SD2) HRV (Guzik et al., 2007). Consecutive RR intervals generate monotonic (i.e., changing in the same direction) runs of the length of 1, 2, 3, 4 or more beats in a row. The acceleration runs are composed of such neighbouring RR intervals which only shorten one after another, the deceleration runs represent trains of RR intervals which consecutively prolong. This method describes the asymmetric structure of heart rate (Piskorski & Guzik, 2007). It is known that concussion leads to autonomic dysfunction, but research analyzing the effects of the 6-bpm breathing on HRV recorded pre- and post-concussion is non-existent.
METHODS: We aimed to compare the parameters of Poincare plots and monotonic runs of RR intervals recorded during the 6-bpm breathing protocol before and after head injury leading to concussion in otherwise healthy athletes. During the prospective observation, we collected data from 14 athletes (n=6 female) who underwent pre-season baseline HRV recording and came back within 72 hours post-head injury to complete the same protocol. All recordings for HRV were acquired at seated rest during the 5-minute spontaneous and the 5-minute paced 6-bpm breathing (guided breathing with equal 5-second duration of inspiration and expiration). Raw ECG tracings were exported at 250 Hz and analyzed beat-to-beat using an RR interval reader to adjust for any artifacts and premature beats. Data were analysed with the non-parametric paired Wilcoxon test and logistic regression models for the differentiation between pre- and post-concussion.
RESULTS: Despite a mean reduction of 5.7 ms in SD1 and 14.6 ms in SD2, there were no significant differences pre- to post-concussion. However, visual representations of the Poincare plots showed clear differences between both conditions. Furthermore, when analysed using a multivariate logistic regression predictive model consisting of decelerating runs of lengths 6 (0.4755, p=0.1290), 7 (-2.4465, p=0.0893), and 9 (-10.2061, p=0.9932), and accelerating runs of lengths 5 (-0.7183, p=0.0319), 7 (-0.3532, p=0.0803) and 10 (-0.6214, p= 0.0579), statistical significant was observed.
CONCLUSION: Our preliminary results suggest that the slow paced breathing at a rate of 6-bpm may reveal different patterns of the mutual relations between the consecutive RR intervals and the asymmetric features of the structure of heart rate. Further prospective research with an increased number of athletes at risk of concussion is required.

INFLUENCE OF ACUTE MODERATE-INTENSITY ENDURANCE EXERCISE ON ENDOTHELIAL FUNCTION IN OLDER HYPERTENSIVE RATS

WU, T.H.1, YANG, A.L.1, SU, C.T.2

1: UNIVERSITY OF TAIPEI ; 2: FU JEN CATHOLIC UNIVERSITY

INTRODUCTION: As the society is gradually entering the trend of aging, the prevalence of hypertension has been parallel increased. Advancing age has revealed the impairments of endothelial function and antioxidant activity which may induce more severity of pathology when combining with the influence of hypertension (Higashi et al., 2012). Moreover, exercise is well known in regulating blood pressure and cardiovascular function (Heckman et al., 2008). However, the effects of a single endurance exercise on endothelial function (i.e. vasorelaxation) in aging hypertension have not yet been clarified.
METHODS: Twelve-month-old spontaneously hypertensive rats (SHR) were randomly divided into two groups: the acute exercise (SHR-AEX) and sedentary control (SHR-CON) groups. The age-matched Wistar-Kyoto rats (WKY) were served as the normotensive control group. The SHR-AEX group was completed by a single bout of treadmill running at the moderate intensity (21 m/min) for 60 min. At the end of experiments, the endothelium-dependent vascular responses of aortic rings were evaluated by the organ bath system. Moreover, serum antioxidant activities, including superoxide dismutase (SOD) and catalase (CAT), were measured and compared among three groups.
RESULTS: After a single bout of treadmill running, the SHR-AEX group showed significantly ($p < 0.05$) higher acetylcholine (ACh)-induced vasorelaxation compared with the SHR-CON group, while that was significantly ($p < 0.05$) lower than the WKY group. Similarly, the serum SOD and CAT activities were significantly ($p < 0.05$) increased in the SHR-AEX group compared with the SHR-CON group.
CONCLUSION: The results of this study suggested that a single bout of moderate-intensity endurance exercise could reverse the endothelial function in terms of vasorelaxation in older hypertensive rats in part via the increase in antioxidant activities. The non-pharmacological modification, such as the moderate-intensity treadmill exercise, could be considered as the prevention and treatment of cardiovascular disorders in aging population with hypertension.

THE METABOLIC CHANGES IN THE HIPPOCAMPUS OF AN ATHEROSCLEROTIC RAT MODEL

LOU, S., LIU, B., LI, J.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: Atherosclerosis has been associated with the progression of cognitive impairment and dementia [1]. Several features, such as high oxygen consumption, a large content of peroxidation-sensitive polyunsaturated fatty acids and a strong dependency on the supply of glucose are features that make the brain vulnerable to metabolic changes even very small [2-3]. The hippocampus is closely related to memory and learning function, and prone to ischemic injury. However, applying Metabolomics technology to explore metabolites of hippocampus from atherosclerosis animals is rarely reported. We aim to reveal the metabolic changes in the hippocampus during atherosclerosis.
METHODS: We established a rat model of atherosclerosis by 10 weeks high-fat diet combined with intraperitoneal injection of vitamin D3 along with control group . Feeding all rats with basal diet for another 4 weeks, a Y maze test was performed to evaluate initial memory and the Metabolomics was applied to detect small moleculer metabolites in hippocampus.

RESULTS: After 4 weeks of diet intervention, The M group entered less frequently into and spent less time in the novel arm than rats from C group . Compared to the control group, metabolites including xylulose 5-phosphate, ribose 5-phosphate, glycerate 3- phosphate, succinate, nonanoic acid, and desmosterol were markedly elevated in the M groups, whereas methyl arachidonic acid and methyl stearate decreased.
CONCLUSION: Atherosclerosis induced by high-fat diet and intraperitoneal injection of vitamin D3 could cause cognitive impairment in rats. A series of metabolic changes implicated in the hippocampus of atherosclerotic rats, including a decrease in anaerobic glycolysis and TCA cycle, an activation of Pentose Phosphate Pathway and a disturbance in fatty acid oxidation and cholesterol synthesis, which could lead to insufficient ATP in hippocampus and relate to the behavioral changes of atherosclerotic rats.

LEFT VENTRICULAR DIASTOLIC FUNCTION IS ENHANCED AFTER PEAK EXERCISE IN ENDURANCE-TRAINED ADOLESCENTS

RUNDQVIST, L.

JÖNKÖPING UNIVERSITY

INTRODUCTION: The cardiac response to an intense exercise session has been widely studied especially in athletic, but also in sedentary adults. However, very little is known about the normal response to exercise of the growing heart in well-trained as well as in untrained adolescents. The echocardiographic technique provides useful insights into systolic function evaluated by using parameters including left ventricular ejection fraction (LVEF), while left ventricular (LV) diastolic function assessment include annular e' velocity and filling pressure estimated by mitral E/e' ratio. Also, cardiac volumes such as left ventricular end diastolic volume (LVEDV) are obtained by echocardiography. During exercise, ventricular filling time is reduced due to the higher heart rate, thus increase in LV inflow velocity is of importance to enable a larger stroke volume without further increase in filling pressure. An improved diastolic capacity in response to exercise may therefore be crucial in endurance trained subjects, to facilitate LV filling when the heart rate rises. The aims of the study were to explore the temporal development of cardiac functional changes after peak exercise in adolescents, and to explore how these functional changes relate to maximal oxygen uptake (VO2max).
METHODS: The participants were 27 endurance-trained adolescents aged 13-19 years, and 27 controls individually matched by age and gender. LV systolic and diastolic function was performed by echocardiography at rest and immediately after a maximal cardio pulmonary exercise test (CPET) on a treadmill. VO2 was estimated by the CPET.
RESULTS: Immediately after exercise, LVEF was increased (from 61% to 73% in the active group, and from 59% to 72% in the controls, $p<0.001$ for both), as well as the septal E/e'-ratio (from 9.2 to 11.0; $p<0.001$ in the active group, and from 8.7 to 10.2; $p=0.008$ in the controls). Further, when comparing the groups after CPET, the E/e' ratio was higher in the active group compared with the controls ($p=0.012$). We also demonstrated a correlation between VO2max and cardiac function after CPET where the strongest correlation was found between VO2max and LVEDV ($r=0.67$, $p<0.001$), and filling pressure E/e' ($r=0.34$, $p=0.013$).
CONCLUSION: LV systolic response to exercise was similar in endurance-trained adolescents and their controls. In addition, enhanced diastolic function was found in both groups, but was more pronounced in the active group. Much of the variation in VO2max was explained by a combination of increased cardiac dimensions (predominantly LV) and filling pressure. Regardless of the intensity of practicing endurance exercise, these findings have practical implications when assessing cardiac function during exercise in youngsters.

EFFECTS OF LOCAL AND REMOTE ISCHEMIC PRECONDITIONING ON CRITICAL POWER AND MUSCULAR OXYGENATION DURING 3-MIN ALL-OUT EXERCISE

CHENG, C.F.1, HSU, W.C.2, PAN, C.H.1, KUO, Y.H.3, LIN, Y.S.3, TING, S.F.1

1: NATIONAL TAIWAN NORMAL UNIVERSITY, 2: UNIVERSITY OF TAIPEI, 3: NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: The local (IPC) and remote (RIPC) ischemic preconditioning, involves brief cycles of ischemia and reperfusion, may have a cardioprotective benefit via humoral and neural pathways, e.g., increases in nitric oxide (NO) or decreases in sympathetic activity [3]. The 3-min all-out cycling test (3MT) has been developed to estimate critical power (CP) and the curvature constant for severe exercise (W') [4]. This study examines the effects of IPC and RIPC on 3MT performance, vascular function, and muscular blood flow in athletes.
METHODS: Fifteen male athletes (VO2max, 59 ± 5 ml/kg/min) were recruited in this study. At visit one, participants performed an incremental cycling test to determine the resistance of 3MT. Visits 2 and 3 served as familiarization and control (CON) trial. During the following visits, participants performed IPC, RIPC, or SHAM trial in a randomized crossover design, separated by 3 days. The 3MT was performed 45-min after each treatment. The tissue saturation index (TSI), deoxyhemoglobin (HHb), and total hemoglobin (tHb) of right quadriceps were measured by near-infrared spectroscopy at each trial. Blood samples for vascular endothelial growth factor (VEGF), NO, norepinephrine (NE), pH, lactate (La) concentrations were drawn before and 30-min after treatment, and 5-min after 3MT. The oxygen uptake (VO2) were continuously measured during 3MT.
RESULTS: The TSI during IPC intervention was significantly lower than those in RIPC and SHAM (IPC vs. RIPC vs. SHAM, 53.4 ± 4.2 vs. 64.5 ± 3.7 vs. 63.8 ± 3.6%, $P < 0.05$). During the rest interval between intervention and 3MT, HHb and tHb in IPC were significantly higher than those in RIPC and SHAM ($P < 0.05$). However, no significant differences on TSI and HHb during 3MT were found among treatments. No significant interaction effects in VEGF, NE, NO, pH, and La levels were found among treatments. There were also no significant differences in peak VO2 (IPC vs. RIPC vs. SHAM vs. CON, 58 ± 4 vs. 58 ± 5 vs. 57 ± 6 vs. 58 ± 4 ml/kg/min, $P > 0.05$), CP (IPC vs. RIPC vs. SHAM vs. CON, 242 ± 32 vs. 244 ± 32 vs. 238 ± 30 vs. 235 ± 34 W, $P > 0.05$), and W' during 3MT among treatments.
CONCLUSION: The IPC or RIPC might result in vasodilation and increase oxygen delivery and extraction [1, 2], thus improving aerobic performance [3]. This study found that IPC might increase the resting blood flow in affected muscles, however, this increase may not relate to the regulating factors of endothelial function. Overall, neither IPC nor RIPC could improve the 3MT performance and muscle blood flow during intense exercise. Supported by grants from Ministry of Science and Technology, Taiwan (MOST 106-2628-H-003-008-MY2).

VALIDITY OF SINGLE POINT ASSESSMENTS FOR DETERMINING LEG PULSE WAVE VELOCITY IN SITTING AND SUPINE POSITIONS

FRYER, S., STONE, K., ZIEFF, G., DICKSON, T., FAULKNER, J., BROWN, M., STONER, L.

UNIVERSITY OF GLOUCESTERSHIRE

INTRODUCTION: There has been a great deal of recent interest in the effects of sedentary behaviour on cardiovascular health. In particular, prolonged sitting has been shown to reduce leg vascular function. However, studies have relied on complicated techniques, which limits further investigation as such studies necessitate: (i) highly skilled investigation, and (ii) small sample sizes. One potential solution is the use of B-mode ultrasound to estimate pulse wave velocity (PWV, arterial stiffness) at a single point in the legs. Therefore, this study sought to determine the accuracy of single point PWV measures obtained using B-mode ultrasound in supine and seated positions by comparing to a criterion, conventional 2-point (femoral-posterior tibialis) pulse wave velocity (fptPWV). Single point PWV assessments were made on the superficial femoral and posterior tibialis (PT) arteries using three different equations. Two equations estimated PWV using local changes in arterial diameter and blood pressure, using a derivative of β-stiffness index or Bramwell-Hill (BH). The third equation estimated PWV using local changes in arterial diameter and blood flow (BF).
METHODS: Thirty-two young, healthy adults (25.7 y, 50% F, 24.7 kg.m2) were recruited, of which 31 had complete data. Following an overnight fast, and 10 minutes of quiet supine rest an ECG gated linear array ultrasound probe was used to capture 3 x 10 s images of the PT and femoral arteries in both seated and supine positions. From this, regional (criterion two-point) and site-specific (single point) measures of fptPWV were determined (transit time from femoral to PT artery) using β-stiffness and BH equations, as well as BF estimations in both positions.
RESULTS: The accuracy of the test was considered acceptable if the absolute standard error of estimates (aSSE) was <1.0 m/s. In the supine position, the aSSE for β-stiffness, BH, and BF equations was 1.7, 2.0 and 5.5 for the femoral artery, and 2.7, 3.2 and 6.1 for the posterior tibialis. In the seated position, the aSSE (m/s) for β-stiffness, BH, and BF equations was 1.5, 1.6 and 3.4 for the femoral artery, and 3.0, 3.4 and 5.6 for the posterior tibialis
CONCLUSION: The single-point PWV equation based on β-stiffness index was consistently closest to the criterion 2-point PWV, for both arteries and both body positions. However, β-stiffness PWV assessments did not meet the criteria for acceptable validity, meaning the two measures cannot be used interchangeably. Further work is warranted to determine whether both types of assessment respond similarly to perturbations, and which type of assessment best explains subsequent central hemodynamic burden.

THE VARIABILITY OF PHYSIOLOGICAL PARAMETERS DURING SPEEDWAY RACING

GABRYS, T.1, SZMATLAN-GABRYS, U.1, STANISZ, L.2

1JAN DLUGOSZ UNIVERSITY , 2PWSZ

INTRODUCTION: Physical effort in motorcycle sports was the subject of studies by Gobbi et al. 2005, DArtibale et al. 2007. A competitor in speedway during start, undertakes 5-6 times, the 60 second physical effort, in the course of which he increases velocity from 55-60km/h to 100 km/h and takes turns 8 times on a surface of variable hardness. The aim of the study was to determine the value of the physiological indexes during the starting effort as compared to the maximum values obtained by a given competitor.
METHODS: The participants of the study were 6 speedway riders (age, height, and body mass were 26 ± 3 years, 175 ± 6 cm, and 68.4 ± 3,2 kg), members of the Polish Speedway League. The subjects undertook, in laboratory conditions, an effort on cycloergometer Velotron (USA), in accordance with the GExT test program (Nolan et al. 2014) After 7 days, the participants undertook the starting physical effort 5 times on a speedway track. The values of the physiological indexes (VO2, VE,HR, VO2HR, and RF) were registered during both physical efforts by means of the K4B2 (Cosmed), and Polar Team (Polar) analyzers.
RESULTS: Physiological indexes during physical effort in speedway obtain variable values, as compared to the maximum values. HR is closest to the maximum values: 88-96% (181-192ud/ min), and so is RF : 82-90% (49-53 b/min) The VO2 values reach the level of 55-68% of the VO2max (35-44ml/kg/min), and VO2HR 60-68% (13-14 ml/bpm). The lowest values as compared to the maximum ones, are characteristic of VE: 40-49 (70-85 l/min). The variability of values between runs 1, and 5, is of the order of 6-8%, with the exception of VO2, and VE which exceed 10 %.
CONCLUSION: A low level of VO2HR during physical effort at the level of 60-70% of the maximum value, with heart systole frequency values from 90-95% of the maximum value, indicates a strong activation of the circulatory system without using it to transport oxygen. The competitor, during the effort on a cycloergometer, with the same HR values, supplies his organism with 30-40% more oxygen. The dynamics of the changes in the values between the runs, indicates a low level of index variability among runs 1, and 5. The greatest differences are: a decrease in the VO2 value by 10%, and an increase in VE by 11% . A competitor in speedway undertakes a physical effort, aided, to a significant extent by anaerobic metabolism, with the activation of the aerobic metabolism indexes, to the level of 55-70% of the individual maximum values.

PECULIARITIES OF MUSCLE OXYGENATION IN WORLD-CLASS KAYAKERS

DADELIENE, R.1, NEKRIOSIUS, R.2, MILASIUS, K.3

1 VILNIUS UNIVERSITY; 2 LITHUANIAN SPORTS UNIVERSITY; 3 LITHUANIAN UNIVERSITY OF EDUCATIONAL SCIENCE

INTRODUCTION: The distance of 1000 m, performed by elite kayak rowers, takes 3-4 minutes. Essential role in such duration intense work is played by aerobic metabolism processes in muscles. Finding the training methods which could improve this metabolism appears as a rather difficult task. Therefore, the aim of the study was to analyze an effect of applying short distances interval training workouts of high intensity for world-class kayak rowers' muscle oxygenation.
METHODS: Case study was carried out during preparatory cycle in 1917- 2018. Two World vice champions (aged 29 and 30 years) participated in this study (K2). Athletes were respectively 184 and 186 cm high, body mass – 62.5 and 64.3 kg., muscle mass - 48 and 50 kg, maximal oxygen consumption – respectively 62.5 and 64.3 ml/min/kg. Muscle oxygenation was measured using MOXY Oxygen Monitor device while athletes worked on kayak ergometer DANSPRINT during high intensity interval training (0-10 sec – 300 W, 11-30 sec 80 W) training load repeated 6 times with 6 min rest. Sensors were fixed on athletes' Quadriceps and Pectoralis Major Muscles.

RESULTS: After 6 times repeated high intensity interval 10 sec training load, muscle oxygen consumption decreased to 45 pct in Quadriceps and to 20 pct in Pectoralis Major Muscle. During light work load (11-30 sec 80W) oxygen consumption recovery in both muscles reached 70-80 pct. After 6 min in rest position, oxygen consumption in the muscles recovered to 85 pct, while the lactate level was less 2 mmol/l.
CONCLUSION: This study revealed that high intensity interval training load provokes big changes in muscles oxygenation while the muscles are working in aerobic metabolism zone.

COUPLING OF LOCAL MUSCLE DEOXYGENATION AND HEART RATE CONTROL DURING INCREMENTAL CYCLING DEPENDS ON EXERCISE INTENSITY – INSIGHTS FROM TRANSFER ENTROPY ANALYSIS

WEIPPERT, M., BRUHN, S., PETELCZYC, M.

UNIVERSITY OF ROSTOCK, WARSAW UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Besides other mechanism (e. g. local vasodilation and stroke volume) an increase in heart rate (HR) contributes to muscle perfusion and thus O2 supply. Regulation of this autonomic adjustment encompasses central command as well as afferent signaling mechanisms, i. a. feedback from local metaboreceptors. Here, we propose the analysis of the driving component between the period between adjacent heartbeats (R-R or instantaneous HR) and working muscle O2-desaturation (= relative portion of deoxygenated Hb/Mb to total Hb/Mb, %HHb) during incremental dynamic exercise performed until volitional exhaustion. Considering different contributions of feedback- and feedforward-mechanisms affecting autonomic HR control during incremental exercise, we hypothesized that during lower intensities the level of %HHb, s. l. afferent signaling from metaboreceptors, dominates R-R control, while the R-R „signal" should dominate over %HHb during higher exercise intensities.
METHODS: Ten regional level male triathletes participated in an incremental cycle test consisting of a 5 min baseline at 50 W, followed by 25 W*min-1 ramp increments until volitional exhaustion and a recovery period at 50 W immediately after peak exercise. R–R intervals and the level of right vastus lateralis (VL) %HHb as well as respiratory responses were continuously recorded. Five corresponding R-R interval and %HHb segments were used for the time series analysis: 1) at baseline; 2) segment before the gas exchange threshold (preGET); 3) between GET and the respiratory compensation point (preRCP); 4) after RCP (postRCP) and 5) during recovery (REC). The time series were interpolated and detrended before bivariate transfer entropy (BTE) [2] computations. A non-zero value of BTE is an indicator of coupling between the components (here R-R and %HHb), with a larger magnitude representing a stronger and a lower magnitude representing a weaker relationship between the physiological signals. The parameter dBTE, a measure of the difference of BTE values, indicates the direction of the coupling.
RESULTS: ANOVA revealed a strong effect of exercise intensity on the coupling between %HHb and HR ($F(4;36) = 4.416$, $p = 0.005$, $\eta p2 = 0.329$).
CONCLUSION: Successive phases during incremental exercise are characterized by changing BTE magnitudes for HR and VL %HHb and thus, dBTE. Significantly different dBTE are obtained for the preGET, preRCP and REC. While %HHb is the leading signal during low intensity aerobic exercise, the opposite relation is observed during moderate intensity exercise. These changes may indicate distinct autonomic modulation patterns and mechanisms of cardiovascular control during incremental cycling [3].

PRESSURE-DEPENDENCY AND MEASUREMENT OF ARTERIAL STIFFNESS

STONE, K.1, ZIEFF, G.2, FRYER, S.1, BURNETT, K.2, KELSCH, E.2, FAULKNER, J.3, STONER, L.2

1UNIVERSITY OF GLOUCESTERSHIRE , 2UNIVERSITY OF NORTH CAROLINA , 3UNIVERSITY OF WINCHESTER .

INTRODUCTION: Arterial stiffening (AS) is thought to be one of the earliest stages of the atherosclerotic process, and is an independent predictor of cardiovascular risk. AS can be measured at a single site of physiological importance using ultrasound. Ultrasound-derived AS measures include distensibility coefficient (DC), compliance coefficient (CC), beta-stiffness index (ß) and estimations of pulse wave-velocity (PWV). Estimates of PWV include a derivative of the ß-stiffness index (PWVß), the Bramwell-Hill equation (PWVbh), as well as an estimation based on local changes in blood-flow (PWVbf). Of concern, measures of arterial stiffness, including those derived from ultrasound, are known to be confounded by blood pressure (BP), making it challenging to compare individuals and track longitudinal cardiovascular risk. The purpose of the current study was to assess which of the six single-point ultrasound-based methods used to estimate AS is least dependent on BP.
METHODS: Twenty healthy young adults (26.7 y, 55 % F, 24 kg/m2) were recruited. BP was acutely manipulated using gravity. In a randomized order, a linear array ultrasound transducer was used to capture three 10 s images of the brachial artery of the experimental left arm, with the arm positioned at (0 deg.), above (+30 deg.) and below (-30 deg.) heart level. Peripheral BP was simultaneously measured on experimental and control arms. The control arm was kept at heart level. The AS markers DC, CC, ß, PWVß, PWVbh and PWVbf were calculated. The AS method with the smallest effect size (partial eta squared, ηp) was presumed to be the least pressure-dependent.
RESULTS: There was a significant main effect of arm position on all AS measures, with a large effect size ($\eta p = 0.297 – 0.511$) for all measures except PWVbf for which the effect size was medium ($\eta p = 0.068$). For all measures, there was a non-significant change when the arm was elevated above the heart; however, each measure, except CC and PWVbf changed when the arm was positioned below the heart. When the arm was positioned below the heart, and when compared to heart level, the contrast indicated a non-significant 23% decrease in CC, and 12% non-significant increase in PWVbf.
CONCLUSION: This study demonstrated that six ultrasound based, single-point methods for assessing AS are all impacted by BP, with the order from least to most dependent on BP being: PWVbf, CC, ß, DC, PWVbh, and PWVß. While the PWVbf method appeared to be the least BP-dependent, potential sources of error, regarding the physiological principles within the mathematical models as well as operator-error, must be considered. Based on the current findings, and considering potential sources of error, CC would appear to be the most robust single-point measure of AS.

PLASMA ATRIAL NATRIURETIC PEPTIDE VS. CVP FOR EVALUATION OF PRELOAD TO THE HEART DURING EXERCISE IN HUMANS

VOLIANITIS, S., YOSHIGA, C., DAWSON, E.A., WARBERG, J., SECHER, N.H.

AALBORG UNIVERSITY

INTRODUCTION: This study evaluated the effect of the presumed different central venous pressure (CVP) response to running and rowing on preload to the heart. Preload was indicated by distension of the atrium as evaluated by plasma arterial natriuretic peptide (ANP) and related to cardiac output (CO).
METHODS: Seven healthy subjects rested in sitting and standing positions and then rowed and ran (in random order) at submaximal workloads, while CVP was recorded, CO (Modelflow) calculated, and arterial plasma ANP determined by radioimmunoassay.
RESULTS: While sitting CO was 6.2 ± 1.6 l/min, plasma ANP 70 ± 10 mg/ml, and CVP 1.8 ± 1.1mmHg (mean ± SD) and decreased to 5.9 ± 1.0 l/min, 63 ± 10 mg/ml, and -3.8 ± 1.2 mmHg when standing ($P<0.05$). Ergometer rowing elicited an increase in CO to 39.9 ± 9.8 l/min as plasma ANP increased to 156 ± 11 mg/ml and CVP to 3.8 ± 0.9 mmHg. Similarly, CO increased to 38.3 ± 9.8 l/min during running with a similar albeit smaller ($P<0.05$) increase in plasma ANP, but with little change in CVP (around -0.9 ± 0.4 mmHg).
CONCLUSION: During exercise the increase in CO is curvilinearly related to plasma ANP, as an indication of preload to the heart, but it is unrelated to CVP. The results indicate that in the upright posture CVP reflects the gravitational influence on central venous blood and not preload to the heart.

EFFECTS OF ENVIRONMENTAL ENRICHMENT ON PHYSICAL ACTIVITY AND BODY TEMPERATURE IN MICE

KIMURA, M., ISHII, R., HIRANO, N., UCHIDA, R., SAITO, Y., SAITO, H.

KEIO UNIV., FACULTY OF PHARMACY

INTRODUCTION: There is little evidence of the effect of Environmental Enrichment (EE) on many research fields. The purpose of this study was to investigate the effects of EE condition on physical activity and body temperature compared to other physical activity increased conditions in mice.
METHODS: 24-week-old male ICR mice were assigned to an EE condition (56x30x38 cm cage with a dome, ladders, tunnels, and wheels), a free wheel running condition (WR), a daytime one-hour treadmill running training condition (TR), or a normal condition (CO: 30x20x12 cm cage) under individual (Experiment I, n=1) or group (Experiment II, n=4) housing. Mice were continuously monitored their 3-dimensional activity and body temperature using the NanoTag wireless telemetry device implanted within their peritoneal cavity. In Experiment III, 4-week-old male ICR mice were assigned to EE (n=8) or CO (n=8) condition for 20 weeks. After the experimental period, a grip strength test, a beam walk test, and an escape test were performed for all mice.
RESULTS: Under EE condition, mice performed more active moving using many equipment in group housing compared to individual housing. They showed high body temperature during night time as same as WR condition. TR condition induced very low activity during night time. Mice in EE condition did not show significant increase in muscle strength, but they could get good balanced walking and quick vertical jumping abilities compared to mice in CO condition.
CONCLUSION: These data suggested that the Environmental Enrichment may produce beneficial effects on the health compared to other physical activity increased conditions especially in group housing mice.

EFFECT OF IMMERSION IN THE VIRTUAL REALITY USING OCULUS RIFT OF THE POSTURAL STABILITY AND CIRCULATION.

TAKAHASHI, K.

TOKYO ARIAKE UNIVERSITY OF MEDICAL AND HEALTH SCIENCES

INTRODUCTION: The oculus rift is very well-developed virtual reality. We have studied injury protection using virtual reality. Further we have studied heart rate and blood pressure using virtual reality. This study investigated biological response to immersion in the virtual reality induced by oculus rift.
METHODS: Healthy ten adult participated in this study. We measured their height, body weight, center of gravity sway and electromyogram (EMG), heart rate (HR), blood pressure. The center of gravity sway was measured by the force plate and total locus length (LNG) and rectangular area (REC.A) were calculated. EMG of rectus femoris muscle, hamstring, gastrocnemius muscle and tibialis anterior muscle were measured. Posture measurements were compared between normal condition and virtual reality condition during a standing position. Video of ski jump was used for the virtual reality condition. Circulation measurements were compared between normal condition and virtual reality condition during a sitting position. Video of roller coaster was used for the virtual reality condition.
RESULTS: REC.A at normal condition was 3.98 ± 2.25 cm2. REC.A significantly increased in the virtual reality condition (8.28 ± 4.38 cm2). LNG also increased in the virtual reality condition. Rectus femoris muscle and hamstring activity did not differ between the two conditions. Gastrocnemius muscle activity significantly increased in the virtual reality. HR and blood pressure was changed after the virtual reality. HR at post was 69.2 ± 8.9 bpm HR significantly increased in the virtual reality condition (80.8 ± 9.7 bpm). Blood pressure significantly increased in the virtual reality condition.
CONCLUSION: The present study indicates that immersion in the virtual reality affect center of gravity and circulation in healthy adults. The present results suggest a possibility that the immersion in the virtual reality is effective to misunderstanding of recognition.

TREADMILL RUNNING IMPROVES WORKING MEMORY IN LACTATIONAL DI-(2-ETHYLHEXYL) PHTHALATE-EXPOSED MALE RATS

LEE, Y.C.

TAINAN UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Aerobic exercise can improve learning and memory by enhancing the expression of brain-derived neurotrophic factor (BDNF) (Singh and Staines, 2015). Early life exposure to di-(2-ethylhexyl)- phthalate (DEHP), a plasticizer usually applied in polyvinyl chloride manufacture, may impair the expression of BDNF in rats (Smith and Holahan, 2014). In this study, we investigated the effects of treadmill running on the expression of BDNF and the performance of working memory in juvenile male rats that were exposed to DEHP during their lactational period.

METHODS: Rat dams were fed with vehicle or DEHP (10 mg/kg per day) during lactation. After weaning, the male offspring were divided into 4 groups: control (C), DEHP (D), exercised control (Cex), and exercised DEHP (Dex). Rats were trained to exercise on a treadmill for 8 weeks from the ages of 4 weeks to 12 weeks and then the working memory was examined by delayed non-match-to-sample task. The biomarker of exercise on brain was evaluated by measuring the plasma levels of brain-derived neurotrophic factor (BDNF).
RESULTS: The results demonstrate that the DEHP-exposed rats exhibited decreased working memory at their juvenile stage. Decreased expression of hippocampal BDNF was observed in the DEHP-exposed animals. Importantly, in the DEHP-exposed animals, treadmill running recovered the working memory by normalizing the expressions of BDNF.
CONCLUSION: Early-life exercise can enhance capacity to evoke memories and reduced risk of neurodegenerative diseases in later life. The findings of this study suggest that treadmill running may provide beneficial effects on ameliorating the dysfunction of brain in the lactational DEHP-exposed male rats at their young age.

EFFECT OF CHRONIC AEROBIC EXERCISE ON OVALBUMIN - INDUCED ANAPHYLAXIS IN MICE.

SHIIBA, D., ONO, D., TOKIMITSU, H., INOUE, S., ITAMI, H., URAKAMI, T., OKAZAKI, T., KURODA, S., YAMAMOTO, K., FURUMOTO, K.

KURASHIKI UNIVERSITY OF SCIENCE AND THE ARTS

INTRODUCTION: Past few decades, there is an increased the patient with food allergy including anaphylaxis in the world, especially western countries. It has hoped that establish the novel approaches for preventing to food allergy. Recently, several studies reported that chronic aerobic exercise induces immunomodulatory cells such as regulatory T cell (Treg) that it involved to prevent the allergic reaction including allergen-specific antibodies production. Therefore, chronic aerobic exercise might prevent food-dependent anaphylaxis. However, effect of chronic aerobic exercise on food-dependent anaphylaxis remains unclear. In this study, it was determine the effect of chronic aerobic exercise on chicken egg ovalbumin (OVA) - induced anaphylaxis in mice.
METHODS: 6-week-old male BALB/c mice were randomly assigned to two groups that sedentary groups (SED) and chronic aerobic exercise (EX). EX mice engaged the voluntary wheel running for eight weeks (from Week 1 to Week 8). SED and EX mice were immunized intraperitoneally with 50μg of OVA emulsified in 2 mg of aluminium hydroxide as adjuvant in a total volume of 100ul on Week 4, 5 and 7. Anaphylaxis was induced by 300μg OVA intraperitoneal injection on Week 8 to SED and EX mice. Anaphylactic symptoms were evaluated with rectal temperature and hematocrit value. Rectal temperatures were measured 5, 10, 15, 20, 25, 30, 45, 60 and 90 minutes after OVA injection. Blood sample were collected to measure the hematocrit value on 90 minutes after OVA injection.
RESULTS: In time-course of the change of rectal temperature, the decreases in rectal temperature by OVA injection were significantly prevented in EX mice compered with SED mice ($p<0.05$). In addition, elevation of hematocrit value were tendency to prevent in EX mice compered with SED mice (SED : 50.3±1.9% vs EX : 46.0±2.3%).
CONCLUSION: Our study suggest that that is voluntary wheel running prevents OVA-induced anaphylaxis in mice. These findings might indicate that chronic aerobic exercise has potential approaches of preventing a food allergy and anaphylaxis.

ACUTE MODERATE INTENSITY CYCLING IMPROVES RECOGNITION MEMORY AND INCREASES CIRCULATING BRAIN-DERIVED NEUROTROPHIC FACTOR IN YOUNG ADULT MALES

MCCREDDIN, S.V., GILLIGAN, K., KELLY A.M.

TRINITY COLLEGE DUBLIN

INTRODUCTION: Regular physical activity targets several aspects of brain function and positively affects brain health across the lifespan (Kelly 2015). A growing body of evidence, however, shows that single bouts of exercise may improve short-term cognitive function, perhaps in a task-specific manner, but the biological mechanisms underlying this effect are not well understood. Furthermore, it has been suggested that exercise-induced cognitive improvements may depend on exercise duration, modality and intensity (Grego et al 2004). Here, the effects of moderate and maximal intensity cycling on measures of executive function and recognition memory were assessed in sedentary young men. In parallel, the circulating concentration of brain-derived neurotrophic factor (BDNF), which has been suggested to mediate exercise-induced effects of exercise on cognitive function in both humans and animals, was also assessed.
METHODS: Participants (n=20) completed an object scene recognition task and a Stroop colour-word task pre- and post-cycling exercise on two separate laboratory visits. In the case of controls, a period of rest was substituted for exercise. Exercise bouts consisted of a VO2max test in the case of maximal exercise, or a 30min cycle corresponding to 60% VO2max in the case of moderate exercise. Venous blood samples were taken prior to exercise, immediately post-exercise and 30min post-recovery; plasma was prepared and later analysed for BDNF by ELISA.
RESULTS: Neither maximal not moderate exercise induced any change in performance of the Stroop task, indicating no modulation of executive function as a result of physical activity. In contrast, recognition memory was improved following moderate, but not maximal exercise. Both maximal and moderate exercise resulted in a transient but significant increase in circulating BDNF, that returned to baseline by 30min post-exercise.
CONCLUSION: The data indicate that exercise-induced improvement in recognition memory is dependent on exercise intensity and suggest that exercise-induced increases in circulating BDNF do not necessarily translate to improvements in cognitive function.

CAN 3DPS METHOD VALIDLY ESTIMATE %FAT OF CHILDREN?

OHTA, M.1, MIDORIKAWA, T.2, HIKIHARA, Y.3, SHITARA, K.4, TORII, S.4, SAKAMOTO, S.4

1: CHUKYO UNIV. , 2: J.F. OBIRIN UNIV. , 3: CHIBA INSTITUTE OF TECHNOLOGY , 4: WASEDA UNIV.

INTRODUCTION: The percent body fat (%fat) can be obtained by using measured values of height, weight, and fat thickness. This method is convenient for the measurement in itself. However, there are some problems: three conversion formulas—formula to calculate body surface area from height and weight, formula to calculate body density from body surface area and fat thickness, and formula to calculate %fat from body density—must be used, errors are more likely to occur in using various combinations of conversion formulas and the conversion formula for children is limited. Therefore, we focused on the three-dimensional photonic image scanning (3DPS) method. We aimed to examine the validity of %fat by using the body surface area and volume data obtained by 3DPS method.

METHODS: 164 healthy boys and girls (age: 9.5 ± 1.7 years, height: 138.0 ± 11.3 cm, body weight: 34.3 ± 9.2 kg) participated in this study. Body surface area and volume data were obtained by the 3DPS method. Subcutaneous fat thickness was measured from the posterior of the upper arm, the subscapular, and the abdomen by using a caliper. The body composition was measured by the dual-energy X-ray absorptiometry (DXA) method. We compared %fat obtained by the following four methods. A: Values calculated from the height, weight, and fat thickness by using the formulas of Fujimoto et al., Nagamine & Suzuki, and Lohman et al. B: Values calculated from the body surface area data that were obtained by the 3DPS method and then used equations of Nagamine & Suzuki and Lohman et al. C: Values calculated from the volume that was obtained by the 3DPS method and then used the equation of Lohman et al. and D: Values obtained by the DXA method.
RESULTS: The %fat obtained were A: 34.8 ± 16.1%, B: 36.7 ± 16.8%, C: 40.9 ± 10.2%, and D: 25.9 ± 8.1%. There were significant differences in every estimate value except between A and B.
CONCLUSION: We would have to say that it is difficult to estimate %fat by using the value obtained by the 3DPS method, especially body volume. However, the reproducibility of the 3DPS method is high, so we consider it possible to adjust by adding other factors.

BODIPY 493/503 IS SUPERIOR TO OIL RED O FOR DETECTING AND QUANTIFYING FIBRE SPECIFIC INTRAMUSCULAR TRIGLYCERIDE IN HUMAN SKELETAL MUSCLE

STRAUSS, J.A., SHEPHERD, D.A., JEVONS, E.F.P., MACEY, M., SHEPHERD, S.O.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Oil red O (ORO) and bodipy are lipid dyes used to investigate lipid metabolism. Importantly though, ORO labels all neutral lipids (including membrane lipids) whereas bodipy specifically detects IMTG. Furthermore, ORO has a large emission spectrum compared to the narrow emission spectrum of bodipy, making it challenging to use in dual or triple labelling experiments and often resulting in a high background level of staining. The aim of this study was to compare the use of bodipy and ORO for quantification of IMTG content and use during exercise as well as investigation of lipid droplet (LD) morphology in human skeletal muscle.
METHODS: Biopsies were obtained from the m. vastus lateralis of six healthy, lean sedentary males (age: 20±1y, BMI: 24.8±1.2kg.m2, VO2peak: 39.8±2.4ml.min-1.kg-1) following an overnight fast and prior to and immediately following 60min cycle ergometer exercise at ~60%VO2 max. Cryosections were labelled using antibodies targeting MHCI and MHCIIa. Anti-laminin was used to identify the cell membrane. LD's were labelled with either bodipy or ORO. Images were captured using confocal immunofluorescence microscopy and analysed using Image Pro Plus.
RESULTS: IMTG content (% area stained) was greater when using bodipy compared to ORO (P=0.006), and bodipy detected more LDs (P=0.03) with a greater mean LD size (P=0.03) than ORO. Regional distribution was also different for the two dyes with IMTG content with bodipy being greater in the central compared to the peripheral region (5um from plasma membrane) in both type I (central: 3.1±0.5% vs. peripheral: 2.8±0.5%) and type IIa fibres (central: 1.4±0.3% vs. peripheral: 1.3±0.2%; P=0.036). The opposite was true when using ORO, with a greater IMTG content observed in the peripheral compared to the central region in all fibre types (P=0.013). These regional differences in IMTG content for bodipy and ORO were attributed to differences in LD number (P = 0.039). Following exercise, using bodipy, IMTG content was decreased in both the peripheral (-58±21%, P=0.014) and central regions (-63±21%, P=0.016) of type I fibres. However, using ORO only a significant decrease in IMTG content in the peripheral region of type I fibres was observed (-85±19%, P=0.021).
CONCLUSION: ORO detects more lipid content and use compared to bodipy in the peripheral region of the cell likely due to the detection of membrane lipids in addition to IMTG. We propose that bodipy is preferable to investigate IMTG in skeletal muscle due to its superior LD detection capabilities and its specificity for detecting IMTG avoiding labelling of membrane structures, compared to ORO. We demonstrate the importance of this in the context of regional distribution of IMTG detected using ORO and bodipy and differences in region-specific IMTG utilisation during exercise. Therefore, it is possible that the choice of lipid dye could impact the conclusions drawn in studies in which subcellular IMTG distribution is considered.

EXERCISE UNTIL EXHAUSTION CHANGES THE SKIN CONTENT OF NICOTINAMIDE ADENINE DINUCLEOTIDE IN HIGHLY-TRAINED ELITE ATHLETES

KANTANISTA, A.1, BUGAJ, O.1, KUSY, K.1, GUZIK, P.2, WIELINSKI, D.1, ZIELINSKI, J.1

1: POZNAN UNIVERSITY OF PHYSICAL EDUCATION (POZNAŃ, POLAND), 2: UNIVERSITY OF MEDICAL SCIENCES (POZNAŃ, POLAND)

INTRODUCTION: Although the nicotinamide adenine dinucleotide (NADH) is produced both in the cytoplasm and in mitochondria, it is oxidized to NAD+ only in mitochondria. The flow-mediated skin fluorescence (FMSF) method measures non-invasively the dynamic NADH changes in the epidermis during the controlled ischemia and reperfusion of the forearm. Intensive exercise usually causes a shift from the aerobic to anaerobic energy metabolism and potentially influences the cellular content of NADH. The study aimed to evaluate the influence an exercise until exhaustion on the skin NADH and its changes during ischemia and reperfusion in highly-trained athletes.
METHODS: The FMSF was measured in 121 highly-trained elite athletes (age 23.4 ± 5.3 years, 27 women) before the exercise treadmill test and within 10 minutes of the post-exercise recovery [1]. All athletes started the exercise at a speed of 4 km/h; the speed was increased by 2 km/h every 3 minutes until athletes reached volitional exhaustion. Skin fluorescence was quantified with the use of the AngioExpert device (Angionica, Poland). The following parameters were recorded: Bmean – the baseline skin fluorescence; FImax – maximal fluorescence during ischaemia; FRmin – minimal fluorescence during reperfusion; IRampl – the amplitude of fluorescence change during ischaemia and reperfusion (an index of the potentially maximal amount of NADH metabolised during ischaemia and reperfusion); CImax – the relative contribution of the NADH generation during ischaemia to the total amount of NADH turned over during ischaemia and reperfusion; and Imax – an increase of fluorescence above the baseline value.
RESULTS: After the exercise, there was a significant (all $p \leq 0.0001$) increase in Bmean (404.19 ± 214.31 vs 455.30 ± 256.76 ku), FImax (480.98 ± 258.19 vs 514.46 ± 282.99 ku), FRmin (321.22 ± 168.90 vs 359.06 ± 196.50 ku) and Rmin (82.97 ± 50.22 vs 96.24 ± 65.98 ku), and a reduction in Imax (76.79 ± 47.64 vs 59.16 ± 36.33 ku) and CImax (0.48 ± 0.08 vs 0.40 ± 0.11). There was no significant difference for IRampl (159.76 ± 944.89 vs 155.40 ± 95.46; $p = 0.2608$).

CONCLUSION: The until exhaustion exercise causes a significant increase in the absolute amount of the skin NADH at rest, during ischemia and reperfusion. However, after such exercise, the magnitude of NADH change during ischemia as well as the contribution of the ischaemic part to the maximal range of the ischemia-reperfusion NADH turnover becomes reduced. Alterations in the cellular metabolism triggered by the until exhaustion exercise significantly shift the NADH-NAD+ balance towards increased absolute amounts of NADH, however with a significant reduction in its availability during ischemia. Translation into the practice of our findings requires further investigations.

INDIVIDUALISING LOADING STRATEGIES TO MAXIMISE THE EFFICACY OF BICARBONATE SUPPLEMENTATION: A PILOT STUDY

SIEGLER, J.C., BOEGMAN, S., STELLINGWERFF, T., SHAW, G.

WESTERN SYDNEY UNIVERSITY; CANADIAN SPORT INSTITUTE PACIFIC; AUSTRALIAN INSTITUTE OF SPORT

INTRODUCTION: Athletes commonly ingest 0.3g/kg body weight (BW) sodium bicarbonate (NaHCO3) 60 to 90 minutes prior to competition under the assumption that this time frame corresponds with a peak in blood buffering capacity. For the past 30 years, this dosing strategy has been widely accepted as best practice, yet the small subject numbers (n < 9) coupled with their non-elite training status of the original research we believe warrants further inquiry (McNaughton 1992). In support, recent studies have illustrated that a large degree of variation exists between individuals' time-to-peak buffering (Stannard et al., 2016), and that this may influence the efficacy of the supplement (Saunders et al., 2014). We are currently undertaking a multi-centre investigation to determine whether administering NaHCO3 doses based on an athlete's blood buffering profile improves the efficacy of this supplement. We initially undertook a pilot investigation to determine the inter and intra-individual variability of NaHCO3 absorption and time to peak buffering capacity (TTP) over multiple sessions at rest, which we present in this abstract.

METHODS: Eight (n=8) volunteers consumed NaHCO3 capsules at 0.3g/kg BW along with 1g carbohydrate/kg BW and 7ml water/kg BW (to minimise gut disturbance) over a 30-min period on two separate occasions. 45 min after ingesting the final capsule, capillary blood HCO3- levels were collected and analysed via one of two blood gas analysers (WSU: ABL 800 series; CSPI: ABL 80 series; Radiometer, Copenhagen, DK) every 10 min for 100 min or until HCO3- declined over three consecutive measurement time points. For both trials, participants replicated diet and training for 24 h before and during each passive ingestion period to minimise the effect of diet, hydration and exercise (confirmed via interview). Measurement time points were compared across the two trials using a customised spreadsheet (Hopkins, 2015). TTP was identified visually for each participant as the highest blood HCO3- measured over a trial.

RESULTS: Week-to-week reproducibility of the HCO3- collection periods (10 min measurement intervals) was good within participants (mean difference 0.52±0.03 (0.37 to 0.57) mmol/L; ABL 800 r=0.87; ABL 80 r=0.82). TTP was consistent within 20 min for each participant, with the range of achieving TTP varying from 40 to 170 min.

CONCLUSION: The findings of this pilot suggest that with proper control measures in place, good measurement reliability exists across weeks and within participants. This data is currently being used to support the larger study investigating TTP buffering capacity and exercise performance.

THE EFFECT OF IPC ON CENTRAL AND PERIPHERAL FATIGUING MECHANISMS FOLLOWING SUSTAINED MAXIMAL ISOMETRIC EXERCISE

HALLEY, S.L., SIEGLER, J., MARSHALL, P.

WESTERN SYDNEY UNIVERSITY

INTRODUCTION: Ischemic preconditioning (IPC) has been speculated to elicit performance benefits by inhibiting neural feedback from metabolically sensitive muscle afferents during exercise. We hypothesized that IPC could affect the mechanism of centrally mediated fatigue following a maximally fatiguing protocol.

METHODS: Eleven resistance trained males completed three 2 min maximal voluntary contractions (MVC's) via an isometric leg extension in a repeated measures crossover design separated by a minimum of 48 h. These tests were preceded by treatments of IPC (3 × 5 min intervals at 220 mmHg bilateral leg occlusion), SHAM (3 × 5 min intervals at 20 mmHg bilateral leg occlusion) or CON (30 min passive rest). Femoral nerve stimulation was utilised to explore central and peripheral mechanisms associated with reductions in maximal force and rate of torque development. This was profiled at baseline (BL), following treatment/prior to the 2 min MVC (Pre), and then again 10 s post (Post). Tissue oxygenation was measured throughout the 2 min MVC's via near-infrared spectroscopy.

RESULTS: MVC torque levels declined (-71 ± 39.7 Nm; p = 0.007) (mean ± SD) between Pre (237 ± 56 Nm) and Post (166 ± 40 Nm) 2 min MVC measures without differences between conditions (p = 0.676). This decline coincided with decreases in twitch torque (-59.1 ± 22.2 Nm; p < 0.005) from Pre to Post however voluntary activation was unchanged (p = 0.298). Neither twitch torque (p = 0.388) or voluntary activation (p = 0.795) was affected by condition. There were no differences between conditions in the total work (p = 0.115) or time profiled work (P = 0.275) completed during the 2 min MVC's. Peak deoxyhemoglobin concentrations were elevated in the IPC trials (Δ15.1 ± 2.8 μmol/L; p = 0.006) relative to SHAM (Δ12.1 ± 3.0 μmol/L) and CON (Δ11.3 ± 3.6 μmol/L), however there were no such differences in oxyhemoglobin (p = 0.687) or total hemoglobin (p = 0.099) measures.

CONCLUSION: These findings demonstrate that IPC does not affect central or peripherally mediated mechanisms of fatigue during a sustained 2 min maximal effort isometric leg extension task. In addition to this, total work was unaffected despite evidence of increased oxygen delivery, suggesting that the ergogenic benefits of IPC are dependent on blood flow.

ADIPONECTIN AND OSTEOCALCIN RESPONSES TO ACUTE ROWING EXERCISE IN FEMALE ROWERS

JÜRIMÄE, J.

UNIVERSITY OF TARTU

INTRODUCTION: The aim of the investigation was to study the effects of acute exercise and menstrual phase on adiponectin and osteocalcin concentrations, and the possible role of these biomarkers in exercise-induced substrate oxidation in rowers.
METHODS: Thirteen female rowers (19.3 ± 2.3 years; height: 172.7 ± 3.9 cm; body mass: 66.5 ± 7.9 kg) performed 1-h rowing ergometer exercise at 70% of maximal oxygen consumption (VO2max) during follicular phase and luteal phase of the menstrual cycle. Oxygen consumption (VO2), total energy expenditure (EE), carbohydrate EE, and lipid EE were assessed during the exercise. Venous blood samples were collected before and after ergometer exercise.
RESULTS: No differences ($p > 0.05$) were observed in substrate oxidation values during exercise across menstrual cycle. Exercise resulted in an acute rise in osteocalcin and no changes in adiponectin at both menstrual cycle phases. Adiponectin and osteocalcin were not related across phase or time ($r < 0.21$; $p > 0.05$). Post-exercise adiponectin was related ($p < 0.05$) to mean VO2 ($r = 0.46$) and total EE rate ($r = 0.60$), while post-exercise osteocalcin was correlated ($p < 0.05$) with mean total ($r = 0.41$) and lipid ($r = 0.56$) EE rates.
CONCLUSION: In conclusion, menstrual cycle phase had no effect on substrate oxidation, and adiponectin and osteocalcin responses to acute exercise. It appears that adiponectin and osteocalcin may serve as signals for metabolic reaction to the energy cost of the acute exercise in female rowers.

EFFECTS OF WATER IMMERSION IN VARIOUS WATER LEVELS ON URINE VOLUME DURING ARM-CRANKING EXERCISE

WADA, T.1, TAMARI, Y.1, YOSHIDA, N.2, HAMADA, H.2, NOSE, Y.3, YOSHIOKA, A.4, ONODERA, S.1

1. KAWASAKI UNIVERSITY OF MEDICAL WELFARE , 2. GURADUATE SCHOOL, KUMW , 3. YASUDA WOMEN'S UNIVERSITY , 4. OU

INTRODUCTION: Previous studies have demonstrated that physiological responses to the different physical environment in water compared to land are different (Onodear et al., 2013). However, subjective micturition during the arm-cranking exercise has not been studied. Therefore, this study aimed to examine if the subjective micturition during hand ergometer exercise causes urine volume changes in water.
METHODS: Seven healthy Japanese adult males (age; 22 years, height; 171 cm, and body weight; 65 kg) participated in this study. All procedures were approved by the Ethics Committee of Kawasaki University of Medical Welfare and conformed to the Declaration of Helsinki. Two experimental conditions ware studied: the xiphoid condition and the greater trochanter condition. The water levels were set to the level of a human xiphoid and that of a human greater trochanter process. Both conditions were performed during constant intensity exercise (20%VO2peak) using a hand ergometer with rotational speeds of 60 rpm. Measurements were urine volume, subjective micturition, rating of perceived exertion and heart rate. Subjects sat on land in a chair (Rest) for 20minutes. Then, for the next 20 minutes, subjects under both conditions performed arm-cranking exercise in the water. Finally, they sat on land in a chair for 20minutes. The water temperature was 30 degrees Celsius.
RESULTS: Urine volume after immersion in the xiphoid condition was higher than that for the greater trochanter condition ($p<0.05$). Subjective micturition after immersion and recovery at 20 minutes the xiphoid condition was higher than that in of the greater trochanter condition ($p<0.05$). No significant differences were found in heart rate and rating of perceived exertion between the xiphoid condition and the greater trochanter condition. It could be concluded that when water level is increase, volume of the venous return could increase, and when water level is decrease, volume of the venous return could decrease.
CONCLUSION: Urine volume and subjective urination after immersion in the xiphoid process were higher than urine volume in the greater trochanter state. Therefore, urine volume and subjective urination increase as the water level increases.

THE EFFECT OF SLEEP RESTRICTION ON PHYSICAL PERFORMANCE, MUSCLE REGENERATION AND ENDOCRINE PARAMETERS IN AN CROSSFIT(R) BASED WORKOUT

GEISLER, S., DWORAK, M., BAYER, S., BAIER, C., DIEL, P.

IST - UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Sleep restriction is a common problem in the western society. Also in the context of elite sports there are certain circumstances that affect do not always
allow athletes to enter a competition or exercise in alert conditions.
Therefore the purpose of this study is to detect the influences of
one night's sleep restriction before a CrossFit (SR) training intervention (half Cindy) on performance and muscle damage.
METHODS: Twelve male healthy, young volunteers (age 23,3 ± 1,5) committed in the program once after normal sleep (6-8h, baseline, K) and once after sleep restriction (4h sleep opportunity, SR). Physical activity levels and sleep behavior was monitored by sense ware detection. Physical activity was measured by senseweare belts. A sleep diary according to the DGSM guidelines was filled and the Epworth Sleepiness Scale (ESS) was measured. At the morning of the second day blood was collected before breakfast and three hours after exercise. In the blood Creatine kinase as marker for muscle damage, Cortisol, Testosterone IL 10 and IGF-1 were detected. After a standardized breakfast, individuals performed the training intervention. At the third day, 24h after exercise, again blood was collected.
RESULTS: Sense wear clearly detected that the volunteers under sleep restriction had an average sleeping time of (03:55:35 +/- 00:47:27h) compared to the control group (06:32:25 +/- 01:27:43h. After sleep restriction Ess data clearly indicate a significantly increased sleepiness. Surprisingly, we did not find significant differences in completed rounds and repetitions between SR- and K. Physical performance was not negatively influenced by sleep restriction. Astonishingly there is a tendency that shows improved performance (more reps at workout) after sleep restriction. Sleep restriction resulted in a significantly decreased cortisol levels 3h after training before training. Neither testosterone, IGF-1 levels nor CK- or IL-10-levels in serum were significantly influenced by training neither under sleep restriction

nor in the control group following the intervention. There is a tendency that shows improved anabolic and reduced catabolic effects following the intervention under sleep restriction.
CONCLUSION: On top of this there is advice, that anti-inflammatory processes are disturbed in the morning after a sleep restricted night. As a reaction to physical strain the anti-inflammatory processes are increased in comparison to the control conditions.However our mayor result is that sleep restriction to four hours the night before short, intensivephysical strain does not significantly influence the performance and muscle damage afterwards. In Future investigations a longer duration of sleep restrictionshould be analysed. Further pro-inflammatory indicators could also be included to generate a complete view of the immunological processes.

EVALUATION OF RESTING AND POST-EXERCISE URINE IN FOOTBALL PLAYERS

SZABÓ, G.P., MIZSEI, O.2, SZABÓ, T.3, OLÁH, A.V.2

1 INSTITUTE OF HUNGARIAN SPORT MEDICINE, 2 UNIVERSITY OF DEBRECEN, DEPARTMENT OF LABORATORY MEDICINE, 3 UNIVERSITY OF DEBRECEN, DEPARTMENT OF PEDIATRICS

INTRODUCTION: Regular evaluation of athletes is mandatory to maintain their good health condition. Upon rigorous exercise and consequent dehydration changes in the water-and electrolyte homeostasis, as well as activation of compensatory endocrine - and vasoregulatory processes are activated.
METHODS: In our pilot study we compared resting and post-exercise urine samples of 39 first-class football players (age: 20-33 years). We detected their daily fluid intake and the overall environmental data such as temperature and humidity. First general (dipstick) urine analysis was performed (Clintek Status, Urisys 1100) followed by ion measurements using Cobra6000 analyzator, then marker of the tubular damage N-acetil-β-D-glukozaminidase (NAG) activity was measured via spectrophotometry and normalized to creatinine.
RESULTS: Either proteinuria or hematuria (4-4 cases), representing 20% of total samples (8/39), were detected in urine samples taken at rest. With emphasize, in post-exercise samples pathological urine alterations were detected in 61.5% of cases (24/39), hematuria n:11 and proteinuria n:18, while both alterations were found in 7 cases. Among 17 players wide anion gap was detected which alteration showed correlation with increment of sodium excretion in the urine. In 9 cases post-exercise wide anion gap (>55 mmol/L) was associated with lower as expected urine Na+ excretion while at the same time higher creatinine values and proteinuria (6/9) were detected. Over 90% of the cases the Cl- excretion decreased to 1/3 of its original value in post-exercise samples which exceeded the rate of Na+ reabsorption. Increasing proteinuria was seen in roughly 50% of the players measured in post-exercise samples (250-1500 mg/L, n:19/39). Among players in whom proteinuria exceeded 1500 mg/L we detected pathological NAG index in 3 cases (3/39) which finding may correspond with tubular dysfunction. We observed increasing creatinine values (18749 μmol/ vs. 31808 μmol/L) in parallel with seasonal changes in temperature (6 °C vs. 37 °C) presumably as a consequence of dehydration.
CONCLUSION: Significant hemodynamic changes occur in the kidney upon rigorous physical activity as a consequence of dehydration and circulatory redistribution. Due to the activation of the RAAS active sodium and consequent water as well as passive Cl- reabsorption occur in the proximal tubular system. Consequently, the level of Cl- anion decreased to roughly 1/3 of its original value. The most plausable explanation for wide urine anion gap measured after exercise is the observed decline of Cl- level. Besides, production of other anions such as lactate and bicarbonate may decrease the excretion of chloride. Adequate hydration before and after training or football game is of great importance. Although exercise-induced proteinuria is a known, benign phenomen, in case of persistent proteinuria further investigation and consultation with nephrologist should be initiated.

CHANGES IN THE MARKERS OF OXIDATIVE STRESS IN RESPONSE TO A SOCCER GAME

DEVRNJA, A., MATKOVIC, B.R.

FACULTY OF KINESIOLOGY

INTRODUCTION: Soccer, as one of the most popular modern sports, is an activity that involves both aerobic and anaerobic activities. During the game, players cover 9 to 12 km in total with different intensities of movement: walking, moving backwards, jogging, running and sprinting (Mohr et al, 2003). Because of the tough schedule and lack of the time for adequate rest and recovery, soccer players are more susceptible to oxidative stress and negative changes related to the development of oxidative stress. The aim of this research was to analyse the changes in the values of some of oxidative stress markers caused by a soccer game (malondialdehyde (MDA), glutathione peroxidase (GPx)) in adolescent soccer players.
METHODS: 43 male soccer players (16.8 ± 1.06 years) volunteered to participate in this research. All subjects signed informed consent. The study was carried out in accordance with and approved by the Research Ethics Committee of Faculty of Kinesiology University of Zagreb. They were divided into two groups according to their age (22 cadets aged 15.86 ± 0.35 and 21 U19 players aged 17.76 ± 0.54) and they played two soccer games. The games lasted 90 minutes each. 30 minutes before and immediately after the game, venous blood samples were taken in order to determine the markers of oxidative stress. Global positioning system (GPS, Catapult Innovations, Scoresby, Australia) was used to analyze player on-field activities. All statistical analyses were conducted by using the SPSS software (StatSoft Inc., Tulsa, OK, USA).
RESULTS: There were no statistically significant differences determined in the changes of concentrations of MDA (p=0,18; arithmetic mean of the differences=0,19; 95% CI=-0,09-0,47) or in the changes of GPx activity (p=0,23; arithmetic mean of the differences =-4,14; 95% CI =-11,03-2,75).
CONCLUSION: Greater GPx activity can be one of the adjustments to long-term participation in regular physical activity or training process (Powers et al, 1994). According to some studies, regular physical activity may also result in decreased lipid peroxidation (Radak et al, 2001). Therefore, the lack of significant changes in MDA concentrations and GPx activity may be explained by the long-term soccer training that subjects are involved in. The correlation with distances covered was not noticed. Based on the obtained results, the conclusion can be made that the intensity during a soccer game is not the only factor in the occurrence of oxidative stress.

BONE METABOLISM IN COLLEGIATE MALE SWIMMERS

WAKAMATSU, K.1, SAKURABA, K.2, FUJITA, S.2, SANOMURA, M.3, GUSHIKEN, T.4, NAGAI, H.5, KANDA, T.5

1: J.F.OBERLIN UNIVERSITY , 2: JUNTENDO UNIVERSITY, 3: TEIKYO UNIVERSITY, 4: NIPPON SPORTS SCIENCE UNIVERSITY, 5: YAMANASHI-GAKUIN UNIVERSITY

INTRODUCTION: Bone strength primarily reflects the integration of bone mineral density and bone quality. Bone quality refers to architecture, turnover, metabolism, damage accumulation, and mineralization of bone. Overuse injuries, including stress fractures, are serious

problems faced by athletes. Sports activities have been reported to be effective in increasing bone mass. However, competitive swimming has been cited as an instance where the effect is not observed. Bone metabolism markers, which can be measured as a result of recent developments, have been reported to be low in swimmers. The purpose of this study was to examine the usability of some bone metabolism markers for the prevention of overuse injury of bones in collegiate male competitive swimmers.
METHODS: The subjects included 18 male collegiate swimming athletes (SA). In addition, 16 men without exercise experience were included as the control group (CON). Bone metabolism markers, such as serum bone-specific alkaline phosphatase (BAP), and circulating bone-specific tartrate-resistant acid phosphatase (TRACP-5b) were measured in both groups.
RESULTS: BAP levels in the SA and CON groups were and 21.3 ± 6.0 and, 16.9 ± 3.7 U/L, respectively, with statistical comparison showing a significantly higher level in the SA than in the CON group ($p < 0.05$). TRACP-5b levels in the SA and CON groups were 610.1 ± 178.0 and, 480.8 ± 143.4 mU/dL, respectively, with statistical comparison showing a significantly higher level in the SA than in the CON group ($p < 0.05$).
CONCLUSION: The subjects are top-level university swimmers whose regular training routine includes running and jumping exercises and high-intensity weight training for the lower legs. Previous studies have demonstrated that the bone resorption marker NTX is not enhanced by the extent of resistance while running (Whipple Tj et al., 2004), and swimmers who undertake high-intensity leg training (running, jumping, etc.) show significantly higher values of TRACP-5b, having a sharp increase as an effect of the exercise (Rogers RS et al., 2011).

Psychology

SALSA DANCE AND PERCEIVED MENTAL HEALTH BENEFIT AT A WEST MIDLANDS, UK UNIVERSITY: A SERVANT LEADERSHIP THEORY-DRIVEN PILOT STUDY

DOMENE, P.A., LAWSON, C.

COVENTRY UNIVERSITY

INTRODUCTION: Salsa dance is a popular physical activity and potentially efficacious in terms of the enhancement of mental health outcomes . Currently, no empirical work has been published in the literature to assess whether Greenleaf's <1977> servant leadership theory can facilitate the teaching of mental health-enhancing physical activity to novice learners in a university setting.
METHODS: An eight-week salsa dance course was taught to university students using principles of servant leadership theory. Upon completion of the course, perceived mental health benefit was measured using a series of 100 mm visual analog scales. The validity of this method has been previously demonstrated . Additionally, dimensions of servant leadership were measured on six-point Likert-type scales using an adapted version of the Servant Leadership Survey validated by Van Dierendonck et al. <2017>.
RESULTS: Forty-three participants completed the study. Skill mastery was the most highly rated perceived mental health benefit in women, whereas in men, it was mood enhancement . There were differences between sexes in the servant leadership dimensions of authenticity , empowerment , humility , and stewardship . Moreover, authenticity was correlated with mood enhancement in women and stewardship was correlated with both mood enhancement and skill mastery in men.
CONCLUSION: This is the first study we are aware of to have applied principles of servant leadership theory in the teaching of salsa dance to novice learners. Servant leadership may have facilitated the high perceived mental health benefit observed.

MOTIVATION IN SPORTS AND "SENSE OF SOCIAL TOGETHERNESS"

NISHIDA, T.

AICHI GAKUIN UNIVERSITY, JAPAN

Motivation in Sports and "Sense of Social Togetherness"
Tamotsu NISHIDA
Faculty of Psychological and Physical Science, Aichi Gakuin University, Aichi, Japan
Introduction: Considering the shift in the focus of research on motivation from individual attributes such as motive and expectancy to environmental variables in which a person is placed, the question of how to build interpersonal relationships with significant others is extremely important. Motivation is connected with the way in which people perceive how they are evaluated by others who are close and important to them. When they feel there are people around them who trust, understand and accept them, their motivation will be strong. These feelings, "a Sense of Social Togetherness ", have a positive influence on human motivation in a range of situations.
This study aimed to clarify the differences in sex and sports experiences of the SST and the relationship between motivation in sports and the SST.
Methods: The subjects were 813 junior high school students <382 boys and 431 girls> from 3 junior high schools in Japan. Their ages ranged from 12 to 15 years . They were 492 students who had taken part in extracurricular sports club activities in the past and 321 students with no such experience.
A 9-item questionnaire test to measure the SST including trust, understanding and acceptance was developed. The reliability and validity of the test were sufficiently high. An 8-item test including motivation in sports was also administered to all subjects. The subjects indicated their degree of agreement with each item statement by responding on a 5-point Likert-type rating scale anchored from "strongly disagree" to "strongly agree".
Results and Discussion: The SST mean score for girls was significantly higher than those for boys . As girls have a stronger need for affiliation than boys, this need may be one of the factors behind the higher score for sense of social togetherness. The SST score for students who had taken part in extracurricular sports club activities in the past was significantly higher than those for students with no such expe-

rience . The results indicate that extracurricular sports programs may provide a valuable setting for the development of a sense of social togetherness. A positive correlation between the SST and motivation in sports activities was found . This finding was all in line with the initial hypothesis. In other words, when there is a strong sense of trust, understanding, and warm acceptance, a person is better able to devote herself or himself to sports activities.
Further investigation is necessary to explore the sense of social togetherness and its role by examining its relationship with other psychological concepts, what factors shape its development, its influence in the sports and school setting, and whether differences exist across different cultures.

A STUDY OF WEIGHTLIFTING ATHLETES' SPORTS PARTICIPATION AND SOCIAL SUPPORT : KUO, HSING-CHUN CASE

HSIEH, Y.T., HSU, K.P.

NATION TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: The Taiwanese weightlifter Guo Hsing Chun won the bronze medal at 2016 Rio Olympic Games, and broke the world record in the clean for the women's 58 kilogram weight class in 2017. Besides her physical ability, social support is an necessary factor (Côté, 1999). In 1974, Caplan advanced that social support is a various forms of assistance and support provided by families, teammates and others to individuals facing stress. Hence, the purpose of this study is to find out how social support, in terms of family, coach and peer, has affected Guo's weightlifting career.
METHODS: This article takes Guo as a case study, using literature analysis and semi-structured interviews to collect informations and documents, and summarize relevant informations.
RESULTS: 1. Family: Guo had participated in several sports and contacted weightlifting at the age of 15. Respecting her participation in sports, her family gave financial and emotional support.
2. Coach: Since Guo was 15, the coach has accompanied her through all the trainings. Besides giving professional knowledge, he cooks on his own to supply nutrition.
3. Peer: They provide technical exchanges, companionship and emotional support.
CONCLUSION: 1. Family: In 2010, Beets, Cardinal and Alderman concluded that family support was one of the major factors influencing the teenage sport. Oral encouragement may increase athletic performance in addition to material support provided by family. As Guo said, family influences her the most by their oral encouragement and presence to the match.
2. Coach: In 2011, Zourbanos mentioned that the forms of social support provided by coaches includes psychological, information and self-esteem level. Guo's got the same supports from her coach and extra material support.
3. Peer: Morgan interviewed 8 NCAA players in 2006 and found that peer support was important in growth process. Peers assist in training, listen to others' thoughts, which is similar to Guos peer support.

MOTIVATION FOR WEIGHT CONTROL AMONG UNIVERSITY STUDENTS IN JAPAN AND SOUTH KOREA

IKEDA, T.O.1, IKEDA, T.2, YAITA, A.3, SAKAGUCHI, H.4, ITO, H.5, AOYAGI, O.5, HONG, Y.6, HAN, N.6, CHOI, T.6, NAM, Y.7, KOO, K.8

1: NISHI-KYUSHU UNIVERSITY, 2: FUKUOKA PREFECTURAL UNIVERSITY, 3: KYUSHU-KYORITSU UNIVERSITY, 4: JAPAN UNIVERSITY OF ECONOMICS, 5: FUKUOKA UNIVERSITY, 6: JEJU NATIONAL UNIVERSITY, 7: DUKSUNG WOMENS U

INTRODUCTION: In Japan, females in their 20s tend to have a thinner body than their older counterparts (Ministry of Health, Labour and Welfare, 2015). As younger females strongly desire to be slender, they also tend to engage in weight control (WC), even if their body weight is appropriate (Urata, 2001; Ikeda et al., 2005). Korean females also desire to be slender (Woo, 2014). The purpose of the present study was to investigate and compare motivational factors for WC between university students in Japan and South Korea.
METHODS: The participants were 823 students (Japan: 81 males, 264 females; Korea: 189 males, 289 females) who are/were engaging in WC and completed a questionnaire composed of 27 items on reasons and/or motivation for WC (Hando & Kawashima, 2009; Nishioka et al., 1993). A factor analysis was applied to investigate motivational factors for WC, and differences in nationality and gender were analyzed using two-way layout analysis of variance (ANOVA) with general linear modeling.
RESULTS: The following five factors were extracted by the factor analysis: Social influence [SI], Appearance [AP], Health [HE], Improvement of overweight [IW], and Economical effect [EE]. The results of ANOVA showed gender differences in SI ($F[1, 803] = 40.6$, M < F) and EE ($F[1, 803] = 11.1$, M > F). Interactions between gender and nationality were seen in AP, HE, and IW. A multiple comparison test showed gender differences for both country (JPN: $t[93] = -11.2$; KOR: $t[362] = -9.5$, M < F) and nationality ($t[255] = -4.8$, JPN < KOR) among males for AP, gender differences ($t[96] = 3.7$, M > F) in Japan and nationality differences ($t[523] = -3.2$, JPN < KOR) among females for HE, and gender and nationality differences (JPN: $t[90] = -5.7$; KOR: $t[350] = -4.2$, M < F) among females for IW in both countries ($t[544] = 8.0$, JPN > KOR).
CONCLUSION: HE and EE were identified as motivational factors for WC among males, whereas SI, AP, and IW were identified as motivational factors for WC among females. Having these factors as motivation for WC among females is problematic because of the already high proportion of thinner females in both countries. Among females, Koreans tend to be healthier, while Japanese tend to want to improve their overweight status. In addition, Korean males tend to want to look thinner than their Japanese counterparts. The present study clarified the five factors and their differences between Japanese and Korean university students on motivation for WC.

COOPERATIVE GAMES AND CHILDREN: REFLECTIONS ON A PSYCHOLOGY GROUP OF A HEALTH CENTER IN FLORIANÓPOLIS (SC, BRAZIL)

MARINHO, A., LECUONA, S.D.

STATE UNIVERSITY OF SANTA CATARINA

Nowadays, it is possible to identify characteristics of competitive behavior in various social spheres. An example is the competition in work environment. However, this social behavior is also shrouding children's relations. It may be possible because of the several competitive sports taught in school, forgetting the cooperative possibilities. The cooperative games have as pretense to redirect the perceptions to this reality, seeking to transform the mode of existence, the barriers on bridges and the treatment of its practitioners, of opponents in solidarity in different contexts. Thus, this study aimed to know the activities promoted to children participating in a Psychology Group in a health center of Florianopolis (SC, Brazil) and to provide practice with cooperative games to investigate its influence and its consequences for the treatment and promotion of health of the participants. The participants were seven children aged eight to twelve years, and the professional responsible for the activities of the group. This field research was configured as descriptive and exploratory in which semi structured interviews were conducted after four meetings with the practice of cooperative games. The data were analyzed using the Content Analysis Technique. For the organization of such information was used NVivo software, version 11.0. The results indicate the acceptability of cooperative games of the children investigated. It also shows that cooperative games can contribute to the promotion of better living among children, and can allow them a perception of change in their attitudes to themselves and each other. These findings emphasize the importance of rethinking the changing needs of the strategies with the "care", which promote, through the effective humanization, the possibility of the patient having a full treatment, able to supply not only their biological needs.

PERCEIVED COACH EMPOWERING CLIMATE AND ENJOYMENT IN MEXICAN PITCHERS: A MODERATED MODEL OF MOTIVATION.

GUTIERREZ, P.1, LOPEZ-WALLE, J.2, BALAGUER, I.3, TRISTAN, J.2

1: UES , 2: UANL , 3: UV

INTRODUCTION: When athletes perceived the environment to be more empowering they reported more autonomous forms of motivation (Smith et al., 2016) and optimal engagement (e.g. enjoyment, wellbeing, embracing the challenge) (Duda, Appleton, Stebbings, & Balaguer, 2018). Studies have revealed that empowering climate predicts optimal consequences, however, less is kwon about the underlying processes that may moderate this relationship. This study examines the moderating role of forms of motivation (autonomous and controlled) between perceived coach empowering climate and enjoyment.
METHODS: Participants were 97 pitchers ranged in age from 13 to 16 years old (M = 14.12, SD = 1.09) representing different childrens baseball leagues in Hermosillo, Sonora, Mexico. At same training camps, the participants were administered the Mexican version of a multi-section questionnaires tapping the variables of interest (EDMCQ-C, SMS-II, SSI). For the analyses of the data, the macro PROCESS for SPSS was used.
RESULTS: The objective of the study was to examine the moderating role of forms of motivation (autonomous and controlled) between perceived coach empowering climate and enjoyment.Model 1. The perceived coach empowering climate was a positive predictor and explain 31% of reported enjoyment (R2 = .307). Change in the R2 with the addition of the moderating effect of autonomous motivation (AM) was low but significant ($F = 7.318$, $p < .01$). The conditional effect between the perceived coach empowering climate and enjoyment in the different values of the AM were not significant. Model 2. The perceived coach empowering climate was a positive predictor and captured 25% of reported enjoyment (R2 = .248). The observed change in R2 with the inclusion of the moderating effect of controlled motivation (CM) was low but significant ($F = 12.049$, $p < .01$). The relationship between perceptions of the coach empowering climate and enjoyment was significant with pitchers of low and medium CM only.
CONCLUSION: The purpose of the study was to analyze the moderating effect of forms of motivation (autonomous and controlled) among the perception of the empowering climate created by the coach and the enjoyment of the pitchers, for which it was confirmed only when the controlled motivation is medium or low. It is reinforced that empowering climates predict welfare indicators (Duda et al., 2018).

EGO AND TASK ORIENTATION DIFFERENCES AMONG UNIVERSITY STUDENTS

TAKSIC, I.

UNIVERSITY OF APPLIED HEALTH SCIENCES

Ego and task orientation differences among university students
Taksic, Iva
University of Applied Health Sciences, Zagreb, Croatia
Introduction: In a last few decades, physical (in)activity has become a big issue that raises a lot of questions in a health community. There are several theories that explain motivation in achievement contexts related to sport and exercise (Nicholls, 1989; according to Baric, 2006). Task- and ego-goal orientations are considered as orthogonal dimensions (Duda, 2001) and a person can be high or low in either or both. The aim of this research was to determine are there any gender and study differences considering task and ego orientation during physical activity.
Methods: Study was conducted on 570 University of Zagreb students; of which there are 329 female and 241 male participant. There were 419 participants involved in social sciences and 159 in technical science studies. Average age of participant was 19,94 (SD=1,74). We used Croatian version of the Task and Ego Orientation in Sport Questionnaire (Baric and Horga, 2006) which consists of two subscales that measure goal orientation: task orientation and ego orientation. Items were modifed so they are appropriate for measuring goal orientation in exercise.

Results: Results have shown that there is a statistically significant difference in ego orientation task; males have shown higher results than females. When it comes to task orientation, no difference has been found. We have found that social sciences students show statisticaly higher results both in ego and task orientation than techincal science studies
Discussion: Men have higher results in ego orientation than women, so we can say that men, while involved in physical activity tend to compete with others, and they think of succes only if theyre performance is better than others (Baric, 2006). When it comes to studies differences, social sciences studies are significantly more ego oriented than technical sciences students. Social sciences students have shown statistically higher results in task orientation than technical sciences students. It means that social sciences students regard their success in the sport environment as a personal improvement in their skills and mastery through the effort invested (Baric, 2006).
Conclusion
In this research, we have shown that men are statistically higher on ego orientation than women, while in task orientation there is no gender difference. Social sciences students show significantly higher results in both ego and task orientation than techincal science studies.

A SELF-DETERMINATION THEORY APPROACH TO INVESTIGATE THE ASSOCIATION BETWEEN MOTIVATION, CARDIO-VASCULAR FITNESS AND OBESITY IN ADOLESCENTS

ABOALMATY, H.
TANTA UNIVERSITY

Introduction: Overweight and/or obesity would cause significant health problems for children and adolescents. Rates of overweight and obesity in children have increased 45% in the last decade and have increased three-fold since 1980. Since children who are physically active are at lower risk for the development of obesity, it is crucial to identify and understand the main factors, which influence childrens physical activity patterns. Evidence from recent research suggested that controlling the cardiorespiratory fitness would offset the association between motivation and weight status. Therefore, this study was undertaken to investigate the relationship between motivation, cardiorespiratory fitness, and weight status, which is defined in this study as obese or non-obese.
Methods: This is a cross-sectional survey, in which participants included were physically active middle school students. Participants age ranged between 11-15 years (N=80, 51% female) who were part of the Teen Eating and Activity Mentoring in Schools. The main aim of this study was improving health and preventing obesity among middle school students. Student involved in this study completed attitudinal questionnaire related to physical activity and self-determination as well as participating in a number of fitness performance tests, health behaviour, and anthropometric assessment.
Results: Non-obese adolescents showed higher intrinsic motivation scores than obese adolescents. Mediational analyses demonstrated that cardiorespiratory fitness mediated the relationship between motivation and weight status.
Conclusions
The results of this study demonstrate differences in physical activity motivation as a function of adolescent weight status, but only for intrinsic motivation. As predicted, adolescents who were intrinsically motivated for physical activity were more fit and therfore less likely to be obese. The findings are consistent with self-determination theory.

EFFECTS OF REGULAR EXERCISE, GENDER AND BODY IMAGE ON SPORTS MOTIVES FOR UNIVERSITY NOVICE ROWERS

NG, S.K.R.
THE CHINESE UNIVERSITY OF HONG KONG

Purpose
The aim of this study was to examine the effects of regular exercise, gender, self-esteem, and body appreciation scale on motives for sport participation of novice rowers.
Method
Before the commencement of the 3-month university rowing team training program which consisted of three 2-hour water and land training sessions per week, one hundred fifty-six novice rowers (103 men, 53 women; mean age: 19.5±1.5 years old; BMI=20.9±2.2 kg/m2) completed the Exercise Motivation Inventory-2 (EMI-2; Markland & Ingledew, 1997), Rosenberg's Self-Esteem Scale (Chinese translation: Ng, Barron & Swami, 2015) and Body Appreciation Scale-2 (BAS-2; Swami & Ng, 2015). They also reported whether they were engaging in regular exercise, defined as at least 150 minutes moderate exercise per week.
Results: In the present study, each of the scales from the Chinese translation EMI-2 demonstrates good internal reliability, ranging from 0.63-0.89. Among all the participants, the three major reasons for participating in training were positive health (M = 4.05, SD = 0.67), strength and endurance (M = 3.97, SD = 0.66), and challenge (M = 3.84, SD = 0.70).
Results of MANOVAs test showed no statistically significant main gender effect on the combined dependent variables, Wilks Lambda = 0.875, F(17, 136) = 0.801, p = 0.317, η2 = 0.125; a significant main effect for regular exercise, Wilks Lambda = 0.745, F(17, 136) = 2.733, p = 0.001, η2 = 0.255; and no statistically significant interaction of gender and regular exercise, Wilks Lambda = 0.909, F(17, 136) = 0.801, p = 0.690, η2 = 0.091.
Independent samples Mann-Whitney U test results revealed that students with regular exercise (n = 105; 68 men, 37 women) had significantly higher mean scores than those without regular exercise (n = 51; 35 men, 16 women) for strength and endurance, competition, stress management, affiliation, enjoyment, revitalization, positive health, self-esteem and BAS-2.
In conclusion, participants with and without regular exercise were motivated to take part in regular training by intrinsic factors such as positive health, strength and endurance, revitalization and challenge.

A QUALITATIVE EXAMINATION OF SOURCES OF STRESS IN INTERNATIONAL TENNIS UMPIRES

MURAKAMI, K.1, MATSUURA, M.1, SAKATA, S.2

1: TOKYO UNIVERSITY OF SCIENCE, 2: KYUSHU UNIVERSITY

Introduction: Sport officials must continuously endure physical pressure; they should, however, also be willing to psychologically endure various stressors. Tennis judgement is also a very exciting occupation and a stressful one in any stage. As the best performance cannot be expected from athletes and coaches who are under a great deal of stress, officials are sometimes unable to demonstrate proper performance (Reilly and Eregson, 2006). The purpose of this study, therefore, is to investigate the source of stress for international tennis umpires, and compare it to those identified in past studies of other sports.
Methods: Eight umpires with International Tennis Association budges of gold, silver, or bronze were interviewed about the stress they experienced as international umpires and asked to identify specific sources of stress. At the time of the interview, the average age of the participating umpires was 46.1 yr. with a range of 37 to 52 yr. Qualitative methodology was utilized in this investigation. An interview guide, comprising a series of open-ended and guided questions was developed for this investigation. Qualitative interviews were between 35 and 60 minutes long and were transcribed, coded, and analysed by three experienced qualitative researchers.
Results: Participants were asked the general question, "Can you think of anything else that may have been a source of stress?" Ninety-one raw data themes were identified from the analysis of the interview data. These raw data responses were content analysed; the three researchers discussed and came to a consensus on the grouping of the raw data responses, transforming them into meaningful subcategories and larger groupings. This procedure resulted in 24 subthemes that were grouped into 26 higher-order themes; these were then summarized with seven overall stressor categories: 1) confrontation, 2) pressure of the game, 3) fear of failure and mistakes, 4) interpersonal conflicts, 5) time demands, 6) financial problem, and 7) prolonged travel for expedition.
Discussion: This study examined the sources of stress experienced by tennis umpires. Overall, the present investigation revealed that the umpires in the present sample experienced similar sources of stress as other sport officials from previous research (Voight, 2009). The research suggests that there is a small minority of sport officials who could benefit from help for their stress, and psychologists have identified several stress management techniques that could be applied to officials. The information gathered from this work also provides insight into how we can better create stress management programs for this population.

A STUDY OF SOCIAL SUPPORT AND RESILIENCE ON THE COLLEGE STUDENT ATHLETES IN TAIWAN

YEH, S.W., CHEN, M.Y., TSAI, Y.T.

NATIONAL TAIWAN NORMAL UNIVERSITY

A study of Social Support and Resilience on the College Student Athletes in Taiwan
Shao-Wei Yeh1, Mei-Yen Chen1, Yi-Ting Tsai2
1 Graduate Institute of Sport, Leisure and Hospitality Management, National Taiwan Normal University, Taiwan
2 Department of Physical Education, National Taiwan Normal University, Taiwan
Introduction: The perceived availability of social support has been found to protect against the potential of stressful events to elicit psychological distress, depression, and anxiety (Schwartzer & Leppin, 1989; Kawachi & Berkman, 2001). Besides, resilience is a multidimensional characteristic that varies with context, time, age, gender, and cultural origin, as well as within an individual subjected to different life circumstances (Garmezy, 1985; Seligman & Csikszentmihalyi, 2000; Werner & Smith, 1992, Connor & Davidson, 2003) and it has been defined that could promote one's positive adaptation under stress and adversity (Wagnild 2003). The purposes of this study are following: (1) to assess the reliability and validity of the scales, and (2) to explore the relationship between social support and resilience of college student athletes, and to examine linear relationship between social support and resilience of athletes.
Methods: The data collected from National Sports Training Center during April, 2017. Consisted 241 collegiate athletes (121 males, 120 females), mean age was 22years (SD = 2.73 years) for all participants, from 15 sport teams. Measures included social support and resilience scales. Data analysis methods included the descriptive statistics, Pearson correlation analysis, regression analysis, and CFA.
Results: Based on the CFA, social support ($\chi 2/df$, $p > .05$, RMSEA = .06, CFI = .90) and resilience scales ($\chi 2/df$, $p > .05$, RMSEA = .08, CFI = .89) were both fit with the data. Also, social support were significantly associated with resilience of college student athletes (Adjusted $R2 = .46$, $p < .05$). The results revealed the positive correlation among social support and resilience. The finding indicated that in spite of the structure for social support and resilience had stronger theoretical support, but lacked enough empirical evidences to support and resolve the issues.
Discussion: This study suggested that when athletes take training to upgrade performance, we will have to provide effectively solution to send the messages to athlete to support them correctly. Furthermore, the study suggested the future study that further to explore the reason to affect the correlation between subscales by approaches of bi-factor or Bayesian factor analysis.

THE IMPACT OF DIFFERENT MOTOR INTERVENTIONS ON EXECUTIVE FUNCTIONS IN HEALTHY YOUNG ADULTS – MULTIMODAL- VERSUS SINGLE-INTERVENTION FORMS.

STUHR, C., STÖCKEL, T.

UNIVERSITY OF ROSTOCK

Introduction: It has long been postulated that executive- and motor functions are functionally intertwined [1]. The idea received convincing support from intervention studies, reporting improved motor skill proficiency and/or participants' physical fitness being associated with

enhanced executive functions, such as working memory, inhibitory control and cognitive flexibility [2]. There is consensus in the literature that different kinds of motor interventions differ in their impact on executive functions and that a multimodal approach could multiply those positive effects [2,3]. Currently most of the studies focused on intervention effects on frail older participants or children [3,4]. The aim of our study was to confirm the gain of a multimodal motor intervention compared to a single-intervention form in healthy young adults.
Methods: A control group (CG) and two intervention groups (IG) completed a pre- and a posttest. We assessed working memory (Corsi Block task), inhibitory control (Flanker; Hearts and Flowers), cognitive flexibility (Wisconsin Card Sort test, Flanker, Hearts and Flowers, Trail Making Test) and planning (Tower of London task). IG 1 undertook a bimanual coordination training with juggles (single-intervention) while IG 2 (multimodal-intervention) completed a training combining both bimanual coordination exercises and running at individual heart rate guided moderate intensity. Participants of the IGs completed 12 training sessions of 40 min over a period of four weeks (3 sessions/ week). A repeated-measures ANCOVA was carried out to test for the effects of time (pre vs. post) and group (CG, IG 1, IG 2) and their interaction on cognitive performance.
Results: ANCOVA resulted in statistical trends for an effect of time × interaction on cognitive performances. Both IGs outperformed CG and the multimodal-intervention form gained advantage over the single-intervention form regarding cognitive flexibility. Detailed results will be presented.
Discussion: Although participant were healthy young adults, results confirm previous research with clinical populations. Outcomes will be discussed respecting the explanatory power of the study due to the limited number of participants as well as the validity of executive function tests.

RELATIONSHIP BETWEEN PHYSICAL FITNESS AND NON-COGNITIVE ABILITY IN YOUNG CHILDREN

TAKAHIRO, N.1, KOSHO, K.2, TOMOAKI, S.1, KAZUO, O.3
1: NAGOYA GAKUIN UNIVERSITY , 2: GIFU UNIVERSITY , 3: GIFU SHOTOKU UNIVERSITY

Introduction We have examined the various aspects of the importance of exercise in young children, such as improving physical fitness. In recent years, it has been observed that improving non-cognitive ability is important for children's future success (Pearce et al., 2016). Considerable research has shown a relationship between physical fitness and measures of cognitive ability such as academic achievement and memory (Castelli et al., 2007); however, there is little research showing a relationship between physical fitness and non-cognitive ability. Therefore, the aim of this study was to examine relationship between physical fitness and non-cognitive ability in young children.
Methods The subjects were 379 young children. We investigated the childrens non-cognitive ability using a questionnaire consisting of 20 items. We carried out a physical fitness test and analyzed the results using values standardized by sex and grade levels. We analyzed non-cognitive ability using both the evaluation value of each item and the composite score. The correlation coefficient between non-cognitive ability and physical fitness was calculated. We further examined the difference in non-cognitive ability between the group with greater than average physical fitness and the group with less than average physical fitness using independent t-test.
Results A significant correlation was found between physical fitness and non-cognitive ability in all sex and grade groups. In particular, standing long jump performance was significantly correlated with non-cognitive ability in all sex and grade groups. Upright handstanding time showed a significant correlation in 3-year- and 5-year-old class boys. In all measures of physical fitness except for sitting trunk flexion, the composite score for non-cognitive ability was significantly higher in the group with above-average physical fitness. The two groups showed marked differences in non-cognitive abilities especially on measures of "leadership," "grit," "coping well with things," and "positive self-perception."
Discussion Therefore, it was confirmed that there was a clear relationship between physical fitness and non-cognitive ability in young children. We suggest that promoting exercise among young children will improve their non-cognitive abilities. In particular, we would expect to see exercise beneficially affecting the qualities of "leadership," "grit," "coping well with things," and "positive self-perception."

PSYCHOLOGICAL DETERMINANTS OF COACHES' EMPATHIC SKILLS

TOTH, L.1, REINHARDT, M.2
1: UNIVERSITY OF PHYSICAL EDUCATION, 2: EÖTVÖS LORÁND UNIVERSITY

Introduction: Development of athletes' performance is going on in an interpersonal context (Poczwardowsky et al., 2002). Coaches have an important role in establishing and shaping the performance of their athletes. Beside sporting knowledge leadership skills are also relevant abilities of the coaches independently whether they are working in individual or team sports. One of the key factors of positive athlete–coach connection is empathic ability of the coach. Emotional closeness is also a major factor in the 3+1Cs relationship model of Jowett (2007) beside commitment, complementarity and co-orientation.
Methods: Our aim was to reveal the psychological determinants of empathic abilities of coaches. 298 coaches (69% male, 31% female) with different qualifications and sports took part in the research. Mean age was 33.97 ys, SD=12.71. We measured the following psychological constructs: empathy, Big Five personality traits, perfectionism and emotion regulation, furthermore the prosocial and antisocial behaviors facilitated by the coach.
Results: According to multiple regression analyses all of the four empathy components (fantasy, empathic concern, perspective-taking and empathic distress) was determined by certain Big Five personality traits and certain emotion regulation strategies, as well as by enhancing prosocial behaviors. The fantasy component of empathy was predicted by openness and rumination. Empathic concern was determined by agreeableness, conscientiousness, emotional stability and the support of the athletes' prosocial behaviors towards others. Rumination and blaming others weakened empathic concern. Perspective taking depends on agreeableness, openness, introversion and adaptive emotion regulation processes, like planning and positive reinforcement. Empathic distress was explained by maladaptive

emotion regulation strategies and emotional instability. Age, gender, level of education, years working as a trainer, and perfectionism have no effect on the components of empathy.
Conclusion
Agreeableness, conscientiousness and emotional stability as personality traits, as well as tendency to encourage prosociality can support the empathic capacity of coaches, which has a positive and stimulating influence on the effective athlete-coach relationship.

A STUDY OF CAREER FORMATION AND IDENTITY STATUSES IN JAPANESE UNIVERSITY FEMALE FOOTBALL PLAYERS

UEMUKAI, K., INABA, K., IIDA, Y.

MUSASHI UNIVERSITY

Introduction: Iida(2012) had conducted quantitative as well as qualitative researches of J-League academy players and their parents by focusing on their career formation and process. On the other hand, there are not many teams for girls and it is not easy for them to continue playing football after junior high school. Furthermore, there is no option available to become a professional even after they continue their football career up to a high level, so the options to play at a university compared to the male players are not enough either. That means female players have to build their career among unclear and limited options. What kind of impact does this environmental difference bring to the career development process? It is also an important factor to consider career formation that it is deeply related to adolescent identity formation such as entering high school, entering university, and occupation decision-making.
Therefore, the purpose of this study was to examine the career formation of university female football players with high competition level and to find out the relationship with identity which is a psychological developmental task of adolescence.
Methods: The content of questionnaire includes: when and why they started to play football; factors to carry on this career; background details and reasons for joining their current team; what they think of their current environment that they play football in; what they think of their future as footballers. Furthermore, the identity status scale was used in order to measure the state of identity. This scale is composed of 12 factors, "present commitment", "past crisis" and "future commitment pursuit". 212 University female football players provided valid data.
Results and Discussion: Almost subjects in this study started to play when they were in a lower grade of elementary school and belonged to local club rather than junior high-school team. This result reflects an issue of girls' football in Japan, which lacks the system of "club activities" at school after they move on to a junior high school. Furthermore, one of the reasons to choose their high school is because that was a school with a strong football team but only less than 20% of the students talked to their coach about their choice of school and a great number of them consulted their mothers. For each of the three factors(present commitment, past crisis and future commitment pursuit), a t-test was conducted to examine the difference between the selected national team and the selected regional team. As a result, a significant difference was recognized only for "past crisis" ($t = 2.39$, $df = 203$, $p < .05$). In other words, the players of the selected national team have not experienced "past crises" compared to the players of the regional team. It seems that they have been walking without worry, distress, discordance with the surroundings about their own career development centering on football.

PERSONOLOGICAL PROFILE AND VALUES ORIENTATION IN FOOTBALL ATHLETIC TRAINERS

VAGO, P.

UNIVERSITÀ CATTOLICA MILANO

INTRODUCTION: This study investigated the personality traits and values orientation in trainers.
Athletic trainers strive to monitor the players with the primary objective of enhancing the performance. Their goal is to achieve the best results on the pitch, physically and psychologically both for the individual player or team.
METHODS: Athletic trainers (N= 62; 23.9 ± 3.5 yrs) following a Masters degree were recruited. The participants completed a socio-anagraphic questionnaire - evaluating education and experience both in a football team and in sports context as fitness centers - the BFO (Big Five Observer) a questionnaire designed to investigate the main dimensions of personality (Energy/extraversion, Agreeableness, Conscientiousness, Emotional Stability, Mental Openness) through a list of 40 pairs of bipolar adjectives and the PVQ (Portrait Values Questionnaire) a list of 40 item that describe the values of a general person and subjects express how much they perceive themselves similar to the hypothetical person (in a Likert 6 points scale). The values orientation is organized in two bipolar dimensions: self-enhancement versus self-transcendence; conservatism versus open to change.
RESULTS: Results revealed that trainers – comparing to general population's standardized values - show high levels of mental openness (T higher points mean 57) and emotional stability (T points mean 58). There was a positive correlation (Pearsons' r 0,166 $p<0,05$) between age and energy/extraversion.
Regarding the bipolar values orientation, the sample showed higher values in self-transcendence (mean 4.37) and open to change (mean 4.79).
Discussion: Football athletic trainers should combine mental strategies in order to improve in their players physical readiness but also to achieve a holistic balance between physical, mental and emotional responses to game stimuli. Some personological aspects are important in this professional field. Trainers should demonstrate positive attitude, intrinsic motivation and willingness to listen the players, and in case of injury, good interpersonal communication skills, positive reinforcement, coach support and keeping the athlete involved with the team (prevalent values orientation of self-transcendence).

ATHLETES' SATISFACTION OF SOCIAL SUPPORT FROM COACHES AND ATHLETIC TRAINERS AT DIFFERENT STAGE OF INJURY REHABILITATION

LEE, M.Y., WU, H.T.

NATIONAL TAIWAN UNIVERSITY OF SPORT

Introduction: Recovering from injury and return to sport can be a tough challenge for athletes. It has been suggested that social support play an important role in the process of sport injury rehabilitation. Athletes who recovered from serious sport injuries have emphasized the importance of social support and how various types of social support from different people had helped them go through different stages of recovery (Bianco, 2001; Bianco, T., Malo, S., & Orlick, T., 1999). The purpose of this study was to examine whether there were differences in athletes' satisfaction of different types of social support from coaches and athletic trainers at different stage of injury rehabilitation.

Methods: Participants were 80 Taiwanese national level athletes form 9 different sports (45 males and 35 females, Mean age =25.22, SD=5.77) who had experienced sport injury with a rehabilitation period more than 14 days. They filled in a questionnaire measuring their satisfaction of different types of social support received (listening support, task appreciation, task challenge, emotional support, emotional challenge, and reality confirmation) from different providers (coaches and athletic trainers) at different stage of injury rehabilitation (early period, middle period, and late period). A 2 × 3 (provider × stage) repeated-measured MANOVA was conducted to analyze the data.

Results: MANOVA found a significant main effect of provider (Wilk'sλ=.68, F= 4.38, p=.001, partialη2=.32) and stage (Pillai's trace=.18, F=1.90, p=.035, partialη2 = .09), but no significant provider × stage interaction (Pillai's trace = .10, F=0.96, p=.489). Further univariate analysis showed that, in terms of provider, athlete trainers had a significant higher score than coaches in all types of social support except for reality confirmation. For main effect of stage, only the scores of task challenge varied across stages, with middle period and late period higher than early period, and no other significant difference was found.

Conclusion

Our data showed that injured athletes were more satisfied with athlete trainers than coaches for various types of social support across every stage of injury rehabilitation. These findings suggested that injured athletes expected more social support from their coaches and again emphasized the importance of coaches in the social support network for injured athletes during recovery.

THE PREDICTION OF ATTACHMENT STYLE ON COACH-ATHLETE RELATIONSHIP AMONG HIGH SCHOOL BASKETBALL PLAYERS: THE MODERATING EFFECT OF EMPOWERING MOTIVATIONAL CLIMATE

CHI, L., CHEN, S., CHEN, J.Y., CHUANG, H.Y.

NATIONAL TAIWAN NORMAL UNIVERSITY

The Prediction of Attachment Style on Coach-Athlete Relationship among High School Basketball Players: The Moderating Effect of Empowering Motivational Climate

Li-Kang, Chi, Szu-Yu Chen, Jo-Yun Chen, Hsin-Yun Chuang

NTNU (Taipei, Taiwan)

Introduction: The main purpose of this study was to combine the attachment theory (Bowlby, 1982) and empowering motivational climate (Duda, 1993) examining the prediction of attachment style and empowering motivational climate on coach-athlete relationship among youth basketball players. Furthermore, to examine the moderating effect of empowering motivational climate between attachment style and coach-athlete relationship.

Method

The participants were 268 high school Division-I basketball players (133 males and135 females). The average age of the athletes was 16.77 years. After received the informed consent, participants were asked to complete questionnaires which assess their coach-athlete attachment style, coach created empowering and disempowering motivational climates, and coach-athlete relationship.

Results: The results of multiple regression analyses indicated that empowering motivational climate positively predicted coach-athlete relationship. Disempowering motivational climate and insecure attachment style negatively predicted coach-athlete relationship. In addition, only the interactional effect of empowering motivational climate and insecure attachment style on coach-athlete relationship was found. Specifically, when perceived high empowering motivational climate, athletes reported better coach-athlete relationship regardless of their attachment style. However, when athletes perceived low empowering motivational climate, athletes who were high insecure attachment style reported worse coach-athlete relationship than those who were low insecure attachment style.

Discussion: The results of this study indicated that high school basketball players reported better coach-athlete relationship when they perceived greater empowering motivational climate from their coaches. In contrast, players reported worse coach-athlete relationship when players' perceived greater disempowering motivational climate and players who had greater insecure attachment style. Moreover, this study also found that empowering motivational climate played as a moderator between attachment style and coach-athlete relationship. It is suggested that coaches can create more empowering motivational climate especially for those athletes who have high insecure attachment style.

Rehabilitation and Physiotherapy

EVALUATION OF THE TREATMENT OF PATELLOFEMORAL PAIN IN SOCCER ATHLETES WITH DYNAMIC VALGUS

EDUARDO, A.C.R., MICHEL, L.F., BEZERRA, R.A., KLAITR, D., BUENO, A.I., SANTOS, T.R. GARCEZ, E.C., SANTORO, C., LUIZ JR, H.S.

FACULDADE MAX PLANCK

INTRODUCTION: The knee, located between the hip and ankle, has its dynamic stabilization actualized by the muscles that are inserted to move this joint. The hip influences indirectly the kinematics and stabilization of the knee. Currently the knee joint is one of the most studied in the field of sports practice, high performance or not, due to the high incidence of injuries. Femoropatellar lesions and pain are related to the so-called dynamic valgus during knee flexion movements. which is attributed mainly to poor gluteal muscle performance
Muscle weakness or neuromuscular inactivation of these muscles leads to contralateral pelvic tumbling, increased internal rotation, and ipsilateral femur adduction during functional movements of the knee when flexing. Dynamic valgus is probably related to strength, coordination, ability, anatomical alignment, and arthrokinematic function.
The gluteus medius is an important abductor of the hip joint and the greater the hip flexion, the greater the activation of this muscle, while the gluteus maximus has primary function in the hip extension and is also an important lateral rotator. The strengthening of the maximal and medium gluteus leads to a decrease of the excess of dynamic valgus being of extreme importance in the treatment of patellofemoral dysfunction
METHODS: Twenty-three male volunteers, amateur footballers at competitive level, aged between 19 and 43 years, were evaluated.
Dynamic valgus evaluation was performed by positioning styrofoam markers fixed with double-sided tape, lateral malleoli, tibial tuberosity and anterior superior iliac spine. The subjects were instructed to climb on a raised platform 20 centimeters high, performing tests prior to the exercise learning exam. After the preparation phase, they were instructed to perform 10 consecutive repetitions of the step of descending the step in unipodal support without removing the calcaneus in the limb that reported patellofemoral pain. The tests were filmed by a digital still camera at a distance of 1.20 meters.
The electromyographic evaluation was performed using electromyographic Myotool, 4 channels, positioned in the gluteus maximus muscle.
The images were analyzed by biophotogrammetry, through SAPO software.
After the first collection, the subjects underwent exercises to strengthen the gluteus medius, using exercises with knee flexion in closed kinetic chain simultaneously performing abduction of the hip in isometry, which occurred by an elastic band where the contraction was maintained.
After 4 weeks of treatment performed 3x per week, the second evaluation was performed.
RESULTS: There was a statistically significant difference between the previous and post treatment for both dynamic valgus degrees as well as for the activation of the contraction of the gluteus maximus and maximal muscle
CONCLUSION: knee flexion exercises in closed kinetic chain with the aid of resistance to abduction promoted an increase in muscle strength the activation of the mean and maximum gluteus musculature, decreasing the dynamic valgus. This study by itself does not close the case, and further studies are needed on the subject

MUSCLE ACTIVATION IN A 10-YEAR-OLD BOY DURING THE ASYMMETRICAL TONIC NECK REFLEX

REILLY, E., RUSSELL, A., HIGGINBOTHAM, T., WILLIFORD, H., SCHAEFER, G.

AUBURN UNIVERSITY AT MONTGOMERY

INTRODUCTION: Children are born with a set of primitive reflexes to assist them as they progress through normal development from birth to around age 1. After age 1, these reflexes are integrated into the brain as children engage in physical movement and play, and should not still be evident. When primitive reflexes are retained beyond this point, children can experience difficulties with coordination, learning, behavior, and physical and emotional development. The asymmetrical tonic neck reflex (ATNR) is a primitive reflex initiated when the head turns to the side, causing the arm on the side of the body the head is turned toward to extend, and the arm on the other side of the body to flex. Although research has found an association between a retained ATNR and conditions such as dyslexia, attention deficit hyperactivity disorder, and autism spectrum disorder, less is known about the muscle activation that occurs during the reflex. Therefore, the purpose of this study was to assess the muscle activation of the biceps and triceps during the ATNR.
METHODS: Muscle activation of the left and right biceps and triceps of a 10-year-old boy with retained left and right ATNR's was measured using surface electromyography (EMG). The boy maintained a quadruped position on his hands and knees and a neutral cervical spine position while a researcher turned his head to the right and then to the left to elicit the ATNR on each side. Maximal voluntary contractions (MVC) of the boy's right and left biceps and triceps were also obtained. EMG values were recorded as the root mean square of the raw signal and analyzed using Acqknowledge 4.2 software (BIOPAC, Goleta, CA). Muscle activation for each muscle recorded was compared to that muscle's MVC value and reported as a percentage of MVC (%MVC). EMG values were recorded for the left arm during the right ATNR and for the right arm during the left ATNR.
RESULTS: During the right ATNR, the left biceps activation was 9.625 %MVC while the left triceps activation was 38.437 %MVC. During the left ATNR, the right biceps activation was 11.265 %MVC while the right triceps activation was 22.139 %MVC.
CONCLUSION: Although flexion of the elbow in the quadruped position is normally achieved by eccentric activation of the triceps, eliciting the ATNR reflex resulted in muscle activation of both the biceps and triceps of the arm that flexed. Antagonist muscle activation during the ATNR may help explain some of the difficulties in coordination experienced by children with this retained reflex. Further study with a larger number of children with retained ATNR's is warranted to determine the muscle activation profile of these children during the ATNR.

CHARACTERISTICS OF GENERAL JOINT LAXITY OF HIGH-SCHOOL COMPETITIVE SWIMMERS

KURIKI, A.1, KOKUBU, H.2, KOGA, T.3, EGO, K.4

1: CHIKUSHI JOGAKUEN UNIVERSITY, 2: TECHNICAL SCHOOL OF MEDICAL AND WELFARE RYOKUSEIKAN, 3: SAKAEMACHI ORTHOPEDIC CLINIC, 4: OMUTA CITY HOSPITAL

INTRODUCTION: Competitive swimmers have high joint flexibility, and the incidence of genu recurvatum is reported to be high (Kuriki et al., 2011). Although the joint laxity is a congenital physical characteristic and thought not to change, it may change under the influence of the muscle-tendon complex. Evaluation of joint laxity is widely used in physical examination, and relationships with sports injuries have

been reported. However, considering the possibility of acquired changes, a comprehensive understanding of the physical characteristics of swimmers is needed. Therefore, we investigated the characteristics of general joint laxity (GJL) of high-school student swimmers.
METHODS: Eighty-seven high-school student swimmers (44 boys and 43 girls) participated. A questionnaire was used to survey the years of experience and previous injuries, and Tokyo University's GJL test (Nakajima et al., 1984) was conducted. The GJL test uses a 7-point scale and requires the performance of 7 manoeuvres for wrist, elbow, shoulder, ankle, knee, hip and spine. The GJL score was calculated by adding 1 point (0.5 points on each side) on the positive side. A score of >4 indicates hypermobility.
The t test was used to compare gender differences. The chi-square test was used to analyse the association between the positive rates of each joint. To analyse the relationship between the score of each joint and the GJL score, the scores excluding the score of each joint from GJL score of the positive and negative groups was calculated and examined using the t test and effect sizes.
RESULTS: The GJL score was 3.5 ± 1.2 for the boys and 3.6 ± 1.5 for the girls, with no statistically significant difference ($p = .629$).
In both the boys and girls, wrist, shoulder, knee and spine had positive rates for GJL scores exceeding 50%. In the boys, the positive rates of right-shoulder and spine were high ($p < .001$). In the girls, the positive rates of left-wrist, right-shoulder and spine were high ($p < .001$). In the girls' ankle, the score of the positive group was significantly higher than the score of the negative group ($p < .05$, $d = .87$).
CONCLUSION: Swimmers GJL scores tended to be higher than other athletes (Narita et al., 2002). The GJL score is influenced by gender, and females are reported to have higher scores than males (Quatman CE et al., 2008); however, there was no gender-related difference among swimmers. The characteristics of swimming performance may have a greater influence than genetic factors.
Comparison of the scores between the positive and negative groups indicated that the girls' ankle suggested the GJL score. This means that if this joint shows positivity, the other joints are also likely to show high laxity. Especially the examination of ankle strongly suggests laxity of other joints and would be useful as a screening for GJL in the girls.
For effective physical examination, each joint should be evaluated in more detail according to these physical characteristics.

EFFECT OF VIBRATION FOAM ROLLING FOR DELAYED-ONSET MUSCLE SORENESS AND ATHLETIC PERFORMANCE

LIU, C.M., OU, S.C.

CHANG JUNG CHRISTIAN UNIVERSITY

INTRODUCTION: Lots of evidence shows that foam rolling can improve range of motion, flexibility, and performance in addition to reducing muscle soreness, pain, and recovery time after workouts. Besides, Vibration technology is also a proven tool of rehabilitation and therapy for sports. Vibration foam roller has become of increasingly common practice for treating soft-tissue restrictions which allows the user to apply vibration directly to a muscle group while also receiving the many benefits of compression and self-myofascial release. However, there's not much research behind this new take on the recovery tool. Therefore, the aim of this study was to explore the effects of the vibration foam rolling on delayed-onset muscle soreness and dynamic performance measures.
METHODS: Twenty-four college male subjects, involving 10 sets of 10 repetitions of back squats at 60% of their 1-repetition maximum, all participants were randomly assigned into vibration foam rolling (n = 8), foam rolling (n = 8), control (n = 8) groups. On Days 0-4, the creatine kinase (CK), lactate dehydrogenase (LDH), range of motion (ROM), visual analog scale (VAS), power, speed, agility and dynamic strength-endurance of all participants, including control subjects were measured. In this study, two-way mixed-design analysis of variance were employed for the statistical analysis. A LSD Post Hoc test was performed to the test for significant differences between interactions. An α level of .05 was used to indicate statistical significance.
RESULTS: After exercise triggered DOMS, the results showed that there were no significant differences within groups on all variables in this study ($p > .05$), but time factor showed substantial significant differences between pre-exercise and post-24 or post-48 after exercise on CK, ROM, VAS, speed, dynamic strength-endurance, respiratory ($p < .05$). According to the results in this study, exercise not only trigger DOMS, but also induced muscle damage. The foam rolling massage or vibration foam rolling cannot relief dynamic performance measures (power, speed, agility and dynamic strength-endurance) and the injury in muscles or connective tissue from exercise-induced muscle damage.
CONCLUSION: Even if the studies showed that foam rolling reduced subjects pain level while enhanced recover after DOMS (MacDonald et al., 2014; Pearcey et al., 2015). But there is no evidence explore how worse muscle damage is after trigger DOMS by intense exercise. This study approves that the foam rolling and vibration foam rolling can't relief DOMS and muscle damage after intense exercises. It seemed that the damaged muscle tissue or connective tissue could not sustain the pressure caused by the rolling massage or vibration directly. However, applying how much pressure on damaged muscle tissue would hinder the muscle tissue and connective tissue from recovering still needs further research to reveal.

CORTICOMOTOR EXCITABILITY ALTERATION OF QUADRICEPS AND HAMSTRING AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION

FAN, T.

NATIONAL TAIWAN UNIVERSITY

INTRODUCTION: Short term or long term adaptations in spinal circuits and brain cortex following anterior cruciate ligament reconstruction (ACLR) is demonstrated, resulting the persisted muscle weakness, muscle activation deficit, poor proprioception and decrease activity level. Diminished corticomotor excitability of quadriceps and hamstrings may associate with impaired physical function, especially agility performance. Previous studies of cortical are focus on the corticospinal excitability of quadriceps muscle, but it is important to evaluate the corticospinal excitability of hamstrings muscle owing to the surgery method. Therefore, the purpose of this study was to evaluate the corticospinal excitability, muscle strength and functional activities in anterior cruciate ligament reconstruction patients.
METHODS: Sixteen male individuals (age = 27.19 ± 3.54 years, mass = 76.86 ± 13.05 kg, time postsurgery = 36.06 ± 29.48 months) who had undergone unilateral, primary ACLR using a hamstrings autograft at least 6 months before the study, and fully returned to pre-injury activity level were recruited. Corticomotor excitability of vastus medialis and hamstrings were quantified via active motor threshold (AMT) by transcranial magnetic stimulation (TMS). Maximum knee extensor and flexor isokinetic strength in 60°/s, one-leg hop, and t-run agility test were measured. Isokinetic strength was normalized by body weight (Nm/kg), one-leg hop was calculated by asymmetry index (between limb differences/construction limb*100%).
RESULTS: Participants with ACLR exhibited less quadriceps and hamstrings active motor threshold in the reconstructed limb than in the contralateral limb (quadriceps _AMT: 68.31 ± 5.13 vs 64.13 ± 5.14, p=0.02; hamstrings_AMT: 66.25 ± 6.67 vs 61.69 ± 5.31, p<0.01). There were no significant differences in both knee extensor (op side: 2.16 ± 0.58 vs control side: 2.43 ± 0.51, p=0.06) and flexor (op side: 1.03 ± 0.21 vs control side: 1.04 ± 0.13, p=0.84) isokinetic strength between limbs. Quadriceps active motor threshold in reconstruction limb was moderate associate with quadriceps_AMT in control limb(r=0.64, p=0.008) and hamstrings_AMT in both limb (reconstruction limb:

r=0.74, p=0.001; control limb: r=0.83, p<0.001). Knee flexor isokinetic strength in reconstruction limb was associated with one-leg hop(r=-0.51, p=0.045) and t-run test(r=-0.58, p=0.019).
CONCLUSION: Higher active motor threshold in both quadriceps and hamstrings muscle of involved leg demonstrated long-term neuromuscular deficits in our ACLR participants. In addition, decreased knee flexor isokinetic strength was associated with poor functional performance. Rehabilitation strategies for corticomotor excitability and knee flexor muscle strength may help improve postoperative outcomes.

ASSESSMENT OF EXERCISE TOLERANCE AND FUNCTION OF THE LOWER LIMBS OF PATIENTS AFTER CABG SUBJECTED TO CARDIAC REHABILITATION

SKOMUDEK, A., WAZ, G., ROZEK-PIECHURA, K.

OPOLE UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Comprehensive cardiac rehabilitation following coronary artery bypass grafting (CABG) can critically impact patient health outcomes including cardiorespiratory function, exercise tolerance, and quality of life. The aim of the study was to assess the exercise tolerance of patients after CABG subjected to the second stage of cardiac rehabilitation.
METHODS: A clinically relevant sample of 47 male CABG patients (aged 59.8 ± 6.80 years) was selected and assessed pre-CR, and post-CR. Body composition analysis was performed by bioimpedance (Tanita BC 418 MA) to obtain body weight, BMI, FAT%, FAT MASS, FFM and TBW. The next analysis was exercise test was carried out according to the modified Ramp protocol (resting HR, exercise HR, MET, Borg scale). Lower limb function (ankle dorsiflexion/plantarflexion) was assessed by isokinetic testing (Biodex Multi Joint 4) to determine peak torque, peak torque relative to body weight, total work, and average power.
Funding for this study was obtained from the National Science Center grant no. UMO-2013/09/N/NZ7/03650 and registration ANZCTR: ACTRN12615000983505. The study protocol was approved by the Senate Ethics Committee for Scientific Research of the University of Physical Education in Wroclaw, Poland (March 27, 2013). They were recruited from October 2012 to April 2016.
RESULTS: Comparing the somatic parameters, a significant reduction in body weight and BMI after the use of rehabilitation was demonstrated (p≤0.0104). In the exercise test, there was a significant increase in MET after rehabilitation. There was no significant difference in resting, exercise and Brain scales before and after rehabilitation in the study group. In isokinetic studies, a significant increase was observed after the use of rehabilitation in the operated limb in the majority of the examined parameters assessing the function of dorsal and plantar flexors both at 60o / s and 120o / s.
CONCLUSION: 1. Before the beginning of rehabilitation, the subjects were characterized by an average level of exercise tolerance and after the 3-week improvement process there was a significant increase in exercise tolerance, which also oscillated at the level of the average level.
2. The assessment of somatic parameters in the examined group showed the effectiveness of the early-follow-up model, which was manifested by a significant reduction in body weight and BMI.
3. All assessed strength-speed parameters of the operated lower limb increased significantly after the use of three-week long-term cardiological rehabilitation.
4. A significant correlation between exercise tolerance (MET) and percentage of adipose tissue, fat mass, percentage of adipose tissue in relation to the limb and gross work of dorsiflexes at 120o / s was demonstrated.

EMG ANALYSIS OF THE FLATFOOT WITH AND WITHOUT ARCH-SUPPORT INSOLE DURING UPHILL WALKING

PENG, H.T., HUANG, Y.P.

CHINESE CULTURE UNIVERSITY

INTRODUCTION: Previous researches indicated that uphill walking with a constant speed can improve the symmetry and cardiovascular condition of body (Globas et al., 2012; Werner et al., 2007). However, people with flatfoot cannot practice the prolonged walking and they will demonstrate over foot-pronation inducing the fatigue of the lower-extremity (Panichawit et al., 2015). The assistive devices such as arch-support insoles could be helpful for people with flatfoot who want to engage a prolonged exercise. A normal foot-arch can make the foot like a spring for absorption or propulsion. The purpose of this study was to examine the effect of arch-support insoles in lower-extremity muscle fatigue on people with flatfoot during uphill walking. We hypothesize that the arch-support insoles can reduce the fatigue of lower-extremity muscles.
METHODS: Fifteen male college students with flatfoot were voluntarily to be the subjects. A Delsys wireless electromyography (EMG) system was used to collect EMG data of rectus femoris (RF), tibialis anterior (TA), bicep femoris (BF) and gastrocnemius (GAS) muscles at 2000Hz. Subjects were instructed to walk on a treadmill with the inclination of 9 degree and speed of 0.75 m/s (2.7 km/h) (Haight et al., 2014) for six minutes (Sparks & Hilton, 2015) to mimic uphill walking and randomly wear insoles with and without arch-support. The power spectral density (PSD) was used to analyze the EMG data for the none-fatigue and fatigue which were the first and last minute during uphill walking, respectively. Hanning window type and 0.5 second window length with 75% overlap (Clancy et al., 2005) were used for the power spectrum. The area under the power spectrum of 15-45 Hz was calculated and the larger area under the power spectrum of the lower frequency indicated the muscle was more fatigue (Allison & Fujiwara, 2002). A repeated-measures 2×2 two-way ANOVA (with and without arch-support insole × none-fatigue and fatigue) was used to examine the difference. The level of significance was set at $\alpha = .05$.
RESULTS: The results showed that there was interaction found in GAS. The simple main effect showed that the area of GAS without arch-support insoles was significant lager than that with arch-support insoles. The main effect showed that the area of TA in fatigue was significant larger than that in none-fatigue.
CONCLUSION: Wearing arch-support insoles can reduce the gastrocnemius muscle fatigue on the college students with flatfoot.

CHANGES IN ACTIVATION OF SERRATUS ANTERIOR, TRAPEZIUS AND LATISSIMUS DORSI WITH SLOUCHED POSTURE

LEE, S.T., MOON, J.K., LEE, S.H., MIN, K.

CHA BUNDANG MEDICAL CENTER, CHA UNIVERSITY

INTRODUCTION: To compare quantitative muscle activation between erect and slouched sitting postures in the muscles around the scapula, and to investigate the correlation between the angle of thoracic kyphosis and the alteration of muscle activity depending on two different sitting postures.

METHODS: Ten healthy males participated in the study. Unilateral surface electromyography (SEMG) was performed for serratus anterior, middle trapezius (MT), and lower trapezius (LT), which are scapular stabilizer muscles, as well as latissimus dorsi. Participants elevated their shoulders for 3 seconds up to 90 degrees abduction in the scapular plane, tilting 30 degrees anterior in the coronal plane. They were told to hold the position for 10 seconds and voluntary isometric contractions were recorded by SEMG. These movement procedures were conducted for three times each for erect and slouched sitting postures and data were averaged.
RESULTS: Activities of MT and LT increased significantly more in the slouched sitting posture than in the erect one. There was no significant correlation between kyphotic angle and the area under curve of each muscle.
CONCLUSION: Because MT and LT are known as prime movers of scapular rotation, the findings of this study support the notion that slouched sitting posture affects scapular movement. Such scapular dyskinesis during arm elevation leads to scapular stabilizers becoming overactive, and is relevant to muscle fatigue. Thus, slouched sitting posture could be one of the risk factors involved in musculoskeletal pain around scapulae.

EFFECT OF POWER ASSIST SUIT ON THE MECHANICAL AND PSYCHOLOGICAL STRESS OF LOW BACK PAIN DURING STOOP LIFTING WITH A HEAVY LOAD

TAKAYOSHI, Y.

UNIVERSITY OF FUKUI

INTRODUCTION: Low back pain is a work-related injury that accounts for 60% of all occupational diseases with a 4-day absence from work. Factors such as a high physical burden, unprepared movement, and maintaining static work for a prolonged duration; environmental factors, such as floor condition, vibration, and cold; and personal factors, such as physique, age, and muscle strength, proliferate the risk of low back pain. Because a power assist suit, which is designed to decrease the burden on low back during the loading and unloading of heavy load, decreases the high physical burden upon lifting a heavy load, the prevention of low back pain is anticipated. This study aimed to assess the effect of the power assist suit on the mechanical and psychological stress of low back pain during stoop lifting with a heavy load.
METHODS: We enrolled 15 healthy males (age, 22.4 ± 4.9 years) after obtaining informed consent from them. All participants were asked to lift a heavy load, which was equivalent to each participant's body mass (0%, 20%, and 40%), in the posture with extending back and knee joint and 90° flexing hip joint. We evaluated the mechanical stress of low back pain from the beginning of the lifting of heavy load to the completion using the peak and mean torque of the low back joint. In addition, we evaluated the psychological stress of low back pain with the lifting of heavy load using the visual analogue scale. Furthermore, the effect of the power assist suit and the difference among heavy loads for the mechanical and psychological stress of the low back joint were assessed using paired two-way analysis of variance. Furthermore, Tukey's honest significant difference (HSD) was conducted for the post-hoc analysis. Statistical significance was set at $P < 0.05$.
RESULTS: During the lifting of all heavy loads, low back joint torques significantly decreased with the power assist suit. In contrast, during the lifting of heavy load without the power assist suit, the low back joint torque linearly increased with an increase in the heaviness, whereas it remained constant with the power assist suit. In addition, the psychological stress during the lifting of all heavy loads with the power assist suit was significantly lower than that without the suit.
CONCLUSION: Thus, our study suggests that the mechanical and psychological stress of low back during stoop lifting with heavy load are significantly decreased using the power assist suit.

Sociology

EQ-INDEX AND SF12 MORE THAN EQ-VAS CORRELATES WITH PHYSICAL FUNCTION IN OLDER ADULTS

MONTEAGUDO, P.1, CORDELLAT, A.1, ROLDÁN, A.1, GÓMEZ-CABRERA, M.C.2, BLASCO-LAFARGA, C.1

UNIVERSITY OF VALENCIA, SPAIN

INTRODUCTION: Quality of life (QoL) measures such as the Euroqol-5Dimensions-5Levels "EQ" (Herdman et al., 2011) and the Short Form 12-item Health Survey Questionnaire "SF-12" (Ware, Kosinski, & Keller, 1996) are important tools to analyze the impact of elderly care interventions such as physical exercise programs. Also the ability to walk for a distance is an important component of QoL in older adults (OA) (Lord & Menz, 2002), as well as a quick and inexpensive measure of physical function (PF). This study aims to analyze the association among these traditional QoL indexes, with special attention to their relationship with this PF, in a population of OA.
METHODS: 53 healthy OA (71.02±4.45 years; 75.29±14.00 kg; 27 women and 26 men) participated in the study. Two questionnaires were provided for QoL assessment. EQ consists of 5 domains: mobility, selfcare, usual activities, pain and anxiety, which score from 1 (no problem at all) to 5 (extreme problems). The final EQ-index ranges between 0-1, and a single question about self-rated overall health (EQ-VAS) is posed (score 0-100). The 12 items in the SF-12 are summarized as the physical component summary (PCS) and the mental component summary (MCS). Finally walking ability (PF) was measured by the 6-minutes-walking-test (Rikli & Jones, 2001). Further correlation analysis (Spearman) were performed, considering: r=-0.1-0.3 small; r=0.3-0.5 means; r=>0.5 large (Cohen, 1988).
RESULTS: Significant positive correlations were found between PF and EQ-index ($r=0.44$, $p<0.01$); PF and PCS ($r=0.48$, $p<0.01$); PF and MCS ($r=0.35$, $p<0.01$); EQ-index and EQ-VAS ($r=0.43$, $p<0.01$); EQ-index and PCS ($r=0.66$, $p<0.01$); EQ-index and MCS ($r=0.47$, $p<0.01$); EQ-VAS and PCS ($r=0.33$, $p<0.05$); EQ-VAS and MCS ($r=0.38$, $p<0.01$); PCS and MCS ($r=0.73$, $p<0.01$). However, no correlations were found between PF and EQ-VAS ($p>0.05$).
CONCLUSION: Our results confirm that both questionnaires can be useful to assess QoL. EQ-index seems to explain better the physical and psychological function, whilst EQ-VAS might be explaining other influential factors in the QoL. The non- correlation between PF and EQ-VAS also reaffirms that QoL and health status constructs are not the same (Zangão, Mendes, & Braga, 2016).

GENDER DIFFERENCES IN LEISURE-TIME PHYSICAL ACTIVITY, EXERCISE MOTIVES AND LOCUS OF CAUSALITY IN EXERCISE IN UNIVERSITY OF ZAGREB STUDENTS

BABIC, J.

UNIVERSITY OF APPLIED HEALTH SCIENCES

Introduction: Influencing physical activity (PA) level should be public health system priority and by identifying and understanding individual variables, together with social, cultural and environmental factors that are potentially connected to PA level, is basis for developing suc-

cessful interventions (Burgos-Garrido et al., 2011). Aim of this research is to determine whether there is gender differences in leisure-time physical activity, exercise motives, locus of causality in exercise in University of Zagreb students.
Methods: Participants were 570 University of Zagreb students (329 female, 241 male), average age 19,94 years. Croatian version of IPAQ (Pedisic et al., 2011) which measures adult PA, Croatian version of EMI-2 (Vlasic et al., 2002) which measure 14 exercise motives, and The Locus of Causality for Exercise Scale (Markland and Hardy, 1997), which consists of 3 items that assess the extent to which individuals feel that they choose to exercise rather than feeling that they have to for some reason, were used.
Results: Male students were more physically active during their leisure time than females and were more motivated for exercise by group of psychological motives (enjoyment, affiliation, challenge), social motives (social recognition, health pressures, competition) and by strength/endurance motives, while female students were more motivated by group of health related motives (ill-health avoidance, positive health, nimbleness, appearance, weight management). Also, male students have more internal perceived locus of causality.
Discussion: Understanding students gender differences regarding their leisure-time PA level and specially their motives behind it is really important when it comes to planning and creating intervention programs that aim to increase student population PA.
Conclusion
Male students are significantly more physically active then female students, have more internal perceived locus of causality, and are more motivated for exercise by psychological, social and stength/endurance motives, while female students are more motivated by health related motives.

ONLINE SPORTS CULTURE: A CASE STUDY OF JAPANESE SPORTS FAN BLOG

OHHASHI, M.
KURUME UNIVERSITY

The scientific significance of the recent Internet information on sports is generally acknowledged by several scholars (Leonard, 2007; Wilson, 2007; Scherer and Jackson, 2008, Milling and Darnell, 2014). In particular, contemporary journalists have much higher chances of gathering information from blogs to write their articles (Farrell and Drezner, 2008). However, Millington and Wilson (2010) point out how "internet-based projects routinely fail to examine the confluence of "virtual" and "real" consumer/user experience". It was widely believed that blog posts were "wall graffiti." Although a large number of Japanese sport researchers have explored the contexts of sport in mass media, little is known about sport in Japanese online media. Also, few studies have examined Japanese online media contents such as blogs in relation to sports disciplines. Bloggers can always post if they connect to the Internet; at the same time, they always pay attention to readers' feedback (Nardi, 2004). This study presents the results of a preliminary exploration of the role of one of the biggest Japanese sports fan blogs, Sportsnavi Plus, in the coverage of one of the biggest sports events in Japan, the Tournament of Japanese High School Baseball (TJHB). In order to outline the characteristics of Sportsnavi Plus, this research tried to answer to the following research questions: (1) Who posts on Sportsnavi Plus? (2) What kind of content is posted? and (3) Are there any differences in the characteristics of the blog posts of the last 10 years? The answers to these questions contribute to describing the online Japanese sports culture, which includes bloggers articles and/or communications. The study analyzed data from Sportsnavi Plus blog posts about TJHB, posted during the month of August each year from 2006 to 2016, as August almost fully coincided with the period of the tournament. Content analysis was employed to analyze the collected data; therefore, it was possible to generalize the features of Japanese sports fan blogs. The bloggers were divided into three main categories: sports journalists, sports magazine editors, and baseball fans. Results show that, although a large part of blog posts dealt with the results of recent games, in the most recent years, the number of posts that analyzed each game in detail increased in comparison with the number of posts that were based on subjective impressions of the bloggers. In conclusion, this study suggests a tendency in Japanese sports fan blogs, which are increasingly becoming a more objective source of information.

DO SPORT JOURNALISTS HAVE COMPETENCE PROBLEMS AND KNOWLEDGE DEFICITS IN THE FIELD OF DOPING IN ORDER TO BE ABLE TO ADEQUATELY REPORT ON THEM?

SCHULZ, T.1, KAUTZ, F.2, SCHAFFRATH, M.2
TECHNISCHE UNIVERSITÄT MÜNCHEN

Introduction: Doping is one of the biggest negative side effects of elite sports. Media have a significant impact on public opinion on doping and attitudes. The way sport journalists report on the issue of doping is repeatedly the focus of criticism of affected athletes, coaches or external observers, as well as the professionals themselves. To what extent sport journalists can even adequately report on doping has not been investigated yet. Therefore, the study deals with the knowledge of sport journalists in Germany on doping and doping reporting.
Methods: To this end, an online survey was conducted among the members of the "Association of German Sports Journalists" (VDS) and the sports network. Of the 3,170 sport journalists who were contacted, 850 took part in the survey. The response rate was 26.8 percent and is very high for journalists. Based on the characteristics "gender" and "age", the study is representative for sport journalists in Germany. The questionnaire included 38 questions with a total of 122 items. 5 questions deal with the topic "education and training", 5 questions with "knowledge and expertise", 13 questions with "opinions and attitudes", 4 questions with the "NADA" as well as 10 questions with the demography, the intensity of the doping employment and the research methods. From the knowledge questions with 13 items a knowledge score was formed. The adjusted data sets were evaluated using descriptive and inferential statistical methods: group differences by means of one-factor ANOVA and correlations.
Results: Sport journalists assess doping reporting as more "superficial", more "person-oriented" and tend to be "prejudiced". The opinion of many respondents regarding the issue of doping is increasingly not "competent" or "adequately trained". Related to "medical", "physiological" and "sports law" aspects and the knowledge of the official definition of doping, only 30 percent state a good or very good knowledge. Deficits are also evident in the knowledge score: 14 percent of sport journalists have a high level of knowledge, 56.3 percent of respondents have a "middle" knowledge, 28.5 percent have a "low level" knowledge and 1.5 percent have "no" knowledge about

doping. Correlation analysis show that deficits in knowledge are significantly related to "reporting intensity", "formal education" or "attending training events on doping".
Conclusion
"Many-publishers" on doping issues know more than sport journalists who publish little or nothing on that topic. Since the sport journalists already admit competence problems and also feel badly educated, further education especially in the field of "sports physiology, sports medicine and sports law" is necessary. This is also the task of sports science institutions.

MIGRATORY PROCESS OF BRAZILIAN OLYMPIC WOMEN

MELO, G., FERRREIRA JUNIOR, N.S., RUBIO, K.
CATHOLIC UNIVERSITY OF BRASÍLIA

The process of professionalization of sport since the 1980s has radically altered the organization of world sport. In the passage to professionalism the athlete has become the representative of brands and commercial interests in a globalized world. Transformed into a worker in search of the job market he lives from the adolescence a migratory process in search of the best opportunities to develop his abilities. In this process he lives intensely phases of adaptation and losses, besides the acquisition of new values that reorganize his subjectivity. This article aims to present the national and international migrations experienced by the Brazilian Olympic athletes who participated in the Olympic editions until London in 2012. For that, were interviewed 444 athletes, and from these interviews variables were removed that made it possible to describe the migratory event. The results allow us to infer that Olympic athletes come from 24 states plus the Federal District, and that those born in the North, Northeast and Central West regions are the ones who experienced the most intense national migration in search of better training infrastructure. With regard to international migration, Brazilian womens sporting athletes are the ones who go out in search of better professional opportunities and go mainly to Europe. On the other hand, the athletes of individual modalities, depart in search of improvement or for the opportunity to undertake a superior course and the most sought after destination are the United States.

WELLFARE AND WELL-BEEING AMONG IN THE HEALTHCARE PROFFESIONALS WORKING

NAGYVÁRADI, K., MÁTRAI, Z.
EÖTVÖS LORAND UNIVERSITY

Introduction: A great number of research studies in the related international literature on sociology and health sciences deal with the state of health in one selected population. In these research studies the chosen sample is connected with special jobs, often with healthcare professionals and their working conditions. Their starting point is that healthcare professionals" jobs differ very much from other occupations" as they have a heavy workload under huge physical and psychological working conditions
Simple and method
The examined psychiatric institute Results: The methodological outcome of the research is that the case study has satisfyingly demonstrated that the results of health status measurements cannot be considered to be definitely true if they are based on self-assessment only. Furthermore, they are really well, whose mental and physical well being are in relative sync with each other.
Discussion: The direction of further research is basically suggested by the fact that the conclusions in the corresponding literature are based merely on subjective self-assessment. Therefore, it is worth conducting research in which the conclusions are based on the comparison of objective data and subjective indicators.

ANALYSIS OF THE INFLUENTIAL FACTORS OF CHINESE PROFESSIONAL FOOTBALL MARKET ORDER STATUS

HOU, H.
MINZU UNIVERSITY OF CHINA

Introduction: After 24 years of development, the overall framework of Chinese professional football market has basically taken shape and achieved some praiseworthy achievements. However, due to the fact that the planned economy and market control coexist during the transitional period of institutional reform, the Chinese professional football market is directly caused by the unreasonable market structure and the irregular market competition. This has become the major obstacle in the development of the Chinese professional football market. Therefore, through the analysis and discussion of the Chinese professional football market order status and influential factors, it provides the basis and guidance for the standard management of the Chinese professional football market order.
Methods: On the basis of interviews with experts, a questionnaire about the influencing factors of Chinese professional football market order was compiled and 15,000 football fans, 800 coaches and athletes and 70 club managers of 29 Chinese professional football teams were investigated. We used the importance exponent= and factor analysis to deal with the original data, which provided an objective basis for analyzing the influencing factors of Chinese professional football market order.
Results: The results show that: firstly, Chinese professional football market is currently in a disorderly structure, an imperfect legal system and disorderly competition. Secondly, judging from a single factor, the existence of match-fixing and black whistles is the most influential factor in Chinese professional football market. From overall view, competition level factor, professional ethics factor, rule of law level factor and service level factor constitute the multi-dimensional structure influencing factor system of Chinese professional football market order.
Discussion: Regardless of single influence factor or overall influence factor, professional football players professional ethics and individual competitive ability are the most important factors, to affect the standard management of Chinese professional football market order. This requires that the Chinese Football Association and clubs should strengthen the professional quality education of professional football players and football practitioners, and at the same time improve the level of scientific training and the competitive ability of professional

football players. In addition, the Chinese Football Association needs to continuously strengthen the system construction and improve the level of legalization management, football clubs should continue to improve service awareness and service level.

Sport Statistics and Analyses

THE CHARACTERISTICS OF EFFECTIVE APPROACH RUN FORM OF THE VAULT OF GYMNASTICS

YAMASHITA, R.1, MORII, D.2

1>UNIVERSITY OF KYUSHUKYORITSU 2>JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION

INTRODUCTION: In general, maximum speed during gymnastics vault run is approximately 8 m/s and at least 10 m/s is required to perform double salto during second flight (Čuk and Karácsony,2004).In recent years, vaulting techniques has developed drastically that an examination of effective running techniques during gymnastics vault run is necessary.
The purpose of this study was to elucidate the characteristics of effective gymnastics vault run to enable fast running speed by analysing gymnastics vault run of the world top gymnasts from a morphological viewpoint.
METHODS: Vault finalists from the world championships and Olympics between 2008 and 2017 were analysed.Gymnasts were divided into group (G) 1 (performed two types of double salto in 2nd flight, N = 12), G2 (performed one type of double salto in 2nd flight, N = 12) and G3 (did not performed double salto in 2nd flight, N = 11). Four to six steps before take-off were analysed by a university lecturer who is specialised in sprinting in athletics. The criteria for effective kicking movement was that a leg lands the floor with a small knee joint angle and a low centre of gravity (Tanigawa et al,2009). The criteria for assessing arm movement was: an angle of the arm swing when seen from the side; an elbow joint angle; an angle of cross arm swings; direction of arm swings (parallel or cross).
RESULTS: Effective kicking movements were performed by 97.1% of gymnasts. The forward arm swing angle which was seen from the side was around 45°in all gymnasts.On the other hand, angle of backward arm swing was different between the groups.A smaller backward arm swing compared to forward arm swing was demonstrated by 75.0%, 25.0% and 27.3% of gymnasts in G1, G2 and G3, respectively.
CONCLUSION: Top-level gymnasts in recent years showed large arm swings which were similar to sprinters in athletics and only a small number of performers demonstrated small arm swings to maintain balance during gymnastics vault run.This adjustment was probably caused by an increase in vault width from 30cm to 95cm which provides a greater number of choices to gymnasts to place their hands on the vault for push-off actions. A rationale for cross arm swings during gymnastics vault run is possibly the body shape of male senior gymnast as their shoulder blade tend to show abduction at resting position. It is difficult to perform parallel arms swings when shoulder blades are abducted and cross arm swings naturally occur. Greater the cross swings, greater the torsion of the body when large back swing is performed and that reduces leg speed.If cross-swing is unavoidable, the gymnasts should take smaller back swings which would probably raise running speed during gymnastics vault run.
Many opinions supported the necessity of improvement in gymnasts arm swing techniques. However, it was suggested that the running speed during gymnastics vault run can be raised by cross-swing and small back-swing even if gymnasts shoulder blades are naturally abducted.

SOMATOTYPES OF ELITE JUNIOR SAMBO ATHLETES FROM DIFFERENT WEIGHT CATEGORIES

DRID, P.1, TABAKOV, S.2, ELISEEV, S.2, AL FAZAZI, S.3, TRIVIC, T.1, OSTOJIC, S.M.1

1 UNIVERSITY OF NOVI SAD, SERBIA; 2 RUSSIAN STATE UNIVERSITY OF PHYSICAL EDUCATION, SPORTS AND TOURISM, MOSCOW, RUSSIA; 3 UNIVERSITY OF GRANADA, SPAIN

INTRODUCTION: Sambo is a relatively novel international martial art founded back in 1930's. It is mainly characterized by specific throws, holds, arm and leg locks, with successful performance in sambo seems to depend on specific technique and tactical skills along with optimal physical fitness (Drid et al., 2017). During a high-intensity action in sambo the opponents are trying to throw each other predominantly on the back or to control the opponent during the ground phase (Drid et al., 2015; Drid et al., 2017). The aim of the present study was to determine the somatotype and anthropometric profiles of elite junior sambo athletes comparing by weight categories.
METHODS: A total of 144 elite junior sambo athletes from 34 countries participants of the World Youth and Junior Championship (12 october - 16 october 2017, Novi Sad, Serbia) participated in the study (50 females and 94 males from 10 weight categories). Anthropometrical variables were taken in order to calculate somatotypes and body fat percentage. The 1 way ANOVA test showed significant differences by weight categories for all anthropometrical variables in both males and females. The 2 way ANOVA analysis showed significant effects of sex and weight category, without a statistically significant interaction between both variables. The Fischer's LSD method was used for post hoc analysis.
RESULTS: Results of this study suggests specific somatotypes for each weight category in elite junior sambo athletes. Lightweight sambo athletes are mesomorphic and ectomorphic, with an increase in the dominance of mesomorphic and endomorphic components in heavier weight categories. Sambo athletes from heavier categories had also a higher body mass index, body fat percentage, and height than sambo athletes from lighter categories.
CONCLUSION: This study highlights the importance of distinguishing between categories during the training and selection processes, since sambo athletes have a specific body composition in function of the weight category in which they compete. In addition, future research should attend to these differences to generate appropiated conclusions about the role of anthropometric characteristics in sambo.

Sport Technology

A THREE COMPONENT APPROACH TO SUPPORT TEAM HANDBALL COACHES

SCHWENKREIS, F.

BADEN-WUERTTEMBERG COOPERATIVE STATE UNIVERSITY STUTTGART

INTRODUCTION: Today, not much information is automatically collected in team handball. However, team handball coaches have a need for information to base decisions on during a match as well for addressing weak points of teams and players during training. While some information is collected by scouts e.g. collecting on behalf of betting service providers, like sportradar, in the German professional leagues of mens team handball, lower leagues as well as womens team handball cannot benefit from such a service. Furthermore,

todays manual collection of information is error prone due to the limitations of human scouters given the volume and complexity of events as well as due to the non-handball-specific application that is used to collect the data.
METHODS: Definition of a software archicteture and implementation of software components.
RESULTS: To overcome the previously described problems to support coaches during matches, we are following an approach based on three components:
1. The scouting app: A tablet-based app which optimally supports comprehensive manual scouting of team handball matches from the point of view of one team.
2. The coaching app: Introducing a tablet-based app for coaches directly providing information regarding the performance of players as well as of a whole team. Furthermore, the current performance is evaluated based on previously collected data and analysis thereof. This evaluation is used to add indicators to the depiction of the raw values for the coach.
3. The data backend: Technically, the two apps are implemented based on the same backend application that uses a SQL database to store collected data as well as to provide data for visualization by the coaching app.
CONCLUSION: The backend has been designed such, that it can be run on an Android tablet and any other operating system that supports PHP and a SQL database (currently PostgreSQL). Hence, the whole infrastructure that is needed during a match consists of two Android tablets and any kind of WLAN to connect the two allowing the coaching app to access the backend (no Internet connectivity is needed). To avoid any network latency problems, it is advisable to co-locate the scouting app with the backend application on the same tablet. However, the system can also be set up such that both Apps access the backend remotely. For instance, if there is the option to have some IT infrastructure (WLAN and a larger computer for the backend database) permanently installed in the home arena. If sensors are used to automatically collect data, then the sensor systems communicate directly with the backend system - either on the scouting tablet or the centralized systems in the home arena. The backend system then merges the sensor events with the events generated by the scouting app which allows to seamlessly replace the manual information collection by an automated sensor based one.

ACCURACY AND PRECISION OF A WEARABLE INERTIA SENSOR DURING A FREE-WEIGHT BACK SQUAT

KAVALIAUSKAS, M.1, MORRISON, P.A.2, POTTS, N.3

1: EDINBURGH NAPIER UNIVERSITY, 2:ANGLIA RUSKIN UNIVERSITY, SPORT & EXERCISE SCIENCES, 3: SCOTTISH RUGBY

INTRODUCTION: Previous research investigating the validity and reliability of the PUSH™ (PUSH Inc., Toronto, Canada) wearable inertia sensor during a back squat exercise has produced conflicting results (Balsalobre-Fernández et al., 2016; Banyard et al., 2017). Therefore, the aim of this study was two-fold a) examine the error in all variables reported by the PUSH™ in comparison to a criterion method of two Kistler force platforms and 3D motion capture system during the free-weight back squat b) briefly discuss the suitability of the PUSH™ as a training monitoring tool in highly trained participants.
METHODS: Seven Scottish Rugby Union academy players (age 18.8±1.2 years; height 1.84±0.08 m; body mass 96.9±11.7 kg) were recruited. Participants performed a total of 134 free-weight back squat repetitions with a mean weight of 117.5 kg (±14.72) as part of their regular training sessions. All repetitions were simultaneously captured using the PUSH™ and two Kistler force platforms (Kistler Holding AG, Switzerland) synced with a 12 Oqus 300+ camera motion capture system (Qualisys, Sweden) sampling at 500Hz. PUSH™, Qualisys and Kistler data were then imported into Matlab (R2014a, The Mathworks Inc., Natick, MA, USA) for the analysis of six variables: mean and peak concentric velocity (MV and PV), mean and peak concentric vertical ground reaction force (MF and PF), and mean and peak concentric power (MP and PP). The accuracy and precision of the PUSH™ system were assessed in two ways. Bland-Altman plots were created for each variable for visual inspection. Then MANOVA and subsequent univariate tests were used to assess the difference between the systems. If a significant difference existed, then bias-corrected root mean square error (RMSE) was reported for that variable.
RESULTS: From the MANOVA there was a significant difference between the systems, $F(6,127) = 904.9$, $p<0.05$, partial $\eta 2 = 0.98$. The subsequent univariate tests also showed a significant difference between PUSH™ and Qualisys/Kistler for all six variables. MV and PV measured by the PUSH™ were underestimated by 0.01 m/s and 0.23 m/s, respectively. PUSH™ also underestimated MP by 219 W and PP by 554 W. In contrast, PUSH™ overestimated MF by 303 N and PF by 206 N. The bias-corrected RMSE were calculated for MV (±0.05 m/s), PV (±0.17 m/s), MF (±83 N), PF (±229 N), MP (±157 W) and PP (±432 N).
CONCLUSION: The accuracy and precision of MV and PV variables show that PUSH™ is unlikely to categorise the movement velocities appropriately. Similarly, high levels of error in MF, PF, MP and PP variables may prevent the PUSH™ from detecting small changes in resistance training adaptations accurately and reliably. This contrasts with previous studies that have suggested that PF (Banyard et al., 2017), MV and PV (Balsalobre-Fernández et al., 2016) in squatting could be measured reliably using the PUSH™. Overall, the PUSH™ band appears to lack the accuracy and precision to be used as a training monitoring tool in highly trained players.

COMPARISON OF DIFFERENT HEART RATE MEASURING METHODS DURING PERFORMANCE DIAGNOSTICS

SCHULZ, S.V.W., ENDERS, K., ROLSER, N., STEINACKER, J.M., LASZLO, R.

ULM UNIVERSITY HOSPITAL

INTRODUCTION: Treadmill ergometer testing with lactate measurement is frequently used in routine performance diagnostics. Here, different methods for heart rate (HR)-determination (ECG-based, heart rate monitor [HRM]) are used whereby little is known concerning their comparability. The aim of the study was to compare different HR measurement methods during performance diagnostics.
METHODS: 76 athletes (28.6 ± 14.7 years, 38% female; Vmax = 14.5 ± 1.9km / h) performed a lactate threshold test (4-2-3) on treadmill ergometer. HR during testing was simultaneously assessed by manual analysis of a 12-lead electrocardiogram (ECG) and a HRM (Polar FT1). ECGs were independently analyzed by two diagnosticians. Concerning potential faulty measurements, HRM values were also evaluated by these physicians. Single measurements were discarded from consecutive creation of heart rate curve of an individual athlete if a measurement was consistently judged as faulty/ artifact. In case of a mismatch, a third physician was consulted for a final decision. Finally, two different HR curves (ECG, HRM) and a lactate curve for each athlete were generated by using Ergonizer® software if ≥4 usable measurement points during exercise were still available after above-mentioned evaluation procedure. Thus, heart rates at different times important for the training control were compared between the two measurement methods.
RESULTS: ECG-based HR detection revealed excellent reproducibility and reliability. Concerning HRM, one or more faulty measurements were detected in 14.5% of all athletes. However, constructions of HR/ lactate curves were still possible in 84.6% of all athletes. HR at different corresponding time points did not differ significantly between HRM and ECG (intraclass correlation coefficient >0.9 and coefficient of variation <5%). In Bland-Altman analysis, mean differences were usually low (3-5 beats). However, limits of agreement were relatively high: ±9 beats at the individual anaerobic threshold, ±18 beats on a regenerative and long jog, ±12 beats on medium endurance run, ±12 beats on speed endurance run and ±13 beats on extensive interval training.

CONCLUSION: Training areas defined by HRs detected by manual ECG evaluation as a gold standard during performance testing may be also used by the athletes for home training control with their own HRM as HRs detected with these two different methods were mostly comparable. If HRM measurements are used for the athlete's final lactate/ HR curves and training recommendations, determined HRs during exercise performance test should be always checked for plausibility and comparability with corresponding ECG measurements by physicians with appropriate expertise due to relevant differences in some athletes.

VALIDATION OF SHOE PADS EMBEDDED WITH TRI-AXIAL ACCELEROMETER IN MONITORING PHYSICAL ACTIVITY

WANG, B., HOU, B., REN, X., ZHAO, D.F., ZHAO, H.Y., YE, J.L., CHEN, Z.X., WANG, C.

SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: A new type of shoe pads embedded with accelerometer overcomes the challenge of placement issues of movement monitors. However, the accuracies of these pads in monitoring physical activity have not been validated. Therefore, the aim of this study was to validate them in estimating acceleration, steps and energy expenditure during stair climbing, walking, jogging and running.
METHODS: After 2-hour fasting, 20 professional female soccer players (17.4±0.2yrs) rested at standing position for 5 minutes. The lowest heart rate (HR) was recorded as resting HR. Thereafter, they performed 10-min climbing on an elliptical trainer (9.6 km/h) and walking (3.2 km/h) or running at four different speeds on treadmill (6.4, 9.6, 11.2 12.8 km/h). They were asked to rest between each two trials to allow their HR recover to resting level. Energy expenditure (EE) was assessed with a portable indirect calorimetry (IC). GT3X+ devices were worn on waist (GWaist) and both ankles (GAnkles), providing acceleration and steps. The shoe pads (Pads) were placed inside running shoes, providing acceleration, steps, and EE estimation. The Vector Magnitude (VM) sum of each axis of acceleration measured by GT3X+ or Pads was calculated for comparison. All data were collected in 10-second interval for paired t-test analysis.
RESULTS: The intra-individual correlations between VM calculated from GT3X+ and Pads were significant for all subjects (r=0.729-0.996, mean=0.975±0.004). However, Pads VM was significantly higher than GT3X+ VM at all trials, with GAnkles significantly higher than GWaist. Pads VM increased to a greater extent than GT3X+ VM with increasing speed, therefore, the difference between Pads and GT3X+ VM measures increased gradually when speed increased. The step counts obtained by Pads and GWaist were highly correlated without significant differences when climbing or running at four different speeds ($p>0.001$), which also happened between the comparison between Pads and GAnkles, except that they were significantly different when running at 6.4 km/h on treadmill. There were significant differences between Pads and GWaist/GAnkles steps when walking on treadmill, and between GWaist and GAnkles steps when walking or running at 6.4 km/h on treadmill ($p<0.001$). EE assessed by Pads was highly correlated with EE from IC, but Pads overestimated EE during walking and underestimated EE when climbing or running at four different speeds ($p<0.001$).
CONCLUSION: The shoe pads embedded with tri-axial accelerometer appear to measure physical activity at moderate intensities most accurately. Modifications should be given to improve accuracies in measuring low or high intensity physical activities.

Sports Medicine and Orthopedics

THE EFFECTS OF CORE STABILITY EXERCISE USING THE FLEXI-BAR ON PATIENTS WITH NON-SPECIFIC LOW BACK PAIN

KUO, H.Y., TSENG, S.C., CHEN, H.S., GUO, L.Y., HSIAO, C.E.

KAOHSIUNG MEDICAL UNIVERSITY, KAOHSIUNG AMERICAN SCHOOL

INTRODUCTION: About 60 to 80 % of the general population has the burden of non-specific low back pain (NSLBP) and this leads to a limited range of activities in their daily lives, poor work efficiency as well as poor sleep and quality of life. Symptoms of mild NSLBP can be alleviated temporarily by medicine and electrical modality, but exercise therapy and health education are recommended to correct the posture, improve the symptoms and decrease the recurrence rate. Core stability exercise with the flexi-bar providing vibration stimulation helps to activate core muscles and muscle groups in proximal lower limbs, and to maintain trunk stability. The purpose of this study was to investigate whether core stability exercise using the flexi-bar is effective in reducing the burden of patients with NSLBP and if it improves quality of life.
METHODS: This experiment was conducted at a local hospital in Southern Taiwan on 20 patients with NSLBP between the ages of 25-55 years old. The duration of the experiment lasted 8 weeks, 2 sessions a week, 30 minutes a session. This core stability exercise with the flexi-bar can be divided into 3 phases: the first phase was a 5- minute warm-up with the flexi-bar; the second phase had the patient to perform 20-minute core stability exercise using the flexi-bar in the quadruped, plank, side-plank, reverse-plank and bridge positions; the third phase was a 5-minute cool down exercise without the flexi-bar.(1) Use the 36-Item Short Form Survey (SF-36) to access quality of life, and the Oswestry Disability Index (ODI) and the Visual Analog Scale (VAS) to access the how the patient feels.
RESULTS: A total of 18 patients completed the full experiment. And they showed a statistically significant improvement in both their quality of life and pain relief after performing the flexi-bar exercise regimen.
CONCLUSION: The results of this study suggest that an 8-week core stability exercise training using the flexi-bar is effective in reducing the burden of patients with NSLBP and improving their overall quality of life.

EFFECTIVENESS OF HIGH-INTENSITY INTERVAL TRAINING ON GLYCEMIC CONTROL AND CARDIORESPIRATORY FITNESS IN PATIENTS WITH TYPE 2 DIABETES: A SYSTEMATIC REVIEW AND META-ANALYSIS

ZHU, L., LIU, J.X., LI, P.J.

GUANGZHOU SPORT UNIVERSITY

INTRODUCTION: The effects of high-intensity interval training as compared with moderate-intensity continuous training on glycemic control and cardiorespiratory fitness in patients with type 2 diabetes have been examined by numerous randomized controlled trials; however, due to these studies' largely inconclusive results [1-3], a meta-analysis was performed to better elucidate their findings.
METHODS: Relevant articles were sourced from PubMed, Embase, the Web of Science, EBSCO, and the Cochrane Library. Randomized controlled trials investigating the effects of high-intensity interval training on glycemic control and cardiorespiratory fitness versus the effects of moderate-intensity continuous or control (no exercise or usual care) regimens were included. Studies were selected according to specified inclusion and exclusion criteria.
RESULTS: Twelve clinical randomized controlled trials involving 367 patients were finally identified. There was a statistically significant change in hemoglobin A1c (mean difference (MD): -0.29, 95% confidence interval (CI): -0.56 to -0.01, P=0.05); fasting insulin (standardized MD: -0.54, 95% CI: -0.94 to -0.14, P=0.008); relative VO2peak (MD: 4.57 ml/kg/min, 95% CI: 2.62 to 6.53, P<0.0001); and absolute VO2peak (MD: 0.33 L/min, 95% CI: 0.13 to 0.54, P=0.001) for patients in the high-intensity interval training group as compared with base-

line. And high-intensity interval training had a greater improvement (MD: -0.39%, 95% CI: -0.58 to -0.20, P < 0.0001) than did moderate-intensity continuous training. Similar results were also found with respect to relative VO2peak (MD: 3.34 ml/kg/min, 95% CI: 1.69 to 4.99, P < 0.0001); and absolute VO2peak (MD: 0.29 L/min, 95% CI: 0.12 to 0.46, P = 0.0002).
CONCLUSION: High-intensity interval training appears to be an effective strategy to improve cardiopulmonary fitness and glycemic control in individuals with type 2 diabetes.More multicenter, randomized controlled trials with large samples and longer-term durations must be conducted to confirm these results.

PREVALENCE AND CHARACTERISTICS OF OSTEOCHONDRITIS DISSECANS OF THE HUMERAL CAPITELLUM AMONG YOUNG BASEBALL PLAYERS

HOJO, T.1, MORIHARA, T.2, KIDA, Y.2, KOTOURA, Y.2, TACHIIRI, H.2, SUKENARI, T.2, FURUKAWA, R.2, NAKAMURA, M.4, IGUCHI, J.3, KUBO, T.2

1>DOSHISHA UNIVERSITY, 2>KYOTO PREFECTURAL UNIVERSITY OF MEDICINE, 3>KYOTOGAKUEN UNIVERSITY, 4>NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: Osteochondritis dissecans of the humeral capitellum (OCD) is primarily a condition of adolescent overhead athletes. Baseball is one of the high-risk sports, which induces OCD. Many players start playing baseball during elementary school. Recently, medical check-ups for OCD in young baseball players utilizing ultrasonography are becoming more popular. The aim of this study was to investigate the frequency and clinical characteristics of OCD among young baseball players.
METHODS: The subjects were 4099 young baseball players from 7 to 17 years (mean, 13.2 years) who participated in medical check-ups for OCD. All players completed a questionnaire asking about the age, present and past elbow pain when throwing and the duration of competitive play. The elbow of each subject's throwing arm was assessed using ultrasonography. Subjects with abnormal results on ultrasonography were further examined through radiographic study. OCD lesions were classified into stages based on radiographic results. We compare the differences of demographic data between OCD players and non-OCD players.
RESULTS: OCD was detected in 119 (2.9%) of 4099 elbows by ultrasonography. One hundred-five of the 119 OCD players underwent further radiographic examination. Twelve of them (11.4%) were stage S (superficial stage, Figure), 21 (20.0%) were stage I (radiolucent stage), 35 (33.3%) were stage II (fragmentation stage), and 11 (10.5%) were stage III (loose body stage). And additional 11 (10.5%) players were stage IV (residual stage), and 15 (14.3%) were stage V (postoperative stage). The mean age of each stage was 9.8, 11.9, 13.5, 15.4, 15.8, and 15.8 years old, respectively. There was no significant difference on the age (p = 0.99) and the duration of competitive play (p = 0.99). They also had present (p = 0.001) and past elbow pain (p < 0.001) compared to non-OCD players, however sixty-eight OCD players in early stage (S, I and II, before loose body stage) had no significant differences on the present elbow pain.
CONCLUSION: The prevalence of OCD was 2.9% among young baseball players. Players with OCD had present elbow pain, but players in early stage do not have significant present elbow pain compared to non-OCD players. The stage of OCD has progressed with age. Medical check-ups of young baseball players who are 10 years old before and after, utilizing ultrasonography are useful for detecting OCD with no associated elbow pain.

COMPARISON OF EFFECTS OF VARIOUS ELECTRICAL STIMULATING METHODS ON FEMORAL BONE STRUCTURES IN RATS.

NAKAI, S., OHSAKO, M.

TOYO UNIVERSITY

INTRODUCTION: We had already recognized that an invasive acupuncture-electrical-stimulation showed an inhibitory effects on a bone loss by decease in mechanical stress. However, the effect of non-invasive transdermal-electrical-stimulation hadn't been reported. A purpose of this study was, using hindlimb-immobilized rats, to compare and investigate effects of the electrical-acupuncture-simulations and the transdermal-electrical-stimulation on bone loss. Furthermore, as for latter, differences of the effects of direct and alternating current was also investigated.
METHODS: Fifty male rats (wistar strain, seven-week-old) were used as materials and were divided into three groups randomly: an immobilized group (IM), an immobilized and acupuncture-electrical-stimulated group (EA), an immobilized and transdermal-electrical-stimulated group (TE), and a control group (CO). Moreover, TE was divided into two subgroups, that is, a group stimulated by a direct electrical current (DC) and a group stimulated by an alternating electrical current (AC). Hindlimbs of rats of each group, except for CO, were immobilized for two weeks, using jacket-type immobilizing apparatus. An acupuncture was inserted until a periosteum in EA and electrodes were put on the surface of skin in TE (DC and AC). EA and AC were stimulated by the alternating electric current (250μsec, 50Hz, 0.02mA) and DC was stimulated by the direct electric current (200μsec, 31Hz, 60V). Those stimulations were performed for 10minuites per day in everyday through the experimental period.
RESULTS: Thickness of a cortical bone and sizes of osteocytic lacunae decreased and a bone strength also declined in IM, but those structural changes inhibited in EA and DC. Many TRAP-reaction positive cells were observed at the wide extent in IM, but the intent was narrow in EA and DC.
CONCLUSION: It was suggested that the bone resorption was inhibited by acupuncture and transdermal electrical stimulations during the hind-limb immobilization. Furthermore, it was understood that those effects appeared notably by invasive acupuncture electrical stimulation and non-invasive transdermal direct-current electrical stimulation.

PREVALENCE OF ABNORMAL ELECTROCARDIOGRAMS IN CZECH ATHLETES DETECTED WITH THE SEATTLE CRITERIA – A ONE-CENTER EXPERIENCE

SOVOVA, M., FILICKA, M., SOVOVA, E., POKORNA, T., MASNY, O., MORAVCOVA, K., STEGNEROVA, L.

FACULTY OF MEDICINE AND DENTISTRY

INTRODUCTION: Sudden cardiac arrest in athletes is a dramatic event. A routine electrocardiogram (ECG) during preparticipation screening can help to reveal cardiovascular diseases and decrease the mortality rate. In 2013, new criteria of ECG assement – the Seattle criteria – were published. Using this criteria can decrease the number of false-positive findings.
METHODS: We analysed the 12-lead resting ECG of consecutive athletes (5-76 years) recorded in the Department of Sports Medicine in Olomouc, the Czech republic, between October 2015 and October 2017. We used the Seattle criteria for assessing the findings.

RESULTS: The ECGs of 3413 athletes were analysed. 47 ECGs (1.3%) were classified as abnormal – one athlet had prolonged QT interval, 12 athletes had premature ventricular contractions, 14 athletes showed signs of left or right ventricular hypertrophy, one athlete had ventricular preexcitation and there were 19 athletes with other pathological findings. After cardiac examination, we detected undelying structural heart disease in 12 athletes (0.3%). In 6 athletes, the heart disease lead to short elimination of sport activities (myocarditis – 2 cases, paroxysmal atrial fibrillation, AVNRT and WPW syndrome).
CONCLUSION: In the analysed group of athletes, the prevalence of pathological ECG is very low.

ELECTROACUPUNCTURE STIMULATION AND THE ABILITY USING THE STRETCH-SHORTENING CYCLE MOVEMENT IN THE LOWER LIMBS

TERADA, K., NAKATANI, T.

TENRI UNIVERSITY

INTRODUCTION: The stretch reflex plays a certain role during movements utilizing the stretch-shortening cycle (SSC) (Aura, 1986). On the other hand, acupuncture or electroacupuncture is one of the most popular types of complementary and alternative health approaches that athletes use to help control pain, treat injury, and hasten recovery (Ahmedov, 2010). Acupuncture or electroacupuncture stimulation suppresses some proprioceptive reflexes (Homma, 1985), such as the stretch reflex (Milne, 1985). This study evaluated the degree to which electroacupuncture stimulation impacts the ability to perform SSC movements.
METHODS: The subjects were 11 young males (age: 21.9 ± 0.8 yrs, height: 173.8 ± 5.2 cm, weight: 67.2 ± 5.6 kg) who were subjected to low-frequency electroacupuncture (2 Hz, 15 min.) of the triceps surae muscle, randomly selecting between the left and the right side. Immediately before, immediately after, and 1, 24, 48, and 72 hours after, the subjects performed five single-legged rebound jumps (RJ), and we calculated an RJ-index (jump height/ground contact time). At the same time, we also measured the range of ankle dorsiflexion, the muscle stiffness of the medial and lateral head gastrocnemius muscles (medial and lateral muscle stiffness), and subjective sensations according to a visual analogue scale (VAS). The measurements were performed bilaterally stimulated side (SS) and non-stimulated side (NS).
RESULTS: In any of the measured variables, no interaction was observed between which side was stimulated and the measurement opportunity. We performed Dunnett's method of multiple comparisons for the SS and the NS. As a result, on the SS we found a significant decrease immediately before and immediately after stimulation in the RJ-index (SS: -17.9%, $p<0.05$, NS: -10.1%, ns) and the medial (SS: -6.8%, $p<0.01$, NS: -6.7%, $p<0.05$) and lateral (SS: -6.2%, $p<0.05$, NS: -3.1%, ns) muscle stiffness. In addition, we found a similarly significant increase in the sense of discomfort according to a VAS (SS: -29.2% to -20.0%, $p<0.05$, NS: -17.4% to -1.7%, ns). On the NS, we found a similar difference only in the medial muscle stiffness.
CONCLUSION: Consequently, these results suggested that the timing of clinical implementation of electroacupuncture therapy requires consideration.

EFFECTS OF INTERMITTENT COLD AND HYPOBARIC HYPOXIA ON MUSCLE STRUCTURE AND FUNCTION: IMPLICATIONS TO IMPROVE RECOVERY AFTER INJURIES

VISCOR, G., SANTOCILDES, G., CABRERA-AGUILERA, I., LARA, S., RIZO-ROCA, D., PAGÈS, T., TORRELLA, J.R.

UNIVERSITAT DE BARCELONA

INTRODUCTION: Mechanical and metabolic properties of mammal muscle fibres can change in response to different environmental stimuli such as altitude exposure, which involves hypoxic and cold stress. The aim of this study was to identify the effects of simultaneous intermittent exposure to cold and hypobaric hypoxia on fibre types, capillarization and fibre morphometry of the rat gastrocnemius, and its usefulness to improve recovery after muscle injury.
METHODS: After inducing injury in the rat gastrocnemius, two groups of animals (n=6) were considered: COHY, submitted to a programme of simultaneous intermittent cold (4ºC) and hypobaric hypoxia (4,500 m) for 21 days; and CTRL, normoxic at 27°C. Histological slides were stained for demonstrating the oxidative and contractile properties of the fibres, classified as slow oxidative (SO), fast oxidative glycolytic (FOG), fast intermediate glycolytic (FIG) and fast glycolytic (FG). Capillary density (CD), fibre capillarization (CCA) and fibre cross-sectional area (FCSA) were measured after ATPase staining. Force properties of contralateral injured and healthy gastrocnemius were registered by electrical stimulation of sciatic nerve. Peak (PF in mN/g) and tetanic force (TF in mN/g), contraction (CT) and half relaxation times (HRT), and fatigue properties at low frequency (30 Hz) were measured.
RESULTS: The protocol did not induce significant alterations in fibre type composition. However, a significant reduction in FCSA of the oxidative fibres and a significant increase in CD was evident. Injured leg from the CTRL group registered significant lower values than the healthy leg in PF (37±9 vs 44±5, $p=0.048$), TF (110±40 vs 148±22, $p=0.016$), and showed lower resistance to fatigue. Simultaneous cold and hypoxic exposure recovered TF (but with lower values for injured leg: 165±19 vs 174±11, $p=0.184$) and resistance to fatigue, but did not show a total recovery in PF (45±6 vs 49±6, $p=0.042$). No alterations were registered neither for CT nor HRT in any group.
CONCLUSION: Oxidative fibres reduced FCSA and increased CCA to maintain their functionality in response to simultaneous exposure to cold and hypoxia, without showing muscle fibre type transitions. It is possible that it would be necessary more time than 21 days to induce changes in metabolic and contractile fibre characteristics. This protocol induced a growth of new capillaries (increased CD), which would have supplied more oxygen, growth factors and nutrients to the satellite cells, favouring their proliferation, differentiation and posterior maturation into myofibre, thus helping the regeneration processes from injury and accelerating to some extent the muscular force recovery.

INVESTIGATION THE RELEVANCE BETWEEN ORAL CONTRACEPTIVES AND SERUM RELAXIN-2 FOR ANTERIOR CRUCIATE LIGAMENT INJURIES IN ELITE FEMALE ATHLETES

NOSE, S.

THE UNIVERSITY OF TOKYO

INTRODUCTION: Anterior cruciate ligament (ACL) injuries occur two to nine times more frequently in female athletes than in male athletes. It was reported that female athletes with ACL injuries have higher serum relaxin-2 concentrations during the luteal phase, and that athletes with serum relaxin-2 levels > 6.0 pg/mL show a more than four-fold increase in the risk of ACL injuries. Relaxin-2 concentrations were reported to be significantly lower in subjects taking oral contraceptives (OC) than in non-OC users. However, it is uncertain whether OC therapy may decrease relaxin-2 levels in female athletes. The purpose of this study was to investigate changes of relaxin-2 levels in athletes taking OC.
METHODS: Levels of relaxin-2, estradiol, progesterone, luteinizing hormone and follicle-stimulating hormone were measured in serum samples (n = 183) from 106 elite female athletes. The participants included 77 eumenorrheic athletes, 13 athletes with amenorrhea and 16 athletes taking OC. In these 77 athletes with eumenorrheic athletes, blood samples were obtained during the follicular (72 samples), ovulatory (25) and luteal (57) phases of the menstrual cycle. Out of 77 eumenorrheic athletes, 5 athletes, whose serum relaxin-2 concentrations were > 6 pg/mL during the luteal phase began to take one OC tablet (norethisterone 1.0 mg/ ethinylestradiol 0.02 mg; LUNABELL tablets ULD) every night from the first day of menstruation, and serum relaxin-2 levels were examined during the second cycle of OC therapy.
RESULTS: Serum relaxin-2 concentrations were significantly higher during the luteal phase (n = 57) than in the follicular phase (n = 72), or in athletes on OC therapy (n = 10) ($p < 0.001$, $p < 0.001$ and $p < 0.05$, respectively). In the luteal phase, 36.8% (21/57) of the athletes had relaxin-2 levels > 6 pg/mL. In 23 athletes, serum relaxin-2 concentrations were measured during both the follicular and luteal phases, revealing that relaxin-2 levels were significantly higher in the luteal phase compared with the follicular phase. In 5 athletes who began to take OC, serum relaxin-2 concentrations decreased dramatically to below the detection limit (0.26 pg/mL) following OC administration.
CONCLUSION: Female athletes that have serum relaxin-2 levels> 6.0 pg/mL might be recommended to initiate OC therapy because it is useful to decrease the risk of ACL injury.

TOTAL HAEMOGLOBIN REACTIVITY CHANGES IN RESPONSE TO A BAROREFLEX MANOEUVER FOLLOWING SPORT-CONCUSSION

SINGH, J., SIRANT, L., DECH, R., NEARY, J.P.

UNIVERSITY OF REGINA, REGINA, SASKATCHEWAN, CANADA, S4S 0A2

INTRODUCTION: Previous research has shown that concussion can alter cardiac function by influencing changes in mean arterial blood pressure (MAP) (Bisop et al., 2017), as well as affect neurological autoregulation by influencing changes in total blood volume (tHb) (Christian et al., 2010). What has not been shown is whether the change in the relationship of blood pressure and total blood volume (tHb/MAP), known as total haemoglobin reactivity (THx), pre-concussion to post-concussion using a non-invasive near-infrared technology (NIRS) when initiating a baroreflex manoeuvre. Therefore, the aim of this study was to compare the THx of individuals in healthy vs concussion groups, by measuring the cardiovascular metrics under baroreflex conditions using a squat-stand manoeuvre.
METHODS: 14 participants (n=7 female) who sustained a sport concussion, were tested within 72-hours post-injury. Participant's blood pressure (finger plethysmography, Finapres) data was collected during 5 minutes of seated rest and 5 minutes of 10-second squat-stands (0.05 Hz), along with tHb (μM) changes using NIRS located over the prefrontal cortex. Participants were given a 3 second count instructing them to squat down and a 3 second count instructing them to stand up. THx data was analysed in the 1-6, 4-7 and 6-10 seconds periods of squatting and the 10 seconds of standing. Paired sample t-tests were used for pre- and post-injury data comparison.
RESULTS: For both female and male participants, significant changes were found in the 1-6, 4-7, 6-10 seconds of squatting and the 10 second standing periods ($p<0.05$). For males, THx was increased for the 1-6, 4-7, 6-10 and 10 second standing periods by 229.7%, 105.8%, 105.6%, and 72.4%, respectively, post-injury, due to increases in MAP (10.7%, 16.7%, 17.6% and 9.0%, respectively) and changes in tHb (225.5%, 157.2%, -153.6% and 92.1%, respectively). For females, THx was actually decreased by 44.3%, 24.0%, 30.3% and 142.0%, respectively, with respect to the mentioned intervals. This was due to changes in MAP (-4.8%, -3.7%, 0.6%, and -0.3%, respectively) and tHb (-41.9%, -26.9%, -29.7% and, -49.6%, respectively).
CONCLUSION: Our squat-stand manoeuver while monitoring THx provides an objective test to assess the pathophysiology of concussion. Changes in THx during the squat-stand suggests that autonomic dysregulation occurs following concussion within the initial 72 hours of injury. A larger sample size is required for validity and more research is required to assess the differences between males and females.

MEASUREMENT ERROR OF TOE PLANTAR FLEXION DUE TO DIFFERENCE IN METHOD - PROPOSAL OF A LIGHT AND EASY-TO-HANDLE BRACE

KOMURO, Y.

OCHANOMIZU UNIVERSITY

INTRODUCTION: According to previous studies, there was a correlation between strength of toe plantar flexion (STPF) and fall history (Mickle et al. 2009), and there was a significant difference in STPF between young people and the elderly (Endo et al. 2002). It was reported that walking speed, swing time and stride were correlated with walking speed (Misu et al. 2014). Knowing and managing our own STPF is important to prevent falls and maintain walking ability. However, the equipment that measures STPF was usually large and difficult to move (Goldmann et al 2013; Allen et al 2014; Senda et al. 1999). Therefore, we made a simple brace that is lightweight, easy to carry and that can be worn easily by oneself. The main muscles of the toe plantar flexion (TPF) are flexor hallucis longus (FHL), flexor hallucis brevis, flexor digitorum longus (FDL), and flexor digitorum brevis. FHL and FL work to flex not only the toes but also the ankle joints. In order to measure STPF in the state of sitting, we had to minimize the influence of ankle joint flexion. we thought that it would be natural to measure the STPF in a state where the ankle was plantar flexed. We hypothesized that large STPF could be obtained with less error in the new method than measurement at the sitting position. The purpose of this study was to compare the data obtained by the new STPF measurement method and measurement method by sitting position.
METHODS: Subjects were 12 young females (average 24.42, SD 4.33 years). In the new measuring method, the brace with the sensor (F-scan II, Nitta Corporation, Japan) was attached to the right foot. Subjects raised their right legs slightly from the floor and allowed the ankle and toes to plantar flex for 5 seconds. The foot was raised back to their original position. There was 5 seconds rest until the next

measurement started. A set of the plantar flexion and rest was repeated 5 times. In the measurement of sitting position, a sensor attached to the right foot was placed on the floor and a set of 5 seconds plantar flexion and 5 seconds rest was repeated five times. The acquired data was analyzed by a single regression analysis of IBMs SPSS version 24.
RESULTS: Three out of five TPF data were analyzed. The value of TPF obtained with the new measuring method was 61.16, SD23.48 N and the value obtained by sitting was 50.36, SD 33.63 N. The regression equation was y = 22.18 + 0.46 x (y = value obtained at the sitting position, x = value obtained by the new measurement method).
CONCLUSION: The value of the STPF obtained by the new measurement method was larger than the value at the sitting position. This result supported our hypothesis. It seems that the subjects could sufficiently contract FHL and FDL. Also, the value of standard deviation was smaller than the value at the sitting position. It can be said that the data obtained by the new method was more accurate.

GENDER DIFFERENCE IN MUSCLE ACTIVATION DURING DROP JUMP AND CUTTING MANEUVER IN PRE-PUBESCENT ATHLETES

SVEINSSON, T., JONSDOTTIR, U.S., BRIEM, K.
UNIVERSITY OF ICELAND

INTRODUCTION: Movement patterns and neuromuscular activation of muscles in the lower extremities may contribute to risks for ACL injuries. For some muscles in pre- and post-pubescent female and male athletes, these have been studied. Although gluteus medius (GM) muscle activity may be important during dynamic activities, its activation patterns have not been much studied. The aim of the study is to identify gender differences in GM activation during drop jump and cutting maneuver among 11 and 12 years old football and team handball players.
METHODS: The design was cross-sectional laboratory trial Players were recruited from local sports clubs, 9 boys and 36 girls. Surface electrodes were used to collect EMG activity from GM during the two dynamic tasks, before and after a standard fatigue protocol. AMTI force plates were used to identify stance phase duration. Stance duration, timing of peak muscle activation and activation levels at initial contact, normalized to peak activation, were analyzed pre- and post-fatigue between genders for each task and were the main outcome measures.
RESULTS: During the drop jump, shorter stance duration ($p=0.03$) and greater activation at initial contact ($p=0.02$) were observed for girls than for boys. Furthermore, peak activation occurred earlier in girls than boys ($p<0.01$). Moreover, GM activation levels at initial contact were overall significantly greater after a fatigue protocol than before ($p<0.01$) and peaked earlier ($p<0.01$). During cutting manuever, a significant main effect of fatigue on activation levels at initial contact ($p<0.01$) was observed. Also, a significant interaction between gender and fatigue was observed for their effects on stance duration ($p<0.01$), where stance duration was increased for boys while it was deceased for girls.
CONCLUSION: Gender differences were identified in activation patterns of GM and duration of stance phase in the current study. To some extent, this may reflect different kinematic strategies during these dynamic tasks or gender biased training methods. Further investigation into muscle activation patterns and lower extremity kinematics are important in the context of injury prevention.

FUNCTIONAL MOVEMENT PERFORMANCE ABILITY IN MARTIAL ARTS AND TEAM SPORT YOUNG MALE ATHLETES

PEDAK, K., RANNAMA, I., BAZANOV, B.
TALLINN UNIVERSITY

INTRODUCTION: The Functional Movement Screen (FMSTM) is widely used in training science and sport medicine and estabilshed as a standard tool to assess functional movement abilites (Kraus et al.,2014). This study aim was to compare the functional movement performance ability of athletes from two different sports groups – team sport (basketball, handball,volleyball) and martial arts (judo, taekwondo, karate).
METHODS: Fourty-five team sport (age =16,27 ± 1,7 years; height=183,2± 6,6 cm and KMI=23,5 ± 3,8) and twenty-seven martial arts athletes (16,7±3,8 years; height=178,7cm and KMI=20,5±3,5) were screened by Functional Movement Screent (FMS) using a 100-point grading scale (Butler et al.,2010).
All participants were free from injury last 6 months. Participants were screened using the functional movement screen protocol that comprised the FMS seven movement patterns: deep squat, hurdle step, in-line lunge, , active straight-leg raise, trunk stability push-up, shoulder mobility and rotary stability. Each participant was videotaped performing the 7 movements of the FMS and scores were obtained. The videos were then analyzed using FMS 100-point scale (viide). Participants were given three trials of each movement pattern. Before testing procedures participants completed a 10-min dynamic warm-up.
All analyses were computed via SPSS® V.21 for Windows. One-way ANOVA was used to compare differences. , and the level of significance for all tests was set at alpha level $p < 0.05$.
RESULTS: We found statistically significant difference between FMS total score of martial art athletes. The mean composite FMS 100-point scale was 55,1±9,3 and team sports athletes 45,0±6,4. Martial arts athletes shows statistically significantly higher score in active straight-leg raise 4,4±3,1 vs 7,9±3,9 ($p<0,05$) and trunk stability push-up test 4,4±3,5 vs 7,1±4,5 ($p<0,001$). There was not statistically significant difference between other five tests.
CONCLUSION: The results of the present study indicate that low FMS 100-point scale in both groups, which increase the risk of injuries. Results of the active leg test show, that team sport athletes have more problems with muscles of the hamstring and gastric-soleus flexibility than martial artists. In addition to this, team sport athletes have more problems with performance of trunk muscles stabilizing, according to the trunk stability push-up test. The results of the test indicate problems specific to the sport. Future studies should also determine the effects of specific movement compensations as defined by the FMS on athletic performance to indicate sport-specific problems.

EXPLORATION OF BLOOD PRESSURE, ARTERIAL STIFFNESS, AND HEART RATE VARIABILITY IN TRIATHLETES

LEE, P.H.1, LIN, Y.Y.2, SU, C.T.3, LIN, C.H.1, YANG, A.L.1

1: UNIVERSITY OF TAIPEI ; 2: CHINA MEDICAL UNIVERSITY ; 3: FU JEN CATHOLIC UNIVERSITY

INTRODUCTION: Regular exercise is known to improve cardiovascular function and exercise performance. However, high blood pressure is one of the common cardiovascular conditions in athletes. Until now, there is little information regarding the cardiovascular characteristics in the triathlon, which is an endurance sport and needs sufficient aerobic capacity (Leischik et al., 2014; Suriano et al., 2010). Therefore, the purpose of this study was to explore the blood pressure, arterial stiffness, and heart rate variability (HRV) in the triathletes.
METHODS: Twelve male elite triathletes and ten non-athlete control subjects (aged 20-25 years old) participated in this study. The resting and maximal blood pressure during exhaustive exercise were measured, including systolic and diastolic blood pressure (SBP and DBP), and pulse pressure (PP). Also, the arterial stiffness index (ASI) and HRV at rest were analyzed non-invasively and compared in both groups.
RESULTS: We found that resting SBP in the triathlete group was significantly ($p < 0.05$) higher than that in the control group. However, there was no significant difference in resting DBP, PP, and maximal SBP and DBP between the triathlete and control groups. Moreover, the ASI values showed no significant difference between the two groups. Regarding the HRV, the triathlete group had significantly ($p < 0.05$) lower heart rate and better R-R interval (inter-beat interval) and high frequency (HF) power compared with the control group.
CONCLUSION: This study indicated that, compared with the control group, the triathletes had higher SBP and better R-R interval. However, similar ASI values were found between the two groups. It may provide some useful information for the health and exercise performance in the triathletes.

FACTORS INFLUENCING DIFFERENCE IN ANKLE JOINT FLEXIBILITY BETWEEN MALES AND FEMALES

KATO, E.

KYOTO SANGYO UNIVERSITY

INTRODUCTION: The methods are used to evaluate flexibility by measuring length and angle. However, as the influence of resistance to a pain cannot be excluded, both these measurements cannot be objective. Stiffness is a mechanical index to assess joint flexibility, and can be measured using evaluating the passive torque of a joint involving a group of muscles that are elongated when the joint is moved. Because it is not affected by resistance to pain, it is thought that stiffness can be used to evaluate joint flexibility more objectively than can be done by measuring length and angle. Although it is known that there is a significant sex difference in flexibility, the responsible factors remain unclear. In this study, we aimed to elucidate how stiffness can be measured in ankle joint, as well as to determine the factors influencing stiffness measurement and how they relate to the sex differences in flexibility.
METHODS: Passive ankle joint dorsiflexion was performed in 27 healthy adults. Subjects took a seated position on a dynamometer and fixed their foot to a foot-plate that recorded passive torques generated by the plantar flexor muscle group from 30˚ of plantar flexion to 20˚ of dorsiflexion. We calculated ankle joint stiffness using linear regression between the ankle joint angle and passive torque. Muscle thickness of the anterior and posterior of shank was measured as an index of muscle volume, and B-mode ultrasound was used to quantify changes in the muscle architecture of the gastrocnemius medialis accompanying a change in the joint angle. In addition, to determine muscle stiffness at each ankle joint angle, the muscle belly of the gastrocnemius medialis was assessed with ultrasound shear wave imaging. Subjects performed isometric maximum voluntary contraction for plantar flexion and dorsiflexion. Furthermore, subjects exerted maximal plantar flexion as fast as possible, and the rate of torque development was calculated. Multiple regression analysis was performed using a stepwise method, with ankle joint stiffness as dependent variables and all the measurement parameters as independent variables.
RESULTS: As morphological parameters, significant sex differences were observed in height, body mass, shank length, muscle thickness in the anterior of the shank and subcutaneous adipose thickness in the anterior and posterior of the shank. There was no significant sex difference in passive torque at each ankle joint angle, but a significant sex difference was found in ankle joint stiffness. With passive torque, the muscle stiffness and fascicle length at each ankle joint angle showed no significant interaction between the ankle joint angle and sex difference, but a significant interaction and a main effect were seen in the pennation angle.
CONCLUSION: Passive torque and stiffness were used to objectively determined joint flexibility. A significant sex difference was found in ankle joint stiffness, with effects on muscle volume, muscular strength, and muscle architecture.

ADAPTIVE IMPLICATIONS OF VITAMIN D CONCENTRATIONS IN SOUTHERN HEMISPHERE NATIONAL RUGBY LEAGUE PLAYERS

ROBERTS, L.A.1, SCOTT, T.2,3, KELLY, V.G.2,3

1; GRIFFITH UNIVERSITY AND MENZIES HEALTH INSTITUTE QUEENSLAND , 2; BRISBANE BRONCOS RUGBY LEAGUE CLUB , 3; UNIVERSITY OF QUEENSLAND

INTRODUCTION: Recent data supports individuals needs for optimal 25(OH)D (Vitamin D; VitD) concentrations to support muscle adaptation. Additional performance adaptations may also occur from VitD supplementation; by promoting or maintaining optimal VitD concentrations, or in e.g. Northern Hemisphere individuals and athletes where deficiencies are common. However, a paucity of data exists relating to VitD status in Southern Hemisphere elite athletes, and particularly any potential associations with immunological and performance adaptation parameters in response to training.
METHODS: Thirty-one elite Southern Hemisphere National Rugby League players (22 +/- 3.57 yr, 1.78 +/- 0.31 m, 99.38 +/- 12.14 Kg), and thirty-one recreationally active Males (Controls; 26.23 +/- 4.12 yr, 1.79 +/- 0.65 m, 83.10 +/- 7.70 Kg), matched for skin pigmentation-type; volunteered to participate in the study. Blood samples were collected from the players before (Pre), half way through (Mid), and after (Post) a 3-week pre-season training block (January, Summer). Blood samples were collected from Controls coinciding with Post. Pre and Post training, concentrations of VitD were measured from all participants, and performance indicators were measured from players. A full blood count was also measured from players Pre, Mid and Post.

RESULTS: All players had adequate, above 50 Nmol.l VitD concentrations at Pre, with 24 players having optimal, above 100 Nmol.l concentrations. Concentrations increased from Pre-Post training (p = < 0.001; d 0.33 (95% CI 4.85 - 9.24 Nmol.l), including two players increasing their rating from adequate to optimal. Concentrations were higher in players compared with Controls (p = < 0.001; d 2.5 (95% CI 35.66 - 65.16 Nmol.l), along with their mean weekly time spent outdoors from 0600 to 1800 over the previous month (4.59 +/- 1.71 Vs 1.00 +/- 0.76 hrs; p = < 0.0001; d 2.7 (95% CI 2.92 - 4.27 hr). VitD concentrations also correlated negatively with skinfold thickness (p = 0.006; r -0.36 (95% CI -0.11 - -0.56)) and tended to correlate positively with estimated maximal oxygen uptake (p = 0.059; r 0.27 (95% CI -0.01 - 0.50)). Leukocyte derivatives including total leukocytes, lymphocytes, monocytes and basophils; and erythrocyte counts, decreased from Pre-Post training (p = 0.001 - 0.031; d 0.58 - 1.13). VitD concentrations tended to positively correlate with monophil, eosophil and basophil counts (p = 0.008 - 0.082; r 0.24 - 0.36), and negatively with measures of platelet architecture (p = 0.004 - 0.077; r -0.35 - -0.53).
CONCLUSION: Players had higher VitD concentrations compared to the Controls, most likely as a result of their increased sun exposure. The players concentrations could also be increased by short-term ambient sun exposure, despite starting concentrations. Immunological markers were decreased by training, and associated with absolute, or changes in VitD concentrations. However, the mechanisms underpinning these associations require further investigation in elite athletes.

EXERCISE-INDUCED LACTATE RESPONSES IN MULTIPLE SCLEROSIS.

OP T EIJNDE, B.

HASSELT UNIVERSITY

INTRODUCTION: Multiple Sclerosis (MS) patients show elevated resting serum lactate concentrations compared to healthy controls (HC). Whether they also exhibit higher lactate concentrations during acute exercise and/or following training (repeated exercise) is unknown.
METHODS: In this retrospective study, blood lactate concentrations (mmol/l) during submaximal (HC, n=11; MS, n=32) and maximal (HC, n=20; MS, n=24) exercise testing (ergospirometry) were analyzed. Submaximal (lactaterest, lactatebout1, lactatebout2) and maximal (lactatestart, lactatemax) lactate concentrations were adjusted to lean tissue mass (/LTM). Hereafter, a portion of both MS groups were enrolled in a 24 week mild to moderate intensity (MSsubmax, n=12) or 12 week high intensity interval (MSmax, n=13) exercise intervention program and hereafter performed POST exercise submaximal and maximal exercise tests.
RESULTS: Under submaximal exercise conditions in MS and compared to HC, lactaterest (MS: 2.7±0.6 vs HC: 2.3±0.7), lactaterest/LTM (6.9±2.1 vs 5.2±1.9) and lactatebout2/LTM (7.7±2.5 vs 5.8±2.8) were significantly ($p<0.05$) elevated in MS. After 24 weeks of mild-to-moderate-intensity exercise training and compared to PRE values, lactatebout2 (2.5±0.7 vs 3.4±1.1) and lactatebout2/LTM (6.3±2.1 vs 8.4±2.7) significantly ($p<0.05$) decreased during submaximal testing in MSsubmax. Under maximal conditions, lactatestart (2.3±1.0 vs 1.7±0.9) and lactatestart/LTM (5.5±2.9 vs 3.9±2.6) were significantly ($p>0.05$) elevated in MS. Twelve weeks of high intensity interval training did not improve this ($p>0.05$).
CONCLUSION: Under the conditions of the present study we conclude that MS patients have higher resting lactate concentrations but during acute submaximal and maximal exercise, lactate responses appear to be similar compared to healthy controls. Moderate intensity exercise therapy (24w) probably improves lactate accumulation but high intensity exercise therapy (12w) did not.

Training and Testing

FUNCTIONAL ABILITY OF THE ANKLE AND FOOT IN FEMALE ATHLETES WITH LONG TERM SPORT PERFORMACE IN THE WATER

CHATZIILIAS, V.1, ATHANASOPOULOS, S.1, MANDALIDIS, D.1

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Aquatic sports that performed in the water require athletes to stay for prolonged periods of time in weightlessness environments such as a pool or the seawater in order to achieve a high level of competitiveness. Other individuals utilize similar environments both for therapeutic and leisure purposes, mainly due to the reduced gravitational loads that act on the human body (Becker, 2009; Matsuda et al., 2008). The effects of these environments on the weight bearing joints of the lower limbs remain unknown. The aim of this study was to examine the effect of prolonged participation in aquatic activities that performed in the water on the functional ability of the ankle and foot.
METHODS: The functional ability of the ankle and foot was assessed in 28 healthy female athletes who were involved for more than 10 years in aquatic sporting activities (AS) that performed in the water, such as water polo and swimming (n=14) and field sporting (FS) activities, such as basketball and handball (n=14). Fifteen healthy females without regular participation in any kind of sport, served as control (CO). The functional ability of the ankle and foot was determined based on (i) the isometric strength of the plantarflexors/dorsiflexors of the ankle joint and the evertors/invertors of the subtalar joint, (ii) the range of motion of the ankle and midtarsal joints and (iii) the reaction time of the peroneus longus muscle. The static and dynamic body balance was also assessed by measuring the displacement of the center of pressure during single-leg-standing tests and the reaching distance during Y-balance test, respectively.
RESULTS: The isometric strength of the dorsiflexors, evertors and invertors muscles was significantly higher in AS athletes ($P<0.05$) compared to FS athletes and the C group. The differences between groups regarding the range of motion of the ankle and midtarsal joints, the reaction time of peroneous longus as well as the static dynamic balance measurements, were not significant.
CONCLUSION: Our findings revealed that functional ability of the ankle and foot as well as body balance was not diminished by long term participation in aquatic activities that performed in the water. Further study is required to determine the functional ability of other weight bearing joints of the lower limb and the trunk.

CHANGES IN RPE, ENERGY EXPENDITURE, ACTIVITY AND FATIGUE OF VASTUS LATERALIS MUSCLE IN SLOPED WALKING.

LEE, S.Y.1, LEE, J.H.1, KIM, Y.H.1, LEE, H.S.1

DANKOOK UNIVERSITY GRADUATE SCHOOL

INTRODUCTION: The task demands for sloped (uphill/downhill) walking result in changes in kinematics and kinetics (Kuster et al., 1995) and electromyography (Lay et al., 2007) in comparison to level walking. Moreover, muscle functional roles likely change in response to

the biomechanical demands of sloped walking (Nathaniel et al., 2016). This study tested the hypothesis that rate of perceived exertion (RPE) and energy expenditure (EE) would increase in uphill treadmill walking (UH) compared with downhill (DH) and level treadmill walking (LV), and increases in activity and fatigue of vastus lateralis muscle (VL) would production in DH compared with LV.
METHODS: 12 healthy adult aged 22 to 29 years, completed on a treadmill in a randomized crossover order 3 walking trials for 30 min at 1.2 m/s walking speed, with three incline (LV, UH and DH with a slope of 10%). RPE and EE were measured continuously during the 30 min of each 5 min interval (T1~T6). Activity and fatigue of VL were collected from electromyography at the all slope session, +0~1 min (T1), +9~10 min (T2), +19~20 min (T3) and +29~30 min (T4) during 30 min treadmill walking.
RESULTS: The changes in RPE and EE were significantly increased (p=0.001, respectively) T1 to T6 in UH as compared to LV. The changes in VL activity were significantly increased (p=0.001, respectively) T1 to T4 in DH as compared to LV, but the changes in VL fatigue were not significantly different between groups and times.
CONCLUSION: It has been reported that uphill exercise increases the RPE and EE as compared to LV (Hagiwara and Yamamoto, 2011), and confirmed the findings of the present study showing that changes in RPE and EE were more due to a cardiorespiratory ability rather than to muscle damage. Eston et al. showed that muscle activity was significantly increased at DH than that at LV. It seems that changes in VL activity are influenced by performing eccentric contractions during DH. However, no significant changes in VL fatigue were evident, it is possible that the magnitude of muscle fatigue was due to a lesser in VL, and thus this warrants further study.

BLOW-OUT 2 HOURS BEFORE THE START OF COMPETITION IN INTERNATIONAL RUGBY-7S PLAYERS: BENEFICIAL OR DETRIMENTAL?

MARRIER, B.

FEDERATION FRANÇAISE DE RUGBY

INTRODUCTION: Preconditioning strategies are considered as opportunities to optimize performance on competition day. However, there is little scientific information available in team sports. The aim of this study was to monitor the changes in physical and psychophysiological indicators among international Rugby-7s players after a priming exercise.
METHODS: In a randomized crossover design, fourteen under 18 international Rugby-7s players completed, at 8:00 am, a pre-loading session consisting of a warm-up followed by small-side games (4 vs. 3), skills and 2 x 50-m maximal sprints (Experimental) or no pre-loading session (Control). Following a 2-hour break, the players performed a set of six 30-m sprints and a Rugby-7s match. Recovery-stress state, salivary cortisol and alpha-amylase (sAA) levels were assessed before the preloading session (Pre), immediately after (Post-1), before the testing session (Post-2) and after (Post-3).
RESULTS: Experimental - Control differences in repeated sprint performance were very likely trivial (+0.2 +/-0.7%, 3/97/1%). During the first half of Rugby-7s match, the sprint distance covered and the accelerations number were almost certainly moderately lower in Experimental than in Control and the accelerations number was likely higher (small) during the second half in Experimental compared to Control. At Post-2, the perceived recovery-stress state was better (small difference) in Experimental compared with Control. No difference was observed for salivary cortisol responses while the preloading session induced a higher stimulation of sAA activity.
CONCLUSION: The priming exercise has no substantial effect on physical performance during a simulated Rugby-7s match, however potential benefits have been reported for psychophysiological indicators.

A LONGITUDINAL STUDY ABOUT THE BODY COMPOSITION OF COLLEGIATE JUDOIST USING DXA

MAEMICHI, T., TORII, S., IIZUKA, S.

WASEDA UNIVERSITY

INTRODUCTION: Body composition is one of the most important factors of motor quality for athletic performance. Exercise prescription based on the results of regional body composition such as side-to-side difference of extremities is expected to improve athletic performance. It is also suggested that participating in athletic training for a long time would change the body composition of athletes as to fit the nature of the sport. Therefore, the purpose of this study was to investigate the effect of continuing judo training during college years on body composition such as bone, muscle and fat.
METHODS: Subjects were 16 male and 7 female collegiate judoists. All subjects were participating in judo training before college admission. Also, they lived the judoist club dormitory. Body composition was measured using dual energy X-ray absorptiometry (DXA) from the first to fourth grade in each year. The values of fat free mass (muscle mass), fat mass, body fat percentage, bone mineral content (BMC), and bone mineral density (BMD) were compared between those at first grade and those at fourth grade.
RESULTS: Body weight and body fat percentage didn't increase between first grade and fourth grade. Bone mineral content and bone mineral density significantly increased in all body regions in male collegiate judoist players. Also, Bone mineral content and bone mineral density significantly increased in several (not all) body regions in female collegiate judoists.
CONCLUSION: Judo is one of the material arts, and makes large mechanical stress on the body, resulting in increase of bone mineral. The authors consider that the reason of sex difference in bone mineral change would account the sex difference of the growth period. Continuing judo training during college years increases bone mineral content and bone mineral density.

INFLUENCE OF THE PLAYER'S PERSONAL CHARACTERISTICS ON THE PHYSICAL DEMANDS OF ELITE JAPAN RUGBY UNION MATCH PLAY

YAMAMOTO, H., TAKEMURA, M., TACHIBANA, M., HASHII, Y., NISHITSUJI, Y,. TSUJITA, J., HOJO, T.

DOSHISHA UNIVERSITY

INTRODUCTION: Physical demands of Rugby union have been analyzed and the characteristics of each position reported (Yamamoto et al., 2017). However, data may be influenced by the match result (won/lost, score margin) or influence of the players personal characteristics, and it is necessary to consider whether the characteristics of each position are indicated appropriately. Therefore, the aim of this study was to analyse the variation among player's in the same position, which is one piece of information required when considering whether physical demands correctly report the characteristics of each position.
METHODS: Subjects were players who participated fully (80 minutes) for more than seven matches in official matches of the 2013 - 2015 season of Japan rugby top league. The number of player by Position were Lock (n = 3), Flanker (n = 3), Fly Half (n = 2), Center (n = 3), Wing (n = 2). Physical demands were recorded by a SPI Pro XII (GPSPORT, Australia) sampling at 5 Hz. Data were categorized into (1)Total distance(TD), (2)movement speed zone, corresponding to low(LSR;0-5m・s-1) and High(HSR;≧5m・s-1), (3)total and high accelerations(TA

and HA;≧2.5 m・s-2), (4)total and heavy impacts(TI and HI;≧10G). Bartletts test for analysis of variance, ANOVA was used for the test when equal variance was confirmed.
RESULTS: With Wings, there was a significant difference between players at TD (p<.01, ES = 0.7). Significant differences were also observed in LSR, HSR, TA, HA, TI, HI (p<. 01, ES = 0.5 – 1.1). Other positions also showed the same result as Wings.
CONCLUSION: A significant difference was found among players in the same position with each parameter, and it became clear that physical demands were influenced by players even in the same position. On the other hand, from results of the Bartletts test, uniformity of variance was confirmed among players at each position. Thus, it was suggested that Physical demands adequately show the characteristics of each position.

RELATIONSHIP BETWEEN UPPER LIMB POWER IN BENCH PRESS AND THROWING SPEED IN CHEST PASS

MURAOKA, Y.1, TAGUCHI, T.1, KUSAYANAGI, K.1, YASUDA, T.2

1: MEISEI UNIV. , 2: NIIGATA UNIV. OF MANAGEMENT

INTRODUCTION: The movement pattern of the chest pass in basketball is similar to that of bench press. The purpose of this study was to examine the throw speed in chest pass and its association with the upper limb power in bench press and to clarify the relationship between upper limb power and throwing performance in chest pass.
METHODS: Nine male basketball players (mean+/-SD: age, 18.8+/-1.1 years; height, 170.6+/-6.1 cm; weight, 65.9+/-7.4 kg; years of basketball experience, 8.2+/-0.8 years) from a university basketball team were tested for maximal throwing speed in chest pass and upper limb power in bench press. The throwing speed in chest pass was measured using a speed radar gun (Bushnell). The subjects were asked to perform a quick and strong chest pass by using a basketball (FIBA approved, category 7) from a distance of 7 m to the tester, throwing 3 to 5 times. One repetition of the maximum (1RM) bench press was measured after warming up. The subjects performed the ballistic bench press with loads corresponding to 30%, 50%, and 70% of 1RM. A linear position transducer (Gymaware, S&C) was attached to the barbell shaft to determine the maximum velocity. Quadratic polynomial regression was calculated from the load and power in bench press, and the maximum power output was determined. Then, power in chest pass was calculated. The relationship between the maximum power in bench press and that in chest pass was examined.
RESULTS: As the load on bench press increased, the velocity decreased linearly. A significant correlation was observed between the maximum velocity of chest pass and the maximum velocity of bench press in 30% of 1RM ($r = 0.77$, $P < 0.05$). In this study, the maximum power in bench press was observed in approximately 50% of 1RM. It was different from that in a previous report (about 30% of 1RM, Kaneko, 1970). In addition, a significant correlation was not observed between the power in chest pass and the maximum power in bench press.
CONCLUSION: In the power output of multiple joints of the upper limbs, the maximum power was not necessarily shown in 30% of 1RM. As the significant correlation was acceptable between the maximum velocity of chest pass and the maximum velocity of bench press in 30% of 1RM, we suggest that for the improvement of the throwing speed in chest pass, lower load should be applied on bench press.

GROUP AND INDIVIDUAL RESPONSES TO A 4-WEEK HEAVY SLED INTERVENTION IN YOUNG PROFESSIONAL RUGBY UNION PLAYERS

ROE, G., MCLAREN, S.J., DARRALL-JONES, J., JONES, B.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Eight weeks of heavy sled training is effective for improving sprint performance in team sport athletes (Morin et al., 2017). Shorter duration interventions, more suitable to preseason training blocks have yet to be investigated. We therefore aimed to assess the group and individual responses to a 4-week heavy sled intervention in rugby union players during a preseason training block.
Ten young male professional rugby union players (age 19.1 ± 1.2 years, body mass (BM) 98.1 ± 15.4 kg, height 184 ± 5 cm) completed a 4-week heavy sled programme in addition to their normal training. Data from the previous preseason exclusive of any sled training was used as a control (including the same (n=5) and different (n = 6) players to intervention (age 18.9 ± 1.3 years, BM 97.6 ± 14.5 kg, height 183 ± 6 cm). Individual sled loads were determined at the beginning of preseason via sprint force-velocity-power profiling, using 0% (40-m), 60% (30-m) and 120% (20-m) BM as external loads and methods similar to previous research (Cross et al., 2017). Subsequently, players completed 2 sets of 4 (week 1), 5 (weeks 2-3) or 6 (week 4) 20-m heavy sled sprints (75-87% BM) on 2 non-consecutive days. Between-sprint and set rests were 3 and 5 min respectively. Linear mixed models with random effects were used to examine the pre-post intervention-control differences in linear sprint times (10-, 20-, 30- and 40-m, unloaded) whilst adjusting for baseline value and training load (derived from session ratings of perceived exertion) accumulated outside the intervention sessions. Standard deviations (SDs) for individual differences in response to the intervention (vs control) were also estimated along with the number of true responders to the intervention (≥ 75% probability that the observed change > control group pre-post typical error and smallest worthwhile change [SWC]).
10-m time was likely faster (> SWC) following the intervention compared to the control period (-2.4%; 90% confidence limits ±1.8%). The pre-post intervention-control difference was unclear for 20- (-0.4; ±1.7) and 30-m times (-0.6; ±1.6), and possibly trivial for 40-m time (0.6; ±1.6). Individual response SDs were moderate for 10-m (3.3%; ±4.0%) and trivial for 20- (-1.3; ±3.6), 30- (-1.7; ±3.5), and 40-m (-3.9; ±2.1). The number of true and substantial responders to the intervention were 5, 1, 2 and 0 for 10-, 20-, 30- and 40-m times.
Four weeks of heavy sled training improves 10-m sprint time in rugby union players, with substantial individual responses apparent. No substantial effects were evident for sprint times greater than 10-m -a finding that may be explained by the specificity of training-induced adaptations. Whether these improvements are maintained beyond the intervention period and to what extent non-responders can be explained requires further investigation.

METHODS: RESULTS: CONCLUSION: HIGH VS. LOW FREQUENCY RESISTANCE TRAINING: AN ANALYSIS OF INDIVIDUAL MUSCLE HYPERTROPHY

LIBARDI, C.A., BARCELOS, C., DAMAS, F., NÓBREGA, S.R., LIXANDRÃO, M.E., SANTOS, L.M.E., UGRINOWITSCH, C.
FEDERAL UNIVERSITY OF SÃO CARLOS

INTRODUCTION: Higher resistance training (RT) frequencies can result in greater weekly total training volume (TTV, sets × repetitions × load) and RT-related outcomes (Schoenfeld, Ogborn, Krieger, 2017). On the contrary, it is reasonable to assume that very high training frequencies (e.g. five times per week) may not be beneficial to RT-related outcomes as one could expect a level of residual fatigue between training sessions that could negatively impact exercise performance. The aim of the present study was to compare the effect of high (HF) or low frequencies (LF) RT on muscle hypertrophy in untrained young men. Additionally, we analysed the hypertrophic responses of each individual at high and low frequency.
METHODS: We used a within-subjects design in which 20 untrained men had one leg randomly assigned to HF (five times per week) and the other to LF (two or three times a week). Vastus lateralis muscle cross-sectional area (CSA) was measured at baseline and after eight RT weeks. Total training volume (TTV) was calculated as sets×repetitions×load.
RESULTS: HF resulted in greater TTV than LF ($P<0.05$). Similar changes were found in muscle CSA comparing legs that trained at HFvsLF (15% and 14%, respectively; $P<0.05$). However, it is interesting to note that some individuals depict larger increases in muscle hypertrophy performing HF, while others had greater gains with LF.
CONCLUSION: In the present study, the LF protocol performed 6-9 weekly sets, while the HF executed 15 sets per week. Thus, our findings suggest that there may be a 'ceiling effect' for muscle hypertrophy on the dose-response relationship of the weekly sets, at least in untrained individuals. It should be noted that the results of muscular hypertrophy were based on group analyses. Thus, it is also interesting to analyse individual responsiveness to HF vs. LF. This analysis showed that some individuals increased more muscle CSA values in response to a HF and consequently greater TTV. We suggest that some individuals might be 'less sensitive' to RT stimulus, requiring HF. Interestingly, some subjects in the present study were more sensitive to lower RT frequencies and TTV. The reason for that is still very speculative, but it may be possible that they require a longer recovery time between sessions in order to maximize RT-related outcomes gains.

EFFECT OF DIFFERENT TYPES OF JUMPING EXERCISE TRAINING ON LOWER-LIMB MOTOR COORDINATION AND MUSCLE POWER IN OLDER ADULTS

NAKATANI, T.1,2, KINO, K.2, YAMAMOTO, H.2, TERADA, K.1,2, SHIRAISHI, A.1,2, NADAMOTO, M.3, MIURA, S.4
HUMAN PERFORMANCE LABORATORY

INTRODUCTION: Age-associated impairment of physical functions may lead to a failure in completing daily tasks (Gralnik et al. 2000). Physical training improves motor performance, and enhanced fitness delays the onset of frailty. This may improve the quality of life in older adults. However, insufficient knowledge about the effects of jumping training on lower-leg muscular coordination, agility and power in older adults is available. The current study investigated the effects of training in different types of jumping exercise on lower-limb motor coordination and muscle power in older adults.
METHODS: Twenty-nine healthy men and women aged 63–80 years participated in this study. Participants were randomly assigned to either a forward jumping (FJ) (n = 16) or in-place jumping (IJ) (n = 13) exercise group. Both groups performed 1 jump per second until they reached a rating of perceived muscle exertion of 15 on the Borg Rating of Perceived Exertion Scale (Borg 1982). The FJ group jumped slightly forward, and the IJ group jumped in place. Both groups trained 3 times a week for 12 weeks. They also participated in 60 min of supervised group exercise once every 2 weeks at a local centre. Outcome measures included right lateral walk (RLW) and left lateral walk (LLW), the four-square step (4SS), foot stepping (FS), two-step stride length (2SL) and chair stand power (CSP).
RESULTS: Repeated measures analysis of variance showed a significant effect of the interaction between exercise and time for CSP, and a significant main effect of time of measurement for RLW and LLW, 4SS and FS in the both groups. In the FJ group, CSP improved significantly after the 12-week intervention (10.3 ± 1.2 vs. 11.6 ± 1.4 kgf/s/kg, $P < 0.05$). FS in the FJ group also showed significant improvement after the 12-week intervention (79.5 ± 14.7 vs. 84.5 ± 10.5 times, $P < 0.05$). The IJ group did not show any significant improvement for CSP or FS.
CONCLUSION: The results of this study suggest that the jumping exercise with slightly forward movement is more effective than in-place movement in improving agility and leg muscle power in older adults. The jumping exercise is simple, can be done at home and is safe. It is a beneficial technique for improving lower-limb muscle strength and power.

CORRELATION OF STRENGTH AND SWIM ERGOMETER PERFORMANCE WITH MAXIMAL SHORT COURSE SWIMMING

PETERSEN, C.1, MASON, T.2, PORTER, C.2
1. UNIVERSITY OF CANTERBURY, 2. SWIMMING CANTERBURY

INTRODUCTION: Minimising drag and maximising propulsive force are key factors in competitive swimming performance, with explosive strength also important for start and turns. Identifying factors that highly correlate with performance may help prioritise strength and conditioning practices. Therefore, our aim was to analyse correlations of several strength variables to 100m short-course swimming performance in adolescent swimmers.
METHODS: Twenty competitive swimmers, 10 male (age: 15.6 ± 3.5 years; mass: 67.0 ± 15.9 kg; height: 170.2 ± 10.1 cm) and 10 female (age: 16.0 ± 1.8 years; mass: 60.3 ± 4.1 kg; height: 165.0 ± 6.4 cm) volunteered to take part in the investigation. Recent 100-m short-course personal best (PB) swim performances in freestyle (Free) (64.58 ± 5.10 s :mean +sd), backstroke (Back) (73.07 ± 7.06 s) breaststroke (Breast) (87.46 ± 7.70 s), butterfly (Fly) (74.67 ± 9.54 s) and individual medley (IM) (74.28 ± 5.31 s) were correlated with swimmers' explosive strength (countermovement vertical jump (CMJ) and broad jump), swimfast ergometer (Kayackpro, USA) arm and leg tests as well as pool kick testing. Spearman's rank order correlation analysis was used to assess correlations between variables and PB swim performances.
RESULTS: Very large correlations were found with; 100m pool kick (96.94 ± 13.64 s) and both Free ($rs = 0.75$; $p<0.001$) and Back ($rs = 0.74$, $p<0.001$), and with CMJ (36 ± 11 cm) and Fly ($rs = -0.75$, $p<0.001$). Pool kick was also largely correlated with IM ($rs = 0.68$, $p=0.001$) and Fly ($rs = 0.53$, $p<0.02$). Large correlations ($rs = -0.54$ to -0.69, $p<0.01$) were found with CMJ and all other swim strokes, while broad jump (183

± 26 cm) was largely correlated with all strokes (rs = -0.52 to -0.53, p<0.02) except Breast (rs = -0.38, p = 0.07). The 100m ergometer arm test (60.06 ± 17.89 s) was largely correlated with performance across all strokes (rs = 0.51 to 0.62, p<0.02); the ergometer leg test (80.37 ± 31.08 s) was largely correlated with Free performance (rs = 0.68, p=0.001), moderated correlated with Back, Fly and IM, (rs = 0.45 to 0.47, p<0.05) but insubstantial correlated to Breast.
CONCLUSION: To improve swimmers training programmes it is useful to understand the correlation between power output in dryland and in-water exercises and actual swimming performance by specific strokes. The current assessment has highlighted useful stroke specific correlations for 100m short-course swimming performance and the importance of power output for these adolescent swimmers. A limitation of the current study was only using a Free kick on the ergometer, future studies should employ a stroke specific kick on the ergometer which will more closely resemble the specificity of leg movement used to produce propulsion in the water.

THE EFFECT OF TOE GRASP STRENGTH TRAINING ON AGILITY CAPABILITY

KUDO, H., SAITO, S.

MEJIRO UNIVERSITY

INTRODUCTION: Agility capability is the ability to perform quick action with acceleration and deceleration in various directions such as abrupt stop and turn.
It is essential that athletes increase agility capability.
On the other hand, the relationship between the toe function and the athletic ability has also been pointed out, and it has been reported that toe training such as towel gather training improves the muscular strength of toe grasp, repeated lateral jump, standing width jump and vertical jump. (Ihara. H, Miwa. M, Ishibashi. T, et. al., 1997)
METHODS: This study comprised 26 healthy male volunteers (13 toe grasp training group and 13 control). The toe grasp training group volunteers performed 8 weeks of towel gather training as the toe grasp training. We conducted an 8-weeks towel gather training at the toe grasp training group s volunteer, measured toe grasp muscle strength and pro-agility test before and after the training , and compared with the control. In the pro-agility test, also the direction turning time were measured.
RESULTS: The toe grasp muscle strength of the toe grasp training group was significantly improved at 0.24 kg / kg before training and at 0.43 kg / kg after training.
This result is an improvement of 181.2%.
As a result of the pro agility test in the toe grasp trainig group, the test time was shortened to 96.6%, the turn time to the left was 79.3%, and the turn time to the right was 83.6% respectively. All of these results were statistically significant results.
CONCLUSION: Discussion: From the results of this study, it was suggested that the toe grasp strength training could be one of the promising training method to improve agility capability, especially direction turning ability.
Furthermore, by adding toe grasp strength training to agility training it may be able to improve agility capability more effectively.
Although we performed kinetic analysis in this study, but it seems that kinematic analysis is necessary from now on.

RELATIVE INDEX OF JUDO-SPECIFIC TEST DISCRIMINATES ATHLETES OF DIFFERENT WEIGHT CATEGORIES

DETANICO, D., KONS, R.L.

FEDERAL UNIVERSITY OF SANTA CATARINA

INTRODUCTION: Specific tests may be used to assess and monitor physical capacities, allowing performance improvements. A specific test widely used in judo athletes is the Special Judo Fitness test (SJFT) that provides an absolute performance index, based in the number of throws (marker of anaerobic capacity) and heart rate (marker of aerobic capacity) (Franchini et al., 2009). However, it seems that relative SJFT index (normalized by body mass) better discriminates the performance of judo athletes in different weight categories (Isik et al., 2017). Thus, this study aimed to analyze the SJFT performance in judo athletes of different weight categories.
METHODS: Twenty eight male judo athletes participated of this study (20.3±3.3 years), divided in two weight categories: Lightweight category (LW) (n=18, 55-73 kg, body mass = 67.2±6.9 kg) and heavyweight category (HW) (n=10, 74-100 kg, body mass = 90.1±9.9 kg). Athletes performed the SJFT that is composed of three sets of 15, 30, and 30 seconds, with 10-s rest interval between each set. During test, athletes performed the maximum number of throws in two participants separated by 3 meters. Number of throws was identified, heart rate immediately after the test and 1 minute after the test were also computed. Absolute SJFT index was calculated through the sum of heart rate (after the test and 1 minute after) divided by the number of throws, while relative SJFT index was calculate by the absolute SJFT divided by the body mass. A t-test was used with level of significance set at p<0.05.
RESULTS: No significant differences were found for number of throws (LW 28±2, HW 27±4, p=0.65), heart rate after the test (LW 176±12 bpm, HW 177±5 bpm, p=0.79), heart rate 1 minute after the test (LW 149±19 bpm, HW 148±8 bpm, p=0.78) and absolute index (LW 11.8±1.5, HW 12.2±1.7, p=0.55); however significant difference was reported for relative index, showing better values in the HW athletes compared to LW (LW 0.18±0.02, HW 0.14±0.02, p<0.001).
CONCLUSION: According to Casals et al. (2017), body mass should be considered in the SJFT interpretation, ratifying our results, that showed only the relative index was able to discriminates heavier and lighter athletes. Although lighter judo athletes generally achieve higher relative power outputs than heavier ones (due to lower body fat) (Isik et al., 2007), in this study they did not present better relative SJFT index, indicating lower performance compared to heavier athletes. We concluded that relative SJFT index discriminated judo athletes of lightweight and heavyweight categories, and it can be used instead of absolute SJFT index for comparison of judo athletes in different weight categories.

EFFECTS OF EQUAL-VOLUME RESISTANCE TRAINING WITH DIFFERENT TRAINING FREQUENCIES IN MUSCLE SIZE AND STRENGTH OF TRAINED MEN

GENTIL, P., FISHER, J., STEELE, J., CAMPOS, M., SILVA, M., PAOLI, A., GIESSING, J., BOTTARO, M.

UNIVERSIDADE FEDERAL DE GOIAS

INTRODUCTION: Training frequency has recently received increased attention 1. Considering that lack of time is a common barrier to exercise adoption 2, identifying the minimal frequency of RT to optimize adaptation is of importance. In this regard, condensing exercise sessions into fewer days, yet performing an equal volume, might be a promising strategy. If trained individuals can obtain similar results with lower training frequencies, this could be a valuable strategy for prescribing RT programs for people with time constraints. Therefore, this study would provide valuable information that might conserve training time and encourage participation whilst optimizing adaptation.
METHODS: Sixteen men with at least one year of RT experience were divided into two groups, G1 and G2, that trained each muscle group once and twice a week, respectively, for 10 weeks. Elbow flexors muscle thickness was measured using a B-Mode ultrasound and elbow extensors and flexors peak torque were assessed by an isokinetic dynamometer.
RESULTS: The results of ANOVA did not reveal group by time interactions for any variable, indicating no difference between groups for the changes in MT or PT of elbow flexors and extensors. Notwithstanding, elbow flexors MT increased significantly <3.1%, P < .05> only in G1. Elbow flexors and extensors PT did not increase significantly for any group.
CONCLUSION: There were no differences in performing RT one or two times a week with equal number of sets in trained men. Nonetheless, only the group that trained once per week significantly increased muscle thickness. The results of the present study seem to contradict the results of previous studies in trained men 3. There are studies reporting positive results in trained men training once a week 4 and this approach has been widely used by bodybuilders using split programs 5. As lack of time is the most frequently cited barrier to exercise adoption 2 using an exercise program that can be performed only once a week may improve adherence in periods where time constraint might be an obstacle to continue training. reducing training frequency in trained men can elicit muscle hypertrophy.

EFFECTS OF UPPER-BODY COMPLEX TRAINING WITH OPTIMAL INDIVIDUAL POST-ACTIVATION POTENTIATION TIME ON KAYAK PERFORMANCE AND INFLAMMATORY RESPONSES IN KAYAKERS

HSU, S.C., LEE, Y.H., LIN, S.C., LEE, M.M., CHAN, K.H.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Complex training is an effective training method for enhancing power output in athletes. An appropriate individual rest interval may be paramount to optimizing the effectiveness of complex training. Upper-body complex training has not received substantial attention compared with lower body complex training. Therefore, the aim of this study was to investigate the effects of 4-week upper-body complex training with optimal individual post-activation potentiation time on kayak performance and the inflammatory responses.
METHODS: Eight male high school canoeists volunteered to participate in this study. The maximal muscular strength (1-RM) of bench press and bench pull, 200 m kayak time trial, as well as the individual post-activation potentiation (PAP) period were determined before the study. Thereafter, subjects perform the complex training 3 times per week for 4 weeks. The training protocol consists 6 sets (2 min between sets) of 3-RM bench press/ 8 repetition medicine ball chest press and 3-RM bench pull/ 8 repetition medicine ball over head throw with the rest time of optimal individual PAP time. Venous blood were drawn before training, 1 and 3 hours after training to determine the concentrations of interleukin-6 (IL-6) and C-reactive protein (CRP) at the first and the last training session. After 4 weeks training, the 200 m kayak time trial were proceed again. Data were analyzed by paired t-test and one-way ANOVA with repeated measures.
RESULTS: After 4-week of complex training with the rest time of optimal individual PAP time, performance for 200 m kayak time trial significantly improved (55.90 ± 10.03 v.s. 57.65 ± 11.19 s, $p < 0.05$). There was no statistically significant difference in the concentrations of IL-6 and CRP within different time points before and after the complex training.
CONCLUSION: The physiological rationale behind complex training has been termed PAP. PAP refers to the phenomenon by which the acute contractile ability of a muscle is enhanced in response to a conditioning stimulus such as a HRE. Previous studies have reported different and contradictory results of PAP, which may due to PAP is an individualized phenomenon (Wang et al., 2016). Therefore, we used the optimal individual PAP time to be the rest time of the training program. Single bout of upper-body complex training had acute effect on power output of bench press throw (Liossis et al., 2013). This study indicated that the 4-week training program used in this study could enhance the kayak performance. Moreover, strenuous exercise induces increased levels in a number of inflammatory cytokines (Pedersen, 2000). The training program applied in this study would not induce the inflammatory responses.

THE RELATIONSHIPS BETWEEN KNEE MUSCLES STRENGTH BALANCE AND SOCCER EXPERIENCE AMONG PROFESSIONAL MALE PLAYERS

MISJUK, M., RANNAMA, I.

TALLINN UNIVERSITY

INTRODUCTION: The game of soccer involves frequent one-sided activities, which may lead to muscle strength asymmetries between two legs and between agonist-antagonist muscle groups (Maly et al.,2016, Dauty et al., 2003). Theoretical model of functional asymmetry in soccer demonstrates that soccer players training age could be one factor that affects formation of functional asymmetry (Fouseks et al., 2010). There is lack of studies that investigate relationships between knee muscular strength balance and soccer experience of soccer players.
The purpose of this study is to investigate relationships between knee muscles strength balance and soccer experience.
METHODS: The study is based on 102 male soccer players from Estonian Premium League teams (22.9±4.3yrs, 181.1±6,8cm, 76.6±8,1kg, soccer experience 15.6±4.2 yrs). Soccer players performed knee extensors and flexors test. Peak torque was measured with an isokinetic dynamometer Humac Norm (USA). Concentric actions were measured at angular velocity of 60, 300°/s, and eccentric actions at angular velocity of 60°/s. The study employs two types of muscular strength balance parameters: H/Q ratio and bilateral symmetry of extensors and flexors. Soccer experience was defined as a period since players started participating in soccer training. Pearson correlation analysis was used to estimating relationships between the variables.

RESULTS: Statistically significant relationships were found between knee muscle strength balance and soccer experience. The longer experience of soccer players was significantly related with higher extensors bilateral strength asymmetry ($p<0.01$) at angular velocity of 60°/s on concentric mode ($r=0.255$) and lower H/Q ratio of non-dominant leg ($p<0.05$) at angular speed 60°/s on eccentric mode ($r=-0.206$). No statistically significant relationships were found between strength balance at angular speed 300°/s and soccer experience.
CONCLUSION: Results of current study are not in line with previous study that found reduction of directional asymmetries of concentric knee flexors at 180°/s and 300°/s with professional training age (Fousekis et al., 2010). In contrast to the previous study, we found that when soccer experience is increasing then muscular balance problems (H/Q ratio and bilateral deficit) are also increasing. Earlier injuries are one possible explanation for it. It is well known that injury rate in professional soccer is high and lower extremity injuries are most common (Ekstrand et al., 2011). Longer the soccer career has lasted, more likely it is that players have had injuries that affected their strength balance of knee muscles.

THE COMPATIBILITY OF EVALUATION OF AEROBIC CAPACITY, BY MEANS OF THE YO-YO, AND BEEP TESTS, OF AMATEUR FOOTBALL PLAYERS

SZMATLAN-GABRYS, U.1, GARNYS, M.2, STANISZ, L.1, STANULA, A.3

1:STATE SCHOOL OF HIGHER EDUCATION IN , 2:4SPORTLAB , 3:UPE

INTRODUCTION: The aerobic capacity is vital in the preparation of amateur footballers when it comes to the safe participation in such a form of physical activity of people who participate in training sessions 4-5 times a week. The studies carried out by Helgerud, J., Engen L., Wisløff U., Hoff J. (2001) , confirmed the normativity of the running tests designed for footballers in order to evaluate their aerobic capacities. The aim of this study was to verify the compatibility of the evaluation of the aerobic capacity of amateur football players, carried out by means of the Yo- Yo, and Beep running tests with direct measurements of physiological indexes.
METHODS: The participants of the study were 41 amateur football players aged 27,5±3.9 years, height 175.7 ± 6.9 cm, body mass 76.4 ± 6.1 kg. All participants regularly took part in training sessions for 8-10 hours a week. The studies were carried out on a football pitch, in accordance with the Yo- Yo Test and Beep Test (Thomas A., Dawson B., Goodman C. 2006) procedures, separated by a 72 hour break. The physiological parameters VO2, VE, RF, and VO2HR were measured by means of the K4b2 analyzer (Cosmed, Italy), and the HR by Polar Team (Finland)
RESULTS: In the study group the mean values in the Beep Test, and in the Yo-Yo Test, respectively, for the particular indexes: VO2max 56,53±5,61 /53,51±2,26 ml/kg/min, VE 135±10,7/ 129±9,4 l/min; RF 56±6,4 b/min/ 59±2,8 b/min; HR 193±4 / 189±3 bp/min; VO2HR 22,3± 3,1 /21,4±1,4 ml/bpm. All the parameters, with the exception of the RF in the Yo-Yo Test, adopt lower maximum values. These differences are of the order of 2-5%.The statistically significant differences of the order of $p=0.05$, occurred among the values of VO2max, RF, and VO2HR. A correlation analysis of analogous indexes, showed a statistically significant relationship in just two cases: the HRmax ($r=.455$ $p=0,01$), and the VO2HR ($r=.311$ $p=0,05$)
CONCLUSION: The lack of a statistically significant correlation relationship among the aerobic capacity index values, recorded in two running field tests, indicates the need for carrying out further studies in this area, and explaining the causes of such a state of affairs. The evaluation of the competitor cannot differ depending on the applied testing tool. The Yo-Yo Test with its velocity increase structure, is more aggravating for an amateur football player, than the Beep Test. This is indicated by lower physiological parameters values, at which the physical effort undertaken in accordance with this program, is stopped. In the Yo-Yo Test, there is an earlier activation of anaerobic metabolism, which is indicated by a higher level of the respiratory frequency (RF), stimulated by the increase of the concentration of CO2 in the exhaled air.

POSITION-DEPENDENT PHYSIOLOGICAL AND SOMATIC PROFILE OF ELITE YOUNG FEMALE BASKETBALL PLAYERS.

MIKOLAJEC, K.1, STANULA, A.1, GABRYS, T.2, GRYKO, K.3

1: AWF , 2: AJD , 3: AWF

INTRODUCTION: Many features characterize physiological profile of team sports players. Considering basketball most important physical abilities are power (jumps and high intensity runs), aerobic endurance (recovering from intense actions) anaerobic endurance (up-tempo style of play), speed (1x1, fastbreak), agility (ball control, multi-directional movements) [2]. Previous investigations have reported that the level of those variables might depends on playing position [1].
Therefore, the purpose of this study was to investigate the relation between selected physical abilities and playing position of youth polish national teams female basketball players at different age levels.
METHODS: 42 elite female basketball players participated in the study (U-16, n=15; U-18, n=12; U-20, n=15). Testing took place during the preparation mezocycle before FIBA Youth European Championships. Players were grouped depends on playing position on guards (playing position 1, 2), forwards (position 3 and 4) and centres (position 5). 10 different tests were carried out including: anthropometric measurement, speed, power, aerobic and anaerobic endurance and agility. One-way ANOVA was used to investigate the mean differences in the tested features according to playing position and age category.
RESULTS: U-16. Results showed that guards were significantly faster than forwards and forwards than guards for 5 m sprint (1.16 s vs. 1.18 s; $p<0.01$ and 1.18 s vs. 1.18 s; $p<0.01$) and total time of RAST test (30.37 s vs. 32.85 s; $p<0.001$ and 32.85 s vs. 30.52 s; $p<0.001$ respectively).
A significant effect of playing position was observed in body height, body mass and FFM. No significant effect was recorded in VO2max and HRmax.
U-18. Results showed that centres are taller than forward and guards (196,0 cm vs 172.0 cm; $p<0.01$ and 182 cm vs 172.0 cm; $p<0.05$ respectively).
U-20. As expected significant effect was reported in body height between centers and guards (194.3 cm vs 173.7 cm; $p<0.001$) and forwards and guards (185.6 cm vs. 173.7 cm; $p<0.01$). Results also showed significant effect of playing position in 5 m sprint between guards and centers (1.09 s vs. 1.2 s; $p<0.05$) and total time of RAST test between guards and centers as well as center and forwards (30.31 s vs. 34.13 s; $p<0.001$ and 34.13 s vs. 31.21 s; $p<0.01$ respectively).
CONCLUSION: Discussion: The body height and body mass differences were mostly observed between centres and guards and centres and forwards which indicates that this position is very specific according to game requirements. Significant effect of playing position in speed ability and anaerobic endurance (RAST test) can be explained by greater number of high-intensity activities in guards and forwards

compared with centres during game performance. No significant difference in VO2max indicates that game requirements in this area are similar despite of the playing position.

THE EFFECT OF TRAINING ON SIDE FOOT-KICK PERFORMANCE AMONG SWEDISH FIRST LEAGUE WOMEN'S SOCCER PLAYERS

CARLSSON, M.1, ISBERG, J.1, NILSSON, J.1, CARLSSON, T.1

DALARNA UNIVERSITY

INTRODUCTION: A high completion rate for passes is important for success in soccer, because longer passing sequences are related to more scored goals (Hughes & Franks, 2005). In a recent study, it was found that female players had a lower pass-completion rate than male players at the highest competitive standard of European soccer, which suggests that elite female players in general do not have the same technical characteristics as elite male players (Paul S. Bradley et al., 2014). The purpose of the study was investigate the effect of a 2-week training intervention on side foot-kick performance among Swedish first league women's soccer players.
METHODS: To investigate the effect of training on side foot-kick performance, a pre-post-intervention study was implemented where four side foot-kick tests were performed before and after a 2-week training period. The side foot-kick accuracy were investigated when kicking a stationary ball using match-relevant ball speed (SBRS) and maximal ball speed (SBMS) as well as subsequent to a 5-m run with the ball from different approach angles (0°, 30°, and 60°) to a predetermined position, where passing of the ball on the move was executed using match-relevant ball speed (RBRS). The fourth test comprised repeated side-foot kicks onto a rebound-box with continuously increasing passing distance (RRB).
Based on the results from the pre-tests, the players were assigned to either the intervention group (INT) or the control group (CON). The training intervention consisted of six 55-min training sessions. In each session, two rounds of five exercises focusing on improvement of side foot-kick accuracy were executed. Within-group and between-group differences were investigated using paired samples Student's t-tests and Mann-Whitney U tests, respectively.
RESULTS: Prior to the training intervention, there were no significant differences between the groups for any of the investigated test variables. The INT group improved RBRS ($P = 0.036$) and RRB ($P = 0.010$) during the training intervention, whereas no significant within-group changes were found for either SBRS or SBMS (both $P > 0.05$). No within-group differences were found for any of the test variables in the CON group (all $P > 0.05$). Significant between-group differences were found for RBRS ($P = 0.040$) and RRB ($P = 0.005$), whereas no differences were found for either SBRS or SBMS (both $P > 0.05$).
CONCLUSION: The fundamental soccer skill of passing a moving ball could be improved in elite women players by a 2-week training period focusing on improving side foot-kick performance.

THE TRACKING PERFORMANCE IN THE TRAINING PERIOD WAS SIGNIFICANTLY BETTER THAN IN THE COMPETITION PERIOD IN ELITE BASEBALL PLAYERS

WU, S.K., CHEN, W.Y., CHIANG, C.H., YANG, H.H.

NATIONAL TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: Baseball players have to track the moving balls, the running teammates and opponents at the same time in order to have a best defense. Baseball players had better performance of attentively tracking multiple moving targets than non-athletes was reported in past work. The purpose of the study is to examine whether the tracking performance is different in the competition period and the training period.
METHODS: Twenty-three baseball players and thirty non-athletes were recruited in this study. The tracking performance for all participants were measured with the modifying task by the Multiple Object Tracking Task . In our task, participants were asked to attentively track specific targets wandering around the computer monitor among some distractors for a few seconds, and they reported those targets in the end of trial. The task manipulated the object moving speeds <0.6, 0.9, 1.2, or 1.5deg/s> and manipulated the tracked target numbers <1 or 2 targets> to have 8 conditions. In addition, another condition was asked participants to simultaneously track one target in 0.6 deg/s and another target in 1.5 deg/s. All participants were run the task in the competition period and in the training period.
RESULTS: The tracking accuracy was significantly decreased as increasing the tracked numbers of targets and the tracking speeds for all participants in the competition period and the training period. An interesting finding was that at slow speeds <0.6 deg/s>, the tracking performance was similar for tracking two targets in the same speeds and in the different speeds. In contrast, at higher speeds <1.5 deg/s>, the tracking accuracy of two targets in the different speeds was significantly higher than two targets in the same speeds. In both periods, the tracking accuracy for baseball players was significantly better than non-athletes. Specially, the tracking performance for baseball players was significantly better in the training period than in the competition period, but non-athletes had similar tracking performance in both periods.
CONCLUSION: The study identified baseball players performed better than non-athletes in tracking performance. Baseball players in Multiple Object Tracking performance may show different results in different periods.

THE MODIFICATION OF THE YO-YO INTERMITTENT RECOVERY TEST LEVEL 1 FOR AMPUTEE SOCCER PLAYERS

MAEHANA, H., MIYAMOTO, A., WATARI, T., SUZUKI, K., WATANABE, T., KOSHIYAMA, K., YOSHIMURA, M.

JUNTENDO UNIVERSITY

INTRODUCTION: Amputee soccer is uniquely designed for the physically challenged, those who have undergone amputations, as well as those with extremity dysfunctions. All outfield players play on one leg using bilateral crutches without wearing an artificial leg during the match. In recent years, studies have been conducted with respect to amputee soccer. Maehana et al. (2017) has evaluated the match

performance and heart rate (HR) response of competitive match in Japanese amputee soccer. Their results demonstrated that the exercise intensity was high in amputee soccer. In particularly, it could be said to effective that improving maximum oxygen uptake in training. However, measurement method has not been established that considers the characteristics of amputee soccer that plays with clutches. Therefore, this study aimed to improve the Yo-Yo intermittent recovery test level 1 (YYIRT1) for amputee soccer players.
METHODS: Subjects were 10 non-disabled males who had experience of amputee soccer. The employed to measure aerobic performance was used YYIRT1. All subjects carried out normally YYIRT1 without carrying a clutch (Standard YYIRT1) and a clutch held (20m YYIRT1). Moreover, subjects carried out two improvement test with crutches that were shortened the setup distance from 20m to 10m (10m YYIRT1) and 15m (15m YYIRT1). The rest between each trial set more than 1 week. The sound source (beep) used in the test was unified to the default sound. Running performances data such as movement speed, acceleration, and deceleration were collected using a global positioning systems technology. HR was recorded using short-range radio telemetry. HR expressed as bpm and classified following categories: 50-150bpm, 150-160bpm, 160-170bpm, 170-180bpm, 180-190bpm and =190bpm.
RESULTS: The mean movement distance were as follows in respective test: Standard YYIRT1; 2115.5±273.1m, 20m YYIRT1; 210.0±20.0m, 15m YYIRT1; 1240±286.0m, 10m YYIRT1; 1820.0±0.0m. The mean HR were as follows in respective test: Standard YYIRT1; 173.9±7.6bpm, 20m YYIRT1; 137.5±10.4bpm, 15m YYIRT1; 171.1±10.6bpm, 10m YYIRT1; 182.0±5.7bpm. The HR categories spent a lot of time were as follows in respective test: Standard YYIRT1; 180-190bpm (25.5%), 20m YYIRT1; 50-150bpm (69.2%), 15m YYIRT1; 180-190bpm (31.6%), 10m YYIRT1; 180-190bpm (33.3%). There were significant correlations between Standard YYIRT1 and 15m YYIRT1 for movement distance ($r=0.73$; $p<0.05$).
CONCLUSION: Subjects in this study are non-disabled subjects but are training for amputee soccer. The 20m YYIRT1 was difficult to catch up with the sound source (beep) because of longer the setup distance. And, many subjects finished the test without HR reaching the target value. On the other hands, 10m YYIRT1 was too easy because all subjects completed the test. As a result of this study, it would be better improvement that reduce the setup distance to 15m. There was high relation between Standard YYIRT1 and 15m YYIRT1 in the movement distance. Therefore, it is necessary to further study the usefulness of 15m YYIRT1.

MONITORING OF HEALTH AND PERFORMANCE DATA FROM A PROFESSIONAL BASKETBALL TEAM DURING FOUR COMPETITIVE SEASONS.

GUERRERO, M.1, RODAS, G.2, FERNANDEZ, D.3, CADEFAU, J.1,4, SOLANAS, J.L.5, CUSSÓ, R.1
UNIVERSITY OF BARCELONA

INTRODUCTION: While winning is the primary goal in professional sport, training is often challenged by conflicting imperatives that of achieving optimal conditioning minimize injury and maximize availability to play. To measure the impact of training models on damage, injury and illness incidence, data of health and performance related variables must be integrated into all aspects of training and competition . Fast and Slow myosin's serum levels are internal indicators of muscle damage and are associated with the risk of injury . Control of the internal load induced by training and competition is a determining factor in the process of functional assessment of the athlete.
METHODS: 44 male professional basketball players from the FCB Basket unit participated in the experiment during four basket's season. Players were examined three times each season, using the periodic health examination protocol. Team followed Verkhosansky's model of contemporary training for high performance sport teams. Myosins were measured by ELISA .
RESULTS: They show that training protects both fibers of damage decreasing the myosin concentration in serum. However work exposition increase significantly the slow myosin in all seasons while fast myosin is significantly different between seasons , 11-12 and 12-13 , 12-13 and 13-14 . The increase in eccentric exercise correlated with an increase in fast myosin and a decrease in slow myosin . The best scored points are related with the lowest slow myosin.
CONCLUSION: The analysis of the four seasons together we observe the best results have been obtained during the 10-11 seasons and the worse during 12-13 and 13-14 seasons. Monitoring of fast and slow myosin as markers of both muscle fiber injuries is a very good option to test the muscular status of each player and make decisions to optimize the development of training during a competition season.

PHYSICAL AND PERFORMANCE CHARACTERISTICS OF JAPANESE DIVISION Ⅱ FEMALE COLLEGIATE BASKETBALL PLAYERS.

IGUCHI, J.1, AKIKO, S.1, HOJO, T.2, FUJISAWA, Y.2, KUZUHARA, K.3
1:KYOTO GAKUEN UNIVERSITY, 2: DOSHISHA UNIVERSITY 3:AICHI TOHO UNIVERSITY

INTRODUCTION: Several sports (e.g., American football, baseball and soccer, etc.) have invented some performance tests such as 1 Repetition Maximum (RM) bench press and squat, 40-yard sprint and Yo-Yo endurance test, which reflect competition time and physiological metabolism in each sport. Based on the studies which analyzed the results of those tests, it has been clear that power, muscular strength and body composition play important roles in deciding whether regular or non-regular player, teams win or loss. Regarding basketball, due to the rule changes in 2000(e.g., shortening of attack time from 30 seconds to 24 seconds) speeding up the progress of the game, players need more anaerobic capacity. In this study, we compared Japanese division 2 female collegiate basketball players with English national league division 2 female players in terms of body composition and physical performance. This research aims to verify whether the above findings apply to womens basketball by comparing between international countries.
METHODS: Twenty-two collegiate female basketball players(n=22, age=19.3±1.1 years) were recruited for this study. All subjects were classified by position: Center, Forward and Guard. Before participation, each subject was informed in detail of the study and provided written informed consent. All subjects were assessed for body composition (Height[cm], body weight[kg] and fat [%]) and performed several performance tests composed of vertical jump (VJ, [cm]), 20-m dash(s), Agility T-test(s), Suicide run(s) and Chest pass(m). Power (kg・s-1) was calculated based on each subjects VJ height and body weight. As data to be compared, we referred to the records collected by Delextrat and Cohen (2009). All comparisons were conducted using 1-sample t-test and the alpha level was set at $p \leqq 0.05$.
RESULTS: Significant differences were found in 25 of 36 comparisons. A significant difference was confirmed in all comparisons by team (table 1). As for the comparisons by position, 2 of 9, 9 of 9 and 5 of 9 comparisons showed a significant difference for center, forward and guard, respectively(table2-4).
CONCLUSION: As an overall trend, English players were taller, heavier, less fat, more power, faster in the 20-m dash than Japanese players. On the other hand, the comparison by center showed that there was no significant difference between the 2 teams except for height and body weight.

HIP ADDUCTOR MUSCLE STIFFNESS CHARACTERISTICS IN SOCCER PLAYERS

SAHO, Y.1, TANIGUCHI, K.2, KATO, T.3, KATAYOSE, M.2

1: TEIKYO UNIVERSITY , 2:SAPPORO MEDICAL UNIVERSITY , 4 OBIHIRO KYOKAI HOSPITAL

INTRODUCTION: Soccer is one of the sports with the most injuries. In particular, many muscle injuries occur in the lower limbs. Groin pain, including adductor muscle strain, is a typical injury among soccer players (Mosler et al. 2017). A better understanding of the mechanical properties of the lower leg muscles may help prevent muscle strain. We sought to investigate stiffness in the lower leg muscles of soccer players.
METHODS: Overall, 78 collegiate male soccer players (age: 19.4±1.0 year) participated in the study. The shear modulus in the hip adductor longus, biceps femoris, medial head of gastrocnemius, and soleus was measured in the resting and stretching position using ultrasound shear-wave elastography. We also examined differences in stiffness between each muscle in resting position, and between the dominant and non-dominant side in the stretching position.
RESULTS: Stiffness at rest was significantly different between muscles ($P < 0.05$). The hip adductor muscle was the stiffest, followed by the soleus, medial head of gastrocnemius, and soleus. Muscle stiffness of the adductor muscle while stretching was higher on the dominant side than on the non-dominant side ($P < 0.05$). Muscle stiffness while stretching in the other three muscles was not different between the dominant and non-dominant side.
CONCLUSION: Soccer includes kicking, stopping, jumping, and cutting. Kicking is an asymmetric motion that requires strong ball kicking in the dominant side leg, while stability in the non-dominant side leg. Most players prefer to kick with their dominant leg. The hip adductor muscle is important on the kicking and stable side. These asymmetric motions may influence muscle stiffness in the hip adductor muscles. Because hip adductor muscles are sometimes linked to groin pain, data on differences in mechanical properties are helpful to identify the mechanism of muscle injury in soccer players.References: Mosler AB, Weir A, Eirale C, Farooq A, Thorborg K, Whiteley RJ, Holmich P, Crossley KM. SHORT-PASSING ABILITY OF AUSTRIAN SOCCER PLAYERS COMPETING AT DIFFERENT LEVELS

WALLNER, D.1, SIMI, H.1, GRIMM, P.1, HAGENAUER, M.1, KLÖCKL, P.1,2

1: FH JOANNEUM UNIV. OF APPLIED SCIENCES; 2: KARL-FRANZENS-UNIV. GRAZ

INTRODUCTION: Passing ability is a fundamental skill for soccer players. Several tests exist to assess short-passing ability (Aki, 2011). They show good discriminative validity between playing levels and ages (Wen et al., 2017). The aim of this study was to analyze the short-passing ability of Austrian soccer players competing at different levels.
METHODS: 168 Austrian soccer players (age: 23.2±4.6 yrs; height: 180±6 cm; BMI: 23.5±1.7 kg) performed a modified Smart Speed passing test (Thiem, 2013). This test requires players to complete 15 passes against four targets in a randomized order as quickly as possible. Targets are 90 x 35 cm and placed in the middle of each boundary line of a 6.5 x 6.5 m field. The best of two attempts counted. The players were divided into groups according to the league they played in: professional (n=33), semi-professional (n=55), amateur (n=62) and hobby players (n=18). Data were analyzed by one-way ANAOVA und Tukey post-test.
RESULTS: There was no difference in body height and BMI between groups ($p>0.05$). The passing test was performed in 24.8±1.5 s, 25.1±2.1 s, 26.6±3.1 s and 28.4±3.0 s, respectively, and revealed significant differences between groups. Post-test showed differences between all groups ($p<0.05$), except between professional and semi-professional players.
CONCLUSION: Most of the players competing at a semi-professional level in Austria are former professional players and/or skilled players trained in a national soccer academy. This may explain why no difference in passing skills between professional und semi-professional players was found. Professional and semi-professional players in Austria may differ in other characteristics, such as physical fitness.

DIFFERENCES IN PERFORMANCE PARAMETERS BETWEEN CYPRIOT AND FOREIGN PLAYERS PARTICIPATING IN FIRST DIVISION IN CYPRUS.

PARPA, K., MICHAELIDES, M., ZACHARIA, A., NICOLAOU, S.

UCLAN UNIVERSITY OF CYPRUS

INTRODUCTION: Football has by far become the most popular sport in Cyprus. The Cypriot league has the highest percentile of foreign players compared to any European league. In 2016, 65.4% of the players participating in the league were of a foreign nationality, while in 2017 that number increased to 80.2% (1). The purpose of this study is to examine different demographic and performance characteristics of Cypriot players compared to this of foreign players. Training protocols and recruitment guidelines can be deduced based on the comparisons between Cypriot and foreign football players.
METHODS: Two hundred and thirty seven professional football players (Cypriots n=100, foreigners n=137) were evaluated using an isokinetic dynamometer. Peak torque and hamstring to quadriceps (H/Q) ratios were evaluated at both 60 degrees/s and 300 degrees/s.
RESULTS: Foreign players demonstrated significantly greater body weight ($p<0.05$) and body mass index ($p<0.05$) compared to the Cypriot players with no significant differences in body fat. In addition, Cypriot players were significantly younger ($p<0.05$) while no significant differences existed in height measurements.
Based on the isokinetic testing it was found that foreign football players produced significantly greater torques (at 60 degrees/sec) in both the right and left hamstring (H) muscles compared to Cypriot players [$F=2.96$, $p<0.05$ and $F=1.51$, $p<0.05$ for right and left H respectively]. In addition, foreign players produced significantly greater torques in the left quadriceps at 300 degrees/sec compared to the Cypriot players ($F=2.54$, $p<0.05$). Finally, significant differences were observed in hamstring to quadriceps ratio (H/Q ratio) of the right leg between Cypriot and foreign players ($p<0.05$).
CONCLUSION: It was concluded that foreign players had higher body musculature (significantly greater BMI and body weight with no differences in body fat) compared to Cypriot players. Cypriot players were significantly younger which may partially explain the selection of more experienced foreign players by the first division teams. Furthermore, foreign players demonstrated greater hamstring strength,

which is of great importance for explosive movements as well as joint balance and stabilization. Therefore, it is suggested that Cypriot players tailor their training routines towards increasing their hamstring strength in order to improve speed and explosiveness. The results of this study may provide the coaches with pertinent information not only on how to maximize exercise performance but also for recruiting more Cypriot players in the first division.

POSITION-DEPENDENT PHYSIOLOGICAL AND SOMATIC PROFILE OF ELITE YOUNG MALE BASKETBALL PLAYERS

STANULA, A.1, MIKOLAJEC, K.2, GABRYS, T.3, STANISZ, L.4, GRYKO, K.5

1-2: AWF , 3: AJD , 4: AWF , 5: AWF

INTRODUCTION: Many features characterize physiological profile of team sports players. Considering basketball most important physical abilities are: power (jumps and high intensity runs), aerobic endurance (recovering from intense actions) anaerobic endurance (up-tempo style of play), speed (1x1, fastbreak), agility (ball control, multi-directional movements) [2]. Previous investigations have reported that the level of those variables depends on playing position [1]. Therefore, the purpose of this study was to investigate the relation between selected physical abilities and playing position of youth polish national teams male basketball players at different age levels.
METHODS: 44 elite male basketball players participated in the study (U-16, n=14; U-18, n=16; U-20, n=14). Testing took place during the preparation mezocycle before FIBA Youth European Championships. Players were grouped depends on playing position on guards (playing position 1, 2), forwards (position 3 and 4) and centres (position 5). Each subject completed 10 different tests: anthropometric measurement, speed, power, aerobic and anaerobic endurance and agility. One-way ANOVA was used to investigate the mean differences in the tested features according to playing position and age category.
RESULTS: U-16. Results showed that centres and forwards are significantly higher than guards (200.0 cm vs. 182.8 cm; $p<0.01$ and 193.8 cm vs. 182.8 cm; $p<0.05$, respectively). An effect of playing position was observed in anaerobic (RAST test) and aerobic (VO2max test) endurance but the differences were not significant.
U-18. Results showed that centres are taller than forwards and guards (208,0 cm vs. 188.0 cm; $p<0.01$ and 196,8 cm vs. 188.0 cm; $p<0.05$ respectively).
U-20. Significant effect was reported in body height between centres and guards (204.0 cm vs. 190.8 cm; $p<0.001$). Results showed that forwards were significantly faster than centres for 5 m sprint (1.03 s vs. 1.12 s; $p<0.05$). Some differences were recorded in VO2max and HRmax between forward and centres, but they were not significant.
CONCLUSION: No significant difference in VO2max indicates that game requirements in this area are similar despite of the playing position. Significant differences in body height observed between centres and guards and centres and forwards which indicates that this position is very specific according to game performance. Significant effect of playing position in speed ability (5 m test) between forwards and centres can be explained by greater number of high-intensity activities in forwards compared with centres during game.

KICK OFF TIME AND TRAVEL AFFECT SLEEP RECOVERY KINETICS

MACLEOD, S., DRAKE, D., DAVIS, J., HAGAN, C., MURPHY, B.

ULSTER RUGBY

INTRODUCTION: It has been consistently reported that athletes sleep can be disrupted during competition phases due to travel and timing of fixtures (Skein et al. 2013; Fullagar et al. 2015). This investigation aimed to evaluate sleep recovery kinetics during an intensive competition phase with varying match kick-off times including travel.
METHODS: Consented data was obtained from 59 male rugby union players during the 16-17 Pro12 competition season. Players sleep-wake cycles were monitored over a 90-day period using Actigraphy (Nokia Go, California, USA) and tablet-based self-reports of sleep quantity (BrainWaveBank Ltd, Belfast). Match types were defined as; early KO: pre 5pm; Late KO: post 5pm; Home fixture or Away fixture. Baseline sleep was defined as the average hours of sleep per night with the exclusion of pre and post match sleep hours.
RESULTS: Pre-match showed significantly greater sleep duration than post-match (+120mins; $p < 0.001$) and baseline nights (+48mins; $p < 0.01$). In addition, a significant difference was present between post-match and baseline sleep duration (-72mins; $p < 0.001$).
Post-match sleep duration for Late KO was significantly less than Early KO (-42mins; $p < 0.05$) although there were no differences for pre-match sleep duration when comparing either kick off time ((Mean ± SD) Early: 522 ± 54 v Late 534 ± 78min) or match location (Home: 522 ± 78 v Away: 540 ± 90min). Also no differences were shown for post-match sleep duration between Home or Away fixtures (417 ± 78 v 396 ± 90min).
After matches, players went to bed significantly later compared to pre-match (+58mins; $p < 0.001$) and baseline (+58mins; $p < 0.001$) and bedtime was significantly later after away fixtures compared to home fixtures (+60mins; $p < 0.001$). Prior to a game, players also extended their sleep by waking significantly later compared to baseline sleep (+62mins; $p < 0.05$).
CONCLUSION: Our data suggest that elite RU players post-match sleep recovery is affected by match type. Following competition, strategies to enhance post-match sleep are required to minimize sleep disturbances. As fixture location has an impact on sleep profiles, optimising travel and training schedules surrounding competition may enhance sleep recovery kinetics in this cohort of athletes. This is due to reduced sleep being observed during the above periods. As a result, this may add to the already impaired recovery state of the athlete due to accumulated training and competition load. This may be particularly relevant over the course of a season or congested fixture block where players are exposed to numerous fixtures and travel.

ACUTE EFFECTS OF DIFFERENT FORWARD LEG SWING TEMPOS ON FLEXIBILITY AND JUMP PERFORMANCE

ARIYOSHI, K.

OSAKA UNIVERSITY OF HEALTH AND SPORT SCIENCES

INTRODUCTION: Forward leg swings (FLSs) are repetitive movements in which the legs rhythmically move forward and backward. It is one of the representative warm-up exercises for the hip joint. However, a more effective FLS tempo needs to be elucidated. Therefore, the objective of the present study was to investigate an FLS tempo that is effective for flexibility and jump performance.
METHODS: The study involved the right legs of nine healthy male student volunteers (age: 21.3 ± 0.7 years; height: 171.9 ± 6.5 cm; weight: 68.2 ± 10.4 kg; leg length: 77.3 ± 5.4 cm). The subjects underwent experiments four times under different conditions on different days and times and in a random order. The four conditions consisted of different FLS tempos (at rest and 34, 44 and 54 bpm). Hip joint range of motion (ROM) and one-leg vertical jump (VJ) were measured before and after each experiment. During the FLS exercises, electromyogram (EMG) data for gluteus maximus (GM), rectus femoris (RF), vastus lateralis (VL), biceps femoris (BF) and gastrocnemius (GC) muscles were recorded, and lateral-view images were recorded using a digital camera. FLSs were performed 10 times at each tempo. VJs were performed with the subjects' arms fixed near their chests to prevent arm reactions. FLS images were categorised as front-flexion, front-extension, rear-flexion and rear-extension. The root mean square (RMS) values for each category were calculated. Normalised values were then obtained by calculating RMS for maximum voluntary contraction. The statistical analysis included the comparison of ROM and VJ scores for each condition before and after FLS and that of the level of muscle activity during FLS. One-way repeated analysis of variance was performed using the Bonferroni post-hoc analysis ($p < 0.05$).
RESULTS: The ROM value significantly increased from 85.6° ± 9.8° to 92.2° ± 9.1° at 44 bpm and from 80.6° ± 10.7° to 87.2° ± 8.3° at 54 bpm. The VJ value significantly decreased from 30.4 ± 3.2 cm to 28.9 ± 2.5 cm at 34 bpm but significantly increased from 28.3 ± 1.9 cm to 30.9 ± 3.4 cm at 54 bpm. Furthermore, muscle activities showed significant differences: At front-flexion, RF activity was 52.9% ± 30.1% at 34 bpm and 25.9% ± 11.6% at 54 bpm; at front-extension, RF activity was 34.7% ± 18.1% at 34 bpm and 8.4% ± 5.1% at 54 bpm; at rear-extension, GM activity was 69.9% ± 27.7% at 34 bpm and 29.0% ± 30.1% at 44 bpm, whereas BF activity was 64.2% ± 40.8% at 34 bpm, 27.0% ± 15.6% at 44 bpm and 38.9% ± 37.6% at 54 bpm; at rear-flexion GM activity was 52.8% ± 22.0% at 34 bpm and 18.0% ± 13.7% at 54 bpm, RF activity was 4.5% ± 2.9% at 34 bpm and 10.0% ± 4.0% at 54 bpm and VL activity was 20.0% ± 13.4% at 34 bpm and 39.9% ± 25.3% at 54 bpm.
CONCLUSION: A faster tempo while performing FLS can improve flexibility and jump performance and is therefore recommended.

VALIDITY AND REPEATABILITY OF SPRINT AND AGILITY TESTS FOR TENNIS PLAYERS THROUGH MANUAL STOPWATCH MEASUREMENTS

UMEBAYASHI, K., IMANISHI, T.

OSAKA UNIVERSITY OF HEALTH AND SPORT SCIENCES

INTRODUCTION: This study aimed to determine the validity and repeatability of agility tests for tennis players through manual stopwatch measurements and by comparing the results with an automatic photocell timing system.
METHODS: Eleven male junior tennis players (age: 13.5 ± 0.5 yr) and five measurers participated in the experiment. The tennis players participated in three tests (sprint tests [5 m, 10 m, and 20 m], a sidestep pro-agility test (SSP agility test), and a 505 agility test). The manual stopwatches and the automatic photocell timing system measured concurrently, and we calculated intraclass correlation coefficient (ICC) using both methods and twice attempt data.
RESULTS: The ICC for assessing the repeatability of the 5 m and 10 m sprint tests through manual measurement was low (below 0.2). When compared with automatic measuring, the 5 m and 10 m sprint tests and the SSP agility test had low ICC (below 0.55). However, the 20 m sprint test and the 505 agility test showed high ICC values (0.75 and 0.94).
CONCLUSION: These results suggest that the 20 m sprint test and the 505 agility test are valid and repeatable assessing methods to test the sprint and agility of tennis players through manual measurement also.

ACUTE AND CHRONIC EFFECTS OF ENDURANCE TRAINING ON SR CA2+ HANDLING IN HIGHLY-TRAINED ENDURANCE ATHLETES

GEJL, K., HOLMBERG, H.C., ØRTENBLAD, N.

UNIVERSITY OF SOUTHERN DENMARK

INTRODUCTION: Endurance capacity of the human skeletal muscle is highly dependent on its mechanistic properties. However, knowledge about the responsiveness of important steps involved in the excitation-contraction (E-C) coupling to acute and chronic endurance exercise in highly-trained endurance athletes remains unclear . The present study investigated acute and chronic effects of endurance training, superimposed with three weekly high-intensity training sessions, on the SR Ca2+ release and uptake in elite endurance athletes.
METHODS: 26 elite triathletes and road cyclists completed four weeks of routine endurance training (≈ 20h/week) including three weekly days with a high-intensity cycling session in the morning and a moderate intensity cycling session in the afternoon. In the morning, the athletes performed 8x5min (6x5min @ 85% HRmax and 2x5min as 15s "all-out" - 45s recovery), while the afternoon session consisted of 120 min of moderate intensity cycling at 65% HRmax. Muscle biopsies were obtained from m. vastus lateralis before (Pre) and after (Post) the training period as well as one hour after the 120min moderate intensity bike session on the 7th day with two bike sessions (Acute). The fluorescent dye technique was used to determine Ca2+ uptake and release rates in SR vesicles in homogenate from the biopsies.
RESULTS: The maximal SR Ca2+ release rate, measured during resting conditions, increased to 110 ± 4 % of Pre during the 4-week training period ($P = 0.01$), while the SR Ca2+ uptake rate remained unchanged (99 ± 5 % of Pre, ns). One hour after finishing the 120min session, on the 7th day with two cycling sessions, the SR Ca2+ release rate was reduced to 78 ± 4 % of Pre ($P < 0.0001$) while the SR Ca2+ uptake rate, measured as the time for free [Ca2+] to decrease by 63%, was increased to 121 ± 10 % of Pre ($P = 0.02$).
CONCLUSION: The present findings demonstrate that the SR Ca2+ handling in the skeletal muscle of highly-trained endurance athletes is plastic and that deteriorations in both SR Ca2+ release and uptake rates may partly explain the development of muscle fatigue during exhaustive exercise. Moreover, improvements in muscle performance after a period of endurance training may be partly explained by chronic adaptations in the SR Ca2+ release rate.

PHYSIOLOGICAL CHARACTERISTICS OF LONG-DISTANCE RUNNERS PARTICIPATING IN INSPIRATORY MUSCLE TRAINING

ROZEK-PIECHURA, K., KURZAJ, M., KUCHARSKI, W., OKRZYMOWSKA, P., MACKALA, K., STODOLKA, J.
UNIVERSITY SCHOOL OF PHYSICAL EDUCATION

INTRODUCTION: The aim of the study was to evaluate selected physiological parameters of long distance runners participating in addition in 8-week inspiratory muscle training.

METHODS: The research was carried out on 20 athletes of the Sports Club AZS AWF Wrocław, long distance runners who were divided into two groups depending on the sex: 1st group: 10 women, average age 21 ± 2.1, average body height 1.69 ± 0.04, average weight body 56.5 ± 5 in which, in addition to the standard sports training, inspiratory muscle and exhalation training was implemented on the Threshold device. II group: 10 men, average age 21 ± 2.4, average body height 1.79 ± 0.07, mean body weight 66.4 ± 4.8, which in addition to the standard sports training was implemented inspiratory muscles and exhalation on the Threshold device.The following examinations were performed before and after 8 weeks of training: lung ventilation (VC, FEV1) and respiratory muscle strength (PImax and PEmax values) on the Jaeger MasterScreen Pneumo spirometer using a special attachment, physical efficiency test using a spiroergometric test on the treadmill, where VO2max, VO2max / kg body weight and HRmax were measured, the lactate concentration after 4-5 minutes was also measured.
Respiratory muscle training took place 5 days a week. In the first week, load was 30% PI max, and each session lasted 5 minutes, twice a day. The value of the initial load was dictated by the safety conditions of conducting the training. In the following weeks, the load and duration of exercise during the day was increased. The maximum training load was 60% PI max, and the time of a single session last week was 15 minutes.
The sports training was carried out during the preparatory period, which included the MWP introductory mesure and MPO mesozoic general preparation. During the race, the athletes worked on improving the running strength in the first range of intensity, running strength in the second range of intensity, general strength, rhythm and fitness.
RESULTS: The average values of ventilation parameters were as follows: in women VC before training 4.08 liters, after 4.21 liters in men, 4.14 liters before and 4.42 liters after, in women FEV1 before training 3.79 liters, 4 each, 14 liters in men 4.2 liters before and 4.55 liters after, in women PImax before training 9.97 mmHg, after 11.56 mmHg in men 9.36 mmHg before and 10.64 mmHg after, in women PEmax before training 9.62 mmHg , at 11.07 mmHg in men, 8.14 mmHg before and 9.55 mmHg after, and lactate was 8.06 in women before and 7.06 after, in men 9.06 before and 7,96 after
CONCLUSION: There was a slight increase in ventilation parameters in both women and men after 8 weeks of training, while the parameters of inspiratory and expiratory muscle strength increased significantly.
2. Physiological characteristics of the VO2max / kg parameter showed a significant increase after 8 weeks of training, while the level of lactic acid decreased, which may indicate improved training of athletes.

EFFECTS OF RAIN WITH WIND ON THERMAL RESPONSES AND ENERGY METABOLISM WHILE RUNNING IN A MODERATELY COLD ENVIRONMENT

ITO, R.
DAIDO UNIVERSITY

INTRODUCTION: Outdoor exercises, such as jogging, football and marathons, often take place in rainy environments, but relatively few reports have described human physiological responses to exercise in cold rainy conditions. We have been investigating the physiological effects of rain on human physiological responses while running in different environmental temperatures. However, the influence of rain together with wind on body temperature and energy metabolism while running has not been investigated. We hypothesized that rain and wind together would increase physiological stress via body cooling during exercise, even in a moderately cold environment of 10°C.
This study aimed to determine the effects of rain with wind on physiological responses while running at 70%VO2max in a moderately cold environment.
METHODS: Seven healthy men (age, 20.7 ± 2.3 y; height, 172.7 ± 6.5 cm; mass, 68.8 ± 7.1 kg; VO2max, 61.9 ± 4.89 mL/kg/min [means ± SD]) who were non-smokers and not currently taking medication, rested for 10 min and then ran on a treadmill at 70%VO2max for 60 min either with 10 mm/h of rain (WR) or without rain (CON) at a climatic chamber of 10°C. Both WR and CON trials included a 2 m/sec wind and an additional headwind blowing at a velocity equal to the running speed of each participant. The participants were randomly assigned to the trials and balanced for order.
RESULTS: Rectal temperature, mean weighted skin temperature and thermal sensation were significantly lower, and oxygen consumption was significantly higher in WR than in CON (all $p < 0.05$). Heart rate did not differ significantly between the two conditions, but the rating of perceived exertion was significantly higher in WR than in CON at 50 and 60 min, and the respiratory exchange ratio was significantly higher in WR than that in CON throughout the entire trial ($p < 0.05$ for both). Plasma lactate and plasma norepinephrine levels were significantly higher in WR than those in CON ($p < 0.05$), whereas plasma glucose and plasma epinephrine did not differ significantly between the two groups.
CONCLUSION: The lower rectal temperature and thermal sensation accompanied by higher plasma norepinephrine levels indicated that rain with wind increased heat loss and cold stress. Furthermore, exercise efficiency that was probably decreased because the body was cold, might have resulted in increased oxygen consumption, carbohydrate oxidation and lactate concentrations.
Rain with wind intensifies body cooling and increases energy expenditure while running at moderate intensity in a cool environment.

PREDICTION OF MARATHON PERFORMANCE TIME USING PROGRESSION RUN

ADACHI, T.
OSAKA UNIVERSITY OF HEALTH AND SPORT SCIENCES

INTRODUCTION: Marathon performance time (MPT) has a high correlation with physiological factors such as maximal oxygen uptake or lactate threshold. However, in order to determine these physiological factors, expensive apparatus and specialized techniques such as blood collection are necessary.
The purpose of this study is to examine the relationship between progression run and MPT in order to find out methods to predict MPT from routine training results quickly.

METHODS: The test subjects were 66 male and female runners (36 men and 30 women) who belonged to a running club. The age of the subjects was 47.7 ± 8.9 years for men and 46.9 ± 5.7 years for women. The MPT for men was 3 hours 31 minutes 06 seconds ± 32 minutes 06 seconds, and for women was 3 hours 58 minutes 48 seconds ± 22 minutes 06 seconds. Further, MPT was not ones personal best record but the closest race result on the day of the implementation of the progression run, with net time adopted as the MPT.
Progression run is an endurance training that starts with running from a slack pace and gradually increasing the pace. For the progression run, a 500m lapel course was used, and a distance of 8-10km was run. The pace setting began with running at a pace of more than 30-40 seconds per kilometer with the MPT as the base to free pace for the last one kilometer. For example, in case of a MPT of 3 hours (4 minutes 16 seconds/km）, the pace was set at 4 minutes 40 seconds for start of running and paced up to 3 minutes 30 seconds. The test subjects were made to run dividing them into six groups from between 3 hours to 4 hours 30 minutes based on MPT. Regarding the pacing of each group, the running coach ran in the lead and controlled the pace. When the test subjects completed a run of 1km at a set pace, that speed was defined as the highest speed.
RESULTS: The maximum speed in the progression run was 247 ± 30 seconds/km for male runners and 280 ± 20 seconds/km for female runners, with a significant difference between them（$p<0.05$）. A comparison of the relationship between the maximum speed in the progression run and the MPT, shows a high correlation for both male and female runners and the regression formula of Y=1.029X-42.714（r=0.947, $p<0.001$）for male runners and, Y=0.989X-38.059（r=0.884, $p<0.001$）for female runners was obtained. As a result of a covariance analysis, no differences were observed between males and females. Based on a comparison between all male and female runners for the relationship between MPT and the maximum speed in progression run, the regression formula of Y=0.964X - 28.659（Y : MPT（minutes）, X : maximum speed of progression run（seconds/km）, r=0.941, $p<0.001$, R2=0.885）was obtained and a high correlation was observed.
CONCLUSION: There was a close relationship between maximum speed in progression run and MPT. The result suggests that it is possible to predict MPT with a contribution rate of 88.5% according to the maximum speed in the progression run.

HIGH-INTENSITY INTERVAL TRAINING ENHANCES CONTRACTILITY EFFICIENCY AND DIASTOLIC FUNCTION OF LEFT VENTRICULAR DURING EXERCISE

WANG, J.

CHANG GUNG UNIVERSITY

INTRODUCTION: Improved myocardial contractility is a critical circulatory adaptation to exercise training. However, the types of exercise that enhance left ventricular (LV) contractile efficiency and diastolic function have not yet been established. This study investigated how high-intensity interval (HIIT) and moderate-intensity continuous training (MICT) influence LV mechanics during exercise.
METHODS: Fifty-four healthy males were randomized to engage in either HIIT (3-minute intervals at 40% and 80% of VO2max, n=18) or MICT (sustained 60% of VO2max, n=18) for 30 minutes/day, 5 days/week for 6 weeks or to a control group (CTL, n=18) that did not engage in exercise intervention. LV mechanics during semi-upright bicycle exercise tests were measured by two-dimensional speckle-tracking echocardiography.
RESULTS: Before the interventions, acute bicycle exercise increased (i) peak radial and circumferential strain rates (SRs) at apical and basal segments, (ii) peak apical rotation and torsion, and (iii) peak systolic twisting and early diastolic untwisting velocities in the left ventricle. After the 6-week interventions, the HIIT group exhibited greater LV mass and diastolic internal diameter as well as higher early diastolic propagation velocity and E/A ratio than the MICT group. Moreover, only HIIT increased peak circumferential SR at apical segment and reduced the time to reach peak untwisting velocity despite decreased peak apical rotation and torsion during exercise. The LV mechanics at rest and during exercise were unchanged in the CTL group.
CONCLUSION: HIIT but not MICT induces eccentric myocardial hypertrophy. Moreover, HIIT effectively improves the LV mechanics during exercise by increasing contractile efficiency and diastolic function.

INCREASED THIGH VOLUME FOLLOWING SHORT-DURATION CYCLING SPRINT INTERVAL TRAINING

SEAMAN, K., JOHNSON, J., SÉNÉCHAL, M., KURUGANTI, U.

UNIVERSITY OF NEW BRUNSWICK

INTRODUCTION: Interval training has been widely examined for its ability to improve cardio-metabolic health. However, sprint interval training (SIT) requires maximal power output of the active muscles which may facilitate hypertrophic adaptations to the active muscles. To date, little research has examined the hypertrophic adaptations to SIT. The purpose of the study was to investigate the impact of eight weeks of 10-second or 30-second SIT on hypertrophic adaptations of the thigh. Due to the high contractile power exerted on the pedal during SIT, it was hypothesized that SIT would influence hypertrophy of the active muscles.
METHODS: Seventeen active participants (age 19-35) were recruited. A voluntary activation ratio of 90% of the knee extensors was required for inclusion in the study. Participants were randomized into either: 10 seconds on:2 minutes off group (SIT-10), 30 seconds on:4 minutes off group (SIT-30), or control group (CON). All training was performed on a Racermate Velotron, with resistance applied at 7.5% of the participant's body mass. Participants began with four intervals per session, with an additional interval added each subsequent two weeks. Training occurred three days a week for eight weeks. The control group was instructed to maintain their typical daily activity patterns. Lean body mass was assessed via the air displacement plethysmography. Thigh volume was calculated based on a three-point girth assessment, with skin fold thickness removed from the volume to obtain lean thigh volume. Force output was assessed via isometric maximal knee extensions/flexions, and co-activation ratio of agonist and antagonist muscles was calculated through surface electromyography.
RESULTS: A significant group by time interaction effect was observed for the thigh volume variable ($F(4)= 5.464$, $p<0.05$). Adjusted pairwise comparisons revealed a significant increase in thigh volume between baseline and Week-4 in the SIT-10 group (0.472 ±0.050m3 vs 0.506 ±0.051m3, $p<0.05$, Cohen's D=0.67)), and baseline and Week-8 (0. 472 ±0.050m3 vs 0.520 ±0.050m3, $p<0.05$, Cohen's D=0.96), representing a 7.6 ±3.7% and 10.3 ±4.4% increase in thigh volume, respectively. No other main or interaction effects were observed for force, lean mass, or co-activation ratio ($P> 0.05$).
CONCLUSION: SIT-10 appears to be a viable means of achieving local muscular hypertrophy following four and eight weeks of training. However, this effect was not observed in the SIT-30 group despite the greater volume of work completed. The greater thigh muscle volume did not result in a significant increase in muscular force output. Future research should assess the additive nature of this training method to traditional resistance training.

EFFECTS OF PLYOMETRIC TRAINING ON JUMPING, SPRINTING AND CHANGE OF DIRECTION ABILITIES IN CHILD FEMALE ATHLETES

DONTI, O.1, PAPIA, A.1, DONTI, A.1, APOSTOLIDIS, N.1, SANDS, W.A.2, BOGDANIS, G.C.1

1: NKUA ; 2: USSA

INTRODUCTION: Plyometric training is an effective method to enhance jumping performance, sprinting and change of direction ability in adults. However, evidence is limited in child-athletes, and especially in girls. The aim of this study was to examine the effect of 8 weeks of plyometric training, on jumping, sprinting and change of direction abilities, in child female athletes.
METHODS: Fifty female 'Gymnastics for All' gymnasts (age: 8.0 ± 0.7 years, training experience: 2.4 ± 0.6 years, height: 129 ± 7 cm, body mass: 28.1 ± 5.8 kg) were randomly assigned to a training (n=33) and a control group (n=17). The gymnasts of the training group performed plyometric training twice per week, in addition to their regular training. Each plyometric training lasted ~20-25 min and included 180 jumps per session during the first 4-weeks, and 210 jumps per session during the last 4-weeks of training. All gymnasts underwent the following tests at baseline, and after 8 weeks of training: one and two-leg countermovement jumps (CMJ), drop jump, squat jump, standing long jump, 10 and 20 m sprints, and two change of direction tests: 10 m (5 + 5 m with a 180° turn) and 20 m (10 + 10 m with a 180° turn). Also, their performance in a gymnastics floor exercise was evaluated. Statistical analysis was performed using 2-way ANOVA (time x group) and Tukey post-hoc test. For pairwise comparisons, effect sizes were determined by Cohen's d (trivial: 0–0.19, small: 0.20–0.49, medium: 0.50–0.79 and large: 0.80 and greater).
RESULTS: Standing height and body mass did not differ between groups at baseline (p>0.485), and there was a similar increase in standing height after 8 weeks between the training (by 0.6±0.3 cm, p=0.001, d=-0.21) and the control group (by 0.6±0.4 cm, p=0.001, d=-0.17), with no difference between groups. Body mass did not change after 8 weeks of training (p>0.05). Plyometric training induced a significant improvement (p <0.05) in the training group, in 10 and 20 m sprint speed tests by 10 and 9%, respectively (d=1.19-1.31), 20 m change of direction test by 5% (d=0.41), one and two-leg CMJ height by 26% (d=0.66) and 13% (d=0.67) and floor exercise performance by 12% (d=-0.79). In the control group, there were small increases in 10 m and 20 m sprint performance by 3%(d=0.52 and 0.29), while 20 m change of direction performance decreased by 4% (d=-0.68). In addition, a modest increase was observed in one and two-leg CMJ height by 16% (d=0.20) and 7% (d=0.40), and floor exercise performance by 8% (d=-0.24).
CONCLUSION: The results of this study suggest that completion of an 8-week plyometric training program in addition to gymnastics training, significantly increases performance in all sprint tests, selected change of direction ability tests, and enhances CMJ height more than gymnastics training alone. Furthermore, addition of plyometric training to regular gymnastics practice, further improves gymnastics performance in child female athletes.

STUDY ON PHYSIQUE AND MOTOR ABILITY OF ELITE JUNIOR BADMINTO PLAYERS IN JAPAN

WATANABE, E.1, MISHIMA, T.2, ABUTANI, H.3, SATO, T.4, SEKI, K.5

<1> SENSHU UNIVERSITY, <2> OSAKA UNIVERSITY OF HEALTH AND SPORT SCIENCES, <3> SMART SYSTEM STRENGTH, <4> JISSEN WOMENS UNIVERSITY, <5> WASEDA UNIVERSITY

INTRODUCTION: Badminton is one of the popular sports enjoyed widely. Many young athletes are doing hard training to participate in the Olympic Games because the Tokyo Olympics are held in 2020. In order to win in the game, it is necessary to prepare for motor ability, skill and mind. In this study, we aimed to clarify the physique and motor ability necessary for elite junior badminton players.
METHODS: Subjects were badminton players who belong to the badminton club. The period of this study started from April 2016 and it was up to February 2018. The total of 1360 players participated in this study (692 male players and 668 female players, 10 to 18 years old). We classified the participants into groups A and B. Group A is a junior national team, representative candidate, national tournament high prize winner. Group B will be other players. We performed body-based measurement (height, weight, %body fat) and motor ability test (20m dash, pro-agility test, standing long jump, side steps, vertical jump, rebound jump index).
RESULTS: A significant difference was almost observed in body-based characteristics and motor ability between male and female. A significant difference was also observed between the group A (both for males and females) and the group B in ages from 10 to 15 years old. In body-based characteristics, there was no difference in male for ages from 16 to 18 years old. In females, height at 16 years, body fat percentage at 17 years, body weight and body fat percentage differed at age 18. In motor ability, there was no difference in male. In female, RJ at 16 years, 17 years at vertical jump and RJ, 20m dash differed at age 18.
CONCLUSION: The differences in motor ability between males and females are considered to be derived from body-based characteristics. The performance difference is strongly involved in motor ability from 10 to 15 years old. After the age of 16, we assume that other elements are complicatedly related. The degree of growth and development is also relevant. However, group A has better results than group B in most measurements, so it is certain that high motor ability is required.
In this study, I got the target value of children playing badminton. These results can be used as a guideline for coaches to adapt their coaching to the level and growth and development of their players. A longitudinal study with players of different ages is necessary to complement this study, and measurements is still continuing now.
ACKNOWLEDGEMENT:
We appreciate all the players, instructors, and guardians who cooperated in this study. This study was supported by JSPS KAKENHI Grant Number 26350790 and Senshu University research grant.

MILITARY PHYSICAL TRAINING - STRENGTH TEST RESULTS FROM THE DANISH ARMED FORCES

SEVELSTED, F., SØRENSEN, K.G.

DANISH ARMED FORCES

INTRODUCTION: The physical stress in military operational tasks is well known to be severe strenuous for the individual combat soldier. The operational tasks often take place in hostile environments and the work effort performed requires high levels of both endurance and strength. To withstand the physical challenges during combat operations as well as daily military training, combat soldiers are being prepared with physical training as part of their daily military training. In the Danish Armed Forces a concept for military physical training has been developed over the last years. The concept consists of test and training protocols to ensure the specific training types and amount required, as well as recommendations and demands for the different types of units in the armed forces. This paper presents the

strength test results from an armored infantry unit in the Danish army who has partly followed the training recommendations in the concept.
METHODS: An armored infantry company was recruited to complete a strength test which consisted of five different exercises; pull-ups, lunges, dips, deadlifts and burpees. The exercises were part of their weekly training routines and technical standards therefore were well known. All exercises were evaluated based on 10 preprogrammed levels. For the pull-ups, dips and deadlifts the participants should perform 5 repetitions with as much load as possible. For the lunges it was 10 repetitions for each leg with as much load as possible, and the burpees were performed as AMRAP (as many repetitions as possible) in five minutes. Individuals were instructed to make their best and had two attempts to achieve the highest level as possible in each exercise.
RESULTS: Results are shown as average (n=99). Pull-ups; level 4,9 which equals 5 repetitions with 4,5kg additional load. Lunges; level 4,2 which equals 10 repetitions (pr leg) with 44kg additional load. Dips; level 6,4 which equals 5 repetitions with 12kg additional load. Deadlifts; level 5,6 which equals 5 repetitions with 106kg additional load. Burpees; level 4,1 which equals 66 repetitions in 5 minutes.
CONCLUSION: The results were roughly as expected. The recommended level for this type of unit (level 5) was not fully met in all exercises. Although the exercises were known from the training sessions, the test method was new and the unit had not trained specific for this type of test. Even though the average is close to the recommended level 5 for all exercises, a closer look at the results reveal, that the variation width of the results ranges from level 0-10 in the exercises; pull-ups, lunges, dips and deadlifts, an level 0-9 for burpees, which is far from optimal. This can either be due to a high incidence of injuries, which has been investigated in a follow-up study, or that the physical training is inadequate in specificity and/or amount. The latter two was not in accordance with the stated training concept. These findings led to corrected training advice and follow-up recommendations for the present unit.

RELATIONSHIP BETWEEN SPECIAL JUDO FITNESS TEST AND MAXIMUM ANAEROBIC POWER AND PHYSICAL PERFORMANCE AMONG MALE JUDO ATHLETES

SANOMURA, M.1, SAHO, Y.1, YAMAMOTO, A.1, WAKAMATSU, K.2, MIYAHARA, Y.3, MARUYAMA, M.3

1: FACULTY OF MEDICAL TECHNOLOGY, TEIKYO UNIVERSITY , 2: J. F. OBERLIN UNIVERSITY , 3: TEIKYO UNIVERSITY

INTRODUCTION: According to an analysis of video images, a judo match can be seen as a repetition of 20 ~ 30 seconds of vigorous activities with 5 ~ 10 seconds of rest periods in-between. To accommodate such pattern and judo specific movements, Special Judo Fitness Test (SJFT) has been devised as a specialized method to evaluate physical fitness among judo players (Sterkowicz, 1995), and previous study has shown a significant correlation to pedaling by upper limbs on a bicycle ergometer for men. The purpose of this study was to examine the relationship between SJFT and maximal anaerobic power (MAnP) and trunk muscle endurance among male judo athletes.
METHODS: 1. Subjects
Twenty-five male college judo athletes (mean ± SD; age: 19.1 ± 0.8 years; height: 168.8 ± 4.9 cm; body weight: 75.5 ± 12.2 kg (range: 60.7 ~ 106.1 kg); judo experience: 12.6 ± 2.5 years (range: 5.5 ~ 16.4 years)) participated in this study.
2. Measurements
SJFT: Two players (partner) are positioned at 6 m away from one another. Subject attempts at throwing the two players using the ippon-seoi-nage technique as many as possible in a set period of time. The procedure is divided in three periods (series A = 15 seconds, B = 30 seconds, and C = 30 seconds) with 10 seconds recovery intervals among them. Heart rate is recorded immediately after the test (HR 1) and 1 minute later (HR 2). Performance index was calculated using the following formula: Performance index = (HR 1 (bpm) + HR 2 (bpm)) / Total number of throwers (series A, B, and C)
MAnP test: MAnP test using a cycle ergometer (PowerMax VIII; Konami Sports & Life, Tokyo, Japan). Procedure is divided in three stages, and maximal efforts pedaling for 10 seconds, and 120 seconds resting time between each stage. MAnP output was recorded as watts and watts per kg.
Prone bridge test (PBT): PBT was to measure the trunk strength and endurance performance. Subject started from prone bridge position (elbow-toe position), and immediately put a weight plate of half weight of the body weight on the lower back and buttock. We instructed neutral trunk and pelvis position (no excessive trunk flexion or extension). We measured the time until the abdominal touches the mat (balance pad) placed on the floor.
3. Analysis
Relationships between the SJFT and MAnP test and PBT were analyzed, and correlation coefficients were calculated using Pearson's test. Significance levels were set at $p < 0.05$.
RESULTS: SJFT (performance index) was significantly and negatively correlated with MAnP (Watts per kg) ($r = -0.605$ and $p = 0.001$).
CONCLUSION: While a significant negative correlation was found between SJFT and MAnP by this study, previous study on MAnP test using a bicycle ergometer has shown lower values for heavier body weights (e.g., 95kg or more). This indicates that such correlations could well be influenced by the number of players in the heavyweight class, hence research according to each weight class should be considered for future studies.

CAN FUNCTIONAL PHYSICAL TRAINING PROGRAM IMPROVE CONSCRIPTS' FITNESS LEVEL BETTER THAN TRADITIONAL PHYSICAL TRAINING?

STAMM, M., STAMM, R., ANTSON, H.

ESTONIAN DEFENCE FORCES

INTRODUCTION: The purpose of the physical training of conscripts is not to achieve sporting performance, but to prepare staff for service loads and to operate in a tactical situation. In this case, it is not essential to go deep into the methodology of a particular sport, but to look at the distribution of methods based on the structure and nature of the exercises (Bompa, 1991). The aim of this study was to check the influence of the implementation of the functional physical training program (FPTP) to conscripts' fitness and functional capabilities.
METHODS: Two separate experiments were conducted: short-term (7 week) and mid-term (15 week). In both experiments the sample consisted of two company-size units, from which one (test-group) trained according to the FPTP and second (control-group) had traditional physical training (PT), which mostly consisted of running and bodyweight exercises. FPTP consisted of 25 physical training lessons with progressive degree of difficulty. Each training consisted of seven parts: warm up; development of flexibility; learning functional training movements; development of endurance; high intensity functional training; development of trunk muscle; relaxing and stretching exercises (Senin, 2017). The standard Army Physical Fitness Test (APFT) was used for the fitness level measurements. Measurements were conducted on the first, the 7th and the 15th week of the training cycle.

RESULTS: The results show that for the short-term training cycle advantages of the implementation of the developed program are limited. Comparing to the traditional PT, the usage of the FPTP provides at least the same improvement in push-up and sit-up tests. At the same time, the FPTP enables to achieve statistically significant higher improvement in the 3,2km running test. It is important that the advantages of the developed program over traditional PT were more apparent during the midterm implementation period. After the 15-week cycle, the application of the FPTP provided significantly higher improvement and better results in all physical test tasks. It is important to mention that FPTP effectiveness becomes more significant in a cycle where physical training volume is limited to one class (90 min) per week.
CONCLUSION: Taking into account the outcome of the experiments we can conclude that successful implementation of the FPTP is possible. Compared to the usual PT the application of the developed program is more effective in terms of soldiers' preparation for battle related physical tasks. That kind of preparations creates conditions for the acquisition of skills and knowledge during collective (tactical) training.

GROSS ECONOMY OF CHILDREN TO TREADMILL EXERCISE

BELCASTRO, A., MATTA, H.
YORK UNIVERSITY

INTRODUCTION: Oxygen cost and metabolic/gross economy (GE) of movement to exercise (increasing speed (TS)) vary with increases in body stature/growth. Whether stature/growth profiles and/or body composition and fitness factors have a similar impact on childrens GE when indexed to physical activity (PA) levels (quantified by accelerometry) is unclear. Is the relationship between GE for PA comparable to GE for TS? The purpose of this study was to determine the GE of childrens participation to varying levels of physical activity and assess their relationships to stature, body dimensions and body composition.
METHODS: Children (9.8±0.9 yrs) were assessed for VO2, HR, VCO2, and RER over treadmill speeds (66.6, 99.6 and 132.6m/min for 3 min each at 0% grade). Accelerometers (ActiGraph GT1X - hip) were used to quantify physical activity (PA) levels in counts/min (3sec epochs). Gross economy (GE) for treadmill speed (TS) was expressed as relative VO2/m/min from 66.6 and 132.6 m/min; and GE for physical activity (PA) was expressed relative VO2/cnt/min from 2000-6000 cnts/min. ANOVA and statistical comparisons were assessed at a p=0.05.
RESULTS: The GE-TS (VO2/m/min) for children (height 155.0±5.6cm; weight 64.6±11.3kg) increased from 0.170±0.017 to 0.213±0.018 over speeds of 66.6 and 132.6 metres/min ($p<0.05$). The relationships (r2) between GE-TS and height and leg length (LL) were -0.92 and -0.88, respectively ($p<0.05$). The PA levels varied from 2071±308 to 5465±1424 counts/min ($p<0.05$). The GE-PA (VO2/cnt/min) values ranged from 0.0056±0.001 and 0.0057±0.001, respectively ($p>0.05$). The relationships (r2) between GE-PA and height and leg length (LL) were -0.13 and -0.31, respectively ($p>0.05$). BMI, body fatness and aerobic power were related to GE-PA but not GE-TS. Minimal relationship was observed for GE-TS and GE-PA (r2=0.01).
CONCLUSION: The primary finding was that metabolic/gross economy for children participating over a range of treadmill speeds and physical activity levels are impacted differently by stature/growth. As predicted GE-TS was highly related to stature/growth; in contrast minimal impact was observed for GE-PA and stature/growth. The GE-PA was related to BMI and aerobic power over the range of PA assessed. Therefore, the GE differences observed for TS and PA needs to be considered when estimating childrens oxygen consumption from ACC-derived PA linear regression during laboratory (i.e., TM), active play and/or activities of daily living.

TRAINING USING A DYNAMIC ERGOMETER IN COMPETITIVE ROWERS

KAMEI, E., HOSHINO, R., TANAKA, T., ENDO, S., KOMINE, T., YASUKAWA, M.
CHUO UNIVERSITY

INTRODUCTION: Because the outcomes of rowing races are decided by fractions of a second, many different training methods have been developed to improve performance. Among them is the ergometer rowing, which is commonly used by coaches and competitive rowers to improve distance per stroke (DPS). However, the most appropriate rowing motion parameter is unknown. The purpose of this study was to determine the most relevant parameter of rowing techniques in competitive rowers.
METHODS: We included one female Japanese collegiate competitive rower. Dynamic Ergometers and video analysis system were used to check the rowing techniques of the subject. DPS (Y), drive length (X1), position of the peak force (X2), drive time (X3), the difference in time (X4) between when maximum angular velocities of the knee and trunk, slide length (X5), angle of the knee (X6), angle of the shin (X7), and shoulder motion (X8) were determined. Multiple linear regression was calculated to evaluate the relationship between these parameters.
RESULTS: The data had an uptrend in the first 30 strokes (Phase 1) and downtrend in the last 23 strokes (Phase 2). Multiple linear regression was calculated for each phase. The regression line obtained for Phase 1 was as follows: $Y = 2.7781X1 - 1194.3483X5 + 2310.4988$ (where Y = DPS, X1 = drive length, X5 = slide length). A significant relationship was observed between Y and Xi for i = 1, 5 ($R2 = 0.5570$, $F = 17.0053$, $P < 0.0001$). The regression line for Phase 2 was as follows: $Y = 2.9317X1 + 1289.3297X5 - 1679.1698$. We found a significant relationship between Y and Xi for i = 1, 5 ($R2 = 0.6100$, $F = 15.5537$, $P < 0.0001$).
CONCLUSION: These findings suggest that there was a relationship between "DPS" and "drive length, slide length," and may help to understand rowing techniques in competitive rowers.

RELATIONSHIP BETWEEN PHYSICAL ACTIVITY LEVEL, SLEEPING TIME, AND EXERCISE CAPACITY IN YOUNG CHILDREN

DEMURA, T.
JIN-AI UNIVERSITY

INTRODUCTION: In recent years, attention has been focused on decreasing the physical activity and physical strength of children; a number of studies have examined the relationship between these factors (Tanaka and Tanaka, 2009; Barnett et al., 2011). In addition, the relationship between lifestyle such as sleep and level of physical activity level has been investigated (Motegi and Ohyama, 2005). The purpose of the present study was to examine the relation between physical activity level, sleeping time, and exercise capacity in young children.
METHODS: The participants included 33 young children (18 boys and 15 girls) aged between four and six years. Physical activity was measured by means of a triaxial accelerometer (Active Style Pro HJA-350 IT, Omron Healthcare, Japan). It measured the number of steps

and moderate-to-vigorous physical activity (<4 METs (Sasaki et al., 2013), MVPA) in the morning on arriving at nursery school until lunchtime. The measurement period lasted for one month in June 2017. A questionnaire was administered to the children's parents to assess their sleeping habits. To determine exercise capacity, three types of 25m running time, standing long jump distance and the distance they could throw a tennis ball were measured.
With reference to gender, a partial correlation coefficient was employed to investigate the relationship between each variable with a consideration for each child's age. The significance level of this study was set at 5%.
RESULTS: In boys, a significant correlation was found between height and weight, MVPA and 25m running time and number of steps, sleeping time and 25m running time ($r = -0.63–0.83$; $p < 0.05$).
In girls, a significant correlation was found between height and weight, MVPA and number of steps, standing long jump and throwing a tennis ball throwing ($r = -0.70–0.71$; $p < 0.05$).
CONCLUSION: Boys had a tendency to run 25m run faster ($r = -0.63$) when the MVPA was long, and ran 25m ($r = 0.49$) slower when they slept for a long time. In addition to the notion that it is difficult to obtain objective data (Motegi and Ohyama, 2005), it is difficult to investigate sleep by means of a questionnaire survey. The latter should be examined carefully in future studies. With reference to girls, there was no relationship between focused MVPA and time slept and other variables. It is believed that girls are already affected by social and cultural influences from early childhood. Therefore, this study shows men and womens different behavior patterns and activities.

PREDICTING MAXIMAL HEART RATE IN YOUNG ADULTS IS INAPPROPRIATE: FURTHER EVIDENCE TO ABANDON THE PRACTICE

LAMB, K.

UNIVERSITY OF CHESTER

INTRODUCTION: While taught often during the PE curriculum that a person's maximal heart rate (HRmax) can be predicted simply from the 220-age ('Fox') equation, and often reinforced during undergraduate Sports Science programmes, the custom has no empirical foundations. Moreover, given its status as a secondary criterion for the attainment of maximal oxygen uptake, and its frequent use in setting exercise intensity training thresholds, the Sports Science community needs to be convinced to abandon it. Evidence exists of the inaccuracy of the Fox equation and numerous attempts have been made to establish more accurate age-based equations from large samples of heterogeneous adults. However, few studies have compared the accuracy of these alternatives among young adults. The aim of this study was to examine the validity of four contemporary HRmax prediction equations against HRmax derived from a maximal treadmill test.
METHODS: Following institutional ethical approval, 47 active male and female university students (aged 20.7 ± 1.6 y; mass 73.05 ± 11.85 kg; peak oxygen uptake 54.4 ± 7.8 ml/kg/min) volunteered to take part in a graded exercise test to volitional exhaustion. Heart rates (HR) were recorded throughout by telemetry. The highest HR recorded was taken as HRmax. Mean HRmax calculated via the equations of Gellish et al (2007; GE), Whaley et al (1992; WH), Nes et al (2013; NE) and Fox et al (1971; FO) were compared to the criterion values and the within-subject variability ('error') quantified by the 95% limits of agreement (95% LoA).
RESULTS: The mean criterion HRmax (195.2 ± 9.3 b/min) was over-estimated by the equations of FO (199.3 ± 1.3 b/min), WH (198.8 ± 1.5 b/min), and NE (197.8 ± 1.0 b/min), and under-estimated by that of GE (192.5 ± 1.1 b/min). The proportions predicted within ± 5 b/min and ± 10 b/min of the criterion HRmax ranged from 36-48% and 64-74%, respectively. For each comparison 95% (LoA) of predicted values varied by up to ± 17 or 18 b/min of the mean difference.
CONCLUSION: These findings highlight the inaccuracy both of the established and newer age-related HRmax equations among young, active adults, and reinforce there is no convincing case for sports scientists or physical educators to continue to advocate their use for prescribing health/fitness enhancing exercise intensities, or for verifying the occurrence of a maximal oxygen uptake. Moreover, if HRmax is to remain an important measure in this context, better predictive approaches need to be devised.

CHANGES OF BIOCHEMICAL MARKERS IN BLOOD PLASMA FOR MILITARY PERSONNEL AFTER HIGH PHYSICAL AND PSYCHO-EMOTIONAL LOAD

PLAVINA, L.

NATIONAL DEFENCE ACADEMY OF LATVIA

INTRODUCTION: Combat training course is a compulsory part of the training program of cadets in National Defense academy of Latvia. Cadets have ten days long Combat training course with high physical load, psycho-emotional stress, nutrition deprivation and limits for rest / sleep. High intensity of physical load in military surrounding is a risk factor for heath disorders, muscular and skeletal pathology and psychological overload. Muscular and skeletal disorders are wide spread in military personnel population. Early diagnostic and management of preventive measures program give results as decreasing impact of external and internal risk factors for development muscular and skeletal disorders. Aim of the study is assessment of biochemical markers that indicate initial stages of muscular skeletal pathology, in the group of cadets, Combat training course participants. Biochemical markers analysis was provided for participants in some days before and directly after the Combat training course.
METHODS: We provided biochemical markers analysis of blood plasma of 59 participants of both genders 12 female and 47 male in aged 23 to 30 years. We provided assessment of following bio-markers of muscular and skeletal pathology: Lactate dehydrogenase (LDH); Creatine phosphokinase (CPK); Alanine amino transferase (ALT) and Aspartate amino transferase (AST). The health status control was organized before and after combat training course, the blood examples were taken before and after ten days long combat training course.

RESULTS: Analysis of the biochemical markers data revealed that the level of CPK , that support creatine phosphorylation to creatinine and ATF (adenosine triphosphate),have jumped four times from the standard interval for more than half participants (50.9%) of CTC participants from the standard interval for one third of participants. The level of CPK increased three times, but for one fifth of participants the level of CPK and only for some individual the CPK analysis data stay in the standard deviation interval. But for some individuals the level of CPK analysis increases sharply, more than five times.
The level of LDH, that characterized glycolysis and oxidative processes of lactates, in the blood plasma increased two times for half of participants (57.9 %) of CTC, but for the rest part of the participants (42.1 %) it stays in the standard level. The level of AST stays in the standard deviation interval, but we have fixed elevation of absolute data of analysis for participants of CTC. The level of ALT biochemical markers increased two times in the blood plasma for half of participants of CTC (56,1 %), for some of participants the level of ALT increased three (7%) and five times (1,7 %).
CONCLUSION: Changes of the level of CPK, LDH reflected functional disorders for muscular and skeletal pathology for participants of Combat training course. Biochemical markers as ALT and AST were less sensitive to influence of high the physical load and emotional stress.

ASSESSMENT RELIABILITY OF MAXIMAL SPRINT CAPACITY ON A NON-MOTORISED TREADMILL IN YOUNG HEALTHY ADULTS

DOMA, K., CONNOR, J., LEICHT, A.

JAMES COOK UNIVERSITY

INTRODUCTION: Maximal sprint ability (MSA) has been documented as a key performance indicator in a range of sports and athletes. Determination of MSA typically involves repeated performances or trials using cycling or field running with appropriate rest between trials. Non-motorised treadmills have been increasingly utilised in MSA assessment but little information exists about these protocols. Therefore, the aim of the current study was to examine the reliability of performance during a typical MSA protocol using a non-motorised treadmill.
METHODS: One-hundred and twenty (77 males, 43 females) young, healthy, active adults volunteered for this study. Following a standardised 10-minute warm-up, participants completed 3 x 4-second sprints on a non-motorised treadmill with each separated by 3 minutes. Peak and mean velocity/power, total work and 1-second acceleration were assessed during each sprint. Comparisons between trials were examined via 1-way repeated-measures ANOVA and pairwise comparisons with Bonferroni correction. Reliability was assessed via intraclass correlations coefficients (ICC), typical error expressed as a coefficient of variation (CV) and bias with limits of agreement (LOA).
RESULTS: All variables assessed during Trials 2 and/or 3 were significantly ($p<0.05$) greater than Trial 1 values while half were significantly ($p<0.05$) greater during Trial 3 compared to Trial 2. Reliability (ICC) for Trials 2 and 3 was excellent ($p<0.001$) for peak and mean velocity (>0.98), peak (>0.95) and mean (>0.98) power, total work (>0.98), and acceleration (>0.94). The CV were small for most variables including peak (<1.7%) and mean velocity (<2.4%), mean power (<4.1%), and total work (<4.1%). Slightly greater CV were identified for peak power (<9.1%) and acceleration (<8.0%). Biases were small (<1.6%) for all variables with LOA identified.
CONCLUSION: The present study has demonstrated that assessment of MSA using a non-motorised, treadmill should involve at least 2-3 trials with these later assessments highly reliable in young, healthy adults. The current non-motorised, treadmill protocol provides sport scientists, researchers, coaches and athletes with a reliable assessment of MSA.

THE DIFFERENCE OF INFLUENCING FACTORS FOR SHOOTING BY PLAYERS' STANDING HEIGHT IN BASKETBALL GAMES

YAITA, A., AOYAGI, O., KURAISHI, O., NODERA, K.

KYUSHUKYORITSU UNIVERSITY

INTRODUCTION: Whether shots are successful or not is affected by various factors depending on shooting situations in basketball games. In general, basketball is characteristized by the fact that the standing height of players impacts various plays and outcomes because the basket is located on a horizontal plane over their heads. Similarly, standing height also affects whether shots are successful or not and shooting areas. Thus, this study aimed to investigate the characteristics of shooting situations according to standing height by examining the factors influencing whether shots are successful or not by the standing height of shooters.
METHODS: The subject matter was 10 men's games held in the quarter finals or later in the 66th All-Japan Collegiate Basketball Championship in 2014. The following items regarding "a> game situation;" "b> shot attempt;" "c> strategy leading to the shot;" and "d> defensive situation of the opponent" and "whether shots were successful or not" were checked or counted in all shots: 1> score difference;" "2> reminder seconds of shot clock;" "3> area where the shot was attempt;" "4> shooting direction;" "5> shooting methods;" "6> standing height of the shooter;" "7> play leading up to the shot;" "8> whether a screen play was conducted or not;" "9> action of the shooter before the shot;" "10> movement of the basketball before a shot;" "11> distance to the defensive player;" "12> hands-up of the defensive player;" "13> block shot;" "14> whether a foul was committed by the opponent or not;" and "15> difference in standing heights of the shooter and the defensive player" 15 items in total.
RESULTS: As the mean standing height of shooters in games concerned was 186.4, they were categorized into two groups, i.e. HG of 187cm or higher and LG of less than 187cm. In the HG, stepwise procedure found the model consisting of "3> the area where the shot was attempted ;" "4> shooting direction ;" "5> shooting method ;" "7> the play leading to the shot ;" "12> hands-up of the defensive player ;" "14> whether a foul was committed by the opponent ;" and "15> difference of standing height between the shooter and the defensive player " to be the best fit . In the LG, the stepwise procedure detected the best fit regression model consisting of "3> area where the shot was attempted ;" "4> shooting direction ;" and "11> distance to the defensive player " with chi-square [df = 9] = 76.72 .
CONCLUSION: "3> area where the shot was attempted" and "4> shooting direction" were commonly chosen as the influencing factors for a shot due to the difference of standing height between both groups. As shot attempts close to the basket and that the defenders are close to the offense are large in number in the HG, three-dimensional items such as shooting methods, strategy leading to the shot and height were shown to be decisive factors for successful shots. On the other hand, two-dimensional items were decisive factors for successful shots in the LG because the shooting area was also wide and the distance from the defender was critical.

WAIST-TO-HEIGHT RATIO AS A BETTER ANTHROPOMETRIC INDICATOR IN THE EVALUATION OF CARDIOMETABOLIC FACTORS IN STUDENTS OF THE SOUTH OF BRAZIL

BRITO, L.M.S., LEITE, N., MOTA, J., CAT, M.N.L., BOGUSZEWSKI, M.C.S.

UNIVERSIDADE FEDERAL DO PARANA

INTRODUCTION: Anthropometric indicators are used to identify children and adolescents with cardiometabolic risk, with the body mass index and the waist-to-height ratio being highlighted. BMI identifies general obesity, whereas the WHtR assesses central obesity and, because it is corrected according to stature, it becomes an anthropometric index which allows comparisons to be drawn between several different age groups with less dependency on age and sex. Therefore, the objective of this study was to verify which anthropometric indicator correlates best with blood pressure and cardiorespiratory fitness in both sexes.
METHODS: An observational study was carried out on 324 students, with 148 boys <45.6%> in three full-time public education schools in the South of Brazil. Anthropometric data , waist circumference , systolic blood pressure and diastolic blood pressure were measured. BMI and WHtR were calculated. The Léger test was used to estimate the maximum oxygen consumption and the CRF level was calculated . Statisc 10.0 software was used for statistical analysis of data, basic descriptive statistics, Spearman correlation coefficient and Odds Ratio, considering a difference of $p<0.05$.
RESULTS: Elevated WHtR was present in 25% of the girls and 22.6% of the boys. 21.9% of girls and 22.7% of boys were overweight . Hypertensive measures of SBP or DBP were found in 38.3% of boys and 48.8% in girls. An unsatisfactory CRF was found in 53.22% of the boys and 77.9% of the girls. An inverse and significant correlation between HM and CRF , a direct and very weak correlation between HM and BMI and a weak correlation with WHtR were all found. OW boys are more likely to have unsatisfactory CRF and OW girls than eutrophic adolescents. High WHtR is more likely to detect HM in girls and boys than high BMI in girls and boys . Adequate levels of CRF act as a protective factor for the presence of high WHtR in boys .
CONCLUSION: The distribution of body adiposity is an important factor in the development of cardiovascular diseases . In this study, the anthropometric indicators BMI and WHtR were increased and correlated with HM and unsatisfactory levels of CRF, which are considered cardiometabolic risk factors in this population . Our results reinforce the usefulness of anthropometric measurements as a tool for the detection of health risks in adolescents, and the WHtR showed to be a better anthropometric indicator for recognizing cardiometabolic factors in both sexes.

COMPARATIVE EFFECTS OF YI JIN JING VERSUS TAI CHI EXERCISE TRAINING ON PROSTATE FUNCTIONS IN OLDER ADULTS

XIANGYUN, L.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: Benign prostatic hyperplasia and its associated lower urinary tract symptoms occur very commonly in older men. Current surgical and pharmacological therapies are expensive, may not effectively improve prostate function and health but cause adverse effects. There is an urgent need to find new and effective non-pharmacological preventions and treatments. Yi Jin Jing and Tai Chi, two common mind-body Chinese tradition exercises, are not or very little studied for being potentially utilized to treatment of benign prostatic hyperplasia-related problems. The purpose of the study is to assess the effectiveness of a randomized parallel group controlled clinical trial of Yi Jin Jing exercise, compared with Tai Chi, on the monographic and functional changes of prostate in older men.
METHODS: This study is a single-center, six-month, randomized controlled trial of Yi Jin Jing versus Tai Chi to be conducted at an urban tertiary of Shanghai, China. One hundred and fifty men at age of 60-70 years old will be recruited from the community. Participants will be randomly assigned to three parallel groups: 50 as a control group and 50 each to two intervention groups. Individuals in two intervention groups will be trained with Yi Jin Jing or Tai Chi exercise continuously for six-months, while the control group has no any intervention. The primary outcomes will be changes of signs and symptoms in BPH and lower urinary tractfrom baseline to post-intervention. The main secondary outcomes will be exercise-induced effects on the circulating levels of estrogen and androgen. All the outcome measures will be assessed at baseline, after the six-month intervention.
RESULTS: There was a significant effect of yi jin jing and tai chi on testosterone but
no significant effect on insulin or glucose. No serious adverse events were observed during the study period.
CONCLUSION: This study is a single-center, six-month, randomized controlled trial of Yi Jin Jing versus Tai Chi to be conducted at an urban tertiary of Shanghai, China. One hundred and fifty men at age of 60-70 years old will be recruited from the community. Participants will be randomly assigned to three parallel groups: 50 as a control group and 50 each to two intervention groups. Individuals in two intervention groups will be trained with Yi Jin Jing or Tai Chi exercise continuously for six-months, while the control group has no any intervention. The primary outcomes will be changes of signs and symptoms in BPH and lower urinary tractfrom baseline to post-intervention. The main secondary outcomes will be exercise-induced effects on the circulating levels of estrogen and androgen. All the outcome measures will be assessed at baseline, after the six-month intervention.

EFFECTS OF A MULTI-COMPONENT EXERCISE PROGRAM ON HEALTH, PHYSICAL FITNESS AND PHYSICAL ACTIVITY OF INSTITUTIONALIZED OLDER ADULTS

UGARTEMENDIA, M., ZINKUNEGI, N., CALVO, J.J., MENDILUCE, N., VIRGALA, J., ZARRAZQUIN, I., IRAZUSTA, A., KORTAJARENA, M.

UNIVERSITY OF THE BASQUE COUNTRY-UPV/EHU

INTRODUCTION: Sarcopenia is the principal cause of fragility and the physical activity based on multi-component exercise program, is the main intervention to stand up to it and not to exacerbate the functional capacity. The aim of this study was to analyze the effects of a multi-component exercise program on health, fitness and physical activity on institutionalized elder people.
METHODS: Participants were 38 institutionalized elder people (age 80.2+7.65) from Zorroaga long-term care facility center in San Sebastian (Spain) who were randomized in two groups: Control and Experimental (a multi-component exercise session, three days per week during 3 months). Inclusion criteria were ≥ 65 years, Barthel index > 60, Mini mental State Examination > 14 and without unstable medical conditions that prevented physical activity. Before and after the program, physical activity was recorded by Yale Physical Activity Survey, intramuscular fat infiltration on quadriceps measured by nuclear magnetic resonance (NMR), fitness was analysed with SFT battery and walking speed, and anthropometric parameters were measured.

RESULTS: After the intervention, the experimental group reduced significantly the waist circumference (p=0.001) and the intramuscular fat (p<0.05). After the intervention, the experimental group improved significantly in fast walking speed at 6 meters (p<0.05), upper (p<0.05) and lower (p<0.05) extremities strength. While control group did not show any change in anthropometric measures neither in fitness parameters (p>0.05). At baseline, none of participants practiced vigorous physical activities but after the intervention, 13.16% of participants achieved vigorous physical activity (p< 0.05). Control group reduced the level of activity (p=0.002).
CONCLUSION: Other studies present an improvement in strength and walking speed, in addition, they also observed improves in aerobic capacity and flexibility. There are some published researches where they showed higher levels of physical activity after the intervention. Few published studies have assessed the muscular composition of elder people by NMR or computerised axial tomography, but they obtained similar results us in our study.
Further studies are needed to assess the specific exercise programmes and strategies to increase physical activity in institutionalized older people.

DISTINCT EFFECTS OF REPEATED-SPRINT TRAINING IN NORMOBARIC HYPOXIA AND BETA-ALANINE SUPPLEMENTATION

WANG, R., FUKUDA, D.H., HOFFMAN, J.R., LA MONICA, M.B., STARLING, T.M., STOUT, J.R., KANG, J., HU, Y.
SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: Muscle buffering capacity is a key mechanism related to high-intensity exercise performance. Many training programs and dietary supplementation strategies have focused on elevating muscle buffering capacity and improving anaerobic performance. Recently, several studies have demonstrated the effectiveness of repeated-sprint training in hypoxia, which is based on the repetition of all-out efforts of short duration activity interspersed with brief incomplete recoveries. Beta-alanine (BA) is commonly employed as an ergogenic aid and has been identified as the rate-limiting precursor to carnosine synthesis which acts as an intracellular buffer. Therefore, the combination of repeated-sprint training in hypoxia and BA may provide independent but additive ergogenic effects on muscle buffering capacity through a variety of potential mechanisms, but it has yet to be evaluated with regard to exercise performance. Considering the lack of research examining the interaction between repeated-sprint training in hypoxia and BA, the purpose of this study was to examine the effects of repeated-sprint training in hypoxia and BA on aerobic, anaerobic, and repeated-sprint performance in recreationally-trained men.
METHODS: Participants were randomly assigned to one of the following groups: normoxia/beta-alanine (NB, n = 11), normoxia/placebo (NP, n = 8), normobaric hypoxia/beta-alanine (HB, n = 10) and normobaric hypoxia/placebo (HP, n = 9). All participants completed 8 training sessions over 4 weeks on a cycle ergometer either in normobaric hypoxia (Oxygen fraction: FiO2 = 14.2%) or normoxia (FiO2 = 20.9%). Participants were instructed to consume a daily dosage of 6.4g of BA or placebo. Changes in performance in a graded exercise test, repeated-sprint test (RST) and 3-min all-out test (3MT) were examined before and after training and supplementation.
RESULTS: No between-group differences were observed for training volume or supplementation compliance. Anthropometric and hematological measures remained unchanged before and after intervention in all groups. A main effect of training condition was shown for oxygen consumption and power output at respiratory compensation point, average power output during the last sprint of the RST, heart rate recovery following the RST, and total work during the 3MT. These measures in the normobaric hypoxia groups were significantly (p<0.05) higher (lower for heart rate recovery following the RST) than the normoxia groups. A main effect of supplement was detected in anaerobic working capacity, with post-intervention values in the BA groups being significantly (p<0.05) higher than the placebo groups.
CONCLUSION: Repeated-sprint training in hypoxia improved aerobic performance, exercise tolerance, cardiovascular recovery and overall working capacity, while BA maintained the anaerobic working capacity. However, BA did not provide additional benefits with respect to attenuating fatigue or enhancing repeated sprint performance.

TEN-SECOND MAXIMAL ANAEROBIC POWER AS A PREDICTOR OF 500M AND 1000M PERFORMANCE IN JUNIOR SPRINT SPEED SKATERS

KUMAGAWA, D., IMAWAKA, T., TSUNODA, N.
KOKUSHIKAN UNIVERSITY

INTRODUCTION: Muscle force and maximal anaerobic power (MAnP) are improved by speed skating training (Nemoto et al. 1990, de Koning et al. 1991). Further, these functional characteristics of muscle are closely related to short-distance skating performance. However, the effects of anaerobic power on skating performance in child and adolescent speed skaters has yet to be elucidated. Therefore, this study evaluated 10-s MAnP as a predictor of 500-m speed skating time (SS500) and 1000-m speed skating time (SS1000) in junior sprint speed skaters.
METHODS: Participants were Japanese sprint speed skaters aged 9 to 20 years old. Subjects were divided into 12 groups according to age in 1-year intervals. MAnP generation capacity was measured using a bicycle ergometer. Participants pedaled for 10 s at the effort determined by their three-step maximum load, and rested for 2 min between pedaling trials. MAnP was calculated from a linear equation relating load and pedaling velocity, averaged over three trials. Participants' recently attained personal best SS500 and SS1000 times were investigated, and correlation analysis was used to obtain a regression equation for the relationship between MAnP and skating time. The SS500 and SS1000 times estimated from this formula were then compared with actual skating times.
RESULTS: A strong positive correlation coefficient was observed between MAnP and SS500 (p<0.01) and between MAnP and SS1000 (p<0.01) using the estimation equation. No significant difference between predicted times and actual times was found for either SS500 or SS1000, in all age groups.
CONCLUSION: The present estimation equation has high accuracy and significance, and low estimation error due to age. Thus, the equation can be considered effective for estimating the necessary muscle power to skate at a target time in junior speed skaters.

COMPARISON OF ALPINE SKIERS' LACTATE KINETICS DURING RECOVERY PHASE FOR WINGATE TEST AND SQUAT REBOUND JUMP TEST

HOSHINO, H.
HOKUSEI GAKUEN UNIVERSITY

INTRODUCTION: The goal of any training regimen is to best prepare an athlete for their particular sport through discipline specific exercise. Choosing what exercises are effective is vital for obtaining peak condition; outside of the sport's competitive season, physiological

tests are used to obtain such information in lieu of competitive results. Many assays yield general fitness data that would be useful over a wide range of physical endeavors (e.g., Vo2 max, heart rate, and lactate kinetics). However, some tests are easy to do, while others require elaborate preparation and equipment. An idyllic test would be convenient, cheap, and speedy and provide a wealth of useful data. The purpose of this study is to compare the lactic acid elimination kinetics in the recovery period in two widely used exercises, the squat rebound jump and the Wingate test, in alpine skiers. However, it is hoped this test will be beneficial to non-alpine sports.
METHODS: Subjects were six male alpine skiers. Subjects ranged from international elite level, to competitive domestic level able to compete at FIS events. Thus, all can be considered as bona fide athletes. Currently the best single test for determining physical characteristics suitable for alpine skiing is the 90 second squat rebound jump exercise developed by Bosco (BRJ); it is a good indicator of the competitive level of an alpine racer, though the Wingate test is also widely used. Both Wingate and BRJ tests were performed over 90 seconds following which subjects rested in the sitting position and lactate levels were assayed every minute for 30 minutes by fingertip puncture using a lactate Pro 2 (Arkray Co., Ltd.). For the Wingate test resistance was set at 7.5% load per body weight. Both tests were performed prior to and after the alpine competitive season.
RESULTS: The maximum lactic acid values following each of the two test types were assayed pre and post competitive season. In the BRJ test, there was a significant increase, while there was no change observed for the Wingate 90 test. Furthermore, when comparing lactate kinetics after exercise, no change in time constant was observed in both tests. The most obvious result is that there was no apparent change in lactate levels pre and post season assayed by both the Wingate and BRJ. This is only based on a sample size of six subjects, but the BRJ looks more promising for finding possible seasonal changes. Though not significant in this study, it would be expected that the BRJ would be more affected by the musculature developed over an alpine competitive season as the BRJ examines muscle groups specifically used by alpine skiers, while the Wingate test is more an indicator of general fitness. Put another way, stretch shortening is required for alpine skiing which the BRJ tests.
CONCLUSION: Peak lactate levels relate to lactate kinetics, but are much more easily obtained. However, in this study of only six subjects, peak lactate levels did not yield any significant findings.
