METHODS: Twenty-five C57BL/6 male mice performed a 4-week training protocol, 5 days/week, after 2 weeks of adaptation. Mice were randomly assigned to either a non-exercised control group (CTL), endurance training on a treadmill (END) or resistance training on a vertical ladder at -5 degrees from vertical (RES).
The training programme was humanized and with increasing intensity during and along the weeks. In the case of END, the velocity in the treadmill varied between 15-40 cm/s and 50-60 minutes of duration. The RES group trained four days a week lifting weights attached to the tail ranging from 25-200% of their body mass. In the middle of the week a recovery training day was performed without external overload.
Mice followed the same standardized diet ad libitum.
To study gut microbiota, gDNA was extracted from frozen caecum feces using EZNA DNA Stool Kit. gDNA samples were PCR amplified following the protocol of Ion 16TM Metagenomics kit. PCR amplification products were sequenced using ION PGMTM Hi-QTM Sequencing Metagenomics kit on a ION 318TM Chip. The consensus table for each metagenomics was downloaded from ION Reporter 5.6 software and used for comparing individuals. For statistical purposes ANOVA with Dunnett's post-hoc test was used.

RESULTS: Both exercise models differentially changed the bacterial profiles of mice gut microbiota, without differences in dietary intake. Alpha diversity index revealed a higher diversity on microbial communities on END compared to CTL and RES. Endurance training significantly increased bacterial phylum Tenericutes, as previously described (2) and families Anaeroplasmataceae, Oxalobacteraceae, Desulfovibrionaceae and Erysipelotrichaceae, while decreased Lactobacillaceae family. On the other hand, resistance training significantly increased Peptococcaceae, Veillonellaceae and Erysipelotrichaceae families. Other significant alterations were observed at the genus and species levels of taxonomy, some of them related to intestinal inflammation and gut immune cell homeostasis. Interestingly, significant correlations between relative proportion of specific taxa and performance improvements were observed.
CONCLUSION: Resistance and endurance training modify gut microbiota but diverge on defining specific profiles.

HIGHER CIRCULATING ANDROGENS AND PHYSICAL ACTIVITY LEVELS ARE ASSOCIATED WITH LESS CENTRAL ADIPOSITY AND LOWER RISK OF CVD EVENTS IN OLDER MEN.

CHASLAND, L.C., KNUIMAN, M.W., DIVITINI, M.L., MURRAY, K., HANDELSMAN, D.J., RIDGERS, N., NAYLOR, L.H., YEAP, B.B., GREEN, D.J.

SCHOOL OF HUMAN SCIENCES , UNIVERSITY OF WESTERN AUSTRALIA, PERTH.

INTRODUCTION: As men age, testosterone (T) levels decline and the incidence of cardiovascular disease (CV) disease rises. Low T is associated with increases in fat mass and decreases in muscle strength and bone mineral density (1), which all respond positively to physical activity (PA) (2). We assessed whether higher circulating sex hormones and higher PA levels were additively associated with lower indices of central adiposity and metabolic syndrome, and whether these factors predict CVD events and mortality.
METHODS: A total of 3,351 men were included in the analysis. Mean age was 77 years at baseline, with 865 CVD events and 499 CVD deaths occurring during 10-year follow-up. Baseline T, dihydrotestosterone (DHT), estradiol (E2), sex hormone-binding globulin (SHBG) and luteinizing hormone (LH) were assayed and free T calculated (cFT). Levels of PA were ascertained via questionnaire. Men were stratified using median splits into high hormone+high PA (H/H), high hormone+low PA (H/L); low hormone+high PA (L/H) and low hormone+low PA (L/L) groups.
RESULTS: Men with higher T, cFT, DHT or SHBG and higher PA had the lowest BMI, waist circumference and risk of metabolic syndrome. Men with higher T or cFT had the lowest risk of incident CVD events, irrespective of PA level (e.g. hazard ratios for T/PA H/H 0.811 p=0.032; H/L 0.730 p=0.002; L/H 0.896 p=0.240; L/L 1.00). Men with higher T, cFT or DHT, and higher PA, had the lowest risk of dying from CVD (e.g. hazard ratios for T/PA H/H 0.757 p=0.031; H/L 0.854 p=0.222; L/H 0.800 p=0.075; L/L 1.00).
CONCLUSION: In older men, higher PA levels and higher circulating androgens are associated with less central adiposity and lower CVD risk. A randomised trial is needed to assess the effect of combining exercise training and T therapy on CVD risk in men.

ANTI-FIBROTIC EFFECTS OF EXERCISE TRAINING COMBINED WITH 17B-ESTRADIOL ON OVARIECTOMIZED RAT HEARTS.

LIN, Y.Y., YANG, A.L., LEE, S.D.

CHINA MEDICAL UNIVERSITY

INTRODUCTION: Estrogen deficiency at menopause could cause left ventricular hypertrophy and systolic dysfunction as well as potentially develop heart failure. 17β-estradiol (E2) or exercise training is well known to provide protection against cardiovascular disease. The purpose of this study was to investigate whether combined 17β-estradiol (E2) and exercise training is better than 17β-estradiol (E2) treatment alone on cardiac anti-fibtotic effects in ovariectomized rats.
METHODS: Histopathological analysis, TUNEL assay, and Western blotting were performed on the excised hearts from four groups of female Sprague–Dawley rats, which were divided into a sham-operated group (Sham), a bilaterally ovariectomized group (OVX), an OVX treated with 17β-estradiol (OVX-E2; 10mg/kg/day, s.c.), and an OVX with 17β-estradiol and treadmill exercise training (OVX-E2-EX; 60 min/day, 5 days/week) for 10 weeks.
RESULTS: The OVX group exhibited abnormal myocardial architecture and interstitial fibrosis relative to Sham group, whereas those parameters were improve in either the OVX-E2 or OVX-E2-EX group when compared with OVX group. After ovariectomy caused the protein levels of ERα and ERβ to become more decreased in the OVX group compared with Sham group, whereas those were significantly increased in either the OVX-E2 or OVX-E2-EX group when compared with OVX group. The protein levels of AT1R, TGF-β, p-JNK, CTGF and MMP9 were increased in the OVX group compared with Sham group, whereas those were significantly decreased in either the OVX-E2 or OVX-E2-EX group compared with OVX group. Furthermore, when compared with the OVX-E2 group, the protein level of ER-β was further enhanced in OVX-E2-EX group as well as the protein levels of AT1R, TGF-β, CTGF and MMP9 were further decreased in the OVX-EX-E2 group.
CONCLUSION: Our results suggest that combined 17β-estradiol (E2) treatment and exercise training exhibited sub-additive protective effect on ovariectomy-induced cardiac fibrosis through suppressing TGF-β/CTGF–driven fibrotic pathways in ovariectomized rats, which might provide a more effective therapeutic effect than 17β-estradiol (E2) treatment alone in menopausal or bilaterally oophorectomized women.

BRAIN MONOAMINE AND BLOOD HORMONE MEASUREMENTS IN GROUP HOUSED RATS

YANAGITA, S., KUBOTA, N.
TOKYO UNIVERSITY OF SCIENCE

INTRODUCTION: Measuring monoamine and blood hormone such as glucocorticoid and ACTH is essential for studying psychological disorders. Numerous studies using laboratory rodents have shown that physical exercise could change the function of monoamine transmissions and/or blood hormone secretions, and then it have beneficial effects to improve the psychological disorders. However, current methods are either using laboratory rodents that individually housed in the cage with attached running wheel or group housed rodents performing treadmill running in another environments. Because laboratory rodents are social animals, these unnatural experimental conditions might influence the outcomes of physical exercise for psychological disorders and its underlying physiological mechanisms such as monoamine transmissions and hormone secretions. In order to improve this issue, it is necessary to conduct new experimental condition that enable rats to live socially and to perform exercise voluntary. In this study, we performed a high resolution, high fidelity assessment of social homecage behavior using radio-frequency identification (RFID) tags to constantly track the position and movements of rats in a social and group housing cage (three rats per cage) with attached running wheel. This study explores the connections between social group- housing, and neuroendocrine functions, and how these traits are influenced by spontaneous physical activity.
METHODS: Wistar rats were implanted with microchips subcutaneously providing each with a unique identification number and group-housed in plastic cages with running wheel. Each cage was equipped to monitor an individual animal's access to running wheel using RFID system. Daily wheel revolutions in each cage were recorded digitally from counters attached to the running wheel. Four weeks later, we obtained a lot of sequential data of individual access to running wheel in group housing by RFID system, and estimated individual running distance to be calculated by multiplying wheel circumference by the number of revolutions based sequential access data.
RESULTS: The result from our behavioral monitoring system using RFID technology numerically showed individual differences in wheel running activity in group housing condition, suggesting that application of RFID technology to laboratory animal study could reveal novel behavioral aspects in group housing condition. The results from measurements of brain monoamines and blood hormone showed considerable differences between group housed- and individual housed- rats.
CONCLUSION: The results of this study indicate that actually social and group housing can influence neuroendocrine functions enhanced by voluntary wheel running, and suggest that it is necessary to use group housing conditions in order to examine the effects of physical exercise for psychological disorders.

MO-BN07 Testing and training muscle strength

RELATIONSHIP OF REACTIVE STRENGTH INDEX MODIFIED WITH ANTHROPOMETRIC MEASURES AND BODY COMPOSITION IN JUNIOR ATHLETES

PETRIDIS, L., KALABISKA, I., UTCZÁS, K., TRÓZNAI, ZS, PÁLINKÁS, G., SZABÓ, T.
UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: Reactive strength index modified (RSImod) is used as a measure of explosiveness and is calculated by dividing jump height with the time to takeoff during a countermovement jump. Body composition and body dimensions may have a direct or indirect effect on RSImod. An increase in muscle mass, and thus in strength, can help to increase performance in explosive movements, whereas body height may negatively affect the ability of an athlete to perform a rapid countermovement and therefore decrease time to takeoff. The purpose of this study is to examine the relationship of RSImod with anthropometric measures and body composition in elite junior athletes.
METHODS: 86 male athletes (16.5±1.0 years old) were measured participated in soccer (n=50), handball (n=18) and basketball (n=18). Body height (BH), body weight (BW), sitting height, thigh length, calf length were collected according to the Martin method. Body composition was measured using Dual Energy X-ray Absorptiometry (Lunar Prodigy). Countermovement jump was measured on a force platform (HUR labs, model FP4). The athletes performed three maximal vertical jumps with one minute passive rest between the jumps; the best jump was recorded for statistical analysis. Time to takeoff was calculated from the start of the countermovement to the instant of takeoff. Three groups were formed based on the mean±0.5sd in RSImod: low RSImod group (mean: 0.34±0.05 m/s; n=27), mid RSImod group (mean: 0.45±0.03 m/s; n=32) high RSImod group (mean: 0.57±0.06 m/s; n=26). Descriptive statistics and ANOVA for inter-group comparisons were performed in Statistica 13.2 software.
RESULTS: Low RSImod group had a slightly higher BW and BH, however there were no differences between the three groups in none of the examined anthropometric measures. Significant difference was found in legs and total body fat mass (FMtotal) in both absolute and relative to BW values. Low RSImod group had higher values compared to the mid and high RSImod groups (FMtotal: 14.9±8.0 vs. 10.9±2.7 and 10.5±2.0 kg respectively or 22.1±6.4 vs. 18.3±3.4 and 17.2±2.7 percent of total BW). There were no differences between the mid- and high RSImod groups. Lean body mass (LBM) differed significantly only as a percentage of total BW; low RSImod group had lower percentage compared to the mid and high RSImod groups (LBM: 76.6±6.1 vs. 80.3±2.7 and 80.9±1.9 percent respectively).
CONCLUSION: Our data suggest that RSImod is not influenced by body dimensions, thus taller of heavier athletes can also achieve high values in RSImod or short times in time to takeoff. Body composition has a significant effect in RSImod, absolute and relative fat mass negatively affects the ability to perform an explosive vertical jump. Lean body mass results indicate that strength and conditioning training should be aiming to obtain an optimal muscle mass, emphasizing, besides the hypertrophy aspects, also the neuromuscular adaptations of strength training.

RELATIONSHIP BETWEEN HAMSTRING ISOMETRIC STRENGTH, FRONTAL PLANE CORE STRENGTH AND DYNAMIC VALGUS DURING A BILATERAL VERTICAL JUMP IN ADOLESCENT FEMALE SOCCER PLAYERS.

BIKANDI, E.

ATHLETIC CLUB DE BILBAO

INTRODUCTION: Due to the devastating impact of the ACL injury on the athlete´s career, many multifactorial prevention screenings have been widely designed specially in female soccer, in order to reduce injury incidences. Functional, biomechanical and neuromuscular contributors have been described. Among the latest, lower limb strength and jumping mechanics, are considered as the main factors that should be evaluated during any ACL injury risk screening procedure. The causal relationship between maximal hamstring muscle force output, frontal plane core strength and knee valgus excursion during the vertical bilateral drop jump (VBDJ) remains controversial. Thus, the objective of this cross-sectional preliminary study was to analyse if players demonstrating greater valgus angular excursions would present with significant correlations with hamstring and or core strength related variables.
METHODS: 19 adolescent female soccer players (age 18,5 1,56) completed a pre-season ACL injury prevention screening conformed by functional, biomechanical and performance testing battery. Bilateral hamstring isometric peak torque (HPT) at 30º knee flexion and 90º hip flexion (long fascicle length), proximal hip muscle abduction strength and core complex stabilization capability in the Side Bridge Test (SBT) and dynamic knee valgus angle (KVA) during a vertical bilateral drop jump landing were registered. Strength measures were normalized by weight. Correlation and significance level between variables interaction were analysed.
RESULTS: Significant correlation at p = <0,05 significance level was observed between SBT and KVA of the left limb (r = -0,537; p = 0,018). Other significant correlations were detected among limb sides in hamstring and hip abduction peak torque, resulting irrelevant for a subsequent interpretation.
CONCLUSION: A considerate level of relation between the hip-trunk-core complex stability and knee valgus angular excursion was the main finding at the present study. According with previous research, the neuromuscular performance of the proximal lower limb segment may influence knee stability during dynamic tasks. However, higher hamstring isometric muscle strength values does not seem to be related to a reduced valgus collapse, exemplifying the controversy existing through the literature. Thus, more exhaustive screening methodologies with stronger measurement procedures are needed in order to detect the main contributors for ACL injury mechanics.

MUSCLE ACTIVITY AND FORCES DURING TRADITIONAL AND SUSPENDED LUNGE

AGUILERA-CASTELLS, J.1, PEÑA, J.3, SOLANA-TRAMUNT, M.1, FORT-VANMEERHAEGHE, A.1,2, MORALES, J.1, BUSCÀ, B.1

1: FPCEE BLANQUERNA RAMON LLULL UNIVERSITY , 2: FCS BLANQUERNA RAMON LLULL UNIVERSITY , 3: UNIVERSITY OF VIC

INTRODUCTION: The assessment of muscle activity and forces had been examined in different upper body exercises like push-ups, inverted row and plank , all of these performed in traditional and suspended conditions. In lower body exercises, Malliaropoulos et al. <2015> assessed the suspension device effect on muscle activity in hamstring curl exercise. However, it seems that there is a lack of evidence about the effect of using a suspension device in the lower body exercises. Thus, the aim of the study was to compare the muscle activation and vertical ground reaction forces when performing traditional lunge and suspended lunge exercises .
METHODS: Ten physically male subjects performed five TL and five SUL. SUL was performed using a TRX Suspension Trainer . Surface electromyography was used to measure the muscle activation and expressed in normalized value <% Maximum Voluntary Isometric Contraction>. The analysed muscles were rectus femoris, biceps femoris, gluteus medius, vastus medialis and lateralis. VGRF <% body mass resistance> were assessed using a Wii Balance Board . Paired samples T- tests were used to determine the exercise conditions effects. EMG and forces values were expressed as mean ± SD.
RESULTS: For the analyzed muscle, biceps femoris showed a significant greater activation during TL in comparison with SUL; t<9> = 3.890, p<0.05. However, no significant activations for quadriceps and gluteus medius were found, but overall mean of all muscles revealed significant differences between TL and SUL; t<9> = 3.267, p<0.05. SUL showed a significant higher VGRF in comparison with TL; t<9> = -3.251, p<0.05.
CONCLUSION: According to Andersen et al. <2014>, biceps femoris activation increases in a TL in comparison with unstable lunge. It seems that SUL condition did not provoke the appropriate degree of instability to lead changes in muscle activation. Conversely, VGRF was higher in SUL, due to body mass resistance is projected in the forward leg, thus body load in TL is more balanced between rear and forward leg. Further research is needed to make a comparison.

PERCEIVED LOADING AND MUSCLE ACTIVITY DURING PULL DOWN EXERCISES: COMPARISON OF ELASTIC RESISTANCE BAND AND MACHINE EXERCISES

CHIU, S.C., LEE, H.J.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Upper body strength training can be performed using a broad variety of different exercises, including machines with self-selected workload or using participant own individually bodyweight as workload. Some studies have demonstrated exercises with elastic resistance band , which can be a feasible alternative to heavyweights in certain situations. Previous research has shown that both lat-pull down and chin-up exercise can exhibit unique training stimulus. However, there is limited research regarding the comparison of muscle activations between pull-down exercises by using LPD machine and ERB. Therefore, the purpose of this study was to compare muscle activity of upper back muscles between two pull down exercises by using LPD machine and ERB.
METHODS: There were 10 healthy males with at least 12 months of resistance training experience participated in the study. EMG activities were recorded from 5 muscles at the upper body during pull-down exercise, using ERB and LPD machines. These recordings were normalized to EMG signals during maximal voluntary contraction. Five muscles have been analyzed during two pull down exercises were latissimus dorsi , pectoralis major , biceps brachii , triceps brachii , and posterior deltoid. The exercises were performed at four levels of

perceived loading reported using the Borg scale of perceived exertion: light , moderate 2–<5>, heavy and near maximum . One-way Anova with repeated measures was conducted for statistical analysis.
RESULTS: Strong associations were observed between perceived loading and EMG signals during the pull-down exercises with ERB as well as in LPD machine. Average normalized EMG showed significant greater muscle activations in the eccentric phase than in concentric phase in both LPD and ERB exercises. For ERB, TB was greater than BB and PM in the concentric phase, whereas TB, LD, PD were greater than BB and PM in the eccentric phase in level moderate, heavy and near maximum. For LPD, BB was greater than LD in the concentric phase in all levels, whereas PM was greater than LD, TB in the eccentric phase in level near maximum. Overall, the results showed that using ERB could facilitate a higher level of muscle activations for upper back muscles.
CONCLUSION: ERB may be able to increase muscular strength of the upper back and arm muscles similar to that of the LPD exercise. This study identified that greater normalized EMG values were found for the TB, LD, and PD during ERB than during LPD. Current results indicated that ERB creating an unstable condition which would require more efforts for the muscle to control and execute. Therefore, significant muscle activations were required to maintain stability throughout the ERB exercises. As a result, ERB could be a useful alternative training method to an LPD exercise, especially when the availability of training equipment is limited.

PREDICTION OF STRENGTH PERFORMANCE BY THE ANALYSIS OF ANTHROPOMETRIC VARIABLES AND AGE

ISENMANN, E., INGLESON, F., FLENKER, U., HETTENKOFER, C., DIEL, P.
INSTITUTE OF CARDIOVASCULAR RESEARCH AND SPORTS MEDICINE,GERMAN SPORT UNIVERSITY

INTRODUCTION: Comparing individual strength performance in human studies has proven to be quite difficult as there are many influencing factors. Bodyweight has been identified to be a strong predictor of strength performance. However the influence of anthropomorphic variables, like length of leg or arm and age has only been marginally investigated so far. The aim of this study was to analyse the influence of specific variables (age, individual length of the body levers used and individual bodyweight) on strength performance using statistical analysis.
METHODS: 160 healthy male subjects with barbell experience were recruited. Age was recognised and bodyweight, length of the femur and total arm length were measured. The subjects performed either a one repetition squat or a one repetition bench press or both at their individual maximum power.
Force (F, expressed in kg lifted, one repetition maximum) was modeled by multiple linear regression. The investigated independent variables were age [y], weight [kg], and for the levers depending on the exercise, length of the femur (LF) or of the total arm (LA), respectively. The software was R in its latest version. Regression models generally were fitted top-down. Starting from the full model, insignificant terms were stepwise removed. Models were then compared by ANOVA.
RESULTS: The multiple R-squared of the model fitted to the squats data is 0.98. LF and allometrically scaled weight (W2/3) are highly significant. By contrast, age turned out to be fully insignificant in combination with LF and W2/3.The multiple R-squared of the model fitted to the bench press data is 0.41. All factors, Age, LA, and W are required and are statistically significant. The effect of age exhibits curvature and can well be described by incorporation of a second order term (Age2). Moreover, sufficient quality of fit requires an intercept.
CONCLUSION: In the squat performance, there is a clear influence of the length of the femur and the body weight both being statistically significant with $p<0.001$ which is again emphasized through the multiple R-squared. Age has no influence, which might be lead back to the small number of subjects or to the subjects being homogenous in regard to age. However, in the bench press performance all three variables show to have a highly significant influence. Following these results more data sets needs to be analysed in order to fully exclude age as an influencing variable on strength performance in squats. Furthermore, it can be said that there is a necessity to include these variables when comparing human strength performance. An outlook hereunto would be a formula combining all three variables to result in a coefficient that could be used to rank each subject on the basis of these variables in their individual strength performance.

CONCENTRIC AND ECCENTRIC ISOKINETIC PERFORMANCE OF SHOULDER EXTERNAL AND INTERNAL ROTATORS IN CHINESE ADOLESCENT VOLLEYBALL ATHLETES

REN, X.
SHANGHAI RESEARCH INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Volleyball is a sport characterized by overhead throwing actions. Chinese athletes start volleyball training and participating in high –performance sports in early childhood. Sport-specific adaptations at the glenohumeral joint could occur in adolescent volleyball athletes. The main of this study is to analyze the concentric and eccentric muscular performance of shoulder external rotators and internal rotators in the Chinese adolescent volleyball athletes.
METHODS: Thirty adolescent volleyball athletes （20 males, 10 females age = 16.33 ± 1.67years, height = 190.13 ± 7.67 cm, mass = 76.67 ± 10.71 kg, body mass index = 21.17± 2.36 kg/m^2） were tested. Concentric and eccentric isokinetic internal and external strength were measured at 60°/s using Iso-Med 2000. The measurements were taken with the participants in a seated modified neutral position, with 90° of elbow flexion, 30° of glenohumeral joint flexion, and 30° of glenohumeral abduction; the participants wore stabilization straps across the hip and upper body. Gravity compensation was employed. Concentric and eccentric strength of the shoulder internal and external rotators and total ROM were tested bilaterally.
RESULTS: The mean of total ROM was 94.6°± 1.04°in the dominant shoulder, 96.07°±0.91° in the non-dominant shoulders. The total ROM was less in the dominant shoulder. The mean peak torque （PT） of concentric IR's and ER's were 38.17±10.46N/M and 26.43±8.85N/M in the dominant shoulder, 37.67±11.12N/M and 29.73±8.85N/M in the non-dominant shoulder. The mean PT of eccentric IR's and ER's were 27.47±8.87N/M and 35.03±11.28N/M in the dominant shoulder, 29.87±8.78N/M and 31.13±9.17N/M in the non-dominant shoulder. There were no significant differences between D and ND in the concentric and eccentric PT of IR and ER. The concentric strength ratios of ER/IR were 0.70±0.16 in the dominant shoulder, 0.82±0.26 in the non-dominant shoulder. Eccentric ER-to concentric IR strength ratio was 0.92 ±0.18 in the dominant shoulder, 0.85±0.20 in the non-dominant shoulder.
CONCLUSION: Chinese adolescent volleyball players had a good performance of concentric and eccentric strength, and proper ratios of ER/IR and eccentric ER to concentric IR. However the total ROM in the dominant shoulder was less in the non-dominant shoulder. In order to prevent shoulder injuries, improving the ROM of dominant shoulder and routine screening to keep the performance of the strength.

ACUTE EFFECTS OF WHOLE BODY ELECTRO STIMULATION DURING A SINGLE MAXIMAL STRENGTH TRAINING SESSION

BURGOS POSTIGO, S., TOBIA, D., RECAREY, A., FERNÁNDEZ-RODRÍGUEZ, A., FERNÁNDEZ-ELÍAS, V.E.

UNIVERSIDAD EUROPEA DE MADRID

INTRODUCTION: Whole body electrostimulation (WB-EMS) devices have been used in both performance and health related training programs and the scientific literature has shown that it can be an effective tool to improve training adaptations. However, WB-EMS efficiency is being questioned nowadays. Further, it has been suggested that WB-EMS could lead to excessive physical strain and health problems due to the lack of a scientific based specific WB-EMS training method and professional formation of coaches. The aim of this study was to assess the training effects of two protocols of WB-EMS during a single maximal strength session.
METHODS: Eleven subjects with previous experience in strength training of 3-5 days/week during, at least, the past 3 years participated in the study. They performed a familiarization trial with the WB-EMS device and a 1RM test based on mean propulsive velocity analysis for bench press and full-squat to stablish their 90%1RM load. Then, subjects performed three maximal strength sessions consisting of 5 sets of 5 repetitions with 3 minutes of rest between sets of bench press and full-squat using different protocols: WB-EMS with continuous stimulus (85 Hz, 250/350 µs ; Cont-EMS), WB-EMS with stimulus coordinate with the movement concentric phase (85 Hz, 250/350 µs, 1 s strain to 2 s rest; Coord-EMS) and a session without WB-EMS (No-EMS).
RESULTS: During sessions, heart rate, peripheral capillary oxygen saturation and perceived exertion showed no significant differences. Also, no differences were found among trials in heart rate variability, squat jump, countermovement jump, Abalakov jump, handgrip and frequency of striking for 5 seconds. Blood lactate (BL) was significantly increased only after Coord-EMS (1.8 ± 2.2 mmol/L: $p<0.05$). Creatine kinase increased significantly immediately after Cont-EMS (12.3 ± 16.7 IU/L) and No-EMS (30.6 ± 47.0 IU/L; $p<0.05$), but not after Coord-EMS (4.5 ± 39.5 IU/L). No differences were found in CK levels 24 after training sessions.
CONCLUSION: According to these data, strength training with WB-EMS device did not mean risk for athlete´s health, in fact, the greatest increased in CK level after training was produced after No-EMS training. In the other hand, BL was higher after Coord-EMS, this could mean that coordinating the electrostimulation with the movement concentric phase provokes a higher impact training due to larger anaerobic effect.

DIFFERENTIAL NEUROMUSCULAR RESPONSES TO EXPLOSIVE VS HEAVY RESISTANCE TRAINING IN STRENGTH-TRAINED MEN

VAJDA, M., SCIBRÁNI, A., BUZGÓ, G., CVECKA, J., VANDERKA, M., SEDLIAK, M., KAMPMILLER, T.

COMENIUS UNIVERSITY

INTRODUCTION: This study examined the effects of a 6 weeks explosive resistance training (EXPLO) versus heavy resistance training (HYP) on neuromuscular adaptation in young strength-trained men.
METHODS: Thirty eight physical education students, who experienced at least 6 months of resistance training during the last 2 years, were assigned to perform either EXPLO (load 50–60% of 1RM, 6-20 reps, 2–3 sets and 90 s/5 min rest) or HYP (load 75–80% of 1RM, 8–10 reps, 3–4 sets and 90 s rest) training program with progressive overload for 3/wk on nonconsecutive days. Neuromuscular responses were assessed through isometric maximal voluntary contraction (MVC) and the rate of force development (RFD) in half squat position, the power output (Pmean) with 40 kg, 60 kg, 80 kg and 100 kg barbell in half squat jump and one repetition maximum (1RM) in bench press.
RESULTS: There was an increase of the MVC in both EXPLO and HYP (Main effect, $p=0.007$, T-test HYP $p=0.022$). Also, the Pmean was improved significantly for EXPLO with 60 kg, 80 kg and 100 kg (T-test, $p=0.007$, $p=0.002$, $p=0.002$) but not for HYP with time × groups interaction with 60 kg ($p=0.008$) and 80 kg ($p=0.001$) barbell. Finally, the 1RM was improved in both EXPLO and HYP (Main effect, $p=0.003$, T-test, EXPLO $p=0.002$, HYP $p=0.002$).
CONCLUSION: In conclusion, the present training programs were designed to be as similar as possible to those used in practice in strength and explosive training among recreational and elite athletes, for increasing strength and power output. Our results indicate that the 6 week explosive resistance training induce improvements in maximal strength and power, without the negative effect on ability to produce power associated with heavy resistance training. Therefore, our explosive resistance training program may be a practical and widely applicable form to accelerate power development and strength gains in a short-term training cycle.

EVALUATION OF ISOKINETIC CONTRACTION AND BALANCE, MUSCLE ACTIVITY AND FOOT PRESSURE DURING WALKING IN PATIENTS WITH FUNCTIONAL ANKLE INSTABILITY

LEE, S.A.1, KIM, A.R.2, YOO, K.T.2, LEE, H.S.1

1: DANKOOK UNIVERSITY, 2: NAMSEOUL UNIVERSITY.

INTRODUCTION: Functional ankle instability (FAI) patients exhibit during walking are not only different than healthy counterparts, but it has no regard to inappropriate coping strategy may have negative consequences for ankle rehabilitation (Feger et al., 2015). Accordingly, dynamic stability such as walking must be assessed when researching FAI. Moreover, although several functional assessment tools of strength and balance in patients with FAI have been suggested (Susanne et al., 2011), the relationship between the dynamic stability deficits and FAI during walking has not been clearly delineated in the studies. Therefore, the purpose of this study was to investigate to evaluate of the isokinetic contraction and balance, muscle activity and foot pressure during walking in patients with FAI.
METHODS: Nine healthy subjects (CON = 9) without FAI and 11 patients (FAI = 11) with FAI participated in the study after they had been screened for the ankle instability instrument and balance error scoring system. In addition, FAI was classified to non-involved (N-FAI) and involved (I-FAI), and dominant and non-dominant as CON. All subjects were evaluated isokinetic contraction (plantar flexion, dorsiflexion, inversion, and eversion of 30˚/sec and 60˚/sec) and balance (static and dynamic), muscle activity (tibialis anterior, peroneus longus and gastrocnemius) and foot pressure (static and dynamic) during walking.
RESULTS: The results showed that the plantar flexion ($p<0.05$), dorsiflexion ($p<0.05$), inversion ($p<0.01$) and eversion ($p<0.001$) of 60˚/sec, gastrocnemius of dynamic muscle activity ($p<0.01$), anterior posterior of weight distribution of static foot pressure ($p<0.001$), and pressure distribution of dynamic foot pressure ($p<0.001$) were significantly decreased in I-FAI than N-FAI. C90 of static balance with the eyes

opened (p<0.01) and closed (p<.001) were significantly increased in FAI than CON. Forward position of dynamic balance (p<0.01) was significantly decreased in FAI than CON.
CONCLUSION: Generally, FAI relates to muscle strength and proprioception of the ankle joint (Tabrizi et al., 2000), and the decreased muscle strength of the ankle while standing and walking was reported to be a compensatory mechanism in response to the displacement of the center of pressure (COP) (Donath et al., 2016). Thus, the decreased muscle strength might be associated with caused flexion of the ankle and hip joints to increase the shifting of the forward of COP (Rachel et al., 2018). According to previous study, during walking, the muscles that seemed the most affected for the FAI are the gastrocnemius and peroneus longus (Moisan et al., 2017). With regard to kinematic parameters, an increased rearfoot inversion, a more externally rotated shank, an increased ankle joint inversion, a decreased ankle joint dorsiflexion and a greater forefoot inversion were observed during walking cycle in the FAI. Our results seem to suggested that patients with FAI undergoing proprioceptive and neuromuscular deficits of the ankles.

ALTERATIONS IN RELATIVE LEG STIFFNESS AND REACTIVE STRENGTH INDEX DURING A TYPICAL TRAINING WEEK IN ELITE YOUTH SOCCER

DE STE CROIX, M.B.A., LEKUE, J., CALLEJA-GONZALEZ, J., MARTIN GARECHANA, I., O'DOHERTY, P., RITSON, D.C., MOSQUEIRA, M., HUGHES, J.D.

UNIVERSITY OF GLOUCESTERSHIRE

INTRODUCTION: Soccer matches can elicit exercise induced changes in neuromuscular function which can be attributed to the high physical demands of landing, accelerating and decelerating experienced during match-play. Evidence shows that neuromuscular parameters may not return to baseline prior to the next competitive match. Even within youth soccer the pressure to re-perform on a weekly basis, means that recovery durations may be shorter than 72 h due to the need to train during the week leading up to subsequent matches. The congested nature of training and matches may increase the risk of injury incidence in maturing players. Increased incidence of injury has been reported during the later stages of training and competition when fatigue is evident, however few studies have tracked neuromuscular recovery after match-play and during the subsequent training week, whilst determining the weekly training load. Therefore, this study sought to explore the potential time frame for neuromuscular variables to return to pre-game levels in elite youth players following competitive match-play and during a typical training week.
METHODS: 44 elite male soccer players were split into three age groups according to chronological age (U13 n = 16; U15 = 13; and U17 n = 15). Relative leg stiffness (RLS) and reactive strength index (RSI) were taken pre-, immediately post competitive match-play and pre-training on 3 occasions (48 h, 72 h and 120 h) during the training week and pre- a 2nd match (168 h). Match and training activities were collected using global positioning system (GPS) (StatSport).
RESULTS: Significant time effects were reported for leg stiffness (P = 0.011). All age groups reported a significant decrease in RLS immediately post-match. RLS was significantly lower than pre-match 1 at all training sessions and before the next competitive match. There were no significant age group differences in RLS at any time point (P > 0.05). There we no significant interaction effects for time*group or main effects of time for RSI. Percentage change in RLS and RSI from pre-match 1 to pre-match 2 was not correlated to total distance covered, total number of accelerations, total number of decelerations or total number of sprints (determined from match 1 and all training sessions).
CONCLUSION: In conclusion 7 days may be insufficient for stretch shortening cycle recovery in youth male soccer players. The reduction in leg stiffness at training sessions and subsequently before the next competitive match may have implications for sprint and jump performance and injury risk. It appears that load parameters, including total distance covered, total number of sprints, accelerations and decelerations are not related to the decrease in RLS. Therefore, specific monitoring strategies to assess neuromuscular recovery between match-play and subsequent training sessions should be considered to track recovery and potentially maintain performance and reduce injury risk.

Mini-Orals

MO-SH03 Performance and training

HOW TO SERVE FASTER IN TENNIS: THE INFLUENCE OF AN ALTERED FOCUS OF ATTENTION AND AUGMENTED FEEDBACK ON SERVICE SPEED IN ELITE PLAYERS.

KELLER, M., KUHN, Y.A., LÜTHY, F., TAUBE, W.

UNIVERSITY OF BASEL

INTRODUCTION: Different approaches such as providing augmented feedback (AF), adopting an external focus of attention (EF), or grunting have been shown to directly enhance performance in recreational athletes [1-3]. Furthermore, in recreational athletes combining AF and EF (AF+EF) was superior compared to AF and EF alone [4]. Here we test in elite tennis players the influence of AF, EF, AF+EF and an internal focus (experiment 1) and grunting (experiment 2) on service speed.
METHODS: In both experiments, elite players were asked to serve to a target zone with maximum speed. Service speed was measured using a speed gun. The precision of the players was evaluated by the number of serves that were landed in the target zone.
RESULTS: In experiment 1, a significant main effect of condition was found ($p \leq 0.001$). Post-hoc comparisons revealed faster serves for AF compared to control serves without instruction/feedback ($p < 0.01$) and compared to EF ($p < 0.05$), whereas no significant difference was found between EF and IF ($p = 0.81$). The fastest service speeds were found in the AF condition, while the combination of AF+EF did not further promote performance. In experiment 2, players served significantly faster when grunting compared to a condition without grunting ($p = 0.03$).
CONCLUSION: In both experiments, no speed-accuracy trade-off was found indicating that enhanced service speeds did not result in more service errors. Thus, the previously reported performance-enhancing effect of grunting in recreational players can also be found in elite players. Furthermore, AF seems most beneficial to instantly enhance performance whereas EF was less effective and did not differ from IF, providing further evidence that expertise level and task-relevant instructions mediate the influence of attentional focus on motor performance.

THE VALIDITY AND RELIABILITY OF CHAMPDAS MASTER SYSTEM: A LIVE FOOTBALL MATCH PERFORMANCE ANALYSIS SYSTEM

GONG, B., CUI, Y., GAI, Y., YI, Q., GÓMEZ, M.Á.

A.TECHNICAL UNIVERSITY OF MADRID, MADRID, SPAIN; B. BEIJING SPORT UNIVERSITY,BEIJING,CHINA

Introduction: One of the main research areas of performance analysis is the data validity and reliability of players and teams' behaviors during competition. The human errors may limit the reliability of manual data collection and measurements in performance analysis of sport. Therefore, the current study was aimed to investigate the validity of match variables and the reliability of Champdas Master System used by trained operators in live association football match.
Methods: The study consisted of a qualitative and a quantitative analysis. The qualitative analysis (coaches' expert point of view) involved twenty professional football coaches (UEFA-A/PRO, AFC-A/PRO) with 13.4±7.3 years of coaching experience from Europe and China. They voluntarily participated in the validation of match variables used by Champdas Master System by completing a questionnaire that aimed to evaluate: i) the degree of variable pertinence to match performance; and ii) the correct definition of each variable. The answers were chosen on a Likert scale of 10 levels (1=none to 10=maximum). Aiken's V was applied to quantify the validity of each item. The quantitative analysis of system reliability was executed by two well-trained operators that independently collected twice (with an interval of two weeks) the match data of the 19th round of Spanish La Liga Santander (2017-2018) between Real Madrid and Villarreal. Afterwards, the intra- and inter-operator reliability of collected match statistics were determined using Kappa statistic, typical error (TE) and intra-class correlation (ICC).
Results: The qualitative analysis showed that the Aiken's V averaged at 0.84±0.03 for the degree of variable pertinence to match performance and 0.85±0.03 for the correct definition of variable, showing high values in relation to content validity of all variables. The quantitative analysis showed that the Kappa values of the events for both teams were 0.97 and 0.89 for Real Madrid and Villarreal, and the ICC and TE ranged from 0.90 to 1.00 and from 0.01 to 0.24 for different groups of match performance variables for two operators within two data collections, showing a very good inter-operator agreement. While Kappa statistics between the first and second data collection of both teams were 0.92 and 0.90 for Operator One, and 0.91 and 0.88 for Operator Two. The ICC and TE varied from 0.93 to 1.00 and from 0.01 to 0.34 for both operators. These exhibited a high level of intra-operator reliability.
Conclusion
The results of the evaluation from professional coaches showed that the system offers a valid tool for gathering tactical and technical performance data from the live matches. Moreover, the high Kappa values, high intra-class correlation coefficients and low typical errors represented a high level of intra- and inter-operator reliability. This suggests the validity and reliability of Champdas Master System in collecting live football match statistics by well-trained operators.

INVESTIGATING SCORING STRATEGIES IN FIBA EUROBASKET 2017

CONTE, D., LUKONAITIENE, I.

LITHUANIAN SPORTS UNIVERSITY

INTRODUCTION: Previous research suggested that assists, successful 2-point field goals and defensive rebounds are the performance indicators best discriminating winning and losing teams in professional basketball (Garcia et al., 2014). However, no information is available about possible different scoring strategies discriminating winning and losing teams. The aim of the study was to examine the scoring strategies able to predict to win or lose a basketball game during FIBA EuroBasket 2017.
METHODS: Data were gathered from the official website of the FIBA EuroBasket 2017. During the tournament 76 games were played, but only 75 games were considered for the analysis since data for one qualification game were not freely available. The considered game-related statistics referred to scoring strategies were: fast break points (FBP); points in the paint (PP); points from the bench (PB); points from turnover (PT) and second chance point (SCP). Games were classified based on their score difference as close, balanced and unbalanced through a hierarchical cluster analysis using Wards method and the Squared Euclidian distance as interval. Furthermore, a univariate binary logistic regression analysis was performed for the total number of game and in each cluster. Game outcome (winning vs. losing) was adopted as dependent variable, while the scoring strategies were used as independent variables. Data were analyzed using the software SPSS (version 25.0; IBM Corporation, Armonk, NY, USA), and the level of significance was set at $p<0.05$.
RESULTS: Cluster analysis grouped the analyzed games in 31 close, 33 balanced and 11 unbalanced games (score difference: 1-10 points; 11-24 points; >24 points, respectively). The analysis of the pooled games showed a statistical significance value for PP ($p=0.004$), PB ($p=0.008$), PT ($p=0.003$) and SCP ($p=0.001$). The analysis of each cluster showed no significant statistical values ($p>0.05$) for any independent variable in close games. In balanced games, winning teams were more likely to score using PB ($p=0.022$) and SCP ($p=0.003$) compared to losing teams, while in unbalanced games the most adopted scoring strategies were PP ($p=0.016$), PB ($p=0.037$) and PT ($p=0.031$).
CONCLUSION: All the scoring strategies adopted seems able to discriminate between winning and losing teams in professional basketball except for FBP. However, none of the analyzed parameter is able to discriminate between winning and losing teams in close games but only in balanced and unbalanced games. These results indicate the importance of the analyzed scoring strategies and might provide useful data for basketball coaches to optimize their training methodologies and game strategies.

SELECTION IN WATER SPORTS IN HUNGARY – COACH PREFERENCES: FARKAS, A., SZMODIS, M., ALMÁSI, G.
UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: Sport selection, as being the base of the successful future sport career, depend on long-term well-organized and planned training process. It is important to be able to recognize and select the talented youngsters, as soon as possible. In our present study we were interested in the selection in water-sports and related branches. It was supposed that the more successful the sport event the more conscious the selection was.
METHODS: Hungarian coaches mostly working with young athletes were asked by questionnaire about their preferences in the selection. The sport events of the coaches were: pentathlon n=5, triathlon=7, swimming n=8, water-polo n=27, swimming and pentathlon n=6 and swimming and water-polo n=4. Altogether 36 questions were asked in relation to their sport event, about the age-group they trained, the duration of the training sessions and about their main aspects of selection.
Data were analyzed by basic satistics, Student t-test, and correlation analysis for the regional and sport event specific comparison.
RESULTS: When comparing the sport event numerous significant differences were found, e.g.: in water-polo, the avergae age at starting regular training was 8.79 years, while in other swimming-related sports was 7.1 years. When starting the competitive period the mean age of the youngsters was 1.65 years, that was near to the ideal opinion of the coaches. The mean age of starting competitions was 8.3 years, despite the opinion of the coaches about ideal starting age of 9.58. Among the selective body parameters the body height was preferred by water-polo coaches most.
The coaches working in the country were younger, preferred shoulder width among body parameters and thought to start regular training and competition earlier, besides, they thought that accelerated children could maintained their better pereformance level. Coaches were graduated at university level in 41 %. Though 82,1% intended to use the knowledge of professionals in the selection, they were more „hanging on" the intuitions and the experience of older practicing coaches. By the answers, 46% of the coaches thought to be able to maintain the performance level of accelerated children, only a quarter of them would choose them.
CONCLUSION: By our results, most of the coaches „believe" and lean on the practical experiences of older colleagues in the selection process. By the age of the coaches some differences, such as younger coaches prefer starting sport events earlier, was seen. It could be explained to reach higher performance level earlier, that is the base of „evaluating"/judging the quality of work of the coaches.

A RELIABILITY AND VALIDITY ASSESSMENT OF AN ATHLETE READINESS TO TRAIN (ART) QUESTIONNAIRE IN FEMALE YOUTH SOCCER PLAYERS

SONGANE, F.1, SPEARS, I.2, WRIGHT, M.1, WESTON, M.1
1: TEESSIDE UNIVERSITY (MIDDLESBROUGH, UK), 2: PRO-FOOTBALL SUPPORT (HUDDERSFIELD, UK). "

INTRODUCTION: Daily monitoring is integral to athlete management with self-report measures frequently being used to assess readiness to train. Practitioners often select and implement recovery items most commonly reported in literature without fully assessing reliability and validity required (Saw et al., 2017) for their own playing squad. Here, we aimed to assess the reliability and validity of an athlete readiness to train questionnaire (ART) within a squad of youth female soccer players in a talent development programme.
METHODS: Thirty female youth soccer players from a Football Association (FA) Regional Talent Club (under 14 and 16 years) were monitored across a 12-week period during the competitive season. The players maintained their usual coach-prescribed training, and reported perceived recovery scores prior to all sessions (<15min) via the ART. The ART contained items most sensitive to recovery status: mood, illness, fatigue, sleep quality, soreness and nutrition (Saw et al., 2017). These items were scored on a 5-point Likert scale (very poor [1] to very good [5]) presented via a mobile app developed in-house. Recovery items were subjected to internal consistency testing via Cronbachs Alpha and exploratory factor analysis via Principal Component Analysis (PCA), with an extraction criterion eigenvalue of > 0.75.
RESULTS: The mean +/- SD scores reported were: mood (4.0 +/- 0.8), illness (3.9 +/- 0.8), fatigue (3.6 +/- 0.9), sleep (3.9 +/- 0.8), soreness (3.7 +/- 0.9), nutrition (4.1 +/- 0.8). Internal consistency was rated good (0.85; +/- 90% limits 0.01). The Kaiser-Meyer-Olkin measure of sampling adequacy was rated great (0.88), with Bartletts test of sphericity (Chi-Square = 1623.52, p<0.001) confirming sufficient item correlations for PCA. The PCA extracted one factor (eigenvalue = 3.49) from the ART which contained all six items, explaining 58.1% of the variance. Factor loadings were lower for soreness and nutrition (<0.69), and higher for the remaining items (>0.75).
CONCLUSION: A high level of internal consistency combined with the extraction of only one factor suggest the ART in its current form may be reduced to just one item, thus potentially facilitating data collection practices for practitioners. As literature suggests readiness is multidimensional, a limitation here may have been that despite some education on the ART the young players failed to differentiate between its items. Therefore, future research should examine the players understanding of the readiness to train items presented within the ART.

AWARENESS AND PERCEIVED VALUE OF EYE TRACKING TECHNOLOGY IN CONCUSSION ASSESSMENT AMONG SPORTS MEDICINE PRACTITIONERS

SNEGIREVA, N.1, DERMAN, W.1,2, PATRICIOS, J.3,4, WELMAN, K.1
1: STELLENBOSCH UNIVERSITY, 2: IOC RESEARCH CENTRE, 3: UNIVERSITY OF PRETORIA, 4: UNIVERSITY OF THE WITWATERSRAND

INTRODUCTION: Sports concussion is a potentially serious and frequently occurring injury. Currently, even though its management has evolved significantly, there is still no one universally accepted tool to detect concussion and determine when it is safe to return to sport. This is aggravated by athletes often being young, motivated individuals who may under-report symptoms. Eye tracking technology (ETT) holds promise as an objective diagnostic biomarker to assess the presence of sports-related concussion. The primary objective of this study was to assess the awareness of sports medicine practitioners about ETT and determine its perceived value in concussion assessment.
METHODS: A cross-sectional survey consisting of eighteen items was distributed internationally online from January until December 2017 and was completed by 171 sports medicine practitioners. The variables included questions regarding utilization of the current concussion diagnostic tools and their perceived limitations, frequency of observed occurrence of eye movement deficits in concussed patients, level of awareness regarding ETT, and perceived benefits of this technology for diagnosing sports concussions.
RESULTS: The survey showed that the subjectivity of assessment criteria remains the major limitation of currently used diagnostic tools, including the SCAT, which was utilised by 75% of the respondents. ETT, despite its potential to attenuate this limitation (42% of the respondents named objectivity as a potential benefit of this technology), was used only by 12% of the respondents. A positive relationship existed between the experience of using eye tracking and its perceived benefit (p = 0.02). Furthermore, a significant relationship was

found between the profession of the respondents and their familiarity with the ETT ($p < 0.01$). General practitioners (GPs) showed the lowest and neuropsychologists the highest level of exposure to eye tracking. A remarkably low frequency of eye movement deficits (observed only in 12.3 ± 21.0 % of patients) was reported by the respondents. Furthermore, with an exception of the abnormal pupil light reflex, which was checked by 68% of the respondents, eye movement deficits were rather infrequently inspected (on average only by 41.1 ± 17.5 % of respondents).
CONCLUSION: The findings of this study suggest that i) there is insufficient awareness that concussion can lead to abnormal eye tracking behaviour even in this "professionally exposed" population; and ii) Despite the potential promise that ETT holds, sports medicine practitioners seem unfamiliar with this technology and therefore reluctant to implement it in their practice. Increasing the education opportunities and practical experience of sports medicine practitioners regarding concussive signs and symptoms, as well as potential innovative technology (including ETT) is strongly advocated.

MO-PM25 Sprinting and Jumbing

A SHORT-DURATION, LOW-INTENSITY HALF-TIME RE-WARM UP INCREASES INTERMITTEN SPRINT PERFORMNCE OVER THE 10-MIN FOLLOWING HALF-TIME

YANAOKA, T.1,2, HAMADA, Y.1,2, KASHIWABARA, K.1, KURATA, K.3, YAMAMOTO, R.1, MIYASHITA, M.4, HIROSE, N.4

1: WASEDA UNIVERSITY, 2: RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE, 3: TOKYO GAKUGEI UNIVERSITY, 4: WASEDA UNIVERSITY

INTRODUCTION: In intermittent team sports, a 7 min of moderate-intensity half-time re-warm up (RW) has been shown to be a favourable strategy to avoid decrements in exercise performance after half-time (Yanaoka et al., 2018). However, a 7 min of RW would not fit into a half-time since a short time (i.e., ~3 min) would typically be available for a RW in actual matches (Russell et al., 2015). Moreover, although a low-intensity warm-up was as effective in increasing intermittent sprint performance as a moderate-intensity warm-up (McGowan et al., 2015), it is not known whether performing low-intensity RW has similar benefits for increasing intermittent sprint performance. Therefore, the present study aimed to investigate the effect of a short-duration, low-intensity RW on intermittent sprint performance after half-time and compare its influence with a moderate-intensity RW when matched for total duration.
METHODS: Using a randomised crossover design, 11 healthy men (age: 22.7±2.4 years, height: 1.73±0.06 m, body mass: 65.3±10.0 kg, maximal oxygen uptake [VO2max]: 52.6±6.2 mL/kg/min) performed three trials in thermoneutral environment (temperature: 20.6±0.5°C, humidity: 50.8±1.4%). In the main trials, participants performed the first 40-min intermittent exercise followed by a 15-min half-time. Half-time interventions were a 15-min of seated rest (control), a 3-min of moderate-intensity RW (cycling at 60% of VO2max; 60% RW) and a 3-min of low-intensity RW (cycling at 30% of VO2max; 30% RW). After half-time, participants performed a 10-min of the Cycling Intermittent-Sprint Protocol (CISP), which consisted of 10 s of rest, 5 s of sprint and 105 s of active recovery at 50% of VO2max, with the cycles repeated (Hayes et al., 2013). Work for each sprint in the CISP was calculated. The surface electromyograms (EMG) from the muscle bellies of the right vastus lateralis was recorded and the mean value of the root mean square (RMS) during the sprints in the CISP was calculated.
RESULTS: The mean work was higher in both RW trials than in the control trial (control: 3976±1055 J; 60% RW: 4258±1045 J, $p=0.009$; 30% RW: 4142±1000 J, $p=0.040$). The mean RMS was higher in both RW trials than in the control trial (control: 144±27%; 60% RW: 156±28%, $p=0.039$; 30% RW: 164±39%, $p=0.037$). There was no significant difference between both RW trials for the mean work and RMS.
CONCLUSION: The major findings of the present study were a 3-min of low-intensity RW increased intermittent sprint performance over the 10-min following half-time compared with a passive rest and was as effective as a moderate-intensity RW when matched for total duration. Our findings indicate that enhanced intermittent exercise performance following both RWs is likely to be mediated by an increase in EMG activity during each sprint.

INFLUENCE OF AGE ON PERFORMANCE IN A REPEATED SPRINT TEST IN YOUNG SOCCER PLAYERS.

SÁNCHEZ-SÁNCHEZ, J.1, GARCIA-UNANUE, J.1, HERNANDO, H.2, LÓPEZ-FERNÁNDEZ, J.2, UBAGO, E.2, COLINO, E.2, LEÓN, M.2, GALLARDO, L.2

1. UNIVERSIDAD EUROPEA DE MADRID, 2. UNIVERSIDAD DE CASTILLA-LA MANCHA

INTRODUCTION: Previous studies have shown that the ability to recover and reproduce the performance in repeated sprints is a specific requirement of football physical fitness. The Repeated Sprint Ability (RSA) test has demonstrated to be a discriminatory variable between professional and amateur footballers. However, few studies have analyzed its effect on different age categories in terms of performance and fatigue. Therefore, the objective of this study was to analyze the influence of age on performance in a repeated sprint test in young soccer players.
METHODS: A total of 62 amateur young football players from 3 different age categories (U14, n=21; U16, n=20; and U18, n=21) participated in the study. Subjects were recruited from an elite football academy, with which was signed an agreement for the realization of this study. The RSA test Included 7 repetitive 30-meters long sprints with 20 seconds of recovery between them. Four pairs of photocells (Witty, Microgate, Bolzano, Italy) placed in 0, 5, 25 and 30 m assessed the performance in this test. The best time of sprint (RSABEST), the mean time (RSAMEAN), the total time (RSATT), the percentage of decreasing (RSADEC) and the difference between the best and worst sprint during the RSA test (RSACHANGE) were calculated. Two-way ANOVA and Bonferroni post-hoc test was used to analyse the differences in RSA time (age category x sprint number).
RESULTS: The analysis of the RSA test according to the category revealed greater sprint times in the U14 players throughout the complete test and all the sections analyzed ($p <0.01$). Differences were greater in the 30-m sprint analysis (ES: U14 vs. U16: 0.92-3.17, U14 vs. U18: 1.11-4.08). However, the comparison between U16 and U18 did not show any significant difference ($p> 0.05$), except a lower RSABEST in U18 (- 0.122 s, ES: 1.09, 95% CI: -0.236 to -0.008, $p = 0.031$). The deterioration of the performance with respect to the first sprint in the

analysis of the 30-meter RSA test is evident from the fifth sprint in all the categories analyzed (p <0.01), although the RSADEC and the RSACHANGE were not significantly different between age categories (p> 0.05).
CONCLUSION: The ability to repeat sprints is differs according to age. Therefore, the results of the RSA test can constitute a discriminatory variable of the age category of the soccer player. However, the deterioration of performance in the RSA test was independent of the age category.

EFFECTS OF WICKET RUN METHOD IN STEP FREQUENCY AND LECNGHT

GONZALEZ-FRUTOS, P.1, MORENCOS, E.1, ARIAS-TOMÉ, A.2, VEIGA, S.3

1: UNIVERSITY FRANCISCO DE VITORIA, 2:UNIVERSITY AUTÓNOMA DE MADRID, 3:UNIVERSITY POLITÉCNICA DE MADRID

INTRODUCTION: An athlete's running velocity is the product of step frequency (SF) and step length (SL). Some researchers have studied which of these factors, SF or SL, had more impact in the maximal running velocity, with different results (Hunter et al., 2004; Mackala & Mero, 2013; Salo et al., 2011).
The aim of the study was to compare the natural pattern of SF and SL with the results of optimal SL and SF wicket run in maximal velocity test.
METHODS: A total of 51 athletes (18 University Students of sport sciences, 18 athletes U-16 and 19 athletes U-14) performed different flying 20 m sprints at maximal-effort: flat and wicket runs at different distances (1.50 – 2.30 m). Sprint velocity, step length and step rate were calculated by high speed video analysis and photocell split times. The speed of the previous 15 m to the flying 20 m was controlled at the last 5m. The difference between the first and second part of the flying 20 m was calculated with a halfway time. The fastest wicket run was selected to compare with the flat sprint.
RESULTS: Results didn´t show differences (p=0.12; ES=0.20) between the first and second part of the flying 20 m of the flat sprint (0.00 ± 0.04s) and the fastest wicket run (0.02 ± 0.10s). Acceleration phase speed in flat condition (6.68 ± 0.69 m/s) showed higher values (p=0.00; ES=0.36) than fastest wicket run (6.43 ± 0.76 m/s). The flying 20 m speed was higher (p=0.00; ES=0.56) in the flat sprint (7.07 ± 0.82 m/s) than in the fastest wicket run (6.52 ± 0.98 m/s). The SL was lower (p=0.01; ES=0.46) in the flat sprint (1.75 ± 0.14 m) than in the fastest wicket run (1.82 ± 0.15 m). The SF presented higher rate (p=0.00; ES=0.84) in flat sprint (4.03 ± 0.37 Hz) than in the fastest wicket run (3.59 ± 0.52 Hz). The analysis of each group showed similar results, except in the SL, that didn´t present significant differences.
CONCLUSION: The flying 20 m after previous 15 m seems to be a maximal speed phase in this level of performance. The difference between the speed in the previous 15 m in flat and wicket run conditions could perhaps decrease with an adaptation phase. The lower speed in the wicket run could be explain by the change in the running technique (mayor elevation of the feet and knees). These modifications lead to an increase of the SL and a high decrease of SF.
The use of a wicket run test modifies the natural pattern of SF and SL. New studies are needed to analyze the improvements in the SF and SL pattern with the wicket runs skills in a long-term training.

COMPARISON OF THE TWO TYPES OF COMPLEX TRAINING WITH INTENSITY OVER 90 % PMAX

KRÁLOVÁ, T.1, VRBAS, V.1, HAMMEROVÁ, T.1, VANDERKA, M.2, CACEK, J.1, KALINA, T.1

MASARYK UNIVERSITY, BRNO1; COMENIUS UNIVERSITY IN BRATISLAVA2;

INTRODUCTION: The alteration of training methods to enhance performance is the main goal of sports training. MacDonald, Lamont and Garner (2012) note, that complex training may be considered an optimal training method for sport-specific athletic strength development, while thanks to the enhanced neural activity it might be more effective at enhancing strength, and perhaps strength-power. According to many types of complex training (Docherty, Robbins, & Hodgson, 2004), the aim of this study was to compare the influence of different combination of squats jumps on intensity over 90 % maximal average power output (90 % Pmax) with plyometrics drops jumps on performance in countermovement jump (CMJ).
METHODS: Fourteen male students randomly assessed into the two groups, performed 8-week training with two practice sessions per week. The performance in CMJ was regularly measured every week. Data were collected using Myotest. External loads for squat jumps were tested individually to achieve 90 % Pmax using the FitroDyne Premium. Group EX1 trained using the complex pairs: squat jumps with a load over 90 % Pmax immediately followed by drop jumps. Group EX2 conducted first the series of squat jumps with a load over 90 % Pmax, then series of drop jumps. For statistical analysis was used one-way ANOVA with repeated measures (group*time).
RESULTS: The major finding was that both groups EX1 (+ 5,93 %) and EX2 (+ 4,99 %) had a significant increase in the CMJ (p<0.05), however, there were no significant differences between EX1 and EX2 in effect on CMJ (p>0.05). There was no significant increase in CMJ within the first four weeks in both groups EX1 and EX2 compared to the pre-test (p>0.05). Significant differences through the 8-weeks period was registered between result in a 5th week compared to post-test in both groups EX1 and EX2 (p<0.05).
CONCLUSION: Both complex training methods are useful for enhancing the performance in CMJ. We recommend coaches to change the type of methods periodically to avoid repeating the same training. These methods can be periodically substituted.

SHORT-TERM PLYOMETRIC TRAINING IMPROVES NOT ONLY CHANGE OF DIRECTION, SPEED, AND JUMP PERFORMANCE BUT ALSO REPEATED-SPRINT ABILITY IN PREPUBERAL MALE SOCCER PLAYERS

CHAABENE, H., NEGRA, Y., FERNANDEZ-FERNANDEZ, J., SAMMOUD, S., BOUGUEZZI, R., PRIESKE, O., GRANACHER, U.

POTSDAM UNIVERSITY, GERMANY. HIGHER INSTITUTE OF SPORTS AND PHYSICAL EDUCATION OF KSAR SAID, TUNIS, TUNISIA, UNIVERSITY OF LEON, LEON, SPAIN

INTRODUCTION: Exercises involving the stretch-shortening cycle of the muscle, commonly referred as plyometric training , are frequently used to improve soccer players' high-intensity actions. Although there is preliminary evidence on the effects of PT in prepuberal soccer players on components of physical fitness , further research still needed to strengthen the effect of it on prepuberal soccer players' measures of physical fitness. Additionally, despite the frequently occurring repeated-sprint ability demands during youth soccer game ,

the effect of PT on such a fitness quality is presently unknown in prepuberal soccer players. Therefore, this study aimed at examining the effects of 8 weeks PT program on CoD, speed, jump-performance, and RSA in prepuberal male soccer players.
METHODS: Thirty-one healthy players were randomly assigned to a PTG or a CG . Pre-and post-training tests included CoD , speed , jumping-performance , and RSA . The PTG conducted five training sessions per-week, including two PT sessions in substitution of some soccer drills. The CG continued their regular soccer training with five sessions per-week. The PT protocol was based on a previously published study .
RESULTS: Within-group outcomes derived from magnitude-based inferences showed large performance improvements in T-test, DJ20, DJ40, THT, and RSAtotal for the PTG compared with pre-test. For 20m sprint and RSAbest, PTG showed small performance improvements from pre- to post-test. For the CG, small performance improvements were shown in the 20m sprint-time test compared with the pre-test. However, T-test, RSAbest, and RSAtotal were substantially altered from pre- to post-test. Between-group analyses showed greater performance improvements in PTG compared with CG in all tests except RSAFI.
CONCLUSION: Eight-weeks of an in-season plyometric training in addition to regular soccer training induced larger increases in measures of physical fitness in prepuberal male soccer players compared with regular soccer training only. More specifically, plyometric training was, particularly, effective in improving RSA performance.

EFFECTS OF 4-WEEKS PLYOMETRIC TRAINING ON MUSCLE ACTIVATION AND DROP JUMP PERFORMANCE IN JUNIOR ELITE FEMALE FOOTBALL PLAYERS.

WALSH, G., DELEXTRAT, A.
OXFORD BROOKES UNIVERSITY

INTRODUCTION: Sex differences in knee joint biomechanics appear to develop during the pubertal growth spurt (Hewett et al., 2004), increasing the risk of injury in young female athletes and highlighting the importance of training strategies to reduce injury risk factors. Plyometrics training has been used to improve performance and reduce the risk of lower limb injuries (Pfile et al., 2013). Therefore, the aim of this study was to determine the effect of plyometrics training in addition to normal football training on drop jump performance and quadriceps-hamstrings coactivation and onset timings during drop jumps in junior elite football players.
METHODS: Seventeen junior elite female football players (14±1 years) were randomised into a plyometrics (PLYO: n=8) or control (CON: n=9) group. Both groups continued with their normal football training and the PLYO group did 3 additional lower body plyometrics sessions per week for 4 weeks. In the week before (PRE) and after (POST) the training period participants performed 3 30 cm drop jumps onto a force plate while activity of the Vastus Lateralis (VL) and Semimembranosus (SM) was recorded. Jump height (JH) and reactive strength index (RSI), VL-SM coactivation and activation onset timings prior to landing were calculated.
RESULTS: There was an interaction for RSI with greater RSI POST than PRE training for PLYO ($p=0.025$, $d=0.81$) but no change for CON. There were no effects for JH. There was also an interaction for VL ($p=0.005$, $d=1.90$) onsets time which occurred earlier before landing POST training in PLYO with no change in CON. VL-SM coactivation was increased between PRE and POST training ($p=0.013$, $d=1.62$) but there was no interaction.
CONCLUSION: The increases in RSI found in this study are in agreement with those found previously for adolescent males following plyometric training (Llyod et al., 2016). Earlier VL activity is also congruent with greater RSI as the quadriceps contract in preparation for the rebound jump, likely developed by plyometrics as the tasks involved required frequent landing and rebound activities. The increased VL-SM coactivation for PLYO is indicative of reduced quadriceps dominance which has been associated with reduced injury risk (Urabe et al., 2005), however the lack of interaction effect suggests this may be the result of normal football training.

EFFECTS OF PLYOMETRIC AND DIRECTIONAL TRAINING ON SPEED AND JUMP PERFORMANCE IN ELITE YOUTH SOCCER PLAYERS.

BEATO, M.
UNIVERSITY OF SUFFOLK

INTRODUCTION: Soccer players perform approximately 1350 activities , such as accelerations/decelerations, and changes of direction during matches. It is well established that COD and plyometric training have a positive impact on fitness parameters in football players. This study analyzed the effect of a complex COD and plyometric protocol compared to an isolated COD protocol training on elite football players.
METHODS: A randomized pre-post parallel group trial was used in this study. Twenty-one youth players were enrolled in this study . Players were randomized into two different groups: CODJ-G and COD-G , training frequency of 2 times a week over 6 weeks. Sprint 10, 30 and 40 m, long jump, triple hop jump, as well as 505 COD test were considered.
RESULTS: Exercise-induced within-group changes in performance for both CODJ-G and COD-G: long jump = 0.32 and ES = 0.26, respectively>, sprint 10 m , after 6 weeks of training. Moreover, CODJ-G reported substantially better results in long jump test .
CONCLUSION: This study showed that short-term protocols are important and able to give meaningful improvements on power and speed parameters in a specific soccer population. CODJ-G showed a larger effect in sprint and jump parameters compared to COD-G after the training protocol. This study offers important implications for designing COD and jumps training in elite soccer.

EMG STRUCTURE OF MOVEMENT AND MUSCLE ACTIVATION PHASES DURING THE SPRINT START

KATARZYNA, P.
UNIVERSITY OF TECHNOLOGY IN OPOLE

INTRODUCTION: The primary purpose of the paper was to identify the pattern of movement of sprinters sprint start. Also, assessment was conducted as to the movement structure expressed by EMG indicators (muscles bioelectric voltage [μV] and timing in muscles activity

[ms]) in the group of sprinters and in the group of students. Identification was made as to the total interdependency in muscles activity in the pre-and post-start phase of sprint start in both tested groups. The research covered a group of 25 specialist stage sprinters of 1st and 2nd sport class and a group of 36 students of masters study programs in physical education major. The sprinter run test was conducted at a distance of 30m from start block along with registration of the EMG signal.
METHODS: The research was conducted using specialized equipment: telemetric system configured with two quick cameras, 16-channel surface electromyography system (EMG) as well as a system for triggering the sound signal synchronized with EMG equipment.
RESULTS: It was presented the movement pattern of the start phase by the best athlete in the group of sprinters. Also, EMG activation timing was presented, supplemented with the actual values of bioelectric voltage signal of muscles at particular phase of pre- and post-start activation of muscle fibres. According to the sprint start sequence structure before appearance of the sound signal, among others, the following muscles were stimulated: TB, RF and BB. Directly after the signal, the following muscles were activated: VL, STN, BF and GAS MED.
A comparison was made also for the aggregate movement structure indicators understood as the number of activated muscles before and after the sound signal in both examined groups. Comprehensively, the number of activated muscles before and after start in the group of students was expressly greater than in the group of sprinters. Sprinters in the pre-start phase, on average, activated 8 basic muscular parts (R = -0.51), while students stimulated, in the same phase, 10 groups. Directly after the signal, the average number of stimulated muscles amounted to 11 in both groups (the sprinters group R = -0.70). According to the sprint start movement structure, stimulation was showed by the following muscles: BB and TB of the right and left limb (as flexors and extensors of the upper limb) and the following muscles: RF and VL of the right and left limb. It can be noticed that the pre- and post-start muscle activation structure demonstrated the anticipated regularities. This confirmed a growth in sprint start effectiveness at reduced number of activated muscles at the level of specialist stage sprinters. A reverse tendency characterized students on second degree studies in the major of physical education.
In conclusion, the analyses of activation of muscle groups using EMG recording proved that advanced sprinters generate movement patterns typical for their level, both at the pre-and post-start phase and then, when running the distance of 30 m.

IS-BN01 Advances in the study of muscle plasticity using real time ultrasonography

EFFCT OF RESISTANCE TRAINING AND INACTIVITY ON VISCOELASTIC PROPERTIES OF HUMAN TENDINOUS TISSUES

FUKUNAGA, T.

NATIONAL INSTITUTE OF FITNESS AND SPORTS

INTRODUCTION: For the last two decades, real time B-mode ultrasonography has been extensively used to examine in vivo mechanical property of human tendon-aponeurosis complex . The purpose of this presentation is to review the significance of viscoelastic property of TAC for human movements.
METHODS: The ULT was used for in vivo scanning of the muscle tendon complex and a realistic determination of the interactions between muscle and TAC during human movement.
RESULTS: Some ULT studies indicated that the TAC-VEP significantly influences performance and efficiency during stretch-shortening cycle exercises such as jumping and walking . In addition, Kubo et al <2000> indicated that the elasticity of knee extensor TAC associated with 100-m sprint time. Furthermore, it is known that the TAC stiffness of plantar flexors for good endurance runners is lower , and that of knee extensors for the most economical runners is more compliant .
The aforementioned evidence suggests that the TAC elasticity will be associated with the magnitude of storage and recoil of tendon elastic strain energy during SSC exercises. At the same time, the previous findings have tempted researchers to examine whether the VEP of human TAC is changeable due to exercise training and/or inactivity. It has been shown that the stiffness and Young's modulus of human TAC increased considerably after isometric training . The training-induced change in TAC-VEP may be an advantage for increasing the rate of torque development and for shortening the electromechanical delay . On the other hand, a prior study failed to find significant change in TAC stiffness after plyometric training, whereas the time to peak torque shortened significantly . Thus, while the available information is limited, the previous findings suggest that the training-induced changes in the human TAC-VEP might differ with the exercise modalities adopted. In any case, further studies are needed to elucidate the influences of physical exercises on the VEP of human TAC and the associations between the training-induced changes of the VEP and physical performance.
It is well known that muscle strength and size decrease under inactivity or microgravity condition . The TAC-VEP is also changed by inactivity; stiffness decreases and its hysteresis increases after bed-rest . These findings imply that inactivity induces a decline in TAC stiffness as an inverse effect of resistance training.
CONCLUSION: The VEP of human TAC can be a determinant factor for the performances of exercises involving SSC, and it is changeable due to exercise training and/or inactivity. However, it must be remarked that the behavior of TAC during sports and exercise has been mainly examined under the prescribed experimental conditions. In future, further examinations should be conducted to clarify the role of the human TAC-VEP for the performances of practical sport scenes such as maximum acceleration sprinting.

STRUCTURAL REMODELING OF HUMAN SKELETAL MUSCLE WITH CHRONIC LOADING AND UNLOADING

NARICI, M., FRANCHI, M.V., FLÜCK, M.

UNIVERSITY OF PADOVA

Skeletal muscle shows remarkable plasticity in response to chronic loading and unloading. Unloading conditions such as bed rest (BR) and unilateral lower limb suspension (ULLS) have been shown to cause an extremely rapid decrease in muscle size, detectable, both microscopically and macroscopically, after just three days of unloading. This remarkably fast decrease in muscle size is accompanied by substantial remodelling of muscle architecture represented by a decrease in muscle fascicle length and pennation angle1 which, togeth-

er with a decrease in single fibre specific tension and unloaded shortening velocity, account for the loss of muscle force and power. Muscle remodeling seems regulated by mechano-sensitive proteins such as FAK2,3 whose content and activity decrease within 8-10 days of unloading reducing protein synthesis through p70S6K. Muscle remodeling with overloading seems instead regulated by contraction mode. While concentric (CON) loading leads to an increase in pennation angle with little change in fascicle length, eccentric (ECC) training causes diametrically opposite changes. In rodents, longitudinal muscle growth (addition of sarcomeres in series) occurs after downhill (ECC) but not with uphill running (CON). These findings support the contention that the direction of muscle growth is dictated by the contraction mode. Interestingly, in humans, the same mechano-sensitive proteins (FAK, meta-vinculin) have been recently shown to be more activated after ECC and closer to the myotendineous junction. This modulation in FAK-related proteins was also correlated with changes in muscle architectural parameters over training3, reinforcing the interrelation between such myogenic mechanisms and structural adaptations. Furthermore, greater phosphorylation of mitogen-activated protein kinases (ERK1/2, p38) has been reported with ECC vs. CON contractions in mice, humans and cardiac myocytes, in which direction of muscle growth is regulated by different activation of ERK1/2. While there is evidence for lengthening contractions resulting in enhanced extra-cellular matrix remodeling the specific molecular signalling pathways and gene expression regulating the direction of muscle growth with CON and ECC exercise are subject of current investigations by our and other groups.

ULTRASONOGRAPHY FOR MULTI-SITE ANATOMICAL MEASUREMENT: ITS USE IN UNDERSTANDING FUNCTIONAL PERFORMANCE AND TRAINING ADAPTATIONS

BLAZEVICH, A.J.

EDITH COWAN UNIVERSITY

INTRODUCTION: With practice, B-mode ultrasonography can be used for the relatively rapid and accurate measurement of numerous anatomical variables, including muscle size and fascicle architecture . Two main aims of research have been to <1> determine the relationship between muscle architecture and muscle function in vivo in humans, and <2> describe the changes that result from interventions such as physical training, detraining/disuse, ageing and illness or disease. However, one issue limiting the interpretation of data is the substantial intra- and inter-muscular variability in muscle architecture and its region-specific adaptive change in response to interventions.
METHODS: To better understand the functional importance and plasticity of muscle architecture it seems obligatory to take measurements from multiple muscles or muscle regions. It is also essential that issues surrounding error in ultrasound recordings are taken into account, and new technologies are embraced that enhance image quality and measurement accuracy.
RESULTS: Recent data indicate that the conclusions drawn a study differ depending on which regions or sites are examined, and we have recently observed that models used to predict functional effects of muscle architecture are particularly sensitive to the sites at which measurements are made. Using extended field-of-view ultrasonography, a greater image detail and accuracy has been provided in some muscles, and this may influence conclusions drawn when compared to images taken with a small imaging window. Future advances may improve our accuracy further, and allow imaging of complex, long muscles more completely.
CONCLUSION: Methods used for accurate sonographic muscle architectural measurements will be described, evidence for the significant variability of muscle architecture and its adaptation will be provided, and the importance of testing site location for input into mathematical models will be revealed. These factors significantly influence the conclusions drawn from muscle architecture data collected using ultrasonography.

OP-PM13 HIGH INTENSITY TRAINING MODALITIES

VARYING LOAD-DISTRIBUTION DURING HIGH-INTENSITY INTERVAL TRAINING (HIIT) IN CYCLING AND RUNNING: EFFECTS ON CARDIORESPIRATORY PARAMETERS.

BELTRAMI, F.G., ROOS, E., VON OW, M., SPENGLER, C.M.

ETH ZURICH

INTRODUCTION: A popular HIIT session to improve cardiorespiratory fitness of already well-trained individuals is the so-called 4x4, consisting of four 4-min bouts at near-maximal intensity interspersed by 3 min of active recovery. As the magnitude of training-related adaptations are believed to depend on the relative intensity of exercise and thus the associated level of physiological responses, manipulating the session in order to elicit higher physiological perturbations at the same exercise intensity could therefore optimize the training stimulus. Thus, this study aimed to test whether the cardiorespiratory strain of a traditional session of HIIT (4x4-TRA) compared with a session of similar duration and average load, but with decreasing power within each intense bout (4x4-DEC; previously shown to elicit higher oxygen uptake [VO2]) was similarly different between protocols in cyclists and runners.
METHODS: 15 cyclists (1 female, age 29 ± 5 years, VO2max 62 ± 6 ml.kg-1.min-1) and 15 runners (4 females, age 30 ± 4 years, VO2max 58 ± 4 ml.kg-1.min-1) performed – following familiarization sessions – a 4x4-TRA and 4x4-DEC session in randomized, counter-balanced order, while gas exchange and heart rate were monitored. Load was initially set at 85% of peak power output of an incremental test and was constant during 4x4-TRA whereas it started at 40 W (2 km/h) higher than average and finished at 40 W (2 km/h) lower than average within each bout of the 4x4-DEC session. The duration of the initial stage of 4x4-DEC was 60 s, and subsequent stages were 30 s long. The average load was adjusted during familiarization to ensure it was the highest tolerated.
RESULTS: Average VO2 during the four bouts, expressed as a percentage of VO2max, was higher in 4x4-DEC compared with 4x4-TRA in cycling (89 ± 4% vs. 86 ± 5%, p=0.002) but not in running (91 ± 4% vs. 90 ± 4 %, p=0.38). The ratio of average VO2 for 4x4-DEC over 4x4-

TRA was significantly higher for cycling (1.03 ± 0.03 vs. 1.01 ± 0.02 for running, p=0.04), and participants stayed for a 27 ± 30 % longer time above 90% VO2max during 4x4-DEC compared to 4x4-TRA in cycling (p=0.007), but not in running. Average heart rate was higher during 4x4-DEC compared with 4x4-TRA for both cycling and running (+3 ± 3 and +2 ± 3 beats.min-1, both p<0.05), and a similar response was seen for pulmonary ventilation (+10 ± 5 and +5 ± 4 L.min-1 higher for 4x4-DEC vs. 4x4-TRA for cycling and running respectively, both p<0.001) and average blood lactate concentration (+0.6 ± 0.7 and +0.7 ± 1.0 mmol.L-1 higher for 4x4-DEC vs. 4x4-TRA for cycling and running respectively, both p<0.05). No differences were seen for perception of breathlessness, leg and respiratory effort.
CONCLUSION: Higher levels of physiological perturbations were achieved during 4x4-DEC sessions in both cycling and running, however, these differences were more prominent in cycling, thus making it a more attractive modality for a future training intervention.

ASSOCIATION OF SKELETAL MUSCLE AND SERUM METABOLITE PROFILE WITH MAXIMUM POWER OUTPUT GAINS IN RESPONSE TO CONTINUOUS ENDURANCE OR HIGH INTENSITY INTERVAL TRAINING PROGRAMS: THE TIMES STUDY

CASTRO, A.1, DUFT, R.G.1, FERREIRA, M.L.V.1, ANDRADE, A.L.L.1, GÁSPARI, A.F.1, MARCHI-SILVA, L.1, OLIVEIRA-NUNES, S.G.1, CAVAGLIERI, C.R.1, GHOSH, S.2, BOUCHARD, C.3, CHACON-MIKAHIL, M.P.T.1

1: UNICAMP, 2: DUKE-NUS-MS, 3: PBRC.

INTRODUCTION: Recent studies have begun to identify the molecular determinants of variability of cardiorespiratory fitness in response to exercise training programs. However, the picture of molecular mechanisms underlying trainability is very incomplete. The aim of this study was to investigate baseline serum and skeletal muscle metabolomics profile and their associations with the gains in maximal power output (MPO) in response to 8-week of continuous endurance training (ET) or high intensity interval training (HIIT) programs matched for total units of exercise (TIMES study).
METHODS: Eighty healthy, young sedentary adult males (18 to 31 years) were randomized to one of three groups and 70 were defined as completers (>90% of sessions): ET (n=30), HIIT (n=30) and control (CO, n=10). Serum and skeletal muscle samples were analyzed by 1H-NMR spectroscopy. The targeted screens yielded 43 serum and 70 muscle reproducible metabolites (intraclass correlation coefficient >0.75; coefficient of variation <25%). Associations of baseline metabolite levels with MPO trainability were explored within each training program via three analytical strategies: (1) correlations with gains in MPO; (2) differences between high and low gainers (HRE and LRE); and (3) metabolite contributions to the most significant pathways related to gains in MPO. The significance level was set at p<0.01 or false discovery rate of 0.1.
RESULTS: MPO improved equally with ET and HIIT (21% and 24% gains, respectively, P < 0.001; range from 8% to 45%). MPO associated baseline metabolites supported by all three levels of evidence were: serum glycerol, skeletal muscle alanine, proline, threonine, creatinine, AMP and pyruvate for ET, and serum lysine, phenylalanine, creatine, and skeletal muscle glycolate for HIIT. Five of 21 significant pathways from metabolites identified in serum or muscle were similar between ET and HIIT: aminoacyl-tRNA biosynthesis, arginine and proline metabolism, glycine, serine and threonine metabolism, glyoxylate and dicarboxylate metabolism, and nitrogen metabolism.
CONCLUSION: For young sedentary men, ET programs performed at moderate to high intensities have the potential to induce similar improvements in MPO compared to HIIT-based programs. We conclude that MPO gains are potentially associated with metabolites indicative of baseline amino acid and translation processes in both programs and with carbohydrate metabolism in ET.

EFFECTS OF HYPEROXIC-SUPPLEMENTED HIGH INTENSITY INTERVAL TRAINING ON ENDURANCE PERFORMANCE, MAXIMAL OXYGEN CONSUMPTION AND MITOCHONDRIAL FUNCTION IN TRAINED CYCLISTS

CARDINALE, D., LARSEN, F.J., LINDHOLM, P., EKBLOM, B., BOUSHEL, R.

THE SWEDISH SCHOOL OF SPORT AND HEALTH SCIENCES

INTRODUCTION: Hyperoxia increases the amount of O2 dissolved in the blood, elevates arterial O2 saturation, and increases arterial O2 concentration, resulting in a higher O2 delivery to the working muscles (Ekblom et al., 1975). Several lines of evidence indicate that breathing hyperoxia (HYPER) lactate metabolism, power output and endurance are improved compared to normoxia (NORM) (Cardinale & Ekblom, 2017). Since acute HYPER enable a higher exercise work rate compared to NORM and considering the O2 delivery limitation at exercise intensities near to maximum, we hypothesized that muscle mitochondrial oxidative phosphorylation (OXPHOS) capacity would be upregulated along with a higher endurance performance following endurance interval training with supplemental oxygen compared to normoxia.
METHODS: 23 trained cyclists (19 men and 4 women) age 35.3±6.4 years (mean ± standard deviation (SD)) body mass 75.2±9.6 kg, height 179.8± 7.9 m, and VO2max 4.5±0.7 L·min-1 performed 6 weeks polarized and periodized endurance training on a cycle ergometer consisting of supervised HIIT sessions 3 days/week (3·8 min or 4·4 min) and additional low-intensity training 2 days/week (120 and 240 min long duration). Subjects were randomly assigned to either HYPER (FiO2 0.30) or NORM (FiO2 0.21) breathing condition during training in a double-blind study design. VO2max, OXPHOS capacity in permeabilized fibers and 20 min cycle performance were tested pre and post training intervention.
RESULTS: Over the intervention change in VO2max (HYPER 1.1±3.8%, NORM 0.0±3.7%; p value = 0.55, ES= 0.08, trivial), OXPHOS capacity (HYPER 27.3±46.0 %, NORM 16.5±49.1%; p value = 0.21, ES= -0.06, trivial) and mean power output during 20 min trial (HYPER 6.0±3.7%, NORM 2.4±5.0%; p value = 0.073, ES= 0.32 small) did not statistically significantly differ between the groups.
CONCLUSION: In line with previous published data (Kilding et al., 2012), these data showed that 6 weeks hyperoxic-supplemented high-intensity interval-training on a cycle ergometer was not superior to conventional training at sea level in improving VO2max, OXPHOS and cycle performance in already trained cyclists. Therefore, despite the small meaningful positive effect in cycling performance that might be relevant in sport, considering the cost/benefit and ethical issues of performing hyperoxic-supplemented HIIT, it is controvertable whether this strategy is worthwhile in maximizing endurance performance in already trained cyclists.

HIGH-INTENSITY INTERVAL TRAINING OPTIMISATION IN CYCLING: THE EFFECT OF POWER OUTPUT DISTRIBUTION

BOSSI, A.H.1, MESQUIDA, C.2, HOPKER, J.G.1, RØNNESTAD, B.R.

UNIVERSITY OF KENT

INTRODUCTION: The scientific optimisation of high-intensity interval training (HIT) is a necessary step to warrant performance improvements of elite cyclists. Theoretically, HIT protocols with large proportions of time spent at a high fraction of the maximal oxygen uptake (VO2max) might be more effective for improving VO2max and performance due to the greater training stimulus (Buchheit & Laursen,

2013). This study investigated whether HIT work intervals with varied power output (vHIT) yields higher fractions of VO2max than work intervals with constant power output (cHIT).
METHODS: Fourteen male cyclists (age: 24 ± 6 years, VO2max: 69.2 ± 6.6 ml·kg-1·min-1, maximal aerobic power (MAP): 387 ± 33 W) performed submaximal exercise bouts to determine MAP, an incremental VO2max test and a 10-min familiarisation of vHIT (visit 1), as well as cHIT and vHIT in randomised order (visits 2 and 3). Both HIT sessions were based on 6 x 5 min at a mean intensity of 84% MAP, with 2.5-min recovery intervals at 30% MAP. However, the work intervals in vHIT consisted of 3 x 30 s at MAP interspersed with two 1-min blocks and a final 1.5 min at 77% MAP. Time >90% VO2max, time >90% HRmax and session ratings of perceived exertion (sRPE) were compared between HIT sessions. Mean VO2 as a percentage of max (%VO2max), total VO2, mean breathing frequency as a percentage of max (%BFmax), blood lactate concentration [La] and acute RPE (following each work interval) were compared between HIT sessions and between work intervals. Data were analysed using paired t-tests and two-way repeated-measures ANOVAs with Bonferroni post-hoc comparisons. Significance level was set at $P \leq 0.05$.
RESULTS: We found a higher time >90% VO2max for vHIT than cHIT (410 ± 207 vs 286 ± 162 s; $t = 2.63$; $P = 0.021$) and no differences in time >90% HRmax ($t = -0.10$; $P = 0.922$) and sRPE ($t = -1.62$; $P = 0.129$). We found a main effect of HIT mode on %VO2max ($F = 11.26$; $P = 0.005$; $\eta p2 = 0.46$) and total VO2 ($F = 10.78$; $P = 0.006$; $\eta p2 = 0.45$), but not on [La] ($F = 1.54$; $P = 0.236$; $\eta p2 = 0.11$) and acute RPE ($F = 1.72$; $P = 0.213$; $\eta p2 = 0.12$). There was a trend of higher %BFmax ($F = 3.61$; $P = 0.080$; $\eta p2 = 0.22$) in vHIT. A main effect of the work intervals was found for all variables (all $F > 30.50$; $P < 0.001$; $\eta p2 > 0.70$), with no interaction (all $F < 1.03$; $P > 0.392$; $\eta p2 < 0.07$).
CONCLUSION: vHIT yields a higher time >90% VO2max, %VO2max and total VO2 than cHIT when the mean HIT intensity is matched, suggesting a higher training stimulus. Moreover, sRPE, %BFmax, [La] and acute RPE are not affected, indicating vHIT can be recommended as an effective HIT session.

ACUTE PHYSIOLOGICAL AND PERCEPTUAL RESPONSES TO THREE MODES OF HIGH-INTENSITY INTERVAL EXERCISE: DEVELOPMENT OF THE BE@WORK (BRIEF EXERCISE AT WORK) INTERVENTION

BURN, N., WESTON, M., ATKINSON, G., WESTON, K.L.

TEESSIDE UNIVERSITY

INTRODUCTION: BE@Work (Brief Exercise at Work) is a controlled trial examining the effects of workplace-based high-intensity interval training (HIIT) on health and fitness outcomes. Despite accumulating evidence that HIIT can improve aspects of cardiometabolic health (Gibala et al. 2012), the feasibility of conducting HIIT beyond laboratory settings is unclear. In preliminary focus groups conducted within BE@Work, employees reported a preference for a choice of activities, with stair climbing, stepping and boxing the preferred exercise modes. As such, we aimed to assess heart rate (HR) and ratings of perceived exertion (RPE) responses to prototype HIIT protocols based on these exercises and explore whether HR and RPE substantially differed across modes.
METHODS: Using a randomised cross-over design, nine employees (five male; aged 38.8 ± 12.3 years; mean ± SD) took part in three exercise sessions (stair climbing, stepping, boxing). Participants completed four 60 s bouts, each interspersed with 75 s rest, and were encouraged to work maximally. Second-to-second HR was recorded via Polar A360 monitors. Peak HR for each bout was expressed as a percentage of participants' age predicted maximal HR (%HRmax), with a high-intensity exercise criterion of ≥85% of age-predicted HRmax (Weston et al. 2014). Session RPE was collected via the Borg CR-10 scale. Using a linear mixed model, mean differences between exercise modes were derived, with magnitude-based inferences subsequently applied. Threshold values for minimal important differences were two percentage points for HR and one Arbitrary Unit for RPE. Given the pilot nature of the study and the small sample size, substantial effects were only declared clear when the probability likelihood for the effect was ≥75% (i.e., likely).
RESULTS: Participants' mean (± SD) peak HR (expressed as % age-predicted HRmax) were 87 ± 9% for stair climbing, 88 ± 6% for stepping and 85 ± 4% for boxing. Mean RPE was 8 ± 3 for stair climbing, 8 ± 3 for stepping and 6 ± 2 for boxing. There were no substantial between-mode differences in HR or RPE.
CONCLUSION: All three exercise modes elicited physiological and perceptual responses indicative of high-intensity exercise, thus presenting viable options for workplace HIIT programmes. The lack of substantial differences between stair climbing, stepping and boxing protocols suggests these could be used interchangeably in a HIIT intervention, without potentially compromising the intensity of the exercise. These findings inform the design and implementation of BE@Work; an 8-week HIIT intervention for workplaces in Northeast England.

OP-PM14 BONE

SEX HORMONES AND BONE MINERAL DENSITY IN FEMALES ATHLETES WITH DIFFERENT HORMONAL PROFILES

RAEL, B.1, CUPEIRO, R.1, PEINADO, A.B.1, ROMERO-PARRA, N.1, ALFARO-MAGALLANES, V.M.1, BUTRAGUEÑO, J.1, COUCEIRO-CANALEJO, J.1, GARCÍA-DE-ALCARAZ, A.1,2, POZAS-KERSTJENS, G.1, PRIETO, M.1

TECHNICAL UNIVERSITY OF MADRID

INTRODUCTION: Although the association between sex hormones and bone mineral density (BMD) in healthy sedentary women has been widely studied (Huitrõn-Bravo et al., 2016), just few studies have evaluated this relation in trained females (Jürimäe, Vaiksaar, Mäestu, Purge, & Jürimäe, 2011). Therefore, the aim of this study was to assess the influence of sex hormones on BMD in females athletes with different hormonal profiles (eumenorrheic females, oral contraceptive users and postmenopausal females).
METHODS: Seven eumenorrheic females (BMI 20,9±1,26 kg/m2; 27,67±5,11 years), seven oral contraceptive users (OCP) (BMI 21,15±1,67 kg/m2; 33,27±4,48 years) and seven postmenopausal females (BMI 20,73±1,7 kg/m2; 50,71±3,20 years), participated in this study. All of them were well trained in endurance and strength training. BMD was assessed by dual-energy X-ray absorptiometry scan (Version

6.10.029GE Encore 2002, GE Lunar Prodigy; GE Healthcare, Madison, WI, USA). One-way ANOVA for independent samples was used to analyse BMD among different groups (p<0,05).
RESULTS: Eumenorrheic group presented a BMD of 1.16±0.06 g/cm2, oral contraceptive users 1.18±0.03 g/cm2 and postmenopausal females 1.13±0.09 g/cm2. No significant differences were observed for BMD among different hormonal profiles (F2,18= 1.2; p = 0.324; η2 = 0.118).
CONCLUSION: The results manifested no difference in BMD among women in different hormonal status, whereas most studies have revealed a BMD decreased in postmenopausal females, because of the estradiol reduction (Huitrón-Bravo et al., 2016). This result may be explained by the fact that our volunteers are well trained, and some researches showed an increase in BMD with impact exercise (Grove & Londeree, 1992). Therefore, exercise could attenuate the possible BMD decrease with the age. With regard to eumenorrheic and oral contraceptive groups, any differences has been reported. On the one hand, these data agree with other findings in healthy non-athletes females (Di Carlo et al., 2013). On the other hand, our outcomes do not agree with a study made with rowers which presented higher levels of bone formation markers in eumenorrheic females (Jürimäe, Vaiksaar, Mäestu, Purge, & Jürimäe, 2011). Future studies are needed in order to elucidate the specific interaction between sex hormones and BMD when studying athletes.

VITAMIN D PROFILE, SEX HORMONE STATUS AND BIOCHEMICAL MARKERS OF BONE TURNOVER IN FEMALE DANCERS: A 12 WEEK HIIT INTERVENTION STUDY

SCOTT, S., KNAPP, K., BRODRICK, A., FULFORD, J., KRUSTRUP, K., TANG, J., FRASER, W., BOWTELL, J.L.
UNIVERSITY OF EXETER

INTRODUCTION: The physiological demands of classical dance alongside aesthetic requirements to maintain a lean physique may impact on bone and reproductive health in females, as a result of relative energy deficiency and perturbation of the hypothalamic-pituitary-gonadal (HPG) axis. As indoor athletes, dancers may also be at risk of vitamin D insufficiency, with further consequences for bone health. This study examined the relationship between gonadal steroid hormones (GSH), vitamin D (25OHD), biochemical markers of bone turnover and calcaneal bone stiffness in response to a 12 week High-Intensity Interval Training (HIIT) intervention in a population of young female dancers.
METHODS: 30 full-time female classical dance students were recruited, of whom 11 second years (17.6±0.7 y) trained as usual (TAU) and 19 third years (18.6±1.2 y) received 15 minutes twice weekly Diverse Movement HIIT in addition to TAU. At baseline (September) and after 12 weeks (December), overnight fasted venipuncture serum samples were collected and a quantitative ultrasound scan (GE Lunar Insight) of the calcaneus performed. Serum was analysed to determine GSH (estradiol, FSH, LH) and 25OHD status, and assayed for P1NP and β-CTX to assess dynamic bone turnover. Two-way mixed model ANOVAs were used to compare between groups (HIIT vs TAU) for all measures pre-and post-12 weeks; data for estradiol (E2) and 25OHD pre- and post-intervention were pooled to examine their relationship with bone outcome measures (P1NP, β-CTX, calcaneal stiffness). Significance was set at p<0.05.
RESULTS: There was no effect of training group on GSHs pre- or post-intervention. At baseline, median E2 in HIIT (191pmol/L) and TAU (191 pmol/L) were below reference values for ovulatory phase E2 (235-1309 pmol/L) and was lower at 12 weeks in TAU (165 pmol/L) but not HIIT (246 pmol/L). Serum 25OHD was lower after 12 weeks in both groups (p<0.001) towards insufficiency in TAU (32-48 nmol/L, 25%-75% IQ) remaining adequate in HIIT (55-130 nmol/L, 25%-75% IQ). There was a significant reduction of β-CTX in HIIT but not TAU (p=0.043 vs p= 0.823; post hoc) no other significant interaction or main effects were observed. P1NP and E2 were positively correlated at baseline (p=0.101, r=0.303) and 12 weeks (p=0.017, r=0.441), and 25OHD and β-CTX at baseline (p=0.047, r=0.364).
CONCLUSION: A diverse movement HIIT protocol superimposed on regular dance training for 12 weeks did not result in increased calcaneal stiffness in young female dancers. However low estradiol status, indicating potential disturbance of the HPG axis in accordance with Triad associated dysfunction, may have exerted a moderating effect on the osteogenic response to exercise, as supported by evidence of a positive relationship between estradiol and bone formation marker P1NP. In contrast bone resorption as measured by β-CTX was suppressed in HIIT but not in TAU, which suggests that in this population a pro-bone HIIT exercise stimulus influenced bone resorption but not formation marker dynamics.

TEN-WEEK TRAINING LOAD HAS AN EFFECT ON ARM BONE MINERAL DENSITY AND BODY FAT FREE MASS IN ADOLESCENCE SWIMMERS

PIND, R., LÄTT, E., PURGE, P., MÄESTU, J.
UNIVERSITY OF TARTU

INTRODUCTION: Swimmers have been characterized as lean athletes, with relatively high proportion of muscle mass and they accumulate relatively high training load from relatively young ages. Despite that, recent review (Gomez-Bruton et al., 2018) has indicated that swimmers bone mineral density might be compromised due to its non-weight bearing nature. The aim of this study was to investigate the effect of different training load intensities to changes in body composition parameters.
METHODS: 7 (2 women, 5 men) national level swimmers (16.1±2.1 years; BMI 19.99±2.75 kg*m-2; VO2max 50.1±4.4 ml*min-1*kg-1) participated in a 10 week study. Their 100 m freestyle swimming time was 57.62±5.92 s prior the study. Before and after the 10 week study period the metabolic parameters together with DXA parameters were measured. 30-minutes after each training session planned by coaches, athletes reported their RPE (Foster et al., 2001). sRPE was then calculated by multiplying training session duration with RPE. Training load was expressed as total load during 10 weeks and also divided into 3 intensity levels as light (RPE<=4), moderate (RPE 5-6) and intensive (RPE>=7) (Seiler and Kjerland, 2006).
RESULTS: Training load from intensive trainings during 10 weeks had the significant effect to changes in fat free mass (p<0.05). Light, moderate and cumulative training load indicated significant effect to changes in arm bone mineral density (p<0.05). Both calculations were controlled for age and sex of the subjects. There was no significant effect of different training load types to changes in other body composition parameters.
CONCLUSION: The most important finding was that there was a significant association between total, light and moderate training load to changes in arm bone mineral density. Although it has been indicated that the effect of swimming might be low to different bone mineral sites, our data show that training load effect might be different for different parts of the body. About 16% of trainings were reported as being intensive by the athletes, which can be considered pretty high. Intensive trainings in contrast were associated to changes in body fat free mass.

DOES BONE GRAFTING INCREASE THE STATIC STRENGTH OF HIGH TIBIAL OSTEOTOMY?

BELSEY, J., DIFFO KAZE, A., JOBSON, S., FAULKNER, J., MAAS, S., KHAKHA, R., WILSON, A., PAPE, D.

UNIVERSITY OF WINCHESTER

INTRODUCTION: Medial opening-wedge high tibial osteotomy (HTO) is a form of knee surgery used to treat tibial deformity and medial osteoarthritis of the knee. It is often indicated in young or active patients who wish to return to physical activity post-operatively. Despite research investigating the clinical benefits and disadvantages of using graft materials during HTO, further research is needed to analyse the mechanical stability of HTO with multiple graft materials. Accordingly, the purpose of this study was to investigate the use of different graft materials during HTO, and their effects on construct strength and stability. It was hypothesised that 1) HTO with a graft, regardless of type, would provide greater static strength when compared to controls without a graft; and 2) that there would be a difference between the graft materials, regarding the stability that they provide the HTO.
METHODS: A 10 mm biplanar HTO was performed on 15 artificial tibiae. In the resultant osteotomy gap, an allograft wedge (n=5), or pairs of synthetic β-tricalciumphosphate wedges (n=5) were inserted prior to plate fixation. An additional control group (n=5) with no inserted wedge was also included in the study. All osteotomies were secured using an internal fixator plate with a monoaxial locking system. Static compression was applied, following a ramp protocol (0.1 mm/s), perpendicular to the tibial plateau of each specimen, until failure of the osteotomy construct. Failure was the point at which there was a fracture of the lateral cortex. Maximum force, horizontal and vertical displacements, valgus malrotation of the tibial head, and specimen stiffness were calculated. Due to the small sample size of each group, statistical analyses were not relevant. The results that are reported in the present study are based on the means from each test group.
RESULTS: The synthetic group failed at 6.25 kN, the allograft group at 6.04 kN, and the control group at 4.46 kN. The most valgus malrotation of the tibial head was observed in the allograft group (2.6˚). The synthetic group showed the highest stiffness at the medial side of the tibial head, but the lowest stiffness at the lateral side. The allograft group showed high stiffness on the medial side of the tibial head as well as the highest stiffness on the lateral side.
CONCLUSION: Allograft and synthetic implants similarly increase the static strength of an HTO compared to no graft. Synthetic grafts provide the highest mechanical strength, however the high increased stiffness that they provide to the medial side of the bone-implant construct may reduce the range of interfragmentary movements of the open wedge, which may affect time-to-union. Allograft implants increase the stiffness of the osteotomy medially and laterally, which may result greater protection of the lateral cortex. These results may have implications for patients returning to physical activities post-surgery that cause high forces to be exerted through their knee.

LONGITUDINAL EFFECTS OF SWIMMING AND VIBRATION TRAINING ON BONE TURNOVER MARKERS IN ADOLESCENTS

MARIN-PUYALTO, J., GÓMEZ-BRUTON, A., MATUTE-LLORENTE, A., LOZANO-BERGES, G., MUÑIZ-PARDOS, B., GÓMEZ-CABELLO, A., GONZÁLEZ-AGÜERO, A., CASAJÚS, J.A., VICENTE-RODRÍGUEZ, G.

UNIVERSITY OF ZARAGOZA

INTRODUCTION: The levels of bone turnover markers in adolescent swimmers are similar to inactive controls and lower than adolescents practising osteogenic sports (i.e. football) (Vlachopoulos et al., 2017). Acute increases in bone turnover markers after performing whole-body vibration training (WBV) have been described in pre-pubertal boys (Harrison et al., 2015); however, the long-term effects of this type of training on bone metabolism in adolescent swimmers are still unknown. Therefore, the main goal of this study was to compare the longitudinal effects of swimming and vibration training on bone formation and resorption markers in adolescents.
METHODS: Sixty-nine swimmers and 41 inactive controls (CG, 14.0 (2.6) years, 14 females) took part in this 24-week controlled trial. Swimmers were randomly assigned to two groups, with one group following an incremental WBV protocol in addition to their regular swimming training (VIB, n=37, 14.4 (1.8) years, 16 females) and the other group practising swimming only (SWI, n=32, 14.1 (1.8) years, 13 females). Baseline and follow-up evaluations included height, weight, Tanner stage and fasting levels of osteocalcin (OC) and C-terminal telopeptide (CTX). Statistical analyses included paired t-tests to evaluate longitudinal changes and repeated measures ANOVA to check group interactions. Statistical significance was set at $p<0.05$.
RESULTS: Groups showed no differences in age, height, weight and maturation status at both baseline and follow-up assessments. After the training period, VIB showed a significant decrease in OC and CTX (both $p<0.05$), CG experienced a decrease in CTX ($p<0.05$) and no change in bone markers were found on SWI. No differences among groups were found at baseline for any bone marker. At follow-up, however, VIB presented lower OC levels than SWI and CG (78.8 (43.0), 118.6 (49.4) and 105.3 (50.7) ng/ml respectively, $p<0.05$) and lower CTX levels than SWI (VIB: 1.45 (0.67), SWI: 1.90 (0.67) ng/ml; $p<0.05$). A group by time interaction was found for OC (partial eta square=0.161, $p<0.05$) but not for CTX (partial eta square=0.036, $p=0.141$). Further analyses stratifying the sample by sex or pubertal stage yielded similar results (data not shown).
CONCLUSION: The main result of the study is that adolescents complementing their habitual swimming training with WBV showed a decrease in both formation and resorption markers, resulting in OC levels lower than those of inactive controls. These results are surprising, especially taking into account the acute increment in bone turnover markers following one week of WBV (Harrison et al., 2015). On the other hand, no decrease of bone metabolism was observed in SWI. Further research could help confirming these results.

A 9-MONTH JUMPING INTERVENTION TO IMPROVE BONE ACQUISITION IN ADOLESCENT MALE ATHLETES: THE PRO-BONE RANDOMIZED CONTROLLED TRIAL

VLACHOPOULOS, D., BARKER, A.R., UBAGO-GUISADO, E., WILLIAMS, C.A., GRACIA-MARCO, L.
UNIVERSITY OF EXETER

INTRODUCTION: Participation in different loading sports during growth can have different effects on bone status and development. However, there is no evidence how to improve bone acquisition in adolescent athletes involved in weight-bearing and non-weight bearing sports. The purpose of the present study is to investigate for first time the effect of a 9-month progressive jumping intervention programme on bone mass, geometry and microarchitecture in adolescent males participating in weight-bearing (football, FOO) and non-weight bearing (swimming, SWI and cycling, CYC) sports.
METHODS: A total of 93 adolescent males (13-15 years) were included. Sport groups were randomized to intervention and sport (INT-SWI=19, INT-FOO=15, INT-CYC=14) or sport only (CON-SWI=18, CON-FOO =15, CON-CYC=12). The intervention comprised a progressive jumping programme of 3 levels (3 months each) using weighted vests (Level 1= 20 jumps, 0 kg, 3 sets/day, 3 times/week; Level 2= 20 jumps, 2 kg, 4 sets/day, 3 times/week; Level 3= 20 jumps, 5 kg, 4 sets/day, 4 times/week). Dual-energy x-ray absorptiometry (DXA) assessed bone mineral content (BMC), hip structural analysis (HSA) assessed cross-sectional area (CSA), cross-sectional moment of inertia (CSMI) and section modulus, trabecular bone score (TBS) assessed bone microarchitecture and quantitative ultrasound assessed bone stiffness before and after the intervention. One-way analysis of covariance (ANCOVA) was used to compare the bone gains after controlling for pre-intervention bone, change in lean mass and post maturity status. Percentages of difference were used to quantify the magnitude of the differences in adjusted bone gains. Significance was set at $p<0.05$.
RESULTS: INT-CYC gained significantly ($p<0.05$) higher total body less head BMC (5.0%), lumbar spine BMC (4.6%), femoral neck BMC (9.8%) and bone stiffness (12.3%) than CON-CYC. INT-CYC gained significantly higher CSA (11.0%), CSMI (10.1%) and TBS (4.4%) outcomes than CON-CYC. INT-SWI gained significantly ($p<0.05$) higher femoral neck BMC (6.0%), legs BMC (4.2%) and bone stiffness (12.7%) than CON-SWI. INT-SWI gained significantly ($p<0.05$) higher CSMI outcomes (10.9%) than CON-SWI. There were no significant ($p>0.05$) differences between INT-FOO and CON-FOO for any bone outcomes (0.9-3.9%).
CONCLUSION: This is the first randomized control trial to investigate the effects of a 9-month progressive jumping intervention programme on bone outcomes in adolescent male athletes. The findings indicate that the jumping intervention programme can significantly improve bone quantity, geometry, stiffness and microarchitecture outcomes in adolescent male athletes involved in non-weight-bearing sports, such as swimming and cycling, but not in weight-bearing sports, such as football. The present jumping intervention programme may indicate a window of opportunity to counteract the lack of osteogenic stimulus of non-weight-bearing sports and can be implemented by non-weight-bearing sports clubs and athletes to improve bone health.

OP-PM15 PROTEIN SYNTHESIS

THE EFFECTS OF INGESTING DIFFERENT DAIRY PROTEINS ON SKELETAL MUSCLE PROTEIN SYNTHESIS RATES DURING RECOVERY FROM CONCURRENT EXERCISE

PINCKAERS, P.J.M.1, CHURCHWARD-VENNE, T.A.1, SMEETS, J.S.J.1, PEETERS, W.M.1, ROLLO, I.2, VAN LOON, L.J.C.1
1: NUTRIM, MAASTRICHT UNIVERSITY, THE NETHERLANDS, 2: GATORADE SPORTS SCIENCE INSTITUTE, UNITED KINGDOM

INTRODUCTION: Protein ingestion during recovery from exercise increases muscle protein synthesis rates and supports muscle reconditioning. The type of protein ingested may modulate muscle protein synthesis rates after exercise. Whey and casein are milk-derived proteins that have been reported to possess different anabolic properties. How whey and casein compare to total milk protein (20% whey and 80% casein) in their capacity to support postprandial muscle protein synthesis rates during recovery from exercise remains to be established. Therefore, this study compared muscle protein synthesis rates following co-ingestion of milk protein, whey, and micellar casein with carbohydrate during recovery from a single bout of concurrent exercise.
METHODS: In a randomized, double-blind, parallel-group design, 48 healthy young recreationally active males (aged 23±0.3 y) received a primed continuous infusion of L-[ring-13C6]-phenylalanine and ingested 45 g of carbohydrate with 0 g protein (CHO), 20 g (total) milk protein (MILK), 20 g whey (WHEY), or 20 g micellar casein (CASEIN) following a single bout of concurrent resistance- and endurance-type exercise (n=12 per group). Blood and muscle biopsy samples were collected over a 6 h postprandial period during recovery from exercise to evaluate muscle protein synthesis rates and molecular signaling through targets of the mTORC1 pathway. One-way repeated measures ANOVA with treatment as between-subjects factor was used to evaluate between group differences in muscle protein synthesis rates over the 0-6 h postprandial period.
RESULTS: Muscle protein synthesis rates were not different between treatments (P=0.12) over the 6 h of post-exercise recovery (CHO:0.051±0.003; MILK:0.061±0.003; WHEY:0.056±0.002; CASEIN:0.062±0.005 %/h). In line, no differences in mTORC1 signaling were observed between groups. All protein treatments increased plasma leucine concentrations (µmol/L) more than CHO. When all protein treatments were collapsed into a single group (PROTEIN), protein co-ingestion was shown to result in greater muscle protein synthesis rates (PROTEIN=0.060±0.002 %/h) when compared to carbohydrate ingestion only (CHO=0.051±0.003 %/h; P=0.042).
CONCLUSION: Total milk protein, whey, and micellar casein do not differ in their capacity to support postprandial muscle protein synthesis rates when co-ingested with carbohydrate following concurrent exercise in young recreationally active males.

LEUCINE-ENRICHED PROTEIN SUPPLEMENTATION DOES NOT AUGMENT MUSCLE MASS AND STRENGTH GAINS FOLLOWING RESISTANCE-TYPE EXERCISE TRAINING IN HEALTHY OLDER MALES

HOLWERDA, A.M., OVERKAMP, M., PAULUSSEN, K.J.M., SMEETS, J.S.J., GIJSEN, A.P., GOESSENS, J.P.B., VERDIJK, L.B., VAN LOON, L.J.C.

MAASTRICHT UNIVERSITY MEDICAL CENTRE+

INTRODUCTION: The proposed benefits of protein supplementation on the skeletal muscle adaptive response to resistance-type exercise training remain unclear. Protein ingestion after exercise and prior to sleep have been shown to augment muscle protein synthesis during recovery from exercise. However, it remains to be established whether dietary protein ingestion after exercise and before sleep augments muscle mass and strength gains during prolonged resistance-type exercise training in older individuals.
METHODS: Forty-one healthy older males (70±1 y) completed 12 weeks of resistance-type exercise training (3 times.week-1) and were randomly assigned to ingest either protein (20 g whey plus 1 g leucine; n= 21) or an energy-matched placebo (n= 20) after exercise and each night prior to sleep. Maximal strength was assessed by one-repetition maximum (1RM) testing before and after training. Muscle hypertrophy was assessed at the whole-body (dual-energy X-ray absorptiometry), upper leg (computed tomography scan), and muscle fiber (biopsy) level. Muscle protein synthesis rates during week 12 of training were assessed by providing deuterated water (2H2O) and collecting muscle biopsies. A two-factor repeated measures ANOVA (time * treatment) was used to compare muscle strength, appendicular lean mass and quadriceps and muscle fiber cross sectional area. Myofibrillar protein synthesis rates were compared using an unpaired t-test.
RESULTS: Leg extension 1RM increased in both groups (placebo: 88±3 to 104±4 kg, protein: 85±3 to 102±4 kg; P<0.001), with no differences between groups (P>0.05). Appendicular lean mass (placebo: 26.7±0.7 to 27.7±0.7 kg, protein: 26.0±0.5 to 26.6±0.5 kg; P<0.001) and quadriceps cross sectional area (placebo: 67.8±1.7 to 73.5±2.0 cm2, protein: 68.3±1.4 to 72.3±1.4 cm2; P<0.001) increased in both groups, with no differences between groups (P>0.05). Muscle fiber hypertrophy occurred in type II (placebo: 5486±418 to 6492±429 µm2, protein: 5367±301 to 6259±391 µm2; P<0.001), but not in type I fibers (placebo: 6059±364 to 6600±269 µm2, protein: 5935±246 to 6171±305 µm2; P>0.05), with no differences between groups (P>0.05). Muscle protein synthesis rates were 1.62±0.06 and 1.57±0.05 %·d-1 in the placebo and protein groups, respectively, with no differences between groups (P>0.05).
CONCLUSION: Leucine-enriched protein supplementation after exercise and before sleep does not further augment skeletal muscle mass or strength gains following resistance-type exercise training in healthy older males.

INVESTIGATING THE ROLE OF VPS34 AS AN AMINO ACID SENSOR IN HUMAN SKELETAL MUSCLE

HODSON, N., DENT, J., SONG, Z., O'LEARY, M.F., NICHOLSON, T.A., JONES, S.W., MURRAY, J.T., HAMILTON, D.L., BREEN, L., PHILP, A.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: It is well established that the ingestion of amino acids (AAs) activates the mechanistic target of rapamycin complex 1 (mTORC1) and elevates muscle protein synthesis in skeletal muscle. However, the mechanisms by which AAs are sensed in skeletal muscle are as yet unknown. Recent in vitro studies have implicated the class III PI3Kinase Vps34 in this process, demonstrating that deletion of Vps34 abolishes AA-stimulated mTORC1 signalling (1). The primary aim of this study was to determine the effects of protein-carbohydrate (PRO-CHO) feeding on Vps34 kinase activity, cellular location and protein-protein interactions in human skeletal muscle. A secondary aim was to test the importance of Vps34 kinase activity for mTORC1 signalling in vitro using primary human myotubes with the specific Vps34 inhibitor SAR405 (2).
METHODS: Skeletal muscle biopsies were obtained from the v.lateralis of young healthy males (n=8, 23.1±0.5yrs) at baseline and 1 and 3 h following the ingestion of a PRO-CHO (20/44/1g PRO/CHO/FAT) beverage. Muscle samples were used for Vps34 and S6K1 kinase activity assays and immunohistochemistry. In vitro analysis was completed on myoblasts isolated from 2 middle-aged orthopaedic patients (1 female, 1 male, 57.5±7.5). Here, cells were collected pre- and post-nutrient reintroduction (30mins DMEM+2%HorseSerum), after overnight EBSS incubation, either in the presence of absence of SAR405 and anabolic signalling assessed.
RESULTS: S6K1 kinase activity was elevated 1h post-feeding (p<.01), coinciding with mTOR translocation toward the cell periphery (time effect, p=.026). Vps34 kinase activity was unaltered at any time point. In contrast, Vps34 was observed to translocate toward the cell periphery (1h > Pre, p=.043) where it co-localised with mTOR (time effect, p=.046). Preliminary results from human myotubes reveal a reduction in mTORC1 activation after nutrient reintroduction, when SAR405 was administered, compared to control conditions.
CONCLUSION: Overall, these data suggest that Vps34 kinase activity is required for optimal nutrient-stimulated activation of mTORC1 in vitro, however, Vps34 activity is not altered by PRO-CHO feeding in human skeletal muscle. Alternatively, our data suggests that alterations in the cellular localisation of Vps34, and its interaction with mTOR may contribute to its potential role in AA sensing.

MEASUREMENT OF MUSCLE, TENDON, LIGAMENT, CARTILAGE, AND BONE PROTEIN SYNTHESIS RATES IN VIVO IN HUMANS

SMEETS, J.S.J., HORSTMAN, A.M.H., VLES, G.F., EMANS, P.J., GOESSENS, J.P.B., GIJSEN, A.P., VAN KRANENBURG, J.M.X., VAN LOON, L.J.C.

MAASTRICHT UNIVERSITY MEDICAL CENTRE+

INTRODUCTION: Skeletal muscle plasticity is reflected by a dynamic balance between protein synthesis and breakdown, with basal muscle protein synthesis rates typically ranging between 0.04 and 0.06 %/h. Though it is evident that other musculoskeletal tissues should also express some level of plasticity, protein synthesis rates of most of these tissues have never been assessed. The present study applies contemporary stable isotope methodology to assess basal muscle, tendon, ligament, bone, as well as cartilage protein synthesis rates in vivo in humans.
METHODS: Six otherwise healthy patients (62±3 y), scheduled to undergo unilateral total knee arthroplasty, were included in this study. Primed continuous intravenous infusions with L-[ring-13C6]-Phenylalanine were initiated 2.5 h prior to surgery and continued during surgery. Throughout the surgical procedure the following tissue samples were obtained: muscle, tendon, cruciate ligaments, cartilage, bone, menisci, fat and synovium. Tissue-specific fractional protein synthesis rates (%/h) were assessed by measuring the incorporation of

labelled L-[ring-13C6]-Phenylalanine in tissue protein and were compared with muscle tissue protein synthesis rates using a paired t-test. Data are expressed as means ± SEM.
RESULTS: Protein bound L-[ring-13C6]-Phenylalanine enrichments did not differ substantially between the different musculoskeletal tissues and skeletal muscle, except for notch bone tissue (P<0.01). Highest enrichment levels were observed in synovium derived protein (0.029±0.008 MPE) and lowest enrichment levels in patellar bone tissue protein (0.005±0.002 MPE). Tendon, bone, cartilage, fat, anterior cruciate ligament, posterior cruciate ligament, and menisci tissue protein synthesis rates averaged 0.06±0.01, 0.03±0.01, 0.04±0.01, 0.11±0.03, 0.07±0.02, 0.04±0.01, and 0.04±0.01 %/h, respectively, and did not significantly differ from skeletal muscle protein synthesis rates (0.04±0.01 %/h; P>0.05). Synovium derived protein and notch bone tissue protein synthesis rates were respectively higher and lower compared to skeletal muscle protein synthesis rates (P<0.05 and P<0.01, respectively).
CONCLUSION: Basal protein synthesis rates in various musculoskeletal tissues are within the same range of skeletal muscle protein synthesis rates, with fractional muscle, tendon, bone, cartilage, ligament, and menisci tissue protein synthesis rates ranging between 0.02 and 0.13 % per hour.

BASAL AND POSTPRANDIAL MYOFIBRILLAR PROTEIN SYNTHESIS RATES DO NOT DIFFER BETWEEN LEAN AND OBESE MALES

KOUW, I.W.K., VAN DIJK, J.W., HORSTMAN, A.M.H., KRAMER, I.F., GOESSENS, J.P.B., VAN DIELEN, F.M.H., VERDIJK, L.B., VAN LOON, L.J.C.

MAASTRICHT UNIVERSITY MEDICAL CENTRE+

INTRODUCTION: Excess lipid availability has been associated with the development of anabolic resistance. As such, obesity may be accompanied by impairments in basal and/or postprandial muscle protein synthesis. We hypothesized that basal and/or postprandial muscle protein synthesis rates are lower in middle-aged obese when compared to lean men.
METHODS: Twelve normoglycemic, obese men (age: 48±2 y, BMI: 37±1 kg·m-2, body fat: 32±2%) and twelve age-matched, lean controls (age: 43±3 y, BMI: 23±1 kg·m-2, body fat: 21±1%) received primed continuous L-[ring-2H5]-phenylalanine and L-[1-13C]-leucine infusions and ingested 25 g intrinsically L-[1-13C]-phenylalanine and L-[1-13C]-leucine labeled whey protein. Blood and muscle samples were taken frequently to assess protein digestion and amino acid absorption kinetics, and basal and postprandial myofibrillar protein synthesis (MPS) rates. Unpaired t-tests were used to compare basal MPS rates between groups. Repeated measures ANOVA were applied to determine differences in postprandial MPS rates between groups over time (time as within, and group as between-subjects factor).
RESULTS: Exogenous phenylalanine appearance rates increased following protein ingestion in both groups (P<0.001), with 58±1 and 58±2% of the dietary protein-derived amino acids appearing in the circulation over the 5h postprandial period in the lean and obese subjects (P=0.82), respectively. Myofibrillar protein synthesis rates increased from 0.030±0.002 vs 0.028±0.003 %·h-1 in the basal period (between groups P=0.60) to 0.034±0.002 vs 0.035±0.003 %.h-1 in the postprandial period (time P=0.03), with no differences between lean and obese subjects (time x group interaction P=0.58), respectively.
CONCLUSION: Basal, post-absorptive myofibrillar protein synthesis rates do not differ between lean and obese males. Postprandial protein handling, including protein digestion and amino acid absorption and the muscle protein synthetic response to protein ingestion, are not impaired in obese males.

OP-BN28 Biomechanics of muscle contraction

NEUROMUSCULAR CHARACTERISTICS AND MUSCLE GEOMETRY IN POWER ATHLETES AND UNTRAINED INDIVIDUALS

MONTE, A., GIURIATO, G., ZAMPARO, P.

UNIVERSITY OF VERONA

INTRODUCTION: Electromechanical delay and rate of force development are important determinants of "explosive" neuromuscular performance. The aim of this study was to investigate the influence of muscular characteristics on EMD, RFD, as well as the effects of gender and training level on the possible correlation between neuromuscular parameters and muscle characteristics.
METHODS: Muscle thickness, pennation angle and fascicle length of the quadriceps extensor muscles of 40 subjects <10 M and 10 F power athletes; 10 M and 10 F untrained> were measured with an ultrasound apparatus. Muscle force and EMG were synchronized and measured continuously in time <1500 Hz>; they were normalized to maximal strength and maximal muscle activity, respectively. EMD and RFD were assessed during a series of explosive and maximal voluntary isometric contractions . RFD was measured in 3 time intervals: 0-50, 50-100 and 100-150 ms.
RESULTS: Muscle characteristics, maximal force and maximal RFD showed significant differences according to gender and training level. Athletes had greater normalised RFD <5.7±0.6 and 3.24±0.6 MVC·s-1> and EMG values during the first 50 ms <69.7±10 and 57.9±8 %EMGMVC> of "explosive" contraction. No differences were observed between athletes and untrained individuals in the other time intervals. Male and female had similar EMD values but athletes showed lower values of EMD <16±1.7 and 19.3±1.7 ms> compared to untrained individuals. Muscle characteristics were found to influence "explosive" contraction: pennation angle showed a significant positive correlation with RFD0-50 and RFD50-100 in all groups, whereas no correlation was observed with RFD100-150. A significant negative correlation was also found between pennation and EMD .
CONCLUSION: This is the first study that analysed the role of muscle characteristics on EMD and RDF in "explosive" contractions. In accordance with Tillin et al. <2010> and Hannah et al. <2012> RFD was greater in athletes during the initial phases of contraction <0-50 mz> and no differences was observed between gender. Our data furthermore indicate an important interaction between muscle properties and "explosive" force production suggesting that a greater pennation angle could increase RFD at contraction onset <0-100 ms> and reduce EMD.

EFFECTS OF MOTOR UNIT PROPERTIES ON ACTIVATION REDUCTION IN THE TIBIALIS ANTERIOR

KUZYK, S.L.1, DALTON, B.H.1, MCNEIL, C.J.1, POWER, G.A.2, JAKOBI, J.M.1

1.UNIVERSITY OF BRITISH COLUMBIA OKANAGAN, KELOWNA, BC 2.UNIVERSITY OF GUELPH, GUELPH, ON

INTRODUCTION: Following an active lengthening contraction, electromyographic (EMG) amplitude of a steady-state isometric (ISO) submaximal contraction is decreased in comparison to a purely ISO contraction, which is known as activation reduction (AR), a phenomenon of residual force enhancement. Alterations in motor unit (MU) activity are thought to contribute to AR as well as torque steadiness (TS) (1,2). However, little is known about the underlying cause of AR, and its functional implication on TS. Our study evaluated the underlying contribution of MU properties in the tibialis anterior (TA) to AR and its effect on TS during an ISO contraction following active lengthening. It was hypothesized that the MU discharge rate (DR) would be lower during AR compared to the torque-matched ISO contraction, which would contribute to less steady contractions in the AR state.
METHODS: Ten healthy males (26±4years) performed torque-matched ISO contractions at 10% maximal voluntary contraction (MVC) at 30° plantar flexion. This was followed by an active lengthening contraction performed from 0° to 30° ankle excursion, ending at the same muscle length as the purely ISO contraction. Indwelling EMG sampled TA MU action potential trains to determine MUDR and DR variability (DRV). Coactivation and AR was assessed using surface EMG of the TA and triceps surae. Torque steadiness was evaluated as the coefficient of variation of torque during the purely steady-state ISO and AR contractions.
RESULTS: In the ISO steady-state after active lengthening, there was a 44% AR ($p<0.05$) compared to ISO, with no difference in antagonist coactivation ($p>0.05$). Following active lengthening, CV of TS was 29% higher during AR than ISO contraction ($p\leq0.01$). There were 51 discrete MUs identified, but only 27 of these were tracked during both the purely ISO and AR contraction. Fewer MUs were recorded during AR and MUDR decreased by 19% ($p<0.05$) compared to ISO. MUDRV did not differ between the two conditions ($p>0.05$).
CONCLUSION: These results indicate that a reduction in MUDR and number of detectable active MUs likely contribute to AR, which in turn leads to reduced TS following active lengthening.

PRELIMINARY INVESTIGATION OF ULTRASOUND IMAGING OF THE GLUTEAL MUSCLES DURING THE Y-BALANCE TEST IN INDIVIDUALS WITH CHRONIC ANKLE INSTABILITY.

DEJONG, A.F., MANGUM, L.C., HERTEL, J.

UNIVERSITY OF VIRGINIA

INTRODUCTION: Altered dynamic balance has been linked with the development and persistent nature of Chronic Ankle Instability (CAI) (Doherty, 2016). However, the interplay between proximal muscle activity and joint mechanics during such tasks in this population is unknown. Ultrasound imaging (USI) is a reliable means to explore muscle activity without issues of muscle cross-talk seen with electromyography (Dieterich, 2015). Thus, the objective of this study is to determine the relationship between gluteus maximus and medius USI muscle activity, lower extremity kinematics, and Y-Balance test (YBT) performance in individuals with and without CAI.
METHODS: An a priori sample size estimate with a beta level of 0.80 and alpha level of 0.05 estimated the need for 25 subjects per group. In this preliminary analysis there were 8 CAI subjects (21.4±2.2 yrs, 173.5±13.3 cm, 73.1±19.2 kg, 4 males) and 8 healthy matched subjects (20.4±2.3 yrs, 176.7±19.0 cm, 69.3±9.6 kg). Bilateral B-mode USI of the gluteals at stance and the pinnacle of YBT reach directions were taken over 3 trials. Lower extremity sagittal plane kinematics were collected with motion capture software. Gluteal thickness measures were normalized to stance to determine muscle activity ratios. YBT reach distances were normalized to leg length, and peak kinematics were obtained at maximum reach. Independent t-tests were run to compare group demographics. Analyses of variance were run to determine differences between groups and within affected and unaffected limbs for gluteal muscle thickness, kinematics, and reach distances.
RESULTS: For preliminary results, the CAI group had significantly different responses for kinesiophobia and ankle instability questionnaires compared to the healthy group, verifying the target populations. There were no significant differences in reach distance, kinematics, or muscle thickness between groups. The CAI group had significantly decreased anterior reach gluteus maximus thickness of the affected limb compared to the unaffected limb (A: 1.01±0.20cm, U: 1.17±0.16cm; $p=0.02$). No differences were seen within healthy limbs.
CONCLUSION: In this preliminary subset of subjects, there were no significant differences between groups which contrasts current CAI literature. The results suggest gluteus maximus activity differs between CAI group limbs without affecting YBT performance or kinematics. Exploration on CAI gluteal muscle activity during the YBT in a larger representative sample is ongoing.

TORQUE-SHARING STRATEGIES IN HAMSTRING AMONG ELITE SPRINTERS

AVRILLON, S., HUG, F., GUILHEM, G.

FRENCH NATIONAL INSTITUTE OF SPORT

INTRODUCTION: Knee flexion torque has been extensively assessed to indirectly estimate hamstring torque for performance or prevention purposes (Van Dyk et al. 2016). However, due to the redundancy within the musculoskeletal system, a given joint torque can be produced using various torque-sharing strategies. Thus, the estimation of knee flexion torque may conceal individual differences or alterations in the relative contribution of each hamstring head. Interestingly, using an indirect index of muscle activity [functional Magnetic Resonance Imaging (fMRI)], Schuermans et al. (2014) showed that altered coordination between muscle heads may contribute to the risk of injury. This study aimed i) to describe torque-sharing strategies within hamstring heads in elite sprinters and ii) to determine whether these strategies are altered by a previous injury.
METHODS: 18 sprinters with a unilateral hamstring strain injury history (< 6 months) were recruited to participate in this study. Muscle volume and moment arm of semitendinosus (ST), semimembranosus (SM) and biceps femoris (BF) were determined from segmented Magnetic Resonance Images (MRI). Fascicle length of BF (short and long heads) and SM were measured using panoramic ultrasound images. Because ST is fusiform, muscle-tendon length from MRI was considered as fascicle length. Participants performed three 10-s isometric contraction at 20% of MVC on an isokinetic dynamometer. During these tasks, electromyographic (EMG) activity was recorded through surface electrodes placed over the ST, SM and BF. The torque produced by each muscle head was estimated using physiological cross-sectional area, moment arm and activation amplitude, as follow:
"Torque index =" "Muscle volume" /"Fascicle length" " × Moment arm x % EMGmax"

The ratio of torque between the hamstring muscles was calculated as the torque of one muscle divided by the sum of all three muscles (Hug et al. 2015).
RESULTS: Note that results from 5 participants are presented here. When considering the dominant leg, torque produced by BF (7.1 ± 2.6) was larger than SM (5.7 ± 3.7) and ST (2.3 ± 0.7). The torque ratio reached 48.8 ± 11.8%, 35.1 ± 14.3% and 16.1 ± 5.7% for BF/Hams, SM/Hams and ST/Hams, respectively. A large variability between sprinters is noteworthy (range: 33.3-60.6%, 28.7-52.5% and 10.7-22.2% for BF/Hams, SM/Hams and ST/Hams).
When considering the torque ratio of the injured and the non-injured, no differences were observed for these 5 participants (39.0 ± 16.6% vs. 43.2 ± 19.1% for the injured and the non-injured muscle, respectively).
CONCLUSION: Our preliminary results suggest that the torque-sharing strategies of the hamstring vary greatly between sprinters. Moreover, previous injuries do not seem to alter torque ratio within hamstring muscles.

MUSCLE HETEROGENEITY ASSOCIATED FUNCIONAL AND METABOLIC ASYMMETRY

SEMIATZH, M.2, ALCANTARA, P.1, PINHATA OTOCH, J.1, SERRÃO, J.3, SEELAENDER, M.1,2

1: FMUSP, 2: ICB-USP, 3: EEFE-USP

INTRODUCTION: Most people present asymmetric lower limbs , one dominant while the other is non-dominant .? This heterogeneity of LL is due to stimuli such as walking, posture maintenance and exercise. The aim of this study was to evaluate metabolic and biomechanical aspects of lower limbs comparing active and very active individuals.
METHODS: Sixteen volunteers, aged between 18 and 65, were divided in AC and VA according to IPAQ Laterality was determined by Waterloo questionnaire. Biopsies were performed in both gastrocnemius medial limbs. Ground reaction force was obtained through force platforms. For Electromyography was obtained through Noraxon Desk Receiver. Gene expression RT-PCR was performed. Two-way ANOVA, Studants T tests and Sperman?s correlates were used for statistics p? 0.05.
RESULTS: Significant interaction effect was detected between laterality and effort in gene expression of Citrate Synthase , fatty acid binding protein , Lactate dehydrogenase, lipoprotein lipase, and the Homer 2. FABP showed a significant difference only in ND limb with higher expression in the AC group, while CS showed differences in DM limb with higher expression in VA group.? In VA group FABP and CS were more expressed in DM limbs. In horizontal impulse braking, difference occurred in ND limbs with the AC group braking more. In AC group the ND limb braking more than the DM. In horizontal propulsion, impulse difference occurred in DM limb with VA propelling more than AC. In vertical propulsion impulse comparing AC and VA groups, DM limbs have lower VIP than the ND. In the AC, we observed there is a methabolic balance between the lower limbs. In VA DM limb is more methaboic adapted to lipolytic profile.As the lipolityc protein expressions increase, the storage machinery decreases, specially when GM muscle contration increases in the breaking phase of the race.
In ND limb, the important correlations also related to the braking phase of the race point to an increase of the fat storage as the aerobic activity increases.
CONCLUSION: The results confirm the hypothesis that there is a functional asymmetry in the gait between AC and VA groups. There are also assimetry and metabolic heterogeneity between AC and VA, with different responses of the DM and ND limbs to endurance training pointing that endurance training exacerbates limb asymmetry.

Oral presentations

OP-PM37 Health and Fitness mixed

ASSOCIATIONS OF VO2PEAK WITH ADIPOSITY AND MOTOR COMPETENCE IN CHILDREN ARE CONFOUNDED BY BODY SIZE

HAAPALA, E.A., YING, G., LAUKKANEN, A., SÄÄKSLAHTI, A., FINNI, T.

UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: Cardiorespiratory fitness (CRF) has been related to adiposity and motor competence (MC) in children. However, most previous studies assessed fitness by field tests or defined it as a peak oxygen uptake (VO2peak) normalised for kg of body mass (BM(-1)). Such normalisation cannot remove the effect of body size affecting the fitness measures leading to spurious correlations with health and MC outcomes. This study investigated the associations of VO2peak, normalised for BM and lean mass (LM) using ratio standard and allometric procedures, with adiposity and MC.
METHODS: Fifteen children (11 girls) aged 7–11 years (median 9.8y) volunteered to the study and gave their informed consent. VO2peak was measured by maximal cardiopulmonary exercise test on a cycle ergometer. CRF was defined as VO2peak/BM(-1) and VO2peak/LM(-1). Based on the data, we utilised scaling exponent of 0.71 from loglinear allometric modeling (Loftin et al. 2016) and defined CRF as VO2peak/BM(-0.71). BM and body composition was assessed by InBody 770. Fat mass index (FMI, kg/m2) and fat free mass index (FFMI, kg/m2.5) were computed. MC was assessed by KTK test battery including walking backwards on a balance beam, hopping for height, jumping sideways, and moving sideways. Maturity offset was estimated by sex-specific equations (Mirwald et al. 2002).
RESULTS: VO2peak/BM(-1) was inversely associated with FMI (r=-0.550, p=0.036) but not with FFMI. It was also positively correlated to jumping sideways (r=0.529, p=0.043), moving sideways (r=0.522, p=0.046), and balance (r=0.526, p=0.044). Although VO2peak/BM(-0.71) was not associated with FMI or FFMI, it was positively correlated to jumping sideways (r=0.601, p=0.018) and balance (r=0.542, p=0.037). VO2peak/LM(-1) was not associated with FMI, FFMI or MC. Further adjustment for age or maturity offset attenuated the associations of the measures of VO2peak with MC. FMI was inversely associated with moving sideways (r=-0.433, p=0.050) and hopping for height (r=-0.628, p=0.003). Adjustment for age or maturity offset had no effect on these associations.
CONCLUSION: As expected, normalising VO2peak for BM(-0.71) instead of BM(-1) attenuated the effect of adiposity on CRF. However, the positive association between VO2peak and MC was disappeared only after normalising VO2peak for LM. Furthermore, the association between CRF and MC were modified by age and maturity. Because of the confounding influence of children's body size and composition on CRF, it is suggested that the measures of CRF should be expressed relative to LM or allometrically modeled BM.

RELATIONSHIP BETWEEN PHYSICAL ACTIVITY AND MUSCULOSKELETAL DISORDERS IN MEN AND WOMEN 19-64 YEARS OLD

MOKHLESABADI FARAHANI, A., JADIDIAN AKBAR, A.

PAYAM-E-NOOR UNIVERSITY

INTRODUCTION: Research on health and physical activity has focused on physiological problems and diseases, such as cardiovascular disease. Focusing on these diseases can lead to loss of common musculoskeletal disorders (Bergman, S., 2007). Musculoskeletal disorders can affect the movement system, which reduces performance, pain, injuries and consequently life quality reduction over time(Barrett et al., 2016).
The aim of this study was to investigate the relationship between physical activity levels in different domains (occupation, domestic, leisure time and transportation) and musculoskeletal disorders among men and women aged between 19 and 64 years in Tehran.
METHODS: Data from a cross-sectional survey were analysed. From a statistical population of 6234, a sample of 540 was selected by cluster random sampling. Physical activity levels data in the domains of occupation, domestic, transportation and leisure time with International Physical Activity Questionnaire (IPAQ) and musculoskeletal disorders (MSDs) data were collected by Nordic Musculoskeletal Disorders Questionnaire. Chi-square and Pearson tests were used to determine the relationship between variables in SPSS software version 22.
RESULTS: There is a significant difference (P=0.003) between the physical activity of men 1571 (SD ±2640) MET-min/week and women 792 (SD ±1415) MET-min/week.Total physical activity in men (occupation, leisure time, transportation) 3582 MET-min/Week was higher in men than women 910 Met-min/week. But the physical activity at domestic in women 2973 Met-min/week was more than men. There was a significant relationship between physical activity of leisure time at all levels and reduction of musculoskeletal disorders (P = 0.009). There was also a reverse relationship between total physical activity at domestic and hip disorders (r = -0.238).
CONCLUSION: Results showed that physical activity in leisure time can significantly reduce musculoskeletal disorders. Physical activity in other areas does not seem to be sufficient to result in positive physical and physiological adaptations. Physical activity at leisure time may increase the musculoskeletal health of the individuals and may reduce the damage caused by sedentary behaviors.

INTRODUCTION: Sarcopenia, the age-related loss of skeletal muscle mass and function, is an independent risk factor for numerous adverse health outcomes in older adults. When obesity is superimposed on sarcopenia, termed sarcopenic obesity (SO), there is an even greater risk of physical disability than is seen with either condition in isolation. The aim of this study was to identify the prevalence of sarcopenia and SO among community-dwelling older adults in Ireland for the first time, and to examine dietary intake in this cohort.
METHODS: In a cross-sectional analysis, 394 community-dwelling adults (age 77.9 ± 7.9 y, range 65-97 y; body mass index (BMI) 27.4 ± 5.1 kg/m2, range 14.0-49.9 kg/m2) were assessed. Skeletal muscle mass was measured using bioelectrical impedance analysis, muscle strength via handgrip dynamometry and physical performance via the Short Physical Performance Battery. A 24 h dietary recall performed by a Registered Dietitian was used to assess dietary intake. Sarcopenia was defined according to the European Working Group on Sarcopenia in Older People criteria (i.e. low muscle mass combined with low handgrip strength and/or low physical performance)1. SO was defined as the presence of sarcopenia in combination with a BMI ≥30 kg/m2.
RESULTS: The overall prevalence of sarcopenia was 32.8% with 20.6% of participants meeting the criteria for severe sarcopenia. Although 26.3% of the cohort were obese, only 4.1% met the criteria for SO. Of those that did not meet the definition for sarcopenia 27.6% were pre-sarcopenic (low muscle mass without a decrement in strength or physical performance) and 49% had low strength and/or physical performance in the absence of low muscle mass. Participants reported consuming 17% of energy from dietary protein, 47% from carbohydrate, 34% from fat and 2% from alcohol. Mean dietary protein intake was 1.05 ± 0.44 g/kg body mass/d, however 29.4% of the cohort reported consuming less than the Recommended Daily Allowance for protein (0.80 g/kg/d) and only 49.3% reported consuming ≥1g protein/kg/d. Dietary protein intake was similar in the participants with normal muscle mass, strength and function (0.98 ± 0.43 g/kg/d) and those with severe sarcopenia (1.13 ± 0.47 g/kg/d, p=0.115).
CONCLUSION: Sarcopenia is prevalent in community-dwelling older adults living in Ireland and, even among those who do not meet the definition for sarcopenia, decrements in muscle mass, strength and physical function are common. Less than half of the older adults reported meeting the minimum dietary protein intake recommendations to support the preservation of muscle mass and function in healthy older adults (1.0 – 1.2 g/kg/d)2,3.

PREVALENCE OF SARCOPENIA BASED ON EWGSOP CRITERIA AND POPULATION SPECIFIC CUTPOINTS IN ADULTS AGED 60 AND ABOVE IN KOSOVO

BOSHNJAKU, A.1,2, BAHTIRI, A.3, FEKA, K.4, KRASNIQI, E.5, TSCHAN, H.1, WESSNER, B.1

1: UNIVERSITY OF VIENNA , 2: UGJFA , 3: UNIVERSI , 4: UNIPA , 5: UMT

INTRODUCTION: Sarcopenia is a condition characterized by the age-related loss of skeletal muscle mass and function [1]. The overall estimates of prevalence are 10%, although population-based differences have been observed [2]. Given the fact that life expectancy and health status in developing countries such as Kosovo are lower as compared to the European average, the prevalence of sarcopenia could differ from other European countries. Therefore, the aim of the current study was (1) to assess the prevalence of sarcopenia in Kosovo, and (2) to evaluate the impact of various covariates on sarcopenia status.

METHODS: 238 adults (f: 47.5%, 68.4±5.3 y; m: 52.5%, 72.1±5.7 y) participated in this study. Sarcopenia was diagnosed using the EWGSOP algorithm using either published or population-derived (Kosovan, KS) gender-specific cut-points for handgrip strength (Jamar), gait speed (6m) and skeletal muscle index (SMI) [1]. IBM SPSS statistics was used to determine differences between continuous variables (independent t-test) and frequencies (Chi-square) as well as to ascertain the effects of age, gender, BMI, nutritional status, health status and educational level on sarcopenia status by binary logistic regression.
RESULTS: Our study population was characterized by a BMI of 29.8±4.7 kg/m² (f: 32.0±4.3 kg/m², m: 27.8±4.1 kg/m², p<0.001), a gait speed of 1.08±0.24 m/s (f: 1.03±0.26 m/s, m: 1.13±0.22 m/s, p<0.001), a handgrip strength of 30.1±8.8 kg (f :24.1±5.1 kg, m:35.4±8.0 kg, p<0.001), and a SMI of 9.9±1.4 kg/m² (f: 9.4±1.0 kg/m², m: 10.3±1.6 kg/m², p<0.001). The frequencies of low handgrip strength (EWGSOP: 21.0%, KS: 25.2%), low gait speed (EWGSOP: 36.1%, KS: 56.7%, p<0.001, and low SMI (EWGSOP: 5.9%, KS: 6.3%) were significantly higher when using KS-specific cut-points (p<0.001). Overall, the prevalence of sarcopenia was only 3.36% (EWGSOP) or 5.46% (KS). The logistic regression model was statistically significant, $\chi 2(8)=15.74$, p=0.046 explaining 46.3% of the variance in sarcopenia status. Increasing BMI and higher educational status were associated with a reduction in the likelihood of being sarcopenic.
CONCLUSION: We have shown that the prevalence of sarcopenia in Kosovo is lower as compared to other European and Non-European countries independent of the underlying calculation method [2]. Interestingly, age and gender did not contribute significantly to the development of sarcopenia, but higher BMI and educational status seem to be associated with a lower risk of developing sarcopenia. Although being "protective" against sarcopenia the high prevalence of obesity, especially in females, should be a matter of concern for general health status Kosovo [3,4].

OP-BN04 GAIT

WHAT IS UNIQUE IN INDIVIDUAL GAIT PATTERNS? UNDERSTANDING AND INTERPRETING DEEP LEARNING IN MOVEMENT ANALYSIS

HORST, F.1, LAPUSCHKIN, S.R.2, SAMEK, W.2, MÜLLER, K.R.3,4,5, SCHÖLLHORN, W.I.1

1: JOHANNES GUTENBERG-UNIVERSITY 2: FRAUNHOFER HEINRICH HERTZ INSTITUTE 3: TECHNICAL UNIVERSITY BERLIN 4: KOREA UNIVERSITY 5: MAX PLANCK INSTITUTE FOR INFORMATICS

INTRODUCTION: Although machine learning techniques such as (deep) neural networks are solving very successfully a plethora of tasks and provide new insights from complex physical, chemical or biological systems [1], in most cases they go along with the disadvantage of acting as a black box, rarely providing information about what made them arrive at a particular prediction. This black box manner is crucial especially in medical applications like gait analysis and strongly hamper their clinical acceptance [2]. In the context of personalised movement analysis, the aim of the study was to examine individual gait patterns by: (1) demonstrating the uniqueness of individual gait patterns using artificial neural networks; (2) decomposing the contribution of each input variable using Layer-Wise Relevance Propagation (LRP) [3]; and (3) explaining which variables at what time of the gait cycle are most relevant for the characterisation of gait patterns from a certain individual.
METHODS: A sample of 57 healthy participants (29 female, 28 male; 23.1 ± 2.7 years; 1.74 ± 0.10 m; 67.9 ± 11.3 kg) walked 20 times a distance of 10 m. Two force plates (Kistler, 1000 Hz) and ten infrared cameras (Qualisys, 250 Hz) recorded the three-dimensional ground reaction forces (GRF) and 12 segment full-body joint angles (JA) during a double step at a self-selected walking speed under barefoot conditions. The subject-classification was conducted by means of deep (convolutional) neural networks and the prediction accuracy was obtained as an average over a ten-fold cross-validation. In order to explain the prediction of an individual based on the participant's gait patterns, the input relevance of each input variable was decomposed using LRP.
RESULTS: Deep neural networks were able to predict the correct individual by average accuracies of 99.6% (GRF) and 100.0% (JA) and verified unique characteristics for individual gait patterns. By attributing portions of the prediction of artificial neural networks back to the input variables (time-continuous GRF and JA), LRP demonstrated which variables at what time of the gait cycle were most relevant for the characterisation of individual gait patterns.
CONCLUSION: The determination of characteristics that are specific for the movement patterns of a certain individual facilitates to support coaches and therapists during the individualisation of their treatments. By measuring the contribution of each input variable to the prediction of artificial neural networks, LRP presents a framework that enables to understand and interpret machine learning in (biomechanical) movement analysis.

RETENTION OF FALL RESISTING SKILLS OVER 1.5 YEARS IN OLDER ADULTS: EFFECTS OF PERTURBATION EXPOSURE AND PLANTAR FLEXORS NEUROMUSCULAR EXERCISE

EPRO, G.1, MIERAU, A.2,3, MCCRUM, C.4, LEYENDECKER, M.3, BRÜGGEMANN, G.P.3, KARAMANIDIS, K.1

1: LONDON SOUTH BANK UNIVERSITY, UK; 2: LUNEX INTERNATIONAL UNIVERSITY OF HEALTH, EXERCISE AND SPORTS, LUX; 3: GERMAN SPORT UNIVERSITY COLOGNE, GER; 4: MAASTRICHT UNIVERSITY, NL

INTRODUCTION: The plantar flexors play a crucial role in recovery from sudden disturbances to gait [1]. In a recent study [2] we demonstrated that older adults are able to increase their triceps surae (TS) muscle strength and Achilles tendon stiffness in response to 1.5 years

TS neuromuscular exercise intervention. The current work assessed whether such exercise-induced changes in the TS affects older adults' ability to retain improvements in reactive gait stability during perturbed walking acquired from single perturbation training sessions.
METHODS: Thirty-four older adults (65±7 years) participated in the study and experienced eight separate unexpected trip perturbations while walking on a treadmill. A motion capture system was used to analyse the margin of stability (MoS; state of the centre of mass in relation to the base of support) at touchdown of the perturbed step and six following recovery steps. In an additional session, dynamometry and ultrasonography were used to assess TS muscle-tendon unit mechanical properties and motor skill performance. The participants were enrolled either to a gait perturbation only training group (GAIT; n=13) experiencing eight trip perturbations during treadmill walking in two separate sessions (once at baseline and once after 14 weeks) or to a group completing the same as GAIT and in addition completing 1.5 years of combined TS neuromuscular exercise 2-3 times a week (GAIT+TS; over 14 weeks n=21; over 1.5 years n=12).
RESULTS: GAIT+TS group showed significantly ($p<0.05$) improved motor skill performance and higher maximal plantarflexion moments along with higher Achilles tendon stiffness after 14 weeks of exercise with no further adaptive changes after 1.5 years. No changes in TS neuromechancial properties were observed in the GAIT group between analysed time points. Regarding the tripping task, both groups were able to improve their recovery response (increased MoS at touchdown of the perturbed leg) in each perturbation training session ($p<0.05$). The GAIT group displayed a partial retention of the improvements in recovery response over both 14 weeks and 1.5 years ($p<0.05$). Despite the changes in TS neuromechanical properties in the GAIT+TS group, no further benefits for fall resisting skills were detected post 1.5 years of exercise.
CONCLUSION: The aged neuromotor system demonstrates a rapid plasticity to repeated exposure to unexpected perturbations and can retain these acquisitions in fall resting skills over a long time period (1.5 years), but an additional exercise-induced enhancement of TS neuromuscular capacities seems not to further augment the effects of perturbation training. Thus, in order to improve the ability to cope with gait disturbances, older adults may benefit more from exposure to unexpected gait perturbations than from interventions targeting to enhance lower limb neuromuscular capacities.

LIMITS OF AGREEMENT BETWEEN A MAGNETOMETER-INDEPENDENT INERTIAL SENSOR SYSTEM AND A MARKER BASED OPTICAL MOTION CAPTURE SYSTEM FOR 3D JOINT KINEMATICS IN GAIT ANALYSIS

TEUFL, W., MIEZAL, M., TAETZ, B., FRÖHLICH, M., BLESER, G.

TECHNISCHE UNIVERSITÄT KAISERSLAUTERN

INTRODUCTION: Inertial Measurement Unit systems (IMUS) provide a mobile alternative for gait analysis [1]. However, there are still drawbacks when considering IMUs. They are prone to magnetic distortions and the measurement of 3D joint kinematics lacks accuracy and validation against optical motion capture systems (OMCS). Hence, the aim of this study was to evaluate the agreement between a magnetometer-free IMU system and an OMCS regarding 3D joint kinematics of the lower extremity.
METHODS: 28 volunteers (15 females, 13 males) participated in the study. The subjects performed one trial of a 6 minute walking test. Global pelvis flexion and obliquity and left (LT) and right (RT) lower extremity 3D kinematics were simultaneously captured by means of seven IMUs and 32 retroreflective markers. Additionally, marker clusters were fixed to the IMUs to eliminate deviations due to soft tissue artefacts. Thus, the mere technical error between the systems was considered. IMU data was processed with an extended Kalman Filter approach [2] omitting magnetometer information. Limits of Agreement (LoA) were calculated per subject and gait cycle for all joint angles to evaluate the comparability of the present systems.
RESULTS: LoA ranged from $-1.3° \pm 0.5°$ to $1.4° \pm 0.7°$ (absolute mean $0.4° \pm 0.6°$). The global pelvis flexion revealed the less biased outcome with mean difference of $0.0° \pm 0.3°$. LT ankle rotation and LT knee rotation showed the biggest mean differences with mean values of $1.4° \pm 0.7°$ and $-1.3° \pm 0.5°$ respectively. Knee and ankle flexion showed the widest range of LoA with limits of $1.1° - 1.3°$.
CONCLUSION: Assessing the LoA analysis between a magnetometer-free IMUS and an OMCS showed mean differences similar to Robert-Lachaine et al. [3]. However, Robert-Lachaine et al. [3] reported limits ranging from $2.8° - 7.0°$. The present results showed limits in bounds of $0.3° - 1.3°$, therefore, indicating acceptable limits of agreement for applications in motion capturing. Ankle and knee rotation showed the highest LoA bias. This could be explained by the missing magnetometer data which can provide additional information in the transversal plane [2]. In summary, despite omitting magnetometer information, the examined IMUS revealed excellent agreement with an OMCS regarding the lower limb kinematics and the global pelvis flexion and obliquity. Therefore, this system provides a highly accurate and mobile alternative for the assessment of 3D joint kinematics of the lower extremity in gait analysis.

ADAPTATION AND INTER-LIMB TRANSFER OF GAIT STABILITY FOLLOWING PERTURBATIONS IN YOUNG AND OLDER ADULTS ASSESSED USING STABILITY-NORMALISED WALKING SPEEDS

MCCRUM, C.1,2, WILLEMS, P.1, KARAMANIDIS, K.3, MEIJER, K.1

1: MAASTRICHT UNIVERSITY, THE NETHERLANDS. 2: GERMAN SPORT UNIVERSITY COLOGNE, GERMANY. 3: LONDON SOUTH BANK UNIVERSITY, U.K.

INTRODUCTION: Healthy young and older adults show differences in gait stability recovery following perturbations but a similar capacity to adapt stability following repeated perturbations (McCrum et al. 2017; Bohm et al. 2015). However, it is not clear if walking speed differences seen with age affect stability and adaptation to perturbations. Here, we assessed if age differences are eliminated when walking speed is normalised to stability and if evidence of (age-dependent) inter-limb transfer of locomotor adaptations could be observed.
METHODS: 14 young (25±3y) and 10 older (73±5y) healthy adults participated. Measurements were conducted on a dual-belt treadmill (CAREN; Motekforce Link). 5 reflective markers (C7, trochanters and halluces) were tracked via motion capture (100Hz; 12 cameras; Vicon Motion Systems). To assess dynamic gait stability, the anteroposterior margins of stability (MoS; Hof et al. 2005; Süptitz et al. 2013) were calculated at foot touchdown. The walking speed that would result in MoS of 5cm was calculated for each subject based on MoS during unperturbed gait at various speeds (0.4m-1.8m/s). Subjects walked for four minutes at this speed and then experienced 10 treadmill belt

acceleration perturbations (3m/s^2 to 180% of walking speed), each occurring every 30-90s. The first and last perturbed the right leg, while the second to ninth repeatedly perturbed the left leg.
RESULTS: Two-way repeated measures ANOVAs with step (baseline and first eight recovery steps) and age group (young and older) as factors with Bonferroni corrections revealed that both the young and older adults required five recovery steps to return to baseline MoS following the first two perturbations (recovery step 4 differed to baseline: P<.05; no age group difference at step 5). After repetition with the left leg, both age groups required only three steps to return to baseline MoS (recovery step 2 differed to baseline: P<.05; no age group difference at any step). The final perturbation (right leg) again required five steps of both age groups to return to baseline MoS (recovery step 4 differed to baseline: P<.05; no age group difference at any step).
CONCLUSION: With the stability-normalised walking speed, no age differences were seen in number of steps to return to MoS baseline and adaptation of gait stability following repeated exposure occurred to a similar magnitude. Therefore, previously reported age differences in perturbed gait may be related to the walking speeds used in the studies. Adaptations in gait stability following repeated perturbations were restricted to the exercised limb, suggesting that healthy adults have a limited ability to transfer motor adaptations to gait perturbations between limbs, irrespective of age, which has implications for falls prevention.

RECOVERY RESPONSES AND ADAPTATIONS IN DYNAMIC STABILITY TO GAIT-TRIP PERTURBATIONS ACROSS THE ADULT LIFESPAN

KÖNIG, M., EPRO, G., SEELEY, J., POTTHAST, W., KARAMANIDIS, K.

LONDON SOUTH BANK UNIVERSITY

INTRODUCTION: Older adults show diminished recovery responses to a novel trip perturbation (Süptitz et al. 2013) and, in comparison to younger adults, tend to show lesser improvements in dynamic stability control in response to repeated unexpected surface compliance perturbations during walking (Bierbaum et al. 2011). However, little is known about adaptability in recovery responses to trip perturbations across the adult lifespan. Therefore the aim of the current work was to examine locomotor stability and its adaptability following repeated trip-inducing gait perturbations in young, middle- and older-aged adults.
METHODS: Ten young, ten middle- and ten older-aged adults (26±3, 50±6 and 72±5 years respectively) walked at 1.4 m/s on a treadmill and experienced eight separate unexpected trip perturbations. A custom-made brake-and-release system was used to apply a resistance to the swing phase of the right leg via an ankle strap. Thirteen reflective markers were tracked by a motion capture system (120 Hz; Vicon Motion Systems, UK). The anteroposterior margins of stability (MoS – the situation of the centre of mass in relation to the base of support; Hof et al. 2005) were calculated at foot touchdown (TD) of the perturbed leg and for six subsequent recovery steps, using accelerometers placed on both tibias. In order to determine potential age-related differences in adaptive changes in dynamic stability, the recovery responses for the first and eighth trip perturbation trial were considered.
RESULTS: Gait-trip perturbations caused a significant ($p<0.05$) reduction in the MoS at TD of the perturbed leg compared to baseline (unperturbed) walking, leading to negative MoS values, with no differences between the age groups. After the first perturbation trial, middle- and older-aged adults required more recovery steps to return to baseline MoS compared to younger adults. After experiencing eight trip perturbations all age groups showed an improved recovery response (increased MoS at TD of the perturbed leg and for the following recovery steps; $p<0.05$) and returned back to baseline MoS with fewer recovery steps when compared to the first perturbation trial.
CONCLUSION: We conclude that the ability to control locomotor stability during perturbed walking is already diminished by middle age, increasing fall risk, but that ageing may not inhibit the neuromotor system from adapting reactive motor responses to trip perturbations. Thus, in order to improve the ability to cope with unexpected gait perturbations and potentially reduce falls risk, middle- and older-aged adults may benefit from repeated exposure to unexpected trip perturbations.

IN FIELD MONITORING OF IMPAIRMENTS IN HUMAN GAIT

ROY, S.H., SHIWANI, B., KLINE, J.C., SAINT-HILAIRE, M.H., THOMAS, C.A., DE LUCA, G.

DELSYS INC. AND ALTEC INC.

INTRODUCTION: Advances in motion capture systems and instrumented force plates have enjoyed widespread use and acceptance for assessing gait abnormalities in laboratory settings. However, there remains a need for a portable system that can provide comparable quantitative metrics of gait impairments outside of the laboratory for clinical, athletic, and home environments.
METHODS: Our group is developing a mobile system of body-worn sensors and automated detection algorithms that provide in-field assessment of clinically relevant characteristics of gait that are of minimal encumbrance to the user and operator. The system tested uses a single sensor to record surface electromyographic activity and inertial measurement from the tibialis anterior muscle of the lower leg. With these data, we designed algorithms to autonomously detect and monitor, in real-time, 3 key characteristics of gait: 1> Angular range and speed- to assess and understand the movements of leg in its natural physiological form of angular displacements; 2> Muscle Activity- to analyze the muscle activation patterns during different phases of the gait cycle; and 3> Heel strike and Toe-off mechanics- to analyze coordination in take-off and landing mechanics of the foot. We tested our system in a case study of post medication monitoring among n=6 patients with Parkinson's disease gait symptoms during unscripted activities for a 3-hour period in a simulated home setting.
RESULTS: We successfully detected the instances of gait during these unscripted activities with 99.5% accuracy from all patients tested using our automated detection algorithm. All 3 objective gait metrics were significantly different when comparing data from ON and OFF periods determined by annotation of video recordings by movement disorder experts. The results indicate that a single body-worn sensor system can provide clinically-relevant gait metrics to evaluate therapeutic interventions in Parkinsons disease.

CONCLUSION: A version of this system is under development to enhance its usability in the field by interfacing it with a handheld tablet and accommodating a greater number of wireless sensors. The final system will facilitate point-of-care gait monitoring for clinicians and therapists working with patients with neurological and musculoskeletal disorders to make real-time objective assessments in the clinic or community.

CONTRIBUTION OF ACHILLES TENDON MECHANICS TO PLANTARFLEXION TORQUE STEADINESS IN PERSONS WITH PARKINSONS DISEASE

SMART, R.R.1, RICHARDSON, C.M.1, WILE, D.2, DALTON, B.H.1, JAKOBI, J.M.1

1: SCHOOL OF HEALTH AND EXERCISE SCIENCES, UNIVERSITY OF BRITISH COLUMBIA OKANAGAN, KELOWNA, BC CANADA; 2: SOUTHERN MEDICAL PROGRAM, UNIVERSITY OF BRITISH COLUMBIA OKANAGAN, KELOWNA, BC CANADA

INTRODUCTION: Parkinsons disease (PD) is associated with increased muscle rigidity (1) and reduced torque steadiness (TS) (2). As TS depends on a smooth transfer of force from muscle to bone via tendons, it is important to understand how tendon mechanics are influenced by PD and determine whether these properties influence TS. Our purpose was to determine how Achilles tendon (AT) mechanics contribute to plantar flexion (PF) TS in persons with PD compared to age- and sex-matched controls. We hypothesized that maximal torque, AT strain, and stress would be lower in persons with PD contributing to reduced TS relative to controls.
METHODS: Nine persons with PD (6 female; 70±5 yrs) tested in the "ON" phase of their dopaminergic medication cycle, and 9 age- and sex-matched controls (70±7 yrs) performed isometric PF maximal voluntary contractions (MVCs) and 5-s submaximal torque-matching contractions of 5, 10, 25, 50 and 75% MVC. Coefficient of variation (CV) was used to evaluate TS. The AT cross-sectional area at rest and elongation during contraction were recorded via ultrasound to determine tendon stress and strain. The influence of MVC and tendon mechanics on CV of torque was evaluated at low (5, 10% MVC) and high (25, 50, 75% MVC) torques using forward multiple regressions.
RESULTS: The PD group was weaker (84.6±26.3Nm) and less steady (4.3±2.2%) than controls (113.8±28.0Nm; 2.14±1.0%; $p<0.05$). Tendon strain was less in persons with PD (4.9±1.1%) than controls (7.2±1.5%) from 50% to MVC ($p<0.05$). Tendon stress did not differ between persons with PD (1.17±0.42MPa) and controls (1.22±0.36MPa; $p>0.05$). At low torques, MVC (r2: 0.39-0.57) and strain (r2: 0.16-0.17) predicted reduced CV of torque in PD and control groups ($p<0.05$). At high torques, MVC (r2: 0.26) and stress (r2: 0.26) predicted reduced CV of torque in controls.
CONCLUSION: Our findings indicate that persons with PD during the "ON" phase of dopaminergic cycle are less steady than age- and sex-matched controls, and this is associated with muscle weakness. At low torques greater strain improved the buffering of torque fluctuations in controls and thereby led to steadier contractions compared to PD group. The contribution of strength was further evident in controls, as stress and MVC predicted enhanced steadiness at high torques, yet not in persons with PD. Thus, muscle strength is the strongest factor in producing steady isometric contractions in those with PD.

GAIT ADAPTATIONS TO TREADMILL TRAINING IN PARKINSON'S PATIENTS: EFFECTS OF PERTURBATION, SUSTAINABILITY, AND MODERATORS

STEIB, S.1, KLAMROTH, S.1, GAßNER, H.2, PASLUOSTA, C.3, ESKOFIER, B.3, WINKLER, J.2, KLUCKEN, J.2, PFEIFER, K.1

FAU ERLANGEN-NÜRNBERG

INTRODUCTION: Gait impairment is a major symptom in Parkinson's disease (PD), and treadmill training is an effective non-pharmacological treatment option (Mehrholz et al., 2015). This secondary analysis of an eight-week interventional trial aims at investigating i) the time course and sustainability of gait adaptations, ii) the effects of additional perturbations during treadmill walking, as well as iii) potential moderators of training effects.
METHODS: 38 PD patients (Hoehn &Yahr 1 – 3.5) were randomly allocated to eight weeks of treadmill training, performed twice-weekly for 40 minutes either with (PTT, n=18) or without (CTT, n=20) additional perturbations to the treadmill surface (Steib et al., 2017). Spatiotemporal gait parameters related to pace, rhythm, symmetry, and variability of gait were assessed during treadmill walking on a weekly basis (T0 – T8), and after three months follow-up (T9). Linear mixed models (random intercept and slope) were specified for each dependent variable (gait parameters) to evaluate within- and between-group changes over time. Moderators were successively included as covariates: age, gender, UPDRS motor score, cognitive function (MOCA), balance (MiniBESTest), and gait speed. Effect sizes are reported as Cohen's d.
RESULTS: Both groups significantly improved gait variability, with positive effects already observed after three weeks of training. The strongest effects were seen in stride time CV in the PTT group ($p<.001$; $d=0.81$), and stride length CV in the CTT group ($p<.001$; $d=0.84$). Gait parameters related to pace and rhythm (stride length, stride time, stance phase, swing phase) improved in the PTT group only, with a significant between-group interaction effect for stride time ($p=.05$; $d=0.33$). Improvements in the PTT group were sustained until T9, while rhythm and variability of gait significantly worsened in the CTT group. Age (stride time CV: $p=.04$; $d=-0.35$) and balance performance significantly moderated improvements in gait variability (stance time CV: $p=.03$; $d=-0.36$).
CONCLUSION: Treadmill therapy substantially improved gait variability in PD, with first positive effects observed after six sessions. Adding postural perturbations during training improved pace and rhythm of gait, and appeared to produce more sustainable effects. Older patients and those with lower balance performance demonstrated larger improvements in stride-to-stride variability.

WALKING BIOMECHANICAL IMPROVEMENTS AFTER 6 WEEKS OF NORDIC WALKING TRAINING IN PATIENTS WITH PARKINSONS DISEASE

FAGUNDES, A.O.1, MONTEIRO, E.P.2, FRANZONI, L.T.3, PANTOJA, P.D.1, OLIVEIRA, H.B.1, CUBILLOS, D.M.1, GOMEÑUKA, N.A.1, MARTINEZ, F.G.1, PAGNUSSAT, A.S.2, PEYRÉ-TARTARUGA, L.A.1

UNIVERSIDADE FEDERAL DO RIO GRANDE DO SUL

INTRODUCTION: Gait disorders are cardinal clinical symptoms of Parkinsons disease (PD). Walking training has been indicated in the literature as a therapeutic tool for gait rehabilitation. In this way, our purpose was to compare the effects of a training program, of Nordic walking (NW) and free walking (FW), on biomechanical parameters, in patients with PD.
METHODS: The sample comprised 33 participants, aged above 50 years, of both sexes, with a clinical diagnosis of idiopathic PD, with the staging of 1-4 in the Hoehn and Yahr scale (H&Y). The participants received two types of intervention: Nordic walking training program (n = 16) and free walking training program (n = 17), during six weeks. Aiming to evaluate the effects of the training program, the participants underwent the tests in the following period: pre-training and post-training. The biomechanical parameters studied were the spatiotemporal parameters during walking and amplitude of the EMG signal of the Vasto Lateralis (VL), Tibialis Anterior (TA), Biceps Femoris (BF) and Gastrocnemius (GM) muscles, initial activation threshold (onset), final activation threshold (offset) and activation time. Outcomes were analyzed using the Generalized Estimates Equations (GEE), to compare groups (NW and FW) and moments (T1 and T2). The Bonferroni post-hoc was used to identify differences between effects and interactions. A significance level of 0.05, was adopted.
RESULTS: There was a reduction in contact time (CT), swing time (ST), stride length (SL) and stride frequency (FP), for NW when compared to FW ($p < 0.05$). Regarding the neuromuscular parameters, an increase in the amplitude of the VL and BF EMG signal, reduction of the final activation threshold (offset) of the VL and GM ($p < 0.05$), reduction in the activation of the VL and BF ($p < 0.05$) and reduction in the co-contraction index of the TA and GM ($p < 0.05$), were found for the NW group, whereas the FW group showed statistically significant improvements only in the amplitude of GM when compared to the NW group.
CONCLUSION: The NW improved the sensory afferents due to the upper limb use, and this enabled the increase of the cortical sensorimotor integration. Therefore, this cortical integration contributed to the gain of motor skills of patients undergoing NW training (Reuter et al., 2011; Fritz et al., 2011). There were greater positive effects after a period of training of NW, indicating that the effects of the NW training were more efficient than the FW.

THE EFFECTS OF NORDIC WALKING ON ASYMMETRY IN MUSCLE'S STRENGTH OF THE LOWER LIMBS AND ON OXIDATIVE STRESS IN PARKINSONS DISEASE

FRACCA, I.1, FONSECA, G.2, LANZA, M.3, VOLPE, D.4

1: STUDIO PREVENZIONE E SALUTE ; 2,3: DEPARTMENT OF NEUROSCIENCES, BIOMEDICINE AND MOVEMENT SCIENCE, UNIVERSITY OF VERONA ; 4FRESCO INSTITUTE FOR ITALY VILLA MARGHERITA

INTRODUCTION: We have analyzed the effects of Nordic Walking (NW) on asymmetry in muscle's strength of lower limbs and on oxidative stress mechanisms in Parkinson's disease.
METHODS: Twenty-nine patients with PD (1-3 Stage Hoehn & Yahr in ON medication) agreed to participated to a multidisciplinary intensive rehabilitative program for 4 weeks. They were randomly assigned in two groups: a Control group (Ctrl) composed by 12 patients and an experimental group (Exp) composed by 17 patients that practiced additional NW 60 minutes, twice a week. As instrumental outcomes we used Peak Torque right and left leg and markers of oxidative stress (AU/CR markers, 8OHdG, 2dG, 8-OH/2dG, HCY, 3NT). As clinical outcomes, we used UPDRS III, PDQ-39, BBS, FES, FOG-Q, TUG, 6MWT. Measures were taken at the beginning (T0) and at end of training (T1). Chi-squared Test, Test-T and two-way ANOVA for repeated measures were used.
RESULTS: In Exp there was a trend towards the symmetry of lower limbs strength. Moreover, Exp showed a reduction in HCY compared with Ctrl where it increased. The 8-OHdG / 2dG ratio seems to have a higher trend in Exp with 2dG increased.
Significant improvement was found for all subject in: UPDRS III ($P < 0.001$), BBS ($P=0.002$), 6MWT ($P<0.001$), TUG ($P<0.05$), PDQ-39 ($P=0.006$), FoGQ ($P=0.001$). PDQ-39 and FoGQ improve ($P < 0.05$) in Exp but not in Ctrl. FES do not shows variation.
CONCLUSION: This pilot study confirms that NW, as well as a good workout, is a valid rehabilitation strategy, contributes to correct the asymmetry in muscle's strength and improves REDOX status, increasing markers of DNA repair and decreasing markers of oxidative stress.

SPRINT EXERCISE IN PARKINSON'S DISEASE PATIENTS: A PILOT STUDY

MONTEIRO, E.1,2, PEYRÉ-TARTARUGA, L.A.2, SOARES, E.2, ZANARDI, A.P.2, MORIN, J.B.3, PAGNUSSAT, A.S.1

FEDERAL UNIVERSITY OF SCIENCE OF HEALTH OF PORTO ALEGRE

INTRODUCTION: Parkinson's Disease (PD) is the second most prevalent neurological disorder in the world, with progressive loss of muscle control and power output. Exercise is recommended in PD for its neuroprotective effect (Alberts et al., 2011). Training programs transitioning from walking to running with pole may induce positive outcomes in neural function and functional mobility (Monteiro et al., 2017). Furthermore, since a single bout of high-intensity exercise promotes changes in the motor cortex neuroplasticity of healthy subjects, it is reasonable to expect that sprint exercise (i.e. short bouts of maximal intensity running) performed after an adapted, progressive training

program, would be beneficial for PD patients. The aim of this pilot study is to test a protocol for describing sprint performance and mechanics in PD patients.
METHODS: 14 male PD patients (1 to 3 on Hoehn and Yahr Scale), followed a transition training program from speed walking to running with poles and then performed two maximal 30-m sprint accelerations (5-min rest). Sprint performance (20 and 30m time) and the main mechanical outputs (theoretical maximal velocity V0, maximal horizontal force F0, and power Pmax) were obtained from high-speed video recording (240 frames/s) and the iPhone 6 App "MySprint" (Samozino et al., 2016). Descriptive data are mean and standard deviation.
RESULTS: The patients studied had the following characteristics: age: 65.1(7.4) yrs, body mass: 77.8(7.0) kg, stature: 1.69(0.04) m, time with PD: 5.5(3.2) yrs, and clinical UPDRS III: 16.8(7.1). The between-trial coefficient of variation for all variables was 6.4(0.05)%. Their 30- and 20-m time were 7.67(1.2) s, and 5.36(0.8) s, respectively. Mechanical outputs were 4.64(0.9) m/s for V0, 5.16(0.8) N/kg for F0, and 6.02(1.2) W/kg for Pmax.
CONCLUSION: This pilot descriptive study showed the feasibility of sprint exercise in PD patients. The performance and mechanical responses observed were consistently lower or within the range of values found in trained master athletes (Pantoja et al., 2016). Furthermore, field observations revealed that during sprinting, patients needed to focus their attention on finalizing the task and did not experience freezing. This study brings encouraging insights into the feasibility and potential benefits of using the sprint exercise in functional training for PD patients.

A FEASIBILITY STUDY FOR A UNIVERSITY-BASED COMMUNITY EXERCISE PROGRAMME FOR PEOPLE WITH PARKINSONS DISEASE

MCGRATH, D., MCMAHON, L., WALSH, A., CUNNINGHAM, C., LENNON, O.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: This study investigated the feasibility of a university-based community exercise programme for people with Parkinson's disease (PwP). It is well known that exercise can improve symptoms and quality of life in PwP. However, many barriers to exercise have been documented for PwP, including lack of information and referral to physiotherapy services, disease-specific issues such as fatigue and depression, setting-related issues such as walking distances, low expectations from exercise, lack of time to exercise, cost and fear of falling. Given the complexity of these issues, any potential exercise service or research undertaking with PwP requires an initial feasibility study to ensure that the intervention is: safe and acceptable to the target population, addressing a real demand, integrated into users' lives, practical for intervention providers, implementable in other settings and shows some level of efficacy1. This study sought to address these issues.
METHODS: Twenty-three PwP were recruited to a 12 week exercise programme taking place at the University College Dublin sports centre. Participants were asked to attend 3 exercise sessions/week, if possible: circuit training, spinning and Tai Chi, and one health coaching session every 2 weeks. Exercise classes were delivered or supervised by an occupational therapist or physiotherapist. Participants were screened by a physiotherapist prior to being enrolled in the programme at which point a timed-up-and-go test (TUG) and 6 minute walk test (6MWT) were recorded. These measures were also recorded at 6 weeks and at 12 weeks. Qualitative interviews were conducted with all participants in weeks 10-12 with resultant data analysed using thematic analysis.
RESULTS: Preliminary data analysis demonstrates a statistically significant reduction in TUG time ($p=0.025$) and a strong trend towards increased 6MWT (23.7 m) at the 6-week mark. There were no drop-outs from the intervention with attendance at classes greater than 90%. Prevalent themes from the qualitative data were enjoyment, support, sense of community, increased motivation for exercise, sense of well-being and concern around termination of the programme. Once or twice a week was seen to be the optimal class frequency, given the challenge of travelling to UCD. Participants enjoyed being part of the fabric of the university and accessible café facilities enhanced the psycho-social benefits of the programme, which were critical to its success.
CONCLUSION: A university sports facility is an ideal setting for a community-based exercise programme from the perspective of PwP, while also providing learning opportunities to students. Universities' health promoting capacity can be developed through engaging their local communities in health promoting activities, particularly in underserved populations. PwP would need supported navigation to and within campus and parking in close proximity to exercise studios.

OP-PM42 Training adaptation

MICROPAUSE RUNNING: A VIABLE ALTERNATIVE TO MODERATE INTENSITY CONTINUOUS RUNNING

WALSH, A., DELAHUNT, E., MATTHEWS, J., BOREHAM, C.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Although the health benefits of regular exercise, such as running, are well known, a lack of time and the unpalatable nature of vigorous effort hinder large sections of the population from participation in routine physical activity. Currently unpublished findings suggest running that incorporates short breaks (micropauses) of either 15 seconds (MP15) or 30 seconds (MP30) is more palatable than moderate intensity continuous running (MIC) in recreationally active young males. As there is a need for exercise interventions suitable to broad populations, this study was conducted to compare the subjective response of recreationally active young females to these protocols.
METHODS: Following institutional ethics approval, 15 recreationally active females (age = 21.2 ± 1.3 years, body mass= 62.9 ± 2.6kg, height= 166.3 ± 4.1cm) were tested on three separate occasions under controlled laboratory conditions with one week between sessions. One week following a preliminary VO2max assessment, participants performed MIC at 65% of their VO2max, running until they expend-

ed 400kcal of energy. Participants' Rate of Perceived Exertion (RPE) was measured at regular intervals throughout the run. Blood lactate concentration (BLa) was assessed immediately post exercise, following which, participants completed the Physical Activity Enjoyment Scale (PACES) and Physical Activity Affect Scale (PAAS). On the two subsequent testing days, participants completed the micropause protocols, running at 80% of VO2max with passive rest of either 15 or 30 seconds interspersed at 3-minute intervals throughout their respective runs. Energy expenditure was isocaloric across protocols and all other methodology was standardised across testing sessions.
RESULTS: The PACES score was significantly higher (P<0.05) in MP15 (84.3 ± 7.9) and MP30 (89 ± 6.8) than MIC (77.7 ± 5.9) while there was no significant difference between MP15 and MP30. There were no significant differences on the positive, negative or fatigue subscales of the PAAS across the three protocols. RPE was significantly higher (p<0.05) in MP15 (16 ± 1) and MP30 (16 ± 1.2) compared to MIC (13 ± 1.6). BLa was significantly higher (P<0.05) in both MP15 (4.8 ± .5mmol/L) and MP30 (4.5 ± .5 mmol/L) than MIC (2.1 ± 0.4 mmol/L).
CONCLUSION: Micropauses resulted in higher levels of enjoyment than MIC, with no difference found between micropause protocols. Micropause running was conducted at a higher intensity than MIC resulting in higher BLa accumulation and RPE scores. Although metabolic strain, and perceived exertion were higher in the micropause protocols, they were perceived as more enjoyable and no more fatiguing than the lower intensity MIC post-exercise. These results are reflective of a male population, and support the use of micropause running as a viable alternative to MIC.

IMPROVEMENTS IN 12-MINUTE RUN PERFORMANCE, PEAK OXYGEN UPTAKE AND MUSCULAR OXIDATIVE ENZYMATIC POTENTIAL ARE RELATED TO INITIAL LEVEL

KILEN, A., NORDSBORG, N.

DANISH ARMED FORCES HEALTH SERVICES

INTRODUCTION: It is evident that humans respond differently to exercise training. It was hypothesized that improvements in both a 12-minute run test, peak oxygen uptake and muscular oxidative enzymatic potential would be dependent on the initial level. Moreover, it was hypothesized that changes in the 12-minute running test would correlate to peak maximal oxygen uptake as well as muscular oxidative potential.
METHODS: A total of 287 conscripts volunteered to participate in a training study for the first 9 weeks of their Basic Army Training program. Weekly cardiovascular training included 30 minutes of running and 30 minutes of muscle endurance training with increasing intensity over the 9 weeks. Besides the scheduled physical training, the army basic training program consisted of low intensity aerobic activity for an average of 20 hours per week, such as closed order drills, loaded marching and low intensity running. Pre and Post testing included a 12-minute run test, a peak oxygen uptake test on a treadmill and muscle biopsies. The conscripts were divided into three equal sized groups, low (LO), medium (ME) and high (HI), according to their initial level of the 12 minute run test, peak oxygen uptake and enzyme activity of citrate synthase (CS) and beta-hydroxyacyl-CoA dehydrogenase (HAD) respectively.
RESULTS: All three groups improved the distance covered in the 12-minute run test and peak oxygen consumption from pre to post. LO significantly increased both more than ME and HI (Lo: 346±206; Me: 156±166; Hi: 81±152 meters, n=209 and Lo: 845±654; Me: 156±512; Hi: -103±565 ml O2*min-1, n=63 respectively, P<0,01). ME improved significantly more in the 12-minute run test than HI (P<0.05) but not peak oxygen uptake. CS (n=65) and HAD (n=63) enzyme activity increased in LO (9,5% and 2,3% respectively) and decreased in ME and HI (ME: 10,1% and 9,7%, HI: 20,1% and 18,8% respectively). There were a weak non-significant correlation (r2<0.10) between adaptations in the 12-minute running test and altered maximal oxygen uptake as well as muscular oxidative potential.
CONCLUSION: The present results support the hypothesis that improvements in both run performance, peak oxygen uptake and muscular oxidative enzymatic potential are dependent on the initial level. A higher initial level within each parameter resulted in a lower adaptation. However, the results do not support the hypothesis that the change in the 12-minute run test would correlate to the change in peak oxygen uptake or muscular oxidative potential.

BLOOD PRESSURE CHANGES DURING SELF-PACED OUTDOOR WALKING IN MIDDLE-AND OLDER INDIVIDUALS AND EVIDENCE-BASED EXERCISE PRESCRIPTION TO EFFICIENTLY DECREASE ARTERIAL STIFFNESS

OTSUKI, T., ISHII, N., NAKAMURA, F., ZEMPO-MIYAKI, A.

FACULTY OF SPORT AND HEALTH SCIENCES, RYUTSU KEIZAI UNIVERSITY

INTRODUCTION: Exaggerated elevation of systolic blood pressure (SBP) during exercise is a risk factor for future cardiovascular disease. We also demonstrated that product of SBP and heart rate during aerobic exercise is correlated with arterial stiffness (Otsuki T et al. Hypertens Res 29: 65-73, 2006), an independent risk factor for cardiovascular disease. Identification of factors affecting on SBP changes during exercise might be of significance for attenuating excessive SBP elevation, leading to an efficient improvement in arterial stiffness by aerobic exercise training. However, there is little information regarding SBP changes during practical outdoor exercise.
METHODS: To explore factors relating to SBP changes during practical outdoor walking, 109 subjects (47–83 years of age) walked outdoors at their own pace wearing a blood pressure monitor on their wrist. In addition, a 6-week intervention study (walking, 3-5 d/wk, 30-60 min/d, 65-75% of maximal heart rate) was performed to investigate effects of exercise prescription based on our findings; subjects were asked to walk at a normal pace for first 10 minutes of walking and at a subjectively assessed fairly hard pace, somewhat faster than their normal walking pace, or both after the lapse of 10 minutes. Arterial pulse wave velocity (PWV), an index of arterial stiffness, was measured before and after the intervention period.
RESULTS: SBP increased during walking compared to rest, but was higher at the 1 km mark than both the 2 and 3 km marks (rest, 124±14 mmHg; 1 km, 140±16 mmHg; 2 km, 136±18 mmHg; 3 km, 135±18 mmHg). SBP at rest, air temperature, body mass index (BMI), and walking intensity during the first 1 km were identified as predictors of SBP at the 1 km mark in the stepwise regression analysis, independent of other confounders (R2=0.606). SBP at the 1 km mark was independently higher in the lower temperature group (11.6–14.3 °C, 145±14 mmHg) than in the intermediate (15.1–16.7 °C, 140±18 mmHg) and higher (17.0–19.6 °C, 136±16 mmHg) temperature groups. In the intervention study, PWV in the training group decreased after the intervention. In the control group, there were no differences in PWV.
CONCLUSION: These results may imply that measures should be taken against the cold on cooler days and an appropriate walking pace would be preferable to attenuate the SBP response during the onset of walking. A lower walking pace during the onset of walking followed by a faster pace may be preferable to efficiently decrease arterial stiffness.

THE ADVANTAGES OF ENERGY TENNIS PROGRAM IN TEACHING TECHNIQUE TO CHILDREN

HEGAZY, K.1,2, SCHMIDT, S.1, WOLL, A.1

1: KIT , 2: UA

INTRODUCTION: Tennis playing necessitates a high complexity of movements. The formation and training in sport must be considered as a unity of coordination, conditioning, technique, tactics, mentality, and social environment (Schönborn, 2000). Moreover, an important aspect that the trainer should keep in mind is that the players are having fun and experiencing early success (Minihan, 2008). Progressive tennis programs aim to combine all aspects. Therefore, the present study aims to investigate the effectiveness of the Energy tennis program (NRGTennis) in teaching tennis to children.
METHODS: A total of 30 children from Tennis Club Singen in Germany, aged between 7 and 11 years old participated in the study. The training unit started with warming up (10 min.) which included running games, then the children were divided into groups of maximum 5. The groups practiced different coordination exercises in stations (30 min.) using tennis balls, rackets, jumping rope, basket balls, split steps, keeping the tempo between all. Further they were divided into groups according to their performance level and practiced tennis skills (forehand, backhand, volley and serve) gradually from easy to difficult (45 min.), with increasing ball contact and keeping the tempo. Last part included stretching exercises (5 min.). The physical fitness test included speed evaluation, rope jumping, basketball dribble, ball throw, dynamic balance and flexibility.
RESULTS: The results of ANOVA with repeated measurements showed a highly significant interaction effect between time and group in tennis technical skills ($F_{1,55}=22.5$; ETA2=.29) and physical fitness exercises ($F_{1,41}=19.8$; ETA2=.33).
CONCLUSION: The improvement of tennis skills performance and physical fitness level indicated that the NRGTennis program has a good impact on learning tennis for children. The advantages of the program are that the lesson aim is very clear, the training is continuous and the lesson is done progressively from easy to difficult, from small to big distance, from slow to fast, from big to medium and small targets, first getting used to the ball and racket, then playing without partner and lastly playing with partner.

OP-PM76 Injury

MOUNTAIN BIKE RELATED INJURIES - FREQUENCIES AND CORRELATIONS AMONG AMATEUR AND PROFESSIONAL MALE ATHLETES.

STOOP, R.1, HOHENAUER, E.1,2,3, VETSCH, T.1, CLIJSEN, R.1,2,3

1: SUPSI , 2: THIM , 3: VUB

INTRODUCTION: Mountain biking has developed into a popular sport performed by both amateurs and professionals. Physical activity is often related to an increasing risk of injury which may lead to high socioeconomic costs. To avoid accident-related injuries, each racing discipline demands its own set of specific skills and training regimens. The aim of this study was to perform a descriptive analysis of the causes and effects of mountain biking related injuries in amateur and professional male athletes.
METHODS: A survey of mountain biking related injuries was conducted on the participants of the Swiss Epic mountain bike event in 2017. The survey included 25 questions and was translated into English, French, Italian, Spanish and German. The questions focused on correlating racing experience, training hours and usage of protection, the possible reasons for accidents, the injury mechanisms, the severity of and recovery from injuries. Exclusion criteria were set a priori. Incomplete data reporting and participants without injuries were excluded from this analysis.
Descriptive statistics were used to analyze the data. Spearmans correlation rank tests were applied. A significance level of alpha = 0.05 was accepted.
RESULTS: After data screening, n = 99 from returned n = 139 questionnaires were assessed for eligibility, from which n = 29 athletes reported never being injured. Thus, n = 70 questionnaires were analyzed. For amateurs, significantly positive correlations were found between the number of injuries and the injured body location , bone fractures and the trunk region , joint injuries and the foot/ankle region , soft tissue injuries and lower extremity body sites , head injuries and concussions . For professionals, a significantly positive relationship between soft tissue injury and hip/thigh region was detected . There was a negative correlation between injury frequency and the use of protective gear . A significantly positive correlation between the amount of protective gear worn and return to sport in days was found .
CONCLUSION: Our results demonstrate that skill level, experience and training hours positively affect the incidence of mountain bike related injuries. No correlation was found for the wearing of protective gear and the occurrence of musculoskeletal injuries. Furthermore, the usage and amount of protective gear does not alter injury frequency, indicating that this cannot replace training load and experience. Therefore, the use of protective equipment might create a false sense of security especially for amateur mountain bikers.

TRACKING SEASON CONTINUITY TO ESTIMATE INJURY INCIDENCE IN DISTANCE RUNNERS AMONG COLLEGIATE PROGRAMS USING PUBLICLY AVAILABLE DATA

BURNS, G.T., LEE, M.J., ZERNICKE, R.F.

UNIVERSITY OF MICHIGAN

INTRODUCTION: Over 30,000 collegiate distance runners compete each year in the NCAA, yet there are no publicly available records of injury incidence across universities. Thus identification of institution-level factors related to injury risk (e.g., athletic expenditure, geographic location, or coaching tenure) are difficult to systematically investigate. Many distance runners compete in both an indoor and outdoor track and field season, and the results of all competitions are available publicly. Individual athlete continuity across seasons may provide an of estimate injury incidence within and across institutions. We hypothesized that season continuity rates could be calculated from

publicly available track and field competition results, and that institution-level season continuity would be predicted by their conference and the amount of annual athletic expenditure.
METHODS: Competition results from 60 NCAA Division I indoor and outdoor track and field conference championship meetings were scraped from the Track & Field Results Reporting Service (TFRRS). Season continuity rates (SCR) were calculated based on the presence of individuals in distance races (1500m–10,000m) in each of the indoor and outdoor seasons for each institution. Total athletic expenditure (TAE), athletic expenditure per athlete (AEpA), and average institutional coaching salary per athlete (CSpA) were mined for each institution. A linear model was used to determine contributions of these factors to the SCRs.
RESULTS: SCR was calculated for 96 teams from 57 institutions (39 male; 57 female) across 5 conferences. Average SCR was 0.73±0.16 across teams. Mean TAE was $49,756,689±31,872,120, mean AEpA was $92,789±42,446, and mean CSpA was $16,805±7,011. From 2010 to 2015, SCR varied significantly between institutions ($p < 0.001$) and between conferences ($p < 0.001$), but not between sexes. The conference with the highest SCR was the Western Athletic Conference (0.81), while the conference with the lowest SCR was the Mid-American Conference (0.68). No financial measures were significant predictors of a team's SCR.
CONCLUSION: This investigation created a new measure to track and compare season continuity in collegiate-level distance runners using publicly available data. A key reason for an individual's lack of participation across seasons is injury, so the SCR can be an indirect indicator of a team's injury incidence. The SCR varied across institutions and conferences, but it was not related to the institution's athletic expenditures. This suggested that season continuity and injury in collegiate distance runners was related to cultural factors and pressures unique to teams and geographic regions, rather than their monetary resources. Additional factors, such as coaching tenure, roster size, and season performance can be mined, in the future, to expand this preliminary investigation. Furthermore, the data mining methods developed, here, can be replicated in other sports to track various metrics using web-based public data.

OVERUSE AND TRAUMATIC INJURIES IN YOUTH ELITE SOCCER: GROWTH AND MATURATION MATTER!

ROMMERS, N.1,2, RÖSSLER, R.3,4, WITVROUW, E.2, GOOSSENS, L.2, VAEYENS, R.2, LENOIR, M.2, D'HONDT, E.1,2
1: VRIJE UNIVERSITEIT BRUSSEL , 2: GHENT UNIVERSITY , 3: VU UNIVERSITY AMSTERDAM , 4: UNIVERSITY OF BASEL

INTRODUCTION: Elite-level youth soccer involves a significant injury risk. Moreover, this risk is known to increase during periods of growth. Previous research identified age and anthropometric variables as risk factors for injuries but these risk factors have not been investigated together, nor regarding specific types of injuries. Therefore, the aim of this study was to assess the role of age, growth rate, weight change, maturational timing and training exposure in all injuries as well as in overuse and traumatic injuries in elite-level youth soccer players.
METHODS: 318 elite-level male soccer players between 9 and 15 years of age (mean age: 11.64 ± 16.69 years) were followed during one competitive season (2016-2017). At the start and the end of the season, body height, body weight and sitting height were measured. These anthropometric variables were then used to determine the standardised growth rate, standardised weight change and the age-specifically standardised age at peak height velocity. Injuries were registered by the medical staff of each participating Belgian youth academy (N = 4) using a standardised injury report form. Average weekly training exposure was calculated per team over the season. Incidence risk ratios (IRR) of potential risk factors were investigated using multivariable Poisson or negative binomial regression models (according to best fit) for all injuries as well as for overuse and traumatic injuries separately.
RESULTS: A total of 297 injuries (134 overuse and 163 traumatic injuries) were registered in 156 players during the competitive season. Only a higher age was a risk factor for all injuries (IRR = 1.30 per year). For overuse injuries, a higher age and weight gain were significant risk factors (IRR = 1.29 per year and IRR = 1.36 per kg, respectively). For traumatic injuries, a higher age and an earlier maturational timing were identified as significant risk factors (IRR = 1.30 per year and IRR = 0.80, respectively). In contrast, the risk for traumatic injuries was lower in players with a higher growth rate (IRR = 0.63 per cm of growth). Average weekly training exposure did not influence the risk for any type of injury.
CONCLUSION: In accordance with previous studies, we can conclude that increasing age is an important risk factor for all injuries in 9- to 15-year-old elite-level soccer players. Adjusted for age, however, weight gain was a significant risk factor for overuse injuries, whereas for traumatic injuries, injury risk was higher in players with an earlier maturational timing and a lower growth rate. These differences between overuse and traumatic injuries should be taken into consideration when assessing injury risk and applying injury prevention strategies.

INJURY RISK IN ACADEMY LEVEL RUGBY LEAGUE MATCH PLAY: A SINGLE SEASON PROSPECTIVE COHORT STUDY

TEE, J., TILL, K., JONES, B.
LEEDS BECKETT UNIVERSITY

INTRODUCTION: Rugby League is an invasion sport characterized by frequent accelerations, decelerations, changes of direction and collisions between players. The game is played world wide at junior and senior age groups and across competitive levels ranging from amateur to elite. Rugby league academy competition is an important step along the pathway to professional player status. Despite the importance of this pathway, to date no research has examined injury risk at senior academy level in England.
METHODS: Three professional rugby league academies were recruited to this observational prospective cohort investigation. Eighty-one players were included in the investigation. Physiotherapists from each academy were recruited and remunerated to act as injury surveillance officers throughout the season. Match injuries were recorded using a time-loss definition consistent with the consensus adopted within rugby union. Injury incidence , injury severity and injury burden were all calculated.
RESULTS: Injury incidence of 85 <95%CI 67 to 103> injuries/1000 h was observed during the 59 matches played. This equates to 1.5 <95%CI 1.2 to 1.8> time-loss injuries per match. The mean severity of injury was 22 ± 19 days resulting in an overall injury burden of 1870 <95%CI 1785 to 1955 days/1000h>. The tackle event was the most common cause of injury <69% of injuries>, with the tackled player injured more frequently than the tackler . Forwards sustained a greater proportion of injuries than backs and ankle sprains <11, 95%CI 4 to 17 per 1000 h> were the most commonly diagnosed injuries, but the shoulder joint was the most commonly injured site <17, 95%CI 9 to 25 per 1000 h>.
CONCLUSION: Overall, the incidence of injury for academy rugby league was similar to that reported in senior professional rugby league <78 injuries / 1000 h> , but the mean severity and overall burden of injury was lower . Injury patterns indicate that academy players are at a higher risk of concussion and shoulder joint injuries than senior professional players. This suggests that the specific focus for injury risk management in academy rugby league should be on players' tackle technique and prevention strategies for concussion and shoulder injuries.

OP-PM77 Training load

DETERMINATION OF THE INTERRELATIONSHIPS AMONG MEASURES OF TRAINING LOAD IN ELITE SOCCER

RUF, L.

CARDIFF METROPOLITAN UNIVERSITY CARDIFF

INTRODUCTION: Numerous training load measures can be derived from wearable microtechnology such as heart rate, GPS devices and accelerometers. Practitioners are faced with the challenge to decide which measures to compute and select for daily monitoring purposes. Therefore, the aim of this study was to outline a systematic process of data reduction and variable selection of a variety of commonly used training load measures in professional soccer.
METHODS: Data were collected in 32 professional soccer players (25.2 ± 4.8 years, 180 ± 5 cm, 75.7 ± 5.4 kg) over the course of 32 consecutive weeks (14-week pre-season and 18-week in-season period). Training load was quantified via heart rate, GPS, tri-axial accelerometers and subjective RPE for all training session. A total of 25 absolute (n = 1639 data points) and 22 relative training load measures (n = 1846 data points) from speed-, acceleration-, accelerometry-, metabolic power-, heart rate- and subjective-related parameters were computed and subsequently subjected to two separate Principal Component Analyses. This statistical technique was used to reduce the dimensionality of a given data set while retaining as much information in the remaining components as possible. The optimal number of components to retain was established by examining the eigenvalues, scree plot and percentage of variance explained by each component.
RESULTS: When analysing absolute measures of training load, five principal components were extracted explaining in total 82% of the variance. Training load measures that were highly loaded on component 1 were associated with measures of total volume, while component 2, 3, 4 and 5 represented measures of high-speed, acceleration, mechanical work and internal load. Results suggest that PlayerLoadTM and total distance can be used interchangeable and explained with ~26% the largest proportion of the total variance. Positional analysis revealed moderate similarities in the structure of the identified components. When analysing relative measures of training load, five components have been identified explaining in total 72% of the variance. Components 1, 2, 3, 4 and 5 were considered to represent relative high-speed, relative total volume, relative internal load, relative acceleration load and relative deceleration load. Large similarities were evident between positions.
CONCLUSION: Multiple training load measures are needed to thoroughly monitor the imposed demands on elite soccer players. Practitioners can select the following absolute variables to capture the largest variance in training load when monitoring the entire squad: PlayerLoadTM, distance covered at high-speed (>19.8 m.s-1), number of accelerations >1.5 m.s-2, PlayerLoadTM >3 m.s-2 and RPE. Similarly, the following relative variables account for the largest proportion of training load: relative high-speed, relative PlayerLoadTM, relative RPE, relative number of accelerations >1.5 m.s-2 and relative number of decelerations >1.5 m.s-2.

QUANTIFICATION OF PRESEASON TRAINING LOAD IN ELITE GREEK SOCCER PLAYERS

KALAPOTHARAKOS, V.I., BASDEKIS, G., TOKMAKIDIS, S.P.

DEMOCRITUS UNIVERSITY OF THRACE, KOMOTINI, GREECE

INTRODUCTION: Quantifying training load is an important part in the training monitoring process of soccer player (Borresen & Lambert, 2009). However, there are few information about the periodization practices of training load across a preseason period in elite soccer players, and how this periodization affects the aerobic performance (Malone et al., 2015; Manzi et al., 2013). The main aim of the present study was to quantify the internal training load of a 6-week preseason period completed by professional soccer players of Greek Super League. Also, this study examined the effects of a 6-week preseason in aerobic performance.
METHODS: Fifteen professional soccer players (mean + SD: age 26.5 + 3.8 years; height 177 + 5 cm; weight 77 + 7.2 kg) from a Greek Super league team participated in the present study. Initially, VO2max and running velocity at VO2max (v-VO2max) before and after the preseason period were determined during a laboratory incremental treadmill for all players. Also, the Interval Shuttle Run Test (ISRT) was performed before and after the preseason period to determine interval endurance capacity. The stage and the velocity (v-ISRT) completed during the ISRT by each player were recorded. The internal training loads completed during the training sessions of six training weeks were determined multiplying the session RPE (CR10-scale) by session duration in minutes. Pre-season period of 6 weeks were analyzed across 6 x 1 week microcycles.
RESULTS: VO2max (57.9+3.4 vs 59.6+2.9 ml/kg/min), v-VO2max (16.6+1.4 vs 19+1 km/h), stage (98.1+18 vs 121+12) and v-ISRT increased significantly ($p<0.001$) after the preseason period. Internal training loads and duration of week 2 (2592+295 AU) week 3 (2519+514 AU) were significantly higher ($p<0.05$) in comparison to week 1 (1736+383 AU), week 4 (1857+517 AU), week 5 (1586+322 AU) and week 6 (1800+306 AU). No significant differences were observed in weekly internal training load and weekly duration among week 1, 4, 5 and 6 of preseason period.
CONCLUSION: VO2max, vVO2max, the stage and the running velocity completed during the ISRT are useful and practical predictors to monitor endurance performance changes during a soccer preseason. The findings of the present study suggest that a variation on weekly internal training load and duration occurred during a 6 week preseason period in a Greek Super League Team. Previous studies have shown conflicting results, with higher or less s-RPE values of elite soccer players from different championships compared to our study. It seems that the variation in internal training load in preseason between the present and previous studies (Malone et al., 2015; Manzi et al., 2013) may be due to their different external loads.

EXAMINATION OF THE EFFICACY OF GPS GENERATED METABOLIC LOAD MEASURES FOR MONITORING INTENSIVE INTERMITTENT RUNNING LOAD IN RUGBY UNION.

SMITH, T.B.1,2, TARRANT, O.P.3, MCINTOSH, N.1

UNIVERSITY OF WAIKATO

INTRODUCTION: Various global positioning system (GPS) metrics are regularly employed to measure locomotion workload in team sports. Common GPS metrics include distance in specific high-speed zones (e.g. > 5.5 m/s) and counts of acceleration/deceleration events occurring beyond a specific intensity threshold (e.g. > 3 m/s/s). During a super rugby match a player sprints approximately 20 meters each minute, which isnt often far enough for all the distance sprinted to fall in the high-speed zone. Some intensive rugby sprints start whilst the player is already moving or acceleration decays during an intensive prolonged sprint, resulting in a low average acceleration. Both scenarios can result in a single count in a low acceleration zone, which limits the ability of the acceleration metric to accurately measure intense workloads. To overcome these limitations, some GPS companies include the high metabolic workload distance (HMLD) metric, despite various studies claiming its unsuitability for this task. HMLD is power output derived from the estimated energy cost calculated from velocity, acceleration and deceleration measurements. We observed a strong relationship between HMLD and player finish order in various on-field rugby union fitness drills and set out to investigate this relationship in more depth.
METHODS: We sought to explore the relationship between (HMLD) measured by a Viper Pod GPS (STATSports Technology Ltd, Courtney Hill, NI) and the time to complete a repeated sprinting task for 27 participants. Two different intensive rugby tests were investigated. The first test involved a maximal 10 m & 20 m out and back shuttle run (SHORT), repeated each minute for ten repetitions. The second test involved a maximal 20 m, 40 m & 60 m out and back shuttle run (LONG), repeated every two minutes for six repetitions. Correlations between the individual HMLD and associated time for all participants various shuttle runs, were determined for each test (SINGLE). For each participant the shuttle times were also combined, as was HMLD, for both the SHORT and LONG tests. This participant data was used to calculate the correlation between the combined HMLD and combined time for each test (COMB). HMLD was set at ≥ 25 watts/kg and all statistics were conducted in SPSS with correlations calculated with Pearsons correlation coefficient (r).
RESULTS: The analysis showed the relationships to be linear and variables to be normally distributed. Correlations were: SINGLE SHORT r = 0.85, SINGLE LONG r = 0.87, COMB SHORT r = 0.88 and COMB LONG r = 0.96.
CONCLUSION: Despite studies questioning the accuracy of HMLD, we found strong correlations between it and the time taken to complete rugby specific intermittent maximal shuttle tasks and this relationship strengthened with longer running distances. We believe these results provide some evidence for the efficacy of HMLD for monitoring locomotion workload in sports such as rugby union that involve intensive intermittent acceleration, deceleration and velocity activities.

CURRENT TRENDS IN BIOLOGICAL MATURATION AND TRAINING LOAD MONITORING IN ELITE ENGLISH ADOLESCENT SOCCER

SALTER, J., TOWLSON, C.

YORK ST JOHN UNIVERSITY AND THE UNIVERSITY OF HULL

INTRODUCTION: Evidence has outlined the enhanced risk of injury during periods of accelerated biological maturation (BM) and the subsequent importance of training load (TL) monitoring. Given the competitive nature of professional soccer, the differences in approach taken by soccer academies to monitor BM and TL is somewhat unknown, with only minimum general legislative guidelines presented by governing bodies. Therefore, this study aimed to explore and quantify the current approaches and attitudes of UK elite youth soccer academy practitioners for monitoring plyer BM and TL in male and female adolescent soccer players.
METHODS: Having ethical approval, 49 respondents completed an online survey who represented male Premier League (n = 38), soccer academies and female Regional Talent Clubs (n = 11) spanning U9-U23 age groups, of which 78% were Sport Science support (SSS) staff. The survey consisted of 16 questions covering two constructs: 1) monitoring of BM (8 questions) and 2) TL monitoring TL (8 questions). Questions were either multiple choice or unipolar scaled (0 = not important; 100 = highly important) and took <10 minutes to complete.
RESULTS: Respondents ranked injury prevention (83 ± 5.3) as the most important reason for BM and TL monitoring with overall development (80 ± 5) second and load management (78 ± 2.6) third. Practitioners ranked resource limitations (71 ± 14) and time constraints (65 ± 6.7) as the primary barriers to implementing monitoring strategies but support from key stakeholders (parents, senior management and players) was not deemed a barrier. The primary methods of BM monitoring conducted by SSS staff (83%) were maturation offset (47%) and predicted adult height (42%). Such data is typically reported to coaches (31%), SSS (18%) and medical staff (17%) via visual presentations (59%) on a quarterly basis (57%). The most common approach taken to TL monitoring was rating of perceived exertion (49%) and global positioning satellite (23%) collated in customised spreadsheets (58%) by SSS (74%) and reported to age group coaches (58%) and medical staff (8%) via presentations (48%) daily (39%).
CONCLUSION: The main findings suggest that although there is some unity around BM and TL monitoring between elite soccer academies, there is still a large discrepancy between approaches. It appears that a club-level approach is employed rather than a standardised approach despite legislative guidelines, which is primarily impacted by time and resource constraints at elite levels. Therefore, although evidence of good practice exists, a more widespread and consistent approach to BM and TL is needed to further understand the complexities between BM and TL on player physical development.

WORKLOAD INFLUENCE ON BIOCHEMICAL AND PSYCHOLOGICAL MARKERS THROUGHOUT PROFESSIONAL RUGBY UNION SEASON.

DUBOIS, R.1, PAILLARD, T.1, PRIOUX, J.2

1: LAPPS , 2: M2S

INTRODUCTION: Roe et al., (2016) showed that physiological stress during rugby union competition induced an acute fatigue characterized by several biochemical and psychological disturbances. Moreover, Slattery et al. (2012) showed that the physical workload also influences these characteristics in team sports players (muscle damages, inflammation, …). Therefore, the aim of this study was to analyse the influence of weekly workload (WWL) (training & competitive stress) on biochemical and psychological responses throughout elite rugby union season (TOP14).
METHODS: This study was carried out throughout a season [48 Weeks (W) - Preseason: 8W & 3 competitive blocks (CB ~ 12 to 14W each)]. 3 blood samplings (W16, 30 & 45) together with 10 recovery-stress questionnaires (RESTq; weeks: 1, 3, 5, 8, 12, 16, 22, 30, 38, 46) were

performed by 14 professional players. The blood samplings were carried out more than 72h after the last game in fasted condition. The RESTq was informed after a full day of recovery about 48h before the next game. Endocrine parameters [Testosterone (T), Cortisol (C), Insulin Growth Factor (IGF-1)] & muscle damages [Creatine Kinase (CK)] were studied.
WWL was assessed through S-RPE methods and GPS/accelerometer monitoring (GPSport, SPI-HPU, 5Hz). These 2 methods were used during training and competitive practices. The GPS units allowed to assess the distance covered and the number of heavy impacts (>8G) suffered. ANOVA for repeated measures showed the evolutions of biochemical and psychological characteristics over the season. Pearson's coefficient of correlation (r) was used to analyzed the influence of WWL on these characteristics. The influence was studied with a certain time lag. The short-term (acute) effects corresponds to the weekly values of the previous and current week, while the moderate-term (chronic) effects corresponds to the average of the 4 last weeks. The global influence over the season were analysed thank to rolling average of these variables.
RESULTS: The WWL and number of impacts were greater during the preseason, and during the 1st CB compared to the 2nd and the 3rd CB ($p<0.05$). [CK], [ASAT] et [ALAT] were higher during the 1st CB ($p<0.05$) whereas T/C & IGF-1/C ratios were lower in 2nd CB compared to 1st CB ($p<0.05$). The acute number of impacts was correlated to [CK] ($r=0.46$, $p<0.01$). [CK] showed correlation with acute competitive load & acute S-RPE ($r=0.56$ et 0.59, $p<0.001$). Specific stress index was correlated to [CK] ($r=0.63$, $p<0.001$), while the general score of recovery was in relationship with T/C & IGF-1/C ratios ($r=0.50$ & 0.45, $p<0.01$).
CONCLUSION: WWL influence changes in biochemical and psychological characteristics of rugby players. Number of impacts and competitive load were the factors that most influence the changes in these parameters

OP-PM51 Nutritional physiology: Energy metabolism/body composition

VALIDITY OF A COMMERCIAL BIOELECTRICAL IMPEDANCE ANALYSIS AGAINST THE DUAL ENERGY X-RAY ABSORPTIOMETRY IN ASSESSING BODY COMPOSITION OF ADULT MALES.

ALJALOUD, K.
KING SAUD UNIVERSITY

INTRODUCTION: Bioelectrical impedance analysis (BIA) is widely used to assess body composition. However, there is lack of studies that evaluated the validity of BIA especially the commercial models such as Omron BF-511. Aim: The main aim of the present study was to examine the accuracy of Omron BF-511 model in assessing body composition in male adults.
METHODS: Apparently healthy men (n=302, mean age=31.7±10.3 years) participated in this cross-sectional study. Anthropometry measurements including body mass, height, and waist circumference (WC) were taking on the same time of the day. Body mass index (BMI) was calculated for all participants.
Body composition (%fat and %SMM) has been assessed for all participants under the same conditions using Omron BF-511 and DXA as a criterion measure. Since DXA do not provide direct measurement for skeletal muscle mass, prediction formula was applied in order to obtain a predicted skeletal muscle mass (SMM). The validity of the prediction formula was evaluated in previous study. skeletal muscle mass (SMM) (Kg)= 1.19* appendicular lean soft tissue (ALST) – 1.65, where ALST measured by DXA. Then, SMM percentage was calculated and presented as mean and standard deviation. Participants who had radiation exposure such as X-rays in the prior two weeks, or had frequent exposure to radiation in the prior year have been excluded for their health safety. Data set were checked for normality using the Kolmogorov-Smirnov test. Independent t tests (two-tail), which examined mean differences in both %BF and %SMM between the two devices (DXA and Omron). Wilcoxon signed ranks tests were used as appropriate. The Limits of Agreement (LoA) was examined for both devices (DXA and Omron) using the Bland-Altman plots method (Bland and Altman, 1986). Pearson's correlation coefficients were applied to assess the association between the two devices in measuring %BF and %SMM. Acceptable percent error limit (±3.5) was calculated for the examined device (Omron BF-511) using a developed equation %error = [(Omron – DXA)/DXA x 100]. Statistical significance was set at $P<0.05$ for all the analyses.
The current study protocol has been approved by the Internal Review Board (IRB) at King Saud University (IRB No. E-16-1785
RESULTS: Although the results showed relatively close values (%fat &%SMM) between the examined instruments (Omron BF-511 & DXA), and the correlation between Omron BF-511 and DXA were high in both %fat and %SMM, the differences existed in both measures were significant (%Fat, Omron=29.02+7.68 vs. DXA=31.93+8.01, P=0.000; %SMM, Omron=34.42+4.83 vs. DXA=35.70+4.66, P=0.002).
CONCLUSION: The current study concluded that Omron BF-511 could provide close estimation of %fat and %SMM. However, caution should be taken when an accurate estimate of %fat and %SMM is crucial. Therefore, more investigations are recommended to develop the accuracy of the commercial BIA (e.g. Omron BF-511) in order to provide accurate body composition assessment.

PREDICTION EQUATIONS UNDERESTIMATE DIRECT MEASUREMENTS OF RESTING METABOLIC RATE IN ELITE YOUTH SOCCER PLAYERS

HANNON, M.P., CARNEY, D., FLOYD, S., PARKER, L., UNNITHAN, V., DRUST, B., CLOSE, G.L., MORTON, J.P.
LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: The prescription of nutritional guidelines for elite youth soccer players is currently difficult owing to the lack of data quantifying daily total energy expenditure (TEE). Given the contribution of resting metabolic rate (RMR) towards TEE, an initial step in developing population specific nutritional guidelines is direct assessment of RMR. Therefore, the aims of the present study were 1) to directly assess RMR in elite youth soccer players and 2) to assess the validity of common RMR prediction equations.
METHODS: Seventy eight elite male youth soccer players from a Premier League Academy (n= 14 U12s; 11 U13s; 14 U14s; 13 U15s; 7 U16s; 19 U18s) were assessed for body composition (DXA) and RMR (indirect calorimetry) after an overnight fast. Measured RMR (from pooled data) was compared to predicted RMR values from seven equations via a one-way repeated measures ANOVA (Cunningham, 1980; DeLorenzo et al., 1999; Henry, 2005; Kim et al., 2015; Molnar et al., 1995; Schofield, 1985; Wong et al., 2012).
RESULTS: Height (U12= 154.9±3.7; U13= 161.0±5.3; U14= 171.1±8.5; U15= 175.0±6.3; U16= 182.4±6.2; U18= 181.3±5.4 cm), body mass (U12= 42.4±5.0; U13= 45.0±5.3; U14= 54.5±9.4; U15= 60.6±6.8; U16= 72.3±8.2; U18= 69.8±8.5 kg) and lean mass (U12= 30.0±3.7; U13= 32.7±4.5; U14= 41.5±8.3; U15= 47.7±6.3; U16= 56.5±5.7; U18= 55.3±6.9 kg) was significantly different between U12-U16 age groups in a hierarchal manner ($P<0.05$). There was no difference in height, body mass and lean mass between the U16 and U18 age groups

(P>0.05). Measured RMR (1855±262 kcal.day-1) was greater (P<0.05) than the predicted values of Cunningham (1468±258 kcal.day-1), DeLorenzo (1608±171 kcal.day-1), Henry (1639±241 kcal.day-1), Kim (1390±176 kcal.day-1), Molnar (1561±206 kcal.day-1), Schofield (1675±232 kcal.day-1) and Wong (1608±171 kcal.day-1).
CONCLUSION: Common prediction equations underestimate RMR in elite youth soccer players. Future research should therefore establish a valid predictive equation for this specific population in order to help formulate population specific nutritional guidelines.

HIGH PREVALENCE OF NEGATIVE ENERGY BALANCE AND HEALTH PROBLEMS ASSOCIATED WITH ENERGY DEFICIENCY AMONG PRE-PROFESSIONAL BALLET DANCERS.

CIVIL, R.1, LAMB, A.1, BROWN, M.2, STEVENSON, E.3, WITARD, O.1

1: UNIVERSITY OF STIRLING , 2: UNIVERSITY OF GLOUCESTERSHIRE , 3: NEWCASTLE UNIVERSITY

INTRODUCTION: Elite ballet dancers are considered to be at high risk of energy deficiency. Previous studies have investigated the energy intake (EI) and energy expenditure (EE) patterns of professional ballet dancers, and have monitored problems associated with low energy availability (EA). However, a paucity of equivalent information exists in young ballet dancers who may even be considered at a higher risk. Therefore, the primary aim of this study was to determine dietary intake and EI, EE, and EA of pre-professional ballet dancers. The secondary aim was to investigate the presence of health problems associated with energy deficiency in this at risk population.
METHODS: In a cross-sectional study design, we measured EI (using food diaries and 24h dietary recall) and EE (by tri-axial accelerometry and activity logs) of 20 pre-professional ballet dancers (age: 18.1 ± 1.1 years; body weight: 54.4 ± 5.8 kg; body mass index: 19.0 ± 1.6 kg·m2; body fat %: 22.8 ± 3.4; Z-score: 1.1 ± 0.9) over a 7-day period, including 5 weekdays and 2 weekend days. We then calculated energy balance (EB) and EA (n=18). In addition, measurements of body composition, bone health (including Z-scores), eating behaviours, menstrual function, and blood glucose were collected, and the Low Energy Availability Questionnaire (LEAF-Q) was conducted (n=20) to identify problems associated with energy deficiency.
RESULTS: The EE of dancers was greater than EI over the 7 days (P=0.003), equating to an EB of -308 ± 372 kcal·day-1. EI (weekdays: 1979 ± 470 kcal·day-1; weekend days: 2058 ± 589 kcal·day-1), carbohydrate, protein, and fat intakes were similar during weekdays and weekend days (P>0.050); while EE, fluid and fibre intakes were lower on weekend days when compared with weekdays (P<0.010). The magnitude of negative EB was greater (P=0.015) on weekdays (-425 ± 465 kcal·day-1) compared to weekend days (-6 ± 506 kcal·day-1), and there was a tendency for EA to be lower on weekdays (38 ± 13 kcal·kg FFM-1·day-1) than weekend days (44 ± 13 kcal·kg FFM-1·day-1, P=0.110). Overall, 83% of dancers (n=15) were in negative EB, 61% (n=11) reported an EA <45 kcal·kg FFM-1·day-1, and 22% (n=4) an EA <30 kcal·kg FFM-1·day-1. Primary amenorrhea was reported in 45% (n=9) of dancers and 40% of dancers (n=8) reported current menstrual dysfunctions, with 5 amenorrheic and 3 oligomenorrheic. When compared to the eumenorrheic cohort (n=7), amenorrheic and oligomenorrheic dancers reported greater LEAF-Q scores (P=0.006), reduced EE (P=0.015), and tendencies for lower EI (P=0.141), EA (P=0.116), and expression of emotional eating behaviour (P=0.056). However, measurements of body composition, bone health, and fasting blood glucose concentrations were similar between eumenorrheic group and dancers with menstrual dysfunctions (P>0.05).
CONCLUSION: Consistent with their professional counterparts, a state of energy deficiency was prevalent among pre-professional ballet dancers. In addition, we identified several health problems associated with low EA.

MAKING WEIGHT SAFELY: MANIPULATION OF ENERGY AVAILABILITY WITHOUT SYMPTOMS OF RED-S IN AN ELITE MALE TAEKWONDO ATHLETE

LANGAN-EVANS, C.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Athletes involved in combat sports may experience transient periods of low energy availability (LEA) when making weight, often manifesting as symptoms of the relative energy deficiency in sport syndrome (RED-S). Additionally, combat athletes may also practice rapid weight loss (RWL) methods (e.g. extreme dehydration) that can also negatively impact health and performance. The aim of this case-study is to outline the impacts of making weight (using a structured nutrition and training intervention) on symptoms of RED-S in a male international level Taekwondo (TKD) athlete making weight for the -63kg bantam weight category.
METHODS: Over an 8 week period, the athlete adhered to a daily energy intake (1,700 kcal.day-1; 2.3 g.kg-1 protein, 3.4 g.kg-1 carbohydrate and 0.9 g.kg-1) equivalent to resting metabolic rate (RMR). Body composition (using Dual X-ray Absorptiometry, DXA), RMR, VO2peak , maximal fat oxidation rates (using indirect calorimetry), strength (1-RM back squat), power (reactive strength index, RSI) and total mood disturbance (TMD) via a profile of mood states (POMS) assessments were made at regular periods. Training consisted of specific TKD, cardiovascular conditioning and strength sessions equating to 12-15 hours.wk-1. Activity Energy Expenditure (AEE) was assessed using a combined actigraphy and HR monitor.
RESULTS: AEE ranged from 407 ± 39 to 1297 ± 71 kcal.day-1 thus equating to estimated EA ranging from 7 ± 1 to 30 ± 1kcal.kg.day-1. Average BM loss was 1.0 ± 0.8 kg.wk-1, equating to a total loss of 9.3kg. This resulted in an overall decrease of fat mass (FM) (11.5kg-7.1kg). LBM remained constant (54.5-55.1kg) and RMR was stable (1698 ± 80-1710 ± 94 kcal.day-1) throughout the period eliciting no adaptive thermogenic responses. The final 3kg of BM loss (4.5%) was achieved in the final 24 hours prior to weigh in via both active and passive dehydration methods. Despite LEA, measures of cardiovascular (VO2peak 52.3ml.kg.min-1/3.7L.min-1 to 62.5ml.kg.min-1/4.3L.min-1), strength (1RM Squat 1.6 x BM to 1.9 x BM) and power (RSI 1.72 to 1.83) based performance all improved with no detrimental effect on bone density (Hip and Lumbar Z-SCORES: 0.9 to 1.0 and 0.8-0.8, respectively) or psychological (TMD ≤2-7) health status. VENOUS BLOODS ARE BEING ANALYSED & WILL BE PRESENTED AT THE CONFERENCE.
CONCLUSION: This nutritional strategy represented a major change in the athletes habitual BM loss practices as he typically employs a number of RWL techniques over an acute period (2 weeks) in order to lose 4 kg for a higher weight category. The intervention demonstrates that a more gradual approach to making weight in TKD athletes can be successfully achieved via a combination of restricted and periodised energy intake (according to the demands of the daily training), increased energy expenditure and limited dehydration techniques, whilst avoiding the negative consequences associated with LEA and RED-S.

THE ACUTE EFFECTS OF COMBINED MONOPHASIC ORAL CONTRACEPTIVES ON BODY COMPOSITION

THOMPSON, B., HILLEBRANDT, H., BARBA, L., SCULLEY, D., KNOX, C., HUNTER, S., JANSE DE JONGE, X.
UNIVERSITY OF NEWCASTLE

INTRODUCTION: Oral contraceptives (OC) are commonly used by both athletes and females in the general population. OC use suppresses the production of endogenous female sex hormones through a combination of synthetic estrogen and progestin. The most common OC is the combined monophasic OC, which usually has a pattern of 7 days of non-active pills followed by 21 days of active hormone pills. Synthetic estrogen is known to influence fluid regulation, however it is not known whether the level of androgenicity of the progestins in OC also influences fluid regulation. As approximately 73% of lean body tissue is comprised of water, variations in fluid regulation throughout the OC cycle may affect body composition measurements. This study aimed to assess whether body composition measurements change throughout the OC cycle and whether the level of androgenicity of the OC has an influence on these measures.
METHODS: Twenty-seven moderately active females aged 18-30 years, BMI 23.5 kg/m2 (SD 3.3), all taking a combined monophasic OC with either high androgenicity (n=14) or low androgenicity (n=13), were tested during the non-active pill phase (days 4-7), the first week of the active OC (days 11-14) and the last week of the active OC (days 25-28). Dual X-ray absorptiometry (DEXA), skinfolds and body weight were measured. Hydration level was assessed using urine specific gravity (USG). Testing occurred at the same time of day and diet for 24 hours prior to testing remained the same for all tests.
RESULTS: There were no differences over the OC cycle for USG, skinfolds or bodyweight in both the high and low androgenicity groups. However repeated measures ANOVA reported a significantly higher body fat percentage for DEXA in the first week of the active OC phase compared with the non-active phase in the high androgenicity group (p=0.023). There were no differences in DEXA body fat percentage over the OC cycle for the low androgenicity group.
CONCLUSION: Our findings suggest that the more sensitive tests of body composition, such as DEXA, may be affected by the different hormones in OC at different time points in the cycle. Therefore DEXA testing should be performed at the same time during the OC cycle, particularly for females taking an OC with high androgenicity. Despite not finding significant differences for the other measures of body composition it is suggested that repeat testing should still be standardised for OC phase and that OC type and androgenicity should be recorded.

OP-BN52 Neuromechanics of cycling

THE BETWEEN DAY VARIABILITY OF ASYMMETRIES IN CYCLING.

MURRAY, K.A., HETTINGA, F.J.
UNIVERSITY OF ESSEX

INTRODUCTION: A number of previous studies have determined that bilateral asymmetries in force and torque production are prevalent during cycling. Research has investigated the effect of intensity, cadence and seat position on the magnitude of asymmetry during cycling. However, at present little is understood about the day to day variation in cyclists asymmetries when performing standardised cycling trials across multiple visits. The aim of this study was to investigate the variability of asymmetry between cycling trials on multiple days.
METHODS: Five well trained cyclists (mean maximal aerobic power of 362.8±28.3W) visited the laboratory on four occasions, each separated by seven days. The initial visit consisted of a maximal incremental cycle test to volitional exhaustion, to determine the cyclists' maximal aerobic power (MAP). The following three visits were all the same, whereby cyclists performed 4 x 4-minute trials at various relative intensities (40%,60%,75% and90% of MAP). Cycling trials were standardised at 90rpm and performed on a Lode Excalibur ergometer fitted with Garmin Vector pedals (GVP's). GVP's were used to measure the bilateral contribution to total power output during each of the cycling trials. Bilateral data from the GVP's were used to calculate the mean Asymmetry Index (AI%) for each trial, to assess the magnitude of each cyclists asymmetry. AI%=((DOM-NONDOM)/DOM)x100, with dominance (DOM) defined by the limb contributing most greatly to total power output. An asymmetry index of 0% would represent an equal contribution of the lower limbs to total power output.
Coefficient of Variation (CV) was calculated for each cyclist to determine their variation in the magnitude of asymmetry between the three visits. CV was also calculated between the three visits for each intensity, to determine whether the variation of AI% is influenced by intensity.
RESULTS: The mean AI% for all participants and cycling intensities was 10.8±6.5% (AI% range 2.4-31.0%). CV calculations demonstrated that, on average, the cyclists AI% varied 40.0±27.1% (CV range 18.7-68.5%) between the three visits. The mean CV of AI% at 40%MAP was 44.4±23.5 (CV range 18.7-68.5%), at 60%MAP was 37.0±27.5% (CV range 9.1–73.3%), at 75%MAP was 39.4±31.4% (CV range 1.5-82.6%) and at 90%MAP was 26.2±33.6% (CV range 3.5–64.7%).
CONCLUSION: The results of this study substantiate others which conclude that bilateral asymmetries during cycling are prevalent. However, our novel finding is that these asymmetries demonstrate considerable variability between visits. The high variability is evidenced by an average CV of 40.0%, present across the range of cycling intensities. These findings demonstrate that single day analysis is not sufficient to assess asymmetry during cycling. Further research should investigate the cause of these highly variable asymmetries, and their impact on performance.
Lastly, these results are currently based on five cyclists, so they should be interpreted with care. Data collection is ongoing.

A STUDY ON EVALUATION OF MUSCLE COORDINATION PATTERN OF BOTH LOWER EXTREMITIES ON PEDALING SKILLS

SATO, T., TOKUYASU, T.
FUKUOKA INSTITUTE OF TECHNOLOGY

INTRODUCTION: Numerous studies have suggested that the central nervous system controls bodily motion through a combination of muscles, which is called muscle synergy. Recent studies have shown that muscle synergies can be extracted from the variation of EMG patterns in spite of the load and cadence during pedaling (Hug et al., 2011). However, many studies have measured the variation of EMG patterns of highly trained cyclists who pedaled with normal pedals. Generally, most trained cyclists use clipless pedals in their daily

training. Thus, the authors of the present study doubted that the EMG data measured in previous studies can be used to understand the pedaling exercise of a competitive bicycle. In a bicycle competition, a cyclist needs both the appropriate muscle coordination between legs and the appropriate saddle height to increase pedaling efficiency and/or to reduce the risk of injury (Bini and Hume, 2011; Blake and Wakeling, 2015). Yet, few studies have investigated the influence of clipless pedals on muscle coordination pattern. The purpose of this study is therefore to investigate the structure of muscle synergy generated in pedaling exercise using clipless pedals.
METHODS: Seven healthy male subjects pedaled for 30 seconds with different cadences and workloads: 70/90/110 rpm with 50/100/150 W. Three of the seven subjects had over two years experience riding a competitive bicycle with clipless pedals; they were categorized as trained subjects. The remainder of the subjects had never used a competitive bicycle or clipless pedals; they were categorized as untrained subjects. Surface electromyogram (SEMG) signals were wirelessly recorded from the tensor fasciae latae, rectus femoris, biceps femoris, and gastrocnemius medialis of both legs at a sampling frequency of 1 kHz. First, the raw SEMG signals were processed with a band-pass filter from 10 to 500 Hz. Next, the signals were transformed into time-varying frequency components using EMG-specific wavelet analysis (Tscharner., 2000), and these components were then integrated at every 10 degrees of the crank rotation angle. To derive muscle synergy, this study used principal component analysis (PCA), in which a correlation matrix is constructed using the integrated time-varying frequency components of both the untrained and trained subjects. This study assumed that the vectors and coefficients derived from PCA implementation represented the structure of muscle synergy.
RESULTS: The structure of muscle synergy has two main aspects: temporal structure and spatial structure. This study focused on temporal structure. The synergy activation coefficients (SAC), the temporal structure of muscle synergy, indicated that with respect to the significant features of coordination pattern between the legs of trained subjects, the peak SAC value was inverted by an interval of roughly 180 degrees of crank rotation angle in most of the experimental conditions. This could not be found in the results associated with untrained subjects.
CONCLUSION: This study investigated the temporal structure of muscle synergy in both legs during the pedaling of a competitive bicycle with clipless pedals. The experimental results showed that the central nervous system of trained subjects evenly controlled both legs and that the muscles adequately acted according to muscle synergy. In the future, spatial aspects of muscle synergy will also be discussed.

H-REFLEXES IN CYCLISTS VS. UNTRAINED SUBJECTS

BERTSCHINGER, R.

UNIVERSITY OF KONSTANZ

INTRODUCTION: It has been reported that aerobically trained subjects show lower Hmax/Mmax ratios in the Soleus muscle (SOL) than untrained or anaerobically trained subjects (Rochcongar et al., 1979; Maffiuletti et al., 2001; Ogawa et al., 2009). However, it is not clear if the differences reported in these studies can be attributed to the aerobic training per se or to sport specific adaptations, like they occur in runners or swimmers. Therefore, this study investigated the H/M ratios in the SOL muscle between a group of highly trained cyclists and a group of untrained subjects.
METHODS: 11 healthy, well-trained cyclists (61.3±1.8 VO2max) and 8 untrained men (46.8±2.3 VO2max) participated in this study. Recruitment curves of the right SOL muscle were obtained in a recumbent position (90° knee angle) at rest. A rectangular pulse of 1ms duration was delivered by an electrical stimulator with a stimulus intensity ranging from 2mA below H-reflex threshold to 2mA above maximal M-wave amplitude with stimuli given in randomized order in steps of 0.5 mA. Finally, VO2max was measured with a cardiorespiratory exercise test to exhaustion on a cycle ergometer.
RESULTS: Paired samples t-tests revealed no statistical difference ($p = 0.33$) in Hmax/Mmax ratio in SOL (Trained 60.3±4.9 % vs. Untrained 60.6±3.3 %) between both groups that differed significantly in VO2max ($p<0.001$).
CONCLUSION: In the present study we were not able to demonstrate a difference in Hmax/Mmax ratios between well trained cyclists and their untrained counterparts. Thus, we found no indications of specific spinal adaptations as a result of chronic endurance cycling training. Our findings question the universality of lower Hmax/Mmax ratios in endurance trained athletes and rather indicate that the observed differences might at least partly be sport specific.

THE EFFECT OF CADENCE ON THE MUSCLE-TENDON MECHANICS OF THE VASTUS LATERALIS MUSCLE AND ITS RELATIONSHIP WITH THE PREFERRED CADENCE IN CYCLING.

BRENNAN, S., CRESSWELL, A., FARRIS, D., LICHTWARK, G.

UNIVERSITY OF QUEENSLAND

INTRODUCTION: When maintaining a constant power output, cyclists prefer to use higher cadences than those that minimise net metabolic cost or the total muscle activation. The preference for higher cadences could be related to the requirement for net positive mechanical power in cycling compared to other movements like running, which require zero net power per cycle. The aim of this study was to investigate if measures of muscle mechanics could help explain the preference for metabolically sub-optimal cadences in cycling. It was hypothesised that cyclists prefer to use higher cadences because at these cadences, muscle mechanics are more favourable for power production.
METHODS: The force-length and force-velocity properties of vastus lateralis (VL) were determined using maximal voluntary isometric and isokinetic knee extension dynamometer protocols with simultaneous ultrasound imaging of VL. Participants (group mean age = 28 years, mass = 76 kg) cycled on a bicycle ergometer with force instrumented pedals at a constant power output of 2.5 W/kg body mass and cadences of 40, 60, 80 and 100 RPM. A preferred cadence condition was also performed where cadence feedback was hidden from the participant. Motion capture data and pedal forces were used to compute leg joint kinematics and kinetics in OpenSim software. VL fascicle mechanics were determined from ultrasound imaging, and indices of fascicle power and efficiency capacity were estimated during cycling based on the normalised fascicle shortening velocity and force-velocity relationships. Surface EMG data were collected for selected quadriceps, hamstring and ankle plantar flexors to compute the total cumulative muscle activation.

RESULTS: Net metabolic cost was lowest while cycling at 60 RPM. Despite the increased metabolic cost, the group mean preferred cadence was 81 RPM. The distribution of joint work remained constant across cadence, with the majority of positive work being performed at the knee during extension. The preferred cadence coincided with the highest mean VL power capacity, without a significant penalty to efficiency, compared to the most economical cadence. The total cumulative muscle activation showed a similar relationship with cadence as net metabolic cost, requiring lower overall activation at slower cadences.
CONCLUSION: The preference for higher cadences during cycling appears to coincide with favourable shortening velocities of major muscles that contribute to power output. The higher preferred cadence was favourable for the VL power capacity, without a large decrease in efficiency. The most economical cadence appears to be related to favourable conditions to reduce overall activation costs while maintaining favourable shortening velocities for efficiency. These results highlight the importance of shortening velocity in muscle performance, and the role it may play in selection of preferred cadence.

THORACOABDOMINAL MOTION PATTERN AT REST OF MASTER ROAD CYCLISTS: PRELIMINARY RESULTS.

LOPES, A.1, BERNARDINA, G.1, RODRIGUES, I.1, MASSARONI, C.2, SILVESTRI, S.2, CERVERI, P.3, BOSSI, A.4, LEITE, R.5, AMORIM, P.1, SILVATTI, A.1

1: UFV , 2: UCBM , 3: POLIMI , 4: UOK , 5: UFES

INTRODUCTION: Intensive sports training can increase the respiratory muscle function and has been shown to change thoracoabdominal motion pattern at rest (Silvatti et al. 2012). Therefore, this study aimed to describe which differences cycling training can induce on the trunk mechanics during breathing maneuvers at rest in master athletes.
METHODS: Six male cyclists (40 ± 5.5 years) with at least five years of competitive experience in road cycling, performed two breathing maneuvers: thirty seconds of quite breathing (QB) and five cycles of vital capacity (VC). For the tridimensional kinematic analysis, eleven OptiTrack Prime 17W cameras (360Hz) were positioned around the subjects and 32 retro-reflective markers were fixed on their trunk (Ferrigno et al. 1994) that was divided in compartments (superior thorax, ST; inferior thorax, IT and abdomen, AB). From the reconstructed 3D coordinates of the markers, the compartmental volumes were calculated (Visual 3D) as a function of time and divided in breathing cycles of QB and VC. For both breathing maneuvers, we calculated: 1) the mean percentage contribution (%C) of each compartment; 2) the mean correlation coefficient (R) of the (ST,IT), (ST,AB) and (IT,AB) pairs. Friedman test ($p<0.05$) and Bonferroni post-hoc comparison test was applied to verify which compartment was more active and to analyze the coordination between trunk compartments.
RESULTS: Differences were found in the %C for QB and VC ($p<0.05$), with greater contribution of AB compartment (QB=41.9%, VC=42%); than ST (QB=24.3%, VC=26.9%). Since we did not find significant difference between the mean correlation coefficient pairs and they were very high positive values, we could suggest that the cyclists had highly coordinated thoracoabdominal motion patterns in QB and VC.
CONCLUSION: The largest contribution of the AB and a coordinated thoracoabdominal motion could be an outcome of the high demands of cycling training and the associated increases in tidal volume and agree with previous results in intensive swim training (Silvatti et al. 2012). Nevertheless, Layton et al. (2011) found different results that could be related to the training history and the age of the sample under testing. Further studies correlating the trunk mechanics with physiological variables could improve the understanding of the cycling training impact on breathing.

INFLUENCE OF LEG MUSCLE SIZE AND POWER ON MAXIMAL AEROBIC CYCLING PERFORMANCE OF MALE AND FEMALE ATHLETES

YAMAGISHI, T.1, SAITO, A.2, KAWAKAMI, Y.1

1:WASEDA UNIVERSITY , 2:THE UNIVERSITY OF TOKYO

INTRODUCTION: High peak oxygen uptake (VO2peak) is a prerequisite for success in the majority of sporting events since VO2peak sets the upper limit of athletes' aerobic capacity. While cycling is commonly adopted for the determination of VO2peak, cycling-derived VO2peak may not entirely represent aerobic capacity. Indeed, the power produced by leg muscle groups (e.g. knee and hip extensors) has been shown to account for most of work completed during cycling (Ericson et al. 1986). Therefore, leg muscle size and/or power may play a role in maximal aerobic cycling performance. This study sought to determine the influence of leg muscle size and power on VO2peak and maximal power output (Pmax) attained in a ramp cycle exercise in male and female athletes.
METHODS: Thirty-nine Japanese (males: 20, females: 19, aged 18.3 ± 3.9 years) athletes competing in various sporting events (e.g. swimming, badminton) participated in this study. All athletes performed a ramp cycle exercise to exhaustion for the determination of VO2peak and Pmax. Axial scanning of the right leg was performed with MRI, and cross-sectional areas (CSAs) of quadriceps femoris (QF) and hamstring muscles at 50% of thigh length were measured. Moreover, bilateral leg extension power was determined. These variables were entered into a forward stepwise multiple regression model with VO2peak and Pmax being dependent variables.
RESULTS: The male athletes had significantly greater VO2peak (3.92 ± 0.60 l/min or 57.0 ± 6.6 ml/kg/min) and Pmax (327 ± 44 W) than the female athletes (VO2peak: 2.67 ± 0.53 l/min or 47.5 ± 5.9 ml/kg/min, Pmax: 229 ± 49 W, $p < 0.05$). In the males, none of the variables was chosen as a predictor for VO2peak while leg extension power was the best single predictor for Pmax ($r2 = 0.22$). In the females, CSA of QF muscle was the best single predictor for both VO2peak ($r2 = 0.58$) and Pmax ($r2 = 0.70$).
CONCLUSION: The results of this study indicate that the female athletes with smaller QF muscle had difficulty pedalling against increasing work rate during the ramp cycle test thereby limiting VO2peak. Unlike male athletes, leg extension power did not explain any parameters of aerobic performance ($r2 = 0.07$ for both VO2peak and Pmax) in the females, suggesting that they were less able to translate leg power into pedalling performance. Greater VO2peak in the males would reflect their cardio-respiratory capacity that well functioned throughout the test (e.g. no plateau in stroke volume), leading to limited influence of non-aerobic factors on the maximal aerobic cycling performance.

OP-SH11 Philosophical, humanities and management perspectives on sport

A CROSS CULTURAL ANALYSIS OF THE MANAGEMENT POLICIES AND THE MOTIVES OF VOLUNTEERS WITHIN SPECIAL OLYMPICS

CARLIN, L., HASSAN, D.

ULSTER UNIVERSITY

Sports organisations have traditionally relied heavily on the work of volunteers, yet research suggests that many organisations struggle to recruit adequate numbers with the sports coaching role being notoriously difficult to recruit and retain. In order to assist the recruitment and retention process, it is important for volunteers to feel connected with the values of the organisation and also that they have an input into the decision-making processes within the organisation. The overarching aim of this paper is to gain an understanding of the volunteers' views on the processes and structures of volunteer management and retention within Special Olympics. Conducting this research in three European countries, with a combination of countries which has and has not hosted an International Special Olympics event: European or World Games, will provide a greater understanding of the different policies adopted by the National Programs as well as outlining any cultural differences in the motives and opinions of the volunteers themselves. An online questionnaire was issued to volunteers within each of the three national programs receiving 403 respondents. Using the Coach Motivation Questionnaire (McLean, Mallett & Newcombe, 2012) volunteers within Special Olympics scored significantly higher on Intrinsic Motivation questions than on questions relating to Amotivation on the Self Determination Theory Continuum (Deci & Ryan, 2002). Additionally, across all countries, Special Olympics volunteers scored higher on all elements of the CMQ than the CMQ average rating except for the amotivation scale which was lower than average. The response rate per country provides significant insight into volunteer engagement with 203 responses (5.05%) from Special Olympics Ireland, 150 responses (3.2%) Special Olympics Hellas and 56 responses (1.2%) Special Olympics Great Britain. Volunteers generally were unaware of the policies and procedures adopted by their National Programs, however there was a general consensus that recruitment is primarily ad hoc and should be more strategic. Special Olympics Ireland volunteers wanted to be more involved in decision making processes within the organisation with Special Olympics Hellas volunteers more likely to state that they did not have the knowledge to do this. Overall, a more co-ordinated response is required from National Programs in relation to the recruitment and retention of volunteers and this response needs to be tailored to the specific demographics of the volunteers within each National Program. Ethical approval for this research was obtained from the Ulster University ethical committee.

THE PHENOMENON OF MOTION

HOGENOVA, A.

CZECH OLYMPIC COMMITTEE

This text deals with the phenomenon of motion, which is still very problematic today in relation to the Olympic Games and their significance for the whole planet

Motion, along with the phenomenon of reality, is one of the greatest mysteries. Both phenomena are used the most, but they are mysterious if we become absorbed in thinking about them. We find that motion is not just the motion of something from one place to another, because the place does not play the most important role here. Every change is a motion, even if we do not see it. Motion is also growth, it is also coming-to-be and ceasing-to-be. It is a matter of fact that in the sub-lunar world everything is a motion, but at the same time we find that motion is also all that is in the supra-lunar world. Motion is therefore understood by the ancient Greeks as something primordial, and peace is just the privation of motion, it is a kind of absence of observable motion, because there must be something protecting against the raids of outside forces that are constant and aggressive. Even peace in our soul is not based on will but on the whole, which is the source of reconciliation with what cannot be changed.

Motion is understood both ontologically and ontically. Ontologically, motion is appearance, phenomenality, it can be "clare et distincte", but it does not have to have margo , and then we are talking only about the phenomenon. If love originates from inside us, then it is a phenomenon that does not have margo, and therefore cannot be defined in a cartesian manner, which is the basis of many misunderstandings today. For example, when a lawyer asks for evidence of a Cartesian character of these phenomena, then it is not possible. Aristotle's ontological and ontic interpretations are linked into one theory. In his "Physics", but also in Metaphysics, we experience motion in this form; he divides motion into coming-to-be and ceasing-to-be, increasing and decreasing, change and local motion. We then talk about substantive motion , quantitative motion , change; we do not understand this as a motion, because we consider "local motion" as the most important physical motion, and that is the most important and often the only motion for us.It is difficult to talk about motion in sport, it is not just physical and mechanical motion , it is also chemical motion , it is also historical motion it is spiritual motion . It is not possible to simplify motion into physical, chemical and social causality in a Cartesian way; it bears life as a basic possibility, and this possibility is motion, which has long been called zoe, bios, i.e. life. Motion remains an obscure phenomenon, despite the fact that we have written so much about it and it is understood by many.

THE PRESERVATION OF SPORT COMPETITION INTEGRITY IS ESSENTIAL IN ANTI DOPING POLICY.

MCNAMEE, M.

SWANSEA UNIVERSITY

Loland, S. Norwegian University of Sport and Exercise Sciences, Oslo; and McNamee, MJ Swansea University, UK.

Within the philosophy of sport the justification of anti-doping practices has traditionally been based on arguments employing the concepts of health and fairness. By contrast, WADA policy is not explicit in this regard. Rather, it makes general ethical remarks at the beginning of its Code relating to the preservation of the spirit of sport (WADA, 2015) and offers three criteria to support potential inclusion of substances on to its central policy tool, the Prohibited List. Strictly speaking, the Code is one of 7 instruments that comprise WADA policy, and it is the criteria used to consider substances and methods for the Prohibited List that has been the core of academic contention. Several scholars have argued mutatis mutandis for the need of the spirit of sport and its place in anti-doping policy (Loland and Hoppeler, 2011; McNamee, 2012; 2014) while others have argued for its abolition (Kornbeck, 2013).
We argue (i) that it is essential that the justification is based on normative grounds, not merely medical or scientific ones; (ii) for a revised justification for anti doping policy, and the criteria for the Prohibited List, based on a reconsideration of the spirit of sport understood as competition integrity (Cleret et al, 2015). We articulate and justify this interpretation, demonstrating how it is more easily operationalised than WADAs current spirit of sport criterion, enhancing its power in line drawing problems between acceptable and prohibited performance enhancing means and methods.

OP-SH17 Anxiety in athletes and overreaching

STUDY OF THE IMPACT OF BIOFEEDBACK TRAINING ON ANXIETY WITH COLLEGIATE LEVEL ATHLETES

SCHOEN, C., LARA, B., STODDART, S.
SALEM STATE UNIVERSITY

Introduction: As college level student athletes (SAs) endure the demands for their sport while balancing academics, reports of debilitating anxiety seem to be on the rise. Statistics published by the NCAA show more than 21% of all college male SAs reported suffering from some form of depression and 31% experienced persistent anxiety within a 12 month period (Kearns, Davoren & Hwang, 2014). For female SAs the numbers are even more troubling (28% and 48%, respectively). Reduced performances as a result of anxiety often spreads to academic work. Ultimately the entire SA experience is diminished.
Biofeedback training (BFBT) has been a technique used by sport psychology practitioners to help athletes improve performance for many years (Collins, 2002). "Biofeedback optimizes the ability to teach athletes cognitive and emotional self-regulation" (Perry, Shaw & Zaichowski, 2011, p.95) by training them to control physiological processes such as muscle tension, blood pressure, or heart rate using computer software and graphic read outs of physiological measures that are captured with sensitive detection devices. Moss and Wilson (2011) have used BFBT to train SAs to recognize and reduce the ruminative thinking and anxiety that often led to reduced performances. The essential impact of BFBT, as hypothesized here, occurs as the athlete learns to regulate physiological functioning, manage their anxiety, and ultimately enhance the collegiate SA experience.
Method
For this project university IRB approval was granted. A total of 11 SAs volunteered to received BFBT as part of a sport psychology class. BFBT was introduced as a method for increasing physiological awareness and for treating anxiety through breathing techniques and emotional regulation strategies. Engaging in BFBT was a course option. Initial measurements using the State-Trait Anxiety Inventory (STAI, Spielberger, 1977) were gathered. The STAI is a self-report measure designed to distinguish (Spielberger, 1977) between in the moment, feelings of anxiety from the more dispositional variety. Baseline heart rate variability (HRV) and coherence measures using emWave™ software were collected. BFBT was conducted with a Wild Divine Iom™ program measuring heart rate variability and respiration. Each unit within the program involved 20-40 minutes of breathing exercises. An entire 10 unit HRVBF program took on average 12 weeks to complete, after which both anxiety and physiology measures were collected.
Results & Conclusions
10 of the 11 SAs completed the protocol. Unanimously they reported that BFBT helped them cope with the demands of their athletics. Most of the SAs scored lower on both state and trait anxiety measures. Eight out of ten experienced improvements in their coherence and HRV measures as a result of the BFBT. These results cannot be considered significant given the small sample size, but the results warrant further study. Implications and future directions will discussed.

A PATH ANALYSIS OF ADOLESCENT ATHLETES' PERCEIVED STRESS REACTIVITY, APPRAISALS, EMOTIONS, COPING, AND PERFORMANCE SATISFACTION

BRITTON, D., KAVANAGH, E., POLMAN, R.
BOURNEMOUTH UNIVERSITY

This study examined the direct and indirect effects of adolescent athletes' perceived stress reactivity on stress appraisals, emotions, coping, and performance satisfaction. The study further aimed to validate the use of the Perceived Stress Reactivity for Adolescent Athletes . 229 Adolescent athletes completed the PSRS-AA followed by a measure of stress appraisals less than one hour before a competitive event. Within an hour after the completion of a competitive event, participants completed a retrospective assessment of their emotions, coping strategies, and subjective performance. Path analysis revealed that perceived stress reactivity had direct effects on the appraisal of higher stress intensity and more negative emotions. Indirect effects were observed on greater levels of threat , more disengagement-orientated coping, , and reduced performance satisfaction. No effects for perceived stress reactivity were observed on positive emotions, task orientated coping, or distraction orientated coping. These findings support the use of the PSRS-AA for assessing individual differences in stress reactivity. Practitioners could use the PSRS-AA to identify young athletes at greatest risk of experiencing negative

emotions and decreased performance as a result of individual differences in stress reactivity, and thus prioritise interventions for these athletes.

INDICATORS OF PSYCHOLOGICAL ADAPTATION IN ELITE SPORTS

RAZUMETS, E., MITIN, I., ZHOLINSKY, A.

FEDERAL MEDICAL BIOLOGICAL AGENCY

INTRODUCTION: Elite sport is associated with potential risk to the athletes' health. Training and competitions are extremely stressful, leading to negative changes in the mental state of athlete. It leads to decrease of psychological adaptation, which causes sport injuries, as well as the development of psychosomatic diseases.
METHODS: To identify indicators of psychological adaptation that affect professional success of athletes we examined 70 Russian national teams male athletes , aged 18-37. First examination was performed before the training part of season. Re-examination was performed after 6 months of the training. After that, the athletes were divided into 2 groups according to the dynamics of change in mental status. Group A included 26 athletes, group B - 44 athletes. The results of both groups were compared with estimates of the athletes success rates from coaches.
We used Yakhin-Mendelevich clinical questionnaire for the identification of neurotic symptoms including anxiety, depression, asthenia, obsessive-phobic symptoms and vegetative disorders.
To study the cognitive processes we used «Landolt rings»; Numerical square test was used for the evaluation of attention; the mental speed was assessed with Intellectual lability test. To assess central nervous system functional state we used a complex of visual-motor reaction. The vegetative-nervous system state was assessed by heart rate variability.
Statistical analysis was carried out using the EXCEL and SPSS 17.0 software and included descriptive statistics, analysis of the normality of the distribution , and the analysis of the reliability of the differences.
RESULTS: In group A before the competition neurotic symptoms, anxiety, depression and asthenia are increased. The motivation to avoid failure began to prevail. The tolerance for stress decreased. There is a significant decrease in the distribution of attention, speed and accuracy of the reaction. There is a tendency to decrease the switching and concentration of attention.
In group B, we see a trend opposite to group A. There is a significant decrease in the neurotic symptoms by the scales of anxiety, depression and asthenia in the group B before the competition. There is a significant increase in switching and concentration of attention with a decrease of the number of wrong actions.
According to the coaches' evaluation after competition, the athletes of group A showed a high performance and result. The athletes of group B did not show a satisfactory result.
CONCLUSION: To identify athletes with the risk of mental adaptation failure, the following indicators should be used:
-Neurotic symptoms, anxiety, depression, asthenia, motivation to avoid failure;
-Increase in the number of wrong tasks in tests of cognitive functions;
-Increase in the number of errors in visual-motor tests.

THE ANALYSIS OF MENTAL STATE FOR COMPETITION IN INDIVIDUAL AND TEAM SPORTS

MLADENOVIC, M.

COLLEGE OF SPORTS AND HEALTH

Introduction: In order to create conditions that would enable athletes to convert their sports potential into a desired outcome at a competition, athlete has to be able to achieve an optimal mental state for competition. The aim of this study was to analyse the relative differences between elite athletes in individual and team sports, using the Color Association method as a diagnostic tool (Mladenovic, 2017).
Methods: The Color Association method (CA) is a projective technique based on Lüscher's color test (Lüscher, 1971). CA measures athlete's self-perception of pain, effort, fear, tiredness, injury, readiness for competition and training, ability to take a risk in competitive situation in sport, and relying on habits in sports context. Result on CA can vary from zero to 100. Sample included 41 elite athlete, members of senior national shooting (N=24) and handball (N=17) team of Serbia. CA method was applied at major international competitions during 2016. or 2017. Descriptive statistics and ANOVA were conducted.
Results: There are significant differences between elite shooters and elite handball players on CA measures of pain ($F=4.514$; $p<0.04$), fear ($F=4.828$; $p<0.034$), training ($F=5.209$; $p<0.028$), competition ($F=3.937$; $p<0.05$) and habit relations ($F=3.935$; $p<0.05$). Shooters showed higher Mean value on CA measures of pain ($M=47.92$; $SD=17.42$), fear ($M=49.1$; $SD=17.74$), habit relations ($M=49.42$; $SD=17.74$) then handball players (pain: $M=36.96$; $SD=14.47$; fear: $M=37.73$; $SD=14.07$; habit relations: $M=39.16$; $SD=14.03$). Handball players showed significantly higher scores on CA measures of training ($M=67.06$; $SD=22.05$) and competition ($M=64.24$; $SD=20.50$) then shooters (training: $M=54.11$; $SD=14.32$; competition: $M=53.61$; $SD=13.85$).
Discussion: Studies usually show individual differences on personality trait-like features in favor of athletes in individual sports (Laborde et al, 2016). This study was investigating state-like features in competitive context and showed more psychological advantage in favor of athletes in team sport (positive readiness for competition and training), while athletes in individual sport showed more intrapersonal sensitivity for potential distractors in competitive situation (self-perception of fear and pain, relying on habits in sports context).

PRACTICAL GUIDELINES TO QUANTIFY THE RISK OF NON-FUNCTIONAL OVERREACHING: EXPLORING PSYCHOLOGICAL QUESTIONNAIRES

DE RYCK, T.1, JANNES, C.2, VAN BRUAENE, N.1, MEEUSEN, R.3

ANACURA

INTRODUCTION: Athletes are all pushing their limits to increase their performance and to reach their personal goals in sport. Nevertheless, it is important to maintain the delicate balance between training and recovery to reduce the risk for non-functional overreaching

(NFO). But when is this balance perfect? For the best guidance of the athletes there is an important need for tools to quantify the risk of non-functional overreaching and to give correct guidelines to athletes.
METHODS: In our field study, 300 endurance athletes were observed during their training towards a sport event such as a marathon or an iron man. All athletes trained at least 4 times a week. To monitor the training load and mental status of the athletes, the SpartaNova monitoring tool was used (including training data, diary and the POMS questionnaire) together with the RESTQ-Sport questionnaire. Different scores were calculated from the questionnaires, all having a slightly other accent within the complex process of NFO. Spearman rank correlation coefficients were calculated to evaluate the correlations between the different scores obtained from the questionnaires.
RESULTS: The differences between the scores were evaluated. Significant correlations ($p<0.01$) were found between scores obtained from the POMS questionnaire and the RESTQ-Sport questionnaire. Nevertheless, some correlations, such as those between the fatigue-scores obtained from the different psychological questionnaires were low (correlation coefficient < 0.5), pointing to important differences between the questionnaires, such as the time period that is reflected when answering the questions. Practical guidelines to use and interpret the questionnaires both on individual as on group level were formulated based on the data obtained from the study. Furthermore the best scoring methods were put forward to interpret the questionnaires in the context of non-functional overreaching.
CONCLUSION: This is the first time that different psychological questionnaires were compared for their usefulness in detecting NFO in a large cohort. Both the advantages and disadvantages of the use of the questionnaires in a practical setting will be discussed. Further research is needed to confirm our results and guidelines in other sports and settings.

OP-PM33 Hypoxia 1

EFFECTS OF NORMOBARIC HYPOXIA AND METABOREFLEX ACTIVATION ON HEART RATE VARIABILITY

MULLIRI, G., SAINAS, G., DONEDDU, A., PINNA, V., PALAZZOLO, G., CRISAFULLI, A.
UNIVERSITY OF CAGLIARI

INTRODUCTION: Exposition to hypoxic enviroments induces a series of acute and chronic adaptations in the human cardiovascular system, which are partly mediated by changes in autonomic nervous system. In previous studies, it has been observed an increase in sympathetic nervous system (SNS) and a decrease in parasympathetic nervous system (PNS) activity in response to hypoxia. The aim of our study was to measure changes in PNS by means of heart rate variability (HRV) after exposure to a normobaric hypoxic gas mixture and during metaboreflex activation by using the Post Exercise Muscle Ischemia (PEMI) method.
METHODS: 8 subjects (6 men 2 women) underwent a rectangular 10 min leg-cycling exercise session at two different levels of normobaric hypoxia, level 0,5 (Fraction of Inspired Oxygen – FIO2- 0,21) and level 12 (FIO2 0,135), pedalling at 80% of their second ventilatory threshold previously determined by cardiopulmonary exercise test (CPET). After each session, the subjects performed a metaboreflex activation protocol at normoxic conditions, which consisted in 3 min of leg cycling at 30% of maximal load measured by CPET, followed by 3 min of PEMI induced through an inflatable cuff applied to one thigh. Results were compared to a Control Exercise Recovery (CER) protocol consisting in 3 min of leg cycling at the same load and 3 min of recovery.
Two HRV indices of PNS activity (RMSSD and LF-HF power) were measured analyzing the electrocardiogram recordings at rest and during CER and PEMI. Students T test was performed to verify significant differences between HRV parameters at rest (lvV 0,5 vs lv12) and during metaboreflex activation (CER vs PEMI at lv 0,5, CER vs PEMI at lv 12, Δ of CER-PEMI at lv 0,5 vs Δ of CER-PEMI at lv12) with a P value set at <0,05.
RESULTS: No significant differences were observed on both RMSSD (p=0,35) and LF-HF power (p=0,46) at rest (lv 0,5 vs lv12). RMSSD showed a statistical significant reduction during PEMI at lv 0,5 (p=0,039) and near-significant at lv 12 (p=0,06), while LF-HF power showed a near-significant reduction at lv 12 (p=0,057) but not at lv 0,5 (p=0,30).
Δ of CER-PEMI at lv 0,5 vs Δ of CER-PEMI at lv 12 did not showed any difference in both parameters (RMSSD p=0,15, LF-HF Power p=0,41).
CONCLUSION: Our results showed a decrease in HRV measures during PEMI in both normoxic and hypoxic conditions which is in line with previous studies on metaboreflex activation and PNS activity. However, hypoxia alone did not induce changes in HRV either at rest or combined with metaboreflex activation, a result in contrast with the current literature in this field.
One possibile explanation could be the delay in hypoxia exposure and HRV measurement, indicating that a brief exposure to hypoxia induces acute PNS responses that rapidly fade.

HYPOXIC VENTILATORY RESPONSES IN PREMATURELY AND FULL-TERM BORN ADULTS

DEBEVEC, T., MRAMOR, M., MILLET, G.P., PIALOUX, V., OSREDKAR, D.
JOZEF STEFAN INSTITUTE

INTRODUCTION: Pre-term birth hinders lung development and can result in life-long anatomical and functional sequelae (Duke et al., 2014). Perinatal hyperoxia, often associated with treatment of premature newborns, induces significant alterations in cardiorespiratory control which can affect ventilatory responses. Hyperoxia-related carotid chemoreceptor dysfunction seems to be among the key factors underlying the abnormal ventilatory responses of prematurely born individuals (Bates et al., 2014). While blunted hypoxic ventilatory response (HVR) is consistently reported in pre-term infants, recent evidence indicates that it can persist with ageing (Bates et al., 2014).
METHODS: Twenty-one prematurely born adult males (gestational age=29±4 weeks (mean±SD)), and 14 age and aerobic capacity matched controls born at full term (gestational age=39±2 weeks) underwent the following three tests: 1) the Richalet hypoxia sensitivity test (Richalet et al., 2012) to determine the resting and exercise HVR responses and a graded exercise test to volitional exhaustion in 2) normoxia (FiO2=0.21) and 3) normobaric hypoxia (FiO2=0.13) to compare hypoxia-related effects on maximal aerobic power (MAP).
RESULTS: The resting HVR was lower in the pre-term (0.21±0.21 L·min-1·kg-1) compared to full-term born individuals (0.47±0.23 L·min-1·kg-1; p 0.05). Surprisingly, no differences were noted in the exercise HVR (pre-term 0.62±0.23; full-term 0.70±0.20; p=0.29). While a lower absolute MAP during the graded test was observed in pre-term compared to full-term individuals in both, normoxia and hypoxia, hypoxia-induced reduction of MAP was comparable (pre-term −8.6±0.4%; full-term −8.5±0.5%; p=0.31).

CONCLUSION: These findings support earlier studies indicating that the blunted resting HVR observed in prematurely born infants persists into adulthood. However, we show, for the first time, that the reduced ventilatory response to hypoxia is attenuated during moderate intensity exercise and even more importantly, that hypoxia-induced reduction of MAP is comparable between healthy pre-term and full-term born adults. Our data therefore suggest that exercise in hypoxic conditions does not seem to pose an additional clinical risk for healthy and physically active prematurely born adults.

SALIVARY CORTISOL UPON AWAKENING CORRELATES WITH RISK OF ACUTE MOUNTAIN SICKNESS

ESTOPPEY, J.2, VUISTINER, P.3, LÉGER, B.3, SARTORI, C.4, KAYSER, B.1,3
1INSTITUTE OF SPORTS SCIENCES, UNIVERSITY OF LAUSANNE, 2UNIVERSITY OF LAUSANNE MEDICAL SCHOOL, 3CLINIQUE ROMANDE DE RÉADAPTATION, 4LAUSANNE UNIVERSITY HOSPITAL , SWITZERLAND.

INTRODUCTION: Non-acclimatized subjects ascending rapidly to high altitude (HA) may develop signs of acute mountain sickness (AMS), such as headache, nausea, fatigue, dizziness and insomnia. Underlying mechanisms of AMS are still unclear. Since corticosteroids are effective for prevention and treatment of AMS, we hypothesised that cortisol homeostasis may be altered in AMS-prone subjects.
METHODS: Upon arrival at the Capanna Regina Margherita (4554m; HA), 102 alpinists completed a questionnaire about personal information, health and medication, acclimatization, history of altitude illness and physical activity. The following morning they provided 3 saliva samples (S) upon awakening (S1: 0, S2: 30, S3: 45 min). AMS was scored with the Lake Louise Score (LLS-5; cut-off≥5) and LLS without the sleep item (LLS-3-NS; cut-off≥3). >4 weeks after descent saliva was recollected at the same wake-up time at home (382±309m (mean±SD); low altitude (LA), N=59). Saliva cortisol was quantified by immunoassay (Salimetrics). Three cortisol indexes were calculated: first sample on awakening (S1), cortisol awakening response (area under curve with respect to S1, CAR) and total post awakening cortisol (area with respect to ground, AUC-G).
RESULTS: AMS prevalence was 31% with LLS-5 and 34% with LLS-3-NS.
S1 (450±190 vs 288±159µg/dl, p<0.0001) and AUC-G (387±137 vs 276±114µg/dl*min, p<0.0001) but not CAR (50±100 vs 60±81µg/dl*min, p=0.5498) were significantly higher at HA compared to LA.
S1 was higher both at HA (495±209 vs 384±176µg/dl, p=0.0156) and LA (354±160 vs 253±142µg/dl, p=0.0154) in LLS-5 AMS+ compared to AMS- participants. AMS+ participants had also lower CAR at LA (24±87 vs 79±72µg/dl*min, p=0.0128) but similar CAR at HA. AUC-G was similar in both groups at HA and LA.
Noteworthy, when AMS was scored with the LLS-3-NS, no differences in cortisol responses were found between AMS+ and AMS- participants both at HA and LA.
CONCLUSION: Salivary cortisol response upon awakening is altered in AMS+ versus AMS- subjects both at HA and LA. S1 was surprisingly higher in AMS+ vs AMS- subjects already at low altitude. This difference was associated with flattened cortisol awakening curves and appears to be related, at least in part, to sleep disturbance. Salivary cortisol assessment at LA may thus contribute to screen individuals at risk for AMS.

EFFECTS OF HYPOXIA ON SKELETAL MUSCLE MOLECULAR ADAPTATIONS TO HEAVY RESISTANCE TRAINING

FYFE, J., INNESS, M., PARKER, L., BILLAUT, F., AUGHEY, R., PETERSEN, A.
INSTITUTE OF HEALTH AND SPORT, VICTORIA UNIVERSITY

INTRODUCTION: We have previously shown that heavy resistance training in hypoxia (IHRT) results in greater strength improvements compared to the same training in normoxia (Inness et al., Front Physiol 2016). However, the mechanisms responsible for enhanced strength gains with IHRT have not been investigated. We therefore determined the effects of IHRT on skeletal muscle molecular adaptations that contribute to muscle strength.
METHODS: A pair-matched, placebo-controlled, single-blind study included 18 resistance-trained participants assigned to either IHRT or placebo (PLA) (n = 9 per group). Both groups performed 20 sessions over 7 weeks with either IHRT (FiO2 0.143) or PLA (FiO2 0.20). Groups were matched for body mass (mean ± S.D.; 83.1 ± 7.5, 80.2 ± 12.0 kg), height (1.83 ± 0.05, 1.81 ± 0.06 m), one-repetition maximum (1-RM) squat (121.4 ± 22.1, 125.5 ± 30.7 kg) and training history. Resting vastus lateralis muscle biopsies were taken following an overnight fast before and after the training programme. Biopsies were analysed for muscle fibre cross-sectional area (CSA), mTOR signalling, proteins involved in sarcoplasmic reticulum (SR) calcium uptake and release, and proteins involved in force transfer between the sarcomeres and extracellular matrix.
RESULTS: Training increased Type II fibre CSA in both groups (mean ± 90% confidence limits (CL), effect size (ES); IHRT: 16.0 ± 25.2%, ES 0.50; PLA: 22.0 ± 31.8%, ES 0.42). Type I CSA only increased in PLA (16.1 ± 23.3%, ES 0.48); however, the changes in Type I or II fibre CSA were not different between groups. Training caused no substantial change in total p70S6K in either group. Training caused a possibly trivial decrease in total mTOR in PLA, and a possibly small increase in IHRT, resulting in a greater increase in mTOR for IHRT compared to PLA (18.9 ± 27.3%, ES 0.65). The content of SR-associated proteins dihydropyridine receptor, SERCA1, and calsequestrin did not change in either group. In contrast, SERCA2 increased in IHRT only (23.5 ± 18.7%, ES 0.33), and this increase was greater compared to PLA (42.6 ± 52.2%, ES 0.63). The content of force transfer protein dystrophin did not change in either group; however, alpha-actinin increased only in IHRT (47.8 ± 67.5%, ES 0.67), and this was greater compared to PLA (63.1 ± 79.5%, ES 1.10).
CONCLUSION: The greater strength increases following heavy resistance training in hypoxia compared to normoxia are possibly due to enhanced SR calcium regulation and force transfer between sarcomeres and the extracellular matrix.

SUBSTRATE UTILISATION IS ALTERED IN NORMOBARIC HYPOXIA, COMPARED WITH NORMOXIA WHEN IN THE FASTED, BUT NOT FED STATE

GRIFFITHS, A., DEIGHTON, K., KING, R., MATU, J., SHANNON, O., OHARA, J.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: The hypoxic exposure experienced at altitude is known to impair endurance performance, which may in part be related to changes in substrate utilisation. However, equivocal findings have been reported regarding the contribution of carbohydrate and fat to the total energy yield in hypoxia. These divergent findings may be due to differences in methodological design, such as the nutritional status of participants prior to exercise. As such, this study was the first to investigate the effect of the fasted and fed state on substrate utilisation during exercise in normoxia and normobaric hypoxia (NH).
METHODS: Twelve men rested and performed exercise twice in sea level (SL) conditions (~20.93% O2) and twice at NH equivalent to 4300m (Fi02~11.7%) in a randomised, crossover design. Participants entered the chamber after an overnight fast. After 1 hour, one trial within each experimental condition remained fasted, while the other included consumption of a high carbohydrate breakfast (567 kcal, 68% carbohydrate, 12% fat, 20% protein). One hour after consumption of breakfast (fed trials) or no breakfast (fasted trials), participants walked for one hour at intensities of 40%, 50% and 60% of altitude specific VO2max. Walking was performed on a treadmill at 10-15% gradient whilst carrying a 10kg backpack to simulate altitude trekking. Expired gas was measured throughout, using online gas analysis for the quantification of carbohydrate and fat oxidation.
RESULTS: Relative carbohydrate oxidation was significantly reduced in NH fasted conditions compared with SL fasted conditions at 40% (SL fasted: 38.5±15.5%; NH fasted: 22.4±17.5%; p = 0.03) and 60% VO2max (SL fasted: 50.1±17.6%; NH fasted: 35.4±12.4%; p = 0.03), with a trend observed at 50% VO2max (SL fasted: 38.0±17.0%; NH fasted: 23.6±17.9%; p = 0.07). Relative fat oxidation in the fasted state was reciprocal to the fasted relative carbohydrate findings at all intensities. No significant differences in relative carbohydrate oxidation were observed in NH fed conditions compared with SL fed conditions at 40% (SL fed: 48.5±13.3%; NH fed: 44.1±20.6%; p = 1.00), 50% (SL fed: 47.1±14.0%; NH fed: 43.1±11.7%; p = 1.00) and 60% VO2max (SL fed: 55.1±15.0%; NH fed: 54.6±17.8%; p = 1.00). Relative fat oxidation in the fed state was reciprocal to the fed relative carbohydrate findings at all intensities.
CONCLUSION: This study is the first to establish that relative carbohydrate contributions to energy expenditure decrease, while relative fat contributions increase, during exercise matched for relative intensities in NH compared with SL when in the fasted, but not fed state. These findings suggest that the feeding state of participants may explain some of the divergence within the current literature regarding the effects of hypoxia on substrate utilisation. Further, these findings should be considered when prescribing nutritional support for mountaineers and military personnel trekking at high altitude.

URINARY ALPHA-1-ACID GLYCOPROTEIN IS A SENSITIVE MARKER OF GLOMERULAR PROTEIN LEAKAGE AT ALTITUDE

TALKS, B., BRADWELL, S., DELAMERE, J., RAYNER, W., CLARKE, A., LEWIS, C., THOMAS, O., BRADWELL, A.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Proteinuria is an established feature of ascent to high altitude and may be caused by a loss of charge on the glomerular capillary wall. To test this theory, we measured two similar size but oppositely charged proteins in urine: negatively charged alpha-1-acid glycoprotein and positively charged dimeric lambda free light chains, size 41-43 kDa and 50 kDa respectively. 24-hour urinary leakage was compared with albumin, a 66 kDa negatively charged protein. We hypothesised that urinary leakage of alpha-1-acid glycoprotein may better reflect changes in glomerular capillary wall charge and provide a more sensitive marker of glomerular protein leakage at altitude than albumin, and second that increases in excretion ratio of alpha-1-acid glycoprotein to lambda free light chains would support a reduction in glomerular capillary wall negative charge.
METHODS: 23 individuals were studied before and during an altitude research expedition to 5035 m on Chimborazo in Ecuador. Participants (age 23-78 years, male = 17) were members of the Birmingham Medical Research Expeditionary Society. In Birmingham (baseline at 140 m) and on each of the 10-day ascent, 24-hour urines and venous blood samples were collected and aliquots stored frozen until analysis in the UK. Alpha-1-acid glycoprotein, lambda free light chains, and albumin concentrations were measured in serum and urine samples using immunoturbidimetry and radial immunodiffusion (Binding Site Ltd).
RESULTS: There was a significant increase in median urinary leakage of alpha-1-acid glycoprotein ($p < 0.0001$; 6.85-fold) and albumin ($p = 0.0006$; 1.65-fold) with ascent to altitude, but no significant increase in leakage of lambda free light chains ($p = 0.39$; 1.14-fold). Urinary excretion of alpha-1-acid glycoprotein ($p = 0.0026$), but not albumin ($p = 0.19$) correlated with the daily ascent profile.
CONCLUSION: Urinary leakage of alpha-1-acid glycoprotein was a more sensitive marker of altitude proteinuria than urinary albumin and lambda free light chains. The differential urinary excretion of positively and negatively charged proteins supported the possibility of loss of glomerular capillary wall negative charges at altitude. Exercise proteinuria may also be attributable to the same loss of glomerular capillary wall negative charges.

OP-PM34 Molecular response/signaling

AUTOPHAGY RESPONSE FOLLOWING A HIGH-INTENSITY INTERVAL TRAINING SESSION, BEFORE AND AFTER 3 WEEKS OF TRAINING, IN HUMANS.

BOTELLA, J., PERRI, E., GRANATA, C., BISHOP, D.J.

VICTORIA UNIVERSITY

INTRODUCTION: Mitochondrial health is critical for skeletal muscle function, and it is improved by both mitochondrial biogenesis and the removal of dysfunctional mitochondria (via autophagy). Although it is well known that exercise training increases mitochondrial biogenesis, little is known about the effects of exercise on markers of autophagy in human skeletal muscle. The purpose of this study was to explore the effects of a high volume of exercise training, which we have previously reported to increase both mitochondrial content and function, on basal markers of autophagy. We also investigated the effects of a single exercise session, before and after training, on markers of autophagy.

METHODS: Ten healthy participants (VO2max; 46.7 ± 8.2 mL/kg/min) performed a high-intensity interval training session (HIIT; 5x4-min at ~90% WPeak) twice-a-day, 7 days per week, for 3 weeks (high volume training; HVT). Muscle biopsies were taken from the vastus lateralis muscle before, immediately post, and 3 hours post a HIIT session performed before and after the training period. Initiation of autophagy was assessed by changes in Unc-51 like kinase-1 phosphorylation at serine 555 (ULK1 s555). Autophagy flux was assessed by changes in the protein content of microtubule-associated protein 1A/1B-light chain 3 (LC3), and sequestesome 1 (p62/SQSTM1) was used as a marker of lysosomal degradation.
RESULTS: LC3II content and the LC3-II/I ratio were reduced immediately following HIIT ($p<0.05$) and remained statistically reduced 3 hours after exercise after the HVT period. p62 content tended to decrease following exercise, both before and after the HVT, but was only significant 3 h post-exercise before the HVT period. No changes in ULK1 s555 were found following exercise. Basal p62 and LC3II content, and the LC3-II/I ratio, did not change from before to after the training period despite a 5-fold increase in training volume.
CONCLUSION: The present study shows that LC3-II/I is decreased following exercise in humans, and that autophagic flux was not increased following a period of HVT. This is in line with previous research showing a decrease in LC3-II/I and LC3-II, while no change in p62 protein content between 0 and 120 min after exercise. The decrease in p62 found in this study at 3 h post-exercise may indicate that lysosomal degradation may occur later in the recovery than previously thought in humans. Contrary to recent rodent studies, ULK1 was not phosphorylated at s555 between 0 and 3 h following exercise. It can be concluded that autophagic flux seems to be blunted acutely following exercise, and that it is not upregulated following a high volume of high-intensity training.

CHANGES IN MUSCLE FASCICLE LENGTH AND ORIENTATION FOLLOWING CONCENTRIC AND ECCENTRIC TRAINING ARE GRADED TO REGION-SPECIFIC MECHANOSENSITIVE RESPONSES OF COSTAMERIC PROTEINS

FRANCHI, M.V., RUOSS, S., VALDIVIESO, P., SMITH, K., ATHERTON, P.J., NARICI, M.V., FLÜCK, M.

UNIKLINIK BALGRIST

INTRODUCTION: Concentric (CON) vs. eccentric (ECC) resistance training (RT) can lead to similar changes in muscle size (1) and similar cumulative muscle protein synthesis (MPS) responses (2) but through distinct changes in muscle architecture (1, 2, 3). To gain insights into the molecular mechanisms underlying these remodelling patterns, we specifically targeted focal adhesion kinase (FAK) and Vinculin isoforms (gamma- and meta-), mechanosensitive costameric proteins, involved in the modulation of muscle remodelling and protein synthesis (4, 5, 6). Furthermore, we assessed the relationships between FAK, MPS, and muscle structural adaptations.
METHODS: Six young males trained both legs unilaterally 3 times/week for 8 weeks; one leg performed CON RT, the contralateral performed ECC RT. Muscle biopsies were collected after training from vastus lateralis midbelly (MID) and distal (Distal, i.e., 4 cm above distal myotendinous junction) sites at 0, 4, 8 weeks. Total FAK content and y397FAK activation were evaluated by immunoblotting. MPS was assessed by deuterium-oxide tracer technique and muscle morphological/architectural adaptations were evaluated by ultrasound and DXA.
RESULTS: The levels of pY397-FAK at the 8 weeks time point were ~4-fold greater after ECC RT at the Distal site compared to CON RT ($p<0.05$). When looking at ratio between pY397FAK and total FAK content (i.e., specific phosphorylation), ECC RT presented a significantly greater ratio at the Distal site at 4 (~2.2fold, $p<0.05$) and 8 weeks (~9fold, $p<0.001$) compared to CON RT. Meta-vinculin was found transiently increased at 4 weeks at the Distal site only after ECC RT. After 8 weeks, ECC RT presented greater fascicle length (Lf) increases (10.5% vs. 4%), whereas CON RT showed greater changes in pennation angle (PA) (12.3% vs. 2.1%). However, MPS did not differ between exercise types or muscle sites at all time points. The values of pY397-FAK and pY397-FAK/FAK at the Distal muscle site positively correlated to changes in Lf at 8weeks ($r=0.76$, $p<0.01$ and $r=0.66$, $p<0.05$, respectively) whereas pY397-FAK/FAK values negatively correlated to the changes in PA at 8Weeks ($r= -0.65$, $p<0.05$). In addition, Positive linear relationships between meta-vinculin and pY397-FAK, and between meta-vinculin and fast myosin levels were found at all time points.
CONCLUSION: The present data highlight that the specific Y397 phosphorylation of FAK in vastus lateralis muscle is modified by training in proportion to the impacting force and in the region, which subjected to the highest degree of loading. Y397FAK activity correlated to contraction-dependent architectural remodeling. Site-specific changes in pY397FAK, and meta-vinculin may play an important role in architectural adjustments of skeletal muscle to distinct mechanical stimuli.

COMPARING THE EPIGENETIC LANDSCAPE OF TWO PHENOTYPIC EXTREME SKELETAL MUSCLES - SOLEUS AND EDL

BENGTSEN, M.1, WINJE, I.M.,1, LANDSKRON, J.2, MEZA-ZEPEDA, L.A.3, GUNDERSEN, K.1

UNIVERSITY OF OSLO, NORWAY

INTRODUCTION: By varying the relative composition of different fiber-types within a muscle, an organism has the ability to fine-tune muscle function according to physiological demands.
The muscle myofibers are in a post-mitotic state hence phenotypical remodelling of adult tissue is achieved by regulating the expression of the genome in order to respond to changes in the environment. This requires alterations of the epigenetic landscape through different processes such as methylation and acetylation of histones.
Skeletal muscle tissue is composed of approximately 40 - 60 % myonuclei, while the remaining are non-muscle cells with a different origin such as stromal and hematopoietic. Therefore, it is important to isolate the subpopulation of interest from the whole tissue, as a mixed-cell population are prone to increase the number of false-positive results.
In this study, we present a novel method for isolating myonuclei from whole native muscle.
The resulting pure myonuclear fraction allowed us to explore the epigenetic landscape for the two phenotypic extremes the oxidative Soleus and the glycolytic Extensor Digitorum Longus muscle (EDL).
METHODS: Biochemical isolation of the myonuclei population from mouse Soleus and EDL muscles, followed by Chromatin Immunoprecipitation coupled with next-generation sequencing (ChIP-Seq) and bioinformatic analyses.
RESULTS: Using our novel method, we show that that the myonuclei epigenetic environment is significantly different compared to the whole tissue. Global analysis of the epigenetic landscape in the Soleus and EDL muscles show that there are large dynamic differences between the two muscle types which correlate with the myo-specific transcriptome and the properties of the muscles.

CONCLUSION: We have developed a novel method to isolate the myo-specific nuclei from skeletal muscle. We use the method to generate a global map of the epigenetic landscape of the two extremes the oxidative Soleus and the glycolytic EDL muscles and find that their physiological different properties are reflected in their epigenome.

TRANSCRIPTION MECHANISMS REGULATING THE INCREASE OF OXPHOS PROTEINS AND TRANSCRIPTION REGULATORS CONTENT IN THE HUMAN SKELETAL MUSCLE

BOKOV, R.O.1, POPOV, D.V.1,2, LYSENKO, E.A.1,2, KUROCHKINA, N.S.1, VINOGRADOVA, O.L.1,2

1: IBMP RAS (MOSCOW, RUSSIA), 2: LOMONOSOV MOSCOW STATE UNIVERSITY (MOSCOW, RUSSIA)

INTRODUCTION: When stress factors (physical exercises) are regularly applied to the muscle cell, the adaptive changes in the content of specific proteins occur. We assume that the mechanisms responsible for these changes may differ for proteins with various functions. The aim of our work is to study at the transcription level the mechanisms regulating the training-induced increase of mitochondrial enzymes and transcriptional regulators content in the human skeletal muscle.
METHODS: Multiple biopsy sampling from human skeletal muscles provides an unique opportunity to assess changes in proteins content and genes expression before and after regularly applied stress (exercise training), as well as after acute stress (single exercise). Ten young untrained males performed the one-legged moderate intensity knee-extension for 1 h. Biopsies from m. vastus lateralis were taken prior to, at 1 h, and 4 h after the exercise. This test was repeated after aerobic training on the cycling ergometer (5/week, 8 weeks). The changes in the content of transcriptional regulators and OXPHOS proteins after 8-wk training were evaluated by Western blot. To evaluate the changes in gene expression after training and after a single exercise qPCR was used.
RESULTS: After 8-wk training, the content of OXPHOS proteins at rest (NDUFB8, SDHB, UQCRC2, MT-CO1, ATP5A1) increased (by 35-162%, $p<0.05$). There were no changes in the expression of genes encoding these proteins at rest and after a single exercise (both before and after 8-wk training). An increase in the content of transcriptional regulators was found after 8-wk training for CRTC2 (60%, $p<0.05$), NR4A3 (100%, $p<0.05$) and TFAM (20%, $p<0,06$). At the same time, the expression of the NR4A3 and TFAM genes increased ($p<0.05$) after a single exercise, both before and after 8-wk training. An increase in the expression of genes in response to a single exercise was also observed for other transcriptional regulators (PGC-1α, ESRRG), but there were no increase in the content of their proteins after 8-wk training, which may be due to the high proteolysis rate.
CONCLUSION: In conclusion, 8-wk training-induced increase in the content of OXPHOS proteins is not associated with changes in their gene expression at rest and after a single exercise. On the contrary, the training-induced increase in the content of some transcriptional regulators is associated with the activation of their mRNA expression after a single exercise.

EFFECT OF AEROBIC TRAINING ON THE BASAL EXPRESSION OF SIGNALING AND MITOCHONDRIAL PROTEINS IN HUMAN SKELETAL MUSCLE

POPOV, D.V.1,2, LYSENKO, E.A.1,2, BOKOV, R.O.1, KUROCHKINA, N.S.1, VINOGRADOVA, O.L.1,2

1 INSTITUTE OF BIOMEDICAL PROBLEMS OF THE RAS, 2 M.V. LOMONOSOV MOSCOW STATE UNIVERSITY

INTRODUCTION: Most of the studies investigating the molecular mechanisms of adaptation of human skeletal muscles to aerobic exercise evaluate the response to a single aerobic exercise. Changes in the basal content of signaling proteins caused by aerobic training remain much less studied. The goal of our study was to investigate the effect of 8-wk aerobic training on the basal content of signaling proteins in human skeletal muscle, namely: 1) the phosphorylation of kinases: ACC1/2_Ser79/222 (a marker of AMPK activity), CaMKII_Thr286, p38_Thr180/Tyr182, and ERK1/2_Thr202/Tyr204, and transcriptional regulators CREB1_Ser133 and FOXO1_Ser256; 2) the content of regulatory proteins involved in mitochondrial biogenesis: NR4A3, CRTC2, ESRRG, PGC-1a, TFAM, and NCOR1 as well as 3) the content of mitochondrial proteins.
METHODS: Ten untrained young males participated in an 8-wk aerobic cycling training. The basal (at rest) content of proteins and expression of genes in vastus lateralis muscle were evaluated before and after 8-wk cycling aerobic training using Western blot and qPCR, respectively.
RESULTS: Training increased aerobic performance (anaerobic threshold), the ADP-stimulated mitochondrial respiration in permeabilized muscle fibers, and the content of mitochondrial proteins in complexes I-V, without changing the expression of myosin heavy chain isoforms. The training caused an increase in the basal content of transcriptional regulators: NR4A3 ($P<0.05$), CRTC2 ($P<0.05$), and TFAM ($P<0.06$), while the content of PGC-1a, ESRRG, and NCOR1 did not change. In addition, an increase in the basal phosphorylation of CaMKII_Thr286 ($P<0.01$), CREB1_Ser133 ($P<0.05$) and FOXO1_Ser256 ($P<0.05$) was found. The basal phosphorylation of ERK1/2_Thr202/Tyr204, ACC1/2_Ser79/222, and p38_Thr180/Tyr182 remained unchanged.
CONCLUSION: In conclusion, it has been shown that in the human skeletal muscle, aerobic training increased the basal content of the transcriptional regulators NR4A3, CRTC2, and TFAM; activated the calcium-dependent signaling at rest, and deactivate the proteolysis regulator FOXO1 and mRNA expression of FOXO1-dependent E3 ligases. Activation of regulatory proteins and expression of genes after a single exercise are transient. Therefore, small but constant training-induced increases in the basal content of regulatory proteins can play an important role in the adaptation of skeletal muscle to aerobic training.

LONG-TERM EFFECTS OF DIFFERENT EXERCISE PROTOCOLS ON ADIPOSE TISSUE THERMOGENESIS-RELATED GENE EXPRESSION MARKERS IN OBESE MICE

MILESKI, K.S.L.1,2, COELHO, M.S.3, OLIVEIRA, F.C.B.3, NEVES, F.A.R.3, PORTO, L.G.G., LOFRANO-PORTO, A.2,3

1: FEF-UNB, 2: PPGCS-UNB, 3:FARMOL-FS-UNB

INTRODUCTION: Physical exercise is known to acutely increase thermogenesis and energy expenditure. However, studies investigating molecular mechanisms underlying the therapeutic potential of long-term exercise in obesity prevention and control were not extensively studied. We evaluated the effects of high intensity interval training and moderate intensity continuous training on the expression of thermogenesis-related genes in white and brown adipose tissue of diet-induced obese mice.

METHODS: Adult male mice C57BL/6 were fed with high-fat diet (HFD) in two different exercise groups: High intensity interval training (HIIT; n=5) and Moderate intensity continuous training (MICT; n=5). Control groups were fed with HFD (HC, n=5) or control diet (CC, n=5). Using a mice treadmill (AVS®), a ramp test was used to determine the maximum cardiorespiratory fitness (CRF) before exercise protocols. HIIT sessions consisted of 4-min high-intensity bouts at 90% followed by 3-min moderate-intensity bouts at 70%. MICT consisted in a single bout at 70%. Exercise training were performed 45-54 min/day, 5 days/week, for 8 weeks. Interscapular brown (BAT) and inguinal white adipose tissues (iWAT) were collected 72h after the last exercise session and weighted. Gene expression of thermogenic markers was analyzed by RT-qPCR. Kruskal Wallis with Dunn's post-hoc was used for comparison between groups (Mean and SE), considering p≤0.05.
RESULTS: In BAT, HIIT and MICT reduced the expression of the Ucp1: HIIT:0.80 ± 0.09 and MICT: 0.82 ± 0.09, versus HC: 2.24 ± 0.28 (p≤0.05). However, none of the exercise modified Ucp1 expression in iWAT- HIIT: 0.37 ± 0.23; MICT: 0.35 ± 0.25; CH: 0.15 ± 0.05 and CC: 1.04 ± 0.01, p>0.05). Unexpectedly, HIIT and MICT did not change thermogenesis-related genes expression in iWAT - Cidea (HIIT: 0.51 ± 0.10, MICT: 0.68 ± 0.22, HC: 0.59 ± 0.18, CC: 1.03 ± 0.01), Prdm16 (HIIT: 2.28 ± 0.40, MICT: 2.27 ± 0.12, HC: 3.02 ± 1.01, CC: 1.14 ± 0.05 and Pgc1a (HIIT 1.39 ± 0.24, MICT 1.83 ± 0.46, HC 1.96 ± 0.56, CC 1.03 ± 0.01, p>0.05).
CONCLUSION: Increased whole-body thermogenesis is one mechanism contributing to increased energy expenditure and weight loss. Ucp1 is the main thermogenic marker of adipose tissue, associated with a browning phenotype in adipocytes, increased mitochondrial biogenesis and oxygen consumption rate. The reduced Ucp1 expression in BAT of obese mice submitted to both exercise intensities may be related, specifically, to a long-term adaptive response to exercise or to an increased rate of Ucp1 protein synthesis and action. Our results are limited to the transcriptional level and may not reproduce direct thermogenic activation in the adipose tissue deposits in vivo.

EFFECTIVENESS OF REPEATED-SPRINT TRAINING IN HYPOXIA INDUCED BY VOLUNTARY HYPOVENTILATION IN RUGBY PLAYERS

FORNASIER-SANTOS, C.1, STRIDGEON, P.2, NOTTIN, S.1, MILLET, G.P.3, WOORONS, X.4

UNIVERSITY OF AVIGNON

INTRODUCTION: Repeated-sprint ability (RSA) is an important fitness requirement in team sports. It has been shown that RSA is significantly improved after 6-8 sessions of repeated-sprint training in hypoxia (RSH) (Millet et al., 2017). In addition, voluntary hypoventilation at low lung volume (VHL) can induce levels of desaturation and muscle deoxygenation similar to those observed at moderate altitude (Woorons et al., 2010). The aim of the present study was therefore to determine the effects of RSH induced by VHL (RSH-VHL) on running repeated-sprint ability in rugby players.
METHODS: Twenty-one highly trained rugby players performed, over a 4-week period, 7 sessions of repeated 40-m sprints (outdoors on a rugby field) either with VHL (RSH-VHL, n = 11) or with normal breathing (RSN, n = 10). Before (Pre-) and after (Post-) the training period, an RSA test was implemented and consisted of repeating 40-m all-out sprints (starting every 30 s) until task failure (85% of the reference velocity assessed in an isolated sprint). Max velocity (Vmax), mean velocity (Vmean) from all the 40-m sprints were recorded and heart rate (HR) was continuously measured. Rating of perceived exertion (RPE) was assessed just after the completion of the last sprint and two blood samples were collected at the 3rd and 4th minute after the end of the test to obtain maximal lactate concentration ([La]max).
RESULTS: The number of sprints completed during the RSA test was significantly increased after the training period in RSH-VHL (9.1 ± 2.8 vs. 14.9 ± 5.3; + 64%; p < 0.01) but not in RSN (9.8 ± 2.8 vs. 10.4 ± 4.7; + 6%; p = 0.74). Vmax was not different between Pre- and Post- in both groups whereas Vmean decreased in RSN and remained unchanged in RSH-VHL. While [La]max was not significantly different between groups both in Pre- and Post, it was lower in Post- compared to Pre- in RSN (p=0.01) and unchanged in RSH-VHL (p=0.23). The mean SpO2 recorded over an entire training session was lower in RSH-VHL than in RSN (90.1 ± 1.4 vs. 95.5 ± 0.5%, p<0.01). In RSH-VHL, 35.5% of the total training session time was spent with SpO2 below 88%.
CONCLUSION: RSH-VHL could represent an effective "on-field outdoor" hypoxic training strategy for improving running RSA in team sport players. RSA enhancement can be obtained in specific conditions and can therefore be easily integrated in a conditioning program.

THE EFFECTS OF RECOVERY DURATION ON PHYSIOLOGICAL AND PERCEPTUAL RESPONSES OF TRAINED RUNNERS DURING FOUR SELF-PACED HIIT SESSIONS

SCHOENMAKERS, P.P.J.M., REED, K.E.

UNIVERSITY OF ESSEX

INTRODUCTION: PPJM Schoenmakers1, KE Reed1,
1School of Sport, Rehabilitation, and Exercise Sciences
University of Essex, Colchester, United Kingdom
The development of non-motorized treadmills allow scientists to study self-paced high intensity interval training sessions (HIIT) in a more ecologically valid manner than was possible with externally controlled motorized treadmills. This study aimed to examine the effects of different recovery durations on self-selected running velocities, physiological responses (time spend ≥ 80, 90 and 95% VO2max and HRmax), and ratings of perceived exertion (RPE) in a commonly used HIIT protocol.
METHODS: Twelve male runners (age: 34±11 years; VO2max: 54.0±8 mL·kg−1·min−1) performed four simulated HIIT sessions on a non-motorized curved treadmill (Woodway Curve XL). Each session comprised six 4-min work intervals, separated by five recovery periods of either 1, 2, 3-min or a self-selected recovery duration (1MIN, 2MIN, 3MIN, ssMIN). In ssMIN, subsequent work intervals started when participants indicated an 'adequate recovery' (Edwards et al., 2011). Oxygen uptake and heart rate were measured continuously during all sessions. Participants were instructed to maintain the highest running velocity they could across the work intervals of each session,

and to finish the HIIT session with a RPE ≥ 17. Differences between protocols in physiological responses, perceptual parameters and running velocity were compared using repeated measures ANOVAs.
RESULTS: Mean running velocity (km·h-1) was significantly higher in 3MIN (12.0±1.0) compared to 1MIN (11.6±1.1), 2MIN (11.5±1.0) and ssMIN (11.7±1.0, P<0.01 for all). Further, the mean running velocity in ssMIN was higher than 2MIN (P=0.001). The self-selected recovery duration in ssMIN averaged 100±34 sec. Time spend ≥ 80% HRmax was significantly higher in 1MIN and 2MIN compared to both 3MIN and ssMIN (1340±72 and 1335±67 sec vs 1305±67 sec and 1303±72 sec respectively, P<0.05), but did not differ in the higher intensity zones (≥ 90 and 95% HRmax) between protocols. No significant differences in time spend ≥ 80, 90, or 95% VO2max were evident between the four protocols. RPE responses were similar across and within the protocols.
CONCLUSION: In a self-paced HIIT session of six 4-min work intervals, the length of recovery durations had a limited effect on the total physiological strain endured in the training. However, running performance was fastest when participants received the longest recovery period (3MIN) between subsequent work intervals. Longer recovery durations may facilitate a higher external training load (higher running intensity), whilst maintaining a similar internal load (physiological stimulus) and may, therefore, allow for greater training adaptations.

RATING OF PERCEIVED EXERTION AND ASSOCIATED FACTORS IN OLDER INDIVIDUALS PERFORMING HIGH-INTENSITY INTERVAL TRAINING: A COMPARISON STUDY.

JABBOUR, G.
QATAR UNIVERSITY

INTRODUCTION: Today, there are a number of potential indicators used in order to increase our understanding of the exercise load and its effect on the individual. The rating of perceived exertion is one of the most popular tool that provide an comprehension on physiological stress during exercise as well as retrospectively information regarding perceived effort during exercise . While much is known about RPE responses and related factors in children and adults, little is known about the perceptual responses to exercise in an older population even more the factors associated with this indicator. Therefore, this study evaluates the Ratings of Perceived-Exertion during a graded cycling test and the effects of 6 weeks of high-intensity interval training on RPE and associated factors in young and older groups.
METHODS: Seventeen healthy young adults with average age of 26.2<2.4> year, and thirteen healthy older adults with average age of 54.5<2.3> year completed a 6-week HIIT intervention on an electromagnetically braked cycle ergometer. RPE were computed across stages corresponding to ventilator thresholds 1 and 2 of graded cycling test and 10 minutes following the end of graded cycling test.
RESULTS: Before training, RPE values were significantly higher in older group at stages corresponding to VT1 [8.9 <0.3>] and to VT2 [9.9 <0.3>] of graded cycling test . At VT2, the RPE index was significantly associated to systolic blood pressure and to oxygen consumption . At 10 min post-training, no significant difference was obtained between groups. After 6 weeks, the RPE decreased significantly compared to baseline for both groups at VT1, VT2 and 10 min following the graded cycling test
and were similar across groups. For both groups the multiple linear regression analysis demonstrated the decreases in oxygen consumption and in SBP correlated significantly to RPE decreases over 6 weeks at VT1 , VT2 and at 10 min following graded cycling test .
CONCLUSION: At moderate-intensity corresponding to 55% of maximal heart rate, older individuals do not appropriately estimate exercise intensity using RPE. However, high intensity interval training improved RPE index among older and adult individuals. These improvements were positively correlated with the declines in the VO2 and SBD values.

THE EFFECT OF TWO DIFFERENT INTERVAL-TRAINING OROGRAMS ON PHYSIOLOGICAL AND PERFORMANCE INDICES

MECKEL, Y., SINDIANI, M., SEGEV, D., ELIAKIM, A.
THE ACADEMIC COLLEGE AT WINGATE

INTRODUCTION: The different training variables in an interval training session are usually constant throughout a single session (Weston et al., 2014; Milanović et al., 2015). Nevertheless, coaches sometimes deviate from this norm, creating incremental protocols where interval's distances are decreased or increased in a single session (Meckel et al., 2011). The aim of the present study was to compare the effect of an increasing-distance interval-training program and a decreasing-distance interval-training program, matched for total distance, on aerobic and anaerobic physiological indices.
METHODS: Forty physical education students were randomly assigned to either the increasing- or decreasing-distance interval-training group (ITG and DTG), and completed two similar relevant sets of tests before and after six weeks of training. One training program consisted of increasing-distance interval training (100-200-300-400-500m) and the other decreasing-distance interval training (500-400-300-200-100m).
RESULTS: While both training programs led to a significant improvement in VO2 max, the improvement in the DTG was significantly greater than in the ITG (14.5 ± 3.6 vs. 7.8 ± 3.2 %). While both training programs led to a significant improvement in all anaerobic indices, the improvements in peak power (15.7 ± 7.8 vs. 8.9 ± 4.7), mean power (10.6 ± 5.4 vs. 6.8 ± 4.4), and fatigue index (18.2 ± 10.9 vs. 7.0 ± 14.2) were significantly greater in the DTG compared to the ITG.
CONCLUSION: The finding indicate that beyond the significant positive effects of both training programs on aerobic and anaerobic fitness, the DTG showed significant superiority over the ITG in improving aerobic and anaerobic performance capabilities. Coaches and athletes should therefore be aware that, in spite of identical total work, an interval-training program might induce different physiological impacts if the order of intervals is not identical.

VIRTUAL-REALITY EXERGAMING CAN INCREASE ENJOYMENT AND PERFORMANCE DURING HIGH-INTENSITY INTERVAL TRAINING

FARROW, M.1,3, LUTTEROTH, C.2,3, ROUSE, P.1, BILZON, J.L.J.1,3
UNIVERSITY OF BATH

INTRODUCTION: High-intensity interval training (HIIT) has the potential to improve human cardiometabolic health, however concerns remain over real-world long-term adherence and compliance (Biddle & Batterham, 2015). Exergaming can increase enjoyment (a key

predictor of exercise adherence) and performance of cycling (Glen et al., 2017; Lewis et al., 2016). The objectives of this study were to determine if: i) virtual-reality (VR)-HIIT (track) can elicit higher levels of enjoyment and performance compared to a standard HIIT (blank) and; ii) performance during VR-HIIT can be increased by having participants race against their own performance (ghost) or by surreptitiously increasing resistance (hard).
METHODS: Sixteen participants (eight males, eight females, maximal aerobic capacity: 41.2 ± 10.8 ml/kg/min) completed four VR-HIIT conditions in a partially-randomised cross-over study; 1a) blank, 1b) track, 2a) ghost, and 2b) hard. VR-HIIT sessions consisted of eight 60 s high-intensity intervals interspersed by 60 s recovery intervals, at a resistance equivalent to 70% (77% for hard) and 12.5% maximum power output, respectively, at a self-selected cadence. Enjoyment was assessed using the Intrinsic Motivation Inventory (Ryan, 1982) immediately post-exercise. Paired t-tests were used (blank vs. track, track vs. ghost, ghost vs. hard) to assess differences between modes.
RESULTS: Enjoyment was higher in the track compared to the blank condition (4.7 ± 0.4 vs. 3.8 ± 0.7, P<0.01), with no other differences observed. Mean power output for each high-intensity interval was 9% higher during the hard compared to the ghost condition (199 ± 57 W vs. 181 ± 51 W, P<0.01) and 3% higher for the ghost compared to the track condition (176 ± 50 W) (P<0.01), with no differences between track and blank conditions.
CONCLUSION: VR-exergaming can increase the enjoyment of an acute bout of HIIT in recreationally active individuals and, given that enjoyment of exercise predicts adherence (Lewis et al., 2016), it may be effective for promoting adherence to HIIT in the general population. By helping individuals race against their previous performance and by surreptitiously increasing resistance, it is also possible to increase exercise intensity without compromising enjoyment. These may be effective techniques to maximise exercise stress and adaptation during a HIIT programme.

OP-PM16 MUSCLE INJURIES

ESR1 RS2234693 POLYMORPHISM AND SPORTS-RELATED MUSCLE INJURIES: A CASE-CONTROL ASSOCIATION AND PHYSIOLOGICALLY FUNCTIONAL STUDIES IN JAPANESE POPULATION

KUMAGAI, H., MIYAMOTO-MIKAMI, E., HIRATA, K., KIKUCHI, N., KAMIYA, N., HOSHIKAWA, S., ZEMPO, H., NAITO, H., MIYAMOTO, N., FUKU, N.

JUNTENDO UNIVERSITY

INTRODUCTION: The incidence of sports-related injuries is associated with athletic success and may result in termination of an athletes career in some situations. Muscle injury is the most common injury in sports that involve sprinting and jumping. Muscle stiffness is one of the risk factors for muscle injury and is lower in females than in males, which implies that sex differences-related genetic factors might influence muscle injury through muscle stiffness. However, whether such relationships exist is largely unknown. Thus, the aim of the present study was to investigate the associations of two genetic polymorphisms (rs2234693 and rs9340799) in the oestrogen receptor 1 gene (ESR1) with muscle injury and muscle stiffness.
METHODS: Study 1: The history of indirect muscle injuries were surveyed by questionnaire in 1,311 Japanese top-level athletes (men: n = 870, women: n = 441) and all muscle injuries were diagnosed by medical doctors (muscle injured group: n = 133, non-muscle injured group: n = 1,178).
Study 2: The stiffness of the biceps femoris, semitendinosus and semimembranosus were assessed by using ultrasound shear wave elastography in 261 physically active young Japanese adults (men: n = 152, women: n = 109). The stiffness of these three muscles was averaged to evaluate stiffness of the overall hamstring muscle. In both studies, the rs2234693 C/T and rs9340799 A/G polymorphisms in the ESR1 were analysed by using TaqMan SNP Genotyping Assay.
RESULTS: Study 1: The genotype frequencies of the ESR1 rs2234693 C/T polymorphism were significantly different between the injured and non-injured groups for the C-allele dominant (TT vs. TC+CC: odds ratio [OR] = 0.62, 95% confidence interval [CI] = 0.43-0.91) and an additive (TT > TC > CC: OR = 0.70, 95% CI = 0.53-0.92) genetic models.
Study 2: The stiffness of the hamstring muscle was lower in subjects with the TC+CC genotype than those with the TT genotype, and a significant linear trend was observed (r = −0.14, P = 0.029). In contrast, no association was found between ESR1 rs9340799 A/G and muscle injury or muscle stiffness.
CONCLUSION: Muscle stiffness is mainly influenced by collagenous connective tissue and oestrogen suppresses collagen synthesis. Aside from this, previous studies have suggested that the rs2234693 C/T polymorphism in the ESR1 alters its gene expression, and the muscle injury-protective C allele is associated with higher gene expression and increases oestrogen-induced actions. Thus, suppression of collagen synthesis by the action of oestrogen is the possible explanation of the relations between rs2234693 polymorphism in the ESR1 and muscle injury or muscle stiffness. In conclusion, we found that the ESR1 rs2234693 C allele carriers had a protective effect against muscle injury and lower muscle stiffness compared with the T allele carriers in Japanese populations. Our results suggest that the rs2234693 polymorphism in the ESR1 is associated with muscle injury due to muscle stiffness.

TRAINING LOAD PRIOR TO INJURY IN PROFESSIONAL RUGBY LEAGUE PLAYERS.

CUMMINS, C., KING, D., THORNTON, H., DELANEY, J., DUTHIE, G., WELCH, M., MURPHY, A.

UNIVERSITY OF NEW ENGLAND; UNIVERSITY OF NEW ENGLAND; LA TROBE UNIVERSITY; VICTORIA UNIVERSITY; AUSTRALIAN CATHOLIC UNIVERSITY; UNIVERSITY OF NEW ENGLAND; UNIVERSITY OF NEW ENGLAND

INTRODUCTION: Injury data analysis methods have focused predominately on univariate or simple multivariate correlations between training loads (TL) and injuries. These approaches result in limited insight into the overall effect of external TL variables and a lack of

reliable predictive power for injury risk. Conversely, machine learning (ML) algorithms are useful for modeling phenomena described by multidimensional data with complex (usually non-linear) relationships. The application of ML to predicting injury risk in high-performance sport is relatively limited to date. Consequently, this study examined the efficacy of applying ML to multidimensional TL in predicting injury risk in rugby league.
METHODS: All TL and injury incidence data (soft-tissue, non-contact) were collected from 46 professional rugby league players across a National Rugby League season. External-TLs were quantified utilising global positioning systems, including total daily distance (TD), daily high-speed distance (HSD) and daily acceleration/deceleration load (AccDec Load). Total, mean and standard deviation (SD) for moving windows of 7, 14, 21 and 28-days were calculated. To mitigate the skewed data (0.7% injuries), a generative data model was created to re-sample balanced, simulated, datasets that each contained 2000 non-injury and injury data-points respectively. Random forests were trained on the simulated data for 7, 14, 21 and 28-days and tested using the original 4,453 external-TL data-points. As these were not used to directly train the classifiers, they provide an out-of-sample test that is grounded in real-world data.
RESULTS: The 7-day window, only correctly predicted 68% of injuries (i.e. belonging to the injury class with a probability of > 50%), however the random forests trained using the 14, 21 and 28-day windows where able to correctly identify 91%, 94% and 92% of injury data-points respectively. All random forests correctly classified approximately 92% of non-injuries. Similar results were also observed when the classifiers were tested on out-of-sample simulated data. The sum of HSD, SD of TD and SD of AccDec Load are consistently highly ranked as important for prediction of injury within all windows.
CONCLUSION: The accuracy achieved (for 14-day or longer windows) indicates that the random forest ensemble classifier is capable of learning the complex underlying patterns required for successful prediction of injury in the following training session. The poor performance on the 7-day window is most likely due to a lack of data-points, providing the classifier with limited discriminative power. The higher importance of the SD of TD and sum of HSD for the prediction of injury is consistent with previous work in other sporting codes. It is important to note however, that the difference in the importance of the different variables is quite small, indicating that they all contribute significantly to the prediction of injury within the classifiers trained in this study.

APPLICATION OF A WHOLE EXOME SEQUENCING APPROACH TO UNRAVEL THE SUSCEPTIBILITY OF MUSCULOSKELETAL SOFT TISSUE INJURIES

SEPTEMBER, A.V., GIBBON, A., SAUNDERS, C.J., COLLINS, M., GAMIELDIEN, J.
THE UNIVERSITY OF CAPE TOWN AND THE UNIVERSITY OF THE WESTERN CAPE

INTRODUCTION: Musculoskeletal soft tissue injuries are complex phenotypes, with genetics as a proposed risk factor. Case-control association studies using the candidate gene approach have predominately been used to identify risk loci for these injuries. However, the ability to identify all risk conferring variants using this approach alone is unlikely. Therefore, this study aimed to further define the genetic profile of these injuries using a multifaceted approach involving whole exome sequencing and a customized analyses pipeline.
METHODS: The exomes of ten exemplar asymptomatic controls and ten exemplar cases with Achilles tendinopathy were individually sequenced using a platform that included the coverage of the untranslated regions and miRBase miRNA genes.
RESULTS: Approximately 200 000 variants were identified in the sequenced samples. Previous research was used to guide the targeted analysis of the TNC and COL27A1 genes located on chromosome 9. Selection of variants within these genes were however not predetermined but based on a tiered filtering strategy. Four variants in TNC (rs1061494, rs1138545, rs2104772 and rs1061495) and three variants in upstream COL27A1 gene (rs2567706, rs2241671 and rs2567705) were genotyped in larger Achilles tendinopathy and ACL rupture cohorts. The CC genotype of TNC rs1061494 (C/T) was associated with the risk of Achilles tendinopathy (p=0.018, OR: 2.5 95% CI: 1.2-5.1). Furthermore, the AA genotype of the TNC rs2104772 (A/T) variant was significantly associated with ACL ruptures in the female subgroup (p=0.035, OR: 2.3 95% CI: 1.1-5.1). Two overlapping inferred haplotypes in the TNC gene were also associated with the risk of Achilles tendinopathy and ACL ruptures respectively.
CONCLUSION: These results provide a proof of concept for the use of a customized pipeline for the exploration of a larger genomic dataset. This approach, using previous research to guide a targeted analysis of the data has generated new genetic signatures in the biology of musculoskeletal soft tissue injuries

CONCUSSION AND SUBSEQUENT LOWER EXTERMITY MUSCULOSKELETAL INJURY: INFLUENCE OF GENDER

BUCKLEY, T., OLDHAM, J.R.
UNIVERSITY OF DELAWARE

INTRODUCTION: Emerging evidence is suggesting that, in addition to subsequent concussion, there is an elevated risk of lower extremity (LE) musculoskeletal (MSK) injury in the year following concussion; however, most studies evaluate male collision sport athletes and women are understudied. Therefore, the purpose of this study is to compare post-concussion LE MSK injury between genders.
METHODS: We recruited 335 student-athletes (62.1% female, mean age, 21.2 ± 1.4 years old; mean collegiate athletic experience, 3.3 ± 1.2 years) across 13 sports from 17 US colleges from 2012 to 2014. The participants completed a previously validated and reliable (ICC: 0.92) 21-item questionnaire pertaining to injuries experienced during their collegiate career. Participants self-reported concussions under three categories: 1) self-reported concussions, 2) acknowledged unreported concussions (e.g., "hidden"), 3) unrecognized concussions (e.g., memory loss following a head impact) and a 4th variables "any concussion" was calculated for participants who reported any of the three categories. The LE MSK injuries were self-reported 1) lateral ankle sprains, 2) knee sprains, or 3) lower extremity muscle strain. Chi-square analyses were performed to identify the association between each of the 4 concussion variables (reported, unreported, potentially unrecognized, and any concussion) and LE variables (ankle sprain, knee injury, muscle strain) between self-reported genders (Male, Female).
RESULTS: For females, there was a significant association between 1) reported concussions and knee injuries (p=0.018, odds ratio=2.22, 95% CI: 1.18 – 4.21), 2) unreported concussions and knee injuries (p=0.005, odds ratio=3.73, 95% CI: 1.51 – 9.22), 3) unrecognized concussions and lateral ankle sprains (p=0.007, odds ratio=2.61, 95% CI: 1.32 – 5.15), and 4) any concussion and knee injury (p=0.003, odds ratio=2.67, 95% CI: 1.43 – 5.00). For males, there was only a significant association between unrecognized concussions and muscle strains (p=0.020, odds ratio=2.39, 95% CI: 1.16 – 4.92).
CONCLUSION: The results of this study suggest females are at higher risk of post-concussion subsequent MSK injury over the course of their collegiate athletic career. This was most evident for knee injuries and it should be noted that females have up to a 6x higher rate of ACL injuries which may contribute to these findings; however, it should be noted that only 24 ACL injuries were reported and 17 were among females thus limiting their overall influence on the outcomes. Consistent with recent concussion related findings, these results may highlight a gender difference in concussion response and suggests future studies continue to differentiate gender during analysis.

Clinically, health care professionals who manage concussion in an athletic population should be aware of an elevated risk of LE MSK following concussion and implement appropriate injury prevention strategies.

MUSCULOSKELETAL INJURIES IN SINGAPORE PHYSICAL EDUCATION TEACHERS- A PROSPECTIVE EPIDEMIOLOGICAL INVESTIGATION

MUKHERJEE, S., JOHARI, M.R., KEE, Y.H., VAN MECHELEN, W.

NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY, SINGAPORE

INTRODUCTION: Physical education teachers (PETs) are at a high risk of musculoskeletal (MSK) injuries as their body parts are regularly exposed to various stresses and mechanical shocks during PE teaching. This study investigated the incidence of MSK injuries amongst PETs in Singapore schools.
METHODS: 103 primary (Pri) and 49 secondary (Sec) school PETs (116 male, 36 female) across 21 schools volunteered to participate. A two-weekly prospective online injury documentation survey was done using Qualtrics. Total 17 rounds of survey were done during the 2017 school calendar year. 50% response rates were 78% and 90.5% during the first and second half of the school year.
RESULTS: 98 PETs (Pri- 63, Sec- 35) reported 238 injuries (males- 168; females- 70; Pri- 155; Sec- 83) during the year. 61 injuries (25.6%) were sustained during PE teaching-related activities and 130 injuries (54.6%) during personal sports participation. Daily mean PE teaching load was 3.59 hours for Pri and 3.08 hours for Sec school PETs. Overall injury risk was 1.50 and 1.69 injuries/PET/year for Pri and Sec PETs respectively. Injury incidence rate was 94.70/1000 hours and 21.64/1000 hours of PE curricular exposure time for Pri and Sec PETs respectively. Practicing or playing with students during PE teaching led to most injuries (39.3%) followed by during skill, technique or movement demonstration (34.4%). Most injuries sustained during PE teaching were recurrent (37.7%) followed by acute injuries (27.8%) and aggravations (26.2%). Majority of injuries were non-contact type (44.2%) and were sustained during the first two PE lessons (54.1%) of the day. Lower back was the most commonly affected part (26.2%) followed by foot-and-ankle (21.3%) and knee (19.6%). Muscle-tendon strain was the commonest injury (PE- 21.3%, personal sport- 32.3%) followed by incomplete ligament sprain (PE- 19.6%, personal sport 17.6%). Injuries led to work absence (24 - 2 days, 7- 6 days, 5 >10 days) as well as pain and discomfort during PE teaching (46- 6 days, 18- 9 days, 63 > 10 days). Injuries also led to PETs missing personal sport participation (32- 9 days, 43- still not able). 82 PETs required medical attention and 46 PETs required long-term physiotherapeutic help.
CONCLUSION: PETs constitute a vulnerable occupational group with both Pri and Sec PETs in Singapore schools at a high risk of MSK injuries. Injuries led to inability to teach PE as well as pain and discomfort while PE teaching. This can adversely affect the quality of PE delivery and achievement of learning outcomes. Injuries also limited personal sport participation that may affect fitness, health gains and quality of life. Furthermore, the majority of injuries being recurrent and affecting muscle-tendon and ligaments present a risk of long-term MSK dysfunction and reducing the career longevity of PETs. Measures should be taken to further optimize the workload of PETs, reduce the incidence of injuries and the minimise the prospect of long-term MSK dysfunction in this population.

THE INDIVIDUAL AND COMBINED EFFECTS OF MULTIPLE FACTORS ON THE RISK OF SOFT TISSUE NON-CONTACT INJURIES IN ELITE TEAM-SPORT ATHLETES

ESMAEILI, A., HOPKINS, W., STEWART, A., ELIAS, G., LAZARUS, B., AUGHEY, R.

INSTITUTE OF HEALTH AND SPORT (IHES), VICTORIA UNIVERSITY, AUSTRALIA

INTRODUCTION: Relationships between common athlete-monitoring-derived variables and injury risk have been investigated predominantly in isolation. The aim of this study was to evaluate the individual and combined effects of multiple factors on the risk of soft-tissue non-contact injuries in elite team sport athletes.
METHODS: A cohort of 55 elite Australian footballers was prospectively monitored over two consecutive seasons. Internal and external training load was quantified using the session rating of perceived exertion and GPS/accelerometer units respectively. Cumulative loads and acute-to-chronic workload ratios were derived using rolling averages and exponentially weighted moving averages . History of injuries in the current and previous seasons was also recorded along with professional experience, weekly musculoskeletal screening, and subjective wellness scores for individual athletes. Individual and combined effects of these variables on risk of injury were evaluated with generalized linear mixed models.
RESULTS: High cumulative loads and acute-to-chronic workload ratios were associated with increased risk of injuries. The effects for measures derived using exponentially weighted moving averages were greater than those for rolling averages. History of a recent injury, long-term experience at professional level, and substantial reductions in a selection of musculoskeletal screening and subjective wellness scores were also associated with increased risk. The effects of high cumulative loads were underestimated by ~20% before adjusting for previous injuries, whereas the effects of high acute-to-chronic workload ratios were overestimated by 10-15%. Injury-prone players were at a more than five times higher risk of injuries compared to robust players despite adjusting for the effects of training load and previous injuries . Combinations of multiple risk factors were associated with extremely large increases in risk; for example, a hazard ratio of 22 <9.7–52> was observed for the combination of high acute load, recent history of a leg injury, and a substantial reduction in the adductor squeeze test score.
CONCLUSION: The information from athlete-monitoring practices should be interpreted collectively and used as a part of the injury prevention decision-making process along with consideration of individual differences in risk.

OP-BN30 Resistance training 2

THE EFFECT OF CONCENTRIC AND ECCENTRIC KNEE FLEXOR STRENGTH TRAINING ON RECOVERY AFTER REPETITIVE SPRINT SESSIONS

DUHIG, S., BOURNE, M., BUHMANN, R., WILLIAMS, M., MINETT, G., ROBERTS, L., TIMMINS, R., SIMMS, C., SHIELD, A.

GRIFFITH UNIVERSITY

INTRODUCTION: To investigate whether knee flexor (KF) adaptations induced by five-weeks of concentric (CON) or eccentric (ECC) strength training have different effects on sprint running recovery.
METHODS: Thirty males (age, 22.8 ± 4.1y; height, 180.1 ± 6.4cm; weight, 85.2 ± 14.6kg) were allocated into either a CON or ECC group, both performing nine sessions of resistance training. Prior to and immediately after the five-week intervention, each participant's bicep femoris long head (BFLH) fascicle length (FL), pennation angle (PA), muscle thickness (MT), peak isometric KF torque and Nordic eccentric strength were assessed. Post intervention, participants performed two sprint sessions (10x80m) 48 hours apart. With reference to the first sprint session, blood samples and passive KF torque were collected before, after, 24 hours and 48 hours post.
RESULTS: After the five-week strength-training period fascicles lengthened in the ECC group ($p<0.001$; $d = 2.0$) and shortened in the CON group ($p<0.001$; $d =0.92$) while PA decreased for the ECC group ($p=0.001$; $d = 0.52$) and increased in the CON group ($p<0.001$; $d = 1.69$). Nordic eccentric strength improvements occurred in both the ECC ($p<0.001$; $d =1.49$) and CON ($p<0.001$; $d = 0.95$) groups. Peak isometric strength ($p=0.480$; $d=0.12$), passive KF torques ($p=0.807$; $d=0.16$), sprint performance decrements within ($p=0.595$; $d=0.24$) and between sprint sessions ($p = 0.910$; $d=0.05$) and creatine kinase ($p=0.818$; $d=0.06$) did not differ significantly between groups.
CONCLUSION: Despite significant opposing alterations in hamstring architecture between ECC and CON groups, no difference was observed for sprint recovery between sessions, which may have implications for strain injury.

TASK-SPECIFICITY AND TRANSFERABILITY OF RESISTANCE TRAINING WITH DIFFERENT STABILITY REQUIREMENTS

SAETERBAKKEN, A.H., BAARDSTU, H.B., ANDERSEN, V.

WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCE

INTRODUCTION: The aim of the study was to examine the task-specificity in trained and transferability to non-trained exercise after attending a resistance-training program with different stability requirements.
METHODS: 59 recreational-trained men attended three weeks of familiarization with three squat exercises with low, medium and high stability requirements: Smith-machine (SM), free-weights (FW) and free-weights on balance discs (BD). After the familiarization, the participants were randomized to attend a 7 weeks squat-training program using SM, FW, BD or a control group (CON) twice a week. All participants were tested pre, after 3 weeks (wk3) and post intervention in 10RM, maximal voluntary contraction (MVC) and rate of force development (RFD) in all three exercises in addition to CMJ on stable and unstable surface and muscle thickness of vastus lateralis.
RESULTS: The familiarization period demonstrated similar improvement in 10RM loads in SM (23%), FW (22.5%) and BD (28%). The MVC increased in BD (16%, $p<0.001$), but not in FW (12%; $p=0.068$) or SM (7%; $p=0.144$). The CMJ increased 4.8% and 8.1% using stable and unstable surfaces ($p<0.001$) with a 14% greater height using a stable surface ($p<0.001$). The muscle thickness increased 2.5% ($p=0.008$). No improvements were observed in RFDs for the three exercises ($p=0.074$-1.000).
In the intervention period, all training groups demonstrated task-specificity in trained exercise (18-26%; $p<0.001$) and transferability of strength to non-trained exercise in 10RM loads (16-23%; $p<0.001$). Still, only the SM-group demonstrated task-specificity SM compared to FW-group (37%; $p=0.044$) and a strong tendency towards greater increase than the BD-group (34%; $p=0.059$). Comparing the other exercises, similar improvements were observed between the groups ($p=0.273$-0.472). Similar improvements between the groups were observed in MVCs, RFDs, CMJ on stable surface and muscle thickness ($p=0.510$-0.831). Still, all training groups improved the MVC in FW (10-20%, $p=0.004$-0.046). In SM, the MVC increased only in the SM- and BD-group (13-15%, $p=0.002$-0.004) and only the BD-group improved the MVC in BD (12%, $p=0.008$). In CMJ, the SM- and BD-group improved 3% and 12% on the unstable surface ($p=0.004$-0.034). However, the BD-group improvements were greater improvement than tall others groups ($p=0.001$-0.027). The CON-group demonstrated similar results at wk3- and post-test for all variables ($p=0.386$-0.866).
CONCLUSION: Despite training with different stability requirements, only the group training with low (SM) or high (BD) stability requirement demonstrated task-specificity. With exception of the 10RM results, the FW-group training with medium stability requirement, did not demonstrate transferability to non-trained exercise in contrast to the SM- and BD groups. Similar improvements may be a result of the massive improvements in the familiarization period and future studies should include a familiarization period to reduce the learning effects.

EFFECTS OF DIFFERENT RECOVERY INTERVALS BETWEEN RESISTANCE TRAINING SESSIONS ON MUSCLE PERFORMANCE ADAPTATION OF ELBOW FLEXORS IN RESISTANCE TRAINED MEN

SOARES, S., FERREIRA-JÚNIOR, J.B., FONSÊCA, A.C., PADILHA, U.C., GUEDES, R.A., VALERIANO, R.O., BOTTARO, M.

UNIVERSITY OF BRASILIA

INTRODUCTION: Recovery interval between resistance training sessions is an important factor for designing resistance training program. It has been recommended for advanced training 72h of interval between training sessions (ACSM, 2009). However, a recent study showed that resistance-trained men presented uncompleted recovery 72h following bench press exercise (Ferreira et al., 2017). Peak torque (PT) returned to baseline at 96h, while total work (TW) did not. An insufficient recovery between resistance training sessions can negatively alter muscle mass protein expression (Alves et al., 2014), suggesting an impaired muscle adaptation. Considering that controlled studies on the optimal recovery interval between training sessions are lacking, the aim of this study was to compare the effects of different intervals between resistance training sessions on muscle performance adaptation of elbow flexors in resistance trained men.
METHODS: Twenty-three trained men (25±5 years) were randomly divided into two groups: 1) G72h - subjects trained at each 72 h; and 2) G168h- subjects trained at each 168 h. All subjects performed 8 training sessions for elbow flexors muscles on Scott bench attached on isokinetic dynamometer. The elbow flexors isokinetic protocol consisted of 4 sets of 6 repetitions with ECC/CON isokinetic mode with

120°.s-1 and 60°.s-1 for eccentric and concentric muscle actions, respectively. Rest interval between sets was 2 min. Elbow flexors concentric mean PT and TW were measured during the 1st, 4th and 8th elbow flexors isokinetic training session.
RESULTS: Mean PT did not differ among G72h (1st= 55.0±9.4 N.m, 4th= 51.6±8.8 N.m and 8th= 53.69.1 N.m) and G168h groups (1st= 53.9±8.3 N.m, 4th= 54.6±8.6 N.m and 8th= 56.6±12.1 N.m) throughout training sessions (p>0.05). However, TW in the G168h group was higher on 8th training session (1781±423 J) when compared to 1st (1460±341 J) and 4th training session (1606±310 J) (p<0.05), while TW in the G72h group was not altered throughout training sessions (1st= 1707±152 J, 4th= 1647±307 J and 8th = 1739±343 J, p>0.05).
CONCLUSION: The main finding of the present study was that a high recovery interval between resistance training sessions is needed to improve muscle performance adaptation. Considering that mean PT was not different among groups, the increased TW of the elbow flexors observed in G168h group may be due to the positive interaction between stress and recovery surpassing the initial levels of training, which corresponds to supercompensation phenomenon (Issurin, 2010). In conclusion, if trained subjects want to improve muscle performance, 168h recovery interval between resistance training sessions is recommended.

CHANGES IN AVERAGE- VERSUS PEAK-FORM MEASURES OF MUSCLE FUNCTION FOLLOWING MULTIMODALITY RESISTANCE TRAINING

JAMES, L., KELLY, V., HAFF, G., BECKMAN, E.

THE UNIVERSITY OF QUEENSLAND; BRISBANE BRONCOS RUGBY LEAGUE FOOTBALL CLUB; EDITH COWAN UNIVERSITY

INTRODUCTION: Decisive athletic actions occur as a consequence of high forces expressed over windows of time lasting approximately 0.1 to 0.3s. However, while light ballistic and heavy strength training modalities have resulted in considerable increases in instantaneous measures of muscle function (e.g. peak velocity) derived from a countermovement (CMJ) jump, improvements in the equivalent average variables (e.g. average velocity) are more modest. This is problematic as average-form variables are calculated over periods more closely resembling those encountered in sport (generally the entire concentric phase), and therefore may provide a better indication of transfer. It is possible that the single exercise modalities previously used limited adaptations throughout the entire range of motion, resulting in attenuated improvements in average-form metrics. It is therefore the purpose of this investigation to determine whether multimodality resistance training would have a greater influence on muscle function measures in their average form when compared to their respective instantaneous variants.
METHODS: Sixteen recreationally trained males undertook 10 weeks of resistance training consisting of weightlifting, ballistic and plyometric actions under a spectrum of loads. Repetitions ranged from 3 to 6 and the loading, volume and exercise selection were structured based on periodisation principles. Muscle function was assessed via the CMJ on a force platform (2000 Hz) at baseline and posttest. Data were processed enabling construction of velocity- and power-time curves. Peak measures represented the highest instantaneous sample on the curve of interest. Average measures were calculated between the bottom of the countermovement (zero velocity) and takeoff. Average velocity and average power were then expressed relative to their respective peak function (average variable/peak variable). This enabled an index of average velocity (AvVindex) and power (AvPindex) to be examined.
RESULTS: Significant improvements in both AvVindex (P<0.001, d= 0.74) and AvPindex (P<0.001, d=0.84) were revealed following training. This was underpinned by a respective increase of 13.6 and 7.4% in average and peak velocity, alongside a 15.8 and 7.5% increase in average peak power, respectively.
CONCLUSION: Although both average and peak measures of muscle function were enhanced after multimodality resistance training, it is the findings of considerably greater improvements in average-form metrics that are most notable. This resulted in significant increases in AvVindex and AvPindex indicating a heightened ability to operate throughout greater ranges of motion and epochs (0.0005 vs 0.280s), and therefore a likely enhanced transfer to athletic performance. These results are in contrast to the common reports of greater increases in peak versus average metrics, and may potentially be attributed to the multiple modalities used in this present intervention.

COMPARISON BETWEEN ECCENTRIC AND CONCENTRIC RESISTANCE EXERCISES WITH BODY WEIGHT FOR THEIR EFFECTS ON MUSCLE AND FUNCTIONAL FITNESS OF OLDER ADULTS

KATSURA, Y.1, TAKEDA, N.1, HARA, T.2, TAKAHASHI, S.3, NOSAKA, K.4

1: KOGAKUIN UNIVERSITY , 2: SHIMANE UNIVERSITY , 3: DAITO BUNKA UNIVERSITY , 4: EDITH COWAN UNIVERSITY

INTRODUCTION: Eccentric resistance exercise training (ECC) of the knee extensors performed once a week for 12 weeks improved physical fitness, insulin sensitivity and blood lipid profiles of elderly men greater than concentric resistance exercise training (CON) (Chen et al. Front Physiol 2017). Basic resistance exercises can be performed without using resistance training machines or equipment, but with body weight (e.g., standing and sitting from a chair). However, no previous studies have investigated their effects on muscle function and physical fitness of older adults. The present study tested the hypothesis that ECC would improve muscle function and functional physical fitness of older adults greater than CON.
METHODS: Elderly healthy individuals (65 - 84 y) were placed into one of the two groups; ECC (n=9) and CON (n=8). No significant differences in the baseline measures were found between groups. ECC and CON consisted of 8 exercises such as chair squat, jump squat, one leg squat, calf raise, knee close and open, push up, sit up, elbow flexion and extension. The exercises were performed once a week for 11 weeks by increasing the range of motion, movement speed and repetitions gradually. In ECC, eccentric muscle contractions were emphasised, and load for concentric phase of each exercise was minimised by the investigators who assisted the movements for the concentric phase. In CON, the exercises were similar to those in ECC, but load in eccentric phase was minimised by the investigators. Systolic (SBP) and diastolic blood pressure (DBP), maximal voluntary isometric contraction torque of the knee extensors (MVC), muscle thickness of quadriceps (MT), balance ability assessed by center of pressure movement length and area with eyes open and close, and several functional physical fitness tests were taken before and after the 11-week training. Changes in the variables from baseline to post-training were compared between groups using a mixed-design two-way ANOVA.
RESULTS: Both groups showed changes (P<0.05) in SBP, MVC, MT, sit and reach, 30-s chair stand (CS) and 2-min step (2MS) from baseline to post-training, and changes (P<0.05) in DBP, timed up and go (TUG), balance ability with eyes close were evident only for ECC group. The magnitude of increases in MVC (38.3 ± 22.6% vs 8.2 ± 8.4%), MT (24.4 ± 12.4% vs 6.7 ± 7.1%), CS (51.0 ± 21.7% vs 34.6 ± 28.3%) and

2MS (9.9 ± 6.0% vs 6.0 ± 7.3%), and decreases in TUG (-16.7 ± 9.9% vs -6.3 ± 7.7%) and balance ability assessed by the length with eyes close (-35.1 ± 6.7% vs -8.8 ± 16.2%) were greater (P<0.05) for ECC than CON.
CONCLUSION: These results suggest that ECC was more effective than CON to improve lower limb strength, mobility and static and dynamic postural stability of older adults. It is possible that focusing on eccentric contractions in exercises that can be performed at home provide significant benefits to elderly individuals, when they are regularly performed.

OP-BN05 MOTOR LEARNING, SKILL ACQUISITION AND COORDINATION

WHITE MATTER PLASTICITY MEDIATES THE BENEFICIAL EFFECT OF ENDURANCE EXERCISE ON MOTOR LEARNING

LEHMANN, N.1,2, VILLRINGER, A.2,3, TAUBERT, M.1,2

1: OVGU , 2: MPI CBS , 3: CHARITÉ AND HU

INTRODUCTION: Despite the fact that endurance exercise has shown to be a promising intervention strategy to facilitate motor learning (Taubert et al., 2015), the neurobiological mechanisms by which exercise elicits its effects on motor functions remain poorly understood. Based on earlier studies demonstrating a crucial role of structural brain properties and their practice-induced reorganization for motor learning (Taubert et al., 2010; Sampaio-Baptista et al., 2014), we hypothesized that structural brain plasticity mediates the effect of exercise on motor learning.
METHODS: To test our hypothesis, we conducted a longitudinal study involving 34 healthy, right-handed adults aged 18-35 y (3 drop-outs). Subjects were randomly assigned to two groups which learned a complex whole-body balancing task (BT) on a seesaw-like platform over a period of six weeks (Taubert et al., 2010). Before the learning phase, group EXELEARN (n = 15) underwent a two-week priming exercise intervention, whereas RESTLEARN (n = 16) continued with their habitual activities in the same period (life-as-usual). During the experiment, we acquired T1- and diffusion-weighted MRI data in regular time intervals, which allowed us to analyze structural neuroplasticity in brain's gray and white matter.
RESULTS: As was expected, behavioral analyses showed that EXELEARN learned the BT at a faster rate compared with RESTLEARN ($p < .05$). Multiple mediation analysis revealed that the intervention influenced learning rate mainly through exercise-induced changes of the diffusion index radial diffusivity in sensorimotor-related fiber tracts (significant indirect effect based on 95% bias corrected bootstrap confidence interval).
CONCLUSION: We conclude that a short endurance exercise intervention increases the speed of complex motor skill learning and that this increase is likely driven by exercise-induced white matter plasticity. Animal and post-mortem studies show that radial diffusivity is correlated with the degree of axonal myelination (Song et al., 2002, Klawiter et al., 2011), thus suggesting that priming exercise might have influenced motor learning by altered speed and/ or timing of information transfer in the brain. The fact that white matter changes were associated with learning rate in a widespread network leads us to speculate that the neuromodulatory effect of exercise might apply in a task-independent fashion.

ANTICIPATION CHANGES NEUROMECHANICS OF DROP JUMPS IN REGARD TO KNOWN OR UNKNOWN GROUND STIFFNESS CONDITIONS

HELM, M., RITZMANN, R., FREYLER, K., GOLLHOFER, A.

UNIVERSITY OF FREIBURG

INTRODUCTION: Anticipation determines the timing and efficiency of reactive motor performance (Leukel et al. 2012). With an emphasis on ballistic movements, an accurately anticipated neural control is an essential prerequisite to deliver a motor response coincidentally with the event of ground contact. This study aimed at investigating how previous knowledge in the ground condition affects proactive and reactive motor control in drop jumps (DJ). For this purpose, human anticipatory capacity of muscle activation was investigated in terms of muscle mechanics, joint kinematics and forces associated with drop jump performance.
METHODS: In 18 subjects, the effect of knowledge of two different surface conditions during DJs was evaluated in four conditions: two surface stiffnesses (hard/soft) were either known or unknown to the subjects. Peak force (Fmax), ground-contact-time (GCT), rate of force development (RFD) and jump height were assessed. Electromyographic (EMG) activities of the m. soleus (SOL), gastrocnemius medialis/lateralis (GM/GL) and tibialis anterior (TA) were assessed 150ms before (PRE) and during ground contact (GC) for the reflex phases short-, medium-, and long-latency response (SLR, MLR, LLR). Ankle and knee joint kinematics were recorded in sagittal plane, and pennation angle (PA) of GL was measured by ultrasound.
RESULTS: Unknown vs. known condition induced a decrease in Fmax, RFD and jump height (P<0.05), whereas GCT increased (P<0.05). A decline in proactive EMG activity in SOL and GM for PRE (hard surface) was measured in the unknown condition. During GC, a decline in EMG activity in the unknown condition was manifested for SOL and GM in all reflex phases (P<0.05), TA showed no changes. On the soft surface, both ankle and knee joint deflections during GC were increased in the unknown vs. known condition (P<0.05). PA was reduced during PRE in unknown vs. known (hard) condition and during GC (hard, soft) (P<0.05). Fmax and RFD were positively correlated to GM EMG in PRE and all reflex phases (P<0.05). Complementarily, negative correlations have been detected between GCT and GM EMG (P<0.05).
CONCLUSION: Results revealed that proactive and reactive changes in muscle activity and mechanics prior and during GC are interrelated to jump performance. Thereby, the unknown condition is described by a general activation pre-set prior to GC that on average is appropriate for both conditions, associated with muscle elongation that may lead to reduced muscle stiffness and thus, augmented joint

deflections. Findings underline that anticipation is the determining factor influencing timing and adjustment of motor responses to accomplish ballistic movements in regard to efficiency and performance.

EFFECTS OF FOCUS OF ATTENTION FEEDBACK ON HIP AND KNEE COORDINATION IN THE LEARNING OF THE CLEAN WEIGHTLIFTING TECHNIQUE

RODRIGUEZ RIVADULLA, A.1,2, LAWRENSON, T.1, PREATONI, E.1

1. UNIVERSITY OF BATH , 2. SPORTS SURGERY CLINIC

INTRODUCTION: The learning of motor skills is thought to be enhanced when feedback is focussed on movement outcome (i.e. external focus of attention, EFOA) as opposed to directing attention to specific elements of movement execution (i.e. internal focus of attention, IFOA) (Wulf, 2013). Typical approaches of motor learning have used outcome measures to assess the effects of focus of attention (FOA). However, only a few studies have used dynamical systems quantities to describe coordination changes as a factor of different FOA feedback. The aim of this study was to assess the effect of FOA on Hip x Knee coordination in the learning of the clean weightlifting technique in a group novel to the task.
METHODS: Sixteen participants (12 males, 4 females) were randomly assigned to the EFOA or IFOA group (n = 8 each), and were asked to complete a 3-session training protocol consisting of 6 sets x 3 repetitions of the clean with individual feedback provided after each set. Motion capture was used to measure 3D full body kinematics. Right hip and knee flex/ext angles were time registered to 1001 data points and angle-angle plots were built. A modified vector coding technique was used to calculate the coupling angle (CA) between the vector connecting two subsequent data points and the positive horizontal axis. CA at each time point was classified into different coordination patterns (e.g. in-phase, anti-phase) and joint dominancy was identified (e.g. hip, knee) (Needham et al., 2015). Time spent on each coordination at post-test and pre-test was subtracted to define change in coordination. A repeated measure ANOVA (2 Groups x 4 Coordination patterns) was used to assess the effects of FOA on the change of Hip x Knee CA.
RESULTS: No Group x Coordination pattern interaction effect was found, suggesting that different type of feedback did not significantly change Hip x Knee CA ($F(1.293,42) = 0.056$, $p = 0.874$). Although not significantly, participants of both groups reduced the time spent on an in-phase coordination with knee dominancy (pre-test: EFOA, 47.3%; IFOA, 48.2%; post-test: EFOA, 44.3%; IFOA, 46.5%) and increased the time spent in an in-phase coordination with hip dominancy (pre-test: EFOA, 42%; IFOA, 39.1%; post-test: EFOA, 45.1%; IFOA, 44.4%).
CONCLUSION: Hip x Knee coordination was equally affected by EFOA and IFOA in inexperienced participants learning the clean weightlifting technique. These results are potentially explained by the skill level of the participants, as experience was suggested as a mediator of FOA effects (Poolton et al., 2006). Coordination variability analysis may help explain the effects of FOA on coordination and body's degrees of freedom. Also, studying experienced athletes could further our current understanding of the effects of FOA on coordination.

EFFECTS OF A SINGLE BOUT OF AEROBIC EXERCISE ON MOTOR SKILL ACQUISITION AND CONSOLIDATION: A COMPARISON OF DIFFERENT EXERCISE INTENSITIES

WANNER, P.1, MÜLLER, T.1, PFEIFER, K.1, STEIB, S.1

1: FRIEDRICH-ALEXANDER UNIVERSITY ERLANGEN-NÜRNBERG

INTRODUCTION: Recent evidence suggests that single bouts of aerobic exercise performed in close proximity to motor practice can enhance skill acquisition and consolidation (Roig et al., 2016). High-intensity bouts have been suggested to be particularly effective in improving consolidation (Roig et al., 2012). However, to date this has only been demonstrated for fine motor skills. Further, high-intensity exercise may interfere with skill acquisition, and is not practicable in all settings. Thus, the aim of this study was to investigate the effects of aerobic exercise i) carried out immediately prior to motor practice, and ii) performed at different exercise intensities on learning a novel balancing task.
METHODS: 35 healthy young adults (age: 25.57 ± 2.66; BMI: 22.99 ± 2.15) were allocated after stratified block randomization to one of three groups performing either 1) high-intensity interval exercise at 90%/60% Wmax (EX-H; n = 10), 2) moderate-intensity interval exercise at 45%/25% Wmax (EX-M; n = 12), or 3) continuous minimal-intense exercise at 25 W (CON; n = 13). All groups exercised on a cycle ergometer for a total of 17 min immediately prior to practicing a novel motor skill. The task required participants to stand on a tiltable (30°) wooden platform (stabilometer), and to stabilize it in a horizontal position for 30 seconds. For each experimental condition, subjects performed 15 trials (3 blocks of 5 trials), followed by a retention test (2 trials) 24 hours later. Time in balance (platform within ±5° from horizontal) and average angular deviation from horizontal (RMSE) were calculated for each trial. Within- and between-group changes over time were tested using repeated measures ANOVA.
RESULTS: On acquisition day, all participants significantly improved balance time (+34.7%; TIME main effect: $F14,270 = 17.8$; $p < .001$) and RMSE (-56.2%; TIME main effect: $F14,277 = 28.2$; $p < .001$), with no differences observed between experimental conditions. At retention, all groups demonstrated sustained performance (change from last two acquisition trials to retention) in balance time ($F1,32 = 0.86$; $p = 0.360$), with no significant group differences ($F2,32 = 0.87$; $p = 0.434$). For RMSE, performance significantly worsened only in the EX-H group (+13.6%; $p = 0.008$), and a similar tendency existed in the CON group (+9.16%; $p = 0.067$).
CONCLUSION: Motor skill acquisition was not improved by aerobic exercise, irrespective of exercise intensity. Interestingly, a trend existed for improved consolidation by moderate-intense cycling. The present findings do not confirm the positive effects of high-intensity aerobic exercise on motor learning, when exercise is performed immediately prior to motor learning.

WORKING MEMORY SUPPRESSION DURING SKILL ACQUISITION: A PILOT STUDY OF A NEW IMPLICIT MOTOR LEARNING PARADIGM

HOSKENS, M.C.J.1, BOAZ-CURRY, K.1, BUSZARD, T.2, MASTERS, R.S.W.1

1 UNIVERSITY OF WAIKATO; 2 VICTORIA UNIVERSITY

INTRODUCTION: Implicit motor learning paradigms seek to reduce the involvement of working memory (WM) in skill acquisition, which has advantages for motor performance. Most of the paradigms use behavioural interventions; however, this study investigated whether WM activity can be suppressed by a cognitively fatiguing protocol in order to cause implicit motor performance.
METHODS: Twenty-nine participants were engaged in a cognitive fatigue intervention (N-back task) or control intervention (documentary viewing). Subjective feelings of fatigue, performance on a verbal WM capacity task were measured before and after the intervention. WM activity was determined by measuring the activity in the left dorsolateral prefrontal cortex (DLPF). Golf putting performance and the extent to which the golf putting task was performed implicitly were evaluated. Brain activity in the left temporal region was measured to determine the verbal-analytical engagement during the golf putting task.
RESULTS: The fatiguing intervention caused significantly higher feelings of fatigue. Activity in the left DLPF was significantly reduced for the cognitive fatigue group, during the post WM capacity task. However, performance on the WM capacity task did not significantly reduce after the intervention. Performance on the golf putting task was not different for groups, but brain activity was reduced in the left temporal region when participants were cognitively fatigued.
CONCLUSION: The results of this study reveal that the feeling of cognitive fatigue was increased, and WM activity changed after performing the cognitive fatigue intervention. However, the intervention did not influence the performance on the WM capacity task. Cognitive fatigue caused depressed activity in the left temporal region during the golf task, suggesting that verbal processing of information may have been reduced. Additional research needs to focus on specific suppression of verbal WM to clearly establish the implications for implicit motor learning. This experiment represents a first step in developing an implicit motor learning paradigm using suppression of WM to prevent conscious accumulation of task-relevant declarative knowledge during skill acquisition.

LEARNING A VISUOMOTOR SKILL FOLLOWING A SINGLE BOUT OF EXERCISE IN HEALTHY ADULTS

KODESH, E.

UNIVERSITY OF HAIFA

INTRODUCTION: Priming the motor system with a single bout of physical exercise (PE) influences brain plasticity and promotes the learning of motor skills. Despite evidence of the positive effects of a single bout of PE on learning, optimal type, duration and intensity of PE are yet to be determined. Aerobic effort has been previously studied, whereas other types of exercise like high intensity interval training have not been investigated. Aims: To compare the effect of three different PE regimes on learning of visuo-motor skill in healthy individuals and determine whether arousal mood and fatigue mediate the outcomes
METHODS: 50 healthy individuals, aged 18-45 years, were randomly assigned to 4 intervention groups: "Aerobic group" exercised continuously for five minutes at 70% of the heart rate reserve, "Interval-20" and "Interval-10" groups performed five repetitions of 20s or 10s respectively, of maximal cycling effort with 40s or 50s recovery periods respectively. Control group sat on the bicycle for five min. Following the interventions all participants performed five repetitions of the star mirror-tracing task. Time and accuracy of the star-tracking task were measured. Upon completion of the intervention participants rated their arousal mood and fatigue. Learning was evaluated using early (20 min. post practice) and delayed (24 hour post practice) retention/transfer that included one drawing of a star or man mirror-tracing. Additionally, upon completion of the intervention, participants rated their arousal, mood and fatigue. Two ways mixed-model ANOVAs were used for time, group and interaction effects. Correlation analyses between arousal, mood and fatigue and learning index were performed.
RESULTS: During practice, the tracing task significantly improved without differences between groups. Comparison of time to complete the task between the early and late retention tests showed a significant interaction effect ($p<0.04$). Whereas movement time significantly increased in the control group by 11.1%, in the PE groups it remained stable or decreased by ~8%.
A positive moderate correlation ($r = 0.32$ $p = 0.025$) was found between fatigue and skill acquisition. No correlation found between mood and arousal with tracking task learning.
CONCLUSION: PE improved delayed retention. This effect was most prominent when effort was maximal and for a short duration (Int-10). A single bout of maximal short PE seems to have a positive priming effect on the learning of a visuomotor task.

OP-BN31 Sports with individuals with physical and intellectual disabilities

THE MEANING OF PARTICIPATION IN A PROFESSIONAL INTEGRATED DANCE COMPANY FOR INDIVIDUALS WITH AND WITHOUT DISABILITIES.

PANTANO, K., STEINERT, R., TUCHOLSKI, J.

CLEVELAND STATE UNIVERSITY

INTRODUCTION: Individuals with physical and cognitive disabilities often encounter social barriers in their daily lives that inhibit them from participating in activities that their non-disabled peers engage in. Integrated dance programs have been increasing in popularity as a way to diminish stereotypes and stigmas about disabled populations by partnering with non-disabled peers in various art forms as a means of inclusion and improvement of physical and psychological function. The purpose of this phenomenological study is to describe the perceptions and experiences of dancers with and without disabilities who participate in a professional integrated dance group.
METHODS: A qualitative study using surveys and in-depth interviews was conducted to study the meaning and experiences of disabled and non-disabled participants in Dancing Wheels, a professional Integrated Dance Company in Cleveland Ohio, U.S.A. Survey information provided descriptive statistics about the dancers studied. Audiotaped interviews were transcribed and data was reduced using thematic analysis. Triangulation established trustworthiness of the data.
RESULTS: Eleven sit-down (disabled) and standing (non-disabled) dancers from the Dancing Wheels Integrated Dance Company were interviewed for this study using a script of open-ended questions. Their average age was 28 years old and average length of participa-

tion in the dance company was 5 years. Qualitative data analysis resulted in thematic descriptions regarding the meaning of participation in an integrated dance group. Each collated theme was ranked in the order in which it was most frequently described during the interview process. The following themes were most frequently reported: First, both sit-down and stand-up dancers perceived that their involvement in an integrated dance company inspired, positively impacted and empowered others. Second, the shared experience of integrated dance advocated social awareness and equality for people with and without disabilities. Third, the integrated dance experience was perceived to promote independence, physical accessibility, team collaboration, and inclusion of all people in the arts.
CONCLUSION: This qualitative study provides a glimpse of the experience and meaning of participating in a professional integrated dance group. Participants expressed similar thoughts about the benefits of dance with the overarching theme being promotion and inclusion of all people in the arts. Integrated dance can be used as a source for creativity and artistic expression while increasing visibility of an under-represented group. Health professionals can be instrumental in promoting meaningful recreational & professional occupations for people of all abilities through inclusive community programs.

RELATIONSHIP BETWEEN MOTOR ABILITIES AND NONVERBAL INTELLIGENCE IN CHILDREN WITH ATTENTION DEFICIT HYPERACTIVITY DISORDER

LIU, S.

PHYSICAL ACTIVITY PSYCHOLOGY

Relationship between motor abilities and nonverbal intelligence in children with Attention Deficit Hyperactivity Disorder
Sin-Chi Liua, Yu-Jung Tsaia, Chung-Ju Huangb, Tsung-Min Hunga
aNational Taiwan Normal University, Taiwan
bTaiwan University of Taipei, Taiwan
Introduction: A large body of studies have found that children with ADHD were impaired in motor skills and cognitive and academic domains . Previous studies suggested that cognitive and motor development could be linked in such a way that movement experiences in early childhood that facilitate interactions with the environment are necessary for cognitive development .
Methods: As research concerning the relationship between motor abilities and intelligence in children with ADHD is scarce, we address this issue by recruiting 54 children <54 boys aged between 7 years and 13 years> whom have been diagnosed with ADHD symptom by a psychiatrist. All participants underwent evaluation by Movement Assessment Battery for Children - Second Edition and Test of Nonverbal Intelligence-Third Edition .
Results and Discussion: Although bivariate correlation revealed that manual dexterity and total score were correlated with Nonverbal Intelligence percentile, the stepwise multiple regression found that only manual dexterity significantly predicted Nonverbal Intelligence percentage <β= .383, R2= .147, p = .004>. The magnitude of association between these two variables was equivalent to those observed in typically developing children . This finding render the legitimacy for examining the causal relationship between motor ability and intelligence, which may shed light on the possibility of utilizing motor abilities enhancement program for improving intelligence in children with ADHD.

THE ASSOCIATIONS OF PHYSICAL ACTIVITY AND SELF-PERCEPTION WITH MOTOR FUNCTIONING IN ADOLESCENTS WITH AUTISM SPECTRUM DISORDER

CHEN, P.L.1, MA, W.Y.2, HUANG, C.Y.1, SUNG, M.C.1, CHEN, F.C.1, PAN, C.Y.1

1: NATIONAL KAOHSIUNG NORMAL UNIVERSITY , 2: NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction: Ample literature describes the impact of autism spectrum disorder (ASD) on social and behavioral skills; yet, information about how ASD is expressed in motor functioning is lacking. The substantial motor delays experienced by elementary-school-age children with ASD (Staples & Reid, 2010) and the persistence of motor skill-related difficulties during adolescence (Abu-Dahab, et al., 2013) indicate the need to identify the determinants of motor performance in this population. This study compared motor performance, physical activity (PA), and physical self-perception between adolescents with ASD and their typically developing (TD) peers, and assessed the associations between the three measures within each group.
Methods: A total of 126 adolescent males, aged 12–17 years, with (n = 63) and without (n = 63) ASD participated in the study. The Bruininks–Oseretsky Test of Motor Proficiency-2 and the Chinese version of the Physical Self-Perception Profile were administered. All participants wore a uniaxial GT1M Actigraph accelerometer during waking hours for 7 consecutive days. One-way multivariate analysis of covariance (i.e., age and BMI) was performed to evaluate the differences between the two groups. Partial correlations and stepwise multiple regressions were computed to identify factors associated with motor performance in each group.
Results: The adolescents with ASD had significantly lower scores (all $p < .01$) in all motor-area composites (i.e., fine manual control, manual coordination, body coordination, strength and agility) and PA levels (i.e., overall PA and MVPA), and viewed themselves as less competent in the domains of physical strength, physical condition, sports competence, and global self-esteem (all $p < .01$) compared with the TD adolescents. Regression modeling revealed that MVPA was a significant predictor of motor performance (i.e., manual coordination, strength and agility, and total motor composite) in the adolescents with and without ASD (all $p < .01$). The present study also confirms the close relationship between low motor performance and poor self-perceived physical condition in adolescents with ASD ($p < .01$).
Discussion: Future interventions aimed at improving motor performance in adolescents with ASD should focus on improving the time spent in MVPA and developing a positive self-perceived physical condition through motor skill or PA participation.

INCREASED DAILY ACTIVITY IMPEDES WEIGHT GAIN AND IMPROVES PHYSICAL ACTIVITY AND STATIC POSTURAL BALANCE OF ADULTS WITH INTELLECTUAL DISABILITY

STANGIER, C.1, REMARK, C.2, LONDON, I.2, TILLMANN, V.2, ABEL, T.1, STRÜDER, H.K.1, ANNEKEN, V.2

1: GERMAN SPORTS UNIVERSITY; 2:RESEARCH INSTITUTE FOR INCLUSION THROUGH PHYSICAL ACTIVITY AND SPORT

INTRODUCTION: Since people with mild intellectual disability (ID) have the same life expectancy as people without ID a regular and life-long physical activity (PA) is of increasing importance to prevent care dependency at an older age and to counteract against the high risk level for dementia (3) and obesity (2). Physical inactivity is also associated with a decrease in postural balance and the resultant higher risk of falling can contribute to inactivity, deconditioning and less mobility. Consequently, this study investigates the effects of increased daily activity on postural balance and level of PA in individuals with ID.
METHODS: A total of 216 individuals with ID were quasi-randomly assigned to either the intervention (42.3±14 y, 165.5±12.9 cm, 80.3±22.4 kg; 70 female, 72 male) or control group (47.7±14.5 y, 164.2±12.4 cm, 76.0±19.8 kg; 32 female, 42 male). While the control group (CG) maintained their daily habits participants in the intervention group (IG) completed 3 additional physical activities of at least 15 min each week for a total duration of 6 months. Participants´ body mass, PA (pedometer: Walking Style IV, Omron©) and static postural balance (5 static stances) (1) were measured pre and post intervention.
RESULTS: While participants in the IG maintained their body mass (80.7±22.7 kg; p=0.47) participants in the CG gained significantly weight (77.9±21 kg; p=0.008). PA was significantly increased after 6 months in the IG (4887±3210 vs. 5552±3509 steps/d; p=0.000) and slightly decreased in the CG (4607±2825 vs. 4408±2777 steps/d; p=0.38). Although both groups showed a significantly improved static postural balance (p=0.001), participants in the IG achieved the increased standing durations with less support (p=0.001) and less compensatory movements (p=0.001) compared to the CG.
CONCLUSION: The results indicate that an increase of daily activity (≥45min/week) is effective to impede weight gain in adults with ID. This is a very important result as people with ID have a higher prevalence of obesity compared to the general population, one of the main risk factors for cardiovascular diseases (2). The completed intervention was also valid to increase participants´ PA and improve static postural balance. Both are highly relevant abilities for an independent and mobile lifestyle. Since even low-threshold exercise elicited positive adaptations, the results demonstrate that a participation in health relevant resources is possible for individuals with ID living in different forms of assisted living.

FACTORS INFLUENCING PHYSICAL ACTIVITY DURING RECESS IN CHILDREN WITH SPECIAL NEEDS: A PRELIMINARY STUDY

HUANG, C.Y.1, SUNG, M.C.1, CHEN, P.L.1, MA, W.Y.2, CHU, C.H.1, PAN, C.Y.1

1: NATIONAL KAOHSIUNG NORMAL UNIVERSITY , 2: NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction: Creating an optimal environment at recess may be necessary to maximize physical activity (PA) participation in children (Huberty et al., 2011), especially those with special needs (Pan, 2008). The purpose of this study was to determine how individual and environmental factors to change PA behaviors (baseline vs. intervention) in children with special needs during school recess time (09:10-09:40 am).
Methods: The System for Observing Childrens Activity and Relationships during Play (SOCARP), the Test of Gross Motor Development-2 (TGMD-2), and the Adaptive Behavior Assessment System-2 (ABAS-2) were used. The SOCARP was designed for the simultaneous observation and recording of childrens PA levels, social group sizes, activity type, and social interactions during play. Eight targeted children with special needs were selected and observed over 4 weeks (1 recess period each day) during school days (Monday through Friday). Baseline data were collected during the first 2 weeks, and the intervention data were collect during the second 2 weeks. During the intervention period, children were give choices to play at 4 different activity zones (classroom, play room, playground, track-and-field) in recess. Data were analyzed using the Wilcoxon signed-rank test and the Spearmans rank correlation coefficient.
Results: The main SOCARP findings were that after the intervention (a) participants spent less time in lying and more time in sitting and vigorous PA (all $p<.05$); (b) participants were observed being alone and in medium groups (both $p<.05$); (c) participants engaged in more playground games and less sedentary activities (both $p<.05$); and (d) participants engaged in less occurrences of positive physical behaviors and negative physical conflict behaviors (both $p<.05$). For the baseline related factors, (a) gross motor skills were not associated with PA; and (b) adaptive behaviors (overall, $p<.05$; practical, $p<.01$) were significantly associated with negative physical conflict behaviors. For the intervention related factors, (a) gross motor skills were not associated with PA; (b) adaptive behaviors (overall, $p<.05$; practical, $p<.05$) were significantly associated with negative physical conflict behaviors; (c) sitting was associated with overall ($p<.05$) and practical behaviors ($p<.01$); and (d) practical behavior was associated with positive verbal behaviors ($p<.05$).
Discussion: The data suggest that school recess time provides children with special needs with daily opportunities to engage in play and social behaviors in a relatively unstructured environment. Some changes in students activity levels and play as well as adaptive behaviors were observed across the intervention period. Reducing recess time from the school day may negatively impact on students play choices, PA levels and social behaviors.

CASE REPORT: EVALUATION OF PROPRIOCEPTIVE PROGRAM IN A PATIENT WITH CEREBELLAR ATAXIA AFTER TRAUMATIC BRAIN INJURY

BARONE, G., ZAMBITO MARSALA, L., BENEDETTI, M.G., BRAGONZONI, L.

ISTITUTO ORTOPEDICO RIZZOLI AND UNIVERSITÀ DI BOLOGNA

INTRODUCTION: Traumatic brain injury (TBI) is one of the main causes of morbidity and mortality in the world. TBI could cause different cerebellar damage, the most common are: postural instability, tremors, balance dysfunctions, cognitive deficits and ataxia.
Proprioception has a significant role in rehabilitation to promote and improve a correct postural control. The aim of this study is to evaluate the effect of proprioceptive training in a patient with cerebellar ataxia after traumatic brain injury using Delos Postural Proprioceptive System (Delos).
METHODS: The subject is a male, 20 years old with a TBI, evolved in severe cerebellar ataxia, weighty gait and postural control disorder. Patient walks with the aid of a stick and shows uncoordinated gait. The patient leads an active lifestyle: water and postural rehabilitation, competitive climbing and amateur thai boxe. The proprioception has been evaluated using static Riva test (single stance) and stabilometric test (double stance) by Delos System (Delos S.r.l. - Torino). The Delos System allows measuring the proprioceptive control with visual feedback. The training consisted of different protocols, performed 2 days a week (45'-60') for 7 weeks. We compared the proprioceptive control before and after the protocol training.
To measure the level of proprioceptive control in single leg stance exercises, we used stability index (SI).
RESULTS: In open eyes tests, SI improve of 7.1% in the left limb and 27.3% in the right one. In close eyes tests, SI improved in left and right limbs respectively of 51.6% and 28.8%. Hands support decrease of 70pp in the left limb and 46pp in right limb. Visual dependence decrease of 17.4%. After training, the variations of the centre of mass were smaller than pre-training once.
CONCLUSION: The specific proprioception program is able to improve the proprioceptive control. The final tests show a higher stability index. The left limb had better result than right one, probably because it started from a worse condition. The patient reduced his support base and was able to perform final tests with heels together. During the first week of training, the patient needed double hands support in single stance training, instead, in the last session, he performed the tests with single hand support. There are few studies about proprioceptive rehabilitation in patients with cerebellar ataxia after TBI. Despite literature recommends proprioceptive rehabilitation techniques in ataxic patients, there are no studies that demonstrate their efficacy.
The proprioceptive protocol will be revise according to the patient's improvements and will be add Delos rocking board to increase instability conditions and range of motion of tibio-tarsal joint.
Other tests could be added as time up and go test, 10m walking test and Tinetti evaluation scale. In the future, a proprioceptive rescheduling protocol could be included in a rehabilitation program for ataxic people.

HAND HELD DYNAMOMETRY FOR FORCE MEASUREMENTS IN ADULTS WITH CEREBRAL PALSY; NORM VALUES AND VARIABILITY

EKEN, M.M.1, KOSCHNICK, S.2, LANGERAK, N.G.3, VEERBEEK, E.B.3, DU TOIT, J.1, FIEGGEN, A.G.3, LAMBERTS, R.P.1,4

1: STELLENBOSCH UNIVERSITY, RSA; 2: SAARLAND UNIVERSITY, GER; 3:UNIVERSITY OF CAPE TOWN, RSA; 4: STELLENBOSCH UNIVERSITY, RSA

INTRODUCTION: Quantifying strength in individuals with physical disabilities, such as cerebral palsy (CP), is essential to compile suitable rehabilitation programs in which strength training has become a central part [1]. However, only limited studies are published on force measurements in adults with CP [2,3]. In addition, no information on variability in force measurements is available in adults with CP, yet crucial for clinically interpreting the data. Hence, the aim of this study was to determine (I) differences in lower limb force between adults with spastic diplegia (CP) and typically developing (TD) peers and (II) differences in variability of force measurements between adults with CP and TD.
METHODS: Adults with spastic diplegia, who can walk with or without assistive devices, and TD peers exerted maximal isometric force against a handheld dynamometer (HHD), held perpendicular in specific movement direction of hip, knee and ankle (three attempts per leg per movement direction). Coefficients of variance (CV) between three force measurements were determined individually for the dominant and non-dominant side. Differences in force and CV between TD adults and adults with CP, categorized either in Gross Motor Function Classification System (GMFCS) level I, II and III, were analysed with a repeated measures ANOVA.
RESULTS: In total, 51 adults with spastic diplegia (GMFCS I: n=25; GMFCS II: n=19; GMFCS III: n=7; mean (SD) age in y:mo=37:6 (6:8)) and 61 TD (mean (SD) age in y:mo=37:10 (7:0)) adults participated in the study. Force and CV were similar for dominant and non-dominant sides within adults with CP and TD adults. Force was significantly lower in adults with CP with GMFCS I, II and III compared to TD in all movement directions ($p<0.001$). CV was significantly larger in CP than TD adults, especially in those classified in GMFCS III. CV ranged from 5.4% to 11.7% in TD adults, while it ranged from 9.3% to 15.1% in CP adults with GMFCS III.
CONCLUSION: Adults with CP were weaker across all movement directions of the lower limbs compared to their TD peers. Adults with CP in GMFCS I had a stronger hip flexion, abduction, adduction and knee flexion than adults in GMFCS III. In general, the variability in the force measurements was higher in the adults with CP than in TD. In addition, hip abduction and ankle dorsiflexion showed more variability in GMFCS III compared to GMFCS I & II. The variability and norm values established in this study will allow clinicians and researchers to better interpret force in adults with CP on a daily basis.

OP-PM40 Respiratory function

THE EFFECT OF 1600 µG SALBUTAMOL ADMINISTRATION ON 30M SPRINT PERFORMANCE IN FOOTBALL PLAYERS.

MERLINI, M.

UNIVERSITY OF KENT

INTRODUCTION: Football players with asthma related conditions are permitted to use inhaled salbutamol in accordance with current World Anti-Doping Agency (WADA) regulations1. Although a therapeutic dose of inhaled salbutamol ranges from 200-400 µg, football players are permitted to inhale up to 800 µg in any 12 hours period and 1600 µg in a 24 hours period. Limited data is available to explain whether football players may gain an ergogenic advantage from doses of inhaled salbutamol up to 1600 µg.
METHODS: In a randomised cross over single blind study 13 male non-asthmatic, football players were recruited (mean ± SD; age 18.1 ± 0.9 years; weight 69.5 ± 8.3 kg; height 178 ± 6.5 cm). Participants completed two visits and were assigned to either (SAL) or (PLA) treatment and performed a set of 3 sprints of 30 meters before and after the Yo-Yo IRT Lev 1test. Best sprint, mean sprint and fatigue index were analysed in addition to the distance covered during the Yo-Yo test; rate of perception of effort and heart rate were collected at the end of each level completed. Mixed Model Repeated Measures ANOVA was performed to investigate the changes in performance between groups.
RESULTS: Following the inhalation of 1600 µg salbutamol neither 30m sprint time (p=0.152; PLA 4,46 ± 0,12 s; SAL 4,45 ± 0,15 s) nor distance covered in the Yo-Yo test reported significant variation between conditions (p = 0.159; PLA 1660 ± 217 m; SAL 1610 ± 229 m). Blood lactate following the pre yo-yo test sprints was not different between SAL and PLA (p=0.455 SAL 6.47 + 1.5 mM vs. PLA 7.0 + 1.2 mM). The post Yo-Yo test sprint lactate values were not different between SAL and PLA conditions (SAL = 9.3 + 2.4 mM vs. PLA 10.0 + 2.1 mM; p=0.881). Moreover, heart rate and RPE did not show difference between groups.
CONCLUSION: The inhalation of 1600 µg salbutamol does not improve 30m sprint in football players either in non-fatigued or fatigued conditions. Our findings suggests the acute inhalation of salbutamol by athletes, in accordance with regulations outline in World Anti-Doping Agencies List of Banned Substances and Methods guidelines, will not lead to improvements in sprint and endurance performance in football players.

A NEW CALCULATION ALGORITHM REDUCES THE NOISE OF ALVEOLAR BREATH BY BREATH OXYGEN UPTAKE DATA

FRANCESCATO, M.P., CETTOLO, V.

UNIVERSITY OF UDINE

INTRODUCTION: Assessment of breath-by-breath (BbB) gas exchange during changes in workload is believed to provide insight into the dynamic responses of aerobic metabolism of exercising muscles. This is true, however, when gas exchange can be referred to the alveolar level, i.e. accounting for the changes in the lung gas stores. The obtained results might be improved by reducing the noise in BbB gas exchange data.
We recently proposed a new implementation of our breath-by-breath alveolar gas exchange algorithm (Cettolo & Francescato, Eur J Appl Physiol, 115:1897–1904, 2015) that was shown to provide reliable gas exchange data, although it neglects the contiguity in time of adjacent breaths. This work aims at illustrating the new algorithm and results obtained during exercise; a comparison with the corresponding values obtained with the most cited breath-by-breath alveolar gas exchange algorithm (i.e. the algorithm implemented by Beaver at al., J Appl Physiol, 51: 1662-1675, 1981), used as reference, was also performed.
METHODS: Respiratory flow, O2 and CO2 fractions at the mouth were continuatively recorded (CPET Metalyzer 3B, Cortex, Germany) in 20 healthy subjects (10 M; 10 F; 40±13 years old; 71±13 kg body mass) over 4 consecutive steps: 5 min at rest, 5 min unloaded pedaling, 6 min moderate intensity pedaling, and 10 min recovery. BbB gas exchange values were calculated from the gas and flow traces with both investigated algorithms, using computerised procedures developed in C language. Functional residual capacity, required to run the reference algorithm, was estimated from anthropometrical data (Roberts et al., Thorax, 46: 643-650, 1991). For every subject, an average value (over 3 min each), together with the corresponding standard deviation, was calculated at steady state of each step, thus obtaining 4 averages for each volunteer. Multivariate analysis of variance for repeated measures (MANOVA) was used to detect statistically significant differences. The slope of the linear regression between paired data was assumed to describe the average relative difference.
RESULTS: Average oxygen uptakes obtained with the two algorithms for the 4 steady state conditions were not statistically different (Algorithm effect, p=NS), the mean difference (i.e. the bias) amounting to –0.1 mL/min (95% limits of agreement: –31.6 mL/min to +31.4 mL/min). In all the conditions, significantly lower standard deviations were observed for the new algorithm as compared to the reference one (Algorithm effect, p<0.001). A significant correlation was observed between the standard deviations calculated with the two algorithms (r=0.727, p<0.001), the slope of the regression line amounting to 0.206.
CONCLUSION: Results showed that the new algorithm provided consistent average oxygen uptake values in steady state conditions, while significantly reducing the overall noise.

EXERCISE VENTILATORY LIMITATION IN CYSTIC FIBROSIS PATIENTS WITH NORMAL BREATHING RESERVE

REUVENY, R.1, VILOZNI, D.2, DAGAN, A.2, ASHKENAZI, M.2, VELNER, V.1, SEGE, M.J.1

1) THE PULMONARY INSTITUTE 2) THE PAEDIATRIC PULMONARY UNIT, THE EDMOND AND LILY SAFRA CHILDREN'S HOSPITAL, SHEBA MEDICAL CENTER

INTRODUCTION: Exercise ventilatory limitation (EVL) is conventionally defined by a reduced breathing reserve (BR). We hypothesized that EVL may be present despite a normal BR in cystic fibrosis (CF).
METHODS: Fifteen adult (f=8, age 34y, 18-43y)) CF patients with a wide range of pulmonary obstruction were studied. During a symptom-limited incremental exercise test on a cycle ergometer, we measured respiratory rate, tidal volume and changes in end expiratory lung volume (EELV). We also performed exercise flow-volume loop analysis. Results are reported as median (range).
RESULTS: Six patients had a severe airway obstruction (FEV1<50% predicted) and conventional evidence of EVL - BR < 11 L/min and VE/MVV > 0.92. The remaining 9 patients had mild to moderate obstructive defects on spirometry (median FEV1 61% predicted, range 50-86%), and a normal BR (21 L/min, 12-44 L/min) and normal VE/MVV (0.72, 0.65-0.81). We evaluated dynamic respiratory mechanics during exercise in these patients. In spite of a normal BR, the patients had a clear evidence of ventilatory limitation during exercise. An

abnormal breathing pattern was observed, including a high respiratory rate (54 min-1, 33-58 min-1), low tidal volume (1600 ml, 1000-2000 ml) and EILV/TLC (0.92, 0.8-0.96) at peak exercise, indicating mechanical constraint on the respiratory system. Inspiratory capacity was decreased by 250 ml (860-40 ml) during exercise, indicating dynamic hyperinflation. The exercise tidal flow met or exceeded the expiratory boundary of the maximal flow volume loop over 78% (41-90%) of the expiratory volume, indicating expiratory flow limitation.
CONCLUSION: We detected EVL in all fifteen CF patients with a wide range of severity of lung disease. BR was reduced in the six patients with the lowest FEV1 values. In the remaining 9 patients with mild to moderate disease , only assessment of dynamic respiratory mechanics during exercise revealed the ventilatory limitation.

EFFECT OF A RESPIRATORY TRAINING IN THE THORACOABDOMINAL MOTION PATTERN OF DANCERS

SILVATTI, A.1, RODRIGUES, I.1,2, LOPES, A.1, BERNARDINA, G.1, MASSARONI, C.3, CHIAPETA, A.2, PEREIRA, E.1, BARONI, G.4, CERVERI, P.4

1: UFV , 2: FACISA , 3: UCBM , 4: POLIMI

INTRODUCTION: The respiratory training (RT) has revealed positive results in athletes (Romer, McConnell and Jones, 2002), besides the years of experience could optimize the breathing pattern, as already showed in athletes (Silvatti et al., 2012). Considering the physical demands of dance practice, we aimed at evaluating whether the years of experience combined with a RT program would affect the dancers thoracoabdominal motion pattern at rest.
METHODS: Eight dancers (20.3±4 years, 1.6cm±0.1 height, 56kg±6.4 weight) with 11±4.5 years of experience and 16±4.9 hours of dance practice per week, were enrolled in performing a RT (nine weeks of daily strength breathing exercises with Respiron® and two times per week of breathing control exercises and manual release of diaphragm). To analyze the thoracoabdominal motions, they executed two breathing maneuvers at stand-up position: quite breathing (QB) lasting one minute and vital capacity (VC) with five breathing cycles. One set of maneuvers was acquired pre (PeT) and post RT (PoT). For the 3D kinematic analysis, 18 OptiTrack Prime 17W cameras (240Hz) were positioned around the dancers, capturing 32 retro-reflective markers fitted on dancer's trunk in a configuration that allowed a compartmental evaluation of breathing kinematics (superior thorax, ST; inferior thorax, IT and abdomen, AB; Ferrigno et al., 1994). The corresponding respiratory volumes were calculated for each compartment as a function of time, resulting in breathing cycles of QB and VC. The percentage of contribution (C%) was calculated to verify the most active compartment. For each compartment, the mean C% of each dancer was used to perform a linear regression ($p < 0.05$) to determine the association between years of experience and C% for QB and VC in PeT and PoT.
RESULTS: The PeT and PoT results in QB did not reveal any significant effect of the years of experience on C% in ST, IT and AB ($p > 0.05$). In VC PeT tests, the years of experience of the dancers caused a significant decrease of the C% in ST ($p = 0.0065$), with a corresponding increase in AB ($p = 0.0022$), but no effects were found in IT ($p=0.5918$). No significant influence of the years of experience were found on C% in any evaluated compartment in PoT VC tests ($p > 0.05$).
CONCLUSION: The results corroborate with Silvatti et al. (2012) that showed the effect of years of experience in swimmers. Moreover, our study suggests that the acute effect of RT could attenuate the effect of years of experience on breathing motion pattern. Further studies are needed to understand the specific effect of dancing training on the thoracoabdominal respiratory motion patterns.

OP-PM65 Children and adolescents

DAY-SEGMENTED PHYSICAL ACTIVITY IN 4 - 7 YEAR OLD CHILDREN: THE GECKO DRENTHE COHORT

WIERSMA, R., LU, C., HARTMAN, E., CORPELEIJN, E.

UNIVERSITY MEDICAL CENTER GRONINGEN, UNIVERSITY OF GRONINGEN

INTRODUCTION: Nowadays, many children do not reach the physical activity (PA) guidelines. More insight is needed in PA patterns across the day to find which moment of the day children can be encouraged to be more physically active. Therefore, the aim of this study is to examine the PA and sedentary behaviour (SB) patterns of 4-7 year old children across the day, and compare these patterns between active and less-active, and overweight and non-overweight children.
METHODS: In children participating in the GECKO Drenthe cohort, daily PA was measured using accelerometers (ActiGraph GT3X) (n=958, age=5.7±0.8 years, 52.2% boys). The PA outcomes were: SB, light- (LPA), and moderate-to-vigorous PA (MVPA). Active and less-active children were classified as the highest and lowest tertile of MVPA, respectively. Overweight was classified according to Cole (2012)1. Five day-segments were used: early-morning, morning, afternoon, late-afternoon and evening. General linear mixed models with adjustments for age, sex and season were performed.
RESULTS: Children were on average most active in the late-afternoon and also the differences in activity levels between children were largest in that time segment. During weekdays, children were less sedentary in the early-morning (-5.9 min, $p<0.001$), and showed more LPA (9.1 min, $p<0.001$) and less MVPA (-5.2 min, $p<0.001$); in the late-afternoon they showed more SB (4.0 min, $p<0.001$) and less LPA (-2.0 min, $p=0.018$), and in the evening less MVPA (-6.4 min, $p=0.029$) compared to weekend days. Active children were more active and less sedentary on all time segments ($p<0.001$), on weekdays as well as on weekend days ($p<0.05$) (differences ranging from 6.4 to 44.9 min per segment), compared to less active children. No significant differences in overall SB and MVPA between overweight and non-overweight children were found, whereas overall LPA was marginally higher (6.33 min/day) in overweight children.
CONCLUSION: With regard to the development of overweight at preschool age, the differences in PA between overweight and non-overweight young children were minimal. The late-afternoon provides the best opportunity to increase MVPA levels in children, inspired by the large inter-individual variation in this segment.

TRACKING OF PHYSICAL FITNESS OF PRIMARY SCHOOL CHILDREN IN TRIER: A 4-YEAR LONGITUDINAL STUDY

ROTH, A., SCHMIDT, S., SEIDEL, I., WOLL, A., BÖS, K.

KARLSRUHE INSTITUTE OF TECHNOLOGY

Tracking of Physical Fitness of Primary School Children in Trier: A 4-Year Longitudinal Study
Roth, A.1, Schmidt, SCE.2, Seidel, I.1, Woll, A.2, Bös, K.2
1: KIT/FoSS (Karlsruhe, Germany), 2: KIT/IfSS (Karlsruhe, Germany)
Introduction: Due to individual differences in motor development, future motor performance is hard to predict. Measuring a sample at different points in time is called tracking, and provides a coefficient for the longitudinal stability of a certain variable (Malina et al., 1996). The aim of this study is to measure the motor development and tracking of physical fitness components of primary school children of Trier (Trier; population approximately 115,000) in Germany.
Methods: Two cohorts, of 1768 children (915f, 853m), aged 5–11 took part 4266 times over the course of the study. Participants of longitudinal cohort 1 (116f 137m; 6.80±0.42 years at baseline) were measured four times from grade 1–4 (2009-2012). Participants of longitudinal cohort 2 (166f, 149m; 6.70±0.36 years at baseline) were examined three times from grade 1–3 (2010-2012) with the German Motor Test 6-18 (DMT 6-18) (Bös et al., 2015).
Results: Physical fitness increased significantly over time in all test tasks except stand and reach. Gender specific differences were found in 20m sprint, 6-minute run, balancing backwards, jumping sideways, and stand and reach. For strength-based tasks, sit-ups and push-ups, results were inconsistent.
74.4% of physical fitness stability coefficients were moderate (r= 0.30 to 0.60). Stability of physical fitness declined with increased time frames. Tracking was lower in girls than in boys. This fact has also been found in other studies (Falk et al., 2001). Flexibility showed the highest stability among physical fitness variables (r>0.50). BMI showed the overall highest stability coefficient with r>0.7.
Conclusion
Gender-specific differences of physical fitness were obvious, but cannot always be secured statistically in primary school. Tracking was only moderate. Variability in the timing and speed of the adolescent growth spurt and sexual maturation influence stability of physical fitness. Results from longitudinal cohort 2 largely confirm those from longitudinal cohort 1.

THE BEST WAYS FOR RAISING AWARENESS OF PHYSICAL ACTIVITIES TO IRISH ADOLESCENTS

NG, K., MCHALE, F., O'SHEA, D., BARRETT, G., CLIFFORD, J., MURPHY, P., WOODS, C.

UNIVERSITY OF LIMERICK

INTRODUCTION: Many school-aged adolescents are unaware of the opportunities to take part in physical activities (PA). A lack of information has commonly been cited as a major reason for inactivity. The school has the largest potential for getting information out to adolescents. However, school budgets may be restricted and this can limit ways to get messages across to the pupils. Therefore, in this study, we investigated how school-aged adolescents perceived existing methods for raising awareness of PA and to find out how they feel messages could be improved.
METHODS: Irish school-aged adolescents (13-16y old), took part in focus groups during their school day. Depending on their availability, one or two groups consisting of two to six pupils were interviewed for up to 40 minutes. A focus group interview guide was used across the sessions, parental consent and pupil assent to take part in audio-recorded sessions was obtained. Adolescents were asked to rate the effectiveness of 1) social media, 2) newsletters, 3) posters, and 4) school intercom messages. They were then asked to discuss their reasons and provide some insight into how they can be more effective. The audio was transcribed and the text was analysed through content analysis.
RESULTS: Nine focus groups took place with 41 adolescents (8 boys, 33 girls). Seven out of nine focus groups placed social media as the most effective way of communicating PA. It was reported, that teenagers are on it all the time and effective messages have visual and text information. However, for some inactive adolescents, they felt there was too much social media around and such messages would be swiped away. The usefulness of newsletters was indecisive, and this may depend on the school culture. Some pupils felt it must be read and thought it was the most effective, whereas others felt the newsletters would never get read and opined it was the least effective. The majority of groups felt posters and intercom messages were the least effective.
CONCLUSION: Messages through social media were perceived to be effective ways of communicating with school-aged adolescents about PA. These results align with the current trends of digital natives and Kelly's ARCS theory of learning (1998). ARCS has four components that are considered as critical elements in student activities; Attention, Relevance, Confidence and Satisfaction. Social media to promote PA compliant with ARCS through multimedia, however targeted engagement may be difficult among adolescents who are generally not interested in PA.

LIPOPROTEIN SUBCLASSES AND THEIR ASSOCIATIONS WITH PHYSICAL ACTIVITY, CARDIORESPIRATORY FITNESS AND ADIPOSITY IN NORWEGIAN SCHOOLCHILDREN: THE ACTIVE SMARTER KIDS STUDY

JONES, P.R.1, KVALHEIM, O.M.2,3, RESALAND, G.K.4, ANDERSSEN, S.A.1, EKELUND, U.1

1: NIH , 2: UIB , 3: HVL , 4: HVL .

INTRODUCTION: Physical activity (PA), cardiorespiratory fitness (CRF) and adiposity are associated with certain lipoproteins. Research in adults has shown that these associations are not consistent across lipoprotein subclasses. We examined cross-sectional associations in children between objectively measured PA and sedentary time (SED), CRF and adiposity with a number of biomarkers of lipoprotein metabolism.
METHODS: We included 1055 healthy fifth-grade (mean age 10.2 yrs) Norwegian schoolchildren (47.4% females). Total PA (tPA), PA intensity (light (LPA); moderate-vigorous (MVPA)), and SED were assessed using triaxial accelerometery. We used the 20-m shuttle run test to assess CRF, and waist circumference to measure abdominal adiposity. We quantified 31 measurements of lipoprotein metabolism including subclass concentrations, and particle size of three major classes (VLDL, LDL, HDL) using nuclear magnetic resonance spectroscopy. We used linear regression (median regression for skewed data) models adjusted for age, sex, sexual maturity and socioeconomic status (standard model). Additional tPA, PA intensity and CRF models were adjusted for adiposity, and additional adiposity models were adjusted for moderate-vigorous PA (MVPA) and CRF separately. An isotemporal substitution regression model quantified associations of replacing 30-minutes LPA or SED with 30-minutes MVPA. We applied a false discovery rate (FDR) adjustment to p-values of each regression model.
RESULTS: Adiposity was significantly associated with all 31 biomarkers in the tPA and MVPA-adjusted models, and 29 biomarkers following adjustment for CRF. CRF was associated with each of the 31 biomarker measures in the standard model and 22 in the adiposity-adjusted model. Total PA, MVPA, LPA and SED were associated with 10, 18, 0 and 5 of the 31 biomarkers, respectively (standard model). The number of significant associations were attenuated after adjusting for adiposity (10, 12, 0, and 0), respectively. Substituting 30-minutes of SED and LPA for MVPA revealed significant associations with 22 and 21 biomarkers, respectively. Following adjustment for adiposity, 10 and 12 associations, respectively remained statistically significant (<0.05).
CONCLUSION: CRF is associated with a number of markers of lipoprotein metabolism independent of adiposity. PA, especially of higher intensity, is associated with some of these biomarkers independent of adiposity. Substituting time spent sedentary or in LPA for MVPA shows favourable associations with these biomarkers. This suggests that improving cardiorespiratory fitness and increasing physical activity of at least moderate intensity may favourably affect lipoprotein metabolism in healthy children. Future work should replicate these findings in other cohorts and determine the clinical significance of differences in these biomarkers.

INFANT CRAWLING AS A POTENTIAL MODULATOR OF THE ASSOCIATION BETWEEN SLEEP FRAGMENTATION AND OBESITY PARAMETERS AT 8 YEARS OF AGE

FONT-LLADÓ, R., CADELLANS-ARRONIZ, A., CAZORLA-GONZÁLEZ, J., PRATS-PUIG, A.

EUSES UNIVERSITY OF GIRONA

INTRODUCTION: Crawling onset is linked to sleep disruption during infancy. At childhood, shorter sleep duration and sleep fragmentation predisposes to obesity. Furthermore, the effect of crawling during infancy in sleep fragmentation and obesity at childhood is unknown. Our aim was to ascertain whether the association between sleep fragmentation index and obesity parameters at 8 year of age can be modulated by crawling during infancy.
METHODS: Sleep duration and fragmentation index were assessed with on average six nights of actigraphy in 59 healthy children (26 boys, 33 girls; age, 7.56 ± 0.35 yr; BMI z-score, -0.32 ± 0.83) included in the PEHC (Physical Education, Health and Children) project. We measured body mass index (BMI) z-score and waist circumference as obesity parameters. Associations between sleep duration and fragmentation index with obesity parameters were tested for crawling.
RESULTS: No differences were seen in Actigraphic sleep duration at childhood according to crawling during infancy. Crawling infants exhibited higher sleep fragmentation index (p=0.032) at childhood. At 8 years of age, children with higher sleep fragmentation index present lower BMI z-score (r= -0.405; p=0.001) and waist circumference (r= -0.364; p=0.003). The association between sleep fragmentation index and obesity parameters at 8 years of age was significant only in children who crawled during infancy [(BMI z-score (r= -0.397; p=0.009); waist circumference (r=-0.383; p=0.012)]. These associations remained significant after adjusting for confounding variables such as age and gender in linear regression models.
CONCLUSION: We report new evidence for infant crawling as a potential modulator of the association between sleep fragmentation index and obesity parameters at childhood.

INTRODUCTION: The metabolic syndrome, a cluster of several cardiovascular disease risk factors, is a complex entity of metabolic disorders that significantly increases the risk of cardiovascular disease. Moreover, cardiovascular disease has been associated with decreased health-related quality of life (HRQoL). Therefore, the aim of this study was to examine the relation between metabolic risk factors and HRQoL in adolescents.
METHODS: A cross-sectional, school-based study was conducted on 521 Portuguese adolescents (262 girls) aged 12-18 years. Anthropometry (weight and height), plasma biomarkers (total cholesterol, HDL-cholesterol, triglycerides), systolic blood pressure, cardiorespiratory fitness, socioeconomic status and adherence to Mediterranean diet were obtained from each participant. HRQoL was measured with the Kidscreen-10 questionnaire. The 20- m shuttle run test was used for the estimation of cardiorespiratory fitness. Adherence to the Mediterranean diet was assessed with the KIDMED index. Adolescents' socioeconomic status was assessed with the Family Affluence Scale.
A metabolic risk score (MRS) was constructed by summing the Z scores by age and sex, of the following individual risk factors: total cholesterol/HDL-cholesterol ratio, triglycerides, glucose, systolic blood pressure, body mass index and cardiorespiratory fitness (multiplied -1). High risk was considered when the individual had ≥1SD of this score.

RESULTS: High MRS was observed in 12.7% of the sample. The mean value of the Kidscreen-10 was 39.3 (with 50 being the highest score). Multivariable linear regression model showed that high MRS was negatively associated with HRQoL (B = -0.171, p = 0.016), after adjusting for age, sex, socioeconomic status and adherence to Mediterranean diet.
CONCLUSION: To the best of our knowledge this is one of the first studies to examine the relation between metabolic risk factors and HRQoL among adolescents. As previously reported in adults (Ford et al., 2008) we found that, MRF is significantly associated with decreased HQRoL scores after adjusting for potential confounders.
Adolescents with high MRS showed lower HRQoL scores. Therefore, it is important to develop preventive strategies concerning cardiovascular and mental health in adolescents.

OP-PM64 Pacing 2

THE INFLUENCE OF PACING ON RACE PERFORMANCE DURING THE 'BIRKEBEINERRITTET' CROSS-COUNTRY MOUNTAIN BIKE EVENT

MOSS, S., FRANCIS, B., CALOGIURI, G., HIGHTON, J.
UNIVERSITY OF CHESTER

INTRODUCTION: Pacing strategy is widely considered as a key determinant to performance in endurance cycling events, although the optimal pacing strategy for cross-country marathon mountain biking events is poorly understood. The aim of this study was to investigate the distribution of pace according to race finish time in an 86 km mass-participation race.
METHODS: Data was recorded from 8,182 participants (male 7,178; female 1,005; elite 169; non-elite 8,013) competing in the 2016 'Birkebeinerrittet' race. Each participant's start, finish and intermediate split times (5 sections) were recorded via a transponder timing system. Individual section split times, average speed and variability in speed across each race section were calculated. Participants were grouped into quartiles according to race speed (first fastest [n = 2,103], second [n = 1,993], third [n = 2,066], fourth [n = 2,020]) for analysis.
RESULTS: Differences in average speed were apparent between quartiles (1st = 25.74 ± 2.3 km/h, 2nd = 23.09 ± 1.9 km/h, 3rd = 21.23 ± 1.7 km/h, 4th = 17.38 ± 2.0 km/h, d = 0.9 – 1.06) with better placed participants exhibiting faster average speeds across all race sections. Faster participants also exhibited higher relative speeds in sections 1 ($P < 0.0001$, d = 0.31 – 0.37), 3 ($P < 0.0001$, d = 0.0.24 – 0.29) and 4 ($P < 0.0001$, d = 0.47 – 0.69), all of which were characterised by an uphill profile. Conversely, the slower groups had a faster relative speed in the final race section ($P < 0.0001$, d = 0.60 – 0.69), which was characterised by non-technical descending. The CV [%] in race speed across each section was lowest in the fastest group (24.02 ± 2.8%), and sequentially increased for each slower group (2nd = 26.83 ± 3.2%, 3rd = 28.44 ± 4.1%, 4th = 32.03 ± 5.8%).
CONCLUSION: To enable fast race completion, this study favours execution of greater relative speeds during uphill sections and lower relative speeds during non-technical downhill sections, resulting in lower variability in race pace. This study is the first to reveal that greater time-savings can be made via more effective distribution of pace, representative of a 'variable' pacing strategy, in a cross-country marathon mountain-biking event. These results could be used to inform training recommendations and pacing strategy for participants motivated by a fast performance time.

THE EFFECT OF ANTICIPATED TASK DIFFICULTY ON PACING AND EFFORT PERCEPTION DURING SELF-PACED 3000M RUNNING TIME TRIALS

BRICK, N.E., TURKINGTON, R., FITZPATRICK, B.L.
ULSTER UNIVERSITY

INTRODUCTION: Existing models of self-paced endurance performance suggest that knowledge of event distance, previous experience of events of varying duration, and perception of effort are important factors influencing pace-related decision-making. No studies to date have investigated the effects of anticipated task difficulty on pace regulation during equivalent distance endurance tasks, however. The present study aimed to address this gap.
METHODS: Twenty-two trained endurance runners (VO2max 52.4 ± 7.5 ml.kg-1.min-1) completed three 3000m self-paced time trials on a motorised treadmill. On separate days, subjects first completed a baseline trial (BL) on a 0% gradient, followed by two trials during which the gradient was elevated from 0% to 7% for the final 800m. One was a Known Incline trial (KI) before which subjects were informed that the incline would increase to 7% for the final 800m. The second was an Unknown Incline trial (UI) before which subjects were informed that the gradient would remain at 0% throughout. The order of KI and UI was randomised (Order 1: BL, then KI, then UI; Order 2: BL, then UI, then KI). The data presented will focus on speed, standardised relative to BL, for the first 2200m and the final 800m and on effort perception (RPE 6-20 scale) averaged over the same segments for each trial. Statistical significance was accepted as $p < .05$ and Cohen's d values are provided as an estimate of effect size.
RESULTS: Trial X Order interaction effects for standardised speed revealed that subjects in Order 1 completed the first 2200m 2.47% slower during KI than BL, but 0.72% faster during UI than BL. In contrast, subjects in Order 2 completed the first 2200m 2.28% faster during KI than BL and 3.34% faster during UI than BL. Trial X Order interaction effects for perceived effort revealed that only subjects in Order 1 reported lower effort perceptions during the first 2200m of KI than BL. In contrast, only subjects in Order 2 reported higher effort perceptions during the final 800m of both KI and UI than BL. Main effects for trial were also noted. Speed over the first 2200m was slower during KI than UI (d = -0.43) and was also slower over the final 800m during both KI and UI than BL (all d > 4.00). Perceived effort was lower over the first 2200m during KI than BL (d = -0.39) but was higher in the final 800m during UI than BL (d = 0.54).
CONCLUSION: Anticipated task difficulty impacted pace regulation such that subjects (Order 1) ran slower and reported lower effort perceptions when they had accurate prior knowledge of a difficult running task, but had no prior task experience. In contrast, prior task experience (Order 2) appeared to moderate this relationship and facilitated running performance. This study adds to knowledge of factors that may impact pace-related decision-making. The findings suggest that anticipated task difficulty, in conjunction with task experience, may be an important, but currently unrecognised factor influencing pace regulation during endurance performance.

ROLE OF COMPETITORS AND MOTIVATIONAL ORIENTATION ON 5 KM TIME TRIAL PERFORMANCE AND PACING STRATEGY

POLMAN, R.C.J., HIBBERT, A.W., BILLAUT, F., VARLEY, M.C.

QUEENSLAND UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Surprisingly few studies have been conducted investigating the presence of other competitors or the potential moderating role of motivational orientation on pacing behaviour in athletes. Therefore the present study investigated how pacing and performance are influenced when exercising in the presence of one competitor or multiple competitors. In addition, it investigated the influence of goal orientation on the magnitude of performance change by manipulating the ability of competitors in a group setting.
METHODS: In a randomized order, 24 participants performed a 5-km cycling TT individually (IND), with one similarly matched participant (1v1), and in a group of four participants (GRP). For the GRP session, two pairs of matched participants from the 1v1 session were used. Pairs were selected so that TT duration was considered either inferior (INF) or superior (SUP) compared to the other pair of participants.
RESULTS: Overall, TT duration (P = 0.86, ?p2 < 0.01) was not different between conditions, whilst heart rate (HR) was significantly greater in GRP compared to IND (P < 0.01, ?p2 = 0.16). For INF, a large effect size for both mean power (P = 0.07, ?p2 = 0.15) and HR (P = 0.05, ?p2 = 0.16), indicates greatest effort in GRP. Pacing behaviour was affected by competition but similar in 1v1 and GRP for SUP, whilst large effect sizes indicate an increased power output in the initial 750-m for INF in GRP. Additionally, for INF, there was a significant correlation with ego orientation for an increase in TT duration between the GRP session and both the IND and 1v1 (r = 0.54, P = 0.01) sessions.
CONCLUSION: The presence of a competitor is known to influence pacing and performance. However, this study found no significant difference in 5-km TT performance between 1v1 or GRP competition settings. Yet, large effects on power indicate that INF participants are motivated to match SUP competitors in the initial stages of GRP exercise that may lead to small improvements in overall performance. Yet in a GRP setting, SUP participants may be detrimental to INF participants who are ego orientated, whilst INF participants provide no benefit to the performance of SUP participants. Overall, these findings demonstrate that competition is an important determinant of pacing and performance, and consideration should be given to the ability of competitors in a group setting to provide adequate motivation to achieve performance improvements.

GETTING THE PACE RIGHT: TESTING PACING STRATEGIES IN NOVICE CYCLISTS

ROBINSON, D.T., CLOAK LAHART, I., LANE, A.M.

UNIVERSITY OF WOLVERHAMPTON

Judging and maintaining an intense pace is important for endurance performance. The popular press and scientific literature give athletes differing advice. An athlete can concentrate on numerous factors during performance like monitoring ongoing pace, which relies on the availability of performance feedback. Alternatively, an athlete could concentrate on internal sensations of effort and perceptions of pace. The aim of the present study was to compare the effects of riding with full feedback versus 'riding on feel' (no feedback), and using either a narrow-internal focus of attention or a broad-external focus of concentration during an ergometer pacing task.
A within-subject design was used. Participants (N = 9; Age, M = 24.3, SD = 4.5 y) were healthy fit individuals but inexperienced cyclists, hence without a history of previous rides on which to monitor performance. First, participants completed three 3-min maximal cycle bouts on an ergometer (WattBike,UK). Participants were then asked to ride at 80% of the average power output (W) achieved over the three maximal bouts under four conditions: A) no feedback; B) narrow-internal focus of attention designed to help the rider concentrate on the skills needed to ride efficiently; C) a broad-external focus designed to help the rider disassociate from the ride; and D) full feedback where the rider had access to ongoing watts and time. Participants completed the blind feedback condition first and full feedback last, whereas the order of narrow-internal and broad-external focus was randomised. All rides were performed on the same day, with five minutes between each ride. A magnitude-based inference approach was used to analyse data, and a Cohen unit of 0.2 was employed as the smallest meaningful change in outcome. All analyses were adjusted for weight.
Participants averaged 220 W (SD = 40W) for the 3-min maximal test. In the no feedback condition, participants average power output was 82.7% of max (M = 182, SD = 52W), which although 2.7% greater than the full feedback condition, cannot be emphasized (95% CI -8.7 to 15.5%, d = 0.13). During the narrow-internal concentration focus participants rode at 75.9% of their max (M = 167, SD = 35W), which was 4.4% lower than when cycling with full feedback (95% CI -14.1 to 6.3, d = -0.23). However, participants maintained only 70.9% of their performance goal (M = 156, SD = 37W) during the broad-external concentration focus condition, which was meaningfully lower compared with full feedback (% MD = -11.3%, 95% CI -19.7 to -1.9, d = -0.60; 93% likely reduction). To show that differences were not due to fatigue, participants rode at 79% (M = 174, SD = 32W) in the final trial with full feedback (MD = 1.84 W, 95% CI -0.2, 3.8).
In conclusion, using an external focus of attention resulted in lower-intensity cycling performance, and full feedback along with ongoing availability of feedback facilitates accurates pacing.

THE INFLUENCE OF AGE, GENDER AND RACE EXPERIENCE ON PACING DURING THE 'BIRKEBEINERRITTET' CROSS-COUNTRY MARATHON MOUNTAIN BIKE EVENT

HIGHTON, J.1, FRANCIS, B.1, CALOGIURI, G.2, MOSS, S.1

1. UNIVERSITY OF CHESTER 2. INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Pacing is an important determinant of performance in mountain biking competitions (Abbiss et al., 2013); however, little is known about the factors that influence a pacing strategy during cross-country marathon events. The aim of this study was to explore the influence of age, gender and race experience on pacing and performance during an 86 km mass-participation mountain bike race.
METHODS: Data was collected from a single Birkebeinerrittet event. Average speed, as well as speed in five race sections (15.1 [predominantly climbing], 31.4, 52.3, 74.4 and 100% [predominantly descending] of total race distance), was analysed for 8182 participants. Participants' relative speed (%) for each race section was also calculated to explore pacing distribution (section speed/average speed x 100). Data was grouped and analysed according to age (16-24 [n = 382], 25-34 [n = 1018], 35-44 [n = 2178], 45-54 [n = 2977], 55-64 [n = 1320], 65+ [n = 307]), gender (female [n = 1004], male [n = 7178]) and prior Birkebeinerrittet race experience (<2 [n = 1620], 2-3 [n = 1887], 4-9 [n = 2952], >9 [n = 1723]).
RESULTS: Males were faster than females (~3.2 km/h) in all race sections. Males' relative speed was also higher than females in the first 3 sections of the race (effect size (d) = 0.16 – 0.39), but was lower in the final race section.
Average speed was fastest in the 16-24 yr age group (~24.5 ± 4.7 km/h; d = 0.31 – 0.85), and slowest in the 65+ yrs group (~19.75 ± 2.8 km/h; d = 0.53 - 0.85). Relative to average speed, 16-25 yr olds were significantly slower in the final race section (d = 0.22 – 0.35), which

was offset by being significantly faster in the second race section (d = 0.27 – 0.66) and the penultimate race section compared to all groups (d = 0.23).
Participants who had previously completed between 4 and 9 races were quickest (~22.81 ± 3.3 km/h) to complete the course (d = 0.26 – 0.5), followed by those who had previously participated on 2-3 occasions (~21.9 ± 3.6 km/h; d = 0.2 – 0.26). Those that had completed 4-9 races exhibited a lower relative speed than all other groups in the final race section (d = 0.21 – 0.34), which was offset by having a higher relative speed across each race section compared to other groups.
CONCLUSION: Pacing and performance in cross-country marathon mountain biking is related to age, sex and race experience. Specifically, better performance was observed in younger age groups, males, and those that had previously performed 4-9 races. These groups typically adopted a greater relative speed in climbing race sections and lower relative speed during later descents.

THE INFLUENCE OF PACING STRATEGY ON MARATHON WORLD RECORDS

SANTOS-CONCEJERO, J., FERNÁNDEZ, E.J., DÍAZ, J.J.

UNIVERSITY OF THE BASQUE COUNTRY UPV/EHU

INTRODUCTION: The limits of human performance in the marathon are still debated although several authors have proposed a potential limit that lays between 1:57:58 and 2:01:52 (Joyner et al, 1991; Denny, 2008). The pacing strategy adopted during the competition is one of the key factors in determining marathon performance as athletes can win or lose depending on their ability to spend energy adequately and prevent premature fatigue before the end of the event. The question arises whether the pacing strategies adopted by world record holders over the last decades and recent years has been ideal and whether there is still margin for improvement. Thus, the aim of this study was to analyse the influence of the pacing strategies used by marathon world record holders when setting every world record in the last 50 years.
METHODS: We divided former marathon record holders into two groups: classic runners (record holders between 1967 and 1988) and contemporaneous runners (record holders between 1988 and 2018). The total distance of the marathon was divided into eight sections of 5 km and one last section of 2.195 km, and the relative average speed of each section was calculated individually.
RESULTS: On average and analysing all world records together, athletes were slightly faster in the first half marathon than in the second one, where they slowed down progressively (ES=0.28, small effect). However, when comparing the first half marathon to the second one in classic vs. contemporaneous athletes, we observed that classic athletes decreased their speed in the second half (ES=1.06, moderate effect), whereas contemporaneous athletes were faster in the second half of the race (ES=1.16, moderate effect). When analysing the normalised relative speed (%) by section of the classic world records vs. contemporary records, we observed that both groups used different pacing strategies: the classic athletes started significantly faster than their contemporaneous counterparts (p=0.03, ES=1.16, moderate effect), although after 25 kilometres, the classic athletes' speed dropped dramatically, being meaningfully slower than in contemporaneous athletes (ES=2.41, very large effect).
CONCLUSION: This study shows that the pacing strategies of the best marathon runners in the world have changed over the last 50 years. Classic athletes used to start off relatively faster, and consequently, they used to slow down dramatically in the second half of the race. Although a negative pace distribution has been proposed as the most efficient option, a pacing strategy characterised by very little speed changes across the whole race may be the way to go in the future.

ENTROPY IN POSTURAL AND CARDIAC-AUTONOMIC CONTROL AS A MARKER OF ADAPTABILITY TO A MENTAL TASK IN YOUNG VS. MIDDLE-AGED HEALTHY MALES

BLONS, E.1, GILFRICHE, P.1,2, ARSAC, L.M.1, DESCHODT-ARSAC, V.1

UNIV. BORDEAUX

INTRODUCTION: A number of studies have shown that the time series generated by diverse free-running healthy physiologic dynamics demonstrate complex fluctuations that are not simply due to uncorrelated random errors. This is true for physiological systems whose main purpose seems to be reducing variability and maintaining a steady state, as for example, postural control and cardiac autonomic control (1). Complexity is closely linked to coordination between systems components so that a too a regular (metronomic) or a too an erratic (random) signal output, has been associated with abnormal control, pointing to a lack flexibility to adapt to everyday life demands. Complexity indices such as signal entropy are believed to be greater markers of neurophysiological control than temporal and frequency markers (2). Here we aimed at assessing signal complexity/regularity (entropy) in both postural and cardiac control when young and middle-aged healthy subjects are challenged by a mental task.
METHODS: Twelve young and eleven middle-aged healthy males participated to the present study. Heart inter-beat (RR) time series and center of pressure (CoP) oscillations were obtained in quite conditions (Control), and again when performing a prefrontal cortex activating task (Cognitive task). RR intervals were recorded (Polar belt) during 10min and CoP displacement (Winposturo platform) during 51.2s at 40Hz. Multiscale Entropy (MSE) was computed between scales 1-4 for RR series and 1-10 for CoP series. The entropy index EI was derived by calculating the area under the curve produced by the calculation of sample entropy at each time scale.
RESULTS: In control situations, the entropy index (EI) in heart and postural control showed no difference between young and middle-aged. In contrast, differences due to age appeared when confronted to a cognitive load both in postural and in heart control. In heart control, EI increased in young (Control: 5.4 ± 0.2 vs Cognitive task: 5.9 ± 0.1, $p<0.05$) but not in middle-aged during mental task (Control: 5.3 ± 0.2 vs Cognitive Task: 5.2 ± 0.3). In CoP signal, EI increased dramatically in young (Control: 5.2 ± 0.4 vs Cognitive task: 7.5 ± 0.4, $p<0.01$) but moderately in middle-aged (Control: 5.8 ± 0.6 vs Cognitive task: 7.5 ± 0.8, $p<0.05$).
CONCLUSION: In young people, prefrontal cortical arousals associated with a cognitive task increased entropy in cardiac and postural signal output, which is interpreted as an improved multiscale coordination in neurophysiological control. No such positive response was observed in middle-aged. This might rely on a disrupted interconnectivity between central and peripheral systems components when constrained by a cognitive task. The present results point to MSE as a sensitive, and thus promising tool, to evaluate early stages in impairments in neurophysiological control associated with ageing.

EXERCISE STIMULATES A PREFERENTIAL INCREASE IN SENESCENT-ASSOCIATED CD28NULL ANGIOGENIC T-CELLS IN OLDER, BUT NOT YOUNGER MALES

ROSS, M.1, INGRAM, I.1, TAYLOR, G.2, MALONE, E.1, SIMPSON, R.3, WEST, D.2, FLORIDA-JAMES, G.1
EDINBURGH NAPIER UNIVERSITY

INTRODUCTION: Ageing is associated with elevated cardiovascular disease risk. As a result of ageing, endothelial dysfunction develops, due to, in part, reduction in vascular regenerative capacity. CD31+ T-cells (angiogenic T-cells) possess highly angiogenic capabilities, however, these cells are significantly reduced in older populations. In addition, older populations possess significantly higher senescent and highly differentiated T-cell levels in circulation, and these are reported to be highly exercise responsive. We investigated if older adults display greater levels of circulating senescent (CD28null) angiogenic T-cells, and if these cells were more exercise responsive than CD28+ TANG cells.
METHODS: Young (18-25yrs; n=9) and older (60-75yrs; n=10) healthy males undertook a 30 minute cycling bout at 70% V̇O2max, with circulating angiogenic T-cells (CD3+CD31+CD28+/null; including CD4+ and CD8+ subsets) measured pre, post and 1 hour post-exercise by flow cytometry.
RESULTS: Older adults display reduced basal levels of angiogenic T-cells, despite a greater proportion of these cells being CD28null (26.26 ± 5.08 vs. 13.36 ± 2.62%, p=0.044). Exercise significantly increased the circulating number of angiogenic T-cells cells in both young and older men, but the response was blunted in older men in comparison to younger counterparts. However, in older men alone, exercise preferentially mobilized CD28null CD8+ angiogenic T-cellss compared to CD28+ subset (Δ74 ± 29 vs. Δ27 ± 15 cells·μL, p = 0.059), with no such difference observed between these phenotypes in the young population.
CONCLUSION: In conclusion, despite observing lower circulating numbers of angiogenic T-cells, older adults display greater levels of senescent cells in comparison to younger individuals, and these cells are more exercise responsive than CD28+ angiogenic T-cells. Lower number of circulating angiogenic T-cells and greater levels of senescent-associated CD28null cells may contribute to greater CVD risk with advancing age.

SYSTEMIC OXIDATIVE STRESS IS DECREASED IN OLDER SUBJECTS WITH COPD AFTER A 12-WEEK EXERCISE PROGRAM COMBINING HIIT AND POWER TRAINING

ALCAZAR, J.1,2, LOSA-REYNA, J.2,3, RODRIGUEZ-LOPEZ, C.1,2, GARCÍA-GARCÍA, F.J.2,3, PEREZ-MARTINEZ, A.2, ESPINOSA-DE LOS MONTEROS, M.J.2, ALFARO-ACHA, A., ALEGRE, L.M., ARA, I., GUADALUPE-GRAU, A.
1:GENUD TOLEDO RESEARCH GROUP, UCLM . 2:BIOMEDICAL RESEARCH NETWORKING CENTER ON FRAILTY AND HEALTHY AGING, CIBERFES . 3:HOSPITAL VIRGEN DEL VALLE, CHT . 4

INTRODUCTION: Oxidative stress has a central role in the pathophysiology of chronic obstructive pulmonary disease (COPD) (1,2). The evidence regarding exercise training as a countermeasure of systemic oxidative stress in older COPD patients is inconclusive (3), while several models of exercise training remain to be investigated. Our main goal was to assess the effects of a concurrent exercise program on oxidative stress in older COPD patients.
METHODS: Eighteen older subjects (78±7 y) with COPD (BODE index=2±1) were randomly assigned to a physical exercise group (PE; N=9; 24 sessions combining high-intensity interval training (HIIT) on a cycle ergometer and power training on the leg press) or a control group (CON; N=9; usual care) during 12 weeks. Quadriceps muscle cross-sectional area (QCSA) (computed tomography), leg press maximal muscle power (Pmax) (linear position transducer), endurance capacity (6-min walking test, 6-MWT) and physical function (5-repetition sit-to-stand test, 5-STS) were evaluated. Oxidative stress was assessed by the identification of protein carbonylation in blood samples (Oxyblot kit, Millipore). Both groups were evaluated again one year after the baseline.
RESULTS: Protein carbonylation decreased significantly in the PE group (-25±27%) compared to the CON group (+73±123%) after the 12-week intervention period (time*group effect: p=0.034), and returned to baseline values in the PE group after 40 weeks of detraining, while no changes were observed in the CON group (time*group effect: p=0.080). Significant differences regarding changes in QCSA (+7% vs -2%), Pmax (+55% vs 0%), 6-MWT (+3% vs -7%) and 5-STS time (-23% vs +9%) were found between the PE and CON groups, respectively (all $p<0.05$). A significant association was found between changes in protein carbonylation and changes in Pmax ($r=-0.46$) and 5-STS time ($r=0.72$).
CONCLUSION: A 12-week exercise program combining HIIT and power training reduced oxidative stress and increased muscle size and power, endurance and physical function in older adults with COPD. Our findings showed that the inclusion of power training in pulmonary rehabilitation might achieve additional benefits for the older COPD patients in comparison with other exercise programs (3).

MUSCLE FIBER SIZE, MYONUCLEAR CONTENT AND SATELLITE CELLS IN THE VERY OLD (83+ YEARS), AND THE EFFECT OF 12 WEEKS HEAVY RESISTANCE TRAINING.

KARLSEN, A., BECHSHOEFT, R.L., MALMGAARD-CLAUSEN, N.M., ANDERSEN, J.L., KJAER, M., MACKEY, A.L.
UNIVERSITY OF COPENHAGEN AND BISPEBJERG HOSPITAL, DENMARK

INTRODUCTION: Age related loss of muscle mass is a combination between loss of muscle fibers and atrophy of the type II muscle fibers. As muscle satellite cells can donate new myonuclei to the muscle fiber to support an increase in fiber size, they have received a great amount of attention in the past years. Several studies have observed a decline in satellite cells in the type II fibers as early as the 7th decade of life, whereas a decline in the number of myonuclei per fiber is normally not observed. However, it is possible that a decline in the number of myonucle/fiber occurs at a later stage of aging (Verdijk et al. 2014), but information on satellite cells and myonuclear content is scarce in very old individuals. Therefore, the aim of the present study was to investigate age-related changes in muscle fiber size, satellite cells and myonuclei in very old individuals (83+ years), and the response to 12 weeks of heavy resistance exercise.

METHODS: 19 men and 11 women (83-94 years) were randomized into either a heavy resistance training group (HRT) or a control group (CON). The HRT group completed 12 weeks of supervised resistance training, 3 times per week, starting at 70% 1RM. A biopsy was obtained from the vastus lateralis muscle at baseline and after the intervention and stained by immunohistochemistry for determination of fiber area, myonuclei and satellite cells. The baseline-biopsies from HRT and CON was furthermore pooled into one group (OLD) and compared with baseline-biopsies from 9 young men (YOUNG), included in a previous study.
RESULTS: At baseline the type II fibers were significantly smaller (-49%, P<0.001), and had a lower number of myonuclei/fiber (-21%, P<0.01) and satellite cells/fiber (-51%, P<0.001) in OLD compared to YOUNG, whereas no significant differences was observed for the type I fibers. In addition the myonuclear domain (fiber area/myonucleus) was slightly lower (-13%, P<0.05) in OLD type I fibers and markedly lower (-37%, P<0.001) in OLD type II fibers. There were no significant changes in muscle fiber size, myonuclei/fiber or satellite cells/fiber in the HRT-group after 12 weeks of resistance training.
CONCLUSION: As expected the OLD had smaller type II fibers and a lower number of satellite cells in the type II fibers compared to YOUNG. Extending the findings of Verdijk et al. (2014), we observed a lower number of myonuclei in the type II fibers in these very old individuals, suggesting that myonuclear content is reduced in type II fibers at very old age. Interestingly, the myonuclear domain was slightly reduced in type I fibers and markedly reduced in type II fibers in the OLD. In theory this should allow for an increase in fiber size, without myonuclear addition from satellite cells. Nevertheless, we did not observe any changes in fiber size, or the number of myonuclei and satellite cells after 12 weeks of resistance training.

MUSCULATURE AND COMPOSITION OF THE THIGH IN THE ELDERLY: A NEW PERSPECTIVE

ICHINOSE, H.1, EVANGELIDIS, P.1, YAMAGISHI, T.1, TANAKA, F.1, SHIBATA, S.2, KAWAKAMI, Y.1
WASEDA UNIVERSITY

INTRODUCTION: Segmental musculature such as the cross-sectional area (CSA) is often assessed as an indicator of exercise performance of the elderly while the amount of non-contractile tissues is overlooked. In addition to the decline of skeletal muscle mass, it has been shown that intermuscular non-contractile tissue (neurovascular & adipose tissue, NVAT) increases with aging (Delmonico et al. 2009). However, it is not clear that whether the amount of NVAT is associated with other age-related parameters including body fatness, subcutaneous adipose tissue and muscle sizes. This study therefore sought to investigate the relationships between NVAT of the thigh and musculature and body composition of the elderly.
METHODS: Participants were 16 healthy older adults (8 males and 8 females: aged 73.3 ± 5.9 years). Axial scanning of the right leg was performed with MRI, and CSA of the quadriceps femoris (QF), NVAT within the fascia lata and subcutaneous adipose tissue CSA (SAT) at a level 50% of the thigh length were measured. Body composition (percentage of body fat, %BF) was determined using bioelectrical impedance analysis. Pearson's correlation coefficients were used to analyze the relationships between NVAT, %BF, SAT and QF CSA.
RESULTS: A strong positive correlation between %BF and SAT ($r = 0.86$, $p < 0.01$), and negative correlation between NVAT and CSA of QF muscle ($r = -0.88$, $p < 0.01$) were found in the females. In contrast, no significant correlation was observed in any parameters in the males. The NVAT was not significantly correlated with %BF and with SAT in either gender.
CONCLUSION: The results show that the amount of intermuscular NVAT are not associated with %BF or SAT in the elderly of both genders. This indicates that changes in the whole-body (%BF) and peripheral (SAT) fat content and those in non-contractile tissues do not occur in parallel with aging. Dependence of NAVT on QF CSA in females suggests the impact of daily exercise habit on the amount of NAVT especially in elderly females which is in line with a previous study (Bang et al. 2018) that demonstrated association of the amount of NVAT with daily step counts in the elderly.

PULMONARY, HEART RATE AND MUSCLE DEOXYGENATION KINETICS IN VERY OLD INDIVIDUALS

FERRI, A.
VICTORIA UNIVERSITY

INTRODUCTION: While is well known that oxygen uptake (VO2) kinetics during moderate-intensity exercise are slowed with ageing, a detailed analysis of the response to high-intensity exercise is missing from the literature. The effects of ageing on skeletal muscle oxidative metabolism, and in particular on VO2, heart rate (HR), and deoxygenation of the vastus lateralis (VL) muscle at the onset of moderate- and high-intensity exercises, were evaluated in 18 elderly (E) (77.1±3.7 y, mean±SD) and 25 young (Y) (27.4±4.6 y) sedentary individuals.
METHODS: After an incremental exercise test to voluntary exhaustion on a cycle ergometer, to evaluate peak VO2 and the gas exchange threshold (GET), individuals completed three, 6-min constant-load exercises below (GET). Pulmonary VO2, VCO2, and ventilation were determined breath-by-breath. HR was measured continuously by 12-lead ECG, and recorded beat-by-beat. VL oxygenation was determined by near-infrared spectroscopy (NIRS), and changes in deoxygenated hemoglobin+myoglobin concentration [deoxy(Hb+Mb)] were taken as a muscle oxygenation index.
RESULTS: VO2peak in E (17.7±4.4 mL·kg-1·min-1) was about 50% lower ($p<0.001$) than in Y (32.2±7.4 mL·kg-1·min-1). The time constant (τ) of the primary component of VO2 kinetics was higher ($p<0.01$) in E than in Y, in both GET (57.0±16.9 vs 36.1±9.7 s). Differently from Y (amplitude of the slow component, SC= 20.8±6.2 %), E did not show a SC of VO2 kinetics for >GET. The HR primary component was also slower in E with respect to Y ($p<0.05$), for both moderate- and high-intensity exercises (59.2±32.7 vs 20.5±18.1 s and 56.4±35.6 vs 31.9±19.7 s, respectively). During exercise >GET, a HR SC was present in both Y and E with a similar amplitude (32.7±17.7 and 32.9±12.0 %). While the Mean Response Time (MRT) of the [deoxy(Hb+Mb)] was similar in E and Y during exercise GET there was a tendency ($p=0.05$) toward a slower MRT in E vs Y (26.6±14.0 vs 18.9±6.3 s).
CONCLUSION: During both moderate- and high-intensity exercises, E presented slower VO2 kinetics with respect to Y, in part due to an O2 delivery limitation (as shown by the slower HR kinetics). In E, MRT was significantly faster with respect to VO2 τ, and for exercise GET in elderly could be explained by a preferential atrophy of type II fibres, or by a reduced differentiation between fibre types.

OP-BN44 EMG

COMPARATIVE ANALYSIS OF BIOMECHANICAL AND ENERGY CHARACTERISTICS OF THE RUNNIING UNDER DIFFERENT GRAVITATIONAL LOAD ON MUSCULOSKELETAL SYSTEM

SHPAKOV, A., ARTAMONOV, A., VORONOV, A.

RESEARCH INSTITUTE FOR SPACE MEDICINE FEDERAL RESEARCH CLINICAL CENTER OF FEDERAL BIOMEDICAL AGENCY OF RUSSIA; FEDERAL RESEARCH CENTER OF PHYSICAL EDUCATION AND SPORTS

INTRODUCTION: The aim of the study was a comparative analysis of the biomechanical parameters of locomotion under different gravitational load (GL) on musculoskeletal system (MSS).
METHODS: 24 healthy men participated in the investigation (25.1±5.2 y.o., 78.5±6.6kg, 179.7±6.3cm). They performed test on the treadmill – running (10km/h). Running were carried out at under different GL on MSS: 100% and 70% of the body weight (100-BW, 70-BW). Change of GL on MSS produced by the vertical suspension. The biomechanical parameters of running were determined using video analysis of movements. Dynamic parameters and ground reaction force (GRF) were determined using force plate housed in treadmill. We analyzed the angles in the joints of the feet (hip, knee, ankle); EMG-activity of mm. Vastus lateralis (VL), Rectus femoris (RF), Biceps femoris (BF), m. Tibialis anterior (TA), Soleus (Sol), Gastrocnemius (GM); dynamic parameters and GRF of the running. To evaluate the locomotion strategy, an analysis of phase trajectories in the joints. We analyzed the kinetic energy of rotational motion associated with flexion (negative angular velocities) and extension (positive angular velocities) of the joint.
RESULTS: During the run 70-BW angular kinematics in all joints of the feet changed both in stance phase and swing phase compared to running at 100-BW. The hip and knee joints revealed less flexion during first peak phase and swing phase. In the ankle joint flexion was increased during first peak phase and extension was increased during push back phase and during swing phase. The EMG amplitude of leg muscles during running 70-BW decreased compared to running at 100-BW. In TA, Sol and BF the reduction was 12%, GM was not detected. The VL and RF amplitude decreased by 36% and 49%. Analysis of dynamic parameters and GRF at 70-BW revealed an increase in the length and time of the step, a change in the ratio of stance and swing phases of the step, a decrease in the values of the support reactions, and an increase in the width of the step. When analyzing the phase trajectories of running 70-BW, a decrease in the area in the hip and knee joints was found, a slight increase in the ankle joint. During running at 100-BW the kinetic energy of flexion prevails over the kinetic energy of extension in the hip joint. With a reduction in the GL of up to 70-BW, this ratio tends to one in the direction of decrease, which indicates an equivalent contribution of flexion and extension to the control of movement in hip joint. The ratio of the ankle flexion and extension of the energy tends to unity in the direction of increasing.
CONCLUSION: The method of vertical suspension can be used in clinical practice and rehabilitation of patients with MSS disorders. By adjusting the level of weight of load and controlling the muscle activity can increase the effectiveness of rehabilitation, optimize and accelerate the recovery process.

EFFECTS OF HIP FLEXION ANGLE ON UNILATERAL AND BILATERAL NORDIC HAMSTRING EXERCISE FORCE AND HIGH-DENSITY EMG ACTIVITY

HEGYI, A.1, LAHTI, J.2, GIACOMO, J.P.3, NOULE, T.2, CRONIN, N.J.1, MORIN, J.B.2

1:NMRC, 2:UCA-LAMHESS, 3:CEAPS

INTRODUCTION: Nordic hamstring exercise (NHE) is a popular injury prevention and rehabilitation exercise. Conventionally, NHE is performed bilaterally and with extended hip joint, i.e. at a relatively short muscle length. According to Askling et al. (2013), exercises performed at longer muscle lengths are more effective in hamstring rehabilitation. Furthermore, it is unclear whether NHE performed unilaterally can elicit higher hamstrings excitation compared to the bilateral condition. Thus, we aimed to examine the effect of hip flexion in unilateral and bilateral NHE on eccentric knee flexion force and hamstring activity.
METHODS: 13 football/rugby players performed unilateral and bilateral NHE both with extended hip joint (NHE0) and with hip flexed in 90 degrees (NHE90) at a pace of 5 seconds on a novel device. Two repetitions at eccentric one-repetition maximum load were performed per condition. Force from each leg was measured via the load cells of the device. Biceps femoris long head (BFlh) and semitendinosus (ST) electromyography (EMG) activities of the dominant (kicking) leg were measured with high-density EMG electrodes recording from 16 cm along each muscle. Peak force in the dominant leg and average EMG activity for each muscle were calculated. ST-BFlh activity ratio was calculated to define their relative contribution to each task. Cohen's d ±90% confidence intervals were calculated to locate and quantify differences.
RESULTS: NHE90 resulted in higher peak force and ST-BFlh ratio compared to NHE0 (d range = 0.58-0.97 and 1.52-1.94, respectively), however BFlh and ST activities were higher in NHE0 than in NHE90 (d range = 0.62-2.07). In both NHE0 and NHE90, peak force was higher unilaterally than bilaterally (d = 0.27 ±0.27 and 0.54 ±0.21, respectively) with no difference in ST-BFlh ratio between uni- and bilateral conditions (d = 0.18 ±0.19 and 0.06 ±0.22, respectively). ST and BFlh activities were higher unilaterally than bilaterally in NHE90 (d = 0.40 ±0.34 and 0.37 ±0.40, respectively), which was not evident in NHE0 (d = 0.14 ±0.44 and 0.02 ±0.53, respectively).
CONCLUSION: NHE90, wherein hamstrings operate at relatively longer lengths, seems to be a good alternative to conventional NHE0, especially when selective ST involvement and higher passive hamstring force is targeted. Higher relative BFlh activity in NHE0 is likely due to an active hip extension effort, which is presumably not present in NHE90. In NHE90, hamstring excitation can be further increased by performing the exercise unilaterally while eliminating the effects of bilateral deficit. These novel combinations of NHE may further improve hamstring injury management practices.

THE INFLUENCE OF EXTERNAL LOADING ON ACCELERATION AND ELECTROMYOGRAPHY ACTIVITY DURING WHOLE BODY VIBRATION OF VARYING FREQUENCIES.

SANDERSON, M.1, SPROULE, J.2, TURNER, A.2

UNIVERSITY OF THE WEST OF SCOTLAND

INTRODUCTION: Whole body vibration (WBV) has had inconsistent effects in the current literature with varying protocols used (Rittweger, 2010). One contributing factor may be differences in participants' body mass and therefore external load applied to the WBV platform, affecting the stimulus and electromyography (EMG) activity. Previous research has inferred a dampening effect by external load on WBV magnitudes (Pel et al, 2009). While the influence of external load on WBV outputs remains largely unknown, direct measurement of the magnitude is now possible (Rauch et al, 2010). However, research is limited by narrow ranges of external loads and lack of simultaneous WBV stimuli and EMG measurements. The aim of this study was to investigate the influence of external loading on acceleration and EMG activity during WBV at varying frequencies.
METHODS: 10 male participants (mean ± sd; 25.5 ± 4.6 years, 176.3 ± 6.2 cm, 73.4 ± 3.1 kg), with a history of resistance training, performed 20s reps of vertical WBV at 4 frequencies (0, 30, 40, 50 Hz) with different total external loads (80, 90, 100 kg) using weighted vests; in a randomised frequency single-blinded design. Tri-axial acceleration (platform, P; tibia, T; iliac, I) and EMG (vastus lateralis, VL; rectus femoris, RF; gastrocnemius, G) were recorded and used to calculate resultant acceleration (AR) and EMG root mean square (RMS) respectively.
RESULTS: Increased external load had no effect on AR ($p=0.08$, effect sizes expressed as Partial Eta2 (r) = 0.50), but increased WBV frequency resulted in an increase in AR ($p<0.001$, $r=0.95$). Lower AR was observed in superior body segments (AR at I < T < P) ($p<0.001$, $r=0.98$). Increased external load increased VL and RF activation ($p<0.001$, $r=0.88$; $p<0.001$, $r=0.77$ respectively), but there were no frequency x load interactions ($p=0.51$, $r=0.24$; $p=0.39$, $r=0.32$ respectively). The direction of oscillation and derived peak to peak displacement values differed to manufacturer's specifications and the latter appeared to be frequency dependent (anecdotal evidence).
CONCLUSION: The WBV stimulus was resistant to loading as AR was external load-independent although as anticipated, AR increased with increasing frequency in agreement with Rauch et al, (2010). In contrast, EMGRMS was independent of frequency (except 0Hz) yet increased with greater external load. An assumption that changes affecting AR necessarily result in proportional changes in EMGRMS activity may need further investigating. Given the lower AR at higher body segments a potential dampening effect appears plausible. This methodological approach may allow for future dose-response monitoring procedures to be developed for specific body segments; as well as development of safe WBV protocols. The results suggest that WBV stimuli and the physiological response (EMG activity) are affected by changes in frequency and external load differently. This more robust methodological protocol quantifying and validating AR output should form the new direction in WBV research.

MUSCLE ACTIVATION CHANGES IN BARBELL HIP THRUST AT INCREASING LOADS

RUEDA, J., COLLAZO, C., OLLERO, E., NAVARRO, E.

UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: In recent years, the development of the muscles of the hip pelvis has gained an interest in the field of fitness and rehabilitation (Bishop et al., 2017) and one of the most commonly used exercises for this is the "Barbell Hip Thrust" (HP) (Andersen et al., 2017). Increasing the load in an exercise has proved to increase muscle activity (Boyden, Kingman, & Dyson, 2000) and this information can be very useful for sport professionals to optimise training load, but to our knowledge no study has focused on analysing these changes in HT and in the muscles considered in this study. Our aim was to analyse the changes in lower body muscles activity in an incremental test of Barbell Hip Thrust.
METHODS: For this study a total of 7 healthy men was selected (Age 29.7±4.6; Height 176.9±5.8 cm; Weight 74.4±8.2 Kg; 1RM in HT 153.6±11 Kg), all of them being personal trainers and used to the technique of the Barbell Hip Thrust. The muscles analsyzed for this study where Rectus Femoris (RF), Vastus Medialis (VM), Vastus Lateralis (VL), Biceps Femoris (BF), Semitendinosus (ST), Gluteus Maximus (GM) and Gluteus Medius (Gme). A Maximum Voluntary Isometric Contraction (MVIC) was recorded for each muscle, and the subjects performed a HT incremental test of at least 5 repetitions starting with 20-30% of RM following a 40-50% of RM and finishing with a 60-70% of RM. EMG data was filtered and rectified and expressed as % of the MVIC of each muscle. A Friedman ANOVA was conducted to analyse difference between the 3 tests.
RESULTS: There were no significant differences between the three test conditions in the RF and Gme ($X2(2)=5.33$;$p=.069$). On the other hand significant differences were found in VM ($X2(2)=10.33$;$p=.006$), VL ($X2(2)=7$; $p=.03$), BF ($X2(2)=7$;$p=.03$), ST ($X2(2)=12$; $p=.002$) and GM ($X2(2)=9.33$; $p=.009$). In all of this muscles the differences were only found between the 20-30%RM and the 60-70%RM: VM($p=.004$), VL($p=.028$), BF ($p=.028$), ST ($p=.002$) and GM ($p=.012$). No significant changes were found between 20-30%RM and 40-50%RM and between 40-50%RM and 60-50%RM ($p<.005$).
CONCLUSION: Our results agree with the works of Boyden G. et al., (2000) and Paoli A. et al., (2009), the EMG activity in a lower body exercise increases as we work with greater loads but only after modifying a 40-50% of the RM (≈60Kg). We suggest that a better way to achieve this could by changing the exercise technique as this has been already shown by these same authors lowering the injury risk as we attempt with lighter loads.

SPINAL AND CORTICO-SPINAL RESPONSES OF THE SOLEUS MUSCLE DURING CONTRACTION, MOTOR IMAGERY AND REST

BOUGUETOCH, A., GROSPRETRE, S., MARTIN, A.

INSERM-U1093 , EA-4660 C3S

INTRODUCTION: Motor imagery (MI) may be defined as a state during which sensations of a given motor act are internally rehearsed in working memory without any overt motor output. This brain activity has been evidenced by the increased size of motor evoked potentials (MEPs), induced by transcranial magnetic stimulation (TMS) over the primary motor cortex, during MI compared to rest conditions (1).

Moreover, some studies have shown that excitability of the spinal reflex was facilitated during MI (2). The aim of this study was to measure the impact of MI on the soleus H-reflex and MEPs on a wide range of intensities and compare the evolution of the response to voluntary contraction (CON) and rest conditions (REST).
METHODS: Six young healthy subjects performed one testing session during which they seated on an isokinetic chair with their foot tied on a pedal and set at a 90°-angle of the ankle. M-waves and H-reflexes of the soleus muscle were elicited by stimulating the posterior tibial nerve with an electrode placed in the popliteal fossa. The intensity of the stimulus was progressively increased from H-reflex threshold to maximal M-wave to build H-M recruitment curves of the soleus. MEPs were elicited by a cone coil placed over the primary motor cortex of the triceps surae with several intensities from the motor threshold to the maximal MEP amplitude. H-M and MEP recruitment curves were recorded under three conditions: MI of maximal plantar flexion, weak contraction (5% of maximal voluntary contraction) and rest.
RESULTS: All intensities used for the H-M recruitment curves were expressed as percentage of Hmax intensity.
No significant difference between the three conditions was observed for any of the normalized H/Mmax (p=0.175). Regarding cortico-spinal excitabilities, a significant difference between all conditions was observed for the three highest intensities of MEPs tested (p≤0.02). The threshold to elicit MEP was lower in contraction than in MI, and lower in MI than at rest.
CONCLUSION: Despite a low sample of subjects, we can observe a significant difference between MEPs elicited in the three conditions (REST/MI/CON). Concerning cortico-spinal factors, MI seems to be an intermediate state between REST and CON.
Regarding spinal excitability, no significant difference was observed at any tested intensities. However, some trends indicate that a higher number of subjects could induce some difference. It can be assumed that a continuum exists between these three conditions, REST≤MI≤CON, for cortico-spinal and probably spinal excitabilities as well.

OP-PM63 Exercise training in diverse populations

WHOLE-BODY VIBRATION TRAINING DOES NOT CONTRIBUTE TO EITHER STRENGTH OR SPRINT SWIMMING PERFORMANCE ENHANCEMENTS IN ADOLESCENT SWIMMERS

MUÑIZ PARDOS, B.1,2, GÓMEZ-BRUTON, A.1,2,3, MATUTE-LLORENTE, A.1,2,4, LOZANO-BERGES, G.1,2,4, MARÍN-PUYALTO, J.1,2,4, GÓMEZ-CABELLO, A.1,2,5, GONZÁLEZ-AGÜERO, A., CASAJÚS, J.A., VICENTE-RODRÍGUEZ G.
UNIVERSITY OF ZARAGOZA

INTRODUCTION: Sports scientists started as early as 1978 to explore the effects of mechanical vibration as a potential stimulus to enhance muscle function and athletic performance (Zagorskaia, 1978). A recent systematic review (Hortobagyi, Lesinski, Fernandez-Del-Olmo, & Granacher, 2015) highlighted the inconsistent effects of the existing vibration training (VT) interventions on different sports and found that the efficacy of VT has not yet been proven in swimmers. Thus, the main aim of the present study is to identify the effects of VT in both strength development and swimming performance.
METHODS: Thirty-three adolescent swimmers [22 males, 11 females; 14.8(1.3) y; 58.2(11.0) kg; 168.3(10.7) cm; 10.3(1.9) h of training/week] were recruited. The intervention group (IG; n=20) was involved in an incremental 6-month whole-body vibration training (WBVT) program, in addition to the habitual swimming training performed by the control group (CG; n=13). Fifty and 100 m swimming official times (SWT) pre- and post- intervention were converted into FINA points in order to compare results from different events. Horizontal jump, 30-m run test, maximal isometric strength of the knee extensors, maximal isometric strength from half-squat position and countermovement jump height were tested before and after the intervention. To determine any potential influence of sex, a group-by-sex interaction was tested. Subsequently, both fitness and SWT variables were subjected to age-adjusted repeated measures ANCOVA to detect any potential group-by-time interaction and, thus, to determine the potential effect of WBVT on both SWT and fitness development.
RESULTS: No group-by-sex interactions were found and therefore the sample was analyzed as a whole. No group by time interactions were found, suggesting that LBVT did not show any positive effects on any of the fitness or SWT performance variables (all p>0.05; partial eta square ranged from 0.00 to 0.04).
CONCLUSION: Supporting previous evidence studying the effects of VT on other sports, the present study rejects the use of WBVT to enhance either strength development or swimming performance in adolescent swimmers. However, the exposure to VT took place during a competitive phase of the swimmers' season. This could hinder the potential effects of WBVT as the athlete's condition may differ vastly at these two time-points.

IMPACT OF EXERGAME VS. TREADMILL EXERCISE ON CARDIORESPIRATORY FITNESS, ENDOTHELIAL FUNCTION AND EPICARDIAL FAT THICKNESS IN PATIENTS WITH HIGH CARDIOVASCULAR RISK

JO, E.
KOSIN COLLEGE OF MEDICINE

INTRODUCTION: Exergame, is a promising technology that uses interactive games to increase exercise behavior, has been used as an exercise modality. However, it is still unclear whether "exergames" are as effective as conventional aerobic exercise for cardiovascular risk factor reduction. The aim of this study was to compare the effects of treadmill exercise and exergame engaged in the aerobic running video game on cardiorespiratory fitness, endothelial function and epicardial fat thickness (EFT) in patients with high cardiovascular (CV) risk.
METHODS: Forty-six patients (mean age: 61.7±12.1 years old) with high CV risk were randomized to aerobic exergame using Exer-heart (n=19), treadmill (n=15) and control (n=12) group. The Exer-heart and treadmill groups performed equal volumes of energy expenditure for 230 MET-min/day with moderate to vigorous intensity. Each group completed a fully supervised 3 times a week for 12-week training. Participants were examined for peak oxygen uptake (VO2peak), EFT measured by echocardiography, and flow-mediated dilation (FMD) using ultrasonography. Blood samples were collected to measure endothelial progenitor cells (EPCs) such as CD34/CD117+ using flow cytometry.
RESULTS: Compared to the baseline, both 12 weeks Exer-heart and treadmill aerobic exercise significantly improved VO2peak (Exer-heart, 38% , p<0.001; treadmill, 27%, p<0.001; control, 0%; p=0.984), EFT (Exer-heart, 0.13mm; p<0.01; treadmill, 0.17mm; p<0.01; control,

0.05mm; p=0.579), FMD (Exer-heart, 9.3%, p<0.001; treadmill, 8.7%, p<0.01; control, 2%; p=0.785), and CD34/CD117+ (Exer-heart, 26/μL, p<0.05; treadmill, 25/μL; p<0.01; control, -2/μL; p=0.552).
CONCLUSION: Aerobic exergame had the similar exercise effects as a conventional treadmill exercise of moderate to vigorous intensity in improving cardiorespiratory fitness, endothelial function and EFT in patients with high CV risk. These finding suggest that the aerobic exergame may have a role as an attractive exercise program in prevention and treatment of CV risk factors.

BENEFICIAL EFFECTS OF ENDURANCE TRAINING ON SKELETAL MUSCLE MICROVASCULATURE IN PATIENTS WITH SICKLE CELL DISEASE.

MERLET, A., MESSONNIER, L., BARTOLUCCI, P., HOURDE, C., LACROIX, R., GELLEN, B., PEYROT, S., RUPP, T., GALACTEROS, F., FEASSON, L.

LABORATORY OF HUMAN MOVEMENT SCIENCES

INTRODUCTION: Sickle cell disease is a genetic haemoglobinopathy leading in two major clinical manifestations: severe chronic haemolytic anaemia and iterative vaso-occlusive crisis. Recently, we have highlighted that SCD is accompanied by a profound and deleterious remodelling of muscle tissue and in particular at the microvascular level . In the literature, the beneficial effects of endurance training on microvascular network are widely known in healthy and pathological population. Since safety and functional benefits were present following an adapted physical activity program in SCD patients, the aim was also to evaluate the effects of this program on muscle microvascular adaptations.
METHODS: Forty SCD patients were randomized in two groups: group E followed a training program in endurance while group C maintained its usual lifestyle. Adaptive physical activity consisted of a 45-minute ergocyle exercise, 3 sessions per week for 8 weeks. The individual intensity was determined by a submaximal cardio-pulmonary exercise test and re-evaluated at the end of the program. A biopsy of the vastus lateralis muscle was performed before and after the training period.
RESULTS: Muscle microvascular benefits was highlighted after the training program with in particular an increases of the i> capillary density , number of capillaries around a fibre , iii> functional surface of exchange . Conversely, the morphology of capillaries was unchanged in response to such program.
CONCLUSION: A well-controlled moderate-intensity exercise endurance training improve the blood supply to muscle tissue and partly reverses the microvascular deficits previously observed in SCD patients.

CMJ TRAINING IS MORE EFFECTIVE THAN DJ TRAINING IN ENHANCING VERTICAL JUMP HEIGHT IN FEMALE AMATEUR VOLLEYBALL PLAYERS

RUFFIEUX, J., ANDREY, S., TAUBE, W.

UNIVERSITY OF FRIBOURG

INTRODUCTION: Vertical jump ability is a key factor in many sports, such as volleyball. The typical jump types in volleyball (attack and block) can be characterized as countermovement jumps (CMJs). Various exercises have been proposed to improve CMJ jump height, including drop jumps (DJ). Due to the greater mechanical output compared to CMJs, DJs have been suggested to be effective in enhancing CMJ performance (Bobbert, 1990). This has been confirmed by multiple training studies (Markovic, 2007). However, to the best of our knowledge, no study has to date compared the effect of a DJ training to that of a "simple" CMJ training on CMJ performance. This was, therefore, the aim of this study.
METHODS: 26 female volleyball players of a regional level (21.2 ± 3.8 years, 169.6 ± 4.4 cm, 63.9 ± 7.4 kg), were allocated to either a CMJ training group or a DJ training group, which were matched for age and jump height at the pre-test. The training comprised 2 sessions per week for 6 weeks. In each session the participants performed 60 jumps, of which 20 % were performed in the jump type of the other group. During pre- and post-measurements, jump height was assessed in 4 different jump types: CMJ (hands akimbo), CMJ with arm swing (similar to a block jump in volleyball), CMJ with run-up (similar to an attack in volleyball), and DJ (37 cm drop height). The best trial out of 5 in each jump type was used for statistical analysis (2x2x4 mixed-design ANOVA: time*group*jump type).
RESULTS: On average, the CMJ group improved jumping height by 16.7 ± 9.2 %, the DJ group by 7.3 ± 5.4 %. The statistical analysis showed that the improvements were significant in both groups ($p < .001$) but that the CMJ group improved more (time*group: $p < .001$). This effect was not significantly different between jump types ($p = 0.068$), although there was a trend toward a greater difference in the CMJ with run-up.
CONCLUSION: The results show that both training forms considerably improved vertical jump ability. However, the CMJ was significantly more effective. This was true for all jump types, including the DJ, but most pronounced for the CMJ with run-up, which resembles the attack in volleyball. These findings suggest that training interventions with a high percentage (80 %) of CMJs and a low percentage of DJs are more efficient than a concentration on DJs to improve volleyball-specific jump abilities.

INFLUENCE OF BELAY TRAINING ON EXECUTION OF THE BRAKE HAND PRINCIPLE IN UNEXPERIENCED BELAYERS

MATIAS SANTOS, V.M.1,2, CRONRATH, M.1, PLATEN, P.2

RUHR UNIVERSITÄT BOCHUM

INTRODUCTION: Most climbing accidents occur during lead climbing [1]. Violating the brake hand principle (BHP) is one of the most frequent operating errors [2]. An exclusive belay training with Grigri does not sufficiently teach the BHP compared to a belay training with Tube. There are belaying devices with safety qualities between Grigri and Tube like the Mega Jul [3]. The purpose of the study was to compare the effects of exclusive belay training with Grigri, Tube, and Mega Jul to analyze the effects on error rate (ER) in BHP.
METHODS: 34 healthy subjects (m = 23; w = 11; age = 22.9 ± 2.2 yrs) were randomly divided into a Grigri group (GG: n = 13), a Mega Jul group (MG: n = 11) and a Tube group (TG: n = 10). The GG, MG and TG were trained 11 hours with their belaying device. Every group was instructed one hour on the other two belaying devices. One week after subsequent training, participants conducted a filmed test session in which they belayed a trained lead climber with a Grigri, Mega Jul and Tube for approximately 5 min per each belay device during fall

training. ER of the three belaying devices in each group were added and afterwards compared between groups. ER in the BHP were evaluated by five independent persons using video recordings. Significance was set at 0.05.
RESULTS: Number of errors in the BHP was significantly higher in GG and MG compared to TG and there was no difference between GG and MG (number of errors, mean ± SD: GG: 2.7 ± 2.4; MG: 2.4 ± 2.3; TG: 0.2 ± 0.4; TG vs. GG, TG vs. MG $p < 0.01$; GG vs. MG $p > 0.05$).
CONCLUSION: Belay training using only a Grigri or a Mega Jul does not sufficiently teach the BHP. Procedural memory is created by procedural learning [4]. A deficit in procedural memory regarding BHP is likely to be attributed to the absence of negative feedback throughout errors in preceded simulations. Therefore, the behaviour during belaying cannot completely be related to the theoretical knowledge but rather to the experience on belaying [5]. Mega Jul does not provide an advantage in learning the BHP despite its similarities with the Tube. In order to train unexperienced belayers a Tube should be the first option. Using other belaying devices like Mega Jul or Grigri after a belay training with the Tube requires at least one hour of specific belay training with the new belaying device.

IS-EX01 ECSS-ACSM exchange symposium: Exercise is Medicine

EXERCISE IS MEDICINE; ON A GLOBAL HEALTH INITIATIVE

SALLIS, R.

UC RIVERSIDE SCHOOL OF MEDICINE

Exercise is a very powerful tool for both the treatment and prevention of chronic disease, for mitigating the harmful effects of obesity, and for lowering mortality rates. In fact, there is a linear relationship between activity level and health status. This association between disease and an inactive and unfit way of life exists in every age group: children, adults, and the elderly. The results of studies consistently show that those who are active and fit are healthier. For this reason, many have suggested that physical inactivity is the major public health problem of our time.
This strong connection between physical activity and health was highlighted in a series of articles that the journal Lancet published in 2012. The series reached this conclusion: "In view of the prevalence, global reach, and health effect of physical inactivity, the issue should be appropriately described as pandemic, with far-reaching health, economic, environmental, and social consequences." Can you imagine the public outcry if such strong words had been used to describe a "pandemic" caused by an infectious disease or injury? You can bet there would have been numerous large-scale campaigns mounted and associated publicity to deal with such a pandemic. Unfortunately, the clear identification of the inactivity pandemic in Lancet barely generated any media response.
It was for the above reasons that the Exercises Is Medicine (EIM) initiative was established. The stated goal of the EIM initiative is "to make physical activity assessment and exercise prescription a standard part of the disease prevention and treatment paradigm for all patients." The initiative was started by the American College of Sports Medicine in conjunction with the American Medical Association in November 2007. A national launch was held in Washington, DC, that was attended by then US Surgeon General Steve Galson, along with the directors of the President's Council on Physical Fitness and Sports and the California Governors Council on Physical Fitness and Sports.
In May 2008 the first World Congress on Exercise Is Medicine was held in conjunction with the American College of Sports Medicine's annual meeting to announce the global launch of this program. Since that time, EIM has spread to more than 50 countries, including 6 regional centers. It has been interesting to note the worldwide acceptance of the basic tenets of EIM, including recommendations for weekly physical activity to improve health. Most countries have established physical activity guidelines that are essentially the same, suggesting that adults should get 150 minutes of moderate to vigorous activity each week. It is amazing to have a major public health problem in which almost everyone worldwide agrees on the proper treatment.
This lecture will celebrate the 10 year anniversary of the EIM initiative, while providing an update and discussion of future directions around the world.

EXERCISE IS MEDICINE AT THE WORKPLACE: A FEASIBLE OPTION?

VAN MECHELEN, W.

VU UNIVERSITY MEDICAL CENTER

The prevalence of lifestyle-related, chronic disease is still on the rise. Physical inactivity is the 4th leading cause of death due to lifestyle-related diseases, according to the WHO. Therefore, it is important to enhance population levels of physical activity worldwide. This is easier said than done, since human nature is geared towards the preservation of energy. Interventions to enhance levels of physical activity can be directed at either the individual him-/herself for instance through Exercise is Medicine initiatives, or at the environment (, or both). These interventions are probably best delivered to a 'captive' audience, in order to maximize intervention effect. One such a captive audience is found in the workplace. Purpose of this presentation is to present research findings of interventions that were carried out at the workplace both for people and places, with the aim to enhance employee's levels of daily physical activity. Also the results will be presented of worksite exercise interventions for disabled workers with non-specific low back pain, with the aim to have them return-to-work. Finally, some issues related to barriers and facilitators of worksite physical activity will be discussed.

INTERFACE PRESSURE, PERCEPTUAL AND MEAN ARTERIAL PRESSURE RESPONSES TO EXERCISE IN DIFFERENT BLOOD FLOW RESTRICTION SYSTEMS

HUGHES, L.

ST. MARY'S UNIVERSITY

INTRODUCTION: Different blood flow restriction (BFR) systems, composed of a cuff and inflation device, are used in BFR application (Hughes et al., 2017). However, the actual pressure between the cuff and the limb, perceptual and mean arterial pressure (MAP) responses to exercise, in the different BFR systems, has not been examined. Therefore, this study aimed to examine the cuff to limb interface pressure, perceptual and MAP responses to exercise in different BFR systems.
METHODS: Eighteen participants completed 4 sets of unilateral leg press exercise at 30% of one repetition maximum with BFR at 80% of limb occlusion pressure in a randomised, crossover, counterbalanced design. Different BFR systems were used across 3 sessions: an automatic rapid-inflation (RI), automatic personalised tourniquet (PT) and manual handheld pump and sphygnamometer (HS) system. Each BFR system comprised a method of pressure regulation: the RI system adjusts pressure automatically; the PT system automatically

adjusts pressure around the set pressure; and the manual HS system does not automatically regulate pressure. Interface pressure was measured using a universal interface device with pressure sensors. A clinical limit of ± 15 mmHg was set a priori, as the recommended pressure window for safe and effective restriction of blood flow (Mcewen, 1981). Inter-set pain and exertion were measured alongside MAP at pre-, 1 min post- and 5 min post-exercise.
RESULTS: Interface pressure was, on average, 10.24 ± 8.01 and 47.65 ± 35.95 mmHg higher than the set pressure in the RI and HS systems ($p<0.01$), with no differences in the PT system ($p>0.05$), during exercise, and within the clinical limit of ± 15mmHg for the RI and PT systems. Pain and exertion were greater in sets 3 and 4 in the RI and HS systems compared to the PT system ($p<0.01$). MAP was higher in the RI and HS systems compared to the PT system at 1-min and 5 min post-exercise ($p<0.01$).
CONCLUSION: Higher interface pressure during exercise may be attributed to a combination of muscle contraction, method of pressure control, cuff properties and participant factors. Automatic BFR systems appear to regulate pressure effectively within an acceptable range during BFR exercise and reduce perceptual and MAP responses.

REGULAR PHYSICAL EXERCISE, PRIOR TO LOWER LIMB ARTERIAL OCCLUSION DEVELOPEMENT, AMELIORATES WALKING CAPACITY AND ISCHEMIC LIMB PERFUSION IN A MOUSE MODEL

PELLEGRIN, M., MAYER, M., BOUZOURÈNE, K., AUBERT, J.F., MAZZOLAI, L.
UNIVERSITY HOSPITAL OF LAUSANNE

INTRODUCTION: Lower extremity artery disease (LEAD) is a significant public health problem characterized by occlusion of lower limb arteries due to atherosclerosis. As a consequence of decreased blood flow and perfusion to the muscles, patients with LEAD can experience diminished walking ability. Physical exercise (PE) is recommended to improve walking capacity in LEAD patients with intermittent claudication (Aboyans et al., 2017). However, little is known about the preventive effect of PE prior to LEAD development. The present study therefore explored whether PE prior to LEAD induction can prevent subsequent walking ability impairment and decreased limb perfusion in mice.
METHODS: Atherosclerotic C57BL/6 Apolipoprotein E-deficient (ApoE-/-) mice were allowed free access to voluntary wheel running (WR) or remained sedentary (SED) for 5 weeks before induction of experimental LEAD via unilateral iliac artery ligation/occlusion (Pellegrin et al., 2014). Thereafter, the two groups were kept sedentary for 5 weeks. Walking capacity was determined by calculating the maximal walking distance (MWD) using an incremental treadmill running test. Hindlimb perfusion was assessed using laser Doppler imaging. Real-time RT-PCR was used to determine macrophage phenotype (pro-inflammatory M1 versus anti-inflammatory M2 macrophages) in hindlimb quadriceps muscle. Flow cytometry was employed to analyze blood circulating monocyte subsets (Ly6Chigh inflammatory versus Ly6Clow anti-inflammatory monocytes).
RESULTS: MWD significantly improved by 23% in WR compared to SED mice at end of the study ($P<0.05$). Compared to SED mice, ischemic hindlimb perfusion in WR animals was significantly increased at week 3 (+40%, $P<0.01$), week 4 (+50%, $P<0.001$), and week 5 (+28%, $P<0.05$) after LEAD induction. In SED mice, M1 marker CD11c mRNA levels tended to increase in ischemic quadriceps muscle (2.1-fold versus non-ischemic contralateral quadriceps muscle, $P=0.065$) while M2 marker CD206 mRNA levels significantly increased in WR mice (1.7-fold versus non-ischemic muscle, $P<0.05$). WR significantly decreased the number of circulating pro-inflammatory monocytes (-41% versus SED) while increased that of anti-inflammatory monocytes (+45%) ($P<0.01$).
CONCLUSION: PE prior to LEAD development is effective in preventing disease severity. Mechanistically, PE polarizes circulating monocytes and muscular macrophages towards an-anti-inflammatory phenotype. Our study provides the first experimental evidence of the role of PE in primary prevention of LEAD.

FACTORS AFFECTING OCCLUSION PRESSURE AND ISCHEMIC PRECONDITIONING

BROWN, H.1,2,3, BINNIE, M.J.1,2, DAWSON, B.1, BULLOCK, N.3,4,5, SCOTT, B.R.6, PEELING, P.1,2
1: UNIVERSITY OF WESTERN AUSTRALIA, 2: WESTERN AUSTRALIAN INSTITUTE OF SPORT, 3: AUSTRALIAN INSTITUTE OF SPORT, 4: AUSTRALIAN CANOEING, 5: BOND UNIVERSITY, 6: MURDOCH UNIVERSITY

INTRODUCTION: Ischemic preconditioning (IPC) literature has reported small beneficial effects on performance, although equivocal results have also been recorded. Uncertain aspects relating to IPC intervention are whether complete arterial occlusion is required to elicit the full impact, and if the cuff pressures typically used in IPC research to date (200-220 mmHg) are sufficient to elicit complete arterial occlusion in athletic populations. Therefore, the aim of this study was to investigate the relationship between selected methodological variables and arterial occlusion pressure (AOP) in athletes.
METHODS: Twenty well-trained athletes were recruited to attend 3 laboratory sessions. Participants were firstly assessed using surface anthropometry and dual x-ray absorptiometry (DXA) to provide measures of body size and composition. In subsequent sessions their blood pressure (BP) was taken, followed by a determination of AOP for each limb using an incremental step protocol and Doppler ultrasound of the posterior tibial and radial arteries. Limbs were measured one at a time, with AOP recorded as the lowest 10 mmHg increment at which no pulse was detected. For arms, small (6 cm) or medium (13 cm) cuffs were used, and for legs medium or large (18 cm) cuffs employed in a crossover design. A 5 min occlusion was then performed at the measured AOP with pulse monitored throughout, and cuff pressure increased by a further 10 mmHg if pulse returned, with the adjusted pressure recorded as the final AOP. Data were pooled between left and right limbs, then AOP was compared between sexes, limbs and cuff sizes. The influence of anthropometric, DXA and other variables on AOP was assessed using linear regression models.
RESULTS: Mean AOP was higher in legs than arms (161±18 vs. 133±12 mmHg; $p<0.001$), and with smaller cuffs in arms (161±16 vs. 133±12 mmHg; $p<0.001$), but not legs (161±16 vs. 170±26; $p=0.222$). Sex and resting systolic BP accounted for 77% (small cuff) to 83% (medium cuff) of variance in AOP for arms, and 61% (medium cuff) to 63% (large cuff) in legs. Including anthropometry accounted for 82% (small cuff) to 89% (medium cuff) and 78% (medium cuff) to 79% (large cuff) of variance for arms and legs, respectively. Adding DXA variables improved the explained variance up to 83% (small cuff) to 91% (medium cuff) and 79% (medium cuff) to 87% (large cuff) for arms and legs, respectively.

CONCLUSION: Upper limb AOP in athletes can be accurately predicted using sex and systolic BP alone, while surface anthropometry should be included for lower limbs. Cuff pressure of 200-220 mmHg is likely sufficient to elicit full arterial occlusion where appropriate cuffs have been used, however, the use of individualised occlusion pressures based on the direct measurement of AOP or regression models may increase the efficacy of future IPC protocols.

EFFECTS OF A FAILURE VS. A SUBMAXIMAL PROTOCOL OF BLOOD FLOW RESTRICTED RESISTANCE EXERCISE ON CHANGES IN MUSCLE SIZE

MANGSETH, H.1, SANDNES, N.V.1, GERBI, S.1, LINDBERG, K.1, SØRLI, T.1, VÅRVIK, F.2, WERNBOM, M.3, BERNTSEN, S.1, PAULSEN, G.4, RAASTAD, T.5, BJØRNSEN, T.1

1UNIVERSITY OF AGDER, 2NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, 3UNIVERSITY OF GOTHENBURG, 4NORWEGIAN OLYMPIC FEDERATION, 5NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Short-term high-frequency blood flow restricted resistance exercise (BFRRE) has been observed to increase muscle size with loads as low as 20% of 1 repetition maximum (1RM) (1). However, the training effort that has the most potent effect on muscle hypertrophy during high-frequency BFRRE is less investigated. Therefore, the aim of the present study was to compare the effects of a failure versus a submaximal BFRRE protocol on muscle- thickness and cross-sectional area (CSA).
METHODS: Twenty-nine untrained men and women (18-45 yrs old) were randomized to either a non-exercising control group (n=9) or a BFRRE group (n=20). The participants in the BFRRE group performed four sets to voluntary failure with one leg, and a submaximal protocol consisting of 20, 10, 10, 10 repetitions with the other leg. Fourteen BFRRE sessions with unilateral knee extensions (20% of 1RM) were distributed over two five-day blocks, separated by a ten-day rest period. To restrict blood flow, a 145mm wide cuff was inflated to a pressure of 100 mmHg. Ultrasound measurements were recorded at 40% (distal) and 60% (proximal) of the femur length in m.rectus femoris (RFdist & RFprox) and m.vastus lateralis (VLdist & VLprox). Statistical analyses were conducted using linear-mixed models with Fishers LSD post-hoc test and independent sample t-tests.
RESULTS: Over the time course of the study, the failure protocol induced significantly larger increase in muscle thickness of RFprox (Fail: 6.2% vs. Sub: 4.4%), VLprox (Fail: 4.9% vs. Sub: 3.2%), VLdist (Fail: 5.3% vs. Sub: 3.9%), as well as CSA of RFprox (Fail: 7.2% vs. Sub: 5.7%) and RFdist (Fail: 10.4% vs. Sub: 8.0%) than the submaximal protocol ($p<0.05$). No differences between protocols were observed in thickness of RFdist. Muscle- thickness and CSA increased significantly from baseline to measurement time points between 10 and 24 days of detraining. The CSA of RFprox, and thickness of RFprox, VLprox and VLdist were increased more in the failure leg compared to the submaximal leg at training day 17 and 19. No changes in muscle size were observed in the control group. The failure leg performed significantly more repetitions per session (78, SD=21) than the submaximal leg (50, SD=3) ($p<0.001$).
CONCLUSION: High-frequency low-load BFRRE to voluntary failure induced larger gains in muscle- thickness and CSA than the submaximal protocol. This might indicate that training to voluntary failure may be favorable, if increased muscle size is the desired outcome. However, the failure protocol induced more muscle swelling during BFRRE than the submaximal protocol. Which in turn could have influenced the post measurements.

SUCROSE BUT NOT NITRATE INGESTION REDUCES HIGH-INTENSITY EXERCISE-INDUCED GUT INJURY

JONVIK, K.L., LENAERTS, K., SMEETS, J.S.J., KOLKMAN, J., VAN LOON, L.J.C., VERDIJK, L.B.

MAASTRICHT UNIVERSITY

INTRODUCTION: During high-intensity exercise many athletes suffer from gastrointestinal (GI) complaints, which are likely related to splanchnic hypoperfusion, resulting in intestinal injury. Increasing circulating nitric oxide (NO) levels or inducing postprandial hyperemia may improve splanchnic perfusion, thereby attenuating intestinal injury during exercise. Therefore, we investigated the effects of both dietary nitrate ingestion and sucrose ingestion on splanchnic perfusion and intestinal injury induced by high-intensity exercise.
METHODS: In a randomized cross-over manner, 16 well-trained male athletes (age: 28±7 y; Wmax: 5.0±0.3 W/kg) cycled 60 min at 70% Wmax following acute ingestion of: sodium nitrate (NIT; 800 mg NO3), sucrose (SUC; 40 g) or a water placebo (PLA). Test days were planned on the same week day and time of day, separated by 1-wk washout. Splanchnic perfusion was assessed by determining the gap between gastric and arterial pCO2 (pCO2gap) using gastric air tonometry. Plasma intestinal fatty-acid binding protein (I-FABP) concentrations, reflecting enterocyte damage, were assessed every 20 min during exercise and up to 60 min of post-exercise recovery. Total area under the curve (AUC) for I-FABP and for pCO2gap, were calculated and analyzed using repeated measures ANOVA with treatment (NIT, SUC or PLA) as within-subjects factor. Continuous data for I-FABP (increase from baseline in %), pCO2gap, plasma nitrate, plasma nitrite and plasma glucose were analyzed using repeated measures ANOVA, with time and treatment as within-subjects factors. Statistical significance was set at $P<0.05$, and any interaction or main effect was subsequently analyzed using a Bonferroni corrected post hoc test for pre-planned comparisons (i.e., SUC vs PLA and NIT vs PLA). All data are presented as means ± SDs.
RESULTS: As expected, plasma nitrate and nitrite concentrations were higher in NIT vs PLA throughout the test day (all $P<0.001$), and plasma glucose concentrations were higher in SUC vs PLA ($P=0.008$). The exercise protocol resulted in splanchnic hypoperfusion, as pCO2gap levels increased during exercise (from ~0 to ~2 kPa, $P<0.001$), with no differences between treatments ($P=0.47$). Although plasma I-FABP concentrations increased during exercise and post-exercise recovery for all treatments ($P<0.0001$), the increase was different between treatments ($P<0.0001$). Post-hoc comparisons showed an attenuated increase in I-FABP in SUC vs PLA ($P=0.020$). In accordance, I-FABP area under the curve (AUC) was significantly lower in SUC vs PLA (4,622±6,291% vs 10,099±6,783%, $P=0.004$). No differences were observed between NIT and PLA ($P=0.78$).
CONCLUSION: Sucrose but not nitrate ingestion lowers gut injury evoked during high-intensity exercise. These results suggest that sucrose ingestion, but not nitrate, prevents hypoperfusion-induced GI damage during exercise and, as such, may help to lower exercise-related GI complaints.

EXERCISE-INDUCED IMPAIRMENTS IN MITOCHONDRIAL ADP SENSITIVITY CONTRIBUTES TO THE INDUCTION OF PGC-1A GENE EXPRESSION THROUGH ENHANCED MITOCHONDRIAL H2O2 EMISSION

MIOTTO, P.M., HOLLOWAY, G.P.

UNIVERSITY OF GUELPH

INTRODUCTION: Acute exercise rapidly induces mitochondrial biogenesis, however, the role of mitochondrial derived reactive oxygen species in regulating this response remains controversial. We reasoned that the reduction in mitochondrial ADP sensitivity that occurs during exercise could have a biological role in increasing mitochondrial-derived ROS production, and ultimately promote the induction of mitochondrial gene transcription.
METHODS: To address this possibility, we utilized mitochondrial creatine kinase knockout mice, an animal model that we have recently shown have improved ADP sensitivity in permeabilized muscle fibres during exercise, to determine if ADP sensitivity influences ROS production and mitochondrial adaptations .
RESULTS: While exercise similarly induced calcium/calmodulin-dependent protein kinase II and AMP-activated protein kinase phosphorylation in wildtype and KO mice, in stark contrast, KO mice exhibited improved ADP sensitivity during exercise in association with reduced mitochondrial ROS emission and the absence of exercise-induced PGC-1α gene transcription . Furthermore, while 4 weeks of exercise training increased markers of mitochondrial content and reduced ADP sensitivity in permeabilized muscle fibres from WT mice , in concert with our acute experiments, KO mice had blunted responses in these parameters.
CONCLUSION: Combined, these data suggest that exercise-induced attenuations in mitochondrial ADP sensitivity mediate redox signals that may contribute to the induction of mitochondrial biogenesis.

THE EFFECT OF LIFE-LONG EXERCISE ON SIRT3 AND SOD2 PROTEIN EXPRESSION IN HUMAN SKELETAL MUSCLE

BORI, Z., KOLTAI, E., RADAK, Z.

UNIVERSITY OF PHYSICAL EDUCATION

INTRODUCTION: Aging causes significant loss in muscle mass and function. Physical exercise is a natural tool to attenuate this process. Since ageing is associated with reduced levels of physical activity and disuse causes muscle wasting and reductions in oxidative capacity master athletes provide an excellent model to study the effects of ageing per se on muscle, not confounded by disuse. The purpose of this investigation was to study the differences in the mRNA and protein mitochondrial expression between master athletes and age-matched controls.
METHODS: We recruited master athletes at European Veterans Athletics Championships (Nyíregyháza, Hungary), and control participants at nursing home (Győr, Hungary). Subjects older than 65 years were included in this study. The master athletes reported that they all had been training for more than sixty years, while control subjects were sedentary. The study was approved by the ethical committee of Semmelweis University (Budapest, Hungary). All participants had given written informed consent before inclusion. Muscle biopsy samples were taken from vastus lateralis. Quantitative real-time PCR and Western blot analyses were performed. Statistical significance was assessed by unpaired, two-tailed Students t-test or χ^2 test. Significance level was set at $p < 0.05$.
RESULTS: The mRNA levels of seven key proteins were studied: Sirtuin 1 (SIRT1) and Forkhead Box Protein O1 (FOXO1) mRNA levels were significantly higher in skeletal muscle of master athletes than that of control groups (Vascular Endothelial Growth Factor, Insulin-like Growth Factor 1, Mechano Growth Factor, Peroxisome Proliferator-Activated Receptor Gamma Coactivator 1-alpha, Mitochondrial Calcium Uniporter were not significant). At protein level immunoblot data revealed that expression of Sirtuin3 (SIRT3) and Superoxid Dismutase 2 (SOD2) proteins from the muscle samples of master athletes were higher than that in the control subjects.
CONCLUSION: FOXO1 is involved in glycolytic and lipolytic flux, and mitochondrial metabolism, hence the exercise-induced expression of FOXO1 in the muscle of master athletes is important part of adaptive response.
Our main finding is that life-long physical exercise significantly increases SIRT3 level thus inhibiting the age-associated decline in SIRT3 levels. This is a powerful beneficial effect of exercise against age-associated functional deterioration of mitochondria. Moreover SIRT3 deacetylates SOD2 and promotes its antioxidant activity, reducing the level of ROS in the mitochondria.
In conclusion physical exercise through the activation of SIRT3 and SOD2 can significantly attenuates the age-associated decline in mitochondrial function and suppress oxidative stress.

THE EFFECTS OF GRADED MUSCLE GLYCOGEN CONCENTRATIONS ON EXERCISE-INDUCED CELL SIGNALLING: IMPLICATIONS FOR TRAINING ADAPTATION

HEARRIS, M., MORTON, J., LOUIS, J.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Commencing exercise with low muscle glycogen augments cell-signalling responses associated with exercise-induced regulation of mitochondrial biogenesis. Accumulating data suggests that a muscle glycogen threshold may exist (Impey et al. in press), whereby a critical level of glycogen must be surpassed for significant activation of signalling kinases and augmented expression of metabolic genes. However, the level of glycogen required to facilitate this response requires further investigation. As such, we sought to investigate the effect of various graded levels of muscle glycogen on exercise-induced cell signalling responses within human skeletal muscle.
METHODS: Eight trained amateur male cyclists, completed three bouts of high-intensity cycling exercise in a randomised, crossover design. Following an evening bout of glycogen depleting cycling, subjects received three graded amounts of carbohydrate over the subsequent 36h; 2.0 g·kg-1 BW (LOW), 6.0 g·kg-1 BW (MED) or 14.0 g·kg-1 BW (HIGH) prior to completing a bout of high-intensity interval cycling exercise. Muscle biopsies and venous blood samples were collected pre, post and 3 h post-exercise. Muscle biopsies will be analyzed for muscle glycogen content, gene expression and phosphorylation of key signalling kinases known to regulate mitochondrial biogenesis and venous blood samples analyzed for blood glucose, lactate, glycerol and NEFA concentrations.

RESULTS: No differences in heart rate (LOW: 175 ± 8, MED: 174 ± 8, HIGH: 173 ± 9 bpm) or RPE (LOW: 16 ± 1, MED: 15 ± 2, HIGH: 15 ± 2) were observed between trials during the high-intensity interval cycling exercise ($P > 0.05$).. Fat oxidation was significantly higher in the LOW trial (0.66 ± 0.19 g.min-1) compared with both MED (0.28 ± 0.23 g.min-1) and HIGH (0.15 ± 0.12 g.min-1) trials ($P < 0.05$). Concomitantly, CHO oxidation was significantly lower in the LOW trial (3.21 ± 1.08 g.min-1) compared with both MED (3.86 ± 0.93 g.min-1) and HIGH (4.39 ± 0.92 g.min-1) trials ($P < 0.05$).
CONCLUSION: We conclude that commencing high-intensity endurance exercise with graded differences in muscle glycogen availability induces significant changes in substrate utilisation, whereby lipid oxidation is augmented under conditions of low glycogen availability. This data has important implications for training prescription where changes in substrate utilisation during exercise are the key focus of the session.

VITAMIN D BIO-AVAILABILITY AND VITAMIN D RECEPTOR EXPRESSION AND TRANSCRIPTOMICS IN THE REGULATION OF SKELETAL MUSCLE MASS AND RESPONSES TO RESISTANCE EXERCISE TRAINING

BASS, J.J.1, WILKINSON, D.J.1, PHILLIPS, B.E.1, SMITH, E., SZEWCZYK, N.J.1, CLEASBY, M.E.2, GALLAGHER, I.J.1, ATHERTON, P.J.1
1MRC/ARUK CENTRE FOR MUSCULOSKELETAL AGEING RESEARCH, UNIVERSITY OF NOTTINGHAM, UK. 2 MOLECULAR PHYSIOLOGY OF DIABETES, ROYAL VETERINARY COLLEGE, UK. 3 FACULTY OF HEALTH SCIENCES & SPORT, UNIVERSITY O

INTRODUCTION: Vitamin D (VitD) deficiency is prevalent in ~25% of the population. VitD deficiency is associated with adverse athletic performance, low muscle mass/function, insulin resistance and whole-body metabolic dysfunction (1). In contrast to this, VitD has positive actions upon skeletal muscle; for instance, combined VitD supplementation and resistance exercise training (RET) has been demonstrated to augment muscle hypertrophy and function (2). VitD regulates and exerts its effects through the ubiquitously expressed VitD receptor (VDR), a transcription factor (TF) upregulated by RET (3), substantiating observational studies suggesting that the VDR mediates muscle growth and regeneration (4). Nonetheless, the roles of VitD and the VDR in the mechanistic regulation of skeletal muscle, remain poorly defined.
METHODS: To investigate the significance of VitD status and muscle VDR expression in relation to muscle, we studied 37 men/women (20-75y) who underwent 20-weeks of whole-body RET (3 times/week fully supervised), with DXA scans and m.vastus lateralis muscle biopsies being taken pre/post RET.
To further examine the mechanistic role of VDR in muscle mass regulation, we constitutively over-expressed (VDR-OE) or knocked-down (VDR-KD) the VDR in rat hind-limbs by cDNA or shRNA lentiviral transfection (under 2.5% isofluorane and 50mg/kg carprofen). RNA from muscles was exposed to RNA-Seq and gene-set/transcription factor enrichment analysis.
RESULTS: Upon examining relationships between VitD bio-availability, VDR expression and muscle responses to RET in humans, neither serum 1,25(OH)2D3 (active VitD) nor 25(OH)D (inactive) were associated with VDR or thigh muscle hypertrophy responses. In contrast to this, VDR gene expression positively corresponded with RET-induced hypertrophy ($p=0.01$, $R2=0.16$), with the greatest upregulation being observed in high responders to RET (+34±8%, $P<0.05$).
In vivo VDR-OE stimulated myofibre hypertrophy (cross-sectional area (CSA) +17±7%, $P<0.05$)), enhancing muscle protein synthesis (+69±7%, $P<0.05$), matched by an upregulation in key growth related extracellular remodeling and integrin pathway gene-sets. Additionally, multiple muscle hypertrophy crucial genesets (i.e. Pax & Srf) displayed heightened TF binding enrichment. Comparatively, VDR-KD induced myofibre atrophy (CSA -8±2%, $P<0.001$) and induced autophagy related processes (e.g. LC3B-II +84±43%, $P<0.05$). This was further substantiated by an upregulation of multiple lysosome and vesicle biogenesis gene-sets. Moreover, many energy metabolism related genes were downregulated i.e. electron transport, glycolysis and citric acid cycle gene-sets.
CONCLUSION: We conclude that VDR expression, not habitual VitD status, is an important regulator of muscle mass responses to RET such that VitD supplementation or therapeutics targeting the VDR (VitD analogs) may enhance RET-induced muscle growth. The VDR is regulated by RET and should not be discounted as a pro-muscle pharmaceutical target.

ESSA-ECSS EXCHANGE: HIGH-INTENSITY EXERCISE IS ABLE TO MITIGATE THE REDUCED MITOCHONDRIAL FUNCTION AND IMPAIRED GLUCOSE TOLERANCE INDUCED BY SLEEP-LOSS

SANER, N., BISHOP, D., BARTLETT, J.
INSTITUTE FOR HEALTH AND SPORT (IHES), VICTORIA UNIVERSITY

INTRODUCTION: Sleep-loss is emerging as an important risk factor for the development of impaired glucose tolerance, insulin resistance (IR) and, subsequently, type 2 diabetes mellitus. While the mechanisms underlying these changes remain to be fully elucidated, there is evidence that IR may be associated with reduced mitochondrial function (Saner et al., 2018). This raises the possibility that sleep-loss may also impair mitochondrial function, but to our knowledge this hypothesis has not been tested. The possible relationship between reduced mitochondrial function and IR, suggests exercise could be used as a strategy to counteract the detrimental physiological changes induced by sleep-loss; however, again, this has not been investigated. Therefore, the aim of this study was to investigate the effect of sleep-loss, with or without exercise, on skeletal muscle mitochondrial function and glucose tolerance.
METHODS: Twenty-three healthy male participants were allocated to one of three experimental groups: a control group (CON, n=7) (8 h sleep opportunity for 5 nights), a sleep-restricted group (SR, n=8) (4 h sleep opportunity for 5 nights), and a sleep restricted and exercise group (SR+EX, n=8) (4 h sleep opportunity for 5 nights and 3 x high-intensity interval exercise (HIIE) sessions). The HIIE bouts consisted of 10 x 60-s intervals at 90% peak power, interspersed by 75 s of active recovery. Oral glucose tolerance tests (OGTT) and muscle biopsies were performed pre- and post-intervention.
RESULTS: Mean sleep duration per night for CON, SR, and SR+EX was 448+25, 230+13 and 237+5 minutes, respectively. There was a significant reduction in mitochondrial respiratory function (O2 flux – pmol/s/mg tissue) from pre- to post-intervention in the SR group (80 + 16 vs 65 + 24, $p=0.0087$), but this remained unchanged in the CON (70 + 5 vs 64 + 12, $p=0.5837$) and SR+EX (78 + 20 vs 79 + 28, $p=0.9998$) groups. OGTT plasma glucose total area under the curve increased post intervention in the SR group (692 + 89 vs 832 + 57 units, $p=0.0018$), but remained unchanged in the CON (741 + 202 vs 677 + 184, $p=0.2379$) and SR+EX (645 + 51 vs 702 + 83, $p=0.2281$) groups. Further, plasma insulin levels (uIU/mL) were elevated post-intervention at 60 minutes (48 + 32 vs 74 + 33) in the SR group ($P=0.001$), but there was no change in either the CON (57 + 50 vs 50 + 40, $p=0.9870$) or SR+EX (26 + 14 vs 35 + 14, $p=0.4176$) groups.
CONCLUSION: Sleep-loss was associated with reduced mitochondrial respiratory function, decreased glucose tolerance, and increased insulin concentration. However, these changes were mitigated by performing HIIE during the period of sleep restriction. These data provide the first evidence that exercise may be a potent and cost-effective strategy to alleviate some of the negative metabolic effects of sleep loss.

MITOCHONDRIAL DERIVED REACTIVE OXYGEN SPECIES INFLUENCE ADP SENSITIVITY, BUT NOT CPT-I SUBSTRATE SENSITIVITY, DURING EXERCISE

HOLLOWAY, G.P., BARBEAU, P.A., MIOTTO, P.M.
UNIVERSITY OF GUELPH

INTRODUCTION: The mechanisms regulating oxidative phosphorylation during exercise remain poorly defined, however, key mitochondrial proteins, including carnitine palmitoyltransferase-I (CPT-I) and adenine-nucleotide translocase have redox sensitive sites. Interestingly, muscle contraction has recently been shown to increase mitochondrial membrane potential and reactive oxygen species (ROS) production. Therefore, we aimed to determine if mitochondrial derived ROS influences the bioenergetic responses to acute exercise.
METHODS: To achieve our aim, we determined the response of acute exercise on mitochondrial substrate sensitivity in WT and transgenic (MCAT) mice possessing attenuated mitochondrial ROS. Specifically, mice were randomly assigned to remain sedentary (n=8/genotype) or completed a 90 min treadmill run (15m/min, and a grade of 5%, n=8/genotype), and the red gastrocnemius muscle was removed for assessments of mitochondrial respiration and rates of mitochondrial hydrogen peroxide (H2O2) emission in saponin permeabilized muscle fibres.
RESULTS: We found that attenuating mitochondrial ROS did not alter mitochondrial protein content, maximal coupled respiration, palmitoyl-CoA (P-CoA) respiratory kinetics or influence the exercise-mediated reductions in malonyl-CoA sensitivity, suggesting mitochondrial ROS does not regulate CPT-I flux during exercise. While attenuating mitochondrial ROS did not alter ADP sensitivity in resting muscle, in contrast, exercise increased the apparent ADP Km (decreased ADP sensitivity) ~30% in WT mice only. Moreover, while the presence of P-CoA decreased ADP sensitivity, it did not influence the basic response to exercise, as the apparent ADP Km was increased only in WT mice. This basic pattern was also mirrored in the ability of ADP to supress mitochondrial H2O2 emission rates, as the attenuation in H2O2 suppression following exercise was absent in MCAT mice.
CONCLUSION: Altogether, these data demonstrate that while mitochondrial derived ROS does not influence CPT-I substrate sensitivity, ADP sensitivity is inhibited during exercise independent of P-CoA. These data implicate mitochondrial redox signalling as a key regulator of oxidative phosphorylation during exercise.

EXERCISE DURING ACUTE TREATMENT OF CHILDHOOD CANCER IN GERMANY – STUDY RESULTS AND FUTURE APPROACHES TO IMPROVE MOTOR PERFORMANCE AND ACTIVITIES OF DAILY LIVING

WISKEMANN, J., SOENTHGERATH, R., GOETTE, M., KESTING, S.
NATIONAL CENTER FOR TUMOR DISEASES

Children and adolescents with cancer experience severe physical and psychosocial consequences during treatment that dramatically affect daily life activities and participation in sports.
We conducted prospective studies in pediatric cancer patients to objectively assess levels of physical activity, motor performance, strengths and health related quality of life (QOL) in pediatric patients at three German children's hospitals. Results indicate musculoskeletal impairments and reduced QOL already early after diagnosis, during treatment and persisting problems in the aftercare ($p<.05$). Especially children with brain und bone tumors are physically inactive during treatment and have problems regarding reintegrating into physical education at school and into leisure time sports activities. To address these aspects we have developed evidence-based long-term concepts offering tailored physical activity and exercise during and after the course of treatment in various places. Analysis of more than 2,000 exercise sessions revealed clearly that exercising for childhood cancer patients within those programs is safe during as well as after treatment. Furthermore, we were able to show that physical function can be stabilized during inpatient chemotherapy treatment and quality of life can be improved ($p<.05$). In addition, refinement studies were able to reveal that adding activity trackers to an individual exercise program might help to improve adherence to certain activity goals (e.g. step goals) in the home-based setting and also increases health-related quality of life ($p<.05$). A currently running study is evaluating the capability of incorporating a strength training close to tasks of everyday life (2-3 times/per week). Overall, evaluations show that the implementation of adapted physical activity and exercise for childhood cancer patients during and after treatment is feasible and safe. Studies further revealed that patients benefit from an exercise intervention in a multidimensional manner. Based on these results insurance companies start to refund up to 85% of the cost for certain programs. Therefore, future main goal must be to increase program accessibility with the final goal to provide access for every childhood cancer patients in Germany.

EXERCISE IN CHILDREN WITH SOLID TUMORS

FIUZA-LUCES, C.
UNIVERSIDAD EUROPEA, MADRID

INTRODUCTION: Fiuza-Luces, C.1,2, Padilla, JR.1, Santana-Sosa, E.1, Morales, JS.1, Rincon-Castanedo, C.1, Lucia, A.1,2. 1: European University , 2: "i+12" Research Institute .
Introduction.
Despite major advances in survival rates, children with cancer are still at high risk for mid-long term therapy-related side effects that severely deteriorate their physical capacity . The aim of this randomized controlled trial was to determine the effects of an in-hospital exercise intervention on pediatric patients with solid tumors undergoing neoadjuvant chemotherapy.
Methods.

Participants were allocated to an exercise or control group . Training included 3 sessions/wk for 19±2wks. Each session lasted ~60-70min including both aerobic <~30min, 60-70% of maximum heart rate> and strength training. Participants were assessed at treatment initiation, termination, and 2 months after end-treatment. Primary endpoints included cardiorespiratory fitness, muscle strength <5RM tests>, functional capacity, physical activity, body mass and quality of life. Secondary endpoints were immune cell subpopulations, natural-killer cell cytotoxicity, and blood cytokine profile.
Results.
Most sessions were performed in the hospital´s gymnasium. Adherence to the program averaged 68±4%. A significant interaction effect was found for all 5RM tests . Performance significantly increased after training ; bench press: 24% <95%CI=6-14kg>; lateral row 25% <95% CI=6-15 kg>>, whereas an opposite trend was found in controls. Detraining values tended to be higher than baseline for leg and bench press . No other significant interaction was found.
Discussion.
An in-hospital exercise program for pediatric patients with solid tumors can be safely applied to increase muscle strength, without negatively affect immune function or inflammatory profile. These results represent an important addition to the current body of knowledge given the deleterious effects that high-intensity chemotherapy has on muscle tissue , which can persist into adulthood . Muscle strength is essential for health and growth, and for individual and social development .

A PARTIALLY SUPERVISED PHYSICAL ACTIVITY PROGRAM FOR ADULT AND ADOLESCENT SURVIVORS OF CHILDHOOD CANCER – SURFIT

RUEEGG, C.S., ZUERCHER, S.J., SCHINDERA, C., JUNG, R., VON DER WEID, N.X., KRIEMLER, S.

PEDIATRIC HEMATOLOGY/ONCOLOGY UNIT, UNIVERSITY CHILDREN'S HOSPITAL BASEL (UKBB), SWITZERLAND & EPIDEMIOLOGY, BIOSTATISTICS AND PREVENTION INSTITUTE (EBPI), UNIVERSITY OF ZURICH, SWITZERLAND

Introduction: Modern childhood cancer treatment strives to preserve long-term health and quality of life (QoL). However, the majority of todays' childhood cancer survivors (CCS) suffers from late effects. Physical activity might mitigate or prevent many of these effects. We therefore started a randomized controlled trial (RCT) to investigate the effect of a 12-month exercise programme on a composite cardiovascular disease risk score in CCS. Secondary outcomes are glycaemic control, bone health, fatigue, physical activity/fitness, QoL, mental health, and adverse effects. We aimed to present the current state of the project as well as results from the baseline assessments accomplished by January 2018.
Methods: In total, 150 CCS aged ≥16y and diagnosed ≥5y prior to the study are recruited from Swiss paediatric oncology clinics. Following baseline assessments CCS are randomized 1:1 into an intervention and control group. Thereafter, they are seen at month 3, 6 and 12 for follow-up assessments. We assess anthropometry, bone health (DXA, pQCT), physical activity (pedometer, accelerometer), fitness (maximal cardiorespiratory exercise test, grip strength), blood parameters, clinical status and self-reported mental health, fatigue and QoL. The intervention group is asked to add ≥2.5h of intense physical activity/week, including 30min of strength and 2h of aerobic exercises. Regular consulting, individual web-based diaries, and pedometer devices are used as motivational tools.
Results: By January 2018, 146 CCS (83 males, median age 28 years, range 17-49) underwent baseline assessment (15% of 950 contacted) and were randomized. Among males and females, 31 and 14% were overweight, 7 and 10% obese, and 25 and 32% had too high waist circumferences, respectively. The median total body bone mineral density standard deviation score (SDS) was -0.8 (range -2.8-2.6); 50 (35%) CCS had a SDS below -1 and 7 (5%) a SDS below -2. Mean age- and sex-stratified relative peak oxygen uptakes (VO2max in ml/min*kg) were 36.9 (standard deviation (SD) 6.4) for males aged 17-29, 34.9 (SD 7.8) for males aged 30-39, and 31.5 (SD 6.1) for males aged 40-49 as well as 30.8 (SD 5.8) for females aged 17-29, 28.8 (SD 7.8) for females aged 30-39 and 25.7 (SD 10.1) for females aged 40-49 which corresponds to 68-73% of predicted. The median number of daily steps was 7356 (range 1351-15106). The recommended amount of 10'000 steps per day was reached on average on 20% of measured days (range 0-100).
Conclusion: SURfit is an efficacy trial that is running according to protocol and finishing in early 2019. The results from our baseline assessments show that the Swiss CCS are a population with unhealthy weight, decreased bone mass, low aerobic fitness and reduced physical activity. We believe that our exercise intervention can improve the cardiovascular health including body composition, bone health, physical activity and fitness and ultimately the well-being of this growing population of CCS

OP-BN12 Footwear and running performance

COUPLING ANGLE VARIABILITY IS UNAFFECTED BY PERCEIVED COMFORT OF RUNNING SHOES

LINDORFER, J., KROELL, J., SCHWAMEDER, H.

UNIVERSITY OF SALZBURG

INTRODUCTION: One potential contributor to running injuries seems to be the indicator "preference of shoes" (Nigg, Baltich, Hoerzer, & Enders, 2015). From a biomechanical perspective the variability of segment coordination is affected in case of injuries and potentially serves as an injury predictor (Cunningham, Mullineaux, Noehren, Shapiro, & Uhl, 2014; Hamill, van Emmerik, Heiderscheit, & Li, 1999). Therefore, the aim of this study was to analyse the effect of shoe preference on segment couplings, as alterations could serve as a functional explanation of the injury contributor "preference of shoes".
METHODS: Most and least preferred shoes were selected by 15 runners from a set of five shoes by pairwise comparisons. Subsequently, kinematic data were collected during treadmill running in the two conditions at submaximal speed. A dynamical systems approach (Needham, Naemi, & Chockalingam, 2014) served as quantification of segment coupling and coupling angle variability (CAV) between

shank rotation and foot inversion/eversion (SHFO) as well as shank rotation and thigh flexion (SHTH) in five phases of the stride (Q1: 11-30%, Q2: 31-50%, Q3: 51-70%, Q4: 71-90%, Q5: 91-next 10%).
RESULTS: A visual inspection of the angle-angle plots revealed similar SHTH coupling, but differences in SHFO coupling. For both CAVs no statistical differences were found within the considered phases between most and least preferred condition.
CONCLUSION: Preference of shoes does not seem to affect CAV in healthy runners. While an increased injury rate in least preferred shoe inserts was found in long-term use (Nigg et al., 2015), it remains unclear if this is a consequence of varied coordinative variability since the actual data reflect only short term adaptations. A prospective study on shoe preference and potential CAV differences could allow deeper insight to injury susceptibility, as differences in coordinative variability have already been shown in injured participants.

SIMPLE METHOD FOR MEASURING EXTERNAL MECHANICAL WORK DURING RUNNING

DEVISE, M., ROSSI, J., BELLI, A.

UNIVERSITY JEAN MONNET

INTRODUCTION: The external mechanical work (Wext) produced during running is an important factor related to the metabolic cost of runners (Bourdin et al., 1993). In order to compute Wext, ground mounted (Cavagna, 1975) or treadmill mounted (Avogadro et al., 2004) force platforms and/or video motion analysis techniques are required but such equipment's are expensive and not practical for field measurements. The purpose of the present study was to propose and validate a simple method for measuring external mechanical work during running, using simple parameters such as contact and flight times, and which could be carried out under field conditions.
METHODS: Twelve male subjects (22.8 ± 1.7 years, 72.3 ± 4.6 kg, 1.80 ± 0.1 m) ran 4 min 30 on a treadmill dynamometer at 3.33 m/s. Vertical and antero-posterior ground reaction forces (GRF) were recorded from 10 consecutive steps at 3 min 30.
In the present method $Wext=1/2*Kleg*\Delta L^2$ where Kleg is the leg stiffness (in N/m) and ΔL the maximum leg spring compression (in m) during contact. Kleg and ΔL were computed using contact and flight times measured with vertical GRF, according to Morin et al. (2007).
Results of the present method were compared to the Wext calculated by reference method developed by Cavagna (1975) based on simple and double integration of respectively antero-posterior and vertical GRF measured by the treadmill.
Absolute bias was calculated for each subject. Statistical significance was accepted at $p<0.05$.
RESULTS: The values of the reference and modeled Wext were 1.73 ± 0.16 and 1.71 ± 0.15 J/kg/step respectively. The proposed method underestimates Wext and the mean error between the two methods was 0.03 ± 0.11 J/kg/step. When analyzing the whole dataset (i.e. 120 individual steps measured with both methods) the bias was 4.61 ± 1.83 %. Correlation coefficient for the relationship between the two methods was 0.82.
CONCLUSION: The aim of this study was to provide a calculation method for Wext, based on few simple parameters as ground contact time, aerial time, body mass, speed and leg length. In this study, the values of Wext were in agreement with literature (Avogadro et al., 2004). The low bias (less than 5%) obtained between the two methods and the high determination coefficients (more than 0.8) show that this method is more accurate than current pedometers (Nelson et al., 2016) which overestimate energy expenditure for jogging by 25-39%. For further studies, it could be interesting to investigate the evolution of Wext with this method at different running speeds and for different step frequencies.

INFLUENCE OF FOOTWEAR ON THE INJURY RISK IN AEROBICS AND CROSS-TRAINING ACTIVITIES: A ONE-YEAR RETROSPECTIVE STUDY

MORIO, C.1, DEMUYNCK, J.1

DECATHLON SPORTSLAB

INTRODUCTION: Aerobics and cross-training grew fast in the last decade. Injuries associated with aerobics were mainly located at the lower limbs (Malliou et al. 2013). However, the effect of wearing specific shoes on the injury risk in aerobics was reported either harmful (Rothenberger et al. 1988) or beneficial (Malliou et al. 2013) in the only two studies available on this question. Moreover, no information is available for cross-training. Therefore, the aim of the present study was to assess the effect of wearing specific shoes on the injury risk in both aerobics and cross-training.
METHODS: A specific questionnaire on the shoe habits, weekly training hours, and the injury history of the past year was sent to 4112 members of the Domoys™ tester database. 513 complete questionnaires were collected. Odds ratio (OR) and chi-square (X2) statistical analyses were used to compare the differences between aerobics and cross-training participants, between male and female participants, and between regular users of specific shoes and users of other shoes (mainly running shoes).
RESULTS: 83.5% of the responders regularly practice aerobics and 16.5% cross-training. 54% of the responders used specific shoes to practice these activities. 232 injuries were reported for the past year including 143 cases of lower limb injuries. This survey revealed risk ratios of 2.13 injuries per 1000h for aerobics, and 3.00 injuries per 1000h for cross-training (OR=0.71; X2=6.79; p=0.005). No significant difference (X2=2.34; p=0.08) was found in the risk ratio between male and female (1.91 and 2.5 injuries per 1000h respectively) but a moderate effect size (OR=0.76) might be considered as an interesting trend for further analyses. Regarding only the lower limb injuries, a significant protective effect was found on the risk ratio while wearing specific shoes (1.15 injuries per 1000h) compared to other type of

shoes (1.83 injuries per 1000h) (OR=0.63; X2=7.61; p=0.003). The latter result showed that wearing a pair of shoes specifically designed for aerobics or cross-training might prevent from some lower limb injuries. This was in accordance with the OR of 0.3 observed by Malliou et al. (2013). Deeper analyses are needed to find the potential interaction between factors.
CONCLUSION: Aerobics and cross-training presented a relatively low risk ratio compared to other sports (less than 3 per 1000h). Even so, wearing specific shoes was found to significantly reduce this risk ratio.

THE STRYD FOOTPOD: A NOVEL WAY OF PREDICTING AND IMPROVING RUNNING PERFORMANCE

BONGERS, C., VAN DELDEN, M., VAN MEGEN, R., EIJSVOGELS, T., VAN DIJK, H., HOPMAN, M.

RADBOUD UNIVERSITY MEDICAL CENTER

INTRODUCTION: The running economy (RE), which is defined as the amount of oxygen required to run 1 kilometer, is one of the main predictors of running performance and can be measured using a metabolic gas analyzer. Furthermore, the mechanical energy cost of running (ECOR), which can be influenced by running power and running technique, is also important for running performance. It might by suggested that running experience impact on running technique and thereby RE and ECOR. Therefore, the aim of this study was to compare the RE and ECOR of both trained and untrained runners at different running velocities. Furthermore, we want to investigate which factors affects the RE and ECOR.
METHODS: Ten untrained and eleven trained runners participated in this study. Subjects completed a predefined running protocol on a treadmill, which consisted of 3 bouts; I) 4 minutes at a self-selected cadence, II) 3 minutes at a high cadence (+10 steps per minute), and III) 3 minutes at a low cadence (-10 steps per minute less). Subsequently, a 5 minutes rest period was included, followed by a 15 minutes run at a self-selected cadence, in which the running speed was increased every 3 minutes. The RE and ECOR were measured continuously using a metabolic gas analyzer and the Stryd Footpod, respectively.
RESULTS: The RE of trained runners at a running speed of 11 and 12 km/h was significantly lower compared to untrained runners ($p=0.038$ and $p=0.016$, respectively). Furthermore, the trained runners had a lower ECOR at 10 and 11 km/h compared to untrained runners ($p<0.001$ and $p=0.040$). Additionally, the RE and ECOR decreased with increasing running speed in both groups (both p-values <0.05), and the highest RE and ECOR were found at the low cadence for both the trained and the untrained runners ($p<0.05$).
CONCLUSION: In conclusion, the RE and ECOR were significantly lower in trained compared to untrained runners, while a lower RE and ECOR were found at a higher running speed in both groups. These results suggests that trained runners had a better running economy and lower mechanical energy cost of running compared to untrained runners. Moreover, the efficiency of running is better at a self-selected cadence compared to a lower cadence.

IMPACT OF FOOTWEAR TYPE AND WALKING SPEED ON ANKLE PLANTAR FLEXOR FINE-WIRE ELECTROMYOGRAPHIC ACTIVITY

PÉTER, A.1, ARNDT, A.2, ANDERSSON, E.2, FINNI, T.1, CRONIN, N.J.1

1: NMRC , 2: GIH

INTRODUCTION: Ankle plantar flexors substantially contribute to propulsion in human walking, and their relative contributions may be affected by the type of footwear used. In this study, we aimed to examine plantar flexor fine-wire electromyography (wEMG) activity in different footwear types and barefoot walking. We further examined the effect of walking speed on the relative activity of ankle plantar flexors.
METHODS: Nine healthy people volunteered to this study (five males) with two sessions. In session 1, participants were familiarized to the study protocol. In session 2, electrical activity of flexor hallucis longus (FHL), soleus (SOL), medial and lateral gastrocnemius (MG and LG) muscles were measured with wEMG during eight overground walking tasks: preferred speed walking with shoes, barefoot and with flip-flops; with shoes: 30% slower and faster than preferred speed walking with shoes, and maximum walking speed; walking barefoot and with flip-flops at the same speed as preferred speed walking with shoes (matched speed). Then they performed maximal isometric plantar flexion contractions and maximal big toe flexions superimposed on ankle plantar flexion (MVICs) in an isokinetic dynamometer for wEMG normalization. Root mean square activity was calculated in the push-off phase of individual step cycles based on ground reaction force data. The relative contribution of each muscle to propulsion was calculated as: (mean RMS value %MVIC of the given muscle / mean RMS value %MVIC of all muscles) * 100. Cohen's d±90% confidence intervals were calculated to define the magnitude of differences.
RESULTS: In all muscles, wEMG activity increased with speed. With increasing speed the relative contribution to propulsion increased in FHL (from 19 to 22%), did not change in SOL (32%), decreased in MG (from 32 to 25%) and increased in LG (from 18 to 21%). There were no differences between preferred and matched barefoot walking speed or wEMG activity level (d range = 0.06-0.17). wEMG activity for all muscles was lower during matched barefoot walking than preferred speed walking with shoes (7-10% MVIC, d range=0.31-0.47). Flip-flop data are under analysis.
CONCLUSION: We found that relative wEMG activity of the examined muscles was affected by speed and absence or presence of shoes. During barefoot walking, wEMG activity of plantar flexor muscles was lower than during shod walking at the same speed, which presumably means that shod walking limits the contribution of intrinsic foot muscles to propulsion, which should be further examined.

BIOMECHANICAL ANALYSIS OF GAIT WAVEFORM DATA: RACE WALKING VS. KENYAN RUNNERS

GOMEZ-EZEIZA, J., HANLEY, B., TAM, N., SANTOS-CONCEJERO, J.

UNIVERSITY OF THE BASQUE COUNTRY

INTRODUCTION: The aim of this study was to analyse the biomechanical parameters of the gait cycle in world-class Kenyan runners and race walkers in a 3D analysis. It was hypothesised that race walkers' kinetics and kinematics would differ from running at the same speed, because of the need to maintain visible contact with the ground and a straightened knee from initial contact until the vertical upright position.
METHODS: Twenty-One Olympic male race walkers and fifteen elite Kenyan runners were recruited for the study. Kinetic and Kinematics were collected using a 3D motion analysis system race walking and running at 12 km/h. Joint kinetics were calculated using inverse dynamics, analysing each plane with a one-dimensional statistical parametric mapping, represented by a waveform.

RESULTS: Race walkers and runners showed differences in their gait patterns, as whereas the elite race walkers had higher ground contact times (ES=6.47), the endurance runners had longer flight times (ES=7.37) and swing times (ES=6.25). The outcome of these differences was that endurance runners used longer strides (ES=3.94) and lower cadences (ES=8.84). Both running and race walking waveforms were found to be different at heel strike for the ankle, knee and hip. The race walkers' heel-strikes were characterised by a more (fully) extended knee (ES=3.08), more flexed ankle (ES=2.25) and less flexed hip (ES=0.56). In the other planes, higher abduction values were measured in the hip (ES=1.8) with external rotation in the ankle for the race walkers and internal rotation for the runners (ES=1.27). During the midstance phase, race walkers maintained or hyperextended the knee, whereas the runners flexed it (ES=8.55). Race walkers and runners showed similar ground reaction forces patterns during initial contact. However, the normalised initial loading rate was higher in endurance runners (p=0.011, ES=5.22).
CONCLUSION: As the first study comparing elite endurance runners and elite race walkers, this study provides very useful information about the three-dimensional gait dynamics. Many differences were showed between both groups during the entire waveform running and race walking at the same speed. As it was hypothesised, due to the requirements of the rule 230.2, race walkers must adopt and optimise this peculiar gait pattern to excel in their event, thus, missing out on the elastic energy absorbed (and returned) by the knee, for example. By contrast, distance runners have no restrictions on their gait, and can therefore move in whatever way is most economical for them. Thus, these differences in the gait pattern, require race walkers a specific and more complex motor control, in addition to specific technical, strength and conditional training programs.

Invited symposia

IS-MI04 The physical activity continuum and other health-related aspects of lifestyle

SYNERGISTIC HEALTH EFFECTS AND INTERACTIONS OF PHYSICAL ACTIVITY, SEDENTARY BEHAVIOUR, AND OTHER HEALTH-RELATED ASPECTS OF LIFESTYLE

STAMATAKIS, E.
UNIVERSITY OF SYDNEY

Health and risk for chronic disease are heavily influenced by physical activity and other aspects of lifestyle. A synergistic effect exists when the combined health effect of two or more behaviours exceeds the sum of the individual effect of each behaviour alone. This is important for public health and clinical practice because there may be scope for targeting pairs of behaviours with strong synergistic links. In this presentation I will discuss the theoretical basis of looking at multiple aspects of lifestyle concurrently and will present results from our recent epidemiological studies that examine the interactions of different aspects of health related lifestyle (incl. physical activity, sedentary behaviour, sleep, alcohol consumption, and smoking). I will also explore the role of socioeconomic circumstances as moderators of these health effects. Our recent research has shown that physically active lifestyles may offset risks associated with alcohol consumption and lifetime smoking; and that the deleterious effects of physical inactivity are considerably amplified by high levels of sedentary behaviours and unhealthy sleep patterns. Many of our recent studies use new methodological paradigms that better handle the effects of time-dependent behaviours such as sleep and physical activity. For example, using isotemporal substitution modelling we can now estimate effects of replacing a time unit of one activity (e.g. 1 hr of sitting) with one unit of another (e.g. 1 hour of sleep) allowing us to better translate the results of epidemiological studies into public health guidance.
Besides the above established aspects of health related lifestyle I will also discuss the less researched area of dog ownership for human health. With physical inactivity being pervasive in all high income countries and dog ownership exceeding 40% in many countries, there may be a largely missed opportunity to systematically promote more incidental daily walking and less sedentary behaviour through canine-human interactions. My lecture will also present results of our recent epidemiological studies and trials that explore the potential of dog ownership as a means to increase physical activity and improve psychosocial health and reduce mortality risk among dog owners.

THE PHYSICAL ACTIVITY CONTINUUM IN RELATION TO MENTAL HEALTH: EPIDEMIOLOGY AND MECHANISMS

HAMER, M.
LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Several decades of evidence suggests that regular participation in exercise/physical activity promotes positive mood state, has anti-depressive effects, and can have favourable effects on cognitive function. More recently, however, researchers have turned their attention to other aspects of the continuum including sedentary behaviors and light activity.
METHODS: I will present our work on sedentary behavior, depressive symptoms, and cognitive function from a range of epidemiological cohorts in children and adults. I will present some of our recent experimental work that investigates biologically plausible mechanisms. In addition, I will touch on new methodologies in this area including ecological momentary assessments of mood.
RESULTS: Emerging data suggest sedentary behavior in certain contexts may be a risk factor for depression and cognitive decline. For example, in over 6,000 men and women from the English Longitudinal Study of Ageing TV viewing time, but not computer use, was associated with higher depressive symptoms. In contrast, objectively assessed sedentary time was inversely associated with psychological distress in 5000 children from Millennium Cohort Study. It therefore remains unclear if these findings are being driven by the context of the sedentary behavior or simply a lack of physical activity. Plausible biological mechanisms remain unclear.
CONCLUSION: In summary, the area of sedentary behavior and mental health is an emerging area, and data should be interpreted in light of several limitations including the use of poor exposure measures, potential for residual confounding, and lack of gold standard experimental data.

UNDERSTANDING THE CARDIOMETABOLIC HEALTH EFFECTS OF THE 24 MOVEMENT BEHAVIOR (PHYSICAL ACTIVITY, SEDENTARY BEHAVIOR, AND SLEEP) USING AN COMPOSITIONAL INTEGRATED THEORETICAL FRAMEWORK

CHASTIN, S.

GLASGOW CALEDONIAN UNIVERSITY

To date the relationship between health and each daily physical behaviours i.e. moderate to vigorous physical activity, light intensity activity , sedentary behaviour and sleep have only been studied in isolation adjusting only for one other behaviour, because standard statistical methods cannot deal with the whole day (time spent in each behaviour is highly collinear and correlated even when correlation indices are low). There is a dearth of information about the combined effect of allocating time to these different behaviours. During the day time is finite, time spent in one behaviour naturally displace time in others. Time budget data are therefore intrinsically co-dependent compositional in nature and require adopting statistical methodology consistent with this type of data. Compositional data analysis enables to investigate how different allocation of time spent in different activity is associated with health outcomes and adequately adjust model for time spent in all behaviours.
We will present results from four studies showing the association between the composition of the day and health outcomes. The results provide insights about different possible route for promotion of healthy pattern of activity and potential to develop 24 hours guidelines.

DOES PLAYERLOADTM CORRELATE WITH MAKERS OF EXERCISE INTENSITY OR NEUROMUSCULAR FATIGUE FOLLOWING REPEATED SPRINTS?

TEMPLE, S., BAUMERT, P., HULTON, A., STEWART, C.E., DRUST, B., ERSKINE, R.M.

LIVERPOOL JOHN MOORES

INTRODUCTION: Global Positioning Systems (GPS) are routinely used in team sports to estimate the "external load" [e.g. PlayerloadTM (PL)] experienced by an athlete following a bout of exercise, to inform recovery and aid periodisation of training. Yet there is a lack of evidence for a relationship between PL and exercise intensity or neuromuscular fatigue response to exercise. Additionally, it is not known if PL is sensitive to the demands of different sprinting tasks, such as straight line sprinting or shuttle sprinting, which may elicit different fatigue responses. The aims of this study were to (i) compare differences in PL and indices of neuromuscular fatigue response between two different sprint protocols associated with team sports movements and (ii) examine relationships between PL and different indices of neuromuscular fatigue.
METHODS: Eighteen recreationally active males (age: 20.7 ± 3.0 yr) performed either 15 x 30 m straight line sprints (SP, n=11) or 15 x (3 x 10 m) shuttle sprints (3T, n=7). PL, heart rate (HR) and rate of perceived exertion (RPE) were measured during SP and 3T. Capillary blood lactate (BL) was measured pre and post SP and 3T. The following assessments were made pre, post and 48h post SP and 3T: knee extensor (KE) and knee flexor (KF) maximum isometric voluntary contraction (MVC) torque, muscle soreness (visual analogue scale), voluntary and involuntary KF rate of torque development (RTD) and torque-frequency relationship (TFR) (measured via electrical muscle stimulation), range of motion (ROM), KF voluntary muscle activation (VA), and serum interleukin-6 (IL-6) concentration and creatine kinase (CK) activity.
RESULTS: PL was higher in SP (126.8 ± 13.8 AU) compared to 3T (107.6 ± 12.7 AU; $P<0.01$). PL correlated positively with HR ($R2=0.497$; $P=0.03$) and RPE ($R2=0.570$; $P=0.03$) only. There was a main effect for time regarding MVC, soreness, BL, ROM, involuntary RTD, CK, IL-6, and TFR ($P<0.05$) in SP and 3T, suggesting both protocols induced neuromuscular fatigue/muscle damage. There was a group x time interaction regarding muscle soreness, with SP exhibiting higher post and 48 h post values than 3T ($P=0.04$).
CONCLUSION: This study demonstrated that PL positively correlated with HR and RPE during exercise but not with any index of fatigue following repeated sprints. Straight line sprinting placed a higher external load upon the body than shuttle sprinting. While both straight line sprinting and shuttle sprinting both exhibited significant levels of neuromuscular fatigue post exercise, there was no difference between groups. However, subjective muscle soreness was significantly higher following straight line sprinting for up to 48 h. Our data support the use of PL to measure exercise intensity but not to predict neuromuscular fatigue. Moreover, performing shuttle sprints may be as fatiguing as straight line sprinting but may not elicit as much muscle damage post exercise.

EFFECT OF A WARM-UP ON THE REACTIVITY OF THE BOTTOM LIMB MUSCLES

PAKOSZ, P., MARIUSZ, K.

OPOLE UNIVERSITY OF TECHNOLOGY

INTRODUCTION: In the majority of professional and leisure athletes, a warm-up is performed as preparation for primary training. A warm-up is usually recommended in order to prevent injuries and increase performance in all the activities. Through our tests, we wanted mainly to examine changes in reactivity of muscles measured after a 15-minute warm-up on a cycloergometer, using modern, although already well-known measurement method - tensiomyography (TMG). TMG is a non-invasive measurement method used to detect properties of skeletal muscles. It is used to estimate the size of change in displacement of the muscle belly measured in millimeters (mm) and duration measured in milliseconds (ms) in reply to a single electrical stimulus. TMG measures geometric changes in the muscle belly, collecting data with the help of a digital sensor located perpendicular to the muscle. Several parameters of the muscle response can be measured with each measurement. Time parameters: Td (Delay Time), Tc (Contraction Time), Ts (Sustain Time), Tr (Relaxation Time), are measured in ms, while the muscle belly displacement parameter – Dm (Maximal Displacement) – is measured in mm.
METHODS: TMG examination covered twenty-six female students, with average age 19.7±1.1 years old, body height 167.3±4.8 cm and body mass 59±3.3 kg. The persons who were designated to the test had not had previous conditions within the examined muscles and joints. The test and retest were conducted with TMG system, before and after a 15-minute warm-up on a cycloergometer. The warm-up proceeded according to Bruce's scheme, where the drive was started from load 50 W (5 MET), and after each 3 minutes of the test, the load was increased by 25 W, until 150 W was obtained (15 MET), riding in the rhythm between 60 and 70 rpm. All the TMG parameters in surface muscles of the two bottom limbs were measured: gluteus maximus (GT), vastus medialis (VM), vastus lateralis (VL), rectus femoris (RF), semitendinosus (ST), biceps femoris (BF), tibialis anterior (TA), gastrocnemius medialis (GM), and gastrocnemius lateralis (GL).

RESULTS: The test results can be characterized by reduction in TMG time parameters of the bottom limb muscles. Td decreased from 24.4 (ms), to 23.9 (ms), at p=0.005, Tc from 33.2 to 32 (ms) at p=0.066, Ts from 194 to 157.3 (ms), at p =0.000, Tr from 73.8 to 59.1 (ms), at p=0.000. On the other hand, displacement of the muscle belly Dm increased from 6 to 6.1 (mm), at p=0.36.
CONCLUSION: After applying a 15-minute warm-up on a cycloergometer, reactivity of the bottom limb muscles to stimuli increased. On the contrary, the muscle belly is subject to greater deformations than in the test before the warm-up. The warm-up seems to have a substantial effect on the changed nervous-muscular profile, and the results can also be used as reference data. The TMG system is an effective tool for detecting changes which the muscles are subject to. Testing with the TMG system permits evaluation of sport programs and gives an opportunity to adjust them.

EFFECT OF TWO EXTERNAL COUNTERPULSATION TREATMENT DURATIONS ON NEUROMUSCULAR FUNCTION AND COMFORT IN PHYSICALLY ACTIVE YOUNG MEN

COLLINS, R.1, MCGRATH, D.1, HORNER, K.1, EUSEBI, S.2, DITROILO, M.1

1: UNIVERSITY COLLEGE DUBLIN, IRELAND, 2: UNIVERSITY OF URBINO CARLO BO, ITALY

INTRODUCTION: External Counterpulsation (ECP) has been well established as a treatment for individuals with coronary disease. Its potential as a sports recovery modality has recently been attracting interest. This study examined the effects of an ECP treatment in a rested state on neuromuscular function (NF). Specifically, different durations of ECP were compared in relation to both NF and participant comfort, the results of which could inform optimal administration strategies.
METHODS: Seven physically active male volunteers received two ECP treatments (Renew Sport, Singapore) of differing duration (20 and 40min) in a randomised, repeated measures crossover design. NF testing and subjective response recording was conducted at three separate timepoints: before treatment (PRE), post-treatment (0h), and 24 hours post-treatment (24h). NF testing consisted of countermovement jumps (CMJs) and 6-second sprint cycling. Rate of Perceived Exertion (RPE, 6 to 20) and Bipolar Comfort Scales (10 to -10) quantified the subjective experience of the participants, and each participant highlighted the "more acceptable" ECP duration. Repeated measure ANOVA and effect size (ES: Cohen's d) were used to analyse the NF testing results, and paired t-tests were used to analyse RPE and Comfort ratings.
RESULTS: A significant timepoint x duration interaction was found for CMJ height ($p<0.05$), with the post-hoc test revealing a significantly greater ($p<0.05$) 24h jump height for 20min (38.5cm) compared to 40min (35.9cm) treatment, with a small ES (0.28). CMJ relative peak power (PP/kg) showed no difference, and trivial ES, in both conditions. The ratio of eccentric/concentric contraction during CMJ was also analysed and despite no statistically significant differences, a trend in ratio reduction at 24h, with small ES, was recorded (20min, d=-0.51; 40min, d=-0.20). While the sprint cycling variables did not display significant differences, PP/kg at 24h showed an increase (d=0.45, small ES) for the 20min condition. Paired t-tests revealed a significant difference in comfort between conditions ($p<0.05$), with 20 minutes rated as more comfortable, and no difference in RPE. This corresponds with 6 of the 7 participants classifying the 20min condition as the "more acceptable" ECP duration.
CONCLUSION: These preliminary results indicate that ECP sessions of different duration yield separate effects upon NF, as indicated by a significant difference between conditions in CMJ height at 24h. The increase in PP/kg at 24h in sprint cycling (non-weightbearing) and no change in CMJs (weightbearing), suggests that the effect of ECP may depend upon the performance modality. This will be verified with continued data collection. Additionally, as no detrimental effects on NF were observed for the treatment duration of 20 minutes, ECP should be further explored as a potential recovery modality in both endurance and power-based sports.

NEUROMUSCULAR ELECTRICAL STIMULATION EXERCISE (NMES): A POTENTIAL COUNTERMEASURE IN MICROGRAVITY

CAFELLO, L.1, CAULFIELD, B.1, COBLEY, J.N.2, CROWE, L.1, COUGHLAN, G.1, MALONE, J.K.3

1: UCD , 2: UHI , 3: ABERTAY

INTRODUCTION: Muscle atrophy and reduced aerobic capacity are among a plethora of negative consequences of prolonged spaceflight (Yoshimitsu et al, 2010; Hargens et al., 2013). Countermeasures include bespoke exercise ergometers, bungee-cord assisted treadmills and resistance based devices. However, such bulky equipment in spacecraft where physical space is limited, has obvious limitations. NMES can induce favourable aerobic and strengthening effects across a range of healthy and clinical populations (Crognale et al., 2013; Banerjee et al., 2005), including the preservation of muscle mass during periods of immobilization (Dirks et al., 2014). This modality is portable and cost effective, and requires no additional physical space, however, evidence of its effectiveness in a microgravity environment is lacking. Therefore, the aims of this study were to compare: 1) the acute physiological effects; 2) degree of limb movements, when using NMES during normo-gravity (1G), micro-gravity (0G) and hyper-gravity (1.8G) environments, to assess its potential as an effective countermeasure during prolonged space flight.
METHODS: During a European Space Agency (ESA) Parabolic Flight Campaign, 11 healthy physically active volunteers (8 M; 3 F) underwent continuous sub-tetanic NMES (4Hz) to elicit rapid rhythmical contractions in the large lower extremity muscle groups (quadriceps and hamstrings) @ max tolerable intensity (48±17% VO2peak) for a total of 15 parabolas (Each parabole consisted of 3 periods: 2 x 1.8G (~ 20s); 1 x 0G (~20s), with ~2 min of 1G between paraboles & ~ 5 min between groups of 5 paraboles). Physiological responses were measured using a portable gas analyser, with limb movements using wireless, inertial motion sensors.
RESULTS: There were no significant differences ($P<0.05$) found for VO2 (18.2±5.4; 17.7±5.4; 17.6±5.5 ml.min-1.kg-1), VE (51.9±19.0; 53.3±18.8; 53.0±19.1 L.min-1), and RER (0.82±0.1; 0.81±0.1; 0.81±0.1) at 1G, 1.8G and 0G respectively. There were significant differences in mean variance of total acceleration of the thigh and shank across the gravitational states, with greatest variance found at 0G.
CONCLUSION: Acute physiological responses to NMES were not attenuated in a microgravity compared to normogravity environment. Furthermore, while there were small but significant differences in the degree of lower limb movements at 0G vs 1G, no uncontrolled limb movements that could be considered unsafe were observed. Therefore, findings suggest NMES may be a safe and effective therapeutic cardiovascular countermeasure in a microgravity environment, where aerobic exercise through weightbearing of the lower limbs is not possible.

AXIAL BODY LOADING INDUCES CHANGES IN THE NEURO-MECHANICS OF HUMAN RUNNING

ATTIAS, J., MILEVA, K.N., RUSSOMANO, T., GREEN, D.A.

KINGS COLLEGE LONDON

INTRODUCTION: Bodyweight loading has been shown to increase neuromuscular activity and alter gait patterns during running. The Mk VI 'SkinSuit' developed as a spaceflight countermeasure provides axial body loading (ABL) via graded vertical compression up to 20% 'body weight'. Thus, we investigated the effect of additional 0.2Gz ABL upon lower limb muscle activation and gait kinematics during running.
METHODS: Nine male (29.4 ±5.2yr; 78.6 ± 6.8kg; 176.4 ± 6.7cm) healthy volunteers completed an incremental treadmill test while wearing either the SkinSuit (~1.2Gz; AL) or loose-fitting clothes (1Gz; CONTROL) in two randomised trials separated by at least 24 hours. The protocol consisted of 9km/h running for 2min with speed increases of 1km/h every minute until 13km/h was completed. Knee range of motion (ROM) was quantified using an electrogoniometer attached laterally to the right knee. Surface electromyography (EMG) activity of the right vastus lateralis (VL), biceps femoris (BF), Tibialis Anterior (TA) and Soleus (SOL) muscles were recorded continuously. Muscle activity levels and patterns were quantified by the Root Mean Square (RMS) and temporal characteristics of the EMG signal (onset, offset and duration), respectively. The main and interaction effects of CONDITION (AL vs. CONTROL) and SPEED (5 levels) were investigated with two-way repeated measures ANOVA.
RESULTS: Knee ROM within a stride was unaffected by load (AL: 82.6° vs CONTROL: 83.1° at 13km/h), but at both heelstrike (-5.51±2.1° vs. 8.1±1.5° [F(1,8) = 68.477 p=0.000]) and maximal flexion (77.1±3° vs. 91.2±5.3° [F(1,8) = 13.412 p=0.006], the knee joint was significantly more extended in AL compared to CONTROL. RMS EMG amplitude increased with SPEED similarly in both conditions for the VL, SOL and GL ($p<0.05$), with no observed CONDITION effect, whereas BF RMS amplitude increased to a greater extent in AL vs. CONTROL at faster speeds vs. 9km/h (SPEED*CONDITION interaction; $p<0.05$). SOL onset and offset, as well as VL and BF duration were affected by SPEED ($p<0.05$). In contrast, BF onset was later and SOL duration was longer in AL vs. CONTROL (main CONDITION effect; $p<0.05$).
CONCLUSION: SkinSuit-induced axial body loading (~0.2Gz) significantly altered gait characteristics during incremental running compared to 1Gz, which were not accompanied by concurrent increases in lower limb muscle activities. Nonetheless, SkinSuit-induced ABL prompted alternative activity patterns likely governed by the central nervous system (CNS) to preserve the same movement under differentially-loaded circumstances.

THE 'POST ACTIVATION POTENTIATION' EFFECT OF RESISTED SLED SPRINTING ON SUBSEQUENT SPRINT PERFORMANCE.

MONAHAN, M.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Introduction; Post-activation potentiation (PAP) describes how performance of an activity involving maximal, or near maximal, muscle contraction may increase the strength/power produced in activities performed shortly afterwards. Previous research has established that various maximal, or near maximal resistance exercise can enhance subsequent sprint performance. However, the potentiating effect of resisted sled sprints (RSS) on subsequent sprint performance is equivocal and has yet to be trailed when using individually prescribed loads. The primary aim of this study was to assess the PAP effect of individually prescribed RSS stimuli, of 'high' (60%) and 'low' (20%) velocity decrement (vdec) loads on subsequent sprint performance.
METHODS: Methods; To compare the PAP effect of a high and low velocity decrement RSS stimulus; 28 field sport athletes (15M, 12 F; age, 22 ± 3 y; body mass, 74.1 ± 16.4 kg) took part in 3 testing sessions for which all took place on an indoor tartan track. To establish loads/vdec profile for each participant, the first testing session measured 0-10m(10m) & 0-20m(20m), unresisted sprint (URS) performance and RSS performance at various loads. Then to assess and compare the PAP effect of low & high vdec RSS on subsequent URS's, trials 2 and 3 measured 10m & 20m URS time (s) & velocity (m/s) prior to (13, 9 & 5 minutes) and post (30 secs, 5, 9, 13, 17, 21 & 25 min) 3 x 20m RSS's (of either a 20% or 60% vdec load). The best 10m & 20m performance pre and post were used to access effect of RSS.
RESULTS: Results; Post 20% vdec, best 10m time and velocity showed significant improvements -0.03(s) ± .06; 0.09(m/s) ± .21 ($p= \leq 0.04$, $d = 0.2$, mag = small) compared to best pre. While post 60% vdec, best 10m and 20m velocity significantly improved -0.06(m/s) ± .15; 1.0(m/s) ± .20 ($p= \leq 0.046$, $d = 0.2$, mag = small; $p= <0.001$, $d = 2.8$, mag = very large) respectively, when compared to best pre. Gender based evaluation showed, post 60% PAP best 20m velocity demonstrated large significant improvements -0.95(m/s) ± .15; 1.04(m/s) ± .23 ($p= <0.001$, $d = 0.-4.9$, mag = near perfect; $p= <0.001$, $d = 5.0$, mag = very large) for females and males respectively.
CONCLUSION: Discussion; Mean sprint velocities over 10m and 20m were similar between trials at pre. Following 3x20m RSS sprints at 60% vdec, subsequent sprint velocity improves at 10m and 20m. With the largest improvement 15% ±3% observed in best 20m velocity. Best time and velocity post 20% vdec at 10m also improved but these were of a smaller magnitude (d=0.2) that may be attributed to inter-day or inter-repetition variability. These improvements were not apparent when males and females were assessed separately.
Conclusion; RSS can acutely enhance subsequent acceleration and 3x20m RSS at 60% vdec can be successfully used to provide a large acute improvement in 0-20m sprint velocity, providing adequate recovery is given.

OP-BN10 Cognitive and motor functions in the elderly

INVESTIGATING THE INTERPLAY BETWEEN COGNITIVE AND LOCOMOTOR ADAPTIVE CAPACITIES USING A DUAL-TASKING PARADIGM

EGAN, S., MCGRATH, D.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Many activities of daily living require concurrent performance in cognitive and gait domains, termed dual-tasking (DT). DT has been widely researched to determine the adaptive capacity of cognitive and locomotor systems in ageing and disease. Nonlinear gait metrics such as local dynamic stability and predictability of gait time series are also thought to capture adaptive capacity of the locomotor system [1]. The purpose of this study was to understand if different measures of adaptive capacity map to each other. This

research sought to a) determine the effect of DT on cognitive performance in older and younger adults, and b) investigate the relationship between nonlinear gait parameters and cognitive performance in DT.
METHODS: Steady-state gait data were collected from 14 healthy older (70.4 ± 5.4 years; 8M,6F) and 27 young adults (21.4 ± 1.7 years 12M,15F) treadmill walking, using an accelerometer attached to the shank and lumbar spine. The largest Lyapunov exponent and sample entropy of the acceleration signal were calculated over a period of 3 minutes per person. A test of verbal fluency - the controlled word association test (COWAT) - was performed, in sitting and then while treadmill walking. Participants completed two dual tasks i.e. two COWAT tests of increasing difficulty while walking (DT1 and DT2). The COWAT was scored by the number of correct words recalled in each condition; the difference in conditions were used for correlation with nonlinear gait variables. A mixed Anova examined potential interaction effects between group and COWAT conditions (seated, DT1 and DT2). Correlation analysis investigated the relationship between nonlinear gait metrics and change in DT performance.
RESULTS: The mixed Anova determined that COWAT performance differentiated between older and younger participants (p=0.048). Participants performed better while walking compared to the seated control (p=0.001). No interaction effect was observed suggesting that DT performance was not different between young and old. A weak relationship existed between DT performance and nonlinear gait metrics.
CONCLUSION: The goal of this work was to empirically examine the theoretical basis for framing nonlinear gait metrics as indices of functional adaptive capacity. Previous studies have shown an interplay between cognitive flexibility, and gait speed - but no other gait variables - in DT [2]. We investigated this from the inverse perspective: locomotor flexibility in steady-state and cognitive flexibility in DT, and similarly found only weak correlations suggesting that these gait variables do not map to adaptive cognitive performance in DT. It is likely that participants employed a 'posture second strategy [3], commonly seen in healthy populations, facilitating preservation of cognitive performance during DT.

INFLUENCE OF COGNITIVE FUNCTIONS ON STAIR ASCENT AND DESCENT IN YOUNG AND OLDER ADULTS

GAILLARDIN, F., BAUDRY, S.
UNIVERSITÉ LIBRE DE BRUXELLES

INTRODUCTION: Stair ascent and descent are among the most complex and hazardous everyday life activity. Due to the age-related decrease in maximal force capacity (1), older adults operated closer to their maximal capacities during stair ascent and descent than young adults (2). As a consequence, stair locomotion is more challenging with advancing age, likely leading to increase the attentional demand of this motor task, as probed by dual-task paradigm (3). However, there is a lack of consensus on cognitive-motor interaction that may reflect, at least in part, the nature of the cognitive process (working memory and executive function) involved by the cognitive task. The purpose was to determine the impact of attention division, working memory and executive function on the cognitive-motor interaction when young and older adults ascend and descend stairs.
METHODS: 20 young and 20 older adults ascended and descended a 3-step staircase with no simultaneous cognitive task (single motor task) or while performing one of the three following cognitive tasks (dual-task): 1/SPAN-2 consisted of recalling a list of words with a number that corresponded to subject's word-span minus 2 words (attention division effects); 2/SPAN-O required to recall a list of words corresponded to subject's word-span (working memory effects) and; 3/SPAN-A was similar to SPAN-O but subjects had to recall the list in alphabetical order (executive function effects). Performance in motor and cognitive tasks was measured as the duration of the ascent or descent, and the number of words recalled, respectively.
RESULTS: Regarding cognitive performance, number of words recalled during stair descent did not differ between young and older adults ($p>0.05$) but was significantly lesser in SPAN-A than SPAN-O ($p < 0.001$). Ascent and descent duration did not differ between age groups in single task, and was similar between single motor task and SPAN-2 for both groups ($p>0.05$). In contrast, ascent and descent duration increased in SPAN-O compared with SPAN-2 for both groups ($p<0.01$). Stair ascent ($p=0.017$) and descent ($p=0.008$) were longer in SPAN-A than SPAN-O only in older adults.
CONCLUSION: This study highlights that healthy ageing was not associated with a decrease in dual-task performance that involve ascending and descending when cognitive task mainly requires working memory. In contrast, a decrease in dual-task performance was observed only in older adults when cognitive task requires executive function. This could reflect a subclinical decline of executive function with ageing.

THE EFFICACY OF THE SQUARE-STEPPING EXERCISE IN IMPROVING COGNITION AND MOBILITY IN OLDER ADULTS WITH MULTIPLE SCLEROSIS: PRELIMINARY RESULTS.

SEBASTIÃO, E.1, ADAMSON, B.2, BOLLAERT, R.1, MCAULEY, E.2, SHIGEMATSU, R.3, ROBERT, W.
1: NIU , 2: UIUC , 3: MU , 4: UAB

INTRODUCTION: There is an increased prevalence of older adults living with multiple sclerosis (MS). Aging with MS as a disabling disease presents a number of consequences such as poor health status and cognitive and walking difficulty [1,2]. This study examined the efficacy of a home-based, square-stepping exercise (SSE) program in improving cognition and mobility in older adults with MS.
METHODS: We conducted a pilot randomized controlled trial involving 25 older adults with MS that were assigned into one of the following conditions: intervention (n=15) or control (n=10). The intervention group participated in the SSE program and the control group participated in a stretching and toning program (STT). Both programs used a hybrid approach and lasted 12-weeks. Participants were assessed at baseline and post-intervention period. Cognition was assessed using the California Verbal Learning Test (CVLT), which is a measure of verbal learning. Mobility was assessed using the Timed 25-foot Walking Test (T25FW), which is a measure of walking speed. Data were analyzed using mixed factor ANOVA and percent delta (%Δ). Statistical significance was set at $p <.05$.
RESULTS: The overall average age of participants was 64.3 (SD 4.5) years and disability level was found to be moderate (Expanded Disability Status Scale; EDSS = 4.0 [IQR = 2.5]) with over 90% of participants having the relapsing-remitting type of MS. ANOVA revealed no

group x time interaction for CVLT [F(1,23)= 0.764; p= .39] or T25FW [F(1,23)= 0.398; p= .53]. A marginal main effect for time was observed for CVLT [F(1,23)= 3.994; p= .06] but no main effect for time was observed for T25FW [F(1,23)= 2.393; p= .14]. Percent delta analysis revealed that participants in the SSE group on average improved verbal learning (i.e., CVLT) by 8.4% (d=.39) compared with 3.4% (d=.12) of the STT group; walking speed (i.e., T25FW) by 13% (d=-.34) compared with 3.4% (d=-.07).
CONCLUSION: Aging with MS has detrimental health consequences. Although no statistical significance was observed in the intervention group (i.e., SSE) regarding the outcome measures, SSE showed potential to improve aspects of cognition and mobility in older adults with MS.

EFFECTS OF COGNITIVELY DEMANDING ACUTE AEROBIC EXERCISE ON WORKING MEMORY

KAMIJO, K.1, ABE, R.2

1: WASEDA UNIVERSITY , 2: SHIMANO INC.

INTRODUCTION: An increasing number of studies conducted over several decades have shown the beneficial effects of chronic and acute aerobic exercise on higher-order cognitive function . Several recent chronic exercise studies have suggested that cognitively demanding exercise has a greater impact on executive function than simple exercise . The chronic effect is seemingly based on the assumption that the beneficial effects of acute aerobic exercise on executive function are greater for cognitively demanding than for simpler exercise. However, little is known about whether the effects of acute aerobic exercise differ depending on the cognitive demands that are made during exercise. This study was designed to examine the post-exercise effects of cognitively demanding acute aerobic exercise on working memory, which is one of the key aspects of the executive function.
METHODS: Three conditions were investigated: <1> the exercise-only condition in which participants only exercised on a bicycle ergometer; <2> the exercise-cognition condition in which participants simultaneously performed cycling exercise and a cognitive task; and <3> the rest-cognition condition in which participants performed a cognitive task on a bicycle ergometer without exercising. Using a within-participants design, middle-aged participants performed a 2-back task that required updating working memory information before and after each intervention.
RESULTS: In the exercise-only condition, a higher hit rate and shorter correct rejection reaction times were observed after acute aerobic exercise compared to pre-exercise baseline, whereas no such effects were observed in the exercise-cognition or the rest-cognition conditions.
CONCLUSION: The results of cognitive performance in the exercise-only condition supported existing evidence indicating acute improvements in working memory following aerobic exercise. By contrast, working memory performance did not change in the exercise-cognition condition or the rest-cognition condition, which may seem counterintuitive. However, several studies have suggested that exercising in environments requiring a high degree of cognitive resources could cause cognitive fatigue , which in turn might result in deduced working memory performance. Therefore, it is suggested that cognitive fatigue caused by additional cognitive demands during acute aerobic exercise might cancel the beneficial post-exercise effects on working memory.

ASSOCIATION BETWEEN COGNITIVE FUNCTION AND PHYSICAL FRAILTY IN OLDER INDIVIDUALS WITH MILD COGNITIVE IMPAIRMENT

RUEDIGER, S., STUCKENSCHNEIDER, T., SCHNEIDER, S.

(A) GERMAN SPORT UNIVERSITY; (B) UNIVERSITY OF THE SUNSHINE COAST, AUSTRALIA

INTRODUCTION: To enable early interventions for dementia patients and to prevent a more rapid rate of cognitive decline, recent research focuses on prodromal stages such as mild cognitive impairment (MCI). Previous studies assessed the functional capacity of older persons and first results suggested that physical frailty is associated with an increased risk of MCI and a further cognitive decline [1]. In order to provide a better insight into the potential utility of frailty measurements as early markers and treatment recommendations in pre-dementia, the aim of this study was to analyse this relationship in an amnestic MCI (aMCI) sample.
METHODS: 85 persons between the age of 61–84 years (74.7±5.6 years) with diagnosed aMCI were included in this cross sectional study. Cognitive function was assessed using the Montreal Cognitive Assessment Battery (MOCA) [2]. The participants were divided into early (EMCI) and late MCI (LMCI), based on their MOCA scores (MOCA 19-22; 23-25). Measures of physical frailty (handgrip strength, lower body strength, and walking speed) were performed using a dynamometer [3] the 30s chair stand [4] and the Timed Up and Go test (TUG) [5].
RESULTS: Participants with LMCI performed significantly worse during the chair stand (p= .03) and the TUG (p= .02), but did not show differences in handgrip strength compared to individuals with EMCI (p= .65). The performance of the TUG and the chair stand test was related to cognitive impairment, whereas higher MOCA scores indicated faster walking speeds (p= .003, r = -.352) and a better performance in the chair stand (p= .02, r= .275).
CONCLUSION: The results show a link between physical frailty and cognitive impairment. However, the cause and response question- does physical inactivity leads to frailty and thus determines cognitive impairment, or does cognitive impairment limits physical activity, which leads to physical frailty- remains unanswered and should be addressed in future longitudinal studies. For now, caretakers should promote regular physical activity for individuals with MCI, as walking speed and leg strength are important factors to perform activities of daily living and live independently as long as possible.

CHINESE FITNESS AND HEALTH PROMOTION STRATEGIES: THE ROLE OF EXERCISE SCIENCE

FENG, L.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: The rapid development of economy and science and technology in China has brought great changes in lifestyle of Chinese people, consequently increasing non-communicable chronic diseases (NCDs) during the past 2 decades. In 2016, the word bank reported that more than 580 million Chinese adults were estimated to have at least one NCD, which account for more than 80% of China's 10.3 million annual deaths. There were 290 million adults aged 18 years and older suffered from cardiovascular diseases. The reported prevalence for hypertension was 25.2%, diabetes 9.7%, overweight 30.1%, and obesity 11.9% in 2012, respectively. The costs for chronic diseases accounted for more than 70% in total medical care. The proportion of people who regularly take part in physical exercise is 33.9%.The increased NCDs were largely due to steadily decreased physical activity and increased poor diet quality, which resulted in "the Healthy China 2030 Plan" to call for increasing public health efforts to expedite the promotion of physical activity and health among Chinese people.
"The Healthy China 2030 Plan" aims to enhance the combination of physical activity and medical care, and to strengthen non-medical care intervention, and to improve the overall population fitness and health. The ultimate goal is to insure that the Chinese average life expectancy reaches to the age of 79.0 years, the premature death rate caused by chronic diseases decreases by 30%, to insure that 92.2% of Chinese urban and rural residents meet the National Physical Fitness Evaluation Standard, and to insure that Chinese exercise population reaches 530 million. The plan addresses the urgent need to promote population-level fitness and health, which is increasingly adversely affected by the unprecedented economic development of China.

SELF-CONTROL RESEARCH AND ITS APPLICATION UNDER HIGH PRESSURE

ZHANG, L.

BEIJING SPORT UNIVERSITY

SELF-CONTROL RESEARCH AND ITS APPLICATION UNDER HIGH PRESSURE
Li-Wei Zhang (Psychology School, Beijing Sport University)
Introduction: In athletic competitions, we often see that some athletes achieve fantastic performance while others show unbelievable choking. All of these phenomena are closely related to their self-control. Self-control refers to abilities of restraining, adjusting and changing impulse, desire and habitual responses, which lies at the center of volition, motivation and emotion and has great impact on cognition. Self control embodies executive function and is a precondition of good social adaptation. Good self-control helps people cope with problems of impulse such as aggressive behaviors, crime, eating disorders, and addictive behaviors. Good self-control can also help people get better academic achievement and work accomplishment, have harmonious interpersonal relationship and increase the level of mental health. With the same logic, athletes' tough training and peak performance in big competitions also require good self-control.
Method
This study uses the method of research evaluation.
Results: This presentation will introduce the concepts, researches and implications that are closely related to self-control in athletic training and competition, focusing on the strength model of self-control (Baumeister, Vohs & Tice, 2007) and the attentional control theory (Eysenck, Derakshan, Santos, & Calvo, 2007) in a microscopic perspective and the model of integrated psychological construction (Liu, 1998, 2001) and the system of Chinese athletes psychological construction (Zhang & Zhang, 2011) in a macroscopic perspective. This presentation will also discuss the unique ways Chinese sport psychologists used to help athletes do mental preparation before Olympic Games.
Conclusion
It is believed that athletes' self-control in very tough training and competitions and related studies could be used as an important reference to people working under high pressure such as students in classroom examinations, doctors in operation rooms, soldiers in battle fields, and pilots in planes.

A MOTIVATION THEORY APPROACH TO INTERVENTIONS FOR SUSTAINED, HEALTH CONDUCIVE ENGAGEMENT IN PHYSICAL ACTIVITY

DUDA, J.

UNIVERSITY OF BIRMINGHAM

Introduction: Besides all of the well documented physical and mental health benefits of regular physical activity (PA), a concerning number of children and adults do not engage in a sufficient level of PA to realise such positive outcomes. With an overarching aspiration to facilitate the adoption and maintenance of an active lifestyle and contribute to population health, it is important that we: (1) sustain engagement in exercise programmes and sport, i.e., settings in which physical activity can be accrued and promoted, and (2) make it more likely that individuals participating in such settings experience well being and optimal functioning. Both aims are more likely to be realised when participation is autonomously motivated and the motivational climate manifested is more empowering/less disempowering

(Duda & Appleton, 2016). In this presentation, a brief overview will be provided of work pulling from contemporary theories of motivation and optimal engagement (such as Self Determination Theory or SDT; Ryan & Deci, 2017). This research has focused on an examination of the interplay between social environmental factors, motivational processes, and relevant outcomes in diverse groups such as: (a) patient groups/people w/ risk factors for disease onset, and (b) children involved in youth sport (Fenton et al, 2016).
Method
Cross-sectional and longitudinal designs including use of mixed methods; intervention.
Results and Conclusion
All in all, this work indicates that more empowering environments (which are more autonomy and socially supportive and task involving) are predictive of greater autonomous motivation, which is positively linked to greater well being and maintained participation. Evidence for the relevance and effectiveness of our theory-grounded interventions (e.g., Empowering Coaching™) is also provided.

OP-PM83 Sports specific training

ASSESSING CHANGES IN AEROBIC FITNESS MEASURES OVER THE PRESEASON TRAINING PHASE IN PROFESSIONAL FOOTBALL PLAYERS

MICHAELIDES, M., PARPA, K., ZACHARIA, A., PETUSIS, C.

UCLAN CYPRUS

INTRODUCTION: The pre-season period in football develops the physical requisites for competition and usually consists of a high volume of aerobic and anaerobic conditioning training including friendly games. The purpose of the study was to determine the effects of pre-season training on aerobic fitness indices on professional football players of division one Cyprus football league.
METHODS: Fifty-four professional male football players (age =26.72 ± 4.12 years) performed an incremental cardiopulmonary exercise testing (CPET) on a treadmill before and after the eight weeks of pre-season preparation. Furthermore, the anthropometric measurements were recorded.
RESULTS: The results were analyzed using paired t-tests revealed significant differences on several indices. The participants improved significantly on maximal oxygen consumption (VO2 max) and lasted significantly longer on the treadmill ($p<0.05$). Heart rate response (Hr) decreased significantly at ventilatory thresholds (VT1, VT2), and at maximum (Hr max). The running velocity at ventilatory thresholds (Vvt1, vVT2) and at VO2 max (vVO2max) increased significantly ($p<0.05$). The VO2 at VT1 and VT2 also increased significantly ($p<0.05$). Furthermore, the body weight (BW) and percent body fat (%BF) decreased significantly ($p<0.05$).
CONCLUSION: The findings of this study clearly demonstrated that eight weeks of pre-season training have a significant impact on the body composition and cardiovascular fitness of professional football players. The study confirms the beneficial changes in the process of adaptations that occurs with this type of training.

PRESEASON TRAINING: THE EFFECT OF A 14-DAY HIGH-INTENSITY SHOCK MICROCYCLE IN HIGH-LEVEL ICE HOCKEY PLAYERS

BROCHERIE, F., PEREZ, J., GUILHEM, G.

FRENCH INSTITUTE OF SPORT

INTRODUCTION: This study aimed to investigate the effects of adding a high-intensity training (HIT) shock microcycle to the usual training content of the preseason preparation of high-level male ice hockey players.
METHODS: Over 14 days, 14 players (age: 23.4±7.2yr) were randomly assigned to HIT (n = 7) or usual preseason on-ice and off-ice training (control, n = 7). For HIT group, additional off-ice training content included two sessions of repeated-maximal resistance training, two sessions of repeated-sprint training and two sessions of high-intensity intermittent training. Control group performed equal number of off-ice sessions using traditional strength and conditioning training. Off-ice Yo-Yo intermittent recovery test level 2 (YYIR2) test and on-ice repeated-sprint ability test (RSA; 8 × 20 m – 20 s of passive recovery) were conducted before (pre-test) and 3 days after the intervention (post-test). A two-way repeated measures ANOVA (group × time) was used for comparison.
RESULTS: After the shock microcycle, significant group × time interactions were found for off-ice YYIR2 performance ($P<0.05$) and on-ice RSA cumulated skating time (RSATT) ($P<0.05$). Compared to pre-test, HIT group significantly improved their fitness level [i.e., increase in off-ice YYIR2 distance covered ($P < 0.01$) and decrease in on-ice RSATT ($p < 0.05$)], while no significant changes were observable in other RSA-related parameters (best time and percentage decrement). No significant pre-to-post-test changes were found for the control group.
CONCLUSION: A 14-day shock microcycle (i.e., including six additional HIT sessions) added to the regular on-ice and off-ice training significantly improved fitness performance in high-level male ice hockey players. Such HIT block periodization offers a promising way to deal with strong schedules constraints (few available time, short pre-competition preparation).

EFFECTS OF A 5-WEEK PLYOMETRIC EXERCISE PROGRAM ON VERTICAL JUMP PERFORMANCE ON RIGID AND SAND SURFACE

SZWAJCA, S., STELZER, L., ZENTGRAF, K., EILS, E.

INSTITUTE OF SPORT AND EXERCISE SCIENCES, UNIVERSITY OF MÜNSTER

INTRODUCTION: Plyometric training has demonstrated to be efficient in improving power-related measurements in athletic performance and muscle-tendon behaviour during stretch shortening cycle (SSC) exercise (Markovic, 2007; Hirayama et al., 2017). In handball, many actions require such attributes. Recently, beach handball was announced to be included into the Olympic Games and is currently, played by indoor handball players during their summer break. Although there are pronounced differences in playing on either rigid or sand ground, information regarding training to optimize performance for each format remains relatively unknown. Therefore, the aim of this study was to examine the effect of a 5-week plyometric exercise program on vertical jump performance on rigid and sand surface.
METHODS: 22 participants (24±3yrs, 177.8±9.1cm, 77.7±11.6kg) were assigned into control (CON, n=9) or plyometric training (PT, n=13) group. While CON proceeded with their normal training routines, PT participated in a 5-week PT regime (2 sessions/week each 45 min) consisting of plyometric exercises on firm ground with a progressive increase in the number of jumps (from 80 to 180). Testing was conducted 48h before (pre) and after (post) PT regime on sand (s) and rigid (r) ground. Jump performance was investigated via vertical displacement of a back marker attached to the body (CMJ, DJ) and reactive strength index (DJ). Surface electromyography (sEMG) evaluation examined preactivation (PA) and short latency response (SLR) of tibialis anterior (TA), gastrocnemius medialis (GM), vastus medialis (VM) and biceps femoris (BF), and ratio of root-mean-square (rRMS) of (TA/GM) and (BF/VM) during DJ only. Magnitude-based inferences (MBI) were used to describe probabilities of substantial differences between conditions.
RESULTS: There were observed improvements of 4.2%, 5.5% and 6.2% for CMJ (PT r), DJ (PT r) and RSI (PT s), respectively. However, no meaningful changes (possibly positive) were perceived in other performance variables. For sEMG, PA and SRL of TA, GM, BF and VM were deemed predominantly unclear pre to post. rRMS (BF/VM) was found likely and very likely positive for both groups and conditions (ES 0.66 to 1.71), whereas rRMS (TA/GM) was observed to be likely (ES -0.46) and very likely negative (ES -0.61) for PT on both conditions.
CONCLUSION: A 5-week PT program on firm ground was not sufficient to markedly enhance vertical jump performance on sand surface in the PT group. Although co-activation of agonist/antagonist muscles was optimized, it remains unclear whether a PT performed on firm ground is practically relevant for indoor team handball players preparation due to negligible improvements in CMJ, DJ and RSI performance. In accordance with Binnie et al. (2014) we suggest that preparation on sand should be preferred as greater training adaptions to be achieved.

THE EFFECT OF IN-SEASON VELOCITY-BASED SLED TOWING ON ACCELERATION IN SEMI-PROFESSIONAL RUGBY LEAGUE PLAYERS

BENTLEY, I.1, SINCLAIR, J.K.1, ATKINS, S.J.2, METCALFE, J.1, EDMUNDSON, C.J.1

1: UNIVERSITY OF CENTRAL LANCASHIRE , 2: UNIVERSITY OF SALFORD

INTRODUCTION: Coaches often employ sprint-specific training methods to improve acceleration. Sled towing provides an external load in the form of a weighted sled towed via a shoulder or waist harness and cord, behind the athlete. Sled loadings can be determined in different ways; however, the velocity-based approach is preferred as it accounts for strength/power and technical ability (Petrakos et al., 2016). This investigation looked to compare velocity-based sled towing (ST) and un-resisted sprint training (URS) as part of a concurrent in-season training programme in order to determine which training modality best enhanced acceleration and explosive power.
METHODS: Twenty-six male (18.8 ± 0.58 years; 87.62 ± 11.41kg; 182.17 ± 5.49cm) semi-professional Rugby League players were randomly assigned to either ST or an URS group. Baseline testing consisting of 5, 10, 20m sprints as well as counter movement jumps (CMJ) was undertaken before, during (week 4) and after an 8-week training intervention consisting of 16 sessions (3x3 20m sprints). The ST or URS intervention sessions were incorporated into the training programme, which also consisted of gym-based resistance training, technical field sessions and competitive games. Sled loadings were adjusted so that sprint time over 10m was reduced by 20%; loadings were re-calculated 4 weeks into the intervention.
RESULTS: Both interventions significantly reduced sprint time over 5, 10 and 20m ($p < 0.01$). CMJ height was increased significantly in the ST group (6.52% increase; $p = 0.012$), there were no significant changes in CMJ height in the URS group (0.79% increase; $p>0.05$). Performance improvements between the ST and URS groups over 5m, 10m and 20m were non-significant ($p > 0.05$), however, the ST group had greater percentage improvements at all distances (5m: ST = 5.59%, URS = 2.50% ; 10m: ST = 3.94%, URS = 1.24%; 20m: ST = 3.20%, URS = 1.22%).
CONCLUSION: The results indicate that the inclusion of ST in an 8-week training programme improves explosive power, but these adaptations did not transfer through to acceleration as distinctly as they did to executing a CMJ. This is likely to be because of the difference between tasks, as CMJ demands are principally force-based, whereas increasing sprint distances tend more towards velocity based demands. Though not statistically significant, the 5.59% greater improvement reported in the ST group over the initial 5m of the sprint is expected to be an important enhancement for game performance. In conclusion, for semi-professional Rugby League players, ST appears to provide marginal benefits over URS when combined with a concurrent training programme.

EFFECT OF HANDBALL SPECIFIC ENDURANCE CIRCUIT TRAINING ON AEROBIC CAPACITY OF MALE HANDBALL PLAYERS

BALASUBRAMANIAN, C.

ANNAMALAI UNIVERSITY

INTRODUCTION: Handball is a fast intermittent sport demands greater amount of aerobic and anaerobic endurance during the match. Today handball coaches acknowledge the importance of sports specific training and employ during training (Kraemer et al. 2002). Sports specific training aims to show adaptation to fitness by replicating playing environment or conditions (Stone et al. 2000). Therefore, the aim

of our study is to assess the effect of handball specific endurance circuit training (HSECT) on aerobic capacity of male handball players at the end of the preparatory phase.
METHODS: We selected thirty trained male handball players who took part in this study. These players were classified into two groups as Handball Specific Endurance Circuit Training Group (HSECTG = 15) and Control Group (CG = 15). Thirty handball players were tested on aerobic capacity before the start and after eight weeks of training. Handball specific endurance circuit training was performed on specifically designed handball circuit 3 days a week for 8 weeks. To assess the training effect 2 × 2 repeated measure ANOVA on last factor repeated was performed.
RESULTS: Repeated measure ANOVA showed significant interaction effect for aerobic capacity ($F = 88.41$, $p < 0.05$) and simple effect displayed significant improvement in HSECTG from pre to post ($F = 173.6$, $p < 0.05$; MD = 4.02 & Cohen's d = 1.95).
CONCLUSION: Our study showed that HSECT has elicited 8.21% of improvement in aerobic capacity. Earlier it was established that game based training improves fitness (Coutts et al. 2010; Chittibabu 2013) and skill. In our study players performed at 90 to 95% of maximal heart rate in the specifically designed handball circuit which resulted in improvement of aerobic capacity. Previous studies confirmed the existence of linear and positive relationship exists between exercise duration spent at high intensity and changes in aerobic capacity (Castagna et al. 2013). We concluded that 8 weeks of HSECT at high intensity is effective enough in improving aerobic capacity of male handball players at the end of the preparatory phase.

PHYSIOLOGICAL PREDICTORS OF AN ON-COURT, SQUASH-SPECIFIC FITNESS TEST

FARRA, S.D., JAMES, C.A.
INSTITUT SUKAN NEGARA

INTRODUCTION: As elite-level squash play simultaneously imposes diverse physiological demands on the body (Murray, 2016), our laboratory developed and validated a novel on-court assessment of squash-specific fitness (James et al, under review). The purpose of this project was to examine the relationship between performance on this assessment and various fitness parameters to identify those critical for squash play and inform training prescription.
METHODS: Nine healthy members of the Malaysian National Squash Program (age = 18.2 ± 1.2 yr; Weight = 64.0 ± 3.1 kg; Height = 171.6 ± 7.9 cm) completed a battery of tests to determine body fat (BF), lean body mass (LBM), time to complete a change of direction (COD) course (Wilkinson et al, 2009), repeated sprint ability (RSA; Wilkinson et al, 2010), and the running stage that elicited a blood lactate of 4 mmol (OBLA) as well as final stage (FS) during the on-court squash test previously developed (James et al, under review). The on-court test was designed for subjects to undergo repeated, multi-directional shuttle runs around a predetermined pattern on the squash court in accordance to audio beeps until volitional exhaustion. Each stage consisted of 5-10 laps, with the audio beeps becoming progressively faster with each stage. The relationship between these variables and FS were examined using a Pearson's correlation.
RESULTS: There were statistically significant correlations between FS (76 ± 11 laps) during the on-court assessment and both COD (9.4 ± 0.7 s; $r = -.726$; $p = 0.027$) and RSA (221.2 ± 12.1 s; $r = -.671$; $p = 0.048$). There was a trend toward significance with OBLA (59 ± 7; $r = .663$; $p = 0.073$). No significant correlations between FS and BF (11 ± 5 %$r = -.570$; $p = 0.140$) or LBM (57 ± 2; $r = .329$; $p = 0.426$) were demonstrated.
CONCLUSION: These provisional findings are part of an ongoing project to identify the critical physiological attributes that are necessary for elite-level Squash. Of the measures studied, these data suggest that training the physical qualities that enhance change of direction ability, repeated sprint ability and OBLA are important to squash performance. Further research investigating the impact of strength, speed, and jumping characteristics on FS will help to extend these findings and facilitate the development of a multifactorial model of squash performance.

THE EFFECTS OF CAFFEINATED COFFEE INGESTION ON REPEATED SPRINT RUNNING PERFORMANCE: A DOSE RESPONSE STUDY

KARAYIGIT, R., YASLI, B.C., ERSOZ, G.
ANKARA UNIVERSITY

INTRODUCTION: The ergogenic effects of caffeine on various sports performance are now well established. Recently, most commonly supplemented form by athletes, caffeinated coffee has been shown to increase performance also in low doses (1). This study investigated for the first time that effects of different doses of caffeinated coffee (3-6 mg/kg) ingestion on sprint running performance in male team players.
METHODS: Thirteen male team players (mean ± SD: age, 22,0±1,9 yr; height, 176,1±5,5 cm; weight, 76,2±4,3 kg; VO2max, 60,9±5,7 ml/kg/dk) took part in this study. Following familiarization, in a randomized, crossover, counterbalanced research design, subjects were submitted to three experimental conditions: decaffeinated coffee (PLA), low dose (3 mg/kg) of caffeinated coffee (LOWCOF), moderate dose (6 mg/kg) of caffeinated coffee (MODCOF). Following 10 hour overnight fasting, subjects ingested coffee dissolved in 500 mL of hot water 1 hour before test and completed 12x30 meters repeated sprint running test protocol with 35 seconds passive recovery between sprints. Heart rate(HR) and rating of perceived exertion (RPE) were measured before begining of the test and after 6. and 12. sprints. Blood lactate(LAC) and blood glucose(GLU) were measured at immediately before and after test.
RESULTS: No significant differences were found in sprint running times, HR, RPE, GLU between any trials. Further, MODCAF and LOWCAF significantly increased blood lactate after test when compared to PLA ($p<0.05$).
CONCLUSION: This study demonstrated that neither moderate nor low doses of caffeinated coffee significantly increases repeated sprint running performance. Despite non significant effect, low and moderate doses of caffeinated coffee showed a trend to increase first three sprint running performance compared to placebo similar to Glaister's study (2).

THE EFFECT OF CAFFEINE INGESTION AND FATIGUING EXERCISE ON LEVELS OF BRAIN-DERIVED NEUROTROPHIC FACTOR IN HEALTHY MEN

MESQUITA, R.N.O., AVELA, J., CRONIN, N., HINTIKKA, J., KYRÖLÄINEN, H.

EDITH COWAN UNIVERSITY; UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: Exercise induces mental health benefits. A member of the neurotrophin family, brain-derived neurotrophic factor (BDNF), plays a crucial role in these exercise-induced effects (Huang et al., 2014). In mice, BDNF synthesis and its modulation of synaptic transmission in the hippocampus are facilitated by the activation of adenosine receptors (Tebano et al., 2008). Caffeine is the most widely consumed drug worldwide, and several studies have documented its ergogenic effects. Caffeine's main mechanism of action is the reversal of inhibitory effects of adenosine by blocking its receptors in the central nervous system (Fredholm et al., 1995). Animal studies have demonstrated that chronic administration of caffeine reduces BDNF synthesis (Costa et al., 2008). However, an effect of this drug on BDNF tone has not been investigated in humans. Thus, this study examined the effects of caffeine ingestion on the exercise-induced production of BDNF.
METHODS: Sixteen males participated in this randomised, double-blind, placebo-controlled crossover trial. Blood draws to analyse serum BDNF (sBDNF) were conducted at three time-points: before administration of caffeine (6 mg•kg-1) or placebo, after a 1-hour rest and post-exercise. Participants performed a fatigue protocol that consisted of stretch-shortening cycle exercise until task failure on a sledge apparatus by repeating series of 40 bilateral rebound jumps, with resting periods of 3 min.
RESULTS: At the group level, caffeine did not increase the number of sets completed during the fatiguing task. Nevertheless, 9 responders and 7 non-responders could be identified. Prior to exercise, caffeine ingestion did not significantly alter the levels of sBDNF. In the fatiguing task there was considerable inter-individual variability in exercise duration, with 8 participants completing 7 or more sets of jumps. In the placebo condition, physical exercise caused a significant ($p = 0.001$) increase in sBDNF (pre-exercise: 9.72 ± 7.49; post-exercise: 15.29 ± 7.53 ng•ml-1), but only in the group of participants with greater fatigue resistance. This exercise-induced increase was not seen in the caffeine condition.
CONCLUSION: These results suggest that BDNF production is dependent on exercise duration. Moreover, the present study appears to provide evidence for a caffeine-related suppression of exercise-induced BDNF synthesis. This study lays the groundwork for future research into the possible negative effects of caffeine on the association between exercise and mental health.

PEA PROTEIN ASCORBIC ACID MICROCAPSULES ARE MORE EFFECTIVE THAN ACORBIC ACID-FREE IN THE ATTENUATION OF OXIDATIVE STRESS BIOMARKERS AFTER SIMULATED SOCCER GAME EXERCISE PROTOCOL AMONG YOUNG PROFESSION

LOUREIRO, L.L., OLIVEIRA, T.M., COSTA, C.S.C., CITELLI, M., PEDROSA, C.M.P., PIERUCCI, A.P.T.R.

FEDERAL UNIVERSITY OF RIO DE JANEIRO

INTRODUCTION: Soccer players reach high intensity effort during competitive games and deleterious body symptoms can occur as consequence of oxidative stress (OS). Depending on metabolic adaptation to OS body hormesis can be delayed, compromising performance. Rapid recovery is relevant during competitive season, when games occur at small intervals. Nutritional interventions with ascorbic acid (AA) were proposed by many researchers aiming attenuation of OS blood biomarkers, however, literature is controversial as concerns its effectiveness. This might be due to the saturation mechanism that occurs in the enteric absorption sites of AA. Thus, we proposed microencapsulation of AA with a matrix of pea protein isolate (PPI) as an alternative to improve AA bioavailability. In this study, our aim was to evaluate the effect of PPI-AA microcapsules over OS biomarkers and AA bioavailability after a simulated game exercise protocol.
METHODS: A duble-blind crossover placebo controlled study was undertaken with 10 young players from a Brazilian elite sport club. Players were submitted to three nutritional treatments: PPI-AA; AA-free and placebo (P); AA doses were 1g. Blood parameters (catalase CAT, AA, total antioxidant capacity TAC, hydroperoxide HP, malondialdehyde MDH and creatine quinase CK) were monitored over time-course analysis up to 60 min after exercise.
RESULTS: PPI-AA had earlier decreasing effect than AA-free ($p<0.05$) on HP levels (20min vs 40mins), while MDH was not attenuated by any AA treatment. Enhancement in TAC was significantly higher ($p<0.05$) in PPI-AA than in AA-free (845.54 ± 56.66 vs 766.53 ± 64.44 µmol.AAeq-1). CAT had no variation. Absorption kinetics of AA from PPI-AA had typical profile of sustained release system, promoted by microencapsulation. All AA-free parameters were not statistically different from P, except for AA blood concentration.
CONCLUSION: Exercise protocol induced a rise on oxidative molecules and PPI-AA microcapsules were more effective than AA-free on their attenuation. Further analyses regarding player's physical performance will furnish more information about microcapsules functionality on body recovery.

DOES LOW-CARBOHYDRATE AVAILABILITY TRAINING INCREASE PROTEIN REQUIREMENTS OF ENDURANCE ATHLETES?

GILLEN, J.B.

UNIVERSITY OF TORONTO

INTRODUCTION: Increased protein requirements in endurance athletes are due in part to the need to replenish exercise-induced amino acid oxidative losses, which may be increased when exercising with low muscle glycogen. Low-carbohydrate (CHO) availability training can enhance markers of aerobic adaptation and has become popular to periodize throughout an endurance-training program. Given the importance of dietary protein to support post-exercise recovery, we aimed to determine the impact of low-CHO availability training on protein requirements. Using the minimally invasive indicator amino acid oxidation technique, we hypothesized that the excretion of our indicator amino acid would be greater after training with low as compared to high-CHO availability, reflecting a heightened protein requirement.
METHODS: Eight endurance-trained males (27±4y, 75±10kg, 67±10ml O2/kg/min) completed two trials matched for energy and macronutrient composition but with differing CHO periodization. In the low-CHO trial (LOW), participants consumed 7.8g CHO/kg during the day,

prior to an evening session of high-intensity interval training (HIIT; 10x5 min run intervals at ~90% HRmax, 1 min recovery) designed to lower muscle glycogen stores. Immediately after exercise 0.3g protein/kg was consumed and CHO intake was restricted for the remainder of the evening (0.2g CHO/kg). In the high-CHO trial (HIGH), participants consumed 3g CHO/kg during the day before HIIT, and subsequently consumed 0.3g protein/kg and 5g CHO/kg that evening to promote muscle glycogen resynthesis. The following morning, participants performed a 10km treadmill run (~80% HRmax) while fasted (LOW) or 1h after consuming 1.2g CHO/kg (HIGH). Following exercise, participants consumed eight hourly meals containing sufficient energy and 0.93g protein/kg/d as a crystalline amino acid mixture. Phenylalanine and tyrosine were consumed in excess to ensure the indicator amino acid ([1-13C]phenylalanine, consumed over the final 4h) was directed towards excretion after maximization of whole body protein synthesis. Breath 13CO2 enrichment (IRMS) and CO2 production (indirect calorimetry) were measured at metabolic and isotopic plateau for determination of 13CO2 excretion (F13CO2).
RESULTS: Fat oxidation (indirect calorimetry) was higher in LOW compared to HIGH (0.94±0.3g/min vs. 0.60±0.2g/min; p<0.05) during the 10km run. Preliminary analyses (n=7) revealed similar F13CO2 after the 10-km run in LOW and HIGH (0.89±0.10 vs. 0.84±0.16 umol/kg/h, respectively; p=0.36), suggesting similar rates of whole body protein synthesis.
CONCLUSION: Protein requirements of endurance-trained athletes appear similar after a 10-km run performed with low- or high-carbohydrate availability. Ongoing urinary analysis will determine if protein flux and oxidation are also similar in order to confirm/refute the observation that contemporary low-CHO availability training does not increase endurance athlete protein requirements above current guidelines.

EFFECTS OF CAFFEINE AND ACUTE EXERCISE ON COGNITIVE PERFORMANCE IN YOUNG ADULTS

LI, L., FENG, L.S., XU, J.F.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: As a psychoactive stimulant, caffeine is a common ingredient in drinks that are consumed wildly in the world. The consumption of caffeine-containing drinks is reported to increase alertness, concentration, and memory. Recent years, some studies found that the acute exercise also have positive effects on cognitive function. However, inconsistent findings were also reported in previous research. Therefore, this study aimed to examine the different effects of caffeine and acute exercise on cognitive performance.
METHODS: Eighteen young volunteers (6 females; 21.3±2.4 yr; 68.5±7.0 kg) completed three experimental trials in a randomized crossover design. A 2-h standard examination was conducted firstly to induce brain fatigue, then the participants were instructed to consume either a caffeine-containing drink (Caffeine trial) or a flavored placebo drink (Placebo trial), or performed 20 min moderate-intensity cycling exercise (Exercise trial) followed by 120 min recovery. 100 mg caffeine was contained in the caffeine drink, and all drinks were consumed within 20 min in Caffeine and Placebo trials. During recovery, the heart rate (HR), blood pressure and blood samples were obtained. Reaction Time Test, Letter Cancellation Test (LCT) and Continuous Calculation Test (CCT) were used to measure the participants' cognitive performance.
RESULTS: At 60 min during recovery, the HR was higher in the Exercise trial (71±1 b/min) than the Caffeine (63±2 b/min) and Placebo (60±2 b/min) trials (p<0.01), but the systolic pressure was lower in the Exercise trial than the two other trials (112±11 mmHg vs. 119±11 mmHg vs. 117±14 mmHg, p<0.05). The reaction performance was better in the Caffeine trial (360±56 ms) compared with the Placebo trial (386±76 ms) at the end of recovery (p<0.05). The completion time was not different between trials in the LCT and CCT tests, but a higher accuracy of CCT test was observed in the Caffeine (63±32%) and Exercise (60±24%) trials than the Placebo trial (44±21%, p<0.05) at 120 min of recovery. There was no difference between trials in the serum serotonin, adrenaline, and brain-derived neurotrophic factor levels.
CONCLUSION: The effects of caffeine-containing drink or acute exercise on cognitive performance are generally small when comparing with a placebo drink. Moreover, the low-dose caffeine and acute exercise have similar effects on cognitive performance in the situations of current study.

RESTRICTING CARBOHYDRATE DURING RECOVERY FROM PROLONGED EXERCISE DOES NOT EFFECT INTRAMUSCULAR TRIGLYCERIDE RESYNTHESIS.

JEVONS, E.F.P.1, GEJL, K.D.2, HVID, L.G.2, FRANDSEN, U.2, JENSEN, K.2, SAHLIN, K.2, STRAUSS, J.A.1, ORTENBLAD, N.2, SHEPHERD, S.O.1

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Intramuscular triglycerides are an important substrate during prolonged moderate-intensity exercise, and therefore post-exercise IMTG resynthesis is an important part of recovery. Nutritional guidelines advise the consumption of carbohydrate following prolonged exercise in order to support glycogen resynthesis, but a high CHO diet impairs IMTG resynthesis. More recent evidence suggests that actually restricting CHO in the post-exercise period may maximise the adaptive response to exercise, but how this strategy effects post-exercise IMTG resynthesis has not been investigated. To address this, this study aimed to examine IMTG resynthesis when acutely restricting CHO in the post-exercise period following prolonged exercise.
METHODS: 14 male elite triathletes <27 ± 1y, 66.5 ± 1.3 mL.kg-1.min-1> were recruited as part of a previous study . Muscle samples were collected pre, post, 4h post and 24h post 4h of glycogen depleting cycling exercise. In the 4h period immediately following exercise 7 participants consumed a high CHO diet while the other 7 consumed only water. For the remaining recovery period <20h> all participants received the same CHO-enriched diet. Muscle samples were analysed using confocal immunofluorescence microscopy to determine muscle fibre type and subcellular-specific IMTG content and LD morphology.
RESULTS: Exercise reduced IMTG content by 53% in type I muscle fibres , and specifically in the central region of the fibre , which was driven by a 47% decrease in LD number . In recovery, IMTG content in type I fibres increased from post-exercise to 24h post in the water condition only . Specifically, IMTG content increased in the central region , with a trend for increases in LD number from post to post 24hr <58%, P=0.084>. However, no significant differences in IMTG content were observed between groups by 24h post .
CONCLUSION: IMTG utilisation during exercise was evident in the central region of type I fibres only, and a corresponding increase in IMTG content was only apparent in the water condition. Although IMTG resynthesis was significantly greater when restricting CHO immediately post-exercise, IMTG content was similar between groups at 24h post-exercise. Together, these results suggest that IMTG resynthesis following prolonged exercise is unaffected when acutely restricting CHO in the post-exercise period. Future studies will investigate the role of lipid droplet proteins in mediating this response.

OP-PM49 Sedentary behaviour

A SYSTEMATIC REVIEW AND META-ANALYSIS OF THE EFFECTS OF INTERRUPTING PROLONGED SITTING WITH PHYSICAL ACTIVITY BREAKS ON BLOOD GLUCOSE, INSULIN, TRIACYLGLYCEROL

LOH, R., STAMATAKIS, E., FOLKERS, D., ALLGROVE, J., MOIR, H.

KINGSTON UNIVERSITY

INTRODUCTION: Sedentary behaviour has been associated with all-cause mortality independent of leisure time physical activity (PA), although such findings have been disputed. The primary aim was to systematically review and meta-analyse experimental trials breaking up prolonged sitting with intermittent bouts of PA throughout the day (INT) compared with sitting (SIT) on glycaemia, insulinaemia and triacylglycerol (TAG). A secondary aim was comparing the effects of INT against continuous exercise (EX), on glucose, insulin and TAG.
METHODS: PRISMA recommendations were followed. PROSPERO Registration: CRD42017080982
PubMed, OvidSP: Journals@Ovid and PsychINFO, Science Direct, SPORTDiscus were systematically searched on 04/03/2017.
Eligibility Criteria: control trials comparing INT vs SIT or INT vs one bout of EX prior to sitting, in participants aged 18 or above, healthy, or with type 2 diabetes, but not with other health conditions such as chronic obstructive pulmonary disease or peripheral arterial disease.
Risk of Bias (RoB) assessed with Cochrane RoB tool
RESULTS: INT vs SIT:
16 trial comparisons, 618 participants for TAG, 30 trial comparisons ,1036 participants for glucose, and 896 participants,24 trial comparisons for insulin, were meta-analysed.
INT vs EX:
6 trial comparisons,62 men, 75 women for TAG, 7 studies,90 men and 60 women for insulin, whereas 160 men and women, 8 studies for glucose, were meta-analysed.
Synthesis:
INT vs SIT: For glucose, SMD of -0.60 [-0.81, -0.39] in favour of INT. For insulin, SMD of -0.69 [-0.98, -0.41] in favour of INT. For TAG, SMD of -0.27 [-0.44, -0.09] in favour of INT. BMI was associated with glucose responses (β= -.064, 95% CI: -0.123, -0.005, p= .034), but not insulin (β= -.066, -0.152, 0.02, p=.122), nor TAG (β= .010, -.048, .067, p= .722)
INT vs EX: For glucose, SMD was -0.24 [-0.56, 0.08] in favour of INT, but not statistically significant (p=0.15). For TAG, SMD of 0.21 [-0.16, 0.57] in favour of EX vs INT, and not statistically significant (p=0.27). SMD for insulin was -0.08 [-0.31, 0.16] in favour of INT, and not statistically significant (p=0.53). When energy expenditure was matched, there was an effect in favour of INT, -0.36 [-0.65, -0.06] (p=0.02) on glucose, but not insulin, -0.16 [-0.40, 0.08] (p=0.20).
CONCLUSION: Most trials did not report randomisation or allocation methods, nor attempted blinding, nor handling of data attrition. There was possible publication bias for TAG. BMI moderates glycaemic response to PA breaks, but insufficient studies reported cardiorespiratory fitness or quantitative PA status, to allow regression.
PA breaks in sitting moderately attenuate post-prandial glucose, insulin, and TAG, with greater glycaemic attenuation in people with higher BMI, but any differences compared to one continuous bout of exercise are small, for glucose when exercise protocols are energy matched, or non-existent for insulin and TAG.
Therefore, PA breaks can attenuate standard markers of metabolic health.

DO THE ASSOCIATIONS OF SITTING TIME AND TV-VIEWING TIME WITH MORTALITY FROM CARDIOVASCULAR DISEASE AND CANCER DIFFER BY DIFFERENT LEVELS OF PHYSICAL ACTIVITY?

EKELUND, U., BROWN, W.J., STEENE-JOHANNESSEN, J, FAGERLAND, M.W., OWEN, N., POWELL, K.E., BAUMAN, A., LEE, I.M.

NORWEGIAN SCHOLL OF SPORT SCIENCES

INTRODUCTION: Sedentary behaviours, usually assessed as daily sitting and TV-viewing time, are highly prevalent and have been considered potentially detrimental to health. Using a harmonized meta-analytical approach we recently reported that moderate and vigorous intensity physical activity (MVPA) of at least 60 minutes per day appears to eliminate the detrimental association between sitting time and all-cause mortality. We here examine whether the associations between sitting/TV-viewing time and mortality from cardiovascular disease (CVD) and cancer differ by different levels of physical activity.
METHODS: Harmonised meta-analysis of prospective cohort studies. Data on exposure variables were harmonised according to a predefined protocol and categorised into four groups for sitting/TV time and into quartiles of physical activity (MET-h per week). Individual studies reported harmonised data on both daily sitting or TV-viewing time across quartiles of physical activity (PA), and effect estimates (Hazard ratio HR and 95% CIs) for CVD or cancer mortality. We then estimated summary HRs with 95% CIs across studies in separate meta-analyses for each outcome with a fixed-effect inverse variance method for sitting time and . TV-viewing time. We tested the trend for the probability of mortality within each stratum of physical activity with a Wald test in a logit model for the numbers of deaths and survivals.
RESULTS: Nine studies (N=850,060; Deaths=25,730) and eight studies (N=777,696; Deaths=30,851) provided data on sitting time and CVD and cancer mortality, respectively. Five studies had data on TV-viewing time, and CVD (N=458,127; Deaths=13,230) and cancer (N=458,091; Deaths=16,430) mortality. A dose-response association between sitting time (9% to 32% higher risk; P for trend<0.001) and TV time (3% to 59% higher risk; P for trend<0.001) with CVD mortality was observed in the 'inactive', lowest quartile of PA. There was no increased risk for CVD mortality with increasing sitting/TV-time in the most active quartile. Associations between sitting/TV-time and cancer mortality were generally weaker; 6% to 21% higher risk with longer sitting time observed only in the lowest quartile of PA.
CONCLUSION: PA modifies the associations between sitting/TV-viewing time and CVD and cancer mortality. These findings emphasize the importance of higher volumes of moderate and vigorous activity to reduce, or even eliminate these risks, especially for those who sit a lot in their daily lives.

METHODS: RESULTS: CONCLUSION: SEDENTARY BEHAVIOR: A REAL THREAT TO A LONG LIFE. THE ELDERLY EXERNET MULTI-CENTRE STUDY

1:GENUD UNIZAR , 2:IA2 , 3:CUD , 4:CIBEROBN, 5:CIBERFES, 6: GENUDTOLEDO UCLM . 7:IMFINEUPM . 8:IBIOMEDUL 9:UE

INTRODUCTION: Nowadays, sedentary behavior (SB), defined as sitting (nonexercising), reclining, and lying down posture with a low energy expenditure (< 1,5 MET), is a public health risk due to its deletereous consequences [Harvey JA et al, 2015]. The aim of this study was to analyze the influence of SB (hours sitting per day) on ten-year mortality in community-dwelling older people.
METHODS: Between June 2008 and November 2009, self-reported sitting time was measured in 2313 Spanish non-institutionalized seniors aged 65 years or over (1131 women), using a validated questionnaire [López-Rodríguez C et al., 2017]. All participants were members of the cohort of the multi-center EXERNET Study [Gómez-Cabello A et al., 2011]. Sedentary behavior was recorded through the following question: "How many hours do you usually spend sitting per day?". Similarly, walking time was recorded through the following question: "How many hours do you usually spend walking per day?". For both questions, each participant had to choose one of the following answers: <1 h/day, 1–2 h/day, 2–3 h/day, 3–4 h/day, 4–5 h/day or ≥5 h/day. Ten years later, the mortality was identified by the Spanish National Death Index (INDEF). Logistic regression models were used to estimate the associations between sitting duration levels and mortality by sex. Models were adjusted for age as possible confounder. To test if walking time could influence on the associations mentioned above, all the analyses were repeated adding this variable into the model.
RESULTS: During the 10-year follow-up, 9.8% of the participants died (172 women, 49 men). Multiple logistic regression model showed a significative relationship between SB (more than 4 hours sitting per day) and mortality [X2(2, N=2313) =99.8; p<0.01] in women. Specifically, sitting more than 4 hours is related with an increase of a 44% of mortality risk in the 10-years follow-up (OR=1.44, 95% CI: 1.03-2.03, p≤0.05). Nevertheless, results become non-significant when including time spent walking as covariable (OR=1.27, 95% CI: 0.88-1.85, p>0.05). In men, no significant associations between sitting time and mortality were found.
CONCLUSION: In women, sitting 4 or more hours per day increases the risk of death, but it seems that walking can stop the premature mortality risk. This results support the benefits of a non-sedentary lifestyle as prevention of morbimortality in elder women.

SEDENTARY BEHAVIORS ARE ASSOCIATED WITH A LATENT MODEL OF METABOLIC SYNDROME, INDEPENDENT OF PHYSICAL ACTIVITY, IN US ADULTS

TAYLOR, K.

EASTERN WASHINGTON UNIVERSITY

INTRODUCTION: Sedentary behaviors have been recognized as contributing to the declining cardiometabolic health of US adults. Traditional research investigates metabolic syndrome (MetS) risk factors as dichotomous variables, which can reduce statistical power. However, advanced statistical techniques, such as structural equation modeling (SEM), present the possibility for researchers to understand MetS as a latent variable and the relationship it has with lifestyle factors. Currently, there is no research investigating the use of SEM in the MetS literature in adults or with lifestyle factors such as sedentary behavior or physical activity (PA). The purpose of these analyses was to determine whether a latent model of MetS was valid in US adults and further, whether sedentary behaviors or PA were associated with this model of MetS.
METHODS: Data from the 2015-16 National Health and Nutrition Examination Survey (NHANES) was collected from 5,991 US adults (age 48.1±18.5 years, BMI 29.4±7.1 kg.m-2). Sedentary behaviors including time spent sitting and screen time (TV and computer) were collected via self-report as were levels of PA. MetS risk factors measured were waist circumference, blood pressure, and fasting glucose, triglycerides and high-density lipoprotein cholesterol. Confirmatory factor analysis (CFA) was used to construct a latent model for MetS and individual indicator variables. SEM was used to assess associations among sedentary behaviors, PA and MetS. Goodness-of-fit indices were used to determine model fit for CFA and standardized estimates with an alpha level of 0.05 were used for SEM models.
RESULTS: The latent MetS model was a valid model in this cohort ($\chi2$=295.39, p<.05; CFI=.92; RMSEA=.08) with all indicator variables significantly contributing to the model (p<.001). On average, participants self-reported engaging in 959.7 minutes/week of moderate PA and 571.0 minutes/week of non-leisure time PA. Further, participants self-reported an average of 449.6 minutes/week of sedentary activities and an average of 6.8 hours per month of screen time. SEM analyses showed that PA variables were not associated with MetS (β=-.01, p>.05). Sedentary behavior as a latent variable of sedentary activity (i.e., sitting) and screen time, was positively associated with MetS (β=.07, p=.002). This association was independent of moderate, vigorous, and non-leisure time PA (β range .07 to .08, p=.002).
CONCLUSION: These findings suggest that MetS may be studied as a latent variable using advanced statistical techniques. Further, sedentary behavior is associated with a latent model of MetS and this relationship is independent of PA levels in US adults. Our analyses suggest that PA may not be strongly associated with a latent model of MetS in this cohort. These findings support recent public health efforts to decrease the time spent in sedentary behavior by US adults and suggest that sedentary behavior may play an important role in cardiometabolic health independent of PA.

PHYSICAL ACTIVITY BUT NOT SEDENTARY TIME IS ASSOCIATED WITH CARDIOMETABOLIC HEALTH MARKERS IN OVERWEIGHT ADULTS

SJÖROS, T.1, VÄHÄ-YPYÄ, H.2, SAVOLAINEN, A.3, SIEVÄNEN, H.2, VASANKARI, T.2, KNUUTI, J.3, KALLIOKOSKI, K.K.1, HEINONEN, I.H.A.1

1: TURKU PET CENTRE, UNIVERSITY OF TURKU 2: UKK INSTITUTE 3: TURKU PET CENTRE, TUH,

INTRODUCTION: A low level of physical activity (PA) has been identified as an important predictor of poor health and all-cause mortality. Recently, there has been a growing interest in assessing sedentary behaviour (SB) instead of moderate-to-vigorous physical activity (MVPA) in the prevention of obesity and metabolic diseases.

METHODS: We examined the associations between cardiometabolic health markers and SB and PA in an overweight (BMI 31.2, SD 4) working aged population (n = 70, 15 men; age 56, SD 7) with high risk for metabolic syndrome and low self-reported PA levels. SB and PA were measured for 4 weeks (mean 25 days SD 5) with hip-worn accelerometers (UKK AM30) using validated mean amplitude deviation (MAD) and angle for postural estimation (APE) algorithms. Fasting plasma glucose, insulin, triglycerides, total, LDL and HDL cholesterol and HbA1c from venous blood samples were analysed using standard assays. Body mass index, waist circumference and blood pressure were measured prior to accelerometry. The associations were examined by Pearson's correlation analysis adjusted for age and sex.
RESULTS: Our analysis shows no association between cardiometabolic health markers and sedentary time. MVPA was significantly associated with lower fasting insulin levels (r = -0.28, p = 0.029) and plasma triglycerides (r = -0.27, p = 0.034) as well as smaller waist circumference (r = -0.29, p = 0.024). In consistency, daily step count was similarly associated with insulin (r= -0.29, p = 0.022), triglycerides (r = -0.27, p = 0.035) and waist (r = -0.29, p = 0.022). Breaks in sedentary time were associated with lower fasting insulin (r= -0.25, p=0.048) and waist circumference (r = -0.41, p = 0.0012). Both breaks and standing time as well as light activity were associated with resting heart rate (r = -0.36, -0.26 and -0.28, p = 0.005, 0.036 and 0.032, respectively).
CONCLUSION: In conclusion, it seems that in overweight adults at high risk for metabolic syndrome MVPA and daily steps, but not objectively measured sedentary time are associated with cardiometabolic health indicators. However, interruptions in sedentary time may also contribute to better metabolic health, overall suggesting that muscle activity is crucially important in cardiometabolic health promotion.

PATTERNS AND GEOGRAPHIC DISTRIBUTION OF OBJECTIVELY MEASURED SEDENTARY BEHAVIOUR IN EARLY YEARS: SYSTEMATIC REVIEW AND META-ANALYSIS.

PEREIRA, J.R., CLIFF, D.P., SOUSA-SÁ, E., ZHANG, Z., SANTOS, R.

UNIVERSITY OF WOLLONGONG

Background
Some studies in children indicate that the excessive sitting time may have harmful effects on children's health. However, the amount of time that young children spent in sedentary behaviour as well as the patterns of this behaviour is largely unknown.
Objective
This systematic review and meta-analysis summarises the current literature that used objective devices to capture patterns of sedentary behaviour on young children, in particular, differences between weekdays and weekend days, between childcare and non-childcare hours, and between indoors and outdoors, in young children. Prevalence of Sedentary behaviour according to geographic location was also assessed.
Methods: Five databases (Sport Discus, MEDLINE, SCOPUS, CINAHL and psycINFO) were searched until 26.10.2017 and meta-analyses were conducted.
Results: Fourty three studies representing 13, 364 children (aged 2 to 5.99 yr) were included. No significant differences on the time spent in sedentary behaviour were found between weekdays/weekend days (estimate difference=-0.4;95%CI=-2.0:1.2;p=0.61) or between childcare hours/non-childcare hours (estimate difference:2.9%;95%CI -0.9to 6.6%;p=0.136).While attending childcare centres, children spent more time in sedentary behaviour indoors than outdoors (estimate difference=14.4%;95%CI=11.8:16.9;p<0.001). When the studies were sorted by continent, prevalence of total Sedentary Behaviour seemed to be higher in North America (59.1%; 95%CI: 55.9 to 62.4) than in Europe (51.1%; 95% CI: 43.5 to 58.7), and in Oceania (47.5%; 95% CI: 22.2 to 73.7).
Conclusions
There is a need for higher-quality studies with strong designs, using age and device appropriate cut-off points, to raise the level of evidence-base and to better establish the prevalence of sedentary behaviour. As some data indicates that excessive sedentary behaviour may be detrimental to children's health and development, and knowing that this behaviour seems to be established at young ages and tracks throughout life, there is an urgent need to tackle sedentariness in early childhood, particularly while young children are indoors at childcare.

ARE PATELLAR TENDON PROPERTIES ALTERED IN PATIENTS WITH CHRONIC PATELLAR TENDINOPATHY?

WIESINGER, H.P.1, KÖSTERS, A.1, MÜLLER, E.1, SEYNNES, O.R.2, HERFERT, J.3, RIEDER, F.1,3

1: PLUS , 2: NSSS , 3: PMU

INTRODUCTION: The mismatch between tendon functional demand and adaptational rate often ends in chronic pathological conditions (Riley 2004). Subsequently, affected athletes continue their daily routines in pain, although the impact of this pathology on tendon mechanics remains debated. Hence, the present study aimed to compare patellar tendon stiffness and, for the first time, hysteresis (i.e. the capacity to recoil elastically stored energy) between patients suffering from patellar tendinopathy and healthy controls.
METHODS: Ten adults with chronic (>3 months) patellar tendinopathy (25±5 yrs; male=7, female=3) were matched to ten healthy controls (29±4 yrs; male=7, female=3) in this pilot cohort comparison study. The clinical examination indicated persistent pain and palpation tenderness at the inferior pole of the patella, impaired functional performance (VISA-P≤80), ultrasonically verified tendon thickening and hypo-echoic area with some cases of neovascularization. Individual knee extension strength capacity, patellar tendon stiffness and hysteresis were obtained by combining isometric dynamometry, ultrasonography and electromyography.
RESULTS: Anthropometric parameters (age, height, body mass) did not differ between groups. There were no differences in maximal voluntary isometric knee extension torque (p=.34; η^2<.05), patellar tendon stiffness (p=.11; η^2<.13) and hysteresis (p=.53; η^2<.02). However, after normalization to body mass^2/3, patellar tendon stiffness was significantly lower in tendinopathy patients compared to healthy controls (-20%.; p=.03; η^2<.24).
CONCLUSION: In this study we observed lower stiffness in affected tendons, however, despite the substantial structural and histological changes occurring with tendinopathy (Magnusson et al. 2010), energy dissipation remains unchanged. The decreased stiffness of the impaired tendon could have important implications for athlete's performance and likely results in an increased strain in response to loading, increasing the risk of further tendon damage.

THE EXTENDED VIEW OF THE PATELLOFEMORAL JOINT

HAEHNI, M.1, TAEYMANS, J.1, CLIJSEN, R.2, ROGAN, S.1

1 BERN UNIVERSITY OF APPLIED SCIENCES, BERN, SWITZERLAND; 2UNIVERSITY OF APPLIED SCIENCES AND ARTS OF SOUTHERN SWITZERLAND, LANDQUART, SWITZERLAND

INTRODUCTION: The prevalence of patellofemoral pain in physically active individuals ranges from 21% to 45%. In adults PFP prevalence rate ranges from 15% to 33% [1]. While in previous years the treatment of PFP focused on the neuromuscular control of the knee [2], the focus is now shifting towards a more functional-anatomical and biomechanical interaction of the hip, knee and ankle alignment. Recent research projects focus on the functional-anatomical circumstances such as lower leg alignment and the resulting biomechanical effects on the PFJ [3]. The main reason of PFP has been described as a chronic overload of the soft tissues with a misalignment of the patella or excessive patellar strain [4].
The prerequisite of an evidence-based physiotherapy to treat PFJ-pain patients is the knowledge of the interacting risk factors and PFJ pathogenesis. In addition, the knowledge of the clinical examination method and possible diagnostic imaging are also needed to establish adequate physiotherapy treatment strategy to tackle PFJ-pain in patients.
METHODS: The aim of this rapid review was to present the status quo of the diagnostic methods and physiotherapy treatment of PFJ-pain. The observed effect-sizes of the included studies were analyzed and discussed.
RESULTS: The diagnostic method of PFJ-pain in patients should include an anamnesis, a visual inspection of the lower leg alignment, a passive examination of the knee as well as a specific test of the PFJ with PFJ imaging. The diagnosis should examine the three anatomical risk factors: the bone, capsule-ligaments and skeletal muscle components.
CONCLUSION: The findings of this rapid review showed that a structured medical history and examination form the basis to prescribe an adequate physiotherapeutic intervention. To verify or falsify PFJ-pain, the anamnesis and visual findings should be made at first. Subsequently, passive examination and specific investigation tests of the PFJ should be performed. Finally, diagnostic imaging should be used for verification or falsification.

SINGLE-LEG HOP FOR DISTANCE AS A PREDICTOR OF PATIENT-REPORTED OUTCOMES FOLLOWING A LOWER EXTREMITY INJURY

SIMON, J.E., YOM, J., GROOMS, D.R.

OHIO UNIVERSITY

INTRODUCTION: The single-leg hop for distance (SLHOP) is a commonly used functional performance measure to determine return-to-play readiness. However, it is unknown if functional performance at return-to-play can predict future patient outcomes. Therefore, the purpose of this study was to determine if SLHOP performance and symmetry at return-to-play following a lower extremity injury would predict lower extremity patient-reported outcomes six months post-injury.
METHODS: Two-hundred thirty-six adolescent athletes (15.7±1.4 years, 171.1±7.6 cm, 70.3±15.3 kg) were recruited for this study. If an individual sustained a non-surgical lower extremity injury during their sports season and missed three days of sports participation they were eligible for follow-up functional and patient outcome assessment Thirty-two adolescent athletes were eligible and completed the follow-up testing (15.0±1.1 years, 166.5±4.9 cm, 67.3±10.4 kg; 14 American football, 8 volleyball, 4 girls' basketball, 6 boys' basketball athletes). The SLHOP was completed by affixing a tape measure to the ground and instructing the participant to hop on one leg as far as possible. Each participant performed three trials per leg at return-to-play (alternating legs). To be counted as a successful trial the participant maintained postural stability for 2 seconds after the landing and the contralateral leg was not allowed to touch the ground. The Pediatric Patient-Reported Outcomes Measurement Information System (PROMIS) Lower Extremity scale was completed six months after return-to-play as the patient-reported outcome measure. A stepwise multiple linear regression was conducted to predict PROMIS Lower Extremity scale score from SLHOP distance on the injured and uninjured leg (cm), and limb symmetry (%).
RESULTS: At step one of the analysis, injured limb SLHOP distance was entered into the regression equation and was significantly related to the PROMIS Lower Extremity scale $F<1,31>=20.8$, $p<.001$. The multiple correlation coefficient was 0.79, indicating approximately 62% of the variance of the PROMIS Lower Extremity scale scores could be accounted for by the injured limb SLHOP distance. Specifically, for every increase in one cm of SLHOP performance there would be an increase of 0.6 points on the PROMIS Lower Extremity scale. Uninjured limb SLHOP distance and limb symmetry did not enter into the equation at step two of the analysis ($p>.05$).
CONCLUSION: The SLHOP conducted at time of return-to-play following a lower extremity injury can predict lower extremity patient-reported outcomes six months later. This indicates that clinicians may be able to use the SLHOP following an injury to not only determine return-to-play readiness but a successful long-term outcome.

PLANTAR FASCIITIS LEVELS IN RUNNERS WITH THE USAGE OF BALANCED SCORECARD

PAZETTI, J.A.T.1, MANCINI, F.1, MARTINEZ, B.R.1, BUCK, I.1, YI, L.C.1
FEDERAL UNIVERSITY OF SÃO PAULO ; UNIVERSITY PAULISTA-UNIP

INTRODUCTION: The way of business management has undergone changes and has impacted in business fields. Fasciitis Plantar (FP) is one of the most common injuries among runners, and the treatment is time-consuming and expensive (WHO,2015). Using a management tool such as the Balanced ScoreCard (BSC), could help Plantar Fasciitis treatment management (BSI,2017).Objective:The aim of the study was to identify the Fasciíte Plantar levels in runners.
METHODS: Thirty four runners, 24 men (70,59%) and 10 women (29,41%) between 30 50 years old (40.03±5.55), Body Mass Index (21.46 ±2.28 Kg/m²), with Plantar Fasciitis (PF), were enrolled in the study. They ran for at least 6 months, with the training volume of at least 20 km weekly and the pain visual analogue scale (EVA) of at least 3 (0-10). To construct the Balance Scored Card (BSC) model to obtain FP levels, indicators and goals were defined from four perspectives: (i) the results; (ii) the patient; (iii) internal process; (iv) learning and growth. The BSC indicators were determined from lower limb clinical assessment tools, as follows: Sports Athlete Foot and Ankle Score (SAFAS), Hop test, Core test, assessment of the feet intrinsic muscles, Jack test, Navicular Drop Test; Visual Analogue Scale Star Excursion Balance Test, Step Down; Range of motion of foot and ankle, and Lunge Test.
RESULTS: From a constructed model from BSC, 4 levels of plantar fasciitis were obtained for the runners, in which the level I subjects have the mild PF and the level IV the worst symptoms, as follows: level I (20.58%); level II (76.47%); level III (2.94%); level IV (0.00%). It was found that 97.06% of the runners concentrate on the first and two levels (I-IV) of the injury.
CONCLUSION: Through a BSC strategic management tool, the levels of plantar fasciitis were identified. The levels I and II composed almost 97% of the runners, probably because they were recruited from the runners club, and still active for running practice, with no symptoms of functional limitation. BSC has shown to be a tool that could help clinicians to guide the treatment of PF, that could give precision in the choice of treatment according to the stage and disease characteristic (Rummler,1994).
Balance Scored Card management tool is useful to identify the Plantar Fasciitis level in runners, in order to assist clinicians to the better treatment, according to the found level.

KINEMATICAL DIFFERENCES BETWEEN POSTERIOR STABILIZED AND CRUCIATE RETAINING PROSTHESIS IN TOTAL KNEE REPLACEMENT USING DYNAMIC RSA

BRAGONZONI, L., BONTEMPI, M., CARDINALE, U., PIZZA, N., ZAFFAGNINI, S., MARCHEGGIANI MUCCIOLI, G., MARCACCI, M.
UNIVERSITY OF BOLOGNA

INTRODUCTION: The purpose of this work is to compare the kinematics of CR and PS TKA prosthesis design during a daily life activity.
Those two models show different features: asimmetrical condyles and lower lateral posterior condyle for the CR and simmetric condyles, frontal geometry and cam kinematics for the PS.
The motor task of the sit-to-stand was analyzed. This motor task is very common and allows to analyze the motion of the prosthesis with active muscle contraction and high stress inside the joint.
METHODS: The used RSA device was BiSTAND DRX (ASSING Group, Rome, Italy). The patients were asked to perform a sit-to-stand task: from the sitting position, the patient stands up.
The kinematic was analyzed using custom dedicated software. The motion parameters were evaluated using the Grood and Suntay decomposition and the Low-point kinematics. The time was normalized in percentage (0% begin, 100% end of the motor tasks). A random cohort of 16 randomly selected patients was operated and evaluated after 9 month follow up. The mean age of the patients was 69 years (95%CI, 64-82).
RESULTS: The kinematical data of the examined motor task were analyzed. The IE and VV rotations did not show any significative difference trend of the femur with respect to the tibia as the flexion angle increase. Otherwise the low point kinematics show a faster anterior traslation in the range between from the 55% to 80% of the movement. PS design show a wider anterior displacement respect to the CR. These two trends are in accordance with the screw-home mechanism. Moreover, the low point show a typical medial pivot during flexion.
CONCLUSION: Results using Dynamic RSA confirm different kinematic patterns between CR and PS. Particularly, the PS prosthesis has a range of displacement larger than the CR and the effect on the quality of life of patients deserves further studies.

KINEMATIC COMARISON OF PRE- AND POST- ACL RECONSTRUCTION DURING SINGLE-LEG-SQUAT USING DYNAMIC RSA

BONTEMPI, M., BRAGONZONI, L., CARDINALE, U., ZAFFAGNINI, S.
UNIVERSITÀ DI BOLOGNA

INTRODUCTION: The aim of this work is to compare, the kinematics of the knee of a cohort of patients with complete and isolated lesion of the Anterior Cruciate Ligament (ACL). The injured knee was evaluated using dynamic RSA pre-operatively and then were re-evaluated after 18 months of follow up. The ACL were reconstructed using the "Non Anathomical Double Bundle" (NADB), or the "Single Bundle with Lateral Plasty" (SBLP) techniques. The patients were asked to perform a single leg squat using the injured leg.
METHODS: A cohort of 27 patients (5 women, 22 men) with an isolated anterior cruciate ligament injury were recruited. The average age was 26 ± 8 years old. The analyzed knees were 16 right and 11 left. The patients were divided in two different groups: 13 were reconstructed using the SBLP, and 14 were reconstructed using the NADB technique. The Dynamic RSA device (BiSTAND DRX, ASSING Group, Rome, Italy) was used to evaluate patients the day before surgery (PRE group) and 18 months post-operatively. The patients were asked to perform a single leg squat using the injured leg: from standing to maximal allowed flexion (forward phase), to standing (return phase). The motion parameters were evaluated using the Grood and Suntay. The quantitative data were then statistically evaluated using the 1-way ANOVA ($p < 0.05$), to find significant differences during the movements.
RESULTS: The maximal flexion was the same in the injured and reconstructed knees. All the groups flexed at a mean angle of 67 degrees. The most important differences concerned the internal/external rotations (IE). The three pattern are very different and statistically signifi-

cant. The IE rotational pattern of the PRE group shows a forward phase values from -2 (external rotation), to +6 (internal rotation), to +4 degrees of rotation at the full flexion. The return phase ranges from +4 to +8 degrees. This pattern highlight a general instability of the knee. On the contrary the reconstructed knees show very different patterns. The NADB is divided in two stable sections. The forward phase has a IE rotation from +2, to 0, to +4 degrees. The return phase ranges from +4, to +8, to +5 degrees. The shape denotes that the patient has a stable rotation during the forward phase, then at the maximal flexion changes the knee rotation and start the return phase. The SBLP show a different, stable trend during the whole motor task. The IE rotations ranges from +5, to +8, to +5 degrees in both the forward and return phases, i.e. the knee maintains the same rotation during the motor task.
CONCLUSION: The analysis of the results, show that PRE group had a chaotic rotation pattern, while the NADB and SBLP are very different and the stabilization of the joint is strongly affected by these techniques. The SBLP demonstrated to be more effective to stabilize the rotations with respect to the NADB. Future studies will include a comparison with non-pathological kinematics of the knee.

OP-SH03 Sociology 1

RE-ENGAGING LOCAL YOUTH FOR SUSTAINABLE SPORT-FOR-DEVELOPMENT

SCHULENKORF, N., HOEKMAN, J., WELTY PEACHEY, J.

UNIVERSITY OF TECHNOLOGY SYDNEY

Despite increasing evidence that sport-for-development programs can contribute to community development, there remains a lack of empirical inquiry into different socio-managerial aspects of SFD. For example, in attempts to achieve locally sustained SFD programs, the roles, responsibilities and potential impact of re-engaged youth need further investigation. We define re-engaged youth as previous program participants who have maintained strong links with the organization and who return to the program at a later stage as volunteers, casual staff, or full-time employees. In this presentation, we examine ways in which re-engaged youth of the Blue Dragon Children Foundation's SFD program contribute to sustainable management and community development within a disadvantaged community setting in Hanoi, Vietnam. Following an interpretive mode of inquiry, we conducted and analyzed 12 in-depth interviews and two focus group discussions with re-engaged youth and key program stakeholders. Based on our thematic analysis, re-engaged youth were recognized as key drivers for organizational success; they were identified as program culture experts, role models, leaders and mentors, and creators of a family feel in SFD and beyond. We argue that re-engaged youth are demonstrating a number of important change agent capabilities that enable them to uniquely gauge and best respond to the needs of program participants and local communities in complex sociocultural environments.

A FULLY-INTEGRATED MULTIDISCIPLINARY INVESTIGATION INTO THE TALENT DEVELOPMENT PROCESS IN AN ENGLISH FOOTBALL ACADEMY

KELLY, A.1,2, WILLIAMS, C.2, WILSON, M.2

1. BIRMINGHAM CITY UNIVERSITY, 2. UNIVERSITY OF EXETER

INTRODUCTION: The ultimate purpose of a player development pathway is to realise the most effective methods to support young individuals to maximise their potential (MacNamara & Collins, 2015). Within a modern football academy setting, the essential developmental characteristics are often termed environmental, psychological, sociological, physiological, technical, and tactical attributes (Sarmento et al., 2018). Although these factors have been explained to independently facilitate the acquisition of expert performance, fully-integrated multidisciplinary evidence from an English context is unknown. Therefore, the aim of this study was to combine these features and to determine, over two football seasons, what outcomes support greater age-specific development within the Foundation Development Phase (FDP; under-9 to 11s) and Youth Development Phase (YDP; under-12 to 16s) at an English professional football academy.
METHODS: A total of 87 players (aged 8 to 17 years) were analysed within their respective phase; FDP (n=36) and YDP (n=51). A combination of 34 holistic factors from the Participation History Questionnaire, Psychological Characteristics for Developing Excellence Questionnaire, socio-economic status, growth and maturation data, physical performance, technical tests, match analysis statistics, perceptual-cognitive expertise (PCE), and game test situations were measured at two time points across two football seasons. Development was measured by comparing the delta change between the overall player profile scores from two seasonal reports. Stepwise regression analyses were conducted to assess the predictive capability of these variables on overall development.
RESULTS: Within the FDP, total touches change (p=0.023), taking advantage of openings quality (p=0.003), and PCE 'post' score change (p=0.029) explained a combined 11.5% of the variance. Within the YDP, PCE 'at' score (p=0.21), total sports played change (p=0.008), and total match-play hours (p=0.009) explained a combined 34.1% of the variance.
CONCLUSION: Results from the FDP support the importance of technical and tactical development during middle childhood compared to other influential factors. From a YDP perspective, results support the significance of the environment players are exposed to, whilst also illustrating the importance of PCE as a key ingredient within adolescence, to support greater overall development. Therefore, professional football academies are encouraged to deliver technical and tactical specific developmental activities within the FDP, whilst offering a substantial games programme alongside providing opportunities to participate in multi-sport activities across both age phases, to support superior development.

PSYCHOSOCIAL ASPECTS OF ASTHMA RELATED EXERCISE LIMITATION IN THE LITERATURE

WESTERGREN, T., BERNTSEN, S., FEGRAN, L.

UNIVERSITY OF AGDER

INTRODUCTION: Perceived exercise limitation in children with asthma is associated with markers of asthma severity and overweight (Westergren et al. 2017), and participation in physical activity (PA) may be avoided for various reasons. We aimed to identify psychosocial aspects of exercise limitation in children with asthma reported in the research literature.
METHODS: In a larger study described elsewhere (Westergren et al. 2017), we systematically searched 9 databases for sport and health science, and 5 databases for unpublished studies in January 2016. We included quantitative primary studies reporting about the relationship between PA and psychosocial factors, and qualitative primary studies reporting about experiences with PA in children and adolescents with asthma. Descriptive qualitative data about limiting aspects of PA participation, and quantitative questionnaire-/instrument-data of the relationship between PA level and psychosocial factors were extracted and sorted in distinct aspects possibly causing perceived exercise limitation.
RESULTS: Records identified were 3633. After removing 1314 duplicates, 2319 records were screened. Thirteen qualitative studies, and 20 quantitative studies were identified and included. Five distinct aspects possibly causing perceived exercise limitation were identified; (a) positive and negative feelings, attitudes, beliefs, and perceptions about PA and health, (b) the perception of self and one´s abilities, (c) perceived psychological distress, (d) perception of one´s social role and interplay, and (e) perception of health service and neighborhood.
CONCLUSION: Aspects reported in this study should be further explored in a meta-synthesis of qualitative literature to reveal more in-depth understanding of perceived exercise limitation. Original research combining an exploration of pathophysiological mechanisms, cardiorespiratory fitness, and subjective experiences should also be conducted, as well as intervention studies to determine causal relationships and to reveal factors worth manipulating to increase level of PA. Instrument development to assess level of, and distinct dimensions of perceived exercise limitation in children with asthma is also needed.

LONG-TERM DEFERMENT POLICY OF NATIONAL SERVICE FOR ELITE MALE ATHLETES – AN AVENUE FOR SPORTING SUCCESS? (A SOCIOLOGICAL PERSPECTIVE)

CHAN, C.

REPUBLIC POLYTECHNIC

ABSTRACT
This study aimed to use a sociological lens to evaluate the long-term deferment policy of military conscription, otherwise known as National Service (NS), for elite male athletes in Singapore. A functionalist perspective will be used to consider the impact of the policy; whether this policy has helped elite male athletes achieve sporting success.
Two cases of long-term deferment from NS for elite sports endeavour are examined. These two cases were for swimmers Joseph Schooling and Quah Zheng Wen.
As mentioned earlier, this study took on a functionalist perspective to consider the impact of the policy. The functionalist perspective is based on the assumption that society is an organized system of interrelated parts, held together by established social arrangements that maintain the system in a state of balance and equilibrium. Therefore it is apt that the Ministry of Defence (MINDEF) has such principles for a long-term deferment to maintain equilibrium in Singapore society.
The results of their long-term NS deferments bore fruit. For the RIO Olympics 2016, Schooling made history as he won the gold medal in the 100m butterfly and became Singapore's first-ever Olympic gold medallist. Quah Zheng Wen clocked personal bests to qualify for the semi-finals of both the 100m and 200m butterfly. Due to these achievements, both swimmers were allowed to extend their deferments for a further four years till after the 2020 Tokyo Olympics.
This study suggested that the continued support from the general public to the policy will hinge on the outcome of whether the deferments from NS, will help elite male athletes concerned, achieve the desired outcome in the sport. While the results from Joseph Schooling and Quah Zheng Wen have been positive thus far, the perception study with the empirical evidence from two cases alone will not be sufficient to form a conclusion on the success of the policy. As this is only a preliminary study, it will only serve as a pilot test because the information collected is only exploratory. It is intended only to assist in the design of a subsequent study (Zikmund, Babin, Carr, & Griffin, 2010). It is therefore recommended that this study is tracked longitudinally with more case studies in the future. Over time, this will provide a more robust basis to inform further policy development.

MOTIVATIONAL FACTORS AND PROFILE OF ROAD RUNNERS IN THE BRAZILIAN CAPITAL

MORAIS, L.1, COSTA, A.2, JUSTE, J.2, RAMOS, L.2, RUSSOMANNO, T.2, SOUSA, A.2

1:UNIEURO , 2:UNB

INTRODUCTION: Road race is a world sport phenomenon, and it also has many kind of products and service involved on it. Some investigations are interested about what factors of motivation are related to the runners. The motivations can be differentiated between those that begin into the race and those remain in the modality. Therefore, the aim of this study was analyze which are motivational factors related to those who joining and those who staying in the sport.
METHODS: A descriptive quantitative research was made, by applying an electronic survey that approached sociodemographic issues, race practice profile and motivational factors related to join (Salgado, 2006) and stay of the runners (Costa, 2016). The survey was sent by web link, through social networks and e-mails of runners that accepted to take part on the survey. For the motivations factors, it was used a scale of 4 points that ranged from 0- did not motivate to 4- motivated a lot. To analyze the results was used a descriptive statistic with cross tables and analysis of the Pearson chi-square test ($p \leq 0.05$). The SPSS software was used to analyze the results.
RESULTS: A total of 361 questionnaires were considered valid. Among the respondents, 51.8% were men. The predominant age group was 31 to 40 years (36.6%). The main schooling was higher education (78.7%). Regarding the profile of practice, 73.4% of respondents have been training for over 2 years, 15.8% six months ago and 10.8% a year ago. As concerns distance ran, 41.6% ran 21km, 26.3% ran 10km and 19.1% ran 42.195km.
The motivations to join, which have scored points, in descending order, are Health; Quality of life and Physical Fitness. The motivation factors to permanence stood out: Overcome limits; Physiological benefits and Plan and achieve news goals. The cross tables of these

variables did not present significant association of trends with the sociodemographic variables. However, the variables of practice profile indicate positives associations between Training time and distance ran with Plan and achieve news goals.
CONCLUSION: The research data suggest that the search for improvements in the objective and subjective aspects related to well-being and body leads the practitioner to start the races. However, the permanence factors seem to be more associated to the establishment of incremental goals and the search for the achievement of these objectives. It is suggested that new studies be done, due to the great demand for practice and to evaluate the profile of these practitioners consumption.

IN SOCIO-ECONOMICALLY HIGHER DEVELOPED COUNTRIES, SPORT PLAYS A MORE IMPORTANT ROLE: CROSS-NATIONAL RELATIONS BETWEEN THE EUROPEAN SPORT INDEX AND SELECTED SOCIO-ECONOMIC INDICATORS IN THE EU.

NADER, M.
UNIVERSITY OF VIENNA

Introduction: Previous research has shown that sport has a major impact on different aspects of European societies. To operationalize the social significance of sport in the 28 member states of the European Union, Weiß et al. (2016) developed an indicator-based statistical benchmarking model: the European Sport Index. Based on this index, the present study analyses the correlations between the social significance of sport and socio-economic development in the 28 members of the EU. Methods: To indicate the socio-economic development of the countries, a set of important indicators was selected (e.g. Human Development Index, All-Cause-Mortality). Beside content-related considerations, the availability, actuality and comparability of the data were crucial criteria for the selection of the indicators. In a next step, a hierarchical cluster analyses (Ward-Method) was applied to group the nations concerning their data structure. Finally, the Pearson's correlation coefficient (r) was calculated to examine the relations between the selected indicators and the European Sport Index. Results: Strong positive correlations (r>0,7) were found between the European Sport Index and the socio-economic indicators. In particular, northern and western European countries (e.g. Denmark, Netherlands) reach higher scores on the European Sport Index and the socio-economic indicators. Countries from southern and eastern Europe (e.g. Bulgaria, Romania), on the other hand, score lower on all observed indicators. The results of the cluster analysis support the northwest-southeast trend. Discussion:
The identified macro-level correlations highlight that in socio-economically higher developed countries, sport plays a more important role. However, deeper research needs to be conducted to analyze causality and robustness of these correlations. References: Weiss, O., Norden, G., Nader, M. & Arnusch, F. (2016). IS-SH03 Is Exercise Medicine?

A CRITICAL SOCIOLOGICAL EXAMINATION OF EXERCISE IS MEDICINE

MALCOLM, D.
LOUGHBOROUGH UNIVERSITY

This paper provides a critical sociological review of the Exercise is Medicine initiative, focussing particularly on the literal extrapolation that: a) exercise is the equivalent of a pharmaceutical; and b) that exercise and medicine as professional practices are becoming synonymous. It argues that the former, narrower, sense of this claim is problematic due to its generalized and open-ended prescription and disregard for potential side-effects. Consequently, exercise is very different to, and subject to different regulations from, medicine as conventionally conceived. The paper further argues that the latter, wider claim, raises questions of jurisdictional legitimacy, the disempowerment of citizens and the obfuscation of what it means to be healthy or unwell. In so doing, Exercise is Medicine raises some key conceptual and medical ethical questions

THE BIOMEDICAL PERSPECTIVE ON EXERCISE - A SOCIOLOGICAL ANALYSIS

MICHELINI, E.
TU DORTMUND

Exercise can be considered as medicine, if the perspective is a biomedical one. Indeed, it has been proven that it can prevent, cure, and rehabilitate diseases, which are the leading causes of death worldwide. However, there are other reasons for exercising which lead to the question: How socially dominant is the biomedical perspective on exercise?
This topic is assessed here by analysing the content of a catalogue of national strategies for promotion of PA issued by national sport and health systems. These documents are selected within a set of countries which are prototypes of differing welfare typologies (Leibfried, 1993): USA (Anglo-Saxon); Germany (Bismarckian); Sweden (Scandinavian); and Italy (Latin Rim). The catalogue has been analysed through a triangulation of systems theory (Luhmann, 1995), medicalisation studies (Conrad & Schneider, 1980), and critical theory (Habermas, 1984) and the qualitative technique of thematic analysis (Braun & Clarke, 2012).
These analyses uncover different systemic perspectives on exercise and the biomedical one's dominance. This logic appears largely dominant even in programmes issued by sport system organisations. Within the health system, a fundamental discrepancy between broad goals of health promotion and narrow biomedical objectives was revealed. As a consequence, the health system ignores its

utopic goals here and ends up focussing 'merely [on] the absence of disease or infirmity' (WHO, 1948, p. 1). Generally, the area of physical activity promotion undergoes a process of medicalisation, which tends to rationalise natural human behaviours for biomedical scopes. While this process is not per se problematic, it raises questions about the chance of disadvantaged population segments to follow guidelines on healthy PA and exercise and on the consequences of not following them.

'SPORT AS MEDICINE' AND OTHER MEANINGS OF SPORT AND PHYSICAL ACTIVITY AMONG PEOPLE WITH CHRONIC CONDITIONS

ELLING, A., STUIJ, M., ABMA, T.
MULIER INSTITUUT

In the research project Sport in Times of Illness, we analyse the construction and negotiations of sport-illness narratives among people with different chronic conditions and the perceptions of and interactions with medical/sport professionals. We used both quantitative and qualitative methods with a main focus on narrative methodology.
The meaning of sport showed less clear patterns than overall illness narratives, although aspects of restitution , quest and chaos could be identified among all groups. The outcomes present an interesting contradiction between an overall positive meaning of sport in managing illness and a rather negative overall evaluation of acquired guidance from health professionals with respect to sport and physical activity in the treatment trajectories.
We discuss meaningful differences related to illness conditions, social determinants and experienced well being, as well as the significance of our findings with respect to mainstream health-physical activity discourses and primarily medically based intervention programmes and guidance.

INTER-INDIVIDUAL DIFFERENCES IN ACUTE BLOOD PRESSURE RESPONSE TO HIGH INTENSITY EXERCISE: A REPLICATE CROSSOVER DESIGN

WILLIAMSON, P., ATKINSON, G., BATTERHAM, A.
TEESSIDE UNIVERSITY

INTRODUCTION: Acute blood pressure responses to physical activity predict hypertension and other cardiovascular-related comorbidities . Robust quantification of individual differences in this blood pressure reactivity requires a controlled replicate crossover design to isolate the participant x condition response variance . Our aim was to conduct the first appropriately designed experiment on individual differences in acute blood pressure reactivity to exercise.
METHODS: After baseline assessment of peak oxygen uptake, twelve normotensive adults <4 women> with mean age: 29.7 <4.9> y, height: 173.9 <10.1> cm, body mass: 72.5 <12.5> kg were randomised in blocks of 2 to one of 6 possible sequences of 2 control and 2 exercise replicates over 4 periods. The exercise comprised two 10-min bouts of cycling at 70% of the power output exhibited at peak oxygen uptake, separated by a 5-min recovery period. In the control condition, participants rested on the cycle ergometer for the equivalent time. Blood pressure was measured at rest and immediately after the last exercise bout . Data were analysed using a linear mixed model, allowing for sex differences in the mean effect of acute exercise and differential period effects between conditions . We included random effects for the participant x treatment interaction to partition the variance and derive the true SD for individual responses.
RESULTS: The mean effect of acute exercise on systolic blood pressure was an increase of 49 <95% CI, 33 to 66> mmHg <67 mmHg in women vs. 32 mmHg in men>. The SD for individual responses - the typical difference between participants in the mean change between a control trial and an exercise trial - was 17 <-18 to 30> mmHg.
CONCLUSION: In the first replicate crossover study quantifying inter-individual variability in response to exercise, we have shown a very large typical difference between participants in the mean effect of acute exercise on systolic blood pressure. We emphasise that although individual response variance was substantial, such a finding does not imply, necessarily, that there are responders and non-responders - in the current study all participants were responders to acute exercise. This model can be applied to future replicate crossover trials to quantify the presence of inter-individual variation in response to acute exercise.

HEART RATE VARIABILITY, MAXIMAL OXIGEN UPTAKE AND ANAEROBIC THRESHOLD

PÉREZ-LASIERRA, J.L.1,2,4, GARATACHEA, N.1,3,4, BAILÓN, R.5,6, HERNANDO, D.5,6, CASAJÚS, J.A.1,2,4
UNIVERSITY OF ZARAGOZA

INTRODUCTION: The VO2max and the Anaerobic Threshold (AT) are two parameters widely known and used in the field of physical exercise either from a focus on sports performance or health (Scribbans et al., 2016), but to know them objectively, complex and expensive techniques are required. Heart Rate Variability (HRV), represented by several indicators, is an easy and inexpensive method to assess the sympathetic and parasympathetic activity of our autonomic nervous system (ANS), which is responsible for controlling variables like heart rate (HR) (Draghici et al., 2016). Therefore, the aim of this study is to estimate the VO2max and the HR at AT from mathematical models that include HRV parameters.
METHODS: In our study we used 25 volunteers trained men (25-45 years). To assess VO2max and HR at AT we used the Gold Standard (GS) method, a maximum stress test on treadmill with gas analyzer; and to assess HRV parameters (HRM, PLF, PHF, LF/HF, FR) we used a spectral analysis of R-R intervals recorded in a resting phase of 5 minutes with a commercial HR monitor.
We use regression analysis to elaborate two models that can predict the VO2max and the HR at AT, and finally we analyse the reliability and heteroscedasticity of the models with Bland Altman plots.
RESULTS: The results show that in our sample it´s possible to estimate the HR at AT from the HRV using a mathematical model that explains 69.6% ($p<0.05$) of the variability, but it is not possible to estimate the VO2max because the mathematical model resultant is not statistically significant ($p>0.05$). Both mathematical models present a significant heteroscedasticity.
CONCLUSION: The possible results could have innumerable and innovative practical applications, but we are aware that in this case they are subject to certain bias and limitations that will have to be solved in future investigations before using those results in a real application.

THE DYNAMICS OF NOCTURNAL HEART RATE (VARIABILITY) IN TRAINING LOAD MONITORING

HYNYNEN, E., VESTERINEN, V., NUMMELA, A.
RESEARCH INSTITUTE FOR OLYMPIC SPORTS

INTRODUCTION: Heart rate (HR) and heart rate variability (HRV) measurements are used in monitoring athlete's recovery status (Buchheit 2014). Theoretically, recordings during night sleep may represent the best disturbance-free condition for this. The effects of training load of the preceding day may be seen especially in the early hours of sleep. As the nocturnal sleep is not just a stable period of recovery, the aim of this study was to identify the underlying relationships between nocturnal HR and HRV in different segments of the night sleep.
METHODS: Nocturnal RR-interval (RRI) recordings of 60 recreational endurance runners after two consecutive "stress-free" days were included in this study. RRI recordings were started when going to bed to sleep and stopped after waking up in the morning. First six hours of the RRI recordings were analyzed as 45-min periods (T1-T8) by using the Firstbeat Sports software. Sample correlation coefficients were calculated among the periods of HR and high frequency power (HFP). Exploratory factor analysis was used to study whether there are unobserved dimensions (factors, latent variables) underlying the observed periods of HR and HFP (factor indicators). Based on the results of the exploratory factor analysis, confirmatory factor model was specified for nocturnal HR and HFP at both measurement points (night 1 and night 2).
RESULTS: Correlations among periods of HR ranged from 0.655 to 0.946 and among periods of HFP from 0.720 to 0.912. The highest correlations were observed between the adjacent measurement periods and the correlations were lower between early and late periods of nocturnal sleep. In exploratory factor analysis the two-factor model showed the best fit to the data. According to the estimation results of the model, the four earliest periods of HR (T1-T4) and the two earliest periods of HFP (T1-T2) loaded on the Factor 1, while the six latest periods of HR (T3-T8) and the five latest periods of HFP (T4-T8) loaded on the Factor 2. Confirmatory factor model for early (T1-T2) and late periods (T5-T8) fitted the data well at both measurement points (two consecutive nights).
CONCLUSION: The results suggest that nocturnal HR and HRV indices should not be analyzed as one period, but separately for early and late periods of the night sleep. First 90 min contains different information than later periods of the night sleep. Previous studies have shown that early hours of nocturnal HRV are reflecting the training load (Buchheit 2014), but further research is needed to confirm the value of the HRV during the late hours of nocturnal sleep.

POST-EXERCISE HYPOTENSION AFTER SIMULATED VOLLEYBALL TRAINING

MANOLAKI, N.1, BARZOUKA, K.2, KARTEROLIOTIS, K.3, GEORGAKOPOULOS, A., BERGELES, N.2, KOSKOLOU, M.1
NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Post-exercise hypotension (PEH) is the reduction in systolic (SBP) and/or diastolic blood pressure (DBP) below control levels and is usually observed after a single bout of continuous exercise of submaximal intensity (50-70% VO2max) and prolonged duration (30-60 min) (1). There are few studies in the literature comparing PEH between interval and continuous exercise (2), but none for a team sport. The aim of the present study was to investigate whether volleyball, as a type of interval exercise, causes PEH. Thus, arterial pressure values measured during recovery after simulated volleyball training (VT) were compared with those measured after a continuous cycling exercise protocol (CC).
METHODS: Ten female, normotensive, experienced volleyball players, 23.6±3.89 yrs, performed a 60-min volleyball training (30 min active time) with continuous monitoring of heart rate (HR) and, on a separate day, a 30-min protocol of continuous cycling at the same intensity (as judged by HR) as the VT. Baseline and post-exercise values of BP and other cardiovascular parameters [HR, cardiac output (CO), stroke volume (SV), total peripheral resistance (TPR)] were monitored noninvasively (Finometer) for 30 min before and 60 min after the exercise protocols.
RESULTS: SBP was lower during the first minutes of recovery compared to baseline in both conditions, but the drop was larger (-16±4 vs. -8±4 mmHg) and longer (10 vs. 5 min) following VT than after CC ($p<0.01$). DBP remained at baseline values in recovery from CC, but after

VT it remained unchanged only for 10 min; afterwards, it was elevated compared to rest and CC (p<0.01). A slight decline (7% from baseline values; p>0.05), similar for both protocols, was observed in TPR at the start of recovery. CO was lower at the first 5 min of recovery after VT compared to CC (p<0.05). SV values were lower during recovery compared to pre-exercise (p<0.01) exhibiting more profound and prolonged decrease after VT than after CC (p<0.01). HR during VT recovery was higher compared to baseline and CC recovery (p<0.01). Both protocols were performed at 78±6% of HRmax or 67±9% of VO2max.
CONCLUSION: The results of the present study suggest that PEH, as judged from the drop in SBP, is more profound among young volleyball players after a single bout of volleyball training, compared to equal time and intensity continuous exercise which elicited the typical phenomenon of PEH as reported in the related literature (3). The steadily elevated values of DBP and HR throughout the 60-min recovery period after VT suggest that sympathetic nervous system activation remained at high levels after volleyball training, as this type of exercise involves the participation of more muscle mass, motor units and fast twitch fibers compared to cycling.

HEMATOLOGICAL ADAPTATIONS DOES NOT EXPLAIN THE INCREASE IN MAXIMAL OXYGEN UPTAKE INDUCED BY 10-WEEKS OF ENDURANCE TRAINING

SKATTEBO, Ø.1, AUENSEN, M.1, CAPELLI, C.1, BJERRING, A.W.2, SARVARI, S.2, HALLÉN, J.1
1: NORWEGIAN SCHOOL OF SPORT SCIENCES 2: OSLO UNIVERSITY HOSPITAL

INTRODUCTION: It is still debated whether improvements in VO2max are mainly dictated by central or by a combination of central-peripheral adaptations. In two recent studies, increased blood (BV) or erythrocyte (EV) volumes (1; 2) induced by endurance training (ET) were removed and it was found that maximal cardiac output (Qmax) and VO2max recovered to pre-ET level. However, hypovolemia due to phlebotomy (Phle) may reduce venous return, increase sympathetic tone, potentially masking the ET induced drop in vascular resistance, and therefore decrease Qmax and O2-delivery. The present study investigated cardiovascular adaptations to ET in upright (UC) and supine (SC) cycling, where venous return is enhanced, before and after normalizing hemoglobin mass (HbM) to pre-ET level.
METHODS: Eleven untrained subjects completed 10-weeks of supervised ET (3 sessions/week) with cardiac morphology (echocardiography) and HbM (CO-rebreathing; CV: 1.1%) assessed pre and post. VO2max and Qmax (Physioflow) were determined pre-ET, post-ET and after Phle in UC and SC in randomized order. Repeated-measures and two-factor within-subject ANOVAs (time x modality) were used for analyses.
RESULTS: ET increased HbM by 25±14 grams (mean±95% CI; P<0.01) and BV by 180±175mL (P=0.04). After Phle, BV was unchanged (9±119mL) compared with pre-ET. VO2max in UC increased from 3.3±0.5 to 3.7±0.5 L/min (11±4%; P<0.01) and remained elevated after Phle (3.7±0.5 L/min). In SC, it was 13±2% lower than in UC (P<0.01), increased 9±5% after ET and remained elevated after Phle (P<0.01). Qmax in UC increased from 20.2±2.6 to 21.9±2.5 L/min (10±6%; P<0.01) after ET and remained elevated after Phle (21.9±2.8 L/min). In SC, Qmax tended to increase (20.9±3.1 to 21.6±2.6 L/min; P=0.23) and significantly so only after Phle (22.5±2.8 L/min; P=0.01). SVmax increased by 12±8% in UC (P<0.01) and 9±8% in SC (P=0.03) and remained elevated after Phle. Arteriovenous O2 difference changed in neither UC (166±16 to 169±17 mL/L) nor SC (142±19 to 149±20 mL/L) after ET. Left ventricular mass increased (123±25 to 137±25 grams; P=0.03) with no change in end-diastolic volume (122±24 to 125±27mL).
CONCLUSION: The present study challenge the previous findings (1; 2) that increased BV is the main factor responsible for improvements in Qmax, but supports that increased Qmax, via elevated SV, is the main factor responsible for improvements in VO2max by short-term ET. In addition, the hypothesis of initial concentric remodeling in early commencement of ET (3) is supported.

IMPACT OF A BLOOD DONATION ON HEMOGLOBIN MASS, IRON STORES AND PERFORMANCE IN WOMEN

WACHSMUTH, N., HAUPT, S., BAUER, P., TREFF, G., STEINACKER, J., SCHMIDT, W.
INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: During a blood donation, about 500 ml of blood are taken regardless of body proportions and sex of the donor. This amount corresponds to a haemoglobin loss of 60-80g. Because of generally lower haemoglobin mass (Hbmass) and lower iron stores in women the blood donation may have a stronger impact in female donors and it might take a longer period of time for them to recover from the blood loss than the suggested 8 to 12 weeks until the next possible blood donation. Therefore, the aim of the study was to determine total haemoglobin mass, iron status and performance (VO2max) in women before and after a blood donation (BD) and to monitor the recovery of these parameters for the following 12 weeks.
METHODS: In total, 10 women (age: 24.6±1.5years, body mass: 63.5±6.6kg, BMI: 22.5±1.9, [Hb]:13.8±0.8g/dl) who fulfilled the criteria to donate blood participated at the study. Hbmass was measured using the optimized CO-rebreathing method before, directly after the BD and periodically until 12 weeks thereafter. Simultaneously venous blood samples were drawn to analyse erythrocyte parameters (e.g. [Hb], Hct, MCV, MCH, and MCHC) and iron status (e.g. Ferritin, CRP, Transferrin, and Transferrin saturation). Before and regular up to 12 weeks after the BD 7 VO2max -Tests were performed.
RESULTS: Hbmass dropped from 562.1±69.5g to 499.0±64.0g (p<0.001) after the BD and increased continuously in the following weeks. For the first time, 8 weeks after the blood donation no significant differences to baseline values were found. Only 3 out of the 10 subjects achieved the baseline values after 12 weeks. Ferritin declined from 40.9±34.2ng/ml to 12.1±6.9ng/ml (p<0.05) in week 6. Even after 12 weeks, iron stores were not refilled (Ferritin: 18.4±12.7ng/ml, p<0.05) and 6 out of 10 subjects showed an iron deficiency (Ferritin <15ng/ml). Immediately after BD, VO2max was reduced by 213±47ml (7.2±1.2%; p<0.001) and remained 3.2±1.4% (p<0.01) below baseline values after 12 weeks.
CONCLUSION: For many women, 12 weeks are not sufficient to recover from a blood donation and to achieve baseline Hbmass and iron stores. A subsequent blood donation might lead to a severe anaemia. It should be evaluated whether an iron supplementation could accelerate the time of recovery.

PREVALENCE OF THE DEGRADATION CARTILAGE MARKER, OLIGOMERIC MATRIX PROTEIN (COMP), IN MALES CROSS-TRAINING AND ULTRA TRAIL RUNNERS

RAMA, L., COELHO E SILVA, M.J., DUARTE, J., COSTA, D., MARTINHO, D., SILVA, P., TEIXEIRA, A.M.

FACULTY OF SPORT SCIENCES AND PHYSICAL EDUCATION OF COIMBRA

INTRODUCTION: Cartilage oligomeric matrix protein (COMP) is a well-known marker of cartilage degradation namely in inflammatory arthritis, rheumatoid arthritis and other. The produced protein fragments diffuse out into the joint fluid, appearing in the bloodstream, making them useful to predict the cartilage degradation in inflammatory joint diseases. An association has been shown between the concentrations of COMP in serum and cartilage degradation. To our knowledge, few studies were conducted to analyze the impact of training on COMP appearance in the serum in healthy athletes. Serum COMP values could be elevated, after exercise, however, tend to return to basal levels upon 36hours of rest. We aim to compare the values of serum COMP in athletes of two sports of distinct exercise demand: Cross training (XFIT) and ultra trail runners (UTR), the former sustained in the high-intensity workouts, the later, by large volumes of training.
METHODS: 19 cross-training(XFIT) and 20 ultra trail runners (UTR), males, of 30,2±9,0 and 39,3±7,6 years old, 175,9±4,8 and 173,8±6,2(cm) height; 85,2±14,8 and 75,8±10,3Kg weight, for XFIT and UTR respectively, volunteered to participate in this study, approved by the Scientific Board of the Faculty of Sports Sciences & Physical Education of University Coimbra. The subjects were informed about the objectives and procedures of the study and gave their written informed consent. 10mL of peripheral blood samples were collected (8:00-9:00h) by venipuncture of the antecubital vein, after 48 hours of rest from the last training session. Blood samples were centrifuged, and the serum was reserved and frozen (-20º) into Eppendorf tubes until analysis. The serum values of COMP were determined ELISA (COMP-ELISA®AnaMar AB, Gothenburg, Sweden). The reference values used to assess ongoing cartilage turnover estimating the risk for joint destruction in the future was as follows: < 12 U/L lower risk of aggressive joint destruction; 12-15 U/L increasing risk of aggressive joint destruction; > 15 U/L high risk of aggressive joint destruction.
RESULTS: No differences were found in the COMP mean values between XFIT (8,7±2,5 U/L) and UTR (8,8±2,4 U/L). Nevertheless, the proportions of athletes that presented an increased risk for future development of joint destruction was higher in XFIT(25%) than in the UTR (4%).
CONCLUSION: The results showed a high proportion of Cross-training athletes with elevated COMP serum values, identified with a higher risk for future cartilage damage. Further research must be done with athletes of other sports and follow-up studies aiming to analyze the temporal effect of the specific sports practice over the risk of cartilage damage.

THE ROLE OF INFLAMMATION IN ACHILLES TENDINOPATHY: INTERLEUKIN-6 LEVELS DROP AFTER PHYSIOTHERAPEUTIC INTERVENTION

LEGERLOTZ, K., RADOVANOVIC, G.

HUMBOLDT-UNIVERSITÄT ZU BERLIN

INTRODUCTION: Tendinopathies are a commonly occurring clinical problem in sports. They are characterized by chronic tendon pain and impaired functionality. Effective treatment options are difficult to develop, because aetiology and progression of this disorder are still poorly understood. The role of inflammation in chronic tendinopathies is highly debated. For many years, the disease was considered to be mainly degenerative. However, recent research indicates that chronic inflammation may be a feature of Achilles tendinopathy . Thus, the aim of this study was to investigate, if plasma levels of the inflammatory cytokine Interleukin-6 are elevated in patients with chronic Achilles tendinopathy and if IL6 levels are affected by treatment, duration of symptoms or anatomical localization.
METHODS: 22 male patients with chronic insertional or mid-portion Achilles tendinopathy were subjected to a physiotherapeutic intervention for 12 weeks. VISA-A scores and blood plasma IL6 levels were determined before and after the intervention phase. Exercise activity was recorded daily in a training diary.
RESULTS: The physiotherapeutic intervention led to improved pain and functionality. This is represented by a significant VISA-A score increase from 56±14 points at baseline to 75±19 points after the intervention. Plasma IL6 levels decreased significantly from 2.7±1.7 ng/l at baseline to 2.0±0.7 ng/l after the intervention period. IL6 levels decreased from 3.7±2.1 to 2.0±0.9 ng/l in 10 patients <7 insertional and 3 mid-portion>, did not change <1.8±0.6 ng/l> in 7 patients <3 insertional and 4 mid-portion>, and increased from 1.8±0.5 to 2.2±0.6 ng/l in 5 patients <1 insertional and 4 mid-portion>. Pre and post IL6 levels did not correlate with any of the other measured parameters. Patients with insertional Achilles tendinopathy did not differ significantly in any of the investigated parameters when compared with patients having mid-portion Achilles tendinopathy.
CONCLUSION: At baseline, IL6 levels were elevated in some but not all patients with Achilles tendinopathy. The anatomical location may contribute to elevated IL6 levels. Inflammation appears to play a role in the progression of Achilles tendinopathies in some patients, making IL6 a potential target for therapeutic interventions in this subgroup.

INFLUENCE OF TART CHERRY JUICE ON AIRWAY BIOMARKERS OF INFLAMMATION AND OXIDATIVE STRESS FOLLOWING A 42.2KM TRAIL RUN

DIMITRIOU, L.1, YAGNIK, D.R.2, WOOD, A.1,3, SINCLAIR, S.1,4, PAICE, K.1, WILSON, L.1, HILLS, F.A.2, GONDEK, M.B.2, KWAN XUE BIN, K.1, HOWATSON, G.5, COCKBURN, E.1,6

MIDDLESEX UNIVERSITY

INTRODUCTION: Tart cherry juice (CJ) has been shown to alleviate the development of respiratory symptoms following a Marathon (Dimitriou et al., 2015) by possibly reducing exercise-induced airway inflammation (Verges et al., 2005). Therefore, this study examined the effects of CJ supplementation before and following a 42.2km trail run on biomarkers of airway inflammation and oxidative stress.
METHODS: Nineteen recreational runners were randomly assigned to either consumption of CJ or placebo (PL) (age 39 +/- 8 years; height 1.75 +/- 0.7 m; mass 71.9 +/- 8.2 kg; completion time 210 +/- 25 min), from 4 days prior to 48h following a 42.2km trail run. Fractional exhaled nitric oxide (FeNO) and hypertonic inhalation-induced sputum (IS) samples were measured immediately before and after the run and then 24h and 48h post run. Both, FeNO and IS are non-invasive methods that can determine the type and severity of airway inflammation. Induced sputum samples were analysed for biomarkers of: a) inflammation (CD163; CD3E; CD44; CD62E; CD66E; Elastase and Interleukin-6 (IL-6)) and b) oxidative stress (protein carbonyls (PC) and superoxide dismutases (SOD)). The percentage of markers expressed on the surface of activated cells was determined using flow cytometry and the remaining biomarkers (IL-6; PC and SOD) were analysed using enzyme-linked immunosorbent assays (ELISA). Data were analysed using magnitude based inferences and results are reported as factor changes.
RESULTS: Compared to PL, CJ was beneficial for changes in CD163 (B-post 1.11 v 0.60, likely moderate; B-48h 1.60 v 0.75, very likely moderate), CD44 (B-48h 1.18 v 0.59, likely moderate), CD62E (B-post 1.08 v 0.69, likely small), CD66E (B-post 0.91 v 0.52, likely moderate; B-48h 1.03 v 0.67, likely small), IL-6 (B-48h 1.32 v 0.83, possible small) and SOD (B-post 1.01 v 0.77, likely small; B-24h 1.14 v 0.80, likely small; B-48h 0.96 v 0.70, likely small). However, CJ was harmful for changes in FENO (B-post 1.09 v 1.28, possible trivial; B-24h 1.04 v 1.21, possible small; B-48h 1.11 v 1.25, possible small) and PC (B-post 1.07 v 1.41, possible small; B-24h 0.99 v 1.22, possible small; B-48h 1.11 v 1.43, possible small). All other effects were unclear.
CONCLUSION: Airway inflammation biomarkers were decreased in the cherry juice group, whereas an increase was observed in the placebo group. However, cherry juice led to greater increases in FENO and PC compared to placebo. Cherry juice was beneficial for limiting exercise-induced airway inflammation.

LIMB-SPECIFIC TRAINING ADAPTATIONS AND A REDUCED ACTIVE MUSCLE MASS CAN ATTENUATE THE ACUTE INFLAMMATORY RESPONSE TO INTERVAL EXERCISE

HOEKSTRA, S.P., WESTERMAN, W., BEKE, F., BISHOP, N.C., LEICHT, A.C.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: While adaptations to a short-term training program can dampen the acute inflammatory response to exercise (Pedersen & Febbraio, 2008), less is known about the influence of chronic training. This study compares the inflammatory response to upper- and lower-body interval exercise in individuals chronically trained in these respective modalities to investigate the influence of limb-specific training status as well as the amount of active muscle mass on the inflammatory response to exercise.
METHODS: 90 min of interval exercise on an arm-crank (ARM) as well as a cycle ergometer (LEG) was performed by 8 trained paddlers (peak oxygen uptake (ύO2peak) ARM: 3.38±0.57 L/min, 0ΌO2peak LEG: 3.57±0.41 L/min) and 8 trained cyclists (0ΌO2peak ARM: 2.65±0.29 L/min, L·O2peak LEG: 4.13±0.41 L/min). Exercise intensities were matched for percentage of peak power output (POpeak) between modalities (10 blocks of 9 min consisting of 40%, 60% and 90%POpeak). Core temperature and heart rate were monitored throughout. Blood samples were taken pre- and post-exercise. Interleukin-6 (IL-6) and extracellular heat shock protein 72 (eHsp72) concentrations were analysed in plasma, while the expression of intracellular Hsp72 in monocytes (iHsp72) was assessed by flow cytometry.
RESULTS: The increase in IL-6 was significantly smaller in ARM compared to LEG (fold change ARM: 7.23±3.56, p<0.001; LEG: 9.03±4.82 p<0.001, Time x Modality p<0.001). The significant increase in IL-6 following ARM as well as LEG was present in both groups (cyclists p<0.001; paddlers p<0.001). ARM induced a significantly smaller iHsp72 response compared to LEG (fold change ARM: 1.07±0.14, p = 0.10; LEG: 1.18±0.14, p<0.001, Time x Modality p = 0.05). Following ARM, only the cyclists increased iHsp72 expression (fold change cyclists: 1.12±0.11, p = 0.02; paddlers: 1.03±0.17, p = 0.64), while iHsp72 expression following LEG increased in both groups (fold change cyclists: 1.14±0.15, p = 0.027; paddlers: 1.22±0.13, p< 0.001). Neither of the exercise modalities induced a significant increase in eHsp72 concentrations (p>0.15). Mean heart rate and peak core temperature were higher for LEG compared to ARM (p<0.001), the pattern being similar between groups (Modality x Group p>0.39).
CONCLUSION: The IL-6 response to lower-body interval exercise was larger when compared with work-matched upper-body interval exercise and, moreover, adaptations to upper-body exercise training dampened the iHsp72 response to this modality. Augmented core temperature increases during cycling might explain the first finding. The latter finding implies that regular exercise training can attenuate the stress response in an exercise modality specific manner. Therefore, exercise might be less effective in reducing chronic low-grade inflammation in individuals relying on their upper body.

POSITIVE IMMUNOMODULATORY AND NEUROPROTECTIVE EFFECTS OF HIGH INTENSITY TRAINING IN AN ANIMAL MODEL OF MULTIPLE SCLEROSIS

EINSTEIN, O.1, FAINSTEIN, N.2, TYK, R.1, TOULOUMIM, O.3, LAGOUDAKI, R.3, HANYA, E.1, GRIGORIADIS, N.3, KATZ, A.1, BEN-HUR, T.2

1: ARIEL UNIVERSITY , 2: HADASSAH HOSPITAL , 3: AHEPA HOSPITAL

INTRODUCTION: Exercise training has beneficial effects in Multiple Sclerosis patients and in experimental autoimmune encephalomyelitis , the animal model of MS. However, optimal training protocols and the underlying mechanisms whereby ET affects systemic immune

responses and/or the central nervous system remain undefined. Recently, we showed that moderate intensity training suppressed peripheral immune responses but did not protect the CNS from encephalitogenic T cells . Still, it is unknown whether higher intensity training may induce both systemic immune-modulation and/or direct protective effects on the CNS. Here we examined the effects of different ET protocols on a clinically relevant model of MS.
METHODS: Healthy mice were subjected to moderate or high intensity running protocols. Performance tests of trained and sedentary mice were performed. Proteolipid protein -induced transfer EAE was used to enable differentiation between effects of ET on systemic autoimmunity vs. direct effects on the CNS. Regarding neuroprotection, we transferred PLP-reactive, encephalitogenic T cells into recipient mice that underwent the training program prior to EAE transfer, and compared the disease severity to that in recipient sedentary mice. Regarding systemic immunomodulation, characteristics of encephalitogenic T cells derived from PLP-immunized trained vs. sedentary mice were evaluated in vitro using proliferation assays.
RESULTS: Moderate intensity ET induced a significant increase in maximal speed and exercise tolerance. High intensity ET increased maximal speed similarly and more than doubled exercise tolerance. Whereas moderate intensity ET did not have direct neuroprotective effects, transfer of PLP-reactive, encephalitogenic LN-T cells resulted in less severe EAE in recipient mice that were subjected to high intensity training program prior to EAE transfer. High intensity ET also had greater suppressive effects on PLP-reactive T cells proliferation than did moderate intensity. High intensity ET inhibited proliferation of PLP-reactive T cells in response to CNS-derived autoantigen, but strongly enhanced their proliferation in response to concanavalin A, a non-specific stimulus.
CONCLUSION: Our data, obtained by using a unique experimental design, indicate positive effects of high intensity training on both systemic immune-modulation and direct neuroprotection in EAE. This study is of clinical significance and may provide a basis for defining exercise recommendations for MS patients.

THE EFFECTS OF AN 8-WEEK STRUCTURED EXERCISE INTERVENTION ON FUNCTION, SYMPTOMS AND QUALITY OF LIFE IN CANCER SURVIVORS WITH CHEMOTHERAPY-INDUCED PERIPHERAL NEUROPATHY: A PILOT STUDY.

SANDLER, C.X.1,2,3, MCCRARY, J.M.1, GOLDSTEIN, D.1, BATTAGLINI, E.1, BARRY, B.K.1,3, MURRAY, J.1, PARK, S.1,4

1 UNIVERSITY OF NEW SOUTH WALES, SYDNEY, AUSTRALIA. 2 QUEENSLAND UNIVERSITY OF TECHNOLOGY, BRISBANE, AUSTRALIA. 3 UNIVERSITY OF QUEENSLAND, BRISBANE, AUSTRALIA. 4 THE UNIVERSITY OF SYDNEY, AUSTRALIA.

INTRODUCTION: Chemotherapy-induced peripheral neuropathy (CIPN) is a significant consequence of chemotherapy, affecting up to 40% of cancer survivors. The symptoms can include dysaesthesia, tingling, and numbness in the hands and feet. Patients may also report alterations in proprioception, perception of touch or vibration and a sense of instability. Exercise interventions have been shown to improve function, balance and quality of life for patients with neuropathy of various aetiologies. Yet the evidence for the benefit of exercise on symptoms and gait in CIPN is limited.
METHODS: Fifteen cancer survivors, 12 female mean age 64.6±10.5 years, who were at least three months post-treatment and displayed National Cancer Institute CIPN grade of ≥2, completed an 8-week exercise intervention. Self-reported symptoms, functional capacity and neurophysiological assessments were conducted at baseline, after an 8-week wait period, and following the 8-week exercise intervention. Outcome measures included the Total Neuropathy Score (TNS, objective assessment), postural sway and balance (Swaymeter), patient-reported symptoms (CIPN-20), quality of life (SF-36), grooved pegboard test (fine motor function), five times sit-to-stand test (lower limb strength and dynamic balance), and six-minute walk test (6MWT, walking function). The intervention involved three one-hour sessions per week, which included components of aerobic, resistance, and balance exercises at a moderate to hard intensity (rating of perceived exertion 13-15/20). Half of the exercise sessions (12 sessions) were supervised by an exercise physiologist, while the other half were home-based.
RESULTS: There was good adherence to both supervised (mean 11.7±0.6, 98%) and unsupervised (9.1±3.5, 76%) sessions. From baseline to the end of the wait period there were no significant changes in outcome measures. The exercise intervention elicited improvements in quality of life (mean difference 9.5±11.5 95%CI: 3.1-15.9, p<0.01), TNS (2.2±3.1,95%CI:0.6-4.0), patient-reported neuropathy symptoms (9.9±12.9, 95%CI: 2.8-17.1, p<0.01) and postural sway (116.6±41.5, 95%CI: 26.8-206.3, p<0.05), but no statistically significant change in 6MWT distance (19.9±55.4 metre increase, 95%CI:-10.8-50.6, p=0.19) or five times sit-to-stand (-1.2±3.5, 95%CI: -0.7-3.2, p=0.19).
CONCLUSION: This study provides preliminary evidence for the effectiveness of exercise to improve symptoms of CIPN, quality of life and function. However, walking function (6MWT) and dynamic balance (five time sit-to-stand) did not improve. Given associations between gait and dynamic balance deficit and increasing symptom severity (Winters-Stone et al, 2017), it seems likely that 6MWT and five time sit-to-stand are not sensitive measures of gait and dynamic balance for people with CIPN. Further studies are needed to examine the exercise benefits related to gait and dynamic balance using CIPN-specific functional measures.

PHYSICAL ACTIVITY REDUCES DYSREGULATION OF THE INFLAMMATORY MEDIATORS IN THE MULTIFIDUS MUSCLE AFTER SPONTANEOUS INTERVERTEBRAL DISC DEGENERATION IN SPARC-NULL MICE

HODGES, P.1, JAMES, G.1, MILLECAMPS, M.2, STONE, L.2

1: THE UNIVERSITY OF QUEENSLAND ; 2: MCGILL UNIVERSITY

INTRODUCTION: A pro-inflammatory response is present in the deep back muscle multifidus after an intervertebral disc lesion. This occurs despite no injury to the muscle and has been proposed to drive structural changes in back muscle fat and connective tissue that are present in low back pain (1) and have been purported to contribute to persistence and worsening of the condition. Exercise and physical activity produce a strong anti-inflammatory response but the effectiveness in ameliorating inflammation in the multifidus muscle is unknown. We assessed whether the inflammatory profile of the multifidus was modified by intervertebral disc degeneration (IDD) using SPARC-null mice that develop this process spontaneous, and whether these changes could be prevented/reduced by physical activity.
METHODS: Wild-type and SPARC null mice that were sedentary or housed with a running wheel. Multifidus muscle segments were harvested from L2-L6 from the mice at 9 months of age after they had undergone an MRI scan to determine levels with IDD. The inflammatory profile of the multifidus was examined using real time PCR assays. Inflammatory cytokine expression was considered with respect to proximity to levels with IDD and compared between wild-type and SPARC-null mice and those that had and had not been exposed to physical activity.
RESULTS: Spontaneous IDD in the SPARC-null mice caused a dysregulation of interleukin-1beta (IL-1β), interleukin 6 (IL6), Transforming growth factor beta1 (TGFβ1) and adiponectin expression. The proximity and degree of IDD was related to levels of IL-1β expression. Physi-

cal activity reduced the pro-inflammatory response to IDD in the multifidus. IL-1β, tumor necrosis factor (TNF), interleukin-10 (IL-10), adiponectin, and leptin levels were lower in the physically active group.
CONCLUSION: These results reveal that spontaneous IDD causes dysregulation of the inflammatory pathways active in the multifidus muscle. These alterations were related to the severity of IDD and were prevented by physical activity.

IMPROVEMENTS IN PHYSICAL FUNCTION AFTER CONCURRENT EXERCISE TRAINING IN OLDER ADULTS ARE AUGMENTED BY A HIGH PROTEIN DIET INTERVENTION TARGETING LEUCINE-RICH MEALS

TIMMONS, J.F., HONE, M., COGAN, K.E., DUFFY, O., MURPHY, J.C., EGAN, B.
UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Most nutrition interventions targeting muscle mass and function in older adults utilise powdered protein or oral nutrition solutions, and few studies have employed food-based nutrition interventions to support exercise training. The amino acid leucine plays a key role in the stimulation of muscle protein synthesis by ingested protein as does an even distribution of protein throughout the day, but these strategies are under-explored in older adults.
OBJECTIVES
To determine if a food-based nutrition strategy targeting the equivalent of 3 g of leucine per main meal can augment exercise training-mediated effects on lean body mass (LBM) and physical function in older adults.
METHODS: Participants [(n=56; M/F, 28/28; age, 69.3±4.0 y; BMI, 26.6±3.7 kg/m2] were randomly assigned to Nutrition (NUT), Exercise (EX), and Exercise and Nutrition (EX+NUT) for a 12 week intervention. Exercise consisted of 3x24 min of concurrent aerobic and resistance exercise per week. The nutrition intervention provided meal plans and weekly engagement targeting leucine-rich meals at breakfast, lunch and dinner. Body composition (DXA), dietary intake (three day diet record), and physical function (test battery including chest and leg press strength and aerobic fitness) were assessed before (PRE), during (MID), and after (POST) the intervention.
RESULTS: Daily protein intake increased in NUT (0.99±0.34 vs. 1.43±0.39 g/kg body mass, $p<0.05$) and EX+NUT (0.90±0.20 vs. 1.57±0.49 g/kg body mass, $p<0.05$), but not EX (1.14±0.35 vs. 1.05±0.28 g/kg body mass). Body mass increased by ~1% in both EX+NUT and NUT (both $p<0.05$), but this was in the form of LBM (1.1±1.7%, $p<0.05$) and leg LBM (1.6±2.6%, $p<0.05$) in EX+NUT, and fat mass (3.3±5.5%, $p<0.05$) in NUT. Several measures of strength, physical function and aerobic fitness were improved to a similar extent in both EX and EX+NUT groups, but leg strength improved to a greater extent ($p<0.05$) in EX+NUT (33.4±37.7%) compared to EX (12.8±16.6%).
CONCLUSION: Concurrent aerobic and resistance exercise training improves aerobic fitness, strength and physical function in older adults, but when combined with leucine-rich meals provides a more effective strategy to increase lean body mass and strength in this population.

NO DIFFERENCE IN RECOVERY FROM EXERCISE-INDUCED MUSCLE DAMAGE WHEN SUPPLEMENTING WITH PLANT-BASED PROTEIN COMPARED TO ANIMAL PROTEIN.

BROWN, M.A.1, EASTGATE, G.1, COLE, M.2, HUGHES, J.D.1
UNIVERSITY OF GLOUCESTERSHIRE

INTRODUCTION: Recent evidence suggests that there is growing visibility of veganism in elite sport populations. Despite this, little is known about the consequences of adopting a vegan diet for athletic performance and recovery. Many athletes experience symptoms of exercise-induced muscle damage (EIMD) during intense training periods, and a common strategy to reduce the associated symptoms involves nutritional intervention; namely with supplementation of protein and protein analogues. Whilst plant-based protein ingestion has been investigated in the context of exercise recovery, few have made comparisons with animal protein and, to our knowledge, no study has explored this in individuals following a vegan diet. Therefore, this study aimed to investigate the effect of plant-based protein supplementation compared to animal protein supplementation on symptoms of EIMD and recovery in physically active males following a vegan diet.
METHODS: Ten males were assigned to consume either a mixed plant-based protein (PB) or whey protein concentrate (WP) supplement twice per day for 3 days post EIMD. Delayed onset muscle soreness (DOMS), countermovement jump (CMJ) height, squat jump (SJ) height, sprint power, creatine kinase (CK) and aspartate transaminase (AST), were collected pre, immediately post, 24, 48, and 72h post-exercise. For four days prior to, and throughout the data collection period, participants consumed a plant-based diet. Procedures were approved by the School Ethics Committee and participants provided written informed consent.
RESULTS: DOMS significantly increased following EIMD, peaking at 48h post-exercise ($p=0.003$). CMJ ($p<0.001$) and SJ ($p=0.001$) height decreased post EIMD and gradually returned to baseline levels during recovery, however sprint power was not affected by exercise ($p=0.137$). AST ($p=0.004$) and CK ($p=0.013$) levels increased post EIMD, peaking at 24 and 48h, respectively. Significant time effects for all variables except for sprint power suggests that participants experienced EIMD. However, there were no group or interaction effects in any dependent variable (all $p>0.05$); suggesting that the EIMD and recovery responses were similar between PB and WP groups.
CONCLUSION: Recovery from muscle damaging exercise is not different between PB and WP supplementation in males following a plant-based diet. This work therefore provides support for the use of PB, as a practical addition to vegans dietary routines in order to promote exercise recovery to a similar extent when compared with animal protein.

THE EFFECT OF MILK ON RECOVERY FROM REPEATED SIMULATED TEAM-SPORT IN FEMALES

RANKIN, P., CALLANAN, D., OBRIEN, K., DAVISON, G., STEVENSON, E., COCKBURN, E.

INSTITUTE OF TECHNOLOGY CARLOW

INTRODUCTION: Team-sport athletes engage in multiple training sessions or games within short periods of time resulting in insufficient recovery, which can impact subsequent performance. This study investigated the effects of milk on recovery from repeated bouts of simulated team games (STG) in females.
METHODS: In an independent-groups design, 20 female team-sport athletes completed an STG circuit (2x~30min bouts with a 10min 'half-time'). Peak torque, rate of force development (RFD), countermovement jump (CMJ), reactive strength index (RSI), sprint performance, muscle soreness and tiredness, symptoms of stress, serum creatine kinase (CK), high-sensitivity C-reactive protein (hsCRP), lipid hydroperoxides (LOOH) and protein carbonyls (PC) were determined pre- and 24h, 48h, 72h and 96h following the circuit. At 48h, following the measurement of dependent variables, a second STG was completed. Performance (5m and 15m sprint performance, lap time, CMJ), physiological (heart-rate) and perceptual (RPE) measures was recorded during each STG. Immediately following each STG participants consumed either 500ml of milk (MILK) or 500ml of an energy-matched carbohydrate (CHO) solution.
RESULTS: Compared to CHO, MILK had a beneficial effect in attenuating losses in peak torque for knee extension (60◦/s) from baseline (B)-24h (-6 v -10%; likely, small) and B-48h (-5 v -9%; possible, small), knee flexion (60◦/s) from B-24h(-4 v -11%; likely, small), B-48h (-5 v -14%; likely, moderate), B-72h (-2 v -11%; likely, small) and knee flexion (180◦/s) B-48h (-3 v -9%; likely, small). A benefit for MILK was also observed for 5m sprint performance B-24h (-1 v -3%; possible, small), B-48h (-2 v -4%; possible, moderate), B-72h (-2 v -5%; likely, moderate), 10m sprint performance B-48h (-1 v -3%; likely, small), B-72h (-2 v -3%; likely, small) B-96h (-1 v -1%; possible, small) and perception of the symptoms of stress B-24h (12 v 21%; likely, small), B-48h (17 v 32%; very likely, small), B-72h (17 v 30%; likely, small). Unclear outcomes were noted for RSI, CMJ and RFD. Unclear outcomes for serum markers were observed, though a harmful effect for MILK was seen for hsCRP B-2h (factor 1.1 v 0.9; likely, small), B-24h (factor 1.5 v 0.9; likely, moderate), B- 48h (factor 1.2 v 0.7; likely, moderate) and for LOOH B-24h (factor 1.0 v 0.9; likely, small). For STG variables trivial (HR, CMJ) and unclear (5m sprint, 15m sprint, lap-time, RPE) outcomes were recorded.
CONCLUSION: In conclusion consumption of 500ml of milk may be a valuable post-exercise intervention strategy as it attenuated losses in muscle function and perceptions of stress following repeated simulated team-sports games. However, further investigation is warranted to determine if MILK can influence subsequent team-sport performance.

POSTPRANDIAL AMINO ACID CONCENTRATIONS AFTER CONSUMPTION OF DAIRY PRODUCTS

KUDLA, U., VAN DEN BORNE, J.J.G.C., GANZEVLES, R.A., KARDINAAL, A., NIEUWEHUIJSE, J.A., LUYTEN, H., HUPPERTZ, T., HORSTMAN, A.M.H.

FRIESLANDCAMPINA

INTRODUCTION: Sarcopenia has been attributed to a diminished muscle protein synthetic response to food intake. The post-prandial increase in muscle protein synthesis is attributed to the rise in plasma essential amino acids concentrations. Most studies on post-prandial aminoacidemia have been done with isolated proteins rather than consumer products and have thereby focused on protein composition but overlooked the effect of product matrix on protein digestion. Consequently, this study was designed to obtain information about the change in postprandial amino acids in blood over time, after consumption of different dairy products in an older population and how this relates to feelings of satiety.
METHODS: Single-blinded within-subject design (cross-over) with 10 men (n=5) and women (n=5) (66.7±4.3 y, BMI 26±3 kg/m2) receiving 6 dairy products (UHT skimmed milk, pasteurized skimmed milk, fat-free yoghurt, full-fat UHT milk, pasteurized non-homogenized full-fat milk, full-fat cheese (semi-matured)) and 2 milk protein ingredients (solutions of whey protein concentrate (WPC) and micellar casein (MC)), with each portion size (700 mL) containing 25 g of protein on a separate test day, with a 1 wk washout period between treatments. Plasma samples were collected before and at 13 time points up to 5 h after consumption of the dairy products. Appetite profile was evaluated using Visual Analogue Scales.
Generalized Linear Mixed Models were used for maximal concentration values (Cmax) and the time point corresponding to Cmax (Tmax). If significant, Bonferroni correction was used.
RESULTS: Significant differences in the change of plasma amino acid (AA) levels over time were observed between the 8 products ($P<0.001$), with the highest (Cmax=139±17 and 117±9 mg/mL, resp.) increase after WPC and yoghurt consumption (both Tmax=60 min). Slightly earlier (t=30 or 45 min), but lower peaks (Cmax between 50±5 and 91±7 mg/mL) and increased levels over a longer period of time were observed for the 4 milk products. MC and cheese consumption resulted in the most extended AA response curves with Tmax both at t=120 min and Cmax=65±7 and 69±7 mg/mL, resp. Full-fat milk products showed delayed response curves compared to skim milk products ($P<0.05$), whereas UHT treatment showed a consistent, but not significant, effect on changes in plasma AA concentration compared to pasteurization. Cheese consumption was associated with the strongest and longest sensations of fullness and satiety, while least fullness and satiety was reported after consumption of UHT skim milk.
CONCLUSION: The fastest amino acid response is seen after consumption of yoghurt, compared to milk and cheese. The results suggest that the product matrix is perhaps even more important than the protein composition These findings may enable us to modulate the rate of absorption of (specific) amino acids, which will open new possibilities in developing products in the areas of e.g. sports or medical nutrition.

DIFFERENT AMOUNTS OF PROTEIN INTAKE INFLUENCE BODY COMPOSITION AND PERFORMANCE IN ELITE CYCLISTS

PAOLI, A.1, MORO, T.2, MARCOLIN, G.1, GENTIL, P.3, BIANCO, A.4

1> UNIVERSITY OF PADOVA, PADOVA, ITALY; 2> UTMB, GALVESTON, TX, US; 3> FEDERAL UNIVERSITY OF GOIAS, GOIANIA, GO, BRAZIL; 4> UNIVERSITY OF PALERMO, PALERMO, ITALY

INTRODUCTION: A higher protein intake has been recommended for either resistance and endurance athletes compared with sedentary subjects. Although ideal protein intake for strength athletes has been widely investigated, less data are available about protein requirement in endurance athletes.
The aim of our investigation was to evaluated the physiological impact of different dietary protein intakes on body composition and performance outcomes in a group of elite cyclists.

METHODS: Forty elite cyclists (1600-1800 km/month) participated in a randomized design diet intervention. Subjects were divided in 4 groups with different levels of protein diet: normal (NP, 1.2 g/kg), moderate (MP, 1.6 g/kg), high (HP, 2.0 g/kg) or very high (VHP 2.4 g/kg)protein for 8 wk. Diets were designed to be eucaloric: fats were maintained constant whilst energy from carbohydrate and protein was modified to ensure the isoenergetic approach. Body composition was assessed via Dual X Ray Absorptiometry (DXA) and via ultrasound to calculate cross sectional area (CSA) of the anterior thigh. VO2max was calculated through expired gas analysis during an incremental test; peak power output and 1 RM half squat test were also performed. Moreover we executed routinely blood exams.
RESULTS: Five subjects withdrew from the experimental protocol. After two months both HP and VHP showed a significant improvement of 1 RM (HP pre 133±14 Kg vs post 141±12 Kg, p<0.001; VHP pre 137±12 Kg vs post 144±11 Kg, p<0.001), PPO (HP pre 505±78 W vs post 534±67 W, p<0.001; VHP pre 512±55 W vs post 541±76 W, p<0.001), and VO2max (HP pre 62.1±5.8 mlO2/Kg vs post 64.5±5.9 mlO2/Kg, p<0.001; VHP pre 61.2±5,5 mlO2/Kg vs post 64.1±7,6 mlO2/Kg, p<0.001), without differences between groups. There were no significant changes of 1 RM and VO2max for both NP and MP whilst NP showed a slight but significant decrease of PPO from 510±68 to 501±45 W, p<0.05. At the end of the experimental period both HP and VHP showed a significant increase of lean body mass (LBM) (HP pre 64.72±1.9 Kg vs post 65.99±2.2 Kg, p<0.001; VHP pre 65.52±2.0 Kg vs post 67.61±1.7 Kg) whilst both NP and MP showed a significant decrease (NP pre 63.31±2.1 Kg vs post 62.4±2.3, p<0.05; MP pre 66.88±1.8 Kg vs post 65.80±2.9). HP and VHP showed a significant increase of anterior thigh CSA (HP pre 50.5±7.8 cm2 vs post 53.4±6.7 cm2, p<0.001; VHP pre 51.2±5.5 cm2 vs post 54.1±7.6 cm2), MP didn't changed CSA showed a significant decrease from 51.0±6.8 cm2 to 50.1±4.5 cm2. No changes of blood values were detected.
CONCLUSION: Taken together our data suggest that an higher protein intake (2.0 and 2.4 g/Kg) may help elite cyclists to improve performance and to increase muscle mass without differences between the two levels of protein intake. Instead 1.2 and 1.8 g/Kg of protein seemed to be not sufficient for this kind of athletes and could impair performance and muscle mass. Future studies directed at mechanisms by which level of protein intake influences performance outcomes are needed.

THE EFFECT OF WHEY PROTEIN SUPPLEMENTATION ON THE TEMPORAL RECOVERY OF SKELETAL MUSCLE FUNCTION FOLLOWING RESISTANCE TRAINING IN RESISTANCE TRAINED MEN.

DAVIES, R.W.1,2, BASS, J.J.1,2,3, CARSON, B.P.1,2, NORTON, C.1,2, KOZIOR, M.1,2, BROOK, M.S.3, WILKINSON, D.J.3, ATHERTON, P.J.3, SMITH, K.3, JAKEMAN, P.M.1,2

1: HUMAN SCIENCE RESEARCH UNIT, CENTRE FOR INTERVENTIONS IN INFECTION, INFLAMMATION & IMMUNITY <4I>, UNIVERSITY OF LIMERICK, IRELAND. 2: FOOD FOR HEALTH IRELAND , PHYSICAL EDUCATION AND SPORT SCI

INTRODUCTION: The recovery of muscle contractile function between successive resistance training (RT) bouts is a determinant of the adaptation to a regimen of RT. Whilst whey protein (WP) augments peri-RT muscle protein synthesis, its effect on the acute recovery of contractile function is equivocal (Davies et al., 2018). This study investigated the effect of supplemental whey protein on the recovery of skeletal muscle contractile function during repeated bouts of RT.
METHODS: Sixteen resistance-trained men (80 [13] kg body mass; 23 [4] y; 2.6 [1.2] y RT experience; mean [SD]) were recruited and habituated to all test procedures. A 7-day dietary supplement intervention study was undertaken using a randomised, double-blind, parallel group design. For the duration of the study subjects consumed a standardised and timed nutrient intake (35 kcal/kg/day; 2 g/kg/day protein; 4.5 g/kg/day carbohydrate; 1g/kg/day fat). Following an overnight fast, subjects were randomly assigned to consume each morning either a WP supplement (WP; n = 8) or an isocaloric, isonitrogenous, non-essential amino acid control (CON; n = 8), dosed at 0.33 g/kg body mass, constituting 17 % of total protein intake.
Peak isometric force attained performing an isometric back squat (PIF) and maximal countermovement jump (CMJ) displacement were used to assess baseline muscle function. Subjects then completed three RT bouts (0.7 1RM back squat; 10 repetitions per set; 0.25 duty cycle; mean point of exhaustion = 8 [2] sets), every other day. Other activities of daily living did not exceed 3 metabolic equivalents. Repeat measurement of PIF, CMJ, muscle pain and serum creatine kinase (CK) activity (an index of muscle damage) was taken pre-RT, +24h and +48h post-RT, each bout. The observed change reported as the mean [low, high] 90% CI, p-value (P) and effect size d (ES).
RESULTS: A 1.0 [0.7, 1.3] fold increase (P < 0.008; ES = 1.0) in CK and muscle pain (20 [10, 30] %; P = 0.011; ES = 1.3) was observed +24h the first RT bout only, confirming that no overt exercise-induced (EIMD) had occurred. An acute loss of PIF was observed following all RT bouts +24h (-19 [-21, -17] %; P < 0.001; ES > 2.0) and +48h for PIF (-19 [-21, -17] %; P < 0.001; ES > 2.0), and +24h for the CMJ (-7 [-9, -5] %; P < 0.05; ES > 0.7). No discernible difference or time x treatment interaction between WP and CON for any measure of function, pain, or CK (ES < 0.4; P > 0.493).
CONCLUSION: This study describes the magnitude and temporal change in skeletal muscle function following single and repeated bouts of RT in resistance-trained athletes. The outcome of the intervention does not support the use of a WP supplement, optimised for enhancement of muscle protein synthesis, to enhance recovery of muscle contractile function. We conclude that, whilst peri-RT supplementation with WP augments muscle protein synthesis, further inference of this pro-anabolic effect should not extend to acute (0 to 48 h) recovery of peri-RT muscle function.

THE EFFECT OF BRANCHED-CHAIN AMINO ACIDS, ARGININE, AND CITRULLINE ON REPEATED SWIMMING PERFORMANCE

HSUEH, C., CHANG, C.

NATIONAL TAIWAN UNIVERSITY OF SPORT

INTRODUCTION: Introduction: Branched-chain amino acids (BCAA) could reduce cerebral uptake of tryptophan, leading to decreased synthesis of serotonin in the brain. Arginine and citrulline could reduce exercise-induced hyperammonemia by increasing nitric oxide synthesis and urea cycle. The combination of these supplements could reduce exercise-induced central fatigue. The purpose of this study was to examine the effect of BCAA, arginine, and citrulline supplementation on repeated swimming performance in teenage athletes.
METHODS: Methods: Eight male and eight female high school swimmers ingested 0.085 g/kg BCAA, 0.05 g/kg arginine and 0.05 g/kg citrulline (AA trial) or placebo (PL trial) in a randomized cross-over design. One hour after the ingestion, the subjects performed a 50 m sprint with their best style every 2 min for 8 times in an indoor 25-m pool. The subjects were asked to swim with their maximal effort each time. The time, stroke frequency and stroke length in each sprint were recorded. Venous blood samples were collected before and after the exercise. The time for each sprint was analyzed by 2-way analysis of variance with repeated measurement.
RESULTS: Results: When all subjects were pooled together, total time for the AA trial was significantly faster than the PL trial (AA: 244.02±22.94 s; PL: 247.55±24.17 s, p<.001). Individual sprint time showed significant trial (p=.001) and trial x time (p=.004) effects. The post-hoc analysis revealed that the AA trial was significantly faster than the PL trial in the 2nd, 5th, and 6th sprint. In female subjects,

there is a significant trial effect (p=.004) with the AA trial being faster in all except the 6th sprint. On the other hand, the trial effect was not significant (p=.072) in male subjects. The AA trial showed significantly lower plasma tryptophan/BCAA ratio. Plasma urea concentration was significantly higher in the AA trial than the PL trial (trial effect p=.023) in females but not males. Plasma concentrations of ammonia and nitric oxide were similar in both trials.
CONCLUSION: Conclusions: The combined supplementation could improve 8 x 50 m performance in high school swimmers, especially in females. The improvement may be the result of alleviated central fatigue, indicated by the lower tryptophan/BCAA ratio.

Oral presentations

OP-BN13 Motor and cognitive training in children

DOES SCHEDULING OF OBJECT CONTROL AND LOCOMOTOR ACTIVITY RESULT IN DIFFERENT EFFECTS ON MOTOR COMPETENCE DURING INTEGRATED NEUROMUSCULAR TRAINING IN 6-7 YEAR OLD CHILDREN?

DUNCAN, M.J., HAMES, T., EYRE, E.L.J.

COVENTRY UNIVERSITY

INTRODUCTION: Combining opportunities to develop fundamental motor skills (FMS) alongside strength and power has most recently been termed 'integrated neuromuscular training (INT) and is becoming increasingly popular as a means to enhance children's motor competence (Fort-Vanmeerhaeghe, et al., 2016). Although INT is effective in enhancing children's FMS and fitness (Duncan et al., 2017), one key aspect that has yet to be examined is whether scheduling of INT activities has an impact on the training response. This study examined whether ordering of object control (e.g., throwing, catching) and locomotor skills (e.g., running, jumping), within an INT program, results in different responses in FMS, muscular fitness and perceived motor competence in 6-7 year old children.
METHODS: Following ethics approval and informed consent 140 children from 3 primary schools were randomised into three, 10-week interventions, Loco First (n = 50) where locomotor skills were dlivered first followed by object control skills; Object First (n =48) where object control skills were delivered first followed by locomotor skills or a control group (n =42, CON) who undertook standard school Physical Education. FMS and muscular fitness were assessed pre and post the 10 week intervention period. FMS: run, jump, throw, and catch were assessed using the Test of Gross Motor Development-2. Three measures of muscular fitness; 10m flying sprint time (secs), standing long jump (cm) and seated 1kg medicine ball (cm) throw were assessed. As baseline scores for FMS differed between groups, data were analysed using ANCOVA with post intervention scores for each variable as the dependent variable and baseline values as the covariate. Gender and Group (Loco First, Object First, CON) were used as between subjects factors.
RESULTS: Results indicated greater total FMS in Loco First and Object First vs CON (P = 0.001) with the increases in FMS being greater for Object First vs Loco First (P = 0.001). Sprint speed (10m) was lower for Object First vs CON (P = .024). Standing long jump distance was greater in Loco First vs CON (P .0001) and Object First (P = .0001). Seated medicine ball throw distance was greater for Loco First and Object First vs CON (Both P = .001).
CONCLUSION: This study suggest that a 10 week INT program in lieu of PE results in positive improvements in FMS and muscular fitness in 6-7 year olds compared to statutory PE. However, scheduling object control skills before locomotor skills within INT has a greater effect on total FMS and muscular fitness in 6-7 year old children.

AGE AND SEX DIFFERENCES IN BALANCE PERFORMANCE IN YOUTH: A SYSTEMATIC REVIEW AND META-ANALYSIS

SCHEDLER, S.1, KISS, R.2, MUEHLBAUER, T.1

1: UNIVERSITY OF DUISBURG-ESSEN, 2: BIELEFELD UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: During childhood and adolescence, neural and muscular capacities responsible for postural control are still emerging (Shumway-Cook & Woollacott, 1985) and particular the former diverge between males and females (Lenroot & Giedd, 2010). This may lead to age- and sex-related differences in postural control potentially affecting the trainability of balance performance in youth. Thus, the aim of this study was to quantify age and sex differences in balance performance in healthy children and adolescents.
METHODS: A systematic literature search was performed in the databases of PubMed, Web of Science, and SPORTDiscus. Inclusion criteria were as follows: (i) participants were healthy non-athlete minors, (ii) at least one measure of balance had to be reported for children (6-12 years) and adolescents (13-18 years) or boys and girls. Weighted standardized mean differences (SMD) were calculated for comparisons of balance performance between age groups (SMDba) and between sexes (SMDbs).
RESULTS: Thirty-four out of 1,366 studies met our inclusion criteria. Data of 7,616 children and 1,037 adolescents was analyzed and revealed a medium-sized effect of age on balance performance in favor of adolescents (SMDba: 0.69). Subdivided by type of balance measure, we observed large effects for static steady-state balance (SMDba: 1.25) and small effects for dynamic steady-state balance (SMDba: 0.25) as well as proactive balance (SMDba: 0.28) in favor of adolescents. Data of 9,537 youths (6-19 years; 5,015 females) was analyzed to study sex differences in balance performance in youth and showed a small effect in favor of girls compared to boys (SMDbs: 0.01). Further analysis revealed a small effect favoring girls for measures of static steady-state balance (SMDbs: 0.28) and a small effect in favor of boys for measures of dynamic steady-state (SMDbs: -0.06) and proactive (SMDbs: -0.19) balance.
CONCLUSION: Results indicate that adolescents outperform children in different measures of balance, which might be attributed to their advanced neural maturation. From a practical perspective, this may influence trainability of balance performance, either in favor of adolescents due to their advanced neural maturation or in favor of children due to their larger adaptive reserve. Regarding sex differences, girls showed better performances in measures of static steady-state balance but not in dynamic steady-state and proactive balance. These inconsistent results and their effects on trainability of balance performance require further research.

THE ROLE OF MOTOR COORDINATION ON EXECUTIVE FUNCTION IN CHILDREN WITH AND WITHOUT AUTISM SPECTRUM DISORDER

MA, W.Y.1, HUNG, T.M.1, HUANG, C.Y.2, SUNG, M.C.2, CHEN, P.L.2, PAN, C.Y.2
1: NATIONAL TAIWAN NORMAL UNIVERSITY , 2: NATIONAL KAOHSIUNG NORMAL UNIVERSITY

Introduction: Autism spectrum disorder (ASD) is a developmental disorder characterized by impaired social interaction, communication, and behavioral development (APA, 2013). Some of the everyday social and non-social behaviors seen in children with ASD may reflect specific executive dysfunction (Rajendran & Mitchell, 2007). In addition, clinicians now recognize that children with ASD experience delayed or impaired motor development (Staples & Reid, 2010). Research suggests important links between motor coordination and executive function (EF) in typically developing (TD) children. To date, information on motor coordination and EF in children with ASD is scarce, and no published study has examined whether there is an association between these two domains in primary school-aged children with ASD.
Methods: Forty-eight children with ASD and 48 TD children, aged 6-12, participated. Motor coordination and EF were measured by using the Bruininks-Oseretsky Test of Motor Proficiency-2 (BOT-2), the Stroop Color and Word Test, the Wisconsin Card Sorting Task (WCST), and the Go/No-go Test. Independent group t tests were used to compare the BOT-2 and EF measures between children with ASD and TD children. Pearson product-moment correlation coefficients were computed to assess the relationships between the BOT-2 scores and the EF measures for each group.
Results: Findings indicate that (a) children with ASD performed significantly poorer than TD children on all four BOT-2 composite scores (all $p < .01$; fine manual control, manual coordination, body coordination, strength and agility) and a total motor composite ($p < .01$), (b) children with ASD demonstrated significantly poorer on EF measures (Stroop interference; WCST total correct, perseverative responses, and conceptual level response; Go/No-go 1-target and 2-taget correct responses) than TD children (all $p < .05$), and (c) children with ASD showed significant more associations between motor coordination and EF than TD children.
Discussion: Continued development of motor coordination in children with ASD is important. Our results demonstrate that motor coordination is a significant correlate of EF in children with ASD, suggesting that further research is required to explore these preliminary findings of potential advantages of motor coordination in promoting EF through physical activity settings for children with ASD.

AGE-DEPENDENT ADAPTATIONS TO ANTICIPATED AND NON-ANTICIPATED PERTURBATIONS AFTER BALANCE TRAINING IN CHILDREN

WÄLCHLI, M., KELLER, M., RUFFIEUX, J., MOUTHON, A., TAUBE, W.
UNIVERSITY OF FRIBOURG

INTRODUCTION: Postural control undergoes rapid changes during child development with improvements in postural responses to perturbations (Westcott & Burtner, 2004). However, postural responses to externally triggered anticipated and non-anticipated perturbations and the influence of balance training (BT) on such postural responses have not yet been investigated in children. This aspect seems very interesting when considering that responses to anticipated and non-anticipated perturbations require different postural control strategies, i.e. feedforward control in anticipated and feedback control in non-anticipated situations. In this regard, it was suggested that children younger than 8 years may not yet have the ability for appropriate feedforward controlled responses (Hay & Redon, 1999).
METHODS: Twelve young (6.7±0.6 years) and 18 older children (12.0±0.4 years) were exposed to externally induced anticipated (direction known) and non-anticipated (direction unknown) perturbations before (PRE) and after (POST) 5 weeks of BT. Age-matched children (9 young and 9 old) served as control groups and attended regular physical education during the 5 weeks between the PRE and the POST measurement.
RESULTS: In PRE-measurements, older children swayed less than younger children after perturbations ($p = .004$). However, no differences were found within age groups between perturbation conditions. Adaptations from PRE to POST between children exposed to BT and the control group were different ($p < .001$). Trained children decreased the sway path (-11.1%), whereas the control group did not improve their performance (+2.7%). Post-hoc analysis of the younger children exposed to BT revealed similar adaptations in anticipated and non-anticipated situations (-7.9% vs. -12.6%; $p = .278$). In contrast, the older intervention group improved significantly more in anticipated (-15.1%) than in non-anticipated perturbations (-8.2%; $p = .026$).
CONCLUSION: At baseline, older children performed better in both perturbation conditions than younger children, assuming that the postural control system was more matured in the older group. However, neither of the two age groups swayed less in the anticipated condition, may indicating that before the BT the children could not profit from previous knowledge about the direction of the perturbation. When exposed to 5 weeks of BT, only the older intervention group showed superior adaptations in anticipated compared to non-anticipated situations. Thus, the older children had better learned to benefit from prior information in the feedforward controlled situation. This finding supports the previously mentioned suggestion (Hay & Redon, 1999) that feedforward control develops at a later stage than feedback control and requires a more mature postural control system.

INTEGRATIVE NEUROMUSCULAR TRAINING PROGRAM TO IMPROVE MOTOR COMPETENCE IN PRIMARY SCHOOL CHILDREN. AN EXPLORATORY INVESTIGATION

FONT-LLADÓ, R., FORT-VAN MEERHAEGHE, A., PRATS-PUIG, A.

UNIVERSITAT DE GIRONA

Introduction: Fundamental movement skills (FMS) such as motor skills associated with locomotor, manipulative, and balance are elementary units of movement which are necessary to be mastered to achieve more specialized movement and engaging children in regular participation in physical activity. Integrated neuromuscular training (INT) is a specific methodology that focuses on the development of FMS and physical fitness in order to achieve motor competence.
Objective
To assess an INT program designed specially to improve motor competence in prepubertal children (8yr) performed during PE lessons in primary schools.
Methods: Participants: 45 children [23 boys, 22 girls; age 7.6•0.3 yr] were included in the PEHC (Physical Education, Health and Children) project. Recruited from 2 schools in a Northern Spain region, randomly divided into either a control (learn to swim) or intervention (INT program and learn to swim) group.
Procedure: Preintervention testing includes the Canadian Agility and Movement Skill Assessment (CAMSA) which measured 7 movement skills in a dynamic environment. Intervention: The INT program incorporates FMS and specific strength and conditioning tasks. It lasts 3 months: 20 minutes, 2 days x week and 24 sessions in total. All sessions were executed during the warm up of Physical Education (PE) lessons and were supervised by 2 persons: 1/ the PE teacher previously formed in INT and 2/ an expert in INT. All sessions integrated increasingly difficult tasks in different aspects: FMS, lower extremity strength, general coordination, general strength, pliomtrey tasks, velocity situations, core strength, and static balance, and use different methodologies (circuits, games, and introjective exercices). Experts provide constant corrective feedback. Postintervention data collection followed the same procedure used for preintervention.
Results: After training, changes in motor skills competence between the INT and control group were evident. The total score for motor competence increased by 4 points in the INT group ($p<0.0001$) and also an increase can be seen in the locomotion and manipulative skills scores ($p<0.0001$ and $p=0.039$, respectively). Compared with the control group, the intervention group improved motor competence ($p=0.018$) including locomotion skills ($p=0.045$) as well as manipulative skills ($p=0.044$). The CAMSA doesn't allow to isolate the balance skills.
Conclusion
In the current study we provide evidence for use this INT protocol adapted to be carried on warm-up in a PE lessons in primary school to improve the FMS in children. The effectiveness of the INT program have been shown only in the intervention group. Those results can be explained by a) integrates conditional capacities in a specific way for the FMS benefist, b) gradually increase the level of difficulty, b) provides an unstable base of support, introducing challenge to core control and lower extremity alignment , c) gives verbal instructions to improve performance

Invited symposia

IS-MI05 Counteracting age-related loss of muscle mass and independence: Experiences from the interdisciplinary CALM-study conducted in the Greater Copenhagen area.

EFFICACY AND EFFECTIVENESS OF RESISTANCE TRAINING AND NUTRITION INTERVENTIONS TO MAINTAIN MUSCLE MASS AND FUNCTION

GREIG, C.

UNIVERSITY OF BIRMINGHAM

Counteracting Age related Loss of skeletal Muscle mass (CALM) is an ambitious interdisciplinary project, at the heart of which sits a combined resistance exercise training (RET) and protein supplementation intervention undertaken at scale (n=208) in independently living older men and women (Bechshoft et al., 2017). The rationale underlying this combined approach, i.e., that exercise can stimulate skeletal muscle responsiveness to protein intake of a particular magnitude and quality both acutely and chronically, is based mainly upon data from younger adults. The accumulating literature relating to older adults is more equivocal, although recent systematic reviews suggests that responsiveness in older adults is reduced compared with young (Morton et al., 2017). Furthermore, additional protein intake in adults who already consume sufficient protein (in the case of CALM 1.1 g/kg/day), may confer no additional benefit to muscle health compared with RET alone, although frailer older adults with suboptimal protein intake based upon recent recommendations, may benefit. The pattern of daily protein intake, rather than the total amount, may be important with administration of 'supra-threshold doses' at regular intervals either with or without exercise, being proposed as an effective regimen to accrue muscle mass (Moore et al., 2015). Again, the data relating to chronic studies in older adults eliciting positive changes in muscle function or body composition in response to training are both limited and equivocal. CALM's multi- and interdisciplinary approach has provided a much needed platform from which to explore combined interventions manipulating exercise intensity and quality of protein supplementation in parallel with innovative approaches centred upon food product development and perceptions of protein consumption and exercise. Together the data highlight the need for the design of future RCTs to be undertaken with knowledge and understanding of social, cultural, and historical influences. Otherwise, the ability to implement particular regimens, even those which have efficacy, may be at best challenging and at worse, ineffective.

SOCIETAL CONSTRUCTION TO SUPPORT AND MOTIVATE HEALTHY AGING

ULIJASZEK, S.

UNIVERSITY OF OXFORD

INTRODUCTION: Despite progressive chronological and biological aging, elderly individuals may have up to several decades of good and active life beyond retirement. New approaches are needed to reframe people post-retirement as being socially and economically important. This presentation will examine the importance of creating and maintaining community, both physically and virtually, to healthy aging.
METHODS: Critical reading of anthropological, sociological, public health and biosciences literature on healthy aging, to create a biocultural perspective on healthy aging in relation to physical activity and sociality.
RESULTS: Societal participation and social communication among aging populations are as important to health and well-being in this group as good diet and physical activity. Environmental, physical, political and social structures interact with human behaviour in maintaining healthy diet, adequate bone and muscle mass.
There are different ways in which physical activities, such as walking and hiking groups, and social dancing help to counter the erosion of social and cultural capital associated with aging, and provide informal support into later life.
CONCLUSION: Societal participation and social communication among aging populations are as important to health and well-being in this group as good diet and physical activity. This should be structured into everyday life politically and behaviourally.

AN ACTIVE OLD LIFE – RATIONALES FOR PARTICIPATION IN A RCT FOCUSING ON PHYSICAL ACTIVITY

JESPERSEN, A.

UNIVERSITY OF COPENHAGEN

Introduction: In this presentation, I will explore the arguments and rationales for participating in a RCT study, focusing on physical activity and healthy lifestyle, as the participants in the trial stated them. In my presentation I will follow a resent proposal in social science to use 'health practices', as an alternative to the concept of 'health behaviour', which tends to separate peoples' engagements with matters of health and illness from the social, political, cultural and economic contexts [Cohn, 2014, Blue et al., 2016]. The argument is that a focus on health practices, i.e. as locally situated and composite everyday doings will provide a much better understanding of the situated conditions that shape peoples (non-)participation in health practices, such as physical activity, in everyday life contexts [Cohn, 2014].
Methods: Based on a selection of short, qualitative interviews (N=50) conducted at baseline with research participants in the CALM study, I examine the personal and practical conditions that the participants pointed to as significant for their engagement with the trial.
Discussion: Understanding the rationales of participation from the point of view of the participants not only allows an understanding of the meticulous efforts invested by the participants in engaging in - in this case an intervention study – but also more broadly in changing lifestyle. It also allows for designing health interventions more appropriately, i.e., interventions that accommodate different rationales and encourage meaningful processes of change.

OP-BN14 Neuromuscular control

MOTOR UNIT CONTROL PROPERTIES IN ECCENTRIC AND CONCENTRIC EXERCISE

KLINE, J.C., SHIWANI, B., ROY, S.H., CHIODINI, J.P., DE LUCA, G.

DELSYS INC. AND ALTEC INC.

INTRODUCTION: The mechanisms used by the central nervous system to coordinate movement during training, exercise and rehabilitation remain poorly understood. Today the most common approaches for investigating the control of human movement typically infer neural control mechanisms using biomechanical measurements from motion capture, instrumented force plates or inertial measuring systems. A more practical solution for directly accessing neural mechanisms of human movement is to develop new ways of analyzing the surface electromyographic signal that can leverage the advanced capabilities and diverse applications of modern wireless sEMG systems. Our group has been working to develop sensors and algorithms for automatically measuring the action potentials of individual motor units directly and noninvasively from the sEMG signal. But while current sEMG decomposition algorithms can be used to study neural control during isometric contractions or constrained cyclic contractions, there remains an unmet need for measuring the motor unit contributions during unconstrained exercise, training and natural human movement.
METHODS: To achieve this goal, we are advancing our decomposition algorithms to overcome three primary challenges of extracting motor unit data from sEMG signals recorded during dynamic movement: 1> tracking non-stationary changes in motor unit action potential shapes that occur with position and length changes of the muscle fibers, 2> improving the temporal resolution of firing rate measurements across dynamically varying activities, and 3> localizing firing detections amongst complex superpositions typically encountered in non-cyclic exercise. We tested these algorithms on n=5 control subjects <3 males, 2 females, mean age 32.8 ± 12.6 yr.> using sEMG signals recorded with the dEMG acquisition system from the biceps brachii muscles during resistive exercise involving both concentric and eccentric contractions at different speeds.
RESULTS: Results from all subjects tested indicated that the algorithms were able to identify a broad range of motor units from 8 to 24 above the 90% accuracy benchmark. The measured activity indicated clear differences in motor unit firing behavior between the concentric and eccentric phases of the exercise, with relatively higher firing rates and greater rate changes during concentric contractions and lower firing rates and more gradual rate changes during eccentric contractions.
CONCLUSION: These results mark a first step towards delineating the neural contributions to dynamic exercise and training, and hold promise for new research opportunities to use quantitative measure of neural control mechanisms to design more efficient training and exercise paradigms and tailor rehabilitation protocols to motor unit-based outcome measures.

INFLUENCE OF CONTRACTION INTENSITY ON NEUROMUSCULAR ADJUSTMENTS DURING A SUSTAINED FATIGUING CONTRACTION IN HAND MUSCLE

ABDELMOULA, A., BAUDRY, S., DUCHATEAU, J.

UNIVERSITÉ LIBRE DE BRUXELLES

INTRODUCTION: During sustained submaximal voluntary contractions, the neural and muscular systems undergo numerous changes with some of them limiting the time to task failure (1). The contributions of neural and muscular changes in time to task failure may vary with the target force to be maintained (2). This work examines the influence of contraction intensity on spinal and supraspinal excitability, and muscle tissue oxygenation during a submaximal voluntary contraction performed with the abductor pollicis brevis (APB).
METHODS: Twelve subjects sustained an isometric contraction at 25 and 50 % of the maximal voluntary contraction (MVC) force until failure with APB in separate sessions. MVC force was measured before and at the end of the sustained contractions. Surface electromyography (EMG), motor evoked potentials (MEP) induced by transcranial magnetic stimulation, short (H) and long latency (LLR) reflex were recorded during the contraction, and responses expressed relative to the maximal compound muscle action potential (Mmax). Muscle tissue oxygenation assessed by near-infrared spectroscopy (NIRS) was measured during the contraction.
RESULTS: As expected, the time to failure was longer for the task performed at 25% (275±90s) than at 50% MVC (113±46s; $p<0.05$). The MVC force decreased ($p<0.05$) by 50±14% and 45±10% at failure for 25% and 50% MVC tasks, respectively. At the end of the sustained contractions, the EMG activity was increased but did not differ between the two contractions (62% and 69 % for 25% and 50% MVC; $p=0.10$; respectively). Muscle tissue oxygenation decreased less during the sustained contractions performed at 25 (-76%) than 50% MVC (-87%; $p<0.001$). M wave area decreased with similar extent at 25% and 50% MVC. Normalized MEP and H reflex area increased with a similar extent during both sustained contractions. In contrast, LLR increased more at 25% (+92%) than 50% MVC (+41%; $p=0.03$).
CONCLUSION: These results suggest that intensity-related differences in muscle oxygenation may have influenced the sensory signal. The different magnitude of change in LLR response in the two contractions without difference in MEP changes between contractions requires, however, further investigations to resolve this apparent discrepancy.

A SINGLE SESSION OF REMOTE ISCHEMIC PRECONDITIONING DOES NOT ENHANCE FINE MOTOR SKILL LEARNING

FISCHER, J., HEGTMANN, C., HENRIKSEN, M.R., KROGH, M., KROGH, M., THOMSEN, G.V., LARSEN, R.G., STEVENSON, A.J.T.

AALBORG UNIVERSITY

INTRODUCTION: Five sessions of remote ischemic preconditioning (RIPC) can enhance gross motor learning (Cherry-Allen et al., 2015, J Neurophysiol, 113(10); Cherry-Allen et al., 2017, J Motor Behav, 49(3)). The aim of this study was to investigate the effect of one session of RIPC on fine motor skill learning. A single session of high intensity exercise is found to improve motor learning (Roig et al., 2012, PLoS ONE, 7(9); Thomas et al., 2016, PLoS ONE, 11(7)), and it is suggested exercise could be considered as a form of RIPC (Hess et al., 2015, Nat Rev Neurol, 11(12)). However, no research has investigated the effect of one session of RIPC when learning a fine motor skill. We hypothesized that a RIPC group will improve performance during retention and transfer tests compared to a sham group.
METHODS: 24 healthy young adults were randomized and stratified by gender into two groups and underwent either five sets of RIPC with 200 mmHg or sham conditioning with 20 mmHg applied to the left arm. Participants then completed five four-minute blocks of visuomotor accuracy-tracking task (VAT) training using the dorsiflexor muscles of the dominant leg, followed by a bilateral transfer test consisting of one block of VAT. To test retention and transfer effects, a single block of VAT was performed in each leg after one day and after one week. Data were analyzed using two-way between-within subjects ANOVAs for retention and transfer blocks separately.
RESULTS: No time-by-group interactions for VAT block performance were identified. There were main effects of time such that both groups improved VAT performance compared to baseline, including retention and transfer.
CONCLUSION: One session of RIPC did not enhance motor learning on a fine motor skill compared to a sham group. Our results provide novel information indicating that a single session of RIPC is inadequate in enhancing motor learning. Future studies are needed to investigate the dosage of RIPC required to enhance motor learning, which may have implications for rehabilitation strategies.

LOAD DEPENDENCY OF THE STRETCH SHORTENING CYCLE - CORRELATION OF MUSCLE ACTIVITY AND RATE OF FORCE DEVELOPMENT

FREYLER, K., KRAUSE, A., GOLLHOFER, A., RITZMANN, R.

UNIVERSITY OF FREIBURG

INTRODUCTION: During bouncing, the stretch-shortening-cycle (SSC) describes the muscular activation pattern and is defined by a stretching of a pre-activated muscle-tendon complex immediately followed by a muscle shortening in the concentric push-off phase (Komi 1984). Regarding the efficiency of bounces, two factors seem to be of considerable importance: the muscles pre-activation that determines an appropriate level of stiffness before initial touchdown (Avela et al. 1996) and the reflex activity after touchdown, which is supposed to contribute to the muscles force enhancement during the eccentric phase (Komi & Gollhofer 1997). Both factors are assumed to be modulated in response to load variation (Taube et al. 2012), and loading is considered to be of major relevance for the force-generating capacity in the SSC. This study aimed to identify load-dependent changes in biomechanical and neuromuscular characteristics of the SSC during bouncing in reduced loading conditions. For that purpose, neuromuscular control of lower limb muscles as well as correlations between the muscles pre-activation, reflex components and the force output have been assessed in 0.16g, 0.38g and 1g.
METHODS: Experiments were executed during a parabolic flight campaign. In 8 subjects, peak force (Fmax), ground contact time (GCT), rate of force development (RFD), jump height (H), momentum and jump frequency were measured. Electromyographic activities (EMG) in M. soleus (SOL), gastrocnemius medialis (GM) and tibialis anterior (TA) were assessed before (PRE) and during ground contact for the reflex phases short-, medium- and long-latency response (SLR, MLR, LLR).
RESULTS: With gradually decreased g-forces Fmax, RFD, momentum and jump frequency were reduced, while GCT and H increased ($P<0.05$). Concomitantly, EMG activity decreased in GM for PRE, SLR, MLR and LLR and in SOL for SLR, MLR and LLR ($P<0.05$). Fmax as well as RFD were positively correlated to SOL EMG in SLR and MLR ($P<0.05$), RFD and Fmax were positively correlated to GM EMG during PRE and LLR ($P<0.05$).

CONCLUSION: Findings emphasize that biomechanically relevant adaptations in response to load-variation were accompanied by muscle- and phase-specific modulations in neural control (Komi 1984). Gravitational variation is anticipated and compensated by a load-adjusted muscle activity. Importantly, pre-activation and reflex phases were differently affected: in the reflex phases SLR and MLR, SOL is assumed to contribute to the decline in force output with decreasing load and complementary in PRE and LLR, GM seems to be of major importance for force generation.

PROTECTIVE EFFECT ON ECCENTRIC EXERCISE-INDUCED MUSCLE DAMAGE BY MAXIMAL ISOMETRIC CONTRACTIONS OF THE CONTRALATERAL LEG

CHEN, T.C.1, TSAI, S.H.1, HO, C.C.1, HUANG, G.L.1, LAI, J.H.1, TSENG, K.W.2, NOSAKA, K.3
1 NATIONAL TAIWAN NORMAL UNIVERSITY, 2 UNIVERSITY OF TAIPEI, 3 EDITH COWAN UNIVERSITY

INTRODUCTION: The magnitude of muscle damage of the elbow flexors is attenuated when the same exercise is repeated by not only the same muscle but also the homologous muscle of the contralateral arm within 4 weeks, which is known as the contralateral repeated bout effect . It has been also reported that two maximal voluntary isometric contractions of the elbow flexors at a long muscle length confer protective effect against maximal eccentric contractions of the contralateral arm performed within 2 days later . However, it is not known whether other muscles than the elbow flexors show this contralateral effect. Thus, the present study investigated the hypothesis that 10 MVIC of the knee flexors would attenuate the magnitude of muscle damage after 100 maximal eccentric contractions <100 MaxEC> of the knee flexors performed by the contralateral leg. This study also compared the magnitude of the protective effect between the contralateral condition and ipsilateral condition in which 10 MVIC and 100 MaxEC were performed by the same leg.
METHODS: Young <20-22 y> men were randomly placed to one of the three groups ; an ipsilateral , a contralateral , or a control group. The IL and CL groups performed 10 MVIC at 20o knee extension at 2 days before 100 MaxEC performed by the opposite leg and the same leg, respectively, and the control group performed two bouts of 100 MaxEC with the non-dominant leg in 2-week apart. Changes in maximal voluntary concentric contraction torque of the knee flexors , range of motion of the knee joint , plasma creatine kinase activity and muscle soreness of the knee flexors before, immediately after and for 5 days after 100 MaxEC were compared between the groups by a mixed-design two-way ANOVA.
RESULTS: MVC-CON, ROM, SOR and CK did not change significantly after 10 MVIC, but changed significantly after 100 MaxEC for all groups. However, the changes in these variables after 100 MaxEC were smaller for the CL and IL groups when compared with the first bout of the control group. When comparing the CL and IL groups, the changes after 100 MaxEC were greater for the CL group than IL group <-7%, 11 mm>. The changes in MVC-CON, ROM and SOR after 100 MaxEC were not significantly different between the IL group and the second bout of the control group, but were greater for the CL group than the second bout of the control group.
CONCLUSION: These results supported the hypothesis that 10 MVIC reduced muscle damage of the contralateral leg, and showed that the magnitude of the protective effect conferred by 10 MVIC was less for the CL than IL condition. It is concluded that MVIC at a long muscle length confer protective effect on the homologous muscle of the contralateral limb, and this adaptation is evident for not only for arm but also leg muscles.

RELIABILITY OF ULTRASONOGRAPHY TO MEASURE VASTUS LATERALIS MUSCLE THICKNESS AND PENNATION ANGLE USING A STANDARDISED OPERATING PROCEDURE.

THORNLEY, I., JOHNSON, M.I., FRANCIS, P.
LEEDS BECKETT UNIVERSITY

INTRODUCTION: Ultrasonography (US) is a portable imaging technique that can be used to quantify skeletal muscle thickness (MT) and subsequently, estimate skeletal muscle mass. In addition to thickness, architectural properties of skeletal muscle such as pennation angle (PA) can be estimated using US. Reliability has previously been reported for the measurement of MT and PA using US.[1] However, there is inconsistency in the methods used and the clarity of their reporting. To overcome this, a systematic review of the literature was conducted, and a standardised operating procedure for measuring vastus lateralis MT and PA was developed.
The aim of this study was to assess the intra rater reliability of ultrasonography to measure vastus lateralis MT and PA using a standardised operating procedure.
METHODS: Following ethical approval from the Leeds Beckett University research ethics 16 healthy adults (males=8, females=8) aged 24-61 years, provided written informed consent to have measurements of vastus lateralis MT and PA taken. Participants were supine with the knee hanging over the edge of a medical plinth to create a relaxed 90° angle. The measurement site was identified by measuring 50% of the distance between the greater trochanter and the lateral femoral condyle; this was then marked. The transducer (5cm in width) was placed on the marked site and three separate images were captured on the right leg of each participant using the ultrasound (LOGIQ E, GE Healthcare). Images were downloaded to Image J where MT and PA were measured for each of the three separate images captured. The intra class correlation coefficient (ICC) and associated 95% confidence interval (95% CI) were calculated in SPPS (version 24) using a 2-way mixed-effects model (absolute agreement). The standard error of measurement (SEM) for MT and PA was obtained using the formula: Pooled SD x Sqrt(1 - ICC).
RESULTS: Excellent levels of intra-rater reliability was achieved for MT (ICC= 0.98; 95% CI 0.97-0.99; p>0.01) and PA (ICC=0.99; 95% CI, 0.97-0.99; p>0.01). The SEM was 0.03cm for MT and 0.08° for PA.
CONCLUSION: Excellent levels of intra-rater reliability and a small SEM could be obtained in the measurement of vastus lateralis MT and PA using a newly established standardised operating procedure. These results were demonstrated in a heterogeneous sample (age and activity levels). This study is the first to report the reliability of MT and PA measurements using a standardised operating procedure. More-

over, it is the first study to provide a clear and reliable standardised operating procedure available for use in the measurement of vastus lateralis MT and PA.

SITE- AND GENDER-DIFFERENCES IN MORPHOLOGICAL AND MECHANICAL PROPERTIES OF THE PLANTAR FASCIA IN ASYMPTOMATIC YOUNG INDIVIDUALS

SHIOTANI, H.1, YAMASHITA, R.2, MIZOKUCHI, T.2, KAWAKAMI, Y.3

WASEDA UNIVERSITY

INTRODUCTION: The plantar fascia (PF) is a dense connective tissue primarily contributing to the foot arch support. Previous studies revealed that the proximodistal site- and gender-differences exist in plantar fascia thickness (Crofts et al., 2014; Huerta & Garcia, 2007). However, few studies have attempted quantitative evaluation of PF elasticity in vivo, and its site- and gender-differences are not clear. In this study, we used the shear wave elastography to test our hypothesis that not only PF thickness but also its elasticity is site- and gender-specific.
METHODS: Forty healthy young participants (20 males, age: 22.7 ± 2.0 years; 20 females, age: 22.2 ± 1.8 years) with no history of lower limb or foot injury were recruited. Ultrasound shear wave elastography (Aixplorer, SuperSonic Imagine, France) was used to obtain PF thickness and shear modulus. The scanning of PF was performed in a longitudinal direction at five different sites from the calcaneal attachment (CAL) to the second metatarsal head. A two-way (site × gender) repeated measures analysis of variance with a Bonferroni post hoc test and an independent t-test was performed. Statistical significance was set at $p < 0.05$.
RESULTS: PF at CAL was significantly thicker and stiffer (higher shear modulus) than the other four measurement sites in both genders. Males' PF were thicker at CAL compared with females (males: 2.8 ± 0.4 mm; females: 2.3 ± 0.3 mm). At all measurement sites, females had significantly stiffer PF than males (males: 69.0 ± 26.6 kPa; females: 96.3 ± 26.9 kPa).
CONCLUSION: In this study, both the thickness and shear modulus showed clear site differences. These results partly support a previous finding on the site difference of PF thickness and further reveal the inhomogeneity of PF elasticity. This may reflect greater loading and mechanical stresses at CAL of PF during daily activities (Arnold et al., 2010; Chen et al., 2015). In addition, the gender differences partly support a previous finding on the PF thickness and further add to the gender specificity of PF elasticity. It has been reported that females have higher joint laxity (Shultz et al., 2007), lower toe flexor muscles' strength (Uritani et al., 2014), and larger deformation of the longitudinal foot arch (Fukano & Fukubayashi, 2012). These findings imply that PF of the female participants compensates for the shortage of other arch supporting tissues by becoming stiffer, to resist the mechanical stress on the foot arch.

TWO-POINT METHOD FOR THE ASSESSMENT OF LEG MUSCLE MECHANICAL CAPACITIES IN FIELD CONDITIONS

GARCÍA-RAMOS, A.1,2, ZIVKOVIC, M.3, DJURIC, S.3, MAJSTOROVIC, N.3, MANOVSKI, K.3, JARIC, S.3

1: FACULTY OF SPORT SCIENCES, UNIVERSITY OF GRANADA. 2: FACULTY OF EDUCATION, CATHOLIC UNIVERSITY OF THE MOST HOLY CONCEPCIÓN. 3: FACULTY OF SPORT AND PHYSICAL EDUCATION, UNIVERSITY OF BELGRADE.

INTRODUCTION: The force-velocity (F-V) relationship during multi-joint exercises has been traditionally determined from the F and V data obtained under multiple (more than two) loads (multiple-point method).1 Since the F-V relationship in these exercises was described as highly linear, it was proposed that the F-V relationship could be accurately determined from the F and V data collected under only two loads (two-point method), considerably reducing testing time and the associated fatigue.2 Although several studies have confirmed the high reliability and validity of the F-V relationship obtained from only two points,3 it should be noted that all these studies examined the feasibility of the two-point method from a testing procedure based on multiple loads. To explore the feasibility of the two-point method in field conditions, this study compared the reliability and magnitude of the F-V relationship parameters (maximum F [F0], maximum V [V0], F-V slope, and maximum power [P0]) obtained through the application of only two loads (i.e., two-point method) vs. six loads (i.e., multiple-point method).
METHODS: Ten physically active men (age: 19.5±0.9 years, body mass: 79.0±9.0 kg, height: 183.9±8.4 cm) conducted 4 testing sessions after a preliminary familiarization session with the leg cycle ergometer exercise. In a counterbalanced order, subjects performed 2 sessions of the multiple-point method (6 loads applied for the F-V modelling) in one week and 2 sessions of the two-point method (only the lightest and heaviest loads were applied) in another week.
RESULTS: The main findings revealed that (I) the reliability of the F-V relationship parameters was high and of comparable magnitude for both the multiple- (CV and ICC range: 1.91%-3.94% and 0.72-0.99) and two-point methods (CV and ICC range: 1.41-4.62% and 0.76-0.95), (II) the P0 assessed from the multiple-point method was significantly lower than the obtained from the two-point method (P=0.041; ES=0.36) due to a significant decrease in F0 (P=0.039; ES=0.41) but not in V0 (P=0.570; ES=-0.15), and (III) the magnitude of the F-V relationship parameters obtained from the multiple- and two-point methods were highly correlated ($r > 0.80$).
CONCLUSION: These results support the two-point method as a reliable, valid, and fatigue-free procedure for assessing the muscle mechanical capacities through the F-V relationship in the leg cycle ergometer exercise.

EFFECT OF FOOT STRIKE PATTERN ON BEHAVIOR OF MEDIAL GASTROCNEMIUS MUSCLE-TENDON COMPLEX DURING RUNNING

TAKESHITA, T., NORO, H., TAGURI, A., KATO, R., YOSHIDA, T., HATA, K., YANAGIYA, T.

GRADUATE SCHOOL OF JUNTENDO UNIVERSITY

INTRODUCTION: In a comparison of the foot strike pattern (FSP), there are many differences in kinematic and kinetic valuables, like typical impact force in the rear-foot strike (Lieberman et al., 2010). Though previous studies showed much difference of kinematics and kinetics characteristics between FSP, there is no study which compared the behavior of muscle-tendon complex. This study aimed to clarify whether the behavior of medial gastrocnemius muscle-tendon complex differs between two FSP.
METHODS: Eight healthy males participated in this study (age: 21.88±0.93yrs; height: 1.75±0.06m; weight: 66.69±3.88kg). They ran on a motorized treadmill for 40 seconds at the pace of 7 minutes per kilometer and were conducted to run with fore-foot strike (FFS) and rear-foot strike (RFS) for each trial. Running motion was captured with a digital high-speed video camera at 240fps. The ground reaction force was collected with the use of mounted force platform. To quantify muscle activity, surface electromyogram data was collected. An ultra-sonographic apparatus was used to measure fascicle length in the medial gastrocnemius. Muscle-tendon complex (MTC) length was estimated using the equation (Hawkins and Hull, 1990). Series elastic element (SEE) length was calculated with the use of MTC length, pennation angle and fascicle length (Fukunaga et al, 2001). These data were normalized to 100% at 1 running cycle time followed by Farris and Sawicki (2014).
RESULTS: Maximal MTC length was significantly longer in RFS ($p<0.05$), but SEE was tend to lengthen after initial contact in FFS ($p<0.05$). Also, fascicle was remarkably lengthened in RFS at the initial contact ($p<0.05$). Lengthening velocity of SEE was higher in FFS in the middle of stance phase ($p<0.05$).
CONCLUSION: From the view of SEE, there is a noticeable occurrence of the stretch-shortening cycle in FFS. Considered occurrence of this phenomenon in spite of such a lower running pace, FFS seems to be comfortable to perform faster running economically. Though there is some definitive difference in behavior of MTC, fascicle, and tendon, it is necessary to consider the effect of elasticity and viscosity in two FSP.

TIME COURSE OF MUSCLE TENDON FUNCTION AND STRUCTURE FOLLOWING A FIVE MINUTE STATIC STRETCHING EXERCISE

KONRAD, A., TILP, M.

KARL- FRANZENS- UNIVERSITY GRAZ

INTRODUCTION: Previous studies have shown that a single static stretching exercise decreases muscle stiffness immediately after the stretch, which recovered 30 minutes after the stretching (Kay and Blazevich, 2012). However, the precise time course of the response of muscle and tendon properties (e.g. muscle stiffness) and function responses (e.g. range of motion (RoM)) within the first 10 min minutes after stretching are not yet known. Therefore, the purpose of this study was to investigate the time course of the changes of the various muscle and tendon mechanical properties and the function responses of the gastrocnemius medialis (GM) and the Achilles tendon (AT) following 5 min of static stretching.
METHODS: Fourteen healthy volunteers (seven healthy females (mean ± SD; 24.9 ± 3.1 years, 166.0 ± 6.1 cm, 60.0 ± 8.4 kg) and seven healthy males (mean ± SD; 27.5 ± 8.3 years, 180.1 ± 6.2 cm, 75.9 ± 6.5 kg)) were tested on four separate days in a random order with three different rest times (0 min, 5 min, 10 min) after 5×60s of stretching or following a control period without stretching. During each test, the dorsiflexion RoM, passive resistive torque (PRT), and maximum voluntary contraction (MVC) were measured with a dynamometer. Ultrasonography of the GM muscle-tendon junction displacement and motion capture allowed us to determine length changes in the AT and GM, respectively, and hence to calculate their stiffness. Two-way repeated-measures ANOVA tests or Friedman tests were performed to test for differences between the conditions.
RESULTS: Following the stretching, we observed a significant increase in RoM and a decrease in MVC at 0 min, 5 min, and 10 min post-stretching. This could be attributed to an increase in muscle elongation which also lasted at least 10 min. Furthermore, a significant decrease in PRT and muscle stiffness was observed up to 5 min after the stretching. A decrease in muscle-tendon stiffness was observed immediately, but not 5 or 10 min after the stretching. No changes in tendon stiffness or in any variable in the control group were detected.
CONCLUSION: We conclude that the effects of a 5×60s static stretching exercise changes the muscle-tendon functions (RoM, MVC), which are related to mechano-morphological changes of the muscle but not the tendon structure, respectively. Although the functional changes last for at least 10 min, changes in muscle stiffness recover within 5 min of the stretching. Hence, we speculate that other factors, such as increased stretch tolerance (Magnusson et al. 1996), lead to longer-lasting changes of muscle-tendon function.

EFFECTS OF SUBJECT'S POSITION ON PLANTARFLEXION TORQUE

STAFILIDIS, S., SICKINGER, C.

UNIVERSITY OF VIENNA

INTRODUCTION: Numerous studies [1,2,3] examined the mechanical and morphological properties of the lower leg muscle tendon unit. The majority of the research was conducted in commercial design isokinetic dynamometers which have been made elastic for comfort (cushioning pads) rather than rigid for accuracy [4]. It has been postulated that the maximal torque can be, among other factors, affected by the elasticity of the dynamometer arm-foot system and the displacement of the dynamometer/ankle joint axis. Although corrections have been proposed [1,2], the elasticity of the dynamometer arm-foot system can alter the geometry of the muscle fascicles through the joint rotation [2] and negatively affect the muscle's force generation capability. Consequently, it is essential to reduce the elasticity of the foot-arm system prior testing. In this study we tested the hypotheses that by increasing the pressure of the foot on the dynamometer plate we can reduce the elasticity, the joint rotation and increase the maximal exerted torque.
METHODS: Eighteen males (29±6y, 77±10kg, 181±5cm) performed in randomized order 3 maximal voluntary plantarflexion contractions on a dynamometer (HUMAC) in 4 different (0-3-6-9cm; toward the dynamometer plate) subject positions. All contractions were performed in the same hip-knee-ankle angle configuration (110-180-90°). Reflective markers were placed on anatomical points of the lower leg and the dynamometer. An insole (Pedar 100Hz) was used to acquire the foot pressure. Kinematics and torque signals were captured at 200 and 2000 Hz respectively. A one-way repeated ANOVA with Bonferroni correction ($p<.05$) was used for the depended variables (torque, pressure and joint rotation) over positions.
RESULTS: A significant main positioning effect ($p<.001$) was found for torque, pressure and joint rotation. Positions 6 & 9cm showed significant ($p<.001$) higher torque (126±29, 148±26, 167±25 and 172±27Nm; 0-3-6-9cm respectively) than 0 and 3cm but not between them. The joint rotation decreased ($p<.001$) from 15.5±3.9 to 7.1±2.5° and the peak pressure increased significantly ($p<.001$) from 71±25 to 339±85 kPa (at 0 and 9cm).
CONCLUSION: The results showed that forward positioning of the subject can increase the maximal exerted torque for >35%. This effect is important in longitudinal study designs, since a not standardized positioning can alter the torque ~4%/cm. The increased torque can be attributed to the reduced joint rotation and therefore the operation of the muscle fascicles in their optimum region of force-length relation. The lack of torque differences between position 6 and 9cm indicates the existence of an optimal subject positioning.

HYPEROXIA SPEEDS PULMONARY OXYGEN UPTAKE KINETICS AND INCREASES CRITICAL POWER DURING SUPINE CYCLING

GOULDING, R.P., ROCHE, D.M., MARWOOD, S.

LIVERPOOL HOPE UNIVERSITY

INTRODUCTION: We have previously demonstrated that critical power is mechanistically related to the phase II time constant <τ_V̇O2> of oxygen uptake kinetics . CP has been shown to be greater in hyperoxia compared to normoxia . However, whether this effect is related to faster V̇f O2 kinetics in hyperoxia is presently unclear. Exercising in the supine position impairs O2 delivery and increases τ_V̇O2•,•raising the possibility that hyperoxia will reduce τ_V̇O2•in the supine position. Therefore, we hypothesised a concomitant reduction in τ_V̇ O2 alongside an increase in critical power when determined in hyperoxia compared to normoxia. Such evidence would demonstrate that τ_V̇O2 is an independent determinant of CP.
METHODS: 8 healthy men completed an incremental ramp test on a supine cycle ergometer to determine V̇8O2 max and the gas exchange threshold . This was followed by 8 visits whereby CP was determined via 4 severe-intensity constant load exercise tests to exhaustion, each repeated once in normoxia and once in hyperoxia . Moderate-intensity exercise bouts at 70% GET were repeated 4 times in each condition to characterise the kinetics of pulmonary V̇sO2, muscle deoxyhaemoglobin <•[HHb]; via near-infrared spectroscopy>, and absolute concentrations of oxyhaemoglobin <[HbO2]>.
RESULTS: CP was greater and τ_V̇ O2•was reduced in H versus N. Additionally, [HbO2] during exercise was greater in H versus N, whereas •[HHb] was unchanged . τ_V̇O2 was significantly inversely related to CP in H , however no relationship was observed in N .
CONCLUSION: This study provides further experimental evidence that τ_V̇O2 is an independent determinant of CP. CP was greater in H, and this was observed alongside measures of increased O2 availability when compared to N. The lack of relationship between τ_V̇O2 and CP observed in N is consistent with previous research for supine exercise . That this relationship was restored in H likely suggests that the supine position introduces a kinetic dissociation between pulmonary and muscle V̇fO2 that was reversed by H, thus demonstrating unequivocally that τ_V̇O2 is an independent determinant of CP.

MORPHOLOGICAL CHANGES OF LEG MUSCLES AND SUBCUTANEOUS FAT FROM COMPRESSION PRESSURES IN ACTIVE-HEALTHY INDIVIDUALS

LEE, C.W.D.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: Wearing sports compression garment is popular however, the efficacy in exercise and recovery performance remains controversial; limited data on the relationship of applied compression pressure (COMP) to tissues morphological responses (Brown et al., 2016; Partsch, 2016) unlike in clinical studies on compression stockings (Partsch and Mosti, 2008). Therefore, we aimed to investigate the muscles and subcutaneous fat morphological responses to different COMPs in active-healthy participants during rest.
METHODS: Thirty-two participants (Male:16; Age = 21.8 ± 1.7 years; Weight = 61.0 ± 8.8 kg; Height = 169.2 ± 7.0 cm; % Body fat: 16.0 ± 8.7%) were provided with three different lower-body COMPs (LOW: gymnastic tights, MED: sports compression tights on top of LOW, and HIGH: sports compression sleeves on top of MED). The leg skinfolds and circumferences were measured with standardized techniques; cross-sectional area of leg muscles (CSAmuscle) and subcutaneous fat (CSAfat) were measured using 0.25T MRI, at calf, knee, thigh levels, and in supine and upright positions.
RESULTS: The COMP at LOW (calf: 2.9 ± 1.4, knee: 1.6 ± 1.5, thigh: 2.2 ± 1.3 mmHg), MED (calf: 16.8 ± 3.0, knee: 11.1 ± 3.6, thigh: 10.7 ± 1.6 mmHg) and HIGH (calf: 38.8 ± 4.4, knee: 26.2 ± 4.3, thigh: 21.3 ± 2.3 mmHg) were monitored. A COMP of 38.8 ± 4.4 mm Hg at calf, and 10.7 ± 1.6 mmHg at thigh, induced significantly smaller CSAmuscle ($P < 0.05$). There was no main effect of COMP at knee ($P = 0.051$) and thigh ($P = 0.087$) CSAfat; and no main effect of position at CSAmuscle and CSAfat ($P < 0.05$). The COMP was negatively correlated to, female's CSAmuscle ($P < 0.01$, $r = -0.4$) and CSAfat ($P < 0.001$, $r = -0.7$); male's CSAmuscle ($P < 0.05$, $r = -0.3$) and CSAfat ($P < 0.005$, $r = -0.5$); but did not correlate to body height and weight, leg skinfold and leg circumference ($P > 0.05$) in females. Males, had bigger CSAmuscle and smaller CSAfat at all leg levels ($P < 0.001$), and experienced higher COMP at calf ($P < 0.05$) and thigh ($P < 0.05$) than in females, in MED and HIGH conditions.
CONCLUSION: Using MRI, we observed that 38.8 ± 4.4 and 10.7 ± 1.6 mmHg are critical COMP for calf and thigh muscles compression in active-healthy individuals during rest. The leg muscle and subcutaneous fat respond differently under different COMPs during rest. We suggest that leg muscle and fat composition could affect the exerted COMP therefore efficacy of compression garment wearing, particularly for high leg skinfold individual.

NEUROPHYSIOLOGICAL MECHANISMS UNDERLYING MUSIC-RELATED INTERVENTIONS IN THE EXERCISE DOMAIN

KARAGEORGHIS, C.I., DELEVOYE-TURRELL, Y., BIGLIASSI, M., GUÉRIN, S.M.R.

BRUNEL UNIVERSITY LONDON

INTRODUCTION: Given recent advances in digital technologies, music applications have rapidly become de rigueur in the exercise domain. Ergonomically-designed personal listening devices are popular with exercisers and millions of music tracks are now available via streaming apps. Over the last 20 years, there has been a large body of scientific work that has addressed the psychological, psychophysical, psychophysiological and ergogenic effects of music during exercise. In very recent years, researchers have shown increased interest in the neurophysiological mechanisms that underlie such effects. Harnessing and understanding the effects of music is important to the central mission of exercise science in getting people in developed countries to become more physically active.
METHODS: The interest in neurophysiological mechanisms has been accelerated by the availability of brain assessment technologies to exercise scientists, such as portable electroencephalography devices, functional magnetic resonance imaging and functional near-infrared spectroscopy . The purpose of this paper will be to provide a synthesis of recent work that has used EEG, fMRI or fNIRS to investigate brain function during exercise with ambient music .
RESULTS: A series of studies using portable EEG in a range of exercise contexts has shown that music can: a> supress theta waves during high-intensity exercise; b> reduce the frequency of the synchronisation–desynchronization–resynchronisation cycle of a neuropopulation; c> reduce the level of connectivity across somatosensory regions of the brain; and d> up-regulate beta waves in the frontal and frontal-central regions during self-paced walking. The few studies that have used fMRI in an exercise context reveal that: a> fast/loud music elicits activation in structures integral to visual perception, allocation of attention and motor control; and b> music increases activation in the left inferior frontal gyrus, and activity in this region is negatively correlated with exertional responses. Work with fNIRS is currently at a nascent stage. Nonetheless, based on some preliminary data, a putative hypothesis will be expounded to suggest that the effects of music on perception of exertion, affective responses and exercise endurance are mediated by corresponding changes in the activity of the dorsolateral prefrontal cortex. Ostensibly, music might delay the increase in brain oxygenation that is evident during exercise.
CONCLUSION: This paper contributes to a proposed paradigmatic shift in exercise psychology, from cognitivism to hedonism , as a means by which to tackle the scourge of sedentariness and obesity.

EFFECT OF THE TREADMILL SURFACE ON PHYSIOLOGICAL DEMANDS DURING CONTINUOUS LONG-DISTANCE RUNNING

COLINO, E.1, GARCÍA-UNANUE, J.2, SÁNCHEZ-SÁNCHEZ, J.2, GALLARDO, L.1

1. UNIVERSIDAD DE CASTILLA-LA MANCHA; 2. UNIVERSIDAD EUROPEA DE MADRID

INTRODUCTION: Differences in long distance running physiological demands between treadmill (TM) and overground (OG) running for well accommodated athletes have been related to the effect of the surface and to the lack of air resistance on the TM. To compensate the overall effect of the TM, it is a common practice to increase the grade of the TM to 1% to approximate the metabolic demands of an OG run. However, the accuracy of that adaptation might differ according to OG surfaces and may not be precise during prolonged exercise involving high metabolic rates. Under those conditions, the lack of air replacement during TM running can affect heat dissipation, contributing significantly to fatigue despite of reducing the energy required to overcome air resistance. The purpose of this study was to analyse the isolated effect of the surface on physiological demands during TM and OG long distance running by controlling air resistance
METHODS: Ten (n=10) recreationally trained male distance runners (age: 28 ± 5 years, height: 174 ± 6 cm, body mass: 70 ± 6 kg, %body fat: 16.4 ± 3.1, VO2peak: 58.2 ± 7.5 ml·kg-1·min-1) completed three 40-min running trials at constant speed in a randomised, counterbalanced order on separate days: 1 on asphalt (AS), 1 on a 400-m tartan track (TA); and 1 on a TM. Trials were performed at the same time and the same day of the week for each subject, and diet, liquid intake and sleeping hours were controlled. The first test was performed at a self-selected, moderately vigorous pace (10K pace). Speed was adjusted to be constant during the test. For tests 2 and 3, the same

constant speed was reproduced. During TM running, athletes ran against an oncoming airflow equal to their running speed. Heart rate (HR) was continuously monitored during the runs. Maximum HR (HRMAX) and mean HR (HRMEAN) were analysed in the 40-min gap and every 10 minutes. Besides, 4 different intensity zones were identified based on athletes' peak HR (low: <75%; moderate: 75-85%; high: 85-95%, and maximal: >95%), and total time spent in each HR zone was assessed. Non-parametric Kruskal-Wallis H Test was used to compare parameters between surfaces. Where differences were identified, post-hoc pairwise comparisons were performed using Dunn-Bonferroni tests
RESULTS: HRMEAN(30'-40') and HRMAX(20'-30'), HRMAX(30'-40') and HRMAX(0'-40') were significantly higher during TM running compared to TA running ($p<0.05$). Also, time spent at maximal HR zone was significantly greater on TM compared to TA (12.22%; ES=1.48; $p<0.05$). No other significant differences were found, although HR-time graph suggests that TA requires less HR during a 40-minute running test at constant speed
CONCLUSION: The effect of the surface itself is responsible for significant changes on physiological stress during long distance running. When subjected to an equivalent airflow, physiological demands of running on TM reproduce faithfully those of running on AS. However, there is a lack of representativeness of TM surfaces with respect to TA surfaces

EFFECT OF PRIOR HEAT EXPOSURE ON THE RECOVERY OF MUSCLE FORCE, MUSCLE OXYGENATION AND MICROVASCULAR FUNCTION FOLLOWING EXERCISE-INDUCED MUSCLE DAMAGE

IHSAN, M.1, SABAPATHY, M.2, HUSSAIN, S.2, HAIYUM, M.3, TAN, F.4

1: ASPETAR , 2: NATIONAL UNIVERSITY OF SINGAPORE , 3: REPUBLIC POLYTECHNIC , 4: SINGAPORE SPORT INSTITUTE

INTRODUCTION: Muscle damage is characterised by a decline in muscle force, decreased movement economy, and impaired microvascular function. Recent reports demonstrating improved muscle contractility (Racinais et al., 2017) and oxidative function (Ihsan et al., 2014) following passive heat exposure renders such treatment a viable strategy to ameliorate the effects of muscle damage. As such, this study investigated the effects of prior heat exposure on the recovery of muscle force and muscle oxidative function following exercise-induced muscle damage.
METHODS: Twenty males were equally assigned to a control (CON) and an experimental group (HEAT), and performed a 30-min downhill run (DHR) to elicit muscle damage. HEAT received three consecutive days of heat treatment (45-60 min of hot water immersion at 40-42°C) prior to DHR. Microvascular function (near-infrared spectroscopy) and maximal voluntary isometric contraction (MVIC) of the knee extensors were assessed. Additionally, participants performed two treadmill-based constant speed runs, during which running economy (RE), muscle deoxygenation and stride parameters were analysed. All measurements were conducted prior to DHR and repeated for four days post-DHR (D1-D4). Data were analysed using Cohen's effect size (d), and assessed qualitatively as - possible; 75–95 %, likely; 95–99 %, very likely; 99 %, almost certain.
RESULTS: When compared between conditions, prior heat treatment resulted in attenuated decrement in MVIC compared with CON throughout D1-D4 (d=0.64-1.49, likely to most likely). Likewise, HEAT resulted in 'likely to very likely' decrease in ROMS (d=0.65-1.19) between D1-D3. Moreover, prior heat conditioning 'likely' attenuated the decline in MVF (d=0.58-0.73) following DHR. HEAT demonstrated no effects on RE or stride parameters during running.
CONCLUSION: This study demonstrates a protective effect of heat exposure against EIMD, as evidenced by the attenuated decrease in muscle force, microvascular function, and improved the sensation of soreness. The mechanisms involved, may in-part be due to a heat-induced up-regulation of HSPs and/or PGC-1α, which in turn have been purported to mediate against cellular damage and stimulate angiogenic events. While we have established that prior heat exposure may reduce the deleterious effects of EIMD, further studies are needed to elucidate the mechanisms involved.

OP-PM84 Validity of physiological tests

DETERMINATION AND VALIDATION OF MAXIMAL FAT OXIDATION IN TRAINED INDIVIDUALS USING AN UPPER BODY GRADED EXERCISE TEST

RØMER, T., HANSEN, M.T., FRANDSEN, J., DELA, F., HELGE, J.W.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: A graded exercise test (GE) on a bicycle ergometer is the commonly used method to determine the maximal fat oxidation rate (MFO) and the intensity that elicits MFO (FatMax). This method is validated in both well-trained and obese individuals. Upper body (UB) exercise MFO and FatMax are not well elucidated and to our knowledge there is no validated UB GE test. Interestingly, the role of training specificity on MFO remains to be explored. Thus, the aim of this study was to develop and validate a GE protocol for determination of MFO and FatMax during UB exercise in trained individuals and to investigate the role of training specificity on MFO. Our hypothesis was that a higher MFO and FatMax would be observed in specific UB trained individuals than in controls.
METHODS: On separate days fat oxidation rate was assessed during GE (GE1 and GE2), with 3 minutes stages and 15W increments until respiratory exchange ratio exceeded 1.0, on a double poling (DP) ski ergometer (ThoraxTrainer) in 10 trained men. Subjects were divided into cross-country skiers (SKI, n=5) and UB endurance trained controls (CON, n=5). The groups were matched on age (28±1 vs. 28±2 yrs. mean±SEM [p=0.89]), body fat percentage (13.1±0.9 vs. 13.2±1.1% [p=0.97]) and treadmill running peak oxygen uptake (VO2peak) (65.5±1.7 vs. 64.4±1.1 ml•min-1•kg-1 [p=0.66]), respectively for SKI vs. CON. The GE was validated against MFO and FatMax determined from fat oxidation rates at rest and during 10 minutes continuous exercise bouts (SCE) at 35, 50 and 65% of DP VO2peak separated by 45 minutes breaks.
Venous blood samples before each test or exercise bout and pulmonary gas exchange measurements during exercise were obtained.
RESULTS: Two-way ANOVA RM analysis revealed no difference in MFO between GE (GE1; 0.421±0.03, GE2; 0.446±0.03 g•min-1 [p=0.29]) or groups (SKI; 0.410±0.03, CON; 0.457±0.05 g•min-1 [p=0.43]). No difference in FatMax was found between GE (GE1; 41.2±1.5, GE2; 43.1±2.5 %VO2peak [p=0.45]) or groups (SKI; 43.6±2.6, CON; 40.7±3.0 %VO2peak [p=0.40]). Pearson's correlation coefficient was excellent for MFO (r=0.77, n=10 [p=0.01]) between GE1 and GE2. Coefficient of variation within-subjects was 8±2% for MFO. A Bland-Altman analysis of the agreement between GE revealed a bias of -0.02 g•min-1 (95% LoA -0.15 to 0.10 g•min-1) for MFO. No systematic difference was observed in MFO between GE and SCE (p=0.48) or groups (p=0.96).

CONCLUSION: These results demonstrate that the GE has a high day to day reliability and validity in determination of MFO in trained individuals. In contrast to our hypothesis no difference was found in MFO or FatMax between SKI and CON, indicating that training specificity does not play a major role on UB exercise MFO. However, considerable intra-individual variation was observed and further studies are thus required.

VALIDITY AND RELIABILITY OF AN ON-COURT FITNESS TEST FOR ASSESSING AND MONITORING AEROBIC FITNESS IN SQUASH

JAMES, C., FARRA, S.

NATIONAL SPORTS INSTITUTE, MALAYSIA

INTRODUCTION: Existing on-court squash fitness tests are predominantly designed to provide a final performance score and do not yield a wealth of physiological data. Such data helps sport science practitioners and coaches understand the adaptations that have led to changes physical fitness, allowing individualised training to be prescribed. Moreover, some on-court tests require specialist computer equipment or involve simulated racket strokes, which are difficult to standardise at high intensities. This study investigated the validity and reliability of a novel squash-specific fitness test that requires only an accompanying audio track to be performed. This test is completed to volitional exhaustion, involves prolonged submaximal exercise stages and is completed without racket strokes.
METHODS: Eight professional squash players, who had been based at the National Squash Centre of Malaysia for at least 2 years, completed three tests in a counter-balanced order; an incremental laboratory treadmill test (LAB) and two tests of the squash fitness test (ST). This test involved repeated, multi-directional shuttle runs at increasing speeds, until exhaustion. Players completed all tests using the same portable metabolic cart (Cosmed K5, Italy).
RESULTS: ṘO2peak measured during ST was agreeable with LAB (typical error [TE] = 3.3 mL.kg-1.min-1, r = 0.79). The mean bias between LAB and ST was smallest when a 10 second rolling average was adopted (2.5 mL.kg-1.min-1), compared with 20 (3.9 mL.kg-1.min-1) or 30 second (4.2 mL.kg-1.min-1) rolling averages. There were no differences between LAB and ST (all p>0.05) in maximum heart rate (LAB=195 [7] b.min-1, ST=200 [7] b.min-1), post exercise blood lactate concentration (LAB=9.2 [1.9] mMol-1, ST=8.6 [1.9] mMol-1) or end of test RPE (LAB=19.6 [0.5], ST=19.1 [0.8]). Test performance in ST was highly reliable, with 74 (10) laps completed in ST1 and 75 (12) laps in ST2 (mean bias = 1 lap, TE= 3 laps, r = 0.97). Physiological markers were also reliable, including V̇O2peak (TE = 1.5 mL.kg-1.min-1, r = 0.95), lap number at 4 mMol-1 (TE = 4 laps, r= 0.77) and average VO2 during the first 4 stages (TE = 0.94 mL.kg-1.min-1, r = 0.95). Similar variability in i V̇O2peak was observed across 10, 20 and 30 s rolling averages (all TE < 1.5 mL.kg-1.min-1).
CONCLUSION: This on-court squash fitness test allows valid and reliable measurements of pertinent submaximal and maximal physiological markers such as peak oxygen uptake (l V̇O2peak), the lactate turnpoint and oxygen cost, whilst providing a performance score in a sport-specific environment. Data from this test can be used to track changes in aerobic fitness from training, as well as monitor training intensity and assist with prescribing individualised training. Consequently, we recommend the use of this test for amateur and elite squash players.

A NOVEL FOOTBALL-SPECIFIC AGILITY TEST: VALIDITY, RELIABILITY AND PRACTICAL APPLICATIONS.

RAGO, V., BRITO, J., ERMIDIS, G., BAGATIN, R., BARREIRA, D., FIGUEIREDO, P., REBELO, A.

PORTUGUESE FOOTBALL FEDERATION

INTRODUCTION: Agility is a key physical capacity in football players. Although various agility tests are commonly employed in team sports athletes (i.e. Illinois test, IAT), currently, there is no football-specific agility standard test. The Arrowhead Agility Test (AAT), (SPARQ, 2009) apparently provide a more football-specific assessment, than other commonly-used agility tests. The aims of this research were: (i) analyse the validity and reliability, (ii) quantify the associations with other physical capacities, (iii) to verify whether the capacity to discriminate between age-groups and competitive standards (CS), and (iv) to establish AAT normative values, of the AAT.
METHODS: Three independent studies were conducted. Concurrent validity and reliability of the AAT were determined in 24 regional-level players quantifying the correlation (r) between performance in AAT and in the IAT, and analysing the AAT test-retest results using ICC and CV. Standard error of measurement (SEM), smallest worthwhile change (SWC), and minimal detectable change (MDC) were also calculated. A backward multiple regression was employed to quantify the association between AAT and other physical capacities [5- and 15-m sprint time (T5 and T15), and countermovement jump] in 56 regional-level players. Normative values for the AAT, and discrimination between age-groups (senior, U18 and U16) and CS (national vs. regional-level), were determined in 264 players, using exploratory data analysis and multiple comparisons, respectively.
RESULTS: Irrespective of the outcome type (one side, or sum of both), the AAT was moderately valid, in relation to the IAT (r=0.86 to 0.89). Absolute reliability of the AAT was good (ICC= 0.76 to 0.85) whereas relative reliability was <5% (CV=1.6 to 2.7%). The ability of the AAT to detect changes in performance was good (SWC, 0.06 to 0.12 s > SEM, 0.01 to 0.03 s). MDC ranged from 0.01 to 0.06 s. T15 explained a significant amount of performance variance in the AAT (R2=0.42; P<0.01). Despite correlated, T5 did not explained performance in the AAT (r= 0.33; P=0.01). National-level players were more agile than regional-level players (ES=-1.9 to -0.3; P<0.05). Senior and U18 players had a better AAT performance than U16 (ES=-2.3 to -0.8; P<0.05). Normative ranges (sum of right and left) of AAT (25th-75th percentiles) for national-level were 15.98-16.82, 16.05-17.06, and 16.70-17.51 s for senior, U18 and U16 players, respectively. Regarding regional-level, ranges were 16.17-16.98, 17.05-18.08, and 17.98-19.40 s for senior, U18 and U16 players.
CONCLUSION: The AAT is valid and reliable to measure agility in football players. The most agile players in the test were also the most quicker (T15), indicating that AAT can simultaneously encompass sprint testing. Moreover, the test discriminates players from different CS. Our findings can be considered by strength and conditioning coaches involved in testing football players.

THE REPEATED SPRINT TEST ON A NON-MOTORIZED TREADMILL IS ABLE TO DETECT CHANGES IN PERFORMANCE IN 4TH LEAGUE AUSTRIAN SOCCER PLAYERS

TRISKA, C.1, KARSTEN, B.2, RIEDERER, P.1, TSCHAN, H.1

1: UNIVERSITY OF VIENNA ; 2: LUNEX UNIVERSITY

INTRODUCTION: Repeated sprint ability is described as the ability to maintain a maximal power output during repeated sprints and also to recover from prior sprints during the rest interval. High levels of RSA are essential in intermittent team sports, such as soccer. RSA is of

high interest in research and RSA tests are commonly implemented in performance assessments throughout the training season. The aim of this study was to assess the RSA before and after the summer preparation in 4th league Austrian soccer players using a non-motorized treadmill .
METHODS: For the determination of the RSA ten male soccer players performed two RSA-tests on the NMT , measuring PO during the sprints at 200 Hz. Horizontal force was measured using a force belt attached to the waist of the participant. The RSA-tests comprised 6x 6 s maximum effort sprints interspersed by 10 s walking. After each test mean PO, peak PO, fatigue index and fatigue rate were calculated. During the 5-week intervention period participants performed a soccer specific training 4x/week that comprised mainly interval game forms and core stability, but no specific sprint training. A repeated measures ANOVA was used to assess the differences between the tests. Effect size was calculated using partial Eta-squared <np2>.
RESULTS: Mean FI was 31.6±6.5% and 22.4±8.0% before and after the intervention . Mean FR was 30.3±7.2 W/sprint and 20.8±8.4 W/sprint before and after the intervention . No significant differences were found for the peak PO for sprints 1-5 between the tests , however, peak PO for sprint 6 was significantly higher in the post-tests . No significant differences were found for the mean PO for sprint 1-4 , however, mean PO was significantly higher for sprint 5 and 6 in the post-tests .
CONCLUSION: This study shows that the RSA-test on a NMT using PO values is sensitive to detect changes in an athletes RSA. It is suggested that results of the post RSA-test reflect the training intervention where, to increase aerobic fitness, participants mainly performed soccer-specific interval games. Moreover, no increase in mean or peak PO was found during sprints 1-5 as no specific strength or power training was performed during the intervention.

RUNNING-BASED ANAEROBIC SPRINT TEST IS SENSITIVE TO THE TRAINING EFFECT AND ASSOCIATED WITH THE PERFORMANCE IN THE MATCH FOR FUTSAL PLAYERS

BARBIERI, R.A.1,3, MILIONI, F.2, BARBIERI, F.A.2, VIEIRA, L.H.2, DO-SANTOS, J.W.2, DE ANDRADE, V.L.4, PAPOTI, M.3
1: ESTÁCIO ,2: UNESP ,3: EEFERP USP ,4: UNESP

INTRODUCTION: Anaerobic power is determinant in certain actions during a futsal match. Running-based Anaerobic Sprint Test (RAST) (Zagatto, et al., 2009) is commonly applied in the futsal (Barbieri et al., 2016) to access the anaerobic power. Therefore, the relationship of the index obtained in the RAST with the match physical demands as well as with training effect is important to the ecological validity of the test. So, the aim of the present study was to verify the relationship between RAST indexes with the physical demands of the official match and verify the training effects on the RAST indexes.
METHODS: Fourteen professional futsal players (25.5±2.2yrs; 75.7±8.1kg; 174.4±6.0cm; 51.4±3.3ml.kg-1.min-1) were recruited. The RAST test was performed before and after the last 6 weeks of the season. The RAST indexes was calculated based on the study of Andrade et al., (2013). The official match was performed in the same week of the re-test and it was record by Two video cameras (SONY® DCD-SR21) adjusted to a frequency of 30 Hz and the automatic tracking was analyzed in the DVIDEOW® software (Vieira et al., 2016). It was individually calculated the time-motion patterns: distance covered (D), distance per minute (Dm) peak of velocity (Vpeak), velocity mean (Vmean), number of sprints (NS) and percentage distance covered in high intensity (above 15.5 km.h-1) (DS).
RESULTS: D, Dm, Vpeak, Vmean, NS and DS of the match were 2810±1501m, 90±28m.min-1, 27.5±4.3km.h-1, 5.4±1.7km.h-1, 24.6±16.5 a.u., 22.3±12.7% respectively. The RAST indexes (Peak power, mean power, Peak velocity and mean velocity) showed strong significantly correlations with peak velocity on the first half of the match (0.76, 0.85, 0.77 and 0.85 respectively; $p < 0.05$). After 6 weeks of training, Maximal and mean power, Maximal and mean velocity and the impulse from the RAST were significantly high in comparison before the training period (pre:9.7±1.7: post:10.9±1.3W.kg-1; pre:7.8±0.8: post8.6±1.0W.kg-1; pre:6.9±0.4: post:7.2±0.3m.s-1; pre:6.5±0.2: post:6.7±0.3m.s-1; pre:1885.2±95.7: post:1991.8±76.4N.s-1; respectively).
CONCLUSION: The RAST test was sensitive to verify the effects of 6 weeks of training on the anaerobic capacity with strongly relationship with the performance of the first half in the official match. Therefore, RAST may be a good test to verify the anaerobic adaptations from the training and predict the performance in the first half in official match.

THE VALIDITY OF RELATIVE SPEED THRESHOLDS DERIVED FROM THE 30–15 INTERMITTENT FITNESS TEST TO QUANTIFY EXTERNAL TRAINING LOAD IN RUGBY LEAGUE

SCOTT, T.J., MCLAREN, S.J.
UNIVERSITY OF QUEENSLAND

INTRODUCTION: Monitoring training load (TL) is an important aspect of player management in rugby league (RL). Running-based external TLs are typically expressed as locomotor output over set arbitrary or relative speed thresholds. The physiological justification for arbitrary speed thresholds has been questioned, however, with relative speed thresholds proposed as superior (Scott et al. 2017). Despite this, little is known regarding the best means of threshold determination. We therefore aimed to assess the validity of relative speed thresholds derived from the of 30–15 Intermittent Fitness Test (IFT) for quantifying external TL in RL players.
METHODS: Forty-five professional RL players competing in the National Rugby League competition participated in this study. Players completed the IFT at the beginning and completion of the pre-season period, with the end-stage velocity (vIFT) used to determine relative speed thresholds. We chose 68% and 87% vIFT to represent estimates of the first and second ventilatory thresholds (VT1-IFT, VT2-IFT), respectively (Scott et al. 2017). Subsequently, distances covered above VT1-IFT and VT2-IFT were recorded in each completed training across the entire 2017 season (n=3160 individual session observations) using Global Positioning Systems. Internal training intensity and TL was quantified via session ratings of perceived exertion (sRPE; CR10) and Edwards training impulse (TRIMP; from heart rate recorded in each session), respectively. Training sessions were categorised as; skills (SK; n=2191), skills-conditioning (SK-CON; n=499), conditioning (CON; n=259) and speed-agility (SP-AG; n=211). A within-player design was used to examine the relationships between VT1-IFT, VT2-IFT and internal measures (construct validity).
RESULTS: Within-player relationships between VT1-IFT and sRPE were large during SK-CON (r=0.57; 90% confidence limits ±0.05) and SP-AG (0.53; ±0.09) and small during SK (0.29; ±0.03) and CON (0.22; ±0.10). For VT2-IFT, relationships with sRPE were large during SP-AG (0.54; ±0.09), moderate during SK-CON (0.44; ±0.06), and small during SK (0.24; ±0.03) and CON (0.16; ±0.11). The within-player relationships between VT1-IFT and TRIMP were moderate during CON (0.38; ±0.10), SK (0.33; ±0.03) and SK-CON (0.33; ±0.07), and small during

SP-AG (0.22; ±0.12). For VT2-IFT, relationships with TRIMP were moderate during CON (0.31; ±0.10) and small during SK (0.28; ±0.03), SK-CON (0.23; ±0.08) and SP-AG (0.18; ±0.12).
CONCLUSION: Distances covered above vIFT-derived relative speed thresholds have substantial and positive relationships between internal intensity/TL in RL players during a range of training modes, suggesting they may be a valid measure of external TL. In agreement with past findings, however, the strength of these relationships are moderated by the speed of the threshold and the mode of training (McLaren et al. 2018).

OP-PM48 Training / Testing: Strength

NO-LOAD TRAINING INCREASED MUSCLE STRENGTH AS MUCH AS TRADITIONAL TRAINING AT 40% OF 1RM

TESSUTTI, V.2, DE O SANTOS, G.B.1, CURTOLO, M.1, DE AZEVEDO, P.H.1, TUCCI, H.T.1, YI, L.C.1
1UNIVERSIDADE FEDERAL DO ESTADO DE SÃO PAULO; 2UNIVERSIDADE DE RIBEIRÃO PRETO-CAMPUS GUARUJÁ.

INTRODUCTION: One of the ways developed to increase muscle strength is a resistance training. Studies suggest, that a training performed at least 40% of 1RM may result in muscle strength gains, based on its prolonged stimulation of the myofibrillar proteins synthesis [1, 2]. There are also some discussion about the possibility of force gain with training without external load (NL), also called mechanotransduction, depending the activation it can make on the involved motor units of the chosen exercise, still sugesting the possibility of muscular growing in this condition [3]. Thus, the aim of this study was to verify if a no load training can increase strength as much as the conventional strength training method, with overload at 40% of 1 RM, in healthy young adults.
METHODS: Twenty-four male college students between the ages of 18 and 30 enrolled in the study, without upper limbs strength training in the last twelve months. All participants underwent an intervention to increase muscle strength for eight weeks, twice a week, lasting 40 minutes for each training. The maximum isometric muscle strength of the brachial biceps and the triceps brachii was measured by the Manual Dynamometer Manual Lafayatte®, model 926644. The results of strength, were measured in kilograms-force, and normalized by body mass, in kilograms, using the formula: [(kg force / body mass) x 100] [4]. For the blood lactate variable, the arterialized blood samples (25 µl) were collected. Blood lactate concentrations were measured using a portable lactate analyzer, which enzymatic determination and reflectance photometry (wavelength 660 nm) was used. The groups performed two exercises to strengthen the biceps brachii and triceps brachii. The Control Group (CG) performed the movements through dumbbells with a load equivalent to 40% of its 1RM.
However, the no-load group (NLG) performed the same of CG movements, performing dynamic maximum voluntary contractions (DMVC), contracting the biceps and triceps brachii muscles simultaneously. The data were analyzed through the statistical program SPSS version 20.0 (SPSS Inc. Chicago, IL, USA). A significance level of 5% was considered for all analyzes.
RESULTS: The NL training through maximal voluntary contraction promoted the same strength gains in the biceps and triceps muscles when compared to subjects underwent strength training at 40% of 1RM, in addition to showing increased metabolic demand.
CONCLUSION: The study shows that dynamic maximal voluntary contraction may be an option for muscle strength training in injured individuals, who for some period of time cannot receive overloads on their joints and bones, but need muscle strengthening as a process of their recovery.

THE EFFECT OF CONCURRENT EXERCISE ORDER ON TRAINING ADAPTATIONS IN ACTIVE MALES

LEE, M.J.1, BALLANTYNE, J.1, BISHOP, D.J.1,2, BARTLETT, J.D.1
1: VICTORIA UNIVERSITY , 2: EDITH COWAN UNIVERSITY

INTRODUCTION: Concurrent endurance (E) and resistance (R) training can interfere with hallmark resistance training adaptations (i.e. strength and hypertrophy). A prior exercise session may hinder training quality and performance in the following session, inducing unfavourable physiological milieus for optimal adaptations to occur. Thus, the choice of exercise session order is an important consideration for training program design. This study investigated the effects of concurrent exercise order on maximal strength, body composition, and aerobic fitness, compared to resistance-only training.
METHODS: Healthy, active males (n = 20) were randomised into: 1) ER, endurance before resistance exercise; 2) RE, resistance before endurance exercise; or 3) RO, resistance-only. Participants trained 3 days/week for 9 weeks with concurrent sessions separated by ~3 hours. E involved 2-min cycling intervals at 40-90% of the difference between lactate threshold (WLT) and peak aerobic power (Wpeak), with 1-min rest. R involved 3-4 sets of upper- and lower-body exercises (12 to 6-RM). Body composition (DXA), aerobic fitness (graded incremental test), and lower-body maximal strength (leg-press 1-RM) were tested pre- and post-training. Percent changes from baseline are reported as mean ± 90% confidence limits (CL). Standardised effects (ES) ± 90% CL were used to determine the magnitude of within- and between-group comparisons, where <0.2 = trivial, 0.2-0.6 = small, 0.6-1.2 = moderate, 1.2-2.0 = large, 2.0-4.0 = very large and >4.0 = extremely large effects.
RESULTS: All groups improved relative leg-press strength (RO: 25.7 ± 4.2%, ES = 1.0 ± 0.15; ER: 25.8 ± 8.9%, ES = 1.0 ± 0.31; RE: 24.8 ± 5.5%, ES = 0.97 ± 0.19), with trivial differences between them. There were likely trivial effects of exercise order on increases in relative VO2peak (-1.0 ± 4.1%, ES = -0.06 ± 0.23) and Wpeak (0.5 ± 5.6%, ES = 0.02 ± 0.26). RE resulted in possibly smaller improvements in WLT than ER (-6.0 ± 9.3%, ES = -0.27 ± 0.44). All training groups increased total lean body mass (RO: 3.1 ± 1.3%, ES = 0.23 ± 0.09; ER: 3.3 ± 1.5%, ES = 0.24 ± 0.11; RE: 3.5 ± 1.3%, ES = 0.25 ± 0.09); however, effects between groups were very likely trivial. RE resulted in possibly greater reductions in fat mass compared to ER (-6.2 ± 11.2%, ES = -0.17 ± 0.31) and RO (-9.3 ± 9.1%, ES = -0.26 ± 0.26).
CONCLUSION: These data do not support the hypothesis of attenuated strength and lean mass gains following concurrent training. In healthy, active males, a 9-week concurrent training program (regardless of exercise order) presents a viable strategy to induce gains in leg-press strength and total lean body mass comparable to resistance-only training, whilst also improving aerobic fitness. However, exercise order effects were apparent for improving lactate threshold (favouring ER) and fat mass loss (favouring RE). Thus, the choice of concurrent session order should be dictated and periodised according to the specific goals in each phase of a training program.

GLOBAL TRAINING EFFECTS OF TRAINED AND UNTRAINED MUSCLES WITH YOUTH CAN BE MAINTAINED DURING 4 WEEKS OF DETRAINING

BEHM, D.G.

MEMORIAL UNIVERSITY OF NEWFOUNDLAND

INTRODUCTION: Global (whole body) effects of resistance training (i.e., cross-education) may be more pervasive with children than adults. Detraining induces less substantial deficits with children than adults. It was the objective of this study to investigate the global responses to 4-weeks of detraining after 8-weeks of unilateral leg press (LP) training in 10-13-year-old, pre-peak-height-velocity stage boys.
METHODS: Subjects were randomly separated into two unilateral resistance training groups (high load/low repetitions: (HL-LR) and low load/high repetitions and control group. Assessments at pre-training, post-training and detraining included dominant and non-dominant limbs, unilateral, one repetition maximum (1RM) and 60%1RM LP, knee extension, knee flexion, elbow flexion, and handgrip maximal voluntary isometric contraction (MVIC), and countermovement jump (CMJ).
RESULTS: All measures significantly increased from pre-test to detraining for both training programs except for elbow flexion MVIC with increases only with HL-LR. All measures except CMJ and handgrip MVIC significantly decreased from post-test to detraining except for elbow flexion MVIC with decreases only with HL-LR. The dominant trained limb experienced significantly greater LP improvements (pre- to detraining) and decrements (post- to detraining) with LP 1RM and 60% 1RM LP. In conclusion, youth HL-LR and LL-HR global training effects of trained and untrained limbs demonstrate similar benefits (pre- to detraining) and decrements (post- to detraining) with detraining.
CONCLUSION: The findings emphasize that training any muscle group in a child can have positive global implications for improved strength and power that can persist over baseline measures for at least a month.

CROSS-EDUCATION EFFECT DEPENDS ON SET CONFIGURATION OF BICEPS CURL STRENGTH TRAINING

FARIÑAS, J.

UNIVERSITY OF A CORUNA

INTRODUCTION: Cross education (CE) consists in strength transfer to untrained contralateral limb after unilateral strength training program (Lee & Carol, 2007; Farthing, Krentz & Magnus, 2009; Ruddy & Carson, 2013; Beyer et al., 2016). The magnitude of this effect has been recently quantified in a strength gain in the non-trained limb of 11.9% (Manca, Dragone, Dvir & Deriu, 2017). The aim of this study was to compare the strength gains in the non-trained arm flexors after two unilateral training programmes differing in set configurations but with the same total volume and repetition-to-rest ratio
METHODS: Thirty-five sport science students were randomly assigned in three groups: traditional training group (TT), cluster training group (CT) and control group (CON). Throughout ten sessions (five weeks; two sessions per week) TT performed with the dominant limb 5 sets of 6 repetitions of unilateral biceps curl with 135 seconds between sets, while CT performed 30 repetitions of the same exercise with 18.5 seconds between each repetition.
RESULTS: For the trained arm, TT improves 1RM ($p<0.001$), number of repetitions with 10RM load (10RMr) ($p=0.005$) and maximum voluntary contraction ($p=0.011$). Performance of the non-trained arm improved significantly only in TT for 1RM ($p<0.001$) and 10RMr ($p=0.012$).
CONCLUSION: Cirer et al. (2017) observed a direct relationship between training load applied and the effect in contralateral limb. According with this, we have demonstrated that a key factor to modulate the magnitude of CE is the set configuration, being necessary to be performed at least a 60% of maximum number of repetitions allowed by a load.
These results suggest that when volume and repetition-to rest ratio are equated, more fatiguing set configurations result in a higher cross education magnitude. Specifically, sets of at least 6 repetitions with the 10RM load seem to be needed in order to optimize the gains in non trained arm flexors.

MUSCLE MASS AND STRENGTH GAINS FOLLOWING A 6-MONTH RESISTANCE TYPE EXERCISE TRAINING PROGRAM ARE LOST WITHIN ONE YEAR WHEN EXERCISE TRAINING IS DISCONTINUED IN OLDER INDIVIDUALS

SNIJDERS, T., VERDIJK, L.B., LEENDERS, M., VAN LOON, L.J.

MAASTRICHT UNIVERSITY

INTRODUCTION: Supervised resistance type exercise training programs implemented over 3-12 months induce substantial gains in muscle mass, strength, and functional capacity in older individuals. However, it remains unclear if older individuals are able to maintain their gains in muscle mass and strength without any supervised interventions. In the present study, we assessed the capacity of older adults to maintain their gains in muscle mass and strength during one year after partaking in a successful 6-month resistance type exercise training program.
METHODS: Sixty-two healthy older men and women were included in a 6-month supervised resistance type exercise training program. Upon the cessation of the training program, participants were not provided with any guidance or incentives to continue exercise training. One year after completion of the training program, all participants were contacted and invited back to the laboratory to assess quadriceps muscle cross-sectional area and muscle strength <1RM leg extension>. A total of 35 subjects who had participated in the supervised training program, responded and agreed to the 1y follow-up measurement. Subjects were divided into two groups: individuals who had continued resistance type exercise training on an individual basis and individuals who had not continued any regular weight lifting exercise .
RESULTS: No significant differences between baseline characteristics and/or response to the initial resistance type exercise training program were observed between individuals who were included in the present study and those who were lost to follow-up 0.05>. The

increases in quadriceps CSA <+506±209 and +584±287 mm2> and leg strength <+32±12 vs +34±10 kg> that had been observed in response to the initial training program did not differ between the individuals assigned to the STOP and CONT group, respectively .
One year after cessation of the exercise training program, participants had lost muscle mass, with a greater decline in quadriceps CSA in the STOP vs CONT group <-579±268 vs -309±253 mm2, respectively; P<0.05>. Muscle strength had decreased significantly compared to values after the 6 month training program , with no differences observed between the STOP vs CONT group <-21±8 vs -18±8 kg, respectively; P>0.05>.
CONCLUSION: Though prolonged resistance type exercise training effectively increases muscle mass and strength in older adults, muscle mass and strength gains will be lost within one year after discontinuation of the program without supervised exercise training.

GREATER INCREASES IN MUSCLE STRENGTH BY PROGRESSIVE ECCENTRIC THAN CONCENTRIC RESISTANCE TRAINING

NOSAKA, K.1, CHEN, T.C.2, LAI, J.H.2, TSENG, K.W.3, TSENG, W.C.3
1 EDITH COWAN UNIVERSITY, 2 NATIONAL TAIWAN NORMAL UNIVERSITY, 3 UNIVERSITY OF TAIPEI

INTRODUCTION: Greater improvement of muscle function after eccentric than concentric resistance training was reported in many studies . Chen et al. reported that 12-week progressive ET of the knee extensors that did not induce muscle damage symptoms, improved muscle function greater than CT. It appears that muscle damage is not a main factor contributing to the improvement of muscle function, but it is not clear why ET can increase muscle function greater than CT. The present study compared between a progressive ET and CT for the time course of changes in maximal voluntary isometric contraction and electrically stimulated torque of the elbow flexors, and upper arm circumference .
METHODS: Sedentary young men were placed to ET or CT group . Both groups performed 5 sets of 6 contractions of the elbow flexors of the non-dominant arm once a week for 5 weeks, in which the load was increased from 10 to 30, 50, 80 and 100% of MVIC. MVIC and ES torque, elbow joint range of motion , CIR and muscle soreness <100-mm visual analog scale> were measured before, immediately after, and for 3 days <10–80% sessions> or 5 days <100%> after each session. Plasma creatine kinase activity was measured before and 3 days <10–80%> or 5 days <100%> after each session. Changes in these variables over time were compared between groups by a mixed-design two-way ANOVA.
RESULTS: Decreases in MVIC <20–29%> and ROM <3–8°> were evident only at immediately after the 3rd–5th CT sessions . Similar decreases in MVIC <14–21%> and ROM <3–7°> were also found at immediately after the 3rd–5th ET sessions. MVIC <6–16%> and ROM <1–4°> decreased, and CIR <1–2 mm>, muscle soreness <2 mm> and CK <73–75%> increased at 1–3 days after the 3rd and 4th ET sessions. After the 5th ET session, significant changes in all variables were evident , but these variables returned to baseline by 2–3 days post-exercise. Significant increases in MVIC and ES torque from the baseline were evident before the 3rd bout, and the differences in the values of these variables between ET and CT became larger after the 3rd bout. ET showed greater increases in MVIC <23%> and ES <24%> when compared with CT <10%, 10%>, but CIR increased similarly between ET <3%> and CT <2%> at 5 days after the 5th session.
CONCLUSION: It appears that minor muscle damage was induced after the 3rd–5th ET sessions. The magnitude of increases in MVIC and ES torque was more than two-fold greater for ET than CT after the 5th session. It is interesting that the differences in the training effects between ET and CT increased after muscle damage was evident for ET. It is possible that some factors associated with muscle damage contribute to the greater increases in muscle function after ET than CT.

OP-BN47 Elite sports

MONITORING OF PHYSIOLOGICAL, BIOLOGICAL AND PERCEPTIVE MARKERS OVER AN ENTIRE SEASON ON WORLD-CLASS HANDBALL PLAYERS.

MAURELLI, O.
UNIVERSITÉ DAMIENS

INTRODUCTION: Few studies have investigated on physiological, biological and perceptive markers during an entire competition season in world class handball players (Bresciani et al., 2010). However, the monitoring of these markers throughout a full season will attempt to illustrate its effects and to reorient, if necessary, training methods. The aim of this study was then to describe the effects of training on the physiological, biological and perceptive markers during an entire season on world-class handball players.
METHODS: Thirteen male handball players, belonging to the professional League 1 (France) were recruited for the study. The players had a training experience (7.6 ± 1.3 years) of the highest level of expertise in France. Mean values (± SD) of age, stature, body mass and fat were 26.6 ± 5.4 years, 189.5 ± 5.1 cm, 93.7 ± 11.9 kg and 10.6 ± 2 % respectively. The 47-weeks season consisted of a pre-competitive preparation period and two competitive periods. During the season, the participants were tested on four occasions: the first test session was performed at the beginning of the season, in July, the second test in November, the third test in March and the fourth test at the end of the season, in June. The tests sessions consisted of jump tests (squat jump and counter movement jump), speed test on a 5 meters start-stop and aerobic test (shuttle-run 20m). Blood samples included haematological examinations (hematocrit (H)), biochemical examinations (creatine phosphokinase (CPK) and ferritin (F)) and blood hormonology (free cortisol (C), testosterone (T), insulin-like growth factor-1 (IGF-1) and insulin growth factor binding protein 3 (IGFBP-3)). In addition, the Hooper index was used every week, early in the week.
RESULTS: The preliminary results of our study show a significant (p <0.05) decrease in H values between T1 and T2, T3, T4 but a significant (p <0.05) increase between T3 and T4. Concerning CPK, our results show no significant change. For F, our results show a significant (p <0.05) decrease between T1 and T4, T2 and T4 and T3 and T4. For C, our results show a significant (p <0.05) decrease between T1 and T4, T1 and T3, T2 and T4 and T2 and T3. Our results also show a significant (p <0.05) decrease in T values between T1 and T2, but an increase between T1 and T3, T1 and T4, T2 and T3, T2 and T4 and between T3 and T4. Finally, our results show a significant (p <0.05) decrease in IGF-1 values between T1 and T4 but no significant change in IGFBP-3 values.
CONCLUSION: The repetition of matches and training during a competitive season causes a drift of biological and perceptives markers among world class handball players. In order to repel fatigue, that can lead to an injury, coaches must carry out a regular follow-up trainng load of athletes throughout the season.

PHYSICAL PERFORMANCE IN ELITE MALE AND FEMALE TEAM HANDBALL PLAYERS

WAGNER, H., FUCHS, P., VON DUVILLARD, S.P.

UNIVERSITY OF SALZBURG

INTRODUCTION: Biological differences between men and women are well known; however, literature-addressing knowledge about the influence of sex to specific and general performance in team handball is almost nonexistent. Consequently, the aim of the study was to assess and compare specific and general physical performance in male and female elite team handball players and to determine if the differences are consequential for general compared to specific physical performance characteristics.
METHODS: Twelve male and ten female elite team handball players performed a game based performance test, upper- und lower-body strength and power tests, a sprinting test, and an incremental treadmill-running test. We measured oxygen uptake, utilizing portable metabolic system (Cosmed K4B2), blood lactate concentration (EKF, Biosen C), heart rate (Polar, Kempele, Finland), sprinting time, and offensive and defensive time actions (Inmotion LPM-system, Abatec, Austria), ball velocity and jump height during a jump shot (PeakMotus, Vicon Peak, UK), leg extension strength (HBM load cell 27-2, Hottinger Baldwin Measuring, Germany), trunk and shoulder rotation torque (ISOMED, D&R Ferstl, Germany), as well as jump height in the counter movement jump (AMTI, Watertown, USA). Independent-samples t-tests were used to determine significant differences between male and female team handball players. Additionally, a multivariate linear model with factors for sex (male vs. female) and test (general vs. specific) was used to determine if sex differences were different in general physical characteristics compared to the specific physical performance characteristics.
RESULTS: Significant differences (P<.05) between male and female players were found for peak oxygen uptake and total running time during the treadmill test, 30m sprinting time, leg extension strength, trunk and shoulder rotation torque, counter movement jump height as well as offense and defense time, ball velocity and jump height in the game based performance test. An interaction (sex × test) was found for time and oxygen uptake.
CONCLUSION: The results of the study revealed that male players are heavier and taller, faster, stronger, jump higher and have a better aerobic performance. However, female players performed relatively better in the team handball specific compared to the general tests. Our findings suggest that especially the significant discrepancy between lower leg strength and specific performance in defense and offense may be an indicator for the significantly higher risk of knee injuries (traumatic and overuse) in females compared to male team handball players.

PHYSIOLOGICAL, CLINICAL AND CHRONOTYPIC PROFILES OF AMATEUR OLYMPIC DISTANCE TRIATHLETES

PUCCINELLI, P., LIMA, G., ANDRADE, M.

UNIVERSIDADE FEDERAL DE SÃO PAULO

INTRODUCTION: As a consequence of the recent existence of triathlon and a great diversity of distances in different events, there are few studies available on the profile of these athletes. Physiological profiles of athletes involved with different sport modalities can provide a basis for understanding the adaptations due to specific training, requirements necessary for sport success and injury risk management. The purposes of the present study are to characterize and compare the differences between sex of anthropometric and physiological profile in addition to medical history, training and daily life habits of triathlon amateur competitors who participated in Olympic distance triathlon races.
METHODS: This is a cross-sectional observational study, which included amateur triathletes (39 men and 6 women), who competed in the same triathlon Olympic distance race. Participants were evaluated for anthropometric characteristics (body mass, height, and body composition through (DXA)), aerobic physical fitness (maximum oxygen consumption (VȮ2máx), anaerobic threshold and respiratory compensation point, maximum aerobic velocity (MAV) and running economy (RE)). Questionnaires on medical history, training routine, sports experience and circadian preference were also applied.
RESULTS: In male group, VĖO2máx, MAV and RE were 59.9 ± 6.3 mL/kg/min, 17.8 ± 1.4 km/h, and 1.17 ± 0.08 kcal/kg/km, respectively. In female group, VfO2máx, MAV and RE were 50.3 ± 6.1 mL/kg/min, 15.0 ± 1.4 km/h and 1.27 ± 0.10 Kcal/kg/km, respectively. From the total participants, 47% (83% women and 41% men) have not conducted any periodic medical follow-up for sports practice, and 36% (50% women and 33% men) have never undergone a pre-participation sports assessment; 49% (16%women and 53% men) still feel tired when they wake up, and 42% (50% women and 61% men) had musculoskeletal injuries in the last year; 69% (40% women and 66% men) exhibit the morning profile for circadian preference.
CONCLUSION: Male triathletes presented higher VĖO2máx and MAV than female, but there were no significant differences in RE between sexes. A high percentage of the athletes, men and women, had no periodic medical follow-up, still felt tired after waking up, and presented musculoskeletal injuries. The comparisons between men and women might be influenced by sample size. However, this data on highly trained amateur triathletes can be compared to other independent evaluations. This will guide the determination of individual weaknesses and strengths and can be useful to design specific training programs and medical care.

THE EFFECT OF 8 WEEKS ALTITUDE'S DIFFERENT TRAINING LOAD ON PERFORMANCE OF ELITE ROWERS

BINHHONG, G.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: Training load is the key point of sports training. The training practice presents that appropriate load during altitude training play a positive role on aerobic ability and performance. This study discusses the different training load for 8 weeks altitude training and the different training effect of performance, provide theoretical basis and methodological reference to improve rowing's altitude training.
METHODS: 32 athletes form national rowing team is spilt into two groups,18 women of single oar and 14 women scullers; They train at Huize Yunnan<2280m> for 8 weeks; We record the training load before, during and after the altitude training; the training volume consist of water training, ergometer training and running; the training intensity consist of 5 levels, and are evaluated by heart rate and blood lactic acid; we test the specific performance by ergometer 6km,2km and 4 level incremental load test before and after altitude training. We test BU and CK at the morning after rest day.
RESULTS: From the view of training volume, the average week's volume of women of singe oar is 7.1km less than women scullers at sea level, volume of water training is 11.2km less; volume of women of single oar decrease form 195km at sea level to 164.1km during altitude training <-15.85%>, whereas volume of women scullers decrease from 184.2km to 171.2km <-7.06%>;From the view of training intensity, proportion of oxygen utilize2 of women of single oar is 118.27% larger than women scullers, whereas proportion of oxygen utilize1, an-

aerobic threshold and oxygen transport of women of single oar are less than women sculler,-30.47% (p<0.01)、-20.29% (p>0.05) and-48.65% (p>0.05);After altitude training, ergometer 6km result of women of singe oar decrease by 0.04%< p>0.05>, whereas women scullers improve by 0.77%, and result of women scullers is better than women of singe oar; the change of power and heart rate at lactic acid threshold of women scullers are better than women of single oar; ergometer 2km result of women of single oar decrease by 0.31% (p>0.05),whereas women sculler improve by 0.73% (p<0.01);During altitude training, average BU and CK of women of single oar is 6.1±1.5mmol/l and 162.6±83.6 U/l, women scullers is 6.4±1.4mmol/and249.4±176.7 U/l; there is significant difference between CK of two groups (p<0.05).
CONCLUSION: After the two groups rowers of similar basic performance finishing 8 weeks altitude training at same place, the different load can lead to different training effect; training volume of rowers during altitude training should remain similar with sea level; the training should rely mainly on water training, and ergometer training and running are supplementary; the training intensity should rely mainly on oxygen utilize1<60-65%>, and focus on developing aerobic ability, and anaerobic threshold and oxygen transport training are supplementary; the main difference of training load is volume and intensity, and the relationship between structure of training load and training effect; and the training intensity is the key reason of different training effect.

Effects of organized sport on the psychological health of children from different socioeconomic backgrounds
ZHENG, H.S.1, GUO, Y.1, HOPKINS, W.G.2, BOREHAM, C.A.3
1: GUANGZHOU UNIVERSITY (CHINA). 2: VICTORIA UNIVERSITY (AUSTRALIA). 3: UNIVERSITY COLLEGE DUBLIN (IRELAND)
Introduction: Physical activity may enhance not only children's physical health but also their psychological health. Here we have examined the relationship between regular participation in organized sport and psychological difficulties in children, and the modifying effect of socioeconomic status.
Methods: Data were provided by 8977 children (age 5 y) and their families in the national Growing Up in Ireland Study (Wave 3). Parents completed the Strengths and Difficulties Questionnaire, and the total score was recoded into a binary dependent variable representing presence or absence of psychological difficulties. Parents also estimated their childs participation in organized sport on a 5-point scale, which was used as a predictor of psychological difficulties in a logistic regression, with adjustment for possible confounding effects of the childs sex and primary caregiver's sex and age. Separate analyses were performed for children in families of lower and upper socioeconomic status. Outcomes derived as odds ratios were converted to prevalence ratios and interpreted using magnitude-based inference.
Results: Children who were never active in sport comprised 47% of the sample, and their prevalence of psychological difficulties was 11.6%. Compared with children this group, there was an unclear small reduction in prevalence of psychological difficulties in those who were active twice a month (prevalence ratio 0.89, 90% confidence interval 0.60-1.33) but clear moderate reductions for children who played sport for 1 h/wk (0.65, 0.56-0.76), 2 h/wk (0.61, 0.50-0.75) and >2 h/wk (0.69, 0.54-0.90). There was little difference between upper- and lower-class children in the effects of 1 h/wk and 2 h/wk of sport, but for more than 2 h/wk there was a clear difference, with upper-class children experiencing a moderate reduction in psychological difficulties (0.58, 0.42 to 0.80) and lower-class children experiencing a trivial but unclear effect (1.09, 0.72 to 1.67).
Discussion: In this sample, levels of participation in organized sport of 1 h/wk or more were associated with similar reductions in psychological difficulties, with the exception of potentially little benefit for the most active lower-class children. Further analysis of sport participation in this group is warranted, along with factors affecting other dimensions of children's psychological health.

WHAT HAPPENS AFTER ALL IS SAID AND DONE? A RETROSPECTIVE ANALYSES OF SPORT-BASED PROJECTS FOR UNDERSERVED YOUTH

ACIKGOZ, S., HAUDENHUYSE, R., ASCI, F.H.

TRAKYA UNIVERSITY, VRIJE UNIVERSITEIT BRUSSELS, MARMARA UNIVERSITY

What happens after all is said and done? A retrospective analyses of sport-based projects for underserved youth
Acikgoz S.1-2, Haudenhuyse R.2, Asci H.3 1: TU (Edirne, Turkey) 2: VUB (Brussels, Belgium) 3: MU (Istanbul, Turkey)
Introduction: Sport-based projects for young people are seen as a versatile tool that provides opportunities for work on different social issues such as employability, crime prevention and social inclusion. Such projects have been in-demand for decades and continue to receive attention from policymakers, academics and practitioners. Yet, the sustainability and the after-effects of these projects are still unclear. Using a retrospective approach (Ragin and Becker, 1992), this study aims to analyse two completed sport-based projects in Turkey.
Methods: The study used a multiple case study design that comprised face-to-face interviews (33 participants), a focus group (5 participants) and field observations (22 days). The data were collected from participants, parents of participants, project coordinators and sport coaches. Using content analysis, themes were generated from the data with open and thematic coding processes (Smith and Sparkes, 2017). The central question that guided our analysis was if and how the selected sport-based projects had an impact on young participants in underserved areas.
Results: The main themes generated from the analyses were: (i) a moralizing discourse on young people's deficiencies, (ii) the reproduction of hegemonic sport discourse, and (iii) socialisation opportunities through sport.
Conclusion
The projects had some problems regarding planning and implementation. One year after the completion of the projects, findings indicated that there was no tangible impact on keeping young people away from health damaging behaviour and developing social skills through sport education. We concluded with implications on challenges (and possible opportunities) of conducting sport-based projects in poorly organized settings.

SYSTEMATIC REVIEW OF MENTAL HEALTH AWARENESS INTERVENTIONS IN SPORT- EVIDENCE TOWARDS POLICY PLANNING

BRESLIN, G., SHANNON, S., HAUGHEY, T., DONNELLY, P., LEAVEY, G.
ULSTER UNIVERSITY & SPORT NORTHERN IRELAND

This is the first systematic review on the effectiveness of sport-specific mental health awareness programs on athletes, coaches and officials mental health knowledge and help-seeking. We sought to determine if such programs enhance mental health literacy, knowledge of mental health and help seeking in response to an increasing recognition that those involved in sport can be vulnerable to mental health problems similar to the general population. All methods of data analysis and reporting followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines with a protocol available on PROSPERO. Six electronic databases were searched: Psychinfo, Medline (OVID interface), Scopus, Cochrane, Cinahl and Sport Discus. Each database was searched from its year of inception. Results: Eleven studies, refined to six were analysed from the 1095 studies retrieved. Five of the six studies found positive changes on at least one outcome measure. Two studies found significant positive changes for all their outcome measures, both finding increased knowledge about mental health disorders. Conclusions: Caution should be taken when interpreting the outcomes of interventions that aim to raise awareness of mental health issues in sport due to weak methodological quality, with the exception of a few studies. Future research should adhere to available guidance from the review as discussed in the presentation when developing and evaluating complex interventions. The findings have guided the development of an Mental Health In Sport Action Plan for Northern Ireland that is worth consideration for other European Countries

THE EFFECT OF A MENTAL HEALTH AWARENESS PROGRAM AMONG ATHLETES: TESTING AN INTEGRATED BEHAVIOUR CHANGE MODEL

SHANNON, S., HAUGHEY, T., LEAVEY, G., BRESLIN, G.
ULSTER UNIVERSITY

Introduction: Athletes involved in competitive sport experience barriers that place them at risk of poor mental health. Recent evidence indicates that few sport-specific, theoretically- informed mental health awareness programs are designed for, and tested, among athletes . To address this gap the State of Mind program was designed using components of the Integrated Behaviour Change framework . The aim was to determine if SOM could increase athletes' intentions to self-manage mental health, and provide a theoretical base on which to modify mental health awareness programs.
Method: A mixed factorial two x two non-randomised controlled trial was conducted, comprising an intervention and control group. Participants' mean age was 21.1 years. The SOM program included self-reflective exercises, vignettes of athlete role models, and group discussions on strategies and resources available for mental health support. The effect of the intervention on mental health self-management intentions was tested through a serial mediation model with four IBC-derived mediators .
Results: In comparison to the control group, the intervention was related to positive changes in mental health intentions , with findings showing some support for the mediating role of IBC variables. Namely, the intervention directly increased autonomous motivation <β=.29> which exerted a positive indirect effect on subjective norms <β=.15>, attitudes <β=.14>, and mental health intentions <β=.12>. Analyses also revealed a positive direct effect for the intervention on attitudes <β=.23> and behavioural control <β=.20>, in which an indirect effect on mental health intentions was facilitated through attitudes <β=.28>.
Conclusions: When attempting to increase awareness of self-management techniques for mental health among athletes, practitioners may consider the promotion of autonomous motives and positive beliefs around mental health optimisation. Components of the IBC, as reported in SOM, may offer a useful framework for behaviour change.

PHYSICAL ACTIVITY AND SELF-ESTEEM IN CHILDREN AND ADOLESCENTS: UPDATE OF REVIEW OF REVIEWS

CIACCIONI, S., THOMAS, G., VERGEER, I., BIDDLE, S.J.H.
UNIVERSITY OF SOUTHERN QUEENSLAND

Purpose: To provide an update to the review (Biddle & Asare, 2011) of systematic reviews and meta-analyses on the effects of physical activity (PA) on self-esteem (SE) in young people.
Methods: A systematic online search was conducted using Cochrane Library, EBSCOhost, ISI Web of Science, MEDLINE (PubMed), ScienceDirect, and Scopus databases. Inclusion criteria were research published from January 2010 to January 2018 that considered the following outcomes: PA, SE, self-concept (SC), school-aged children and adolescents (5-18 years). Screening and data extraction were conducted in duplicate. Data were analysed and systematically graded for their methodological quality (NIH, 2016).
Results: Ten systematic reviews and meta-analyses were included. Of 295 primary studies, the majority used a cross-sectional design (34.9%), with 30.2% being randomised controlled trials (RCT), and 12.5% non-RCTs. Other designs (i.e., experimental, longitudinal, quasi-experimental, correlational, pre-post) accounted for the remaining 22.4%. The most common exposure variables were general PA, sports, and exercise. Other exposures were yoga, physical education, dance, and weight/strength/aerobic/fitness training. Quality assessment of the reviews indicated that 50% were of "good" quality and 50% of "fair" quality. Partially consistent with meta-analytic reviews in adults, results showed that, in general, PA can lead to improvements in SE and SC, with effect sizes varying from large to small. In particular, associations between PA and self-worth, perceived competence/fitness/appearance were evident, while effects on perceived attractiveness and body image were often only seen over the short-term.

Conclusions: Following a review and update of higher quality systematic reviews and meta-analyses, a recent rapidly growing literature and associations between PA and SE emerged. Findings may be used to inform future research and policy designed to increase levels of SE through PA. However, better quality intervention research is required to increase the confidence in the findings.
Keywords: young people, self-concept, mental health, sport, exercise.

HOW DOES PSYCHOLOGICAL EMPOWERMENT AFFECT THE MEANING IN LIFE BASED ON PASSION? A CONDITIONAL PROCESS MODEL.

CALISKAN, G., OZER, A., INCE, I.
1GAZI UNIVERSITY, 2HACETTEPE UNIVERSITY, 3YILDIRIM BEYAZIT UNIVERSITY

Introduction: Victor Frankl's logotherapy (1985) specified that meaning in life is discovered by creating a work, doing good or loving the others and maintain a stance toward unavoidable suffering. In this context, we can assume that life coaches experience meaning in life getting in relationship with creating teams, making athletes/team successful, explore talents, commitment with passion for works. But, coaches are shown responsible for the failures in the first place. Hence, In Frankl's view, it can be argued that coaches' meaning in life depend on acceptance their failures bravely and perform their decision without being influenced by others. On the other hand, the support of the clubs is important when they come to overcoming difficulties. Therefore, the aim of this study is to examine whether the passion (CP) moderates indirectly psychological empowerment (PE) to have ML in the workplace.
Methods: 227 volunteer Turkish coaches (Mage = 35.89, SD = 9.78) from different sport branches participated in this study. PE (Spreitzer, 1995), CP (Vallerand et al., 2003) and ML Scales (Steger at al., 2006) were used. Process script was performed (Hayes Model 1). Before the moderated analysis, outliers, normality, homoscedasticity, linearity, multicollinearity were checked.
Results: A positive correlation has been determined between the scores of PE and ML. (r =.31, p <.01), whereas the correlation between CP and ML is not significant. One unit increase perceived PE scores leads to an increase of 21 points in ML scores (B =.21, t = 4.88, p =.00) but, CP does not predict ML (B =.03, t =.84, p =.40). However, the relationship between PE and ML scores vary depending on CP in high and moderate groups (B = .01, t = 2.17, p = .03).
Discussion: PE increases ML scores, by virtue of PE supports a more purposeful life (Melton & Schulenberg, 2008). CP doesn't have a direct effect on ML, however, CP*PE increases the ML. Accordingly, the Coaches believe that CP is not enough to realize their aims because of bureaucratic obstacles, Therefore, PE provides making responsive and adaptive decisions and they see their profession as useful, and so it may effect ML positively.

PL-PS03 BRAIN AND MUSCLE LEARNING: MODERN DAY PERSPECTIVES

LINKING BRAIN DYSFUNCTION AND MOTOR UNIT PHYSIOLOGY IN ESSENTIAL TREMOR

VAILLANCOURT, D.
UNIVERSITY OF FLORIDA

Essential tremor is a neurological syndrome of heterogeneous pathology and aetiology that is characterized by tremor primarily in the upper extremities. Several studies have found an association of blood-oxygen level-dependent signal in the cerebello-thalamo-cortical pathway with essential tremor, but there is behavioural evidence that also points to the possibility that the severity of tremor could be influenced by visual feedback. In a series of studies, we directly manipulated visual feedback and hypothesized that an increase in visual feedback would exacerbate tremor in essential tremor patients in the 4–12 Hz range. Further, we used functional MRI, high density electroencephalography, and motor unit physiology to better understand the neural pathways and mechanisms from the cerebellum to cortex to muscle related to abnormal tremor. We have found that regions well beyond the classically hypothesized cerebello-thalamo-motor cortical pathway, such as visual and parietal areas, directly relate to essential tremor severity. Further, the cortical oscillations appear to be abnormal with increased visual feedback in the parietal and motor cortex within the 4-12 Hz and 13-30 Hz bands. At the muscle, we observed that the variability of motor unit action potentials relates to tremor severity in essential tremor. This set of studies therefore provides new evidence that a widespread functional network is associated with the severity of tremor in patients with essential tremor measured at the hand during functional imaging and electroencephalography, and is also associated with the clinical severity of tremor. These findings support the idea that the severity of tremor is exacerbated by increased visual feedback, suggesting that designers of new computing technologies should consider using lower visual feedback levels to reduce tremor in essential tremor.

MUSCLE MEMORY AND A NEW CELLULAR MODEL FOR MUSCLE ATROPHY AND HYPERTROPHY

GUNDERSEN, K.

UNIVERSITY OF OSLO

We suggest that skeletal muscle fibres display the hallmarks of a cellular memory, entailing encoding, storing and retrieving information. The muscle cells are the largest cells in the body and are served by multiple nuclei. The classical cell biological model for muscle atrophy has implied that during atrophy, muscle nuclei are lost by apoptosis as to maintain a constant cytoplasmic domain volume for each nucleus. Similarly, during hypertrophy, nuclei are recruited form satellite cells that fuse with pre-existing muscle fibres. Although supported by a large body of literature, newer more precise methods, indicate that this model is not correct.
In particular, direct observations of myonuclei by in vivo time laps microscopy indicates that nuclei are not lost during atrophy. Thus, the number of nuclei reflect the previous size of the muscle fibre, and not its atrophic state. The number of nuclei then represents a long lasting cytoarchitectural imprint or "memory" of the original fibre size.
Newer methods have confirmed that nuclei from satellite cells are added during de novo hypertrophy, and that also these nuclei are maintained during subsequent disuse atrophy, serving as a cytoarchitectural "memory" of a previous hypertrophy. The muscles with an elevated number of myonuclei induced either by previous steroid exposure or exercise (encoding), grow faster with retraining (retrieval), even after a prolonged period of detraining (storage). In humans the memory storage could be very long lasting since our myonuclei probably have half-lives in excess of 15 years. Our findings might have implications for doping rules, and for training advice. It might be beneficial to do early strength exercise since myonuclei are more easily recruited in younger than in old individuals.

EFFECTS OF LONG-TERM LOW INTENSITY EXERCISE ON OXIDATIVE CAPACITY IN AGED RAT MUSCLES

SAKAMOTO, M.1, ONAGA, N.1, YONA, M.2, MURO, M.3, TADANO, C.3

1: KITASATO UNIV. , 2: TUPLS , 3. TOHO UNIV. MED.

INTRODUCTION: Ageing leads to a reduced capacity for oxidative phosphorylation in muscle, likely due to a decline in mitochondria content and/or function. Peroxisome proliferator-activated receptor-gamma coactivator 1-alpha (PGC1-alpha) regulates the promotion of muscle mitochondrial biogenesis in response to prolonged exercise (Kang et al, 2013). However, aged muscles are more susceptible to contraction-induced damage. Therefore, setting of a safe and effective intensity of exercise is needed for aged muscles. The purpose of this study was to examine the effect of long-term low intensity exercise on oxidative enzyme capacity in soleus and gastrocnemius muscles.
METHODS: Male Fischer rats were used in this study. These rats were divided into a non-exercise group (Control; N=5), a flat loading group (0 degree; FL, N=2) and a downhill loading group (-16 degree; DL, N=2). The rats were reared from 8 weeks old until 112 weeks old, and the FL and DL rats performed treadmill exercise (10 m/min, 15 min, 2 times/week) during the rearing period. One week after the last exercise, soleus and gastrocnemius muscles were excised and made into frozen serial sections. Serial sections were stained with succinate dehydrogenase (SDH), hematoxylin and eosin. The expressions of PGC1-alpha were measured by immunoblot analysis. SDH activity was analyzed by semi-quantitative measurement using Image J software. Results are expressed as a percent of control value.
RESULTS: Regarding the histological findings of skeletal muscles, there was no observed muscle damage in either the FL or the DL group. The expression of PGC1-alpha in soleus muscle was increased to 230 % of control group in the DL group. In FL group, the expression of PGC1-alpha in soleus muscle was elevated to 178 % of control group. On the other hand, the expressions of PGC1-alpha were not different among the 3 groups in gastrocnemius muscles. In terms of the SDH activity of the soleus muscle, no group-dependent differences were observed in either the soleus or the gastrocnemius muscles.
CONCLUSION: The effects of prolonged low-intensity exercise differed in relation to each muscle and exercise type. It seems that the contribution of fiber type and recruitment pattern of motor units depends on exercise type. These results suggest that long-term low intensity exercise, especially DL exercise, is effective for promoting mitochondrial biogenesis in the soleus muscle.

EXPRESSION OF MARKERS OF BROWNING IN WHITE ADIPOSE TISSUE IN LIFE-LONG ENDURANCE TRAINED ATHLETES

REITZNER, S., KISSLING, S., CHAPMAN, M., SUNDBERG, C.J.

KAROLINSKA INSTITUTET

INTRODUCTION: Physical exercise and training results in adaptations in adipose tissue. Such adaptations may in part be mediated through “cross-talk” with skeletal muscle. One of these adaptations potentially relevant to energy metabolism in endurance athletes is the beiging of white adipose tissue (WAT). Beiging is the process by which WAT shows characteristics of brown adipose tissue (BAT), possibly increasing basal metabolic rate. While the process of beiging in rodents and the existence of BAT in humans has been shown previously, it is unknown if and how life-long endurance exercise influences beiging of WAT depots.
METHODS: Periumbilical subcutaneous adipose tissue biopsies were collected from 14 life-long trained sub-elite endurance athletes (8 male, 6 female; VO2max performance over 90th percentile for their age group) and 13 age-matched controls (6 male 7 female). Gene expression was analyzed on extracted RNA. Fold induction was statistically analyzed by Student’s-test.
RESULTS: UCP-1 gene expression was significantly higher in trained women compared with the control group (p=0.046). No significant difference was found in men when comparing UCP-1 expression (p=0.257). Expression of CIDEA was, again, significantly higher compared with controls (p=0.049), but also in men (p=0.024). Finally, expression of PPAR-γ was significantly higher in trained women (p=0.005). Again no differences were found in men (p=0.924).
CONCLUSION: Life-long endurance training results in a higher expression of brown adipose tissue markers in periumbilical WAT in women, in men only in expression of CIDEA, a factory closely associated with metabolic health. Previous results in rodents show a higher

susceptibility of females to upregulate BAT markers following β-adrenergic signaling. A similar mechanism might be possible in humans. This effect might also be caused by differences in body fat distribution and functionality, with women having a higher prevalence for BAT.

THE EFFECTS OF LEARNING "TACTICS FOR WINNING" FOR LONG-DISTANCE RACES IN JUNIOR HIGH SCHOOL PHYSICAL EDUCATION CLASSES

MATSUMOTO, Y.

HIROSHIMA UNIVERSITY

THE EFFECTS OF LEARNING "TACTICS FOR WINNING" FOR LONG-DISTANCE RACES IN JUNIOR HIGH SCHOOL PHYSICAL EDUCATION CLASSES
Matsumoto, Y.1, Saito, K.1 1: Hiroshima University
Introduction: In Japanese junior high schools, students tend not to have a positive attitude towards long-distance races in physical education (PE) classes. In order to cope with this difficult situation, there have been many studies on long-distance races in junior high school PE classes. However, little is known about the effects of learning "tactics for winning" (Takashima et al., 2017) on student perceptions of long-distance races. The purpose of this study was to analyze the effects of learning "tactics for winning" for long-distance races in junior high school PE classes. Considering the purpose of the study, we set the following two research questions (RQ). RQ1: Does the attitude towards long-distance races of the participants become positive by learning "tactics for winning?" RQ2: Is participant stamina improved by learning "tactics for winning?"
Methods: In this study, a questionnaire was developed based on Takashima (2017) which was used as a pre and posttests. This questionnaire included Likert items based on a five-point scale and open-ended questions. The questionnaire was given to participants at the beginning and the end of the learning unit "long distance races." By analyzing the results of the pre and posttests, we examined for RQ1whether or not the participants' attitudes towards long-distance races became positive after learning "tactics for winning." As for RQ2, the times of the participants' 1000m run were recorded at the beginning and the end of the learning unit "long distance races." By using this measurement, we examined whether the participants' stamina was improved as a result of learning "tactics for winning."
Results: The results of the questionnaire surveys showed that participants' attitudes towards long-distance races became more positive with a statistically significant difference between pre and posttest data. Further, the times recorded on the 1000m run showed that those participants who were in the top 20 for the total time recorded of pre and post runs improved their stamina, with a statistically significant difference between these pre and post runs.
Conclusion
Considering the descriptions in the open-ended questions, participants reported that their attitudes towards long-distance races became positive because learning the "tactics for winning" was perceived as being less monotonous than learning through the previous style of even-pacing. Likewise, many participants stated that they felt the reason why their records of 1000 m run became faster was because they were motivated to run harder in order to win. These results suggest that learning "tactics for winning" for long-distance races is an effective strategy in helping junior high school students to develop a positive attitude towards long-distance races and for improving their stamina.

EFFECTS OF THAI FOLK GAMES ON CARDIOVASCULAR ENDURANCE IN OVERWEIGHT CHILDREN.

BUNGMARK, W.

SILPAKORN UNIVERSITY

Background: At present, Thai children have a lot of weight problems. Because of the rapid technological development, children lack physical activity.
Early Thai people invented folk games to promote physical activity and physical fitness. The Thai folk games provide fun, harmony and good relationships between players.
Objective: This study aims to study effects of Thai folk game on cardiovascular endurance in overweight children.
Method: Volunteers are 27 overweight students from the demonstration primary school grade 1-3 of Silpakorn University. Training by join Thai folk game for 4 weeks, 3 days per week, with 3 different games for a hour per day. Before and after participating in the activity, the volunteers must evaluate the cardiovascular endurance with a 1,200 meters distance run.
Results: After training Thai folk games for a hour, 3 games per day, 3 days per week for 4 weeks. We found that children had a higher run speed of 1,200 meters. Average running speed before training is 13.17±2.75 min. and after 4 weeks of training is 11.90±2.68. When analyzed statistically with pair t-test were significant at level .05.
Conclusion: Thai folk games are the wisdom of the Thai people. Invented in ancient times to promote physical fitness for children and youth. Because of the rapid technological development, children lack physical activity. Thai children have a lot of weight and health problems. Therefore, promoting children play Thai folk games make children run faster and cardiovascular endurance improved. It is also a Thai cultural preservation.

CHANGES OF VARIOUS HEMATOLOGICAL PARAMETERS IN RESPONSE TO VIGOROUS CONTINUOUS ENDURANCE EXERCISE TRAINING IN HEALTHY YOUNG MEN: A SINGLE GROUP ANALYSIS

KNUIMAN, P.

WAGENINGEN UNIVERSITY

INTRODUCTION: Changes of various hematological parameters in response to vigorous continuous endurance exercise training in healthy young men: a single group analysis
Pim Knuiman1, Maria Hopman1,2 and Marco Mensink1
1Wageningen University & Research, the Netherlands
2Radboud University Medical Centre, the Netherlands
It has previously been observed that endurance exercise training affect hematological parameters including erythrocyte volume, hematocrit value, hemoglobin concentration, mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC). Moreover, changes in hematological parameters contribute to changes in VO2max with endurance exercise training, predominantly by influencing circulatory oxygen transport capacity to the working muscles. To date, there is little data on the effects of temporary changes in hematological parameters in response to vigorous continuous cycling training. Therefore, the aim

of this single group sub-study was to assess the response of various hematological parameters with prolonged vigorous continuous exercise training.
METHODS: Twenty-four recreationally active young healthy men [mean ± SD (age 22.2 ± 2.7 years; BMI 22.6 ± 1.4 kg·m-2; VO2max 49.8 ± 4.2 ml·kg-1·min-1)] were recruited to participate in the study. Over a 12-week period, subjects performed three cycling sessions of 60 minutes per week on 85% of their heart rate reserve. Blood was taken at baseline, week 2, 4, 6, 8, 10 and 12, at least 48 hours after the last exercise session. Hematological parameters were analyzed on whole blood samples using an automated hematology analyzer. MCV, MCH and MCHC were calculated from erythrocyte count, hematocrit and hemoglobin concentration.
RESULTS: Endurance training led to a decline in erythrocyte count when compared with baseline values following 2 weeks of exercise training and remained at this decreased level until week 12. Hematocrit was significantly lower at week 2, 4, 8, 10 and 12, however, hematocrit concentrations at week 6 were not different compared to baseline. Hemoglobin concentration remained decreased at week 2 and 4 without any further significant change over the course of the training period. Compared to baseline, both MCH and MCHC were increased at week 4, 6, 8, 10 and 12 without any significant differences at week 2. MCV remained unchanged over the course of the training period.
CONCLUSION: In conclusion, the reduction in erythrocyte count, hematocrit and hemoglobin concentration are most likely explained by hemodilution secondary to plasma volume expansion, a typical feature of endurance type activity. Also, intravascular hemolysis may contribute to the decrease in these hematological parameters. The increase in MCH and MCHC may reflect an improved oxygen carrying capacity of the red blood cells and might be a compensatory adaptation for the observed decreases in erythrocyte count, hematocrit and hemoglobin concentration secondary to hemodilution and hemolysis.

APPLICATION OF THE CRITICAL POWER MODEL OF ENDURANCE CAPACITY TO CHANGE-OF-DIRECTION EXERCISE: A PROOF OF CONCEPT

TILLIN, N.A., REES, M.

UNIVERSITY OF ROEHAMPTON

INTRODUCTION: The critical power/speed (CS) model of endurance capacity describes the hyperbolic relationship between exercise speed and time to exhaustion (Tlim). The model is composed of 2 parameters: CS, representing the last sustainable speed; and W' (or D'), the finite work/distance that can be completed above CS before Tlim. The CS model has been robustly applied to different exercise modalities (cycling/running/rowing), and both constant and intermittent speed activities (Jones & Vanhatalo, 2017). However, the CS model has not been applied to exercise involving changes of direction, and proof of its applicability might have important implications for monitoring athletic performance in sports (team/racket) which involve frequent directional changes. This study aimed to: (i) establish proof of concept that the CS model could be applied to change of direction exercise; and (ii) validate a 3-min all-out test for establishing CS and D'.
METHODS: Ten, young, male team-sport players completed a familiarisation and 5 randomly ordered experimental trials, in which they ran continuously between 2 floor plates 15 m apart. Timing gates were at 1.5 and 13.5 m between the plates. In 4 of the experimental trials participants ran between the plates at different constant average speeds, set by a metronone to elicit Tlim within 5-20 min. Both the hyperbolic CS model [Tlim = D' / (S – CS)] and a linear expression of the CS model [Dlim = D' + CS*Tlim] – where S is constant average speed and Dlim is total distance covered – were fitted to each individual data set from the 4 constant average speed trials to determine CSHyp and D'Hyp (hyperbolic), and CSLin and D'Lin (linear). In the 5th experimental trial participants ran as quickly as possible backwards and forwards between the plates for 3 min; with average running speed over the last 30 s defined as CS3min, and distance covered above CS3min defined as D'3min.
RESULTS: Excellent fits of the constant average speed data sets were provided by both the hyperbolic (R2 = 0.96 ± 0.03 and RMS error = 44 ± 26 s), and linear (R2 = 0.99 ± 0.03 and RMS error = 17 ± 12 m) models. CSLin was higher than CSHyp ($P<0.001$) for all participants but varied (coefficient of variation) between the two models by only 3 ± 1%. In contrast, D'Hyp ad D'Lin were statistically similar ($P = 0.981$) between models but varied by 11 ± 9%. CS3min was greater than CSHyp ($P = 0.005$) though similar to CSLin ($P = 0.886$), whilst D'3min was typically 27% lower than both D'Hyp and D'Lin ($P<0.05$).
CONCLUSION: These results provide proof of concept that the CS model can be applied to change of direction exercise, with both hyperbolic and linear expressions of the model providing excellent fits for the constant average speed data. The 3-min all-out test provided accurate estimates of CS but considerably underestimated D', so is only a valid determinant of the former.

EFFECTS OF DOWNHILL INTERMITTENT AEROBIC TRAINING ON ENDURANCE PERFORMANCE IN HUMANS

DIRY, A.1, DAUSSIN, F.2, JEANSOULE, N.3, FREY, A.1, COUTURIER, A.1, THOMAS, C.1

1:INSEP , 2:UREPSSS , 3:UNIV PARIS SACLAY

INTRODUCTION: For many sports, aerobic and strength qualities are required simultaneously. Currently, few training strategies can develop these specific qualities in a unique training session. The aim of this study was to determine, if a high-intensity eccentric training induced a concomitant development of aerobic and strength capacities.
METHODS: 2 groups of 10 subjects performed 12 high intensity interval training (HIIT) sessions in 4 weeks on a treadmill (Little et al., 2010). The control group (CON) ran with 2% uphill and the eccentric group (ECC) performed eccentric trainings from -7 to -10% slope. Before and after the training program, subjects performed an incremental test to determine their maximal aerobic speed (MAS), and their VO2max, an endurance test (4km), a repeated-sprints test ability (RSA), and a strength test on isokinetic ergometer.
RESULTS: Both groups showed a significant improvement for endurance time, with a preservation of initial strength level only for ECC, whereas a strength decrease was observed for CON. No effect was observed on MAS, RSA and VO2max in ECC compared to CON.
CONCLUSION: Our results agree with previous studies on the aerobic capacities improvement in response to HIIT trainings (Gibala & McGee, 2008; Robineau et al., 2016). Positive effect of ECC training on endurance test could be explained by an improvement of endurance capacity per se or by an improvement of energy cost (Yamamoto et al., 2008), rather than by metabolic adaptations. Indeed, the metabolic training intensity was maybe too low in the eccentric modality to improve the VO2max as the metabolic stress is a key factor to improve it (Dufour et al., 2004). Moreover, the strength stimulus associated to decline running was sufficient to maintain strength, but not enough to lead to its improvement as previously reported (Hawley, 2009). Nevertheless, it could be difficult to increase the intensity thanks to the slope due to the important mechanic pressure and the risk of injuries in this modality.
In conclusion, downhill HIIT improved endurance performance with protective effect on strength reduction, compared to classic HIIT.

EFFECTS OF DYNAMIC SLING TRAINING EXERCISES ON TRUNK MUSCLE ACTIVATION

MORAT, T., HOLZER, D., TRUMPF, R.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: To improve trunk muscle strength and stability, unstable devices can be applied in strength training. However, the number of studies which have investigated trunk muscle activation during sling training exercises is still not very extensive. The purpose of this study was to examine the level of trunk muscle activation during different dynamic sling training exercises in healthy, young adults.
METHODS: Thirty-six young adults <18 women, 25.1 ± 3.3 years, 1.78 ± 0.1 m, 71.5 ± 10.4 kg> performed seven different sling training exercises while muscle activation of eight different trunk muscles was measured unilaterally by surface electrodes. Four of the exercises were conducted at two different difficulty levels using the principle of body angle.
RESULTS: The seven sling training exercises differed regarding muscle activation, with significant differences between the three body parts . High muscle activation of the trunk flexor muscles was measured during the body extension <87%>, side plank <81%>, and suspended crunch exercises <76%>. The back muscles tested reached more than half of their maximum reference trial values only during hip abduction <52%>. Regarding the side muscles, the suspended crunch <92%>, side plank <70%> and hip drop <66%> exercises achieved muscle activations of 60% and higher. For body extension, hip drop, and rowing, all eight trunk muscles tested demonstrated a significantly higher muscle activation in the harder version compared with the easy version. During hip abduction, only m. obliquus externus abdominis showed a significant difference between the two difficulty levels.
CONCLUSION: Based on the results, the sling training exercises tested in this study seem to be most effective for the abdominal muscles whereas the back muscles rarely reach 50% of their full muscle activation potential during the sling training exercises investigated. As assumed based on the former literature, changing the body angle during sling training exercises is shown to be a feasible way of adjusting the intensity of sling training. This could potentially be used in longitudinal sling training studies to assure a controlled, progressively increasing training intervention.

EFFECT OF DIFFERENT TRUNK POSTURE ON THE SCAPULAR MUSCLE ACTIVITIES AND KINEMATICS DURING SHOULDER EXTERNAL ROTATION

MIYAKOSHI, K.1, UMEHARA, J.1, KOMAMURA, T.1, UEDA, Y.1,2, TAMEZAWA, T.1, KITAMURA, G.1, ICHIHASHI, N.1

1: HUMAN HEALTH SCIENCE, GRADUATE SCHOOL OF MEDICINE, KYOTO UNIVERSITY 2: DEPARTMENT OF REHABILITATION, NOBUHARA HOSPITAL

INTRODUCTION: Trunk rotation during shoulder exercises affects scapular kinematics and muscle activities (Yamauchi, 2015). Shoulder external rotation at shoulder abduction is a notable motion in overhead sports such as baseball because it causes strong stress to the elbow and shoulder joint. However, no study has focused on the difference of trunk posture during shoulder external rotation at shoulder abduction. Therefore, the purpose of this study was to investigate the effect of different trunk posture on scapular kinematics and muscle activities during shoulder external rotation.
METHODS: Thirteen healthy young men participated in this study. Subjects randomly performed shoulder external rotation at 90° abduction with the dominant arm in 11 trunk postures while sitting on a stool. Eleven trunk postures included flex-extension condition(4 postures: slouch, 20° trunk flexion [flex20], 20° trunk extension [ext20], and maximum trunk extension [ME]), rotation condition (6 postures: maximum contralateral rotation [MCR], 30°contralateral rotation [CR30], 15° contralateral rotation [CR15], 15° ipsilateral rotation, 30° ipsilateral rotation [IR30], and maximum ipsilateral rotation [MIR]), and upright posture as a control. Muscle activities of upper trapezius (UT), middle trapezius (MT), lower trapezius (LT), serratus anterior (SA), infraspinatus (ISP) and latissimus dorsi (LD) were assessed at maximum shoulder external rotation using surface electromyography. Additionally, 3-dimentional scapular kinematics was measured by 6-df electromagnetic tracking device. In each condition, one-way analysis of variance (ANOVA) with repeated measures and Dunnett's comparison for post-hoc test were used to compare upright posture with each posture. A confidence level of .05 was used in the entire statistical test.
RESULTS: For the flex-extension condition, scapular posterior tilt and external rotation significantly decreased but the muscle activities of LT and ISP significantly increased in slouch. In flex20, scapular posterior tilt and external rotation significantly decreased. Also, scapular upward rotation and the activity of SA significantly increased in ME. For the rotation condition, scapular posterior tilt and external rotation significantly decreased but the activity of SA significantly increased in MCR. In CR15, scapular external rotation significantly decreased. There were no significant differences of kinematics but the activity of trapezius muscles significantly increased in MIR and IR30.
CONCLUSION: Difference in trunk posture affects scapular kinematics and muscle activities during shoulder external rotation at 90° shoulder abduction. Our results suggested that the activities of LT and SA which are the muscles that induce scapular posterior tilt are activated in the different trunk posture. In addition, ISP, a shoulder external rotator, tended to be activated in the postures with limitation of scapular movement by rib cage.

INFORMING ATHLETE REHABILITATION WITH TENSIOMYOGRAPHY: A CASE STUDY

MACGREGOR, L.J., SHANKS, N., HUNTER, A.M.

UNIVERSITY OF STIRLING

INTRODUCTION: Collecting the requisite objective evidence to provide informed interventions in training and rehabilitation is a challenge for practitioners working with elite athletes. Tensiomyography (TMG) has been applied to monitor training (de Paula Simola et al, 2015) and recovery (Rey et al, 2012) in sporting settings, and has been proposed as a predictor of injury risk (Alentorn-Geli et al, 2015). This case study examined neuromuscular function of a competitive female swimmer following a period of detraining, after suffering sudden onset knee pain. The aim was to combine TMG with electromyography (EMG) to guide individualised training interventions to optimise retraining.
METHODS: Cross sectional area (CSA) of each thigh was measured; and single leg balance time and 10-repetition maximum (RM) leg press were assessed for each leg. TMG was used to measure muscle displacement (Dm) of vastus lateralis (VL), rectus femoris (RF) and

vastus medialis (VM) on each leg. EMG was used to examine pre-motor time (PMT) of VL, RF and VM during maximal voluntary isometric contraction. The results of the affected limb were compared to those of the contralateral limb. The athlete presented muscle atrophy in the affected leg, along with impaired strength and motor control. Compromised contraction of VM, in the affected limb, was evidenced by impaired Dm and prolonged PMT. Training interventions, aimed at maximising VM activation, were prescribed. Interventions included: blood flow restriction, time under tension and classic strength training principles. Neuromuscular assessments were repeated following 5 weeks undertaking individualised strength training.
RESULTS: At initial assessment, the affected limb displayed 4.3% smaller CSA, and 49% lower 10-RM and 50% shorter single leg balance time, compared to the contralateral limb. TMG revealed similar Dm between limbs in VL (2.2mm vs 3.9mm) and RF (4.8mm vs 6.7mm), but substantially lower Dm in VM of the affected limb (0.5mm vs 2.3mm). VM also displayed longer PMT in the affected limb (233.3ms vs 211.7ms). Following 5 weeks of training, the difference between limbs in CSA, 10-RM and balance time were reduced compared to initial assessments (1.3%, 24.1%, 16%, respectively). VM Dm and PMT were similar between limbs (3.2mm vs 2.8mm and 226ms vs 216.5ms, respectively).
CONCLUSION: In this case study, application of TMG in combination with EMG informed the return to training of an injured athlete, allowing targeted intervention towards impaired muscle. Muscle mass and function were both improved within 5 weeks following initial assessment.

PLAYING THROUGH THE PAIN: SELF-REPORTED SHOULDER FUNCTION OF UNINJURED RUGBY PLAYERS

PARTNER, R., FRANCIS, P.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: The shoulder is the most commonly injured joint in rugby league and among the top 3 in rugby union. Contact injuries make up the majority of shoulder injuries in rugby, but many shoulder pathologies are of insidious onset or linked to training loads. Given that previous injury is the greatest risk factor for future injury in many sports, it is pertinent to develop methods which detect early stage pathology. At present, it is not yet known what the prevalence of players playing with an existing sub-clinical shoulder dysfunction are. The Rugby Shoulder Score (RSS), a uni-dimensional 120-point scale (20 - 140), was developed to monitor shoulder function in players undergoing rehabilitation from shoulder injury. The aim of this study was to use the RSS to estimate the prevalence of sub-clinical shoulder dysfunction in a sample of professional and amateur rugby players.
METHODS: Following ethical approval from the Leeds Beckett University research ethics committee, 86 uninjured players provided written informed consent. RSS assessments were administered, via paper questionnaire, at the mid-point of the season. All players were participating in training and match play at the time of assessment. The sample consisted of 34 professional and 52 amateur players respectively. A RSS of 20 represents a perfect score. An increasing RSS indicates increasing shoulder dysfunction.
RESULTS: The mean RSS score for the entire sample was 35. Professional players demonstrated greater shoulder dysfunction than amateur players (RSS 42 vs. 30; $P<0.05$). Fifty five percent of all players indicated varying levels of shoulder dysfunction (mean 47, range 22-105). Of players with a recorded shoulder dysfunction, 17 reported it affecting their match play or training despite being classified as uninjured. The mean RSS of this sub group (n=17) was 62 (CI 50-75). Players who did not have a perfect RSS but did not report it affecting their match play or training had a RSS of 41 (CI 36-45).
CONCLUSION: The results of study indicate that the RSS can detect sub-clinical shoulder dysfunction in a sample of rugby players classified as uninjured. The prevalence of shoulder dysfunction (RSS >20) was more than half of the sample. Professionals tended to have greater shoulder dysfunction than amateurs. A threshold for minimal clinical importance of the RSS does not exist. However, for a sub group of players (n=17) an RSS range has been identified which appears to indicate a level of dysfunction which may affect match play and training.

EFFECT OF SITTING POSITION HOLDING DEVICE FOR ELDERLY CEREBRAL PALSY PATIENTS – TWO CASES WHERE ACTIVITY OF DAILY LIFE (ADL) AND QUALITY OF LIFE (QOL) WERE IMPROVED –

INAGAWA, T.

NTT MEDICAL CENTER TOKYO

INTRODUCTION: We developed the sitting position holding device for 2 elderly patients with severe disability originating from cerebral palsy. It corrected their abnormal sitting postures and reduced their disability.
METHODS: Case 1: A 61-year-old woman with spastic hemiplegia who stayed in a nursing care home experienced progression of poor posture with aging, and the upper body tilted significantly to the right on a wheelchair. Therefore, she could not have taken a meal by herself for a long time. In order to correct her posture, in cooperation with facility-staff and wheelchair-producers, we made a modular type wheelchair with posture holding devices such as large-head-rest, trunk-hold-lateral-pad, chest-belt, and adduction-prevention-pad of hip joint.
Case 2: A 63-year old man with spastic quadriplegia who received home care services spent the daytime sitting on the sofa in the living room. Because his sitting position was poor, muscle tone of the lower limbs always increased, and flexion contracture of both knees became aggravated. Instead of this sofa, we developed a mold type sitting position holding device, and installed it in the wooden frame with a reclining function.
RESULTS: Case 1: These posture holding devices enabled to reduce sever tension of upper body, and she could take a proper sitting posture. As a result, the upper body no longer tilted to the right. Especially, as the pelvis was in a good position, the movement in both upper limbs improved. Using cut-out-table, she could eat meals by herself. From such good changes in this patient, the caregivers at the nursing home began to reconsider how to care for them from now on.
Case 2: By preventing excessive stretching of the trunk and keeping the hip joint moderately flexed, the flexion position of both knees improved. Using a cut-out-table, he could take meals by himself. In addition, we developed a wheelchair with a sitting position holding device for him. Keeping the good sitting position, tilting and reclining function of the wheelchair reduced his fatigue on the wheelchair; therefore, he could take chance to go out and travel with this wheelchair.
CONCLUSION: Physical function in the patients who have disability due to cerebral palsy tends to decrease easily with their aging. We experienced physical function improvement in these patients who had serious disability and needed physical assistance in every aspect of daily lives by keeping their sitting postures good. Through these cases, we cordially appreciated that providing nursing and home care services, keeping a close eye on their body posture was an important approach to maintaining and improving their ADL and QOL. Also, when making a sitting position holding device like this, liaison with nursing care and medical as well as cooperation with regional and hospital staff appeared to be essential.

THE METHOD USED TO DEFINE LIMB DOMINANCE IN UNINJURED GROUPS AFFECTS THE RESULTANT LIMB SYMMETRY INDEX STATISTICS AND THE IDENTIFIED DIFFERENCES BETWEEN ACL-RECONSTRUCTED AND UNINJURED GROUPS.

MCFADDEN, C., DANIELS, K., STRIKE, S.

UNIVERSITY OF ROEHAMPTON, LONDON. SPORTS SURGERY CLINIC, DUBLIN.

INTRODUCTION: Large asymmetries in joint loading and functional performance observed in individuals following anterior cruciate ligament reconstruction (ACLR) compared to uninjured groups have been associated with risk of re-injury (Sward et al. 2010). The limb symmetry index (LSI) is used to quantify these asymmetries. LSI is calculated using one limb as a reference. Normally the unaffected limb is used as a reference for injured groups and the dominant limb is used for uninjured groups. As multiple definitions of lower limb dominance exist, the reference limb selected and the LSI results reported for uninjured groups may depend on the definition used. The aims of this study were to determine the effect of three common dominance definitions on uninjured LSI group statistics and to evaluate if changes to LSI groups statistics as a result of dominance definition affected the interpretation of differences between LSIs in post-ACLR and uninjured groups.
METHODS: Fifteen healthy male athletes and 15 post-ACLR (mean 28 weeks) participants completed a vertical drop jump, single-leg counter-movement jump and a single-leg hop for distance. Kinetic and kinematic data were recorded for each exercise using a Vicon motion capture system. Peak knee abduction moment (KAM), jump height and hop distance were calculated. KAM has been associated with increased ACL loading and injury while jump height and hop distance LSI are regularly assessed during rehabilitation (Xergia et al. 2013). LSI was calculated using the uninjured limb as a reference in the ACLR group and using three different dominance definitions for the uninjured group: preferred kicking leg (K), highest jump (J) and furthest hop (H). A repeated measures ANOVA model was used to test the effect of dominance definition on LSIs in the uninjured group. Student's t-tests and Cohen's d effect sizes were then used to compare ACLR and uninjured asymmetries for each dominance definition.
RESULTS: Dominance definitions affected reference side selection in 93% of uninjured participants. Hop distance and jump height LSI group means were significantly affected by dominance definition ($p = 0.038$, $p = 0.025$) but KAM LSI was not. Standardised between-group effect sizes (D) and significance values (P) varied considerably for KAM (DK 0.55, PK 0.138; DJ1.03, PJ 0.08; DH 0.56, PH 0.136), jump height (DK 1.73, PK 0.00; DJ 1.09, PJ 0.006; PH 0.001, DH 1. 33) and hop distance (DK 0.98, PK 0.12; DJ 0.37, PJ 0.319; DH 0.08, PH 0.815) depending on the definition used.
CONCLUSION: Different dominance definitions can significantly alter LSI group statistics in uninjured groups and result in diverse and potentially contradictory interpretations when comparing LSIs between post-ACLR and uninjured groups. The definition of lower limb dominance must be considered when evaluating the results of studies assessing LSI in uninjured groups.

EVALUATING THE KNEE VALGUS WITH DROP AND ATTACK JUMPS AND THE USE OF THE LANDING ERROR SCORING SYSTEM AS A SCREENING METHOD IN YOUNG ELITE FEMALE AND SEMI-PROFESSIONAL VOLLEYBALL ATHLETES

BRODATZKI, Y.

INSTITUTE OF SPORT AND EXERCISE SCIENCES

INTRODUCTION: Volleyball athletes, male and female, have been observed to jump approximately 100 times during a game. Ferretti, et al. (1992) reported 52 cases of serious knee ligament injuries after landing, often found in a pronounced knee valgus position, of which females are more susceptible than males. To reduce the risk of knee injuries, coaches implement methods to evaluate landing mechanisms. The Landing Error Scoring System (LESS) (Padual et al., 2009) is often used to screen players for potential risk of injuries, such as ACL damage and to establish preventive strategies. Therefore, the aim of the study was to investigate whether there are differences between the drop and attack jump with regard to the knee valgus angle and whether improved performance in the LESS is apparent between semi-professional and young elite volleyball players.
METHODS: 18 active female volleyball athletes, 8 young elite academy players and 10 semi-professional 3rd division players (20 ± 5y, 179 ± 0.3cm, 70 ± 4.5kg), participated in the study. The players performed firstly three valid consecutive drop jumps from a box with a height of 20cm and secondly three valid attack jumps, with 30 seconds rest between the single jumps. Both groups were tested on different days. The jumps were recorded with two cameras, filming from a frontal and sagittal plane. Data was preceded with the free software Kinovea, using the frontal plane angle to evaluate the knee valgus. LESS scoring system was applied afterwards by one rater.
RESULTS: The results of repeated-measures ANOVAs showed a significant difference between jump types, $F(1, 16) = 42.3$ $p < .001$, $eta^2 = .73$, but no significant difference between the groups $F(1, 16) = .04$, $p = .95$, $eta^2 = .0$. Post-hoc comparison showed that knee valgus angle in attack jumps is significantly higher than in drop jumps ($p < .001$). Concerning the LESS, the young elite volleyball players on average scored a result of 'good' (LESS score >4 to ≤5) whereas the semi-professional group were classified on average as 'poor' (Less score, >6).
CONCLUSION: It was observed that the knee valgus angle of the semi-professional players was numerically higher than those of the young elite players. Furthermore, the LESS score of the semi-professional athletes were worse than that of the young elite athletes. Both, the higher knee valgus angle (37.8 ± 18.6°) and the higher LESS score (7.3 ± 3.5) plus the partly inexperience in drop jumping, which has been determined in a previous questionnaire, may indicate that semi-professional players are at potentially greater risk to suffer knee injuries. Due to these findings, coaches and practitioners should be aware of greater knee valgus angles and worsened LESS score in this population and therefore attempt to implement interventions or specific landing training in attempt to alter these trends.

COULD MUSCLE INJURY INDUCES CHANGES IN TENDON STRUCTURAL AND MOLECULAR PROPERTIES?

BARIN, F.1,2, RAMOS, G.1, NETO, I.1, OLIVEIRA, A.1, RUIVO, A.1, DURIGAN, J.1, MARQUETI, R.1

1: UNIVERSIDADE DE BRASÍLIA , 2: CENTRO UNIVERSITÁRIO DE BRASÍLIA

INTRODUCTION: Studies have shown that transmission of physiological loads in the tendon mediated by muscle contraction are required to maintain tendon homeostasis and architecture. Thus, the objective of the present study was to evaluate the effects of injury in the gastrocnemius muscle (GA), on the morphological and molecular properties of the calcaneal tendon (CT) of rats.
METHODS: Wistar rats were randomized in four groups (n = 9 animals per group): control without intervention (C), 3 days (3D), 14 days (14D) and 28 days (28D) after muscle cryolesion. Histological techniques (staining with hematoxylin and eosin) were used to analyze cells and vessels volume density (Vv%) in proximal and distal regions (considering the tendon proper and the peritendinous sheath) in CT. Total RNA isolated from frozen tendon samples was analyzed by qPCR for collagen I (COL1A1), collagen III (COL3A1), mothers against decapentaplegic homolog 3 (SMAD3), connective tissue growth factor (CTGF), matrix metalloproteinase-2 (MMP2) and tissue inhibitor of metalloproteinase-2 (TIMP2) to verify molecular changes in CT.
RESULTS: The GA muscle lesion (confirmed by qualitative histological analyzes) culminated in an increase peritendinous sheath cells (Vv%) in the 14D and 28D when compared to the C and 3D groups. The blood vessels (Vv%) increased in the 14D when compared to C group (tendon proprer). No statistical differences were observed in the distal region of the CT for all histological variables in tendon proprer and peritendinous sheath.
COL1A1 mRNA expression decreased in 3D compared with C group, with subsequent increased in 14D compared to 3D group. COL3A1 mRNA expression decreased in 14D compared to C group. The level of CTGF mRNA was decreased in 3D compared to C group, however we observe increased in 14D and 28D compared to 3D group. SMAD3 mRNA expression increase in 14D compared to 3D and 28D group. The gene expression of MMPs and TIMPs were similar after GA muscle injury. MMP2 and TIMP2 decreased in 3D compared to C groups. Besides that, the 14D and 28D groups increased compared to 3D (MMP2 and TIMP2 mRNA expression) and C group (TIMP2 mRNA expression).
CONCLUSION: The main findings (decrease in the mRNA expression of CTGF, COL1A1, MMP-2 and TIMP-2 in the 3D group) evidenced a loss of tendon homeostasis after muscle injury, probably related to the lack of mechanical stimuli induced by contractile tissue injured (stress shielding). Due this fact, the tendon can to be mechanically weak and susceptible to injury. However, the increase observed in these same genes, still linked to SMAD3 in the 14D and CTGF, MMP2 and TIMP2 in the 28D, could be correlated with increases at peritendinous sheath cells may suggest a tissue remodeling, following muscle recovery as well.

CP-PM18 Health and Fitness: Children and adolescents

IS PHYSICAL ACTIVITY LEVEL CORRELATED TO NEIGHBORHOOD CHARACTERISTICS? AN 15 YEARS FOLLOW UP FROM CHILDHOOD TO ADULTHOOD.

FIGUEIRA JUNIOR, A.1,3, ANDRADE, E.2, CESCHINI, F.1, MONTENEGRO, C.G.3, BOCALINI, D.4, ANDRADE, D.5

SÃO JUDAS TADEU UNIVERSITY1, UNIVESIDADE NOVE DE JULHO2, INSTITUTO DE ENSINO ALBERT EINSTEIN3; UNIVESIDADE FEDERAL DO ESPIRITO SANTO4; UNIVERSIDADE DE SÃO PAULO5

INTRODUCTION: Physical activity is a complex behavior because is related to different determinant factors that increase or not the total amount of daily body movement. Among all determinant factors, the neighborhood environment contributes to the physical activity level for al ages. However it is not clear how neighborhood is perceived for childhood to adulthood. Thus this study aimed to determine the perception of living neighborhood and its association with physical activity behavior of male and female from young to adult live time.
METHODS: We evaluated 192 subjects at 10, 15 and 20 years of age throughout a questionnaire with questions about neighborhood characteristics including the perception of pleasure and 5 to 20 minutes of walking to school, sports facilities, fitness club, convenience stores, bakery, bank, post office, sidewalk quality, traffic, streets connectivity, safety and relationship with other neighbors. Physical activity was determined by frequency, duration of walking to these places at different period of live. The classification in active or insufficient activity is based in total of 300 min/week of movement. Statistical analysis was determined for non-parametric variables by Kolmogorov-Smirnov and Shapiro-Wilk. The comparison among childhood-teenagerhood-adulthood was performed by Chi-Square and Friedman test and Cochran Q test. The significance was $p<.05$
RESULTS: Data evidenced a decrease in amount of physical activity from childhood to adulthood from 332.9% to 30.8% in 5 days or more per week, with similar phenomena to no activity from 18.9% to 16.8% at the same ages. Sports practice decrease from 15.2% to 7.7% at same periods of life. Neighborhood environment was positively related to total amount of physical activity if: the place or facility were at least 5-10 minutes from home; street were save; sidewalks were in good condition; green areas on the way.
CONCLUSION: Data allow us to conclude that good perception of neighborhood positively correlates to the total amount of physical activity, suggesting the urban areas can decrease the physical activity level over life.

GROWTH TRENDS IN AGILITY EVALUATED BY A NOVEL AGILITY TEST, N-CHALLENGE, IN JAPANESE ELEMENTARY SCHOOL CHILDREN

OKUDA, T., MORITA, N., SHIDE, N., OYAMA, Y., AMBE, H., YAMAMOTO, R., SATO, T.

HOKKAIDO UNIVERSITY OF EDUCATION IWAMIZAWA

Introduction: Agility is defined as "a rapid whole body movement with change of velocity or direction in response to a stimulus" (Sheppard and Young 2006). It is one of the main physical fitness components and is also considered a crucial component for success in many sports such as tennis, basketball, and soccer (Hachana et al. 2014). Previous studies regarding agility have compared the agility performance of elite athletes with that of non-elite athletes. However, there was little information on the growth of agility and its related factors, especially increasing body size, in elementary school children. The aims of this study were to clarify growth trends in agility and its related factors in elementary school children.
Methods: We designed a new agility test set on an N-shaped (7.2 m length; 3m width) course, which consists of six sections as follows: 1) response time to light stimulus (the time from emitting light to 60 cm forward of a start line), 2) 6 m straight sprint, 3) change of direction

(right turn), 4) five small hurdles (20 cm height; 80 cm apart), 5) change of direction (left turn), and 6) 6 m zigzag run using 5 poles (1.2 m height; 1.2 m apart). The section times and total time for the six sections were measured by phototube sensors. 1206 elementary school children (1st through 6th graders) performed the test twice. The growth tendency of agility ability from 1st to 6th graders was analyzed.
Results: In total time for the six sections, the 1st graders were the slowest (boys, 11.39 ± 1.06 sec; girls, 11.80 ± 0.91 sec), and the 6th graders were the fastest (boys, 9.51 ± 0.85 sec; girls, 9.94 ± 0.76 sec). A one-way ANOVA revealed a significant main effect for age differences (boys, $F = 69.28$, $p < 0.01$; girls, $F = 78.52$, $p<0.01$). As a result of Tukeys HSD test, the total time for the six sections shortened with increasing age, especially from 1st to 4th graders, in boys and girls. However, total time in girls was not shortened significantly between 4th and 5th graders, or between 5th and 6th graders. Also, total time for the six sections in boys did not improve significantly from 4th to 5th, 4th to 6th, or 5th to 6th graders. There was a significantly weak and moderately negative relationship between body size measures (height and weight) and running time in boys and girls.
Discussion: The agility of elementary school children could be related to an increase in height and weight, but it was shown that agility improved only from 1st to 4th grade. Further study is needed for elucidating growth trends in agility of school children, including other types of agility.

SEASONAL VARIATION OF URINE SPECIFIC GRAVITY, TOTAL WATER INTAKE, AND ASSOCIATION WITH SUBJECTIVE FEELINGS OF ADOLESCENT STUDENT-ATHLETES

APHAMIS, G., GIANNAKI, C.D., STAVRINOU, P.S.

UNIVERSITY OF NICOSIA

INTRODUCTION: Adolescents have been shown to be prone to hypohydration as they fail to meet daily required fluid intake (Iglesia et al., 2016). Individuals living in warm countries face a higher risk of dehydration, especially those involved in sport. At the moment there is a lack of published data on seasonal variations between winter and summer. The aim of the present study was to monitor urine specific gravity, water intake and feelings related to hydration in the winter and summer time, among a sample of student-athletes.
METHODS: Thirty-one adolescent (boys n=20) student athletes (age 14-16y) volunteered for this study. Urine specific gravity (USG) was assessed on two occasions: once in the winter and once in the summer time, on arrival at school and at the end of the school day. At the same time points, a subjective feelings questionnaire related to thirst, fatigue and concentration was completed by the participants (alertness (10-cm visual analog scale, Shirrefs et al., 2004). Detailed food and fluid intake records were kept during the study, to allow total water intake estimation. Dehydration cut-off point was set at USG 1.025. Comparisons between seasons and time of day were performed using Repeated Measures ANOVA. Asocciations between USG and subjective feelings were performed using Pearsons correlation.
RESULTS: In the winter, only 36% of the participants arrived hydrated to school, as opposed to 61% in the summer. There was a season effect on USG (USG winter1.027±0.001, USG summer 1.023±0.001, $p=0.001$).USG remained unchanged between beginning and end of school-day. There was no difference on water intake between seasons (winter 960±509ml, summer 951±627ml, $p=0.692$). USG negatively correlated with concentration (winter $p=0.004$, summer $p=0.055$) and fatigue (winter $p=0.016$). There was no correlation between USG and thirst, and there was no difference on thirst between winter and summer ($p=0.753$).
CONCLUSION: A large proportion of adolescents were hypohydrated, and more students were hypohydrated in the winter time compared with the summer time. Thirst did not drive hypohydrated individuals to drink more. Hypohydration was associated with increased feelings of fatigue and decreased feelings of concentration, which can adversely affect school, training and competition performance. Drastic measures must be taken to educate adolescents on fluid intake, especially during winter time.

EFFECTS OF THE DAILY MILE ON MEASURES OF PHYSICAL FITNESS IN 9 – 10 YEAR OLDS.

GAULT, M., POTTER, J., LAUDER, M.

UNIVERSITY OF CHICHESTER

INTRODUCTION: School-based interventions are an effective way to counteract low physical activity and fitness in children (Kriemler et al., 2011). The Childhood Obesity Strategy (HM Government, 2016) endorses The Daily Mile for schools to engage children in physical activity and improve health. However, despite widespread uptake of The Daily Mile and its endorsement by UK policy, evidence is anecdotal. The current study investigated the effects of The Daily Mile on fitness in 9-10 year olds.
METHODS: In a repeated-measures design, year 5 pupils (9-10 year olds) from 2 schools in West Sussex, UK, were compared during 2 school terms (Jan-July, 26-weeks). School 1 (28 pupils) participated in The Daily Mile (an additional 15-minutes of running/walking integrated into the school day) and school 2 (39 pupils) acted as the control, participating in usual practice for physical activity. At week 0 (Jan) and week 26 (July) body mass index (BMI) z-scores, back-saver sit-and-reach (BSSR, left, L and right, R), handgrip strength (HGS, dominant, D and non-dominant, ND), counter-movement jump (CMJ) and 1-mile run times were recorded. Delta values of best of three trials for BSSR, HGS and CMJ, were analysed, with all parameters assessed by 2-way repeated-measures ANOVA (school x time).
RESULTS: Growth was evident across the intervention period in both schools (mean 3cm, $p<0.0001$) and body mass increased (mean 1.3kg, $p<0.0001$). BMI z-score decreased for both schools from week 0 (mean 0.42, SD 0.90) to week 26 (mean 0.29, SD 0.84), with no difference between the intervention and control school ($p=1.86$). 10 children in school 1 and 9 in school 2 were overweight or obese, according to BMI percentiles, at week 0, with 8 and 5, respectively at week 26. BSSR R did not change from week 0-26 ($p=0.97$), however School 1 was significantly greater than school 2 at week 26 (37 vs 35, $p=0.04$). BSSR L decreased from week 0-26 for both schools ($p=0.038$). Improvements in strength and power were observed in both groups: HGS D was lower for school 2 at week 0 ($p=0.038$), however at week 26 they were similar ($p=0.89$) with a 13% increase for school 2 ($p<0.0001$). Both schools had a similar increase in HGS ND ($p<0.0001$) and CMJ power ($p<0.0001$) at week 26, with no change in 1-mile run time ($p=0.436$).
CONCLUSION: The Daily Mile may be a simplistic and low-cost intervention (Breheny et al. 2018), however, with limited physical benefits in the short-term, compared to usual practice, it has no added value for year 5 pupils. Further research needs to establish additional physi-

cal activity participation by children, impact on attainment and concentration, and the potential contribution of The Daily Mile to physical inactivity in later life (Fairhurst and Hotham, 2017).

WHAT IS HEALTH-RELATED FITNESS? INVESTIGATING THE UNDERLYING FACTOR STRUCTURE OF FITNESS IN YOUTH

BRITTON, U., BELTON, S., ISSARTEL, J.

DUBLIN CITY UNIVERSITY

INTRODUCTION: Health-related fitness (HRF) is generally seen as a multidimensional construct containing components such as cardiovascular endurance, muscular strength, muscular endurance, flexibility and body composition. Evidence exists for the association between health and cardiovascular endurance, and muscular strength/endurance, but not for flexibility. Additionally, the inclusion of body composition as a component can pose problems given the frequency with which body composition is used as a dependent variable where HRF is an independent variable. This study aimed to 1) investigate the underlying factor structure of a four-component (cardiovascular endurance, muscular strength, muscular endurance, flexibility) HRF construct, taking into account problems posed by the inclusion of body composition and 2) identify field-based tests representative of HRF in youth.
METHODS: Participants were 261 children (53% female, 47% males; mean age 12.22 ± 0.48 years). Indicators of four fitness components (20m shuttle run, curl-ups, push-ups, horizontal jump, vertical jump, grip strength, and modified-back-saver-sit-and-reach) were measured. Independent t-tests were used to identify sex differences across all measures. Confirmatory factor analysis (CFA), using maximum likelihood estimation methods, was used to analyse the underlying structure of HRF as a four-component construct.
RESULTS: Significant differences for sex for absolute scores on 20metre shuttle run, horizontal jump, push-ups, flexibility ($p < .001$), vertical jump ($p < .01$), and curl-ups ($p < .05$) were found. When age and sex-specific values were assigned a significant sex difference remained for curl-ups only ($p < .05$). CFA of the four-component HRF model revealed a low contribution of flexibility ($r = .10$) to the overall model, leading to its removal. The subsequent three-component model showed better fit across all fit statistics (NFI, TLI > .90; CFI > .95; RMSEA = .077; SRMR = .045). Analysis of indicator loadings in the three-component model led to the removal of grip strength ($r = .37$) as an indicator of muscular strength, further improving model fit (TLI > .90; NFI, CFI > .95; RMSEA = .10; SRMR = .037). The reduced three-component model was re-specified as a first-order model containing five indicators. Multiple-group analysis of this first-order HRF model found the HRF model to be invariant across gender (CMIN = 5.547; $p = 0.236$) for factor loadings. Measurement intercepts were significantly different between males and females (CMIN = 51.618; $p = 0.000$).
CONCLUSION: These findings suggest that HRF in youth is adequately represented by five indicators representing three components of fitness. Tests of these indicators are practical and time-efficient for measuring HRF in field-based settings. Significant sex differences were found for absolute scores of indicators within the model, but HRF as an overall construct was found to be the same across males and females.

A COMPARATIVE STUDY ON THE PHYSIQUE AND PHYSICAL FITNESS OF CHILDREN IN EAST ASIA

MURAKAMI, K., ICHIMARU, N., ZEONE, K., WENG, C.C., SUZUKI, C., FUJII, M., MAEDA, A.

GRADUATE SCHOOL OF PHYSICAL EDUCATION, NATIONAL INSTITUTE OF FITNESS AND SPORTS

A Comparative Study on the Physique and Physical Fitness of Children in East Asia
Murakami K.1, Ichimaru N.2, Zeone K.3, Weng C.C.4, Suzuki C.1, Fujii M.1, Maeda A.5 1: Graduate School of Physical Education, National Institute of Fitness and Sports in Kanoya(Kagoshima, Japan), 2: University of Teacher Education Fukuoka(Fukuoka, Japan), 3: Kangwon National University(Kangwon, Korea), 4: National Taiwan University of Sport(Taichung, Taiwan), 5: National Institute of Fitness and Sports in Kanoya(Kagoshima, Japan)
Introduction: The purpose of this research is to measure the physique and physical fitness of children in East Asia (Japan, Korea, Taiwan), and to conduct basic research to propose the physical problem of physical strength and physical fitness of each country and the health problems accompanying.
Methods: we measured physique and physical fitness for junior high school students in East Asian three countries. The total was 190 students. (70 Japanese (38 boys, 32 girls), 66 Korean (33 boys, 33 girls) and 54 Taiwanese (25 boys and 28 girls).). The measurement contents were Height, Weight, Body fat percentage, Grip strength, Standing width jump and Throwing.
Results: As a result of boys, Height was 161.0 cm in Japan, 166.8 cm in Korea, 165.7 cm in Taiwan. There was a significant difference between Japan and Korea and Taiwan. Weight was 52.8 kg in Japan, 60.7 kg in Korea, 58.4 kg in Taiwan. Body fat percentage was 17.1% in Japan, 21.2% in Korea, 18.9% in Taiwan. There was a significant difference between Japan and Korea. Grip strength was 30.9 kg in Japan, 31.1 kg in Korea, 28.5 kg in Taiwan. Standing width jump was 194.3 cm in Japan, 187.4 cm in Korea, 192.0 cm in Taiwan. Throwing was 19.6 m in Japan, 17.8 m in Korea, 18.3 m in Taiwan. As a result of girls, height was 153.5 cm in Japan, 158.7 cm in Korea, 155.8 cm in Taiwan. There was a significant difference between Japan and Korea. Weight was 45.6 kg in Japan, 54.2 kg in Korea, 51.4 kg in Taiwan. There was a significant difference between Japan and Korea and Taiwan. Body fat percentage was 18.0% in Japan, 18.3% in Korea, 16.0% in Taiwan. There was a significant difference between Korea and Taiwan. Grip strength was 24.7 kg in Japan, 20.7 kg in Korea, 18.7 kg in Taiwan. There was a significant difference between Japan and Korea and Taiwan. Standing width jump was 176.5 cm in Japan, 139.4 cm in Korea, 150.6 cm in Taiwan. There was a significant difference between Japan and Korea and Taiwan. Throwing was 13.8 m in Japan, 8.5 m in Korea, 10.2 m in Taiwan. There was a significant difference between Japan and Korea and Taiwan.
Conclusion
From the results of this study, Ⅰ. Korean children have a high proportion of obese children. There is a need for improvement. Ⅱ. Recent Japan has a low level of physical strength. However, children in Korea and Taiwan were lower in physical strength than such Japan. It was remarkable especially in girls.

THE EFFECT OF INTRODUCTION OF STANDING DESKS TO AN ELEMENTARY SCHOOL

TANAKA, R., SHIKANO, A., NOI, S.

NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: In recent years, the children's risks of being sedentary for too long have been pointed out. Primack et al (2009) reported in a longitudinal study that the length of time spent sitting can predict depression seven years prior to it's onset. Studies on the introduction of standing desks have been conducted with regards to time spent in a sedentary state, and suggest that as the number of steps increases, low intensity exercise time decreases (Sherry et al., 2016). In addition, Rosenbaum et al (2017) reports that standing work has a

more positive impact on executive function when compared to working whilst seated. These previous studies may indicate that the introduction of standing desks within schools could increase the amount of physical activity, improve their executive function and decrease the likelihood of depression.In this study, we aimed to examine the introduction of standing desks and their influence on physical activity, executive function, depression and subjective symptoms of fatigue among elementary school students in Japan.
METHODS: The subjects were 88 students from fifth grade classes in elementary school, Tokyo, Japan, and the study was carried out throughout October to December 2017. Of the three classes, one class (N=30) was the intervention class, the second class (N=58) was the control class. For evaluation of depression, the DSRS-C (Depression Self-Rating Scale for Children) abbreviated version, was conducted before and after the intervention. For measurement of executive function, the "Flanker task" was conducted. For evaluation of subjective symptoms of fatigue, "Jikakushoshirabe" was conducted. A Pedometer with an accelerometer (Lifecorder GS, manufactured by Suzuken Co., Ltd.) was used for measuring the amount of physical activity during the intervention period.
RESULTS: A comparison between the number of steps taken before the intervention and after,The total number of steps per day increased significantly in the intervention class compared to the control class. There was no change in the proportion of those who scored highly for depression, both in the control class and the intervention class. In addition, the subjective symptoms of fatigue the feeling of sleepiness decreased, and the feeling of malaise increased in the intervention class compared with the control class. Detailed results, including results of executive functions evaluated using Flanker tasks, should be reported on the day.
CONCLUSION: The results of this study suggested that the introduction of standing desks can help combat the problem of child sleepiness.
This research was implemented a part of research conducted by collaboration between Nippon Sports Science University Noi Laboratory and Okamura Mfg. Co.

PARENTAL WILLINGNESS TO PAY FOR THE PREVENTION OF CHILDHOOD OVERWEIGHT AND OBESITY IN PRESCHOOLS

LAUER, R.1, HERMELING, L.1, KELSO, A.1, STEINACKER, J.M.1, KESZTYÜS, D.1,2

ULM UNIVERSITY

INTRODUCTION: Willingness to pay (WTP) can be used as a threshold for cost-effectiveness analyses in the field of prevention. The aim of the present study was to examine parental WTP to reduce the incidence of childhood overweight and obesity in a sample of preschool children from Southwest Germany participating in a multi-level (physical activity, sedentary behaviour and diet) health intervention study.
METHODS: Cross-sectional data from children aged three to five years and their parents were assessed in the fall of 2016 within the scope of the health survey, an evaluation study of the health promotion program "Join the Healthy Boat". Children´s anthropometric data were taken by trained staff, while parental data (anthropometrics, socio-demographics and health-related variables, such as parental physical activity) were assessed via questionnaires. Parents were asked if they were in general willing to pay for a reduced incidence of childhood overweight and obesity by half (general WTP; "yes", "no"). Further, parents who answered "yes" were asked to indicate the amount of money they were willing to pay for this measure each month (amount of WTP). Man-Whitney-U tests and Fishers exact tests were used to assess group differences according to general WTP (α=0.05). A logistic regression analysis for general WTP was conducted.
RESULTS: Data for general WTP were available for 708 parents. A general WTP was declared by 46.6% of the parents with a mean amount of 32.09 (median WTP= 20.00, IQR=40, n=294). Parents considering overweight and obesity as a problem, having a higher household income, fathers staying at home more often to care of a sick child, fathers with higher BMI, and mothers having more working hours a week were significantly more often willing to pay ($p<0.05$), according to bivariate analyses. Surprisingly, there was no association with children´s weight status, migration background, parental education level as well as their physical activity level. The regression analysis showed that general WTP was associated with fathers staying at home to care for a sick child and father´s BMI. Mother´s working hours per week and household income were marginally significant.
CONCLUSION: The high general willingness to pay for the prevention of childhood overweight and obesity found in this sample of the surveyed parents indicates an awareness towards this health-related issue. Worktime-related factors seem to be associated with parental WTP, while astonishingly no associations with children´s weight, some socio-demographics and parental physical activity were visible.

PREVALENCE OF HYPERTENSION AND CARDIAC FUNCTION IN OVERWEIGHT AND OBESE CHILDREN AND ADOLESCENTS

PANAYIOTOU, G.1, ANTONIADES, O.1,2, DOUDA, H.2, SMILIOS, I.2, SPASSIS, A.2, TOKMAKIDIS, S.P.2

1: EUROPEAN UNIVERSITY CYPRUS , 2: DEMOCRITUS UNIVERSITY OF THRACE

INTRODUCTION: The association between obesity and hypertension has been demonstrated by clinical studies in children (Lu et al., 2013; Rosner et al., 2013) and increased adiposity is associated with an adverse cardiovascular risk (Falaschetti et al., 2010). The purpose of the present study was to determine the prevalence of hypertension as well as practical clinical indicators of cardiac function in overweight and obese children and adolescents.
METHODS: A total of 1.987 healthy Greek and Cypriot children and adolescents were divided according to their age (8-10 yrs, 11-12 yrs, 13-15 yrs, >16 yrs), the stage of hypertension (Normotensive, Hypertensive) and the obesity level (Normal weight, Overweight, Obese). Measurements were obtained on anthropometric characteristics (height, body mass, BMI), blood pressure (SP: systolic, DP: diastolic) and resting heart rate (HR) in order to determine the pulse pressure at rest, mean arterial pressure, rate pressure product and cardiac index using specific equations.
RESULTS: The prevalence of hypertension was about 25.7% in both overweight/obese males and females. The normotensive non-obese participants presented better values in systolic ($p<.001$), diastolic ($p<.001$) and mean arterial pressure ($p<.001$), heart rate ($p<.05$), rate pressure product ($p<.05$) and the cardiac index ($p<.001$) as compared to hypertensive overweight/obese participants. When a stepwise multiple regression was applied in the overweight/obese group, using the cardiac index as a dependent variable ($y=3.570-.034\times W+.040\times HR-.061\times DP+.031\times SP-.036\times Age$), 95.7% of the total variance was explained by body mass (W:45.4%), heart rate (HR:22.6%), diastolic (DP:14.5%) and systolic (SP:12.7%) blood pressure and age (Age:0.5%). In addition, a negative correlation was found between BMI and cardiac index ($r=-.662$, $p<.001$) while positive correlations were observed with other hemodynamic parameters ($r=.33$ to $.55$, $p<.05$).

CONCLUSION: The results of this study revealed that increased body mass affected the cardiac function of overweight/obese young people, irrespective of gender, and they were also associated with hypertension. In clinical practice, it is necessary to implement such useful prognostic indicators in childhood and adolescence in order to detect risk factors leading to cardiovascular disease at an early age.

ACUTE EFFECT OF DIFFERENT KINDS OF RECOVERY PERIODS IN METABOLIC PARAMETERS AND PERFORMANCE DURING SETS IN RESISTED EXERCISE

PEREIRA, A.C.C., FERREIRA, H.F., SILVA, W.D., GOMES, N.G.S., SILVA, E., FREITAS, W.Z.
INSTITUTO FEDERAL DE EDUCAÇÃO, CIÊNCIA E TECNOLOGIA DO SUL DE MINAS GERAIS

INTRODUCTION: Recovery periods between repeated resistance efforts determine the magnitude of resynthesis of energy sources, in addition to promote removal of metabolic products (FLECK; KRAEMER, 2006). Studies by Robergs, Ghiasvand and Parker (2004) and Rafo et al. (2008) reported that the accumulation of cellular metabolites such as Lactate (Lac) and H + resulting from high intensity exercise are negatively related to the performance of individuals. Thus, the objective of the present study was to verify the acute effect of active and passive recovery periods and their combination on Lactate concentrations [LAC], blood pH and performance during the series in resisted exercise in the bench press.
METHODS: Eight males (23 ± 2.9 years, 75.5 ± 9 kg, 174.8 ± 4 cm), exercising for at least 6 months, were evaluated in the maximum load on the 1 repetition maximal test (1RM) in the bench press and, after 48h, the anaerobic threshold (AT) through the Conconi test. AT was used to determine the intensity of the active recoveries periods. After one week the subjects started the 4 protocols (randomized) passive recovery (PR), active recovery (AR), passive / active recovery (PAR) and active / passive recovery (APR). All breaks were 2 minutes long. Duration of the recovery periods (PAR/APR) was 1 minute for each kind of pause totaling 2 minutes. The active pauses were performed 2 km / h below the AT of the subjects, in a treadmill. In each protocol the subjects performed six sets in the bench press until the concentric failure at 70% of 1RM to verify strength (performance). Lactate and pH blood samples were taken prior to the protocols and after the 3rd and 5th series. Statistical analysis was performed by the SPSS-20, using the Shapiro-Wilk test, ANOVA with post hoc Bonferroni for groups and moments, with a significance level of $p < 0.05$.
RESULTS: Significant increases in [Lac] and significant decreases in pH comparing pretest values for 3rd and 5th grades were observed for all the kinds of recoveries, intra-group. However, AR, PAR and APR were more efficient in the significant reduction of [Lac] and increase of pH values, in the 3rd and 5th grades, when compared to the same PR moments, intergroups. It was also observed that in all kinds of pauses performance was significantly reduced throughout the series (intra-group), but no significant differences (intergroups) were found for all moments evaluated.
CONCLUSION: It was concluded that, although AR, PAR and APR were more efficient in the significant reduction of [Lac] and increase of pH values, especially in the 3rd and 5th grades, when compared with the same PR moments (intergroups), do not positively influence on performance.

TENSIOMYOGRAPHY AS A TOOL TO ASSESS MUSCLE SPECIFIC TRAINING ADAPTATIONS.

WILSON, M.T., RYAN, A., VALLANCE, S.R., DIAS-DOUGAN, A., CONTRERAS, B., MACGREGOR, L., HUNTER, A., HAMILTON, D.L.
UNIVERSITY OF STIRLING

INTRODUCTION: The Gluteus Maximus (GM) is a prime mover for the hip extension (HE) movement, which is important to performing many athletic movements such as sprinting and jumping. Thus, athletes pay considerable attention to training hip extension through exercises such as the back squat (BS) (Schoenfeld, 2010). We know that improving lower limb strength through BS training can lead to improvements in sprint time (Seitz et al, 2014); a common measure of athletic performance and predictor of sporting success (Kuzmits and Adams, 2008). Very little is known however, about how specific muscle groups respond to training a compound movement such as the BS. The non-invasive technique of Tensiomyography (TMG) may allow us to determine adaptive responses within specific muscle groups.
TMG provides an objective assessment of skeletal muscle function (Simola et al, 2016). However, to our knowledge TMG has never been employed in a training study to assess or predict changes in specific skeletal muscle groups. Therefore, the aim of this study was to investigate whether TMG is capable of tracking contractile property adaptations of the GM, in response to 6 weeks of HE training in men naive to resistance training.
METHODS: TMG analysis of GM velocity of contraction (Vc), was performed on 17 non-resistance trained males, before and after a 6-week HE resistance training programme. Pre and Post-training measures of 1 rep max BS, and HE maximal isometric voluntary contraction (MVC) were performed to establish changes in dynamic and static strength of the hip extensors.
RESULTS: A significant increase in BS 1 rep max strength ($P < 0.0001$) was found between pre and post training measures, in addition to a significant increase ($P = 0.0024$) in GM Vc. A significant increase ($P = 0.0139$) in HE MVC was found between pre and post training measures. To investigate a possible interaction between the change in GM Vc and HE strength, Pearsons correlation coefficients where calculated between the changes of the two variables ($r = 0.05933$, $P > 0.05$).
CONCLUSION: HE resistance training was shown to be effective in increasing BS 1 rep max strength, a desirable outcome for athletes seeking improvements in sprinting time.
TMG has shown that it may be used to track training adaptations in the GM and may provide a novel method of assessing training adaptations within specific skeletal muscle groups. Our results also suggest that changes in Vc of the GM are not reflective of changes in isolated GM strength, and therefore not reflective of changes in functional strength of the GM.

EFFECTS OF EIGHT WEEKS OF BENCH PRESS AND SQUAT POWER TRAINING ON STABLE AND UNSTABLE SURFACES

ANTIC, V., RADOVANOVC, D., IGNJATOVIC, A.
FACULTY OF SPORT AND PHYSICAL EDUCATION - UNIVERSITY OF NIS

INTRODUCTION: Resistance training exercises under unstable conditions, such as with unstable devices have gained popularity in the past decade, and additionally, numerous studies have evaluated the role of instability in resistance training programs. In the literature, loads between 30% and 60% have been suggested as the loads that produce the highest values of muscular power in bench press output and 40-65% of 1RM in half squats. The load of 50% of 1RM should be considered reasonable for power enhancement on unstable surfaces, allowing proper techniques to be employed during the exercises, without any excessive anxiety about falling. The purpose of this study was to determine the differences in muscular strength and power outputs after eight weeks of stable and unstable resistance training.
METHODS: Seventy two male recreationally active subjects were divided into three groups . Unstable and stable training groups trained twice a week for 8 weeks. Each training session consisted of bench press and squat exercises <6 sets of 6 repetitions for each exercise>. In both conditions, all of the participants performed the exercises with their maximal velocity of movement during concentric phase with the load of 50% of 1RM. Pre and post-training measures included 1RM and peak power in stable and unstable conditions for bench press and squat.
RESULTS: The results showed that both training programs produced greatest power gains on the surface on which the training was performed. This specificity during testing indicated that strength gains were in part specific for the type of exercise velocity used in the training. Moreover, the results showed that there was a significant difference in main effects found with the training induced improvement between the training groups in pre- to post-test in squat 1RM, showing the transfer of specific unstable training exercises on 1RM squat. However, this was not the case in 1RM bench press. Additionally, both modalities produced significant training effects.
CONCLUSION: The findings of this study showed that explosive training with 50% of 1RM on unstable conditions was more effective regarding maximal strength in squat then in bench press exercises.

INFLUENCE OF DIFFERENCE COMPETITION LEVEL OF 400-M SPRINT ON 3-AXIS ACCELERATION OF CENTER OF GRAVITY

KATO, R., YOSHIDA, T., TAKESHITA, T., NORO, H., TAGURI, A., HATA, K., YANAGIYA, T.
GRADUATE SCHOOL OF JUNTENDO UNIVERSITY

INTRODUCTION: Maintaining higher running velocity in 400-m race is thought to be important for runners to achieve faster running. Hanon and Gajer (2009) had reported that the faster sprinter tends to lower the latter half speed, others had reported the faster sprinter suppress lowering the latter half speed. On the other hand, Christine et al (2009) had reported the faster sprinter suppress lowering the latter half speed. Moreover, Yamamoto et al (2014) classified the speed pattern of 400-m race as following 3 types, that is higher speed type in the former half, speed maintain type for all the race, and speed decline type in the latter half of the race. However, it is not known the race pattern related differences in the movement of center of gravity of runner during 400-m running. Therefore, the purpose of present study was to investigate the effect of athletic performance level on the motion of center of gravity using 3-axial accelerometer.
METHODS: Twelve male sprinters (age:19.2±1.16yrs, height:176.0±5.24cm, weight:67.31±3.95kg), their specialization event was 400-m or 400-m hurdle, were served as subjects of this study. After enough warming up, they ran for 400-m in all their effort from crouching start. They were divided into two groups, that is faster group and non-faster group. A wireless wearable 3-axis accelerometer is fixed on their waist by rubber belt, the direction setting of the vectors were as follows, vertical (x), medio-lateral (y), and anterior-posterior (z) during sprinting. Three-axial acceleration were recorded at 100Hz during 400-m sprint running. Digital video movies of sprint running were recorded by panning shot for the purpose of counting running times. Running time every 100m were measured by Doppler sensor.
RESULTS: Significant group difference was observed in 400-m sprint times between faster group (48.53±0.35 sec in faster group (n=6), and 51.69±1.09 sec in slower group n=6). Two way ANOVE revealed no main effect was obtained in acceleration among groups. On the other hand, main effect of distance was obtained in acceleration of vertical, anterior-posterior.
CONCLUSION: There was a significant difference between two groups in latter half section. Therefore, it is important to keep running speed in latter half section. In 3-axis acceleration, faster group showed higher impulsive force than non-faster group. And faster group showed lower upper force than non-faster group. Therefore, impulsive force is maintenance by reduce vertical motion. In 400-m sprint, the factor of high performance is running speed continuation in latter half section. Therefore, it is important to reduce up-and-down and to keep higher impulsive force.

PEAK POWER DURING SLEDGE PUSHING ON SKILLRUN(TM) TREADMILL CORRELATE WITH 15 M SPRINT PERFORMANCE

FEDELE, G.1, CUZZOLIN, F.1,3, ESSER HORSHAM, E.1, SENNI, S.1, ZANUSO, S.1,2, PAVEI, G.4
1 TECHNOGYM SCIENTIFIC DEPT, CESENA 2 UNIVERSITY OF COVENTRY, 3 UNIVERSITY OF PADOVA, 4 DEPARTMENT OF PATHOPHYSIOLOGY AND TRANSPLANTATION, UNIVERSITY OF MILAN

INTRODUCTION: Sledge towing is a common training modality in many track and field disciplines and team sports (Monte et al. 2017; Morin et al. 2017). This training is usually performed outdoors or indoors in large spaces, with the consequent weather and space limitations respectively. Recently, a new treadmill (Skillrun(TM), Technogym) with the capability to perform sledge pushing as well as walking and running was launched in the market. Treadmill output during pushing is the mechanical power and the maximal speed achieved.

The aim of this study was to test the correlation of the power output of the embedded pushing test with the performance parameters derived from the 15 m sprint test.
METHODS: Twenty-seven physically active male subjects (34.6±7.2 years old, 81.3±15.7 kg body mass, 1.79±0.07 m height; mean±SD) participated in this study. Subjects, after having familiarize with the testing procedures, visited the testing facility twice in two consecutive days at the same time of the day. On day 1, they completed the sledge test embedded on the treadmill: three 15 m maximal sprints on the passive treadmill pushing a sledge with a load corresponding to 50%, 70% and 90% of their body mass; each sprint was separated by 3 minutes of passive recovery. Peak power (W/kg) for each added load condition was recorded and the highest considered for comparison. On day 2, three 15 m sprints were performed indoor, with 3 minutes of passive recovery among sprints. Sprint speed over 15 m was recorded by photocells (Microgate Witty), the best trial was considered for comparison. Each sprint was videotaped by a GoPro6 camera at 120 Hz in order to calculate acceleration every two meters; maximal acceleration was considered for comparison. The video analysis was performed with Tracker software using vertical poles as references placed at 2-meter intervals.
RESULTS: Peak power output was 12.4±1.4 W/kg; for 66% of participants peak occurred at load =70% of body mass. Fifteen m speed was 5.79±0.27 m/s and maximal acceleration 10.7±2.2 m/s^2. Peak power correlated significantly with 15 m speed (Peak Power = 3.54*speed -8.116, with speed in m/s, R^2=0.472, p<0.01) and demonstrated a weak correlation with maximal acceleration in the 15 m sprint (Peak power = 0.344*acceleration +8.693, with acceleration m/s^2, R^2=0.274, p<0.01).
CONCLUSION: peak power evaluated with the sledge test embedded in the Technogym SkillRun correlates with the 15 m sprint performance test and could be used by coaches to evaluate sprinting capabilities directly on the treadmill. Thus, the improvement in peak power while pushing can be an effective method to evaluate training adaptations. The novelty of the power profile (and peak) during sledge pushing on the treadmill could also be a new valuable tool for coaches to prescribe training intensity.

COMPARISON OF PEAK POWER MEASURED IN A KEISER AIR POWERED LEG PRESS MACHINE, AND PEAK AND AVERAGE POWER OBTAINED IN A 30 SECONDS WINGATE ANAEROBIC TEST IN WELL-TRAINED CYCLISTS.

HAFSTAD, A., GUNDERSEN, H., IVERSEN, V., KRISTOFFERSEN, M.
WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: In cyclists, sprint performance and anaerobic power are commonly measured using a 30-second Wingate Anaerobic Test (WAnT). The aim of the present study was to compare peak power (PP) output in watt (W) measured in a Keiser air powered leg press (LP) machine, and PP and average power (AvgP) measured by a WAnT.
METHODS: Twenty-one well-trained cyclists (age: 29 ±6 year, bodyweight: 75.93 ±10.6 kg, VO2max: 61.3 ±5.8 ml/kg/min) were included in the study. Participants performed tests at three occasions: at baseline, and 4 weeks and 10 weeks after baseline. Prior to the baseline test, all participants had a familiarization session at the Keiser LP machine (A300, Modell 002531BA, Keiser Co. Inc., Fresno, California, USA) where 1-repetition maximum was obtained. At each occasion, all testing was performed over two days with a minimum of 48 hour in-between tests. At day one, a 10-step power profile in the Keiser LP machine was performed, in addition to a VO2max and lactate profile test. The second day a WAnT were performed as part of a 100 min cycling test on an electromagnetically braked cycle ergometer. The WAnT (load 80g/Kg) was carried out after 5 min cycling at 150 W, 5 min at 175 W and 5 min at the same power that gave a blood lactate concentration of 2 mmol/L (calculated individually from the lactate profile test).
RESULTS: Peak power values (W·Kg-1) obtained in the LP machine was 19.9 % higher compared with PP in the WAnT (17.47 ±2.67 W·Kg-1 vs. 14.57 ±2.42 W·Kg-1, p<.001) and 87.2 % higher compared with AvgP in the WAnT (17.47 ±2.67 W·Kg-1 vs. 9.33 ± 1.0 W·Kg-1, p<.001). There were significant correlations between PP obtained in LP (W·Kg-1) and in the WAnT (W·Kg-1) (r = .71, p<.001), and between PP in LP (W·Kg-1) and AvgP in the WAnT (W·Kg-1) (r = .70, p<.001).
CONCLUSION: Our results show that PP for well-trained cyclists measured in the Keiser LP machine are significantly higher than PP and AvgP measured in the WAnT. The correlation between PP in LP and PP and AvgP in the WAnT indicates that well-trained cyclists that produce high power output in a Keiser LP machine, also have the ability to produce a high PP and AvgP output in a WAnT.

DISTANCE RUNNING PERFORMANCE AND HIGH-INTENSITY RUNNING ECONOMY IN HIGHLY TRAINED FEMALE DISTANCE RUNNERS

TANJI, F.1, NABEKURA, Y.2
1: JAPAN INSTITUTE OF SPORT SCIENCES , 2: UNIVERSITY OF TSUKUBA

INTRODUCTION: Distance running performance can be estimated by physiological variables: maximal oxygen uptake and running economy . In particular, RE is more important than VO2max in highly trained athletes. Moreover, RE measured at an intensity above the lactate threshold is demonstrated to be strongly related than RE measured at an intensity below the LT . However, this has not yet been reported in female runners. Both aerobic and anaerobic energy metabolisms contribute to the energy metabolism during track events; however, women have a lesser anaerobic capacity than men. Hence, it is unclear whether REaLT and/or anaerobic capacity are essential for female distance runners. This study aimed to reveal the association between the distance running performance and physiological variables, including both the REaLT and anaerobic capacity, in highly trained female distance runners.
METHODS: This study included 26 female distance runners participated in this study. They underwent multi-incremental running tests on a treadmill to assess the aerobic [RE at 15.0 km·h−1 as REbLT and at 16.2 km·h−1 run as REaLT, VO2max, and LT] and anaerobic [maximal blood lactate concentration] capacities.
RESULTS: There was a significant association between the IAAF score and RE15.0 and Lamax but not with RE16.2 , VO2max , and LT . Furthermore, 76.8% of the difference in the IAAF score could be explained by RE15.0 , Lamax and VO2max . However, RE15.0 and RE16.2 showed an inverse association with VO2max.
CONCLUSION: The main finding of this study is that not REaLT but both superior REbLT and Lamax are essential for distance running performance in highly trained females, and high VO2max seems to be a precondition for them. However, runners with a high VO2max tend to have lower RE, suggesting that it is difficult to achieve superior both VO2max and RE. Distance runners should not only focus on improving REbLT but also on maintaining VO2max training.

THE BLOOD LACTATE RESPONSE TO ANAEROBIC SWIMMING SETS

MOUGIOS, V., KABASAKALIS, A., NIKOLAIDIS, S., TSALIS, G.
ARISTOTLE UNIVERSITY OF THESSALONIKI

INTRODUCTION: Blood lactate is considered the gold standard for assessing the metabolic profile of training sets. In competitive swimming, a plethora of training sets is recommended for anaerobic metabolism enhancement. However, data on the blood lactate concentration after such sets are scarce. Thus, the aim of this study was to bring together our experience on the blood lactate response to anaerobic swimming training sets and translate this experience into practical guidelines.
METHODS: A total of six investigations, including training sets differing in terms of distance per bout (25 to 100 m), total distance (200 to 400 m), and work-to-rest ratio (1:1 to 1:9), were assessed. A total of 155 competitive male and female swimmers, aged 12 to 20, participated in these investigations.
RESULTS: Large increases in blood lactate were achieved with all sets, although they were highest after sets of 50 and 100 m (not 25 m) bouts with work-to-rest ratios ranging from 1:7 to 1:9. Mean (SD) post-exercise lactate concentrations ranged from 9.2 (3.0) to 18.5 (2.7) mmol/L. Effect sizes were high, ranging from 3.3 to 5.0. Where a test-retest design was used, swimming speed and blood lactate concentrations were highly reproducible (intraclass correlation coefficients being > 0.9 for speed and > 0.7 for lactate). A significant correlation between speed and lactate was found in the minority of cases and was rather weak (r ranging from 0.45 to 0.59).
CONCLUSION: Training sets with bouts of 50 or 100 m and long rest intervals are suitable for inducing top blood lactate concentrations. It is then up to the coach to use the set that best fits the specific aims of a training session; for example, either pursue the enhancement of anaerobic metabolism through high lactate concentrations or work with lactate levels closer to those achieved during competition (Vescovi et al., 2011). The anaerobic training sets evaluated exhibit low day-to-day and time-of-day variability. Thus, using and comparing training sets at different time points is fairly safe. Finally, since swimming speed can explain only a small part of the variability in blood lactate, other factors, like stroke rate (Morouço et al., 2017), must be considered in order to explain the metabolic cost of swimming training sets.

EVALUATION AND COMPARISON OF AMATEUR RUNNERS' CRITICAL SPEED AND RUNNING SPEED IN A 10-KM RUNNING RACE

RIBEIRO, H., KELLY, L., BARROSO, M., CORREA, H., MAYA, A., CUNHA, V., BAIÃO, V., FERREIRA, A.
CATHOLIC UNIVERSITY OF BRASÍLIA

INTRODUCTION: By the increase in the number of amateur runners, understanding race speed has become important to the definition of running strategy and the ideal training throughout the preparation period, especially through tests of easy application, low cost and good accuracy (Gomez-Molina et al, 2017; Knechtle et al, 2016). Thus, the present study aimed to evaluate and compare critical speed (CS) and running speed in a 10-km running race (RR) in amateur runners.
METHODS: A cross-sectional study has been performed in 34 runners of both genders (42.4 ± 11.0 years old). Participants underwent anthropometric evaluation and CS determination using distance/time in 400 and 2,000m tests on an official athletics track, in addition to performing an official 10-km RR. In order to analyze the reproducibility between the speeds established in the 10-km RR and the CS, the Intraclass Correlation Coefficient (ICC) and the Cronbachs Alfa were calculated.
RESULTS: We have found a VO2MAX of 49.5±8.1 ml/kg/min and 45.9 ± 7.3 minutes to the 10-km RR. The CS delta analysis overestimated the running speed by 0.55km/h, with Total Error = 0.97 and Standard Error of Estimation = 0.29. The agreement and reproducibility between the speeds was CCI = 0.93 (0.86 - 0.96) and Cronbachs Alpha = 0.96.
CONCLUSION: It has been verified good agreement and reproducibility between the speeds determined by the CS with the real time of a 10-km RR, presenting values considered excellent. Our results corroborate the findings of Santos et al. (2012) study, which associated the VO2MAX and CS with the performances in different surfaces tests in both genders, being noticed that CS was high and significantly associated with all evaluated distances in the study, proving to be an adequate predictor of aerobic performance. Therefore, we conclude that CS determined on a track with only two distances (400 and 2,000 m) was valid to estimate the running speed of 10-km.

EFFECTIVENESS INDEX OF MECHANICAL ENERGY UTILIZATION IN 400-M RACE

TAGURI, A., KATO, R., TAKESHITA, T., NORO, H., YOSHIDA, T., HATA, K., YANAGIYA, T.
GRADUATE SCHOOL OF JUNTENDO UNIVERSITY

INTRODUCTION: Running efficiently is important for distance runners to run faster. Effective Index (EI) is known as the index of availability of mechanical energy during running, and Enomoto et al. (1999) reported that the faster 5000-m race time, the higher EI was. On the other hand, increasing maximal running velocity is thought as necessary for sprinters to run faster. However, not only higher sprint running speed but also adequate pacing distribution is thought as important to run with higher performance in 400-m race. Therefore, evaluation of running efficiency may also effective to run with higher performance in 400-m race. Therefore, evaluation with EI may also effective to run with higher performance in 400-m race. So, the aim of present was to evaluate 400-m running in the point of view of EI.
METHODS: Subjects were 2 male 400-m sprinters and 2 male 400-m hurdlers (age:19±1.1yrs, height:1.74±5.1m, weight:65.4±3.8kg). They ran 400-m after enough warm up. Running motion was captured with digital high-speed video camera at 240fps from sagittal plane around 150-m and 350-m points. Captured running motion were digitized with motion analysis software. Kinematic variables were calculated and EI was computed by equation. 400-m sprint times were measured by photo determination device.
RESULTS: Higher EI runners showed higher running velocity and faster 400-m times than lower EI runners. Running velocity around 150-m point was higher than 350-m.
CONCLUSION: Results suggest that increasing EI is important for 400-m running. Value of mechanical work is used for calculating EI, therefore examination of differences in running motion is necessary to clarify factors which affect EI.

PROFICIENCY ASSESSMENT OF ADOLESCENT MALE VOLLEYBALL PLAYERS AT ESTONIAN CHAMPIONSHIPS IN 2017

STAMM, R., STAMM, M., TUULA, R.

TALLINN UNIVERSITY

INTRODUCTION: In order to gain maximum experience from competitions, games have to be recorded and players' proficiency has to be analysed (Silva, M. et.al., 2014). The aim of the present study was to find which technical elements were performed significantly better by the winners of sets at the Estonian championships for boys; which activities led to winning of sets.
METHODS: The material consisted of young male volleyball players aged 13–15 years from eight most successful volleyball teams who participated in Estonian Championships in Kiili in 2017 (round-robin system). The proficiency of all the boys was recorded; a total of 28 games were played. Each player's indicators were summed up separately in sets won and lost. The number of boys in sets won was 65 and in sets lost 61. The means and SD of performance of technical elements separately in sets won and sets lost and the value of $p<0.05$ or statistically significant difference between the means were calculated.
RESULTS: At attacks, statistically significant differences between the winners and losers appeared in the number of spikes into the block, total number of spikes and index of proficiency. There were no statistically significant differences in the number of successful spikes and in the number of spikes that remained in play. In serves, there were statistically significant differences in ace serves and difficult serves, in the percentage of difficult serves from the total and the proficiency index of serves. There were no differences in the results of the sets won and the sets lost, in serve errors and weak serves. In reception, there were statistically significant differences in reception errors and the index of proficiency; there were no differences in good and very good receptions. In block, there were no significant differences at all between the winners and the losers, and in defence, there were differences only in the total number of balls played in defence.
CONCLUSION: In children of this age, statistically significant differences appeared in the number of spike errors, not in the number of attacks won. This shows that, to win a set, fewer errors should be made at attack. As for serves, stronger serves should be used more bravely, and the players should not to be afraid of errors, as there were statistically significant differences in ace serves and difficult serves, but not in serve errors or weak serves. Attempts should be made to avoid weak receptions or reception errors. Block did not decide the results of sets. In defence, an attempt should be made to receive more balls, if one wants to win the set.

THE DEVELOPMENT OF A HEALTH AND WELLBEING CONCEPTUAL FRAMEWORK AND MEASUREMENT INSTRUMENT IN PROFESSIONAL RUGBY

CHEN, Y., BUGGY, C.J., KELLY, K.

UNIVERSITY COLLEGE DUBLIN

Introduction: Considerable media attention has recently focussed on an increased number of rugby players that have experienced forced retirement due to severe unanticipated injuries. Surprisingly, despite the special employment nature of professional athletes and the unique features of sport culture, no occupational health conceptual framework or related measurement instrument exists in professional sport. In response to this concern, and having regard for possible concerns regarding the application of an occupational health conceptual framework in elite sport, this research is focussed upon the design and development of a health and wellbeing conceptual framework customised to the needs of professional rugby. More specifically, the design of a questionnaire for measuring occupational health values among professional rugby players is proposed, the application of which, if successful, could point the way forward for application in a wider range of sports internationally.
Methods: After reviewing research literature, structured protocols for focus groups and interviews will be designed for qualitative data collection. The population will consist of players registered in professional rugby clubs and will also include the support staff who are involved in the health and wellbeing of rugby players. The questionnaire developed will initially be applied to Irish professional rugby players and subsequently will be applied to a cohort of full-time state supported professional rugby players in China. The responses of each cohort will be compared and contrasted in the context of the two countries socio-economic and political systems and recommendations made for the implementation of an appropriately designed and effective framework.
Results: This poster will present the development of the framework and structured interview instrument including data from a pilot study, possibly with data from the initial interviews and focus groups. Data will show the categorised factors influencing rugby players' awareness of health and wellbeing.
Conclusion: This study aims to utilise the occupational health conceptual framework in the development of a health and wellbeing framework for professional sport, especially rugby. The framework developed will then advance to the design and validation of a quantitative instrument for testing of the conceptual framework.

CULTURAL IDEOLOGIES IN SPORT AND THEIR EFFECTS ON TEAM COHESION AND PERFORMANCE

OTTEN, M.P., LEON, A., GRIFFITHS, M.

CALIFORNIA STATE UNIVERSITY, NORTHRIDGE

The present research investigated cultural ideologies and their effect on team cohesion within a sport setting. Past research has focused on cultural ideologies in business but not sport settings, and studies on diversity in sport have not looked at teams through a cultural ideology lens. Therefore, the current study looked to address those gaps in previous research of cultural ideologies and cohesion in sport. The first hypothesis was that a team with one of two cultural ideologies would have better cohesion than a team with no cultural ideology. It was also hypothesized that team cohesion would act as a mediator between cultural ideology and team success.

Participants (n = 97, in progress; projected n = 200) were a culturally diverse sample of students that were recruited from a local university. Upon arrival, participants were asked to form together as a team of four players and given the team goal, which was to have every member of the team pass the ball (without allowing it to touch the ground) to a different teammate before scoring a basket. Each team member was to score twice, as quickly as they could. A modified Group Environment Questionnaire (GEQ) was used to measure team cohesion across three conditions (colorblind, multicultural, and control). Written prompts, unique per condition, were read by participants and adapted from previous research. A colorblind prompt highlighted the idea that players should come together as a team, regardless of background. A multicultural passage argued that having many cultural groups represented on a team could be a great asset. A control prompt highlighted cohesion and how it is important and can be applied to sport. Performance variables (e.g., task completion time) were then compared across conditions.
The results (in progress) indicate partial support of the hypotheses, showing a relationship between condition and performance, but no mediation by cohesion between cultural ideologies and performance. For these analyses, cultural ideologies (colorblindness and multiculturalism) were combined as a single condition to compare against the control. Thus far, analyses suggest that both 1) having been presented a cultural ideology and 2) higher levels of cohesion were each significant predictors of better performance. These analyses showed that being prompted with a cultural ideology was not a significant predictor, however, of cohesiveness within the team.
The results have positive implications for cultural ideologies and their effect on the team and performance. The hope is that the current sample better represents the diversity of an international league, thus improving upon the external validity of past studies. The influence that cultural ideologies have on cohesion and performance may be important for anyone trying to manage or form a team (e.g., a general manager). A manager might not only consider the diversity of the team, but also how diversity is approached and managed within the team.

NOTATIONAL ANALYSIS OF ELITE BADMINTON SERVICE AND SCORING STRATEGIES IN WOMEN'S SINGLES EVENT

CHO, P.P., LIU, Y.T.

NATIONAL TAIWAN SPORT UNIVERSITY; NATIONAL TAIWAN NORMAL UNIVERSITY

NOTATIONAL ANALYSIS OF ELITE BADMINTON SERVICE AND SCORING STRATEGIES IN WOMEN'S SINGLES EVENT
Cho, P-P.1, Liu, Y-T.2,
1: NTSU (Taoyuan, Taiwan), 2: NTNU (Taipei, Taiwan)
Introduction: Badminton is a racket sport that is characterized by bouts of repetitive movements with medium to high intensity (Lees, 2003). Recording and analyzing shots played in the badminton games provides technical and tactical information of the games. The purpose of the study was to examine the service strategies and scoring strategies of the elite badminton players in women's single event. A notational analysis of the service and scoring strategies was used in the finals of the 2017 All England Open Badminton Championships and the 2017 Badminton Asia Championships.
Methods: One hundred and four rallies were analyzed. Two observers used Simi Scout game analysis system to record the data that include scores, player, type of shots, hitting positions on court, and the results of the rally. Cohen's Kappas for the inter- and intra- observer reliability tests were all above 0.85. Chi square tests of independence and goodness of fit were used for data analyses.
Results: The results showed a significant association between types of serves and serve receptions, $\chi 2(4)=103.00$, $p<.001$, Cramer's V=1.00, where the high serves (86%) were mostly followed by the smash receptions. The type of shots also had a significant association with the rally results, $\chi 2(6)=28.91$, $p< .001$, Cramer's V=.53, the smash shots contributed to the most scores whereas the underarm clears contributed to the most faults that resulted in scoring for the opponent. The type of shots that committed faults had a significant association with the type of faults, $\chi 2(6)=34.32$, $p <.001$, Cramer's V =.57, the underarm clears had the most landing out of bounds whereas the remaining faults were mainly from net shots. The analysis of the type of shots that leading up to the opponent's fault showed a significant difference, $\chi 2(6)=26.97$, $p <.001$, where the net shots had the highest percentage followed by the overhead clears and underarm clears.
Conclusion
The finding that the high serves were mostly followed by smashes supports the common concept that high serves in badminton are considered a defensive strategy. The high serves, however, were still the most frequently used type of serves in elite women's single event. The smash shots in women's singles contribute to the most direct scoring results, which are consistent with those observed in the men's singles (Abián et al., 2014). In addition, the net shots had the highest rate leading up to the opponents' fault also contributes to scoring indirectly.

THE RELATIONSHIP BETWEEN PHYSICAL AND PHYSIOLOGICAL CHARACTERISTICS AND SIMULATED ARTISTIC SWIM PERFORMANCE.

VIANA, E., FERNANDES, E., LANGFORD, K., KOPTIE, J., BENTLEY, D., SPRENGER, H.

CANADIAN SPORT INSTITUTE ONTARIO

INTRODUCTION: The purpose of this study was to examine the relationship between laboratory performance testing and the results of a simulated ('solo') artistic swimming competition. Highly trained artistic swimmers (n=12, 15.8 ± 0.8 yrs) who were members of a provincial level program completed a series of laboratory and pool-based testing, as well as a simulated competition where artistic swimming 'elements' were evaluated by three trained adjudicators
METHODS: The testing used included (1) a maximal incremental cycle test to exhaustion to determine peak oxygen uptake (VO2peak), (2) a vertical jump (VJ) test for height (cm) (3) the number of pike crunches in 30 sec as a measure of abdominal endurance (4) A pool based tested was performed comprising a 275m swim (overall swim time) containing underwater swimming, freestyle and other form strokes to simulate the length of an artistic swimming competition. Blood lactate (BLA) concentration (mM) was determined 3 min after the swim test and simulated competition using a portable lactate analyser (L-Lactate Pro). The 'boost' and 'barracuda' movements were performed before and after the 275m swim test and the change (delta, Δ) determined.
RESULTS: There were no significant relationship between VJ height (23.9 ± 2.6 cm) and any elements or overall performance during the simulated competition. There was also no significant correlation (r=0.13 to 0.28) between VJ height and pre swim boost (13.45 ± 3.38cm), pre swim barracuda (24.72 ± 7.5cm), post swim boost (11.2 ± 2.4cm) and post swim barracuda (25.9 ± 7.1 cm). VO2peak (48 ± 4 mL. kg.-

1min-1) was positively correlated with six of the nine group elements (R=0.60, r=0.60, r=0.66, r=0.66, r=0.69, r=0.66, p<0.05), the overall performance score (r=0.59, p<0.05), and one of the five solo elements (r=0.59, p<0.05). The BLA obtained three minutes after the simulated competition (8.73 ± 2.07mM) revealed significant negative correlation to all elements during the simulated competition (r=-0.60 to 0.78; p<0.01). There was a decrease in boost (13.4 ± 3.4 vs 11.2 ± 2.4 cm) but not barracuda (24.7 ± 7.5 vs 25.9 ± 7.1 cm) height after the 275m swim. The 275m swim time (181 ± 13 sec) and the heart rate (t .min-1) (172 ± 10) were negatively correlated to overall performance score in the group elements (r=-0.59, r=-0.69 respectively, p<0.05). The lactate concentration measured after the 275m swim (7.19 ± 1.91 mM) was positively correlated with the change in boost height (-0.99 ± 10.85cm) before and after the 275m swim (r=-0.76, p<0.01).
CONCLUSION: These data indicate greater aerobic fitness together with lactate metabolism is correlated with higher scores during simulated artistic swimming competition. In contrast, performance of two important components (boost and barracuda) before and after a 275m swim was not related to any competition elements. Concurrent training for artistic swimming might include a focus on improving aerobic capacity via in water and dryland methods of training.

EVOLUTION OF PEAK PERFORMANCE IN ELITE JUNIOR TO SENIOR FEMALE TRIPLE JUMPERS

NIESSEN, M., HARTMANN, U.

UNIVERSITY LEIPZIG - FACULTY OF SPORT SCIENCE

INTRODUCTION: The female triple jump (TJ) is a young, motion tech- and physically demanding discipline in competitive athletics, starting 1991 at indoor World Championships (WC). After quick improvements the performance evolution in elite TJ seems to stagnate, and the youth world best, junior & senior world records outdoor are untouched since 21-23 yrs. Its questionable whether success at World Youth (WYC) & Junior Championships (WJC) are a criterion for achievements as senior athlete in WC & Olympic Games (OG). Aim is to investigate the competitive success and performance improvement in elite female junior to senior triple jumpers.
METHODS: The data were extracted from a renowned database (www.iaaf.org) through 12/2017. Competition results of finalists (1st-8th place) at WYC (1999-2017; n=80), WJC (1998-2016; n=80), WC (1993-2017; n=104) and OG (1996-2016; n=48) as well as profiles of legally achieved outdoor season bests (SB) of TJs personal bests (PB) ≥15m (G1; n=25 athletes) and of selected finalists of above mentioned champs with PB between 14.50-14.99m (G2; n=41), 14-14.49m (G3; n=40), 13-13.99m (G4; n=70) and <13m (G5; n=11) were empirically analysed. Comparisons of selected age groups, of athletes careers (AC) and champs were made.
RESULTS: The above mentioned champ-final results did not alter significantly within the last 25yrs, except for OG. They showed a low sig. short-term performance increase in 2004. A total of 21 senior G1 won at least 48 medals at WC & OG; 2 of them were elite juniors (2 medals). The AC of G1-5 showed negative quadratic trends with sig. longer AC for G1 & G2. Age at peak competitive performance was 27.1±2.7yrs (G1), 25.4±3.2yrs (G2), and <21yrs (G3-5) ($F(4,307)=79.5$; $p\leq0.001$). G1 attained the PB distance (increase from first world-listed performance: +1.5±0.8m) within 6.3±3.9yrs, sig. earlier than for elite male TJ and G4 ($T(37)=3.7$; $p\leq0.001$). The attrition rate of 9 WYC & 4 WJC medallists was 22%. They reached a PB of 14.0±0.5m within 2.5±1.5yrs after medal success and ended AC near entering age group under 23yrs after 5.8±2.0yrs.
CONCLUSION: The probability of the transition to senior performances (G2) was greater if the junior athlete won a medal. WYC & WJC could be an initiate for entry into elite TJ. But also >64% of G1 were late entrants or sub-elite juniors. The increasing age of WC & OG medallists as well as long ACs till 22 yrs appear to be due to changes in societal expectations & climates and better physical precondition. Maturation in peak performance age in women brought them closer to the peak performance age of male athletes. Further research is needed to accompany athlete's long-term development pathway and identify qualitative factors to extent carefully the TJ performance in women.

SUPERIOR TRAINING SPECIFIC ADAPTATIONS WITH AN 8-WEEK YOAK PUSH-UP TRAINING PROGRAM

LIMA, C., LI, Y., LOW, J., HERAT, N., BEHM, D.

MEMORIAL UNIVERSITY OF NEWFOUNDLAND

INTRODUCTION: There are few progressive metastability training programs in the literature. The purpose of this study was to investigate changes in strength, endurance, muscle activation and neuromuscular efficiency after an 8-week progressive, push-up training program under stable and unstable conditions.
METHODS: Nineteen male and female recreationally-trained participants performed a twice per week, 8-week push-up training program, using either a relatively unstable suspension system or under stable conditions. Participants were tested in two separate sessions pre- and post-training for maximal voluntary isometric contraction , and unstable and stable push-up endurance. Participants were tested during all testing measures for anterior deltoid , biceps brachii , triceps brachii and serratus anterior electromyography activity. The training progression consisted of altering the suspension configurations, push-up height and increasing the number of sets <1-3 sets>.
RESULTS: Both groups increased the number of push-up repetitions by 56% with a greater number of push-ups performed during stable testing condition. The stable trained group when performing push-ups on the Yoak suspension system performed 153.3%, and 33.8% less repetitions than the Yoak trained group when performing push-ups on the Yoak or on the stable floor respectively . Both groups increased MVIC forces <4.8%; p<0.05> from pre to post training. However, the Yoak MVIC forces exceeded the stable group by 9.2% . For neuromuscular efficiency Yoak group decreased <30.4%; p=0.01> and stable group increased <97.8%; p=0.02> BB EMG activity from pre to post-training. AD and SA EMG activity decreased for Yoak group for both testing conditions. Only the stable group decreased <62.2%; p=0.04> SA EMG activity after the Yoak push-ups testing condition. Both training groups demonstrated decreases with the TB fatigue index from pre- to post-training. Nevertheless, Yoak group demonstrated 12.5% and 8.9% lower fatigue index with TB and SA respectively than the stable group.
CONCLUSION: These findings suggest that Yoak training demonstrates superior improvements over stable training for push-up endurance, neuromuscular efficiency, MVIC and fatigue index.

LATERALITY IN BOULDERING: INSIGHTS INTO THE RELATION BETWEEN SIDE DOMINANCE AND PERFORMANCE CAPACITY

DE SOUZA SILVEIRA, R., BLANKE-SCHELLE, R., WIGGERS, N., JULIAN, R., EILS, E.

UNIVERSITY OF MÜNSTER

INTRODUCTION: Side dominance has been suggested to be a determining factor when it comes to sport-specific performance. To date however, there is little evidence on laterality aspects during climbing activities. Therefore, the aim of the current investigation was to assess the relation between side dominance and parameters of strength and endurance capacity during bouldering.
METHODS: 17 right-handed recreational bouldering athletes were assessed on 3 different appointments (48 h pause between days). Day 1, baseline values for grip strength, campus-board propelled reach, and hanging endurance (isometric dead-hang) were collected. During days 2 and 3, participants were randomly assigned to either a dominant right (RB) or a left boulder (LB), and then attempted maximal amount of ascents with 15 sec pause between attempts. The routes consisted of 11 identical (mirrored) movements and holds were set on a 9° overhanging climbing wall. Boulders were set to stimulate each body side as equally as possible. At the end of each boulder bout the measurements performed at baseline were repeated. To determine the differences between all test parameters a paired t-test was implemented ($\alpha = 0.05$) and effect sizes were calculated. All values are presented as mean ± SD.
RESULTS: There were no significant differences in the average amount of boulder ascents 49 ± 47 (RB) and 45 ± 33 (LB). Grip strength (right and left) significantly differed after the RB bouts 38.5 ± 8.0 and 35.6 ± 6.9 kg respectively (P = .007). However, after the LB bouts there were no observed differences 35.0 ± 7.3 and 34.7 ± 7.5 kg (P = .869). Right hand grip strength differed significantly after the LB bouts in comparison to RB (P = .016), with a moderate effect size of .45 and reduced 42 % when compared to baseline. Right hand propelled reach on campus-board was 89.1 ± 14.9 (RB) and 86.4 ± 15.8 cm (LB) (P = .073). Similarly, left hand propelled reach was 90.0 ± 13.8 (RB) and 87.0 ± 17.6 cm (LB) (P = .314). Isometric dead-hang lasted for 45.2 ± 9.9 and 42.2 ± 14.8 sec after RB and LB respectively (P = .180).
CONCLUSION: Throughout the results, common trend was observed that the LB bouts evoked a decrease in values in comparison to baseline (especially for the dominant side) for grip strength, campus-board propelled reach, isometric dead-hang and number of ascents. These findings are indicative of a higher effort when bouldering on the non-dominant side. The current findings also underline the necessity to focus training/strengthening strategies on the non-dominant side when aiming to reduce fatigue, improve strength symmetry between sides and potentially improve performance capacity when bouldering on the non-dominant side. Future analyses should look at objective aspects of fatigue (e.g. blood lactate build up, heart rate and blood-born inflammatory markers), and with that offer a broader interpretation of the relation between laterality and performance capacity during climbing activities.

PHYSIOLOGICAL RESPONSES ON TRAINING AND COMPETITION LOAD IN KARATE KATA DISCIPLINE

CIERNA, D., BARINEC, P.

COMENIUS UNIVERSITY

INTRODUCTION: Blood lactate measurement is one of the most frequently used procedures of indirect load intensity evaluation, regeneration level and prevailing energy metabolism.
METHODS: Our research focused on the physiological response to training and competition load of three Slovak kata female national team members (17.3±0.6 years old, 161.7±7.4 cm, 55.7±1.2 kg). Competitors participated in model training and 5 competitive kata rounds. Blood lactate was measured after each round in the 4th minute of recovery. Heart rate values were measured by Polar H7 device connected to Polar Beat application, blood lactate values were measured by Accutrend device made by Accusport.
RESULTS: Wilcoxon T-test proved that maximum heart rate is higher in competition (190±3.6, T=p≤0.01) compared to training (178±9.4). Friedman Anova did not prove significant mean heart rate increase with progressing competition rounds (p=0.5). Blood lactate level in individual katas is higher (p=0.39) in competion (5.7±2.2) compared to training (5.2±1.8). Blood lactate does not increase significantly with progressing rounds in competition and in training (p=0.294). Kata load is considered to be continual ($\overline{p}$=2:17±0:37), with quick and slow techniques alternation, which makes this load intermittent.
CONCLUSION: Load intensity and prevailing energy metabolism in kata is influenced by kata length, quick to slow techniques ratio, fighting determination, volition effort of competitors, quality of competitors and competition importance. We recommend regular intensity load monitoring during trainings, especially in high-performance training and increasing functional reserves of the organism in intensification and transformation period by means of intermittent load (building lactate resistance).

PHYSIOLOGICAL DEMANDS OF AN INTERNATIONAL TAEKWONDO COMPETITION

MCLAUGHLIN, A., LANGAN-EVANS, C., SADLER, D., MORTON, J.P., LOUIS, J.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Taekwondo is an Olympic combat, intermittent sport (Bridge et al., 2014). A limited number of studies have investigated the physiological demands of international competition (Bridge et al. 2009). However, these studies were carried out prior to the 2008 Beijing Olympics when the rules of Taekwondo were changed marking the data ecologically invalid. Therefore, we aimed to profile the physiological demands of modern Taekwondo competition at a 2018 international Taekwondo event.
METHODS: 10 Taekwondo athletes (8 male, 2 female) took part in an international Taekwondo competition. Each combat included three 1 min 30 s rounds with 30 s recovery between rounds. Body mass (BM) was measured at the official weigh in (day prior to competition). BM and hydration status were measured fasted on the morning of and immediately after competition. Heart rate (HR) was recorded at 1 sec intervals during each fight. Capillary blood lactate samples were taken from the fingertip no more than 10 min before the fight commenced and immediately after each round. Athletes' rating of perceived exertion (RPE) was recorded for each round using Borg's 0-to-10 scale.
RESULTS: Athletes were tested during 24 fights in total with a bronze and silver medal attained and two QF finishes. BM increases represented 2.84 ± 1.18 kg from weigh in to the morning of the competition and an increase of 1.16 ± 0.91 kg on the day of competition when

heavyweight athletes were removed (n = 3). Mean urine osmolality was 862 ± 165.78 mOsm L-1 and 585 ± 275.32 mOsm L-1 on the morning of and on completion of competition. Mean blood lactate values did not change significantly between pre- and post- (2.04 ± 4.33 vs 2.80 ± 0.88 mmol.L-1) warm up measures. In-fight mean blood lactate values were 3.01 ± 0.86 mmol.L-1 pre-fight, 9.85 ± 4.8 mmol.L-1 after round 1, 13.73 ± 3.70 mmol.L-1 after round 2 and 15.94 ± 4.38 mmol.L-1 after round 3. The mean increase in blood lactate between pre-fight and round 1 was 6.85 ± 4.64 mmol.L-1, between round 1 and round 2 was 3.88 ± 3.05 mmol.L-1 and between round 2 and round 3 was 2.21 ± 3.24 mmol.L-1. Mean RPE scores for round 1, 2 and 3 were 6.32 ± 1.76, 7.48 ± 1.54 and 8.52 ± 1.53, respectively. **HR data is still being analysed but will be presented in July
CONCLUSION: International-level Taekwondo competition elicited near-maximal cardiovascular responses and high blood lactate concentrations and perceived intensity which increased across rounds and thus places a high demand on aerobic and anaerobic metabolism. Furthermore, contemporary Taekwondo appears to produce higher anaerobic lactic contribution and perceived intensity than the erstwhile variety which will inform training practice.

ANALYSIS OF THE MARTIAL ARTS POSTURE KAMAE WITH H-REFLEX

HASEGAWA, K., NAKAJIMA, T., KANOSUE, K.

1> GRADUATE SCHOOL OF SPORT SCIENCES, WASEDA UNIV., SAITAMA, JAPAN. 2> FACULTY OF MEDICINE, KYORIN UNIV., TOKYO, JAPAN. 3> FACULTY OF SPORT SCIENCE WASEDA UNIV., SAITAMA, JAPAN.

INTRODUCTION: In martial arts there is a unique posture, "Kamae", which can be shifted quickly to both defense and offense. It is important to understand the mechanisms of Kamae for coaches and athletes to master this posture appropriately. In the present study, we focused on the effect of Kamae on the characteristics of spinal H-reflex, which is an important reflex for postural control.
METHODS: Subjects were 8 sumo wrestlers from a university team having experiences of sumo more than 10 years. The posterior tibial nerve of the dominant leg was electrically stimulated with a single pulse (pulse width 200 μs, intervals 3 s). H- and M-waves were obtained from the EMG of the soleus muscle. The recruitment curves of the two waves were built by increasing stimulus intensity. The maximum H-wave amplitude was normalized with the maximum M-wave amplitude (%Hmax). The tibial nerve stimulation was applied when subjects kept three different postures, quiet standing, Kamae with an image of a real match (Kamae-image) and Kamae without the image (Kamae-no image). For Kamae-image subjects were instructed to have an image to react to an opponent's attack as quickly as possible. We compered %Hmaxs among those three postures.
RESULTS: In 6 out of 8 subjects, the %Hmax was highest in the Kamae-image task. To the contrary, the %Hmax was smallest in the standing task in 6 out of 8 subjects.
The averages of %Hmaxs were 48 ± 16 % in the standing task, 55 ± 15 % in the Kamae-image task, and 53 ± 14 % in the Kamae-no image task. The %Hmax of the Kamae-image task tended to be higher than that of the standing task (p = 0.062).
CONCLUSION: The %Hmax is an index of spinal excitability (S. Grosprêtre et al. 2012). According to the present results, the image and posture of Kamae tended to increase spinal excitability. Since the motor imagery alone doesn't affect H-reflex(B. Hale, et al. 2003), the enhancement of H-reflex might be caused by the combination of the specific posture and the imagery of preparing at an opponent's attack. The long years of practice might cause this effect.

TIME-MOTION ANALYSIS OF ELITE MALE PENCAK SILAT FIGHTERS

JOEL, P.1, JACKY, S.2, AZIZ, A.R.1, FRANKIE, T.1, IHSAN, M.3

1: SINGAPORE SPORT INSTITUTE (SINGAPORE), 2: NATIONAL INSTITUTE OF EDUCATION (SINGAPORE), 3: ASPETAR (DOHA, QATAR)

INTRODUCTION: Pencak Silat is a South-East Asia martial art that has grown in popularity over the last decade. Combat Silat matches are point based and comprise of three 2 min rounds with 1 min rest between. Despite its popularity, data examining the physical and physiological demands of competition is limited. Increased understanding of such demands would enable optimisation of sport-specific training programs and consequently Combat Silat performance. Therefore, this study aimed to 1) examine the physical and physiological demands of elite male Silat fighters during a match, and 2) determine any differences in these demands between weight classes and rounds.
METHODS: Time-motion analysis of 42 Male category matches from the 2015 SEA Games and 2016 Silat World Championships were analysed for the frequency and duration of individual movements. Movement categories were classified into low, moderate and high movement intensities with work referred to as high intensity movements and recovery as low and moderate intensity movements. Athlete weight classes were classified as light (45-60 kg), middle (60-75 kg) and heavy (75-95 kg). Differences in work duration during matches were compared between weight classes and rounds using magnitude-based Cohen's effect size (ES), assessed using the following criteria: 0.20 = small, 0.50 = moderate, and 0.80 = large.
RESULTS: Mean match time and a work duration of 15:51±04:46 min:s and 1:19±0:30 min:s, respectively. There were 42±15 high intensity movements, accounting for 8±3 % of a match. High intensity movements lasted, on average, 1.89±0.50 s, with a mean recovery period of 17.91±6.29 s; an overall work:rest ratio of 1:9.5. Small-moderate differences were observed between light, middle and heavy weight classes for total mean work duration between light and middle (1:13±0:24, 1:28±0:36, ES: 0.49, CI: 9.87, -12.23), light and heavy (1:14±0:28, ES0.06, CI: 9.44, -10.40) and medium and heavy (ES: 0.43, CI: 10.89, -12.30) with work:rest as 1:9.4, 1:9.2 and 1:9.8, respectively. Furthermore, average work duration progressively increase from round 1 to round 2 (0:17±0:12 mm:s, 0:27±0:13 mm:s, ES: 0.75, CI: 2.10, -3.23), round 1 to round 3 (0:35±0:11 mm:s, ES: 1.55, CI: 4.02, -0.89) and round 2 and 3 (ES: 0.69, CI: 3.53, - 1.76) as well as the frequency of high intensity activity (9.3±6.8 s, 14.0±5.7 s and 19.1±6.4 s). Differences in average work:rest ratios between round 1, 2 and 3 (1:11, 1:9, 1:8 respectively) were also observed.
CONCLUSION: Combat Silat is a high intensity intermittent sport requiring short explosive efforts, but these efforts can vary from 0.76 s to 4.12 s with an average match work:rest ratio of ~1:10 indicating a training emphasis towards anaerobic alactate and aerobic energy system. The increase in work across rounds and range of work:rest ratios, regardless of weight class, is an interesting finding that can be useful to guide training prescription to meet the specific demands of competition for male Combat Silat.

GROSS EFFICIENCY AND PEAK OXYGEN UPTAKE IN VISMA SKI CLASSICS ATHLETES

SAGELV, E.H.1, PEDERSEN, S.1, THOMASSEN, T.O.1, HEITMANN, K.A.1, PETTERSEN, S.A.1, MATHISEN, G.1, WELDE, B.1, STÖGGL, T.2

1UIT THE ARCTIC UNIVERSITY OF NORWAY, 2UNIVERSITY OF SALZBURG, SALZBURG, AUSTRIA

INTRODUCTION: Cross-country skiing (XCS) has been studied extensively, and is unique due to its high demands for endurance capacity and complex regulation and fluctuation of oxygen delivery for both upper and lower body (Holmberg et al., 2007). The Visma Ski Classics (VSC) merges the most traditional long distance XCS events (14-90 km) in Europe and worldwide. To our knowledge, the physical capacities of VSC athletes have not yet been explored. The aim of this study was to examine the gross efficiency (GE) and peak oxygen uptake (VO2peak) of the VSC athletes in diagonal stride (DS) and double polling (DP).
METHODS: Nine male athletes (26±4 yrs, 182±7 cm, 78±7 kg) participating in the Reistad race of VSC volunteered to undergo two laboratory tests with both DP and DS in randomized order while roller skiing on a treadmill (Rodby, Sodertalje, Sweden): 1) Measurements of VO2 (Oxycon Pro, Jaeger GmbH, Hoechberg, Germany) during two submaximal stages (8 and 10 km•h-1, 10.5% inclination) for the calculation of GE and 2) VO2peak during an incremental test to exhaustion at 15% inclination. GE was calculated according to the formula by Sandbakk et al. (2010). Paired sample t-tests were performed to check for differences in GE between and within the two skiing techniques at different velocities, and for differences in VO2peak between DS and DP.
RESULTS: There was a significant difference in GE between DS and DP at 8 kmh-1 (18.5±0.7% vs. 17.2±1.4%, p=0.02), but not at 10 km/h (18.2±1.2% vs. 17.6±1.2%, p=0.48). GE was higher in DP at 10 km/h compared with 8 km/h (diff.:-0.88±0.65%, p=0.003), whereas no such difference was found for DS (diff.:0.29±1.13%, p=0.47). The VO2peak in DP was 90.3% of DS (68.1±4.1 vs. 75.4±5.0 ml/kg/min, p=0.001).
CONCLUSION: VSC athletes have higher GE in DS compared with DP at 8 km/h but not at 10 km/h, and higher in DP at 10 km/h compared with 8 km/h. These findings may be explained by specificity of training, as VSC athletes usually perform a high volume of DP in high speeds, whereas DS is performed in lower speeds. The difference in VO2peak between the techniques may be explained by higher stroke volume, higher arterial desaturation and higher maximal ventilation (Holmberg et al., 2007) and possibly larger proportion of muscle mass used in DS compared to DP.

DIFFERENCES OF MAXIMAL OXYGEN CONSUMPTION BETWEEN PROGRESSIVE ON-ICE AND CYCLE ERGOMETER TESTS WITH SHORT TRACK SPEED SKATERS

ST-JEAN MIRON, F., WALSH, E., MAROIS, B., COMTOIS, A.S.

UNIVERSITY OF QUEBEC IN MONTREAL

INTRODUCTION: Currently there are no sport-specific tests to directly evaluate the aerobic capacity for short track speed skating athletes on the ice. While cycling assessment tests seem to be favored in this discipline, the aim of this project was to create an on-ice test to estimate skaters VO2max and compare those results to a cycling ergometer VO2max test. We hypothesized that the VO2max results obtained during on-ice skating test would be lower than during the cycling ergometer test. This is because the position that short track speed skaters adopt on the ice impacts cardiovascular response with a restriction of blood flow to the lower limbs.
METHODS: 24 Canadian short track speed skaters, (11 women and 13 men;19.6±3.2 years old; 66.9±6.6 kg; 171.5±6.6 cm) of the provincial level or higher, participated in the study. Skaters took part in two separate (48hrs-7days in between) progressive maximum tests on ice and on a cycle ergometer. Heart rate (HR) and oxygen consumption (VO2max) were continuously monitored during both tests with a portable metabolic analyzer. Blood lactate concentration and perceived effort for cardiovascular effort and leg pain (Borg scale) were measured at the end of both tests.
RESULTS: The maximum speed reached at the end of the on-ice test was 9.7±0.49 m*s-1 and maximum power on the cycle ergometer was 349±56.3 Watts. Both tests were significantly correlated (r=0.85; p<0.001). The relative VO2max reached at the end of both tests was significantly different with 53.0±7.1 and 63.3±6.9 ml*kg-1*min-1 (p<0.001), and in absolute terms with 3.56±0.65 and 4.28±0.79 L/min (p<0.001). respectively. A significant difference was also noted for the perception of cardiovascular effort (15.9±2.1 vs 17.0±2.1, p=0.005). No differences, however, were detected in HRmax reached (193±6.2 vs 195±7.6 bpm, p=0.121, respectively), for blood lactate concentration (13.4±2.1 vs 12.6±3.1 mmol*L-1, p=0.145, respectively) and for the perception of leg pain (18.5±1.1 vs 18.4±1.5, p=0.671, respectively).
CONCLUSION: The on-ice test allows for skaters to reach their physiological maximal skating speed as measured by the HRmax, blood lactate concentration, and the perception of leg pain. Nonetheless, the VO2max reached during the on-ice test was significantly lower, regardless of similar HRmax values. This indicates the importance of muscle recruitment patterns on the metabolic cost of leg exercise. As well, VO2max obtained on a cycle ergometer is not representative of the VO2max obtained on-ice, despite the significant correlation between the maximum on-ice speed and the cycle ergometer power output. Finally, the on-ice test reveals the importance of test specificity because of leg activity dichotomy in speed skating that is not present in cycling.

ASSESSMENT OF ON-ICE BIOENERGETIC COST OF SKATING PERFORMANCE DURING FORWARD, BACKWARD AND AGILITY TESTS IN ELITE YOUTH ICE HOCKEY PLAYERS

LEONE, M., ALLISSE, M., DESJARDINS, P., LÉGER, L., BUI, H.T., COMTOIS, A.S.M.

UNIVERSITÉ DU QUÉBEC À CHICOUTIMI

INTRODUCTION: Introduction The purpose of this study was to evaluate and propose equations to predict the energy expenditure during different skating situations commonly found in game situations (skating forward, backward, with and without controlling a puck, during cornering, stops and starts and changes of direction).
METHODS: Methods Twenty-four (24) male elite ice hockey players of categories Peewee (11-12 years old), Bantam (13-14 years old) and Midget (15-16 years old) participated in this study. Anthropometric measurements were taken and four different on-ice high-intensity and short duration (5-9 s for forward and backward skating and 27-29 s for agility tests) tests were performed on a standard Canadian ice rink. Execution time, heart rate, oxygen uptake and skating strides were measured for each of the tests.
RESULTS: Results A regression equation was extracted for each of the four tests to predict of oxygen cost based on age, body mass, heart rate, skating strides and skating stride index. Correlation coefficients ranged from 0.90 to 0.93 and standard error of estimate (SEE) was between 2.20 and 3.11 ml·kg-1·min-1.

CONCLUSION: To the authors' knowledge, this is the first time oxygen cost has been evaluated and corresponding prediction equations developed for different skating situations involving short-duration and high-intensity efforts. This could be useful to establish the energy cost during different skating situations on individual basis. This information can help coaches to better target their interventions using simple tools, such as video analysis for stride number and heart rate monitors.

PHYSIOLOGICAL LOAD DURING AN ACTIVE VIRTUAL REALITY GAME

PERRIN, T., FAURE, C., NAY, K., CATTOZZO, G., SOREL, A., KERHERVÉ, H., BIDEAU, B., KULPA, R.

UNIV RENNES, M2S - EA 7470, F-35000 RENNES, FRANCE

INTRODUCTION: Strategies to curb the development of pathologies associated with sedentary lifestyles are usually geared toward limiting sitting time and screen use, and increasing energy expenditure (EE) through exercise. Since the early 2000's, active games (AG) have been developed where players use upper limb or whole body motion to interact with a virtual gaming environment. AG have been documented to elicit greater oxygen consumption (VO2, +2-10 mL/min/kg) and EE (+150-250 kJ/min) than seated games (~5-10 mL/min/kg and ~150 kJ/min, respectively). The aim of this study was to evaluate the physiological load of an AG in a portable Virtual Reality (VR) system with stereoscopic vision and head tracking, as these provide greater immersive feeling than 2D screens and might lead to greater physical engagement.
METHODS: Nine healthy males (28±6 yr, 182±5 cm, 86±8 kg) took part in this study. After a habituation phase, participants completed three tests in a randomized order: a submaximal walking test on a treadmill at 6 km·h-1 (W6), one bout of active gaming at body weight (AGBW), and one bout of active gaming with weights amounting to approximately 2.5% of body weight worn on wrists (AGW%). The active game was a free-to-play, upper-body oriented virtual bow and arrow shooting game pre-installed with the VR system (HTC Vive). We measured VO2 and heart rate (HR) and the number of shooting actions continuously, and subsequently calculated energy expenditure based on energy equivalents for oxygen in the standard manner. Effect sizes (ES) for pairwise comparisons were calculated using Cohen's d.
RESULTS: All variables were measured when participants reached a similar level of difficulty in the game (3rd wave of opponents, lasting ~15 min). VO2 in AGW% (20.6±4.5 mL/min/kg) was 22±7% and 21±19% greater than AGBW and W6, respectively. EE in AGW% (657±174 kJ/min) was 27±10% and 48±18% greater than AGBW and W6, respectively. Average HR in AGW% (116±7 bpm) was 16±6% greater than both AGBW and W6. The total number of shooting actions was lower in AGB% (361±81) than AGBW (-10±18%). Large ES were calculated for AGB%/AGBW and AGB%/W6 comparisons, and trivial to small ES for AGBW/W6 comparisons except for EE (large).
CONCLUSION: We observed consistently higher physiological load (VO2, EE, HR) in AGW% compared to AGBW and W6, and EE was also higher in AGBW than in W6. Despite marked differences in EE, similar average HR were measured in AGBW and W6, indicating HR may not provide suitable indicators of EE during AG, which may explain some of the differences in EE we measured in this study compared to the literature. Therefore, the development of whole-body AG in VR with and without extraneous weights provides an exciting avenue to increase EE during leisure or indoor activities, and may pave the way to accompany the development of e-sports and health applications.

IDENTIFYING THE PERFORMANCE CHARACTERISTICS OF ELITE PENCAK SILAT FIGHTERS

JACKY, S.1, 2, CARL T.W.3, SARAVANA, A.P.1, AZIZ, A.R.2, IHSAN, M.4. 1: NATIONAL INSTITUTE OF EDUCATION (SINGAPORE), 2: SINGAPORE SPORT INSTITUTE (SINGAPORE), 3: PORT ADELAIDE FOOTBALL CLUB (ADELAIDE

SSI INSTITUTION

INTRODUCTION: Pencak Silat is a weight categorised combat sport originating from the South East Asian (SEA) region. Historically practiced as self-defense, the growth of this sport has been considerable, with 37 countries reportedly participating at the recent 2016 World Championships. Given its growing popularity, identifying key movement patterns associated with superior performance is fundamental for coaching practices, and the continued development of the sport (Aziz et al., 2002). This study aims to 1) identify performance characteristics associated with successful Silat fighters and 2) to examine the relationship between performance indicators and match outcome using linear and non-linear statistical approaches.
METHODS: Time-motion analysis was undertaken on the Male category matches (n=161) recorded during the 2015 SEA Games and the 2016 Silat World Championships. Preliminary analysis was undertaken to identify all combat techniques, which were then categorised into offensive, defensive and counterattacking movement patterns. Successful performances were identified by comparing the categorised movement patterns between the Semi Finalist (SF) and Non-Semi Finalist (NSF). Additionally, eight performance indicators were collated and analyzed via a linear (binary logistic regression) and non-linear (Conditional Interference (CI) classification tree) statistical approach.
RESULTS: Results from the independent t-test showed that SF tend to use more single strikes compared to NSF ($p < 0.05$). The preferred strike of SF were the single offensive front kick, defensive front and side kick, and counterattacking roundhouse kick ($p < 0.05$). SF also executed more throws and defensive and counterattacking scissor takedown ($P < 0.05$). The most parsimonious binary logistic regression model retained 'catch success', 'defending takedown success', 'defending throw success', 'total sweep success', and 'total takedown success' (delta AIC <0.01; Akaike weight = 0.15) with an average model accuracy of 75%. Conversely, three performance indicators were retained with the CI classification tree with an average classification accuracy of 75%. However, it was the combination of 'total takedown success and 'defending takedown success' that provided the greatest probability of winning (90.3%).
CONCLUSION: The present findings highlight the key fighting characteristics and performance indicators associated with match success. The incorporation of the non-linear CI classification tree may provide coaches with a more practical approach in enhancing match success.

EFFECT OF ABDOMINAL PRESSURE TRAINING ON THE GUT MICROBIOTA FOR PREVENTING LIFESTYLE DISEASES IN MIDDLE-AGED AND ELDERLY INDIVIDUALS

MATSUO, K.1, KAWAMURA, T.2, FUKUDO, S.3

1.KAWASAKI UNIVERSITY OF MEDICAL WELFARE, KURASHIKI, OKAYAMA, JAPAN., 2. TOHOKU FUKUSHI UNIVERSITY, SENDAI, MIYAGI, JAPAN., 3. TOHOKU UNIVERSITY GRADUATE SCHOOL OF MEDICINE, SENDAI, MIYAGI, JAPAN.

INTRODUCTION: Revealing the association between exercise and the gut environment can substantially contribute to health promotion. Many previous studies evaluating the effect of exercise training intervention in the elderly have focused on skeletal muscle hypertrophy or prevention of atrophy. However, in the present study, we considered the possibility that abdominal pressure training prevents lifestyle diseases by improving the gut environment. Moreover, a recent study reported that lifestyle diseases such as obesity are associated with the type and composition of the gut microbiota. Many studies on exercise training intervention for preventing lifestyle diseases in middle-aged and elderly individuals have been conducted. Recent studies have also suggested that oral bacteria are associated with alveolar pyorrhoea and lifestyle diseases and have relevance with the gut environment. In our study, abdominal pressure training for middle-aged and elderly individuals with exercise habits was conducted for 6 weeks. We examined whether the gut microbiota would change and whether the defaecation status would improve. In addition, the association between the number of oral bacteria and the gut environment was investigated.
METHODS: This study included 16 subjects who regularly attended exercise classes (11 men and 5 women, mean age: 72.5 ± 6.9 years). The changes in gut microbiota were examined before training, after 6 weeks of regular training (e.g. stretching), and after 6 weeks of abdominal pressure training for a total of three times. In addition, the number of oral bacteria was measured, and a Bristol stool scale was used to evaluate the form of faeces into seven types.
RESULTS: All subjects had a different gut microbiota. In addition, there was no change in the gut bacteria after abdominal pressure training. However, there was a significant negative correlation between the number of oral bacteria and the Bacteroides, Prevotella spp. and Clostridium cluster IX in the gut microbiota. Six subjects showed an improvement in the form of faeces upon assessment using the Bristol stool scale.
CONCLUSION: There was no change in the mean levels of gut microbiota after abdominal pressure training in middle-aged and elderly individuals. This result may have been obtained because the gut bacterial flora was basically different in each subject. The results from the survey using the Bristol stool scale suggested that exercise training that enhances the abdominal or intraperitoneal pressure may be effective in improving the defaecation status of individuals who show an improvement in the gut environment.

HIIT-INDUCED TOTAL AND VISCERAL FAT MASS LOSS IS NOT LINKED TO ALTERED GUT MICROBIOTA COMPOSITION IN OBESE RATS

MAILLARD, F.1,2, VAZEILLE, E.2,3, SAUVANET, P.2,4, SIRVENT, P.1, COMBARET, L.5, SOURDRILLE, A.1, BONNET, A.2,4, OTERO, Y.1, DELCROS, G.1, BARNICH, N.2, BOISSEAU, N.1

1. AME2P LABORATORY; 2. UMR 1071 INSERM; 3.INSERM, 3IHP; 4. CHU CLERMONT-FERRAND; 5. INRA, UNH, UMR 1019.

INTRODUCTION: Overweight and/or obese subjects have an increase of visceral adipose tissue and a dysbiosis promoting chronic inflammation and the development of cardiovascular diseases. If numerous studies demonstrated that moderate-intensity continuous training (MICT) can favorably alter gut microbiota composition, little data is available concerning the potential impact of High-Intensity Interval Training (HIIT). However, HIIT has grown in popularity in the last few years as a time-efficient and powerful strategy to reduce total and visceral visceral fat mass. Thus, the aim of this study is to compare the effects of MICT and HIIT programs on gut-adipose tissue cross-talk in obese rats.
METHODS: Male Zucker rats (fa/fa, n = 36) aged of 8 weeks were fairly subdivided into MICT, HIIT or control (CON) group. Trained animals ran on a treadmill (0° slope), 5 days/week during 10 weeks (MICT group: 51 min at 12m.min-1 ; HIIT group: 6x (3 min at 10m.min-1 followed by 4 min at 18m.min-1). Body composition was analyzed by EchoMRI and the weighing of tissue was realized post-mortem. Adipose tissue inflammation was evaluated by secretion of cytokines (IL-6 and KC) measured by ELISA. Gut microbiota was analyzed using 16S rRNA gene sequencing on an Illumina MiSeq Platform. Dosage of tight junction proteins (ZO-1 and occludin; by western-blot) was used as a marker of intestinal permeability. Fecal short-chain fatty acids (SCFA: acetate, propionate and butyrate) concentrations were determined using gas liquid chromatography. Lipid profile (plasma TG, total cholesterol, HDL and LDL) was measured and glycemic control was evaluated through fasting glycaemia, insulinemia and an oral glucose tolerance test.
RESULTS: Results: After 10 weeks, total body mass and lean mass were not different but total fat mass was reduced in HIIT group from week 5 to the end of protocol. Epididymal adipose tissue (reflecting visceral fat mass) was reduced in HIIT group only. Secretion of KC from AT was decreased in MICT and HIIT groups. No change was observed in lipid profile except an increase of LDL in MICT group. Both trainings improved glucose tolerance. Concomitantly, no change was demonstrated in gut microbiota composition (alpha and beta diversities) and fecal SCFA levels in any group. However, ZO-1 was increased in trained groups whereas occludin was more elevated in HIIT group.
CONCLUSION: HIIT is a time-efficient method to decrease total and visceral fat mass that favors inflammatory and metabolic profiles. However, these changes were not associated with change in gut microbiota composition but only to a greater level of tight junction proteins in this group.

IS MUSCLE DAMAGE AFFECTED BY GUT BACTERIA ELIMINATION- AN MRI STUDY.

NUNOMIYA, A., OSANA, S., TAKADA, H., NAGATOMI, R.

TOHOKU UNIVERSITY GRADUATE SCHOOL OF BIOMEDICAL ENGINEERING

INTRODUCTION: Several studies have reported that gut microbiota influence muscle metabolism. Although there is still an on-going debate about the presence of "gut-muscle axis", influence of intestine flora on muscle wasting has been receiving attention. The relationship, however, between gut microbiota and recovery from muscle damage has been little studied.

Until now, the time course analysis of muscle recovery from damage required distinct mouse for each time point for muscle histological examination. Magnetic resonance imaging (MRI) may allow the assessment of muscle damage and recovery of a same individual mouse.
The purpose of the study was, therefore, to examine the effect of gut bacterial elimination with antibiotics on the recovery of cardiotoxin induced muscle damage using MRI.
METHODS: Ten male C57BL/6 mice were divided into control group (n = 5) and antibiotics treatment group (n = 5). To deplete gut bacteria, 0.2 ml of antibiotics cocktail was administrated to mice in antibiotics treated group via a feeding needle for consecutive 7 days. Control group received 0.2 ml of sterile distilled water in the same way. Following antibiotics treatment, 50μl of cardiotoxin (CTX) was injected into each left tibialis anterior (TA) muscle of all mice. Saline buffer was injected in to right TA muscle as control. Three days, 1 week and 2 weeks after CTX injection, MRI acquisitions with MSME (T2 and proton density weighted: PD_T2) were performed. Body weights were recorded daily during antibiotics treatment, and were measured again 3 weeks after the CTX injection.
RESULTS: Body weight gains after antibiotics treatment in antibiotic treated group (0.458 ± 0.35 g) was significantly less than control group (1.778 ± 0.24 g) ($P < 0.05$). We observed the distinct contrast MRI images corresponding to muscle damage in both control and antibiotics treated groups 3 days after the CTX injection. The signal intensities were weakened but the damage was still distinguishable 1 week after the CTX injection. After 2 weeks, the contrasted area had visibly been shrunk. The recovery period considered from PD_T2 image was almost the same between control and antibiotics treated groups. The average weight of injured TA muscle/control TA muscle (left/right) after 3 weeks were smaller in the antibiotics treated group, but the difference was not statistically significant.
CONCLUSION: Non-invasive MRI technique was found to be feasible for tracking the course of muscle damage and recovery. Using this technique, we found no effect of gut bacteria elimination on the course of muscle recovery.

THE IMPACT OF THE COMETITIVE PHASE ON THE GUT MICROBIOTA AND CYTOKINE PROFILE IN AMATEUR LEVEL COMPETITIVE CYCLISTS

SZURKOWSKA, J.1, KAROLKIEWICZ, J.1, GALECKA, M.2, BARTNICKA, A.2

1: POZNAŃ UNIVERSITY OF PHYSICAL EDUCATION , 2: INSTYTUT MIKROEKOLOGII

INTRODUCTION: Gut microbiota plays a crucial role in the preservation of intestinal barrier, the modulation of inflammatory signaling and in the protection against infections. Professional athletes as well as amateur level sportsmen are the most sensitive to respiratory and gastrointestinal tract infections. In cyclists gastrointestinal problems most likely result from the redistribution of blood flow from the gut to the peripheral circulation for cooling purposes. The detailed information on the profile of the gut microbiota and cytokines can allow a better understanding of the relationship between the digestive and immune systems of the amateur level competitive cyclists.
METHODS: The study was conducted in 30 men, aged 20–44years: 15 cyclists with the mean training experience of 5 ± 2 years and 15 untrained (control group). The only significant difference between the groups was found in the level of VO2max ($p<0.001$). Subjects enrolled to the study fulfilled all inclusion criteria, and did not present any of the exclusion criteria (determined by both questionnaire and interview). During the study, cyclists underwent two series of measurements, before and after the competitive phase of the annual training cycle. The control group participated only in the first measurement, before the competitive phase. Blood samples were collected for the biochemical analyses. The consistency and pH of feces and quantitative assessment of the main aerobic and anaerobic bacteria, yeasts and fungi of the gut were measured in the feces samples. Dietary energy and macronutrients intake were assessed on the basis of a three-day food diary completed by each study participant.
RESULTS: There were no significant differences between the surveyed cyclists and the control group in the pH of feces and in the amount and composition of faecal microbiota, however in the cyclists some changes in abundances of Clostridium spp. and Lactobacillus spp. were found. Significant differences in cytokine profile (IL-4,IL-12, TNF-alpha) and the dietary macronutrients intake were observed between the two groups. In the cyclists group, in spite of the significant changes in the applied training loads and the dietary macronutrients intake, there were no differences in the pH of feces and quantitative assessment of the faecal microbiota, between beginning and the end of the competitive phase. The significant increase in the level of IL-4 ($p<0.01$) and the decrease in TNF- alpha level ($p<0.05$) were observed after the competitive phase of the annual training cycle
CONCLUSION: The main competitive phase didn't affect the gut microbiota but caused the change in the cytokine profile in amateur level competitive cyclists.

L-TYPE AMINO ACID TRANSPORTER 1 PLASMA MEMBRANE TRANSLOCATION ON CULTURED MYOTUBES DURING PROLONGED ELECTRICAL STIMULATION

TAKADA, H., NUNOMIYA, A., OSANA, S., NAGATOMI, R.

TOHOKU UNIVERSITY GRADUATE SCHOOL OF MEDICINE

INTRODUCTION: Diet and exercise are major factors to modulate protein synthesis and breakdown in our daily life (Manal A, et al., 2012). Leucine, one of the branched chain amino acids, is known to not only be incorporated in structural proteins but also stimulates protein synthesis. Leucine is considered to activate protein synthesis through activation of mammalian target of rapamycine (mTORC1). In skeletal muscle, leucine may be oxidized during exercise and induces protein synthesis through mTORC1 pathway after exercise (Dohm L, et al., 1980). leucine is transported into the cell through L-type amino acid transporter 1 (LAT1). LAT1 forms a heterodimeric protein complex with a glycosylated heavy subunit (CD98) responsible for import of large neutral amino acids, such as leucine. Expression of LAT1 is known to be up-regulated by an increased demand of intracellular leucine. We have previously identified that expression of LAT 1 mRNA in muscle tissue was increased after electrically induced contraction in mice (Takada, unpublished observation). In order for LAT1 to be functioning, LAT1 needs to be translocated to plasma membrane, but whether ES could induce membrane translocation is unknown. Therefore, this study was aimed to identify LAT1 plasma membrane translocation after ES.
METHODS: All experiments were performed on cultured C2C12 myotubes (7 days after differentiation) and mouse primary culture myotubes (7 days after differentiation). C2C12 myotubes were divided into ES for 30 min groups and ES for 24 hour groups, non-ES (control) groups, (Method: 1). C2C12 myotubes and primary myotubes were divided into ES groups and control (Method: 2). ES was performed as below : 1 Hz, 2 msec, 40 V, non interval, 24 hours or 30 min. After ES, samples were fixed for immunocytochemistry. LAT1 translocation was measured by immunocytochemistry of LAT1 and CD98, lamp2. Lamp2 is protein of lysosome membrane.
RESULTS: ES for 24 hours caused LAT1 to aggregate into the cytoplasm in C2C12. However, 30 min of ES did not aggregate LAT 1 into the cytoplasm (Method: 1) . Similarly, electrical stimulation for 24 hours caused LAT1 to aggregate in the cytoplasm . However, the aggregation of LAT1 at C2C12 was more aggregated than the primary culture (Method2).

CONCLUSION: Aggregation of LAT1 observed after 24 hours of electrical stimulation was not seen with 30 min of ES. These results suggest that stimulation time to cells may alter behavior of LAT1. Furthermore, the behavior of LAT1 24 hours after ES in C2C12 was greater than that of Primary culture, suggesting that the behavior of LAT1 by ES depends on cell type. Our future research will show its mechanism of behavior of LAT1 after ES.

RESPONSE OF BRAIN-DERIVED NEUROTROPHIC FACTOR TO HIGH-SPEED AND LOW-RESISTANCE CYCLING EXERCISE IN HEALTHY ADULTS: A RANDOMIZED CONTROLLED TRIAL

TOSHIAKI, M., NISHIWAKI, E., UHO, T., MIZUTANI, R., TAKEDA, C., FUJIOKA, H.

HYOGO UNIVERSITY OF HEALTH SCIENCES

INTRODUCTION: Brain-derived neurotrophic factor (BDNF) is well known as one of the essential mediators responsible for the beneficial effects of physical exercise on preventing cognitive impairment. Moderate- to high-intensity during physical exercise is required to increase blood BDNF levels (Coelho et al., 2013), however there are many people who cannot perform such a high-intensity physical exercise because of orthopedic problems or frailty. Although high-speed and low-resistance physical exercise (HLE) has been considered as one of the exercise methods to improve muscle functions and physical performances (Bellumori, et al., 2017), the response of blood BDNF levels to HLE has been unknown. The purpose of this study is examining the response of blood BDNF levels to HLE in healthy adults.
METHODS: Seventeen healthy adult men randomly performed three experimental sessions; a 40-min cycling exercise at a workload of 40% peak oxygen uptake and a pedaling cadence of 50-60 rpm (Standard Exercise; SE), a 40-min cycling exercise at a workload of 40% peak oxygen uptake and a pedaling cadence of 90-100 rpm (HLE), and a session of complete rest for 40 min (CON). Heart rate was monitored throughout each session, and blood examinations for serum BDNF and lactate levels were performed before and after each session. All variables were analyzed using two-way repeated measures analysis of variance with session and time as within-participant factors.
RESULTS: There was a significant interaction between session and time for BDNF levels ($p < 0.05$), and HLE significantly increased BDNF levels compared to CON ($p < 0.05$) whereas SE had no significant changes in BDNF levels compared to CON ($p > 0.05$). Heart rate and lactate concentration in HLE were significantly higher than those in CON and SE, respectively (all $p < 0.05$).
CONCLUSION: Our main finding was that HLE could increase blood BDNF levels. This result suggested that the HLE might improve cognitive function through the increase of serum BDNF. However, the heart rate significantly increased during the HLE protocol performed in the present study. Therefore, it is necessary to examine the reasonable pedaling cadence and to establish the optimal HLE protocol for elderly people in the future.

STUDY OF THE PROTEIN SYNTHESIS IN MUSCLE CELLS USING NON-CANONICAL AMINO ACIDS

OSANA, S., NUNOMIYA, A., TAKADA, H., SUZUKI, N., AOKI, M., NAGATOMI, R.

TOHOKU UNIVERSITY GRADUATE SCHOOL OF MEDICINE

INTRODUCTION: Skeletal muscle mass is considered to be regulated by the balance between synthesis and degradation of proteins. It has been reported that muscle protein synthesis is induced by resistance training (Drummond MJ et al., J Appl Physio 2009), and intake of amino acids (especially leucine) also induces muscle protein synthesis (Volpi E et al., Am J Clin Nutr 2003). The metabolism of muscle proteins is, therefore, an important index to evaluate the effect of exercise and nutrition on skeletal muscle. In previous studies, metabolism of skeletal muscle protein is evaluated by surface sensing of translation (SUnSET) method using puromycin (Goodman CA et al., FASEB J 2011) and tracer method using stable isotope-labeled amino acids (Phillips et al., Am J Physiol 1997). However, the former is unsuitable to detect the long-term protein metabolism due to toxicity, and the latter had only shown the rate of turnover. In this study, we used a methionine analog azidohomoalanine (AHA), the incorporation of which may be visualized by conjugation of azide bound dye, to evaluate long term muscle protein metabolism.
METHODS: Mouse C2C12 myoblasts were cultured in growth medium (GM; 10% fetal bovine serum and 100mg/ml penicillin streptomycin solution) for proliferation. We replaced GM with serum free DMEM, and then cultured for 18 hours to synchronize the cell cycle. Next, we replaced the culture medium with fresh one containing AHA with or without protein synthesis inhibitor cycloheximide (CHX). Cells were harvested at 1, 4, 8 and 18 hours after the replacement of fresh media. AHA incorporation was evaluated by signal intensity of fluorescence activated cell sorter (FACS) and western blot analysis (WB).
RESULTS: AHA was detected in C2C12 myoblasts by FACS and WB. The survival rate of cells cultured with AHA was not significantly different from control cells. Additionally, signal intensity of AHA gradually increased as the culture time increased. CHX addition significantly reduced the AHA incorporation.
CONCLUSION: AHA loading to cultured cells was capable of tracking amino acid incorporation into muscle proteins.

RELATIONSHIP BETWEEN CHILDREN'S PREFERENCES FOR PHYSICAL EDUCATION, ENJOYMENT OF PHYSICAL ACTIVITY, EXPERIENCES AND ENVIRONMENT, AND MASTERY OF MOVEMENT SKILLS IN JAPAN AND SOUTH KOREA

IKEDA, T.1, HAN, N.2, CHOI, T.2, AOYAGI, O.3

1 FUKUOKA PREFECTURAL UNIVERSITY, 2 JEJU NATIONAL UNIVERSITY, 3 FUKUOKA UNIVERSITY

INTRODUCTION: Children's physical fitness levels are decreasing in Japan and South Korea, and inactivity among Asian children has been cited as a reason for this decline (Muller et al., 2013; Tomkinson et al., 2012). Children's preferences for physical education depend on their experiences, environment, and/or mastery of movement skills (Sugihara, 1988), and several factors regarding children's joy of exercise have been extracted (Tokunaga & Hashimoto, 1980). The purpose of the present study was to investigate the relationship between children's preferences for physical education (PPE), enjoyment of physical activity (EPA), experiences and environment (EE) and mastery of movement skills (MMS) in Japan and Korea.

METHODS: The research participants were 1,520 children (758 Japanese children, 758 boys) aged 10–12 years in Japan and Korea. All participants completed a questionnaire related to their PPE (12 types), EPA (21 items), EE (14 items) and MMS (10 items). Factor analysis and structural equation modeling (SEM) were applied to investigate the factors determining all 57 items and the factor relations.
RESULTS: Factor analysis extracted 14 factors, 10 of which could be interpreted as follows: 1) Jumping and gymnastics; 2) Swimming; 3) Running; and 4) Ball games for PPE, 5) Performing and 6) Watching for EPA, 7) Environment and 8) Negative experiences for EE, and 9) Axis and 10) Limb for MMS. The results of SEM showed a covariate relationship between PPE and EPA conforming to the model in each group based on country and gender (all GFIs and CFIs were over .900). The Korean model (AIC = 154.4) provided a better fit than the Japanese model (172.2), and the girls' model (179.3) provided a better fit than the boys' (195.1). The models of the causal relationship (Cause = EE and MMS, Results = PPE and EPA) showed the characteristics of each country. In the Japanese model (GFI = .935, CFI = .894), EE significantly affected PPE (Path Coefficient: beta weights [PC] = .13, $p < .01$). On the other hand, in the Korean model (GFI = .936, CFI = .908), EE (PC = 2.20, $p < .01$) and MMS (PC = 2.17, $p < .01$) significantly affected PPE.
CONCLUSION: Akizuki and Kanbayashi (2016) reported gaps in physical fitness among children in Korea owing to problems in the physical education curriculum. Their findings are supported by the results of the present study, namely that MMS affects PPE among children in Korea, and that MMS does not affect PPE among children in Japan. The present study indicated the differences between Japan and Korea on PPE and their relating factors.

TEACHER PSYCHOLOGICAL NEEDS SUPPORT, GENDER AND AUTONOMOUS MOTIVATION IN PHYSICAL EDUCATION STUDENTS

CASTILLO, I.

UNIVERSITY OF VALENCIA

Teacher psychological needs support, gender and autonomous motivation in Physical Education students
Isabel Castillo.1, Jorge Zamarripa.2, Inês Tomás.1, Octavio Álvarez.1, Maritza Delgado.2 & Maria Marentes.2
1. University of Valencia (Spain)
2. Autonomous University of Nuevo Leon (Mexico)
Introduction: The purpose of this study was to consider if the interaction between the perception of Physical Education (PE) teachers' support of their students' needs of autonomy, competence and relatedness, teachers gender and students gender predicts autonomous motivation during PE classes. We argue that to the extent that PE teachers affect the motivation levels of their students, these effects are likely to be moderated in part by teacher gender and student gender. Extending previous research in the school domain, we hypothesize that student gender and teacher gender will interact favorably when student and teacher genders match, but unfavorably when they do not.
Method
Participants were 724 secondary school students (389 males, 335 females), between 11-17 years old (M = 13.7; SD = 1.09) across 40 secondary schools from Nuevo Leon (Mexico) who volunteered to participate in this study. 569 participants informed that the gender of their PE teacher was male, and 155 that it was female.
Results: The results using moderated regression analysis showed that the effect of students' perceptions that the teacher created context supporting their autonomy, competence and relatedness on students' autonomous motivation depends on the extent to which the student and the PE teacher are males or females. Concretely, students' perception of teacher support positively predicted students' autonomous motivation in both genders, but this relation was higher for females. Moreover, students' perception of teacher support positively predicted students' autonomous motivation for both, males and females teachers, but this relation was higher when the teacher was a female. Finally, when female PE teachers teach male and female students the relation between teachers' psychological needs support and autonomous motivation is higher than when male PE teachers teach male and female students.
Conclusion
In contrast to predictions on gender stereotypes and the matching hypothesis, our results revealed that students' perceptions that the PE teacher supported their psychological needs were higher in PE classes taught by female teachers, regardless of the students gender, than in classes taught by male teachers. Indeed, the effect of teacher support on students' motivation was much larger for female students than for male students. The findings hold implications for educational intervention, suggesting that teachers in general and PE teachers in particular, should focus on supporting students despite their gender as it is relevant to promote autonomous motivation, which in turn has numerous positive cognitive, behavioral and affective consequences.

THE IMPACT OF PARTICIPATION IN A GAME OF TAG, AN ACTIVITY PROMOTING HELPING BEHAVIOR, ON HELPING BEHAVIOR-RELATED SELF-EFFICACY AND SUBJECTIVE ADJUSTMENT TO THE CLASSROOM AMONG CHILDREN

UENO, K.

KAGAWA UNIVERSITY

Introduction: With recent social issues such as breakdowns in classroom discipline, bullying, and social withdrawal, there are increasing expectations about the role of physical education, which generalizes fair play in sports from the gym to the classroom. Ueno (2017) developed a game of tag that promotes children's helping behavior. In this tag game, helping other children avoid the catcher without regard for personal safety is evaluated as fair play. Accordingly, this study aimed to examine the impact of participation in the game of tag, an activity promoting helping behavior, on helping behavior-related self-efficacy and subjective adjustment to the classroom among children.
Methods: Sixty elementary school children played one round of two types of tag in a PE class. In the first class (i.e., regular tag), children had to run around and avoid being caught. In the other, which was developed by Ueno (2017) and named "Nakama-oni," the catcher could touch only those children who were running alone and not those who held hands with each other (a child could hold hands with only one other child at a time). This feature of the game was intended to elicit helping behavior. Children were told before the game that there is significant value in helping others avoid the catcher without regard for personal safety. Children's helping behavior-related self-efficacy and subjective adjustment to the classroom were assessed before and after the game using the scale for helping behavior-related self-efficacy (Ueno, 2017) and a subjective adjustment scale for elementary school children (Emura and Okubo, 2012).
Results: Two-way repeated measures ANOVA and simple main effect tests were conducted on the both scales' scores. About helping behavior-related self-efficacy, a significant interaction effect was found between timing and the type of tag. The results of the simple main

effect tests showed that the scale score after Nakama-oni was significantly higher than it was either before Nakama-oni or after regular tag. About subjective adjustment to the classroom, a significant main effect was found between before and after the games of tag.
Discussion: From the results of helping behavior-related self-efficacy, findings suggest that experiences of helping others, even in a game of tag, may enhance helping behavior in daily living by increasing self-efficacy. From the results of the subjective adjustment to the classroom, tag games, in which classmates play with each other, enhance subjective adjustment to the classroom among children regardless of whether they include helping behavior.

DEVELOPMENT OF TRAINING FOR NURSERY TEACHER USING RECOGNITION OF DIFFERENT EVENTS ON INFANT PHYSICAL EDUCATION

SAKON, S.

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

Development of Training for Nursery Teacher using Recognition of Different Events on Infant Physical Education
Sakon, S.1, Nishihara, Y. 1: NUHW (Niigata, Japan)
Introduction: The basis of development of personality that is to be maintained for their entire life is founded in the childhood through daily life mainly consisting of playing. It is very high technique to prepare materials, teaching tools and environment that enrich and support children's play when they request new play and/or activities. Thus, nursery teachers and other school teachers are required to prepare the environment and have abilities to make appropriate judgment in order to respect childrens identity and to take flexible actions for various events on the site. The purpose of this study was to extract the ability of nursery teachers for recognizing different events on the scene of physical education and to develop the teaching skill improvement program.
Method
In order to extract event recognition on the scene of infant physical education, we viewed physical education (video) through child's play, observed and evaluated events on the site, and extracted "recognition of different events" and "recognition of identical events" by sufficiently experienced nursery teachers (7) and inexperienced nursery teachers (7). The obtained event recognition was categorized to "knowledge of the contents of teaching materials (hereinafter referred to as the "contents of teaching materials")," "knowledge of teaching method (hereinafter referred to as the "teaching method")," and "knowledge of children," and comparative review was performed. The contents of teaching materials (video) were as follows. Children sing and dance along with the song by the teacher (at three levels of speeds). Children pretend to be the specified thing and wait quietly – (1) pretending to be a stone and staying still, (2) pretending to be a sticker and adhering to the floor, and (3) pretending to be an animal and moving freely, and the teacher tries to push, pull, etc. the children with the force competing with theirs. Children try to resist the force that the teacher tries to move them. Interactive stimulation to neural transmission and peripheral nerves, development of concentration power and improvement in ability to wait calmly is expected.
Results: As for identical events recognized from the experienced nursery teacher and inexperienced nursery teacher, it was confirmed that "the teacher exploits children's concentration power" in terms of the contents of teaching materials and that "children stay calm for a long period of time." Not many points were noticed in the teaching method of inexperienced nursery teachers.
Recognition of different events was categorized into "the fun of the activity is transmitted to children," "their identity and desire is exploited" and "children put power into their peripheral nerves in finger tips" in terms of the contents of teaching materials, and "leading of simultaneous motio

LONGITUDINAL TRANSFORMATION OF SPRINT MOTION CAUSED BY ADOLESCENT AWKWARDNESS IN THE EARLY ADOLESCENCE

KOKUDO, S., KONDO, R., KAWAKATSU, S., UEDA, K.

KOBE UNIVERSITY

INTRODUCTION: The adolescent awkwardness of sprint was investigated from the speed decline (Bounen & Malina(1988)) and the motion deterioration through the age difference with cross-sectional data (kokudo(2017)); however, the longitudinal change of sprint motion caused by adolescent awkwardness is unclear. The purpose of this study was to investigate the longitudinal transformation of sprint motion in the early adolescence.
METHODS: The subjects was 157 children (81 boys and 76 girls) of 4th - 6th grade of elementary school in 2016. Their intermediate (25-35m of 50m sprint) sprint speed (SS) were measured by sensor timer and their sprint motions(SM) was recorded with digital video camera on May 2016 and May 2017. Observational sprint motion causal model, which includes 38 checkpoints, was developed based on the biomechanical findings and the descriptive checkpoints of previous studies (e.g. Knudson & Morrison (2002)). Their forms were played in slow motion or frame-by-frame, and 2 investigators evaluated the checkpoints.
Categorical factor analysis on pooled two years of data and oblique rotation by promax criteria was applied in order to identify SM factors and factor scores. Children were classified into two groups, improved group(Gi) and stagnant group(Gs) in SS change(SSC). Repeated ANOVA was applied in each SM factor score in order to investigate the difference of SM between 2016 and 2017 by SSC and sex.
RESULTS: As the result of factor analysis, 6 factors were extracted and 52.8% of total variance was explained by these factors. The factors were interpreted F1: leg grounding preparation and drive motion, F2: weighting motion, F3: arm-swing motion, F4: grounding and push direction, F5: free leg swing motion and F6: pinching motion, respectively. Since SSC showed a bimodal distribution at 0.2 m / sec., the SSC group was divided into Gi (54 boys, 42 girls) and Gs (27 boys, 34 girls) at 0.2 m / sec. Significant interaction between repeated measurement and SSC ($F = 6.07$, $p < 0.05$) was found on F1 Score; the F1 score of the Gi was increased though that of Gs was decreased. Significant main effect of the sex ($F=9.31$, $p<0.01$)) and SSC group ($F4.08$, $p<0.05$) was found on F3 score; the boys score was higher than girls and the score of Gi was higher than Gs both 2016 and 2017.
CONCLUSION: Adolescent awkwardness in sprint motion occurs in leg grounding preparation and drive motion, and it affects stagnation of sprint speed improvement.

THE ACTIVATICS PROGRAM TO INCREASE PHYSICAL ACTIVITY OF HIGH SCHOOL PE STUDENTS*

RAMIS, Y., PONS, J., BORRUECO, M., VILADRICH, C., CRUZ, J.

UNIVERSITAT AUTONOMA DE BARCELONA

ACTIVATICS is an action-research project aimed at improving the physical activity (PA) levels of adolescents, elderly and former elite athletes. In the case of adolescents, this project is framed on Self-Determination Theory (SDT; Ryan & Deci, 2000), and built upon Su & Reeve's (2011) systematic review on the effectiveness of SDT-based interventions to enhance motivation towards PA. We designed an intervention program to improve motivational skills of High School PE teachers which consisted on three phases: (a) a review of previous knowledge on the field of PA interventions, (b) the organization of focus groups both with experts on PA promotion and with PE teachers and students, (c) the development of a tailored education package adapted to motivations and objectives of the PE teachers attending the program. A total of 11 PE teachers, responsible of 57 high school PE groups, followed the program consisting of a 3hr workshop, a self-monitored phase and a 2,5hr follow-up session. The workshop primarily focused on providing recommendations to fulfill autonomy-supportive styles (i.e., provide meaningful rationales, acknowledge negative feelings, use of non-controlling language, offer choices, and nurture inner motivational resources. The workshop final exercise assessed (a) the understanding of the contents of the session, (b) perceived ability to implement changes on sessions, and (c) behavioral commitment to effectively include changes to their teaching style. On the self-monitored phase, PE teachers established their own individual objectives for subsequent classes. The diaries included information about the success of the implementation as well as perceived barriers or acknowledgement from their students. The follow-up session allowed PE teachers to share their experiences with both peers and the educator and to reset new goals for their PE classes. We will discuss the effectiveness of the program focusing on the satisfaction of the teachers regarding the resources provided in the program.

THE FEASIBILITY OF WALKING INTERVENTIONS FOR PROMOTING PHYSICAL ACTIVITY WITHIN THE SCHOOL ENVIRONMENT

CARLIN, A.1, MURPHY, M.H.1, GALLAGHER, A.M.2

ULSTER UNIVERSITY

INTRODUCTION: Physical activity (PA) levels have been shown to decline as children move into adolescence, with this decline most notable amongst females. Schools have the potential to contribute to daily PA in adolescents. The aims of this study were to firstly evaluate the experiences of adolescent females who participated in a peer-led school-based brisk walking intervention (the WISH study) and secondly, to evaluate the potential for schools to further promote PA through walking programmes delivered within the school setting.
METHODS: A sample of female participants who participated in the WISH study (Carlin et al., 2018) were randomly selected from 5 post-primary schools to participate in focus group discussions to explore their experiences of the intervention. Discussions were audio-recorded, transcribed verbatim and analysed thematically. In addition, an online survey was distributed to all post-primary schools (n=208) in Northern Ireland to assess the current provision of extra-curricular PA and to evaluate the feasibility of the WISH study within the school setting. The questionnaires were completed by a member of staff familiar with the schools extra-curricular provision of PA (excluding PE staff).
RESULTS: In total, 6 focus groups were conducted comprising a total of 45 adolescent females (mean age 13.1 years). Helping participants overcome current barriers to PA, support from friends and peers and the provision of activities that met the needs of adolescent females within the school setting were all highlighted as possible strategies to promote PA. Walking during the school day was viewed as an acceptable form of PA, providing opportunities to be active with friends, and helped participants overcome a number of barriers previously associated with PA during school recess. 59 post-primary schools completed the online survey. Responding schools identified adolescent females and 'non-sporty' pupils as sub-groups that would benefit most from participation in a school-based walking programme. The majority of responding schools did not currently offer walking programmes. A number of barriers were identified by schools in relation to walking, for example, safety concerns and supervisory/staffing issues.
CONCLUSION: This study has highlighted that the delivery of a walking programme within the school setting is feasible. Incorporating strategies such as social support and peer mentoring may be effective in promoting PA during school recess. Positive experiences identified in this study should be reinforced when recruiting adolescent females onto future PA interventions, and the barriers identified by schools in relation to safety and staffing concerns should be addressed.

FAMILY STRUCTURE INFLUENCE ON PHYSICAL ACTIVITY OF PORTUGUESE ADOLESCENTS WITH OVERWEIGHT RISK – FAMILY IN MOVE PROJECT

LAGOA, M.J.1,2, AIRES, L.2,3 , SÁ, C.1,2, VIANA, J.L.1,2, SILVA, G.1,2

UNIVERSITY INSTITUTE OF MAIA, ISMAI

INTRODUCTION: Children's physical activity (PA) behaviours are decreasing worldwide and Portugal follows the same trend; few adolescents attain health recommendations for PA intensities. Family is an important agent that can have a positive influence on the promotion of adolescents' health-related PA behaviours. Therefore, the aim of this study was to analyse the effect of family structure on adolescents' PA.
METHODS: Portuguese adolescents (n = 285, mean age 12.8±1.8 years) took part in a school-based project, named Family in Move. This project aims to identify barriers, motivations and family perceptions, reported by parents and adolescents, and in particularly related to healthy lifestyles. The family's demographic information and grandparents' support were measured by questionnaire, as was the Adolescents' PA; the overall maximum possible number of points of PA questionnaire was 22 and total score as a PA index (PAI) was used. The weight and height of adolescents were measured and body mass index (BMI, kg/m2) was determined by Cole cut-off points. Paren-

tal weight and height were self-reported and BMI was also determined. To analyse the effect of family structure on adolescents' PA, univariate analysis of covariance, controlling for gender, with Bonferroni adjustments was performed.
RESULTS: Only 22% of these 285 Portuguese adolescents are active, including 55% girls and 45% boys. 22% of the adolescents were overweight and 5% were obese, but 84% are at risk of being overweight, because at least one parent was obese. Most adolescents living with both parents (83%) and with siblings (58%). In addition, most families were emotionally supported by grandparents (58%). Few families reported daily support (39%) and financial support (15%) by grandparents. "Adolescents living with both parents" and "grandparents' support" variables had no significant effect on the adolescents' PA. Furthermore, the adolescents' PA was significantly higher in those living with siblings ($F = 4.03$, $p<0.046$, $\eta 2= 0.05$).
CONCLUSION: Our results showed that family structure had a favourable effect on adolescents' PAI through the siblings influence. Therefore, a family environment specifically on siblings may be an important element to consider in interventions for adolescents active life promotion.

THE EFFECTS OF PHYSICAL EDUCATION COURSES ON UNIVERSITY STUDENTS' EXERCISE EFFICACY AND SCHOOL ADAPTATION

SHIMIZU, Y.1, MIYAZAKI, M.2, ANNEAR, M.1, TAKANASHI, M.1, YAMAUCHI, H.1
1:INTERNATIONAL CHRISTIAN UNIVERSITY , 2:J.F.OBERLIN UNIVERSITY

Introduction: Lack of exercise is widespread in Japan and some young adults are reluctant to exercise because of negative past experiences in school sports and physical education (PE). Currently, undergraduate physical education courses are compulsory at 66% of Japanese universities. This study examines the veracity of a hypothetical model for students' PE course evaluation and their self-efficacy for physical activities and school adaptation. It assesses the relationship among factors concerning PE instruction and students' attitudes towards exercise and campus life.
Methods: Subjects included 515 university students enrolled in PE courses (male: 149, female: 366, mean age=20.49, SD=1.21) who voluntarily answered a questionnaire composed of items from the Teaching Evaluation Scale for Physical Education Courses (TESPEC), Adaptation Scale for Physical Education Courses (ASPEC), Benefit Scale for Physical Education Courses (BSPEC), Self-Efficacy Scale for Physical Activities (SESPA) and School Adaptation Scale (SAS). Covariance structure analysis was conducted to confirm the acceptability of the hypothetical model and the relationship among the factors of the scales.
Results: The results of analysis showed that our hypothetical model yielded acceptable fit indices with teaching evaluation influencing exercise self-efficacy and school adaptation, mediated by adaptation to and perceived benefits of PE classes (GFI: 0.933, AGFI: 0.887, CFI: 0.954, RMSEA: 0.080). Among the mediating variables, direct effects were found from teaching evaluation to adaptation to PE classes (pass coefficient: 0.66, $p<0.001$), which in turn influenced perceived benefits of PE classes (pass coefficient: 0.90, $p<0.001$). Furthermore, perceived benefits of PE classes had direct effects on exercise self-efficacy (pass coefficients: 0.20, $p<0.001$) and school adaptation (pass coefficients: 0.39, $p<0.001$). .
Discussion: The results indicate that the hypothetical model can be used in predicting students' exercise self-efficacy and university adaptation and that instructors' perceived teaching skills and communication styles in university PE courses have an impact on students' exercise behavior as well as their adaptation to university. This implies that improving PE class experience for students is one of the ways to ameliorate negative attitudes towards exercise. Further research is needed to assess what types of interventions are most efficacious and which elements of PE classes (e.g. making friends in team sports) affect students' adaptation to university.

AEROBIC EXERCISE TRAINING REDUCES PLASMA 3-HYDROXYISOBUTYRATE LEVEL IN OVERWEIGHT AND OBESE MEN.

KANAE, M.1, TORU, Y.1, JIYEON, P.1, TERUO, M.2, AKIRA, H.2, NOBUTAKE, S.1, SEIJI, M.1
1.UNIVERSITY OF TSUKUBA, 2.TOKYO MEDICAL UNIVERSITY IBARAKI MEDICAL CENTER

INTRODUCTION: Obesity is a major public health problem all over the world and strongly relates to insulin resistance, which is a crucial risk factor for type 2 diabetes mellitus. Recent studies suggested that a higher circulating level of 3-hydroxyisobutyrate (3-HIB; a catabolic intermediate of valine), which was observed in obesity, caused insulin resistance. Aerobic exercise training has been recognized as an established strategy for preventing type 2 diabetes mellitus. However, its mechanisms have not been fully clarified. The purpose of the present study was to examine the effect of aerobic exercise training on plasma 3-HIB level in overweight and obese men.
METHODS: Twenty-one overweight and obese men completed a 12-week aerobic exercise training program under the supervision of exercise instructors (walk/jog, 60-80%HRmax, 30-60 min/day, 3 days/week). Participants were asked to maintain their dietary habits during the intervention. Before and after the exercise program, step counts, peak oxygen uptake, body mass index, body fat percentage, and plasma hemoglobin A1c (HbA1c) were measured, and 75-g oral glucose tolerance tests (OGTT) were performed. Plasma glucose, serum insulin, and plasma 3-HIB were measured at 0 min, 60 min, and 120 min after glucose loading.
RESULTS: After the 12-week aerobic exercise training, step counts and peak oxygen uptake increased significantly, whereas body mass index, body fat percentage, HbA1c, and plasma 3-HIB level decreased significantly. At the points of 60 and 120 min in the OGTT, plasma glucose level was significantly lower after than before the training, although there was no difference in plasma insulin level between before and after the training. Before the training, plasma 3-HIB level significantly and gradually decreased at 60 and 120 min-points in the OGTT. After the training, plasma 3-HIB level was maintained by 60 min after the glucose ingestion, and then, significantly decreased after 120 min to the equal level of the same point in the before training.
CONCLUSION: In result of the 12-week aerobic exercise training, plasma 3-hydroxyisobutyrate level significantly decreased accompanied with the improvements of body composition, physical activity and blood marker of diabetes in overweight and obese men. Furthermore, the response of plasma 3-hydroxyisobutyrate level significantly changed during OGTT after the training in the subjects. The decreased 3-hydroxyisobutyrate level in blood may be a part of mechanisms underlying prevention of the onset of diabetes by aerobic exercise training.

PHYSICAL ACTIVITY AND SALIVA CORTISOL CONCENTRATIONS DURING MILITARY FIELD TRAINING

OJANEN, T., VASANKARI, T., HÄKKINEN, K., KYRÖLÄINEN, H.

FINNISH DEFENCE RESEARCH AGENCY

INTRODUCTION: Military field training (MFT) exposes soldiers to both physical and psychological stress. These stressors have been shown to lead changes in both hormonal profile and physical performance (Tanskanen et al. 2011). The purpose of this study was to investigate changes in volume and intensity of objectively measured physical activity and changes in daily variation of saliva cortisol concentrations during MFT.
METHODS: A total of 167 (age 20±1yrs., height 180±7cm, body mass 74.5±10.7kg) male soldiers participated in the study. The measurements were made during the years of 2014-2016 in MFTs. Physical activity was measured with a 3-dimensional accelerometer placed on the waist. The activity data were analyzed by using a mean amplitude deviation (Vähä-Ypyä et al. 2015). The saliva samples were collected in Salivette tubes, a total of six times per day (06:00, 09:00, 12:00, 15:00, 18:00 and 21:00), before MFT (PRE), during a shooting training day (ST) and during a normal MFT day (MFT). In addition, body composition, maximal isometric force of the upper and lower extremities, muscular endurance tests with a standing long jump and the 12-min running test were measured in order to identify possible relationships with physical activity and saliva cortisol concentrations.
RESULTS: The mean (±SD) time for light physical activity (MET 1.5-3.5) was 3:28±0:56 h:min and for moderate physical activity (MET 3.5-6.0) 1:22±0:41 h:min in the PRE measurement day. The respective values for the ST day were 4:43±1:34 h:min and 2:02±1:07 h:min, and for the MFT day 4:03±1:21 h:min and 2:03±0:57 h:min. The mean (±SD) number of steps for PRE, ST and MFT were 12237±5140; 15030±5367; 14406±5102. The saliva cortisol concentration values were the lowest during the PRE day and the highest during the ST day in all measurement points.
CONCLUSION: The present study showed the highest values in physical activity and saliva cortisol concentration during the ST day. Morgan et al. (2002) found that soldiers who were exposed to stressful situations had higher saliva cortisol concentrations than soldiers who were not exposed to stressful situations. Similar findings were also observed in the present study. Physical activity was the same for the ST and MFT days, but ST had higher saliva cortisol concentrations. The results suggest that live-ammo shooting exercises are more stressful to soldiers mentally than normal MFT.

CHANGES IN SALIVARY CORTISOL LEVELS AND SUBJECTIVE CONDITION DURING 2016 AFC U-23 CHAMPIONSHIP PERIOD

NAKAMURA, D.1, NAKAMURA, M.1, HAYAKAWA, N.2

1 JAPAN INSTITUTE OF SPORTS SCIENCE , 2 JAPAN FOOTBALL ASSOCIATIONS

INTRODUCTION: In international football competitions, players have to play matches with only 2~4 days recovery days in between. Therefore, it is very important for team to monitor training load during the competition to prevent fatigue
To date, several studies indicated the usefulness of monitoring internal training load, such as hormonal response, heart rate variability, but there is few data available on changes in these variables during actual international football competition.
Thus, the aim of this study was to examine the changes in cortisol response and subjective fatigue of players during 2016 AFC U-23 Championship (Qatar).
METHODS: Twenty-three U-22 Japan national team football players were participated in this study. To monitor internal load, saliva cortisol level, body weight, and subjective condition were measured in the morning during 2016 AFC U-23 Championship period. Saliva cortisol level was measured using lateral flow device (LFD), and subjective conditions were evaluated using visual analogue scales (VAS). Before conducting this measurement, the validity of the device was checked by examining correlation coefficient between enzyme immunoassay (EIA) and LFD in salivary cortisol level.
RESULTS: The correlation coefficient between EIA and LFD in salivary cortisol level was $r = 0.82$ ($p < 0.01$).
Salivary cortisol levels of some players were increased after the matches, and returned to the original value after a few days of recovery during the competition period. However, there were some players who showed successive increase in the salivary cortisol levels when the number of matches was increased.
CONCLUSION: There was a relationship between the external load (match playing time) and changes in internal load (salivary cortisol and VAS) for some players, but not for all players. This might be explained by a different response against external load among individuals. These results from our present study indicated that the monitoring salivary cortisol level was useful tool to detect internal load of the players during international competition period. Also, internal training load should be evaluated individually since each player show different response to an external load.

THE RELATIONSHIP BETWEEN SALIVARY CORTISOL AND TRAINING LOAD IN ELITE RUGBY UNION PLAYERS

TIERNAN, C.1, LYONS, M.1, COMYNS, T.1, NEVILL, A.2, WARRINGTON, G.1

UNIVERSITY OF LIMERICK, UL, IRELAND, 1. UNIVERSITY OF WOLVERHAMPTON, WLV, ENGLAND, 2.

INTRODUCTION: Increased physiological stress can have negative effects on performance, particularly if there is an imbalance between training load (TL) and recovery (Meeusen et al. 2013). Salivary cortisol (sC) has been found to be a marker of physiological stress (Lindsay et al. 2015). There is limited research comparing weekly TL and sC levels in Rugby Union. The aim of this study was to investigate the association between weekly sC and TL in elite Rugby Union players.
METHODS: Nineteen male elite Rugby Union players (19.7 years±1.1, 184.5 cm±7.7, 96.2 kg±12.5) volunteered to take part in a 10-week pre-season study. Players provided saliva swabs twice a week (Monday and Friday morning). Session rate of perceived exertion (sRPE) was taken after every training session and TL was calculated by sRPE x session duration. Multi-level analysis, using MLwin software, was performed to analyse the association between sC and TL.
RESULTS: No significant association ($p>0.05$) was found between Monday sC and TL of the previous week ((0.00050 (0.00088) ng.ml) (Beta (Standard Error)) or between Friday sC and TL of the same week ((0.00079 (0.00071) ng.ml). Compared to baseline, a significant increase

(p<0.05) was found for Monday sC in weeks 4, 6, 8 and 9, and TL in weeks 2, 4, 6, 7, 8, 9 and 10. No significant weekly differences (p>0.05) were found with respect to Friday sC.
CONCLUSION: The results from this study found no association between TL and sC. This may be due to the large individual player variability in sC and may also indicate the expertise of the coaches in terms of appropriately regulating TL (Agostinho et al. 2017). The weekly differences indicate the changes in Monday sC and TL over the pre-season period, highlighting the importance of week by week analyses. The results imply that sC does not reflect weekly TL when assessed over a 10-week period. Future research is needed to investigate whole season variations in weekly sC and TL in Rugby Union players.

THE EFFECT OF PRIOR EXERCISE ON MEASURES OF RESTING METABOLIC RATE IN TRAINED MEN.

BONE, J.L., BURKE, L.M.
AUSTRALIAN CATHOLIC UNIVERSITY

INTRODUCTION: Resting energy expenditure (REE) is one tool that can be used to support the diagnosis of low energy availability. However to accurately measure REE and to be able to detect changes between measurements, it is important to investigate how certain variables may artificially increase the REE, potentially masking evidence of a supressed metabolic rate. One such variable is exercise. The REE following exercise has been reported to last up to 39 or 72 h in homogeneously trained populations(1,2). The aim of this pilot study was to profile REE when measured at 12 h intervals up to 48 h post exercise in a heterogeneous group of athletes undertaking self-selected training sessions.
METHODS: Ten trained males (age 30.3±6.2 y; weight 81.5±11.6 kg; height, 187.8±6.9 cm) from a variety of sports participated in this study. Participants undertook a standard training session of their choosing on Day 0, either in the morning or afternoon. The next morning they presented for their 1st REE (post-exercise-day) and DXA with no exercise being permitted following the REE on Day 1. Participants returned on Day 2 for their 2nd REE (post-rest-day). They then repeated this process the following week, however with the training session completed at the other time of day. Participants were assigned to train either in morning or the afternoon in the first week and in the alternative time in the second week. This provided REE approximately 24 and 48 h post exercise following morning training session and 12 and 36 h post exercise following the afternoon training session. The training session and diet was replicated from week to week. REE was determined following a minimum 8 h overnight fast using indirectly calorimetry as previously described(3). Linear mixed modelling was used to determine the difference between the different time points. The typical error for REE is 478 kJ/d.
RESULTS: There was a statistically significant decrease in REE of 345 kJ/d when measured 48 h post exercise compared to 12 h. There was a trend for REE to be lower with increasing rest from exercise. All differences between time-points were within the typical error for the outpatient protocol.
CONCLUSION: There was a trend for REE to decrease with increasing rest period from exercise. However, no clear effects of acute exercise on subsequent morning measures of REE could be detected in participants from a mixed sport population undertaking self-selected training sessions.

BREAKING UP PROLONGED SITTING AND POSTPRANDIAL GLUCOSE IN ACTIVE YOUNG MALE ADULTS WITH CENTRAL OBESITY

WONGPIPIT, W., LEUNG, M.L.E., CAO, X.Z., FU, X., YU, J., WONG, S.H.S.
THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: Greater time spent on sedentary is associated with an increased risk of morbidity and mortality independent of time spent in moderate-to-vigorous-intensity physical activity (MVPA) (Wilmot et al., 2012). In previous studies, frequent breaking up prolonged sitting protocols have been used (i.e., 2-min light-intensity walking every 20 minutes of sitting or 3-min light-intensity walking every 30 minutes (Dunstan et al., 2012; Dempsey et al., 2016). Practically, some people may prefer breaking up prolonged sitting less frequently (i.e., 6-min light-intensity walking every 60 minutes) (Bond et al., 2014). The purpose of this study was therefore to determine whether 3-minute walking every 30 minutes of sitting is comparable to 6-minute walking every 60 minutes of sitting in influencing postprandial glucose among young men with central obesity.
METHODS: This study used a randomised crossover design. Thirteen physically active centrally obese men (mean age: 25.08 ± 3.2 years; body mass index: 29.36 ± 3.46 kg/m2; waist circumference: 98.12 ± 8.04 cm; % body fat: 28.58 ± 4.37%) were recruited. Physical activity levels and sedentary time were measured using an ActiGraph accelerometer and an activPAL, respectively, during 7 days of screening and washout periods. Consumed standardised meals calculated using Mifflin and St.Jeor's formula (Mifflin et al., 1990) (Carbohydrate = 55%, Fat = 30%, and Protein = 15%). There were three main 7-hour conditions separated by 6-14 days washout: uninterrupted sitting (SIT); sitting + half hourly bouts of walking (3.2 km/h for 3-min) (3-MIN); sitting + hourly bout of walking (3.2 km/h for 6-min) (6-MIN). Plasma glucose was measured 30 minutes after the meal and hourly using an enzymatic-amperometric method. Plasma glucose was changed to the net total area under the curve (tAUC) using the Trapezoidal method. Two-way ANOVA with repeated measures was used to examine differences among three conditions over time for plasma constituents. The Bonferroni post-hoc test was used for multiple comparisons where appropriate.
RESULTS: During screening visit, the averages of MVPA and sedentary time were 53.63 ± 21.76 minutes per day and 559.68 ± 90.70 minutes per day, respectively. Compared with SIT, both interrupted conditions did not significantly reduce tAUCs for glucose (SIT mean 38.32 ± 2.13 mmol.h/L vs. 3-MIN 38.67 ± 2.23 and 6-MIN 38.84 ± 2.96) (P = .316).

CONCLUSION: These data demonstrate that breaking up prolonged sitting with both 3 minutes and 6 minutes of light-intensity walking every 30 minutes and 60 minutes of sitting, respectively, may not be able to influence postprandial plasma glucose in physically active young male adults with central obesity. It is possible that breaking up prolonged sitting with activities of greater intensity than light-intensity walking or longer duration may positively enhance postprandial glucose metabolism.

ACUTE AND CHRONIC INFLAMMATORY RESPONSES DURING A SEASON TRAINING IN YOUNG SWIMMERS

NAFPAKTITOU, D.1, PHILIPPOU, A.2, VAGIAKAKOS, G., VAGIAKAKOS, N., MANTALOUFAS, M., CHROUSOS, G.3, KOUTSILIERIS, M.2, PLATANOU, T.1

NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: It is well established that prolonged strenuous exercise suppresses some aspects of immune function, while intense exercise training not accompanied by sufficient rest periods may induce chronic, low-level systemic inflammation. These exercise-induced negative effects can be counteracted by the production of inflammatory and anti-inflammatory cytokines which influence many immune cell activities. Swimming exercise training is heavy and demanding and may lead to immunosuppression and associated chronic fatigue.
METHODS: To investigate the acute and chronic effects of a full season swimming training on serum C-reactive protein (CRP), interleukin (IL)-1beta and IL-10, both at rest and after a maximal exercise bout, twelve well-trained male swimmers (14.08±1.0 yrs) were recruited. Measurements were carried out at the beginning of the training season (T1) and pre- and post the taper of each of the two competitive periods (i.e., T2, T3 for the first macrocycle, and T4, T5 for the second macrocycle, respectively). At each of the above time points, blood samples were collected pre- and 1 hour post a maximal, 400m swimming testing. Serum IL-1beta and IL-10 levels were measured by ELISA using a commercially available kit, while CRP was analyzed by electrochemiluminescence. Adjustment for exercise-induced plasma volume changes was performed before all data analyses.
RESULTS: Pro-inflammatory biomarkers CRP and IL-1beta had similar pre-testing responses, exhibiting a significant decrease between T1 and T4 ($p = 0.034$ and 0.023, respectively) and a no significant increase between T4 and T5 ($p>0.05$). However, a significant pre-testing decrease of IL-1beta between T2 and T4 was also observed. There were no significant differences among the post-testing responses either for CRP or IL-1beta throughout the experimental period. Significant pre-post testing differences were found for the anti-inflammatory cytokine IL-10 T1 ($p = 0.001$) and T2 ($p = 0.028$). Also, post-testing IL-10 levels were significantly different between T1 and T3 ($p = 0.055$), while pre-testing values exhibited no significant differences throughout the experimental period; however, there was a tendency to increase from T2 to T5, and to remain constant at T1 and T2.
CONCLUSION: These findings indicate that acute (pre-post testing) inflammatory responses are greater during the first swimming training macrocycle, while prolonged training may activate an adaptive mechanism, which attenuates the magnitude of these responses. Interestingly, long-term exercise training induced an increase in serum IL-10 and a decrease in IL-1beta and CRP at rest, showing an adaptive anti-inflammatory change. Our findings confirm the notion that IL-1beta and IL-10 are reciprocally related, exhibiting a biphasic training-induced pattern, with large acute systemic post-exercise changes, i.e., elevation of IL-10 and decrease of IL-1beta, and low-grade chronic changes during long-term exercise training.
The authors would like to express their sincerest appreciation to the A. G. LEVENTIS FOUNDATION for supporting this research.

AGES VALUES AND EATING HABITS BETWEEN REGULAR AND ATHLETE FEMALE UNIVERSITY STUDENTS: A COMPARATIVE ANALYSIS

NAKAJIMA, S.1, KOIZUMI, K.2, CHO, C.2

1> KYORITSU WOMENS JUNIOR COLLEGE, 2> JAPAN WOMAN'S COLLEGE OF PHYSICAL EDUCATION. JAPAN

INTRODUCTION: Advance glycation end products (AGEs) are harmful substances produced by excessive proteins and sugars in the human body. Reportedly, the excessive accumulation of these substances accelerates the ageing process and contributes to multiple diseases, such as arteriosclerosis and diabetes. Studies have established a correlation between AGEs accumulation and food intake. However, little information is available regarding AGEs in younger populations than in elderly population in Japan, which comes with a higher risk of lifestyle-related diseases. In this study, we aimed to elucidate the association between food intake and AGEs value by investigating the food intake of female university students and then evaluating their AGEs values. Furthermore, we investigated the variation in AGEs values between regular and athlete female university students.
METHODS: We evaluated AGEs values using a TruAge scanner by obtaining measurements from the front part of the left forearm. This nonintrusive method assesses in vivo AGEs accumulation by exposing and exciting accumulated AGEs to light (mild ultraviolet exposure). Then, we used the specific fluorescence of AGEs to evaluate the level of AGEs accumulation under the skin. Further, we conducted a food intake survey according to the Food Frequency Questionnaire.
RESULTS: In regular female university students, we obtained higher scores on items regarding the attitude about food, and the awareness of food indicated better dietary habits and a correlation between the two. However, both items did not correlate with AGEs levels as a single item. Moreover, the lipid ratio, animal protein ratio and grain energy ratio did not correlate with AGEs levels. The ratio of green and yellow vegetables was negatively correlated, indicating that the consumption of large amounts of green and yellow vegetables decreased AGEs levels. Although there was no correlation between muscle mass and AGEs levels, AGEs levels tended to be lower with higher muscle mass.
CONCLUSION: Our findings suggest that good dietary habits, maintained muscle mass and exercise might be associated with AGEs levels. Nevertheless, further extensive studies are warranted because data obtained from university students can be a useful comparison against that collected from middle-aged or elderly individuals, who tend to exhibit higher AGEs accumulation values.

VITAMIN D STATUS OF ELITE ATHLETES IN SINGAPORE AND ITS ASSOCIATION WITH MUSCLE FUNCTION AND BONE HEALTH

HUANG, L., ANG, S., TEO, C., LUM, D., JOSEPH, R., FAIRBAIRN, K.

SINGAPORE SPORT INSTITUTE

INTRODUCTION: Despite residing in a tropical country, Singaporeans may still be at risk of Vitamin D deficiency. Indeed, 91% of male Qatari athletes and 82% of Spanish athletes have presented with insufficient Vitamin D status (Hamilton et al. 2010; Valtuena et al. 2014). Due to common sun avoidance habits in Singapore, local athletes, especially indoor sport athletes, may have low Vitamin D status.
Emerging research suggests that vitamin D may regulate skeletal muscle function and modulate immune and inflammatory functions. A recent study conducted among professional soccer players found that vitamin D supplementation in vitamin D deficient athletes significantly improved sprint and vertical jump performances (Close et al. 2013). Currently, the vitamin D status of athletes in Singapore is unknown.
The primary aim of this study is to determine the prevalence of vitamin D deficiency among Singaporean athletes participating in indoor and outdoor sports in Singapore while the secondary aims are to examine vitamin Ds relationship with skeletal muscle functions and bone density.
METHODS: Serum 25(OH) D concentrations were measured from n = 92 athletes (52 indoor & 40 outdoor athletes) from various indoor and outdoor sports in Singapore. Skeletal muscle strength and performance were assessed using the isometric mid-thigh pull (IMTP), drop jump test and 30 m sprint test. Bone Mineral Density was measured using dual-energy x-ray absorptiometry (DEXA). Independent t-test, Mann Whitney-U and Chi-Square tests were used to determine differences between indoor and outdoor sports.
RESULTS: Mean serum 25(OH)D of indoor and outdoor sport athletes were 28.6 ± 8.9 ng/ml and 39.2 ± 13.2 ng/ml respectively ($p < 0.05$). Significantly more indoor sport athletes (62%) were insufficient in vitamin D compared to outdoor (28%) ($p < 0.05$). Muscle strength and performance outcomes were not different between groups except for peak force generation. Peak force and rate of force development from the IMTP were 1869 ± 546 N and 7156 ± 3408 N/s respectively for the indoor group and 2079 ± 470 N and 6444 ± 3270 N/s respectively for the outdoor group ($p = 0.027$; $p = 0.343$). Sprint times and reactive strength indices of indoor and outdoor sport athletes were 4.84 ± 0.5 s and 1.12 ± 0.9 and 4.72 ± 0.6 and 1.08 ± 0.3 respectively ($p > 0.05$). z-scores reflecting bone mineral densities were higher among outdoor sport athletes (1.39 ± 0.9) compared to indoor sport athletes (1.02 ± 0.8) ($p < 0.05$).
CONCLUSION: To our knowledge this is the first time that Vitamin D status has been assessed in Singaporean athletes. Despite residing in a tropical country, there is a high prevalence of vitamin D insufficiency among elite Singaporean athletes. Routine monitoring of vitamin D levels among indoor athletes should be in place to ensure optimal health and performance.

ACUTE EFFECT OF RESISTANCE EXERCISE AND SUBSTANTIAL BREAKFAST ON MUSCLE BREAKDOWN IN HEALTH YOUNG MEN

KUME, W., YOSHIKAWA, M., YASUDA, J., HASHIMOTO, T.

RITSUMEIKAN UNIVERSITY

INTRODUCTION: Few studies have investigated on the optimum timing of resistance exercise (RE) in the day. A previous study found that muscle hypertrophic effect of RE in the morning was less than evening, although the mechanism remains unknown 1). In the morning, RE-induced muscle breakdown (MB) could be abundant due to malnutrition such as the fasting state 2). On the other hand, testosterone (T) and cortisol (C) were reported to be associated with muscle synthesis (MS) and MB, and thus T/C ratio may affect RE-induced muscle hypertrophy 3). However, responses of T, C, and MB against RE and substantial breakfast (BF) are not evident. The purpose of this study was to examine the acute effect of the order of substantial BF with RE on the responses of T, C, and MB in healthy young men.
METHODS: In this crossover study, twelve healthy men were divided into three conditions: 1) BF before RE condition (Pre), 2) BF after RE condition (Post), and 3) RE without BF condition (No). They performed 5 types of multiple RE at 70% repetition maximum intensity 4). In all conditions, RE was performed from 8:30 to 9:30. The time of BF in the Pre was at 7:00, while the time of BF in the Post was at 9:30. The standard Japanese lunch menu with 21 g of whey protein and 200 ml of milk (total energy, 1019 kcal; protein, 53.4 g [21%]; fat, 25.1 g [22.2%]; carbohydrate, 139.5 g [56.8%]) was provided as a substantial BF. Whole saliva samples were collected at 7:00, 10:00, and 12:00, and used for T and C measurements. Urinary samples were collected at 7:00, 10:00, 12:00, 15:00, and 18:00, and urea nitrogen (UN), creatinine (Cre), and 3-methylhistidine (3-MH) concentrations were measured.
RESULTS: 3-MH and UN, which are markers of MB, were normalized by Cre. The area under the curve (AUC) of 3-MH was significantly higher in Pre than that in No ($P < 0.01$). On the other hand, there was no significant difference between Post and No in the AUC of 3-MH. The AUC of UN was significantly higher in Pre than that in Post ($P < 0.05$) and No ($P < 0.01$). The T/C ratio of Post was significantly higher at 12:00 than at 10:00 ($P < 0.05$), while the T/C ratio in other conditions did not change throughout the experiment.
CONCLUSION: These results suggest that an acute effect of dietary intake before RE in the morning may not be effective for muscle hypertrophy.

CP-PM24 Physical activity promotion sedentarism

EFFECTS OF PHYSICAL ACTIVITY PROMOTION AMONG UNIVERSITY STUDENTS: THE #STUDIOXLAVITA PROJECT

D'ELIA, M.1, CAMELIO, S.1, BRUSEGHINI, P.2, CREMA, C.3, FAGONI, N.2, RONCHINI, C.2, TABONI, A.1, VINETTI, G.2,3, FLAMMINI, A.3, FERRETTI, G.2

UNIVERSITY OF BRESCIA

INTRODUCTION: Sedentariness is a major health problem in our time and physical activity promotion is an imperative commitment for healthcare systems. Recommendations from WHO indicate a minimum of 150 minutes of moderate intensity aerobic exercise as weekly standard for adults. Strategies to increment PA practice are implemented in different settings, such as house care, school, University and workplace. The project #studioxlavita <#SXLV> was launched by the University of Brescia in 2016 with the aim of collecting data about undergraduates lifestyle and encourage healthy behaviours. In particular we focused on PA assessment and promotion in a University-based setting.
METHODS: Two consecutive surveys were sent to all students . Q0 included the short form of the International Physical Activity Questionnaire , the Kessler Psychological Distress Scale and additional questions on several lifestyle aspects. Among responders, we selected 40 students who agreed to take part in one of the following 15-week practical sport courses: ultimate frisbee, muscle strengthening and dance fitness. Before and after being engaged in practical sport courses, students underwent cardiopulmonary exercise test and skinfold thickness measurements, in order to assess peak oxygen consumption and percent body fat . Finally, to assess possible lifestyle changes, we sent them additional surveys at the end of the practical sport courses and 30 days after . Paired t-test was used to analyse significant differences.
RESULTS: 27 students <16 female, 11 male; age: 22.7±3.7> concluded sport activity courses and filled in Q1. Of them, 20 completed also Q2. Overall courses attendance was 57%. At T1 , normalized $\dot{V}O_2$peak increased with respect to T0 <37.0±6.9 vs 35.2±7.4 ml/min/Kg, p=0.03>. Conversely, percent body fat decreased <16.5±6.4 vs 18.3±7.5, p=0.01>. In Q1, 20 students declared to have a more active lifestyle since the beginning of the courses. In Q2, IPAQ-SF-derived total weekly energy expenditure was higher than in Q0, although not significant <5,839 ±7,035 MET*min vs 2,770±2,457 MET*min, p=0.1>. Q2 showed a reduced K6 scale score with respect to Q0 <13.8±4.6 vs 15.8±4.9, p=0.03>.
CONCLUSION: With the sport activity courses established in #SXLV we gave students the opportunity to comply with WHO recommendations. After courses, they appeared to practice more PA, have a higher maximal aerobic capacity, a lower percent body fat and a lower grade of psychological distress than before courses. Simple activities as those proposed by #SXLV are sufficient to reduce sedentariness and improve the quality of life of students.

LIFESTYLE ASSESSMENT AND IMPROVEMENT WITH FOCUS ON LEISURE TIME PHYSICAL ACTIVITY AMONG UNIVERSITY STUDENTS: THE #STUDIOXLAVITA PROJECT

CAMELIO, S.1, D'ELIA, M.1, BRUSEGHINI, P.2, CREMA, C.3, FAGONI, N.2, RONCHINI, C.2, TABONI, A.1, VINETTI, G.2,3, FLAMMINI, A.3, FERRETTI, G.2

UNIVERSITY OF BRESCIA

INTRODUCTION: Sedentariness, smoking, alcohol abuse and unbalanced feeding are harmful for health, leading to chronic diseases and increasing mortality rate. For young adults, University is a new social and cultural context: parents' imprinting could be easily altered, new lifestyles take shape and personal choices emerge. Intervention programmes to advance awareness on harmful lifestyle and promote healthy habits are essential. The #studioxlavita project, launched in 2016 by the University of Brescia with these purposes, investigated students' lifestyle, with special emphasis on physical activity .
METHODS: We developed two consecutive facultative surveys, of 15 <1st level> and 52 items <2nd level>, addressed to all the University's students. Questions were about leisure time physical activity , use of fitness technology, relationship with friends, classmates and parents, feed, physical appearance, body self-perception, physical and mental health, use of certain substances or products , night-time rest and beliefs concerning healthy behaviours. In the 2nd level survey we also adopted the Kessler Psychological Distress Scale and the short form of the International Physical Activity Questionnaire to estimate the amount of PA carried out in the last 7 days. Students who filled in both questionnaires received a personal report including the aggregate data analysis, a comparison with other investigations and indications about healthy habits, according to recommendations and guidelines.
RESULTS: 3,436 out of 15,688 students filled in the1st level survey. Of them, 778 accepted to participate in the 2nd level survey, and 456 completed it. 1st level survey revealed that 72% of the students practised LTPA <45% regularly and 27% occasionally>. LTPA is largely performed <44% of the student> in non-competitive form, with recreational and/or health purposes. According to IPAQ-SF categorical score, 24%, 34% and 42% of the students performed low, moderate and high levels of PA, respectively. In 2st level survey, 76% of the students wished to practise more PA; 42% would participate in practical sport courses.
CONCLUSION: University is an ideal setting for promoting lifestyle change among a captive audience. Intervention programs to increment PA are acclaimed by students. The students from University of Brescia reported higher LTPA practice than the national average people between 18 and 34 years <47%, data from Italian National Institute of Statistics, 2015>, although this parameter was assessed with different methods.

ASSESSING PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOR USING ACCELEROMETERS IN A YOUNG UNIVERSITY POPULATION IN THE UNITED ARAB EMIRATES

DALIBALTA, S., DAVISON, G.

AMERICAN UNIVERSITY OF SHARJAH

INTRODUCTION: Physical inactivity is inextricably linked to the onset of cardiovascular disease (CVD) and diabetes. Data suggests that nearly 58% of the UAE population is physically inactive and only 22% of secondary school graduates and 26.3% of university graduates get the sufficient amount of exercise recommended to stay healthy (DHA, 2009). As a result, the prevalence of overweight and obesity in children in the UAE is over 30%; one of the highest in the world (Malik et al., 2007). The aim of this study was to obtain the first data set

that assesses body composition as well as compares physical activity and sedentary behavior between genders using accelerometers in a young university population in the UAE.
METHODS: Upon approval by the Institutional Review Board, 125 students attending the American University of Sharjah, 55 males and 70 females, participated in this study. The study took place between January-December 2017. Students were from different ethnic backgrounds and had an average age of 20 years old. Using a body composition analyzer (TANITA, Japan), we obtained an accurate measure of weight, body fat, fat percentage, Fat Free Mass (FFM), muscle mass, bone mass, BMI as well as a segmental distribution of muscle and fat mass. In addition, subjects were asked to wear an accelerometer device (ActiGraph wGT3X-BT, UK) for 7 consecutive days. Summary measures of physiological parameters as well as physical activity and sedentary behavior values were compared between males and females using a sample T-test (Minitab software).
RESULTS: Analysis of body composition revealed that males had statistically higher values of weight, BMI, muscle mass, and fat free mass although females had a statistically higher fat percentage (29.4%) compared to 18.8% in males ($p \leq 0.05$). Time spent in sedentary behavior was similar in both males and females and calculated as an average of 8374 minutes. This translates to approximately 85.6% of their time spent sedentary. Their physical activity was primarily in the light exercise range (10.9%), although males spent a significantly greater amount of time in moderate and vigorous intensity exercise with MVPA values of 403.7 minutes (4.1%) compared to 294.8 minutes (3%) in females ($p \leq 0.05$). Males also took a greater number of steps per day (8410.7 steps) compared to females (6899.3 steps) and expended 528.9 kcal/day compared to an average of only 281.4 kcal/day in females ($p \leq 0.05$).
CONCLUSION: This data demonstrates that this young UAE population is extremely sedentary with an alarming average of 12.4 hours a day. Although males have a lower fat percentage and appear to spend more time in moderate and vigorous intensity exercise, they still do not meet the minimum recommendations of exercise to stay healthy. This data highlights the need for further research and targeted interventions in order to reduce the risks of CVD and obesity in this highly susceptible population.

ASSOCIATIONS BETWEEN SEDENTARY BEHAVIOUR AND PHYSICAL CAPABILITY WITHIN THE WORKPLACE

SOUTHALL-EDWARDS, R., TAYLOR, M., GLADWELL, V.
UNIVERSITY OF ESSEX

INTRODUCTION: Physical capability is vital for conducting tasks of daily living and in older populations is associated with improved quality of life. Detecting reductions in physical capability in adults, may highlight individuals at risk for future adverse health outcomes. Research into associations between physical capability and sedentary behaviour (SB) is limited and has been confined to older populations. The purpose of this research was to investigate associations between physical capability and SB, in adults within the workplace, who spend large periods of their time sitting.
METHODS: Forty-two (19 male) healthy adult volunteers (aged 42.1 ±1.9 years), had their SB measured over a six-day period using accelerometry. Physical capability was assessed using tests of dynamic balance, grip strength and walk speed. Regression analyses were run to determine if time spent in overall daily SB, was associated with measures of physical capability; the effect of prolonged (>15 mins) SB was also considered.
RESULTS: Overall daily (β:0.98) and prolonged (β:0.81) SB were independently associated ($p<0.05$) with balance in males but not females ($p>0.05$). For males, overall daily SB explained 40% and prolonged SB 42% of the variance in balance scores. Grip strength and walk speed were not independently associated ($p>0.05$) with any measures of SB.
CONCLUSION: Spending more time in SB throughout the entire day was associated with impairing the balance of males. Grip strength and walk speed were not associated with SB, however, they were reduced compared to population norms. This may highlight how in these adults, working in an occupation requiring large periods of inactivity, that a range of physical capabilities are impaired. The workplace has been considered as a potential environment to help reduce SB and increase physical activity. Interventions should be designed to improve physical capability and not just focused on reducing SB and together this may decrease the risk of future adverse health outcomes and improve quality of life, especially in later years.

COMPARISON OF PHYSICAL ACTIVITY AND STEP COUNTS BETWEEN ACTIGRAPH ACCELEROMETERS, PACER PHONE APP AND YAMAX PEDOMETER IN FREE LIVING YOUNG ADULTS.

MCKEE, D.P., WALLACE, S.H., RUTHERFORD, P.W.
STRANMILLIS UNIVERSITY COLLEGE

INTRODUCTION: Coupled to the general consensus that increased levels of physical activity lead to enhanced health outcomes there has been an increased interest in the assessment of physical activity (PA) in both researchers and the general population. This has led to a greater range of objective measures of PA including research and consumer grade devices. What is less clear is the comparability of these devices even when they purport to assess the same dimensions of PA e.g. moderate and vigorous PA (MVPA) or accumulated steps. This investigation was therefore designed to compare MVPA and steps assessed by Actigraph GT3x accelerometers, Pacer PA app for mobile phones and the Yamax SW200 pedometer
METHODS: 23 adults (11M) aged 21-27 yrs wore an Actigraph GT3x (AG) accelerometer and a Yamax SW200 pedometer (Yamax) on an elasticated belt over their left hip for one day from 10am until their bedtime. They also assessed PA via the Pacer phone app (Pacer) for the same period. Raw data from the AG was downloaded and converted to minutes of MVPA via propriety software using the cut points of Troiano et al (2008), MVPA and steps from Pacer, and Yamax steps were recorded by participants at the end of the day. Mean scores were compared via ANOVA (steps) or T-Test (MVPA). Correlations were calculated between variable pairs. All analysis were carried out using SPSS (IBM v 24) with alpha set at 0.05.
RESULTS: Mean (SD) minutes of AG and Pacer MVPA were 44.0 (18.1) and 58.0 (25.7, $p< 0.05$, $r= 0.79$). Daily steps were: AG, 6375 (2292); Pacer, 5629 (2369); Yamax, 7077 (2648). All three measures of steps were significantly different from each other ($p< 0.05$) and strongly correlated ($r= 0.81$ to 0.97).
CONCLUSION: As evidenced by the inter-variable correlations there are strong relationships between the various measures of MVPA and between the daily step counts but there are also substantive differences between mean scores. These findings indicate that in terms of both MVPA and daily steps results from different devices are not comparable.

THE EFFECT OF PHYSICAL ACTIVITY AND SUNLIGHT EXPOSURE ON KOREAN JUVENILE MYOPIA

JI, C., KIM, S.

KOREA UNIVERSITY

INTRODUCTION: East Asian region ranked second behind the West Pacific region concerning the population of the refractive index disorder in the world. Three phenomena are noticeable in Asian countries. First, the rate of increase in myopia prevalence in East Asian is faster than the world average. Second, the age range of myopia is expanding to children and adolescents. Third, high levels of myopia associated with vision impairments are increasing. The exact medical or socio-environmental cause for refractive error remains yet to be found. It seeks to analyze proneness using big data.
METHODS: This study used data collected during health interviews carried out as part of the fourth Korean National Health and Nutrition Examination Survey. The subjects, in total 1,410 adolescents aged 12 to 18 years, were classified into two groups based on the amount of sunlight exposure and physical activity. PA is classified as dynamic group<>3,000MET/week>, moderate group<3,000-600MET/week>, inactivity group<<600MET/week> using the formula from the International Physical Activity Questionnaire. Sunlight exposure data were classified as "less than 5 hours" compared to "5 hours or more".
RESULTS: First, when the practice rate of moderate intensity PA and walking <5times/week and 30min/week> is "Nonparticipation", each myopia prevalence<≤-0.75 Diopter> odds is 1.78 times and 1.54 times higher than "Participation". Second, when the PA is "Inactivity" or "Moderate", each myopia prevalence odds is 1.55 times and 1.64 times higher compared to "Dynamic". Also, each high myopia<≤-6.0> prevalence odds is 2.36 times and 2.66 times higher, and each moderate myopia<≤-3.0 and ≥6.0> prevalence odds is 1.79 times and 1.98 times higher. Third, when the amount of sunlight exposure is "Less than 5 hours", myopia<≤-0.75> prevalence odds is 1.61 times higher, and high myopia<≤-6.0> prevalence odds is 2.74 times higher compared to "5 hours or more".
CONCLUSION: It was found that insufficient PA and sunlight exposure affect the development of myopia. Physical activity and sports activities in the outdoors in adolescence, which is a period of accelerated development of nearsightedness, will help to reduce the rate of myopia. Recently, a typical high myopia prevalence rate in Asia is associated with a decrease in outdoor activities. These results provide a sound basis for reducing the prevalence of myopia. If it complies with the national policy, it is thought that it helps the decrease of the medical expenses of the youth and the health promotion.

OUTDOOR EXERCISE IS MORE EFFICIENT THAN INDOOR EXERCISE IN SENIOR CITIZENS. PHYSIOLOGICAL EVIDENCE FROM THE HERO PROJECT

AHNESJÖ, J., BERGMAN, P.

DEPARTMENT OF SPORT SCIENCE

INTRODUCTION: Introduction: Physical exercise has been proven beneficial for health in all ages. In elderly, physical exercise, may contribute to prolonged life with maintained high quality and less costs associated with health care for society. In this study we explore if exercise out of doors may provide extra benefits as compared to exercise indoors and we measure power output, lactate levels and perceived effort in 49 senior citizens performing 20 minutes of moderate physical activity.
METHODS: Method
The HERO project is a randomized cross-over experiment with three different treatments . The study sample consisted of 49 healthy senior citizens. They performed 20 minutes moderate intensity physical activity on an ergometer bike in all three conditions. Before immediately after and at minutes 10, 20, 30, 60 and 120 we sampled blood lactate. Power output was computed at 7 occasions during the 20 minutes of cycling, as was the rating of perceived exertion . Data was analyzed using mixed linear models.
RESULTS: Results: Our findings show that there were no differences between the two indoor treatments in any of the measured variables. In the outdoor treatment, however, there were significant effects on blood lactate levels and power output but not in perceived exertion, suggesting that exercise out of doors makes the test person more efficient although the experience of effort stay unaffected.
CONCLUSION: Discussion/conclusions
Our results support the notion that the outdoors may provide extraordinary conditions for exercise, not only because it appear to results in more exercise/effort, the outdoors is also an "arena" with high availability and most often totally for free.
Previous results from the HERO project also suggests that white blood cell counts are affected by the outdoor treatment, something that may be related to the observed increased power output herein.

DETERMINATION OF FRAMEWORK CONDITIONS FOR THE DEVELOPMENT OF A TARGET-GROUP SPECIFIC HEALTH EXERCISE TRAINING FOR SENIORS OVER 70 YEARS

LANGKLOTZ, M., SCHULZ, H.

CHEMNITZ UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Health exercise training developed for the special needs of the elderly can counteract the age-related decline in conditional, coordinative and cognitive abilities. The content of a training can additionally be derived from the reasons for or against sporting activity or the organizational requirements for participation in the offer. The aim of the analysis of needs was therefore to check to what extent the information and wishes of the respondents are suitable for the development of health exercise training in a foreign-organized setting.
METHODS: 316 people (P) (75±6 years, 63% female, 88% without help in everyday life/ 6% need help (family/friends)/ 2% home care service) voluntary participated in a survey (self-filled questionnaire). They were questioned about their physical (PA) and sporting activity (SA) (85% PA and SA/ 9% only PA/ 2% only SA/ 4% neither PA nor SA), their reasons against and for SA (based on the motives of the BMZI-HEA; possible answers from 1 = is not true to 5 = is very true) and the organizational requirements for the SA.
RESULTS: For the reasons against SA, the 39 items were answered by 32±2 of the 42 athletic inactive. The main reasons with a median of 4 were due to the impaired health and many low-intensity activities in everyday life. Other reasons were: long time sporting inactivity, fear of falling, do not feel like it, too many other commitments/leisure activities, missing accompaniment (median 3).
Each of the 36 reasons for SA was answered by 258±15 P. The field of everyday life competence took the highest rank (median 5). This was followed by: physical health/fitness, cognitive functioning, positive movement experiences (each median 4). In addition, 97% of 264 P stated that it is important or very important to enter a sports offer specialized on the skills needed at a higher age.
77% (of 353 nominations) of the offer should be foreign-organized (30% commercial establishment, 39% association, 8% other educational institutions). 85% (of 230 P) would take part in the sports offer together with strangers, 98% (of 226 P) in a group, 91% (of 234 P)

mixed (female/male), 97% (of 234 P) inside und 98% (of 227 P) together with P over 70 years. The offer should take place mainly one or two times a week (44% or 37% of 225 P) with a duration of 60 min each (62% of 224 P). Most P want a year-round offer (77% of 210 P), preferably Monday till Thursday (78% of 538 n.), in the time until 13/14 oclock (50% of 194 P).
CONCLUSION: Regarding the reasons against SA could be counteracted with a health exercise training especially in the areas of impaired health, low-intensity activities, long time sporting inactivity or fear of falling. The reasons for SA can be implemented very well in terms of content. Also in the area of the formal organization of the offer, it can be seen that exist optimal prerequisites for foreign-organized health training for persons over the age of 70 in a mixed group.

„INCLUSION AND SPORTS WITH HANDICAP" - A PROJECT TO BRING PUPILS CLOSER TO INCLUSION AND DISABILITY

SCHULZ, A.

UNIVERSITY OF ROSTOCK

Introduction: Inclusion is a much debated topic in politics, society and science. To bring it closer to pupils we started the project „Inclusion and Sports with Handicap" in cooperation with a local integrated school. The purpose was to raise the children`s awareness for people with disabilities and for an inclusive education system. The combination of contact with handicapped people, simulation of different disabilities, access to information and trying sports for people with disabilities was shown to be the most effective method for changing the attitude towards people with disabilities (Cloerkes, 2007) and was applied in this project.
Methods: In ten lessons within six weeks 32 participants aged 15-16 received information and opportunities to discuss and reflect. They further tried different sports for handicapped people including wheelchair basketball, blind football, athletics (wheelchair racing, running with visual impairment, running without the support of the arms), obstacle courses with a wheelchair and simulation of visual impairment. Experts for these disciplines who also shared their experience of living with an impairment supported this project. For measuring changes in attitude towards peers with disabilities we analysed written questionnaires at the beginning and end using the „Chedoke-McMaster Attitudes Towards Children with Handicaps Scale" (CATCH) which is one of the most complete instruments in this field (Vignes et al., 2008).
Results: Out of the 32 data sets 21 were analysed, 11 were excluded because of incomplete data in both questionnaires before and after the project. While before starting the project 38.1 % of the respondents strongly agreed that they would not mind if a handicapped child sits next to them, 76.1 % strongly agreed after the project. Similar effects were found in other items concerning affective, behavioural and cognitive components of attitude. Specific results of several attitude-changing effects are presented at the poster.
Conclusion
Even after a relatively short period of six weeks the attitude towards people with disabilities changed measurable. Pupils came in contact to people with an impairment and empathized with them. In conclusion, a comparably short sensitization period is sufficient to raise children`s awareness for people with disabilities and inclusion.

A RAPID REVIEW OF THE EVIDENCE REGARDING PHYSICAL ACTIVITY FOR DISABLED ADULTS: RECOMMENDATIONS FOR PUBLIC HEALTH

KIRBY, N., SKINNER, B., LUCAS, R., SMITH, B.

UNIVERSITY OF BIRMINGHAM

A RAPID REVIEW OF THE EVIDENCE REGARDING PHYSICAL ACTIVITY FOR DISABLED ADULTS: RECOMMENDATIONS FOR PUBLIC HEALTH
Kirby N.1, Skinner B.1, Lucas R.1, Smith B.1, 1: University of Birmingham (UK)
Introduction: People with disabilities are typically less active as they face unique barriers to access, inclusion and participation in physical activity (PA; Rimmer & Braddock, 2002). Current PA recommendations for able-bodied people do not address these barriers. Therefore, recommendations that are inclusive and applicable for all disability groups are urgently needed. This rapid review aims to address the quality and level of evidence for the relationship and effectiveness of PA to improve disabled adult's health, the outcomes of investigations of FITT (frequency, intensity, time, type) principles, and the safety of PA for disabled adults.
Methods: Four databases (Medline, Web of Science, SportDISCUS, and Cinahl) and grey literature were searched using MeSH terms and free texts in February 2018. Inclusion criteria were articles from 2007-2018 focusing on adults in one or a combination of the outlined disability groups (visual impairments, hearing impairments, cerebral palsy, spinal cord injury (SCI), amputation, restricted growth or learning and/or intellectual disability (ID)) and the relationship and effectiveness of PA to improve health. Results from the UK or comparable contexts were prioritised, with other articles showing a high level of evidence also included. Exclusion criteria were articles that did not focus on PA or did not differentiate results between able-bodied and disabled people. A total of 1081 articles were identified and screened, with 247 articles meeting the inclusion criteria for this rapid review. Outcomes were grouped into aerobic, muscular strength/endurance, functional skills, disease risk/prevention, safety, and social, community, or individual wellbeing.
Results: The level of evidence for the relationship and effectiveness of PA to improve disabled adult's health, the outcomes of investigations of FITT principles, and the safety of PA for disabled adults is reported. Evidence-based exercise recommendations and guidelines for PA among disabled people are provided. Common themes include individualised prescriptions, coping strategies, mechanical assistance for exercise, community-based programs, gait or mobility improvements, injury prevention, leisure time PA and aerobic capacity. The results also highlight that the majority of studies investigate SCI, ID, and amputees, and thus future research needs to examine other disabled groups.
Discussion: Final results and recommendations are presented following the close involvement with end-user expert groups. Data will be used in the dissemination of guidelines and PA strategies to disabled people.

ELDERLY WOMEN PRESENT DIFFERENT RATINGS OF PERCEIVED EXERTION IN RESPONSE TO MAXIMAL INCREMENTAL TESTING AS COMPARED WITH YOUNG WOMEN

VIEIRA, D.C.L.2,4, NASCIMENTO, D.C.1, ERNESTO, C.3, PRESTES, J.1

1: UCB , 2: UDF , 3: FACIPLAC , 4: UNB .

INTRODUCTION: The ratings perceived exertion (RPE) is a helpful tool utilized during incremental tests to help identify physiologic markers and may be used in populations of different ages. However, it is not yet known if there are differences between young and older women. In this sense, the objective of this study was to compare the rating perceived exertion response between young and elderly untrained subjects at different intensities during a maximal incremental test.
METHODS: Nine young women (YW) and eleven older women (OW) performed an incremental treadmill test with rating perceived exertion measured at each minute by using the 6-20 Borg's scale. RPE were compared between groups on three different intensities zones: low intensity (LI), corresponding to RPE at 50% of the time between start the test and ventilatory threshold (VT), moderate intensity (MI), corresponding to RPE at 50% of the time between VT and respiratory compensation point (RCP) and high intensity (HI), corresponding to RPE at 25% of the time between RCP and finish of the test. Moreover, RPE at VT and RCP were also compared between YW and OW.
RESULTS: RPE at LI, VT, MI, RCP and HI for YW were: 8.11±1.05, 10.89±2.57, 13.11±2.42, 15.56±1.94 and 16.00±2.00, respectively. RPE at LI, VT, MI, RCP and HI for OW were: 8.72±1.27, 9.91±1.64, 11.27±1.79, 13.27±1.56 and 14.54±1.63, respectively. There were no differences between groups on RPE at LI (p=0,33) and VT (p = 0,31). However, on MI (p=0,05) and RCP (p=0,01), older individual showed lower RPE than young individuals. Althougth, no statistical difference was found between groups on RPE at HI. There was a tendency to OW show lower RPE at this point (p = 0,09).
CONCLUSION: Despite the exact mechanism associated with differences on RPE between YW and OW still unclear. Speculatively, a lower cerebral blood flow in older individuals during exercise (Ogoh & Ainslie, 2009) would cause impairments on cognitive function affecting RPE (Groslambert & Mahon, 2006). In summary, the results of this study suggest that OW have lower RPE at MI, RCP and HI than YW.

RELATIONSHIP BETWEEN MATCH WEEK LOAD, PERCEIVED LOAD AND MARKERS OF WELLNESS DURING THE FIFA WORLD CUP 2018 QUALIFYING STAGE

MCMAHON, G., MARTIN, D., KENNEDY, R., WALSH, P., MCCANN, R.

ULSTER UNIVERSITY

INTRODUCTION: Previous research has demonstrated that there is a strong relationship between total load, changes in load and markers of wellness in professional soccer players (Buchheit et al. 2013; Thorpe et al. 2017). However, currently no data exists on these relationships at international level. Therefore, the aim of this study was to look at the relationships between acute load, changes in load and markers of wellness in the immediate pre-match preparation phase of World Cup 2018 qualifying matches in international level soccer players.
METHODS: Training load (TL; 10Hz GPS Units,) Perceived load (PL; session RPE x time [mins]), and markers of wellness (sleep quality, sleep duration, muscle soreness, physical fatigue, mental fatigue and mood state) were collected daily at match day minus 4 days (MD-4), minus 3 days (MD-3), minus 2 days (MD-2) and 1 day (MD-1) prior to international World Cup 2018 Qualifying matches during 2016-2017 (n=8). Wellness markers were scored individually and also summated for a total wellness score.
RESULTS: There were significant correlations (P <0.01) between TL and PL at MD-4 (r=.49), MD-3 (r=.69), MD-2 (r=.58) and MD-1 (r=.48). TL was significantly greater (P<0.01) at MD-4 compared to MD-2 and MD-1, with no significant difference between MD-3. TL MD-3 was significantly greater than MD -2 and M-1, TL MD-2 was significantly less than MD-4 and MD-3 and greater than MD-1 (all P <0.01). There were no significant differences (P >0.05) in total or individual wellness score at any time point. Despite significant within-day correlations (P <0.01) between TL, PL and individual wellness marker scores at each time-point, there were no correlations between changes in TL and PL, and wellness markers at any time point.
CONCLUSION: At international level, soccer players' perceptions of load are sufficiently sensitive to detect changes in measured load. Despite significant variation, different volumes of load were not sufficient to alter players' perceptions of wellness at any time point. This may be due to the nature of training and prioritisation of freshness in close proximity to an international match.

MOTIVATION, PAIN, ENERGY EXPENDITURE AND ENERGY INTAKE DURING A 35 KM ROAD MARCH WITH LOAD CARRIAGE OF SWISS ARMY SOLDIERS

OESCHGER, R.1, ROOS, L.1, WYSS, T.1

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN SFISM

INTRODUCTION: During military service, loaded marching is a common and physically demanding task. Studies showed that endurance training programs with a progressive increase in intensity and duration can improve the soldiers' endurance performance and decrease injury and attrition rates (Roos et al., 2015). However, little is known about the effect of different levels of cardiorespiratory fitness on the soldiers' responses during a long distance march. Therefore, the aim of the present study was to compare soldiers in the lowest (ltVO2peak) and highest tertile of peak oxygen uptake (htVO2peak) concerning motivation, pain or physical complaints, rating of perceived exertion (RPE) as well as energy expenditure and the energy uptake during a 35 km road march with additional load carriage.

METHODS: One week previously to the march, 41 soldiers performed a progressive endurance run to assess VO2peak, data on marching day was collected with pre and post march questionnaires. Total energy expenditure (TEE) of the soldiers during the march was calculated according to Ainsworth et al. (2011), provisions were available ad libitum.
RESULTS: The main outcomes were that soldiers of htVO2peak (mean VO2peak = 61.6 ± 2.2 ml•kg-1•min-1) were significantly more motivated to perform (t (39) = -4.728, p < 0.001, d = -1.514) compared to soldiers of ltVO2peak (mean VO2peak = 45.9 ± 4.4 ml•kg-1•min-1) while RPE and pain values were similar in both. The locations of pain after the march were primarily the feet (52.4% and 60.0%) and shoulders (19.0% and 40.0%) for htVO2peak and ltVO2peak, respectively. When excluding soldiers that aborted the march, those in ltVO2peak reported a lower energy uptake in form of solid food than soldiers in htVO2peak (Med = 853.5, IQR = 366.0 kcal vs. Med = 1327.0, IQR = 858.5 kcal; U = 234.0, p = 0.021) The comparison of the TEE revealed no differences between the groups (M = 4289.6 ± SD = 699.0 kcal and M = 3980.7 ± SD = 387.4 kcal).
CONCLUSION: The htVO2peak group was capable to take in 33.3% whereas the ltVO2peak group was able to refuel only 19.9% of their TEE with solid food. The negative energy balance is considerable in both groups but the results of this study suggest that soldiers with a high cardiorespiratory fitness are more motivated in advance and have better capabilities to refuel their energy stores during a long-lasting and mentally challenging military task.

EFFECTS OF PROPHYLACTIC NAP ON PHYSICAL FITNESS/EXERCISE ABILITY AND EXECUTIVE FUNCTION IN HEALTHY TRAINED YOUNG MALES

TANABE, K., NAKAZATO, K., NOI, S.
NIPPON SPORT SCIENCE UNIVERSITY

INTRODUCTION: It has been widely reported that diurnal sleepiness impair various performance. Prophylactic nap is one of the effective strategies to improve for diurnal sleepiness induced by circasemidian rhythm. The purpose of this study was to examine the effects of different length prophylactic naps on physical fitness/exercise ability and executive function. We hypothesized that nap including slow wave improved both physical fitness/exercise ability and executive function because sleep with slow wave is thought to decrease brain energy metabolism dramatically and to play important role in cerebral restoration and recovery.
METHODS: Seven healthy trained males (mean age = 21.1, S.D. = 0.4) participated in four experimental conditions (counter balanced design): sitting rest of 90 minutes from 12:30 (con group); nap of 30 minutes from 13:30 (nap30 group); nap of 60 minutes from 13:00 (nap60 group); nap of 90 minutes from 12:30 (nap90 group). Physical fitness/exercise abilities were assessed by grip/back strength (muscle strength), postural control (balance ability), darts task (psychomotor skill), Wingate test (anaerobic power). Simple reaction time task (SRT), choice reaction time task (CRT), modified flanker task (mFl) were used for assessing executive function. Changes in oxyhemoglobin in the prefrontal cortex during executive function tests were monitored with near-infrared spectroscopy. These performance tests began at 15:00.
RESULTS: All nap groups did not improve on all physical fitness/exercise tests. The nap30 group showed significantly shorter reaction time (RT) of SRT and CRT than those of the con group (p < 0.05). The nap60 group improved only in RT of SRT. The nap90 group produced improvement of RT in all executive function tasks. The increases in oxyhemoglobin during executive function tasks in the nap30 and 90 groups were matched with improvement of each executive function tasks, but the changes in oxyhemoglobin of nap60 group were not observed in all function tasks.
CONCLUSION: The 90-minutes is the most effective nap duration to improve executive function tasks and activate prefrontal cortex in the afternoon. These findings are meaningful for understanding performance optimization in athletes regarding countermeasure diurnal sleepiness by circasemidian rhythm. In sports situations, it is possibilities that afternoon performance is more improve by 90-min nap in reaction time.

EFFECTS OF LOW-LEVEL LASER THERAPY (LLLT) AND LIGHT-EMITTING DIODES (LEDT) APPLIED DURING COMBINED TRAINING ON PERFORMANCE AND CLINICAL OUTCOMES: RANDOMIZED PLACEBO-CONTROLLED TRIAL

MACHADO, A.F.1, CUSTODIO JUNIOR, A.1, ESPINOZA, R.M.C.P.P.1, HIDALGO, R.B.R.1, LEAL-JUNIOR, E.C.P.2, PASTRE, C.M.1
1. SÃO PAULO STATE UNIVERSITY; 2. NOVE DE JULHO UNIVERSITY

INTRODUCTION: Previous studies have shown positive results of phototherapy on improving performance and accelerating recovery; however, the effects of phototherapy adjusted to a model of training remain unclear. The aim of this study was to analyze the effects of phototherapy associated with a combined training on clinical and functional outcomes.
METHODS: This is a randomized placebo-controlled trial by stratified sample that involved 39 healthy male participants. Participants performed a 12-week (24 sessions) training program divided in two phases. Phase 1: six weeks of combined training with sprints and squats. After stratified randomization (based on adaptation capacity) participants were allocated into three groups: phototherapy, placebo, and non-treatment control. Phase 2: new six-week training (load adjusted) with recovery strategy applied between sprints and squats. Phototherapy (low-level laser therapy – LLLT and light-emitting diode therapy – LEDT; dosage total per site: 30J) was applied in six areas of quadriceps muscle bilaterally. Maximal voluntary isometric contraction (MVIC), squat jump and sprint test were assessed on baseline, six and 12-weeks post-training. Muscle soreness and perception of recovery were assessed in the training sessions with higher energetic spending during both training phases (sessions 9 and 21). Statistical analysis was conducted in SPSS. The ANOVA repeated measures (Greenhouse-Geisser corrections when required) was used to analyze functional outcomes, and the paired samples T-test and one-way ANOVA (Bonferroni's post-hoc) were used to clinical outcomes.
RESULTS: A large effect for time for squat jump and sprint test [P<0.01; SJ (ES=0.187); sprint (ES=0.251)] and moderate effect for MVIC was observed [P=0.032; MVIC (ES=0.091)]. There were no significant group and interaction effects (time x group) for functional outcomes (P>0.05). No differences from phase 1 and 2 were observed in clinical outcomes (P>0.05). The findings of this study suggested that all recovery strategies acted in a similar way concerning functional and clinical outcomes. The present results agree with those reported by

Vieira et al. 2012 and Ferraresi et al., 2011 that observed a significant effect time after a program training but no differences between groups.
CONCLUSION: In conclusion, no evidence was found to reduce muscle soreness, as well as to improve perception of recovery and performance when phototherapy is associated with combined training.

EFFICACY OF MICROCURRENT TO MAXIMISE EXERCISE OUTCOMES AND ATTENUATE DELAYED ONSET MUSCLE SORENESS IN RESISTANCE-TRAINED ATHLETES: A PILOT STUDY

SEIJO, M., LARUMBE-ZABALA, E., KARSTEN, B., NACLERIO, F.
UNIVERSITY OF GREENWICH

INTRODUCTION: Microcurrent based treatments have been recently proposed as a suitable strategy to maximize exercise and recovery outcomes in athletes. This study aimed to analyse the potential benefits of regularly wearing a new commercially available microcurrent device (Arc4health, UK) during the post-workout time after performing resistance training in male recreational athletes. Variables measured where changes in body composition, upper and lower strength, muscular thickness and delayed onset muscle soreness (DOMS).
METHODS: According to individual baseline body composition and maximal strength values, twelve participants (24.7±6.3 yr) were pair-matched and consequently randomly assigned to one of the following experimental groups: microcurrent (MC, n=6) or sham (SH, n=6). Both groups trained 3 non-consecutive days per week over a period of 8 weeks (24 total sessions), with a moderate to high resistance training (10 to 6 Repetition Maximum) routine. A microcurrent or a sham device was used for 3 h immediately after training or in the early morning during non-training days. Assessment of fat, fat-free mass (via Air Displacement Plethysmograph), upper and lower body strength and muscular thickness (via ultrasound) were performed at pre and post intervention. DOMS via VAS scale was measured at 12, 24 and 48 h after performing an exhaustive 100 repetitions concentric eccentric lower body protocol.
RESULTS: Both groups similarly improved body composition from the baseline, decreasing total and relative body fat and increasing total and relative fat-free mass ($p<0.05$). Furthermore, upper and lower body dynamic strength increased in both groups with no differences between groups. Elbow flexor thickness increased only for the MC group ($p=0.001$) while triceps, vastus medialis and vastus lateralis thickness improved in both groups ($p<0.05$). Nonetheless, the MC showed higher ($p<0.01$) elbow flexor and triceps muscle thickness compared to the SH condition. DOMS was significantly reduced in the MC ($p<0.01$) but not in the SH group at all time points (12h, 24h and 48h). Furthermore, DOMS at 48h was significantly lower in the MC compared to the SH group ($p=0.050$).
CONCLUSION: Wearing a commercially available microcurrent device Arc4health during 3h post workout may maximises upper body hypertrophy outcomes and reduces DOMS in recreationally trained males following 8 weeks of resistance training. Even though no differences were observed for strength, body composition and lower body hypertrophy, the present pilot study highlights the potential benefits of microcurrent technology to optimise recovery and training outcomes for athletes.

MUSCLE MASS AND HANDGRIP STRENGTH IN ELDERLY COMMUNITY-DWELLERS: A COMPARATIVE DESCRIPTIVE ANALYSIS BETWEEN RURAL AND URBAN REGIONS IN TAIWAN

WU, H.J., TSAI, C.C., CHEN, L.H.
NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Taiwan is one of the most rapidly aging regions in the world. Ageing is known to be associated with decline in muscle mass (MM) and muscular strength (MS), specifically handgrip strength (HGS), the risk factor of sarcopenia. Preventive screening for MM and HGS is essential for older adults, however, little is known regarding differences in those above-mentioned muscle-related measures between rural and urban elderly in Taiwan.
METHODS: We used secondary data from I-Lan Longitudinal Aging Study (ILAS) (Liu et al., 2013) as rural reference sample. The other 470 between 50-85 years old were recruited as urban samples from two Taipei Lohas EXPO occasions in Sept., 2017 and Jan., 2018. Demographics, MM (bioelectrical impedance analysis, BIA, Inbody 720) and HGS (TKK-5401, Japan) data were collected. Appendicular skeletal MM (kg, ASM) was divided by squared height (ASM/ht2). Cutoff value for low HGS was defined as male <22.5kg, female <14.5kg (Wu et al., 2009). Urban samples were divided into three age groups as 50-64 (late middle age, LM), 65-74 (young-old, YO), and >75 (old-old, OO) complied with the reference data. Descriptive statistics was conducted to compare divergence in MM and HGS between I-Lan and Taipei City.
RESULTS: The number and mean age in rural and urban samples were 532 (64.6±9.5 y/o, male 53.0%) and 453 (66.2±7.1y/o, male 31.6%). Across all age groups, samples from rural area held higher BMI and higher MM (ASM/ht2) than urban samples. Both rural and urban data showed an age-related decline rate in MM (ASM/ht2) and HGS, with rural OO held the highest HGS decline rate than their younger groups. Meanwhile, prevalence of low HGS was also higher in rural samples in both genders as compared to their counterparts (28.0% vs. 4.2% in male, 34.0% vs. 3.9% in female).
CONCLUSION: Although higher in BMI and MM, rural sample held a much greater low HGS rate in both genders. Study showed MS decline with age preceded the loss of MM (Manini and Clark, 2011). Muscle quality, normally defined as strength per unit MM, may be another consideration when justified the MM-MS relationship (Mitchell et al.,2012). Since HGS is another strong predictor of cardiovascular mortality (Leong et al., 2015), further more study may be needed to clarify this urban-rural discrepancy in rate of low-HGS, specifically for the elderly reside at rural community in Taiwan.

CORRELATION BETWEEN PHYSICAL MATURENESS AND SPRINT PERFORMANCE IN YOUNG TRACK AND FIELD ATHLETES

DUCA, M., FORMENTI, D., TRECROCI, A., CAVAGGIONI, L., ALBERTI, G.

UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Sprint performance is a key factor in both track and field and team sports. Young athletes with the same age display large variability in terms of physical matureness, which may impact performance. This study aims to investigate the relationship between physical development and sprint performance in young track and field athletes.
METHODS: 8 male track and field athletes (age 14.1±0.7 years, height 1.60±0.08 m, weight 51.1±9.7 kg) took part in present study. Mechanical effectiveness (DRF), Velocity (V0), total and relative force and power (F0t, F0r, Pt, Pr) were assessed for each participant over a 20 m sprint using Samozino's method (Samozino et al. 2016). Relationship between those variables and maturity offset (MO) (Mirwald et al. 2002) and height reached in countermovement jump with free arms (CMJa), measured using a photocell system (Optojump, Microgate, Bolzano, Italy), were investigated using Pearson's correlation coefficient after normality check.
RESULTS: CMJa is inversely correlated with sprint performance over 20 m (r=-0.732, p=0.039) and directly correlated with V0 (r=0.848, p=0.008). MO is linearly correlated to 20 m and V0 (r=-0.789, p= 0.020 and r=0.743, p=0.035, respectively), besides to F0t (r=0.918, p=0.001), Pt (r=0.942, p=0.000) and Pr (r=0.821, p=0.012).
CONCLUSION: Evidence from this study confirms that a strong correlation between jump and sprint performance stands, as was reported in adult sprinters (Kale et al. 2009). This study informs that MO is equally correlated to sprint times as CMJa and is also powerful at predicting F0t, Pt, and Pr (R=84%, R=88%, R=67%). From those findings it can be understood how physical matureness influences force and power capabilities in youths and therefore sprint performance. Conversely, mechanical effectiveness is not correlated to MO. Those findings show how, while total force produced could be dependent on physical matureness, the ability to apply this force effectively into the ground is not. These results help better understand underlying factors affecting sprint performance and lead selection and training practice.

MORPHOLOGICAL RESPONSES OF ADIPOSE AND HEPATIC TISSUE TO A FATTY-DIET AND SEDENTARY LIFESTYLE MODEL IN RODENTS.

BOVOLINI, J.A.1, ROLIM FILHO, N.1, ANDRADE, M.A.2, DUARTE, J.A.1

<1> SPORT FACULTY OF PORTO UNIVERSITY; <2> FEDERAL UNIVERSITY OF PERNAMBUCO;

INTRODUCTION: Sedentarism and diet are recognized risk factors for a panoply of metabolic pathologies, mostly through overweight and obesity. In fact, changes in adipose tissue, especially the adipocyte expansion, has been pointed out as a triggering factor for metabolic imbalances in obese individuals. As well, the liver is an organ highly reactive to metabolic environment changes, being its phenotype deviation a good indicator of metabolic disorders. Given the noxious skill of obesity and the hepatic reactivity to this unbalance environment, this work aimed to evaluate the hepatic and adipose tissue morphological responses, particularly the adipocyte expansion, to a fatty-diet and sedentarism model in rodents.
METHODS: 28 Wistar rats were divided into four groups: sedentary standard diet (SSD, n=7), active standard diet (ASD, n=7), sedentary high-fat diet (SHFD, n=7) and active high-fat diet (AHFD, n=7). The rats were fed with a standard or a high-fat diet (70% calories from fat; Research Diets, Inc.) for 21 weeks. The active groups had free access to the voluntary running wheel while the sedentary groups remained restricted to their cage space. At the protocol end, the animals were weighed, euthanized and samples from retroperitoneal adipose tissue (RAT) and liver were collected. For histological analysis, the samples were stained with Hematoxylin-Eosin to analyze hepatic fat deposition and adipocyte cross-sectional area (CSA), and with Sirius Red to assess collagen deposition. The NIH ImageJ, Image Pro Plus 6 (USA) and GraphPad Prism 7 (USA) software were used for images evaluations and statistical analysis.
RESULTS: After 21 weeks, both groups HFD-fed showed a decrease in relative BW (P <0.05 vs. SSD). Both groups showed similar hepatic weights with a marked deposition of lipids and collagen (P <0.05 vs. standard diet groups). Despite BW losses, HFD-fed groups showed a higher RAT (P <0.05 vs. standard diet groups). In line, the ASD and AHFD groups presented, respectively, the lowest (P <0.05 vs. SSD, SHFD, AHFD) and higher (P <0.05 vs. SHFD, AHFD) adipocyte CSA. No difference in adipocyte CSA was observed between HFD and SSD.
CONCLUSION: The results demonstrate the experimental model efficacy in inducing morphological changes in both adipose and hepatic tissue. The adipocyte CSA was associated with deleterious hepatic morphological alterations. Results also suggest an additional harmful effect of a sedentary lifestyle in adipocyte CSA and liver morphology, given the exacerbation of those items in the sedentary animals.

THE EFFECT OF EXERCISE-INDUCED FACTORS ON ADIPOSE BROWNING

SEVERINSEN, M.C.K., PEDERSEN, B.K., SCHEELE, C.

RIGSHOSPITALET, CENTRE FOR PHYSICAL ACTIVITY

INTRODUCTION: Brown fat represents a tissue that, when activated, increases energy turnover and insulin sensitivity as well as glucose and fatty acid clearance. Brown fat may therefore be involved in the protection against obesity and lifestyle related diseases such as type

2 diabetes. During the past decade, functionally competent brown fat has been identified in adults, which has been shown to negatively correlate to obesity. Brown fat is activated by cold exposure via adrenergic stimulation and is mediating non-shivering thermogenesis through mitochondrial uncoupling protein (UCP)-1. Little is however known about how brown fat tissue is maintained during adulthood and to which degree lifestyle contributes to preservation and activation of brown fat. It has, however, been suggested that brown fat biogenesis is increased by stimuli from other organs, such as the muscle and the liver. As brown fat is sympathetically it might be stimulated by exercise. Furthermore, skeletal muscle progenitors and brown fat progenitors share a common origin and might also be induced by similar growth factors, which are increased during muscle contraction. If we can identify pathways for increasing the proportion of brown fat cells, we might be able to counteract obesity and obesity-related diseases.
METHODS: We hypothesized that factors released to the circulation during exercise would have browning effect on adipose tissues. We collected visceral and subcutaneous adipose biopsies from humans and isolated fat precursor cells, which we differentiated into lipid droplet containing adipocytes in vitro. To investigate if exercise factors could have a differential effect on subcutaneous compared to visceral adipocytes, we stimulated our cell cultures during differentiation.
RESULTS: Our ongoing studies show that IL-6 induced an increase in UCP-1 expression of adipocytes isolated from visceral, but not subcutaneous adipose.
CONCLUSION: Our present results may suggest that muscle-released IL-6 during exercise may be involved in mediating muscle-adipose cross-talk, not just with regard to lipolysis as previously shown, but also with regard to browning.

EXERCISE TRAINING INDUCED CHANGES ARE RELATED TO ADDIPOSE TISSUE CHARACTERISTICS IN ELDERLY WOMEN

STEPAN, M., MATOUS, M., DADOVA, K., SONTAKOVA, L., HLADOVA, J., STICH, V., KRAUZOVA, E., SIKLOVA, M.
3RD MEDICAL FACULTY, CHARLES UNIVERSITY IN PRAGUE

INTRODUCTION: Regular physical exercise has been proven to improve an individual health status, namely increasing cardiorespiratory fitness status and insulin sensitivity. In this study we aimed to investigate if these changes might be associated with changes in adipose tissue (AT) characteristics in elderly women.
METHODS: We recruited a group of 23 elderly non-diabetic women (mean age 69.7 years ± 3.5 years, average BMI 26.07 ± 3.78), generally healthy (without any previous history of malignancy, or any other systemic non-compensated illness. We excluded women regularly taking peroral antidiabetic drugs, anti-inflammatory medication and betablockers). All women have undergone a 4month long training program containing of three one hour supervised training sessions per week, two of which consisted of resistance training sessions and one aerobic session (usually intervals of Nordic walking of various intensity levels). At the beginning and at the end of exercise training intervention each subject underwent a bicycle spiroergometry, and a battery of senior fitness tests to determine their cardiorespiratory fitness level, X-ray densitometry (DXA) to analyze body composition and hyperinsulineamic-isoglycemic clamp to determine sensitivity to insulin. Free fatty acid levels were measured in plasma.
RESULTS: After exercise intervention we observed a statistically significant decline of subject's weight by 0.6kg (±9.16kg, p=0.043), which was associated with a significant decrease in fat mass by 1.22kg (±5.9kg, p=0.001) and an increase in fat free mass by 0.6kg (±4.52kg, p=0.027) on average. Insulin sensitivity determined as glucose disposal value significantly improved from average 5.34 mg/kg/min to 6.45 mg/kg/min (±2.46 mg/kg/min, p=0.016). In response to the intervention we observed a significant drop in plasma values of free fatty free acids from 1.48 mmol/l to 1.21 mmol/l (±0.42mmo/l, p=0.002), which suggests decrease in lipolysis in AT. Cardiorespiratory fitness level determined by maximum oxygen consumption (VO2max) during bicycle ergometry increased from 21.4 ml O2/kg/min to 22.9 ml O2/kg/min (±4.33ml O2/kg/min, p=0.01). Multiregression analysis has shown a significant correlation of VO2max with fat mass and glucose disposal (insulin sensitivity) (p=0.007 r=-0.543; p=0.001 r=0.646, respectively), while VO2max did not show statistically significant correlation to fat free mass (p=0.153).
CONCLUSION: Exercise intervention had beneficial effects on subject's cardiorespiratory capacity, physical performance and insulin sensitivity, which was associated with decrease in fat mass and lipolysis in adipose tissue. The declined levels in free fatty acids might also contribute to decreased storage of fatty acids into ectopic fat depositions. Interestingly, the cardiorespiratory fitness improvement was strongly associated with fat mas decrease but not with muscle growth (fat free mass increase) in elderly women.

PROFILING OF HIGH-INTENSITY EVENTS IN ELITE CHINESE FEMALE FIELD HOCKEY MATCHES

CAI, X.1,3, LOMBARD, W.2, MAO, L.1, SPENCER, M.4, CHEN, X.1,3
1: SUS , 2: UCT , 3: NBU , 4: NSSS

INTRODUCTION: Physical performance in field hockey (here on in referred to as hockey) is determined by many different factors. Recently, the development of small wearable inertial measurement units (IMUs) has provided new possibilities to profile the physical demands in different team sports, especially in the high intensity events (HIEs) aspect of competition and training. Therefore, the aim of this study was to profile the position-specific HIEs in elite female hockey matches with the use of IMUs.
METHODS: Sixteen matches analyzing 22 elite Chinese female hockey players (height: 168.5±4.6 cm, body mass: 62.4±5.3 kg) were record by using IMUs (OptimEye S5, Catapult Sports, Australia) during the 2016-2017 Chinese national competition season. Players were categorized in three different playing positions: strikers, midfielders and defenders. Mean speed (MS), PlayerLoadTM (PL), accelerations (Acc), decelerations (Dec), changes of direction (CoD) and the sum of later three, HIEs, were extracted from raw-data files using the manufacturer's software (OpenField, version 1.14.0). All Acc, Dec, CoD and HIEs $>$2.5 m/s2 were analyzed. Data were reported as mean±SD. Multiple paired t-test was used to compare data between different positions. Significance was set at P≤0.05.
RESULTS: The mean on-field time for individual players was 48.8±15.8 min and the mean PL and MS when combining all playing positions were 9.4±1.3 PL/min and 108.6±12.3 m/min respectively. The mean HIEs, Acc, Dec and CoD combined for all players were 1.1±0.3 HIEs/min, 0.2±0.1 Acc/min, 0.2±0.1 Dec/min and 0.7±0.2 CoD/min respectively. Defenders showed significantly lower PL and MS (8.7±1.2 PL/min, 100.7±11.9 m/min) than strikers (9.7±1.4 PL/min, 114.2±10.6 m/min) and midfielders (9.8±1.0 PL/min, 111.9±9.2 m/min) ($P<0.01$).
CONCLUSION: The mean playing time reported in the present study was similar to data from international hockey matches (48.8 ± 15.8 vs. 44.7±11.0 min), yet PL and MS from the present study was lower than that of elite international players (9.4±1.3 vs. 11.2±2.1 PL/min; 108.6±12.3 vs. 113.3±13.5 m/min; McMahon et al.). Competition level (national vs. international) is the most likely reason for these differences (Jennings et al.). Although HIEs have not been previously reported in hockey matches, compared to elite female handball players, the present study showed considerably lower HIEs (1.1±0.3 vs. 3.9±1.6 HIEs/min; Luteberget et al.). Competition level and player density (hockey: 251.4 vs. handball: 66.7 m2/total number of players; Davies et al.) in different sports are probably the two main reasons for these discrepancies. The present study was conducted on elite Chinese national level female hockey players, and further research should focus on the HIEs' performance of elite international level hockey players.

THE EFFECTS OF HEAD AND NECK COOLING DURING INTERMITTENT TREADMILL EXERCISE IN THE HEAT.

NAUGHTON, M.1, BAYNE, F.1, TYLER, C.J.1, JUDELSON, D.A.2

1. UNIVERSITY OF ROEHAMPTON, LONDON UK. 2. NIKE INC., BEAVERTON, OREGON, USA

INTRODUCTION: Intermittent exercise performance is compromised in hot and humid environments due to elevations in actual and perceived heat strain. Cooling interventions can improve exercise performance in the heat, particularly as exercise duration increases, due to alterations in pace-selection and/or pacing profile and the effectiveness of a cooling intervention appears to be related to the magnitude of actual or perceived cooling. The head and neck are disproportionately thermally sensitive and might be a practical and effective site to cool. The aim of the present study was to examine the effects of repeated application of head and neck cooling on exercise pacing during intermittent exercise in the heat.
METHODS: Participants (n=10) completed two ~112 min intermittent Basketball simulation exercise protocols of self-paced walking, jogging, running, and sprinting on a non-motorised treadmill (Woodway Curve) in the heat (36°C, 50% relative humidity). One trial was conducted with head and neck cooling (COOL), the other trial was conducted without head and neck cooling (NON-COOL). Trial order was randomized and counterbalanced. The protocol was interspersed with rest periods mimicking the work-to-rest ratios of basketball. Core temperature (TGI), forehead skin temperature (TH), heart rate (HR), rating of perceived exertion (RPE), thermal comfort (head [TCHEAD]) and body [TCBODY]), and thermal sensation (head [TSHEAD] and body [TSBODY]) were recorded throughout, with mean speeds for each jog, run, and sprint bout recorded. Each dependent variable was averaged over the quarter. Two-way (group x quarter) ANOVA were performed and effect sizes were calculated (Hedges g and r).
RESULTS: TH, RPE, TCHEAD, TCBODY, TSHEAD, TSBODY, and mean jogging speed were significantly improved in COOL ($p < 0.05$). Post hoc analysis revealed these differences were primarily observed in the latter stages of the protocol (i.e. Quarter 3, and 4) with a large effect observed for TH ($g \geq 0.8$), TCHEAD, TSHEAD, TSBODY ($r > 0.5$) in Quarter's 2, 3, and 4, and a moderate effect ($r = 0.3$-0.5) on RPE favoring COOL was observed in Quarter's 2, 3, and 4. There were no significant differences between COOL and NON-COOL for mean running or mean sprint speed, HR, or TGI ($p > 0.05$), with small to moderate effects on HR, mean running and sprint speed favoring COOL.
CONCLUSION: Head and neck cooling reduced forehead skin temperature and improved perceptions of exertion, thermal comfort and sensation, and mean jogging speed. The attenuated perceptual response had small to moderate effects on performance, however these were mainly non-significant. Inspection of performance data showed a consistent trend whereby exercise performance improved in the final stages for COOL, whilst performance deteriorated for NON-COOL, suggesting that COOL improved the ability to pace during intermittent exercise in the heat.

MUSCLE MEMORY WITH A RAT CLIMBING MODEL

EFTESTØL, E.1, JUVKAM, I.1, OCHI, E.2, GUNDERSEN, K.1

UNIVERSITY OF OSLO

INTRODUCTION: Previous work from Prof. Kristian Gundersens lab have shown that myonuclei obtained during hypertrophic stimuli are not lost after a prolonged period of atrophy, and we hypothesize that these extra myonuclei can aid in later muscle re-growth when re-introduced to hypertrophic stimuli (Egner et al., 2013). This mechanism is dubbed "muscle memory". Briefly, mice received a supraphysiological supplementation of the anabolic-androgenic steroid (AAS) testosterone propionate, leading to an increased myonuclear number and muscle growth. After a washout period without AAS, muscle size was back to baseline, but the myonuclear number was still increased. When subjected to a second hypertrophic stimulus by overloading the lower leg muscles by synergist ablation, muscles previously treated with AAS had a much more pronounced growth than controls without the history of AAS treatment. We hypothesize that the muscle memory mechanism is important also during more physiological relevant training, detraining and retraining. Thus, the aim of the present study was to test the muscle memory hypothesis with a rat climbing model.
METHODS: 4-week-old male Sprague Dawley rats were housed in cages designed with the walls and ceiling covered with a climbing mesh, and the food supply in the middle of the ceiling. Thus, the rats had to climb in order to feed and were thereby trained (1. training). After 5 weeks in climbing cage, rats were housed in normal cages for 10 weeks (detraining). Age-matched rats in standard cages were used as ground controls. After detraining, both detrained and ground-control rats were subjected to one of two different retraining regimes: 1) 2 weeks in climbing-cages or 2) 2 weeks overload of soleus by synergist tenotomy of gastrocnemius in order to maximize the hypertrophic response and thereby potential differences between groups. The soleus and tibialis anterior muscles were frozen in melting isopentane in liquid nitrogen, cryosectioned, stained with the myonuclei-specific antibody PCM1 (Winje et al., 2018), dystrophin antibody to visualize the fiber border and DAPI to visualize all nuclei, followed by analysis of myonuclear number and myofiber cross-sectional area.
RESULTS: The 1. training led to a significant increase in both myonuclear number and myofiber cross-sectional area of both the soleus and tibialis anterior muscles compared to ground-controls. After detraining, cross-sectional area was back to the level of the ground-control, but the myonuclear number were still significantly elevated. Preliminary results indicate that retrained rats had a stronger hypertrophic response compared to age-matched ground controls performing the training for the first time.
CONCLUSION: Our results support the muscle memory hypothesis under more training-relevant conditions.

FREQUENCY OF DIRECTIONAL CHANGE IS AN IMPORTANT MEDIATOR OF THE PHYSIOLOGICAL RESPONSE IN SHORT DURATION INTENSE SHUTTLE RUNNING PROTOCOLS

MAASAR, M.F.1, HULTON, A.T.2, SHARPLES, A.P.3, DRUST, B.1

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Pitch area is often manipulated to achieve specific training goals in team sports. Limited information exists on the role that changes in movement pattern (i.e. changes in direction (COD), accelerations/decelerations) may play in differences in exercise intensity under these conditions (Hill-Haas et al. 2009). The purpose of this study was to investigate the impact of an increase in COD on the physiological responses observed in an intense shuttle running protocol.
METHODS: Ten recreational active male team sports players (age: 24+/-2 yrs; height: 1.8+/-0.0 m; weight: 74.0+/-7.9 kg) were recruited to participate in this study. Participants were required to attend 2 pre-test trials; (1) to complete a yo-yo intermittent endurance test and to

familiarize with the centiMax 100RPE scale; (2) estimate maximal shuttle running speed for a 5m (COD5), 10m (COD10) and 15m (COD15) shuttle run. The three experimental trials involved the completion of a 30m shuttle run protocol using either a 5 (COD5, 5mx6, 50 total turns),10 (COD10,10mx3, 20 total turns), or 15m (COD15, 15mx2, 10 total turns) shuttle distance. Ten repetitions (300m total distance) and running intensity (mean intensity 3.3 +/- 0.2 m.s-1; the max speed for COD5) was controlled. All CODs were performed at 180degrees. A minimum of 20 min rest was allocated between running protocols to allow recovery. Participants performed all running condition in randomized, counterbalanced study design. The physiological demand of each protocol was estimated using post shuttle heart rate (PostHR) and post exercise blood lactate (BlaPost). Subjective "load" was also recorded using differential RPE (dRPE) for breathlessness (RPE-B) and leg muscle (RPE-L) as well as session (RPE-S). 'Movement load' was estimated using moderate to high inertial movement analysis for acceleration (IMAaccel) and deceleration (IMAdecel), Player Load (PL) and Player Load 2D (PL2D).
RESULTS: COD5 generated a significant higher PostHR response when compared to COD15 (p= 0.021). COD5 was also significantly higher for BlaPost (p=0.001) in comparison to COD10 and COD15.The dRPE (RPE-B, RPE-L, RPE-S) were also significantly greater in COD5 and then COD10 and COD15 protocol (p=0.001). IMAaccel were significantly difference between COD5 and COD15 (p=0.036). No significant difference between protocols were recorded on IMAdecel though PL showed a significant differences (p=0.012) between COD5 vs. COD15 protocols. COD5 also recorded the highest response in PL2D when compared to COD10 and COD15 (p=0.002 and 0.001 respectively).
CONCLUSION: These findings suggest that the increasing number of COD in an intense shuttle running protocol increases physiological, subjective and 'movement load' compared to exercise protocols that have fewer COD's. Such information may be important in enabling practitioners to better manage the prescription of both acute and chronic training loads.

CHARACTERISTICS OF 3-D FOOT SHAPE IN JAPANESE SWIMMERS BY USING HOMOLOGOUS BODY MODEL.

SOMA, M.1,2, KASHIWAGI, Y.1, FUJIMORI, T.1, WAKATSUKI, R.1, FUNATO, K.1

1: NIPPON SPORT SCIENCE UNIVERSITY , 2:JUMONJI UNIVERSITY

INTRODUCTION: Univariate anthropometric data have documented the differences in foot shape proportions. However, it has been unknown how different swimmers foot populations have. Constructing the homologous human body model and analysing it by principal component statistical analysis are useful for describing and assessing the specific features of 3-D shape(Chang et al., 2015). The purpose of this study was to compare the morphological foot shape characteristics between Japanese elite swimmers and non-swimmers by quantifying 3-D foot shape established by a Principal Component Analysis (PCA) of Homologous Body Model (HBM).
METHODS: Swimmers (SW; Age; 20.5±3.0yrs, BH; 173.4±4.7cm, BW; 70.0±5.2kg) and non-swimmers (NS; Age; 20.7±2.2yrs, BH; 172.9±5.3cm, BW; 65.1±8.8kg) participated in this study. Foot anthropometry was measured by three dimensional whole foot scanner (INFOOT; I-Ware Laboratory Co. Ltd). Subjects were stand asked to upright with weight distributed equally on both feet. HBM consisted of 20,000 vertex of the same topology, and then it was constructed by fitting the foot polygon date to generic template model based on anatomical landmarks.
RESULTS: The 17 PCs had explained 92.7% of the shape variability, respectively. In particular, PC2 (contribution ratio; 17.9%) explained naviculare bone height and foot arch height and PC4 (contribution ratio; 7.4%) explained ball width and toe length. In normalized HBM as to body height, it showed the larger foot length and foot wide slender was characteristics for swimmer. Homology model of the 3-D body shape enabled to quantify the individual differences and characteristics of foot shape. The following results suggested that morphological characteristics of foot shape could be influenced by daily training. One of the advantages of Principal Component Analysis statistical shape analysis was that it provided intuitive visualization of the shape variation. The shape analysis results revealed the differences that cannot be detected from 1-D and 2-D measurements.
CONCLUSION: Characteristics of 3-D human foot shape using by homologous body model revealed that swimmers had larger foot length and foot wide slender as well on flatter foot shape. Specific foot shape of Japanese swimmers was quantified. Homologous body model is useful for athletes and coaches to identify the foot shape from the view points such as growth, development and training.

OXYGEN UPTAKE AND HEART RATE RESPONSES TO PASSIVE PEDALING EXERCISE USING A TANDEM BICYCLE ERGOMETER

ONODERA, S.1, TAMARI, Y.1, WADA, T.1, YOSHIDA, N.1, HAMADA, H., SAITO, T.1, MURATA, M.2, ARATANI, Y.1, HAYASHI, S.3, TAKAHARA, T.2, YOSHIOKA, A.4, YAMAGUCHI, H.2, KATAYAMA, K.5, OGITA, F.6

1: KUMW , 2: KIU , 3: FCU , 4:OU , 5: NU , 5: NIFS

INTRODUCTION: We have developed a tandem bicycle ergometer of the pist-type braking that two persons can share one load (Onodera at al. 2015,2017). By using this ergometer, when one person performs active pedaling exercise, the other person can be allowed to passive pedaling exercise. This study aimed to clarify oxygen uptake (VO2) and heart rate (HR) responses to passive pedaling exercise at different the number of pedal rotations.
METHODS: Healthy seven adult males were participated in this study as a volunteer (Age; 24 ± 3 year, Height; 172 ± 5cm, Weight; 67 ± 12kg, VO2peak; 44.3 ± 6.6 ml/kg/min). Because we thought that HR and VO2 responses of passive pedaling cyclist would show a similar tendency regardless of active pedaling cyclists, a passive pedaling cyclist in this experiment was fixed by one person and the others were responsible for active pedaling cyclists. The load of cycle exercise was set at 1.5kp and the exercise duration was for 15 minutes. The number of pedal rotations was set at 40 rpm at the beginning, and then it was increased 10 rpm every 3 minutes. The subject, who performed the passive pedaling exercise, also performed the active pedaling exercise by himself using a same protocol. HR was measured throughout the exercise for 15 minutes using the electrocardiograph and VO2 was measured last 1 minute each the number of pedal rotations. The differences in HR and VO2 were detected among the different cadence using the one-way ANOVA. When differences were found to be significant, comparisons were made using Bonferroni's post hoc test. Values of $p<0.05$ were considered as statistically significant.

RESULTS: HR (bpm) (40rpm: 124 ± 13, 50rpm: 142 ± 16, 60rpm: 156 ± 19, 70rpm: 168 ± 22, 80rpm: 182 ± 19, mean ± SD) and VO2 /kg (ml/kg/min) (40rpm: 18.2 ± 2.8, 50rpm: 20.9 ± 3.3, 60rpm: 24.4 ± 4.1, 70rpm: 29.2 ± 4.5, 80rpm: 34.9 ± 4.8, mean ± SD)of active pedaling cyclists increased significantly with an increase in the number of pedal rotations ($p<0.05$). Similar results were observed in the passive pedaling cyclist ($p<0.05$), and VO2 of passive pedaling cyclist corresponded to 23% of that of active pedaling cyclist. It is considered that the increases in VO2 and HR responses to passive pedaling exercise are attributed to the facilitation of the muscular mechanoreceptor reflex.
CONCLUSION: VO2 and HR responses to passive pedaling exercise, which was determined using our tandem bicycle ergometer, increased significantly in the number of pedal rotations. These data suggest that passive pedaling exercise using our tandem ergometer could be applied to the rehabilitation for the people exercise that is not able to do voluntarily exercise.

ACUTE RESPONSES OF SELECTED CARDIAC DIMENSIONS DURING REPEATED MULTIDIRECTIONAL AGILITY-LIKE SPRINTS IN TRAINED TEAM SPORT ATHLETES.

DÜKING, P.1, KUNZ, P.1, KOHL, M.2, SPERLICH, B.1
1 UNIVERSITY OF WÜRZBURG, 2 UNIVERSITY OF APPLIED SCIENCES KOBLENZ

INTRODUCTION: Team-sports are characterized by an intermittent exercise profile involving repeated sprints and rapid multidirectional changes-of-direction (COD) following an external stimulus [1-3]. Understanding the acute physiological responses of repeated multidirectional agility-like sprints (RMAS) is paramount to design appropriate interventions for the athlete. While e.g. muscular factors or energy supply mechanisms have been investigated intensively [2], there is little to no data concerning variations in cardiac stroke volume (SV) and cardiac output during RMAS in trained team sport athletes. This is astonishing since SV contributes to cardiac output, and consequently to maximal oxygen consumption and aerobic ATP provision which accounts for approx. 40% of total energy supply during repeated sprints [2]. Therefore, the aim of this study was to evaluate the acute responses during and in between RMAS on SV in trained team sport athletes.
METHODS: After determination of maximal SV (SVmax) in an incremental treadmill test, 14 trained team sport athletes (n=14, VO2peak: 53.4 ± 5.6 ml/min/kg) performed 16 RMAS interspersed with recovery of 12 s duration performed on the SpeedCourt (Globalspeed GmbH, Hemsbach, Germany). The running path of each run was defined by the investigators to ensure standardization between participants. Yet, running path and angles of COD where unknown to the athletes. SV was measured continuously using thoracic bioimpedence (Physioflow, Manatec Biomedical, France). The SV data was separately analyzed for sprints and recovery, and between sprints 1-8 and 9-16.
RESULTS: SVmax during treadmill test was 172.0 ± 32.5 ml. During the RMAS, mean SV was 160.5 ± 3.3 ml and 121.4 ± 2.6 ml during sprints and recovery, respectively. For sprints 1-8, SV was 162.4 ± 2.0 ml and 119.8 ± 1.5 ml, and for sprints 9-16 SV was 158.8 ± 2.9 ml and 122.7 ± 2.3 ml during sprints and recovery, respectively. T-tests analysis revealed a significant difference in peak SV during sprints ($p= 0.03$) and minimal SV during recovery periods ($p = 0.02$) between sprints 1-8 vs. 9-16. There was no significant difference between SVmax during incremental test and peak SV in RMAS ($p = 0.13$).
CONCLUSION: Our findings indicate that RMAS elicits near maximal SV. With increasing number of RMAS, SV decreases with each sprint and increases in the recovery periods. The decreasing SV during sprints could be due to an increase in heart rate which consequently may reduce left ventricular filling time. An increasing SV during recovery periods in between sprints could indicate a diminished recovery from RMAS, however, this needs to be confirmed by future studies. Peak SV during sprints and SV during recovery periods may be useful to describe aspects of cardiovascular load imposed to trained team sport athletes performing RMAS.

THE DIFFERENT RESPONSES IN REGIONAL PULSE WAVE VELOCITY TO WATER IMMERSION AT 30°C

SAITO, T.1, HAMADA, H.2, NISHIMURA, M.3, MURATA, M.4, NISHIMOTO, T.1, YOSHIOKA, A.5, YANO, H.2, ONODERA, S.2
1: KAWASAKI UNIV OF MEDICAL WELFARE , 2: GRADUATE SCHOOL, KAWASAKI UNIV OF MEDICAL WELFARE , 3: TOTTORI UNIV , 4: KIBI INTERNATIONAL UNIV , 5: OKAYAMA UNIV

INTRODUCTION: It has been reported that water immersion increase brachial-ankle pulse wave velocity (baPWV). Although, in japan, swimming pools are commonly maintained at around 30°C, we already showed that even 30°C significantly increased baPWV (Saito et al., 2014). PWV is useful method for evaluating arterial stiffness. However, it is unclear whether or not the increase in baPWV is associated with peripheral and/or central vascular responses. The purpose of this study was to compare changes the regional PWV while resting on land and during water immersion at 30°C.
METHODS: Subjects comprised six healthy adult males. All subjects signed the informed consent forms prior to participation in this study. The subjects remained in a supine position in two different conditions, on land condition and in water condition (water temperature: 30°C). On land condition, we recorded measurements when participants were resting in the supine position for 25 min. After resting in the supine position on land for 10 min, a water tank was used to immerse the subjects' entire body, with the exception of their faces, for 15 min. We measured the heart–carotid PWV (hcPWV), heart–femoral PWV (hfPWV), femoral–ankle PWV (faPWV), baPWV, heart rate, blood pressure (brachial and ankle), rectal temperature, skin temperature and skin blood flow.
RESULTS: The hfPWV, faPWV, baPWV and diastolic blood pressure (ankle) at water condition were significantly higher than that on land condition ($P < 0.05$). There was no significant difference between the land and water condition in any other measurement items.
CONCLUSION: Pulse waves conduct from the central to the peripheral arteries. Previous studies reported that there were significant changes in the lower body PWV, but not aortic PWV, in response to lower limb heat stimulation (Kosaki et al., 2015). In contrast, in younger females sensitive to cold, there is a decrease in blood flow into the toes and a decrease in body temperature and an increase in arterial stiffness both in the lower limbs and the whole body (Yamato et al., 2016). In conclusion, this study suggests that a cold stimulus to the whole body in water immersion at 30°C induces not only increase in faPWV which associated with peripheral vascular reaction, but also increase in hfPWV.

PHYSICAL ACTIVITY INDEX INFLUENCE ON ALL-CAUSE MORTALITY AND VASCULAR HEALTH MEASURES: FINDINGS FROM THE FRAMINGHAM HEART STUDY

MUGGERIDGE, D.J., RAE, M., FLORIDA-JAMES, G., ROSS, M.

UNIVERSITY OF THE HIGHLANDS AND ISLANDS

INTRODUCTION: Exercise training, and regular physical activity (PA) are known to positively benefit vascular function and reduce all-cause mortality. Endothelial progenitor cells (EPCs) play an important role in maintenance of vascular health, due to their regenerative capabilities. These cells are also predictive of mortality, and are lower in vascular disease states in comparison to a healthy population. Exercise is known to stimulate mobilisation of EPCs into circulation, which may offer a window of vascular protection. It is therefore plausible that enhanced vascular function and reduced mortality may potentially be mediated via increasing the circulating levels of these vascular regenerative cells. Using data collected from the Framingham Heart Study (FHS), we aimed to investigate the relationship between PA levels and EPCs, as well as other key vascular health measures (Peripheral Arterial Tone (PAT), carotid Intima-Media Thickness (CIMT)), and subsequent effects on all-cause mortality risk.
METHODS: 3002 participants' (1352 male/1650 female, age 67 ± 7yrs) data were included from the offspring cohort of the FHS. Data for EPCs (CD34+, CD133+CD34+VEGFR2), PAT and CIMT were assessed from exam7 (Dates 1998-2001). All-cause mortality rates were based on a 10-12 years follow-up period. PA Index (PAI) scores were calculated as previously described and participants were split equally into LOW (24.0 – 34.1) and HIGH (34.2 – 70.9) activity groups. Data was transformed where normality violated. Cox proportional hazard analysis assessed the effect of PAI groups on all-cause mortality. Multiple linear regression assessed the impact of PAI groups on vascular health outcome variables after controlling for age, sex, ethnicity, BMI, smoking, diet and cardiovascular medication.
RESULTS: Following 12 year follow-up, 202 participants died. LOW PAI was associated with an increase in all-cause mortality (Total deaths = 142, hazard ratio 2.512, 95% confidence interval (CI) 1.907 – 3.311, P<0.001) versus HIGH PAI (Total deaths = 60, hazard ratio 0.398, 95% CI 0.302 – 0.5245, P<0.001). Multiple linear regression models explained a small but significant variation in left (L_) and right (R_) CIMT (L_CIMT r2 = 0.222, R_CIMT r2 = 0.218) and PAT augmentation index (r2 = 0.182), but not circulating EPCs (CD34+: r2 = 0.053, CD133+CD34+VEGFR2: r2 = 0.017). The impact of PAI was minimal in all of the models (r2 change all < 0.003, all P>0.1).
CONCLUSION: Physical Activity Index from the Framingham Heart Study is a strong predictor all-cause mortality in the offspring cohort. Whilst vascular measures have been shown to previously influence all-cause mortality, data from the present findings suggest that PAI had little or no effect on the vascular health measures assessed. In conclusion, increases in PAI may benefit mortality rates but this may be independent of effects on vascular health measures.

INFLUENCE AND RELIABILITY OF LOWER-LIMB ARTERIAL OCCLUSION PRESSURE AT DIFFERENT BODY POSITIONS.

PATTERSON, S., HUGHES, L., JEFFRIES, O., WALDRON, M., ROSENBLATT, B., GISSANE, C., PATON, B.

ST MARYS UNIVERSITY

INTRODUCTION: Total arterial occlusive pressure (AOP) is used to prescribe pressures for surgery, blood flow restriction (BFRE) and ischemic preconditioning (IPC). AOP is often measured in a supine position; however, the influence of body position on AOP measurement is unknown and may influence of level of occlusion in different positions during BFR and IPC. The aim of this study was therefore to investigate the influence of body position on AOP
METHODS: Fifty healthy individuals (age = 29 ± 6 y) underwent AOP measurements on the dominant lower-limb in supine, seated and standing positions in a randomised order. AOP was measured automatically using the Delfi Personalised Tourniquet System device, with each measurement separated by 5 min of rest.
RESULTS: AOP was significantly lower in the supine position compared to the seated position (187.00 ± 32.5 vs 204.00 ± 28.5 mmHg, p<0.001) and standing position (187.00 ± 32.5 vs. 241.50 ± 49.3 mmHg, p<0.001). AOP was significantly higher in the standing position compared to the seated position (241.50 ± 49.3 vs. 204.00 ± 28.5 mmHg, p<0.001).
CONCLUSION: AOP measurement is body position dependent, thus for accurate prescription of occlusion pressure during surgery, BFRE and IPC, AOP should be measured in the position intended for subsequent application of occlusion

THE EFFECTS OF AEROBIC EXERCISE TRAINING IN WATER ON ARTERIAL STIFFNESS IN OLDER ADULTS

MATSUI, T.1, TATSUMI, J.1, SAITO, T.2, ONODERA, S.2, KURATO, R.3

1: OTEMON GAKUIN UNIVERSITY, 2: KAWASAKI UNIVERSITY OF MEDICAL WELFARE, 3: KAGAWA UNIVERSITY

INTRODUCTION: It is well known that large elastic arteries stiffen with age, which increases the risk of cardiovascular disease. Physical exercise affects arterial stiffness; especially, moderate intensity aerobic exercise on land leads to a transient decrease in arterial stiffness (Hefferman et al., 2007; Nogami et al., 2011), as does continuous exercise training (Kim HK et al., 2017). However, few studies have reported the effects of exercise in water on arterial stiffness. In addition, the effects of exercise training in water in older adults are unclear. Therefore, we investigated the effects of exercise training in water on arterial stiffness in older adults compared to those of exercise training on land.
METHODS: In this interventional study, 51 elderly subjects were divided into 2 groups: a water-based aerobic exercise training group (WEG: n = 23 (10 male), 70.7 +/- 3.4 yrs) and a land-based one (LEG: n=28 (4 male), 72.3 +/- 4.6 yrs). They performed the trainings twice a week for 3 months. The average total number of participations was 21 in WEG, and 24 in LEG. The exercise duration per time was 45 min, including warm-up exercises. The WEG performed aquatic dance and / or walking in water. The LEG performed aerobic dance and / or other exercises. The brachial-ankle pulse wave velocity (baPWV) were measured in the pre and post training period.
RESULTS: The pre-training baPWV of WEG and LEG were 1822.0 +/- 556.1 and 1804.5 +/- 361.8 cm/sec. The post-training baPWV were 1840.1 +/- 533.8 and 1841.9 +/- 338.6 cm/sec. There were no significant differences in baPWV between the pre and post period in the same group. Additionally, there were no significant differences in baPWV between WEG and LEG in the same period. We examined the subjects who showed absolute changes (from pre to post) in baPWV more than 100 cm/sec and who showed a final value of 1900 cm/sec compared to the pre training period. In the WEG, the subjects who met these conditions showed a significantly negative correlation between baPWV changes and number of training (p <0.05). On the other hand, there was no similar relationship in the LEG group. The number of subjects who showed more than 100 cm/sec improvement in baPWV was 8 (35%) in the WEG and 6 (21%) in the LEG.
CONCLUSION: It is suggested that water-based aerobic exercise training twice a week could be effective in lowering arterial stiffness (measured using baPWV) compared to land-based exercises in older adults.

SUPERVISED EXERCISE TRAINING IMPROVES PHYSICAL FUNCTION IN PATIENTS WITH LOWER EXTREMITY ARTERY DISEASE: PRELIMINARY RESULTS.

LANZI, S., CALANCA, L., MAZZOLAI, L.

DIVISION OF ANGIOLOGY

INTRODUCTION: In lower extremity artery disease (LEAD), supervised exercise training (SET) is recommended as one of the primary baseline measure in patients with intermittent claudication to improve walking capacities and reduce cardiovascular risk. Aim of present study was to investigate the effects of combined SET (Nordic walking and lower limb strengthening) on physical function.
METHODS: Fontaine stage II LEAD's patients following a 3-month SET were investigated. SET consisted in 3 weekly 50-min sessions: twice Nordic walking and once lower limbs strengthening. Ankle-brachial Index (ABI), treadmill pain-free walking distance (PFWD) and maximal walking distance (MWD) were measured before and after SET. Monthly time course evolution of 6-min walking distance (6MWD), physical function of lower extremities [assessed by Short Physical Performance Battery (SPPB) score and stair climbing test (SCT)], and postural stability (assessed by a posturographic platform) were also assessed (pre-SET, 1 month and 2 months, post-SET). Wilcoxon signed-rank test and one-way repeated measures ANOVA (with Bonferroni correction) were used for comparison.
RESULTS: Fourteen consecutive LEAD patients (64.8±2.8 years, 86% men) were analyzed. Following SET, walking performances significantly increased (PFWD: 97.7±14.0m pre- vs. 208.5±46.6m post-SET; P=0.011; MWD: 370.8±59.0m pre- vs. 662.3±127.8m post-SET; P=0.004). ABI did not change significantly (0.89±0.07 pre- vs. 0.86±0.04 post-SET; P=0.86). 6MWD, SCT, and SPPB score significantly improved during SET (P≤0.001, P≤0.001, P=0.011; respectively). 6MWD was significantly increased at 1 month (+8%, P=0.012), 2 months (+9%, P=0.004), and after SET (+10%, P=0.01) compared to pre-training. However, increase was not significant at 1 and 2 months compared to end of SET. Similarly, time during SCT significantly decreased at 1 month (-13%, P=0.003), 2 months (-17%, P=0.001) and after SET (-17%, P=0.006) compared to pre-training, Again, no significant difference was found at 1 and 2 months compared to end of SET. SPPB score tended to slightly increase at the end of SET (+8%, P=0.06) compared to pre-training. No significant difference was found after 1 or 2 months of SET. Postural stability did not change significantly during SET.
CONCLUSION: These results confirm beneficial effects of SET on walking performances. Additionally, they suggest that SET is also effective in improving physical function in LEAD patients. Monthly time course evolution of different physical function measures revealed that these adaptations mainly occur during the first month of SET, suggesting that training adaptations (volume, intensity) may be considered in the second part of SET to further increase benefit.

CP-PM15 Genomics

PRELIMINARY ANALYSIS OF THE GENOFIT GENOMICS OF HEALTH AND FITNESS STUDY.

RYAN, A., CROGNALE, D., QUINN, E., BUTLER, A., DOLAN, J., PRATT, J., MAGALHAES, T., CARR, R., MORAN, R., O'CONNELL, K., CONROY, J., DEVITO, G., BOREHAM, C., ENNIS, S.

GENOMICS MEDICINE IRELAND

INTRODUCTION: Health, fitness and well-being are influenced by both environmental and genetic components. By integrating genomic and phenotypic data, the GenoFit study aims to identify genetic variants that contribute to various aspects of human health and fitness.
METHODS: Participants (age range 18 – 89 years) complete a detailed lifestyle questionnaire and are physically assessed for general health and fitness measures including adiposity, blood pressure, heart rate, bone mineral density and muscle health. The genomes of all enrolled individuals will be whole genome sequenced to a depth of 30x and genotyped using an Affymetrix precision medicine research array containing over 800,000 markers. The final target sample size is 5,000 individuals.
RESULTS: To date, 277 individuals have been genotyped. Analysis using linear regression for quantitative trait association (PLINK v1.9) have yielded nominally significant (uncorrected $P < 0.05$) association signals for several traits including adiposity, hand-grip and bone density. However, with the current sample size, no loci have reached genome-wide significance.
CONCLUSION: Active sample collection, phenotypic characterization and molecular analysis are ongoing, with the aim of developing a valuable resource for future genomic studies.

ASSOCIATION BETWEEN MAPT POLYMORPHISM BUT NOT APOE PROMOTER AND ELITE RUGBY ATHLETE STATUS.

ANTROBUS, M.R.1, BRAZIER, J.1, HERBERT, A.J.1, STEBBINGS, G.K.1, DAY, S.H.1, HEFFERNAN, S.2, ERSKINE, R.M.3, KILDUFF, L.P.4, WILLIAMS, A.G.1

1: MANCHESTER METROPOLITAN UNIVERSITY , 2: UCD , 3: LJMU , 4: SU .

INTRODUCTION: Incidence and outcomes of concussions have been hypothesised to be genetically influenced. The APOE Promoter G219T (rs405509) polymorphism has been associated with differential promoter activity and unfavourable outcomes after traumatic brain injury. The TT genotype is associated with a 3-fold greater risk of multiple concussions. The TT genotype of MAPT (rs10445337) has also been associated with poorer outcomes after concussion. Rugby has one of the highest incidences of concussion in sport, so it was hypothesised that APOE Promoter TT and MAPT TT genotypes would be less prevalent in elite rugby athletes because those genotypes, previously associated with increased risk, would be less compatible with achieving elite athlete status.
METHODS: Participants were from the RugbyGene project, comprising elite Caucasian male rugby athletes (n = 528; mean (standard deviation) height 1.85 (0.07) m, mass 101 (14) kg, age 29 (7) yr), including 420 rugby union (RU) athletes that for some analyses were divided into forwards and backs and 108 rugby league (RL) athletes. Non-athletes were 592 Caucasian men and women (57% male, height 1.72 (0.10) m, mass 74 (14) kg, age 31 (7) yr). PCR of genomic DNA was used to determine genotypes using TaqMan probes, then groups were compared using $\chi 2$ and odds ratio (OR) statistics.
RESULTS: All genotype data were in Hardy-Weinberg equilibrium. For MAPT (rs10445337), the risk genotype (TT) was underrepresented in rugby athletes (60%) compared to non-athletes (66%), CT more common in rugby athletes (34%) than non-athletes (29%) and little difference in CC genotype frequencies ($\chi 2 = 7.092$, $P = 0.029$; TT genotype frequency OR = 0.80, 95% confidence intervals (CI) = 0.62-1.02). There were no differences in MAPT (rs10445337) genotype frequencies between RU forwards and backs. For APOE Promoter G219T

(rs405509), there were no differences in genotype frequencies between all athletes (RU and RL) and non-athletes (27% TT genotype in players and non-athletes), nor between RU forwards and backs.
CONCLUSION: The MAPT (rs10445337) TT genotype is 6% less common in elite rugby athletes than non-athletes. Therefore, carrying at least one rs10445337 C allele appears to increase the probability of sustained career success in the high-risk concussion environment of elite rugby, perhaps via a greater ability to recover from concussions.

ASSOCIATION OF MMP3 BUT NOT TIMP2 GENE VARIANTS WITH ELITE RUGBY PLAYER STATUS AND RUGBY CODE

BRAZIER, J.1, ANTROBUS, M.R.1, HERBERT, A.J.1, STEBBINGS, G.K.1, DAY, S.H.1, HEFFERNAN, S.2, ERSKINE, R.M.3, KILDUFF, L.P.4, WILLIAMS, A.G.1

1: MANCHESTER METROPOLITAN UNIVERISTY , 2: UCD , 3: LIMU , 4: SU .

INTRODUCTION: Achilles tendon pathology and anterior cruciate ligament rupture are multifactorial conditions for which genetic risk factors have been identified. Single nucleotide polymorphisms (SNPs) within the MMP3 (rs591058, rs679620, rs650108) and TIMP2 (rs4789932) genes have previously been associated with tendon and ligament pathologies. Although not entirely clear, prior literature indicates the risk alleles for Achilles tendon pathology as T (rs591058), G (rs679620) and A (rs650108) for MMP3. However, prior evidence regarding TIMP2 is equivocal. MMP3 is considered an essential regulator of matrix degradation and remodelling within diseased and normal musculoskeletal soft tissues. TIMP2 maintains homeostasis in the extracellular matrix in part by inhibiting MMP function. Given the high incidence and severity of tendon and ligament injuries in elite rugby athletes, we hypothesised that the aforementioned SNPs would be associated with career success.
METHODS: Participants from the RugbyGene project were elite Caucasian male rugby athletes (n = 566; mean (standard deviation) height 1.85 (0.07) m, mass 101 (14) kg, age 29 (7) yr), including 420 rugby union (RU) athletes that for some analyses were divided into forwards and backs and 120 rugby league (RL) athletes. Non-athletes were 589 Caucasian men and women (n = 589, 57% male, height 1.72 (0.10) m, mass 74 (14) kg, age 31 (7) yr). PCR of genomic DNA was used to determine genotypes using TaqMan probes, then groups were compared using X2 and odds ratio (OR) statistics.
RESULTS: The MMP3 rs591058 risk genotype (TT) was less frequent in rugby athletes (28%) compared to non-athletes (33%) (X2 = 7.265, P = 0.026; OR = 1.18, 95% confidence intervals (CI) = 0.86-1.63). No differences were found for MMP3 rs679620, rs650108 or TIMP2 rs4789932 between rugby athletes and non-athletes. When RL athletes were compared to non-athletes, the risk genotype (TT) of MMP3 rs591058 was underrepresented in RL athletes (19%) compared to non-athletes (33%). The MMP3 rs679620 'protective' allele (C) was more frequent in RL athletes (55%) compared to non-athletes (48%) (OR = 1.3, 95% CI = 0.98-1.74). However, for MMP3 rs650108 the 'risk' allele (A) was overrepresented in RL athletes (32%) compared to non-athletes (26%). There were no genotype differences for any gene variant between RU athletes and non-athletes. The 'risk' allele (T) of the MMP3 rs679629 polymorphism and the 'protective' allele (G) of the MMP3 rs650108 polymorphism were less common in RL (45%, 68%, respectively) than RU athletes (54%, 76%, respectively).
CONCLUSION: We provide evidence for elite rugby athletes possessing a protective genetic profile regarding tendon and ligament injury risk. Notably, a less frequent rs591058 TT genotype in athletes suggests a lower risk of injury could therefore enhance career success in rugby. Furthermore, RL players appear to have differing genetic characteristics compared to their RU counterparts, which might reflect some differences in physiological demands.

G-PROTEIN COUPLED ESTROGEN RECEPTOR (GPER) RS3808350 POLYMORPHISM IS ASSOCIATED WITH CENTRAL ARTERIAL STIFFNESS IN HEALTHY JAPANESE PEOPLE

HAYASHI, K.1, IEMITSU, M.2, MURAKAMI, H.3, SANADA, K.2, KAWANO, H.4, GANDO, Y.3, TANAKA, N.5, KAWAKAMI, R.6, MIYACHI, M.3

1: KOKUGAKUIN UNIVERSITY, 2: RITSUMEIKAN UNIVERSITY, 3: NATIONAL INSTITUTES OF BIOMEDICAL INNOVATION, HEALTH AND NUTRITION, 4: KOKUSHIKAN UNIVERSITY, 5: NAGOYA UNIVERSITY, 6: WASEDA UNIVERSITY

INTRODUCTION: The G protein-coupled receptor (GPER) is an estrogen receptor, and has been shown to mediate estrogenic effects on arterial functions such as endothelial function and blood pressure (Han et al., 2013). However, the effect of the GPER gene polymorphism on arterial stiffness in humans remains unclear. In addition, regular physical activity brings higher cardiorespiratory fitness and results in the reduction of arterial stiffening, but the effect of the GPER gene polymorphism on the relationship between cardiorespiratory fitness and arterial stiffness has also not been clarified. The purpose of this study was to clarify the effects of the GPER gene genotype on central arterial stiffness and higher-cardiorespiratory fitness related reductions in arterial stiffness.
METHODS: Seven hundred and fifty Japanese people (18-84 yrs old) participated in a cross-sectional study. Three single nucleotide polymorphisms (SNPs) of the GPER gene (rs11544331, rs3808350, rs3808351) were determined by real-time PCR with the Taqman probe. Central arterial stiffness was evaluated by beta-stiffness index of the carotid artery using ultrasound and applanation tonometry. Brachial blood pressures, blood lipids and glucose levels and VO2peak were also measured. Subjects were divided into high- or low-cardiorespiratory fitness groups based on the median value of VO2peak in each gender and decade.
RESULTS: BMI and blood glucose level of individuals with AA genotype (n=158) in rs3808350 polymorphism were higher than those of individuals with AG (n=368) and GG (n=224) types. There were no differences in age, blood pressures of brachial artery and blood lipid levels among the genotypes in the polymorphism. beta-stiffness index of the carotid artery of individuals with the GG type (7.55 ± 0.20 A.U., Mean ± S.E.) in the polymorphism was significantly lower than those of other two genotypes (AA type: 8.50 ± 0.40, AG type: 8.57 ± 0.20 A.U.) after adjusting for covariates such as gender and BMI ($P<0.05$). However, the rs3808350 had no impact on the difference of beta-stiffness index associated with cardiorespiratory fitness level. Other polymorphisms (rs11544331 and rs3808351) were not associated with beta-stiffness index of the carotid artery and higher fitness related improvement of the carotid arterial stiffness.
CONCLUSION: rs3808350 genotype of the GPER gene is associated with stiffness of central artery in healthy Japanese population but had no impact on the higher fitness-related reduction of arterial stiffness. Reference: Han G et al. (2013) Pharmacol Res, 71, 53-60.

ASSOCIATION ANALYSIS OF COL1A1 AND COL5A1 POLYMORPHISMS WITH MUSCLE STIFFNESS

MIYAMOTO-MIKAMI, E.1, HIRATA, K.1, KIMURA, N.1, FUKU, N.2, MIYAMOTO, N.1

1: NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA , 2: JUNTENDO UNIVERSITY

INTRODUCTION: Muscle stiffness is considered to be one of the primary contributors to joint flexibility (Magnusson et al, 1997) and to influence muscular injury risk (Witvrouw et al, 2003). There is a large individual difference in muscle stiffness (Hirata et al, 2018). However,

genetic determinants of the individual difference remain unclear. Muscle stiffness is influenced by the concentration of intramuscular collagenous connective tissues, such as perimysium and endomysium (Gajdosik, 2001). Therefore, we hypothesized that genotypes affecting collagen expression can contribute to the individual difference in muscle stiffness. To test this hypothesis, we examined the associations of muscle stiffness with polymorphisms affecting the expression of type I and V collagen.
METHODS: Polymorphisms affecting the expression of type I and V collagen were selected based on the Genotype-Tissue Expression database (GTEx) and previous studies. Seventy-seven healthy young male subjects were genotyped by TaqMan SNP Genotyping Assay, for rs1107946 and rs9893529 polymorphisms associated with expression of collagen type I alpha 1 chain (COL1A1) and rs12722 polymorphism associated with collagen type V alpha 1 chain (COL5A1) mRNA stability. Passive muscle stiffness of each of the hamstring (biceps femoris long head, semitendinosus, and semimembranosus) of the right leg was assessed in a seated position using ultrasound shear wave elastography.
RESULTS: Stiffness of the semimembranosus significantly differs among the COL1A1 rs1107946 genotypes ($P < 0.05$ by ANOVA). CC genotype carriers showed higher passive stiffness of the semimembranosus than AC genotype carriers (CC: 51.6 kPa vs. AC: 39.2 kPa, $P < 0.05$ by Bonferroni post hoc test). There was no association of the other two polymorphisms with passive stiffness of the hamstring muscles.
CONCLUSION: Type I collagen is the major component of perimysium and endomysium (Light et al, 1984). rs1107946 A to C polymorphism is located within the COL1A1 promoter region, and in vitro functional assay showed that the C allele has a higher transcriptional activity than the A allele. Indeed, according to the GTEx, the C allele is associated with higher gene expression of COL1A1 in human tissue. Taken together, our result suggests that the rs1107946 polymorphism contributes to the individual difference in muscle stiffness through altered COL1A1 expressions.

ASSOCIATION ANALYSIS OF ACE I/D AND ACTN3 R577X GENE POLYMORPHISMS IN ELITE INDIAN ATHLETES

GROVER, V.K., KUMAR, A., VERMA, J.P., SHARMA, N., TIWARI, P.K.

LAKSHMIBAI NATIONAL INSTITUTE OF PHYSICAL EDUCATION

INTRODUCTION: Success in sports relies upon the aerobic and anaerobic capacities of an individual depending upon the energy metabolism requirement of a particular sport. The genetics plays an important role in determining these capacities of an individual in sports. ACE I/D gene polymorphism was the first gene variant that was investigated with respect to physical performance (Montgomery et al., 1998). In the Australian rowing team that won most rowing medals in 1996 Olympics, most of the team members had I allele and I/I genotype of ACE I/D gene polymorphism (Gayagay et al., 1998). 155 DNA polymorphisms have been found to be associated with sports performance or related phenotypes (Ahmetov et al., 2016). The ACE I/D and ACTN3 R577X gene polymorphisms are the most studied gene polymorphisms worldwide in different cohorts (Ahmetov et al., 2016). However, none of the studies has been conducted so far to find the association in Indian elite athletic cohort. Here, we investigated the association of ACE I/D and ACTN3 R577X gene polymorphisms with athletic status of Indian elite boxers, endurance athletes, power/speed athletes as compared to nonathletes.
METHODS: In the present study, 51 elite boxers, 40 elite endurance athletes, 40 elite power/speed athletes and 100 nonathletes (healthy individuals who have never competed in sports) participated in the study. Around 2 ml saliva was collected in a vial containing 2 ml STE buffer from the subjects for genetic analysis as per the ethical guidelines of the Institutional Human Research Ethics Committee, Jiwaji University, Gwalior. DNA was isolated by spin column based method. Further, ACE I/D gene polymorphism was determined by simple PCR and ACTN3 R577X gene polymorphism by PCR-RFLP method.
RESULTS: The genotypic and allelic frequencies of selected gene variants were compared among Indian elite boxers, elite endurance athletes, elite power/speed athletes and nonathletes. The I allele and I/I genotype of ACE I/D gene polymorphism was found to be significantly associated ($p<0.05$) with Indian endurance athletes as compared to non athletes. In Indian boxers, we observed higher frequency of I allele as compared to non athletes. In ACTN3 R577X gene polymorphism, significant allelic and genotypic frequencies were observed in Indian athletic cohort as compared to non athletes.
CONCLUSION: Taken together, we showed for the first time the analysis of ACE I/D and ACTN3 R577X gene polymorphisms in Indian elite athletic cohort. Our results support the earlier findings in other population based studies done worldwide.

INTRODUCTION: Exercise is one of the main mitochondrial regulation factors. The number of mitochondria can increase by 50-100% depending on the training program, improving the energy production capacity of the organism, thus, improving global health. Besides, several genetic polymorphisms in the nuclear genes related to the PPARGC1A-NRF-TFAM mitochondrial biogenesis pathway have been found to correlate with the elite athlete status and with other markers of physical performance and fitness. In addition, several authors have shown that alterations in mitochondrial biogenesis of tumor cells could be risk factors for cancer progression. Thus, the aim of this study is to analyze the frequency of the main genetic polymorphisms involved in these mitochondrial biogenesis pathways in samples of healthy women and women with colorectal cancer.
METHODS: We analyzed 84 DNA samples from tumors of women with colorectal cancer (group 1) and 449 DNA samples from peripheral blood of healthy women as control group (group 2) paired by age with group 1. All the samples were ceded by the Spanish National DNA Bank Carlos III (BNADN) and donated voluntarily after informed consent signature. The genetic polymorphisms rs2267668, rs8192678, rs6949152, rs12594956 and rs1937 of the genes PPARD, PPARGC1A, NRF1, NRF2 y TFAM, respectively, were analyzed by Q-PCR with a StepOne equipment (Life Technologies) with Taqman probes pre-designed for Life Technologies.
RESULTS: All the genetic polymorphisms (rs2267668, rs8192678, rs6949152, rs12594956 and rs1937) satisfied the Hardy-Weinberg equilibrium ($p>0,05$), except for the NRF-1 rs6949152 polymorphism in colorectal cancer ($p=0.044$). No significant differences were found between the genotypic frequencies of the control group and the colorectal cancer group, except for PPARGC1A and NRF-1 ($p=0.035$ and $p=0.023$, respectively). Furthermore, comparing the two groups for the TT genotype frequencies vs. CT and CC genotypes frequencies of

the PPARGC1A rs8192678 polymorphism, we found that having the TT genotype increase 1.9 times the probability to develop colorectal cancer (OR 95% CI=1.905; 3.598-1.008).
CONCLUSION: The presence of the T allele in homozygosis of the PPARGC1A rs8192678 polymorphism may represent a risk factor for the colorectal cancer development. Our results highlight the possible important role of the mitochondrial biogenesis in the development of this kind of cancer. Taking into account that mitochondrial biogenesis is strongly increased by physical exercise, we suggest that it is necessary to further study: i) the role of mitochondrial biogenesis in cancer development and ii) the protective role that physical exercise may play against cancer through the stimulation of mitochondrial activity.

APOLIPOPROTEIN E ε4 ALLELE IS NOT ASSOCIATED WITH ELITE RUGBY STATUS BUT IS PRESENT IN 30% OF ATHLETES

HEFFERNAN, S.M.1,2, KILDUFF, L.P.3, ERSKINE, R.M.4, DAY, S.H.1, STEBBINGS, G.K.1, COOK, C.J.5, GRAINGER, A.2, BRAZIER, J.1, ANTROBUS, M.R., WILLIAMS, A.G.1

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: The APOE ε4 allele is a candidate genetic marker for risk and severity of mild traumatic brain injury (mTBI) including sport-related concussion. ε4 allele carriers experience reduced motor rehabilitation outcomes, poorer neurocognitive outcomes, increased cognitive impairments, amnesia and memory defects following mTBI. Concussion injury (mTBI) rates in elite rugby players are substantial and, consequently, elevated risk and severity of mTBI due to carriage of the ε4 risk allele may be detrimental to both the short-term and long-term health of elite players and reduce their likelihood of career success. Therefore, we investigated APOE ε2/ε3/ε4 of athletes at the elite level of competitive rugby.
METHODS: Genomic DNA was collected from 1006 Caucasian participants, comprising 523 elite rugby athletes and 483 non-athlete controls (RugbyGene study). All samples were genotyped for the APOE ε2/ε3/ε4 variants (rs429358 and rs7412) using real-time PCR. Pearson's Chi-square ($\chi 2$) tests were used to compare genotype frequencies between groups.
RESULTS: No genotype differences ($P > 0.05$) were identified between controls (ε4/ε4 = 2.3%) and either rugby union (ε4/ε4 = 3.7%) or rugby league (ε4/ε4 = 1.3%) athletes. Similarly, when the presence of the ε4 allele (ε4+) was compared to non-carriers, no allelic differences were observed between controls (ε4+ = 28%) and either rugby union (ε4+ = 29%) or rugby league (ε4+ = 33%). Rugby union athletes with international competitive experience showed an underrepresentation of the ε4/ε4 genotype compared to those without international experience (2.6% versus 4.7%, $P = 0.01$), but exhibited a similar frequency to controls (2.3%).
CONCLUSION: These results suggest that APOE ε4 plays little or no role in the likelihood of a rugby athlete achieving elite competitive status. However, our data suggest that ~30% of rugby athletes could be at greater risk of poor recovery from concussion due to carriage of the ε4 APOE allele and this warrants research to establish if previously identified APOE ε4-mTBI associated outcomes exist in elite rugby.

IS-BN03 Do prosthetic legs enhance or hinder running performance?

NATURAL VS. ARTIFICIAL RUNNING: FROM BIOLOGICAL AND PROSTHETIC LIMBS TO GAIT MECHANICS AND SPEED

WEYAND, P.

SOUTHERN METHODIST UNIVERSITY

The sprinting performances of runners with artificial limbs have markedly improved as lightweight, carbon-fiber running prostheses have become more widely available. In the last half-decade, amputee performances have approached or met international standards for non-amputees in two Olympic sprint running events. As the performance gap has narrowed, and the specter of amputee athletes outperforming Olympic medalists has ceased being unrealistic, a basic scientific and athletic policy question has emerged: do artificial limbs artificially enhance sprint running performance? This presentation will consider the evidence currently available to answer this question in two steps. Initially, the relationships between stride timing parameters and the ground reaction forces required to attain elite sprint running speeds in non-amputees will be established. Next, the conformation, or lack thereof, of amputee athletes to the established biological relationships will be considered. Conclusions will be provided regarding speed-enhancement via technology for amputee athletes.

EFFECTS OF RUNNING-SPECIFIC LEG PROSTHESES ON RUNNING, SPRINTING, AND JUMPING PERFORMANCE

GRABOWSKI, A.

UNIVERSITY OF COLORADO BOULDER

INTRODUCTION: Running-specific leg prostheses (RSPs) are made of carbon fiber, mimic the spring-like function of tendons, and allow elastic energy storage and return during level, steady-speed running; however, unlike biological legs, passive-elastic RSPs cannot generate mechanical power anew, vary stiffness, or allow ground clearance during leg swing. Athletes with transtibial amputations (TTAs) using RSPs have lower stance-average vertical ground reaction forces (vGRF) in their affected vs. unaffected leg across running speeds (Grabowski et al. 2010). Also, athletes with bilateral TTAs using RSPs have 23% slower starting block acceleration compared to non-amputees (Taboga et al. 2014). Moreover, when athletes with TTAs negotiate curves, their inside leg and affected leg limit speed (Taboga et al. 2016). It is possible that the RSP configurations used by athletes with TTAs do not optimize performance. Thus, we determined how different RSP model, stiffness, and height affect running and sprinting in athletes with TTAs. We also determined the effects of using an RSP for the long jump.

METHODS: I will present a series of studies that assessed biomechanics, metabolic costs, and top speeds of athletes with unilateral and bilateral TTAs who used 15 different RSP model, stiffness, and height configurations for running and sprinting. I will also present a study of the effects of using an RSP for the long jump.
RESULTS: Athletes with TTAs using J-shaped vs. C-shaped RSPs had 3.4–4.7% lower net metabolic cost of transport (CoT) at 2.5-3m/s (Beck et al. 2017a, b). Use of less stiff RSPs lowered net CoT for athletes with bilateral TTAs. Athletes with TTAs using J-shaped vs. C-shaped RSPs had 6.9–9.8% faster top speeds. Further, RSP stiffness and height affect the biomechanics of athletes with TTAs across speeds (3-9m/s) (Beck et al. 2017a, b, c). Athletes with bilateral TTAs using stiffer RSPs had greater peak and stance average vGRF and overall leg stiffness (inversely related to speed), briefer contact time, and faster step frequency; these effects were mitigated at faster speeds. ±0.02m RSP height changes did not affect biomechanics across speeds (Beck et al. 2017c), but increased RSP height resulted in more asymmetric peak vGRF in athletes with unilateral and increased peak braking GRF in athletes with bilateral TTAs at 2.5-3m/s (Beck et al. 2017a, b). Use of an RSP impairs performance during the approach, but may enhance performance during the take-off step of the long jump.
Discussion:
J-shaped and less stiff than recommended RSPs optimize performance for athletes with TTAs.

SUPER-HUMANS? ATHLETIC PERFORMANCE OF AMPUTEES USING RUNNING-SPECIFIC PROSTHESES

HOBARA, H.

NATIONAL INSTITUTE OF ADVANCED INDUSTRIAL SCIENCE AND TECHNOLOGY

Introduction: Recent developments in carbon fiber running-specific prostheses with energy-storing capabilities have allowed individuals with lower extremity amputation (ILEAs) to regain the ability to run. This phenomenon exemplifies how ILEA sprinters are highly motivated and work hard as well as how current prostheses have advanced. This raises the following question: How fast would running-specific prostheses allow ILEA sprinters to run? The aim of this study was 1) to assess the progression of the winning times of the men's 100-m sprint in the ILEA sprinters at the past Paralympic games, and 2) to investigate average spatiotemporal parameters during 100-m sprint in the ILEA sprinters.
Methods: The winning times of the men's 100-m sprint in the Olympics and Paralympics were obtained from the official website of each organization. For Paralympics, we included the winning times of the men's 100-m sprint in the C (1976 and 1980), A4 (1984), A4-A9 (1988), TS2 (1992), T43-44 (1996-2016) classifications. We performed regression analyses to predict the winning time for future Olympics and Paralympics for non-amputees and ILEA sprinters, respectively. Further, we calculated average step frequency and step length during 100-m sprint in four groups (bilateral transfemoral, unilateral transfemoral, bilateral transtibial and unilateral transtibial amputees) by using publicly-available Internet broadcasts.
Results: The difference in winning times between non-amputees and ILEAs was over 4.0 s in 1976. The ILEAs shaved approximately 1.5 s off the time difference from 1984 to 1988. As of 2018, the difference between the two groups has gone down to 1.00 s. We totally collected 505 samples of spatiotemporal parameters during sprinting from four amputee groups. In our dataset, bilateral transtibial amputees was characterized by the highest step frequency and relatively longer step length when compared to other three amputee groups.
Discussion: Our regression model predicted that ILEA sprinters would outperform non-amputees in 2068, where the predicted winning times could be 9.039 and 9.046 s, respectively. These results indicate that if current trends continue, the fastest sprinters in the world may be ILEAs from 2068 onward. Further, bilateral transtibial amputees may be the 'nearest positions' to surpass non-amputee's sprinting performance because of its step characteristics in conjunction with mechanical leg properties.

OP-PM27 Muscle mass regulation

LOW RESPONDERS TO ENDURANCE TRAINING ALSO EXHIBIT IMPAIRED MUSCLE HYPERTROPHY AND EXACERBATED ATROPHY

DOERING, T.1, WEST, D.2, THOMPSON, J.1, BUDIONO, B.1, LESSARD, S.3, KOCH, L.4, BRITTON, S.5, STECK, R.6, PEAKE, J.6, ASHTON, K.1, COFFEY, V.1

1BOND UNIVERSITY, AUSTRALIA; 2UNIVERSITY OF CALIFORNIA DAVIS, USA; 3HARVARD UNIVERSITY, USA; 4UNIVERSITY OF TOLEDO, USA; 5UNIVERSITY OF MICHIGAN, USA; 6QUEENSLAND UNIVERSITY OF TECHNOLOGY, AUSTRALIA

INTRODUCTION: Variation in the adaptation response to exercise has been well documented, with a significant proportion attributed to genetic factors. Whether there is specificity in the magnitude of adaptation in skeletal muscle with divergent contractile activity is not known. We determined the adaptation response in skeletal muscle of rats selectively bred for high and low response to endurance training when subjected to contrasting stimuli of compensatory hypertrophy and short-term atrophy.
METHODS: Sixty-week old (G19) female rats selected from high responders to training (HRT) or low responders to training (LRT) after an eight-week treadmill training protocol (3×/wk) underwent synergist ablation to induce functional overload of plantaris muscle (14 d, n=7/grp) and unilateral hind limb casting (3 d, n=6/grp). Puromycin injections were administered 30 min prior to sample collection to determine muscle protein synthesis (MPS) via SUnSET method and whole muscle mass was quantified. Muscle mass and Western blots were analyzed using two-way ANOVA with Tukey's post-hoc test ($p<0.05$) and Cohen's d effect sizes.
RESULTS: There were divergent responses for running distance from pre-to-post endurance training which increased in HRT (57 ±28%) but not LRT (-3 ±15%, $p<0.05$). Functional overload induced greater plantaris hypertrophy compared to control limb in HRT (109 ±49 g, $p<0.01$) than LRT (61 ±21 g, $p=0.05$; ΔHRT-LRT d=1.5) but MPS was reduced compared to control in HRT (-26%) and LRT (-13%). Plantaris atrophy was greater in LRT immobilized limbs relative to control group (-58 ±25 g, $p<0.05$) compared with HRT (-23 ±15 g; ΔHRT-LRT d=1.7) which

was associated with lower rates of MPS in LRT (-65%) versus HRT (-48%; ΔHRT-LRT d=1.2). LRT also had more soleus atrophy (-15 ±16 g) than HRT (5 ±13 g; ΔHRT-LRT d=1.8) and rates of MPS were lower in LRT (-75%, p<0.05) than in HRT (-37%; ΔHRT-LRT d=1.0).
CONCLUSION: Selectively bred low-responders to endurance training have impaired muscle plasticity regardless of the mode of contractile overload. Our findings indicate the ability to adapt to diverse training stimuli may share common heritable, genetic underpinnings with profound effects on the specificity and magnitude of adaptation. HRT also appear 'protected' from short-term muscle atrophy and the exacerbated atrophy in LRT was associated with lower rates of translation for muscle protein synthesis. Our novel approach using a unique rat model system shows low responders to endurance training have compromised responses to muscle loading/unloading attributable to a maladaptive genotype.

COUNTERMEASURES TO ALLEVIABLE THE HYPOXIA-INDUCED ATROPHY OF SKELETAL MUSCLE CELLS.

BENSAID, S.
UNIVERSITY OF LILLE

INTRODUCTION: Chronic exposure to severe hypoxia has deleterious effects on the muscular system, in particular on skeletal muscle mass. Hypoxia leads to imbalance of protein homeostasis, decreasing protein synthesis (mainly regulated through PI3K-Akt-mTOR pathway) while increasing protein degradation (mainly through autophagy and proteasomal degradation). In contrast, mechanical stimuli and nutrients, particularly the branched-chain amino acids (BCAA), induce activation of the mTOR pathway in human and rat skeletal muscle as well as and in cultured muscle cells, and decrease protein catabolism. In a model of skeletal muscle cell culture, we attempt to determine whether the combination of mechanical stimulation, nutritional supplementation and reoxygenation could reverse the deleterious effects of hypoxia on protein homeostasis.
METHODS: We induced a hypoxic stress on skeletal muscle murine cells differentiated into myotubes C2C12: four days after differentiation, the C2C12 myotubes were placed into a hypoxic chamber at 4% O2 for 24h. Electrical stimulation (ES) was applied to the cells using a pulse generator to provide electric pulses (30 V at 1 Hz for 3 ms at 997 ms intervals) during 1 hour. Following the ES treatment, myotubes were firstly supplemented with branched-chain amino acids (BCAA: mixture of leucine, isoleucine and valine added to culture media, at concentration of 5 mM) while placed to normoxia during 2 hours (corresponding so to a reoxygenation protocol).
RESULTS: After 24 hours of hypoxia, the morphological analysis of myotubes shows a significant decrease in their diameter, translating the activation of protein degradation pathways at the expense of protein synthesis pathways. When applied separately, each treatment has little effect on the mTOR pathway and morphology of myotubes. However, the combination of EM, supplementation BCAA and reoxygenation lead to an increase of the phosphorylation of key proteins involved in protein synthesis pathway (Akt and p70S6 kinase), thus reflecting their activation state. In addition, morphological analysis shows a significant increase in myotube diameter and fusion index (reflecting the state of differentiation), a sign of the presence of muscle hypertrophy.
CONCLUSION: Our preliminary results suggested that mTOR pathway responds to a combination of electrostimulation, nutrient supplementation and reoxygenation by phosphorylation of key regulators of protein synthesis, and could reverse the protein loss induced by hypoxia.

SUBCUTANEOUS HORMONE INJECTIONS AS MUSCLE FILLERS: CASE OF NECROSIS IN A BODYBUILDER.

SANTOS, A.
SÃO PAULO UNIVERSITY

INTRODUCTION: Use of oil injections in bodybuilding and for body sculpting is highly controversial. Nevertheless, intramuscular oil injections and hormones are being used to enlarge and shape muscle mass among some athletes (Friedman et al., 2016, Ghandourah et al., 2012, Banke et al. 2012). The aim of of this study is to present the case of a 27-year-old, male, Brazilian bodybuilder and personal trainer, with a long history of competitive bodybuilding and anabolic-androgenic steroid use.
METHODS: Employing a qualitative methodology with in-depth interviews, we qualitatively investigated the "discourse analysis" according to Gill (2006), where the interest is the material (interview), in order to tabulate and organize the data about the related case. We describe how hazardous this practice is in order to document the increasing number of victims of this practise.
RESULTS: He injected testosterone enanthate, an oil-based anabolic-androgenic steroid, into his biceps, in a series of subcutaneous injections, with the purpose of "muscle sculpting" his arms. While the right biceps absorbed the substance, the left biceps did not. Following several days with pain, swelling, high fever, and no physical training, our subject was admitted to the emergency room of a local hospital. Magnetic Resonance Imaging revealed multiple, inflamed oil-filled cysts, fibrosis, and necrosis in his left arm, requiring immediate surgical intervention to remove the necrotic tissue, including muscle mass, through a 4-inch incision. Treatment with various antibiotics and anti-inflammatories and several days of hospitalization followed. Treatment continues to the present, including regular monitoring via MRI, and our subject has returned to an exercise regime as part of the recovery program.
CONCLUSION: We call attention to this controversial and clandestine practice (also known as "aesthetic" doping, Santos & Bahrke., 2017), as it is not an isolated phenomenon, but an ever-increasing popular means to build and sculpt the body. Unfortunately, this practice is often associated with dire, unintended adverse effects, including death (Rollins, 1997).

SHORT-TERM DHEA INTAKE AND SUPRAMAXIMAL EXERCISE IN YOUNG RECREATIONALLY TRAINED WOMEN

GRAVISSE, N., VIBAREL-REBOT, N., LABSY, Z., DO, M.C., GAGEY, O., DUBOURG, C., AUDRAN, M., COLLOMP, K.
UNIVERSITY OF ORLEANS

INTRODUCTION: DHEA, as anabolic agent, is banned by WADA because it may improve performance. However, previous studies in young or middle aged men shown no effect on performance and only one study suggested an anabolic effect . The ergogenic and anabolic effect of DHEA in female athletes has never been investigated while DHEA induced a large increase of anabolic hormones in

blood in this population . The aim of this study was to determine whether short-term DHEA intake would improve performance during a supramaximal field exercise in healthy young recreationally trained women. The impact on body composition, salivary steroid hormones, metabolic responses and mood state was also evaluated.
METHODS: Eleven young female volunteers <20.6 ± 0.6 years> under estroprogestative contraception completed four running-based anaerobic sprint tests: just before and after treatment with either oral placebo or DHEA <100 mg/day for 4 weeks>, following a double-blind and randomized protocol. Bioelectrical impedance assessed body composition and subjects responded to a Profile of Mood States questionnaire. At rest and after 5 min of passive recovery, blood samples were collected for lactate measurement and saliva samples for DHEA, testosterone and cortisol analysis.
RESULTS: There was no significant difference in body composition or performance parameters after DHEA administration, despite a tendency toward increased peak power and decreased fat mass. However, DHEA treatment induced a very marked increase in saliva DHEA <3-fold> and testosterone <20-fold> concentrations, with no change in cortisol or lactate levels. No effect on mood state was noted.
CONCLUSION: Short-term DHEA intake did not improve performance or have an anabolic effect in young female recreationally trained athletes like previously noted in men , despite the striking increase in androgenic hormones also observed in blood with this population . Further studies are needed to determine whether a higher dosage would generate an ergogenic and/or anabolic effect in young female athletes.

NANDROLONE DECANOATE ADMINISTRATION DOES NOT ATTENUATE MUSCLE ATROPHY DURING A SHORT PERIOD OF DISUSE

HORSTMAN, A., BACKX, E., SMEETS, J., VAN KRANENBURG, J., DE BOER, D., DOLMANS, J., SNIJDERS, T., DE GROOT, C., VAN LOON, L.

MAASTRICHT UNIVERSITY

INTRODUCTION: A few days of bed rest or immobilization following injury, disease, or surgery can lead to considerable loss of skeletal muscle mass and strength. Such short, successive periods of muscle disuse may be largely responsible for the age-related loss of muscle mass throughout the lifespan. Protein supplementation beyond habitual protein intake levels does not prevent muscle loss during limb immobilization. Therefore, adjuvant pharmaceutical interventions may be required to preserve muscle mass and/or strength during short periods of bed rest or limb immobilization. Prolonged nandrolone decanoate (NAD) administration has been shown to increase fat free mass or muscle performance in several pathological conditions in vivo in humans. Based on these findings it could be speculated that NAD administration may represent an effective adjuvant pharmaceutical strategy to prevent or attenuate disuse atrophy. Therefore, our aim was to assess whether intramuscular injection of NAD prior to leg immobilization can attenuate the loss of muscle mass and strength in vivo in humans.
METHODS: Twenty-eight healthy males (22±1 y) were subjected to 7 d one-legged knee immobilization by means of a full leg cast with (NAD, n=15) or without (CON, n=13) prior intramuscular NAD injection (200 mg). Before and immediately after immobilization, quadriceps muscle cross-sectional area (CT) and leg strength (1-RM) were assessed and muscle biopsies were taken to assess type I and II muscle fiber cross-sectional area. Pre- versus post-immobilization data were analyzed using repeated-measures ANOVA with Group (CON-NAD) as between-subjects factor and Time (pre-post immobilization) as within-subjects factor.
RESULTS: Quadriceps muscle size decreased during immobilization from 7,712±324 to 7,287±305 mm2 and from 7,805±221 to 7,352±202 mm2 in the CON and NAD group, respectively (P<0.01). No differences were observed in muscle loss between CON (6±1%) and NAD (6±1%; P=0.59). Leg strength declined from 56±4 to 53±4 kg (-6±2%) and from 64±3 to 60±3 kg (-7±3%), respectively (P=0.001), with no differences between groups (P=0.55). No changes in type I or II muscle fiber size, number of myonuclei, or satellite cell content were observed in both groups (P>0.05).
CONCLUSION: Intramuscular nandrolone decanoate administration does not preserve skeletal muscle mass and strength during a short period of leg immobilization in vivo in humans.

IGF-I IS NOT SUPPRESSED IN ADOLESCENTS SUBMITTED TO RESISTANCE TRAINING AND CAN BE A MARKER OF TRAINING STATUS.

CORREA-JUNIOR, M., TOURINHO-FILHO, H., MARTINELLI-JUNIOR, C.

SCHOOL OF MEDICINE OF RIBEIRAO PRETO - USP

INTRODUCTION: Regular physical exercise during childhood and adolescence can promote growth and development of muscle and bone mass. Although physical exercise is closely linked to the anabolic function of the GH /IGF-I axis the real impact of resistance training on GH/IGF axis is still unclear. The kinetics of IGF-I and IGFBP-3 during chronic training is not fully understood yet and an initial catabolic phase followed by an later anabolic phase has been reported in swimmers. The aim of the present study was to analyse the kinetics of IGF-I and IGFBP-3 in adolescents undergoing ten weeks of hypertrophy training.
METHODS: Twenty-two male volunteers aged 18 to 25 years with at least 6 month experience in resistance training were enrolled and submitted to a standard hypertrophy training program during 10 weeks. Serum IGF-I and IGFBP-3 concentrations were determined before, 30 min-after and 24h-after the training session at the 1st, 5th and 10th week of resistance training. Body composition, lean mass, muscle mass, fat percentage and body mass index were also evaluated at the 1st, 5th and 10th week and compared to the changes in serum IGF-I and IGFBP-3. Data were paired compared.
RESULTS: IGF-I levels increased during the training session at the 1st evaluation (P=0.03) and also increased during the 10 weeks of training (P<0.003). No changes in IGFBP-3 levels were observed during a training session or during the 10 weeks of training. Body mass, lean mass, fat percentage and body mass index of the volunteers remained unchanged throughout the 10 weeks of training. A negative correlation was observed between the changes in serum IGF-I concentrations and the variation in muscle mass or lean mass when data from the 1st and the 10th weeks were compared (r=-0.62; P=0,002).

CONCLUSION: In summary, no catabolic phase was detected in adolescents during hypertrophy training; IGF-I was sensitive to the acute and chronic effects of resistance training and can be considered as a biomarker of training status in non-athlete volunteers. The negative correlation between the variations in lean mass and IGF-I could suggest a training induced increase in IGF-I sensitivity.

SCLEROSTIN RESPONSE TO HIGH INTENSITY WEIGH BEARING VS NON-WEIGHT BEARING INTERVAL EXERCISE IN MALES AND FEMALES

KLENTROU, P., KOUVELIOTI, R., KURGAN, N., BROWN, D.

BROCK UNIVERSITY

INTRODUCTION: Canonical Wnt/B-catenin signaling pathway is critical for osteoblastogenesis. Sclerostin is an osteocyte-derived osteokine that inhibits bone formation by inhibiting Wnt signaling . Mechanical loading has shown to decrease sclerostin expression, and subsequently enhance bone formation, in cell and animal studies . However, there are only few studies examining the effects of exercise on sclerostin in humans. The aim of this study was to compare the response of sclerostin to two modes of high intensity interval exercise in young men and women.
METHODS: Forty young men and women <22.3 ± 2.5 years old; BMI: 23.5 ± 3.1 kg/m2> performed two high intensity interval trials on the treadmill and cycle ergometer, respectively. Trials consisted of eight 1-minute high intensity cycling or running intervals , separated by 1-min passive recovery. Blood samples were collected pre-exercise, and 5 minutes, 1 hour, 24 hours and 48 hours post-exercise. Serum sclerostin levels were measured by ELISA.
RESULTS: A 3-way repeated measures ANOVA showed significant time and sex effects, as well sex-by-time interaction , while the exercise mode effect was not significant. Sclerostin levels significantly increased at 5 min post HIIE , and returned to near baseline values by 1 hour following the exercise without significant differences between the two modes of HIIE.
CONCLUSION: In young men and women, one session of weight bearing and non-weight bearing HIIE leads to an increase in sclerostin 5 min post-exercise. Such an increase in sclerostin was previously found 5 min post plyometric exercise in men . This finding suggests that regardless of impact, high intensity exercise stimulates a similar osteocyte response in both sexes. Further research is required to explore how mechanical loading and/or other systemic factors, such as post-exercise induced inflammation, contribute to the effects of exercise on sclerostin and bone metabolism in general.

LEUCINE INDUCES EXPRESSION OF IGF1 AND IGF1-DEPENDENT GENES IN HUMAN MYOBLASTS

LEDNEV, E.M.1,2, FURALYOV, V.A.3, KRAVCHENKO, I.V.3, LYSENKO, E.A.1,2, POPOV, D.V.1,2

1:INSTITUTE OF BIOMEDICAL PROBLEMS OF THE RAS,2:FACULTY OF FUNDAMENTAL MEDICINE,LOMONOSOV MOSCOW STATE UNIVERSITY,3:RESEARCH CENTER OF BIOTECHNOLOGY RAS

INTRODUCTION: IGF1 plays an important role in the regulation of connective tissue, bone and muscle homeostasis in adults. Experiments in rodents demonstrated that leucine (Leu) intake increases the systemic IGF1 level (Teodoro et al., 2012; Pedrosa et al., 2013; Pedroso et al., 2014). Studies in HeLa, HEK293T and COS7 cells revealed an obligate two-step mechanism of mTORC1 regulation: pre-activation (priming) by arginine (Arg) and then activation by Leu (Dyachok et al., 2016). The aim of our research was to investigate effect of Leu on expression of IGF1 and IGF-1-dependent genes in human myoblasts. We have assumed that Leu may regulate the gene expression in human myotubes, and this effect may be improved by pre-activation with Arg.
METHODS: After starvation (1 h), myotubes were incubated with Arg (0,4 mM, 30 min), or Leu (0,8 mM, 30 min), or Arg and then Leu. The 4E-BP1Thr37/46 and S6K1Thr389 phosphorylation (targets of mTORC1) was evaluated by Western blot. In the second experiment, after starvation (1 h) myotubes were incubated with Leu (0,8 mM, 24 h), or Arg (0,4 mM, 24 h) and then Leu (24 h). Expression of IGF1, COL1A1, COL3A1, COL5A1, SREBF1, HMGCR, LOX genes was measured by qPCR.
RESULTS: Arg did not affect the S6K1Thr389 or 4E-BP1Thr37/46 phosphorylation, whereas Leu increased proteins phosphorylation (10-fold and 3,5-fold, respectively), but the most significant effect was related with consecutive Arg-Leu stimulation. Leu had little effect on the IGF1 and IGF1-dependent genes expression. The consecutive Arg-Leu stimulation increased expression of IGF-1Ea, MGF, COL1A1, COL5A1 and SREBF1 (3-fold, 5,8-fold, 3,6-fold, 1,4-fold, and 1,4-fold, respectively).
CONCLUSION: Two-step mTORC1 activation by Arg and Leu in human myoblasts was shown. The same effect for leucine-stimulated gene expression was found: the consecutive Arg-Leu stimulation leads to the most significant activation of genes expression. It means that expression of IGF1 and IGF1-dependent genes is regulated by amino acids via a two-step mechanism.
The study was supported by the Science research program of RAS presidium «Fundamental research for biomedical technologies» for 2018-2020 yy.

MUSCLE FIBRE TYPE SPECIFIC EXPRESSION OF LIPOLYTIC PROTEINS IN SKELETAL MUSCLE OF ENDURANCE TRAINED INDIVIDUALS

SHAW, C.S., SWINTON, C., MORALES-SCHOLZ, G.M., ALDOUS, A., MURPHY, R.M., HOWLETT, K.F.

DEAKIN UNIVERSITY

INTRODUCTION: A high capacity for fat oxidation during exercise in endurance trained athletes is attributed to a greater utilisation of intramuscular lipid (IMCL) in type I muscle fibres. IMCL breakdown is regulated by lipolytic enzymes and proteins contained on the lipid droplet surface but little is known about the muscle fibre type specific abundance of these key lipolytic components in endurance athletes. Recent findings suggest that autophagic degradation of lipid droplets and chaperone-mediated autophagy may also regulate lipolysis, however their role in IMCL breakdown has not been explored. This study investigated the muscle fibre type specific abundance of LD proteins, lipolytic enzymes and components of the autophagy/lysosome system in endurance trained individuals.
METHODS: Endurance trained (n=7, 28±3 years, BMI 24.0±0.8, VO2max 62.6±1.6 ml·min-1·kg-1) and untrained (n=8, 25±1 years, BMI 25.1±0.6, VO2max 44.9±1.9 ml·min-1·kg-1) males were recruited. An incremental exercise test was performed to determine maximal fat oxidation rates and maximal oxygen uptake. Muscle biopsies were collected and muscle fibre type composition and fibre type-specific IMCL content was assessed with immunofluorescence microscopy. Muscle fibre type specific analysis of lipolytic and autophagy-related proteins was performed with immunoblotting of pooled single muscle fibres.
RESULTS: Endurance trained individuals displayed a higher peak fat oxidation rate (0.49±0.05 vs. 0.20±0.03 g·min-1, $P<0.05$), a greater proportion of type I muscle fibres and higher IMCL content compared to untrained individuals ($P<0.05$). Type I muscle fibres from endurance trained individuals had a greater abundance of ATGL. In whole muscle, the endurance trained group also had greater abundance of PLIN2, PLIN5 and ATGL compared to the untrained group ($P<0.05$) but there were no differences in HSL. Furthermore, the trained group had greater abundance of markers of autophagy flux (LC3-II/I, GABARAP), lysosome content (LAMP2) and chaperone-mediated autophagy (LAMP2A, all $P<0.05$).
CONCLUSION: These results demonstrate that the higher rates of IMCL utilisation during exercise in endurance trained athletes are related to fibre type specific upregulation of IMCL storage and expression of lipolytic regulatory proteins, alongside a greater proportion of type I muscle fibres. These results also demonstrate that muscle from endurance trained athletes has a greater abundance of the autophagic machinery which may have relevance for the regulation of IMCL breakdown.

COMPARATIVE ANALYSIS OF INFLAMMATORY, METABOLIC AND IGF-1 GENE EXPRESSION AFTER AEROBIC, RESISTANCE AND COMBINED EXERCISE IN MUSCLE OF TYPE 1 DIABETIC PATIENTS

ANNIBALINI, G.2, MINNOCK, D.1, CONTARELLI, S.2, SALTARELLI, R.2, GUESCINI, M.2, LEROUX, C.1, STOCCHI, V.2, BARBIERI, E.2, DE VITO, G.1

UNIVERSITY OF URBINO CARLO BO

INTRODUCTION: The identification of the optimal exercise modality, in Type 1 diabetes (T1DM) patients [1], is essential to maximize the beneficial effects of exercise. In this study, muscle biopsies from T1D patients were obtained before and after an acute bout of either aerobic, or resistance or combined exercise to quantify the mRNA expression level response of genes involved in inflammation, metabolism and muscle growth.
METHODS: Six sedentary T1DM patients (3M/3F) performed on separate days, 40 min of either aerobic (AER; 80% of HRR), resistance (RES; 30%-80% of 1RM) or combined resistance and aerobic, exercise (COMB; 20 min each). Muscle biopsies were taken from vastus lateralis muscle before and immediately after each session. A 4th no-exercise session was used as control. Gene-specific primers were used to amplify TNF-α, IL-6, MCP-1, IGF-1 isoforms, PGC-1alpha, PPAR-alpha, PPAR-delta and GLUT4 mRNAs by real-time PCR. Significant effects were assessed by analysis of variance with repeated measures.
RESULTS: Post-exercise TNF-α, IL-6, MCP-1 mRNA levels significantly increased compared to no-exercise. Metabolism-related gene expression (PGC-1alpha, PPAR-alpha, PPAR-delta and GLUT4) did not change. Both AER and RES sessions promoted the splicing of IGF-1Ea variant while the mRNA expression of IGF-1Eb and IGF-1Ec did not change.
CONCLUSION: In this study, we showed an increased expression of muscle cytokine mRNAs after an AER, RES and COMB exercise in T1DM patients. This inflammatory response is probably implicated in the activation of anabolic processes, underlying muscular repair and regeneration [2]. We also demonstrated that the AER and RES exercise both increased IGF-1Ea/IGF-1Eb ratio in the muscle of T1DM patients. The observed increase in muscle IGF-1Ea mRNA is particularly important since local (paracrine/autocrine) IGF-1Ea expression plays a central role in skeletal muscle hypertrophy [3]. A deeper understanding of the adaptive response in molecular signalling to acute exercise may facilitate efforts to improve skeletal muscle health in T1D adopting a more informed and effective exercise prescription in these patients.

THE ACUTE EXERCISE METABOLISM OF THE SO-CALLED MYOKINE BAIBA

STAUTEMAS, J.1, VAN KUILENBURG, A.2, STROOMER, L.2, VAZ, F.2, LEFEVERE, F.1, BLANCQUAERT, L.1, EVERAERT, I.1, DERAVE, W.1

1.GHENT UNIVERSITY 2. UNIVERSITY OF AMSTERDAM

INTRODUCTION: Beta-aminoisobutyric acid (BAIBA), also known as 3-amino-2-methylpropanoic acid, is a non-proteinogenic amino acid. Recently, Roberts et al. (1) suggested that BAIBA is a myokine involved in browning of fat. However, the authors did not provide evidence for an acute effect of exercise supporting their statement and did not take into account the metabolic distinct R- and S-enantiomer of BAIBA. R-BAIBA is an intermediate of the thymine degradation pathway, whereas S-BAIBA is derived from valine degradation. Thymine degradation primarily occurs in liver, whereas valine degradation also takes place in muscle. Concerning these enantiomers, there is at this point no consensus about the concentration of R- and S-BAIBA in plasma.
METHODS: In order to elucidate plasma ratios of R- and S-BAIBA and to investigate the acute effect of exercise on these enantiomers, 15 healthy recreationally active subjects were recruited. They participated in a randomized crossover control trial where they exercised for 1h at 40% of Wmax or remained at rest. R- and S-BAIBA were determined in plasma samples (2). Results were analysed using 2 x 4 Repeat-

ed Measures ANOVA with condition (exercise vs rest) and time (4 time points) as within factors. Paired sample t-tests were performed following significant interaction effects.
RESULTS: The mean plasma concentration of baseline R-BAIBA was 67 times higher (1.734±0.821 vs 0.029±0.008 μM) compared to S-BAIBA. The amount of baseline R-BAIBA was not correlated to the amount of baseline S-BAIBA in plasma ($r = -0.263$; $p = 0.344$). Exercise was able to induce a 13% ($p < 0.001$) and 20% ($p < 0.001$) increase in R-BAIBA and S-BAIBA, respectively (condition*time: $p < 0.001$). The increase in S-BAIBA is only 6 ± 4 nM. During a 30 minutes recovery, R-BAIBA concentrations returned to lower levels whereas the S-BAIBA increased even further up to 35±12 nM.
CONCLUSION: We report that S-BAIBA is only 2.03±0.99% of the total amount of BAIBA in plasma. A low intensity exercise was able to induce an acute increase in both R- and S-BAIBA. Our data suggest that although both enantiomers acutely increase during exercise, only S-BAIBA is likely muscle derived and therefore a true myokine.

ASSOCIATIONS BETWEEN SUBJECTIVE MUSCLE SORENESS AND REDOX BIOMARKERS IN AMERICAN COLLEGE FOOTBALL

MCKAY, B.A.1, DELANEY, J.A.2, MURRAY, A.2, PEDLAR, C.3,4,5, SIMPKIN, A.J.4,6, LARKIN, T.A.1, LEWIS, N.A.3,4, SAMPSON, J.A.1

1UNIVERSITY OF WOLLONGONG, AUSTRALIA 2UNIVERSITY OF OREGON, EUGENE, USA 3ST MARY'S UNIVERSITY, TWICKENHAM, UK 4 ORRECO LTD, NATIONAL UNIVERSITY OF IRELAND BUSINESS INNOVATION CENTRE, GALWAY, IRELAND 5

INTRODUCTION: American College Football (ACF) is a high-impact, collision-based sport, that frequently requires repeated maximal efforts, that results in high levels of fatigue and muscle damage [1]. Subjective questionnaires are commonly used to monitor player wellbeing, offering basic but informative athlete wellness data. Objective biological measures are an attractive tool for athlete monitoring for example, endogenous measures of oxidative stress (OS) are associated with excessive fatigue and underperformance [2]. However, limited data exist describing the relationship between subjective and objective measures. This investigation will therefore assess whole blood measures of OS to determine associations between OS and subjective measures of soreness in ACF players.
METHODS: 23 male ACF players (21.1±1.2 years; 108.0±20.0 kg) participated in this longitudinal study; Three samples/player were taken in week one (prior to pre-season training) to determine baseline and then once per week over a 9-week data collection period during the college football season. Redox was assessed using FORT (free oxygen radicals test) and FORD (free oxygen radical defense) assays from a fingertip blood sample. The FORT:FORD ratio provided an index of oxidative stress (OSi). Perceived muscle soreness was recorded each morning using a 5 point scale (1 = high soreness and 5 = low soreness). Linear mixed models were used to analyse the effect of a two within-subject standard deviation (SD) change in OS on subjective muscle soreness. The effects were interpreted using a magnitude-based inference network, and are presented as standardised effect size ± 90% confidence intervals (ES; 90% CI).
RESULTS: At baseline, FORT and FORD averaged 1.95±0.3 mmol·L-1 and 1.47±0.2 mmol·L-1 respectively. Similar mean values were observed during the college football season (FORT=1.94±0.4 mmol·L-1 and FORD=1.43±0.2 mmol·L-1). However, variations in FORT (1.02±0.26 mmol·L-1) and FORD (0.43±0.10 mmol·L-1) were evident across the 9-week data collection period. A two SD change in FORT and FORD were associated with likely small increase and decrease in perceived muscle soreness (4.9%±3.1%, ES = 0.44±0.3 and -3.4%±2.8%, ES = 0.39±0.3) respectively. Collectively, a two SD change the in OSi was responsible for a very likely small increase in perceived muscle soreness (9%±5.5%, ES = 0.56±0.3).
CONCLUSION: In this investigation, perceptions of muscle soreness were likely associated with changes in OS. Further investigations to determine the cause of the fluctuations in OS observed in team sport are warranted. This information may be useful for sports scientists to help select appropriate athlete monitoring variables.

OP-PM29 Epidemiology

THE EFFECT OF MATCH FREQUENCY ON THE PERCEPTUAL RECOVERY AND WELLBEING RESPONSES OF ADOLESCENT RUGBY UNION PLAYERS.

PHIBBS, P.J., JONES, B., TILL, K.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Adolescent rugby union players can play multiple matches per week, but the subsequent effect on recovery and wellbeing is unknown. The aim of this study was to determine the perceptual recovery and wellbeing responses of under-18 rugby union players during weeks with different match frequencies.
METHODS: Match and training load data , perceptual recovery <0-10 perceived recovery scale: PRS>, and wellbeing <1-5 Likert scales for fatigue, sleep quality, upper and lower-body soreness, stress, and mood> were collected daily from 20 academy players across a 14-week school rugby union season. Differences in weekly summated training and match loads, PRS, and wellbeing between 0, 1, and 2-match weeks were assessed using Cohens d effect sizes <±90% confidence intervals> and magnitude-based inferences.
RESULTS: Total weekly match and training sRPE loads increased substantially with match frequency <1210 ± 571, 1511 ± 489, and 1692 ± 517 AU for 0, 1, and 2-matches/week, respectively>. Perceived recovery was reduced with increases in match frequency <45.4 ± 7.8, 44.0 ± 8.3, and 41.9 ± 8.8 AU for 0, 1, and 2-matches/week, respectively>. PRS was possibly lower with 1 match/week, and likely lower with 2 matches/week compared to weeks with no matches, respectively. PRS was also possibly lower in weeks with 2 matches compared to 1 match. Wellbeing was also reduced during weeks with matches <145.2 ± 15.1, 141.6 ± 15.7, and 141.0 ± 15.5 AU for 0, 1, and 2-matches/week, respectively>. Wellbeing was possibly lower with 1 match/week, and possibly lower with 2 matches/week compared to weeks with 0 matches, respectively. Differences in wellbeing between 1 and 2-matches/week were unclear. There were likely increases

in perceptual fatigue and lower-body soreness during weeks with matches, but differences in sleep quality, stress, and mood were either trivial or unclear between all match frequencies.
CONCLUSION: This is the first study to examine the effects of playing multiple games per week on perceptual recovery and wellbeing in adolescent rugby union players. There were small reductions in perceived recovery and wellbeing during weeks with either 1 or 2 matches compared to weeks with 0 matches, associated with an increase in total match and training loads. However, there were no substantial differences between perceptual recovery and wellbeing between weeks with 1 or 2 matches. Strength and conditioning training, and other activity loads were reduced to compensate for additional match loads during weeks with multiple matches, which may not be optimal for developing important physical qualities for rugby union . Rugby match-play also carries a significantly higher risk of injury compared to training. Therefore, decisions regarding appropriate match exposures for adolescent rugby union players should also take these factors into consideration.

INCIDENCE OF SPORTS INJURY-RELATED HOSPITALISATIONS IN AUSTRALIAN CHILDREN OVER A TEN-YEAR PERIOD: A NATIONWIDE POPULATION-BASED COHORT STUDY

LYSTAD, R.P., CURTIS, K., BROWNE, G., MITCHELL, R.

MACQUARIE UNIVERSITY

INTRODUCTION: Injury is a leading cause of death and disability among children worldwide, and participation in sport and active recreation is a common contributor to this burden. To date there have been no nationwide population-based study examining trends in sports-related injury among Australian children. This study aims to (1) quantify and describe the incidence and cost of sports injury-related hospitalisations in Australian children, and (2) examine the temporal trend over a 10-year period.
METHODS: This population-based cohort study used linked hospitalisation and mortality data of children aged ≤16 years who were hospitalised for sports-related injury in Australia during 1 July 2002 to 30 June 2012. Age-standardised incidence rates were calculated with 95% confidence intervals (CI). Negative binomial regression was used to examine change in temporal trends in incidence rates.
RESULTS: There were 130,167 sports injury-related hospitalisations of Australian children aged ≤16 years during the 10-year study period. The overall incidence rate was 281.0 (95%CI: 279.5–282.6) per 100,000 population. The incidence rate in male children (419.7 [95%CI: 417.1–422.4] per 100,00 population) was more than three times that of female children (134.8 [95%CI: 133.2 to 136.3] per 100,000 population). There was no significant decline in the annual incidence rate during the 10-year study period (-1.05% [95%CI: -3.01% to –0.95%]; P=0.302). The most common sports activities resulting in injury-related hospitalisation were team ball sports (43.1%) and wheeled non-motor sport (22.3%). The total direct hospital costs of sports injury among Australian children was AUD$39.6 million per year over the 10-year study period.
CONCLUSION: There has been no significant decline in sports injury-related hospitalisation rates among children in Australia during 2002–03 to 2011–12. This suggests that sports injury prevention initiatives in Australia to date have either been inadequate or ineffective. There is a clear need to develop and implement a national injury prevention strategy to reduce the burden of sports injuries among Australian children.

SELF-REPORTED COGNITIVE DIFFICULTIES ARE NOT SUPPORTED BY OBJECTIVE MEASURES IN RETIRED CONTACT SPORT ATHLETES; A SYSTEMATIC REVIEW

CUNNINGHAM, J., BROGLIO, S., OGRADY, M., WILSON, F.

TRINITY COLLEGE DUBLIN

INTRODUCTION: In the last decade, a dramatic shift in both public and scientific perception around the long-term consequences of sports-related concussion (SRC) is evident. An injury which was once viewed as a short-lived impairment of neurological function, is now being implicated in a number of long-term neurocognitive sequelae. While the short-term effects of concussion on cognitive processes are known, the long-term consequences are less understood. The purpose of this paper aimed to synthesize and present the available evidence examining cognitive health status in retired athletes.
METHODS: Six databases were systematically searched from inception to October 2017 using medical subject headings and keywords. Cross-sectional studies of living retired male or female athletes in which at least one cognitive test was used as an outcome measure were included. Two reviewers independently screened studies for inclusion. Data extraction was performed using STROBE guidelines. Methodological quality was assessed independently by two reviewers using the Downs and Black methodological quality tool.
RESULTS: The search yielded 18 cross-sectional observational studies that were included in a qualitative synthesis. Overall methodological quality of the included studies was moderate. Ten of 18 studies found significantly increased subjective reports of cognitive difficulties experienced by former athletes in comparison to non-athlete control groups/normative data. There is mixed evidence of measurable cognitive deficits in neuropsychological testing in retired athletes. Six studies reported a frequency-response relationship, with greater cognitive impairments (subjective/objective) in those with greater levels of exposure to head impacts or concussions. Eight other studies did not find such a relationship. Thus, evidence for long-term cognitive dysfunction in retired athletes with a history of head impact exposure is mixed.
CONCLUSION: Findings are inconsistent and investigations are commonly influenced by methodological biases and flaws, reducing the overall quality of the studies. Retired players have increased self-reported cognitive issues in retirement. However, these subjective complaints are not detected in the majority of standard neuropsychological tests being used. Significant associations between head impact exposure and performance on neuropsychological tests are not present. Studies which have explored the rate of mild cognitive impairment (MCI) in retired players to date have been based on self-reported cognitive difficulties and findings have been mixed. Current evidence suggests that large gaps remain in understanding the potential cause-and-effect relationships between SRC and long-term brain health in athletes. Further research is required to unravel the complex interaction between previous head impact exposure and the many other factors which may influence cognitive health in the aging retired athlete.

REQUIREMENTS FOR HEALTH RELATED EXERCISES IN PRIMARY PREVENTION FOR EMPLOYEES OF STATIONARY NURSING HOMES

OTTO, A.K., STAACK, S., WIGGERING, C., WOLLESEN, B.

UNIVERSITY OF HAMBURG

INTRODUCTION: The percentages of older people receiving care are increasing and characterized by multimorbidities. This results in work intensification and high stress levels for employees in nursing homes. Frequent stressors are confrontation with death and dealing with elderly people suffering from behavioral disorders (Pélissier et al., 2015). In addition, physical loads in combination with psychosocial work factors affect the risk of musculoskeletal disorders (Jansen et al., 2004). Prevention programs should target the specific problems and requirements of the different professions in nursing homes. The aim of this study is to analyze the specific health related problems of the professions (geriatric nurses [1], professional housekeepers [2], psycho-social carers [3]) to develop individualized health promotion programs.
METHODS: N= 194 (N[1]= 139, age: 40.5±12.2 years; N[2]= 28, age: 44,5±11,5 years; N[3]= 27, age: 49.8±8.2 years) employees of six stationary nursing homes were included in a quantitative survey (Nordic Questionnaire, Questionnaire of Slesina, SF-12, TICS, preferred physical activities). The evaluation was conducted considering the three professions. The analysis incorporated Chi²-Tests and Analysis of variance (SPSS 23).
RESULTS: The comparison of the professions revealed a significant (p= 0.033) lower mental score of the SF-12 for geriatric nurses in comparison to professional housekeepers (5.94, 95% -CI [0.35, 11.53]). There were no significant differences between groups regarding stress values. All professions were burdened by time pressure and pressure to perform. In addition, the geriatric caregivers and professional housekeepers were adversely affected by high physical demands and poor postures. Musculoskeletal disorders like low back, shoulder and neck pain were identified in all types of professions. Results indicate that geriatric nurses and professional housekeepers preferred strength training whereas psycho-social carers preferred relaxation training.
CONCLUSION: Specific health promotion programs according to the profession are desirable to reduce work related stress as well as musculoskeletal disorders. Especially geriatric nurses and professional housekeepers require programs to reduce mental stress in combination with ergonomic movement programs. Surprisingly, psycho-social carers reported musculoskeletal disorders in spite of low physical demands. Furthermore, future research should assess whether these effects are caused by age or high stress levels.

THE PREVALENCE OF BAREFOOT ACTIVITY IN NEW ZEALAND SECONDARY SCHOOL BOYS

FRANCIS, P., SCHOFIELD, G., MACKAY, L.

LEEDS BECKETT UNIVERSITY, AUCKLAND UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Humans were barefoot for millions of years during evolutionary history. During the past few centuries, particularly in industrialised countries, walking and running have generally been carried out in shoes. It is often assumed that economic resource is the major reason that non-industrialised countries such as Africa have a higher prevalence of barefoot activity. New Zealand is an industrialised country with comparable resources to that of many European countries, however, it seems to remain socially acceptable to carry out barefoot activities. A chance observation of students competing barefoot on a tartan track, prompted us to determine the prevalence of barefoot activity in an all-boys secondary school in Auckland New Zealand.
METHODS: Following ethical approval from Auckland University of Technology research ethics committee, an 11 question survey was administered at an Auckland boys secondary school to determine the footwear habits of students during: a) daily life (at home, in the supermarket and on the bus) b) school life (c) physical education class and (d) sport in general. Participants were asked to select whether they were barefoot: 1) most of the time, 2) around half of the time or 3) none of the time. Participants were also asked to specify, when running at their most recent athletics event (100m – 3,000m) on a track, whether they ran barefoot, in shoes, in spikes or another type of footwear. Descriptive statistics were computed using SPSS.
RESULTS: A total of 714 students (Year 9 – Year 13; 12 – 19 years) responded to the survey. The school was located in an area of high socioeconomic status (Decile 9 out of 10). More than half of the sample reported being barefoot most of the time at home (n=404, 56.6%) and during PE class (n=420, 58.8%). More than half of the sample reported being barefoot around half of the time or more during sport (n=380, 53.2%). A smaller amount went to the supermarket (n=140, 19.6%) or took the bus (n=59, 8.3%) whilst barefoot around half of the time or more. Over 50% of students competing in the 100m (n=200/397) and 200m (n=118/231) competed barefoot. The percentage of barefoot competitors decreased with increasing distance from the 400m (n=68/147; 46%) to the 3,000m (n=21/67; 31%).
CONCLUSION: The results of this survey demonstrate that over 80% of students at an all-boys secondary school, of high socioeconomic status, take part in physical education classes around half of the time or more in bare feet. These results point towards a cultural difference between New Zealand and other modern industrialised countries, rather than the absence of resources to purchase shoes. Given that differences in foot morphology occur between those who grow up barefoot and shod, we need to consider what the evidence is for shoe prescription in otherwise healthy adolescents.

MOTOR CONTAGION IN SINGLE-LIMB STANCE BY MEANS OF BIOLOGICAL AND NON-BIOLOGICAL POINT LIGHT DISPLAYS DOES NOT INDUCE POSTURAL REACTIONS BUT ENHANCES MUSCLE ACTIVITY

EILS, E., BROCKMANN, T., DE LUSSANET, M.H.E., ZENTGRAF, K.

INSTITUTE OF SPORT AND EXERCISE SCIENCES

INTRODUCTION: Copying the actions of others is relevant in sports-related settings, e.g. when motor learn-ing of new motor skills. Although there seems to be evidence that humans are prone to copying the action of others (Heyes, 2011), it might not be as generalizable

as previously suggested (Tia et al., 2011) and the mechanisms why and when subjects are influenced to copy others' movements are still unclear. A motor contagion effect (MCE) resulting in increased body sway when observing a point-light display (PLD) of a model in postural imbalance in comparison to a non-biological stimulus might not only result in increased movement, but also in an adjustment of muscle activity. Therefore, the aim of the present study was to investigate the influence of biological and non-biological stimuli on muscle activity when observing a PLD of postural imbalance.
METHODS: 29 subjects participated in the study. Subjects stood in single limb-stance (SLS) and observed different PLD conditions: a person in single-limb-stance (biomotion-BM), moving dots without biological information (non-BM), and a static control stimulus (CON). Center of Pressure (COP) excursions were captured by means of a force plate, muscle activity of tibialis anterior (TA), peroneus longus (PL) and medial gastrocnemius (GM) by bipolar EMG-electrodes, and body sway by using reflective markers (Qualisys, Sweden). Sway excursions of the COP and the markers as well as RMS muscle activity were used for analyses. A one-way repeated measures ANOVA was used for statistical analysis (Bonferroni-Holm method for post-hoc testing).
RESULTS: The results showed no significant differences between the three conditions for COP and body-part movements. Significant differences were found in muscle activity of PL between conditions ($F(2,56) = 4.2$, $p = .02$, $eta^2 = .13$). Post-hoc tests revealed differences between CON and BM but not between BM and non-BM.
CONCLUSION: Muscle activity of PL is of importance when regulating postural sway in SLS (Louwerens et al. 1995). Although results indicate an increased muscle activity for BM compared to CON, the expected MCE could not be identified. Complementary inhibition processes preventing loss of balance especially in SLS might play a crucial role, masking MCE. Results indicate again that the observed MCE postulated from Tia et al. (2011) could not be verified.

MIRROR OBSERVATION IN COMBINATION WITH MOTOR IMAGERY REDUCES INTRACORTICAL INHIBITION IN THE IPSILATERAL PRIMARY MOTOR CORTEX DURING UNILATERAL PLANTARFLEXIONS.

MARQUEZ, G.1, TAUBE, W.2, SCHMID, N.2, KELLER, M.2,3

1. CATHOLIC UNIVERSITY OF MURCIA; 2. UNIVERSITY OF FRIBOURG; 3. UNIVERSITY OF BASEL

INTRODUCTION: Literature suggests that both motor imagery (MI) and mirror observation (MO) promote skill learning (1). These behavioural adaptations are explained by neural activation in motor centers of the brain while imagining and/or observing a specific motor task. In order to provide recommendations for the conception of interventions using non-physical training, the current study elaborated how the brain is activated during MI and MO but also during a combination of MO with MI (MO+MI). It was hypothesized that MO+MI results in enhanced brain activations compared to using solely MO or MI.
METHODS: Sixteen healthy participants (26.9 ± 4.6 years, 6 female) were recruited for the study. Participants were instructed to perform unilateral plantarflexions with the right leg while the left leg (from which was measured) was always at rest. Contractions of the right leg triggered the stimulator. Transcranial magnetic stimulation was used to assess corticospinal excitability (CSE) and short-interval intracortical inhibition (SICI) in the left hemisphere. To test for modulations in spinal excitability, peripheral nerve stimulation was applied to the left posterior tibial nerve. Neural activation in the right (ipsilateral) hemisphere to the contracting leg was recorded in four experimental conditions: control (neither MO nor MI), MO, MI and MO+MI. To test for a muscle-specific activation, the left soleus (SOL) and left tibialis anterior (TA) muscles were recorded.
RESULTS: Plantarflexor contractions of the right foot were performed identical in the four conditions indicating that stimulations occurred at the same phase of the movement. The size of the motor evoked potentials of left SOL and TA did not differ between conditions ($p>0.08$). However, our results revealed significantly ($p<0.01$) reduced SICI of the resting left SOL during MO+MI (25.5%) compared to the control condition (36.8%). In addition, this modulation of SICI was not evident in left TA. Regarding the SOL H-reflex of the left leg, no differences were found between conditions.
CONCLUSION: The present study demonstrated that the MO+MI-condition was most effective to influence motor cortical inhibitory networks within M1 of the resting (right) hemisphere. Furthermore, it seems that this modulation is direction- and/or muscle-specific because it was not evident for the left TA. Future studies should determine whether the use of MO+MI could enhance interlimb transfer effects. Thus, the data of the present study could help to improve the rehabilitation of patient groups with unilateral orthopaedic and neurological conditions.

THE CORTICOSPINAL EXCITABILITY INCREASE AFTER SOMATOSENSORY STIMULATION AT REST AND DURING MOTOR IMAGERY IS TIME INTERVAL-DEPENDENT

TRAVERSE, E., LEBON, F., MARTIN, A.

INSERM UNIVERSITÉ BOURGOGNE FRANCHE-COMTÉ

INTRODUCTION: Saito et al., 2013 demonstrated that corticospinal excitability increased during motor imagery (MI) combined with somatosensory stimulation (SS) induced by electrical stimulation of the peripheral nerve. These modulations may involve peripheral and/or cortical processes, especially the primary motor cortex and primary somatosensory cortex, known to be activated during kinesthetic MI modality. The aim of the current study was to assess the interaction between SS and MI on CSE using different time-interval.
METHODS: Six subjects performed the experiment. Transcranial magnetic stimulation (TMS) of the primary motor cortex was applied at an intensity of 120% of rest motor threshold to evoke an unconditioned motor evoked potential (MEP) at rest or during an imagined maximal plantar flexion of the right foot. SS was induced using a triplet electrical stimulation applied on the posterior tibial nerve at 80% of motor threshold at rest or during MI. To test the effect of afferences on CSE, TMS was applied 1 to 150ms after SS to evoke a conditioned MEP (MEPc) at rest and during MI. Peak-to-peak MEP and MEPc amplitudes were analyzed for the soleus muscle and expressed as function of the unconditioned MEP.
RESULTS: At rest, MEPc amplitude increased for the time intervals of 20 to 50ms (mean : +38 ± 24%) and from 100ms (+37.4 ± 29%). During MI, unconditioned MEP increased by +61.1 ± 13% in comparison to rest. MEPc amplitude was not modulated up to 100ms and increased at 150ms (+46.4 ± 22%). At 150 ms, MEPc increased during MI and rest was similar.

CONCLUSION: At rest, CSE increased when the stimulation was induced at least 20ms after the SS. This latency allows the somatosensory volley to reach the cortical level (Carson & Kennedy, 2013), specifically the primary somatosensory cortex that modulates the primary motor cortex activity (Veldman et al., 2015). During MI, SS did not further increase CSE. This lack of modulation could be possibly due to a conflict that arises at the primary motor cortex level between neural activities induced by MI and those induced by SS. Beyond 100ms, the cortical network possibly returns to its basic state and so the CSE similarly increased at rest and during MI combined with SS.

CHANGES IN BRAIN OSCILLATIONS AND EVOKED-RELATED POTENTIALS DURING PROLONGED MOTOR IMAGERY AND SUBSEQUENT ACTUAL ISOMETRIC KNEE EXTENSIONS

JACQUET, T., PAGEAUX, B., BARD, P., PFISTER, P., LEPERS, R., POULIN-CHARRONNAT, B.

UNIVERSITÉ BOURGOGNE FRANCHE-COMTÉ

INTRODUCTION: Motor Imagery (MI) is the mental simulation of action without concomitant movements. Recently, it has been shown that prolonged MI increases feeling of fatigue and impairs motor control, suggesting that MI may induce mental fatigue. The present study, which used electroencephalography (EEG), aims first at analyzing the changes in EEG-spectral parameters during prolonged MI, and second at examining Movement-Related Cortical Potentials (MRCPs) and Event-Related Spectrum Power (ERSP) during both imagined and actual isometric knee extensions.
METHODS: Twelve participants completed a prolonged MI session and a control session. The prolonged MI session, consisted of imagining 200 maximal isometric knee extensions (5 s ON – 10 s OFF, duration 50 min). The control session consisted of watching a documentary for the same duration. Each session was followed by 150 voluntary isometric knee extensions (2.5 s ON – 5.5 s OFF) at 50% maximal force. MRCPs and ERSP analyses were computed for both imagined and actual isometric contractions. During both prolonged MI and documentary viewing, Power Spectral Density (PSD) was analyzed for the first and last 5 minutes.
RESULTS: MRCP amplitude increased over time during imagined and actual contractions, and this increase was greater after prolonged MI. For actual contractions, ERSPs conducted on MRCP time-window showed over time lower desynchronization in delta power during muscular contraction. In addition, greater synchronization was observed in both delta and gamma power during relaxation phase. These changes were more pronounced following prolonged MI. Similar results were observed during imagined MRCPs, but to a lesser extent. Finally, PSD analyses showed a decrease in alpha and beta power over time during prolonged MI, but not during the documentary viewing.
CONCLUSION: Changes observed in both MRCP amplitude and associated ERSP analyses suggest an increased difficulty to perform contractions during and after prolonged MI. As observed in previous studies dealing with mental fatigue, PSD analyses showed a decrease in beta power. However, and contrary to what has been previously observed, the alpha power decreased over time. This decrease could be due to an increase of vigilance during prolonged MI in order to compensate for mental fatigue effects. Taken all together, these results confirm that when prolonged, MI induces a state of mental fatigue. Future studies should take into account the duration of MI to limit the extent of MI-induced mental fatigue.

COMPENSATION OF MOTOR MEMORY DEFICIT BY MOTOR IMAGERY TRAINING IN THE ELDERLY

RUFFINO, C., BOURRELIER, J., PAPAXANTHIS, C., MOUREY, F., LEBON, F.

INSERM UNIVERSITÉ BOURGOGNE FRANCHE COMPTÉ

INTRODUCTION: Motor learning plays a crucial role on the everyday life. However, the literature presents contradictory results concerning the capacity of the elderly to acquire new motor skills, compared to the young adults (Anguera et al., 2011). For example, Malone and Bastian (2016) presented similar locomotor adaption between young and elderly adults. Nevertheless, the results showed that elderly still forgot much of the new pattern after a short break; the motor memory was impaired in this population. Previous studies demonstrated that motor imagery capacities should be preserved correctly with aging (Saimpont et al., 2013). In the current study, we tested the putative role of motor imagery training (MIT) to compensate the motor memory deficit observed in the elderly.
METHODS: We recruited 20 young (27±5years) and 23 elderly (73±5years) adults, divided in four groups: 1) young control group, 2) elderly control group, 3) Young MIT and, 4) Elderly MIT. In pre- and post-tests, the subjects performed three actual trials on a dexterity manual task, commonly used in clinic (the Nine Hole Peg Test), consisting in moving sticks, as fast as possible. The two control groups viewed a non-emotional documentary movie during 30 minutes and the MIT groups mentally repeated the task (50 imagined trials). We used the movement duration as a performance factor.
RESULTS: First, we observed a performance improvement throughout the three pre-test trials for all groups. Immediately after the break (post-test1), the young control group showed a preservation of motor performance compared to the one realized before the break (pret-test3). As expected the young adults increased their performance after MIT. For the elderly, the control group showed a deterioration of motor performance at post-test1, attesting the motor memory deficit observed with aging. Interestingly, the elderly MIP group showed a preservation of motor performance between the pre-test3 and the post-test1.
CONCLUSION: In this study, we demonstrated the beneficial effects of MIT, used alone, in the elderly population. Indeed, our results showed that mental training could compensate motor memory deficit observed with aging. This method would be an alternative, non-drug, to prevent the deterioration of motor skills.

OP-PM38 Heart rate monitoring

NON-ATHLETES REACH CLOSE TO HEART RATE MAXIMUM IN STANDARD CARDIORESPIRATORY FITNESS TESTING

MOHOLDT, T., SØRÅS, S.E., RELLING, B.E., LUNDGREN, K.M., KIEL, I.A., BERGLUND, I.J.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: It is suggested that individuals will not reach their heart rate maximum (HRmax) at an incremental cardiorespiratory fitness (CRF) test, and commonly five beats per minute (bpm) are added to the highest heart rate (HR) reached. To our knowledge, there is not sufficient data justifying such estimation. Although established that HRmax decreases with age, the effect of sex and CRF on HRmax is still controversial (1,2). Our aim was to assess the relationship between the highest HR reached during an incremental CRF test compared

to the same values obtained during an exercise test designed to reach HRmax in non-athletes. We also investigated whether age, sex or CRF would affect the relationship between the highest HRs in these two tests, as well as whether HRmax differed between males and females and between those with high versus low CRF.
METHODS: Fifty-one males and 57 females (aged 22-70 years) completed both an incremental CRF test and a test designed to reach HRmax (with repeated work bouts at high intensity before maximal exertion, ≥ 48 hours apart). To compare the difference between HRmax and HRcrf we used a two-sided, paired sampled t-test. We assessed the relationship between the highest HR in the two tests using linear regression analysis, with HRmax from the HRmax test as a dependent variable, and the highest HR reached at the CRF test (HRcrf), whether maximum oxygen uptake was reached on the CRF test, CRF, sex and age and as independent variables. CRF was categorized as low or high for age and sex, according to a reference material of 4631 healthy Norwegian men and women (3). Additionally, to assess whether HRmax differed between males and females or between those with high versus low CRF, and to assess if there was an interaction between sex and CRF, we performed an age-adjusted two-way ANOVA (sex x CRF).
RESULTS: HRmax was 2.2 (95% confidence interval, 1.5 ,2.9) bpm higher in the test designed to reach HRmax than in the CRF test ($p<0.001$). Only HRcrf significantly predicted HRmax, with no contribution of the other variables in the model. HRmax was predicted from the highest HR reached in an incremental CRF test by: 8.197 + (0.967×HRcrf]) bpm. Individuals with low CRF had on average 5.8 (95% CI, 1.8-9.9) bpm higher HRmax than individuals with high CRF (adjusted for age). There was no effect of sex ($p = 0.38$) and no interaction between CRF and sex ($p = 0.13$) on HRmax.
CONCLUSION: We observed a small (about two bpm), but significant, difference between the maximum HR reached during an incremental CRF test and a test designed to reach HRmax in male and female non-athletes aged 20-70 years. Such a difference is not relevant for exercise prescription in most settings. Based on our findings, the common practice of adding five bpm to the highest HR achieved during a CRF test may be excessive in non-athletes.

HEART RATE MONITORING IN ELITE BADMINTON PLAYERS – USEFULNESS OF A SUBMAXIMAL SHUTTLE-RUN TEST TO ASSESS STRAIN AND RECOVERY

SCHNEIDER, C., RÖLEKE, L., WIEWELHOVE, T., DÖWELING, A., FERRAUTI, A.

RUHR-UNIVERSITY BOCHUM

INTRODUCTION: Assessing changes in fatigue, fitness and (aerobic) performance with exercise heart rate (HRex) during submaximal, non-exhaustive tests became very popular in training research and practice. As HRex may decrease due to (acute) fatigue and/or (long-term) adaptation [1], contextualization and multivariate approaches are required for a valid evaluation of athletes' individual training responses [2]. Therefore, the aim of this observational study was to investigate strain and recovery-related short-term changes in HRex in elite badminton players.
METHODS: 10 elite German badminton players (3 male, 7 female; mean±SD, age 23±4 yrs) were monitored during a 3-month preparatory period in the lead up to the World Championships. HRex and rating of perceived exertion (RPE, 6-20 scale) were repeatedly measured on Mondays (MON) after 1-2 days of pronounced recovery and on Fridays (FRI) following 4 consecutive days of training with up to 2 sessions per day using a submaximal shuttle-run test (approx. 1, 1 and 3 min at 8.2, 9.6 and 11.0 km/h, respectively; 12.8 m shuttle length) during the warm-up of the morning sessions. For HRex and RPE, we examined long-term responses (i.e., intraindividual linear regression [3]), 'overall' differences between MON and FRI (i.e., intraindividual difference between mean values on MON and FRI) and, if possible, individual short-term response patterns (i.e., repetitive intraindividual changes from MON to FRI (strain) or vice versa (recovery), if ≥3 changes were present).
RESULTS: Long-term responses ranged between -0.7 to 0.5 bpm/week for HRex and between -0.1 to 0.2 units/week for RPE. On FRI mean HRex was 2.9±1.7 bpm lower than on MON (-5.5 to 0.1 bpm). Mean RPE was 0.4±0.8 units higher on FRI than on MON (-0.7 to 2.3 units). Repetitive short-term strain and recovery responses were observed in 9 and 6 players, respectively. On average HRex decreased (-3.2±2.7, -7.2 to 1.0 bpm) from MON to FRI and RPE increased (0.5±0.8, -0.5 to 1.3 units). Conversely, HRex increased (2.0±2.0, -1.0 to 4.2 bpm) on average from FRI to MON and RPE remained unchanged (0.0±0.7, -1.2 to 1.0 units).
CONCLUSION: Overall, our preliminary results indicate that HRex during a submaximal shuttle-run test may decline after short-term strain and may increase again after days of pronounced recovery. Mean HRex changes were larger than a previously proposed smallest worthwhile change of 1% but smaller than a suggested typical error of 3% [2]. These findings are limited by the small sample size, non-available training logs and the purely observational character of the study. Nonetheless, the changes in HRex as a response to the training load changes within the usual weekly schedule were surprisingly high compared to similar observations after an ultramarathon [4].

HEART RATE IS INADEQUATE TO PRESCRIBE AND MONITOR INTENSIFIED TRAINING

TEN HAAF, T.1, FOSTER, C.1,2, MEEUSEN, R.3,4, ROELANDS, B.3,5, PIACENTINI, M.F.3,6, VAN STAVEREN, S.7, KOENDERMAN, L.7, DAANEN, H.A.M.1, DE KONING, J.J.1,3

1: VU , 2: UWLAX , 3: VUB , 4: JCU , 5: FWO , 6: UNIROMA4 , 7: UMCU

INTRODUCTION: Heart rate can easily be measured and is often used to prescribe and monitor training. Yet, the effect of intensified training on submaximal heart rate is not completely clear. Therefore, the aim of this study was to investigate whether (sub)maximal heart rate is affected by intensified training, and whether this potential change is associated with the change in performance.
METHODS: The study included 30 participants who performed cardiopulmonary exercise tests to exhaustion 2 weeks before (pre), 1 week after (post) and 5 weeks after (follow-up) an 8-day non-competitive cycling tour (TFL). The exercise volume during this tour was 9 fold the

volume during the preparation period. Heart rate, O2pulse, VO2, VCO2, respiratory exchange ratio (RER) and pulmonary ventilation (VE) were obtained at standardized absolute submaximal workload (low, medium and high intensity) and at peak levels. Performance, defined as the peak power output (PPO), and the ventilatory threshold were obtained each test.
RESULTS: The peak power output post TFL was 8.8 W (95% CI [2.5, 15.1]) lower than pre TFL. Heart rate decreased significantly at low (-4.4 beats/min, [-8.6, -0.2]) and medium (-5.5 beats/min [-8.5, -2.4]), but not at high intensity (-2.3 beats/min [-4.9, 0.2] after the 8 day non-competitive tour. Peak heart rate decreased -3.4 beats/min [-6.3, -0.6]. In contrast, O2pulse was on average 0.49 ml O2/beat [0.09, 0.89] higher at all intensities after intensified training. No changes in VO2 (P=.44) or the ventilatory threshold (P=.21) were observed. The change in heart rate was negatively associated with O2pulse at low (r=-.56, P<.01) and medium intensity (r=-.54, P<.01), but not with PPO or any other cardiopulmonary parameter. Changes in O2pulse and VO2 were associated at all exercise intensities. The change in RER (r=-.54, P<.01) and VE (r=-47, P=.02) at high intensity were negatively associated with the change in PPO.
CONCLUSION: This study showed that heart rate at submaximal and maximal exercise intensity is lower after an 8-day non-competitive cycling tour. However, this decrease does not result in lower VO2 and is unrelated to the change in our measure of performance (PPO). Coaches and athletes should, therefore, be aware of the limited practical value of heart rate for prescription and monitoring of intensified training.

INDIVIDUAL ASSESSMENT OF STRESS AND RECOVERY IN ADOLESCENT ELITE ROWERS USING THE HEARTRATE RECOVERY (HRR) DURING SUBMAXIMAL ERGOMETER TESTING

PELZER, T., GÖTZ, A., ULLRICH, B., COLLETTE, R., PFEIFFER, M.
JOHANNES GUTENBERG UNIVERSITY, MAINZ

INTRODUCTION: Accompanied monitoring of athletes recovery status is helpful to counteract overreaching and overtraining symptoms in athletes and has recently been highlighted in many works (Le Meur et al., 2016). The heartrate recovery (HRR) assessment dur submaximal training intensities hereby provides a promising approach to optimize training output (Le Meur et al., 2013). In this study, HRR was used to assess stress and recovery in adolescent elite-rowers.
METHODS: Five adolescent elite-rowers (R1-R5; Age: 17.6 ± 1.9 years; Size: 178.1 ± 9.3cm, Mass: 67.1 ± 2.5 Kg) completed four weeks of rowing training, using different intensites (Le Meur et al., 2013). Hereby, the individual given workload of the first training week (TW1=Baseline=100%) was calculated as sRPE (Foster et al. 2001) and used for further workload calculations (TW2-TW4). TW2 and TW3 represented the overload-period (OL) with 140% workload and TW4 served as taper period (TP) with 60%. A submaximal ergometer test (Le Meur et al. 2013) was applied for HRR-measurement and maximal rowing performance was determined with a 1.000m All-Out test. Additionally, acute recovery and stress scale data were daily documented with questionnaires.
RESULTS: Maximal rowing power (1.000m All-out) of all participants increased from 369.2 ± 61.2W (TW1) to 372.8 ± 70.4W after OL and 380.6 ± 62.8W after TP. Mean HRR increased for R1 and R3 (+13.6%) and decreased for R2, R4 and R5 (-12.8%) following OL. After TP, HRR values nearly returned to basic level for R1-R4 and remained increased for R5.
CONCLUSION: In this study, a submaximal ergometer test (LeMeur et al. 2013) was adopted to rowing to assess stress and recovery. HRR showed interindividual differences inbetween the applied training intensites (Baseline-Overload-Taper) what might indicate different levels of adaptation and maladaptation in response to overload training. For individual interpretation of HRR in athletes, results necessarily should be linked to training history, performance output as well as psychometric data. Although only 5 athletes participated for this work, our results provide practical benefits for coaches using the heartrate recovery for training monitoring.

CAN RESTING HEART RATE INFLUENCE VAGAL REACTIVATION AFTER SUBMAXIMAL EXERCISE TEST?

GARCIA, G.L., FONTANA, K.E., CRUZ, C.J.G., SOARES, E.M.K.V.K., PORTO, L.G.G., JUNQUEIRA JR., L.F., MOLINA, G.E.
UNIVERSITY OF BRASÍLIA – UNB

INTRODUCTION: The resting heart rate (RHR) and vagal reactivation (VR) during the short recovery period after exercise testing (5min) have been commonly used as noninvasive assessment tools of the cardiovagal activity. Therefore, it is reasonable to expect that RHR can influence the VR immediately after submaximal exercise test (SET). The aim was compare VR after SET in active young men with different RHR patterns.
METHODS: We evaluated 42 active men (IPAQ-questionnaire). Volunteers were divided into the Bradycardia Group – RHR < 60 bpm (BG n = 21), aged 24.5 (20-38) years and body mass index (BMI) of 23.8 (20.1-27.4) kg/m2 and the Normocardia Group - RHR = 60 = 100 bpm (NG: n = 21), aged 25.5 (20-40) years and BMI of 25.3 (21.6-28.2) kg/m2. A Polar RS800® was used to record RHR and the RR-interval series during the 5 minutes recovery period after SET. RHR was defined as the mean heart rate recorded for 5 minutes at rest in supine position after 10 minutes of resting. The heart rate variability was analyzed by Kubios software and VR was assessed by the rMSSD index, a vagal marker, from 1st to 5th minute of active recovery at 2.4 km/h and 2.5% grade after SET. Due to non-normal distribution of variables (Shapiro-Wilk test) the Mann Whitney test was used to compare groups and the Spearman correlation test was used to correlate RHR with rMSSD after SET, at the 5% level of significance. Data are shown as medians and extreme values (min-max).
RESULTS: The RHR was BG: 57 (46-59) bpm and NG: 67 (60-76) bpm (p < 0.001). We observed a negative correlation (n=42) between RHR with rMSSD in the 3th (rs = -0.30, p = 0.02), 4th (rs = -0.35, p = 0.01) and 5th (rs = -0.45, p = 0.001) minutes of recovery after SET. A trend of higher values of VR were observed in the 2nd minute on the BG [rMSSD2: 8.3 (4.5-16.4) ms;] as compared to the NG [rMSSD2: 6.5 <3.0-17.10) ms (p = 0.06) and higher values of VR from 3th to 5th minute of recovery on the BG [rMSSD3: 9.5 (5.2-17.2) ms; rMSSD4: 10.3 (4.7-18.7) ms; rMSSD5: 8.7 (5.3-18.5) ms] as compared to the NG [rMSSD3: 6.8 (3.0-11.6) ms; rMSSD4: 5.9 (2.6-17.4) ms; rMSSD5: 6.1 (3.1-16.2) ms](p = 0.001).
CONCLUSION: We observed higher vagal reactivation from 2sd to 5th minute of recovery after SET on group BG comparatively with NG. The significant negative correlation between the RHR and VR from 3th to 5th minute of recovery after SET reinforces the association between RHR and VR. These results support the hypothesis that pre-exercise RHR in supine position could influence the degree of cardiovagal reactivation, and consequently, the speed of cardiovagal activity return to baseline levels after SET.

OP-BN17 Neuromuscular fatigue

NEUROMUSCULAR FATIGUE IN HYPOXIA REVISITED

RUPP, T.1, MIRA, J.1,2, FLOREANI, M.2, SAVOLDELLI, A.2, AMERY, K.2, KORAL, J.2, ORANCHUK, D.2, MILLET, G.Y.1

*1: LIBM , 2: HPL . * BOTH AUTHORS CONTRIBUTED EQUALLY TO THE WORK*

INTRODUCTION: The magnitude and etiology of fatigue following whole-body exercises at different altitudes remain equivocal owing to i) the actual degree of hypoxemia (arterial saturation, SpO2) achieved by the subjects, ii) the consideration of relative vs absolute workloads and iii) the lag time between exercise cessation and fatigue evaluation, which permits some recovery of neuromuscular function (NMF) and leads to possible fatigue misinterpretation. The aims of this study were to evaluate the rate of fatigue development and its etiology during cycling and right at exhaustion (EXH) in normoxia, moderate and severe hypoxia at relative and absolute workload intensities.
METHODS: Thirteen active subjects first completed three incremental tests to determine maximal aerobic power output (Wmax) in normoxia, moderate hypoxia (MOD, SpO2 clamped at 85%) and severe hypoxia (SEV, SpO2 clamped at 70%). Five fatigue cycling tests were then randomly performed up to EXH on a new cycle-ergometer with instrumented pedals, which allows NMF evaluation in isometric mode within 1-s. In three tests (N, MODabs, SEVabs) initial power output was set at 55% Wmax determined in normoxia (ie. absolute intensity). Two other tests (MODrel, SEVrel) started at 55% Wmax determined in the same environmental condition (ie. relative intensity).
NMF evaluations assessed before, during and immediately at EXH comprised force recordings and electrical stimulation to assess maximum voluntary contraction (MVC) and peripheral fatigue (high-frequency doublet, Db100; Twitch, Pt).
RESULTS: Time to EXH of NORM (84±15 min) was significantly longer than MODabs (50±23 min), SEVabs (25±17 min) and SEVrel (58±19 min, all P<0.001). Times in MODrel (73±20 min) and SEVrel were longer than MODabs and SEVabs, respectively (P < 0.001).
The MVC, Pt and Db100 decreases throughout exercise were similar, at isotime, in NORM, MODrel and SEVrel. While NORM and MODabs also showed similar MVC and Db100 patterns, Pt was more depressed in MODabs than NORM and MVC, Pt and Db100 impairments were exacerbated in SEVabs. Besides, MVC depression was greater in MODabs vs MODrel and MVC, Pt and Db100 impairments were greater in SEVabs vs SEVrel.
However, at EXH, MVC and Db100 decreases were not different among tests (–26 to –31% and –25 to –35%, respectively) even if Pt was less decreased in relative sessions (MODrel, SEVrel).
CONCLUSION: Time to EXH of absolute (as expected) but also relative sessions was increasingly reduced with altitude level. Fatigue magnitude (MVC decrease) and its peripheral component was not altered when exercising at moderate and severe altitude at relative workloads compared to normoxia, whereas the rate of fatigue development was enhanced for higher (absolute) workloads, particularly for low SpO2. Finally, force loss at EXH was similar among sessions, but the amount of peripheral fatigue (e.g. Pt) was likely triggered by exercise intensity per se rather than by the degree of hypoxemia.

H-REFLEX CHANGES ARE NOT DIFFERENT BETWEEN GIRLS AND WOMEN AFTER A SUBMAXIMAL FATIGUE PROTOCOL.

PAPAVASILIOU, A.1, BASSA, E.1, XENOFONDOS, A.1, SFYRIOU, E.1, TSATALAS, T.2, KOTZAMANIDIS, C.1, PATIKAS, D.1

ARISTOTLE UNIVERSITY OF THESSALONIKI

INTRODUCTION: Fatigue is a complex phenomenon with numerous central and peripheral mechanisms contributing to its existence and magnitude. Limiting factors in performance located at spinal level can be examined with non-invasive methods, such as the H-reflex. During fatigue, afferent feedback and input from supraspinal centres may alter the α-motoneuron excitability and the level of presynaptic inhibition, which can be assessed by means of H-reflex. Regarding fatigue during youth, previous studies have shown that recovery after fatigue is faster in children than adults, possibly due to peripheral mechanisms. However, the α-motoneuron excitability and the input they receive from the Ia afferents may have implications to the faster recovery in children. Therefore, the purpose of this study was to examine the H-reflex during the recovery period after a fatigue protocol until exhaustion applied in children and adults.
METHODS: Fourteen women (age 22.2±3.2 years) and 17 prepubertal girls (age 11.2±1.0 years), performed voluntarily a sustained isometric plantar flexion at 30% of their maximal voluntary contraction (MVC) torque, until they could not reach the target torque for more than 5 s. The soleus H-reflex (every 10 s) and maximum M-wave (Mmax, every 30 s) were measured before and for 10 minutes after the fatigue protocol. Furthermore, MVCs were performed at 0, 3 and 6 min. after the fatigue protocol and compared to the pre-fatigue values. Peak to peak amplitudes of the H-reflex and Mmax as well as the MVC and soleus EMG values were statistically processed using a two-way (GROUP and TIME) repeated measures ANOVA model with alpha set at 0.05.
RESULTS: After fatigue the MVC plantar flexion torque and soleus EMG were decreased in both age groups but recovered faster in children. The H-reflex amplitude decreased for both age groups and recovered within 3 minutes. The Mmax revealed a potentiation during the first minute of recovery only for the women's group and recovered to the baseline values afterwards.
CONCLUSION: Although our data show that girls recover faster than women in terms of plantar flexion torque and soleus EMG, the H-reflex revealed the same behaviour in both age groups. This indicates that the Ia afferent feedback as well as type III and IV afferent inhibitory input may not contribute to the lower rate of recovery in women. In contrast, the potentiation of Mmax observed in women only, indicates possible changes in membrane excitability after fatigue that could have some implications to performance.

RIGOROUS ANALYSIS REVEALS CONSISTENT MOTOR UNIT FIRING ADAPTATIONS DURING MUSCLE FATIGUE

CONTESSA, P., KLINE, J.C., LETIZI, J., DE LUCA, G.

DELSYS & ALTEC INC.

INTRODUCTION: The study of motor unit firing behavior during fatigue reveals how muscle control adapts to the increasing demand of long duration or strenuous tasks, such as those often endured as part of sports training and exercise. However, inconsistencies in reports of fatigue-induced motor unit firing adaptations hinder the understanding of muscle control during fatigue. To clarify the control mechanisms of fatiguing muscles, we explored whether different approaches in the analysis of motor unit data may lead to inconsistencies in the observation of motor unit firing behavior during a repeated task.
METHODS: We investigated the firing behavior of individual motor units in a smaller muscle of the hand, the First Dorsal Interosseous (FDI), and in a larger muscle of the quadriceps, the Vastus Lateralis (VL), of five healthy subjects during constant force isometric contractions sustained at 30% and 50% maximal voluntary contraction force and repeated to exhaustion. We recorded sEMG signals during index

finger abduction (for the FDI) and leg extension (for the VL) using a four-channel dEMG array sensor (Delsys Inc.) place on the skin over the muscle. The signals were decomposed into their constituent motor unit action potential (MUAP) trains. The MUAP amplitude, the recruitment threshold and the firing rate of each motor unit was measured. Single-differential sEMG signals were recorded from surrounding muscles that may contribute to measured force.
RESULTS: We were able to identify four factors that contribute to inconsistencies in the observations of motor unit firing behavior during fatigue. They are: 1) the practice of grouping and averaging motor unit data within a contraction that obscures motor unit-specific firing properties; 2) the practice of analyzing motor unit firing rate as a function of recruitment threshold when recruitment threshold decreases with fatigue; 3) the practice of grouping motor unit data across different subjects that obscures subject-specific adaptions to muscle fatigue; and 4) changes in muscle co-activation that alter the relative contribution of different muscles to the fatigue tasks. When these factors were avoided in our study, consistent adaptations in firing behavior were observed across all subjects and muscles. That is, as fatigue develops, motor unit firing rates increase, new higher-MUAP amplitude motor units are recruited, and motor unit recruitment thresholds decrease.
CONCLUSION: These adaptations indicate that motor unit firing behavior responds to increasing excitation to the motoneuron pool of the muscle that compensates for decreasing muscle force generation capacity with fatigue.

ACUTE AND DELAYED KNEE EXTENSOR FATIGUE AND MUSCLE DAMAGE FOLLOWING RESISTANCE TRAINING LEADING OR NOT TO FAILURE.

GONZÁLEZ-HERNÁNDEZ, J., COLOMER-POVEDA, D., TVARIJONAVICIUTE, A., CERÓN, J.J., JIMÉNEZ-REYES, P., MÁRQUEZ, G.
CATOLIC UNIVERSITY SAN ANTONIO DE MURCIA UCAM

INTRODUCTION: During resistant training (RT) the set configuration (volume, intensity, number of sets and repetitions, inter-set rest time, etc.) has a profound impact on mechanical, neuromuscular and biochemical responses (Río-Rodríguez et al. 2016) and may account for the long-term neuromuscular adaptations. In this regard, it has been previously demonstrated that RT sessions leading to failure produced higher levels of muscle damage (i.e.: increased creatin kinase (CK) values) than those performed not leading to failure (Gorostiaga et al. 2012). However, it remains unknown whether central and peripheral fatigue after sessions leading or not to failure are related with changes ocurring at biochemical level (i.e.: CK). Therefore, this study aimed to compare the acute and delayed effects of two different RT protocols, leading or not to failure, on central and peripheral fatigue, muscle damage and performance.
METHODS: Twelve trained men after three familiarisation sessions, performed two different RT protocols (with sets leading or not to failure) in a counterbalanced order one week apart. The protocol leading to failure consisted of 6 sets of 10 repetitions maximum (RM) of full squat, while the other protocol (not leading to failure) consisted of 6 sets of 5 repetitions with the same load of 10RM. The inter-set rest was 5 minutes for both protocols. Twitch interpolation technique was used to assess neuromuscular function of the knee extensor muscles before (Pre), immediately after each set (Post1…Post6), 60 minutes later (Post60min), 24h (Post24h) and 48h (Post48h) after the cessation of each training session. Muscle damage was inferred via serum CK measured before and after (60min, 24h and 48h) each training protocol.
RESULTS: Our results displayed a significant decrease ($P<0.05$) in maximal voluntary contraction, voluntary activation (central fatigue) and high frequency fatigue (100Hz potentiated twitch) during and after the performance of both training protocols. However, low frequency fatigue (10Hz potentiated twitch) was significantly higher ($P<0.05$) after the 3rd set of the protocol leading to failure when compared to the session not leading to failure. These higher levels of low frequency peripheral fatigue observed in the more challenging protocol (6x10RM) were evident even after 48h of recovery. Regarding muscle damage, we found a significant ($P<0.05$) increase in CK levels after both training protocols, however, our results also displayed significant higher levels of CK after the protocol leading to failure when compared to the other one ($P<0.05$ in the Post24h and Post48h).
CONCLUSION: Training leading to failure produces a greater extent of peripheral fatigue compromising the excitation-contraction coupling machinery and thus, performance. Furthermore, these peripheral impairments could be attributed to higher levels of muscle damage.

ETIOLOGY AND RECOVERY OF FATIGUE FOLLOWING HEAVY-RESISTANCE, JUMP, & SPRINT TRAINING

THOMAS, K., BROWNSTEIN, C.G., DENT, J., PARKER, P., GOODALL, S., HOWATSON, G.
NORTHUMBRIA UNIVERSITY

INTRODUCTION: Training methods that require maximal intensity efforts against light- and heavy-resistance are commonly used in the athletic preparation of athletes in a range of sports. Typically these sessions are separated by at least 48 hours recovery on the assumption that such efforts elicit marked fatigue of the central nervous system (CNS), but this posit has not been well-studied. The aim of the study was to assess the etiology and recovery of fatigue after heavy-resistance, jump, and sprint training methods.
METHODS: Ten male athletes completed three training sessions requiring maximal efforts that varied in their loading characteristics; i) heavy resistance exercise (10 × 5 back squats at 80% 1RM) (HRE); ii) jumping exercise (10 × 5 jump squats) (JUMP); iii) maximal sprinting (15 × 30 m) (SPRINT). Pre-, post- and at 24, 48 and 72 h post- participants completed a battery of tests to measure neuromuscular function using electrical stimulation of the femoral nerve, and single- and paired-pulse magnetic stimulation of the motor cortex, with evoked responses recorded from the knee extensors. Fatigue was self-reported at each time point using a visual analogue scale.
RESULTS: Each intervention elicited fatigue that resolved by 48 (JUMP) and 72 h (HRE & SPRINT). Decrements in muscle function (reductions in the potentiated quadriceps twitch force) persisted for 48 h after all exercise. Reductions in voluntary activation were present for 24 h after JUMP and SPRINT and 48 h after HRE. No other differences in CNS function were observed as a consequence of training.
CONCLUSION: Resistance, jumping, and sprint training requiring repeated maximum efforts elicits fatigue that requires up to 72 h to fully resolve, but this fatigue is not primarily underpinned by decrements in CNS function.

DOES MAINTAINED GROUP III/IV AFFERENT FEEDBACK AFTER HIGH-INTENSITY EXERCISE OF THE LEG CONTRIBUTE TO CROSSOVER FATIGUE IN THE ARM?

KENNEDY, D.S.1,3, RAPER, E.C.2, FIN, H.T.3, TAYLOR, J.T.3

1. UNIVERSITY OF TECHNOLOGY SYDNEY; 2. ROYAL NORTH SHORE HOSPITAL; 3. NEUROSCIENCE RESEARCH AUSTRALIA

INTRODUCTION: Cross-over fatigue occurs when fatigue of one muscle group is associated with a decrease in the ability to generate force in non-exercised muscles within the same limb (1) or between lower and/or upper limb muscles (2,3). The decrease in muscle force is thought to be mediated by afferent feedback from the exercised muscle. This study aimed to determine whether maintained fatigue-related group III/IV muscle afferent feedback from the quadriceps results in cross-over fatigue to the ipsilateral elbow flexor muscles.
METHODS: Sixteen subjects (mean age = 23, female=9) attended on two days. On both days, they performed a 2-min sustained quadriceps maximal voluntary contraction (MVC). Following this contraction, on one day blood flow to the quadriceps was occluded for 2 min to maintain muscle afferent feedback. During that time, subjects performed four elbow flexor contraction sets comprising one MVC and two submaximal contractions. Voluntary activation (VA) using transcranial magnetic stimulation (TMS), force (MVC), biceps motor evoked potentials (MEP), and pain (Borg scale) were recorded.
RESULTS: Maintained group III/IV afferent firing of the quadriceps had no effect on VA (93.3±5.3% on no-cuff day; 91.5±6.6% on cuff day (mean±SD); p=0.74) or torque (94.5±5.1% Peak MVC on no cuff day; 95.3±6.7% on cuff day, p=0.75) of the elbow flexors. Furthermore, there was no effect on the excitability of the motor-cortical output cells of biceps (MEP) (57.1±15.7% Mmax on no-cuff day; 52.7±16.4% on cuff day; p=0.88). Subjective pain ratings during maintained quadriceps ischaemia were higher (Borg: 6.0±1.6; p<0.001) compared to when the muscle was allowed to recover (2.6±2.1).
CONCLUSION: Despite high levels of group III/IV muscle afferent feedback after fatiguing leg exercise, torque and voluntary activation of the elbow flexors were unchanged. This suggests that group III/IV muscle afferent feedback does not mediate cross-over fatigue from the leg to upper limb, at least during multiple brief elbow flexor MVCs.

THE EFFECT OF FATIGUE ON REACTIVE STRENGTH IN SOCCER PLAYERS

STEWART, R.1, FLANAGAN, E.2, DITROILO, M.1

1 INSTITUTE FOR SPORT AND HEALTH, UNIVERSITY COLLEGE DUBLIN.

INTRODUCTION: Reactive strength denotes the ability of the musculotendinous unit to produce a powerful concentric contraction immediately following a rapid eccentric contraction. The reactive strength index (RSI) is a common method of quantifying reactive strength performance. However, for numerous sporting events it is important to consistently produce repetitive reactive strength. Few studies have investigated the relationship between maximal reactive strength and reactive strength fatigue. Therefore, this study aims to examine the effect of fatigue on RSI and its components.
METHODS: Nineteen semi-professional male soccer players (20.2±1.3 years; 76.9±5.6kg; 181.4±4.8cm) participated in a familiarisation and a testing session. Sessions consisted of a standardised warm up, a 10 to 5 repeated jump test (10/5) (Harper, 2011), and a 30 second repeated jump test (30RJT). Contact time (CT) and Jump height (JH) were measured using an Optojump photocell system (Microgate, Bolzano, Italy). RSI was calculated by dividing JH by CT. The 10/5 test determined participant's unfatigued, maximal RSI (RSImax). Subsequently, a median split categorised the data into low (n=10) and high (n=9) RSI groups. Data from the 30RJT was split into discrete five second phases and were analysed as percentages of RSImax. A two way (time and group) repeated measures ANOVA determined the effect of time and group on fatigue, with post hoc testing (Tukey) for analysis of group differences. The magnitude of effect was assessed using Cohen's d effect size (Rhea, 2004).
RESULTS: Participants completed 43±2 jumps during the 30RJT. RSImax scores for the low and high groups were 1.58 ±0.21 and 1.98 ±0.15 respectively. There was a significant effect of time for the 3 variables analysed (RSI and JH, p<0.01; CT, p<0.05), however no effect of group and no interaction between variables was detected. Large effect sizes were observed between RSImax and RSI at the 25-30sec time phase for both low (d=1.08) and high (d=2.3) groups. Even though no significant differences in RSI, CT and JH were identified between groups at any time phase, moderate to large effect sizes between groups were observed across time phases for RSI (d=0.52–1.01) and JH (d=0.59-0.87), with the low group consistently showing a higher percentage of RSI compared to high group. Trivial to moderate effects were observed between groups for CT (d=0.01-0.52).
CONCLUSION: The results of this study demonstrate that the 30RJT is an appropriate protocol to elicit reactive strength fatigue. Although differences in fatigue response between low RSImax and high RSImax groups were non-significant, large and moderate effect sizes were observed. Changes in RSI were predominantly attributed to fluctuations in JH, while much smaller changes were observed in CT. The results could inform the testing and training of reactive strength in soccer players.

MULTI-SENSOR AND VIDEO SYNCHRONOUS ACQUISITION AND ANALYSIS IN SPORTS ACTIVITIES

LIU, Y., CHEN, Q.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Sports data acquisition in sports training and competition mainly uses various kinds of sensors and video devices. With the rapid development of microelectronics technology and the rise of flexible circuits, multi-sensor can be mounted on a very small area of circuit board which brings great convenience for collecting sports data by using wearable devices. Video-based movement analysis has been widely used for sports technique and tactic analysis, such as Dartfish® Video Analysis Software from Switzerland and so on. Nevertheless, the motion monitoring by sensor and video is usually separated. It's not conducive to understand the sports data of users in each individual skilled movement, nor to accurately judge the reasonableness of the motion state of the users in the whole skilled movement. Therefore, the aim of this study was to design a multi-sensor and video synchronous acquisition and analysis system to meet the needs of field testing and field analysis of sports events.

METHODS: The proposed multi-sensor and video synchronous acquisition and analysis system includes four modules: sensor data acquisition subsystem, video acquisition device, synchronization equipment and software. Sensor data acquisition subsystem integrated a variety of types of sensors consisting of accelerometer, gyroscope, magnetometer, heart rate, and pressure sensor. The video acquisition device has the external trigger function, which can adjust the frame rate and the resolution. Time synchronization between the sensor data acquisition subsystem and video acquisition device is performed by the synchronization equipment. The computer software configures the whole system parameters and displays the data acquired by sensors and video. Besides, the data processing and analysis will be performed by software, including multi-sensor data fusion, synchronous analysis of sensor and video data, and so on. The validation of effectiveness and performance analysis is tested by swimming enthusiasts.
RESULTS: The effectiveness and applicability of the multi-sensor and video synchronous acquisition and analysis system are verified by experiments and site tests in natatorium. The test results show that the synchronous acquisition sensors data including acceleration, angular rates, terrestrial magnetic field, heart rate, depth of water and the video data can effectively reflect the motion state of the user. Data processing and analysis such as comparison of the force of the left and right arms in the freestyle, play an important role in sports technical analysis.
CONCLUSION: The effectiveness of the proposed multi-sensor and video synchronous acquisition and analysis system is demonstrated through the results. Researches on the multi-sensor and video synchronous acquisition and analysis system in future mainly includes: increasing the function of collecting user location information by using the integration of indoor and outdoor positioning technology, studies on the data processing and analysis to provide more suitable advanced motion parameters by using sensor data for sports techniques analysis in various types of sports, researches on improving the possibility of integration of more types of video acquisition devices to provide the most suitable services for various types of users.

SOCCER PERFORMANCE ANALYSIS AND INJURY PREVENTION USING WEARABLE ACCELERATION SENSOR.

MAGOME, T.1, GOUDA, N.2, TANAKA, T.3, YAMAGUCHI, T.3, NAKATA, K.1

1:OSAKA UNIVERSITY GRADUATE SCHOOL OF MEDICINE, 2,3: HITACHI,LTD

INTRODUCTION: To keep the role of QOL that can maintain physical health to the future is important. [1] Sports is responsible for that role, therefore it is also essential for the health promotion to prevent an injury in our daily life. Analysing the relationship between physical activity level and injury prevention in sports is important, but it still tends to be difficult today. In this study, we conducted the measurements using wearable acceleration sensor to classify and analyse the relationship between physical activity level and injury prevention among players belonging to professional soccer youth team in Japan.
[1] UN Inter-Agency Task Force on Sport for Development & Peace, 2003
METHODS: The measurements with wearable acceleration sensor were performed for two weeks. Players attached the acceleration sensors of the 20Hz sampling [2] to their arms and the momentum in soccer game and skill training was estimated. Relationship between physical activity level and injury prevention in the group was examined from the collected data.
[2] Tanaka T., et al., Life microscope: Continuous daily-activity recording system
with tiny wireless sensor, INSS 2008: 5th International Conference on Networked
Sensing Systems: 162165, 2008.
RESULTS: We extracted an interesting fact that the correlation between occurrences of the football injury and daily soccer performance. The variance of players' intensity data who got injured was much higher than the other players and it is statistically significant ($p<0.05$).
CONCLUSION: This study showed the relationship between daily physical activities, ball game and skill training, and injury occurrences by using a simple monitor in a daily setting. Having the positive impression for sports through a daily training will enhance the important awareness leading to injury prevention and health promotion. Continuous measurements are needed for further analysis. Therefore, the relative evaluation with this study is possible by comparing the results from the other data including acceleration of football players etc. To establish the scientific grounds leads to the evidence construction in the physical activities and contributes to the development of sports medicine. Based on this study result, we are going to develop the algorithm to predict the injury occurrences of athletes by applying the method we developed

COMPARISON OF LABORATORY METHODS FOR CALCULATING TOTAL JUMP HEIGHT AND DEVELOPMENT OF A CONSTANT TO IMPROVE FIELD BASED METHODS.

WADE, L., LICHTWARK, G., FARRIS, D.J.

THE UNIVERSITY OF QUEENSLAND

INTRODUCTION: Jumping is commonly used in research and athlete development. Measurement of total jump height (TJH) requires the measurement and summation of two discrete distances, heel raise (HR) and flight height (FH). The three most common laboratory methods to measure TJH are double integration of force plate data (DI), marker based video tracking (MARKER), and rigid-body modelling from motion capture data (MODEL). Although, presently these methods have never been compared directly [1, 2]. This project aimed to examine and contrast these methods as well as a hybrid (HYBRID) method for calculating TJH. As a result, a HR constant (HR-C) was created to be used with field based methods such as flight time (FT).
METHODS: TJH was defined as the displacement of the centre of mass (COM) between standing and jump apex. Participants (N=24, Mass = 71±9kg, Height = 174±8cm) performed 5 countermovement jumps on two force plates (1000 Hz). DI used integration of acceleration determined from net ground reaction forces to find COM take-off velocity (used to calculate FH) and displacement (HR). MODEL used 3D motion capture (200 Hz) to create a rigid body model to estimate COM position. MARKER averaged the 3D position of 4 pelvis markers to estimate COM position. MODEL and MARKER methods calculated HR and TJH as displacement of COM from standing to take-off or jump apex, respectively. HYBRID method calculated TJH using HR from MARKER and FH from DI [1]. Linear mixed modelling enabled method comparison. Mean standard deviations (STD) within participants were compared using a repeated measures ANOVA. FT method determined TJH based on time spent in the air and combined this with our estimated HR-C, modelled as the distance from medial malleolus to tip of 1st toe, minus the distance from medial malleolus to the ground. TJH of FT was compared with and without the HR-C, to TJH of HYBRID using Bland-Altman comparisons.
RESULTS: There was a main effect of method on TJH ($P < 0.001$) with the greatest difference between DI and MODEL; being 1.8 cm higher on average in DI. STD of TJH was significantly different only between DI and HYBRID ($P = 0.002$). Mean STD's of HR were less than half of TJH and were not significantly different between MARKER, HYBRID and MODEL ($P = 0.583$), however DI STD was higher than all other methods ($P = 0.007$). HYBRID vs FT reported -9.66 ± 1.47 cm bias. HYBRID vs FT + HR-C reported 1.79 ± 1.7 cm bias.

CONCLUSION: While all methods reported slightly different jump heights, mean STD differences between methods were relatively small (max = 3 mm) and therefore all 4 methods appear suitable for repeat measures of TJH in a research setting. HR was extremely consistent and well estimated by the constant we developed. TJH height bias using FT + HR-C was reduced by 8.3 cm compared to FT alone and therefore it is recommended that this constant be included when calculating TJH from FT.

THE NUMBER OF TRIALS REQUIRED TO OBTAIN A TRUE REPRESENTATION OF BIOMECHANICAL FEATURES EXTRACTED DURING A SINGLE LEG HURDLE HOP EXERCISE

GRIFFIN, C.1,2, RICHTER, C.2, FRANKLYN-MILLER, A.2, MORIN, J.B.1
UNIVERSITY OF NICE SOPHIA ANTIPOLIS

INTRODUCTION: Lower extremity stiffness has been linked to running performance and injury risk(1) with various hopping tests used to measure stiffness(2). However, it is unclear how many trials are required for a forward hop exercise. The aim of this study was to determine the number of trials required to obtain a true representation of the biomechanical variables in a single leg hurdle hop task.
METHODS: Ten recreationally active males participated in 2 testing sessions 14 days apart involving a standardised warm-up including 3 familiarisation trials on each limb, before performing a forward hop over two 15cm hurdles, rebounding off a force platform in between. The participants completed 10 trials on each limb unshod with their arms akimbo, and were instructed to rebound as fast and as far as possible. Ten infrared cameras (250Hz; Vicon, UK) synchronised with two force platforms (1000Hz, AMTI, USA) were used to capture reflective markers placed at the pelvis (reference for centre of mass [COM]) and ground reaction forces (GRF). Motion and GRF data were filtered using a fourth order low pass Butterworth filter. Vertical stiffness (Kvert), peak GRF, contact time (CT), total hop distance from the start of the hop to the landing position (HD), and rebound distance from the force platform to the landing position (RD), were calculated and examined. Kvert was calculated as the ratio of GRF at the lowest CoM, to CoM displacement. A true mean was generated by a simulation where the mean of 7 randomly selected trials were calculated over 100 iterations and averaged. A correlation was used to judge from which trial a true representation could be expected, with a correlation threshold set at 0.9.
RESULTS: All trials for the variables of peak GRF, RD and HD demonstrated high correlations for both testing sessions from trial 3. While CT fluctuated within the first session, it demonstrated a high correlation in the second session from trial 3. Correlation of Kvert fluctuated over both sessions, while it reached its highest correlation (r=0.7) also at trial 3 in both sessions.
CONCLUSION: This study suggestets that 3 trials may be optimal to obtain a true representation for all measured variables in a single leg forward hurdle hop exercise. The low correlation (r=0.7) of Kvert and CT in the latter trials may be indicative of fatigue, movement variability, or may not be a reliable variable to obtain a representative measure. Overall, the single leg hurdle hop exercise test may be a convenient clinical tool for lower limb injury rehabilitation requiring less trials to be performed.

PLAYER MONITORING IN INDOOR SPORTS: VALIDITY OF INERTIAL MEASUREMENT UNITS TO QUANTIFY ACCELERATION VALUES

ROELL, M.1, ROECKER, K.1,2, GEHRING, D.1, MAHLER, H.1, GOLLHOFER, A.1
1: ALU , 2: HFU

INTRODUCTION: A growing interest in assessing physical demands in team sports has led to the development of various player monitoring systems. Their majority is specified for outdoor settings, whereas recently developed inertial measurement units (IMU) enable three dimensional measures of acceleration also indoors. However, gravity acting on the IMU and its unknown orientation relative to the global coordinate system are basic problems challenging the extraction of discipline relevant data in indoor sports. Sensor fusion algorithms solve these problems by estimating a device's orientation relative to gravity without the aid of external references (Valenti et al., 2015). Aim of this study was to validate two different sensor fusion algorithms as well as conventional gravity compensation applied to IMU signals to obtain acceleration values in all movement planes.
METHODS: Data of an IMU were compared to a 3D motion analysis (MA) system during simulated sports specific movement patterns (n=56). Low-pass filtering for gravity correction (LF) and two sensor fusion algorithms for orientation estimation (Complementary Filter, CF; Kalman-Filter, KF) were applied to the IMU's output. Mean and peak values for resultant acceleration (CF, KF, LF) were calculated as well as for acceleration and deceleration in each of the 3D-axis (CF, LF) and compared to MA system data.
RESULTS: Significant differences were found between LF and MA data but not between sensor fusion algorithms and MA. Higher precision and lower relative errors were found for CF (RMSE=0.05; CV=2.6) and KF (RMSE=0.15; CV=3.8) both compared to the LF method (RMSE=1.14; CV=47.6) regarding the resulting acceleration. Comparing both sensor fusion algorithms, CF revealed slightly lower errors than KF and additionally provided information about positive and negative acceleration in all three axes with moderate to good validity (CV=3.9–17.8).
CONCLUSION: The results show that after sensor fusion IMU-based acceleration values do not substantially differ from conventional kinematic data. Slight advantages of CF might result from its faster rate of convergence (Ricci et al., 2016). Analysis in global x-,y- and z-axis revealed acceptable validity, although superior results were visible for the z-axis compared to x- and y-axis, which is probably caused by a missing heading correction of the CF algorithm (Valenti et al., 2015). Overall, IMU-based tracking devices quantify acceleration values in all three axes with acceptable validity and provide the potential to become a meaningful tool for monitoring indoor sports.

CONCURRENT VALIDITY OF FOUR SYSTEMS ASSESSING MOVEMENT VELOCITY IN THE FREE WEIGHT BACK SQUAT

MITTER, B., HELMREICH, V., HOELBLING, D., BAUER, P., STOECKL, M., BACA, A., TSCHAN, H.

UNIVERSITY OF VIENNA, INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Monitoring and regulating resistance training based on barbell velocity feedback has increasingly drawn interest of researchers and practitioners over the past years (Jovanovic & Flanagan, 2014). To the extent of our knowledge, no study investigated the accuracy of required measurement technology in free weight barbell exercises with an appropriate gold standard so far. Therefore, the present investigation was designed to determine validity of four systems assessing movement velocity in the free weight barbell back squat by means of an approved reference technique (Windolf et al., 2008).
METHODS: Twenty-four competitive powerlifters (18 male and 6 female; age: 25.1±5.1 y; body mass: 99.2±15.1 kg; relative squat 1-RM: 1.96 ± 0.25 kg.kg-1) performed a test protocol with progressing loads at maximum voluntary concentric velocity to establish the 1-RM and load-velocity profile in the back squat. Tests yielded a total of 385 repetitions across various intensities. Movement velocity was recorded using 3D motion capturing (Vicon-460, i.e. gold standard) and four commercially available systems: GymAware (GA), Fitrodyne (FD), PUSH (PU) and Beast Sensor (BS). Validity analysis for vertical peak (PV) and mean velocity parameters (MV) included the calculation and interpretation of Pearson correlation coefficient (r), effect size of differences (ES), and the typical error of the estimate expressed as a coefficient of variation (CV). Fisher's r to z transformation was used to evaluate differences in correlations at a 95% confidence level.
RESULTS: Linear position transducers (GA and FD) showed a higher correlation (r: [.95, .99]), lower differences (ES: [-.05, -.29]) and lower typical error (CV: [1.81%, 12.06%]) in vertical velocity compared to inertia sensors PU and BS (r: [.84, .95], ES: [-.20, -.74], CV: [16.25%, 28.42%]). A Bonferroni-corrected comparison of correlations revealed significant differences between systems in all cases except for peak velocity between GA and FD (p=.03), as well as mean velocity between FD and PU (p=.30).
CONCLUSION: The findings of the present study are in line with previous research showing that linear position transducers provide a more accurate estimation of vertical velocity than inertia sensors (Banyard et al., 2017). Interestingly, there also appear to be divergent levels of accuracy within a technological category (i.e. linear position transducers, inertia sensors) and between velocity parameters amongst all evaluated systems.

OP-PM80 Acute Exercise

RECREATIONAL TEAM HANDBALL: ACUTE PHYSICAL AND PHYSIOLOGICAL RESPONSES IN ADULT SEDENTARY FORMER PLAYERS

PÓVOAS, S.1,2, CASTAGNA, C.3,4, RESENDE, C.2,5, COELHO, E.6, SILVA, P.2,7, SANTOS, R.2,7,8, SEABRA, A.7, TAMAMES, J., LOPES, M.2,7, RANDERS, M.9, KRUSTRUP, P.9,10

1:CIDESD,2:ISMAI,3:ST-FIGC,4:UTV,5:CIFI2D,6:FAP,7:CIAFEL,8:ESRI,SE,FSS,UW,9:SHSC-SDU,10:S&HS,UE

INTRODUCTION: A third of the world population is not meeting the recommended daily physical activity guidelines (1). Thus, new exercise options should be studied, since lack of motivation to exercise is a major cause of sedentary behavior in adulthood (2). This study describes the acute physical and physiological demands of recreational team handball and evaluates whether it could be suggested as an exercise mode for fitness and health enhancement in adult sedentary men formerly trained in the sport.
METHODS: Fifteen 33-55 year-old sedentary former male team handball players were evaluated for activity profile, heart rate (HR), blood lactate and rating of perceived exertion (RPE) during 4 recreational matches. The matches (7v7) consisted of 2x30-min with a 10-min half-break, and were preceded by a standardized 15-min warm-up.
RESULTS: During the matches the players covered ~6 km, and changed match activity 388±70 times, of which high-intensity runs and unorthodox movements amounted to 59±18 and 26±26 per match, respectively. Jumps and throws were the most frequent highly demanding playing actions. Match average and peak HR were 82±6% and 93±5%HRmax, respectively. Players exercised at intensities between 81-90%HRmax for 47% (28±14 min) and >90%HRmax for 24% (14±15 min) of total match time. For only 9 min of total match time (11%) the players showed HRs equal or lower than 70%HRmax. Match average and peak blood lactate values were 3.6±1.3 and 4.2±1.2 mM, respectively. Post-match RPE was 4.8±2.5 AU (hard).
CONCLUSION: The recreational team handball players covered a higher total distance than their elite counterparts (3), with higher percentage of total time walking and lower standing still, as well as less activity changes, but similar time spent with high-intensity movements. Cardiovascular strain was similar to that found in elite team handball and recreational football players (3,4). This study results show that recreational team handball is an intermittent high-intensity exercise mode with physical and physiological demands in the range of those found to have a positive effect on aerobic, anaerobic and musculoskeletal fitness in adult individuals (4). Training studies considering recreational team handball as a health enhancing intervention are warranted.

HEART RATE MARKERS OF AUTONOMIC FUNCTION ARE UNCHANGED FOLLOWING MAXIMAL EXERCISE IN PATIENTS WITH MYALGIC ENCEPHALOMYELITIS/ CHRONIC FATIGUE SYNDROME

NELSON, M.J., BUCKLEY, J.D., THOMSON, R.L., BELLENGER, C.R., CLARK, D., DAVISON, K.

UNIVERSITY OF SOUTH AUSTRALIA

INTRODUCTION: There are no known objective biomarkers to assist with the diagnosis of Myalgic Encephalomyelitis/Chronic Fatigue Syndrome (ME/CFS). ME/CFS patients have been shown to exhibit an earlier onset of ventilatory threshold (VT) on the second of two progressive maximal exercise tests performed on consecutive days, which represents one of the only biomarkers of the condition. However, maximal exercise can cause significant post-exertional malaise and is therefore not an ideal method for differentiating between ME/CFS

patients and controls. Assessment of heart rate (HR) parameters which are known to track post-exertional fatigue may negate the need for maximal exercise testing to assist with ME/CFS diagnosis.
METHODS: 16 ME/CFS patients and 10 healthy controls underwent maximal exercise testing on two-consecutive days. HR parameters (including resting HR [RHR], HR variability [HRV], post-exertional HR recovery [HRR], and maximal rate of heart rate acceleration [rHRI]), ventilatory parameters, ratings of perceived exertion (RPE) and work rate (WR) were assessed on both days.
RESULTS: WR at VT decreased from day one to day two and by a greater magnitude in ME/CFS patients ($p<0.01$ group × time interaction). No interaction effects were found for any other parameters, including all HR parameters. ROC curve analysis of the percentage change in WR at VT revealed decreases of -6.3% to -9.8% maximised sensitivity and specificity respectively for distinguishing between those with ME/CFS and those without.
CONCLUSION: HR parameters are unchanged following maximal exercise in ME/CFS patients and are unlikely to be useful as diagnostic markers in this form. The decrease in WR at VT of 6.3-9.8% on the second day of consecutive-day maximal exercise tests may represent an objective biomarker of ME/CFS, and may assist with differential diagnosis between individuals who have ME/CFS and those who do not.

THE ASSOCIATION BETWEEN RUNNING ECONOMY AND RESPONSE OF C-REACTIVE PROTEIN TO MARATHON RUNNING IN COLLEGE RECREATIONAL RUNNERS

TAKAYAMA, F.1,2, AOYAGI, A.1, TAKAHASHI, K.1, NABEKURA, Y.1

1: UNIVERSITY OF TSUKUBA, 2: RESEARCH FELLOW OF JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE

INTRODUCTION: Running is a popular form of endurance exercise, with physical and psychological health-related benefits. However, strenuous running such as marathon running can disrupt numerous biomarkers. Among the biomarkers, C-reactive protein (CRP) is useful for assessing the extent of inflammation. Running economy, defined as the oxygen cost (O2 cost) for a given velocity of submaximal running, differs between individuals even when the maximal oxygen consumption (VO2max) is similar. Since runners generate energy based on the amount of oxygen consumed, O2 cost can estimate energy expenditure. Additionally, the CRP response is partially dependent on energy expenditure. This study aimed to investigate the association between running economy and the CRP response following marathon running.
METHODS: Sixteen college recreational runners (13 men, 3 women) who completed a marathon race within 4 hours 7 minutes 43 seconds±44 minutes 29 seconds (mean±standard deviation) were included. The VO2max and O2 cost were measured for all subjects 1-2 weeks before running the marathon using a treadmill running test. Before the race (PRE) and on days 1 (POST1), 2, and 3 after the race, blood samples were collected to assess inflammation.
RESULTS: The VO2max and O2 cost were 47.9-75.5 ml/kg/min (mean, 57.4) and 193.6–264.8 ml/kg/km (mean, 225.1), respectively. The CRP level significantly increased POST1 and remained high throughout the 3-day recovery period. Spearman correlation analysis revealed that the change in the CRP level (difference between PRE and POST1) was significantly correlated with the O2 cost ($r=0.619$, $p=0.011$), whereas it was not correlated with the VO2max ($r=-0.066$, $p=0.807$).
CONCLUSION: Our study revealed a positive correlation between the change in the CRP level and O2 cost, which suggested that inflammation in runners with excellent running economies (low O2 cost) was minor. Additionally, on assuming that the running economy was similar among runners during the race, the difference in energy expenditure was calculated to reach 37%. It is possible that differences in energy expenditure affected the extent of inflammation following the race. Kampus et al. (2008) reported that acute exercise-induced elevation of the CRP level may affect small artery elasticity, which is an important cardiovascular risk factor. Therefore, we recommend improving the running economy of runners to prevent excessive inflammation.

AFFECTIVE AND SELF-EFFICACY RESPONSES TO ACUTE HIGH-INTENSITY INTERVAL TRAINING IN INSUFFICIENTLY ACTIVE YOUNGER AND MIDDLE-AGED MALE ADULTS

POON, E.T.C., SHERIDAN, S., CHUNG, A.P.W., WONG, S.H.S.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: High-intensity interval training (HIIT) has been recognized as an emerging trend in public health promotion (Thompson, 2017), but its age-specific differences in psycho-perceptual responses have yet to be investigated. The purpose of this study was to compare the psycho-perceptual responses after a single session of HIIT versus moderate-intensity continuous exercise (MICE) and vigorous-intensity continuous exercise (VICE) in young and middle-aged insufficiently active males respectively.
METHODS: Twelve young (age: 24.3 ± 1.7 yrs) and twelve middle-aged (age: 46.8 ± 7.5 yrs) healthy insufficiently active males were recruited. Using a within-subject, randomized cross-over design, participants undertook three main trials (with 7-day apart): HIIT (10 x 1-min run at 100% VO2max interspersed with 1-min active recovery), MICE (40-min run at 65% VO2max) and VICE (20-min run at 80% VO2max). Affective responses were assessed at 10 in-task time points for each trial, whereas self-efficacy and exercise preference were evaluated at the end of the final trial. These variables were analyzed separately for each age group (within-subject comparison). Two-way ANOVA with repeated measures (mode x time) was used to determine in-task affective response, while one-way ANOVA with repeated measures was used to compare self-efficacy and exercise preference.
RESULTS: In the young adult group, the in-task affective response scores were higher at 95% and 100% of exercise completed in HIIT than in MICE ($P < 0.05$), indicating a more positive affective response towards the end of exercise session. Middle-aged adults reported higher affective response scores in HIIT from 40% of exercise completed onwards than VICE ($P < 0.05$), suggesting a more positive affective response in HIIT than VICE. However, middle-aged adults displayed significantly lower exercise task self-efficacy scores towards HIIT (42.7 ± 25.3) and VICE (49.2 ± 23.9) than MICE (63.4 ± 18.3, both $P < 0.01$) based upon pairwise comparison. No significant difference in self-efficacy was observed in the young adult group. Additionally, only 17% of participants in the middle-aged group reported a preference to engage in HIIT as opposed to either MICE (50%) and VICE (33%). 33% of the young adults preferred HIIT, 67% preferred VICE, while none chose MICE as their preference.

CONCLUSION: Our findings revealed distinct affective and self-efficacy responses to acute HIIT versus both MICE and VICE in the two age groups which assists in our understanding of how individuals in various age populations perceive HIIT. This allows for both the design and implementation of effective exercise programs for public health, especially for insufficiently active individuals. Future research examining the long-term adherence to HIIT in different age populations is warranted.

CONSISTENCY OF ACUTE EXERCISE PERFORMANCE AND RESPONSE USING AN EFFORT-BASED INTENSITY PRESCRIPTION

OGRADY, C., HOPKER, J.H., PASSFIELD, L.

UNIVERSITY OF KENT

INTRODUCTION: Individual variability in training response is often seen in exercise training studies, indicating that the methods used to prescribe training (e.g. %VO2max), cannot elicit consistent responses between and within individuals (Mann, Lamberts, & Lambert, 2014). Effort-based training in which athletes are required to self-pace their effort provide an alternative method of prescription that may reduce the variability observed in acute training session stimulus. This study aimed to investigate the individual variability in the performance and acute physiological response of various training formats using an effort-based approach.
METHODS: 17 male competitive cyclists (VO2max: 59.44±8.17ml·kg·min-1) completed 9 exercise trials, using either short (S) or long (L) interval, or continuous (C) formats, each format repeated 3 times. Intensity prescription used a maximal session effort-based approach. The performance and physiological responses were analysed to identify the within-athlete (intra-individual) and between-athlete (inter-individual) variability using coefficient of variation (CV). Total variability is how much the within-athlete variability differs between all cyclists and is calculated as the CV across all cyclists for the intra-individual CV's.
RESULTS: Performance was different in the 3 formats (S; 382±54W, L 310±45W, C: 262±40W: P< 0.001), with no difference in heart rate (S: 164±9bpm, L: 163±9bpm, C: 164±10bpm). Average blood lactate during S & L was higher than C (9.49±2.71mmol & 9.07±2.1mmol vs. 6.26±1.97mmol, P<0.001). Average session RPE was highest in S & L compared to C (18±1 & 18±1 vs. 17±1, P < 0.001), final RPE was matched between all formats (S: 19±1, L: 19±1, C: 19±1). Intra-individual variability in session power output was highest in S (3.4%), and similar between L and C (2.8% & 2.6%). Inter-individual variability in session power was highest in C (15.3%), and similar between L and S (14.5% & 14.2%). Total variability of session power was lowest in L (54.6%), followed by C (69.0%), and S (87.5%). Intra-individual variability in expired gas responses was highest in S (5.8%), followed by C (5.3%) & L (4.9%). Inter-individual variability was highest in C (12.5%), and similar between S and L (10.5% & 11.0%). Total variability was highest in C (84.4%), followed by S (73.7%) and L (62.6%).
CONCLUSION: L interval format sessions display the greatest overall consistency in both performance & response compared to S and C sessions. Using long intervals (5min) and an effort-based intensity prescription elicits a more homogenous training stimulus compared to shorter intervals or continuous exercise. A more consistent training stimulus may translate into lower variability in observed adaptations to exercise training regimes.

ACUTE EXERCISE INHIBITS MITOCHONDRIAL L-CARNITINE SENSITIVITY IN AN INTENSITY-DEPENDENT MANNER: IMPLICATIONS FOR FUEL INTERACTIONS

PETRICK, H., HOLLOWAY, G.P.

UNIVERSITY OF GUELPH

INTRODUCTION: While exercise activates a number of metabolic processes, at higher power outputs a coordinated shift towards carbohydrate utilization occurs at the expense of fatty acid oxidation. The underlying mechanisms remain elusive, yet carnitine palmitoyl transferase-I (CPT-I) flux and creatine-independent phosphate shuttling are attractive control points subject to external regulation. We therefore examined if acute exercise altered 1) mitochondrial ADP and inorganic phosphate (Pi) sensitivity, or 2) the sensitivity of CPT-I to L-carnitine, in an intensity-dependent manner.
METHODS: We performed mitochondrial respiration experiments (Oroboros) in permeabilized muscle fibers of female C57Bl6 mice randomly assigned to remain sedentary (SED) or perform a single bout of low (LI, 15m/min, 5% grade, 90min) or high (HI, 20m/min, 15% grade, 30min) intensity treadmill running.
RESULTS: Acute exercise did not alter maximal respiratory capacity or Pi-supported kinetic properties. In contrast, the apparent ADP Km was increased following exercise, however this response was similar between LI (1093μM) and HI (1047μM) compared to SED (817μM, p<0.01), and therefore cannot contribute to the intensity-dependent shift in substrate utilization. We next examined CPT-I supported respiration, as reductions in intramuscular carnitine availability have been proposed to limit lipid oxidation at intense aerobic workloads. While L-carnitine sensitivity was comparable between SED (apparent Km=22.2μM) and LI (apparent Km=23.8μM), HI exercise attenuated this response almost 40% (apparent Km=36.2μM, p<0.03). Relating our kinetic models to known skeletal muscle metabolite concentrations predicts a 16% decline in CPT-I flux at higher power outputs, which is equally driven by reductions in L-carnitine content and sensitivity (~8% each). In support of this, we performed experiments utilizing substrate concentrations associated with each metabolic state, indicating lipid-supported respiration was 30% lower following HI (45pmol/sec/mg dry wt) compared to LI (65pmol/sec/mg dry wt, p<0.02). Moreover, only LI lead to improvements in L-carnitine sensitivity in the presence of malonyl CoA (lower apparent Km vs. SED), further indicating greater CPT-I mediated respiration at low but not high intensities of exercise.
CONCLUSION: These findings implicate CPT-I flux as a key event influencing metabolic interactions and aerobic energy production, as a decline in L-carnitine sensitivity, in addition to availability, with high intensity exercise could impair fatty acid oxidation.

HIP AND SPINE BONE MINERAL DENSITY ARE GREATER IN MASTER SPRINTERS, BUT NOT ENDURANCE RUNNERS COMPARED WITH CONTROLS

PIASECKI, J.1, MCPHEE, J.S.1, HANNAM, K.2, DEERE, K.C.2, ELHAKEEM, A.2, PIASECKI, M.4, DEGENS, H.1,3, TOBIAS, J.H.2, IRELAND, A.1

1MUSCULOSKELETAL PHYSIOLOGY RESEARCH GROUP, NTU, UK,2.SCHOOL OF HEALTHCARE SCIENCE, MMU, UK,3.MUSCULOSKELETAL RESEARCH UNIT, UOB, UK4.LSU, LITHUANIA, 5MRC-ARUK CENTRE FOR MUSCULOSKELETAL AGEING, UON,

INTRODUCTION: Regular running exercise may maintain skeletal health during ageing and there is burgeoning participation in masters athletics, particularly mass-participation endurance events. Whether endurance running offers any skeletal benefits remains unclear and it is also unknown whether clinically-relevant skeletal differences exist between sprint and endurance runners because most research in this area has examined peripheral bones of the limbs, not key clinical sites including the hip and spine which are susceptible to fracture.
METHODS: We recruited master sprint runners (28 men, 10 women, mean age 71±7y), master endurance runners (111 men, 38 women, mean age 70±6y) and non-athletic controls (29 men, 30 women, mean age 74±5y). Dual X-ray absorptiometry was used to assess hip and spine bone mineral density (BMD), lean mass and fat mass. Jump power was assessed with jumping mechanography. In athletes, vertical impacts were recorded over 7 days from a waist-worn accelerometer to determine whether skeletal benefits of sprint or endurance running were related to regularity or magnitude of impact loads. Details of starting age, age-graded performance and training hours were also recorded.
RESULTS: In fully-adjusted ANOVA models (adjusting for age, height, sex, fat mass, lean mass, absolute power), sprinter hip BMD was 10% and 14% greater than endurance runners and controls, respectively. Sprinter spine BMD was 88% greater than both endurance runners and controls (both $P < 0.05$). There were no differences in hip or spine BMD between endurance runners and controls. Whilst discipline (sprint/endurance), jump power, starting age, low and medium impacts were independent predictors of athlete hip and spine BMD, in stepwise regression, only sex and discipline were identified as predictors (both $P < 0.0005$).
CONCLUSION: Regular sprinting is associated with greater BMD at the fracture-prone hip and spine sites, but this was not the case for endurance runners whose BMD was similar to those of non-athletic controls. This suggests sprint training may reduce the age-related decline in BMD. These advantages in sprinters are partially explained by differences in vertical impacts, body composition and jump power compared with endurance master athletes. Further studies should investigate whether the advantages in hip and spine BMD in masters sprint, but not endurance runners, are explicable by differences in horizontal impacts, training history and/or nutritional status.

HIGH PLANTAR PRESSURE MAY POSITIVELY AFFECT BONE GEOMETRY AND STRENGTH IN MALE ADOLESCENT FOOTBALL PLAYERS

LOZANO-BERGES, G.1,2,3, MATUTE-LLORENTE, A.1,2,3,4, GÓMEZ-BRUTON, A.1,4,6, ESCAMILLA-GALINDO, V.2, ALFARO-SANTAFÉ, V.7, GONZÁLEZ-AGÜERO, A.1,2,3,4, VICENTE-RODRÍGUEZ, G.1,2,3,4, CASAJÚS, J.A.1,3,4,5

UNIVERSITY OF ZARAGOZA

INTRODUCTION: Bone microdamages caused by high-impact football loads increase bone remodeling activity (Schneider, 2011). However, the effect of these load intensities on bone geometry and strength has not been study yet. Thus, the aim of the present study was to compare bone geometry and strength parameters between adolescent football players with different plantar pressures monitored when performing specific-football drills.
METHODS: Forty male players (13.2 (0.5) y) from different Spanish football clubs participated in this study. Biofoot/IBV insoles were used to measure peak plantar pressures at non-dominant lateral foot, medial foot, forefoot, midfoot and rearfoot during a combination of some specific-football actions. A k-means cluster analysis was conducted to classify players into two different groups from pressures above-mentioned as follow: 15 football players with high pressures (HP; mean of all peak pressures 392.7 (68.2) kPa) and 25 with low pressures (LP; mean 261.0 (49.6) kPa). Bone geometry and strength were measured at the 38% site of the length of the non-dominant tibia by peripheral quantitative computed tomography (Stratec XCT-2000 L pQCT scanner). Multivariate analysis of covariance was performed to examine bone differences between football players with HP and LP, using weight and tibia length as covariates.
RESULTS: Football players with HP demonstrated higher total ($F(1, 35)=4.7$, $p=0.038$, partial eta squared=0.12) and cortical bone mineral content ($F(1, 35)=5.4$, $p=0.026$, partial eta squared=0.13) than those players with LP. Furthermore, total area ($F(1, 35)=1.2$, $p=0.284$, partial eta squared=0.03), total bone mineral density ($F1, 35=2.1$, $p=0.156$, partial eta squared =0.06), cortical thickness ($F(1, 35)=2.3$, $p=0135$, partial eta squared=0.06) and polar strength strain index ($F(1, 35)=2.7$, $p=0.109$, partial eta squared=0.07) were higher but not significantly different in football players with HP in comparison to those players with LP.
CONCLUSION: Developing high plantar pressures in some specific football actions might be associated with high bone geometry and structure parameters. On the other hand, the type of surface and footwear should be considered because of their influence with the impact received by the player (McGhie & Ettema, 2013).

FEAR AVOIDANCE BELIEFS AND MUSCLE STRENGTH EFFECT ON FUNCTIONAL OUTCOMES TWO MONTHS POST ARTHROSCOPIC SHOULDER INSTABILITY REPAIR

GOTTLIEB, U., SPRINGER, S.

ISRAELI DEFENSE FORCE, ARIEL UNIVERSITY

INTRODUCTION: Arthroscopic surgical repair of the shoulder is usually recommended when conservative treatment for shoulder instability (SI) fails. However, only less than half patients undergoing this procedure return to same level of activity. Psychological factors as well

muscle strength were shown to be associated with postoperative outcomes in musculoskeletal conditions. The purpose of this study was to determine the influence of fear-avoidance and shoulder muscles strength on functional status during the initial rehabilitation of people post arthroscopic repair of SI.
METHODS: Twenty-one soldiers (mean age 20.6±1.2 years) who underwent arthroscopic surgical repair due to SI participated in this study. Patients with known rotator cuff injury or prior injury in the contra-lateral shoulder were excluded. Baseline fear avoidance beliefs were assessed using the Fear Avoidance Belief Questionnaire (FABQ) up to two weeks post-surgery. Subjects received standard rehabilitation protocol. Follow-up examination at 7-8 weeks post-surgery and included the FABQ, functional assessment using the Disability of Arm, Shoulder and Hand questionnaire (DASH), and muscle strength. Internal rotation (IR) and external rotation (ER) maximal isometric strength were measured with the participants in a seated position, and the shoulder positioned at 45° abduction in the plane of the scapula. Muscle strength was calculated as the ratio between the operated and non-operated limb peak torque. Paired t-tests were used to compare between the FABQ and DASH scores at baseline and follow-up. Multiple linear regression analyses were conducted to investigate the effect of fear avoidance and muscles strength on functional status.
RESULTS: The level of fear avoidance decreased ($p<0.001$) and the functional status improved ($p<0.001$) at follow-up. Baseline FABQ score and IR strength on follow-up were significantly associated with follow up DASH score ($R^2=48.7\%$, $p=0.002$).
CONCLUSION: Post-surgical fear avoidance beliefs and IR strength may influence initial rehabilitation outcomes after a SI surgical repair. Although additional studies are needed to generalize these findings, practitioners should consider the current results during post-surgical repair of SI rehabilitation.

ROWERS WITH LOW BACK PAIN SHOW A DIFFERENT DISTRIBUTION OF ERECTOR SPINAE MUSCLE ACTIVITY DURING AN INCREMENTAL TEST TO VOLITIONAL EXHAUSTION

WILSON, F., MARTINEZ-VALDES, E., FLEMING, N., MCDONNELL, S.J., FALLA, D.

TRINITY COLLEGE DUBLIN

INTRODUCTION: Rowing is a highly repetitive activity involving cyclical flexion-extension and loading of the lumbar spine. Repetitive movements combined with high levels of muscle fatigue during training sessions and competitions; place the lumbar spine at a high risk of injury. Although rowing is one of the sports with the highest incidence of low back pain (LBP), there are a lack of studies investigating activation of the lumbar muscles and the potential change in activation with LBP. We aimed to assess the spatial distribution of erector spinae (ES) muscle activity in rowers with and without a history of low back pain during rowing, using high-density surface electromyography (HDEMG).
METHODS: Ten healthy rowers were the control group (CONT) (8 men, 2 women of 27 ± 18 yrs; 179 ± 8 cm; 77 ± 12 kg) and eight rowers with LBP history (5 men, 3 women of 32 ± 18 yrs; 179 ± 8 cm; 77 ± 8 kg) performed 7x4-min exercise bouts (rowing ergometer) until maximal exertion. Loads (W) were adjusted according to each athlete's best time in 2000m (loads increased at a rate of 15 to 45W p/bout according to performance level). HDEMG was recorded with two 13 x 5-electrode grids placed bilaterally over the lumbar ES while 2D sagittal-plane kinematics were acquired with an electrogoniometer (knee joint). HDEMG data was analyzed in three epochs according to the stroke phase (first epoch: full flexion to 66% of extension, second epoch: 66% of extension to 33% of extension and third epoch: 33% of flexion to full extension) for the first five exercise bouts. Root mean square (RMS) amplitude, mean spectral frequency (MF) and entropy of the HDEMG amplitude map were analyzed. In addition, the y-axis coordinate of the centroid of the RMS map (cranial-caudal direction) was used to assess changes in spatial distribution of ES activity.
RESULTS: As the rowing ergometer load increased, rowers with LBP history showed higher RMS amplitude for the ES bilaterally compared to the CONT ($p<0.01$). LBP rowers also showed less heterogeneity in ES activity as revealed by the entropy values, which did not decrease across the task as observed in the CONT group ($p<0.001$). In addition, rowers with LBP showed an opposite displacement of the centroid of the EMG amplitude map, with the LBP group showing a caudal shift of the centroid, while for the CONT group, a cranial shift was observed ($p<0.001$). No differences in MF were observed between groups ($p=0.5$).
CONCLUSION: Both the magnitude and distribution of ES activation differed in rowers with LBP compared to asymptomatic rowers. The more homogenous activation within the muscle combined with a caudal displacement of activity within the ES with progressive rowing in the rowers with pain, might suggest an inefficient pattern of ES activation as the load progressed (e.g. recruitment of a portion of the muscle with a shorter lever arm). Modification of the rowing technique in conjunction with feedback from HDEMG might prove useful in future studies.

DIFFERENCES IN VERTEBRAL COLUMN MORPHOLOGY BETWEEN BLUE AND WHITE COLLAR WORKERS USING A NON-INVASIVE METHOD

DVORÁK, M.1,2, CZIRÁKI, P.2, TÓTH, M.1

1.UNIVERSITY OF PHYSICAL EDUCATION; 2.ZÖLDPONT MEDIA AND SPORT ASSOCIATION FOR SPORT

INTRODUCTION: Sedentary behaviour during work time has a harmful effect on the health. Although a huge number of studies found a connection between daily sitting hours and cardio-metabolic status, obesity, metabolic syndrome, just some of them measured the influence on the musculoskeletal system, especially the spine. In this study we investigated the difference between the white collar workers and the blue collar workers in the same company.
METHODS: In this cross-sectional study the total of 188 white collar worker (male n=79, female n=109, age 43,6 ±10,8) and 46 blue collar worker (male n=38, female n=10, age 45,4±8,7) were measured with SpinalMouse® (Idiag, Volkerswill, Switzerland) noninvasive device. All participants were free of disease according to self-report. The device was used to measure the thoracic kyphosis angle, lumbar lordosis angle in neutral and flexion standing position, whilst thoracic - lumbar ratio (T/L) was calculated as an indicator of spine balance. The Matthiass test was used to assess changes in the measured angles upon loading (weight depends on sex and bodyweight) for 30 seconds. All tests were made by the same specialist.
RESULTS: Between the two groups of subjects, there were no significant differences in thoracic kyphosis and lumbar lordosis angles both in neutral and flexion standing position, and in Matthiass test. However, there were significant differences ($p<0,05$) in the T/L ratio in neutral standing position (white collar workers 1,98, blue collar workers 2,36), which was the opposite of the expected results.
CONCLUSION: Both the white and blue collar workers have spinal values below little more than the average, but except some results we did not find significant differences between them. Moreover, although we experienced the contrary results in T/L ratio (which means slightly decreased lumbar lordosis followed by poor sagittal balance), neither of the groups have pathological spine balance. The cause

might be that because of modernisation the blue collar workers spend most of their time in front of computers nowadays (like the office workers), just in 12 hours. Even more, the shift work has harmful effects for their health as well, according to other studies.
This study investigated the difference in vertebral curvature between blue collar and white collar workers, but found ambiguous results. For better understanding, we need further researches which contain not just sagital but frontal measurements with SpinalMouse® and use activity trackers for objective daily activity datas in both groups.

OP-PM44 Cardiovascular diseases

A PROSPECTIVE COHORT STUDY TO ASSESS THE MECHANISM OF ACTION OF CLINICAL IMPROVEMENT WITH SUPERVISED EXERCISE IN PATIENTS WITH INTERMITTENT CLAUDICATTION (PREDICT STUDY)

HARWOOD, A.E., TOTTY, J., CARRADICE, D., WALLACE, T., SMITH, G.E., CHETTER, I.C.

HULL YORK MEDICAL SCHOOL

INTRODUCTION: Intermittent claudication (IC); ischaemic muscle pain precipitated by exertion, is the most common presenting symptom of peripheral arterial disease, affecting 20 % of the population over 70. IC is frequently associated with reductions in walking ability quality of life and physical activity levels. The USA, European and UK guidelines all recommend a supervised exercise programme (SEP) as first line treatment. Whilst there is evidence demonstrating walking improvements following a SEP, there is limited data on the mechanism behind this. Therefore this study aimed to explore the relationship between changes in clinical outcome and potential underlying candidate physiological mechanisms.
METHODS: A single centre prospective cohort study was undertaken at a vascular unit in England. Usual ethical approvals were granted. Following written informed consent patients were recruited for SEP, 3 times per week for 12 weeks. Measures recorded included; clinical indicators of lower limb ischemia, quality of life (QoL), cardiorespiratory fitness (CRF), flow mediated dilatation (FMD) and muscle strength and endurance (MSME). The primary endpoint the association between maximum walking distance (MWD) at 3 months, mechanism of action and patient characteristics. 100 patients were required to detect significance ($p>0.05$) at 90% power.
RESULTS: A total of 109 patients were recruited, with just 55 completing a full course of SEP. MWD and intermittent claudication distance was significantly improved at all time points. QoL was significantly improved at all time points in 7/9 and 4/5 domains of the SF36 and VascuQol respectively. Only VE/VCO2 was significantly improved with the SEP. All other markers of CRF did not demonstrate a significant improvement with exercise. FMD demonstrated at 50 % improvement but was not significant. MSME was significantly improved at all time points. Multivariate regression demonstrated CRF and QoL to be the most important factors for determining improvements in 12 week MWD.
CONCLUSION: SEPs are the recommended first line treatment for all patients diagnosed with IC and there have been several purported mechanisms of action in the literature that may lead to improvements following a programme. This study identified that cardiorespiratory fitness and muscle strength and endurance are the most likely candidates for improvements following exercise. Furthermore the anaerobic threshold appears to be the most significant predictive factor for 3 month MWD. Future studies should endeavour to prioritise these outcomes and address whether different exercise programme regimes have similar affects.

CARDIORESPIRATORY FITNESS AND HABITUAL PHYSICAL ACTIVITY IN ADULT RENAL TRANSPLANT RECIPIENTS

TRÁJER, E., TÓTH, SZ., PROTZNER, A., BOSNYÁK, E.1, SZMODIS, M., KOMKA, ZS., TÖRÖK, SZ., TÓTH, M.

UNIVERSITY OF PHYSICAL EDUCATION BUDAPEST

INTRODUCTION: Chronic renal failure is a progressive and irreversible syndrome. At the final stage of chronic kidney disease (end-stage renal disease, ESRD) a dialysis or renal transplant is necessary. Patients with ESRD have an altered psychological and physical status which results in decreased health-related quality of life. Being physically inactive leads to muscle atrophy and to the loss of absolute strength. Although a successful KTx improves quality of life, cardiovascular disorder is still the leading cause of mortality among kidney transplant recipients. Hypertension, diabetes mellitus, obesity and sedentary behavior are risk factors for cardiovascular disorders.
METHODS: 35 adult kidney transplant recipients (12 women, 23 men) participated in our study. Members of the Hungarian National Transplant Team (n=21 patients) represented the active kidney transplant recipient group. The control group consisted of 14 sedentary kidney transplant patients. After anthropometric measurements an incremental spiroergometric exercise test was performed on a cycle ergometer until exhaustion. Heart rate (HR) was monitored with a 12-lead electrocardiogram throughout the test. Capillary lactate concentration was taken at rest, test completion and 5 minutes after the test. Gas exchange parameters were measured during the exercise test using breath-by-breath analysis. The following maximal parameters were recorded: oxygen uptake (VO2peak), ventilation (VE), oxygen pulse (O2p) and load (P). The level of urea, serum creatinine (SeCr), estimated glomerular filtration rate (eGFR), hemoglobin and hematocrit were measured.Habitual physical activity was measured using an accelerometer-based assessment method on 7 consecutive days. The level of significance was set at $p \leq 0.05$.
RESULTS: There were no significant differences between the two study groups in body mass index, age, age of graft, hematocrit, hemoglobin, SeCr, eGFR and O2p. Hemoglobin, Urea ($p=0.010$), VO2peak ($p=0.009$), VE ($p=0.016$), P ($p=0.000$), LAC ($p=0.027$) and HR ($p=0.001$) showed significant differences between the two groups. There were also significant differences between the two groups in time spent in sedentary(SEDsum; $p=0.0094$), as well as moderate to vigorous physical activities intensity (MVPA) (MVPAsum; $p=0.0047$). Significant correlations were found in the study group between eGFR and VO2peak ($r=0.49$), VE ($r=0.51$), P ($r=0.54$), age ($r=-0.46$), graft age ($r=-0.44$), SeCr ($r=-0.87$), hemoglobin ($r=0.48$) and urea ($r=-0.68$). The relationship between LACmax and urea ($r=-0.48$), SeCr ($r=-0.41$) and eGFR ($r=0.48$) was also significant. Significant correlation was found in the control group between eGFR and VO2peak ($r=0.69$).
CONCLUSION: Habitual physical activity (for example organized sport programs, more time spent in MVPA and less sedentary behavior) improves cardiorespiratory capacity and physical performance among renal transplant recipients which is related to a better graft function and could increase metabolic capacity.

OP-BN45 Cognitive training and performance

THE EFFECTS OF LOWER EXTREMITY VISUOMOTOR TRAINING ON COGNITIVE AND MOTOR PERFORMANCE – A RANDOMIZED CONTROLLED TRIAL

GIESCHE, F., ENGEROFF, T., NIEDERER, D., WILKE, J., SCHWARZ, S., VOGT, L., BANZER, W.

GOETHE-UNIVERSITY

INTRODUCTION: The ability to quickly and accurately adjust movement patterns in response to an external stimulus is a key demand for open skill sports performance (Scanlan et al. 2013) and effective injury prevention (Wilkerson et al. 2017). Although research focused mostly on physical abilities recent evidence suggests that cognitive and perceptual abilities might be considered as major discriminating factors for such open skill tasks (Scanlan et al. 2013). One approach to analyze and train these tasks are visuomotor choice reaction time (VMRT) paradigms (Wilkerson et al. 2017). Here, participants have to activate one out of multiple sensors in response to a visual sensory stimulus. This study analyses the impact of a self-administered VMRT training on cognitive processing of visual stimuli and motor performance.
METHODS: Twenty-two healthy, physically active individuals (24.7±2.4 years; 173±9 cm; 70.7±11.4 kg; 11 male) participated in a four-week randomized, controlled trial. Ten participants performed a lower extremity VMRT exercise (The QuickBoard, LCC, Memphis, United States of America); twelve participants served as controls. Training was performed in an upright standing position three times a week. Motor performance was assessed using drop jump, hexagon test, postural control, and lower extremity VMRT. The latter was also performed on the QuickBoard. Cognitive choice reaction (Cogstate Identification test) and inhibitory control (Stop-Signal task) were captured via validated computer-based neurocognitive testing in seated position.
RESULTS: Two-by-two ANCOVAs (time x group), with subjective attention as co-variate, revealed significant interaction effects for lower extremity choice reaction performance (from 13.6±.84 to 18.00 ± 1.63 hits per 10 seconds in the training group vs. from 14.00± 1.70 to 14.42± 1.24 in the control groupp; $p < .05$) as well as for change of direction speed (Hexagon; from 13.7± 1.6 s to 12.1 ± 1.4 s vs. from 12.1±1.42 s to 11.1± 1.6 seconds; $p < .05$). Cognitive processing tests and further motor performance measures revealed no interaction effects ($p > .05$).
CONCLUSION: The VMRT training affects the performance within comparable movement patterns with or without cognitive processing of visual stimuli. The improvements found in VMRT performance seem to be mediated by changes in task-related motor coordination skills (Paul et al. 2016) rather than changes in cognitive processing speed.

AN EEG INVESTIGATION OF THE NEURAL CORRELATES UNDERLYING THE PROCESSING OF KINEMATIC AND CONTEXTUAL INFORMATION ON ANTICIPATION IN CRICKET BATTING

SIMONET, M.

ST MARYS UNIVERSITY

INTRODUCTION: Anticipation refers to the ability to accurately predict the outcome of an opponent's actions ahead of the act itself. This ability is underpinned by the use of information from at least two broad sources, namely, the pick-up of low-level biological motion information from an opponent's movement kinematics (i.e., postural cues) and the use of high-level contextual information related to the event, such as game score or position of fielders. The neural correlates associated with the processing of these two information sources in expert athletes is yet to be investigated.
METHODS: The neural activity in 15 expert and 15 novice cricket batters when anticipating deliveries from bowlers in a video-based simulation task was recorded using electroenchephalography (EEG). Altogether, 120 videos clips were displayed across three conditions, including 24 clips where participants were only exposed to contextual information (game situation and field setting), 24 clips where only kinematic information was provided (bowler shown) and 72 clips with both information sources provided. Trials were occluded immediately after the ball release and anticipation accuracy measured by marking predicted ball location on scaled diagrams. Time-frequency analyses were used to assess any changes in electrocortical activity.
RESULTS: Initial results demonstrated that expert batters showed better anticipation accuracy across the three conditions. While there was no difference in anticipation accuracy between the kinematic and the contextual condition in the expert batters, the novices were better at anticipating in the kinematic condition compared to the contextual condition. Both groups were more accurate when both kinematic and contextual information sources were presented. The EEG data showed a decrease in the power of the alpha band (8-13 Hz) over sensorimotor areas in the kinematic condition, while in the contextual condition alpha synchronisation was observed over more frontal sites.
CONCLUSION: Anticipatory expertise in cricket batting relies on the ability to successfully process both kinematic and contextual information, as shown by the experts' skill advantage across the three conditions compared to novices, whose performance relies largely on processing kinematic cues only. EEG results suggest that bottom-up mechanisms are engaged when anticipatory decisions predominantly rely on kinematic cues, while contextual information processing appears to be supported by frontal regions involved in higher cognitive mechanisms. Findings have implications for those interested in identifying and enhancing the neural mechanisms involved in anticipation in sport.

THE EFFECT OF QUIET EYE AND HIGH ATTENTION TRAINING ON THE ACQUISITION, RETENTION AND TRANSFER OF A GOLF PUTT

WATTS, M., HAYES, S., BENNETT, S., CAUSER, J.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: A longer Quiet Eye (QE) period, the final fixation before movement onset, has been associated with improved performance in various sporting tasks (Vickers, 1996). QE duration and performance have been found to be negatively affected by increased anxiety and attentional load, however, through QE training these effects may be negated (Vine & Wilson, 2011). Therefore, the aim of the current study was to examine whether QE training under single or dual-task conditions, compared to that of traditional technical training (TT), enhanced the acquisition, retention and transfer of a golf putt.

METHODS: A three-week training programme was designed with 36 novice participants being randomly assigned into one of three groups: Low Attention QE-trained (QELA), High Attention QE-trained (QEHA) or TT. 10 pre-test golf putts from 8ft were followed by 90 acquisition phase putts, 10 retention putts, 10 attention transfer test putts and 10 anxiety transfer test putts. Prior to the acquisition phases, both QE groups were shown an expert example of visual gaze during the same putt and were given instructions as to where to direct their gaze during their own putts. TT participants received the same video but with the gaze cursor removed and were given technical instructions of how to correctly swing their putter. The QEHA group was also required to perform a secondary, tone recognition task during all 90 of their acquisition phase putts. QE was measured using a Tobii Glasses 2 eye tracking system whilst mental effort and anxiety were recorded using the MRF-3 and RSME forms respectively.
RESULTS: Separate mixed-design ANOVAs were conducted on all dependent variables. All groups significantly reduced their performance error and increased their QE duration (QED) from pre-test to retention and both transfer tests ($p < .05$). Both QE trained groups performed significantly better than TT in both attention and anxiety transfer tests ($p < .05$), with QEHA performing significantly better than QELA in the attention test ($p < .05$). QED significantly reduced for the TT group in both attention and anxiety transfer tests ($p < .05$).
CONCLUSION: The results of the current study provide further support that QE training can help protect performance under increased pressure over that of TT (Vine & Wilson, 2011). Further, the study provides a valuable insight into the role of HA training in the acquisition, retention and performance under pressure of a golf putt. QE training, specifically under HA, can help to prevent significant decrements in performance under high attention and high anxiety situations.

THE EFFECT OF MINDFULNESS TRAINING ON COGNITIVE AND PHYSICAL PERFORMANCE IN ELITE YOUNG HANDBALL PLAYERS

STAIANO, W., NIELSEN MAJ, L., HOVGAARD-HANSEN, L., ROMAGNOLI, M., KIRK, U.

UNIVERSIDAD DE VALENCIA

INTRODUCTION: Mindfulness is the act of increasing present-moment awareness of physiological, mental, and environmental events without imposing judgment on the quality or meaning of them. The application of mindfulness-based intervention (MBI) to elite sport performance has recently become very popular as its practice increase decision-making, focus and attention in particular in fatigued states. The aim of this study was to test the efficacy of MBI in reducing fatigue and thus improving performance during a battery of generic cognitive and handball-specific physical tests in elite young handball players. The hypothese were that the combination of MBI and standard physical training (SPT) increases cognitive ability and handball-specific physical performance more than SPT alone.
METHODS: 24 young elite handball players from the same team were randomly assigned to two different groups: MBI and control. Both groups trained regularly during 6 weeks. However, the MBI group completed a mindfulness training program of 4 hours a week. Players were tested twice, at baseline and at completion of the training period. Cognitive performance was assessed with mind wandering test (SART) and 30-min STROOP test. Physical performance was assessed with the reactive agility test (RAT) and a handball specific agility test. Coefficient of mind wandering (CMW), reaction time (RT) and number of correct responses were measured for cognitive performance while 5 m sprint, decision-making time (DMT), time and hand mistake rate were parameters of physical performance. Data were analysed using mixed model ANOVAs.
RESULTS: Players in the MBI group showed a significant improvement in cognitive abilities compared to the control. CMW was significantly higher in the MBI group (pre 28.5; post 56.4) than in the control (pre 25.5; post 33.3). During the STROOP test the MBI group showed significant faster RT (pre 1026ms; post 749ms) compared to control (pre 1017ms; post 905ms); and a higher number of correct responses (MBI: pre 688; post 785 vs Control: pre 673; post 723). In the physical performance domain during the RAT, MBI group showed a significantly higher DMT (pre 1.78 sec; post 1.61 sec) compared to the control (pre 1.76 sec; post 1.74 sec) while time over 5 m sprint did not change significantly across groups. In the handball specific agility test the MBI group produced at post-test a significant lower rate of hand mistakes (pre 9; post 4) compared to the control (pre 8; post 7) and they completed the test in a faster time (pre 131 sec; post 121 sec) compared to the control (pre 129 sec; post 126 sec).
CONCLUSION: The results of this study provides evidence that the combination of MBI in addition to SPT improves both cognitive and physical abilities in elite young handball players. MBI seems to improve decision-making processes and reduce the negative effect of fatigue, both determinant factors for elite handball performance.

MECHANISMS UNDERLYING EXERCISE-INDUCED BENEFITS FOR INHIBITORY CONTROL IN ADOLESCENTS: CHANGES IN RETINAL VESSEL DIAMETERS AND THE ALLOCATION OF ATTENTIONAL RESOURCES

LUDYGA, S., HANSSEN, H., BRAND, S., PÜHSE, U., GERBER, M.

UNIVERSITY OF BASEL

INTRODUCTION: Accumulating evidence suggests that regular engagement in cognitively-challenging aerobic exercise elicits benefits for executive function (i.e. ability to use thought flexibly to guide action) in children and adolescents. However, less is known on the mechanisms that underlie exercise-induced improvements in this cognitive domain. Therefore present study investigated A) the effects of combined aerobic and coordinative training on the inhibitory aspect of executive function, and B) how changes in neurophysiological indices of inhibitory control and (retinal) microvasculature contribute to the observed effects.
METHODS: Using cluster-randomisation, 36 adolescents were allocated to an exercise and control group. The exercise group performed 20 min of aerobic and coordinative exercise during school-break time on 5 days per week over a period of 8 weeks. Before and after the intervention, the P300 component of event-related potentials elicited from a Stroop task was recorded using electroencephalography. Additionally, retinal photographs were taken to assess the central retinal arteriole equivalent (CRAE).
RESULTS: Based on analysis of variance, greater improvements of behavioural performance on the Stroop task were found in the exercise compared to the control group. Cluster-based permutation testing revealed similar effects for the P300 component. For CRAE, a trend towards a more pronounced increase in the exercise group was observed. Correlational analyses further showed that changes in P300 amplitude and CRAE were interrelated and both associated with improvements of behavioural performance over the intervention period.
CONCLUSION: The findings indicate that a combined aerobic and coordinative exercise program implemented during school-break time enhances adolescents inhibitory control. An increased allocation of attentional resources towards the cognitive task and favourable changes in retinal microvasculature provide some indications that the benefits for behavioural performance are due to improvements in both brain function and structure.

COMPARISON OF COGNITIVE PERFORMANCE AFTER AN ACUTE BOUT OF MODERATE INTENSITY BACKWARD AND FORWARD EXERCISE

GROBLER, L., TERBLANCHE, E.

UNIVERSITY OF STELLENBOSCH

INTRODUCTION: Literature suggests that acute bouts of cardiovascular exercise positively affects executive cognitive function (Chang et al., 2015), however, previous research is limited to forward modes of exercise. For most individuals, backward locomotion is a novel task, requiring greater inputs from the prefrontal cortex and skeletal muscles. However, little is known about the influence of backwards locomotion on executive function. Thus, the aim of this study was to compare the effect of an acute bout of forward (FW) and backward (BW) exercise on executive function.
METHODS: 17 trained participants (age: 19-24 years) volunteered for this cross-over design study. All participants were inexperienced in BW running. Participants performed three familiarisation sessions, where after 20 minute acute bouts of FW and BW running on a motorised treadmill was completed at a moderate intensity (65% of heart rate reserve) (Chang et al., 2015) and on separate days. 20-30 minutes post-exercise, participants completed a modified computer-based Stroop test. The reaction times of the simple (ST) and complex tasks (CT) of the Stroop were analysed. Interference scores (IS) were calculated by subtracting the reaction time of the simple from the complex tasks (Coetsee et al., 2017). T-tests and Cohen's d effect sizes were used to test for statistical significance.
RESULTS: There were no statistically significant differences in the cognitive performance of the participants for the ST (FW: 20.83 ± 2.85ms; BW: 20.83 ± 2.63ms), the CT (FW: 28.57 ± 5.89ms; BW: 26.70 ± 4.18ms), or the IS (FW: 7.74 ± 4.07ms; BW: 5.87 ± 2.85ms) of the Stroop task ($p > 0.05$). Cohen's d effect sizes for the three outcomes were 0.00 (ST), 0.37 (CT) and 0.53 (IS), indicating no to small practically faster reaction times during BW running than FW running.
CONCLUSION: To the authors knowledge this is the first study attempting to determine the influence of BW in comparison to FW exercise on cognitive function. It was expected that the novelty of BW exercise would induce faster reaction times in the Stroop test, however, results show that there are likely only negligible differences in the reaction times of trained individuals after a bout of FW and BW exercise. This may be attributed to the intensity at which the exercise was completed, as previous literature has shown higher intensity exercise to be more effective in the facilitation of neuronal efficiency (Wohlwend et al., 2017).

OP-SH10 Exercise effects on cognitive functioning and emotional responses

INFLUENCE OF ACUTE HIGH-INTENSITY INTERVAL TRAINING BOUT ON COGNITIVE PERFORMANCE

CASOLO, A.1, ANTONIETTI, A.2, GAGGIOLI, A.2, TOMIO, N.2, CAZZOLA, C.2, BRUSEGHINI, P.2,3, GALVANI, C.2

1 UNIVERSITA DEGLI STUDI DI ROMA

INTRODUCTION: High-intensity interval training (HIIT) appears to be a time-efficient and safe exercise, promoting improvements in aerobic fitness and in some cardiometabolic risk factors in both healthy subjects or clinical patients1. Acute bouts of exercise have an influence on cognitive function even if the exercise-cognition relation is complex, depending on the type, duration and intensity of exercise and the type of the cognitive task required2. The aim of this study was to analyze the influence of an acute bout of low volume-high intensity interval training (LV-HIIT) on visual-spatial ability.
METHODS: Thirty-six healthy active young women (age: 22.0±1.4 yr; BMI: 21.4±1.9 kg/m2; V'O2max: 40.5±3.8 mlO2/kg/min) engaged in (1) a LV-HIIT session, consisting of 3 repeated 20s Wingate against a resistance of 5.0% body mass interspersed by 2 min of active recovery3 followed by a cognitive training (LV-HIIT, N=18) or (2) a control session, consisting of a same time period of listening to music (CON, N=18). The day before and immediately after each experimental session, cognitive performance was assessed by the Paper Folding & Cutting Test (PFC)4 and Mental Rotation Test (MS, MRT)5,6.
RESULTS: A significant ($p<0.0001$) decrease in mean power output and a significant ($p<0.001$) rise in Borg Scale were found (mean power: Bout1 389±45 W, Bout2 373±52 W, Bout3 357±61 W; Borg Scale: Bout1 3±1 RPE, Bout2 4±2 RPE, Bout3 6±2 RPE), detecting an increased fatigue state in the LV-HIIT group. The time to complete the PFC test was significantly ($p<0.05$) lower (pre: LV-HIIT 456±129 s, CON 429±129 s; post: LV-HIIT 240±89 s, CON 226±77 s) and the number of errors significantly ($p<0.001$) decreased in the post test (pre: LV-HIIT 9±3 n, CON 9±3 n; post: LV-HIIT 13±2 n, CON 12±3 n) compared with pre test for both groups.
CONCLUSION: Our study demonstrated that a LV-HIIT session does not impair cognitive performance on visual-spatial ability in healthy active young women when mediated by cognitive training, confirming, in accordance with Alves7, that cycling could be associated with enhanced performance after exercise regardless exercise intensity.

EFFECTS OF PHYSICAL ACTIVITY INTERVENTIONS ON COGNITIVE AND ACADEMIC PERFORMANCE IN CHILDREN AND ADOLESCENTS: A NOVEL COMBINATION OF A SYSTEMATIC REVIEW AND RECOMMENDATIONS FROM AN EXPERT PANEL.

SINGH, A., VAN DEN BERG, V., SALIASI, E., DE GROOT, R.H.M., JOLLES, J., CHINAPAW, M.J.

VU UNIVERSITY MEDICAL CENTER

INTRODUCTION: The physical and mental health benefits of PA are widely acknowledged, but less is known about the potential effects of PA on cognitive and academic performance. A number of reviews on this topic have been conducted during the last decade, mainly concluding that PA is positively associated with cognition and with structural and functional brain health and a neutral association with academic achievement for children. Not all of these reviews were systematic, took into account the methodological quality of the studies included, and were exclusively looking at intervention studies. Above all, most reviews summarized the existing evidence at study level. Therefore, the aim of this review was to summarize the current evidence on the effects of physical activity (PA) interventions on cognitive and academic performance in children, and formulate research priorities and recommendations.
METHODS: We performed a systematic review (following PRISMA guidelines) with a methodological quality assessment and an international expert panel. We based the evaluation of the consistency of the scientific evidence on the findings reported in studies rated as of high methodological quality.
RESULTS: Eleven (19%) of 58 included intervention studies received a high quality rating for methodological quality: four assessing effects of PA interventions on cognitive performance, six assessing effects on academic performance, and one on both. All high quality studies contrasted the effects of additional/adapted PA activities with regular curriculum activities. For cognitive performance ten of 21 (48%) constructs analysed showed significant beneficial intervention effects of PA, while for academic performance, 15 of 25 (60%) analyses of the high quality studies found a significant beneficial effect of PA. Across all five studies, assessing PA effects on math, beneficial effects were reported in six out of seven (86%) outcomes.
Experts put forward 46 research questions. The most pressing research priority cluster concerned the causality of the relationship between PA and cognitive/academic performance. The remaining clusters pertained to PA characteristics, moderators and mechanisms governing the 'PA – performance' relationship and miscellaneous topics.
CONCLUSION: There is currently inconclusive evidence for beneficial effects of PA interventions on cognitive and overall academic performance in children. We conclude that there is strong evidence for beneficial effects of PA on math performance.
The expert panel confirmed that more 'high quality' research is warranted. By prioritizing the most important research questions and formulating recommendations we aim to guide researchers in generating high quality evidence. Our recommendations focus on adequate control groups, adequate sample size, the use of valid and reliable measurement instruments for physical activity, cognitive and academic performance and analysis.

AN ACUTE BOUT OF HIGH-INTENSITY INTERVAL EXERCISE MAKES YOUNG MEN SMARTER

COETSEE, C., TERBLANCHE, E.

STELLENBOSCH UNIVERSITY

INTRODUCTION: From a health perspective, cognitive ability is an essential aspect in maintaining a high quality of life. Most studies report that acute aerobic exercise cause a small but significant improvement in cognitive function. While studies investigated the effects of traditional exercise modalities on cognitive function, less is known about the effect of high-intensity interval exercise (HIIE). The purpose of this study was to investigate the acute effect of HIIE on cognitive function in healthy young men.
METHODS: Twenty healthy young men (mean age 20.7 ± 1.6 years) were randomly assigned to a HIIE group (n = 10) or a control (CON) group (n = 10). The HIIE treadmill protocol consisted of ten 1-minute intervals at 90-95% HRmax interspersed with 1-minute active recovery intervals performed at 60-70% of HRmax, while the CON group did a stretching session. Two categories of the Stroop task were included to measure cognitive function, with the neutral category (simple task) assessing information processing speed and the incongruent category (complex task) assessing executive cognitive function.
RESULTS: There was a statistically significant improvement in reaction time on the incongruent category of the Stroop task following a single HIIE session ($P = 0.004$), but no change was observed for the neutral category ($P = 0.061$). The CON group showed a statistically significant improvement on the neutral category ($P = 0.044$), but no significant change was observed for the incongruent category ($P = 0.120$). Trial accuracy did not show any significant within-group difference for either Stroop task category ($P > 0.05$).
CONCLUSION: Some authors have previously suggested an inverted-U relationship for improvement in cognitive function following exercise (Kashihara et al, 2009). It was proposed that improvements may only be found up to an optimal point, and if intensities increase past this point it would result in detriments in cognitive performance. Alves et al. (2014) reported results to the contrary in middle-aged adults. The researchers found that an acute HIIE cycling session resulted in improvements in executive cognitive function. The results of the present study also show that an acute session of HIIE does not cause detrimental effects on cognitive performance and significantly improves executive cognitive function in healthy young men. Future studies are needed to shed light on this dose-response relationship between exercise intensity and cognitive performance in younger adults.

EFFECTS OF ACUTE EXERCISE AND SELF-SELECTED MUSIC ON WORKING MEMORY IN YOUNG ADULTS

HUNG, T.

NATIONAL TAIWAN NORMAL UNIVERSITY

Effects of Acute Exercise and Self-Selected Music on Working Memory in Young Adults
Tsung-Min Hung1, Yu-Jung Tsai1, David Garrido Catalán1, & Chung-Ju Huang2
1. Department of Physical Education, National Taiwan Normal University, Taiwan
2. Graduate Institute of Sport Pedagogy, University of Taipei, Taiwan
Introduction: The study aimed to explore the effects of a single bout of moderate intensity exercise accompanied with self-selected music on affective states and cognitive performance. In particular, to provide evidence of positive affect and arousal moderation by self-selected

music after exercise; and offer behavioral and neuroelectrical information of verbal working memory performance due to exercise+music combination.
Methods: Thirty-seven healthy young adults (20-35 years old) participated in two exercise conditions and a video-watching control condition. Exercise conditions consisted of 5-min of warm-up, 25-min of jogging at moderate intensity (approximately 60% HR reserve) with and without music, and 5-min of cool down. Aural versions of Sternberg working memory test were administered after each condition.
Results: Positive affect and feeling states were significantly enhanced after exercise with self-selected music. Furthermore, shorter RT was observed for both exercise conditions compared to control condition. In addition, a shorter P3 latency and a smaller P3 amplitude at frontal region was showed for exercise + music compared to control condition.
Discussion: A single bout of aerobic exercise of jogging with/without music at moderated intensity resulted in improved working memory performance. However, only exercise + music further showed improvement at the neural level and offered an appreciable improvement on emotional wellness. Interestingly, exercise+music could induce more efficient information processing as reflected by shorter P3 latency while at the same time required less resources indicated by smaller P3 amplitude at frontal region. P3a is thought to reflect the engagement of the frontal lobe and other cortical areas such as the auditory cortex in a conscious evaluative process elicited by a novel and unpredictable "bottom-up" stimuli (Polich, 2007). This finding is similar to perceptual priming that resulted in more efficient and faster response to a stimulus and decreased hemodynamic responses in prefrontal cortex (Bunzeck et al., 2006). In conclusion, self-selected music combined exercise not only provides cognitive benefits but also brought about more pleasant exercise experience that may have implications for increasing exercise adherence.

EFFECTS OF MUSIC ON AUTONOMIC CONTROL AND EMOTIONAL RESPONSE DURING EXERCISE

HSIAO, C.S., CHU, I.H.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Many people listen to music during exercise. In previous studies, music has been shown to increase running performance and enhance positive emotion . Moreover, several studies indicated that listening to music could affect autonomic control . Previous research reported that there is an association between the autonomic control and emotional response, and that the better the autonomic control, the better the emotional response regulation . However, studies that investigated the effects of music on autonomic control and emotional response during exercise are scarce.The aim of the study was to investigate the effects of music on autonomic control and emotional response during exercise.
METHODS: Ten participants were recruited for the study. All of the participants completed one exercise test and two experimental conditions which included running with music and running without music in a randomly assigned order. In both experimental conditions, participants were running at an intensity of 70% heart rate reserve. Felt Arousal Scale and Feeling Scale were used to evaluate emotional response during running. Heart rate variability was measured before and after running to assess the effects of music on autonomic control.
RESULTS: HRV decreased significantly after both running with music and without music conditions. There was no significant difference between the two conditions in HRV changes. The FS scores of the running with music condition were significantly higher at 6 min, 9 min, 12 min, and 15 min as compared to the running without music condition. The FAS scores of the running with music condition were significantly lower at 12 min and 15 min as compared to the running without music condition.
CONCLUSION: The preliminary results of this study suggest that listening to music during exercise may have positive impact on emotional responses. The negative emotions appeared to be attenuated while running at high intensity. On the other hand, listening to music did not seem to affect HRV responses after running. Also, this study did not find any associations between the autonomic control and emotional response. Future studies with larger sample sizes are needed to further investigate the effects of music on autonomic control and emotional response during exercise.

INVESTIGATION OF THE EFFECT OF PHYSICAL ACTIVITY ON SECONDARY SCHOOL STUDENTS METACOGNITIVE LEARNING STRATEGIES AND CREATIVITY LEVELS

TEKIN, M.1, SAVAS, M.S.2

1 KARAMANOGLU MEHMETBEY UNIVERSITY SCHOOL OF PHYSICAL EDUCATION AND SPORTS, 2 AKSARAY UNIVERSITY SOCIAL SCIENCES INSTITUTE PHYSICAL EDUCATION AND SPORTS DEPARTMENT

Introduction: Creative thinking skills of the individual play an active role in the development of the individual.The development of motor skills is important for the development of this effective role.Effective use of both creativity and imaginative learning skills will dynamically interact with motor skills to enable the individual to use learning processes more effectively and to think independently in the educational environment by revealing new ideas.The purpose of this studyis to investigate the effect of physical activity on secondary school students metacognitive learning strategies and creativity levels.
Method
The research group was made of 5th,6th,7th,8th 44 boy,28girls,72(age=11.2917+1.08040) in total studying secondary school located in the Karaman province to achieve the purpose of the research,Creativity Scale developed by Torrance(1966) adapted to Turkish by Aslan (2001) and Metacognitive Learning Strategies Determining Scale By Cögenli and Güven(2014)were based on and applied to the students that participated in the research.15 weeks of instruction in physical education and sports courses including of physical activity and In the study, an experimental research design with pre-test/post-test and control group was used.
In the analysis and assessment of the data, Shapiror Wilk Test, Paried Samples t-Test, and Pearson correlation test,Two-WayAnova for MixedMeasures Test was used and significance was taken as $P<0.05$
Results: Within this study;there was a significant difference between the results of the experimental and control groups;and there was significant difference between post-test results of the experimental and control groups.
Also,According to research results;there was a significant difference between total scores mean for fluency,originality, abstractness of titles, enrichment,resistance to early close, creativity forces list of in favor of post test, in primary students that participated Experimental study
When the obtained results were examined for the lower dimensions of TTCT Verbal Form B there was a significant difference between total scores mean for fluency,flexibility and originality, scores of in favor of post test
Discussion: As a result of this study; reveals that the physical activity applied to secondary school students positively influences the level of students imaginative learning strategies and creativity.

These findings us;The most important purpose of physical activity is; not only to improve the attitudes and skills of individuals,same time, demonstrates that the cognitive, social and affective levels of individuals are improved

OP-SH19 Psychological aspects of sport and exercise; history

A QUALITATIVE APPROACH ON MOTIVES AND ASPECTS OF RISKS IN HIGH-RISK SPORTS

FRÜHAUF, A., KOPP, M.
UNIVERSITY OF INNSBRUCK

A qualitative approach on motives and aspects of risks in high-risk sports
Frühauf,A.1; Kopp,M.1
1: University of Innsbruck, Austria
Introduction: Largely seen through the one-dimensional view of sensation seeking, recent research has shown that there are multiple motives for high-risk sport participation [1]. However, most of the research was based on a questionnaire approach or on qualitative analyses including only few high-risk sport participants [1, 2]. This may have biased reported motives of high-risk sports. Therefore, the aim of the present study was to better understand the motives, benefits and risk-related aspects of specific high-risk sport participants, using a qualitative approach in a large sample.
Methods: Semi-structured interviews were conducted with several high-risk sport participants 50> including freeride skiers and snowboarders, wingsuit flyers, big wave surfers and alpinists. All participants were highly experienced, of different age, gender and profession. Analyses were done using MAXQDA software following a code theme approach.
Results: Themes were separated according to sport participation type. The majority of participants were freeriders with the five emerging themes of Challenge , Friends , Nature , Balance and Freedom . Those motives were shown upon different extent in the disciplines of wingsuit flying, big wave surfing and alpinism. With regard to risk management, participants decided upon a risk calculation strategy which included multiple factors . Trusting in one's own abilities, avoiding negative fear and having trusted partners were among the protective factors. Changes in behavior were reported to occur after experienced accidents and close calls. Relations to risky health behaviors such as gambling and fast driving were not detected in the cohort since most participants only reported to take risks when they were in charge of the outcome. Deliberately seeking out dangerous situations was not a motive.
Discussion: High-risk sports were shown to provide positive effects through participation especially in terms of self-efficacy and well-being. The major motivational drivers for participants were named as: challenging oneself, experiencing nature, contributing to deep friendships, practicing the high-risk sport as a counterbalance to everyday life and escaping from restrictions. Contrary to prior research reports on sensation seeking, experienced high-risk sport participants do not search the risk; they seem to minimize it based on knowledge and experience.

INJURIES IN PROFESSIONAL SOCCER AND IMPLICIT PERSONALITY TRAITS

SPRECKELS, C., WOLLESEN, B.
UNIVERSITY OF HAMBURG

Injuries in professional soccer and implicit personality traits
Spreckels, C.[1] & Wollesen, B. [1]
[1] UHH (Hamburg, Germany)
Introduction: Investigation showed that 5% - 10% (Kleinert 2012) of all injuries in sports are caused by psychological reasons. Due to a higher level of stress a higher level of muscle tension could be responsible for a lot more injuries in soccer. Lazarus (1974) showed that perceiving a situation as stressful is an individual process, what underlines that multiple psychosocial factors could interact with the increase of injury vulnerability. Ivarsson, Johnson and Podlog (2013) investigated personality traits of soccer players like trait anxiety or perfection and state stress-level are predictors for injuries. Podlog (2017) found out that in addition to the higher muscle tension which could cause especially muscle injuries there is another responsible factor: The stress conditioned wrong decision which a player might take when he finds himself in a stressful situation. If and how this process is caused by individual unconscious personality traits is the object of this investigation.
Methods: N= 250 professional soccer players, age: 24,5 ± 7 years. Medical informations of 58 players include absence of training and competition. Due to the investigation that implicit personality traits like fear of failure are responsible for experiencing situation as stressful we used the implicit personality trait test visual questionnaire (ViQ) which is developed in support of the personality system interaction theory (PSI) of Kuhl (2001). He postulates the 4 main characters worker, teamplayer, creative and dominant combined with the 4 motivational factors, which sums up to 16 different types. The medical informations of the 58 soccer players were correlated in a crosstab calculation (SPSS 23) with personality traits.
Results: Results show that the 2 certain types out of 16, who theoretically feel more competitive stress than the 14 others, are more often absent from training and competition because of injuries. It is the teamplayer, who needs good relationships and appreciation with a high need for security which is accompanied by a prevalent negative affect system. These results show that there is a correlation (,618; p=0,05) between implicit personality traits and injury vulnerability.

Conclusions
To know the vulnerability of certain personality types in advance should be a good argument to put athletes in general but especially these 2 personality types in a proactive mental training program including adaptive coping techniques like accepting defeats or positive reframing to minimize their stress level.

SPORT SUPPLEMENT USE PREDICTS DOPING LIKELIHOOD VIA SPORT SUPPLEMENT BELIEFS

HURST, P., BOARDLEY, I., KAVUSSANU, M., RING, C.
UNIVERSITY OF BIRMINGHAM

Introduction: The gateway hypothesis posits that athletes are at risk of progressing to doping if sport supplements are already used for performance enhancement. Recent research has indicated that athletes with stronger beliefs in the effectiveness of sport supplements in improving performance are more likely to use sport supplements (1). Hypothetically, therefore, if athletes' beliefs about sports supplements influence supplement use, and if supplement use predicts doping (i.e. the gateway hypothesis), it is reasonable to suggest a relationship between beliefs about supplements and doping likelihood. However, this relationship remains untested. This study aimed to test the mediating role of sport supplement beliefs on the relationship between sport supplement use and doping likelihood.
Method
Four hundred and eighty one competitive athletes (mean ± SD: age = 19.6 ± 2.2 yrs, hour per week training = 6.3 ± 4.5, years competing = 5.9 ± 4.6) were recruited from sports clubs and asked to complete measures of sport supplement use, sport supplement beliefs and doping likelihood.
Results: Sport supplement use was associated with sport supplement beliefs ($r = 0.46$, $p < 0.01$) and doping likelihood ($r = 0.14$, $p < 0.01$), and sport supplement beliefs were correlated with doping likelihood ($r = 0.22$, $p < 0.01$). Mediation analysis indicated that sport supplement beliefs significantly mediated the relationship between sport supplement use and doping likelihood ($\beta = 0.20$, 95% CI = 0.10 to 0.30), whereas sport supplement use was not directly related to doping likelihood ($\beta = 0.04$, 95% CI = -0.05 to 0.15).
Conclusion
The results of this study indicate sport supplement use predicts doping likelihood via sport supplement beliefs. These findings provide novel evidence to suggest that athletes using sport supplements are more likely to dope due to their belief in the effectiveness of these substances and could help further explain why athletes using sport supplements are more likely to progress to doping (i.e. gateway hypothesis).

PHYSICAL ACTIVITY-RELATED HEALTH COMPETENCE: USING THE PARC-AVE STUDY FOR AN EXTENDED MODEL VALIDATION

CARL, J., SEMRAU, J., PFEIFER, K.
DEPARTMENT OF SPORT SCIENCE AND SPORT

Introduction: Recently, the concept of physical activity-related health competence (PArC) has been introduced to the field of health-enhancing physical activity. In addition to considerable elaborations on a theoretical level, it is further necessary to validate PArC in a holistic manner. Therefore, the goal of the present study was to extend existing validations of the PArC model.
Methods: Data was taken from the baseline assessment of the PArC-AVE study that centered on the PA behavior of apprentices from the nursing care and car mechatronics sector (n=745, age: 19.1±3.4 years). Confirmatory factor analyses (CFA) were undertaken to re-check the factorial structure of an existing three-factor model and to examine the factorial structure of an extended nine-factor model (38 Items). Subsequently, the model was expanded to a structural equation model to analyze associations with the physical activity behavior.
Results: The CFA indicated a good overall fit for the three-factor model as well as for the extended nine-factor model ($\chi^2/df=2.60$, RMSEA=0.046, SRMR=0.042). Even a model including the second-order factors movement competence, control competence, and self-regulation competence revealed an acceptable fit ($\chi^2/df=2.90$, RMSEA=0.051, SRMR=0.066). However, compared with initial validations, the competence facets in this study explained a surprisingly low variance ($R^2=0.131$) in the amount of physical activity.
Discussion: Within the present study, it was possible to work out and validate a nine-factor model on PArC in which the facets could be assigned to three overarching competence domains. A further study is necessary to cross-validate the extended model and to put more focus on associations with physical activity.
The study was funded by the German Federal Ministry for Education and Research (BMBF)

ADOLESCENT'S PHYSICAL ACTIVITY AND SLEEP DURATION: ASSOCIATION WITH PARENTAL ROLE MODELING INFLUENCE AND PARENTING STYLE

SHI, Y., YU, J.J., HUANG, W.Y., WONG, S.H.S.
THE CHINESE UNIVERSITY OF HONG KONG

Background: Research has shown that parental role modeling has important influences on physical activity and sleep duration of young children, but this relationship is unclear among adolescents. Meanwhile, no study investigated the influence of parenting styles on the physical activity and sleep duration of adolescents. This study therefore examined the association of adolescent's physical activity and sleep duration with parental role modeling and parenting style.
Methods: One thousand and thirty-nine adolescents and parents from Hong Kong participated in this study. Adolescents wore the waterproof activPALTM for 7 consecutive days, time (minutes) spent in moderate-to-vigorous intensity physical activity (MVPA) and sleep duration (hours) of the adolescents were calculated. Physical activity (light intensity physical activity (LPA), MVPA) of parents and sleep duration were collected using self-reported questionnaires. Parenting style were measured by adolescent reported Parenting Styles and Dimensions Questionnaire (PSDQ). Linear mixed models (LMM) were conducted to assess the relationship between parents' role model-

ing of LPA and MVPA, parenting style and the MVPA of adolescents (girls or boys). Association between parents' role modeling of sleep duration, parenting style and the sleep duration of adolescents were also investigated by LMM. Analyses were split by girls and boys.
Results: Of all the participants, data from 656 pairs of adolescents and their parents (adolescents: 14.6 ± 1.6 years, 48% of girls; parents: 46.0 ± 7.1 years, 60% of mothers) were available and valid for analyses. Adolescents had 39.5 ± 15.6 mins/day of MVPA and 8.0 ± 0.9 hours/day of sleep duration, with no gender difference. Parents had 87.3 ± 121.4 mins/day of LPA, 56.8 ± 126.5 mins/day of MVPA, and 7.4 ± 1.2 hours/day of sleep. Mothers slept longer than fathers (7.5 ± 1.1 vs 7.2 ± 1.2 hours/day). Fathers parenting boys more authoritative than girls (26.0 ± 12.2 vs 23.3 ± 11.7). Results showed that there was no significant relationship between adolescents' physical activity and parental role modeling. Authoritative parenting style from father was inversely associated with MVPA of sons (-0.49, 95% CI = -0.95 to -0.03 mins/day). Sleep duration of mother was associated with sleep duration of daughters (0.20, 95% CI = 0.02 to 0.36 hours/day), with a similar association between father and sons (0.16, 95% CI = 0.01 to 0.32 hours/day).
Conclusions: Parental role modeling has influence between mother-daughter pairs and father-son pairs for sleep duration. Adolescent boys are less physically active when their fathers had a more authoritative parenting style. Further studies could investigate more mechanics of parenting style influence on physical activity of adolescents.

AESTHETICS OF AFRICAN DIASPORA: RELATIONS BETWEEN THE FLOURISHES OF CAPOEIRA (BRAZIL) AND THE ACROBATIC PANTHER DANCE (IVORY COAST)

PASQUA, L., TOLEDO, E.

UNICAMP

Introduction: The African Diaspora resulting from the slave trade allowed the cultures of different regions of Africa to cross the Atlantic and reach new spaces, transforming these territories into a melting pot of corporal practices that have been re-signified (Deschil Obi, 2008; Costa e Silva, 2011). This research aims to establish relations between capoeira (Brazil) and the acrobatic panther dance (Ivory Coast).
Methods: This is a documentary analysis whose research source is the video The Panther Dance, part of the documentary The bridge of spirits produced by New Atlantis Wild, in order to identify elements related to Capoeira in general, arranged in books and articles of the area. The categories of analysis were: characterization of cultural manifestation, musicality and body elements.
Results: As for the characterization of cultural manifestation, panther dance is part of the Senufo culture in Ivory Coast which a demonstration dispute takes place, in which different clans demonstrates their abilities, performed in a circle form with male individuals , dressed as panther clothes. In Capoeira the contest takes place in the form of a struggle, in which two people establishes a corporal dialogue with another, performed in a circle form, with individuals of both sexes, dressed in clothes from their capoeira group. The musicality is present in both, with similar instruments, in the acrobatic dance there is an instrument similar to berimbau. As for the body elements, acrobatic dance presents acrobatics and dances while capoeira strokes, rotateds strokes, defenses, unbalanced movements, and may or may not appear acrobatic elements, the well-known flourishes (Pasqua, 2011). We highlight that we found similar acrobatic elements between panther dance and capoeira, namely in portuguese: bananeira, parada de cabeça, aú de frente, pulo do gato, giro de cabeça, mortal e mola.
Conclusions
In conclusion the panther dance presents different dynamics from Capoeira, but there are similar elements, such as the fact that it happens in a circle form, followed by instruments and singing and acrobatic body elements that resemble the flourishing. In panther dance, the flourishing presents a character of challenge and demonstration, while in capoeira the flourishing takes on importance depending on the goal of the game, from challenge, demonstration, to ambush and theatricality.

IS-PM07 The application of novel exercise interventions to maximise benefit in health and disease

THE UTILITY OF TRANSCUTANEOUS NEUROMUSCULAR ELECTRICAL STIMULATION IN COPD

MADDOCKS, M.

KINGS COLLEGE LONDON

Impaired skeletal muscle function is a common feature of COPD, particularly in the lower limbs, and contributes to increased morbidity and mortality. There is substantive evidence demonstrating the benefit of resistance exercise (RE) training in COPD and it is currently recommended RE training should be incorporated into rehabilitation programmes for this group. However, not all patients with COPD are able to perform conventional voluntary RE training of sufficient intensity to bring about meaningful gains in muscle function. This may be due to limiting symptoms, advanced deconditioning, acute exacerbations and/or hospitalisation.
Transcutaneous neuromuscular electrical stimulation (NMES) provides a non-volitional means of evoking muscle contraction that places minimal demand on the cardiorespiratory system and does not induce a significant ventilatory response. NMES may therefore be an effective strategy for targeting skeletal muscle function in instances where voluntary RE training cannot be tolerated. Increasing evidence from clinical trials supports this application of NMES. Gains in muscle strength are consistently shown, and in groups where impaired muscle function limits whole body exercise, changes in the peripheral muscle are associated with improved exercise capacity.

THE APPLICATION OF HIGH-INTENSITY INTERVAL TRAINING (HIIT) PREHABILITATION TO MAXIMISE POST-SURGICAL RECOVERY

PHILLIPS, B.

UNIVERSITY OF NOTTINGHAM

There are over 3.5 million new cancer cases in Europe each year, with prostate and colorectal cancers the second and third most common cancers, respectively. Indeed, when combined with breast and lung cancer, these four cancers represent over half the overall burden of cancer in Europe1. As we experience demographic ageing across Europe, one clinical implication of this is that more older individuals are presenting for surgical treatment of cancer. Cardiorespiratory fitness and muscle mass both decline with advancing age, each independently increasing the morbidity and mortality associated with surgery2,3, subsequently delaying or preventing return to normal activities4. Therefore, interventions that are able to improve cardiorespiratory fitness and muscle mass in older cancer patients before surgery hold much therapeutic potential. In the UK, cancer guidelines impose a 31-day target time to operation from decision-to-treat5 and as such, any pre-surgical interventions must be applicable within this time-frame. We have previously shown that a time-efficient high-intensity interval training (HIIT) programme, can be used to improve the cardiorespiratory fitness of older individuals age-matched to those most commonly presenting for colorectal cancer surgery, within 31-days6, with this HIIT protocol also eliciting increases in lean leg mass. This HIIT protocol was deemed acceptable and enjoyable by healthy older adults, with the time-efficiency of this protocol (15-minutes per session), addressing one of the most commonly cited barriers to exercise. This same HIIT protocol was not however able to improve the cardiorespiratory fitness of colorectal cancer patients prior to surgery, despite a trend for increased lean leg mass and improved exercise performance. Conversely, the cardiorespiratory fitness of urological cancer patients was improved by this same exercise regime with concomitant increases in lean leg mass and the expected increase in exercise performance. Although not yet fully elucidated, proposed mechanisms for this heterogeneity of exercise adaptation between cancer types include variations in systemic disease burden and the degree of anabolic resistance7. Further research is required to explore these mechanisms fully and to optimise prehabilitation for different cancer types.

ECCENTRIC EXERCISE IN MAXIMIZING PATIENT REHABILITATION

HOPPELER, H.

UNIVERSITY OF BERN

In concentric contractions muscle activation produces torque that is greater than the resistance encountered. This leads to muscle shortening and positive work is done. In eccentric contractions, the load applied to the muscle is larger than the torque that it produces. As a consequence, the activated muscle undergoes lengthening and negative work is done. Physiological properties differ between concentric and eccentric contractions. The torque that is produced by muscle tissue in eccentric muscle contractions is several times higher than that during concentric contractions. Muscle tissue can thus be subjected to higher stress during eccentric than during concentric contractions. Acute high-load eccentric contractions can lead to severe muscle and tendon damage. Repeated low-load eccentric contractions are responsible for delayed onset muscle soreness (DOMS). Eccentric contractions are more difficult to control as integrated EMG levels of eccentric contractions are only half those of same load concentric contractions. The metabolic energy required to fuel negative work is typically four fold lower than that required to produce the same amount of positive work. This makes moderate load eccentric exercise an excellent choice for the rehabilitation of patients with limited aerobic performance capacities. In these patients muscle tissue can be subjected to high mechanical loads that could not be achieved with concentric exercise due to metabolic constraints. For similar reasons we have used eccentric exercise in elderly patients with the aim of preventing sarcopenia. Eccentric exercise training is best performed on specifically designed eccentric ergometers which allow for controlled application of negative work. Eccentric exercise programs best start at very low loads such as 50-70 Watts and for short, 5 minute, periods. Loads are increased gradually. We aim for a total of 20 minutes of eccentric training divided into four blocks of 5 minutes with 2 minutes pause. Depending on the training goal, target loads of 250 to 350 Watts can be reached in 2-3 weeks. We do not train more than 3 times per week. If the ramping of the load is carried out carefully, unwanted muscle soreness is circumvented completely. Currently available data on moderate load eccentric exercise suggests that training regimes of 2 to 6 months result in muscle strength gains similar to those achieved with classical high-load strength training. Eccentric exercise protocols have been used in various patient populations such as patients with cardiopulmonary diseases, neurological diseases, metabolic diseases, patients with arthrosis and tendinopathies, patients in rehabilitation after anterior cruciate ligament injury and cancer survivors. Currently the results of these interventions are encouraging but the evidence for effect size is scarce and the choice of training protocols is still experimental.

Invited symposia

IS-SP01 THE APPLICATION OF SCIENCE AND PRACTICE TO OPTIMISE SPORTING PERFORMANCE - SPONSORED BY CATAPULT

DEVELOPING SCIENCE FOR PRACTICE

TWIST, C.

UNIVERSITY OF CHESTER

Understanding the efficacy of training and nutritional interventions and their influence on performance is necessary before practitioners can apply them to practice. While the assessment of an individual's physical qualities is often used as a proxy for performance, practitioners and coaches would be better informed if they understood the interventions influence on match- or training-related activity before

selecting it for real-world use. Training and match play are influenced by numerous contextual factors that mean studying the efficacy of any training or nutritional intervention in a real-world setting is problematic. Controlled simulations that replicate training or match play are offered as a model to understanding how conditioning or nutritional manipulations might influence an individual's performance capabilities. These studies typically employ simulation models that are reliable, yet their ability to replicate important elements of match play and training are often compromised. Understanding the strengths and challenges of these simulation models is essential if they are to be of use in developing science that informs practice.
This talk will explore a series of studies to develop a simulation model that has then been applied to understand the efficacy of various conditioning and nutritional interventions on the match and training performance characteristics of rugby players. The strengths of such research approaches will be presented in the context of how these data might be used to inform applied practice. The limitations of these types of study will also be considered, alongside highlighting the challenges of replicating the activity characteristics of athletes during training and match play.

ACCESSING SCIENCE FROM POLICY AND PRACTICE

JONES, B.
LEEDS BECKETT UNIVERSITY

Practitioners and policy makers are required to make decisions to inform training practices, competition structures and develop sport. Decisions should be informed by available evidence, which has been developed through rigorous scientific research. While this appears a logical approach, it can be problematic. Applying scientific studies to policy and practice can be challenging, given the different methodologies, data analysis and reporting methods used between studies. Furthermore, while academic researchers in sports science may focus on the development of knowledge through efficacy studies, the effectiveness of this knowledge to real-world practice is sometime unknown.
This talk will challenge the application and usefulness of scientific research to real-world problems, policy and practice. It will highlight the need for more effectiveness studies, and provide potential solutions to increase the usability of scientific research in policy and practice.

BLENDING SCIENCE AND PRACTICE

ROE, G.
LEEDS BECKETT UNIVERSITY

Best practice requires the integration of scientific evidence and practical knowledge. A challenge for practitioners working in the field is staying up-to-date with the latest research and applying it in practice. The scientific literature within a discipline (e.g., physiology or biomechanics) can act as a good start point, but given the multidimensional complexity associated with sports performance, it is often reductionist to apply evidence from only one discipline. A particular aspect of athlete care where this becomes problematic is the rehabilitation and return to performance of injured athletes. When supporting the return to performance of an athlete following injury, a blend of science from clinical (i.e. physiotherapy and sports medicine), sports performance (i.e. physiology, biomechanics, strength and conditioning, sports science) and coaching is required, in addition to the contextual factors unique to the athlete and sport.
This talk will discuss the application of blending science and practice during the return to performance process in rugby union players and will provide examples of how information from various disciplines can be merged to optimise performance.

IS-PM13 Blood flow-restricted exercise; mechanisms, training responses and applications in sport and rehabilitation.

BLOOD FLOW-RESTRICTED EXERCISE; A GOOD ALTERNATIVE TO TRADITIONAL HEAVY-LOAD STRENGTH TRAINING FOR MUSCLE HYPERTROPHY AND INCREASED STRENGTH?

RAASTAD, T.
NORWEGIAN SCHOOL OF SPORT SCIENCES

Low load resistance exercise (~20-50% of 1 RM) in combination with blood-flow restriction (BFR) by the use of pressure cuffs has repeatedly been shown to induce muscle hypertrophy in both untrained individuals and in highly trained athletes. Accordingly, low-load blood flow restricted resistance exercise (BFRRE) has been suggested as an effective alternative to traditional heavy-load strength training (HLS) in increasing muscle size and strength in untrained as well as elite athletes. The reported increase muscle strength is, however, in some studies lower than with HLS, and there seems to be a marked difference between BFRRE and HLS in tendon adaptations. Furthermore, BFRRE is claimed to be a gentle exercise form with short recovery needed after exercise. Consequently, some high-frequency BFRRE training protocols have shown impressive results with regard to rapid hypertrophy, but there are also reports of severe muscle damage in athletes after BFRRE. Because of the low load, BFRRE is often used in early rehabilitation after injuries and some athletes use BFRRE in deloading periods where they want to maintain the muscle mass while reducing the stress on bones and tendons. The aim of this presentation is to discuss the potential for BFRRE in normal training an in rehabilitation and to point at some benefits and limitations that should be considered when training is planned for different groups.

MECHANISMS OF MUSCLE HYPERTROPHY INDUCED BY BLOOD FLOW-RESTRICTED EXERCISE

WERNBOM, M.
CENTER FOR HEALTH AND PERFORMANCE

Because of the many potential applications of BFRRE, it is of great interest both from a practical standpoint and from a basic research point of view to try to clarify how occlusion training induces gains in strength and muscle size. Several stimuli have been suggested as possible upstream triggers of adaptations in muscle size and strength, including (but not limited to):
• Motor unit recruitment and consequent mechanical loading of the active muscle fibres

• Metabolic stress
• Ischemia-reperfusion and consequent formation of reactive oxygen and nitrogen species
• Release of growth factors and hormones
• Cell swelling
• Muscle damage
Downstream, changes in muscle size and strength may be mediated by:
• Increased muscle protein synthesis
• Decreased muscle protein breakdown
• Satellite cell activation, proliferation and subsequent myonuclear addition
The aim of this presentation is to discuss some of these mechanisms and possible upstream stimuli behind these effects, and the evidence for each of them.

THE EFFECTS OF BLOOD FLOW-RESTRICTED EXERCISE AS A COUNTERMEASURE AGAINST DISUSE ATROPHY

PLOUTZ-SNYDER, L., DOWNS, M., HACKNEY, K.

UNIVERSITY OF MICHIGAN, KBRWYLE, NORTH DAKOTA STATE UNIVERSITY

INTRODUCTION: Introduction: Loss of skeletal muscle cross-sectional area (CSA) and function is a consequence of disuse such as in spaceflight, bed rest, or unilateral lower-limb suspension (ULLS). High-load (HL) resistance exercise or low-load blood flow restricted (BFR) exercise are effective training techniques to improve muscle strength and CSA in ambulatory participants. Recent evidence suggests the anabolic response to training stimuli are blunted during unloading or disuse conditions (i.e. anabolic impairment, prompting the need to explore the effectiveness of each type of resistance exercise training during both weight bearing and non-weight bearing. This study examined the muscular exercise training adaptations from HL and BFR resistance exercise training during weight bearing and non-weight bearing.
Methods: Participants performed all ambulatory activity on crutches for 25 days, while wearing one shoe with a 10-cm sole on the right foot. This eliminated ground contact by the left foot, thereby unloading the left lower limb. The right limb continued to have ground contact and remained weight-bearing throughout the ULLS period. By training both legs, this experimental design allowed for the direct comparison of the training program in loaded and unloaded muscle. Participants were assigned to a training group: HL resistance exercise (n=6) or BFR exercise (n=7). Training consisted of 3 sets each of supine leg press and plantar flexion with as many repetitions as possible to volitional fatigue. HL used loads of 70-80% of 1 repetition maximum and BFR used loads of 20-30% with continuous inflation pressure. Muscle CSA, strength, and endurance data from the upper and lower legs were obtained the week prior to starting ULLS (Pre-ULLS) and on either day 24 or 25 of ULLS (Post-ULLS).
Results: In weight-bearing legs HL and BFR increased knee extensor and plantar flexor CSA and strength. In non- weight bearing legs both knee extensor and plantar flexor muscle CSA and strength increased in the HL group, but decreased in the BFR group. Dynamic leg press endurance increased with HL and BFR training in the weight bearing legs and was maintained in the unloaded legs with both types of training.
Discussion: HL and BFR resistance exercise were both effective exercise programs for the weight-bearing leg. However, BFR exercise was not as effective as HL resistance exercise in the nonweight-bearing leg. These data show that exercise that improved muscle CSA and strength in ambulatory weight-bearing conditions was not sufficient to maintain muscle function during unloading.

IS-PM03 Can exercise hurt your heart?

EXERCISE IS MEDICINE: AT ANY DOSE?

EIJSVOGELS, T.M.H.

RADBOUD UNIVERSITY MEDICAL CENTER

INTRODUCTION: Habitual physical activity and/or regular exercise training are effective strategies to reduce cardiovascular morbidity and mortality. Therefore, the World Health Organization recommends adults to engage in at least 150 min/week of moderate intensity aerobic activities or 75 min/week of vigorous intensity aerobic activities, or an equivalent combination thereof. Despite these international recommendations, only a minority of the population meets the proposed criteria, whereas sedentary behaviour becomes increasingly prevalent.
METHODS: This lecture will discuss the dose-response relationship between aerobic exercise volumes and the associated health benefits. For example: what is the lowest effective dose of exercise needed to elicit a risk reduction? What are health benefits of higher exercise volumes? What is the optimal dose? Does exercise intensity matter when prescribing exercise? Should I exercise more or reduce my time spent sitting? Is there is there evidence for an upper limit beyond which additional exercise training does not induce additional health benefits?
RESULTS: While physical inactivity is a problem for the majority of the general population, the popularity of endurance exercise races and the average age of its participants have increased worldwide over the last 3 decades. Completing 42 km marathon or similar endurance events has become a personal goal for many individuals. This provides an impetus for both from the medical and lay community to understand the effect of extreme endurance exercise on cardiac health.
CONCLUSION: Recent studies suggested that extreme exercise volumes may attenuate longevity and accelerate atherosclerotic coronary artery disease. Available evidence from physiological, epidemiological and cardiac studies will be discussed to place these observations in an appropriate perspective and answer the question whether exercise is medicine at any dose.

EXERCISE-INDUCED DAMAGE: EVIDENCE FROM BIOMARKERS AND ECHOCARDIOGRAPHY

GEORGE, K.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: There has been a significant amount of speculation recently that extremely high volumes of endurance exercise may lead to cardiac damage and/or cardiac dysfunction. Further it has been proposed that these phenomena are linked.
METHODS: .
RESULTS: Firstly, we will present a historical timeline of studies that have demonstrated increased concentrations of cardiac biomarkers of damage (e.g. cardiac troponin T) after strenuous exercise. We will then try to unpick the clinical implications of this data and reflect on putative mechanism(s). This content will reflect changes in assay availability and the application to a range of different populations and exercise loads.
Further we will present a historical timeline of studies that have demonstrated a reduction in systolic or diastolic function in the early recovery period from strenuous exercise. We will reflect on data related to both the left and right ventricles and will document the significant technical developments in echocardiography that have illuminated this field. We will discuss the clinical impact of such changes and address a limited evidence-base related to mechanistic underpinnings.
Finally, we will review available evidence that these two issues (cardiac damage and cardiac dysfunction) are directly related to one another.
CONCLUSION: We will summarise the evidence-base to date, reflect on continuing research priorities and provide initial reflections on how this information aligns with the central belief that exercise is a potent medicine.

CARDIAC REMODELING TO EXERCISE TRAINING: PHYSIOLOGICAL VERSUS PATHOLOGICAL RESPONSES

SCHARHAG, J.

TECHNICAL UNIVERSITY MUNICH

Already since the legend of the ancient marathon run of Pheidippides, possible exercise induced cardiac damage is under debate. Although a lot of studies in elite athletes have shown the physiological nature of the athletes heart, studies from recreational up to competitive athletes on exercise induced increases in cardiac biomarkers, myocardial late gadolinium enhancement in cross sectional studies, elevated coronary calcification, or a transient decrease in ventricular function after prolonged strenuous endurance exercise heated up the discussion within the last years. However, many methodological differences between the studies and studied subjects have to be taken into account. Therefore, the presentation aims to give an overview on current studies which describe physiological and pathological responses to exercise training and competition.

Invited symposia

IS-BN02 The Effects and Mechanisms of How Exercise interventions Reduce Old Adults' Mobility Impairments

CRITICAL FACTORS TO DOSE EXERCISE INTERVENTIONS IN THE PREVENTION OF AGE-RELATED MOBILITY LOSS

GRANACHER, U.

UNIVERSITY OF POTSDAM

INTRODUCTION: As the proportion of senior citizens increases in western industrialized societies, there is the need to identify old adults with first signs of limited mobility in order to delay the onset of mobility disability and subsequent loss of autonomy through the implementation of adequate intervention programs. According to Newfield and colleagues [1], mobility limitation is defined as a state of impaired mobility, a condition in which an individual experiences a limitation in independent physical movement, or is at risk for experiencing limitations. Owing to the rather broad definition of mobility limitation, prevalence rates range from 20 to 50 % for seniors age =65 years [2, 3]. Thus, there is the need to develop and implement adequate training programs for the prevention of age-related mobility impairments. While there is ample evidence for the general effectiveness of balance and/or resistance training to maintain mobility and prevent disability in seniors [4, 5], less is known regarding the required exercise dose.
Thus, the aims of my presentation will be threefold: (i) to present data on the importance of balance and muscle strength for mobility in seniors, (ii) to describe and discuss the general effectiveness of balance and resistance training on mobility related outcomes in seniors based on an extensive review of the literature, and (iii) to present critical factors related to the dose of balance and resistance training to provoke practically and clinically relevant responses in healthy seniors. Practitioners, therapists, rehab experts, and exercise scientists will benefit from the presentation by learning how to adequately implement balance and resistance training in primary prevention using sufficient dosage.

RECOVERY OF LOST MOBILITY IN FRAIL OLDER ADULTS: EVIDENCE OVERVIEW

SHERRINGTON, C.

UNIVERSITY OF SYDNEY

The benefits of resistance training for older people are often discussed. Many trials have now also evaluated the impact of "neuromotor" exercises that, as defined by the American College of Sports Medicine, involve balance, agility, and coordination. These exercises focus more on motor skill and appropriate muscle activation rather than on greater maximum force generation. This talk will outline systematic review (from a Cochrane review underway1) and clinical trial evidence for the effectiveness of neuromotor exercise in regaining mobility in frail older people with reference to trials indexed on PEDro (the Physiotherapy Evidence Database www.pedro.org.au) including trials of home-based neuromotor exercise undertaken by the presenter and colleagues (eg2,3,4).

MECHANISMS OF HOW EXERCISE INTERVENTIONS REDUCE OLD ADULTS' MOBILITY LOSS THROUGH GAIT SPEED MAINTENANCE

HORTOBAGYI, T.

UNIVERSITY OF GRONINGEN MEDICAL CENTER

INTRODUCTION: Walking ability is a cornerstone of quality of life . Observations of gait in old age and under a variety of clinical conditions suggest that humans adapt their gait mechanics to environmental and biological constraints .

METHODS: The presentation will review two elements of the data concerning gait.

RESULTS: Part I the presentation will integrate the evidence from inverse dynamics, modeling, and neural activation data to support the concept of biomechanical plasticity of human gait . Part II will address how exercise interventions help minimize the age-related slowing of gait speed . It will, somewhat provocatively, also draw attention to a virtually complete lack of understanding of the biomechanical mechanisms mediating the intervention-induced gait speed increases in aging humans.

CONCLUSION: Practitioners, basic and applied exercise scientists, and rehab experts will all benefit from the presentation by learning how gait speed is emerging as a fundamental function, representing the sixth vital sign.

BENEFICIAL EFFECTS OF SMALL-SIDED GAMES AS CONCLUSIVE PART OF WARMUP ROUTINE

DELLO IACONO, A., VIGOTSKY, A.D., LAVER, L., HALPERIN, I.

THE ACADEMIC COLLEGE AT WINGATE

INTRODUCTION: The aim of this study was to compare the effects of small sided games (SGG) and traditional warm-up (WU) strategies on neuromuscular, physiological and perceptional responses of elite handball players.

METHODS: A randomized, crossover study design was implemented in which 12 male players completed a general 8 min WU which was concluded with an 8 min section of either specific handball shooting drills or 3 x 2 min of SSG with a passive recovery of 1 min between bouts. By the mean of a force plate, countermovement jumps (CMJ) and plyometric press-ups (PP) were assessed before and immediately after the WU regimens, heart rate (HR) was assessed during the WUs and rating of perceived effort (RPE) was only assessed after the WUs. Linear mixed-models and permutation tests were carried out to assess the effects of SSG relative to a traditional WU.

RESULTS: The results revealed marked improvements in vertical jump [Δ = +2.67 (95% CI = 1.97 – 3) cm], eccentric force during the CMJ [Δ = −2.19 (−3.56 – −0.82) N], peak eccentric force during the CMJ [Δ = +3.05 (2.18 – 3.92) N], peak concentric force during the CMJ [Δ = +2.45 (2.02 – 2.89) N], vertical jump power [Δ = +3.02 (2.29 – 3.74) W], eccentric PP force [Δ = +1.52 (1.19 – 1.85) N], concentric PP force [Δ = +1.73 (1.19 – 2.27) N], and PP power [Δ = +2.06 (1.37 – 2.76) W] relative to the traditional warm-up. Permutation tests did not reveal any remarkable differences between SSG and traditional warm-up conditions in RPE (Δ = +0.08; z-score = 0.44; p = 1.00) or mean HR (Δ = +1.42; z-score = 1.88; p = 0.08).

CONCLUSION: This study point to the effectiveness of SGG as a WU strategy. Compared to a more traditional handball WU, SSG led to greater benefits even the HR and RPE are similar and when matched for WU duration among elite level athletes. It is thus speculated that the superior effects of the SGG WU are related to muscular potentiating effects, however, this reminds to be directly investigated in future studies. Coaches should consider implementing SSG not only as a training strategy, but also as WU considering its beneficial effects on relevant athletic performance.

DOES MAN-MARKING INFLUENCE RUNNING OUTPUTS AND GAME INTENSITY DURING SMALL-SIDED SOCCER GAMES?

KILDING, A.E., AASGAARD, M.

AUT UNIVERSITY

INTRODUCTION: Small-sided games (SSGs) are an effective training tool for physical development in soccer [1]. SSGs can be modified in several ways to manipulate the physical demands to best match player characteristics and session objectives. The aim of this study was to compare the physiological, perceptual and time-motion characteristics of man marking (MM) versus non-man marking (NMM) SSGs.
METHODS: In an acute cross-over design, 8 amateur soccer players (mean age ± SD: 23.6 ± 3.3 years) played 2v2, 3v3 and 4v4 SSGs, on separate days, adopting either MM or NMM rules. During each game, physiological (heart rate, HR), GPS-derived running outputs, and perceptual measures (rate of perceived exertion, RPE) were determined.
RESULTS: Small to moderate (unclear) differences in mean percent HR (%HRave) (%Δ = 1-2.7%; ES = 0.22 to 0.65) were observed between MM and NMM. Comparisons between varying player number in MM indicated a decrease in %HRave with increased player numbers (%Δ = -1.6-3.5%; ES = 0.39 to 0.86). Perceptual load increased with MM compared to NMM (%Δ = 6.7-17.6%; ES = 0.66 to 2.09), while increases in player numbers (MM only) reduced RPE output (%Δ = 9.4-24.3%; ES = 1.14 to 3.61). Time-motion characteristics revealed substantially greater total distance covered in MM irrespective of player number (%Δ = 6.8-14.7%; ES = 1.34 to 2.82). There were very likely increases in distances covered for striding (%Δ: 23.4-33.2; ES = 2.42 to 4.35) and high intensity running (17.9-21 km/h) (%Δ: 47.3-104; ES = 0.91 to 1.68) for MM compared to NMM irrespective of player number.
CONCLUSION: Man-Marking during soccer SSGs can substantially elevate perceptual load and running distances across a range of speed zones (striding to high intensity running), regardless of player number. While differences between NMM and MM for internal load (HR) were unclear, MM during SSGs maybe an effective rule modification to alter training load.

BILATERAL KICKING PERFORMANCE IN GAELIC FOOTBALLERS

O'SULLIVAN, M., CROGNALE, D., SUSTA, D.

DUBLIN CITY UNIVERSITY, UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: The ability to proficiently undertake sport specific tasks with each side of the body plays a major role in both sport performance and injury prevention: In elite football (FIFA) players non-dominant leg shows lower strength and different motor strategies while performing two types of kicks were identified (McLean and Tumilty, 1993). One side dominance can increase the risk of injuries in Australian rules, a sport where movements are similar to Gaelic football (Orchard 2001). Accuracy in kicking was defined as 'the ability to kick a ball to a specified area' (Finhoff et al., 2002). Aim of the present study is to assess ambidexterity among female and male GAA players.
METHODS: Twenty-one female senior club and inter-county footballers and fifty-two male senior club and inter-county footballers volunteered to participate in this study (23.3± 6.1 years). Ladies were asked to kick a size 4 ball from 5 different pitch positions from the same distance (15 m to the goalposts) and men were asked to kick a size 5 ball from 5 different pitch positions 25 m from the goalposts.
Every participant had to kick five times with the preferred and five times with the non-preferred foot. Statistical analysis was done SPSS version 17. A one way ANOVA was performed to identify the difference in using the preferred or non-preferred foot on performance in the kicking accuracy task. The level of significance was set at $p<0.05$. The research project was approved by Dublin City University Research Ethics Committee.
RESULTS: Female GAA footballers score of 15.7±2.4 (mean ± SD, range 10/25 to 21/25) points while kicking using their preferred foot was significantly higher ($p=0.004$) than their performance while kicking with their non-preferred foot, 10.1 ± 4.1 points (range 2/25 to 16/25).
Male GAA footballers scored 14.7 ± 3.9 (range 4/25 to 22/25) points with their preferred foot, a significantly higher ($p=0.002$,) number of points compared to 9.3 ± 4.8 (range 0/25 to 19/25) score with their non-preferred foot.
CONCLUSION: Our results show that GAA players can benefit from training bilateral kicking accuracy.

PERFORMANCE CHANGES OF FAST BOWLERS DURING A TWENTY20 FAST BOWLING SIMULATION

VICKERY, W.1, MILNE, E.2, BORGES, N.2

<1> NORTHUMBRIA UNIVERSITY, NEWCASTLE UPON TYNE, UK <2> THE UNIVERSITY OF NEWCASTLE, NEWCASTLE, AUSTRALIA

INTRODUCTION: Due to the limited access to players during a cricket match, it is difficult to provide a detailed analysis of the demands associated with fast bowling. A reliable fast bowling match-simulation was developed to overcome this difficulty (Milne et al., 2018). This study examined the changes in physical, psycho-physiological and technical performance of fast bowlers during a Twenty20 fast bowling simulation (FBS-T20) to further understand the demands of fast bowling whilst competing.
METHODS: The physical (distance covered, bowling approach speed, 10 m sprint time), psycho-physiological (heart rate, RPE) and technical (bowling accuracy) demands of six amateur fast bowlers (age= 23.6 ± 1.4 yr, body mass= 82.3 ± 8.8 kg, height= 185.4 ± 5.3 cm) were measured during three sessions each of the FBS-T20. The distance travelled along with heart rate and RPE were measured throughout entirety of the protocol. The approach speed and bowling accuracy of fast bowlers was measured during each ball of the bowling overs. 10 m sprint time was measured once during each fielding over. One-way ANOVA with Bonferroni post hoc ($p<0.05$) was used to determine differences between measures during the bowling and fielding overs.
RESULTS: Fast bowlers covered 7917 ± 934 m over 78 ± 9 min during the FBS-T20, with a mean and maximum heart rate of 148 ± 8 b.min-1 and 184 ± 11 b.min-1, respectively. No significant difference ($p>0.05$) in the approach speed of fast bowlers or bowling accuracy was reported between the bowling overs. A significant difference was evident between the bowling overs RPE ($F(3,76)= 10.352$; $p<0.00$). RPE (6-20) following overs 18 (13.0 ± 1.8) and 20 (13.3 ± 2.1) were both significantly greater ($p\leq0.03$) than overs 2 (10.4 ± 1.8) and 4 (11.2 ± 2.0). No significant difference ($p>0.05$) in the 10 m sprint speed was reported during the fielding overs. RPE appeared to be lowest during the initial 5 overs of the FBS-T20 (9.0 ± 1.8) when compared to the other fielding blocks (over 6-10= 10.4 ± 2.2, $p\leq0.00$; over 11-15= 10.8 ± 2.2, $p\leq0.00$; over 16-20= 10.9 ± 2.2, $p\leq0.00$).
CONCLUSION: The results suggest that fast bowlers are able to maintain their speed and bowling accuracy throughout the FBS-T20 whilst bowling and fielding. Despite few changes in the physical and skill demands of fast bowlers, their perceptual response increased

throughout the FBS-T20 which may be representative of the increased demands on cricket players towards the end of an innings. By using this simulation cricket coaches may be able to provide a physically and technically specific training environment for fast bowlers.

Milne, E., Vickery, W., Dascombe, B. &. Borges, N. (Under Review). Development of a Twenty20 field-based simulation for cricket fast bowlers (FBS-T20). International Journal of Sports Physiology and Performance.

QUANTITATIVE ANALYSIS OF HIGH GOAL POLO: A PILOT STUDY

BEST, R., STANDING, R.

TEESSIDE UNIVERSITY; WAIKATO INSTITUTE OF TECHNOLOGY

INTRODUCTION: Academic literature on Polo players is limited. Polo is a global and professional sport played professionally by males and females, but the dearth of literature remains. We aimed to quantify the characteristics of the winning team of a High Goal Polo tournament, through group and knockout stages (seven games; five wins, two losses).
METHODS: Footage from the 2017 Jaeger le Coultre Gold Cup was viewed via Pololine, a dedicated online platform (www.pololine.tv/fullmatches), and analysed using a customised matrix devised in consultation with recreational and professional Polo players. Two raters (R) performed quantitative analysis for each game. Percentage success rates were calculated for forehand and backhand shots of differing lengths and ride-offs (two players contesting for the right to play a shot). Raw differences for melees (coming together of two or more players from each team), penalties awarded (short and long) and turnovers conceded were recorded. Means and 90% Confidence Intervals are shown.
RESULTS: Intra-rater reliability was large to very large (R1 ICC: 0.69 90% C.I.: 0.52 to 0.89. R2 0.72; 0.52 to 0.89), with inter-rater reliability displaying similar values (0.71; 0.62 to 0.78). In games won, fewer turnovers conceded (-3.00; -5.69 to -0.31) and more penalties were awarded (1.43; -0.32 to 3.18) than the opposition. Long penalty (0.86; 0.02 to 1.69) and short penalty (0.57; -0.13 to 1.28) conversion values suggest penalties present advantageous attacking and goal scoring opportunities. Counterintuitively, more melees were won in games lost (4.00; 3.12 to 4.88) than in games won (-0.57; -3.28 to 2.14). Forehand success rates were similar between wins and losses, as were ride-offs. Backhands demonstrated variability in games won (Middle: -1.71; -10.59 to 7.16 and Long: 0.29; -20.28 to 20.85), but were more unsuccessful in lost games (Middle: -6.00; -12.16 to 0.16 and Long: -17.5; -24.09 to -10.91).
CONCLUSION: We recommend Polo players and teams aim to develop their backhand success rate, whilst conceding fewer penalties than the opposition. The role of melees and ride-offs in the present analysis was unclear. We suggest future research scrutinises these contested actions, especially ride-offs that take place off the ball as these may facilitate attacking play by other team members, much like blocking plays in grid-iron football.

OP-BN19 Digital health and exercise tools

WEARABLE DEVICES-BASED PHYSICAL ACTIVITY INTERVENTION FOR ELDERLY WOMEN : A RANDOMIZED CONTROLLED TRIAL

PARK, S., LEE, S.

KOREA INSTITUTE OF SPORTS SCIENCE

INTRODUCTION: Physical inactivity as well as prolonged sitting may lead to the adverse health effects including cardiovascular disease and mortality. Wearable devices to promote physical activity (PA) and/or to reduce sedentary time are commercially available. However, PA intervention studies using the devices have been limited to the specific population such as adults and/or adolescents. Thus, the purpose of the study was to investigate the effect of the short-term PA intervention using wearable device on cardiorespiratory fitness and cardiovascular risk factors in elderly women.
METHODS: Community dwelling elderly women (n=39, 69.5± 3.96yrs) participated in the 8-week wearable device-based PA intervention study. They were randomly assigned to one of the following groups; a continuous PA (one 30-minute bouts of walking, n=13), an intermittent PA (three 10-minute bouts of walking, n=12), or a control (Cont, n=15) group. Both PA groups were asked to participate moderate-to-vigorous PA (MVPA, 40-70% of heart rate reserve) self-monitored by a wearable device for their PA time and intensity. The control groups were asked to keep their usual PA. All the participants wore an accelerometer at least for 10 hours per day for baseline and during the 8-week intervention period to confirm any changes of PA. Cardiorespiratory fitness (6-minute walk test) and cardiovascular risk factors including carotid intima-media thickness (c-IMT) and carotid artery stiffness (Ep, AC, D_min, P_min) using ultrasound, the brachial-ankle pulse wave velocity (ba-PWV) and the ankle brachial index (ABI) using an oscillometric vascular profiling device were measured at baseline and after the intervention. Analysis of covariance (ANCOVA) were used with the baseline as covariate and post hoc Bonferronis multiple t test were used for group comparison($p<.05$).
RESULTS: Significant effects were found in MVPA ($p<.001$) and total PA time ($p=.047$), but not in sitting time ($p=.259$). In the continuous PA, MVPA and total PA time were increased compared to the Cont. MVPA was only increased in the intermittent PA compared to the Cont. Sitting time tended to decrease in the intermittent PA. 6-min walk was only improved in continuous PA compared to the Cont ($p=.020$). There were significant differences in carotid artery stiffness (Ep; $p=.033$, AC; $p=.018$, D_min; $p=.016$, P_min; $p=.009$), ba-PWV($p=.036$), and ABI($p=.043$), but no difference in c-IMT. Carotid artery stiffness, ba-PWV, and ABI were improved in the continuous PA compared to the Cont.
CONCLUSION: Wearable device–based physical activity intervention was useful to increase PA in elderly women. This was the first study to show the effectiveness of the wearable device to increase PA in elderly and was effective in cardiorespiratory fitness and other cardiovascular risk factors. Thus, wearable device for elderly needs to be developed for diverse PA program.

THE USE OF A MOBILE APPLICATION TO SUPPORT PHYSICAL ACTIVITY AND LIFESTYLE CHANGES IN PERSONS LIVING WITH HIV: THE SMARTAPP STUDY

BONATO, M., TURRINI, F., VITOBELLO, C., GIORDANI, A., PASSERI, L., MELONI, A., GALLI, L., LA TORRE, A., MERATI, G., PAVEI, G., CINQUE, P.

UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Although physical activity has been shown to improve fitness, metabolic and inflammatory parameters in people living with HIV, adherence to exercise programs is usually low when not strictly supervised. Therefore, the aim of this study was to assess if the use of a mobile application will favor engagement to exercise by providing motivational inputs, and therefore adherence to training. We hypothesized, as a consequence an improvement of physical fitness, and therefore of health status.
METHODS: This pilot study was a two-armed, parallel group, randomized controlled trials in which HIV-infected subjects were enrolled and assigned to either an experimental group (EG), which trained with a smartphone application, or a control group (CG), which trained with a hard copy training program. Physical activity program included an initial coach-supervised period of 4 weeks, followed by 12 weeks where participants were instructed to train independently. The program consisted of walking or jogging three times/week for 60 minutes. At baseline (BL) and after 16-weeks (W16), patients underwent measurement of CRF by peak oxygen consumption (VO2peak), body composition (body mass, body mass index-BMI, waist, hip circumferences, %fat mass and %fat free mass by bioimpedentiometry), and metabolic parameters (total-, HDL-, LDL-cholesterol). Results are given as number (%) or median (IQR) values. Intention-to-treat analysis regarding an improvement of the 15% of VO2peak was performed with a Chi-Square test. Percentage changes between BL and W16 regarding EG and CG were assessed by Wilcoxon matched-pairs signed rank test.
RESULTS: Thirty-seven subjects were screened and 28 were eligible and divided in EG [n=13, age: 52 (36-56) y-o, height: 176 (170-180) cm, BMI: 24.4 (22.1-27.1) kg/m2, CD4+: 648 (439-762)], and CG [n=15, age: 50 (36-56) y-o, height: 172 (170-180) cm, BMI: 24.8 (22.1-27.1) kg/m2, CD4+: 619 (439-762)]. During training we had 1 and 2 drop-outs for EG and CG, respectively. Median training adherence was 100% (IQR 91-100%) during the initial coach supervised period, and 70% (IQR 41-91%) during the independently training period, with 15/28 (54%) who trained for at least 50% of the sessions. Intention-to-treat analysis showed post-intervention improvement in VO2peak (+ 15%, p=0.005), % fat mass (-10%, p=0.014); %fat free mass (+ 8%, p=0.008), total cholesterol (- 6%, p=0.016) between EG and CG were observed.
CONCLUSION: Adherence to training is fundamental, but seems to be low when not strictly supervised in HIV infected patients. The preliminary results from this pilot study showed that patients trained using a smartphone application were more adherent and as consequence improved physical fitness, body composition and metabolic parameters.

STEP COUNT ACCURACY OF SMARTPHONES DURING VARIOUS WALKING CONDITIONS WHEN WORN AT DIFFERENT WEARING POSITIONS

HÖCHSMANN, C.

UNIVERSITY OF BASEL

INTRODUCTION: Activity trackers can increase physical activity among unmotivated inactive individuals. Commercial PA monitors, such as activity wristbands and smartwatches, and especially smartphones with their various applications have increasingly gained popularity in recent years and are most commonly used for PA assessment today . The fact that there are approximately two billion smartphone users worldwide , most of which carry their phones with them throughout the day, make them promising tools for PA assessment in public health, given that they prove to be accurate. Because not all smartphone users wear their smartphones in their pants pocket, the aim of this study was to examine the accuracy of smartphones and different accelerometer apps to detect steps during various walking conditions while assessing the impact of different phone positions on the accuracy of step detection.
METHODS: Participants from two different age groups walked on a treadmill at four pre-defined walking speeds <1.6, 3.2, 4.8, and 6.0 km/h> and completed an outdoor walking course at a self-chosen walking speed while wearing three iPhone SE smartphones , one Samsung Galaxy S6 Edge , one Garmin Vivofit 2 wristband, and two ActiGraph wGTX+ devices . In addition to the built-in accelerometer apps Apple Health and Samsung S Health, all smartphones recorded steps via the apps Runtastic Pedometer, Accupedo, and Pacer. We used video observation as the gold standard and evaluated validity by comparing each device with the gold standard using mean absolute percentage errors .
RESULTS: The MAPE of the iPhone SE, independent of the phone's position, was small <<3> for all treadmill conditions ≥3.2 km/h as well as for free walking during the outdoor walking course. The Samsung Galaxy showed a small MAPE only for treadmill walking at 4.8 and 6.0 km/h and for free walking. The commonly used research-grade accelerometer ActiGraph wGTX+ was inaccurate for walking speeds <4.8 km/h when worn on the hip and entirely inaccurate for all walking conditions when worn on the wrist .
CONCLUSION: The iPhone SE including all used apps is suitable to accurately measure steps in various walking conditions while the phone's position does not impact the accuracy of step detection. This may have important implications for public health as it could increase the applicability of smartphones for PA assessment in various settings.

FOOT TYPE ANALYSIS BY KNOWFOOT APPLICATION FOR MOBILE

YI, L.C., PAZETTI, J.A.T., PEREIRA, G.B., RUMAQUELLA, M.R.1, TESSUTTI, T.U. SOUZA, V.T.O.C., TESSUTTI, V.

FEDERAL UNIVERSITY OF SAO PAULO

INTRODUCTION: Identifying the foot type allows to find out how the foot interacts with the ground or with the footwear during the functional tasks or in a static position. It is necessary to develop methods to evaluate it, in an easy and practical way. The Foot Posture Index (FPI) [1] allows visual assessment of the foot type in three dimension. The Navicular Drop Test [2] is another way of evaluation, considering the vertical height from the navicular bone to the ground, in the sitting and standing positions. Both tools, used in a clinical practice, are easy to apply, validated and accepted in the scientific community. The use of these tools, developed for mobile, would allow more people to use, provide greater accessibility and fast diagnosis. The aim of this study is present a mobile application developed to evaluate foot type.
METHODS: KnowFoot is an easy use application (app) that allows the user to identify their foot type. The application uses two methods to obtain the foot type as follows: neutral, supinated, hyper supinated, pronated and hyper pronated. The first method, Foot Posture Index [1], evaluates through 6 different aspects, in three dimensions, by previously determined photographs, where the user will score the different foot aspects based on a scale that ranges from -2 to +2. The second method, the Navicular Drop [2], identifies the foot type

through the difference between the navicular bone to the ground in the sitting and standing position. After choosing the images and foot scores in method 1 and inserting the vertical measurements in the sitting and standing positions in method 2, the application provides the classification of foot types, based on standard scores for each of the methods. KnowFoot app allows capturing photos of the feet and store information of the evaluated individuals for further analysis. The technologies used for App construction were Ionic 3, Angular, Javascript, HTML, CSS e Firebase and the technologies used in its styling and design were Adobe Photoshop CC 2018, Adobe InDesign CC 2018.
RESULTS: This is the first app created to provide a foot type analysis for mobile. A reliability research are in process. The results will be soon published.
CONCLUSION: knowfoot is an easy use app, developed to evaluate the foot type in a static condition. It can provide the foot type in an easy and fast way, as well as to store evaluated feet pictures and daily life activities information for later analysis, thus providing a database construction.

EVALUATION AND RELIABILITY OF A NEW MOVEMENT QUALITY ASSESSMENT TOOL USED TO GUIDE EXERCISE PRESCRIPTION .

BENNETT, H.

UNIVERSITY OF SOUTH AUSTRALIA

INTRODUCTION: While the assessment of movement quality is commonplace in practice, there is currently no movement assessment tool specifically designed to guide exercise prescription and track training induced changes in movement quality. The purpose of this study was to (1) introduce a new system for assessing movement quality designed to inform exercise prescription practices (MovementSCREEN), (2) evaluate its suitability for this purpose and (3) establish the intra and inter-rater reliability of the tool for both novice and experienced assessors.
METHODS: The tool assesses movement quality across 9 movements (squat, lunge, deadlift, single leg squat, overhead reach, thoracic rotation, four point, push up, active straight leg raise), and was qualitatively appraised across six key domains to identify the rigor in which it was developed, and its applicability to professional practice. Additionally, 30 apparently healthy adults (mean age 27.3 yrs, SD 5.4) were video recorded completing the MovementSCREEN assessment two times, two weeks apart. The recording was scored two times, two weeks apart, by two expert and two novice assessors to establish inter- and intra- rater reliability. Estimates of systematic and random error were computed with paired t-tests, intraclass correlation coefficients (ICCs), standard error of measurement (SEM95), and minimal detectable change (MDC95).
RESULTS: Despite some limitations in developmental rigor, the tool appears to offer an appropriate method of assessing movement quality with the intent to guide exercise prescription practices. It is presented clearly and its applications are outlined with detail. Intra-rater reliability for the component items (Kappa) ranged from 0.619 – 1.000 and 0.233 – 1.000 for expert and novice assessors respectively, while ICC for the movement quality scores ranged from 0.707 – 0.952 and 0.502 – 0.958. SEM95 for the individual movements ranged from 4.39 to 18.85, while MDC95 ranged from 6.21 to 26.66. The MDC95 for the composite movement quality score was 6.1 points, with an ICC 0.901.
CONCLUSION: The MovementSCREEN has been developed to meet the needs of practitioners working within strength and conditioning or general fitness based exercise prescription environments. Results suggest that the tool can reliably assess movement quality on a test-retest basis when used by experienced assessors, although there is some variability in scoring between assessors. The MDC95 for the composite score of movement quality is approximately six points, suggesting a capacity to track training induced changes in movement quality when assessed by the same practitioner.

OP-BN20 Concussions and other injuries in contact sports

USA UNIVERSITY RUGBY-7S TOURNAMENT PLAYERS INJURY RATES: AN EMERGING U.S. GENDER NEUTRAL SPORT

LOPEZ, V.JR.1,2, MYERS, L.S.D.1, MA, R.1,2,3, WEINSTEIN, M.G.1,4, HUME, P.A.1,2, VICTORIA, C.1,2,4, MARCANO, E.D.1,5, METTRY, M.T.1,6, ALLEN, A.A.1,2,7

1: RRIPG-HSS , 2: AUT/SPRINZ , 3: UNIV. MISSOURI-MOI, 4: NYU , 5: PHLEXPT , 6:CUNY , 7:HSS .

INTRODUCTION: The Olympic sport of Rugby-7s, is played on many U.S. universities. Due to its status as a club sport, data to support the development of prevention protocols is scarce. The aim of this study was to document match injury incidence in USA Rugby sanctioned collegiate 7s tournaments.
METHODS: Prospective epidemiological data were collected using the Rugby Injury Survey & Evaluation (RISE) Report methodology (Lopez et al, 2012), compliant with best practices (Fuller et al., 2007) to capture injury rates. USA Sevens Collegiate Rugby-7s Championship and Rugby Invitational (1,138 athletes) over 2011-2012, 2014-2015 competitive divisions (men and women collegiate and small college championships) match injuries were evaluated.
RESULTS: Injury rates overall (including time-loss and medical attention) were higher among university men (183.9/1000ph, CI:148.8-224.8) compared to women (95.1/1000ph, CI:50.6-162.6; RR: 1.93, p=0.018). Time-loss injury rates were observed higher among men (67.8 /1000ph, CI:47.2-94.2) than women (14.6/1000ph, CI:1.8-52.9, RR:4.63, p=0.012). Mean injury severity was 85.2 mean days absent (men 82.6d, SD:16.6; women 130.0d, SD:40.0). Backs had higher rates (69.6/1000ph, CI:45.5-102.1) of time-loss injuries than forwards (32.1/1000ph, CI:14.7-61.1; RR: 2.17, p=0.039). Mean severity of injuries was higher among forwards (133.4d, SD:122.8) than backs (74.2d, SD:84.5, p=0.117). Most injuries (overall 69.4%) occurred during the first two matches of the tournaments. Injuries overall were acute, among combined genders at 82.4% and occurred during the tackle (63.0%) and running/open play (12.1% overall; from 12.5% in 2012 to 21.1% in 2014). Among all players, 57.4% were injured during a shoulder tackle, which was more prevalent than other tackle types (p<0.001). Recurrent injuries were observed at 34.9% of all injuries (56.6/1000ph, CI:39.9-78.1). Most common injuries were concussions (11.2%, 18.4/1000ph), shoulder dislocations (11.2%, 18.4/1000ph) and ankle sprains (9.4%, 15.3/1000ph). Concussions were frequently observed among men (12.7% of all injuries among males; 23.2/1000ph, CI:12.0-40.6).
CONCLUSION: Increasing risk of head/neck injuries, is a concern with the expansion of collegiate U.S. Rugby-7s over 2011 and 2012, 2012 and 2014, 2012 and 2015 (RR: 2.17, 4.7, 3.3, respectively). Head/neck injury rates in the current study were found to be higher than inter-

national elite males Rugby-7s (5%) (Fuller et al., 2010) and U-20 international Rugby-15s (12%) (Fuller et al, 2011). Largest injury increase was seen in running/open play, possibly due to the variability of training regimens among programs. Developing institutional support as other U.S. collegiate sanctioned sports can help reduce injuries.

NON-CONTACT INJURY INCIDENCE AMONG U.S. WOMENS RUGBY-7S

VICTORIA, C.1,2, LOPEZ, V.2,3, MA, R.2,3,4, WEINSTEIN, M.G.1,2, HUME, P.A.2,3, HALEEM, S.Y.2,5, DELALLO, J.F.2,6, ALLEN, A.A.2,3,7

1:NEW YORK UNIVERSITY , 2:RRIPG-HSS , 3:AUT/SPRINZ , 4: UNIV. MISSOURI-MOI, 5:CUNY , 6:TULANE SCHOOL OF MED. , 7:HSS

INTRODUCTION: Rugby-7s, is growing in popularity, with a lack of injury data among women. Aims were to report non-contact risk factors in U.S. women's Rugby-7s.
METHODS: Injury incidence (per 1000 player-match hour (ph)) and non-contact factors were cataloged with the Rugby Injury Survey & Evaluation (RISE) Report methodology (Lopez et al., 2012). Injury data were collected from 10,328 U19 to elite U.S. women players (age: 8-50 years) on 852 teams involving 1,895 matches in 80 USA Rugby sanctioned tournaments (2010-2015). Medical attention injuries were injuries with no absence from play and time-loss injuries were where players were unable to return to play the same day. Injury severity was defined as days absent before return to training/competition. Non-contact injuries were defined as no contact with an opposing player or collision-type mechanism, and further subdivided into classic-non-contact (CNC) (ie: cutting, accelerating); or other non-contact (ONC), influenced by another factor (Marshall, 2010).
RESULTS: Non-contact causes of injury occurred frequently (29%; n=167) over the study period (CNC=92%, n=153; ONC=8%, n=14; P<0.001). Non-contact injuries overall (including time-loss and medical attention) were found at similar rates among backs (58%, 23.9/1000ph, CI:19.1-29.6) and forwards (42%, 19.3/1000ph, CI:14.4-25.3; RR:1.04, p=0.816). CNC time-loss injuries were observed at similar rates among positions (backs 6.1/1000ph; forwards 5.9/1000ph, RR:1.03, p=0.933). Non-contact injuries resulted in 58.4 mean days absent (CNC 58d; ONC 60d). Injuries overall were acute (90%) and occurred during attempted tackling (35%) and running/open play (32%). Most injuries (70%) occurred during the first two matches of the tournaments. Recurrent injuries were observed at 40% of all injuries (10.0/1000ph, CI:7.7-12.8). Most common time-loss injuries were ankle sprains (18%). Knees were most commonly injured (23%, 5.9/1000ph, CI:4.1-8.1) followed by ankles (17%, 4.3/1000ph, CI:2.8-6.3). Non-contact injuries were higher on artificial playing surfaces (36.6/1000ph) as compared to grass (24.7/1000ph, RR:1.48, p=0.044).
CONCLUSION: The incidence of head/neck injuries among U.S. women is of concern, reemphasizing the need for more focus on attempted tackling techniques, among women and non-contact factors (Ma et al., 2016). The current study's increase in injury with running/open play phases supports the need for training and conditioning necessary to meet Rugby-7s demands (Portillo et al., 2014). To avoid overtraining, a balance must be between pre-season, competition conditioning and tournament demands, since a single Rugby-7s tournament reduces neuromuscular function and players may not be fully recovered by the start of the second competition (West et al., 2014). Injury reduction of non-contact soft tissue and ligamentous injuries to the lower extremity may be achieved by increasing muscular load tolerance and proprioception during training to include open field maneuvers (Hrysomallis 2007).

CHANGES IN COGNITIVE PERFORMANCE AND CEREBRAL OXYGENATION IN YOUNG RUGBY UNION PLAYERS OVER ONE SEASON

TERBLANCHE, E., CLARKE, A.

STELLENBOSCH UNIVERSITY

INTRODUCTION: Changes in functional brain connectivity, as well as impaired cerebral haematological function and neurocognitive function have been reported in contact sport players, even in the absence of a diagnosed concussion. Specifically, studies described compromised executive cognitive function in both active and retired rugby union players Shuttleworth-Edwards et al, 2008; Hume et al, 2017). The aim of this study was to determine whether a fifteen-week high-level competitive season elicits changes in the cognitive function and cerebral oxygenation of young rugby players.
METHODS: Twenty-nine athletes (16 rugby players and 13 non-contact sport athletes) were assessed before and after the 2017 Varsity Cup rugby competition, held in South Africa. None of the participants experienced, or were diagnosed with concussion over the 15 weeks. Each participant completed the CNS Vital Signs® Core testing battery, during which continuous measurements of cerebral oxyhaemoglobin (COX) were made using near-infrared spectroscopy. The cognitive testing battery consisted of seven tests that assessed eleven cognitive domains. Training and match time were noted for each individual on a weekly basis. Cohen's effect sizes and 95% confidence intervals (CI) were calculated to compare the magnitude of differences in cognitive function and COX between the groups.
RESULTS: There was no difference in training and competition time in the two groups over 15 weeks (P>0.05). Rugby players performed better in the domains of information processing speed (ES=0.4, 95% CI -0.44, 1.03) and psychomotor speed (ES=0.47, 95%CI -0.5, 0.99), but worse in the 'higher' domains of executive function (ES=0.77, 95%CI -1.4, 0.1) than the non-contact players. COX during cognitive testing was higher in the rugby players than in the non-contact players at the end of the season (ES = 0. 57, 95%CI -0.23, 1.34).
CONCLUSION: The findings of this study are inconclusive whether repetitive subconcussive events, as experienced during rugby training and matches over one season, negatively affect the cognitive performance of young rugby players. It is possible that 15 weeks were too short to measure changes in brain health, or that the actual subconcussive events were minimal. However, this does not exclude the possibility that exposure to contact over multiple seasons may not cause neural impairments to the extent that cognitive function, and health, are affected later in life.

RECOVERY OF VESTIBULAR AND OCULOMOTOR IMPAIRMENTS IN AMATEUR ATHLETES FOLLOWING SPORT-RELATED CONCUSSION; A PROSPECTIVE STUDY.

BÜTTNER, F., HOWELL, D., DOHERTY, C., RYAN, J., BLAKE, C., DELAHUNT, E.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Vestibular and oculomotor symptoms are frequently self-reported by athletes following sport-related concussion. However, clinical assessment strategies, that longitudinally identify the presence of vestibular and oculomotor impairments, remain elusive in the absence of a baseline assessment. Few longitudinal studies exist that clinically evaluate the natural history of vestibular and oculomotor impairments following sport-related concussion.
METHODS: Objective: To prospectively and longitudinally describe the recovery of vestibular and oculomotor impairments in amateur athletes following sport-related concussion.
Design: Prospective, longitudinal study.
Setting: Clinical evaluation at a university biomechanics laboratory.
22 amateur athletes diagnosed with sport-related concussion by an emergency medicine physician, and 22 sex-, age-, and activity-matched control participants, were assessed on 3 separate occasions: within 7 days following sport-related concussion, prior to return-to-activity [range (days)= 6 - 24], and 2 weeks after return-to-activity. Control participants were assessed at matched time-points.
At each assessment, a Chartered Physiotherapist administered the Vestibular/Oculo-Motor Screening (VOMS) to study participants. The VOMS assesses smooth pursuits, saccades, convergence, vestibular-ocular reflex, and visual motion sensitivity via a 7-item symptom provocation tool. Following each test item, participants self-report their symptom provocation of headache, dizziness, nausea, and fogginess.
A mixed-methods analysis of variance was performed to evaluate participants symptom response to vestibular and oculomotor test items. The independent variables were group and time. The dependent variable comprised the Percentage of Potential Change (PoPC) in total symptoms, a valid measure of symptom change that accounts for the burden of reported pre-test symptoms. The PoPC was calculated using participants self-reported symptoms at baseline (directly prior to the administration of the VOMS) and subsequent symptom reporting following each test item.
RESULTS: A significant time*group interaction was observed ($F(1.5, 64.4) = 7.6$; $p = 0.003$; $N2p = 0.15$). Concussed participants reported significantly greater percentage of potential symptom exacerbation at time-point 1 (mean PoPC = 9.1%; 95% CI = 5.9 - 12.3) compared to control participants (mean PoPC = 2.0%; 95% CI = -1.2 - 5.2). No between-group differences in PoPC were observed at time-point 2 (mean diff. = 0.9%; 95% CI = -1.8 - 3.6) or at time-point 3 (mean diff. = 1.5%; 95% CI = -1.4 - 4.5).
CONCLUSION: Amateur athletes demonstrated, on average, a greater percentage of potential symptom exacerbation within one-week following sport-related concussion compared to matched non-concussed athletes. Between-group differences were no longer present prior to, and following, return-to-activity, suggesting full recovery of concussion-induced vestibular and ocular symptoms by the time amateur athletes resumed physical activity.

LOW RISK OF CONCUSSIONS IN TOP-LEVEL KARATE COMPETITION

ARRIAZA, R., CIERNA, D., ROMAN, F., AGRASAR-CRUZ, C., SAAVEDRA-GARCIA, M.

UNIVERSITY OF A CORUÑA

INTRODUCTION: Although it is well known that injuries take place in combat sports, the true incidence of concussions is not clearly defined in the literature for karate competition
METHODS: Injuries in a total of 4,625 fights (2,916 in the male category and 1,709 in the female category), in four consecutive World Karate Championships (from 2008 to 2014) were prospectively registered. Concussions were identified and analyzed separately for frequency (rate per fight) and injury risk
RESULTS: A total of four concussions were diagnosed by the attending physicians after carrying on the athletes examination. Globally, there was 1 concussion in every 1,156 fights, or 0.43/1,000 AE. In male athletes, the rate of concussion was 1/5,832 minutes of fighting, and in female athletes, it was 1/6,836 minutes. Odd Ratio is 0.57 (95% CI: 0.06-5.47; z=0.489; p=0.6249) and Risk Ratio is RR 1.478 (95%CI 0.271-8.072), p=0.528, representing a higher risk of definite concussions in males than in females, but not statistically significant. Neither in men nor in women there is a significantly higher risk of injury in team competition (no weight-limit) when compared to individual competition (held with strict weight limits for each category)
CONCLUSION: The risk of concussions in top level karate competition is low, with a tendency for an increased risk for males and for competition without weight limits, not statistically significant with respect to females or individual competition

IS-SH08 Sport for All? Inclusion of Female Refugees in European Sports

PHYSICAL ACTIVITY AND SPORT FOR GIRLS AND WOMEN: A POSSIBILITY OF INTEGRATION INTO GERMAN SOCIETY?

HOFMANN, A.

LUDWIGSBURG UNIVERSITY OF EDUCATION

In 2015 almost half a million persons applied for asylum in Germany. Sport, physical activity and exercise are often used as means to raise awareness for social problems and it is generally thought that they can support integration. This can be seen in the fact that state governments often act as partners of sport federations by giving financial support to set up sport and physical activity offers for refugees. Women with migration background participate to a much lesser extend participate in these programs than males. Several reasons account for this: Not only are there fewer female refugees, but also, due to their religious background women and girls are much more drawn to the private sphere and to family life. This means they often do not participate in public sport or exercise activities to the same extend. In addition, many refugee women and girls were to a lesser extent than men, involved in sports and physical exercise in their home countries. This paper will examine and compare chosen examples how to include refugee women within German sports and show the difficulties and barriers in doing so.

OUTDOORS, SPORT AND INTEGRATION – A SCANDINAVIAN PERSPECTIVE

RADMANN, A., HEDENBORG, S.
MALMÖ UNIVERSITY

During the last five years the number of people who have applied for asylum in Sweden and Norway has increased dramatically as a result of the severe draughts in the Middle East and the war in Syria. Governments have set aside special means for working with the newly arrived and a strategy has been to work with integration using "Friluftsliv" (Outdoors) and sports. The Norwegian White Paper No. 18 (Stortingsmelding 18 (2015-16) "Outdoors – nature as a source of health and overall life quality" declare that it is a strong political commitment to involve refugees in the Norwegian tradition of Outdoors/Friluftsliv since Friluftsliv is considered to be an important arena for inclusion and integration. As a means for integration the Swedish government decided to set aside 32 and later 64 million Swedish Crowns per year for work directed to the Swedish Sport Confederation's integration projects. The aim of this presentation is to critically analyse the perceptions of "friluftsliv" and "sport" in relation to integration/inclusion. Why these activities are seen as important in the process of integration as well as in what ways the use of these concepts reveals ideas of what it is to be a "typical" Norwegian or Swede will be discussed using an intersectional perspective and a critical analysis of how good intentions of integration/inclusion simultaneously include and exclude groups (cf Popkewitz 2008).
Popkewitz, T, Cosmopolitanism and The Age of Reform (2008).

˝TRAIN THE TRAINERS˝: GENDER AND INTERCULTURAL COMPETENCES IN COURSES FOR COACHES FOR TRAUMATIZED FEMALE REFUGEES

DIKETMÜLLER, R., LEY, C.
UNIVERSITY OF VIENNA

Knowing that refugees show a particularly high prevalence of psychosomatic and psychosocial disorders and that exercise and sport gain somatic and psychosocial health benefits, this lecture focuses on the relevance of gender and intercultural competencies of ongoing coaches for traumatized women. Previous studies (e.g. Ley et al., 2016) indicate that these benefits are very relevant for traumatized refugees, torture and war survivors. Nevertheless, especially for migrant (muslim) women the person who offers physical activity and sport is crucial. Till now, competencies of coaches for traumatized female refugees are currently scarcely researched and curricula on this issue are still missing. The research analyses how gender, cultural, religious and health-status issues are addressed within a program for coaches who wanted to work with traumatized female refugees. It got clear that intersectional approaches were needed in order to contribute to the understanding of the specific needs of the target group and to the development of a target-group oriented program. This lecture focuses on the results regarding the program-development, the experiences of the coaches in offering physical activity and sport and finally discusses the role of gender and intercultural issues in the framework of trauma work with female refugees.

OP-PM78 Cycling

THE EFFECT OF PHYSIOLOGICAL AND ANTROPOLOGICAL PARAMETERS ON SCORING RESULTS OF SLOVENIAN CYCLISTS IN THREE AGE CATHEGORIES

JUROV, I., MILIC, R., RAUTER, S.
FACULTY OF SPORT, UNIVERSITY OF LJUBLJANA

INTRODUCTION: Physiological markers in cycling that are typically used in assessing performance are VO2max, peak power, power per unit of body mass, lactate values and heart rate. Cycling is an athletic discipline favouring leanness and body mass is a known anthropological factor contributing to athlete's performance. However, some parameters like peak power are more dependent on fat free mass as opposed to body mass. Markers like peak power per unit of fat free mass (W/kg FFM) have been proposed for assessing and comparing values of power measurements. All these markers are known to influence performance. We have conducted a research on Slovenian cyclist in three age categories (U17, U19 and U23) to find a correlation with their overall result in cycling in that year.
METHODS: The aim of the study was to find correlations between cyclist's overall yearly results and physiological parameters obtained on the cycle ergometer in the laboratory. The study involved 110 cyclists, 43 in the U17 category (age 16 ± 0 years, BM = 67,7 ± 6,6 kg, BH = 179,8 ± 7,0 cm, % fat = 9,1 % ± 2,7 %), 42 cyclist in the U19 category (18 ± 0 years, BM = 68,3 ± 6,1 kg, BH = 179,4 ± 6,3 cm, % fat = 9,9 ± 3,1 %) and 25 cyclists in the U23 category (20,4 ± 0,5 years, BM = 71,2 ± 6,0 kg, BH = 181,8 ± 4,3 cm, % fat = 9,5 ± 2,1 %) who performed incremental cycle exercise test (100W + 20W/min). We used their results in the Slovenian cycling cup and in the international level and compared them to their VO2max, peak power, power per kg, power per kg FFM, BM, body fat percentage and efficiency. Binary regression model was used.
RESULTS: Results showed that there were significant correlations between VO2max (r=0,394, p=0,005), W(max) (r=0,547, p=0,000), W/kg BM (r=0,631 p= 0,000), W/kg FFM (r=0,594, p=0,000) and scoring results in the U17 group. In the U19 category, VO2max (r=0,399, p=0,004), W(max) (r=0,371, p=0,008), W/kg BM (r=0,460 p= 0,001), W/kg FFM (r=0,447, p=0,002) also significantly correlated with the overall result. In the older U23 group, no correlations were found.
CONCLUSION: VO2max, W(max), W/kg BM and W/kg FFM were positively correlated with overall scoring in the U17 and U19 group. However, in the U23 group no correlations were found. In the younger cyclists physical abilities appear to be more relevant, whereas in the older group other factors contribute greatly to the overall result.

FUNCTIONAL OVERREACHING IN PROFESSIONAL FEMALE CYCLISTS; IMPLICATIONS FOR MONITORING AND PRESCRIBING TRAINING

LAMBERTS, R.P.1,2, DECROIX, L.3, MEEUSEN, R.3

1: STELLENBOSCH UNIVERSITY, RSA; 2: STELLENBOSCH UNIVERSITY, RSA; 3: VRIJE UNIVERSITEIT BRUSSEL, BEL

INTRODUCTION: The Lamberts and Lambert Submaximal Cycle Test (LSCT) has shown to be promising tool to monitor and prescribe training in cyclists [1]. However, it has not yet been well documented if and how the LSCT is able to reflect a state of functional overreaching [1-3]. Therefore, the aim of this study was to monitor a team of professional female cyclists during an 8-d training camp and 3 recovery days.
METHODS: Six professional female cyclists performed an LSCT on days 1, 5, and 8 of the training camp
and 3 d after the training camp. During each stage of the LSCT, physiological parameters as power, cadence and hear rate were captured, while a rating of perceived exertion (RPE) at the end of each stage was also given. Upon completing the last stage, heart rate recovery was
were also measured. In addition to the LSCT, cyclists also completed a Profile of Mood States (POMS) and indicated their level of fatigue on a visual analogue scale.
RESULTS: In addition to traditional statistics, magnitude-based inferences (MBI) were used interpret the LSCT data. Power output within the LSCT increased throughout the training camp reaching higher values in stage 2 on day 8 ($p = 0.009$) increased RPE levels in stage 2 on day 5 and 8 ($p < 0.05$). MBI indicated that power during stage 2 and 3 were 'likely' and 'very likely' higher on day 5 and 8, respectively, while RPE's were 'likely' to 'most likely' higher on days 5 and 8. HRR was likely to be faster on day 5, while HRR could not be accurately used on day 8 due to cyclist not being able to elicit their predetermined target heart rates. The different LSCT parameters returned to baseline after 3 days of recovery.
CONCLUSION: The LSCT reflects a state of overreaching in elite professional female cyclists by increased power output levels in combination with higher RPE levels and a faster HRR. The power and HRR response are counter intuitive and without the RPE data, might be interpreted as a positive training adaptation rather than a state of functional overreaching. Therefor a multi-variate approach is needed to correctly monitor and fine-tune training prescription in athletes.

THE DIFFERENCE IN INTENSITY AND LOAD CHARACTERISTICS BETWEEN MEN'S AND WOMEN'S PROFESSIONAL CYCLING RACES

SANDERS, D., VAN ERP, T., DE KONING, J.J.

UNIVERSITY OF STIRLING

INTRODUCTION: There is little known about the differences between men's and women's professional cycling races in terms of exercise intensity and load demands. Knowledge of possible differences is relevant for coaches and practitioners with respect to preparation strategies for competition. This study aims to provide an in-depth analysis of a large competition database describing the intensity and load demands of professional road cycling races, highlighting the differences between men's and women's races.
METHODS: Twenty male and ten female highly trained professional cyclists, part of a current World Tour professional cycling team, participated in this study. During 4 consecutive years, whenever possible, heart rate (HR) and power output (PO) data was collected during competitions for both the males and females within the team. Intensity distribution as time spent in five predetermined HR zones was quantified. Load was calculated using different metrics including Training Stress Score (TSS) and Training Impulse (TRIMP). Magnitude based inferences was used to evaluate differences in load and intensity between men and women. Standardized effect size is reported as Cohen's d.
RESULTS: A total of 667 women's and 3024 men's races were analysed. Higher values ($d = 1.36 – 2.86$, large to very large) were observed for distance, duration, total work (kJ) and mean PO in men's races. Mean HR and mean HR as % of maximal HR ($d = 1.60 – 1.80$, large) was higher in women's races as well as time spent in high intensity HR zones (i.e. zone 4 and zone 5) ($d = 1.38 – 1.55$, large) compared to men's races ($42 \pm 11\%$ and $21 \pm 16\%$ versus $24 \pm 12\%$ and $6 \pm 6\%$). Higher absolute loads were observed in men's races quantified using TSS ($d = 0.53$, small) and TRIMP ($d = 0.23$, small). However, relative load (per km) was higher in women's races for TSS·km-1 ($d = 1.50$, large) and TRIMP·km-1 ($d = 2.31$, very large).
CONCLUSION: This study highlights substantial differences in intensity and load characteristics between men's and women's cycling races. Although men's cycling races are longer with a higher total load, the intensity of women's races is substantially higher compared to men's races. This is highlighted by the longer time spent in higher intensity zones and the higher relative load in women's races. Differences in pacing strategies as well as a higher variability in performance level in women's cycling most likely contributes to these results. Coaches should consider these differences in race demands in the preparation of professional cyclists. These results may indicate that preparation strategies between men's and women's races cannot be used interchangeably.

INFLUENCE OF CHRONOTYPE ON PERFORMANCE AND PACING IN A SIMULATED CYCLING TIME TRIALS

SCHWINDLING, S.1, SKORSKI, S.1, SPIEß, F.1, KLÜTSCH, A.1, ABBISS, C.2, MEYER, T.1

1 SAARLAND UNIVERSITY , 2 EDITH COWAN UNIVERSITY

INTRODUCTION: Circadian rhythms regulate key physiological processes involved in athletic performance, e. g. core temperature and serum cortisol. As such, the Chronotype (CT) is defined as an individual's circadian predisposition towards morningness (M) and eveningness (E). It is discussed that CT might influence endurance performance as M-types seem to perform better in the morning and E-types in the evening. However, current results are equivocal (Vitale et al. 2017) as research using sport-specific performance tests is still lacking. Therefore, the aim of this study was to determine the influence of CT on pacing and performance in self-paced cycling time trials.
METHODS: 76 competitive male cyclists and triathletes completed the Morningness-Eveningness Questionnaire to differentiate between CTs (Home et al. 1976). Participants categorized as "definite" M- (n=10) and E-types (n=7) were included in the study. In a randomised order and separated by 2 to 7 days participants performed 4 self-paced 20 km cycling time trails (TT) with a standardised warm-up on an electromagnetically braked cycle ergometer at 4 different times of the day (6 am, 12 pm, 6 pm, 10 pm). Rating of perceived exertion (RPE)

was collected every 10 % and power output (PO) averaged every 10 % of each trial. Perceived mental performance (MP), sleepiness (S) and motivation (M) were collected via visual analogue scales before each trial.
RESULTS: Overall time of day had no significant effect on mean power output (POmean; p=0.12). No significant differences between CT were observed in Pmean (p>0.05) and/or total time (p>0.05) at any time of the day. Furthermore, neither daytime nor CT had a significant effect on pacing (p>0.05) and/or RPE (p>0.05). However, MP of E-type was significantly lower 6 am, compared to 6 (p=0.02) and 10 pm (p=0.01). S and M did not significantly differ between the CT and daytime (p>0.05).
CONCLUSION: Previously published findings observed differences in endurance performance throughout a day as well as between CT. However, in the current study neither time of day nor the individual CT seem to affect cycling performance and/or pacing. This might be explained by the inclusion of a standardised warm-up as it is speculated that this might increase core body temperature, and thus blind potential circadian influences. Additionally, behavioural factors, such as habitual training time might have further influenced the results, as participants regularly train in the afternoon/evening. Interestingly, E-types subjectively rated their MP to be worse before the morning test, however this did not affect their performance.

DECEPTION OF CYCLING DISTANCE ON PACING STRATEGIES, PERCEPTUAL RESPONSES AND NEURAL ACTIVITY

WINGFIELD, G.
CHARLES STURT UNIVERSITY

INTRODUCTION: The aim of this study was to examine the effect of deception of cycling distance on pacing, cerebral oxy (O2Hb) and deoxy (HHb) haemoglobin concentrations and alpha (α) brain wave activity.
METHODS: 10 well-trained male cyclists completed three cycling time trials (TT) on a stationary air-braked cycle ergometer and were informed the study was to examine the reliability of 3 x 30 km time trials (TT). However, participants unknowingly completed three distances (24, 30 and 36 km) in a randomised order. Performance (power output; PO), physiological (heart rate; HR), perceptual (rating of perceived exertion; RPE) and hemo-neurological (O2Hb, HHb and α activity) measures were recorded at rest and throughout each TT. Data were converted to a percentage relative to the total distance covered.
RESULTS: At 100% completion, HR and PO was lower during the 36 km compared to the 30 km trial (P=0.01). Further during the 36 km compared to the 24 km trial, α waves were reduced at 100% (P=0.02), while O2Hb was greater at 70% of completion (P=0.03). RPE was also higher for 36 km compared to 30 km trial at 80% and the 24 km trial at 10% and 40 – 100% of completion (P=0.00-0.02).
CONCLUSION: We conclude that the increase in O2Hb and RPE during the 36 km trial while a reduction in HR and PO is present, may indicate that the pre-frontal cortex could influence the regulation of exercise performance when deceived of the duration end-point by increasing perception of effort to reduce premature onset of physiological strain

CARBOHYDRATE FEEDING STRATEGIES TYPICAL OF PRO-TOUR CYCLING IMPROVE EXERCISE CAPACITY IN TRAINED CYCLISTS IN A DOSE-DEPENDENT MANNER.

FELL, J.M.1, ELLIS, D.G.1, MORAN, J.1, HEARRIS, M.1, STRAUSS, J.1, COCKS, M.1, LOUIS, J.1, SHEPHERD, S.O.1, MORTON, J.P.1
1LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: It is well accepted that carbohydrate (CHO) feeding during exercise improves exercise performance and/or capacity. Nonetheless, the optimal dose of CHO to exert ergogenic effects is not yet established in those instances where exercise duration is > 3 hours. Previous dose-response studies (Newell et al., 2015; Smith et al., 2013) have also administered CHO drinks per se as opposed to feeding strategies typical of elite cyclists whereby a mixture of drinks, solids and gels are typically consumed. Accordingly, the aim of the present study was to test the hypothesis that CHO feeding as comprised from a mix of CHO sources improves exercise capacity in a dose-dependent manner.
METHODS: In a repeated measures crossover design and after a 36 h CHO loading protocol (12 g/kg body mass) and pre-exercise meal (2 g/kg body mass), eight male trained cyclists (VO2max 61 ± 5 mL.kg-1.min-1) completed three experimental trials comprising of 3 h steady state (SS) cycling at lactate threshold (208 ± 11 W). Subjects consumed CHO during exercise at a rate of 0, 45 or 90 g/h as achieved via a mixture of fluids, solids and gels with fluid being matched within each trial. Muscle biopsies were obtained from the vastus lateralis muscle immediately before and after completion of the 3 h SS protocol after which point, subjects then completed an exercise capacity test at 150% lactate threshold (312 ± 18 W). Venous blood samples and expired gas were also collected throughout exercise.
RESULTS: Exercise capacity was different between trials (P=0.01) where 90 g/h was longer (233 ± 133 s) than both 45 (156 ± 66 s; P = 0.06) and 0 g/h (108 ± 48 s; P = 0.013). Additionally, exercise capacity was greater in 45 g/h compared with 0 g/h (P=0.029). During the final hour of SS exercise, total CHO oxidation rates were greater in the 90 g/h (1.87 ± 0.27 g/min; P=0.07) and 45 g/h (1.74 ± 0.13 g/min; P=0.05) compared with the 0 g/h trial (1.36 ± 0.18 g/min). Accordingly, fat oxidation rates were lower in the 90 g/h (0.81 ± 0.08 g/min) compared with the 0 g/h (0.98 ± 0.06 g/min; P = 0.073) trial but were not different from the 45 g/h (0.87 + 0.05 g/min) compared to the 0 g/h (P = 0.14) trial. Muscle fibre type-specific glycogen and intramuscular triglyceride utilisation during exercise is currently being assessed using immunohistochemistry.
CONCLUSION: Data demonstrates that CHO feeding improves exercise capacity in trained male cyclists in a dose-dependent manner. Given the higher rates of CHO oxidation observed in the CHO feeding trials, such data are likely due to maintenance of plasma glucose availability and/or muscle and liver glycogen sparing.

ELECTROMYOGRAPHY ANALYSIS OF FRONT CRAWL SWIMMING, PULL UP AND BENCH PRESS EXERCISES

CROWLEY, E., HICKEY, S., QUILTER, C., HARRISON, A.J., LYONS, M.

UNIVERSITY OF LIMERICK, IRELAND

INTRODUCTION: Resistance training is intended to increase maximal force output and therefore improve swimming performance. Resistance training exercises for specialised preparation and development refer to the improvement in human performance with regards to specific performance movements. Therefore, the transfer of resistance training to swimming performance is imperative. Specificity is an underlining concept that aids in the positive transfer of resistance training exercises to human performance due to the improved coordination of the musculoskeletal system. Therefore, an analysis of the neuromuscular system through the investigation of electromyography (EMG) on both resistance training exercises and swimming performance is required.
METHODS: Fourteen male national and international level swimmers (18.2 ± 2.5 years) were recruited. EMG and 2D kinematic data were collected whilst swimming and performing the barbell bench press and prone pull ups in a randomised order. A standardised race warm up was conducted at the start of each testing session. The participants then swam 3 x 35 m front crawl swimming repetitions, with 5 minutes' passive rest between repetitions. The first set was conducted at approximately 70% of the swimmer's maximal effort with sets two and three at maximal exertion. A standardised resistance training warm up was conducted before performing bench press and pull ups at 70% of their 5 RM with set two and three conducted at their 5 RM. EMG data were filtered using a 4th order Butterworth filter. The data were normalised to peak EMG values for each muscle only during the propulsive phase of front crawl swimming and the concentric phase of the bench press and pull up exercises. Technical parameters (stroke length, stroke rate and maximal swimming velocity) were extracted from the 2D kinematic data collected and Pearson correlations were conducted.
RESULTS: The muscle activation data were presented using a 50% threshold of peak EMG values of each muscle during front crawl swimming, bench press and pull up. The onset and offset EMG data displayed overlapping muscle activation patterns between the propulsive phase of front crawl swimming performance and bench press or pull up exercises. 2D kinematic data found moderate to strong Pearson correlations between stroke rate, stroke length and maximal swimming velocity.
CONCLUSION: The results of this study show similarities between muscle activation patterns between the propulsive phase of front crawl swimming performance and pull up or bench press exercises. Further investigation is required to compare the linear envelopes of the pull up and bench press exercises to front crawl swimming performance to support these findings. Methods such as functional data analysis and statistical parametric mapping are two such methods that could provide a further indication of the specificity of these resistance training exercises to swimming performance.

THE EFFECT OF POST-EXERCISE APPLICATION OF EITHER GRADUATED OR UNIFORM COMPRESSION SOCKS ON THE MITIGATION OF DELAYED ONSET MUSCLE SORENESS.

MCDONNELL, A.C., COOPER, D., MLINAR, T., MEKJAVIC, I.B.

INSTITUTE JOZEF STEFAN

INTRODUCTION: A series of studies were conducted to test the hypothesis that compression socks worn following an exercise comprised of eccentric contraction of the calf muscles mitigate exercise induced delayed onset muscle soreness (DOMS). Secondly to compare the effects of compression strategy, whether uniform or graded compression is better suited to mitigate the perception of DOMS.
METHODS: A total of 59 (39 male and 20 female) participants took part in three exercise protocols, anticipated to induce a detectable degree of muscle soreness. Participants wore either ankle height socks with no compression (NoCo), knee height socks with uniform (UNI) or graduated compression (GRAD) for 8hrs/day following exercise. Before, immediately after and at regular intervals during the recovery period, we measured muscle strength, flexibility and the perception of DOMS. The three exercise protocols were: 1) Hike trial (Low pain): A 10-km treadmill hike with a 1000m mountain ascent and descent phases, assessed the effects of GRAD socks in mitigating DOMS, by comparing the results to those of the NoCo socks. 2) Trail Run trial (Moderate pain): compared the effect of GRAD and UNI socks in mitigating DOMS following a 14km trail run with 250m ascent and descent. 3) Calf exercise trial (moderate to severe pain): compared the effect of GRAD and UNI socks in mitigating DOMS following a predominately eccentric calf exercise.
RESULTS: GRAD socks significantly mitigated subjective perception of muscle pain in the calf on day 2 compared to NoCo (Hike Trial). The UNI socks were superior to the GRAD socks in mitigating the perception of pain during the recovery period in the Trail Run. No statistical difference noted in the perception of pain between the UNI and GRAD socks after the Calf exercise trial.
CONCLUSION: Properly sized compression socks mitigated the perception of DOMS induced by eccentric contractions of calf muscles (Hike trial), with UNI compression socks providing more benefit compared to GRAD socks (Trail Run trial) following a trail run. No differences between the effects of UNI and GRAD socks were observed when eccentric contractions of the calf muscles were severe (Calf exercise trial). Compression socks aid in the perception of recovery following low to moderate pain from DOMS.
ACKNOWLEDGEMENTS:
This study was funded in part by Intersocks d.o.o. (Kočevje, Slovenia), who also provided the socks for the participants.

VALIDITY AND REPRODUCIBILITY OF THE FUNCTIONAL THRESHOLD POWER TEST

MC GRATH, E., DONNE, B., FLEMING, N., MAHONY, N.

TRINITY COLLEGE DUBLIN

INTRODUCTION: Coggan and Allen have sold 100,000 copies of their cycling manual "Training and racing with a power meter". This textbook introduces the "Functional Threshold Power" (FTP) test and the commensurate FTP measurement. FTP purportedly reflects sustainable power output in a "quasi-steady state" for approximately 60-min without fatiguing. However, the test has not been validated nor proven reliable. The juxtaposition of an invalidated "scientific test" being embraced by a large number of cyclists creates a chasm between sport science and sport in-vivo. Models for power using a hyperbolic model to predict a "fatigueless power" as the asymptote of a curvature constant have stressed that duration is actually limited to about 30-min (Poole et al. 2016). The purpose of this investigation was

initially to determine the repeatability of the FTP test. Thereafter, to assess validity of computed FTP (cFTP) against estimates of lactate threshold and the assertion that cFTP could be maintained for 60-min in a quasi-steady state (60min TT).
METHODS: Participant were highly trained male and female cyclists and triathletes (n=13). Four non-randomised exercise tests were completed on a Wattbike across successive weeks. Test one comprised a 3-min incremental test to volitional exhaustion to compute Dmax (Cheng et al. 1992), and TLac using a double linear regression model (Beaver et al. 1986). Sequentially, two 20-min FTP tests were completed and FTP calculated (cFTP1 and cFTP2, respectively). Lastly, participants were tasked with sustaining their cFTP2 power for 60-min.
RESULTS: The 95% limits of agreement (LoA) between cFTP1 and cFTP2 test were deemed acceptable (+15 to -20 W, mean bias 2 W, ICC=0.98 and %TEM of 2.4%). The 95% LoA between load at Dmax and TLac with cFTP1 extrapolated to +46 to -10 W, mean bias 18 W, ICC = 0.85 and %TEM of 6.5% and +78 to -46 W, mean bias 16 W, ICC = 0.74 and %TEM of 9.2%, respectively. These disparities were considered unacceptable, despite ANOVA failing to detect significance ($P > 0.05$) between variables. The 60min TT was successfully completed by 12 of 13 participants assessed at a load equivalent to their cFTP.
CONCLUSION: Comparing cFTP1 with the Dmax and TLac would intimate that cFTP may be a proxy substitute. However, the effectiveness of Dmax or TLac to predict 60minTT should be questioned. We suggest that in highly trained athletes cFTP is a superior predictor for 60mTT than either Dmax or TLac. However, based on physiological measures recorded during testing, cFTP should not be used as a stand-alone pivot for exercise prescription.

PRACTICE EFFECTS OF SYNCHRONOUS AND ASYNCHRONOUS SUBMAXIMAL HANDCYCLING

KRAAIJENBRINK, C., VEGTER, R., HENSEN, A., WAGNER, H., VAN DER WOUDE, L.

UNIVERSITIES OF GRONINGEN AND MUENSTER

INTRODUCTION: The handcycle crank system is based on bicycle technology and was initially asynchronous. Although a shift from asynchronous to synchronous crank mode took place in the eighties, an asynchronous crank mode is still seen, especially in non-western countries (Mukherjee et al. 2001). It is suggested that asynchronous is more strenuous than synchronous handcycling, due to trunk stabilization (Bafghi et al. 2008). Our aim is to compare asynchronous (ASYN) and synchronous (SYN) low intensity handcycling (15 W) and study effects of practice on cardio-respiratory variables. We hypothesize that asynchronous handcycling is more straining than synchronous handcycling. Over time, trunk instability is controlled and energy expenditure, oxygen uptake, ventilation and heart rate reduce in both modes.
METHODS: Twelve able-bodied men performed a pre-test, 3 practice units (see Kraaijenbrink et al. 2017) and a post-test in an add-on handcycle on a treadmill at 1.94 m/s and was repeated for SYN and ASYN. Pre and post-tests consisted of 3x4-minute exercise at 15 W with 60 rpm with 2-minute rest in-between. Oxygen uptake (VO2, ml/min), ventilation (VE, L/min) and heart rate (HR, bpm) were continuously measured. Energy expenditure (EE, W) was calculated according to Garby & Astrup (1987). Values were averaged over the last minute of each block to ensure steady state. Effects were analyzed with a repeated measures ANOVA ($P<0.05$) with crank mode (SYN-ASYN), test (pre-post) and time (4th, 8th and 12th minute) as within-subject factors.
RESULTS: EE is significantly higher ($P=0.004$) in ASYN (416 W) than SYN (386 W). No test, time or interaction effects are found. VO2 is significantly higher ($P=0.015$) in ASYN (813 mL/min) than SYN (741 mL/min), and decreases significantly after training ($P=0.008$) and over time ($P<0.001$). An interaction effect between crank mode and time exists ($P=0.021$). VE is significantly lower ($P=0.018$) in the post-test (20 L/min) than in the pre-test (22 L/min) and has an interaction effect of crank mode and time ($P=0.006$). The HR in the SYN mode increases significantly over time ($P=0.042$).
CONCLUSION: The difference between SYN and ASYN reduces over time for EE, VO2, VE and HR values. Asynchronous handcycling is a difficult motor task, but even after short practice, the cardio-respiratory variables reduce supported by a motor learning effect, as represented by an interaction effect in VO2 and VE.

OXYGEN UPTAKES SLOW COMPONENT AND EFFICIENCY OF HALF-SQUAT EXERCISE

GARNACHO-CASTAÑO, M.V.1, PALAU, G.1, SERRA-PAYÁ, N.1, GOMIS, M.1, SAMATIER, B.1, GUIRAO, L.1, PLEGUEZUELOS, L.1, VILCHES-SÁEZ, S.1, MATÉ-MUÑOZ, J.L.2

TECNOCAMPUS-POMPEU FABRA UNIVERSITY

INTRODUCTION: While several studies have focused on evaluating the oxygen uptakes slow component (VO2sc) in endurance exercises, the VO2sc phenomenon and gross mechanical efficiency (GME) in resistance exercises has not been studied. This study aimed to assess VO2sc and GME in half-squat (HS) exercise during constant-load test at lactate threshold (LT) intensity.
METHODS: Twelve healthy young men completed 3 HS exercise tests separated by 48-hour rest periods: one-repetition maximum (1RM) HS test to determine the % loads to be used in the incremental test, incremental-load HS test to establish the %1RM corresponding to the LT, and constant-load HS test at the LT. During the last test, VO2, lactate and mechanical responses were monitored. GME was calculated as the ratio of work accomplished per minute (ie, W in kcal · min-1) to energy consumed per minute (ie, in kcal · min-1). Fatigue in the lower limbs was assessed before and after the constant-load tests using a counter movement jump test.
RESULTS: A slight and sustained increase of the VO2sc was observed. In blood lactate, no significant differences were observed between set 3 to set 21 ($P > 0.05$). Significant inverse correlations were observed between VO2 and GME ($r = -0.91$, $P < 0.001$). Significant losses were observed in jump height ability and in mean power output ($P < 0.001$) in response to the constant-load HS test.
CONCLUSION: VO2sc tended to rise slowly during constant-load HS exercise testing at LT intensity. We postulated that the VO2sc phenomenon might be explained, at least in part, by the change in GME, which estimates the effects of blood alkalinization on the gradual loss of muscle efficiency (Gaesser and Poole, 1996). Effectively, an inverse relationship between GME and ΔVO2 was observed during the constant-load test, which means that VO2 was slightly increasing and GME was decreasing as the time of the test or sets was extended. It has been reported that a decrease in efficiency coincides with significant increases in VO2 during repeated submaximal exercise (Passfield and Doust, 2000). Thus, a lowering in maximal voluntary force- and power-production is induced in muscle ability (Lucía et al., 2002). This was corroborated by the mechanical fatigue detected after constant load test.

This comprehension would allow to elucidate the underlying fatigue mechanisms produced by resistance exercises in a predominantly aerobic metabolism.

PROBIOTIC SUPPLEMENTATION INCREASES CHO OXIDATION IN TRAINED MALE CYCLISTS: A RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED CROSS-OVER TRIAL

PUGH, J., WAGENMAKERS, A.J.M., MORTON, J.P., CLOSE, G.L.
LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: In vitro and animal studies suggest probiotic supplementation can enhance glucose absorption and subsequent oxidation. This study aimed to investigate the effects of a multi-strain probiotic supplementation on substrate utilization, markers of gastrointestinal damage, permeability, subjective symptoms of discomfort and performance during endurance cycling.
METHODS: Methods - Nine male cyclists were randomized to two periods of daily supplementation with a probiotics capsule (25 billion CFU of Lactobacillus acidophilus (CUL60 and CUL21), Bifidobacterium bifidum (CUL20), Bifidobacterium animalis subs p. Lactis (CUL34), Proven Probiotics) or placebo for four weeks, separated by a 14-day washout period (double-blind cross-over trial). After each supplementation period, cyclists consumed a 10% maltodextrin solution (initial 8 ml.kg-1 bolus at commencement of exercise and 2 ml.kg-1 every subsequent 15 min) while exercising for 120 minutes at 55% Wmax followed immediately by a time trial performance test (100 kJ of work). Markers of GI permeability, damage and GI discomfort were assessed as well as substrate utilization via venous blood and breath samples. Magnitude-based inferences were employed to determine differences in substrate utilization between trials.
RESULTS: Results - Probiotic supplementation resulted in a likely large increase in the proportion of total carbohydrate oxidation (ES = 5.7; ±7.2) and a likely large decrease in the proportion of total energy contributed by fat oxidation (ES = 5.7; ±7.2). No difference was observed in overall energy expenditure (5747 ± 555 vs 5821 ± 451 kJ) between probiotic or placebo supplementation. Comparing probiotic to placebo, there was no change in LR (0.047 ± 0.028 vs. 0.045 ± 0.019), or I-FABP (298 ± 171 vs. 317 ± 95 pg.ml-1). Performance during the time trial was not different in probiotic (301 ± 74s) or placebo trial (308 ± 69s).
CONCLUSION: Conclusion - Probiotic supplementation enhances carbohydrate oxidation while simultaneously attenuating fat oxidation during moderate intensity cycling. However, probiotic supplementation was not associated with improved symptoms of GI symptoms, damage, permeability or performance.

GUT MICROBIOTA VARIABILITY IN MALE BODYBUILDERS DURING COMPETITION PREPARATION

MITCHELL, L., LUK, A., OCONNOR, H., HOLMES, A.
UNIVERSITY OF SYDNEY

INTRODUCTION: Diet can exert profound effects on human physiology that are exploited by athletes to modify physique and improve performance. However, a limiting factor is that the effect of diet varies between individuals. This variable response to diet has been demonstrated to arise through mechanisms that are influenced by the gut microbiota. During competition preparation bodybuilders typically undergo a progressive series of diet modifications aimed to achieve reductions in fat mass. Since this process involves change to the macronutrient profile and total energy intake it is possible that the effectiveness will be influenced by inter-individual differences in the gut microbiota. The purpose of this study was to describe the association between the gut microbiota and dietary intake of males spanning a period of body composition modification, and identify factors which may determine these.
METHODS: Five competitive bodybuilders (28.0±11.9 yrs, 77.7±6.7 kg, 177.0±2.8 cm) were followed over 12 weeks with stool samples collected at 8 and 1 week before, and 4 weeks after, competition. Weighed food record (7 days), body composition, resting metabolic rate (RMR), and serum hormones were measured. QIIME was used for microbial analysis, to cluster operational taxonomic unit at 97% sequence identity, and measure alpha- and beta-diversity. Linear discriminant analysis effect size was used to identify differences in microbial taxa and dietary factors between time points and participants. Repeated measures ANOVA was used to assess change in diet composition, body composition and serum variables.
RESULTS: Carbohydrate and starch provided a significantly greater, and protein a significantly lesser, proportion of dietary energy post-competition than pre-competition ($p<0.05$). Fat mass, lean mass, and IGF-1 were significantly increased in the four weeks after competition ($p<0.05$), with no change in RMR, testosterone, insulin, cortisol or leptin ($p>0.05$). The gut microbial diversity of all participants was typical of healthy humans, with diversity indices for each sample showing no significant differences across the dataset ($p>0.05$). Analysis of patterns of beta-diversity (difference between samples) indicated that although the diet shifts induced changes in the microbial abundance distribution over time, each participant maintained distinct differences to other participants. A consistent effect was a post-competition increase in Bacteroides (LDA score=4.91) that corresponded with increased dietary starch (LDA score=4.47).
CONCLUSION: The dietary strategies of bodybuilders impact their microbiota as well as host physiology and metabolism. Despite similar dietary alterations at the level of macronutrient composition and energy intake, the microbial composition varied markedly between individuals. Hence, individual starting microbial compositions and specific food choices also need to be considered to predict the effects of dietary strategies used during competitions.

INTRA-INDIVIDUAL VARIABILITY IN NITRATE REDUCING FACULTATIVE COMMENSAL BACTERIA IN THE ORAL CAVITY

LIDDLE, L.1, BURLEIGH, M.1, MONAGHAN, C.1, MUGGERIDGE, D.J.2, SCULTHORPE, N.1, BUTCHER, J.1, HENRIQUEZ, F.L.1, EASTON, C.1
1 UNIVERSITY OF THE WEST OF SCOTLAND, 2 UNIVERSITY OF STRATHCLYDE

INTRODUCTION: The ingestion of nitrate (NO3-) rich beetroot juice (BRJ) increases the bioavailability of nitric oxide (NO) and, in some cases, has been shown to improve exercise performance. Crucial to this process is the reduction of NO3- in saliva to nitrite (NO2-) by NO3-

reducing bacteria in the oral cavity, of which there are fourteen known species. However, the extent to which the abundances of these bacteria vary over time is unknown. The aim of the study was to determine the intra-individual variability (CoVi) in the abundance of known NO3- reducing bacteria in the oral cavity and to assess whether this influences the variance in salivary and plasma [NO2-].
METHODS: Nine healthy male participants (age 25 ± 5 years, stature 177 ± 5 cm, and body mass 81 ± 11 kg) completed three identical trials. At the beginning of each visit, a bacterial scrape was taken from the posterior section of the dorsal surface of the tongue for 16s rRNA next-generation sequencing. During each visit, the collection of blood and saliva were obtained at baseline and 2.5 h after the ingestion of BRJ, for later analysis of [NO2-]. Taxonomic classification and bacterial abundance were quantified using Qiime software and clustered based on 97% identity and taxonomy using RDP classifier trained to the GreenGenes database (October 2013 release).
RESULTS: The CoVi for the sum of the NO3- reducing bacteria during the study was 20 %. At the species level, the CoVi for the NO3- reducing bacteria detected in these analyses were: Prevotella Melaninogenica (27 %), Veillonella Dispar (31 %), Rothia Mucilaginosa (41 %), Veillonella Parvula (44 %), Neisseria Subflava (58 %), Haemophilus Parainfluenzae (91 %), and Rothia Dentocariosa (118 %). Salivary (Δ768 ± 193 μM) and plasma (Δ154 ± 38 nM) NO2- were all significantly elevated 2.5 h after the ingestion of BRJ in each of the three experimental trials (all $P < 0.01$). The CoVi for salivary and plasma NO2- following BRJ were 19 and 24%, respectively. The variance in the abundance of NO3- reducing bacteria (sum of all species) was not associated with the variance in salivary (baseline, $r = -0.34$, $P = 0.08$; 2.5 h, $r = -0.18$, $P = 0.37$) or plasma (baseline, $r = -0.11$, $P = 0.59$; 2.5 h, $r = 0.08$, $P = 0.71$) [NO2-].
CONCLUSION: These data demonstrate that the abundance of NO3- reducing bacteria on the tongue can vary profoundly from week to week. However, such variation in the abundance of these bacteria does not appear to account for the CoVi in plasma and salivary NO markers. Further work is required to determine whether it can influence the physiological and performance responses to BRJ.

GUT MICROBIOTA DYSBIOSIS INDUCED BY ANTIBIOTICS AND RESEEDING : FUNCTIONAL AND METABOLIC IMPACTS ON SKELETAL MUSCLE

NAY, K., JOLLET, M., GOUSTARD, B., BAATI, N., VERNUS, B., BONNIEU, A., OLLENDORFF, V., DERBRÉ, F., RAMONATXO, C.
INRA, UMR866 DYNAMIQUE MUSCULAIRE ET MÉTABOLIQUE, MONTPELLIER, FRANCE

INTRODUCTION: Gut microbiota cross-talks metabolically with many organs, such as brain, lung and liver. Recently, the hypothesis of a dialogue between microbiota and skeletal muscle has emerged, however no study has thoroughly explored this functional link with potentially significant scientific and implications in the athlete performance.
METHODS: We determined in C57BL/6 mice the effects of a broad-spectrum antibiotic mixture on both running endurance performance and fatigability using ex-vivo assessments of muscle contractility. These results were compared to those obtained in animals sacrificed 11 days after the end of antibiotic treatment to observe the potential recovery on muscle performance after reseeding. Muscle structure and typology, as well as cellular mechanisms involved in skeletal muscle atrophy, mitochondrial biogenesis and substrate bioavailability were also explored;
RESULTS: Antibiotic-treated mice exhibited a significant decrease of running time limit, and an increased ex-vivo fatigability of skeletal muscle. However, maximal aerobic speed (MAS) and maximal ex-vivo strength remained unaffected. These deleterious effects on endurance performance were rapidly corrected after a period of reseeding, supporting a direct link between gut microbiota and skeletal muscle function. No major changes were evidenced for muscle mass, mitochondrial biogenesis, proteosynthesis/proteolysis or muscle fiber typology. Interestingly, promising analyses suggest that muscle glycogen content could play a role in alterations of muscle endurance related to antibiotic treatment-induced dysbiosis.
CONCLUSION: Our data suggest the existence of a functional crosstalk between microbiota and skeletal muscle. These results, beyond gut dysbiosis, questions on altered endurance performance observed in athletes treated with antiobiotics, and thus highlight the need of further studies on potential beneficial effects of correcting dysbiosis in athletes.

GUT MICROFLORA DIVERSITY IS INDUCED BY RESISTANCE TRAINING IN AGED MICE, BUT ITS ACQUIRED DIVERSITY MIGHT NOT BE CONTRIBUTED WITH THE HIGH PHYSICAL PERFORMANCE

YANO, H., HORII, N., KREMENIK, M.J., AOKI, T., UCHIDA, M., IEMITSU, M., OYANAGI, E.
KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: It has been reported that aging-dependent changes in gut microbiota might induce physical and psychological aging. To clarify whether or not the anti-aging by exercise is regulated by changes in the gut microbiota, we investigated the effect of the fecal microbiota transplantation (FMT) from exercised aging mice on the phenotype of each recipient mouse.
METHODS: Male SAMP1 mice (38 weeks old) were divided into SAMP 1 - Ex (resistance training for 12 weeks, n=8) and SAMP 1 - Ctrl (sedentary condition, n=6). Feces were collected from each group, and then meta-genome analysis of gut microbiota was carried out. Moreover, cecal contents were collected and transplanted into recipient mice (C57BL/6 mice). In the control group, the cecal content from the same age- and strain- recipient mouse was used. Analysis of gut microbiota of donor mice and the evaluation of physical activity and anxiety behavior of recipient mice seven weeks after FMT were carried out.
RESULTS: The alpha-diversity (phylogenetic diversity whole tree, Chao1 and observed species) of gut microbiota in SAMP1-Ex mice was significantly higher than that in SAMP1 Ctrl. Additionally, the difference of the microbiome communities between the 2 groups could be observed using traditional PCoA. Especially, the abundance of Akkermansia muciniphila in SAMP1-Ex was significantly lower than that in SAMP1-Ctrl. Although, in the recipient mice, the muscle strength was reduced by FMT from the SAMP1 groups, there was no big difference by FMT from between SAMP1-Ex and -Ctrl groups. Also, the FMT did not affect the physical activity in the recipient mice.
We found that resistance training induced high-diversity of gut microbiota in senescence accelerated mouse SAMP1. Since it is known that A. muciniphila increases in Parkinsons disease or multiple sclerosis patients, resistance training might have a preventive effect on those diseases via gut microbiota alteration. However, at least this FMT experiment showed that high muscular strength and muscle hypertrophy of resistance trained mice did not transmit to recipient mice via gut microbiota.
CONCLUSION: These results suggest that resistance training in senescence accelerated mice might induce changes in the gut microbiota.

INTRODUCTION: Physical activity is known as an effective strategy for prevention and treatment of obesity. For years, the moderate-intensity continuous training (MICT) has been the most widely popular type of exercise advised to improve body composition, cardiorespiratory fitness, lipid profile and to decrease obesity-induced oxidative stress. However, recent studies demonstrated that high-intensity interval training (HIIT) was more efficient than MICT to decrease visceral fat mass. Moreover, the long-term adherence to HIIT would be likely increased compared to MICT since the subjects perceive HIIT as less monotonous and more enjoyable. Thus, the aim of this study was to compare the effects of a traditional MICT with a HIIT on pro/antioxidant status in obese rats in different tissues.
METHODS: Male Zucker rats (fa/fa, n = 36) aged of 8 weeks were subdivided into MICT, HIIT or control (CON) group. Trained animals ran on a treadmill (0° slope), 5 days/week during 10 weeks (MICT group: 51 min at 12m.min-1; HIIT group: 6 x [3 min at 10m.min-1 followed by 4 min at 18m.min-1]). Tissues (muscle [gastrocnemius], adipose tissue [epididymal and subcutaneous]) and plasma were collected to measure markers of pro/antioxidant status (oxidative stress markers [AOPP, oxLDL], antioxidant system [FRAP, SOD, CAT, GPx], prooxidant enzymes [NADPHox and XO activities, MPO content]).
RESULTS: In muscle, MICT induced beneficial effects by increasing antioxidant system (SOD activity) without effects on oxidative stress markers (AOPP) whereas HIIT was able to increase both SOD and GPX activities leading to a reduced AOPP level compared with CON. In addition, HIIT had greater effect than MICT with higher GPX activity and lower AOPP. On the contrary, in adipose tissue (epididymal), only MICT exerted beneficial effects by increasing GPX and SOD activities and FRAP level. In subcutaneous adipose tissue, HIIT had negative effects by increasing AOPP level. Finally, in plasma both training programs were equally effective to reduce MPO content.
CONCLUSION: Both HIIT and MICT are efficient to improve pro/antioxidant status but training responses are tissue-specific. HIIT was more helpful than MICT to improve pro/antioxidant status in muscle, ie. the tissue where reactive oxygen species are mainly produced.

EXERCISE TRANING MODULATES TOTAL ANTIOXIDANT CAPACITY AND GENE EXPRESSION IN RAT CARDIAC AND SKELETAL MUSCLE

FUSI, J., FEDERIGHI, G., CERRI, E., BANDUCCI, R., PETROCCHI, A., SANTINI, V., SCURI, R., FRANZONI, F., GALETTA, F.

VAT N. IT00286820501 UNIVERSITY OF PISA

INTRODUCTION: Regular exercise play an important role in the prevention of cardiovascular and muscular diseases. Such effects seem to be mediated by changes in anti-oxidative status, but limited information is available on the nature of molecular pathways supporting the antioxidant effects of exercise in the cardiac and skeletal muscle.
METHODS: In this study 3-5-month-old male Wistar albino rats were subjected to three times/week moderate intensity exercise on a rodent treadmill for a period of 6 weeks. The tissue antioxidant activity towards various reactive oxygen species (ROS) was determined in the cardiac and gastrocnemius muscle. In addition, to identify the molecular pathways that may be involved in ROS metabolism, the expression of sirtuins (SIRT1 and SIRT3) were measured.
RESULTS: Our results showed a higher anti-hydroxyl and anti-peroxynitrite antioxidant activity in both the cardiac and gastrocnemius muscle of physically trained rats compared to sedentary controls. Furthermore, exercise induced an up-regulation of SIRT1, possibly related to an improved redox balance in the cardiac tissue.
CONCLUSION: These results suggest that physical exercise might prevent age-induced oxidative damage in the cardiac and skeletal muscle.

IMPAIRED AUTOPHAGY IN THE LIVER, BUT NOT SKELETAL MUSCLE OF MICE FOLLOWING A HIGH FAT, HIGH SUCROSE DIET

MORALES-SCHOLZ, M.G., SWINTON, C., HOWLETT, K.F., MURPHY, R.M., KOWALSKI, G.M., BRUCE, C.R., SHAW, C.S.

DEAKIN UNIVERSITY

INTRODUCTION: Autophagy is a cell nutrient sensitive degradation process promoting homeostasis by recycling dysfunctional components. Insulin resistance (IR) and ectopic tissue lipid deposition have been recently associated with autophagy impairments. Autophagy responses to acute glucose administration were examined in mouse skeletal muscle and liver following a chronic, high fat, high sucrose diet intervention.
METHODS: Forty 8-week-old, male C57BL/6J mice were randomly divided into 2 groups (n=20 each) and were fed either a high-fat, high-sucrose (HFSD) or standard chow control (CON) diet for 16 weeks. At the end of the diet intervention each group was further divided into 2 subgroups, either receiving water (sham) or glucose (50 mg) via oral gavage after a 5 h fast. Quadriceps and liver samples were collected from each subgroup and tissue lipid accumulation was assessed. Furthermore, markers of autophagy activity, lysosome and lipid-droplet associated protein content, as well as upstream signalling events were measured by immunoblotting and gene expression analyses.
RESULTS: Both the liver and muscle from HFSD groups displayed higher lipid content compared to CON ($P<0.05$). In the liver, the levels of lipidated LC3B and GABARAP, as well as p62, were increased in the HFSD group compared to CON (all $P<0.05$) without any changes in gene expression. HFSD also resulted in upregulation of the lipid-droplet associated proteins PLIN2 and PLIN3 ($P<0.05$). HFSD liver displayed features of IR such as reductions in pAkt (Thr308) post glucose gavage, as well as increases in pmTOR (Ser2448) and pULK-1 (Ser758) compared to CON (all $P<0.05$). In skeletal muscle, there were no differences in autophagy markers (LC3B, GABARAP or p62) between groups, despite a tendency for a reduction in pAkt (Thr308) levels in HFSD ($P=0.07$). LAMP1 protein levels were increased in HFSD

compared to CON (P<0.05), without significant changes in gene expression. Furthermore, there were no changes in any autophagy markers in liver or muscle following acute glucose administration.
CONCLUSION: Taken together, a high-fat, high-sucrose diet intervention induces tissue-specific autophagy impairments. In muscle, no differences in autophagy activity were found after a HFSD intervention. Whereas in the liver, increases in p62 and the lipidated LC3B and GABARAP in the HFSD group indicate autophagosome accumulation, potentially due to a failure of lysosomal autophagosome clearance. These autophagy impairments may contribute to hepatic lipid accumulation and metabolic dysfunction following HFSD.

THE EFFECT OF RAT HIND-LIMB FNDC5 OVEREXPRESSION UPON SKELETAL MUSCLE METABOLISM, IN VIVO

FARRASH, W.1,3, BROOK, M.1, BASS, J.J.1, CROSSLAND, H.1, PHILLIPS, B.E.1,2, CEGIELSKI, J.1, WILKINSON, D.J.1,2, SMITH, K.1,2, CLEASBY, M.3, ATHERTON, P.J.1,2

THE UNIVERSITY OF NOTTINGHAM

INTRODUCTION: Fndc5, a type I transmembrane protein, is up-regulated in skeletal muscle via the transcriptional co-activator PGC-1α after exercise training. Fndc5 is cleaved and its product, Irisin, is secreted and purported to elevate energy expenditure, via causing increased mitochondrial biogenesis/futile cycling through non-shivering thermogenesis - leading to loss of body fat. Moreover, recently, Irisin was purported to regulate skeletal muscle hypertrophy. Similar adaptions occur in skeletal muscle in response to exercise, albeit where Fndc5's/Irisin regulatory pathways are unestablished, and where myokines, such as Irisin, are thought to exert physiological effects on skeletal muscle in an autocrine/paracrine fashion. In this study, we aimed to investigate the mechanistic role of Fndc5/Irisin upregulation in skeletal muscle.
METHODS: Overexpression (OE) of Fndc5 in rat hind-limb muscle was achieved by in vivo electro-transfer techniques i.e. bilateral injections of Fndc5 harbouring vectors for OE rat (n=8) and empty vector for controls (n=8). Seven days later, D2O (7.2mls/kg) was administered via oral gavage for muscle protein synthesis (MPS) analysis. After an overnight fast on day 9, 2-deoxyglucose (2-DG 6mg/kg) was provided during an intraperitoneal glucose tolerance test (IPGTT, 2g/kg) with regular blood sampling. Animals were euthanized and muscles harvested. Metabolic changes in transfected skeletal muscles (tibialis cranialis (TC)) were evaluated.
RESULTS: Gene expression of Fndc5 mRNA in OE TC muscles was increased ~2-fold to that of control values (P=0.001), with concomitant increases in protein expression to 1.4-fold of control animals (P=0.036). In addition, plasma Irisin concentrations were elevated from 1.5 ng/ml in Ctrl, to 3.5 ng/ml in OE animals (P=0.097). As a result, glycogen content and its regulatory gene GYS1, was elevated in Fndc5 OE (P=O.O4 and 0.02, respectively). However, no changes in whole-body glucose disposal were evident with Fndc5 OE i.e. AUC of IPGTT (P=0.75). Similarly, no changes in plasma membrane Glut4 (P=0.15) or its mRNA (P=0.61) were observed. Fndc5 OE had no major effect on muscle mitochondria, as no changes were detected in gene/protein markers of mitochondrial biogenesis. Similarly, anabolic processes relating to muscle growth genes were unaffected by muscle Fndc5 overexpression. Finally, systemic Irisin elevation accompanying Fndc5 OE had no effect on thermogenesis markers, PGC-1α, uncoupling Protein 1 (UCP-1), or cell death activator (CIDEA) in sub-cutaneous fat.
CONCLUSION: Fndc5 overexpression yields limited metabolic impacts in muscle in terms of anabolic and mitochondrial biogenesis processes, and extra-muscular endocrine effects. Nonetheless, increases in glycogen accumulation in Fndc5 OE TC muscle point to a local harnessing of tissue glucose uptake that cannot be discerned on a whole-body level. This study casts further doubt over claims of Fndc5 as a hypertrophic or thermogenic gene product.

PROTECTION OF THE SKELETAL MUSCLE INSULIN SIGNALING PATHWAY IN FEMALES WITH TYPE 2 DIABETES

GORRES-MARTENS, B., SCHMIDT, E., FIELD, T., MUNGER, K.

AUGUSTANA UNIVERSITY

INTRODUCTION: Previous studies suggest that oestrogen loss increase one's risk for type 2 diabetes , and combining oestrogen loss with a high-fat diet poses an even greater risk. The extent to which exercise can ameliorate the deleterious effects of oestrogen loss combined with a HFD and the molecular mechanisms accounting for the whole body changes remains unknown. Therefore, this study analyses the whole body changes and the skeletal muscle insulin signalling pathway in female rats fed a HFD in the presence and absence of oestrogens and examines the extent to which exercise can ameliorate the deleterious effects.
METHODS: Female Wistar rats were fed a standard diet or a HFD for 10 weeks. The rats fed the HFD were either ovariectomised or their ovaries remained intact. A subset of the HFD/OVX rats also underwent exercise training on a motor-driven treadmill. Throughout the study, body weight and food consumption was measured weekly. After 9 weeks, a glucose tolerance test was performed, and blood glucose and insulin levels were measured. After 10 weeks, anaesthetised rats were injected with insulin, and the soleus and extensor digitorum longus muscles were removed and frozen in liquid nitrogen. The amount of abdominal white adipose tissue was removed and weighed. Western blot analyses determined activation of the skeletal muscle insulin signalling pathway via measuring .
RESULTS: Even when combining the HFD/OVX state, exercise significantly decreased the total body weight gain, WAT, hyperglycaemia, and hyperinsulinaemia. However, no significant changes were observed in the skeletal muscle insulin signalling pathway. These results suggest that the skeletal muscle insulin signalling pathway is not responsible for the whole body change seen in this study and is not involved in exercise's ability to combat the whole body changes.
CONCLUSION: Maintenance of the skeletal muscle insulin signalling pathway shown in this study is markedly different from male rodents fed a HFD who show reductions in the insulin signalling pathway and glucose uptake . In human females, increased whole body insulin sensitivity can be explained by greater skeletal muscle glucose uptake . Thus, the insulin signalling pathway in female skeletal muscle may be better suited to respond to insulin and may also possess resilience against defects in the signalling pathway, although more studies are needed to confirm this hypothesis. Furthermore, this study demonstrates the ability of exercise to act as a prophylactic treatment for T2D even when combining two challenging physiological states.

OP-SH13 Depression, stress and exercise

EXERCISE EFFECTS ON DEPRESSION IN CHILDREN AND ADOLESCENTS: A SYSTEMATIC REVIEW OF META-ANALYSES

BUDDE, H., KAULITZKY, A., AMATRIAIN, S., WEGNER, M., MURILLO-RODRIGUEZ, E.

MEDICAL SCHOOL HAMBURG, UNIVERSIDAD ANÁHUAC MAYAB

INTRODUCTION: Depression is a common threat for children and adolescents in terms of affecting their psychosocial development and increases the risk of suicide. Apart from conventional treatments of depression such as psychotherapy and pharmacotherapy, physical exercise has become a promising alternative. This paper aims at systematically reviewing the extant meta-analyses that focus on the impact of physical exercise on depressive outcomes in children and adolescents.
METHODS: All used meta-analyses were found on PubMed, PsycINFO, PsycARTICLES or hand-searched. The literature research was limited to a period of publication between 1985 till February 28th, 2017. Study eligibility criteria were whether the papers presented mean effect sizes for the impact of physical exercise on dependent variables, the use of randomized controlled trials and other study designs such as quasi-experimental, prospective and cross-sectional observational designs. The overall mean effect was calculated according to Wegner et al., <2014>.
RESULTS: Nine meta-analyses were included that investigated over 50 single studies with over 16,416 participants. The overall mean effect of physical exercise on depression was medium .
CONCLUSION: This study provides a summary of all published results of the effect of exercise on depressive disorders in children and adolescents. Effective exercise programs should be implemented over a longer period of time and, ideally, should integrate an educational dimension. Physical exercise seems to be especially helpful for young patients suffering from either depression or physical health problems with comorbid depression.
References: Wegner, M., Helmich, I., Machado, S., Nardi, A. E., Arias-Carrion, O., & Budde, H. <2014>. Effects of exercise on anxiety and depression disorders: review of meta- analyses and neurobiological mechanisms. CNS & Neurological Disorders Drug Targets, 13<6>, 1002–1014.

DEPRESSION SCORES PREDICTION WITH AEROBIC FITNESS, BODY FATNESS, PHYSICAL ACTIVITY, AND VAGAL INDICES IN FEMALE WORKERS

BOULLOSA, D., TONELLO, L., OLIVEIRA-SILVA, I., MEDEIROS, A.R., DONATO, A.

UNIVERSIDADE CATÓLICA DE BRASÍLIA

INTRODUCTION: The aetiology of depression is multifactorial, with women being most affected than men (WHO, 2017). Previous studies demonstrated an inverse moderate relationship between depression scores and aerobic fitness, appearing stronger in men than in women (Papasavvas et al., 2016). In addition, other factors as body fatness, physical activity (PA) levels, and vagal indices (heart rate [HR] variability [HRV], and HR recovery [HRR]) have been independently demonstrated to be related to depression scores in women. Thus, the aim of the current study was to investigate the relationships between depression scores and all those factors in women; and subsequently elaborate on the best predictive model of depression scores.
METHODS: Thirty-five female workers at two universities (age: 34.5±0.9 yrs; VO2max: 25.2±0.9 ml/kg/min; 29.2±1.1% body fatness; Beck Depression Inventory (BDI) scores: 12.3±1.2) volunteered for participation. In the first day of evaluations, they were evaluated for: aerobic fitness with an incremental cycling test; body fatness with the sum of 7 skinfolds; and depression scores with the BDI. In the second day, HRV was evaluated at rest (sitting and standing), and HRR after a submaximal cycling exercise. PA levels were recorded with an accelerometer over 5 consecutive days. Multicollinearity was defined with correlations >0.7 between independent variables. A stepwise regression and various linear multiple regression models were tested to find the better predictive model of BDI scores.
RESULTS: Only VO2max (r=-0.446, p=0.007) and the sum of skinfolds (r=0.435, p=0.009) were significantly and independently correlated to BDI scores. A stepwise regression analysis showed that only VO2max could significantly predict (R=0.446) BDI scores. Multiple linear regression analyses revealed a slightly better model (R=0.586) when adding the sum of skinfolds, moderate PA, and standing HRV to VO2max.
CONCLUSION: It is concluded that VO2max, an index of aerobic fitness, is the main factor influencing depression scores in overweight female workers, with other health related parameters (body fatness, moderate PA and resting HRV) maybe contributing for depression scores prediction. Further studies should elaborate on these relationships in both sexes, while controlling other potentially confounding factors, for a better understanding the aetiology of depression.

SUPERIOR EFFECTS OF SPRINT INTERVAL TRAINING VS. CONTINUOUS AEROBIC EXERCISE TRAINING ON SYMPTOMATOLOGY IN DEPRESSIVE DISORDER

DONATH, L.1, MINGHETTI, A.2, FAUDE, O.2, ZAHNER, L.2, HANSSEN, H.2

<1> GERMAN SPORT UNIVERSITY, <2> UNIVERSITY OF BASEL

INTRODUCTION: Psychiatric disorders are associated with a higher prevalence of cardiovascular disease and mortality. Regular exercise has been shown to reduce depressive symptoms and improve arterial stiffness as a biomarker of cardiovascular risk. We aimed to investigate the effects of different exercise modalities on depression severity index and arterial stiffness in patients suffering from unipolar depression
METHODS: 34 patients suffering from unipolar depression [female: 25, male: 9, age: 37.8, Beck-Depression-Inventory-II (BDI-II) score: 31.0] were enrolled in this two-armed randomized controlled trial. Central hemodynamics, augmentation index at heart rate 75/min (AIx@75) and aortic pulse wave velocity (PWV) were obtained by an oscillometric monitoring device. Maximal bicycle ergometer exercise testing yielded maximal fitness parameters. Patients were assigned to either high-intensity low volume (HILV) or moderate continuous aerobic training (MCT). Both intervention groups trained three times a week during a 4-week intervention period. BDI-II were filled out by the patients before and after the intervention period.
RESULTS: We found moderate interaction effects on depression severity reduction (η2p=0.10). HILV showed a 85% beneficial effect in lowering BDI-II scores compared to MCT (HILV: pre: 28.8 (9.5), post: 15.5 (8.5), SMD = 1.48), MCT: (pre: 33.8 (8.5), post: 22.6 (7.5), SMD =

1.40). Reduction of AIx@75 was more pronounced after MCT (SMD = 0.61) compared to HILV (SMD = 0.08), showing 37% possibly beneficial effects of MCT over HILV. PWV remained unchanged in both training groups.
CONCLUSION: Both training regimes showed large effects on the reduction of depressive symptoms. While HILV was more effective in lowering depression severity, MCT was more effective in additionally lowering peripheral arterial stiffness. Exercise should be considered an important strategy for preventive as well as rehabilitative treatment in depression

PREVALENCE OF DEPRESSIVE SYMPTOMS IN RETIRED JOCKEYS

KING, L., CULLEN, S.J., LOSTY, C., WARRINGTON, G.

WATERFORD INSTITUTE OF TECHNOLOGY

Introduction: Retiring from sport has many difficulties associated with it which may have implications on mental health (Martin et al., 2014). Limited research is available investigating the prevalence of depression in retired athletes and given the demanding and challenging lifestyle of jockeys (Wilson et al., 2014), this study aimed to investigate the incidence of depression in retired jockeys.
Methods: 36 ex-jockeys (age=41.1±12.85) completed a self-report measurement tool, the Center for Epidemiological Studies Depression Scale (CES-D) (Radloff, 1977), to assess prevalence of depressive symptoms. Demographic information including age, license type, years retired, number of winners, race involvement, making weight difficulties and concussion history was also collected. Information was gathered through distribution of an anonymous online survey.
Results: Mean score for depression in retired jockeys was 15.17±12.19 (range: 1-49), which was below the threshold indicative of depression (<16). Despite this, 44.2% of the retired jockeys met the caseness (criteria) for depression. Using a pearsons correlation, there was a negative weak but significant association between symptoms of depression and years holding a license (r2=-.335;p=.046). Mean scores of depression were higher for jockeys who had been retired for less than ten years (<10 years 19.31±14.57 vs >10 years 11.85±8.95; p>0.05) and those who retired through pressure of the job (24.75±10.5) and injury (18.55±11).
Conclusion
Results of this study suggest that while the group of retired jockeys did not meet the criteria for depression, nearly one in two retired jockeys display symptoms of depression. This indicates a higher prevalence of depression amongst retired jockeys in comparison to retired rugby union and football players (Gouttebarge et al., 2015; 2016). Further research is needed to understand the predictors and causal mechanisms behind these figures.

ASSOCIATIONS BETWEEN SELF-REPORTED PHYSICAL ACTIVITY AND CHRONIC STRESS IN EMPLOYEES OF STATIONARY NURSING HOMES

BISCHOFF, L.L., OTTO, A.K., LAUBENSTEIN, H., WOLLESEN, B.

INSTITUTE OF HUMAN MOVEMENT SCIENCE

Introduction: Shortages in the labor market and higher percentages of old people in need of care result in work intensification and high stress levels among the nursing personnel in stationary nursing homes [1]. Earlier studies report a positive association between physical activity (PA) and perceived stress levels [2]. Yet, there are no studies examining this association in employees of stationary nursing homes. Thus, the purpose of this study was to examine the effect of PA on chronic stress levels among employees of nursing homes.
Methods: An extensive questionnaire was distributed to N=120 employees in three stationary nursing homes in Northern Germany. The survey included the German versions of the Copenhagen Psychosocial Questionnaire, Screening Scale of the Trier Inventory for the Assessment of Chronic Stress (TICS-SSCS) and the WHO Global Physical Activity Questionnaire. A total of N = 44 employees (9 men, 32 women) completed the questionnaire. n=5 were excluded.
Results: 66.7% of the participants had "above average" stress values (TICS-SSCS > 12). The mean SSCS value was 15.7±9.1. The WHO criteria of 600 MET minutes of activity per week were met by 85.3% of the participants. 76.5% met the German national recommendation for PA during leisure time of at least 150 min activity of moderate intensity per week. No significant correlations were found between PA and chronic stress or other work related outcomes. The only significant differences were identified with regard to transportation activities: participants who walked or cycled regularly felt significantly lower demands for hiding emotions (p=0.026).
Discussion: Since working in the providence of health care is physically demanding, it is not surprising that the majority of the nursing personnel met the WHO's MET criteria. However, the majority of respondents also met national recommendations of leisure time PA. Surprisingly, there were no associations between PA and chronic stress in employees of stationary nursing homes. These findings differ from previous studies in other professions, e.g. teachers [3] and might be a result of the specific stressors in stationary nursing homes. Nevertheless, in view of the relatively small sample size at this stage, these associations will be reevaluated in this ongoing survey study.

IMPLEMENTING PHYSICAL ACTIVITY INTERVENTIONS FOR ELDERLY CARE NURSES WITH HIGH STRESS LEVELS

HOLD, C., WOLLESEN, B.

UNIVERSITY OF HAMBURG, INSTITUTE OF HUMAN MOVEMENT SCIENCE

Introduction: Elderly care nurses are exposed to high workloads, which can lead to chronic stress (Gandoy-Crego et al., 2009). Physical activity can affect employee well-being (Brown et al., 2011), but little is known about appropriate interventions for this occupational group. To implement workplace health promotion interventions for elderly care nurses, the aims of this study were to examine how work-related behavior affects chronic stress and what kind of physical activity interventions will be suitable for this sample.
Methods: Data was collected by using questionnaires in a sample of elderly care nurses (N=78) from small and medium-sized facilities of residential aged care. The Screening Scale (SSCS) of the Trier Inventory for Chronic Stress (TICS) was used to assess chronic stress. The Occupational Stress and Coping Inventory (AVEM) assigned the respondents into four different work-related behavioral and experiential patterns. Furthermore intervention requirements were collected. Statistical analysis included Chi²-tests and ANOVA.
Results: The lowest stress levels were found in subjects classified in the healthy patterns G - "Health" (13,06±7,64) and S - "Protection" (14,45±8,55). Higher levels were found in risk pattern A - "Typ A behavior" (23,57±7,92) and risk pattern B - "Burnout" (25,42±9,99). The ANOVA showed significant differences between the assignment to the work-related behavioral patterns and perceived stress (F (3,69)=8,787; p=.000; N=73). Bonferroni-adjusted post-hoc analysis revealed a significant difference ($p<.05$) in perceived stress between all patterns except between risk patterns A and B and between patterns G and S. Back exercises (19,8%), relaxation exercises (17,9%), strength training (15,1%) and endurance training (9,4%) were the most requested physical activity interventions. There was no significant relationship between work-related behavioral patterns and intervention requirements (N=48, $\chi^2=23.87$, p=.878).
Conclusion
Work-related coping behavior plays an important role in stress experience among elderly care nurses and should be considered when conducting interventions. Exercise interventions were demanded by elderly care nurses in this study. Especially the request for relaxation exercises matches the complaints. Since no relationship was found between work-related behavioral patterns and intervention requirements further research needs to address the specific requirements for an effective intervention of the high risk patterns (A and B). Implementation of the interventions has not taken place yet.

OP-SH12 Applications of sport psychology to performance

EVALUATION OF A BRIEF MINDFULNESS BASED INTERVENTION ON PUTTING PERFORMANCE IN AMATEUR GOLFERS

O DONOGHUE, C., CAMPBELL, M.J., TOTH, A.

UNIVERSITY OF LIMERICK IRELAND

Introduction: There has been an increasing trend for mindfulness to be viewed as a trainable psychological skill for performance enhancement. Published practitioner protocols and a growing evidence base have allowed for more systematic study, with early evidence for effectiveness across a range of performance and surrogate measures such as attention, emotional regulation and flow states (Sappington & Longshore, 2015). This study evaluated impacts on putting performance of a four-day mindfulness based intervention (MBI) programme on amateur golfers and assessed changes in dispositional mindfulness and underlying facets, while exploring related cognitive skills.
Methods: A non-randomised controlled trial evaluated an adapted Mindful Sports Performance Enhancement (MSPE) protocol (Kaufman et al., 2017) (n = 9 intervention, n= 7 wait-list control). Informed consent and demographic information was gathered at baseline. At baseline and post-test all participants completed a computerised Five Facet Mindfulness Questionnaire (FFMQ) (Baer et al., 2003), computerised Stroop test (Stroop, 1935) and a putting task measured manually and with SAM PuttLab motion analysis technology (www.scienceandmotion.com).
Results: ANOVA pairwise comparisons of putting performance revealed only the MBI group improved significantly from baseline to post-test ($F(1,15) = 11.228$, $p = .005$). One tailed independent samples t-test found a significant difference in the mean difference score improvements for MBI group vs control ($t(15) = -1.995$, $p = .033$).
ANOVA pairwise comparison for overall FFMQ scores revealed significance only in the MBI group ($F(1,14) = 13.597$, $p = .002$). Significant improvements in the underlying facets of 'Observing' ($F(1,14) = 15.209$, $p = .002$), 'Describing' ($F(1,14) = 19.53$, $p = .001$), 'Acting with Awareness' ($F(1,14) = 4.983$, $p = 0.42$) and 'Non-Judging Ineer Experience, ($F(1, 14) = 9.223$, $p = .009$) were found only for MBI group.
Stroop score analysis revealed significance in MBI group improvements for total ($F(1,14) = 18.276$, p=.001), congruent ($F(1,14) = 19.393$, $p = .001$), incongruent ($F(1,14) = 9.985$, $p = .007$) and control conditions ($F(1,14) = 18.537$, $p = .001$). Controls significantly improved only in the control condition ($F(1,14) = 4.712$, $p = .048$).
Conclusion
This study provides supportive evidence that brief MSPE interventions are effective in increasing dispositional mindfulness and can confer meaningful sports enhancing effects. Further research is required to corroborate these finding, assessing further performance parameters and examining further the effect mechanisms involved.

MENTAL TOUGHNESS IN RUGBY

POWELL, A.J., MYERS, T.D.

NEWMAN UNIVERSITY BIRMINGHAM

MENTAL TOUGHNESS IN RUGBY UNION
Powell, A. 1, Myers, T., D. 1
1: NUB (Newman University, Birmingham)
Mental toughness (MT) is important for performance, goal progress, and thriving despite stress, and can vary across contexts. Whilst the importance of MT has been established, the dimensionality of MT needs further investigation; qualitative studies highlighting its multidimensionality, yet recent quantitative studies suggesting MT is unidimensional (Guccardi et al., 2015). The aim of the study was to investigate MT, its development and dimensionality in Rugby Union by exploring the perceptions and experiences of rugby players across performance levels and contexts.
Methods: A purposive sample of rugby players (n=468) across performance levels were recruited to complete a repertory grid online. Participants were asked to rate fixed qualities across fixed contexts in a grid produced from idiographic analysis of interviews with elite rugby players and coaches. Participants rated various qualities of MT from 1-10 (irrelevant-essential) including: motivated by self-development; focus in pain; perceiving challenge positively; effective decision making under pressure; and responsibility to the team. Participants had to consider how important these qualities were in: training; a match; dealing with pressure; adversity; injury; defeat; and being dropped from the team. Descriptive statistics were calculated, cluster analysis conducted to determine groupings of contexts, and Bayesian regression used to examine differences of ratings across playing levels.
Results: The highest mean rating of constructs across contexts was for playing a match (mean=8.39, SD=0.59); the lowest for dealing with injury (mean=7.58, SD=1.43). The highest rated individual construct was being motivated by continuing development (9.35) when dealing with being dropped from the team. The lowest rating was for staying focused in pain (5.79) when dealing with defeat. Cluster analysis suggested contexts formed two distinct groupings. Differences were found between playing levels, the largest difference in the responsibility for team success when dealing with an injury: Premiership (8.51) compared to international (4.50) with a high probability of a difference (p=0.99).
Discussion: The results suggest different qualities of MT are required for dealing with different contexts. The MT qualities required to deal with being dropped, coping with defeat and dealing with injury form one group, and the qualities for playing a match, dealing with pressure, and dealing with adversity, form a second group. The differences in the ratings of Premiership and international players may be explained by different cohesion levels resulting from the seasonal disparity in the time playing and training together as a team.

PREPARING FOR A DUAL CAREER IN THE AFL DRAFT YEAR – REFLECTIONS OF SUCCESSFUL PLAYERS

SAUNDERS, J., PINK, M.

AUSTRALIAN CATHOLIC UNIVERSITY

Introduction: In Australian football players become eligible for the draft in the year they turn 18. This presents an issue in the process of developing a dual career because of the conflict with the final year of schooling, when results obtained in the school leaving certificate will influence access into future careers, particularly those requiring competitive grades. A previous report (Saunders and Pink, 2017) examined the experience of role strain by young men seeking to be drafted at the end of 2015, pursuing the notion of developmental mismatch previously found by de Bruyn (2005) to be negatively associated academic achievement. This study found that those who reported experiencing lower levels of overload between their football and their other roles including that of student were 5.81 times more likely to be drafted. Likewise, those who experienced less overload in their school role were 2.99 times more likely to be drafted. These findings were interpreted as demonstrating that players were already discounting their academic and alternative career aspirations as a means of coping with the pressures of trying to reconcile the demands of forging dual careers.
Methods: This study sought to supplement the earlier findings of how potential draftees were experiencing their draft year with the reflections of successful draftees on how their experiences had impacted on both their ongoing development as footballers and their ongoing personal and alternative vocational development. Data comprised semi-structured interviews with eighteen players recruited from three clubs. Interviews were transcribed and imported into the NVivo 10 qualitative analysis software before being subjected to a deductive-inductive content analysis. The players' attitudes, abilities and beliefs about their football, school and alternative career plans were reviewed within the environmental influences provided by their schools, their families and their football clubs.
Findings
A common theme amongst all participants was the passion they held for their football and the priority placed on achieving the goal of being drafted. There was however some variety in the nature of the alternative career plans nurtured and in the ways in which the environmental influences of the educational, family and football club contexts interacted to support the players as they strove to fulfil their ambitions. Some of this variety and richness is captured in the anecdotes and stories provided
Discussion: On the issue of whether the draft age should be raised to reduce the conflict between academic and football milestones, there was no clear consensus. However, the benefit of supportive personal and educational environments emerged as important in the ability to achieve any kind of academic success in parallel with football success. For those who are successful in entering into the AFL environment with its well-developed player support system and programs there is the opportunity for future success in developing alternative career and personal development outcomes. For those who are unsuccessful, the impact of the draft process on their alternative career prospects appears to be more problematic.

YOUTH TALENT DEVELOPMENT ENVIRONMENT OF WORLD-CLASS CARIBBEAN TRACK AND FIELD ATHLETES

THOMAS, C.E., CHAMBERS, T.P., MAIN, L.C., GASTIN, P.B.

DEAKIN UNIVERSITY

Candice E Thomas1, Timothy P Chambers2, Luana C Main1, Paul B Gastin1

1School of Exercise and Nutrition Sciences, Deakin University, Melbourne, Australia
2School of Psychological Sciences, Australian College of Applied Psychology, Melbourne, Australia
Presenter: Candice Thomas
Aim: This qualitative investigation sought to explore the youth training and competition experiences of world-class Caribbean track and field athletes and the influence of psychosocial factors on their decision to invest in high-performance sport. Design: The study was underpinned by the developmental model of sport participation (Côté, Baker, & Abernethy, 2007) and informed by ontological relativist and epistemological constructionist perspectives. Method: Sixteen world-class track and field athletes (8 males and 8 females; M age = 29, SD = 5 years) from 6 English-speaking Caribbean islands took part in semi-structured interviews. An inductive thematic analysis (Braun & Clarke, 2006) was performed on the transcribed data. Findings: Four major themes were identified: (1) functional support network, (2) sporting culture, (3) reasons for success and (4) challenges. Findings revealed that world-class Caribbean athletes perceived themselves to be significantly influenced by the motivationally-relevant behaviors of the extended family, coaches and peers at the sampling, specializing and investment stages of development. Additionally, the youth sporting culture revealed a generally ad hoc approach to sport at the sampling level and a more structured and goal-oriented approach at the specializing/investment levels. The complex, interactive and multifaceted motivational atmosphere and support experienced at the youth stage encouraged participant athletes to remain engaged and progress to international success. Conclusions: The findings of this study provide insight into the youth sporting environment of world-class track and field athletes and the motivational climate experienced within a Caribbean socio-cultural context.

QUALIFICATION PATTERNS OF OLYMPIC AND IAAF WORLD CHAMPIONSHIP MIDDLE DISTANCE RUNNERS

HETTINGA, F.J., HANLEY, B.

UNIVERSITY OF ESSEX

INTRODUCTION: Introduction: The 800 m and 1500 m are the two middle distance events contested at the Olympic Games and other major championships. On most occasions, athletes must negotiate two qualifying rounds to reach the final. The theoretically optimal method of competing in these rounds is to obtain an automatic qualifying position in the slowest possible finishing time; however, elite athletes are often ego oriented and this might have led them to try to win all races. The aim of this study was to identify whether elite athletes adopted these theoretically optimal tactics, or whether the will to win overrode them.
Methods: Finishing positions and times of the eventual finalists in the men's and women's 800 m and 1500 m competitions at Olympic Games and IAAF World Championships between 1999 and 2017 were analysed. The performances of 606 athletes were analysed (800 m men: 122; 800 m women: 120; 1500 m men: 183; 1500 women: 181). The finalists' finishing positions and times, as well as their overall ranking in the heats and semi-finals, were also obtained. Athletes were allocated to groups based on finishing position in the final: medallists (800 m and 1500 m), non-medallists finishing in the top eight ('Top 8': 800 m and 1500 m), and those athletes finishing outside the top eight ('Top 12': 1500 m only). One-way repeated measures ANOVA was conducted on the heat, semi-final and final finishing times. In addition, one-way ANOVA were conducted with Tukey's post-hoc tests to compare finishing times between groups. Statistical significance was accepted as $P < .05$. Kendall's tau-b (τb) correlations determined the relationships between finishing position in the final with qualifying round positional, rank and finishing time data.
Results: Across the four events, 70% of the 57 gold medallists won both qualifying rounds, whereas 36% of the silver medallists and 19% of the bronze medallists achieved the same positions. Nineteen gold medallists set a season's best or personal best time in the final. In each event, finishing position in the final was correlated with finishing position in the heats and semi-finals ($P \leq 0.002$), but not with finishing time in those rounds. In the 800 m, medallists were faster than non-medallists in the final only ($P < 0.001$); in the 1500 m, medallists and Top 8 finishers were faster than Top 12 finishers in the final only ($P < 0.001$).
Discussion: Most World and Olympic champions won both their heat and semi-final, even though this was unnecessary, but managed to do so with slower times than in the final. These tactics showed a long-term pacing strategy that optimised overall competition success. In addition, the gold medallists did so in most cases in times slower than their best that year. Head-to-head elite championships, where winning is more important than time recorded, encourage a performance climate for both men and women athletes where ego orientation is more likely to occur.

METHODS: RESULTS: CONCLUSION: APPLIED SPORT PSYCHOLOGY IN SOUTH AFRICA: REFLECTIONS OF AN EDUCATIONAL PSYCHOLOGIST

LEWIS, A.

UNIVERSITY OF THE WESTERN CAPE

Applied Sport Psychology is in its infancy in South Africa. Given the popularity of sport and physical activity participation in this country, one would expect an abundance of Sport Psychology practitioners applying their knowledge and skills at all levels. This however is not the case with past discriminatory practices and having no formal association and registration category as being a few reasons for this phenomenon. Another reality is that applied knowledge and training within this context are not freely available. The aim of this paper is to reflect on practising this applied science from the framework of a registered Educational Psychologist in a specific context in South Africa as an initial step so that this practice can be understood, practised and expanded on. As a registered Educational Psychologist, by means of a reflexive, qualitative approach, I would like to contribute towards this body of knowledge and field of practice. It is also hoped that this will stimulate debate within this field so that it can lead to knowledge creation, practise and an even greater professionalization of this applied field.

IS-PM02 Muscle injury: acute injury cellular responses to contemporaneous rehabilitation strategies

CELLULAR RESPONSES TO MUSCLE INJURY

MACKEY, A.

UNIVERSITY OF COPENHAGEN AND BISPEBJERG HOSPITAL

INTRODUCTION: The presence of resident stem cells in skeletal muscle affords a potential to regenerate fully after injury and yet the incidence of injury recurrence suggests that muscle repair is often complete.
METHODS: Also it is known that ageing is associated with a decline the satellite cell content of muscle together with an increase in resistance to activation. A better understanding of the activity of different cell types involved in muscle repair following injury, or muscle growth with exercise training, could contribute to the development of interventions capable of improving repair after injury, not to mention the adaptive response to heavy resistance training.
RESULTS: The focus of this presentation will be on the regeneration of young and old human skeletal, with particular focus on the distribution and activity of satellite cells, macrophages and fibroblasts in relation to regenerating muscle fibres.
CONCLUSION: It is believed this topic will be of interest to people concerned with sarcopenia, muscle regeneration and hypertrophy adaptation to resistance exercise training.

MAXIMIZING HEALING OF MUSCLE INJURY USING MECHANICAL LOADING: A CLINICAL PERSPECTIVE

GLASGOW, P.

ULSTER UNIVERSITY

Rehabilitation is a dynamic continuum during which the nature and difficulty of exercises are progressed in response to tissue healing and the functional abilities of the athlete. Pain is the most commonly used clinical outcome measure to progress rehabilitation. The level of discomfort tolerated during rehabilitation should be guided by the rationale for the specific exercise. For example, where the primary goal of the exercise is tissue loading some discomfort may be acceptable. In contrast, where the focus is on restoring movement quality it is more appropriate that for exercises to be painfree.
A number of key questions assist in optimising load during rehabilitation. What is happening at a tissue level? What outcomes are you trying to achieve? And, what is the specific adaptation associated with different exercise types?
Muscle tissue is highly sensitive and adaptable to mechanical loading. Following injury, muscle undergoes a number of changes in architecture and function as a direct consequence of tissue insult and as an indirect consequence of reduced loading and recruitment. Architectural characteristics of muscle are related to a range of performance variables. Muscle force is proportional to PSCA, while muscle velocity is proportional to muscle fibre length. Following injury there are reductions in fascicle length and physiological cross-sectional area (PSCA) as well as alterations in neuromuscular activation). Rehabilitation should therefore focus on restoring muscle structure.
Key goals during the acute stage are to limit the size of the haematoma and scar formation as well as facilitating re-capillarisation and neuronal resprouting. Early loading should be viewed as a way of enhancing stimulus for regeneration. There is good evidence from animal studies that progressive early loading of muscle results in enhanced histological and mechanical outcomes.
Eccentric exercise has become the primary mechanism by which these adaptations are achieved. Low-level, controlled eccentric exercises performed early in rehabilitation have the potential to reduce pain inhibition and facilitate tissue adaptation. These should then be progressed in line with healing and adaptation.
Restoration of neuromuscular deficits is also important. Prolonged deficits in NMC following muscle injury may have a role to play in recurrence. Reduced activation of previously injured muscle may further compound architecture components as well as limit function. Early inclusion of simple dynamic recruitment of muscles throughout range during functional movements often help to restore pain free range of motion and normalise pain. Sport-specific function is further developed through progressive neuromuscular rehabilitation aimed at improving the central nervous system's ability to fine tune muscle coordination and improve the skill execution.

HOW CAN WE AVOID RECURRENT MUSCLE INJURY?

WITVROUW E.

GHENT UNIVERSITY

The recurrence rate of muscle injuries is about 25%, with an extended rehabilitation period as a result. This rate is unacceptably high and needs reflection. At first it can be stated that the average time to return to sports (RTS) is at 2-3 weeks, when insufficient maturation of the scar tissue is present. A recent study identified that 25% of the re-injuries happen in the first week after RTS, and that all these injuries were situated at exactly the same location as the previous injury. This reinforces the idea that time should also be taken into account as a criteria for RTS.
In addition, the content of the rehabilitation program should be modified according to the latest research. Stretching as a treatment modality should still be included in the rehab approach, but the aim should be to improve the elasticity of the connective tissue, and not to improve the muscle range of motion. Consequently, different techniques should be used. Concerning strengthening, new research identified that the injured muscle is the victim, but very frequently not the cause of the muscle injury. As a consequence, other muscles than the injured muscle must be targeted during the rehab and prevention. Considering the very high incidence of muscle injuries and re-injuries in different sports the physiotherapies should know these new treatment approaches in order to reduce the amount of (re)injuries by composing evidence based and state of the art prevention and rehabilitation programs.

Invited symposia

IS-PM04 Proteome dynamics: new insights into the effects of exercise, diet and ageing on the turnover of human muscle proteins

DYNAMIC PROTEOMIC PROFILING: A NEW TOOL FOR STUDYING THE TURNOVER OF HUMAN MUSCLE PROTEINS

BURNISTON, J.

LIVERPOOL JOHN MOORES UNIVERSITY

The functional characteristics of muscle are determined by its protein composition and changes to the abundance or post-translational modification of proteins are well-acknowledged mechanisms that can alter characteristics, including muscle force production and substrate utilisation. In addition, the rate of turnover of proteins is also an important and modifiable feature that can influence muscle function, but this aspect of adaptation has been less widely studied due to a lack of suitable analytical methods. Recently, deuterium oxide (D2O; 'heavy water') has reemerged as a popular stable isotope for metabolic labelling studies of protein turnover because it can be delivered via the drinking water so the burden on the participant is less and the scope for investigating the long-term effects of diet and exercise is broadened compared to amino acid tracers that require intravenous infusion. D2O-labelled proteins are also more amenable to analysis using proteomic techniques, and I will give an introduction to the measurement of protein turnover using liquid chromatography and peptide mass spectrometry, termed dynamic proteomic profiling. This technique brings new opportunities to interrogate protein-specific changes in turnover rate associated with exercise and diet interventions. I will present a selection of proteomic data from D2O metabolic labelling experiments conducted in muscle cell cultures, laboratory animal models and human participants. The data illustrate the broad range of turnover rates across abundant proteins within myotubes or rodent and human skeletal muscle. I will also provide examples where the average rate of turnover of mixed proteins is indistinguishable between experimental groups but significant differences can be uncovered when turnover is investigated at a protein-specific level, offering new insight to the mechanisms of muscle adaptation.

PROTEOSTASIS AND SLOWED AGING: IDENTIFYING CONTRIBUTIONS OF THE SELECTIVELY TRANSLATED PROTEOME AND CELL PROLIFERATION IN MODELS OF SLOWED AGING

HAMILTON, K.L., DRAKE, J.C., ZHANG, Q., PEELOR, F.F., WOLFF, C.A., MUSCI, R.V., REID, J.J., LAWRENCE, M.L., PRICE, J.C., MILLER, B.F.

COLORADO STATE UNIVERSITY

Maintaining protein homeostasis, or proteostasis, is among the mechanisms that likely contribute to slowed aging and increased healthspan. Analyses in multiple tissues from growth-restricted slowed aging models suggest that slowed aging is consistently characterized by a greater ratio of protein synthesis rates:DNA synthesis rates in multiple protein fractions. This greater ratio is accompanied by two observations. First, slowed aging models are characterized by selective synthesis of proteins that include mitochondrial and other proteins that are likely important for maintaining cellular energetics and resistance to stresses encountered during aging. Second, tissues from slowed aging models have slower rates of DNA synthesis-indicative of slower cell proliferation-compared to controls. These consistent findings suggest that proteostatic mechanisms are maintained in growth-restricted slowed aging models, with more of the newly synthesized proteins allocated toward replacing damaged and degraded proteins in existing cells and less toward proliferation. These findings are consistent with theories of slowed aging in which limited energetic resources are directed toward somatic maintenance rather than growth. This session will include a discussion of the critical information that could result from identification of the selectively translated proteome, and the contribution of changes in cell proliferation rates to proteostasis in models of slowed aging and increased healthspan.

IDENTIFYING EXERCISE-DIET INTERACTIONS ON HUMAN MUSCLE PROTEIN RESPONSES.

HAWLEY, J.

MARY MACKILLOP INSTITUTE FOR HEALTH RESEARCH

A high-fat diet (HFAT) reduces rates of muscle protein synthesis, but resistance exercise (REX) may attenuate or rescue this diet-induced impairment. Using Dynamic Proteomic Profiling (DPP), we determined the contributions of synthesis and degradation to changes in the abundance of individual proteins in response to HFAT and REX. Two groups (n=8) of age-matched, overweight, untrained males consumed a HFAT (65% Fat, 20% CHO, 15% Protein) while ingesting deuterium oxide (200 mL/d) for 9-d. Participants were assigned to control (HFAT) or REX, who performed REX on days 1, 4 and 7. Blood and muscle samples were analyzed to determine precursor enrichment and the rate of incorporation of deuterium in to newly synthesised proteins. Synthesis of mixed sarcoplasmic proteins was similar in control and REX. In the myofibrillar fraction, the rate of synthesis was 45% higher in REX (1.6 vs. 1.1 %/day; $P<0.05$). DPP found 24 proteins differed in either their synthesis rate or abundance after REX ($P<0.05$). These findings provide empirical evidence that the contribution in rates of synthesis and degradation to changes in the REX-induced increase in protein abundance differ on a protein-by-protein basis. Determining how exercise-nutrient interactions impact on individual protein responses in skeletal muscle is the first step to delaying the age-related decline in muscle mass observed with ageing and could provide an entry point for personalized exercise-diet prescription.

OP-PM31 Fatigue

THE EFFECT OF PRE-EXERCISE COOLING ON PERFORMANCE CHARACTERISTICS: A SYSTEMATIC REVIEW AND META-ANALYSIS

CLIJSEN, R.1,2,3, HOHENAUER, E.1,2,3, STOOP, R.1, CLARYS, P.3, DELIENS, T.3, TAEYMANS, J.3,4

1: SUPSI , 2: THIM , 3: VUB , 4: BFH

INTRODUCTION: Exercising in high environmental temperatures may cause precocious hyperthermia induced fatigue resulting in a decreased athletes performance output. This systematic review with meta-analysis investigated the possible effects of pre-exercise cooling on performance output.
METHODS: This study was performed according to the PRISMA guidelines and the PICO model was used to establish the research question. The Cochrane Risk of Bias Tool was applied to assess the validity of the included studies. Study eligibility was given when the studies compared the effects between any kind of pre-cooling and non-cooling strategies prior to exercise on performance output.
RESULTS: Twenty-nine studies met the inclusion criteria for quantitative analysis. Risk of bias was high or unclear but the performance bias was low. The estimated standardized mean difference revealed that external pre-cooling <21 studies> enhanced performance , with the main effect observed in endurance cycling or running. Internal <7 studies> and mixed-method <5 studies> pre-cooling failed to significantly affect performance parameters. However, the main output parameter, evaluated in these studies, was peak power output. Subgroup analysis for different outcome measures was not possible because meaningful grouping was not plausible. Limitations of this meta-analysis were the high or unclear risk of bias and the comparability of the included studies.
CONCLUSION: Based on the results of this meta-analysis, it can be concluded that there is some evidence in favour of external pre-cooling to avoid precocious hyperthermia induced fatigue in endurance athletes exercising in hot environments.

THE EFFECT OF ISOLATED LOCOMOTOR MUSCLE FATIGUE ON PACING REGULATION WITH AND WITHOUT AN OPPONENT

KONINGS, M.J., HETTINGA, F.J.

UNIVERSITY OF ESSEX

INTRODUCTION: Exercisers are required to decide continuously about how and when to invest their limited available energy resources, a process that is also known as pacing (Smits et al. 2014). This study will further explore the importance of locomotor muscle fatigue onto this decision-making process involved in pacing during competition. This will be done by manipulating the level of induced locomotor muscle fatigue (internal bodily state) and the presence of an opponent (external stimulus). It is hypothesised that the induction of isolated locomotor muscle fatigue via an eccentric fatiguing protocol results in a reduced average pace (De Morree & Marcora, 2013). However, the faster initial pace and enhanced performance evoked by the opponent's presence in unfatigued conditions (Konings et al. 2017) is expected still to be present when isolated muscle fatigue is induced via an eccentric fatiguing protocol. This would indicate that the pacing response to an opponent is not related to the level of isolated locomotor muscle fatigue.
METHODS: Ten trained cyclists performed four experimental, self-paced 4-km time trial conditions on a VeloTron cycle ergometer in randomised, counterbalanced order. In the time trials participants had to ride alone (NO) or against a virtual opponent (OP). In addition, prior to the time trials participants had to complete an eccentric fatiguing protocol (80 drop jumps; DJ) or a control resting condition (CO). As such the experimental conditions were 1) CO-NO, 2) CO-OP, 3) DJ-NO and 4) DJ-OP. Differences in pacing, performance and perceived exertion were examined using repeated-measures ANOVA ($p<0.05$).
RESULTS: A faster initial pace was adopted during CO-OP (341±56W) versus CO-NO (324±50W; $p=0.029$), and during DJ-OP (327±81W) versus DJ-NO (304±58W; $p=0.009$). Moreover, participants showed a lower mean power output in CO-NO compared to CO-OP ($p=0.023$), DJ-NO compared to CO-NO ($p=0.007$), DJ-OP compared to CO-OP ($p=0.034$), DJ-NO compared to CO-OP ($p=0.005$), and DJ-NO and DJ-OP ($p=0.010$). No differences in mean power output were found between CO-NO and DJ-OP ($p=0.297$). RPE did not differ between experimental conditions at any point during or after the time trials (all $p>0.05$).
CONCLUSION: Trained cyclists adopted a slower average pace after an eccentric fatiguing protocol in advance of their time trial. However, the evoked response by the opponent to adopt a faster initial pace remains present when isolated locomotor muscle fatigue was induced via an eccentric fatiguing protocol. These findings illustrate that the behavioural response to an opponent is not directly related to the level of locomotor muscle fatigue, and highlight the importance of perceived exertion and the complex interplay between external stimuli and internal bodily state in the pacing decision-making process.

DIFFERENCES IN NEUROMUSCULAR FATIGUE BETWEEN PREPUBERTAL CHILDREN, UNTRAINED ADULTS AND WELL-TRAINED ADULT ENDURANCE ATHLETES.

PIPONNIER, E., BONTEMPS, B., CHALCHAT, E., JULIAN, V., BOCOCK, O., DUCLOS, M., MARTIN, V., RATEL, S.

UNIVERSITY OF CLERMONT-AUVERGNE

INTRODUCTION: It is now well acknowledged that prepubertal children have a greater net contribution of energy derived from aerobic metabolism in exercising muscle and reduced susceptibility to muscular fatigue than untrained adults. However, children and well-trained adult endurance athletes could have a comparable oxidative metabolic profile and thus similar muscular fatigue rates during high-intensity exercise (Ratel and Blazevich, 2017). To check this hypothesis, we aimed at comparing the development and etiology of neuromuscular fatigue during repeated maximal voluntary contractions (MVC) of the knee extensor (KE) muscles between prepubertal children, untrained adults and well-trained adult endurance athletes.

METHODS: Eighteen 9-to-11-year-old boys (B), nineteen 18-to-30-year-old untrained men (UT) and thirteen 21-to-45-year-old well-trained endurance male athletes (WT) performed a fatigue protocol consisting in a repetition of 5-s isometric KE MVCs interspersed with 5-s recovery periods until MVC reached 60% of its initial value. Single magnetic stimulations were delivered to the femoral nerve every five MVC to quantify the time course of potentiated twitch amplitude (twpot), i.e. the peripheral fatigue. M-wave amplitudes of vastus lateralis and rectus femoris were determined to quantify sarcolemmal excitability. The maximal voluntary activation level (VA) was determined every five MVC using the twitch interpolation technique to quantify the central fatigue.
RESULTS: The number of MVC was significantly lower in UT (15.9 ± 3.9) than B (40.4 ± 19.7, p<0.001) and WT (51.7 ± 19.6, p<0.001). However, this difference was reduced between WT and B (p<0.05). The relative decrement in twpot was significantly greater in UT (-51.6 ± 14.8%) than B (-18.8 ± 19.5%, p<0.001) and WT (-8.3 ± 14.6%, p<0.001) but similar in B and WT. M-waves remained unchanged whatever the groups considered. Finally, VA decreased significantly more in B (-38.4 ± 22.5%) than UT (-4.6 ± 5.5%, p<0.001) and WT (-20.3 ±10.1%, p<0.001) but this difference was reduced between B and WT (p<0.01).
CONCLUSION: Our results confirm that children experience less peripheral and more central fatigue during high-intensity exercise than untrained adults. However, they point out reduced differences in central fatigue and similar peripheral fatigue between children and well-trained adult endurance athletes. Therefore, children could be metabolically comparable to well-trained adult endurance athletes.
Ratel, S., Blazevich, A.J. Are Prepubertal Children Metabolically Comparable to Well-Trained Adult Endurance Athletes? Sports Med. 47, 1477-1485, 2017.

IMPACT OF A PAIN STIMULUS OF REPEATED SPRINT EXERCISE

JAKEMAN, J., LEANEY, S.

OXFORD BROOKES UNIVERSITY

INTRODUCTION: Several studies have shown that exercise training can increase pain tolerance, which can lead to improvements in subsequent exercise performance. However, during exercise, pain may alter neural drive and reduce performance, although the extent to which exposure to pain can acutely influence subsequent exercise performance is less well established.
METHODS: Fourteen physically active males (21.4 ± 1.6yr, 1.87 ± 0.08m, 86.8 ± 13.8kg) were recruited for the study, and completed two sessions of four, thirty second maximal cycle sprints (with a four minute recovery) on an electronically braked cycle ergometer, separated by a minimum of one week. In a randomised counterbalanced order, participants were exposed to an ischemic pain stimulus, which progressively increased pain severity until pain tolerance was reached, or had no pain exposure, five-minutes before completing cycle sprint exercise. Measures of power output, fatigue index and energy expenditure were recorded during each sprint.
RESULTS: Data analysis showed that there were significant differences between the pain and no pain conditions on mean power output (722.7 ± 124.8W v 736.1 ± 124.8W, η2p 0.31), minimum power output (484.0 ± 152.2W v 514.3 ± 142.5W, η2p 0.43) and energy expenditure (21.7 ± 3.7kJ v 22.08 ± 3.7kJ, η2p 0.31), with the pain stimulus causing reductions in performance and energy expenditure. There were no significant differences in fatigue index (53.2 ± 13.6% v 50.4 ± 10.9%, η2p 0.17) or peak power output (1046.3 ± 203.4W v 1034.5 ± 177.9W, η2p 0.017) for pain and no pain groups respectively (data presented as mean ± SD).
CONCLUSION: While peak power was statistically unaffected by the pain stimulus, mean power output was negatively influenced. These data indicate that while maximum force generation was unaffected, the ability to sustain force production was negatively influenced, which may be related to alterations in neural drive associated with changes in afferent fibre activity. As this pain stimulus reduces some exercise performance indicators if experienced immediately before sprint interval training, it may have implications for the intensity and type of pre-exercise preparation undertaken by individuals in high intensity competition.

MAXIMAL RATE OF HEART RATE INCREASE TRACKS FATIGUE-INDUCED CHANGES IN ANAEROBIC EXERCISE PERFORMANCE

DUNIENVILLE, N.M., NELSON, M., BLAKE, H., BELLENGER, C., BUCKLEY, J.

UNIVERSITY OF SOUTH AUSTRALIA

INTRODUCTION: The maximal rate of heart rate (HR) increase (rHRI) reflects the maximal acceleration of HR at exercise onset, and has been shown to track fatigue-induced changes in endurance exercise performance. Recent evidence suggests that rHRI may be modulated by efferent signals arising from fatigued muscle, raising the possibility that rHRI might track performance changes for exercise modalities other than endurance activities. The purpose of this study was to determine whether rHRI tracked fatigue-induced changes in maximal anaerobic cycling performance.
METHODS: Nineteen (13 M, 6 F) recreational strength and power athletes had rHRI and maximal anaerobic cycle performance (peak power during 6 sec maximal effort [PP6] and work done during 30 sec maximal effort [W30]) assessed prior to (baseline), and one and three hours after, an acute fatigue-inducing sprint-cycling intervention. rHRI was assessed during 3-min of cycling at 100W (F) or 120 W (M).
RESULTS: rHRI and PP6 were unchanged across test sessions (P>0.05). Compared with baseline W30 was very likely decreased at 1-hr (-5.8±2.1%; ES±90% CI=-0.38±0.14; P=0.002) and 3-hr (-3.8±2.4; -0.25±0.16; P=0.048) post-fatigue. There was no significant within-subject correlation between rHRI and PP6 across test points (P>0.05), but there was a large positive correlation between rHRI and W30 (r=0.50; p<0.01).
CONCLUSION: rHRI appears to track fatigue-induced reductions in maximal exercise performance not only for endurance activities but also for anaerobic activities. rHRI might be a useful submaximal method for monitoring readiness to perform in athletes to guide training and competition schedules.

MUSCLE METABOLIC RATE AND MUSCLE TORQUE COMPLEXITY ARE INVERSELY CORRELATED DURING FATIGUING INTERMITTENT ISOMETRIC CONTRACTIONS

PETHICK, J., WINTER, S.L., BURNLEY, M.

UNIVERSITY OF KENT

INTRODUCTION: Muscle torque output is characterised by inherent fluctuations, which possess an irregular temporal structure, or complexity. This complexity reflects the ability to adapt motor output rapidly and accurately in response to task demands, with changes in muscle torque complexity having important functional implications. It has been suggested that a system's complexity is inversely related

to its metabolic rate (Seely and Macklem, 2012), but this hypothesis has yet to be tested. Fatiguing muscle contractions represent the ideal model with which to test this hypothesis, as it has been repeatedly demonstrated that neuromuscular fatigue reduces the complexity of muscle torque output. We hypothesised that muscle torque complexity would be closely related to muscle metabolic rate, and would only change under conditions in which muscle metabolic rate changed.
METHODS: Twelve healthy participants performed intermittent isometric contractions of the knee extensors to task failure at a high-intensity (40% MVC), where a progressive increase in muscle metabolic rate would be expected, and for 30 minutes or until task failure (whichever occurred sooner) at a low-intensity (20% MVC), where a change beyond the initial transient would not be expected. The duty factor for the contractions was 60%, i.e. 6 seconds contraction, 4 seconds rest. Torque and surface EMG were sampled continuously. Muscle metabolic rate ($\dot{m}O_2$) was determined using near-infrared spectroscopy and arterial occlusion, while whole-body metabolic rate ($\dot{w}b\dot{O}_2$) was determined on a breath-by-breath basis using respiratory gas analysis. Complexity and fractal scaling of torque were quantified using approximate entropy (ApEn) and the detrended fluctuation analysis (DFA) α scaling exponent. Global, central and peripheral fatigue were quantified using MVCs with femoral nerve stimulation.
RESULTS: Results are presented as means ± SEM. At 40% MVC, task failure occurred after 11.8 ± 1.6 minutes, while all participants were able to continue for 30 minutes at 20% MVC. Complexity decreased significantly during the contractions at 40% MVC (ApEn, 0.54 ± 0.06 to 0.15 ± 0.03, $P < 0.001$; DFA α, 1.36 ± 0.02 to 1.60 ± 0.03, $P < 0.001$), but did not change at 20% MVC. Similarly, $\dot{m}O_2$ increased significantly at 40% MVC (2.66 ± 0.44 to 3.99 ± 0.037%·s-1, $P < 0.001$), but did not change at 20% MVC. The rates of change of complexity and $\dot{m}O_2$ at 40% MVC were negatively correlated (ApEn, $r_s = -0.555$, $P = 0.03$; DFA α, $r_s = 0.559$, $P = 0.027$).
CONCLUSION: These results provide the first experimental evidence for the hypothesised inverse relationship between a system's complexity and prevailing metabolic rate.

A 10+-YEAR FOLLOW-UP STUDY OF KNOWLEDGE, ATTITUDES, AND PRACTICE BEHAVIORS USED BY COLLEGE COACHES AND ATHLETIC TRAINER'S IN THE U.S. FOR THE FEMALE ATHLETE TRIAD.

MORAN, P.D., PANTANO, K.J., LOWERY, M.C.
CLEVELAND STATE UNIVERSITY

INTRODUCTION: The female athlete triad or relative energy deficiency in sport, is a condition that involves an imbalance between energy intake and energy expenditure. This deficiency can lead to serious health consequences, such as menstrual dysfunction, low bone mineral density, cardiovascular disease, and comprised bone health. Given potential outcomes, it is important that coaches and athletic trainers understand the condition and how it can be treated and prevented. Despite greater exposure, it is not known whether gaps in knowledge about the triad among U.S. coaches and trainers continue to exist. The aim of this research was to conduct a follow-up study on the knowledge and practice behaviors in U.S. college coaches and athletic trainers regarding the female athlete triad and compare results to a similar study conducted 10 years ago.
METHODS: A survey instrument was designed to assess knowledge and practice behaviors used by U.S. college coaches and athletic trainers for recognizing, treating and preventing the female athlete triad (RED-S). Databases of U.S. college coaches and certified athletic trainers practicing were purchased and randomly selected from approximately 1,000 surveys administered through an online survey tool, Qualtrics. Descriptive statistics summarized demographic and practice information about the survey participants and the most commonly used methods of treatment and prevention for the triad.
RESULTS: Fifty-seven college coaches and 48 athletic trainers responded to the survey; the majority were women between the ages of 25-55 who practiced 16 years or more. While 98% of the survey participants reportedly noticed disordered eating in female athletes, less than 40% could identify that "energy deficiency" was a component of the triad. Twenty-six percent of coaches and 35% of trainers still thought that irregular or absent menstruation is a normal consequence of exercise. The most frequently reported modes of treatment for both professions included contacting the athlete's physician, consulting with a dietitian and sports psychologist, and addressing the issue with the athlete. Nutritional counseling and pre-participation exams (PPE) were the most frequently reported means of prevention.
CONCLUSION: Promoting optimal health for all athletes is a desired goal for coaches and athletic trainers. This goal requires having adequate knowledge and awareness of potential deleterious conditions involved in sport participation, such as the female athlete triad or RED-S. The current study shows that while knowledge of the female athlete triad or RED-S has improved and practice behaviors have positively changed in the last 10 years, some concepts about the condition are still misunderstood. A limitation of this study is the generalizability of the results.

HEART RATE VARIABILITY CHANGES DURING THE MENSTRUAL CYCLE PHASES OF ATHLETIC WOMEN

DOYLE-BAKER, P.K., KOKTS-PORIETIS, R., MINICHIELLO, N.
UNIVERSITY OF CALGARY

INTRODUCTION: The menstrual cycle (MC) remains a major barrier to the inclusion of women in sport and health research. This limits the depth of knowledge pertaining to how the MC interacts and effects homeostasis in sport performance. Regulation of homeostasis is largely impacted by the autonomic nervous system (ANS) and its two divisions, the sympathetic and parasympathetic systems. Heart rate variability (HRV) has evolved as a measurement tool to assess ANS function and overall health. The objectives of this study, exploratory and descriptive in nature, were to determine how daily measures of HRV shift over the course of the MC and whether the menstrual phases (Follicular; FP or Luteal, LP) affect the range in measures of HRV in an athletic population of women.
METHODS: Eumenorrheic women without oral contraception between the ages of 18-45 yrs., and cycling greater than 3 hour/week (self-reported) were included through a rolling recruitment. Oral basal body temperature (BBT) was measured upon waking using a low-reading digital thermometer (Geratherm) and self-reported menstruation was used to align subject's MCs at ovulation. HRV was assessed by the time (SDNN, RMSSD) and variance in high and low frequency (HF and LF) domain analysis using a smartphone application (HRV4Training) with measurements recorded upon waking for one minute in the supine position. Descriptive statistics were employed to

characterize shifts in daily measures of HRV: 1) across the MC and between the phases using the mean difference of consecutive days. Seven women (mean, standard deviation (±); age 28.57 ± 8.36 yr.; height 167.0 ± 6.3cm; weight 66.41 ± 7.89kg; %BF 21.1 ± 4.93%) completed the study with regular MCs (28.4 ± 2.3 days; ovulation day 14.57 ± 0.98 day).
RESULTS: Time and frequency domain decreased across the MC, however the LF decreased before ovulation and increased following it. The mean difference in SDNN between consecutive days decreased around ovulation and showed a -32.76 ms shift four days before the end of the MC. The HF band displayed a 0.078 increase followed by a -0.053 difference at the beginning of the MC. Approaching ovulation the mean difference in consecutive days of HF showed only slight change while after ovulation an oscillatory pattern emerged with greater magnitude. The mean difference between consecutive days in the LF band began with a sudden decrease followed by a large increase before shifting to smaller magnitude changes leading to ovulation. After ovulation, larger magnitude fluctuations occurred for the duration of the MC.
CONCLUSION: The mean difference between consecutive days demonstrated a negative trend with less fluctuation in RMSSD and HF, primarily around ovulation. Along with the increase in the range of mean difference of consecutive days in the LP compared to the FP, suggests MC phase may impact HRV in athletic women. A larger sample size is still needed to capture and confirm the HRV variation of MC and the phases.

DIFFERENTIAL RESPONSES IN CIRCULATING ADRENAL STEROID LEVELS IN RESPONSE TO EXTREME PHYSICAL, BUT NOT TO EXTREME MENTAL STRESS IN MALE ATHLETES

CSÖNDÖR, É., KARVALY, G., LIGETVÁRI, R., VÁSÁRHELYI, B., KOMKA, Z., FARKAS, I., VÉGH, J., SZILÁGYI, G., TÓTH, M.V., TÓTH, M., STROMÁJER-RÁCZ, T., BETLEHEM, J., OLÁH, A., ÁCS, P.

FACULTY OF HEALTH SCIENCES, UNIVERSITY OF PÉCS, SEMMELWEIS UNIVERSITY, EÖTVÖS LÓRÁND UNIVERSITY, UNIVERSITY OF PHYSICAL EDUCATION, INTERNATIONAL TRAINING CENTRE, BUDAPEST,HUNGARY

INTRODUCTION: Adrenal steroid molecules play a significant role in the regulation of cardiovascular, metabolic and other functions in response to acute stress situations.
METHODS: We investigated the effects of stress on the steroid homeostasis in male athletes (n=44) using a combined model of extreme acute physical (vita maxima treadmill test) and mental stress (simulated military combat situation). The levels of 16 adrenal and gonadal steroid substances were evaluated in serum using ultra performance liquid chromatography-tandem mass spectrometry (UPLC-MS/MS). Heart rate (HR) and blood pressure (BP) values were monitored in both models in addition to metabolic (lactate) and gas-exchange (VO2 maximum) parameters which were evaluated in the physical stress experiments. All values were measured at baseline, at maximum stress situation and thirty minutes into the restitution phase.
RESULTS: BP and HR were elevated in both stress models. No significant changes could be observed in the serum concentrations of steroids as a result of mental stress, while dehydroepiandrosterone (DHEA, baseline: 3.46±2.44 ng/mL, peak: 4.30±3.13 ng/mL, restitution phase: 6.72±4.14 ng/mL), corticosterone (CORT, baseline: 4.58±4.78 ng/mL, peak: 4.75±4.32 ng/mL, restitution phase: 9.87±4.94ng/mL) and cortisol (CL, baseline: 143.14±44.39 ng/mL, peak: 138.38±43.63 ng/mL, restitution phase: 180.45±41.66 ng/mL) levels showed significant ($p<0.05$) elevation in the restitution phase in the physical stress model.
CONCLUSION: Both stress models induced similar responses in the cardiovascular system. The cardiovascular and steroid effects have a different time frame showing maximum levels of BP and HR at the peak of the stress, while steroid levels are elevated thirty minutes later, and only in the physical stress model. The three elevated steroid molecules originate from three structurally different parts of the adrenal gland pointing to the fact that mineralocorticoid, glucocorticoid and androgenic lines are all involved. The interaction of the cardiovascular system and the adrenal gland with such mediators as steroids, catecholamines and possibly peptides, (i.e. adrenomedullin) needs further systematic investigations.

ASSESSING BASAL INFLAMMATORY MARKERS AND SYNTHETIC OVARIAN HORMONE USE IN FEMALE AUSTRALIAN ATHLETES SELECTED FOR THE RIO OLYMPIC GAMES

LARSEN, B., COX, A.J., COLBEY, C., DREW, M.K., MCGUIRE, H.M., FAZEKAS DE ST GROTH, B., HUGHES, D., VLAHOVICH, N., WADDINGTON, G., BURKE, L., LUNDY, B., WEST, N.P., MINAHAN, C.

GRIFFITH UNIVERSITY - GOLD COAST CAMPUS

INTRODUCTION: Athletes have enhanced susceptibility to illness and infection during periods of intense training and competition (1), which may be compounded in an Olympic environment. Data from the London 2012 Olympic Games found that female athletes were 60% more likely to fall ill than male athletes, and one in five illnesses was expected to result in absence from training and/or competition (2). This absence is associated with decreased sports performance outcomes (3). Thus, factors that contribute to an increased risk of infection or illness in elite female athletes must be further examined. This study measured C-reactive protein (CRP) and other inflammatory markers in Australian elite female athletes three months before the 2016 Rio Summer Olympic Games. We sought to determine the association between synthetic ovarian hormone use (i.e., the oral contraceptive (OC) pill) and basal CRP, peripheral blood immune cell subsets, and circulating pro- and anti-inflammatory cytokine concentrations.
METHODS: Elite female athletes (n = 53) selected in Rio 2016 Summer Olympic squads participated in this study. Of the 53 participants, 25 were taking the OC pill (AthletesOC) and 28 were not taking the OC pill and were considered naturally hormonally cycling (AthletesNC). Venous blood samples were collected at rest for the determination of sex hormones, cortisol, CRP, peripheral blood mononuclear memory and naïve CD4+ T-cells, CD8+ T-cells and natural killer cells, as well as pro- and anti-inflammatory cytokine concentrations.
RESULTS: C-reactive protein concentrations were elevated ($p < 0.001$) in AthletesOC (median = 2.02, IQR = 3.15) compared to AthletesNC (median = 0.57, IQR = 1.07). Conversely, no differences were reported for cortisol, serum cytokines, or PBMC immune cell subsets, although there was a trend ($p = 0.062$) for higher IL-6 concentrations in AthletesNC.
CONCLUSION: This study is the first to investigate the effect of OC use on acute phase hormonal and systemic inflammatory parameters in elite female athletes prior to the Olympic Games. Elite female athletes had substantially higher levels of CRP, a marker of inflammation and tissue damage, in the months before the 2016 Rio Olympic Games if they used the OC pill. Thus, future research should further examine the relationship between OC use and immune function, and the potential consequences for performance and recovery, in elite female athletes.

PHYSICAL PERFORMANCE IN RELATION TO MENOPAUSAL STATUS AND PHYSICAL ACTIVITY

BONDAREV, D., LAAKKONEN, E.K., FINNI, T., KOKKO, K., KUJALA, U.M., AUKEE, P., KOVANEN, V., SIPILÄ, S.
UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: Low muscle strength and decline in the power are associated with low walking speed (Rantanen et al, 1999) and with mobility limitations, disabilities and falls among older populations (Sipilä et al, 2006). The menopausal sequelae may influence later years by contributing to functional limitations among women. The aim of this study was to examine differences in physical performance across menopausal stages and potential contribution of physical activity to modify the impact of the menopausal transition on physical performance.
METHODS: This cross-sectional study is a part of the ERMA study. Women aged 47 to 55 were randomly selected from the Finnish National Registry and categorized as premenopausal (n=233), perimenopausal (n=381) or postmenopausal (n=299) based on serum concentrations of follicle stimulating hormone and bleeding diary. Physical performance was measured by knee extension force, hand grip force, vertical jumping height, maximal walking speed and six-minute walking distance. Physical activity (PA) level was assessed by self-report and categorized as low, moderate or high. Multivariate linear regression modeling and marginal means differences were used for data analysis.
RESULTS: After including fat mass, height, PA and education in the model, the postmenopausal women were 12.0 N weaker ($p<0.001$) in hand grip force and performed 1.1 cm worse ($p<0.001$) in vertical jumping height than the premenopausal women. There was no significant interaction between menopausal stage and PA on physical performance. However, the peri- and postmenopausal women with high PA performed better in the maximal knee extension strength and 6-min walking test, and lower body muscle power than those with low PA.
CONCLUSION: Menopausal status is associated with muscle strength and power, whereas the association between menopausal status and mobility/walking is clearly weaker. A high PA level provides more capacity to counteract the potential negative influence of menopausal factors on muscle function.

IS-BN07 Gait stability and adaptability among older adults: implications for falls prevention

THEORY-DRIVEN INTERVENTION FOR IMPROVING REACTIVE BALANCE CONTROL IN THE ELDERLY

ARAMPATZIS, A.
HUMBOLDT-UNIVERSITY BERLIN

One important factor which contribute to increased risk of fall in the elderly population is deficient reactive balance responses after sudden, unexpected perturbations. Therefore, exercise interventions aiming to improve the reactive balance control in older people may progressively reduce the risk of falling. It is widely accepted that resistance training aiming to improve muscle strength within the lower extremities is a successful therapeutic modality for increasing stability performance. Although muscle strengthening has the potential to improve balance recovery, the direct transfer of improvements in strength in the motor control of responses to sudden unexpected gait perturbations and/or the handling of control errors initiated from deficits in the perception and processing of sensory information within the motor system is limited. First we provided evidence that predictive and reactive adaptation, remains highly effective in the elderly, showing only minor, not statistically significant age-related deficits. In a second step we designed a generic exercise intervention including mechanisms of dynamic stability and we applied this intervention for 14 weeks to elderly adults. We found an average improvement in the ability of the old adults to regain balance during simulated forward falls (35%) and unexpected gait perturbation (20%) without any improvements in muscle strength after the intervention. A training intervention of mechanisms of dynamic stability that also improves muscle strength akin to a conventional resistance exercise intervention is likely to improve the efficiency of the training. Currently we developed a perturbation-based intervention for old adults, exercising mechanisms to control dynamic stability (i.e. increase of BoS and counter-rotation of segments around the CoM) on unstable conditions to expose the participants to repeated and variable disturbances. Our strategy in the perturbation-based intervention aimed to increase the amount of muscle activation in the lower extremity muscles during training and, thus, muscle strength over time, and to increase the need of the nervous system to perceive sensory signals and to generate appropriate motor commands. We found improvements in muscle strength of the plantar flexors and in the ability to regain balance after sudden forward falls at the same level as a conventional muscle strength intervention. Further, the perturbation-based training was the only one that introduced improvements in standing balance ability as assessed by measuring the approach of the CoM to the anterior limits of stability. We conclude that a perturbation-based training program focusing on exercising mechanisms of dynamic stability on unstable conditions has the potential to enhance muscle strength as well as sensory information processing within the motor system during sudden and static balance tasks and, as a consequence, reduce the risk of falls in old adults.

PERTURBATION-BASED GAIT ASSESSMENT USING VARIOUS PERTURBATION TYPES IN YOUNG AND OLDER ADULTS

PIJNAPPELS, M.
VU UNIVERSITY AMSTERDAM

The ability to resist or recover from a gait perturbation has been shown to be associated with mobility problems and fall risk in older adults. However, knowledge on which perturbation type is most suitable to quantify gait stability is lacking. We therefore developed a protocol containing ipsi- and contra-lateral sway, belt acceleration and deceleration, visual and auditory perturbations and tested it on

healthy young and older adults. Gait stability was most affected by contra-lateral sway and deceleration perturbations hence these perturbation types may be appropriate for fall risk assessment in the elderly. The results of this protocol will be discussed.

GAIT STABILITY AND ADAPTABILITY ACROSS THE ADULT LIFESPAN: THE IMPACT OF MUSCLE AND VESTIBULAR FUNCTION

KARAMANIDIS, K.

LONDON SOUTH BANK UNIVERSITY

The ability to respond to expected and unexpected environmental changes during ongoing gait is important for preventing a fall. In a series of studies, we investigated how gait stability and adaptability during perturbed walking are affected by age, muscle strength and vestibular function in order to better understand the underlying mechanisms of the decline in locomotor function across the adult lifespan. We found that the ability to control dynamic stability in response to a single perturbation during walking has already begun to deteriorate in middle age, but that even in old age the ability to adapt gait and improve stability following repeated perturbations is preserved, although the rate of adaptation may be diminished. Lower limb muscle weakness partly limits gait stability during novel perturbations, as stronger older adults require fewer recovery steps to regain gait stability after a sudden perturbation. However, the potential for adaptive improvement after repeated perturbations during walking seems not to be related to muscle strength in older adults. This adaptation potential is, however, negatively affected in patients with vestibulopathy, indicating a potential role of the vestibular apparatus in gait adaptability. Currently, we are investigating whether muscular changes over medium- or long-term periods (muscle strengthening interventions over months or years) impact gait stability and adaptability and whether older adults are able to retain gait stability improvements over 1.5 years.

Invited symposia

IS-MI01 Sedentary behaviour and physical activity – is there a best bet for public health in young people?

PHYSICAL ACTIVITY AND SEDENTARY TIME, ADIPOSITY AND CARDIO-METABOLIC HEALTH – CAUSAL ASSOCIATIONS?

EKELUND, U.

NORWEGIAN SCHOLL OF SPORT SCIENCES

Physical activity guidelines for young people were first published in 1994. Based on the available evidence these guidelines proposed that young people should be physically active daily or almost every day and engage in at least three sessions per week of at least 20 minutes of more vigorous exercise. An expert panel conducted an update of the scientific evidence in 1998, which concluded that young people should engage in at least 60 minutes of moderate intensity activity daily and preferably more vigorous activities three times per week. Since then the available evidence about the importance of physical activity for health in young people has increased exponentially, largely explained by the development and application of objective monitoring methods. These methods are currently the primary option when assessing physical activity in young people. More recently, prolonged sedentary time has also been suggested to influence on health. However, most data in young people suggest that sedentary time is unrelated to adiposity and cardio-metabolic health when moderate and vigorous intensity physical activity is taken into account. In contrast, self-reported TV-viewing (and other screen-based behaviors) may be detrimentally associated with these health outcomes possibly mediated by other unhealthy behaviors associated with prolonged screen time. This talk will discuss whether the magnitude of associations between physical activity and health outcomes is intensity dependent; the role of substituting sedentary time with light, moderate and vigorous intensity in relation to health outcomes; and the issue of reverse causality for the associations between sedentary time, physical activity and metabolic health outcomes in young people.

SEDENTARY BEHAVIOUR IN YOUTH: IS SITTING FATTENING?

BIDDLE, S.

UNIVERSITY OF SOUTHERN QUEENSLAND

INTRODUCTION: Introduction. Changes to lifestyles for young people over the past decades include ubiquitous access to screens, including TV and computers. The use of such devices usually involves sitting for long periods. Over 30 years ago it was suggested that young people were being 'fattened' at the TV set, and subsequent research on TV viewing, screen time and wider use of sedentary behaviours has provided debate on this issue.
Methods. Synthesis of review-level evidence, appraisal of causality, and commentary.
Results. While some have suggested that the link between sedentary behaviour and adiposity is strong, others have taken a more cautious view. This may depend on what exposure and outcome variables are being assessed, and how. For example, the link between sedentary behaviour and adiposity seems stronger and more consistent for the exposure of TV viewing than it does for device-measured 'total sedentary time'. Important issues include co-existing behaviours (e.g. diet and MVPA) and measurement (e.g., recall by self-report). An assessment suggests that it cannot be claimed that a causal association exists between sedentary behaviour and adiposity in young people.
Conclusions. The association between sedentary behaviour and adiposity in youth is complex but current evidence is not supportive of a causal association.

METHODS: RESULTS: CONCLUSION: THE ACTIVITY INTENSITY DEBATE: IMPLICATIONS FOR GUIDELINES AND INTERVENTION

VAN SLUIJS, E.

MRC EPIDEMIOLOGY UNIT

The high burden of inactivity and (childhood) obesity worldwide makes the promotion of physical activity and/or reduction of sedentary behaviour key public health targets. One crucial question is how to translate these epidemiological findings into public health guidelines

that are believable, understandable and achievable. An understanding of how people interpret the guidelines and how they might act upon them is thereby critical. Physical activity and sedentary behaviour are complex behaviours, consisting of multiple behaviours across the day and week, performed in different locations and with differing levels of control to change. This complexity needs to be considered when communicating guidelines and targeting change in these behaviours. This talk will discuss the implications of the emerging evidence base for public health guidelines and how they are translated to behaviour change interventions.

OP-BN22 Injury prevention

PREVENTION OF MUSCULOSKELETAL INJURIES IN VOLLEYBAL AND FIELD HOCKEY: DEVELOPMENT AND FEASIBILITY OF TWO INTERVENTIONS

GOUTTEBARGE, V.1, VERHAGEN, E.2, ZWERVER, J.3

1: DUTCH CONSUMER SAFETY INSTITUTE , 2: AMC/VUMC IOC RESEARCH CENTER , 3: UNIVERSITY MEDICAL CENTER GRONINGEN

INTRODUCTION: Volleyball and field hockey are very popular sports, especially in The Netherlands. Both sports are associated with a risk for musculoskeletal injuries, incidence reaching 10.7 and 90.9 injuries per 1000 playing hours in volleyball and field hockey, respectively (Barboza et al., 2018; Kilic et al., 2017). Therefore, a research program started in order to (i) develop an injury prevention intervention in volleyball and in field hockey and (ii) assess their feasibility.
METHODS: The injury prevention interventions were developed in accordance to scientific frameworks (Intervention Mapping and Knowledge Transfer Scheme) based on (i) needs assessment within volleyball and field hockey, (ii) scientific literature, and (iii) experts in injury prevention and either volleyball or field hockey. Subsequently, two quasi-experimental studies based on a one-group pre-post-test design (survey and interviews) were conducted during 4-8 weeks in order to explore the feasibility (knowledge/skills, relevancy, suitability, usability) of both interventions.
RESULTS: The needs assessment revealed that an intervention in both sports was needed, ideally embedded within the warm-up, delivered by trainers/coaches, and available digitally. Therefore, 'VolleyVeilig' and 'Warming-up hockey' were developed as warm-up programme, involving more than 50 distinct exercises, lasting around 15 minutes and being available as application for smartphone/tablet (Gouttebarge et al., 2017a; Gouttebarge et al., 2017b). Calculated effect size (d=0,23-0,34) showed a moderate positive effect on level of knowledge/skills of coaches. All exercises within 'VolleyVeilig' and 'Warming-up hockey' were positively assessed with regard to their relevancy, suitability and usability.
CONCLUSION: Being available as application for smartphone/tablet, the warm-up programmes 'VolleyVeilig' and 'Warming-up hockey' were developed in order to prevent or reduce the occurrence of musculoskeletal injuries in volleyball and field hockey. Both were found feasible in terms relevancy, suitability and usability, leading to more knowledge/skills among coaches. Similar warm-up programmes were developed across different sports such as rugby and football, reaching up to 50-60% injury reduction (Bizzini and Dvorak, 2015; Sewry et al., 2017). If similar injury reduction rates are reached with 'VolleyVeilig' and 'Warming-up hockey', their nationwide implementation will be legitimate and thus facilitated.

MUSCULOSKELETAL PREDICTORS OF NON-CONTACT INJURY IN CRICKETERS – FEW AND FAR BETWEEN? A LONGITUDINAL COHORT STUDY

OLIVIER, B., GRAY, J.

UNIVERSITY OF THE WITWATERSRAND

INTRODUCTION: The determination of predictors of injury in cricketers is a building block towards developing effective injury prevention strategies. The objective of this study was to determine the musculoskeletal predictors of injury amongst professional, domestic cricket players.
METHODS: Professional, domestic cricket players completed a pre-participatory musculoskeletal screening battery consisting of 21 tests including flexibility, neural tension, stability, strength, balance and pain provocation tests at the start of the cricket season. Non-contact, low back and lower limb injuries were monitored throughout the season. Binary logistic regression and receiver operating curves were used to determine predictive value of each test.
RESULTS: During the course of the cricket season, 38 of the 97 <39.2%> cricketers sustained a non-contact low back and/or lower limb injury. Increased hip internal rotation ROM on the dominant side, no symptoms on active slump dominant side, decreased combined elevation, increased shoulder internal rotation ROM on the non-dominant side and increased GIRD predicted in-season non-contact lower quarter injuries. Although statistically significant, none of these variables were strong predictors of injury as shown by the logistic regression models, the area under the curve of the receiver operating characteristic curves and the cut-off scores which revealed high sensitivity, but low specificity.
CONCLUSION: Amongst the many tests included in the battery, only a few showed predictive validity. Investigations into the predictors of injury within the specific roles of cricket e.g. fast bowler or wicket keeper may reveal more appropriate answers to our search for risk factors for non-contact injury.

THE INFLUENCE OF COMPLIANCE ON THE EFFICACY OF THE INJURY PREVENTION PROGRAM 11+ KIDS

LICHTENSTEIN, E., ROESSLER, R., JUNGE, A., BIZZINI, M., VERHAGEN, E., CHOMIAK, J., AUS DER FÜNTEN, K., MEYER, T., DVORAK, J., BEAUDOUIN, F., FAUDE, O.

UNIVERSITY OF BASEL

INTRODUCTION: Physical inactivity has arisen as one of the major challenges of today's society and its prevention has received increasing attention. It is now considered important to motivate people to live an active life starting in childhood. Football (soccer) is one of the most widespread sports among youth. Unfortunately, it entails a considerable risk of injury to the musculoskeletal system, especially to the lower extremities. Injuries could present a stumbling block for lifetime engagement in physical activity. Therefore, prevention of injuries is at the center of research focus. The injury prevention program "11+ Kids" has been developed to tackle the issue. Compliance to this program might be a corner stone to its efficacy, but the magnitude of compliance's effect on the reduction of injury risk has so far not been investigated in children. Also, the program's recommended frequency of usage has so far not been established. Therefore, this study aims to quantify the compliance's influence on the efficacy of the injury prevention program "11+ Kids" among players aged 7 to 12 years and determine a recommended dosage.
METHODS: As part of a cluster-randomized controlled trial injury incidences were compared between the participants of the intervention group with low (LC), medium (MC) and high compliance (HC) as well as to the control group (CON) utilizing hazard ratios. Participants of the intervention group (IG) performed "11+ Kids" as warm-up whereas the control teams (CG) followed their regular training regime. It was also quantified how many injuries could potentially be prevented by additional trainings per month. Coaches and staff entered exposure times and injuries into an online-tool. Anthropometric data was gathered from the parents by questionnaire.
RESULTS: Data were obtained from 3895 participants (IG: 2066; CG: 1829) with a mean age of 10.8 (SD: 1.4) years. The HC group had 50% [95 %-CI: 16;71] fewer injuries compared to LC and 54% [31;72] less injuries compared to CON, but no significant difference was found compared to the MC group (-23% [-54;+30]). The MC group sustained 38% [3;60] fewer injuries compared with CON but not significantly less than LC (-36% [-61;+6]). No significant difference was observed between LC and CON (-32% [-60;15]). Additional session of "11+ Kids" were associated with a significantly reduced injury incidence.
CONCLUSION: The compliance to the injury prevention program "11+ Kids" plays an important role for the efficacy of the program. Frequent use of the program seems advisable to maximize its efficacy and too infrequent use might lessen its preventive effect considerably. Based on the findings of this study, it is suggested that the program is used at least six times per month.

ELITE WOMEN ATHLETES WITH SUPERIOR KNEE FUNCTION PRESENT SIMILAR DYNAMIC KNEE STABILITY, ALTHOUGH DIFFERENT MOVEMENT STRATEGIES, WHEN COMPARED TO CONTROLS

MARKSTRÖM, J.L.1, GRIP, H.2, SCHELIN, L.3, HÄGER, C.K.1

1-3: UMEÅ UNIVERSITY

INTRODUCTION: Neuromuscular training (NMT) of the lower limb is vital for athletes in learning correct movement technique to avoid risk of injury to the anterior cruciate ligament (ACL). The NMT aims for improved knee control while maintaining dynamic knee stability (DKS; resistance to linear/angular accelerations) during knee-challenging tasks. Assessing DKS is commonly attempted by evaluating discrete values of kinematic and kinetic variables during one-leg hops, but these measures may not sufficiently capture knee dynamics. We aimed to evaluate if elite women athletes who regularly perform NMT have greater DKS and/or different landing technique than normally active women who do not perform NMT, and if there are any correlations of DKS to peak knee extensor or flexor strength.
METHODS: A motion capture system (Qualisys) synchronized with two force plates (Kistler) registered hip and knee 3D joint angles and moments during one-leg standardized lateral side hop landings for 39 women (19 athletes, 20 controls). Ten trials were performed for the dominant leg with hands behind their back holding a rope (25 cm), deemed successful following 3 s of single leg stance after landing without putting the contralateral foot on the ground or making major adjustments with the ipsilateral foot. DKS was evaluated using the inclination angle of the knee's helical axis relative to the flexion-extension axis calculated for rotation intervals of 10 degrees, as has been proven useful (Grip and Häger, 2013), to quantify how much knee joint motion deviated from pure flexion-extension at landing. Hip and knee joint angles were analysed at initial contact (IC), and peak angles and peak moments were analysed during the deceleration phase of landing from IC to peak knee flexion (ind. t-tests, $p < 0.05$).
RESULTS: Athletes had more successful hops, faster task execution, greater knee extension strength, greater hip flexion angle at IC, and higher peak moments of hip adduction and knee flexion than controls. There were however, no group differences in DKS or any significant correlations between DKS and knee extensor or flexor strength for any of the groups ($r <$ absolute values of 0.41).
CONCLUSION: Elite women athletes that perform NMT on a regular basis had superior knee function but similar DKS to controls when performing a sport-specific one-leg side hop maneuver. The greater hip flexion at IC for athletes shows a different movement strategy for landing preparation. Potential benefits of NMT in sports contexts, e.g. less ACL injuries (Sugimoto et al., 2016), may be due to movement alterations of the hip to increase landing control to avoid positions that strain the ACL rather than improving DKS. Further emphasis on knee-specific landing control may be important to also improve DKS, which seems unrelated to strength.

NEUROPLASTICITY OF NEUROMUSCULAR TRAINING WITH AUGMENTED BIOFEEDBACK TO REDUCE INJURY RISK

GROOMS, D., KIEFER, A., RILEY, M., DIEKFUSS, J., ELLIS, J., KITCHEN, K., THOMAS, S., DICESARE, C., GADD, B., BONNETTE, S., BARBER-FOSS, K., SILVA, P., GALLOWAY, R., WEIHONG, Y., LEACH, J., BERZ, K.

OHIO UNIVERSITY

INTRODUCTION: Non-contact anterior cruciate ligament injury is associated with reduced lower extremity motor coordination. Neuromuscular training has been shown to reduce ACL injury risk, but the relation between motor control and neural changes following NMT are unknown. The purpose of this study was to determine the relation between brain activation and biomechanical changes following NMT with real-time biofeedback.

METHODS: Twenty high-school female soccer athletes <15.7±0.95 years; 1.68±0.05 m; 59.91±5.62 kg> participated. Ten participants completed 6 weeks of NMT augmented with real-time biofeedback designed to reduce knee injury-risk movements, and 10 acted as controls completing no training. Brain activation changes were measured with functional magnetic resonance imaging during a unilateral knee extension and flexion positioning task. Knee injury-risk motor changes were captured using a drop vertical jump task with a motion capture system . Neuroimaging and motor assessment were completed before and after 6 weeks of NMT.
RESULTS: Sensory , visual-spatial and motor planning brain activity increased for leg positioning after NMT. This network of increased brain activity was correlated with a post-training decrease in knee abduction moment <28%±6.47% p<.050> during landing . No significant changes or relationship between brain activity and motor control were seen in controls.
CONCLUSION: Increased sensory, visual-spatial, and motor planning network activity for knee positioning control after NMT may improve neural processing to control knee positioning during landing, reducing injury risk. Future work enhancing NMT with sensory, visual-spatial, and motor anticipatory exercises may further improve NMT efficacy.

INDIVIDUALISED RECOVERY: THE BELIEFS, PERCEIVED EFFECTIVENESS, AND PREFERENCES OF RECOVERY METHODS OF ELITE RUGBY LEAGUE PLAYERS

KELLY, V.G.1,2, CAIA, J.1,2, SCOTT, T.M.J.1,2

1:THE UNIVERSITY OF QUEENSLAND , 2: BRISBANE BRONCOS NATIONAL RUGBY LEAGUE CLUB

INTRODUCTION: The implementation of recovery modalities in elite team sport is common. However, athletes have individual preferences and little is known about whether these personal preferences align with perceived and/or reported benefits. Therefore, the aim of this investigation was to examine the recovery methods used and compare the perceptual understanding with personal preferences of different recovery modalities in elite Rugby League players. These findings could assist in the development of personalised recovery protocols.
METHODS: Twenty-five elite National Rugby League with a mean full-time playing experience of 3.1 ± 2.8 yrs volunteered to participate in the study. Players completed a questionnaire containing 11 questions designed to determine the reasons for, the perceived benefits and personal preferences of 16 different recovery modalities. The reasons why the athletes performed recovery was also investigated using a 5-point Likert scale while a 10-point Likert scale was used to examine the perceived benefits of recovery. Players ranked their personal preferences from a list of the recovery modalities.
RESULTS: When comparing the effectiveness of each recovery modality, players perceived massage (36%), sleep (26%), cold water immersion (12%), self-massage (8%) and external counterpulsation (ECP) (7%) to be the most effective. This aligned with their beliefs on the importance of these modalities with massage, sleep, self-massage, ECP and stretching believed to be the most beneficial (9.1, 9.1, 8.4, 8.4 and 8.3 out of 10, respectively). However, there were significant differences ($p > 0.05$) between player's perceived effectiveness of the modalities and their individual preferences. The majority preferred massage (52%), followed by sleep (19%) then ECP (11%). Sleep, massage and stretching were ranked the top 3 methods used on a regular basis, while of the newer methods; ECP (9th/16), was used more than peristatic pulse dynamic compression (13th/16) or cryotherapy (15th/16). The primary reasons players performed recovery was to alleviate 'soreness' (4.7/5) and to assist in the 'ability to back up' (4.5/5) between training sessions and matches. The majority of players (48%) felt there were no barriers to completing recovery with lack of time (28%) or motivation (28%) being the greatest barriers for the remaining players.
CONCLUSION: There were significant differences found between the perception of the importance of recovery and players personal preferences. This study provides information on the prevalence of new recovery methods along with contextual information that could be used by coaches and support staff to individualise recovery strategies. When recommending an individualised recovery protocol it is important to consider athlete's personal preference along with the evidence supporting each modality.

APPLICATION STATUS, OPPORTUNITIES AND CHALLENGES OF WEARABLE DEVICES FOR CHINA PREPARATION FOR THE OLYMPIC GAMES

LI, H.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: This presentation analyzes the application status and challenges of wearable devices for China to prepare for 2020 Olympic Games and 2022 winter Olympic Games. This presentation sums up the problems existing in athletes preparing for the Olympic Games and puts forward countermeasures in order to make the Olympic preparation training much more scientifically and reasonably.
METHODS: This presentation distributes 65 questionnaires to coaches and scientific researchers. Besides, this presentation interviewed five athletes and five researchers respectively about the usage of wearable devices.
RESULTS: It is found that wearable devices are much more widely used in football, basketball and hockey than in ice hockey and cross-country skinning. Secondly, gyroscopes and accelerometers are highly stable and reliable when wearable devices are used to evaluate the sports training, but the influence of moving speed, nonlinear movement and signal interference on the measurement results should not be neglected. Nowadays the wearable devices made in China are same as foreign devices in terms of wearable form, main techniques and measurement indicators, but they need to be improved in the field of application, technique support and software matching. The original data that wearable devices can measure is very rich, and the parameters of wearable devices of different brands are different.
CONCLUSION: In the process of preparing for the Olympic Games, how the sports teams draw specific indicators that reflect the characteristics of specialized training to measure the training load scientifically depends on the researchers and coaches' understanding of specialized training and the deeper meaning behind the data. It should be realized that any monitoring method has its limitations. There are still some controversies for wearable devices in integration, measurement error, data integrity and sustainable development.

EVALUATION OF PLAYERLOAD™ DURING A PRE-SEASON INTER-COUNTY GAELIC FOOTBALL COMPETITION

GAMBLE, D.1,2, MOYNA, N.2, MCCARREN, A.2, SPENCER, M.3

1:SPORT NORTHERN IRELAND SPORTS INSTITUTE , 2: DUBLIN CITY UNIVERSITY 3:NORWEGIAN SCHOOL OF SPORTS SCIENCE

INTRODUCTION: The running performance profiles of Gaelic footballers have been reported previously (Malone et al. 2016). Microsensors now enable accelerations, decelerations, changes of direction and impacts to be quantified as PlayerLoad™ (PL; Boyd et al. 2011), which may provide a useful measure of the total load experienced by players (Young et al. 2012). Thus, the aim of this study was to evaluate PL in Gaelic football players during pre-season games.
METHODS: OptimEye S5 devices (Catapult Sports, Australia), incorporating a 10 Hz GPS and 100 Hz; tri-axial accelerometer were used to collect 50 full-game player files from 3 teams during 5 games. The male players (24 ± 3 years, mean ± SD) were grouped as; full-back (FB, n=12), half-back (HB, n=12), midfield (MF, n=4), half-forward (HF, n=10) and full-forward (FF, n=12). The PL was analysed between match halves and positions to examine differences. A two level multi-level analysis was conducted on repeated measurements over the two halves where player was level 1 and match was level 2. Player position and half were treated as fixed effects and an intercept was included for the random effects. An additional post-hoc analysis was conducted on the fixed effects and was adjusted using a Bonferroni correction factor.
RESULTS: Mean PL declined from 341.3 ± 77.0 to 327.7 ± 72.6 from the first to the second half. In FB players, PL increased by 3.2% in the second half, whereas reductions of -3.5 (FF), -5.1 (HF), -6.1 (HB) and -10.3 (MF) were observed. Position and half were both found to be significant for PL ($F_{4, 45} = 10{,}739$, $p<0.001$, $F_{1, 49} = 5.078$, 0.029) using a Type III analysis. There were no significant half-position interactions. Using a post hoc analysis pairwise comparisons demonstrated that the FB position was significantly different from the remaining positions (FF: $p=0.037$, HB: $p<0.001$, HF: $p<0.001$, MF: $p=0.009$).
CONCLUSION: The second half decrease in PL observed in the HF, HB and MF players simulates the greater decline in running performance reported for these nomadic players compared to the inside FF and FB players (Malone et al. 2016). It is plausible that fatigue contributed to this decrement, although the influence of tactical or pacing strategies also needs to be considered (Aughey 2010). The increase in PL in the FB players may be explained by a tactical change requiring these players to track their FF opponents instead of adopting territorial defensive positions or to counter the physical performance of new FF players introduced as substitutes. As PL was designed to evaluate impacts from running and contact related events, this variable may be a potential indicator of muscle damage (Young et al. 2012).

CONCURRENT VALIDITY OF LPS, GPS AND OPTICAL POSITIONING SYSTEMS TO MEASURE COVERED PLAYER AREA AGAINST A VALIDATED COMPUTER VISION MODEL (FIFA EPTS)

ELLENS, S.1, DUTHIE, G.2, AUGHEY, R.1, ROBERTSON, S.1, SERPIELLO, F.1, VARLEY, M.3, EVANS, N.4, BALL, K.1

1: IHES-VICTORIA UNIVERSITY , 2: ACU , 3: ASPIRE , 4: FIFA

INTRODUCTION: Player position is an important value for team sports. It can provide useful behaviour of a team on the pitch as a whole such as area covered, tactical decisions and geometric centre of players. Most of the team behaviour measures involve calculating the distance and area between players from x,y position data. Any error in the x,y data will be magnified in the calculated covered area between players, resulting in erroneous team information. Thus, it's important that position values are true for analysing team behaviour. However, comparison of positioning systems to calculate covered area has not been done. Therefore, the aim of this study was to concurrent validity of a GPS, LPS and optical positioning system to a validated computer vision system.
METHODS: Three soccer games were played by six different teams, every game was analysed with a different player positioning system. The used player positioning systems were GPS, LPS and optical positioning. For the GPS/LPS games players were equipped with a GPS/LPS unit on their upper back. The data of the player position systems were all analysed at 10Hz in Matlab R2016b. Covered area was calculated between 3 players with the triangles formula and 4 players with the polygons formula, both stated by Younhee L. and Woong, L (2017). Statistics were assessed using mean bias in raw units (m^2), SD of bias (95% CR) and typical error of estimate (TEE) in raw units.
RESULTS: The best performing tracking system was LPS followed by GPS and Optical. Calculated surface in the 3-player situation, GPS (mean bias:35.5, TEE:10.6) and Optical (mean bias:1.26, TEE:32.2) and in the 4-player situation GPS (mean bias:15.9, TEE:23.2), LPS (mean bias:0.69, TEE:8.33) and Optical (mean bias:2.83, TEE:45.1) were higher compared to the criterion system. All systems showed strong correlation ($r > 0.95$) and trivial to small measurement errors.
CONCLUSION: The comparison of covered player area calculated out of the different positioning systems predominantly returned trivial mean bias (<2.83) and trivial to small TEE (<45.1), with exception of the GPS mean bias (15.9,35.5) which returned small measurement errors although it had high correlation values ($r > 0.95$). This suggest that the GPS mean bias was lager towards overestimating the area than LPS or Optical systems. This was probably due to signal obstruction and user satellite geometry measurement errors (Gray et al., 2010).

THE PHYSICAL DEMANDS IN ALPINE SKIING

GILGIEN, M., KRÖLL, J., SPÖRRI, J., MÜLLER, E.

NORWEGIAN SCHOOL FOR SPORT SCIENCES

INTRODUCTION: External forces, such as ground reaction force or air drag acting on athletes' bodies in sports, determine the sport-specific demands on athletes' physical fitness. In order to establish appropriate physical conditioning regimes, which adequately prepare athletes for the loads and physical demands occurring in their sports and help reduce the risk of injury, sport-and/or discipline-specific knowledge of the external forces is needed.
METHODS: Due to methodological shortcomings in biomechanical research, data comprehensively describing the external forces that occur in alpine super-G (SG) and downhill (DH) are so far lacking. Therefore, this study applied new and accurate wearable sensor-based technology to determine the external forces acting on skiers during World Cup (WC) alpine skiing competitions in the disciplines of SG and DH and to compare these with those occurring in giant slalom (GS), for which previous research knowledge exists. External forces were

determined using WC forerunners carrying a differential global navigation satellite system (dGNSS). Combining the dGNSS data with a digital terrain model of the snow surface and an air drag model, the magnitudes and temporal pattern of ground reaction forces were computed as a measure of physical demand.
RESULTS: The study revealed that: 1) the method was effectively applied to capture external force data from WC races; 2) the physical demands in alpine ski racing were mainly characterized by fluctuations in the ground reaction force, which followed a cyclic pattern and was most pronounced for GS, followed by SG and DH, while median and peak ground reaction forces were highest for GS, followed by SG and DH).
CONCLUSION: This study 1) illustrated that the validity of high-end dGNSS systems allows meaningful investigations such as characterization of physical demands in highly dynamic sports; and 2) showed that the physical demands were substantially different between GS, SG and DH (specifically, the ground reaction force fluctuations followed a cyclic pattern, which was most pronounced for GS, followed by SG and DH.

SPORTS TRAINING RECOGNITION WITH WEARABLE SENSOR DATA IN FOOTBALL TEAM

TANAKA, T.1, GOUDA, T.2, MAGOME, T.3, NAKATA, K.3

1:HITACHI, LTD., 2:HITACHI, LTD., 3:OSAKA UNIVERSITY GRADUATE SCHOOL OF MEDICINE

INTRODUCTION: Sports using IT is introduced actively into competitive sports. For prevention of injury and effective training, quantitative assessment of player's performance with measurement technologies is required [1]. However, the actual data measured by sensors such as GPS and accelerometer is too complicated to recognize causal relationship to performance for the staffs of sports teams. Therefore, our purpose is to simplify evaluation of measurement data for injury prevention.
[1] Malone, Shane, et al. "The acute: chonic workload ratio in relation to injury risk in professional soccer." Journal of science and medicine in sport 20.6 (2017): 561-565.
METHODS: We propose new method to normalize and evaluate a daily variation of exercise intensity data. Our approach is extracting periods of a specific training from measured continuous data because a daily variation of exercise intensity in periods of a same training is considered to be correlated to player's performance mainly.
To extracting the periods, we develop the process of classifying the data of a sports team into any types of training automatically using only time-series exercise intensity data measured by our wearable accelerometer [2]. The first process is detecting intervals between training periods and splitting the data. The split period corresponds to a period of a single training. The second process is clustering the data of the each split periods with multiple statistical characteristics of time-series exercise intensity data.
We performed the experiment to assess the accuracy of our developed method. We measured the continuous time-series exercise intensity data per second of 15 players in the U -18 team of the Japanese professional football club for 14 days (only the duration of training). After measurement, we extracted the data of our focused training from the measured data with our developed methods, and compared the result with the observation record of training for 2 days. Data were obtained according to the standards of internal review board on R&D group, Hitachi, Ltd.
[2] Tanaka T., et al., "Life microscope: Continuous daily-activity recording system with tiny wireless sensor." INSS 2008: 5th International Conference on Networked
Sensing Systems (2008): 162165.
RESULTS: The accuracy rate of detecting intervals was 100%, and that of the classification into 5 types of training was 80 % in the training of 2 days. Moreover, classifying into our focused training (the pass possession training) were all corrected.
CONCLUSION: Our developed method realizes extracting exercise intensity of a specific training from measured continuous exercise data, and make it easy to evaluate sports performance for staffs of sports teams. Next, we are going to apply our developed method to injury prevention of athletes.

MEASURING SPORT PERFORMANCE IN TALENTED ATHLETES: THE SPORTS REPORT.

ELFERINK-GEMSER, M.T., HENDRIKS, S., HIJLKEMA, A., HENGEVELD, M., VAN DUINHOVEN, S., VISSCHER, C.

UNIVERSITY OF GRONINGEN, UMCG

INTRODUCTION: In talent identification and development programs, a multidimensional and longitudinal approach is recommended. Underlying performance characteristics, such as anthropometric, physiological, technical, tactical, and psychological skills are best monitored in relation to performance and performance development (Elferink-Gemser et al., 2011). However, measuring the latter in a feasible, reliable, and valid way which can be compared between various sports remains a great challenge (Swann et al., 2015). The goal of the current study is to design and test the psychometric characteristics of such measurement tool: The Sports Report.
METHODS: The Sports Report is a pen and paper tool consisting of a simple 10 cm horizontal line. Outcome measure is the percentage an athlete performs above the average level of performance, ranging from 0% ('average level of performance') to 100% ('top performance'). Trainers/coaches score their athlete's level of performance by comparing them to competitive athletes of the same sex and age. Concerning intra-rater reliability, n=7 licensed trainers (age 36,4 ± 9,5) filled out the Sports Report twice with 2 weeks in between for n=21 talented athletes (age 14,8 ± 1,8) in a variety of sports. A comparison was made between test and retest scores. Concerning criterium and construct validity, n=2 licensed trainers (age 33,5 ± 1,0) filled out the Sports Report for n=41 talented speed skaters), of which n=25 were elite and n=18 were sub-elite speed skaters. A comparison was made between scores on the Sports Report and national ranking as well as between elite and sub-elite skaters. Concerning feasibility, interviews were conducted with n=10 licensed trainers (age 36,4 ± 9,5).
RESULTS: Relative (ICC=.92, p<.05) and absolute intra-rater reliability (95% CI-interval of differences: -0,96-1,25) was good with similar scores on test and retest (p>.05). A strong positive correlation between the scores on the Sports Report and position on the national ranking has been found (Spearman r=.663, p<.05). Elite skaters were assigned higher scores than sub-elite skaters (p<.05). In the interviews, trainers stated the Sports Report to be an easy, clear and useful tool taking minimal time.
CONCLUSION: With support for feasibility, reliability, and validity, the Sports Report seems a promising tool to monitor the sport performance of talented athletes in a variety of sports.

ANTHROPOMETRY, PHYSICAL PERFORMANCE, AND MOTOR COORDINATION OF MEDALLIST AND NON-MEDALLIST YOUNG FENCERS

NORJALI WAZIR, M.R.W., MOSTAERT, M., PION, J., LENOIR, M.

UNIVERSITEIT GENT

INTRODUCTION: Fencing is a sport that relies a complex intra play of numerous performance characteristics. Evaluation of these characteristics is important in the field of talent identification and talent development. Multidimensional test batteries have proven their value in different sports. The aim of the present study was to identify anthropometric, physical performance and motor coordination characteristics that discriminate medallist and non-medallist fencers.
METHODS: In this cross-sectional study, 83 young fencers (21 national medallist, 62 non-medallist) between 11 and 16 years old were tested in 2010-2015 using a test battery consisting of four anthropometrical, nine physical performance and three motor coordination tests. The fencers were divided into two groups (medallist and non-medallist at national youth championships). First, descriptive analysis explained their general score (means) for anthropometric, physical performance and motor coordination. Second, MANCOVA was used to explain to what extent the two groups were different from each other, taking into account the effect of maturity (age at peak height velocity – APHV) and calendar age (CA).
RESULTS: APHV significantly affected anthropometry and several strength, speed and explosivity variables. Chronological age had an effect on nearly all parameters of anthropometry, physical performance, and motor coordination. MANCOVA, correcting for APHV and CA showed no significant difference for anthropometric, physical performances and motor coordination between medallist and non-medallist fencers.
CONCLUSION: This study aimed to provide reference values of young fencers and to identify the factors that discriminate between being or not being successful at national level. Generally, the results showed no differences between medallist and non-medallist fencers in anthropometry, physical performance and motor coordination. This study a shows significant effect of APHV and chronological age in anthropometric, physical performance and motor coordination among young fencers. The possibility that only taking into account anthropometry, physical performance, and motor coordination of young fencers in the talent identification process is limited due to the complexity of fencing is discussed.

ABSA CAPE EPIC – TRAINING AND RACING DEMANDS

REINPÕLD, K.1, BOSSI, A.H.2, HOPKER, J.G.2

TALLINN UNIVERSITY

INTRODUCTION: The Absa Cape Epic is an 8-day mountain bike race involving a total distance in excess of 650 km with over 13000 m of climbing, suggesting athletes require targeted ultra-endurance training to develop the necessary capabilities. Despite attracting the worlds best mountain bikers, training and racing demands are yet to be described.
METHODS: Six male mountain bikers (age: 39 ± 7 years; VO2max: 61.9 ± 10.9 ml·kg-1·min-1) were monitored for 4.5 months, including the race. Training was divided into two phases—base (November to December) and pre-race (January to mid-March). In October, January and March, riders performed incremental tests to determine the second ventilatory threshold (VT2) and VO2max. VT2 was used as an anchor point to calculate training-intensity distribution bins: soft-pedalling/coasting (<56%VT2), endurance (56–75%VT2), tempo (76–90%VT2), threshold (91–105%VT2), VO2max (106–120%VT2) and anaerobic (>120%VT2). As the race is contested in pairs, we only analysed prologue and stage-one data, given that two athletes from different teams abandoned on stage two due to injuries. Paired t-tests and one-way repeated-measures ANOVAs with Bonferroni pairwise comparisons were performed. Significance was set at $P \leq 0.05$.
RESULTS: Athletes trained 193 ± 28 h of cycling in total (base: 79 ± 18 h, pre-race: 85 ± 13 h; $t = -0.65$, $P = 0.543$), at mean power outputs of 2.58 ± 0.59 W·kg-1 during base and 2.61 ± 0.48 W·kg-1 during pre-race ($t = -0.23$, $P = 0.826$). Despite no changes in VO2max ($F = 5.18$; $P = 0.069$; $\eta p2 = 0.51$), VT2 improved during the training period ($F = 7.09$; $P = 0.012$; $\eta p2 = 0.59$). VT2 was higher in March (4.08 ± 0.64 W·kg-1) than January (3.89 ± 0.61 W·kg-1; $P = 0.050$), while it tended to be higher in March than October (3.82 ± 0.67 W·kg-1; $P = 0.076$). No differences were found between base and pre-race for proportions of training time spent in each intensity bin. Riders completed the prologue and stage one in 1.5 ± 0.2 and 6.5 ± 1.1 h, at mean power outputs of 3.08 ± 0.74 and 2.43 ± 0.66 W·kg-1, respectively. We found lower proportions of time spent in soft-pedalling/coasting and endurance bins (30.4 ± 6.6 vs 40.5 ± 9.4 %, 14.0 ± 4.1 vs 21.8 ± 5.3 %) and higher proportions in VO2max and anaerobic bins (11.6 ± 4.0 vs 5.8 ± 3.5 %, 15.0 ± 7.7 vs 5.2 ± 2.5 %) during prologue than stage one (all $P < 0.006$), but no differences in tempo and threshold bins (14.5 ± 4.1 vs 15.7 ± 2.8 %, 14.6 ± 1.7 vs 11.0 ± 4.5 %; all $P > 0.129$).
CONCLUSION: Mountain bikers preparing for the Absa Cape Epic typically adopt a pyramidal training intensity distribution, with large proportions of low-intensity cycling (56–75%VT2) and no major shifts across training phases. Race form is achieved through improvements in VT2 but not in VO2max. The prologue involves large proportions of high-intensity efforts (>90%VT2), particularly anaerobic efforts (>120%VT2), whereas stage one involves comparatively greater proportions of low-intensity exercise.

COMPETITIVE GAME DEMANDS OF FEMALE AUSTRIAN LACROSSE PLAYERS

HAUER, R., TSCHAN, H.

UNIVERSITY VIENNA

INTRODUCTION: Lacrosse is one of the fastest growing team sports. However, there is a general lack of research in game-play activity profiles (Polley, Cormack, Gabbett, & Polglaze, 2015). Therefore, this study aims to analyse the activity profile in female lacrosse gameplay using micro technology.
METHODS: Activity in 4 games was recorded from ten female Austrian lacrosse athletes (age: 29.1 ±6.1ys; body mass: 64.2 ±5.0kg; height: 165.3 ±4.1cm) using GPS player-tracking (Polar Team Pro). Activity profile variables included percentage of mean heart rate (% HRmean) in relation to maximum heart rate, time spent (s) in HR-zones (1: 15-59%; 2: 60-69%; 3: 70-79%; 4: 80-89%; 5: 90-100%), total distance covered (m), number of sprints, distance covered (m) in speed zones (1: 0.00-6.99km/h; 2: 7.00-10.99km/h; 3: 11.00-14.99km/h; 4: 15.00-18.99km/h; 5: >19.00km/h), and number of accelerations (1: 0.50-0.99m/s²; 2: 1.00-1.99m/s²; 3: 2.00-2.99m/s²; 4: 3.00-

50.00m/s²) and decelerations (zones staggered the other way round compared to accelerations). Players were separated into position of attack, midfield and defence. Differences between positions were analysed using one-way ANOVA. Significant results were interpreted using post-hoc-analyses. Statistical significance was set at $p<0.05$ with a confidence interval of 95%.
RESULTS: Results showed no significant differences for average HR (75.55 ±7.2%) between positions. Similar results have been found for time spent in HR-zones (1: 842.2 ±775.6s; 2: 813.6 ±503.9s; 3: 89.9 ±280.7s; 4: 957.7 ±376.4s; 5: 878.7 ± 602.7s), with only significant differences in zone 1 between attackers and midfielders. Significant differences in number of sprints (10.2 ±4.8) could be found between defenders and midfielders. Analysis for total distance covered in a game showed a mean value of 3,679.7 ±1,005.7m, with significant higher numbers for defenders compared to other positions. Further, results showed significant differences for distance covered in speed zones (1: 1,408.4 ±407.1m; 2: 789.8 ±256.0m; 3: 838.6 ±251.4m; 4: 468.2 ±196.6m; 5: 174.8 ±129.6m), number of accelerations (1: 214.5 ±55.3; 2: 129.1 ±33.5; 3: 40.1 ±12.0; 4: 6.1 ±3.6) and decelerations (1: 4.9 ±3.1; 2: 33.7 ±13.3; 3: 142.9 ±37.7; 4: 257.7 ±54.9) between positions.
CONCLUSION: The analyses of this study suggest that the game-play activity profile differ between positions in women's lacrosse. These differences should be considered by coaches when preparing lacrosse athletes for competition. Nevertheless, further work needs to be done to determine competitive game demands of female lacrosse athletes.

ENERGY DEMANDS IN HIGHLY TRAINED ALPINE SKI RACERS DURING DIFFERENT DURATION OF IN SITU SLALOM AND GIANT SLALOM RUNS

PRIOUX, J.1, BOTTOLLIER, V.1,2, LE QUELLEC, L.2, COULMY, N.2

1ENS - M2S . 2DDSS - FFS .

INTRODUCTION: There are gaps in the understanding of alpine ski racing metabolic demands: (i) there is still no real consensus on metabolic demands in giant slalom (GS); (ii) the metabolic demands in slalom (SL) have not yet been clarified; and, (iii) the difference in metabolic demands between durations of competitive run races for a discipline have not yet been clarified. Consequently, a more complete understanding of the energetics of in situ alpine ski racing could lead to more focused and specific training goals, and subsequent adaptations. Improving these knowledge have the possibility of both improving performance and reducing injury risks. The purpose of this study was to investigate energy demands of different duration in situ SL and GS events in highly trained alpine ski racers.
METHODS: The sample consisted of eight highly trained alpine ski racers (age: 18.2 ± 0.8 years; stature: 1.72 ± 0.10 m; body mass: 65.8 ± 12.0 kg) who performed an incremental lab-test on cycle ergometer and four in situ standardized alpine ski runs: two SL and two GS, each of which was short (ST) and long (LG) (SLST, SLLG, GSST, GSLG). Oxygen uptake (VO2) and heart rate (HR) were recorded continuously in all conditions. VO2 were recorded (breath-by-breath) using a portable gas exchange system (Metamax, Cortex, Germany) and HR using a HR monitor (V800 and H7, Polar, Kempele, Finland). Blood lactate ([La]b) was determined immediately pre-run, and 3 and 5 minutes post-run. The contribution of aerobic and anaerobic lactic energy systems was estimated by energetic flow method (Di Prampero, 1981).
RESULTS: The aerobic system was the primary energy system involved in the GSLG (64 ± 3.9%) and anaerobic lactic was the primary contributor of energy in SLST (63 ± 9.7%) and SLLG (54 ± 7.1%). No significant difference in the contribution of energy systems was observed in GSST. Peak [La]b was higher in SLLG (11.10 ± 2.41 mmol.L-1) than in GSST (8.01 ± 2.01 mmol.L-1). There was no difference in VO2peak between GSST and GSLG.
CONCLUSION: Energetic training goals should focus on the improvement of both aerobic and anaerobic lactic systems for alpine ski racers who perform SL and GS, with SL specialists' emphasis on the improvement of the anaerobic lactic system and GS the aerobic power system.

PHYSIOLOGICAL DEMANDS OF A SIMULATED BMX RACE

BUBECK, D., BRENNER, M., ALT, W.

UNIVERSITY OF STUTTGART

INTRODUCTION: Bicycle Motocross Cycling (BMX) as a young and upcoming sports discipline is new at the Olympic games since 2008. According to this there is a great demand on interest about the physiological and mechanical requirements for this discipline. So an aim of this study was to investigate the oxygen demands and uptakes needed during the race and to compare it to the values of VO2max achieved during a stationary VO2max test.
METHODS: 12 athletes who regularly participate at international races take part at the project. It consists of a preliminary testing session of VO2max on a stationary bike ergometer and week later of a simulated BMX competition with 6 runs interrupted by 20 min breaks on the BMX training track in Zolder (BEL). In both situations oxygen uptake was measured with a Cosmed K5 spirometer.
RESULTS: Results indicated that there was no clear increase of the VO2 values from race 1 to race 6. But it can be seen that in the individual analysis of the athletes some athletes were limited during the race by their aerobic capacity by reaching their VO2max. Other athletes don't reach VO2max so it was assumed that they were limited due to power output factors like their strength capacity.
CONCLUSION: The comparison of the oxygen uptake during a simulated race situation with the values of a stationary VO2max test reveals interesting information about the athletes capacity needed for a race. Therefore recommendations can be given for the athletes about their main training goals.

A COMPARISON OF THE MAXIMUM LOCOMOTOR INTENSITIES IN AGE-GRADE INTERNATIONAL AND ACADEMY RUGBY UNION

READ, D., TILL, K., BARRON-DALTON, N., BEASLEY, G., JONES, B.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Age-grade (e.g., U18) rugby union players play in multiple playing levels across a season, including international and academy competition. One method for quantifying the physical characteristics of different playing levels is to calculate the maximum locomotor intensity using relative distance (m·min-1) and high-speed (>5.5 m·s-1) relative distance (HSm·min-1). The aims of the study were to quantify the maximum locomotor intensities from match-play and compare between U18 international and academy levels.
METHODS: In total, 142 U18 male rugby union players provided 232 observations. During match-play each player wore a micro-technology device (S5 Optimeye, Catapult Sports) that contained a global positioning system. Using the raw instantaneous speed (m·s-1) downloaded at 10 Hz, variables were calculated through the use of a 0.1 s rolling mean for time durations (15, 30 s and 1, 2, 2.5, 3, 4, 5, 10 min) relevant to academy rugby union. Players were split into four positional groups of: front row, back five, scrum-halves, and inside and outside backs. A linear mixed model was used to account for the repeated measurements of players and then results were interpreted with effect sizes (ES) ±90% confidence intervals and classified as trivial (0.00-0.19); small (0.20-0.59); moderate (0.60-1.19) and large (1.20-1.99). Ethics approval was granted from Leeds Beckett University.
RESULTS: Differences between levels in relative distance were trivial or small for all time durations and positions, with the relative distance ranging from 148 ± 16 to 189 ± 17 m·min-1 in the one-minute duration. High-speed relative distance for one-minute ranged from 26 ± 11 to 71 ± 24 HSm·min-1 and throughout all comparisons were greater in international players. The differences in high-speed relative distance were moderate to large (ES = 1.17 ±0.64 to 1.59 ±0.64) in front row players. The differences between the back five positional groups were small (ES = 0.31 ±0.52 to 0.45 ±0.57) for high-speed relative distance. There were small differences between the groups of scrum halves in the 15 s, 30 s and 1 min durations (ES = 0.56 ±0.79 to 0.59 ±0.78), with moderate to large differences in time durations ≥2 min (ES = 0.82 ±0.87 to 1.24 ±0.93). The differences in high-speed relative distance were trivial to small (ES = 0.02 ±0.51 to 0.39 ±0.58) in the inside and outside backs comparison.
CONCLUSION: Relative distance was similar between playing levels but appears to be comparable to data from senior international rugby union match-play in previous studies. There is a greater amount of high-speed relative distance per minute completed during U18 international matches compared to U18 academy matches. Coaches working with rugby players can use this information to appropriately overload the intensity of running, specific to time durations and positions.

PITCH DIMENSIONS IN ELITE YOUTH SOCCER TRAINING: IMPACT ON EXERCISE INTENSITY

CONNOLLY, D.R.1, GUALTIERI, A.1, FERRARI-BRAVO, D.1, SASSI, R.1, RAMPININI, E.2, COUTTS, A.J.3

1: JUVENTUS FC , 2: MAPEI SPORT . 3: UNIVERSITY OF TECHNOLOGY SYDNEY .

INTRODUCTION: Soccer training drills are often designed with the aim to replicate movement demands, physiological intensity and technical requirements of match play. Pitch dimensions and the number of players involved can influence the intensity of Small-Sided Games (SSGs) (Hill-Haas et al., 2011) and tactical drills. In this study, we aimed to investigate how pitch dimensions are utilized in youth soccer and the differences in intensity induced across different age groups.
METHODS: In-season training sessions of elite level youth soccer players, ranging from U15 to U17 (age: 15.7±0.9yrs, height: 176.6±6.7cm, weight: 66±7.8kg), were monitored (306 observations) using 10Hz GPS units (StatSports, Ireland) and heart rate monitors (Polar, Finland). The pitch dimensions of each drill were noted to calculate the relative pitch area per player. The pitch dimensions utilized were divided into 3 groups: Large, match-derived relative pitch areas (L, >250m2), Medium (M, 150m215km/h (DS15) and number of accelerations >2ms (ACC)) of each drill were monitored and normalized for time. A sub-analysis was performed on 33 players to investigate the effect of pitch dimensions on exercise intensity. Pearsons Chi-square test was utilized to assess the distribution of pitch sizes. Differences between the pitch dimensions and age groups were analyzed using two-way mixed ANOVAs with Bonferroni post-hoc test. Significance level was set at $p<0.05$.
RESULTS: Overall, more training drills were performed on S pitches ($p<0.001$), however the distribution of pitch dimensions was significantly different between the different age groups. Significantly less D and DS15 was covered in S ($p<0.001$) compared to M and L pitches. A significant interaction between pitch size and age group was found for D and DS15, with increases in pitch dimensions influencing U15 players output significantly more than U16 and U17 ($p<0.01$). More ACC were performed in S ($p<0.001$), with U17 performing less ACC than the younger age groups. No significant effects observed for 85%HR induced by the different pitch dimensions ($p=0.567$); however, U15 performed greater 85%HR than U16 and U17 ($p<0.012$).
CONCLUSION: Pitch dimensions commonly used during training are smaller than match dimensions, producing a greater number of ACC, while contributing lower distance and speed than M and L SSG pitches. Changes in pitch dimensions appear to have a greater impact upon younger players external load.

EVALUATION OF THE EXTERNAL AND INTERNAL MATCH-PLAY DEMANDS OF ELITE UNDER 17 HURLING

YOUNG, D., MOUROT, L., BEATO, M., CORATELLA, G.

UNIVERSITY FRANCHE COMTE

INTRODUCTION: Hurling is an Irish stick and ball invasion game, which has previously been described as one of the fastest and skilful field games in the world. Match-play demands of underage hurling have never been quantified. The current study aimed to quantify the match-play workload of elite male under 17 hurling players, measuring the differences between first and second half and between positions.
METHODS: Fifty elite male hurlers with a mean (± SD) age, height body mass and predicted VO2max of 16.71 ± 0.39 years, 178.40 ± 6.26 cm, 69.32 ± 6.02 kg, and 54.55 ml.kg-1.min-1 respectively, volunteered to participate in the study. GPS (10-Hz Viper, STATSport) and heart-rate (HR) monitors (Team Polar, Polar Electro Oy, Kempele, Finland) were used to collect data from three elite male U17 teams during 12

matches. The participants were categorized into common outfield playing positions of full backs (n=10), half backs (n=11), midfielders (n=9), half forwards (n=10) and full forwards (n=10). Data collected from the GPS units included total distance (TD) (m), high-speed running (HSR) (17-22 km·h-1) (m), the total number of sprints (≥ 22 km·h-1) and sprint distance (≥ 22 km·h-1) (m). Peak HR (HRmax) was taken as the highest HR recorded and mean HR (HRmean) was assumed as the mean value logged during games.
RESULTS: Players' TD, HSR, number of sprints, sprint distance, HRmax and HRmean were 6141 ± 1024 m, 514 ± 158 m, 10 ± 4 and 389 ± 74 m, 192 ± 29 b·min-1 and 160 ± 13 b·min-1 respectively. Decrements in TD ($p < 0.001$, ES = 0.81), HSR ($p < 0.001$, ES = 0.69), number of sprints ($p < 0.001$, ES = 0.78), sprint distance ($p < 0.001$, ES = 0.76) and HRmean ($p < 0.001$, ES = 0.80) were found between halves. Midfielders covered greater TD than full backs ($p < 0.001$, ES = 3.23), half forwards ($p = 0.008$, ES = 2.08) and full forwards ($p = 0.003$, ES = 2.01). However, no differences were found between positions for the total number of sprints, sprint distance or HRmax during the full duration of match-play.
CONCLUSION: The current results are the first to highlight the differences in external and internal position specific workload in elite male under 17 hurlers. The overall total running performances were lower than found at elite senior hurling level. Players need to be sufficiently prepared to be able to perform the match-play demands, with an emphasis placed on being able to repeat HSR distance, sprint distance and the number of sprints for the full duration of the match. Training sessions and drills or matches design should include activities that provide the necessary stimulus to elicit specific positional match-play responses.

CHANGES IN THE PHYSICAL DEVELOPMENT OF ELITE ADOLESCENT RUGBY UNION PLAYERS IN IRELAND: A LONGITUDINAL ANALYSIS OF DEVELOPMENT BY PLAYING POSITION

CASSERLY, N.1, NEVILLE, R.1, DITROILO, M.1, GRAINGER, A.2

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: The wellbeing of elite rugby union players has been subjected to intense scrutiny in recent years. Understanding the physical development of adolescent players is particularly indicated in this context, since new knowledge in this area can aid in improving programming and help adolescents prepare for the demands of senior rugby.
This study focuses on the physical development of elite adolescent rugby union forwards (n=8) and backs (n=7) over the final two years of their junior competitive career. The focus of the study was on the relative development of players over time taking into account an inventory of performance measures which are widely regarded as discriminators of playing position.
METHODS: Fifteen players (body mass, 90 ± 14; height, 183 ± 9) completed anthropometric measures, CMJ, Yoyo-IR1 and 10m acceleration at baseline, year 2 and year 3. Mixed linear model equations were derived to assess both player development over time and the extent to which this development differed by playing position. Data was analysed by means of standardisation where Magnitude Based Inference (MBI) was used to assess the size and likelihood of the differences between years and differences between groups.
RESULTS: There was a substantial improvement in 10m acceleration (Standardised Improvement, 0.2; 90%CL, 0.7: MBI, small*) and in aerobic capacity as measured by the Yoyo-IR1 (0.5; 0.6: small**). Differences between backs and forwards in relation to these changes are also noteworthy. There was a large difference in 10m acceleration, comparing backs and forwards (-1.3; 1.3 - large**), with backs appearing to get substantially faster over time (-0.8; 0.9: moderate**). A similar trend was observed for aerobic fitness. Backs improved substantially over time (1.0; 1.3: moderate**). However, outcomes for forwards (0.1: 0.5) as well the postdoc estimates regarding differences between groups (0.9; 1.3) were unclear. There is some indication that differences in weight between groups can explain some of the difference in acceleration over time. The effect of weight was moderate in size (0.6; 2.6); however, the confidence interval for this estimate was too wide to be deemed clear. Change in CMJ height and differences between groups in relation to this change were unclear and are therefore not presented.
CONCLUSION: Improvements in acceleration and aerobic capacity for backs reflects the demands of gameplay within this positional unit. Backs are required to cover greater distances at a higher intensity than forwards (Roberts et al, 2008) and to use speed qualities to avoid contact while ball carrying. Differences in body mass can potentially explain some of the difference in performance between positional units. More data is required, however, to ascertain the true magnitude of this effect.
Roberts, S.P. et al, 2008. The physical demands of elite English rugby union. Journal of sports sciences, 26(8), pp.825-833.

PROFESSIONAL YOUTH PLAYERS' DECISION SKILLS: A VALIDATION OF A VIDEO DIAGNOSTIC BASED ON AGE, PLAYING POSITION AND PLAYING STATUS

MURR, D.1, LARKIN, P.2, HÖNER, O.1

UNIVERSITY OF TUEBINGEN, GERMANY <1>; VICTORIA UNIVERSITY, AUSTRALIA <2>

Introduction: In previous research psychological talent predictors in soccer has been investigated extensively. Moreover, cognitive skills, in particular players' ability to make the right decision in different game situations under time constraints are an important performance indicator for soccer. However, there is a lack of diagnostics that accurately measure decision-making performance using soccer specific stimuli in combination with a sport-specific motor response. This study aimed to validate a video-based test battery that assesses decision-making at one of the leading German youth academies. In detail, adolescent soccer players' competence in decision-making was examined based on playing status, age and playing position.
Methods: The sample consisted of 140 data points from 86 German youth academy players born between 1996 and 2001 (16,7 ± 0,9 ys.). The decision-making task required players to interact with a game situation projected on a large video screen by dribbling and passing to one of three targets. The video-based test-battery included 48 video clips, which were separated into two categories: (1) build up (BU); and (2) offensive decision (OD). A total score (SC) and a score for each category (SCBU, SCOD) were calculated and analyzed based on playing status (i. e., first team regular player (FTRP) vs. reserve player (RP)); age (i.e., U16, U17, and U19); and playing position (i.e. defender (DF) vs. midfielder (MF) vs. forward (FW)).
Results: The test instrument showed a satisfactory reliability (odd-even-method) for SC ($r = 0.72$; $p < .01$). Diagnostic validity was assessed with independent two-sample t-tests comparing players' decision-making skill relative to their playing status. FTRP performed significantly better than RP (SC; $d = 0.46$; $p < .01$). One-way ANOVAs identified differences in decision-making competence with regard to age and playing position. Post-hoc analysis revealed U19 and U17 players performed significantly better than U16 players (SC; $d = 0.68$ and $d = 0.79$; $p < .01$). In regard to playing position, MF's performed better in SC, albeit not significantly, compared to DF and FW. Within the individual categories, MF and FW scored higher in SCOD, DF in SCBU.
Conclusion

Overall the applied video-based test, which aims to replicate game situations, seems to be a suitable instrument for discriminating playing status. In addition the findings indicate older players have better decision-making skills than younger players. For playing position no differences in decision-making performance were found at this stage. Ultimately, the success in discriminating playing status makes it of interest for future prospective studies.

OP-PM67 Heat exposure

HEAT ACCLIMATION ALTERS PACING STRATEGY AND IMPROVES END-SPURT IN FEMALE ENDURANCE ATHLETES

LUCAS, R.A.I, KIRBY, N., LUCAS, S.J.E.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Self-paced time trial performance is impaired in the heat, with less work completed during the end-spurt of time trials (Levels et al., 2017). Heat acclimation (HA) is known to improve self-paced time trial performance in the heat via thermoregulatory adaptations and improved aerobic capacity resulting from plasma volume expansion and reduced cardiovascular strain. However, the effects of HA on pacing strategies are unknown. Therefore, this study examined the effect of HA on pacing strategies and end-spurt during self-paced cycling time trials.
METHODS: Following two familiarisation sessions, 7 female recreational endurance athletes (mean ±SD age 28 ±5 yrs, mass 61 ±5 kg, VO2max 45 ±5 mL/kg/min) completed a 15-minute self-paced time trial in hot conditions (HTT; 35°C, 30%RH) before (HTT1) and after (HTT2) 9-days isothermic HA (40°C, 30%RH). Power output during HTTs were split into the start, middle, and "end-spurt", which consisted of minute 0-2, minute 2-13, and minute 13-15, respectively. Data from HTT1 and HTT2 were compared using paired t-tests.
RESULTS: Following HA there was an increase in overall distance cycled (+260±150 m (3.3%), P=0.003) and mean power output (+10.4±7.4 W (5.5%) P=0.003) in HTT2. Area under the curve (AUC) for power output was greater in HTT2 (P=0.003) and presented a different pacing pattern (HTT2: U-shaped curve vs. HTT1: "even until end-spurt" or J-shaped curve). In HTT2, power output was higher during each of the three phases (start, P=0.017; middle, P=0.005; and end-spurt, P<0.001). Distance completed during the end-spurt increased (+30±10 m; P<0.001) in HTT2. Rectal temperature at rest was lower (-0.13±0.17 °C; P=0.038) and thermal sensation (TS) reported at rest was improved (P= 0.039; inside chamber) following HA. Blood lactate, HR and thermal comfort were similar between HTT2 and HTT1.
CONCLUSION: Alterations in pacing strategy and improvements in each phase of the self-paced time trial were observed following HA in recreational female endurance athletes. Pre HA pacing patterns mirrored patterns from similar shorter distance self-paced time trials (Borg et al., 2018); however, following HA, a more U-shaped curve was observed via the disproportional power output increases during the start phase of HTT2. This improvement during the start may be due to a reduced rectal temperature and improved TS at the initiation of HTT2. Improved aerobic capacity (evident from increased power output without significant increases in HR) likely contributed to improvements during the middle phase of HTT2. However, from these data it is unclear the mechanisms underlying improvements in power output during the end-spurt (the point of supposed greatest fatigue).

EFFECTS OF ACUTE OR CHRONIC HEAT EXPOSURE, EXERCISE AND DEHYDRATION ON PLASMA CORTISOL, IL-6 AND CRP LEVELS IN TRAINED MALES

COSTELLO, J.T., RENDELL, R.A., FURBER, M., MASSEY, H.C., TIPTON, M.J., YOUNG, J.S., CORBETT, J.

UNIVERSITY OF PORTSMOUTH

INTRODUCTION: This study examined the acute and chronic effects of euhydrated and hypohydrated heat exposure, on biomarkers of stress and inflammation.
METHODS: Eight trained males [mean (SD) age: 21 (3) y; mass: 77.30 (4.88) kg; V?O2max: 56.9 (7.2) mL·kg-1·min-1] undertook two heat acclimation programmes (balanced cross-over design), once drinking to maintain euhydration and once with restricted fluid-intake (permissive dehydration). Days 1, 6, and 11 were 60 min euhydrated exercise-heat stress tests (40 °C; 50 % RH, 35% peak power output), days 2–5 and 7–10 were 90 min, isothermal-strain (target rectal temperature: 38.5 °C) exercise-heat sessions. Plasma was obtained pre- and post- exercise on day 1, 2, and 11 and analysed for cortisol, interleukin-6 (IL-6), and C-reactive protein (CRP). Cortisol and CRP were also assessed on day 6.
RESULTS: IL-6 was elevated following the initial (acute) 90 minute isothermal heat strain exercise-heat exposure (day 2) with permissive dehydration ((pre exercise: 1.0 pg.mL-1 [0.9], post-exercise: 1.8 pg.mL-1 [1.0], P = 0.032) and when euhydrated (pre-exercise: 1.0 pg.mL-1 [1.4], post-exercise: 1.6 pg.mL-1 [2.1], P = 0.048). Plasma cortisol levels were also elevated but only during permissive dehydration (P = 0.032). Body mass loss was strongly correlated with ?cortisol (r = -0.688, P = 0.003). Although there was a trend for post-exercise cortisol to be decreased following both heat acclimation programmes (chronic effects), there were no within or between intervention differences in IL-6 or CRP.
CONCLUSION: In conclusion, acute exercise in the heat increased IL-6 and cortisol only when fluid-intake is restricted. There were no chronic effects of either intervention on biomarkers of inflammation as evidenced by IL-6 and CRP returning to basal level at the end of heat acclimation.

THE EFFECTIVENESS OF A MIXED ACTIVE AND PASSIVE HEAT ACCLIMATION PROTOCOL FOR PARALYMPIC AND ABLE-BODIED TRIATHLETES

STEPHENSON, B., TOLFREY, K., GOOSEY-TOLFREY, V.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Despite the volume of heat acclimation (HA) studies in the literature, their applicability to the multi-modal sport of triathlon is relatively unknown. Furthermore, given the popularity of the Paralympic Games, surprisingly few studies have examined the effective-

ness of HA for Paralympic athletes. Therefore, the aim of the study was to investigate the efficacy of a novel HA protocol for Paralympic (P) and able bodied (AB) triathletes.
METHODS: 20 triathletes participated in the study, which comprised of 7 elite paratriathletes (4 male, 3 female) of mixed physical impairments (amputation n = 3, spinal cord injury n = 1, cerebral palsy n = 1, lower leg impairment n = 1, visual impairment n = 1) and 13 AB triathletes (9 male, 4 female). Both groups completed an 8-day HA protocol consisting of 5 active and 3 passive heat exposures in 35oC and 60% relative humidity. Active HA was performed in a quasi-isothermic manner whereby participants were instructed to maintain a constant heart rate (HR) for 45 or 90 min each day whilst cycling on an ergometer. During passive HA, participants rested in the heat for 60 min, immediately after the completion of a 30 min moderate intensity run. A 50 min fixed, moderate intensity cycling trial was conducted on the first and last day of HA to assess changes in core temperature (Tc), HR, blood lactate concentration (BLa), and plasma volume (PV). Changes in the aforementioned parameters were assessed via two-way ANOVA or paired samples t-test. Effect sizes were calculated via the use of partial ?2 or d (Cohen, 1988).
RESULTS: During the fixed intensity trial, there was a large decrease in Tc for P (38.02 ± 0.41oC to 37.68 ± 0.53oC, p = 0.039, ?2 = 0.228) and AB (38.11 ± 0.48oC to 37.82 ± 0.56oC, p = 0.041, ?2 = 0.327) post-HA. Whilst HR was practically unchanged for P (133 ± 14 bpm to 130 ± 13 bpm, p = 0.878), there was a large decrease in AB (152 ± 16 bpm to 147 ± 15 bpm, p = 0.008, ?2 = 0.453). BLa was lower to a large extent post-HA in both groups (P: 1.47 ± 0.46 mmol·l-1 to 1.23 ± 0.40 mmol·l-1, p < 0.001, ?2 = 0.899; AB: 2.02 ± 0.76 mmol·l-1 to 1.64 ± 0.73 mmol·l-1, p = 0.002, ?2 = 0.573). There was a large increase in PV for both groups (P: 12.7 ± 10.7%, p = 0.019, d = 2.592; AB 4.4 ± 7.5%, p = 0.025, d = 1.570).
CONCLUSION: A mixed, active and passive, quasi-isothermic HA protocol stimulated beneficial adaptations in both AB and Paralympic triathletes. Whilst the P group did not display any significant changes in submaximal HR, this is the first evidence that athletes with a mix of physical impairments can display positive thermoregulatory adaptations.

PASSIVE HEAT ACCLIMATION IMPROVES SKELETAL MUSCLE CONTRACTILITY IN HUMANS

RACINAIS, S., WILSON, M.G., PERIARD, J.D.
ASPETAR ORTHOPAEDIC AND SPORTS MEDICINE HOSPITAL

INTRODUCTION: In vitro and animal studies have suggested that heat stress can promote skeletal muscle cell proliferation and increase force. The aim of this study was to investigate the effect of repeated passive heat exposure on muscle contractility in humans. It was hypothesized that heat acclimation would improve human skeletal muscle force and contractility in both hot and temperate conditions.
METHODS: Fourteen non-heat acclimated males completed two trials including electrically evoked twitches and voluntary contractions of the plantar flexors in temperate and hot ambient conditions on consecutive days in a counterbalanced order. Rectal temperature was maintained at ~39°C throughout HOT. The trials were repeated after 11 consecutive days of passive heat acclimation <1 hr per day, 48-50°C, 50% RH>.
RESULTS: Heat acclimation induced a decrease in core temperature in CON and an increase in sweat rate during heat exposure . Moreover, passive heat acclimation improved skeletal muscle contractility as evidenced by an increase in electrically evoked peak twitch amplitude without altering contractile speed. Maximal isometric voluntary torque production was also increased in both CON and HOT , despite voluntary activation remaining unchanged. Further, the slope of the relative torque/EMG linear relationship was improved post-acclimation .
CONCLUSION: These adjustments demonstrate that passive heat acclimation improves skeletal muscle contractile function of the plantar flexors in humans. The improvement was verified across both CON and HOT, with voluntary and electrically evoked contractions, at rest and at different contraction intensities <10, 25, 50, 75 and 100% of maximal voluntary torque>. In conclusion, this infers that passive heat acclimation improves skeletal muscle contractile function in humans, irrespective of ambient testing conditions.
PRACTICAL APPLICATIONS:
These results highlight a novel passive method to improve muscle function via repeated heat exposure that may be used with athletes and patients during a period of musculoskeletal unloading, such as post-surgical immobilization.

OP-PM46 Nutritional supplements

EFFECTS OF ACUTE INGESTION OF A KETONE ESTER ON PHYSICAL AND COGNITIVE PERFORMANCE IN TEAM SPORT ATHLETES DURING A SIMULATED SOCCER PROTOCOL

EVANS, M., EGAN, B.
DUBLIN CITY UNIVERSITY

INTRODUCTION: The ketone bodies beta-hydroxybutyrate (βHB) and acetoacetate are lipid-derived metabolites that play a role in energy provision under physiological states characterised by reduced glucose availability, such as prolonged starvation and ketogenic dieting. The role of ketone bodies in relation to fuel provision during exercise has become of interest due to the development of exogenous ketone supplements, namely ketone salts and ketone esters. To date, the research on ketone supplements has focused on endurance athletes with a lack of data both in high intensity team sports, and for their effect on cognition function in humans.
METHODS: In a double-blind, randomised crossover design, eleven male team sport athletes undertook two experimental trials during which they performed the Loughborough Intermittent Shuttle Test (Part A: 5x15 min intermittent activity, Part B: run to exhaustion). Before and after exercise, participants completed a battery of cognitive tests (CANTAB Cognition, UK). Each experimental trial was identical with the exception of the drink consumed throughout exercise, which consisted of either (i) a 6% carbohydrate solution (1.2 g min-1 of exercise) (PLA) or (ii) a 6% carbohydrate solution (1.2 g min-1) combined with 745 mg kg body mass-1 of a ketone monoester (KET). KET was ingested in three boluses (50:25:25) at 20 min prior to exercise, and after 30 and 60 min of exercise, respectively. 15 m sprint times and heart rate were collected during exercise, and blood samples were collected at rest and at the end of each 15 min block of exercise for measurement of plasma glucose, lactate and βHB.
RESULTS: KET ingestion produced acute nutritional ketosis with plasma concentrations of ~2-3 mM during exercise. Run time to exhaustion in Part B was not different between PLA and KET (p=0.123, ES=0.45) nor were 15 -m sprint times during Part A. Plasma glucose and lactate concentrations were reduced during exercise in KET compared to PLA, with effects sizes being moderate-to-large. No differences

in heart rate were observed during any block of exercise. The number of incorrect responses in the multitasking test increased from pre- to post-exercise in PLA (2.0±2.4), but not in KET (0.4±1.9) (p=0.019, ES=0.73).
CONCLUSION: Ingestion of a ketone monoester had no effect on run time to exhaustion or 15 m sprint times during simulated soccer performance in team sport athletes, but may have attenuated the decline in managing multitasking with fatiguing exercise. The reduction in plasma glucose and lactate suggest an attenuation of carbohydrate utilisation during exercise, suggesting that exogenous ketones are a readily available source of energy during intermittent running.

NOVEL PLANT-BASED NUTRACEUTICAL SUPPLEMENTATION AND LYMPHOCYTE CELL DNA DAMAGE FOLLOWING HIGH INTENSITY EXERCISE

WILLIAMSON, J., HUGHES, C.M., DAVISON, G.W.

ULSTER UNIVERSITY

INTRODUCTION: The generation of reactive oxygen species is an integral part of the biological redox equilibrium, and play a salient regulatory role in cell signalling (Elokda & Nielsen, 2007). Plant-based nutraceuticals are categorised as nutritional supplements which contain a high concentration of antioxidants, with the intention of minimising the deleterious effects of an oxidative insult. The primary aim of this novel study was to determine the effect of exogenous barley-wheat grass juice (BWJ) on indices of exercise-induced oxidative stress.
METHODS: Ten (n=10) apparently healthy, recreationally trained (V̇O2max 55.9 ± 6 ml·kg-1min-1), males (age 22 ± 2 yrs, height 181 ± 6 cm, weight 87 ± 8 kg, BMI 27 ± 1) volunteered to participant in the study. In a randomised, double blinded, placebo-controlled crossover design, participants consumed either a placebo, a low dose (70ml per day) of BWJ, or a high dose (140ml per day) of BWJ for 7-days. Experimental exercise consisted of a standard maximal oxygen uptake test until volitional fatigue.
RESULTS: DNA damage as assessed by the single cell gel electrophoresis comet assay increased following high intensity exercise across all groups (time x group; $p<0.05$, ES = 0.7), although there was no selective difference for intervention ($p>0,05$). There was a main effect for time in lipid hydroperoxide concentration (pooled group data, pre- vs. post-exercise, $p<0.05$, ES = 0.2) demonstrating that exercise increased lipid peroxidation. Superoxide dismutase activity (SOD) increased by 44.7% following BWJ supplementation (pooled group data, pre-vs. post supplementation). The ascorbyl free radical ($p<0.05$, ES = 0.26), α-tocopherol ($p=0.007$, ES = 0.2) and xanthophyll ($p=0.000$, ES = 0.5) increased between the pre- and post-exercise time points indicating a main effect of time. Although not significant ($P>0.05$), DNA damage and lipid hydroperoxides were reduced by 7.2% and 5.1% in the BWJ group respectively; additionally, supplementation of BWJ increased SOD activity by 14.7% compared to the placebo group.
CONCLUSION: This study demonstrates that exhaustive, high-intensity exercise causes DNA damage and lipid peroxidation, and these perturbations may be physiologically pertinent for normal biological function. Seven-day supplementation of a novel plant-derived nutraceutical product is insufficient at attenuating exercise-induced oxidative damage; however, future research should consider a larger sample size as marginal changes were observed in biomarkers associated with exercise-induced oxidative stress.

THE EFFECT OF MAGNESIUM SUPPLEMENTATION ON MUSCLE FITNESS: A META-ANALYSIS AND SYSTEMATIC REVIEW

WANG, R.1, CHEN, C.2, LIU, W.1, ZHOU, T.1, XUN, P.2, HE, K.2, CHEN, P.1

1 SHANGHAI UNIVERSITY OF SPORT; 2 BLOOMINGTON, INDIANA UNIVERSITY

INTRODUCTION: Increasing evidence supports a role of magnesium in skeletal muscle function. However, no systematic review or meta-analysis has summarized data on Mg supplementation in relation to muscle fitness in humans. Thus, this study aimed to quantitatively assess the effect of Mg supplementation on muscle fitness.
METHODS: Medline database and other sources were searched for randomized clinical trials through July 2017. Studies that reported results regarding at least one of the following outcomes: leg strength, knee extension strength, peak torque, muscle power, muscle work, jump, handgrip, bench press weights, resistant exercise, lean mass, muscle mass, muscle strength, walking speed, Repeated Chair Stands, and TGUG were included. Measurements of the association were pooled using a fixed-effects model and expressed as weighted mean differences with 95% confidence intervals <95% CIs>.
RESULTS: Fourteen randomized clinical trials targeting 3 different populations were identified: athletes or physically active individuals <215 participants; mean age: 24.9 years>, untrained healthy individuals <95 participants; mean age: 40.2 years>, and elderly or alcoholics <232 participants; mean age: 62.7 years>. Beneficial effects of Mg supplementation appeared to be more pronounced in the elderly and alcoholics, but were not apparent in athletes and physically active individuals. The results of the meta-analysis suggested that no significant improvements in the supplementation group were observed regarding isokinetic peak torque extension [WMD = 0.87; 95% CI = <-1.43, 3.18>], muscle strength [WMD = 0.87; 95% CI = <-0.12, 1.86>] or muscle power [WMD = 3.28; 95% CI = <-14.94, 21.50>].
CONCLUSION: Evidence does not support a beneficial effect of Mg supplementation on muscle fitness in most athletes and physically active individuals who have a relatively high Mg status. But Mg supplementation may benefit individuals with Mg deficiency, such as the elderly and alcoholics.

PRO –REGENERATIVE EFFECTS OF A NUTRITIVE ADMINISTRATION OF CARBOHYDRATES AND PROTEIN BY FOOD-STUFFS ON LEG STRENGTH AFTER ACUTE ENDURANCE EXERCISE

ISENMANN, E., PAGANO, S., BIZYAK, D., DIEL, P.

DEUTSCHE SPORTHOCHSCHULE KÖLN

INTRODUCTION: Ingestion of proteins and carbohydrates after exercise is believed to result in an enhancement of regeneration and physical performance after training. Mostly these nutrients are ingested by athletes via whey protein and glucose based shakes. In this study protein and carbohydrates were administrated via a meal. Effects of this meal delivered carbohydrate and protein ingestion directly after acute endurance exercise on leg strength were investigated.
METHODS: 15 male subjects <22,9J±1,98; 185cm±6,26; 79,8kg±7,71>. performed a 10km run at 80% of the individual anaerobic threshold. After exercise subjects ingested nothing , a whey protein based protein/carbohydrate shake, or white bread and sour milk cheese . All 15 subjects were exposed to these nutritive interventions after exercise in a cross over design. As a parameter for skeletal muscle regeneration leg strength was determined in a 3-repetition maximum <3-RM> squat assay of all subjects before endurance exercise and 24 h after endurance exercise.

RESULTS: As expected CK values at T24 were increased in all groups. Hemograms showed no significant changes between T0 and T24 in all groups. Leg strength at T24 was significantly reduced only in the control group. Here the maximum average weight lifted was reduced around 3.00 kg ± 5,10. In comparison in the intervention groups leg strength was only reduced around 0,63 kg ± 4.78 in the SHAKE and around 1,67 kg ± 3,50 in the bread-cheese group. So the leg strength in these groups was nor significantly different between T0 and T24.
CONCLUSION: Our results clearly indicate, that the skeletal muscle damage induced by 10 km running , which is documented by the increase in CK, is associated with a reduced leg force 24h after running. This leg force decrease can be counteract by the uptake of protein- carbohydrate combinations, indication a better regeneration after exercise. Obviously as well an uptake of protein carbohydrate by shake but also by food can result in this effect. These results are in agreement to our previous findings demonstration that parameters of muscle damage and inflammation, induced by physical activity, can be reduced by uptake of protein- carbohydrate combinations immediately after exercise. Moreover they are demonstration that eating a suitable combination of food after exercise can result in the same pro–regenerative effects like consumption of nutrition supplements.

COMPARISON EFFECT OF SHORT TERM AND PROLONGED VITAMIN C SUPPLEMENTATION ON EXERCISE INDUCED MUSCLE SORENESS AND DAMAGE IN SEDENTARY MEN

ATAEI, L.

UNIVERSITY OF NICOSIA

INTRODUCTION: The need for energy in intensive exercise necessitates an increase in oxygen consumption that can lead to increasing accumulation of free radicals and induce oxidative stress in the body . A number of studies have investigated the effect of antioxidant supplementation. However, there is a paucity of information regarding the effect of vitamin C on exercise induced muscle soreness, in sedentary men, in either the short term or with prolonged supplementation. Therefore, this study was conducted to compare the effect of short term and prolonged vitamin C supplementation on exercise induced muscle soreness and damage, in sedentary men.
METHODS: 32 healthy sedentary male volunteers with average age 23.5 ± 2.5 years, body weight 72.2 ± 7.2 kg, and height 175.3 ± 4.3 cm were randomly assigned to one of two experimental groups, namely A) The Prolonged Group (4 weeks supplementation) and B) The Short-Term Group (consumed supplement only 3 hr before Eccentric Exercise).
In both groups participants randomly received either 2gr Vitamin C (VC) – 8 people or Placebo (P)- 8 people. To minimize the effect of diurnal biological variations, each subject was tested at the same time of the day. Therefore, At the end of the 4weeks, all subjects in group A and B , performed Eccentric Exercise(EE) they were also required to take supplement (VC or P) 3hr before EE. First blood samples were collected as base line before supplementation, that was, before 4wk supplementation for group A and for group B on their attendance at the laboratory on the test day. Second blood sample was taken from both groups a 3hr hours after supplementation and before EE. A third test was taken immediately after EE and then further tests 24hr and 48 hr following EE, for the analyses of serum creatine kinase (CK), malondialdehyde (MDA) and VC. The level of perceived muscle soreness in leg extensors was also evaluated.
RESULTS: Plasma vitamin C concentrations in both group increased significantly in the VC in response to supplementation and exercise but there is no significant different between group A and B ($P<0.05$).
CK increased immediately and 3 h after exercise in both groups and 24 h after exercise only in placebo group compared to pre-exercise ($P<0.05$). MDA levels were similar between groups at the baseline, it increased significantly 24 h after exercise, only in the Placebo group. There was no significant difference in the results shown between the VC and P subjects in each group A and B. ($P<0.05$).
Perceived muscle soreness in leg extensors did not show significant change between VC and P in both group after exercise.
CONCLUSION: This finding shows that Vitamin C supplementation might play a role in protecting individuals from eccentric exercise-induced muscle damage but there is no significant different between the influence of prolonged or short time VC supplementation in this .

OP-BN42 Applied sports biomechanics and motor control

BIOMECHANICS OF NON-CONCENTRIC MARTIAL ARTS

YEUNG, Y.

UNITED KINGDOM PANGRATION ATHLIMA FEDERATION

INTRODUCTION: Non-concentric Martial Arts are those arts that claim to be not using any concentric muscle contraction or known as "brute force" by the practitioners of Internal Chinese Martial Arts. The aim of this research project is to identify and validate the various non-concentric techniques in Martial Arts. Non-concentric techniques are those movements using eccentric muscle contraction and restored muscle elasticity according to the Yin Yang theory of passive and active muscles actions.
METHODS: The research methodology is qualitative exploratory with a panel of long time practitioners and teachers of Taijiquan, Qigong , and other exercise and martial arts. The non-concentric techniques were identified from the review of literatures and videos, and discussions in various internet forums. The panel of experts verified these techniques by practice, observation, and discussion to ascertain their consistency and can be correctly performed by anyone.
RESULTS: The result is established a list of techniques identified and verified as follows: passive stances with various distribution of body weight; rotation of the crotch in moving between forward stance and backward stance; movements of the ribcage which included open, close, ascent and decent; push and pull by arm rotation; connection and coordination between joints; transitions between movements.
CONCLUSION: This research project enabled further research in isolated muscle activities for performance enhancement with eccentric muscle strength and muscle elasticity.

THE RELATIONSHIP BETWEEN CORE STRENGTH AND COUNTERMOVEMENT JUMP WITH AND WITHOUT ARM SWING

GUO, L.

GUANGZHOU SPORT UNIVERSITY

INTRODUCTION: Countermovement jump (CMJ) is a very frequent skill in many physical activities.Core strength (CS) played an important role in transferring energy or maintaining stability to promote CMJ performance (Kibler et al., 2006). But some research observed inconsistent results, they suggested the "specificity" of CS to sport event should be considered (Yaggie et al.,2006).
Therefore, we designed 12 core strength measurements (CSM) (Waldhelm et al., 2006) to investigate the specific relationship between CS and CMJ height with / without AS.
METHODS: 20 active college students were recruited (age: 22.1±0.3 year, body mass: 75.2±3.5 kg, height: 1.72±0.02 m, 7 males and 11 females) from local university.
CMJ height was calculated from vertical ground reaction force data collected using a force platform (AMTI Corporation, Watertown, MA, USA). CSM were conducted on an isokinetic training machine (Biodex Medical Systems, Shirley, NY, USA). The isokinetic tests measured core strength during extension and flexion at speeds 60°/s, 120°/s and 180°/s. The isometric tests measured core strength with the core flexed at 60°, 90° and 120° angles.
RESULTS: All of the CSM were correlated with HAS and HNAS ($p < 0.05$) significantly. No CSM correlated with the difference of CMJ height with / without AS (DAN) significantly. F180 and T120 shared 68.0% variance with HAS. T120 shared 57.0% variance with HNAS.
CONCLUSION: F180 and T120 were good predictors for HAS. T120 was a good predictor for HNAS. Core strength in specific position could be considered for coaches, athletes and recreational players to improve CMJ performance.

CONSISTENCY OF MUSCLE SYNERGIES BETWEEN LEVEL AND UPHILL LOCOMOTION

SAITO, A.1, TOMITA, A.2, ANDO, R.3, WATANABE, K.4, AKIMA, H.2

1: THE UNIVERSITY OF TOKYO , 2: NAGOYA UNIVERSITY , 3: JAPAN INSTITUTE OF SPORT SCIENCE , 4: CHUKYO UNIVERISTY

INTRODUCTION: Human locomotor behaviors responds to changes in the speed and environment . Assuming the existence of the modular control strategies based on the muscle synergy hypothesis, human locomotion might be controlled by a sequence of several muscle synergies . However, modulation of muscle synergies during locomotion on different inclines is unclear. Here, we examined similarity of muscle synergies of the lower limb between level and inclined locomotion.
METHODS: Eight subjects <26.5 ± 6.9 years old> walked and ran on a treadmill at three different speeds <1.0 to 1.6 m/s for walking and 2.5 to 4.1 m/s for running> and two grades <0% and 10% incline> for each locomotor mode. Surface electromyographic signals were recorded from 10 muscles of the lower limb, including deeper muscles such as vastus intermedius , adductor magnus, and adductor longus . Rectified EMGs were smoothed with a low-pass filer and normalized to the peak EMG across all speeds and inclination for each mode. Muscle synergies were extracted applying a non-negative matrix factorization algorithm, and relative co-activations across muscles and the temporal recruitment pattern were identified by muscle synergy vector and synergy activation coefficient, respectively. We determined the number of synergies using threshold which accounted for more than 90% of the variance accounted for in each subject. The scalar product between pairs of synergy vectors and synergy activation coefficients during level and uphill conditions were analyzed as a similarity index, with values above 0.8 recognized as similar.
RESULTS: Mean numbers of synergies were ranged from 3.8 to 4.3 for each condition 90%>. No significant difference in number of synergies was evident between level and uphill conditions at each speed. Synergy vectors 0.83> and synergy activation coefficients 0.84> at each type of synergy were similar between the conditions at each speed.
CONCLUSION: The results of this study suggest that approximately four basic patterns of locomotor muscle activity are consistent between level and uphill locomotion. Specific synergy was additionally recruited to the basic patterns when subjects added a voluntary task to their normal walking . Therefore, the recruited synergies in the lower limb may be shared across different locomotor conditions, because the natural motor behavior of locomotion was performed for individual subjects regardless of the conditions. We conclude that muscle synergies are consistent between the conditions at each locomotion speed, with only minor modulation across different locomotor tasks.

MULTI-JOINT RATE OF FORCE DEVELOPMENT TESTING PROTOCOL EFFECTS THE RELIABILITY OF MEASURES

DRAKE, D., KENNEDY, R., WALLACE, E.

ULSTER UNIVERSITY

INTRODUCTION: Isometric multi-joint tests have traditionally been used to assess peak force and rate of force development (RFD) capacity. However, the reliability of RFD variables is a notable limitation of such tests (Maffiuletti et al., 2016). Given test protocol and instruction are known to effect performance outcome in isometric tests (Sahaly et al., 2001). The aim of this study was to assess the reliability of RFD measures in the isometric squat test by comparing two test protocols and two testing angles.
METHODS: Eight male and two female participants took part in this study (age: 26.8, SD 4.5 years, strength training experience: 7.1, SD 3.03 years). Following familiarisation, participants completed two testing sessions (test and retest) one week apart. A traditional isometric peak force test (isopeak) and novel isometric explosive force (isoexp) test was assessed at two joint angles (knee flexion angle 100° and 125°). Ground reaction force-time traces were sampled at 1000Hz using force plates (Kistler type 9286BA, Winterthur, Switzerland), a custom isometric rack (Samson Equipment Inc, NM, USA) and subsequently analysed for common rate of force development measures (Haff et al., 2015). Thresholds for relative and absolute reliability were set as, ICC ≥ 0.70 and CV ≤ 15% (Haff et al., 2015).
RESULTS: Average and instantaneous RFD variables did not meet reliability criteria in isopeak at 100 or 125. The Isoexp test at 100 met reliability criteria in the RFD 0–200 (ICC = 0.92, CI = 0.77–0.97; CV = 7.00, CI = 5.06-11.78) and 0–250 variables (ICC = 0.94, CI = 0.81–0.98; CV = 6.18, CI = 4.47-10.36). The Isoexp test at 125 met reliability criteria in the RFD 0-150 (ICC = 0.95, CI = 0.85–0.98; CV = 5.83, CI = 4.22-9.77), 0–200 (ICC = 0.97, CI = 0.92–0.99; CV = 4.13, CI = 2.99-6.88) and 0–250 variables (ICC = 0.94, CI = 0.82–0.98; CV = 5.19, CI = 3.76-8.69). Instantaneous RFD variables did not meet reliability criteria in the Isoexp test at 100 or 125.
CONCLUSION: This study provides new insights into the reliability of RFD testing. Average and instantaneous RFD measures obtained using a traditional peak force test do not meet basic reliability criteria. Our findings are in opposition to the findings of Haff et al., (2015) who suggests RFD variables using the traditional test protocol demonstrates adequate reliability. Researchers assessing multi-joint RFD should proceed with the explosive RFD test rather than the traditional test.

MECHANICAL DETERMINANTS OF SPRINTING ACCELERATION IN RUGBY ATHLETES

CROSS, M.R., BROWN, S.R., MORIN, J.B., BRUGHELLI, M., DE, R., SAMOZINO, P.
UNIVERSITÉ SAVOIE MONT BLANC

INTRODUCTION: The mechanical determinants of short distance sprinting performance are currently unclear. While analyses have been performed on longer distance sprints (Morin et al. 2012), the importance of magnitude and expression of horizontal force production capabilities has not been clearly defined for short distances. This data would provide insight into important variables for targeted training development and monitoring. Our aim was to assess the relationship between key mechanical variables of horizontal force production and sprinting acceleration performance.
METHODS: Rugby code athletes (total N=238, from all levels of the game [club to elite]), performed >30m maximal sprints in field conditions. Instantaneous velocity-time data were collected using radar and processed using a macroscopic-method to determine split times at 5, 10, 20 and 30m, and horizontal force-production capabilities. Force- and power-velocity relationships (Cross et al. 2017) were compiled with associated theoretical maximal force (F0) and velocity (v0), maximum power (Pmax), and slope of the force-velocity curve (SFv). Mechanical variables were then assessed for association with split times using two stepwise regression models: 1) Pmax and SFv and 2) F0 and v0.
RESULTS: Both models explained >98.0% of the variance in performance at all distances (all $P<0.001$). Pmax strongly explained the variance in performance at all distances (88.1 to 98.0%). SFv contributed to model 1 at all distances, despite explaining less variance than Pmax (~0.2-10.0%). In model 2 both F0 and v0 significantly explained variance at all distances, with F0 primarily determining 5 and 10m performance (>78.9%), and v0 primarily determining the variance at 20 and 30m (>63.3%).
CONCLUSION: In rugby athletes, it appears that maximal horizontal force is key to sprinting ability over distances up to ~10m. However, given the frequency and importance of longer distance sprints in game scenarios, it would seem the development of maximum velocity capabilities is warranted - depending on the athletes positional requirements (Quarrie et al. 2013). Given the strong predictive power of Pmax at all distances, coaches might prioritise the development of power in deficient athletes. Once this deficiency is reduced, focus might be placed on a more balanced approach of targeting the expression of distinct force and velocity abilities. Practitioners may use these results to inform their training decisions by prescribing horizontal loading aligning with the mechanical underpinnings of targeted sprint distances.

USE OF RECOVERY STRATEGIES BY SWIMMERS DURING TRAINING AND COMPETITION

SHELL, S.1,2, CLARK, B.3, SLATTERY, K.1,4, MILLER, J.2, HALSON, S.2, KELLMANN, M.5, BROATCH, J.2,6, COUTTS, A.1
1: UNIVERSITY OF TECHNOLOGY SYDNEY, SYDNEY, AUSTRALIA, 2: AUSTRALIAN INSTITUTE OF SPORT, CANBERRA, AUSTRALIA, 3: UNIVERSITY OF CANBERRA, CANBERRA, AUSTRALIA, 4: NEW SOUTH WALES INSTITUTE OF SPORT, SYD

INTRODUCTION: Training and competition demands induce disturbances to homeostasis, and an imbalance between training stress and recovery may increase athlete fatigue. Swimmer fatigue can be reduced through inclusion of recovery strategies. Despite the perceived importance of recovery strategies, there is limited research into athlete recovery beliefs and practices during training and competition in swimmers. Therefore, the aim of this study was to understand why and how athletes, specifically swimmers, use recovery during training and competition.
METHODS: A custom-made questionnaire was developed and administered via an online survey tool (Qualtrics, Utah, U.S.A) to 76 Australian competitive swimmers (33 male, 43 female, 17 ± 3 y). The questionnaire consisted of a combination of short answer, multiple choice and 5-point Likert scale questions, and investigated the swimmers' use/implementation of different recovery techniques (active recovery, stretching, sleep, massage, compression, cold water immersion, and contrast water therapy) during training and competition. The questions focused on athlete practices and perceptions of recovery including the importance, effectiveness, timing, barriers, frequency/duration/mode of use and reasons for inclusion of each strategy in both training and competition.
RESULTS: Differences in the types of recovery strategies used during training and competition were identified, as well as the frequency and duration of use. Specifically, self-reported sleep duration was 11% greater in competition compared to in training. Likewise, cold water immersion was used 32% more in competition compared to training. However, self-reported beliefs of the importance of sleep and cold water immersion were similar for both training and competition. The biggest challenge swimmers reported was managing tiredness/fatigue during training.
CONCLUSION: Competitive swimmers use different recovery strategies in training and competition. To minimise disturbances to performance, athletes are encouraged to develop post-race recovery routines in training for use during competition. Sport scientists and coaches may benefit from using similar questionnaires to understand how and why recovery is used by their athletes. This knowledge may inform athlete education activities, and allow for enhanced individualisation of recovery.

OP-SH21 Development and effects of exercise interventions

IN SEARCH OF KEY ATTRIBUTES OF PEER LEADER FOR THE PROMOTION OF PHYSICAL ACTIVITY IN OLDER ADULTS

KRITZ, M., THØGERSEN-NTOUMANI, C., NTOUMANIS, N., MULLAN, B.

SCHOOL OF PSYCHOLOGY, HEALTH PSYCHOLOGY & BEHAVIOURAL MEDICINE RESEARCH GROUP, CURTIN UNIVERSITY

IN SEARCH OF KEY ATTRIBUTES OF PEER LEADER FOR THE PROMOTION OF PHYSICAL ACTIVITY IN OLDER ADULTS
Kritz, M., Thøgersen-Ntoumani, C., Ntoumanis N., Mullan B.
School of Psychology, Curtin University (Perth, Australia)
Introduction: Regular physical activity can help older people maintain/and or increase independence, mobility, physical health, mental wellbeing and quality of life. However, the majority of older adults are physically inactive. Peer-led interventions are considered a promising method of promoting physical activity behaviour and these approaches may be cost-effective. However, the attributes making an older peer leader effective at encouraging physical activity among their peers are currently unknown. The aim of the present study is to determine what older adults, differing in their physical activity engagement, perceive to be ideal peer leader characteristics.
Methods: A mixed-methods concurrent triangulation design was used to identify key attributes of effective older peer leaders, as perceived by participants differing in their physical activity engagement and leadership experience. Participants (N=100; M age (SD) = 75.53 (7.58); age range: 60-93) were recruited from retirement villages and existing walking groups in Perth, Australia. Participants consisted of inactive individuals interested in joining a walking group (N=46), physically active residents interested in the peer leader role (N=22), and individuals who had already served as walk peer leaders (N=15) or had taken part in other peer-led walking programs (N=17). Semi-structured interviews (N=68) were conducted and complemented with questionnaire data (N=100) to identify leadership traits that were considered important by participants. Interviews were analysed using content analysis.
Results: Questionnaire data showed that, both prospective and experienced, walkers rated the attributes "friendly", "outgoing and dependable" as the most important traits of an older peer leader. Content analysis revealed that being encouraging (47%), compassionate (44%) and inclusive (41%) were the most frequently mentioned leadership attributes across the whole sample. Most experienced leaders described effective leaders as communicative (62%), caring (62%) and enthusiastic (54%). In contrast, inexperienced leaders placed higher importance on the leader being encouraging (65%) and showing leadership competence (47%). Most experienced walkers described effective leaders as friendly (73%) and inclusive (67%) while the majority of inexperienced walkers sought a leader who can function as a competent (48%) motivator and "role model" (43%).
Conclusion
Results suggest that perceptions of an effective older peer leader may differ depending on individual leadership experience and physical activity engagement. These differing perceptions may need to be taken into account in the planning of future peer leader training in order to effectively promote walking in older adults.

HEALTH COACHING IN A PILOT EXERCISE INTERVENTION FOR PEOPLE WITH PARKINSONS DISEASE TO SUPPORT BEHAVIOUR CHANGE

MCCLEAN, S., OREILLY, G., MCGRATH, D.

UNIVERSITY COLLEGE DUBLIN

Introduction: The benefits of exercise for people with Parkinson's (PwP) are numerous however, PwP have to overcome many barriers before they can reap these benefits e.g. access to safe and affordable exercise services, disease related apathy and depression, difficulties around diagnosis, and social stigma. Only one study to date has explored the use of behavioural change theories to change and maintain exercise behaviours in PwP, focusing on Bandura's Social Cognitive Theory (SCT)1. It is currently not known what theory of behaviour change is most appropriate in the design of exercise interventions in PwP, given the complex array of motor and non-motor symptoms experienced with the condition. This pilot study sought to explore this question from a qualitative perspective.
Methods: Twenty-three PwP, split into two smaller groups, were recruited to a 12-week exercise intervention that consisted of 3 x 1 hour exercise classes per week plus one hour of health coaching every two weeks. Group A's health coaching session was based on SCT while Group B's health coaching was based on "Multi-theory model"2, which integrates different elements from a number of behavioural change theories, including self-efficacy from SCT. The structure of the sessions for both groups were therefore quite similar in terms of goal setting exercises, sharing of exercise-related knowledge, outcome expectations and focus on social support. The main difference between these approaches is that Multi-theory model incorporates the person's emotional experience, whereas SCT does not. The health coach was an exercise scientist and accredited psychotherapist. He¬ facilitated both Group A and Group B sessions with a participatory, person-centred approach. Following each session with the agreement of participants, the health coach provided an anonymous report of the session on the themes that were discussed in both sessions. These reports were analysed using thematic analysis.
Results: Improvements in self-efficacy and deriving strong social support from the group were prevalent themes in both groups. Both groups reported similar life challenges e.g. uncertain future, anxiety, self-consciousness, safety and physical debilitation. Similarly, themes such as hope, inspiration, learning and humour were evident in both groups. A prevalent theme in Group A was task-specific self-efficacy. Socio-cultural challenges featured more in Group B's, and the personal and emotional experiences of those challenges.
Conclusions
PwP need a supportive environment to develop the psycho-social competencies required to self-manage their complex condition, and this can be achieved in a group setting. Providing space for emotional expression is an important element that should be incorporated into health coaching with an appropriately trained facilitator.

COMPARATIVE EFFECTIVENESS OF EXERCISE TO TREAT BINGE EATING DISORDERS: A META-ANALYSIS

HUANG, S.

CHINA INSTITUTE OF SPORT SCIENCE

Background

In 1959, Binge Eating Disorders (BED) was to describe recurrent episodes of eating a large amount of food without self-control as a consequence of uncomfortable full feelings and senses of guilt, listed in DSM-5 in 2013. Different to Bulimia Nervosa, BED patients will not adopt subsequently compensatory behaviors, like vomiting or taking cathartics, therefore BED groups were usually diagnosed with obesity or overweight. Exercise was viewed as an effective intervention for obesity, so this study collected all previous published trials using exercises to quantify the effect of exercises to treat BED group.
Methods: Medline and PubMed databases were searched to identify eligible randomized clinical trials published in English from 1996 to 2016 with keywords "exercise", "physical activity", "binge eating disorder", "RCT", and "human". A total of 27 studies were identified. Compared with the control group, moderate intensive exercise was chosen as the treatment. Considering the inconsistent measurements of intervention outcomes, studies containing Binge Eating Scale(BES), Beck Depression Inventory (BDI) and prevalence of BED abstinent were chosen. As a result, only 8 studies were included. All data analysis was conducted using Stata 14.1. Random effect meta-analysis was used for categorical and/or continuous responses, where appropriate.
Findings
Based on 8 RCT studies, 3 heterogeneity studies recorded the prevalence of BED abstinent (I2=83.9% , p=0.002), and no significant differences between control and exercise groups(R2:10.05, 95%CI: 0.54~186.83). 5 studies reported scores of BDI. Because 2 of them used combined interventions, the subgroup analysis was applied, totally, I2=70.4%, p=0.009, and exercise treatment demonstrated a significant reduction of BDI (i.e., exercise-only group, SMD:-1.14, 95%CI: -1.85~-0.43; exercise-combined group, SMD:-1.54, 95%CI:-2.35~-0.73). Lastly, the remission data provided by 4 studies, based on the scores of BES. Because 2 of them used combined interventions, the subgroup analysis was also applied. There was heterogeneity among 4 studies, I2=71.6%, p=0.014, and treatment demonstrated significant changes in scores, exercise-only group, SMD: 1.46, 95%CI: 0.75~2.17; combined group, SMD: 0.589, 95%CI: 0.202~0.976.
Conclusions
According to meta-analysis, exercise-only intervention did not show any statistically significant effect on BED abstinent, but in terms of reduction in binge eating behaviors. Whereas, combined therapy showed the more positive results in all clinical indicators, which indicated combined treatment would be more beneficial for BED patients recovery.

EFFECT OF EXERCISE INTERVENTION ON EXECUTIVE FUNCTION OF CHILDREN WITH AUTISM SPECTRUM DISORDERS: AN EVENT-RELATED POTENTIAL AND BEHAVIORAL STUDY

SUNG, M.C.1, CHEN, P.L.1, MA, W.Y.2, HUANG, C.Y.1, CHU, C.H.1, PAN, C.Y.1

1: NATIONAL KAOHSIUNG NORMAL UNIVERSITY , 2: NATIONAL TAIWAN NORMAL UNIVERSITY

Introduction: Autism spectrum disorders (ASD) are neurodevelopmental disorders that identified through developmental deficits in social interaction, communication, and restricted and repetitive patterns of behaviors (American Psychiatric Association, 2013). In addition, the children with ASD also experience executive function deficits such as attention and inhibitory control (Tsai, Pan, Wang, Tseng, & Hsieh, 2011). To-date, many studies have already confirmed that exercise intervention is beneficial to typically developing children on executive function. Nonetheless, few studies have probed into exercise intervention as a means of improving the executive function of children with ASD. To the best of our knowledge, this study provides the first electrophysiological evidence for the brain activity induced in children with ASD's by long-term exercise intervention.
Methods: Twenty children with ASD, aged 6 to 12, were divided into intervention group (n = 10) and control group (n = 10). The intervention group took 12 weeks of in-line skating exercise intervention, and another group continued their daily activities throughout the study. Visuo-spatial attention orienting task was administered for executive function while recording event-related potentials (ERPs) simultaneously before and after the 12 weeks intervention. Mixed design of three-way and four-way ANOVAs were used to compare the behavioral (i.e., reaction time, accuracy) and ERP (i.e., N2, P3 and CNV components) performance, respectively.
Results: There were no significant differences between the experimental group and control group before and after the intervention in the reaction time, accuracy, N2, P3 and CNV components.
Discussion: The current study reveals that there were no significant improvements in both behavioral and ERPs performance of the intervention group after the 12 weeks in-line skating exercise intervention, which might be attributed to the small sample size and large within person variability. Our results provide initial evidence of brain activity in children with ASD after the long-term exercise intervention. Since engaging in the physical activity and exercise is crucial for the children with ASD; future research is required to clarify which types of exercise intervention are most conducive to executive function in children with ASD.

LONG-TERM EFFECTS OF PARTICIPATION IN A 12 WEEK COMMUNITY-BASED EXERCISE REHABILITATION PROGRAMME ON CANCER SURVIVORS LEVELS OF FATIGUE, DEPRESSION AND QUALITY OF LIFE

CANTWELL, M.1, MOYNA, N.M.1, FURLONG, B.1, MCCAFFREY, N.1, WOODS, C.2

1 DUBLIN CITY UNIVERSITY; 2 UNIVERSITY OF LIMERICK

INTRODUCTION: The aim of this study was to determine the long-term effects of a community-based exercise programme, 'MedEx Move On', on cancer survivors' levels of fatigue, depression and quality of life.
METHODS: Adults with an established diagnosis of cancer, who had completed their adjunctive therapy, were referred to 'MedEx Move On'. Participants attended two 60 minute supervised exercise classes each week for 12 weeks. Fatigue, depression and quality of life were measured using questionnaires (Functional Assessment of Cancer Therapy (FACT)–Fatigue Scale, Patient Health Questionnaire

Depression Scale and FACT–General Questionnaire) at baseline, programme completion (week 12) and 12 month follow-up. One-way repeated measures ANOVAs were used to compare mean differences. Post-hoc tests were conducted to identify where the differences occurred.
RESULTS: Twenty cancer survivors (mean age 52 ± 9 yrs; 70% female) completed the trial. Cancer diagnoses were breast (60%), colorectal (20%), prostate (15%) and cervical (5%). There was a statistically significant reduction in depression and fatigue measures at 12 weeks, which was maintained at the 12 month follow-up ($F=7.463$, $p<.05$; $F=10.598$, $p<.05$). A statistically significant improvement was observed for quality of life from baseline to week 12 and the 12 month time point ($F=9.771$, $p<.05$).
CONCLUSION: Participation in a 12 week community-based exercise rehabilitation programme has a long-term effect on cancer survivors' self-reported levels of fatigue, depression and quality of life.
This research is funded by the Irish Cancer Society.

(FROM) VIRTUAL (TO) REALITY: CAN VIRTUAL EXPERIENCES OF NATURE ENCOURAGE PEOPLE TO VISIT NATURAL ENVIRONMENTS?

CALOGIURI, G., LITLESKARE, S., BIRKHEIM, S.L., THURSTON, M.
INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

Introduction: Visiting natural environments has been shown to be beneficial for people's health: not only can being in nature facilitate physical activity, it can also promote psychophysiological restoration from stress. Virtual reality (VR) has emerged as a potentially valuable tool in the field of lifestyle-change interventions. Specifically, it might also be used to encourage people to engage in 'active visits' to natural environments. Thus, the purpose of this study was to explore the potential of VR as a tool for eliciting enhanced motivation for visiting real natural environments.
Methods: This study is part of a larger project investigating the effectiveness of VR in reproducing 'green-exercise' outcomes (Calogiuri et al., 2017). Twenty-six healthy adults (46% females; 26±8 yo; BMI: 23.12±5.03) were exposed, in a randomized cross-over design, to two VR conditions: one while sitting on a chair and one while walking on a manually driven treadmill. The VR technology consisted of a head-mounted display with headphones reproducing a first-person 360o video and sound of a nature walk. After each condition, the participants reported their motivation for visiting the natural environment shown in the VR video ('motivational effect'; ME), alongside measurements of enjoyment and affect. Additional measurements included presence, perceived environmental restorativeness (PER), and background characteristics (sex, age, BMI, and exercise levels). Moreover, data from open-ended questions were analysed thematically to give in-depth insight into participants' perceptions.
Results: The ME did not significantly differ between the sitting and the treadmill condition, although enjoyment and positive affect were significantly higher in the treadmill. The ME was significantly and positively correlated with 'realism', PER and (in the treadmill) enjoyment, whereas no significant correlation was found with affect or any of the background characteristics. In both conditions, a mediational analysis showed an indirect effect of 'realism' on ME via the PER component 'fascination'. The qualitative data corroborated the quantitative findings, but also revealed large inter-individual differences in participants' perceptions of the VR experience as well as the extent to which they thought it could influence people's motivation.
Discussion: VR technology might have the potential to encourage people to engage in 'active visits' to natural environments, especially if the VR is highly realistic and shows environments with high restorative value. Because of better affective responses, administering the VR in concomitance with treadmill-based walking might have a stronger effect on future behaviour. In order to explore these associations further, future studies should apply intervention designs with follow-up assessments.

OP-MI03 Multidisciplinary perspective on youth to young adults athletes

PSYCHOLOGICAL CORRELATES BETWEEN SPORT COMMITMENT PROFILES AMONG ADOLESCENT ATHLETES.

BERKI, T., PIKÓ, B.
UNIVERSITY OF SZEGED

Introduction: Physical activity and sport participation is one of the key for healthy lifestyle. Many motivational theories tried to understand reasons behind adolescent sport participation; therefore, the purpose of this study was to examine psychological scales and sport motivation among different sport commitment profiles.
Methods: Participants were 526 adolescent athletes ranging in age from 14 to 18 years . Several scales were used in this study: Sport Commitment Questionnaire 2 , Satisfaction with Life Scale , Consideration of Future Concequences Scale and Aspiration index . Sport Commitment profiles were created by cluster analysis using commitment determinants and ANOVA were used for further analysis.
Results: Three Sport Commitment profiles were emerged. The first profile was based on the Enthusiastic athletes and they had higher scores on Sport Enjoyment, Desire to Excel, Social Support, Personal Investment, Valuable Opportunities, but lower on Other Priority. The second profile were the based on the Obligatory athletes : they had higher scores on Other Priorities and Social Constraints, but lower on Sport Enjoyment, Social support, Desire to Excel, Valuable Opportunities and Personal Investment. The last group, Entrapped athletes had low scores on all of the determinants. Analyses of variance compared emergent clusters on different psychological scales. Enthusiastic athletes had significantly higher scores on SWL, CFC and intrinsic aspirations. Obligatory athletes had significantly higher scores on extrinsic aspirations. Age differences showed that Entrapped athletes were significantly older than athletes with other profiles.
Discussion: The cluster analysis showed diverse sport commitment profiles. As it was expected results revealed that Enthusiastic athletes had significantly higher scores on most of the psychological scales. Positive experience of physical activity and sport may have a significant role in life satisfaction and affect the short- and long-term future goals. Our results suggest that athletes who participate in sport only for obligatory reasons are more likely to have extrinsic aspirations. As the age increases, the motivation to sport decreases. More investigations are needed to understand the psychological background of sport motivation, but we believe that our study provides useful information for better understanding of young athletes' sports participation.

MATURITY STATUS AND INJURY RISK IN HIGHLY TRAINED MIDDLE-EASTERN YOUTH ATHLETES

REJEB, A., JOHNSON, A., FAROOQ, M., PULLINGER, S., VAEYENS, R., WITWROUV, E.

ASPETAR, GHENT UNIVERSITEIT

INTRODUCTION: There is limited and contrasting evidence on the relationship between maturity and injury in youth sports. Studies of the anthropometric characteristics and biological maturity status as injury risk factors in youth middle- eastern are also limited, highlighting the need for more research to be conducted.
The purpose of the present study was to investigate injury according to biological maturity in highly trained youth athletes based at a Middle Eastern Sports Academy
METHODS: A total of sixty-seven male athletes representing four sport disciplines were enrolled and grouped into 2 sport categories: individual sports and racquet sports .
Assessment of risk factors:
Athletes' anthropometric characteristics were assessed using non-invasive methods to calculate age at peak height velocity and total years from PHV. Participants predicted mature height were collected and categorized into four PMH quartiles. Consenting athletes had wrist and hand radiographs taken for assessment of skeletal age , using Fels method. Early and late maturers were those with a SA of >1 year older or younger than their chronological age , respectively.
RESULTS: For the total sample across all sport groups, 43 <64%> athletes had one or more injuries totaling 212 injuries. Injury incidence was 4.9 injuries per registered athlete. Survival analysis using Cox regression of maturity status found that early mature athletes had two-fold higher injury risk over time compared to late maturers HR <2.04, 95%, 1.15-3.61, P=0.015>. PMH was associated with injury risk HR <1.05; 95% CI: 1.01-1.08, p=0.006>.
Compared to participants in the 1st quartile <<176cm> for PMH, athletes in the 4th quartile <≥ 184 cm> have higher injury risk HR <2.41, 95% CI: 1.42 – 4.08, p=0.001>.
In this study, injury risk in racquet sports was similar to individual sports HR 1.14 <95% CI: 0.86 – 1.52, p= 0.37>.
CONCLUSION: Early maturity and gradient for PMH were significant predictors of injuries in youth.

AN EXAMINATION OF THE FUNCTIONAL MOVEMENT SCREEN IN YOUTH ATHLETES.

WRIGHT, M.D.

TEESSIDE UNIVERSITY

INTRODUCTION: The Functional Movement Screen (FMS) is an assessment tool consisting of 7 functional tasks, rated on a scale of 0 to 3 and totalled to quantify movement quality (FMS total). Whilst FMS total is often used in youth sport, it assumes the FMS is uni-dimensional and does not consider that the tasks may measure different constructs, or how each task may be affected by maturation. The aims of this research were to identify the internal consistency and factor structure within the 7 tasks in youth athletes and to investigate the effect of maturity upon each task.
METHODS: The seven FMS tasks and anthropometric variables were measured in 144 youth athletes (96 female, 48 male) from multiple sports as part of an athlete support programme (age 14.1 ± 2.3 years; standing stature, 162.0 ± 13.9 cm; sitting stature, 66.6 ± 20.7 cm; body mass, 71.0 ± 14.9 kg; 1.27 ± 2.0 years from peak height velocity [PHV]). Biological maturation was estimated from anthropometric data and players were categorised as before-PHV (<-0.5 years), at-PHV (-0.49-0.50 years) and after-PHV (>0.51 years). Each FMS task-score was converted to standardised units (z-score) and the internal consistency evaluated before subjecting the data to principle component analysis (PCA). Principle components were extracted when an eigenvalue was greater than 1. A General Linear Model was used to evaluate differences between maturation groups whilst controlling for differences in gender.
RESULTS: The 7 tasks of the FMS showed poor internal consistency (Cronbach's Alpha, ±90% Confidence Limit; 0.53, ±0.10). The Kaiser-Meyer-Olikn measure of sampling adequacy and Bartlett's test of sphericity indicated the data were suitable for PCA, with values of 0.64 & p<0.01 respectively. Two components were extracted, representing 47% of the total variance. The highest loadings for principle component 1 were; In-line Lunge (0.71), Rotatory Stability (0.67) and Hurdle Step (0.61). The highest loadings for principle component 2 were Shoulder Mobility (0.73) and Active Straight-Leg Raise (0.66). Small but likely decrements in task performance were observed in athletes who were before-PHV. In-line Lunge (Effect size ±90% Confidence Limit; -0.45, ±0.49), Hurdle Step (-0.48, ±0.49), Rotatory Stability (-0.37, ±0.49) and Trunk Stability Press-up (-0.55, ±0.46) were all lower compared with athletes at-PHV, whilst In-line Lunge (-0.44, ±0.37), Rotatory Stability (-0.44, ±0.37) and Trunk Stability Press-up (-0.33, ±0.34) were lower than those after-PHV. No likely differences were observed between athletes at- or after-PHV or for the other tasks (Deep Squat, Active Straight-Leg Raise or Shoulder Mobility).
CONCLUSION: The 7 task have poor internal consistency and do not represent a single uni-dimensional factor. When evaluating FMS data on youth athletes, individual task scores are more relevant than a total score. Furthermore, in our population of young athletes, a small but clear maturation affect was observed in four of the seven tasks.

DO PERFORMANCE DETERMINANTS CHANGE WITH AGE IN YOUNG SWIMMERS?

SEFFRIN, A., LIRA, C.A.B., ANDRADE, M.S.

UNIVERSIDADE FEDERAL DE SÃO PAULO

INTRODUCTION: Swimming is a very popular sport with great adherence of children and adolescents. It is known that swimming performance is influenced by several factors, such as anthropometric and physiological aspects. However, it is not clear if the level of association of these variables with swimming performance depends on the age of the swimmer. The aim of the present study was to describe the level of association of height, total body mass, body composition and muscular strength and the performance in 100 meters freestyle and to compare the association of variables between different age groups from 11 to 23 years old.
METHODS: Sixty swimmers participated in the study (13.80 ± 2.61 years, 1.62 ± 0.10 m, 52.36 ± 12.01 kg]), 44 males and 16 females were divided into three groups (A, B e C) according to age. (A) 11 or 12 years old, (B) 13 or 14 years old and (C) 15 to 23 years old. They were submitted to anthropometric evaluations to determine total body mass (kg), height (m), fat mass (%) and fat free mass (kg) through Dual-energy X-ray absorptiometry. Isokinetic peak torque (Nm) of flexors and extensor knee muscles were assessed at 60°/s. Handgrip strength (kgf) was measured using a handheld dynamometer with an accuracy of 2 kgf. The relations of these variables along with the performance were analyzed by scatter plots and Pearsons linear correlation coefficients, with a significance level of 5%.
RESULTS: The data presented normal distribution (Shapiro-Wilk) and homogeneous variances (test F). Performance over 100 meters was significantly associated with: total body mass for male groups A (r = -0.58, P = 0.02) and female group A (r = 0.84, P = 0.04) and male group B (r = -0.78, P < 0.01), height for male groups A (r = -0.51, P = 0.05) and male group B (r = -0.57, P = 0.02), fat mass for female

group A (r = 0.84, P = 0.04) and female group B (r = 0.84, P = 0.04), fat free mass for male groups A (r = -0.60, P = 0.01) and male group B (r = -0.83, P < 0.01). Considering the neuromuscular properties association with performance, significant values were shown for PT Flex for male groups A (r = -0.62, P = 0.01) and male group B (r = -0.84, P < 0.01) , and for female group C (r = -0.99, P = 0.01), PT Ext for male group A (r = -0.51, P = 0.04) and male group B (r = -0.76, P < 0.01) and the handgrip strength for male group A (r = -0.77, P < 0.01) and male group B (r = -0.74, P < 0.01).
CONCLUSION: The data of the present study show that the performance was related to anthropometric and neuromuscular variables and, in addition, the associations vary according to age and sex. Height, fat free mass and muscular strength are significantly associated with performance for males between 11 to 14 years old, but for females of the same age, the fat mass was the most significantly variable associated with performance. The understanding of these variables can contribute to the development of proper training programs for each age group, thereby maximizing results.

THE MISCONCEPTION OF LEARNING THE TENNIS SERVE: THE AD VERSUS THE DEUCE COURT PARADOX

FERRAUTI, A., FETT, J., VUONG, J., OBERSCHELP, N.

RUHR-UNIVERSITY BOCHUM

INTRODUCTION: The official rules of the International Tennis Federation say that players have to serve from two different basic positions (deuce and ad court side) into two different target boxes during singles and doubles tennis match. Principally, the applied techniques could be the same regarding the underlying kinematics. While coaches and scientists agree that the serve is one of the most important techniques in todays top level tennis (Girard et al, 2005; Kovacs, 2007) we recommend to adjust both techniques in order to improve the time cost: learning benefit ratio. In a comparative study, elite junior squad players of the German Tennis Federation were analyzed with respect to kinematic parameters during the service from the ad and the deuce court side.
METHODS: For the investigation, the service motions (flat 1st serve) of 15 elite junior squad players (age: 14.7 ± 1.8 years, weight: 61.3 ± 15.7 kg, height: 175.8 ± 15.4 cm) were captured from both service positions in a matched and counterbalanced order by using a Vicon Motion Capturing System. A specifically modified version of the whole body model originally designed by the University of Western Australia (Reid et al., 2008) was used to record the kinematic parameters. After a warm-up consisting of serves with increasing velocity, eight first serves were performed to a target in the middle of both service boxes. For comparative analysis of the parameters, the respective values of the fastest three serves were averaged. The detection of the peak ball speed was recorded using a Stalker Professional Sports Radar.
RESULTS: Mean service velocity was similar from both sides (deuce: 151.4 ± 19.8 vs. ad: 150.5 ± 19.4 km/h; ES 0.04). In the basic position, the front foot angle to the baseline (deuce: 39.7 ± 17.6 vs. ad: 31.1 ± 17.4°; ES 0.50*) and the thorax axis (deuce: 60.9 ± 15.7 vs. ad: 69.6 ± 15.0°; ES 0.57*) were significantly different, each showing moderate effect sizes. Total thorax rotation from the end of the loading phase until the hitting point showed a strong significant effect with a larger rotation angle from the deuce court side (deuce: 114.9 ± 16.5 vs. ad: 96.2 ± 16.6°; ES 1.13*).
CONCLUSION: The results indicate a partly but insufficient adjustment of the foot positioning when changing from the deuce to the ad court side. Coaches can be recommended to teach an adjustment of foot positioning in relation to the target box and not in relation to the baseline. It can be speculated that the baseline seems to be the more logical reference point for young players.

THE INFLUENCE OF WANTED SUPPORT AND RECEIVED SUPPORT ON AFFECT: A CROSS-CULTURAL STUDY AMONG ATHLETES IN UK AND CHINA

FU, D.

UNIVERSITY OF ESSEX

Introduction: The presence of supportive relationships can play a crucial role in sporting contexts yet the actual receipt of supportive behaviours from these relationships is sometimes ineffective. The support adequacy model predicts that optimal social support occurs when the amount of support individuals receive matches what they want (Dehle, Larsen, & Landers, 2001), but limited research has examined this model in sport. Further, research has highlighted that cultural differences may exist in social support processes (Kim, Sherman, & Tylor, 2008). As such, this study examined the support adequacy model among British and Chinese athletes.
Methods: The study comprised 236 British athletes (107 females, Mage = 20. 7, SD = 2.4 years) and 265 Chinese athletes (189 females, Mage = 20. 8, SD = 2.5). Participants reported the amount of support they wanted and received during the week, along with the satisfaction with support, and their positive and negative affect. Polynomial regression analyses were conducted and response surface graphs plotted.
Results: British athletes wanted [t(499) = -2.54, p = .01, d = .23] and received [t(499) = -2.38, p = .02, d = .21] less support than Chinese athletes, but there was no statistically significant difference for satisfaction with support [t(499) = 1.67, p = .10, d = .15]. The total effects of support adequacy model explained 30% and 36% of the variance in positive and negative affect respectively in the British sample ($p < .05$), and 32% and 37% of the variance in positive and negative affect respectively in the Chinese sample ($p < .05$). More specifically, across both samples: 1) athletes experienced better positive affect (but not the negative affect) when they received adequate support (received= wanted), especially at higher levels of received and wanted support; 2) athletes experienced worse affect (both positive and negative) when wanted and received support were not congruent; 3) athletes experienced better affect when they experienced overprovision of support rather than underprovision; 4) support (in)adequacy predicted affect indirectly through satisfaction with support.
Discussion: Overall, the study found that received support was associated with more favourable affect when it was congruent with what athletes wanted, these effects were partially mediated by support satisfaction, and these relationships were generally consistent across British and Chinese athletes despite differences in the absolute amount of support each sample wanted and received. The findings provide support for the support adequacy model and highlight that novel insights can be provided by using polynomial regression in social support research.

IS-PM12 Mechanisms and strategies to increase mitochondrial biogenesis

MOLECULAR REGULATION OF MITOCHONDRIAL ADAPTATIONS TO EXERCISE

ZIERATH, J.

KAROLINSKA INSTITUTET, STOCKHOLM AND UNIVERSITY OF COPENHAGEN, COPENHAGEN

The circadian clock, an intrinsic molecular system in virtually all cells, is a key element in homeostatic regulation that controls a large array of metabolic genes. Disruption of the circadian clock is linked to the development of type 2 diabetes. Importantly, intimate links between epigenetic regulation and the circadian clock exist that are likely to contribute to the plasticity of insulin sensitive organs to exercise and nutrition. Therefore, we are currently addressing whether synchronizing exercise and nutrient interventions to the molecular circadian clock will maximize the health promoting benefits of exercise to enhance insulin sensitivity and mitochondrial biogenesis. Work is now underway to identify the time of day for optimal exercise intervention to induce the greatest metabolic effect on signal transduction, mitochondrial function, and expression of exercise-responsive genes. The ultimate goal is to develop novel strategies to maximize the health promoting effects of exercise and nutrition by synchronizing these interventions with the peripheral clocks.

CAN WE OPTIMISE THE EXERCISE TRAINING PRESCRIPTION TO MAXIMISE IMPROVEMENTS IN MITOCHONDRIA FUNCTION AND CONTENT?

BISHOP, D.

VICTORIA UNIVERSITY

While there is agreement that exercise is a powerful stimulus to increase both mitochondrial function and content, we do not know the optimal training stimulus to maximise improvements in mitochondrial biogenesis. This presentation will focus predominantly on the effects of exercise on mitochondrial function and content, as there is a greater volume of published research on these adaptations and stronger conclusions can be made. The results of cross-sectional studies, as well as training studies involving rats and humans, suggest that training intensity may be an important determinant of improvements in mitochondrial function (as determined by mitochondrial respiration), but not mitochondrial content (as assessed by citrate synthase activity). In contrast, it appears that training volume, rather than training intensity, may be an important determinant of exercise-induced improvements in mitochondrial content. The importance of mitochondria for both athletic performance and health underlines the relevance of this topic for ECSS delegates. This topic will therefore be of interest to both delegates interested in athletic performance, as well as those interested in population health.

NUTRITIONAL STRATEGIES TO ENHANCE MITOCHONDRIAL ADAPTATION TO ENDURANCE EXERCISE

PHILP, A.

GARVAN INSTITUTE OF MEDICAL RESEARCH

Endurance exercise, when performed regularly as part of a training program, leads to increases in whole-body and skeletal muscle-specific oxidative capacity. The increase in mitochondrial biogenesis (increased volume and functional capacity) following endurance training is fundamentally important as it leads to greater rates of oxidative phosphorylation and an improved capacity to utilize fatty acids during sub-maximal exercise. Given the importance of mitochondrial biogenesis for skeletal muscle performance, considerable attention has been given to understanding the molecular cues stimulated by endurance exercise and the role that alterations in nutritional status may play in augmenting this adaptive response. In this session, I will discuss a variety of exercise and nutritional approaches used to augment mitochondrial adaption to exercise, examine proposed modes of action and finally discuss the feasibility of such approaches to alter mitochondrial adaptation to endurance training in humans.

INTRODUCTION: Over the previous twenty years, various genetic markers have been associated with endurance athlete status. Here, we used a whole-genome approach in different ethnic groups to detect genetic markers associated with endurance athlete status and related phenotypes.
METHODS: We used a multi-stage genome-wide association study to identify genetic markers linked with endurance and functional analysis, such as VO2max, VO2max trainability, muscle fibre composition.

RESULTS: In the discovery phase, we identified 15 gene polymorphisms associated (P<0.05) with endurance athlete status in three case-control studies (211 elite Russian long-distance athletes vs 252 controls; 96 elite Russian middle-distance athletes vs controls; 60 elite Japanese endurance athletes vs 406 controls). In the replication phase, we confirmed the association of 4 markers (favorable alleles: HFE rs1799945 A, NACC2 rs4409473 C, near LINC00444 rs4941615 T, CTC-229L21.1 rs6878578 C) in additional case-control studies (25 African endurance athletes vs 661 controls; 21 American endurance athletes vs 347 controls; 163 European endurance athletes vs 503 controls). Overall, 11 genetic markers passed meta-analysis criteria (P<0.0033), with one polymorphism (NACC2 rs4409473) reaching genome-wide significance level (P<10-9). To explain these associations, we performed a functional analysis, revealing 6 SNPs associated with maximal oxygen consumption rate (mVO2max): RPL15P3 rs12199205 A, near SMIM20 rs17685537 A, HFE rs1799945 G, near CNR1 rs3857490 T, NACC2 rs4409473 C, ARHGAP15 rs938817 A. In addition, NACC2 rs4409473 CC genotype was associated with greater increase of VO2max following a 12-week aerobic training in Polish women (P=0.039). Furthermore, rs3857490 T allele (near CNR1) was associated with an increased percentage of slow-twitch muscle fibres (P=0.018).
CONCLUSION: In conclusion, we identified 6 genetic markers associated with endurance athlete status and related phenotypes.

AGE-SPECIFIC RESPONSE OF SKELETAL MUSCLE EXTRACELLULAR MATRIX TO ACUTE RESISTANCE EXERCISE

CSAPO, R., LIEBENSTEINER, M., NACHBAUER, W., WESSNER, B.
UNIVERSITY FOR HEALTH SCIENCES, MEDICAL INFORMATICS AND TECHNOLOGY

INTRODUCTION: Skeletal muscle is a highly malleable tissue that is sensitive to mechanical and metabolic stress as imposed by physical exercise. While studies typically report the effects of exercise on contractile muscle cells, little is known about the adaptability of the extracellular matrix (ECM), which has been shown to play an essential role in the development[1], growth and repair of muscles[2] as well as the transmission of contractile force[3]. The fibrotic phenotype often observed at older age[4] indicates altered ECM regulation. The purpose of this pilot study was to compare the changes in ECM gene expression induced by an acute bout of resistance exercise between young and elderly men.
METHODS: Five young (23.8 ± 2.2 y) and 5 elderly (66.8 ± 4.1 y) untrained men participated in a single training session consisting of unilateral leg press and leg extension exercise (3 × 12 reps at 70% 1-RM). Six hours post-exercise, biopsies were taken from the m. vastus lateralis of both the trained and non-trained leg. Total RNA was extracted and used to profile the expression of 84 genes related to the ECM by a PCR array. Eight selectively chosen genes that were either induced or repressed by exercise were validated on individual samples using quantitative real-time PCR. Differences in (> 1.5–fold) changes between young and old participants were determined by Mann-Whitney U tests (IBM SPSS Statistics).
RESULTS: PCR array data showed differential gene expression, with 4 (COL7A1, SELE, MMP15, CTNND2) and 9 genes (ITGB3, COL1A1, ITGAL, CD44, LAMB3, CDH1, SELL, ADAMTS1, ADAMTS8) being selectively down- and upregulated, respectively, in either young or older subjects. Four further genes (MMP3, LAMA1, MMP9, SPP1) were upregulated in young but downregulated in older subjects. Of the 8 genes validated on individual samples, MMP9 gene expression increased in young and decreased in older subjects (Y: 9.7-fold vs. O: 0.2-fold change, p = 0.032). MMP15 was downregulated in older subjects only, although differences between age groups failed to reach significance (Y: 1.0-fold vs. O: 0.6-fold change, p = 0.056). A significant correlation between leg extension 1-RM and COL7A1 expression (ρ = -0.71, p = 0.023) further indicated a potential influence of baseline fitness levels.
CONCLUSION: The results of our pilot study indicate that acute resistance exercise induces or represses ECM gene expression in skeletal muscle in an age-specific manner. In particular, the activity of genes encoding several matrix metalloproteinases (MMP3, MMP9, MMP15) may be of relevance for the pathogenesis of muscle fibrosis. Further research including larger samples is required to verify the age-associated differences in gene expression profiles and establish their functional implications.

DNA INSTABILITY FOLLOWING ACUTE AEROBIC EXERCISE: A SYSTEMATIC REVIEW AND META-ANALYSIS

TRYFIDOU, D.V.1, MCCLEAN, C.1, NIKOLAIDIS, M.G.2, DAVISON, G.W.1
1: UU , 2: AUTH

INTRODUCTION: Exercise is widely recognized for its health enhancing effects, contributing to the prevention of cardiovascular disease and other chronic conditions. Despite this, previous research has establish a link between strenuous/exhaustive exercise and the increased formation of reactive oxygen and nitrogen species (RONS). An overproduction of RONS without sufficient antioxidant defence mechanisms can lead to a state of (chronic) oxidative stress. DNA is a vulnerable target of RONS attack and thus can be altered in several ways. If left unrepaired, such DNA modifications may cause genetic instability. This review/meta-analysis aimed to systematically investigate studies reporting DNA damage after an acute aerobic exercise bout, assessing the overall effect.
METHODS: Web of Science, PubMed, MEDLINE, EMBASE and Scopus were searched until March 2017 and limited to articles published in English. Risk of bias was assessed using a tool recommended by the Cochrane Back Review Group. Outcomes included multiple time-points (TPs) of measuring DNA damage post-exercise, two different quantification methods (Comet Assay and 8-OHdG) and protocols of high-intensity (≥75% VO2 max) and long duration (≥42km).
RESULTS: Literature search identified 4202 non-duplicate records of which 32 studies were included in the meta-analysis with a total of 423 participants. Across studies, risk of bias was found to be low. The evidence was strong, showcasing an increase in DNA alteration immediately following acute aerobic exercise with a large effect size at TP 0 (SMD = 1.19; 95% CI: 0.95, 1.42; P < 0.05) while significance remained at TP 1 with a moderate effect (SMD = 0.62; 95% CI: 0.31, 0.94; P < 0.05) but no differences were observed in further TPs. When comparing the two methods of DNA damage, significance was observed only in studies using the Comet Assay. Finally, when isolating protocols of high-intensity and long duration, significance remained stable (SMD = 1.65; 95% CI: 0.46, 2.83; P < 0.05 & SMD = 0.53; 95% CI: -0.25, 1.32; P < 0.05, respectively).
CONCLUSION: A large increase in DNA damage occurs following acute aerobic exercise. The relationship between exercise and DNA damage can be explained through the hormesis concept, which is somewhat one-dimensional. This describes how exercise modulates any advantageous or harmful effects mediated through levels of RONS by increasing DNA oxidation between the two end points of the hormesis curve, physical inactivity and overtraining. We propose a multi-dimensional model in order to develop a better understanding of the complexity of the relationship between DNA integrity and exercise.

SEROTONIN GENETIC VARIANTS' LINKAGE TO EXERCISE MOTIVATION AND AEROBIC/ANAEROBIC PERFORMANCE

BEN-ZAKEN, S.

WINGATE ACADEMIC COLLEGE

INTRODUCTION: Motivation plays a pivotal role in physical activity (PA) and performance. However, the genetic mechanism underlies motivated performance is unknown. A possible modulator of PA motivation is serotonin - a neurotransmitter affecting a wide range of physical and psychological functions. We explored the role of serotonin receptor (SR) genetic variants in PA motivated performance.
METHODS: One hundred and sixty-three participants responded to aerobic/anaerobic motivation questionnaires, performed aerobic/anaerobic tests, and their genomic DNA was analyzed.
RESULTS: Three SR genetic variants (rs6311, rs6313, rs3742278) were associated with motivation and performance. Participants carrying zero or one minor alleles were characterized by moderate aerobic/anaerobic motivation and low aerobic/anaerobic performance. Participants carrying more minor alleles were more motivated aerobically and less anaerobically, with higher aerobic and anaerobic performance.
CONCLUSION: We conclude that carrying more of the minor alleles is associated with higher aerobic and anaerobic performance. A direct linkage between carrying minor alleles, motivation, and performance was revealed, mainly for aerobic exercise.

IMPROVEMENT OF IRON METABOLISM RESPONSE AFTER MARATHON RACE IN ACTN-3 XX GENOTYPE

CURY-BOAVENTURA, M.F.1, SIERRA, A.P.R.2,3, OLIVEIRA, R.A.1, SILVA, E.D.4, LIMA, G.H.O.4, BENETTI, M.P.2, KISS, M.A.P.2, SIERRA, C.A.3, GHORAYEB, N.3, PESQUERO, J.4

1 CRUZEIRO DO SUL UNIVERSITY, 2 UNIVERSITY OF SÃO PAULO, 3 DANTE PAZZANESE INSTITUTE OF CARDIOLOGY, 4 FEDERAL UNIVERSITY OF SAO PAULO

INTRODUCTION: The iron deficiency is associated to impairment on oxygen transport and utilization, consequently on athletic performance and increases the risk to sports anemia. The aim of this study was to determine the influence of ACTN3 R577X polymorphisms on iron metabolism response induced by marathon race.
METHODS: Blood samples (30 mL) were collected 1 day before, immediately after marathon race and 1, 3 and 15 days after marathon race (81 amateurs runners). ACTN3 R577X polymorphism and the following parameters were carried out to evaluate iron metabolism: Iron, Ferritin, Transferrin, erytropoetin, total bilirubin, direct bilirubin and indirect Bilirubin. age, 39 ± 1 years; height, 1.74 ± 0 m; body mass, 74 ± 1 kg; % of fat mass, 20 ± 1%; body mass index, 25 ± 0.3 kg/m2; average training race, 56 ± 2 km/week; training experience, 6 ± 0.5 years; frequency of training, 4.4 ± 0.7 time/week; time on 10 km race, 46 ± 0.7 minutes.
RESULTS: Immediately after race we observed an increase on transferrin (by 2%, $p<0.05$), total and direct bilirubin (by 22 and 33 %, respectively, $p<0.05$). In addition, our results demonstrated an elevation on Iron (by 20%, $p<0.05$), total and indirect bilirubin levels and transferrin saturation (by 23%, $p<0.001$) one day after race. Three days after race iron (19%, $p<0.05$) and transferrin levels (6%, $p<0.05$) decreased and erythropoietin (33%, $p<0.05$) increased as a compensatory response. We not observed differences on the effect of marathon race on erythropoietin response between RR, RX and XX genotypes. Iron concentration increased in XX and RX genotypes one day after race and decreased 3 days after race in RR and RX genotypes. Ferritin levels elevated immediately after race and returned to baseline levels one day after marathon in XX genotypes and 3 days after race in RR and RX genotypes. The transferrin saturation (%) elevated one day after race in RR, RX and XX genotypes, however, decrease 3 and 15 days after race in RR and RX genotypes, while was reestablished 3 days after race in XX genotypes. We also observed lower levels of transferrin immediately after and 15 days after race in RR and RX genotypes, but not significantly. In RR genotypes, total bilirubin and unconjugated bilirubin decreased 3 and 15 after race while in XX genotypes increased one day after race. In RX genotype total and unconjugated bilirubin increased 1 day after race and then decreased 3 days after race.
CONCLUSION: Marathon race induced impairment on iron metabolism increasing the risk of iron deficiency and sports anemia. The ACTN-3 XX genotype has an improvement on iron metabolism response after the marathon race.

TRANSCRIPTOME-WIDE RNA SEQUENCING ANALYSIS OF IMMOBILISATION-INDUCED MUSCLE ATROPHY

ASHTON, K.J., THOMPSON, J.M., BUDIONO, B.P., SHIKE, K., MACKENZIE-SHALDERS, K., DOERING, T.M., COFFEY, V.G.

BOND UNIVERSITY

INTRODUCTION: Disuse atrophy is a secondary complication that often exacerbates the aetiology of injury and chronic disease. Identifying the mechanisms that control muscle mass associated with changes in function is necessary to characterize atrophy and better understand the effects of disuse on skeletal muscle. RNA sequencing was used as a high resolution, untargeted approach to study gene expression in human skeletal muscle following short-term limb immobilisation.
METHODS: Twenty-one healthy male participants (aged 20-45 years) completed 4 weeks of standardized physical activity prior to a 14-day limb (left leg) immobilisation period. Participants also underwent 21 days (7 days prior; 14 days during immobilisation) of dietary control. Skeletal muscle biopsies were collected from the m. vastus lateralis before and after 3 and 14 days of immobilisation. Skeletal muscle RNA was isolated and analysed using Illumina RNA next generation sequencing to determine differential gene expression with subsequent GO term/pathway analysis. Strength testing, DEXA and MRIs were also performed pre- and post-immobilisation to determine changes in muscle mass and function.
RESULTS: Following 14 days of limb immobilization, strength (-16.4%), leg lean mass (-3.2%) and quadricep cross-sectional area (-8.5%) were all significantly reduced. RNA sequencing identified significant changes in mitochondrial processes and carbohydrate metabolism which became more pronounced throughout the immobilisation period. Furthermore, changes in transcription regulation and chromatin remodelling processes occurred during the early unloading phase at 3 days, but not later at the end of 14 days. Conversely, changes in protein localisation, ribosome biogenesis, translation, nucleotide metabolism and oxidoreductase activity were identified after 14 days of immobilisation but were unchanged at 3 days.
CONCLUSION: This study provides the first transcriptomic sequencing of short-term disuse atrophy in human skeletal muscle. These data provide further support for changes in gene expression related to mitochondrial dysfunction and reduced protein synthesis as key events. Interestingly, changes in transcription regulation including chromatin remodelling processes were observed as an early event and may be responsible for modifying later transcriptomic responses to short-term disuse atrophy.

MUSCLE BLOOD OXYGEN LEVEL DEPENDENT (BOLD) RESPONSES TO BRIEF CONTRACTION AND CUFF OCCLUSION: EFFECTS OF HYPOXIA AND HYPEROXIA

LARSEN, R.G.1, KARBING, D.S.1, ROKKEDAL-LAUSCH, T.1, FRØKJÆR, J.B.2,3, FRANCH, J.1, THOMSEN, L.P.1

AALBORG UNIVERSITY

INTRODUCTION: Blood oxygen level dependent (BOLD) MR imaging monitors muscle oxygenation, and BOLD responses to brief maximal voluntary contraction (MVC) and cuff occlusion (reflecting hyperemia) are used as indices of microvascular reactivity (Meyer, 2004; Schulte 2008). While oxygen availability is proposed to influence vasomotor tone, the purpose of this study was to examine the effects of acute normobaric hypoxia and hyperoxia on microvascular reactivity in response to brief MVC and cuff occlusion in human skeletal muscle.
METHODS: Nine normotensive men were positioned supine in a 3T MR scanner with the dominant foot secured to a foot plate, and a cuff wrapped around the thigh. Participants were breathing through a face mask connected to a gas mixing chamber controlling the fraction of oxygen in the inspired air. The BOLD images (TR = 1000 ms, TE = 40 ms, FOV = 18 cm, Slice thickness = 10 mm) were acquired from the belly of tibialis anterior (TA) during i) 5 min of acclimatization, ii) five brief (1-2s) MVCs of the TA with 1 min of rest in between, and iii) 5 min of cuff inflation (250mmHg) + 5 min of reperfusion. These procedures were performed during normoxia, hypoxia (~12% O2), and hyperoxia (100% O2) in a randomized and balanced order. Time-to-peak (TTP, s) and peak (% of minimum) of the BOLD responses were analyzed using one-way (condition) repeated measures ANOVAs, with pairwise comparisons when appropriate. Data are reported as means±SEM.
RESULTS: The BOLD response to MVC was altered by condition, such that TTP was delayed in hypoxia (10.8±0.6s) compared with normoxia (7.8±0.3s, p=0.003) and hyperoxia (8.2±0.4s, p=0.01). Peak BOLD was lower in hypoxia (1.9±0.4%) compared with normoxia (3.3±0.6%, p=0.004) and hyperoxia (4.5±0.9%, p=0.002). Similarly, the BOLD response to cuff occlusion was altered by condition, such that TTP was delayed in hypoxia (75.2±12.4s) compared with normoxia (31.5±5.4s, p=0.006) and hyperoxia (32.5±3.4s, p=0.003). Peak BOLD amplitude was lower in hypoxia (3.2±0.9%) compared with normoxia (6.6±1.1%, p<0.001) and hyperoxia (9.1±1.8%, p<0.001), and higher in hyperoxia compared with normoxia (p=0.03).
CONCLUSION: Delayed and blunted BOLD responses during hypoxia indicate impaired microvascular reactivity in response to brief MVC and cuff occlusion. Acute exposure to hypoxia may elevate sympathetic vasoconstrictor activity and subsequently constrain vasodilation of the microvasculature. In contrast, maintained BOLD responses during hyperoxia suggest preserved microvascular reactivity in response to brief MVC and cuff occlusion during acute exposure to hyperoxia.

EFFECTS OF ACUTE HYPOXIA ON CARDIAC AUTONOMIC MODULATION FOLLOWING MAXIMAL CARDIOPULMONARY EXERCISE TESTING (CPET)

FORNASIERO, A., SAVOLDELLI, A., SKAFIDAS, S., STELLA, F., BORTOLAN, L., BOCCIA, G., ZIGNOLI, A., SCHENA, F., MOUROT, L., PELLEGRINI, B.

CERISM - UNIVERSITY OF VERONA

INTRODUCTION: Hypoxia acts as a stimulus for an increased sympathetic activity and a reduced parasympathetic cardiac control, that can turn in slower recovery of HR (HRR) and HRV indices after sub-maximal exercise, but not after brief periods of supra-maximal exercise (Al Haddad et al., 2012). However, the effects of hypoxia on cardiac autonomic recovery after a maximal exercise, where cardiovascular and respiratory systems are maximally stressed, have not yet been investigated. This lack of knowledge certainly limits recovery interpretation of hypoxic exercise. Therefore, the purpose of this study was to investigate the effects of hypoxia on post-exercise cardiac autonomic modulation following maximal cardiopulmonary exercise testing (CPET).
METHODS: 13 healthy men (age 34.1 ± 9.7 years, VO2max 55.3± 7.1 mL/kg/min) performed maximal CPET in normoxia (N) and normobaric hypoxia (H) (FiO2=13.4%, ≈3500m asl). Post-exercise cardiac autonomic modulation was assessed during subsequent recovery (300s) through the analysis of fast-phase HRR, slow-phase HRR and recovery of HRV indices.
RESULTS: An increase in resting HR (MD 4.2 bpm, 95% CI 0.6 to 7.8, p=0.025, ES 0.76) with concurrent reduction in HRpeak (MD -6.2 bpm, 95% CI -9.3 to -3.2, p<0.001, ES -0.50) was found in H. Both short-term, T30 (MD 60.0 s, 95% CI 18.2 to 101.8, p=0.009, ES 1.01) and long-term, HRRt (MD 21.7 s, 95% CI 4.1 to 39.3, p=0.020, ES 0.64) time constants of HRR were increased in H. Fast-phase (30s, 60s) and slow-phase (300s) HRR indices were reduced in H when expressed in bpm or as percentage of HRpeak (p<0.05). Differently, chronotropic reserve recovery (CRR) was reduced in H at 30s (p=0.028) and at 60s (p=0.003) but not at 300s (p=0.436). Concurrently, Ln-RMSSD was reduced in H at 60s (p= 0.007, ES -0.87) but not at 300s (p=0.578, ES -0.12).
CONCLUSION: Acute hypoxia (FiO2=13.4%, ≈3500m asl) modified post-exercise cardiac autonomic modulation, causing a reduction in fast-phase HRR, slow-phase HRR and recovery of HRV indices, suggesting both delayed parasympathetic reactivation and reduced sympathetic withdrawal after maximal exercise. However, a similar cardiac autonomic recovery was re-established within 5 minutes after exercise cessation. The findings of this study have several implications in cardiac autonomic recovery evaluation and in HR assessment in response to high-intensity hypoxic exercise.

ADAPTATIONS IN MUSCLE OXIDATIVE CAPACITY, FIBER SIZE AND OXYGEN SUPPLY CAPACITY AFTER REPEATED-SPRINT TRAINING IN HYPOXIA COMBINED WITH CHRONIC HYPOXIC EXPOSURE

VAN DER ZWAARD, S., BROCHERIE, F., KOM, B.L.G., MILLET, G.P., DELDICQUE, L., VAN DER LAARSE, W.J., GIRARD, O., JASPERS, R.T.

VRIJE UNIVERSITEIT AMSTERDAM

INTRODUCTION: In this study, we investigate adaptations in muscle oxidative capacity, fiber size and oxygen supply capacity in team-sport athletes after six repeated-sprint sessions in normobaric hypoxia or normoxia combined with 14 days of chronic normobaric hypoxic exposure.
METHODS: Lowland elite field hockey players resided at simulated altitude (≥14 h·d-1 at 2800-3000 m) and performed regular training plus six repeated-sprint sessions in normobaric hypoxia (3000 m; LHTLH; n=6) or normoxia (0 m, LHTL; n=6) or lived at sea level with regular training only (LLTL; n=6). Muscle biopsies were obtained from the m. vastus lateralis before (pre), immediately after (post-1) and 3 weeks after the intervention (post-2). Changes over time between groups were compared using magnitude and likelihood of effect sizes (ES).
RESULTS: Succinate dehydrogenase activity in LHTLH largely increased from pre to post-1 (~35%), likely more than LHTL and LLTL (ES = large-very large), and remained elevated in LHTLH at post-2 (~12%) vs. LHTL (ES = moderate-large). Fiber cross-sectional area remained fairly similar in LHTLH from pre to post-1 and post-2, but was increased at post-1 and post-2 in LHTL and LLTL (ES = moderate-large). A unique observation was that LHTLH and LHTL, but not LLTL, improved their combination of fiber size and oxidative capacity. Small-to-moderate differences in oxygen supply capacity (i.e. myoglobin and capillarization) were observed between groups.
CONCLUSION: In conclusion, elite team-sport athletes substantially increased their skeletal muscle oxidative capacity, while maintaining fiber size, after only fourteen days of chronic hypoxic residence combined with six repeated-sprint training sessions in hypoxia.

THE PATTERN OF BREATHING DURING NORMOXIC AND HYPOXIC EXERCISE IN PREPUBERTAL CHILDREN AND ADULTS: KIDSKI PROJECT

MEKJAVIC, I.B., DEBEVEC, T., KAPUS, J., UŠAJ, A., MCDONNELL, A.C., NAJDENOV, P., MEKJAVIC, M., JAKI MEKJAVIC, P.

JOZEF STEFAN INSTITUTE

INTRODUCTION: Families with children now take advantage of the easy accessibility of ski resorts in the European Alps situated at altitudes in excess of 3000m. The aim of the KidSki project was to investigate the effect of hypoxia at these altitudes on the physiological functions relevant for ensuring safe skiing, particularly in children. We have previously shown that breathing pattern is not modified during exercise in normobaric and hypobaric hypoxia. In this study, conducted within the framework of the KidSki project, we compared the normoxic (940 m) and normobaric hypoxic (3000 m) exercise breathing pattern between adults and prepubertal children.
METHODS: Thirteen prepubertal children (5 females and 8 males; age= 8.3 ± 1.6yrs, body mass = 29 ± 7 kg, FVC= 2.09 ± 0.69 L) and thirteen adults (6 females and 7 males; age= 39.9 ± 3.8 yrs, body mass = 73 ± 12 kg, FVC=5.11 ± 1.21 L) participated in this study conducted at the Olympic Sport Centre Planica (Rateče, Slovenia) situated at an altitude of 940m. Subjects were confined to the facility for 48 hrs. During the first 24 hrs they were exposed to normoxia, and during the second 24 hr period to normobaric hypoxia (simulated altitude of 3000m). They performed an incremental load exercise on a cycle ergometer on two occasions: once in normoxia (PIO2= 134 ± 0.4 mmHg), and again in normobaric hypoxia (PIO2= 105 ± 0.4 mmHg) while being confined to the facility. During the exercise we measured capillary-oxygen saturation (SpO2), and cardiorespiratory responses, specifically tidal volume (Vt, Litres) expressed as a percentage of forced vital capacity (%FVC), and inspiratory time (Ti, sec).
RESULTS: SpO2 was significantly ($p<0.05$) lower in hypoxia (91 ± 2%) than in normoxia (97 ± 1%), with no difference between the groups. Both the children and adults exhibited the expected increase in Vt with a concomitant decrease in Ti. The normoxic breathing pattern, reflected in the relation of %FVC as a function of Ti, was not modified by hypoxia. However, at any given inspiratory flow rate (Vt/Ti, L.sec-1), children had a significantly ($p<0.05$) lower Ti and Vt compared to the adults. The adults attained a Vt of 49.6 ± 12% FVC upon completion of the exercise, whereas in children Vt attained 41 ± 4 %FVC.
CONCLUSION: The pattern of breathing during normoxic exercise, defined as the Vt-Ti relation, remained unaltered at 4000m in both groups. The exercise breathing pattern of children is different from that of the adults, such that a given inspiratory flow rate is achieved with a higher frequency of breathing and lower relative Vt (expressed as %FVC).

OP-PM21 Diabetes

OXYGEN UPTAKE KINETICS AND VASCULAR FUNCTION WITH TYPE I DIABETES

THOMAS, S., GOODMAN, J., RIDDELL, M., MERINO, D.

UNIVERSITY OF TORONTO FACULTY OF KINESIOLOGY & PHYSICAL EDUCATION

INTRODUCTION: Slower oxygen kinetics may occur when oxygen delivery is slow relative to oxygen uptake at the muscle. We tested two hypotheses: 1) Oxygen kinetics and blood flow (plethysmography) will be correlated in those with T1D; 2) Measures of vascular health, and fitness (VO2 max), and oxygen uptake kinetics will not differ between people with T1D compared with controls.
METHODS: People with type I diabetes and age matched control participants (20-40 y), with no other health impairments were recruited. Vascular function was measured using pulse wave analysis (PWA), velocity (PWV), and plethysmography. Following determination of aerobic fitness (VO2max) participants performed 6 repeated work; rest intervals (85% of ventilation threshold; 3 min 0 load pedaling) to estimate oxygen kinetics. The correlation between oxygen kinetics (measured as tau) and blood flow measured via plethysmography was calculated to assess the strength of the relation between oxygen delivery and blood flow.
RESULTS: Twenty-one participants (9 T1D; 12 control) completed the study. There were a total of 7 men and 14 women with an average age of 24.9 ± 4.9 years. All T1D participants had adequate blood glucose control with an average HbA1C of 7.41 ± 0.62%. Measures of

vascular health PWA (T1D: 0.00 ± 9.25%, Control: 8.55 ± 8.86%), PWV (T1D: 6.87 ± 0.83 m/s, Control: 7.34 ± 1.14 m/s) and plethysmography blood flow (T1D: rest: 4.23 ± 1.73, max: 59.18 ± 12.5 mL100mL-1 min-1); Control: rest: 4.82 ± 2.21, max: 50.94 ± 12.69 mL100mL-1 min-1) were not significantly different between the two groups (p=>0.005). Aerobic fitness (T1D: 36.11 ± 6.79 mLkg-1min-1); Control: 36.24 ± 9.43 mLkg-1min-1), perceived exertion (T1D: RPE: 12.8 ± 2.6, RPD: 2.7 ± 1.3; Control: RPE: 13.5 ± 1.7, RPD: 2.6 ± 1.8), and oxygen uptake kinetics (T1D: 27.9 ± 4.5 s; Control: 29.2 ± 9.3 s) were not significantly different between the two groups (p=>0.05). Finally, non-significant correlations between resting blood flow and oxygen kinetics (r=0.15, p=>0.05), and maximal blood flow and oxygen kinetics (r=0.10, p=>0.05) were observed across both groups.
CONCLUSION: The absence of differences in oxygen kinetics in participants with T1D and controls may be a consequence of their similar aerobic fitness and rapid kinetics. The lack of a significant relationship between oxygen kinetics and blood flow suggests this aspect of blood flow did not limit oxygen kinetics for these participants. However, this study did show that vascular health and exercise capacity between the groups were not significantly different. This result suggests that people with T1D can have comparable vascular health and exercise capacity to a control population of a similar age. This result could encourage people with T1D to participate in regular exercise and maintain appropriate glucose levels to achieve good vascular health.

EFFECTS OF SPIRULINA SUPPLEMENTATION ON SKELETAL MUSCLE MASS, PROTEOSYNTHESIS/PROTEOLYSIS MARKERS AND EXERCISE-INDUCED MUSCLE DAMAGES IN DIABETIC RATS

MEZIAT, C., GROUSSARD, C., BAZUREAU, E., COSTE, P., ANDRÉ, J., CHAOUHACHI, M., LEMOINE-MOREL, S., SALIGAUT, D., LEFEUVRE-ORFILA, L., VINCENT, S.

LABORATOIRE MOUVEMENT SPORT SANTÉ - UNIV RENNES

INTRODUCTION: Diabetes is characterized by chronic hyperglycemia, inflammatory and oxidative stress state. Inflammatory markers (TNFα, NFκB) can reduce proteosynthesis and increase proteolysis, leading to loss of skeletal muscle (SM) mass. This phenomenon increases the risk of exercise-induced skeletal muscle damages (SMD). Nutritional supplementations are now integrated into the therapeutic management of diabetes as additive strategies. Spirulina (SPI), a microalgae presenting high content of proteins, and exhibiting anti-inflammatory, antioxidant and insulin-sensitive effects could be an interesting strategy to protect SM in diabetes.
The aim of this study was to evaluate SPI supplementation effects in diabetic rats on the SM proteosynthesis/proteolysis markers and it potential protective effect on SMD induced by eccentric exercise
METHODS: 68 male Wistar streptozotocin-diabetic rats were divided into placebo (P, n=34) or Spirulina (SPI, n=34, Arthrospira platensis: 300 mg/kg/day/4w) groups. Rats of exercise groups (n=22 per group P or SPI) realized an individualized treadmill downhill exercise (-16°,16m/mn) until exhaustion. Plasma glycemic assessment (glucose and fructosamine) and creatine kinase (CK) concentrations were determined. Markers of inflammation were evaluated by histological staining (CD68, CD163, macrophages) or western blotting (TNFα), as markers of proteosynthesis/proteolysis (mTor, FoxO3a, NFκB) on Soleus. Assays were performed after the exercise (T0) or 24h after (T24) (respectively; n=11/condition).
RESULTS: 4w of SPI supplementation did not improve glycemic assessment nor the body and SM mass. Proteosynthesis (mTor expression) was increased in SPI group, but there was no decrease in proteolysis (NFκB and FoxO3a expression).
However SPI seemed to reduce basal SMD as shown by CK concentration. SMD was induced by eccentric exercise as it shown by plasma CK content at T0 and T24 in both groups. SPI supplementation significantly reduced CK levels in T24 group, and tended to increase time to exhaustion.
Histological data seemed to show different profiles of CD68 and CD163 markers (M1 and M2 types of macrophages, respectively) in both groups.
CONCLUSION: 4w SPI supplementation was not sufficient to improve SM mass but increase proteosynthesis whithout limiting proteolysis. Theses effects are probably linked to AO and anti-inflammatory effects of SPI. Moreover, SPI alters positively post-exercise SMD and regeneration profile.

EFFECT OF THE MUSCLE METABOREFLEX ACTIVATION IN TYPE 2 DIABETES MELLITUS

ROBERTO, S.1, MILIA, R.1, DONEDDU, A.1, PALAZZOLO, G.1, SERRA, S.1, PINNA, V.1, ORRÙ, A.1, MULLIRI, G.1, PAGLIARO, P.2, CRISAFULLI, A.1

1UNIVERSITY OF CAGLIARI, 2UNIVERSITY OF TORINO

INTRODUCTION: It is well known that, in healthy subjects, when the muscle metaboreflex (MM) is activated, mean blood pressure (MBP) increases due to a sympathetic-induced increase in both systemic vascular resistance (SVR) and cardiac output (CO)1. It has been reported that this reflex is dys-regulated in patients suffering from metabolic diseases, such as type 1 Diabetes Mellitus (DM1) and Metabolic Syndrome. In detail, in DM1 it was demonstrated a blunted MBP response during the MM due to sympathetic impairment2; moreover, patients suffering from metabolic syndrome show an exaggerated SVR during the MM because of their sympathetic hyperactivation. Several evidence suggests that, similarly to what observed for metabolic syndrome, also in type 2 Diabetes Mellitus (DM2) there is an exaggerated sympathetic tone in response to exercise. Our aim was to discover whether or not the MM is dys-regulated in these patients.
METHODS: Two groups took part in this study: DM2 group composed by 14 subjects (4 females, 62.7±8.3yrs); and a control (CTL) group composed by 15 healthy subjects (4 females, 65.5±8.2 yrs). After a preliminary cardiopulmonary exercise test on cycle-ergometer up to exhaustion, they underwent randomly assigned the following protocol: the post-exercise muscle ischemia (PEMI) session, to study the MM, and a control exercise recovery (CER) test. Response to the metaboreflex for each cardiovascular parameter was assessed as PEMI minus CER level. Hemodynamic parameters were measured by impedance cardiography.
RESULTS: Patients with DM2 showed an exaggerated SVR response as compared to the CTL group (+392.5±549.6 vs. -38.2±278 dynes•s-1•cm-5 respectively, p<0.05), and a decrease in ventricular emptying rate response as compared to CTL (-10.1±30.9 vs. +10.6±23 ml•s-1 respectively, p<0.05) whereas MBP response was not significantly different between groups (+8.9±5.7 vs. +9.5±11.6 mmHg respectively, p>0.05).
CONCLUSION: This investigation indicates that patients with DM2 have an exaggerated vasoconstriction in response to the MM activation. This phenomenon is different to what observed in DM12 and similar to what reported for metabolic syndrome3.

EFFECTS OF A PROGRESSIVE SELF-DIRECTED STEP TRAINING AND WALKING PROGRAMME INVOLVING SHORT ACCUMULATED BOUTS ON SEDENTARY INDIVIDUALS WITH TYPE 2 DIABETES MELLITUS: A PILOT STUDY.

BYRNE, H.1,2, CAULFIELD, B.1,2, LOWEREY, M.1,3, GRIFFIN, M.4, SMITH, D.5, THOMPSON, C.J.5, DE VITO, G.1,2

1 = INSIGHT CENTRE, IRELAND 2 = UCD SCHOOL OF PUBLIC HEALTH, PHYSIOTHERAPY & SPORTS SCIENCE, IRELAND 3 = UCD SCHOOL OF ELECTRICAL AND ELECTRONIC ENGINEERING, IRELAND 4 = BEACON HOSPITAL, IRELAND 5 = B

INTRODUCTION: Compliance to self-directed exercise is poor in individuals with type 2 diabetes. Step training and walking offer simple forms of exercise that may yield high adherences in any setting. Progressive programmes of short accumulated bouts may also boost motivation and evidence suggests that short bouts of step training or walking improve health related benefits. This pilot study evaluates the effects of a novel self-directed exercise programme on individuals with type 2 diabetes mellitus. It aims to identify if the programme yields compliance and improves health-related outcome measures.
METHODS: 10 sedentary individuals with type 2 diabetes mellitus were included in this study (2 female, Age = 51.7 ± 6.5 years, Disease duration = 8.1 ± 4.7 years, BMI = 30.1 ± 2.5 kg/m2, HbA1c = 59.4 ± 4.9mmol/mol). The novel exercise programme consisted of small bouts of walking and/or step training spread throughout the day over 16 weeks. The programme began with 2-minute sessions twice/day at 12/20 on the Borg RPE scale on 3 days for the first week and progressed to three 12-minute sessions each day at 16 on the Borg scale in week 16. Participants were given the choice of carrying out step-training and/or walking for all exercise sessions to provide them with greater autonomy and remove Irish weather as a potential barrier to exercise.
RESULTS: Of 245 total sessions the mean attempted and completed were 82.6 ± 24.7% and 81.6 ± 25.4% respectively. Self-reported minutes of physical activity per week increased from 106.0 ± 38.3 at baseline to 397 ± 305.5 at follow up (P = 0.01). Six-minute walk test distances increased from 466.9 ± 32.7m to 535.7 ± 59.9m (P < 0.01), bodyweight reduced from 93.7 ± 13.0kg to 91.5 ± 13.3kg (P = 0.73), BMI decreased to 29.4 ± 2.5kg/m2 (P = 0.56), and HbA1C reduced to 55.7 ± 5.0mmol/mol (N = 9, P = 0.15). Handgrip strength increased from 41.2 ± 6.7 to 45.2 ± 7.2 kg (P = 0.24).
CONCLUSION: The results of the pilot study indicate that this novel progressive self-directed exercise programme of accumulated short bouts of step training and/or walking has the potential of yielding high adherences in previously sedentary individuals with type 2 diabetes mellitus, increasing overall levels of physical activity and improving health related outcomes including functional fitness. Further work will need to include a control group of supervised training and a larger sample size.

EFFECTS OF INTENSIVE LIFESTYLE INTERVENTION ON PANCREATIC BETA-CELL FUNCTION IN PATIENTS WITH TYPE 2 DIABETES – A SECONDARY ANALYSIS FROM THE U-TURN TRIAL.

RIED-LARSEN, M., JOHANSEN, M.Y., HANSEN, K.B., ELLINGSGAARD, H., ALMDAL, T.P., PEDERSEN, B.K., KARSTOFT, K.

RIGSHOSPITALET, UNIVERSITY OF COPENHAGEN

INTRODUCTION: The objective of the study was to investigate the effects of an intensive lifestyle intervention with high volume of exercise on indices of pancreatic beta-cell function in patients with type 2 diabetes.
METHODS: This is an explorative analysis of data from the U-TURN trial. The U-TURN trial was a single center assessor-blinded, randomized study conducted from April 2015-August 2016 at RH, Denmark. Adult participants with short standing, non–insulin-dependent type 2 diabetes (T2D, time from diagnosis<10 years) were included (n=98). Participants were randomly assigned (2:1; stratified by sex) to a lifestyle intervention group (U-TURN, n=64) or a standard care group (StC, n=34). All participants received individual T2D counseling and standardized, blinded, target-driven medical therapy. In addition to this, the U-TURN group also received dietary plans as well as 5-6 weekly aerobic training sessions, of which 2-3 sessions also included resistance training. Indices for pancreatic beta-cell function were based on a 2-hour standard oral glucose tolerance test (2h-OGTT) performed following 48 hours of pharmacological and exercise discontinuation at baseline and at 12-month follow-up. Differences between the groups in change from baseline to 12-month follow-up for the Disposition (DI, primary outcome), Matsuda (ISI) and Insulinogenic (IGI) indices are reported. Data are presented as mean differences with [95% confidence intervals] adjusted for sex and the respective baseline values.
RESULTS: Among the 98 randomized participants (mean age, 54.6 years; women, 48%; mean baseline HbA1c, 6.7%), 60 and 27 participants in the U-TURN and StC groups, respectively, completed both 2h OGTT's. Insulin secretion normalized for insulin sensitivity (DI) improved in both groups (U-TURN; 90% [62-123] and StC; 38% [8-77]), but the U-TURN group improved 38% [2-86] more than the StC group. Whole body insulin sensitivity (ISI) improved 23 % [1-51] more in the U-TURN than in the StC group. No difference in the change in beta-cell responsivity (IGI) from baseline to follow-up was observed between the groups.
CONCLUSION: A 12-month intensive lifestyle intervention with high volumes of exercise improved indices of pancreatic beta-cell function in patients with short standing type 2 diabetes. However, more studies are needed with gold-standard measures of beta-cell function in order to clarify mechanisms and exercise dose.

IS-BN08 Neuromuscular fatigue in children

DIFFERENCES IN NEUROMUSCULAR FATIGUE BETWEEN CHILDREN AND ADULTS

RATEL, S.

CLERMONT AUVERGNE UNIVERSITY

INTRODUCTION: Fatigue, as a concept, has initiated many debates over the last century. However, fatigue could be defined as an exercise-induced reduction in muscle performance. Two different measurement models have been used in children to quantify such impair-

ment. The first consisted of quantifying the reduction of power output during real exercise such as maximal cycling (1) or short running bouts (2). The second was based on the assessment of maximal muscle force-generating capacity during repeated maximal voluntary contractions (MVC) in isometric or dynamic conditions. Taken together, studies have reported a lower fatigability in children compared to adults whatever the nature of the task (1-3). No sex-related difference in fatigue development was observed before and after the pubertal period. The fatigability may be maturity-dependent given that studies have reported a greater fatigability in adolescents compared to children and in adults compared to adolescents (1). This lecture will be devoted to provide an overview of recent studies on the effects of age, maturation and sex on the development of fatigue during repeated MVC or real activities. Practical implications that emerge from these findings will be discussed in relation with sports settings.

MECHANISMS UNDERPINNING CHILD-ADULT DIFFERENCES IN NEUROMUSCULAR FATIGUE

PATIKAS, D.A.

ARISTOTLE UNIVERSITY OF THESSALONIKI, GREECE

INTRODUCTION: Fatigue is a complex phenomenon that is affected by the function of several neuromuscular mechanisms on both peripheral and central levels. Structural and physiological differences between children and adults could underpin some age-related diversities in the behaviour of the neuromuscular system. The topic of this lecture will focus on such neuromuscular differences between children and adults and will distinguish between peripheral (muscular) and central (neural) factors of fatigue. Recent findings, consistently converge to a less peripheral fatigue in children compared to adults (1). These differences could be explained by the lower force production, the higher proportion of fatigue resistant slow-twitch fibres and the higher muscle oxidative capacity in children compared to adults. The contribution of central factors is more controversial, since Ratel et al. (3) and Streckis et al. (2) reported higher reduction in the voluntary activation (VA) in children after fatigue, which possibly acts as a protective mechanism to prevent any extensive peripheral fatigue. However, we have recently reported no difference in the VA after fatigue between children and adults (1). The presented findings have significant implications in future research in this field and should be accounted when planning training programs in young populations.

FATIGUE OR FATIGABILITY IN PATIENTS WITH NEUROMUSCULAR DISEASE

HABETS, L.

HU UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Paediatric patients with neuromuscular fatigue often report their daily activities are limited by fatigue. In many situations, the patients are describing the feelings to exert more than the usual amount of effort to accomplish a task. This lecture will focus on exercise testing in patient with Duchenne and Becker Muscular atrophy as well as fatigability in patients with Spinal Muscular Atrophy (SMA). Fatigability, defined as the decline in performance during and after prolonged motor tasks, has emerged as a rather common but often overlooked complaint among patients with SMA. Fatigability is a highly disabling symptom during repetitive activities of daily living e.g. eating, walking and computer use. The currently used outcome measures for SMA have been developed to determine muscle strength and specific motor skills, but do not specifically assess fatigability. The aim of this lecture is to discuss the role of exercise testing in neuromuscular disease using the development of a new outcome measure to assess fatigability as an example.

IS-MI02 Physical activity and cognitive function

THE EFFECTS OF ACUTE AND CHRONIC PHYSICAL ACTIVITY ON COGNITIVE AND BRAIN HEALTH

HILLMAN, C.

NORTHEASTERN UNIVERSITY

There is a growing public health burden of poor health behaviors among children of industrialized nations. Children have become increasingly inactive, leading to concomitant increases in the prevalence of being overweight and unfit. Particularly troubling is the absence of public health concern for the effect of physical inactivity on cognitive and brain health. It is curious that this has not emerged as a larger societal issue, given its clear relation to childhood obesity and other inactivity-related disorders that have captured public attention. My program of study has examined the relation of health behaviors and their related physiological correlates to cognitive and brain health across the human lifespan, with particular interest in preadolescent childhood. My techniques of investigation involve a combination of neuroimaging, behavioral assessments, and scholastic achievement in an effort to translate basic laboratory findings into everyday life. Central to this translational approach is the identification of etiological substrates of brain structures and networks that are susceptible to health behaviors. Findings from my area of research have indicated that greater amounts of physical activity, aerobic fitness, maintenance of healthy body weight, and diet quality are positively related to brain structure and function, cognition, and scholastic achievement.

EFFECTS OF AEROBIC EXERCISE ON INHIBITORY CONTROL IN ADOLESCENTS AGED 16-19 YEARS

GEJL, A.K.

UNIVERSITY OF SOUTHERN DENMARK

Background and objectives: Aerobic exercise has been acknowledged as a promising approach to induce brain alterations in humans, also implying changes in cognition and behavior. However, literature in adolescents is scarce and more studies are needed to elucidate details about the exact relationship between aerobic exercise and cognitive performance. Therefore, we conducted two studies including adolescents with the following aims: Study I) to clarify the acute effects of short bouts of aerobic exercise at different intensities on inhibitory control, and Study II) to clarify the effects of nine weeks of aerobic training on cardiorespiratory fitness, inhibitory control and plasma BDNF.
Methods: Study I was conducted as a randomized crossover study including 52 adolescents. In a randomized and counterbalanced order, participants completed three 5-minutes cycling conditions varying in exercise intensity (50%, 65% and 80% of maximal oxygen reserve (VO2R)), one 30-minutes cycling condition at 65% VO2R and one rest condition. Inhibitory control was assessed following each condition using a modified flanker task. Study II was conducted as a three-arm randomized controlled trial including 115 subjects. Subjects were randomized to three conditions: 1) non-intervention (control), 2) low-to-moderate intensity aerobic exercise, or 3) high-intensity intermittent aerobic exercise. Inhibitory control (flanker task), cardiorespiratory fitness and plasma brain-derived neurotrophic factor (BDNF) were measured at baseline and following nine weeks.
Results: Study I: No specific effects of the 5-minutes conditions were observed for inhibitory control. However, compared to the rest condition, better performance (i.e. response accuracy) was observed across stimuli requiring variable amount of inhibitory control after all 5-minutes conditions, with the high-intensity exercise demonstrating the largest differences (i.e. response accuracy and reaction time). Study II: Cardiorespiratory fitness was increased in both exercise groups, with the largest effects in the high-intensity group. There were no effects of nine weeks of aerobic exercise on either inhibitory control or plasma BDNF.
Conclusion: Short bouts of aerobic exercise, and particularly high-intensity exercise, may be an efficient approach to improve information processing in general, but not specifically inhibitory control in adolescents. Nine weeks of aerobic exercise increase cardiorespiratory fitness, but not inhibitory control or plasma BDNF in adolescents.

DO PERIPHERAL BRAIN-DERIVED-NEUROTROPHIC-FACTOR RELATE TO COGNITIVE FUNCTION? A VALIDATION STUDY.

ANDERSEN, L.

WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCES

Brain derived neurotrophic factor (BDNF) is believed to be a key mechanism for the effect of Physical Activity to improve cognitive function. Animal models have shown increased level of BDNF in Hippocampus in relation to increased physical Activity. However, in humans BDNF can only be measured in blood and this Level may not reflect what happens in the brain. Recent studies found a positive Association between cardiovascular disease risk factor levels and serum BDNF, which is t opposite of what we would expect given the fact that high Fitness is positively Associated With cognitive function, but negatively Associated With CVD risk factors. In blood, 99% of BDNF is stored in platelets and they cannot pass the blood-brain barrier. Therefore we conducted a validation study of different measurements of BDNF in serum and plasma samples. The aims of the study were to investigate the impact of storage time and centrifugation strategy on brain-derived neurotrophic factor (BDNF) levels in human serum and plasma samples, and to clarify how these measures are related. Moreover, we aimed to establish whether BDNF levels associated with cardiorespiratory fitness and waist circumference.
Method. The study included seventeen male students (mean age=25.2 (4.1) years). Fasting blood samples were drawn and treated according to different protocols varying in time before centrifugation (30, 60, 180, 240 and 300 min.) and subjected to different centrifugation strategies. Mature BDNF was analysed in serum, normal and platelet-poor plasma after ~eight months storage. In addition, waist circumference and cardiorespiratory fitness were measured.
Result. A systematic increase in BDNF was observed over time in serum, but not in normal plasma or platelet-poor plasma. No correlation was observed between serum and plasma BDNF levels. Waist circumference was positively associated with serum BDNF levels in samples left for 300 min., whereas cardiorespiratory fitness was negatively associated with the difference in BDNF levels in serum left for 30 min. and 60 min., respectively.
Conclusion. BDNF levels measured in serum and plasma, respectively, differ and have different biological relevancies. Our data suggest that the rate, rather than the full extent, of BDNF release is associated with cardiorespiratory fitness. In future using measures of peripheral BDNF, it is essential to consider the biological medium and treatment hereof carefully, as these factors significantly affect the results.

OPTIMAL CONTROL BASED STUDIES OF RUNNING MOTIONS IN SPORTS

MOMBAUR, K., KLEESATTEL, A.L.

HEIDELBERG UNIVERSITY

In this talk, we want to show how optimal control methods based on whole-body dynamic models of human athletes can be used to analyze and generate running motions in sports. The goal of this research is to gain a better understanding of the underlying principles of these movements and to ultimately use this knowledge to improve the individual movements and training of athletes. It is a common assumption that human movement is optimal due to evolution, development and learning, in this case in form of a specific training, which motivates the use of optimization techniques in this context.
Different types of optimization problems are of interest:
• Optimal control for motion analysis, using recorded motions of human athletes and solving a least squares fitting problem. If a reliable model is used, this leads to a detailed reconstruction of the motion including also variables that cannot be measured;.

• Optimal control for motion synthesis or motion prediction, generating new motions and computing optimal position and velocity histories as well as inputs at the same time by using some suitable objective function . Several choices will be discussed that are relevant for the situation.
• Inverse optimal control which solves the problem to identify which optimization criterion was optimized in a particular situation for which human recordings are available. Typically the criteria consist of several components, and the goal is to identify classes of motions and subjects for which they are valid.
Running is considered as a multiphase motion with alternating single foot contact ad flight phases. We use multibody system models of athletes that describe the full dynamic properties of the segments relevant for a motion. Depending on the particular question asked, our models are either fully 3D or in the sagittal plane and have typically between 16 and 35 degrees of freedom. Equations of motion are set up based on our multibody system modeling tool RBDL and the human meta-model HeiMan. If a particular athlete is studied, subject specific parameters can be identified from motion capture by the tool Puppeteer or by more detailed MRT based information. As input variables we use joint torques or so-called muscle-torque generators that summarize the accumulated torque of all muscles at a joint. Other details of interest could be added to the model, e.g. external compliance models at the soles describing the effect of different shoe types.
Different results will be presented in this talk including running motions that are optimal with respect to different criteria such as energy minimization, efficiency maximization, speed maximization, as well as criteria mimicking pain in different parts of the body.

APPLICATIONS OF FUNCTIONAL DATA ANALYSIS IN SPORTS BIOMECHANICS

HARRISON, A.J.

UNIVERSITY OF LIMERICK

Theoretical Background: Most biomechanical data present as temporal waveforms or time series representing specific biomechanical measures such as angles, moments, or forces measured over time, generating large quantities of high-dimensional data that can be represented as curves or groups of curves. Analysis of such data is challenging and although various procedures have been explored, no standard technique for analysis of curve data has been established. Experimental studies often aim to determine differences in curve-based data between several groups or individuals. Functional data analysis (FDA) was developed by Ramsey and Dalzell (1991) and in contrast to other methods; FDA considers the entire sequence of measurements in a trial as a single functional entity rather than a series of individual data points. There are four main steps in FDA:
1. Data representation: derivation of smooth functions often using B-spline basis functions
2. Registration of data (i.e. time normalisation or landmark registration)
3. Functional principal component analysis (fPCA)
4. Visual representation and statistical analysis
This presentation focuses on steps 3 and 4 and demonstrates the potential benefits of implementing fPCA using various sports biomechanics data sets. In fPCA, the functional principal components (FPC) are presented in the same domain as the original function with high and low scorers on each FPC presented as functions in comparison to the ensemble mean function. In addition, each trial is assigned an FPC score which can be analysed using conventional group statistics and/or effect sizes.
Applications in Sport Science: fPCA has previously been used by Donoghue et al. (2008) to examine the effects of in-shoe orthoses on the kinematics of the lower limb function in subjects with previous Achilles tendon injury compared to uninjured controls. The results provided evidence of in-shoe orthoses constraining some movement patterns while restoring some aspects of variability in other movements.
Dona et al. (2009) applied fPCA bilaterally to sagittal knee angle and net moment data in race-walkers of national and international level. They concluded that fPCA was sensitive enough to detect potentially important technical differences between higher and lower skilled athletes, and therefore fPCA might be a useful and sensitive aid for the analysis of sports movements, if consistently applied to performance monitoring in sport.

POSSIBILITIES AND LIMITATIONS OF MUSCULOSKELETAL MODELLING IN SPORT, TRAINING AND REHABILITATION

LORENZETTI, S.

SWISS FEDERAL INSTITUTE OF SPORT MAGGLINGEN SFISM

INTRODUCTION: Muscle strengthening activities are recommended by the WHO for adults to maintain general fitness and health . Strength training guidelines should aim to guide correct exercise execution for stimulating positive tissue adaptation without overloading. Here, musculoskeletal modelling has become a powerful tool to estimate the internal loading conditions during strength exercises in vivo for science-based training recommendations . The aim of this study is to validate the accuracy of musculoskeletal modelling in predicting the knee joint reaction forces during the "squat" exercise using data from instrumented knee arthroplasty as gold standard.
METHODS: Using a synchronised system of motion capture and ground reaction force plates, 6 subjects <5M, 68 years, 88 kg, 173cm> with an instrumented knee implant were measured while performing five valid repetitions of a squat exercise without additional weight . The internal total joint forces were derived from the kinetic and kinematic input parameters using the software OpenSim with a generic musculoskeletal model that was uniformly scaled to subject-specific dimensions.
RESULTS: The measured total joint contact forces from the instrumented implant were between 2 and 3.3 times bodyweight. The absolute magnitudes of the predicted joint forces were only accurate within 20 % error for a limited knee flexion range of about 25 to 60 degrees; yet, a relative comparison was still possible.
CONCLUSION: The present results indicate that generic musculoskeletal models are valid tools for predicting peak values of total joint forces during loading. Further efforts are needed to better capture subject-specific musculoskeletal anatomy for analysing joint forces throughout exercise execution, and thus, allowing the targeted design of exercises for specific structures while avoiding overload of other structures.

HOW IS SCANNING BEFORE BALL POSSESSION RELATED TO PERFORMANCE WITH THE BALL? AN INVESTIGATION OF FOOTBALL PLAYERS' EXPLORATORY ACTION

MCGUCKIAN, T.1, COLE, M.1, CHALKLEY, D.1, SHEPHERD, J.2, JORDET, G.3, PEPPING, G.J.1

1. AUSTRALIAN CATHOLIC UNIVERSITY, 2. GRIFFITH UNIVERSITY, 3. NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Performance analysis in football is commonplace in applied and research settings (Sarmento et al., 2017), however, researchers have rarely investigated players' off-the-ball behaviour, before they gain possession of the ball. As they are surrounded in 360-degrees, players need to visually explore (i.e. scan, head-check) in order to gain knowledge of their environment and prospectively guide their actions with the ball. Preliminary investigations suggest that field constraints influence players' exploratory actions (McGuckian et al., 2017) and that more frequent exploratory actions prior to receiving the ball is related to better pass success (Jordet et al., 2013). However, the relationships between these exploratory actions that occur before gaining ball possession and subsequent performance with the ball are unknown.
METHODS: We used inertial measurement units to quantify the exploratory head movements of 15 (mean (SD) age = 18.67 (3.90) y/o) competitive football players during 11v11 match-play and manually coded subsequent actions. Here we report on pass direction, one-touch passes and turns with the ball. Odds Ratios (OR) were calculated to estimate the effect of head turn frequency before receiving the ball on the occurrence of subsequent actions with the ball. An OR above 1 indicates the action with the ball occurred more often when players' head turn frequency was higher than their individual average. Ten time-periods (0-1s, 0-2s, … up to 0-10s) before possession were analysed, and the time-period before possession with the highest OR (i.e. most important time-period for that action with the ball) are reported.
RESULTS: When players turned their head more frequently before receiving the ball they were more likely to play a forward pass (0-8s, OR=2.80), play a one-touch pass (0-1s, OR=1.68), turn with the ball (0-4s, OR=2.53) and play a pass in the direction opposite to which it was received (0-2s, OR=4.49).
CONCLUSION: When players had a higher frequency of head movement, they were more likely to play a forward pass, a one-touch pass, turn with the ball, and play a pass in the opposite direction it was received. This suggests a higher frequency of head turns is related to increased knowledge about their surroundings. The findings demonstrate the value of exploration and frequent head movements before receiving a pass, and therefore the development of these behaviours in training should be a high priority.

USING STROBOSCOPIC VISION TO RESTRICT VISUAL FEEDBACK IN A SOCCER SPECIFIC SKILL ASSESSMENT

BEAVAN, A.1,2, FRANSEN, J.3, HANKE, L.4, SPIELMANN, J.5, SKORSKI, S. , MAYER, J.5, HAUSER, T.2, MEYER, T.1

1: SAARLAND UNIVERSITY , 2: DFB . 3: UTS , 4, DHFPG , 5: TSG 1899

Introduction: The most prominent source of sensory information required during sport specific skills is visual feedback. When visual feedback was limited, skilled (S) soccer dribblers suffered greater performance decrements compared to their lesser-skilled (LS) counterparts in a dribbling test (Fransen et al., 2017). Yet soccer performance requires players to find functional movement solutions based on problems dictated by the performance environment and the requirements of the task. Therefore, soccer skill assessments require external factors to dictate how and when the skill is performed (Sunderland et al., 2006). Therefore, this study aims to investigate how restricted visual feedback affects a soccer-specific skill assessment that requires a more complex, reactive perception-action coupling.
Methods: Eighty-four amateur male participants completed two counterbalanced sessions in the Footbonaut under separate conditions: stroboscopic vision (frequency of 1Hz, clear vision for 266ms, opaque for 620ms) and full vision. The Footbonaut consists of a 14x14m artificial turf surrounded by 72 square targets (1.5x1.5m). An auditory and visual cue alerted the participant which gates the ball would be dispensed from and passed into. Ten familiarisation balls were given prior to the first session, and each session consisted of 32 consecutive balls separated by a 10 minute rest.
Results: Players were subdivided into S and LS participants using age-standardised z-scores. A MANOVA with points, accuracy, and speed as dependent variables revealed a multivariate effect of stroboscopic vision on performance (p=<.001). Univariate analyses revealed significantly larger decrements (full–stroboscopic session performance) in S participants in the stroboscopic session in points (S: 13653au; LS: 5391au; p=<0.001) and accuracy (S: 11.7%; LS: 0.4%; p=<.001), but not in speed (S: 0.21s; LS: 0.18s; p=.543) compared to their LS counterparts.
Conclusion
The results are comparable with previous research in a soccer-dribbling task (Fransen et al., 2017), where restricting visual feedback affected the S participants to a greater extent than their LS counterparts. The interpretation of these findings is twofold: i) the specificity of practice hypothesis states greater performance decrements are apparent in more experienced players when afferent feedback conditions are dissimilar to the environment which they learned the skill (Proteau & Marteniuk, 1993) and ii) stroboscopic vision relates to a higher amount of visual restriction in absolute terms when skills are executed faster. In conclusion, stroboscopic vision may be used to induce performance errors during practice to stimulate larger skill training effects, particularly in more skilled players.

COGNITIVE LOAD IMPAIRS THE USE OF CONTEXTUAL PRIORS DURING ACTION ANTICIPATION IN SOCCER – AN EEG STUDY
Gredin NV.1, Broadbent DP.1, Williams AM.2, Bishop DT.1
1: Brunel University London (Uxbridge, UK), 2: University of Utah (Salt Lake City, USA)
Introduction: In elite sport, performance analysts are an integral part of the coaching process, providing athletes with information relating to the tendencies of forthcoming opponents (i.e., contextual priors). In soccer, expert players use such information to enhance performance when anticipating the actions of oncoming opponents (Cañal-Bruland and Mann, 2015). However, the cognitive demands of this process have typically been measured using self-report ratings rather than more robust neurophysiological measures. We used electroencephalography (EEG) to assess the cognitive demands of processing contextual priors and examined the impact of cognitive load on the use of this information during anticipation.
Methods: Altogether, 18 male soccer players (age = 21 ± 1 yrs [M + SD]; playing experience = 11 ± 2 yrs) performed a video-based task where they anticipated the actions of an oncoming opponent. They performed the task with and without contextual priors pertaining to the opponent's action tendencies (dribbles = 67%, passes = 33%), under conditions with high (secondary n-back task) and low (no secondary task) cognitive load. Cognitive demands were assessed using self-report ratings and EEG recordings of electrical power within the Theta and Alpha frequencies obtained over frontal and parietal regions, respectively (Brower et al., 2012). Anticipatory performance was registered via a button-press system that captured both accuracy and response time.
Results: The provision of contextual priors increased the EEG manifestation of cognitive demands (d = 0.27 ± 0.20 [90% CL]), but the self-reported demands concurrently decreased (d = -0.33 ± 0.36). Under low-load conditions, contextual priors enhanced anticipatory performance (d = 0.29 ± 0.34) but this improvement was not found under high-load conditions (d = 0.03 ± 0.45).
Conclusions
Our findings provide the first evidence that contextual priors increase cognitive demands during action anticipation in sport – seemingly in the absence of self-awareness of these demands. The contradictory self-report and EEG findings have methodological implications for the assessment of cognitive demands during task performance. Furthermore, we found that the beneficial performance effects of contextual priors may not be retained under task conditions with high cognitive load. This novel finding makes a significant contribution to the development of an overarching theoretical framework that can predict anticipatory behaviour in sport (Cañal-Bruland and Mann, 2015).

THE IMPACT ON PASS RECEPTION AND DELIVERY OF A FOOTBALL FOLLOWING A TRAINING INTERVENTION WITH SPATIAL OCCLUSION GOGGLES.

DUNTON, A., ONEILL, C., COUGHLAN, E.K.

CORK INSTITUTE OF TECHNOLOGY

INTRODUCTION: Visual Occlusion is comprised of temporal and/or spatial occlusion and is the process of limiting the vision of an object, limb or critical information source from the visuomotor workspace (Vickers, 2007). The aim of the current research was to measure the impact on pass reception and delivery of a football following a training intervention using spatial occlusion goggles on a skilled soccer player cohort.
METHODS: Fifteen male skilled soccer players were randomly assigned to one of three groups; Occlusion (OCC), Practice (PRA) and Control (CON). Participants were instructed to stand in a designated zone on a synthetic grass surface in front of a concealed ball projector where a ball was delivered at a speed of 40 km/h. Concurrently, a series of randomly generated numbers were displayed on a wall behind the ball projector for the duration of the task. Participants were required to call each number presented while attempting to control and pass the ball towards one of two mini goals in front of the participant. The direction of the pass was determined by a timed presentation of an arrow next to one of the displayed numbers to coincide with a ball release, every three, four or five seconds. Performance was determined by three variables: Number Call Error, Outcome Error and Control Error. The study design consisted of a pre-test, acquisition phase (400 trials), post-test and a 2-day retention test.
RESULTS: A 3 group x 3 test ANOVA was conducted to analyse the impact of the acquisition phase on each of the three selected variables. There was a significant decrease in number error ($p < 0.05$) and outcome error ($p < 0.05$) for the OCC group from pre- to post-test and pre- to retention test. No significant decrease was experienced from post-test to retention test ($p > 0.05$) demonstrating a learning effect. There was no significant decrease in control error ($p > 0.05$) for the OCC group across any test. No significant decrease was experienced for the PRA or CON group across any variable.
CONCLUSION: Using spatial occlusion goggles to remove vision of an incoming football showed a significant improvement for performance. There was a significant reduction in number call error and outcome error for the OCC group. Although a different form of visual occlusion was used in the current research the results are consistent with results from studies that have used visual occlusion as a training tool to improve sports performance (Farrow et al, 2005; and Muller & Abernathy, 2014).

THE EFFECT OF A 4-WEEK STROBOSCOPIC TRAINING ON SPORT-SPECIFIC VISUOMOTOR PERFORMANCE AND VISUAL FUNCTION IN TOP LEVEL BADMINTON PLAYERS

HÜLSDÜNKER, T.1,2, RENTZ, C.1, STRÜDER, H.K.1, MIERAU, A.1,2

<1> GERMAN SPORT UNIVERSITY COLOGNE, <2> LUNEX INTERNATIONAL UNIVERSITY OF HEALTH, EXERCISE AND SPORTS

INTRODUCTION: An increasing number of studies suggest stroboscopic training is a promising training approach to improve visuomotor performance in sports. However, previous research mainly focused on untrained participants. Thus it remains unclear if stroboscopic interventions are also effective for athletes that already reached a high skill level in visuomotor demanding sports. Further, previous experiments were restricted to behavioural parameters although research indicated visuomotor performance in experienced athletes is substantially determined by visual processes. Therefore, this study evaluated stroboscopic training at the behavioural and neurophysiological level in skilled athletes.
METHODS: Ten German top level badminton players (intervention: n=5, control: n=5) participated in this study. Within a training period of 4 weeks, athletes performed identical badminton-specific visuomotor tasks either wearing shutter glasses (intervention) or under normal visual conditions (control). Prior to and after the training period, smash defence tests were performed to examine modulations in sport-specific visuomotor abilities as indicated by the proportions of successful hits, frame hits and missed balls. In addition, neurophysiological analyses of the N2 motion onset visual evoked potential (VEP) latency identified adaptations of visual motion perception/processing speed in the athletes' motion sensitive mid-temporal visual area MT.
RESULTS: Badminton training improved visuomotor performance in both groups however, performance gains were significantly higher following stroboscopic training. Specifically, athletes participating in the stroboscopic intervention group achieved stronger improvements in the proportion of successful hits (p=0.028) as well as a greater reduction of missed balls (p=0.007). In contrast, N2 latency modulations in area MT following training did not significantly differ between groups. Nonetheless, there was a strong correlation between changes in N2 latency and visuomotor performance (r=-0.55) indicating higher performance gains following training were associated with a stronger reduction of the N2 latency.
CONCLUSION: The results indicate badminton training under stroboscopic conditions may be more effective than conventional visuomotor training to improve visuomotor abilities even for athletes performing at high skill level. Furthermore, visuomotor performance gains may potentially be mediated by neural adaptations in the cortical visual motion system. Given the importance of visuomotor abilities in badminton, the results suggest stroboscopic training is a promising training approach for visuomotor demanding sports. Moreover, information about the underlying neural mechanisms could help coaches to individualise stroboscopic training interventions based on the athlete's neurophysiological profile.

EFFECTOR-SPECIFIC RESPONSE INHIBITION OF TEAM HANDBALL EXPERTS AND RECREATIONAL ATHLETES

HEPPE, H., ZENTGRAF, K.

UNIVERSITY OF MUENSTER, UNIVERSITY OF FRANKFURT

INTRODUCTION: In interactive sports, athletes have to respond quickly to their teammates´ or opponents´ actions and, equally important, frequently inhibit initiated responses (e.g., when reacting to feints or when the previously opened passing lane is suddenly closed). There is some evidence that athletes from interactive sports are superior in inhibiting their motor responses based on perceptual input, both for younger (Huijgen et al., 2015; Verburgh et al., 2014) and adult athletes (Wang et al., 2013; Zhang et al., 2015). In previous studies, participants had to respond by pressing buttons with their index fingers. In this experiment, we aimed at investigating whether response inhibition is effector-specific and related to motor expertise. Apart from the usage of their hands, handball athletes likewise respond to actions with their lower extremity (e.g., reactions on feints). Therefore, response inhibition of hands and feet was tested. We hypothesized that handball players perform better in both conditions compared to recreational athletes.
METHODS: Male professional handball players playing in the second league in Germany (n = 30) and male recreational non-handball athletes (n = 30) were tested in a response inhibition paradigm (DV was stop-signal reaction time, SSRT). A repeated-measures ANOVA with factors response-effector (hands, feet) and group (expert, recreational) was conducted.
RESULTS: Results showed significant main effects of response-effector ($F(1,58) = 26.54$, $p < .001$, $\eta p^2 = .314$) and group ($F(1,58) = 7.89$, $p = .007$, $\eta p^2 = .120$) with shorter SSRTs in the hands condition and shorter SSRTs of handball experts. The interaction between response-effector and group was not significant ($F(1,58) = 2.87$, $p = .096$, $\eta p^2 = .047$).
In the feet condition, a post-hoc test (one-tailed) showed no significant difference between handball experts ($M = 259.5$ ms, $SD = 41.6$) and recreational athletes ($M = 276.74$ ms, $SD = 38.4$), $t(58) = 1.67$, $p = .10$, 95% CI [-0.08, 0.943], $d = .43$. In the hands condition, a post-hoc test (one-tailed) showed a significant difference between handball experts ($M = 229.36$ ms, $SD = 32.83$) and recreational athletes ($M = 261.52$ ms, $SD = 39.00$), $t(58) = 3.46$, $p = .001$, 95% CI [0.362, 1.423], $d = .89$.
SSRTs of hands and feet were positively correlated, Pearson´s $r(58) = .625$, $p < .001$.
CONCLUSION: In general, our findings replicate previous findings that expert athletes from interactive sports show better performance in tests on response inhibition and speak for the relevance of cancellation of initiated responses in handball. When responding with their hands, handball experts showed substantial shorter SSRTs, indicating superior response inhibition, compared to recreational athletes. When responding with their feet, the difference between groups halved. Since the frequent use of hands is an important feature in interactions in handball, it could be speculated that this explains why handball experts show superior performance when responding with their hands.

SUPERIOR EXECUTIVE FUNCTIONS IN ELITE GAME SPORTS THAN IN ENDURANCE SPORTS ATHLETES

BIRKLBAUER, J., GONAUS, C., WINKLER, B., MÜLLER, E.

UNIVERSITY OF SALZBURG

INTRODUCTION: There is converging evidence that cognitive and academic performance is causally linked to cardiovascular fitness (e.g. Fedewa & Ahn 2011), which is attributed to several neurobiological mechanisms that benefit from physical activity (e.g. Vivar & van Praag 2017). Besides physical demands of endurance sports (ES), games sports (GS) provide additional demands on higher-order cognitive functions, such as working memory, inhibitory control and cognitive flexibility, since players need to consider large amounts of information in every new moment, rapidly suppress responses and quickly change strategies. Therefore, we hypothesized that GS athletes outperform ES athletes in general executive functioning.

METHODS: The performance of executive functions in 122 elite GS athletes (including soccer, ice hockey, basketball and tennis) and 112 elite ES athletes (including triathlon, swimming, cycling, running, orienteering and speed skating) were tested by means of the non-verbal Design Fluency test. At time of testing, athletes in GS (age: 24±5) and in ES (age: 24±8) were competing at the national top level and trained on average 10.7±2.5 and 12.4±5.4 hrs/wk, respectively. In order to control for confounders we assessed age, sex, test time, school education, training age, starting age, training frequency, age at inception, type of sport and second sport.
RESULTS: As predicted, GS athletes showed significantly better executive functions than ES athletes in all three sub-conditions ($p<.001$; eta2=.061-.078). Taken all conditions together, in the best design fluency quintile 68% were GS athletes, while in the quintile with the lowest test results 74% of the subjects belonged to ES (corrected for the sampling distribution). The best results were achieved by soccer players, who performed on average 28% more designs than road cyclists and long-distance runners. Remarkably, both groups, GS and ES athletes, performed much better on the executive test than the standard population.
CONCLUSION: Our findings confirm that general executive functions are important in GS, which is in line with a number of studies in various ball sports that found superior metacognitive functioning in elite players than in sub-elites or normal population (e.g. Vestberg et al. 2017). However, it is still unclear whether this is the consequence of practice or the result of a selection process. In the former case, it opens new possibilities for further performance improvements in GS by early interventions and it emphasizes the importance of game-based exercises as an integral part of school sports programs. In the later case, it may change the way how new talents are recruited. To further unravel this issue, longitudinal and long-term intervention studies are needed.

IS-SH02 Encountering Transnational Sports Migration

DREAMS TO REALITY? RIGHT TO DREAM, FC NORDSJÆLLAND AND FEMALE FOOTBALL MIGRATION FROM GHANA TO DENMARK

AGERGAARD, S., DARBY, P.
AALBORG UNIVERSITY

In May 2013, Right to Dream (RtD), a Ghanaian based football academy with a considerable record of producing migrant professional football players, opened the first residential girls' football academy in Africa. Following its purchase of the Danish Superleague team FC Nordsjælland (FCN) in late 2015, FCN and RtD announced their intention to launch a woman's football academy in 2018, to establish a team in the elite women's league in Denmark the following year and to pursue entry into the Women's Champions League by 2023. This paper is based on three bouts of ethnographic fieldwork in Ghana, Sweden and Denmark which involved interviews with the first cohort of girls recruited by RtD (n: 16), key personnel involved in the inception and development of the academy in Ghana (n: 7), and the core staff who lead the women's football academy in Denmark (n: 3). The paper presents preliminary findings on how the collaboration between an African football academy and a Danish football club came about; what its key objectives are, and how these objectives are likely to be realised in the future. Also, the paper describes, how young Ghanaian girls imagine the possibilities of transnational mobility through football, how they act to produce mobility and enhance their visibility, and how the RtD/FCN collaboration might facilitate these processes. The paper concludes that the collaboration between RtD and FCN on women's football calls for new perspectives on transnational connections between African and European football and on migration pathways for African players seeking professional football careers in Europe.

HUMAN TRAFFICKING IN FOOTBALL: DEBATES, POLICIES AND ETHICS

ESSON, J.
UNIVERSITY OF LOUGHBOROUGH

Reports of human trafficking within the football industry have become a topic of academic, policy, and media concern. The movement of young hopeful footballers from Africa to Europe, and more recently to Asia, dominates these accounts. This paper examines academic debates over the trafficking of African footballers, and evaluates the key policy responses that have emerged to address this issue. It is argued that existing understandings of football trafficking suffer from two key limitations, namely, a receiving country bias, and a tendency to misread the significance of socio-economic conditions within origin countries. Building on these insights, the paper draws on ethnographic fieldwork with would-be football migrants in Accra (Ghana) to demonstrate how a critical examination of the contemporary perception of professional football as a vehicle for social mobility can help extend conceptual understandings of this issue, particularly in relation to understanding better the risks young people are willing to take to migrate through football. Through doing so, I seek to illustrate why existing policy responses may prove to be ineffective, and to think through how we can generate responses that are ethically sound, feasible and practical.

PRECARIOUS POST-CAREERS. OCCUPATIONAL CHALLENGES AMONG FORMER WEST AFRICAN FOOTBALLERS IN NORTHERN EUROPE

UNGRUHE, C.
AARHUS UNIVERSITY

Entering a career's "after life" is a challenging turning point in the lives of many professional athletes. In general, lack of alternative occupational opportunities, financial difficulties and a declining social status have been identified as crucial and (often interconnected) obstacles for their post-career trajectories. While migrant athletes form a notably vulnerable group, this counts in particular for athletes from

the so-called global South who have embarked on professional careers in Europe. So far, however, existing studies on the phenomenon have focused on experiences of athletes from the global North, leaving others, e.g. African athletes out of the picture.
Taking former West African footballers in Northern Europe as a case study, this paper focusses on the reasons for and experiences of occupational challenges that migrating players from the global South face after their careers conclude. It particularly highlights the impact of low salaries, the subordinate role of education, and the problem of limited job opportunities outside football. While pointing to specific precarious challenges for this group of migrants, the paper also aims to expand knowledge about the phenomenon of transnational football migration from the global South beyond the time of pre- and actual careers. It is based on multi-sited ethnographic research and 20 interviews with West African footballers who played in Northern Europe between the mid-1990s and 2015.

IS-SH07 Acute and chronic exercise effects on attention and executive function: domain-specific implication for sport and domain-general relevance across the lifespan.

ACUTE AND CHRONIC EXERCISE EFFECTS ON ATTENTION AND EXECUTIVE FUNCTION: DOMAIN-SPECIFIC IMPLICATION FOR SPORT AND DOMAIN-GENERAL RELEVANCE ACROSS THE LIFESPAN

MEMMERT, D.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Attention is a crucial factor regarding sport related performance. As athletes and referees are constantly overwhelmed with a multitude of visual and auditory stimuli, which they cannot process at once due to a limited capacity of in-formation processing, the question arises how attention can be directed efficiently to make optimal decisions. Athletes and referees should also be able to control the direction of their attention to such an extent that they can distinguish between relevant and irrelevant information. Based on neurological and psychological findings, different kinds of attentional sub-processes are presented. Additionally, I will demonstrate that the new attention window paradigm is important to measure attention breadth in complex environments like training situations of athletes. Different testing procedures were developed regarding measurements of all dimensions of attention, and numerous strategies for optimal attentional direction and control were tested. This has direct consequences for the development of new training programs for players and referees.

PHYSICAL EXERCISE, BRAIN AND SUSTAINED ATTENTION: EVIDENCE FROM CROSS-SECTIONAL STUDIES.

SANABRIA, D.1, HUERTAS, F.2

1. UNIVERSITY OF GRANADA; 2. UNIVERSIDAD CATÓLICA DE VALENCIA "SAN VICENTE MÁRTIR"

The ability of being vigilant is fundamental for maintaining optimal performance in many daily tasks such as driving or attending to an academic lesson. Here, we show that the vigilance capacity is positively related to the level of regular practice of exercise, in children, adolescents and young adults. Over a series of studies, we consistently reported that individuals who practice exercise regularly outperformed those with a sedentary life style . In an attempt to pinpoint the factors that might drive that relationship, we will present data revealing the influence of both the type of exercise activity and cardiovascular fitness. Finally, we propose a novel hypothesis to explain the influence of the regular practice of exercise on cognitive and brain functioning based on the enhancement of brain-heart communication and interoception.

THE CONTRASTING EFFECTS OF PHYSICAL ACTIVITY ON ATTENTIONAL AND COGNITIVE AGING: DO THE QUANTITY AND QUALITY OF PHYSICAL ACTIVITY MATTER?

PESCE, C., FORTE, R., CONDELLO, G., CAPRANICA, L.

UNIVERSITY OF ROME

Physical activity, fitness and expertise in cognitively demanding sports seem to benefit not only domain-specific cognition, but also domain-general cognition, as executive function and attention, across the lifespan until old age. This presentation provides an overview of aging studies that try to disentangle the effects, on executive function and attention, of being physically active and fit from those of being an experienced athlete in cognitively demanding sports [1,2,3]. Both individual and joint effects of acute exercise bouts and chronic physical activity and sport practice are considered. Aging research data gathered with a testing paradigm that taps the efficiency of orienting and executive attention networks are summarized to show to what extent physical activity and deliberate sport practice may preserve attention or promote the development of compensatory strategies. Finally, we propose designed exercise training for older non-athletes realized by embedding cognitive and specifically executive function challenges into physical activity tasks [4,5]. We discuss potential mediating mechanisms and associations between cognitive and functional mobility outcomes of designed physical-cognitive dual-task training.

OP-PM60 Injury/injury prevention

A NEW TAPING TREATMENT: TREATMENT OUTCOME FOR RESTRICTION OF ANKLE DORSIFLEXION FOLLOWING LATERAL ANKLE SPRAIN

TAKESHI, T.1, AKITO, T.1, SHIRO, S.1,2, KEITA, N.1, SATORU, N.1
1:NISHIKAWA ORTHOPEDIC CLINIC, 2:CHIBA UNIVERSITY

INTRODUCTION: Restriction of ankle dorsiflexion is one of the sequelae of lateral ankle sprain. Although some factors that might influence the sequelae have been reported, reports on conservative treatment outcomes are lacking. In addition, Kobayashi et al. have reported that the fibula of the ankles with chronic ankle instability had more lateral position than that of the healthy ankles. This study aimed to report the efficacy of our original taping treatment based on patients characteristics.
METHODS: We evaluated medical records of our outpatients who were diagnosed with lateral ankle sprain within 1 month of trauma and underwent diagnostic magnetic resonance imaging. Inclusion criteria were restriction of ankle dorsiflexion and receiving our original taping. Of 65 potentially relevant patients, 15 met the inclusion criteria. First, we assessed improvement rate and duration for improvement of the restriction of ankle dorsiflexion with the taping treatment. Second, on the basis of these assessments, we divided the patients into the improvement and remaining groups. Periods of attendance at our clinic, ratio of anterior talofibular ligament (ATFL) tear as well as of bone bruise of the talus, and the distance between the tibia and fibula were compared between the two groups. Categorical variables were compared using Fishers exact test, whereas continuous variables were analyzed using Students t-test or Mann-Whitney U test, as appropriate.
RESULTS: The improvement rate of restriction of ankle dorsiflexion was 64.7%. The average period of up to improve from the first visit to our clinic was 37.1 ± 24.6 days. Statistical analyses showed a significant difference ($p < 0.01$) both in the period of attendance at our clinic (improvement group: 37.1 days; remaining group: 89.5 days) and ratio of bone bruise of the talus (improvement group: n = 3/9; remaining group: n = 5/6). No significant difference was observed in both the distance between the tibia and fibula (improvement group: 0.07; remaining group: 0.08) and ratio of ATFL tear (improvement group: n = 6/9 remaining group: n = 6/6).
CONCLUSION: Our study suggested that our taping treatment might be effective only for patients with restriction of ankle dorsiflexion without bone bruise of the talus. Hence, a new treatment method for patients with restriction of ankle dorsiflexion with bone bruise of the talus should be investigated.

STRESS AND FATIGUE AS RISK FACTORS FOR INJURIES IN AMATEUR FOOTBALL PLAYERS

FERRARI, P.1, GAZZANI, D.2, ASSISI, E.1, SPIRIDONOVA, M.1, GROSSGASTEIGER, S.1, MUR, C.1, RESNYAK, S.1
1 AZIENDA SANITARIA DELLALTO ADIGE, BOLZANO, ITALY 2 UNIVERSITÀ DI VERONA,VERONA, ITALY

INTRODUCTION: Adult amateur football players (AF) are the major part of football players worldwide, despite this the interest and number of researches on them are fewer compared to professional football players. Indeed there are few informations on AF and their injuries. In particular, on our knowledge few researches evaluate amateur outfield players (OP) who are for more aspects completly different in respect to goalkeepers and represent most part of the team. Therefore our aim was to evaluate OP, their injures and the possible risck factors.
METHODS: The partecipants undergo to anthropometric measurements and they had to complete a questionnaire. In the questionnaire we required information about player characteristic and about football injuries in the previous year. In addition, it was asked if playing football generally causes them significant physical fatigue or emotional stress. We considered AF who were over 20 years old.
RESULTS: 365 OP partecipated in the study, 27,7% were overweight and 99 had an injury. The total number of injuries was 129 and the more frequents were on muscle (29,4%). The OP injured were older and referred important physical fatigue and emotional stress compared to non injured players. We used multivariate logistic regression analysis in which the outcome was to be injured and the factors were age, BMI, role,years of playing, physical fatigue, emotional stress. Fatigue (OR 2.4; 95% CI 1.4-4.2; p=0.002) and stress (OR 2.5, 95% CI 1.06-5.9; p=0.037) were significantly and indipendently associated with injury.
CONCLUSION: In our study, an intresting result is that above a quarter of non goalkeeper players were overweight and that the more frequent site of injury was muscle. Previous studies reported an older age as a risk factor, but our final results were different; we found that, in OP only stress and physical fatigue are significative risk factor for injuries.

PERFORMING PART 2 OF THE FIFA11+ AFTER TRAINING REDUCES SEVERE INJURIES AND DAYS LOST TO INJURY WHILST INCREASING PLAYER DOSE EXPOSURE

WHALAN, M., LOVELL, R., STEELE, J.R., SAMPSON, J.A.
UNIVERSITY OF WOLLONGONG, WESTERN SYDNEY UNIVERSITY

INTRODUCTION: The FIFA11+ warm up has been shown to reduce injuries in sub-elite football (Thorborg et al., 2017) and high program compliance augments the injury reduction effect (Silvers-Ganelli et al., 2015). However, poor program compliance (Bizzini et al., 2015) and potential fatigue associated with Part 2 of the program (Lovell et al., 2016) suggest that strategies to optimize the delivery of the FIFA11+ are necessary. This study therefore examined the effect of re-scheduling the Part 2 of the FIFA11+ after training upon injury incidence and individual player exposure.
METHODS: 806 semi-professional Australian football players from 20 clubs were recruited during the 2017 season. Clubs were randomly allocated to either the control group (standard FIFA11+ program; 10 clubs; 398 players) or experimental group (Part 2 post training; P2post; 10 clubs; 408 players), with clubs instructed to perform the program twice a week. Coaches and trainers undertook a FIFA11+

training course and were provided with reference material. Injury and exposure data were collected by an on-site primary data collector as per the Football Consensus statement (Fuller et al, 2006). Individual player FIFA11+ dose was recorded and an independent sample T-test performed to examine any significant between group difference. A Poisson regression assessed between group differences of the total injury count, total severe injuries and total days lost to injury considering group, FIFA11+ dose, and total football exposure (hours) as predictor variables (SPSS v25, IBM, USA).
RESULTS: 651 time loss injuries were recorded during 54604 hours of exposure (training and matches combined) across both groups. Players in the P2post (29.1 ± 15.3) had a higher FIFA11+ dose exposure versus FIFA 11+ (18.9 ± 18.6; p<0.0001). Injury incidence rates of 12 injuries/1000hrs and 11.8 injuries/1000hrs were observed in the FIFA 11+ and P2post groups with no between group differences (p=0.636; Exp(B)=1.04; 95% CI, 0.88 to 1.23) observed. P2post had a lower number of severe injuries (33 vs 58 injuries; p<0.002; Exp(B)=2.03; 95% CI, 1.30 to 3.17) and total days lost to injury (4300 vs 5925 days; p<0.0001; Exp(B)=1.66; 95% CI, 1.59 to 1.73) versus FIFA 11+.
CONCLUSION: Rescheduling Part 2 of the FIFA11+ resulted in a higher individual player exposure yet a similar injury incidence was observed when compared to the normal program. However the scheduling approach yielded a reduction in severe injuries and total days lost to injury. Rescheduling Part 2 post-training may thus provide an avenue to improve FIFA11+ uptake and support, as well as enhance the effectiveness of the program.

A DESCRIPTIVE ANALYSIS OF INCITING EVENTS AND MECHANISMS OF CALF MUSCLE INJURIES IN PROFESSIONAL GERMAN FOOTBALL.

STEENDAHL, I.1,2, TRÖß, T.1, AUS DER FÜNTEN, K.1, HAUSER, T.2, MEYER, T.1

1: SAARLAND UNIVERSITY, SAARBRÜCKEN, GERMANY. 2: GERMAN FOOTBALL ASSOCIATION , FRANKFURT, GERMANY.

INTRODUCTION: Understanding both, mechanisms and the inciting events of an injury, is considered a vital part of developing appropriate injury prevention strategies (Bahr & Krosshaug, 2005). Although calf muscle injuries (CMIs) constitute 13% of all muscle injuries in professional football (Ekstrand, Hägglund & Waldén, 2011), limited research has investigated their characteristics in detail. This study therefore aims to analyse injury circumstances and general lower limb biomechanics of CMIs sustained during match play in professional German male football.
METHODS: From a database of publicly available information, where match injuries in professional German football from the 2008/09 to the 2016/17 season have been recorded, 55 non-contact CMIs were identified. Fourteen of these injuries had acute onsets visible on video material of the matches obtained through the publicly available platform Wyscout.com and were included for initial analysis.
Using a standardised analysis form modified from previous research (Waldén et al., 2015; Grassi et al., 2017), the injuries were analysed in relation to the playing situation, player and opponent behaviour as well as to the biomechanical details of player movements while sustaining the injury.
RESULTS: Preliminary results indicate that seven of the 14 CMIs (50%) occurred while the injured player performed a movement transition, either by changing direction, accelerating or decelerating. Five (35%) of them occurred when the player seemed to be either out of balance or moving in one direction whilst focusing on the match play taking place in a different direction. Four (29%) of the injuries occurred when kicking the ball and three (21%) while closing-down an opponent.
CONCLUSION: Although only a limited number of injuries (n=14) were eligible for this analysis, CMIs seem to occur in various match situations. A further refined analysis of the inciting events of CMIs may reveal whether specific situations result in the sudden combination of knee extension and ankle dorsiflexion, a movement pattern, which has been considered the main mechanism of CMIs (Green & Pizzari, 2017). Therefore, a more detailed examination of a larger sample of CMIs may yield the potential to provide valuable information for appropriate development of future prevention strategies.

YOUNG AND SENIOR INTERNATIONAL ÉLITE ATHLETES ON-FIELD COMPARISON FOR TECHNIQUE ENHANCEMENT AND INJURY PREVENTION DURING RUGBY SIDE-ON TACKLE

PAVAN, D.1, CIBIN, F.1, GUIOTTO, A.1, SPOLAOR, F.1, SGORLON, A.2, PAVANELLO, A.2, CASAGRANDE, T.2, SBROCCO, G.2, SAWACHA, Z.1

UNIVERSITY OF PADUA

INTRODUCTION: During a Rugby match, the tackle has been recognized as the task leading to the higher number of injuries [1,2]. Despite injury rate has already been correlated with athletes' age [4], literature reports no information about technique comparison between young and experienced athletes. The present study aims to investigate the international élite young and senior athletes tackling technique, to highlight differences both in technique effectiveness and ACL injury risk.
METHODS: 5 athletes from Benetton Treviso (mean ± standard deviation (SD) BMI: 29.26±4.41, age: 24.20±4.49 years), and 5 athletes from the Italian Rugby Federation U18 Academy (BMI: 28.32±2.96, age: 17.13±0.64 years) participated in the study. All the athletes take regularly part in international fixtures. Participants, after signing informed consent, performed 4 repeating tackles in the rugby field. Video sequences and plantar pressure distribution were acquired by means of a Novel Pedar system and 4 synchronized cameras (GoPro Hero3); hence peak vertical ground reaction force (PV) was recognized, and specific features were tracked on the motion sequences [5,6]. Key instants were recognized as: left foot PV (LPV), right foot PV (RPV), contact between players (C).

At key instants, sagittal plane kinematics, along with sagittal and coronal plane joint moments at hip, knee and ankle joints were determined and their position, in the tackle task, evaluated (Matlab R2013a). Moments were hence normalized in percentage of the body weight times height (%BW*h).
Tackler's centre of mass acceleration have been calculated basing on 2D trajectory reconstruction; hence peaks have been recognized in specific task sections: start-contact (SC), contact-grounding (CG), and grounding-ball retrieve (GR).
Student's indipendent T-Test has been performed to highlight differences between the two groups.
RESULTS: Senior athletes shown a significantly earlier LPV and C, along with an earlier, higher acceleration during the SC cycle ($p<0.05$). Significant difference in hip flexion at C was underlined (Senior: 108°±24°; Young: 140°±40°), along with higher ankle eversion (Senior: -5,2±3,3 %BW*h; Young: -9,1±5,5 %BW*h), knee valgus (Senior:-6,8 3,8± %BW*h; Young: -12,5±9,8 %BW*h) and hip adduction (Senior: -6,9±4,6 %BW*h; Young: -17,0±10,4 %BW*h) moments at RPV.
CONCLUSION: The more experienced athletes displayed as expected a quicker, hence more confident, execution of the tackle, while keeping the valgus torque at low values. The lack in experience affected the tackling efficiency and posture in FIR U18 athletes, exposing some of them to ACL injury risk. This screening tool can be useful to coaching and clinical staff, to improve players safety and effectiveness.

OP-PM56 Physiological characteristics of trained individuals

OVERLOAD IN TENNIS TRAINING; EFFECTS ON PHYSICAL PERFORMANCE AND PHYSIOLOGICAL AND PERCEPTUAL RESPONSES.

DUFFIELD, R.1, AUBRY, A.2, SUDOUR, W.3, MORIN, J.B.3, HAUSSWIRTH, C.2,3
1: UTS , 2: MOURATOGLOU TENNIS ACADEMY , 3: UCA-LAMHESS

INTRODUCTION: Weekly tennis schedules are typically represented by variable and uncontrolled training loads (TL) during tournament phases, punctuated by spikes in TL during periods of training [1]. Such spikes in TL are reported as potential precursors to injury or overreaching states in many athletic populations [2]. Given the effects of high TL have not been reported in tennis players, the current study determined the acute physiological, perceptual and performance responses to high TL in well-trained youth tennis players.
METHODS: Eleven male, national-level, youth tennis players (age: 16+/-1y and 8+/-1y training experience) undertook 1 week of normal training (CTRL) and a week with a 30% increase in TL (HiL). The 30% higher TL was delivered by increased training duration distributed equally to on-court tennis and gym-based conditioning. TL was monitored by stroke counts from wrist-mounted accelerometers, court-based movement from Global Positioning Satellite devices and session rating of perceived exertion (sRPE). At the start and end of both CTRL and HiL weeks, physical performance measures (counter-movement jump, drop jump, change of direction and internal/external shoulder rotation force) were recorded. Further, heart rate, heat rate recovery, (Masimo oximetry) and RPE responses to a standardised 5min sub-maximal cycle test were measured. Finally, perceived muscle soreness was also collected throughout each respective training week.
RESULTS: Effect size (ES) analysis showed training volume (30+/-3%), stroke counts (32+/-3%) and sRPE TL (50+/-10%) were all increased in HiL (ES>6.0). Trivial changes (ES<0.20) in jump height, change of direction speed or shoulder rotation force measures were evident during the HiL week or compared to CTRL week. However, perceived muscle soreness was increased during HiL week compared to CTRL (ES>1.30). Moderate effects for a decrease in heart rate and heart rate recovery (ES<0.50) and increase in RPE (ES>1.0) to a standardised 5min cycle test were evident following the HiL compared to CTRL week.
CONCLUSION: A 30% increase in weekly on-court and gym TL resulted in no clear short-term change in physical performance markers in trained youth tennis players. However, increased RPE to a submaximal cycle test and perceived muscle soreness following training show responsiveness to the higher TL. Despite suggestions of the negative consequences of spikes in TL and risk of overreaching, no negative short-term consequences of a large increase in TL were evident in the current tennis cohort.

CHANGES IN MUSCLE VOLUME, SPRINT MECHANICAL PARAMETERS AND PERFORMANCE IN SPRINTERS DURING AN INDOOR TRACK AND FIELD MACROCYCLE.

NUELL, S., ILLERA-DOMINGUEZ, V., CARMONA, G., ALOMAR, X., PADULLÉS, J.M., LLORET, M., CADEFAU, J.A.
INEFC BARCELONA

INTRODUCTION: Many factors may influence the sprint performance, although force production seems to be the most critical. It has been recently shown that the ability to orientate the resultant ground reaction force (GRF) vector forward, in other words to produce higher horizontal component of GRF throughout the sprint is the strongest predictor of acceleration and sprint performance, as well it is the differential factor between recreational and top level sprinters. Muscle mass seems the major determinant of maximal force. In addition, joint torque and power generation capabilities are largely determined by the muscle volume rather than cross sectional area. Therefore, seems logical the belief that muscle mass and more specifically muscle volume, could play an important role regarding sprint performance.
METHODS: 12 Senior and Under-23 national level sprinters (23.5 ± 4.2 y.o.) were screened during an indoor macrocycle. They were tested before they started their training regime and before the main competition. Testing procedures included Magnetic Resonance Imaging of the thighs to compute volumes of quadriceps (vQUAD), hamstrings (vHAMS) and adductors (vADD) muscle groups; a 40m dash using a

radar gun to asses sprint mechanical parameters of the sprint such as: theoretical maximal horizontal force (F0) and theoretical maximal velocity (V0); and 40m, 80m and 150m sprint performance tests using photocells.
RESULTS: vQUAD increased 6.66 ± 4.58 % (P < 0.01), vHAMS increased 10.09 ± 5.1% (P < 0.01) and vADD increased 12.14 ± 4.34% (P < 0.01). V0 increased 5.25 ± 2.35% (P < 0.001), no significant changes were seen in F0 through the macrocycle. Time to run 40m, 80m and 150m was decreased by 4.88 ± 1.72% (P<0.001), 4.38 ± 1.63% (P < 0.001) and 4.55 ± 1.84% (P < 0.001).
CONCLUSION: Improvements of sprint performance were accompanied of increases in vQUAD, vHAMS, vADD and V0 showing the importance of this parameters in sprint performance. The relative higher increase of vHAMS and vADD compared with vQUAD could explain the role of the hip extensors and hip flexors, rather than knee extensors, in sprinting due to the role of hamstrings and adductor magnus in hip extension and the rest of the adductors in hip flexion. The increase in V0 and not in F0 give us some information about the importance of the "velocity-oriented" profile in sprinters, as shown before V0 is the most determinant variable when comparing elite vs. average sprinters.
From a practical point of view we strongly believe knee-extensors exercises are overused in sprinters strength training. We also want to encourage coaches to asses sprint mechanical parameters in order to individualise the training.

PHYSIOLOGICAL CHARACTERISTICS OF FIRST DIVISION FEMALE FOOTBALL PLAYERS IN GAUTENG, SOUTH AFRICA

COOPOO, Y., WILLIAMS, K., FORTUIN, C.

UNIVERSITY OF JOHANNESBURG

INTRODUCTION: In Africa, South Africa has been among the pioneers of womens football . However, successive teams have repeatedly missed continental success at various championships over the past 15 years . This study aimed to determine the profiles of first division female football players in Gauteng with specific reference to physiological characteristics.
METHODS: The research methods included both fieldwork and questionnaires. A questionnaire was used to gather descriptive information with regard to the demographics of players and various field tests were used to describe the physiological profile of the female football players. The stratification of the sample was 12 teams, comprising 148 players who completed the full testing procedures.
RESULTS: The outcomes of the study showed that the fitness levels for all playing positions were statistically not significant, however, differentiated according to playing position. Specific training should occur for various playing positions within female football players. These are the first set of norms available for female footballers in South Africa.
CONCLUSION: it would appear that the conditioning programmes for female football players are alike.The forwards, backs, midfielders and goalkeepers are all provided with the same conditioning programme with no differentiation for playing positions.

MAXIMAL JUMPING PERFORMANCE IN THE MAASAI PEOPLE OF EAST AFRICA

BOJSEN-MØLLER, J.1,2, SEYNNES, O.R.1, MAGNUSSON, S.P.3, HERNÆS, H.1, REFSDAL, A.1, CHRISTENSEN, D.L.4, AAGAARD, P.2

1: NORWEGIAN SCHOOL OF SPORT SCIENCES , 2: UNIVERSITY OF SOUTHERN DENMARK , 3: BISPEBJERG HOSPITAL, , 4:UNIVERSITY OF COPENHAGEN

INTRODUCTION: The Maasai of East Africa have an ancestral tradition of ritual jumping during which some individuals demonstrate quite extreme jumping ability as evidenced mainly by anecdote. The aim of the present study was therefore to (1) assess vertical jumping ability in detail, (2) examine anatomical and biomechanical lower limb characteristics in order to investigate the possibility of an acquired or inherited jumping capacity in male Maasai jumpers.
METHODS: A field study was carried out in Tanzania, where 22 male Maasai jumpers (172.0 ± 5.6 cm, 58.3 ± 5.4 kg) performed maximal counter-movement jumps (CMJ) and maximal repetitive jumps (RJ) on a force plate. Twelve Scandinavian males (177.7 ± 4.5 cm, 69.3 ± 4.4 kg) served as controls (CON). Anthropometrics of the body and legs were recorded, and kinematic and kinetic data were obtained during jumping. Achilles tendon stiffness during isometric MVC as well as tendon and muscle fascicle mechanics during RJ were measured using ultrasonography.
RESULTS: The Maasai jumpers had longer legs relative to body height, shorter and more proximal calf muscles, longer (23.2 ± 0.7 vs. 19.8 ± 0.6 cm, P<0.05) and more compliant (241 ± 15 vs. 311 ± 22 N/mm, P<0.05) Achilles tendons compared to CON. Maximal vertical jump height was similar between Maasai and CON (CMJ: 46.5 ± 4.3 vs 46.5 ± 6.1 cm, RJ: 30.4 ± 6.2 vs 29.7 ± 5.0 cm, respectively), but relative to body mass the Maasai jumped 20% higher in both conditions. Maximal CMJ execution was faster in Maasai vs CON: eccentric deceleration phase (114 ± 29 vs. 172 ± 22 ms, P<0.05), concentric phase (213 ± 38 vs. 286 ± 43 ms, P<0.05) accompanied by a more shallow counter movement amplitude with 24% greater peak vertical force (29.7 ± 5.3 vs. 24.0±1.4 N), 12% higher power exertion (55.2 ± 8.3 vs. 49.2 ± 5.8 W/kg), 148% higher rate of force development (219.9 ± 199.2 vs. 88.6 ± 28.24 N/kg/s), 156% greater lower limb stiffness (246 ± 135 vs. 96 ± 26 N/m) and 13% greater vertical jump efficiency (5.1 ± 0.5 vs. 4.5 ± 0.5 cm/J/kg). In RJ the Maasai had lower self-selected frequency, and greater joint range of motion. Fascicle behavior was generally isometric during RJ in both groups however, the tendon length change was greater for the Maasai during RJ (9 ± 2 vs. 3 ± 4 % (relative to resting MTU length), P<0.05).
CONCLUSION: Although some Maasai jumpers demonstrated outstanding vertical jump performance no differences in raw jump height was seen on a group basis. Notably however, force, power, limb stiffness and vertical jump efficiency were greater in the Maasai during maximal CMJ. The Achilles tendon was longer and more compliant in the Maasai, and during repetitive jumping the elongation/shortening of the series elastic element was greater in the Maasai. The present data show that the Maasai jumpers have an explosive-type CMJ execution, and a high mechanical efficiency during both CMJ and maximal RJ which may relate to the observed differences in anatomy and mechanical properties of the series elastic element.

PHYSICAL DEMANDS OF AIRPORT FIRE BRIGADE AND ITS EFFECTS ON PERFORMANCE

KLEINÖDER, H., DÖRMANN, U., DIETZSCH, M., RAPPELT, L., WIRTZ, N., MICKE, F., DONATH, L.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: In general, fire brigades have high physical demands such as working with heavy equipment or carrying injured people. Moreover, airport fire fighters have to fulfil these tasks wearing up to 70 kg additional load. A warm-up is not possible due to the extreme time restrictions to reach each place at the airport in emergency. Accordingly, the final question deals with best possible preparation for this profile to save health and secure work capability. Therefore the first aim of this study was to analyze typical physical specifications of airport fire brigades and its effects on performance.

METHODS: The analysis of typical physical demands of the Cologne airport fire brigade (n=10; av. 38y, 21-54y; av. 86.6kg , 66-115kg) consisted of dummy (personal rescue) and firehose pulling with and without protective clothing. The first issue were the force requirements during these tasks (measured with a force sensor, mechatronic 5kN) and the second the loss of essential strength parameters due to fatigue and equipment. After dummy (75kg, 66 m) or firehose pulling (mass constantly increasing, 40 m) maximal force and speed strength was measured at different time intervals at a leg press machine (gym 80, edition line) with force and distance sensors (mechatronic, 10kN).
RESULTS: Time for dummy pulling was av. 69.9s (56-86s) without pre-exhaustion and without protective equipment and increased significantly to av. 84.9s (76-100s) resulting in a loss of performance of around 20% (with HF av. 152bpm, range 122-172bpm, av. lactate 7.74mmol/l, range 5.78-10,2mmol/l). Force values decreased significantly from beginning to end from 418N+-30N to 369N+-41N with an increase of amplitude (144+-32N to 165+-66N, n.s.) and a simultaneous significant decrease of frequency (7 peaks/s +-1.7 to 4.4 peaks/s +-1.5) of measured force peaks. Maximal force directly after dummy pulling decreased significantly from 2897N+-490 (pre) to 2583N+-511 and recovered after 10 min (2809N +-560). In contrast to this, RFD did not recover significantly (12191N/s +-3821 pre; 8166N/s +-2981 post; 8856N/s +-3073 post 3min; 9415N/s +- 3265 post 10min). The results of firehose pulling were generally similar with recovery of maximal force not before ten minutes but no restoring of RFD. Force values increased with length of firehose.
CONCLUSION: Since physical demands are very high on airport fire fighters it is necessary to prepare them especially for these requirements during their professional career. This esp. includes an increase of maximal force (cp. Sharky/Davis 2008) and speed strength in order to cope with these repeated demands during exercise and emergency of airport fire brigades.

OP-BN41 Neuromuscular exciatability and motor control

EFFECTS OF CONTRACTION INTENSITY ON THE RESPONSES TO BRAIN AND CORTICOSPINAL TRACT STIMULATION AFTER A SINGLE SESSION OF RESISTANCE TRAINING

COLOMER-POVEDA, D.1, ROMERO-ARENAS, S.1, LUNDBY-JENSEN, J.2, HORTOBÁGYI, T.3, MÁRQUEZ, G.1

1. CATHOLIC UNIVERSITY OF MURCIA. 2. UNIVERSITY OF COPENHAGEN. 3. UNIVERSITY OF GRONINGEN.

INTRODUCTION: A single session of resistance training (RT) increases the excitability of the corticospinal tract probably due to increases in motoneuronal or cortical neuron excitability or a higher corticospinal synapse efficacy (Nuzzo et al. 2016; Selvanayagam et al. 2011). Such acute changes may precede chronic adaptations underlying strength gains after a period of RT. To explore neural adaptations to RT, most studies used loads near maximal voluntary contraction (MVC). Yet RT at lower intensities (<60% MVC) can also improve muscle strength (Schoenfeld et al. 2017). We hypothesized that neural adaptations to a single session of RT are proportional to contraction intensity. We thus determined the effects of acute RT on the responses to brain and corticospinal tract stimulation.
METHODS: In four experimental sessions, healthy young adults (n = 14) performed 12 sets of eight isometric contractions of the elbow flexors at 0 (control), 25, 50, and 75% of MVC. Before and after the acute exercise bouts, we measured motor and cervicomedullary evoked potentials (MEPs, CMEPs) in the biceps brachii every five minutes for 30 minutes (7 blocks).
RESULTS: Mean amplitude of all MEP obtained during the 30 minutes after training increased by 70% ($P<0.05$ vs. all other conditions) after muscle contractions at 75% intensity, and by 39% after 50% intensity bout ($P<0.05$ vs. CON and 25% intensity). MEP amplitude did not change after the 25% intensity bout (11%) and CON (-5%). CMEPs amplitudes increased by 28% ($p < 0.05$) but not differently after the 25, 50, and 75% intensity bouts, while it decreased by 16% ($p < 0.05$) in CON.
CONCLUSION: According to the hypothesis, corticospinal excitability increased after single bouts of RT in proportion to the intensity of muscle contraction used in the acute bouts of RT. Our data agree with the increases reported previously for the 75% condition (Nuzzo et al. 2016). In contrast, the increases in spinal excitability, indexed by CMEPs, were independent of contraction intensity. The data tentatively suggest that motor cortical compared with spinal motoneurons may be more sensitive to intensity of muscle contraction performed during acute bouts of RT. Future studies will examine if such changes in neuronal excitability are also proportional to the larger strength gains normally observed after high compared with low intensity RT.

STRONG VOLUNTARY CONTRACTION BUT NOT A WEAK ONE ENHANCES MOTOR CORTICAL EXCITABILITY

DAI, W.1, KATO, K.2, KANOSUE, K.2, ZHANG, J.3

1: WASEDA UNIVERSITY, 2: WASEDA UNIVERSITY, 3: SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: Motor learning facilitates motor cortical excitability through long-term potentiation (LTP) (Ziemann et al., 2004). However, a single session of simple muscle contraction can also enhance motor cortical excitability (Rosenkranz et al., 2007). It is not yet clear whether mechanisms underlying the two phenomena are the same. This research explores whether changes in cortical excitability after a single session of simple muscle contraction are related to changes in LTP produced by paired associative stimulation (PAS).
METHODS: Eight healthy subjects were asked to perform two types of rapid voluntary thumb contraction 90 times at 0.2Hz. In the "comfortable" task, the subjects were only required to complete thumb flexion as quickly as possible, whereas in the "strong" task the subjects were required to complete a similar movement, but at 65% to 85% of the force level for a maximum voluntary contraction. The LTP induced with PAS involved the same numbers and frequency as with the contraction tasks. Motor cortical excitability was measured with a motor-evoked potential (MEP) using transcranial magnetic stimulation. We utilized a "1 mV MEP" intensity for each subject as the baseline and stimulated with the same intensity at 0, 5, 10, 15, 20, 25, 30, 45, and 60 min after intervention (the contraction tasks or PAS).
RESULTS: The average contraction level for the "comfortable" task was significantly lower than that of the "strong" task. For the "comfortable" task, MEP amplitude gradually decreased with time and was significantly lower than baseline at 25, 45 and 60 min. In contrast, MEP amplitude gradually increased and was significantly greater than baseline in the period of 15-25 min for the "strong" task. The MEP amplitude after PAS exhibited a facilitation with a time course similar to that of the "strong" task.

CONCLUSION: Over the one-hour MEP observation, thumb contractions at the two strengths produced opposite results, probably due to a difference in the degree of concentration during the tasks. In the "comfortable" task, the subjects did not need to control contraction strength. However, in the "strong" task they were required to perform rapid contraction and simultaneously control force level. This would require a greater level of concentration.

PRECONDITIONING TDCS FACILITATES EFFECTS OF SUBSEQUENT TDCS APPLIED DURING CYCLING EXERCISE ON CORTICOSPINAL EXCITABILITY AND WORKING MEMORY IN YOUNG ADULTS

SIDHU, S.K., POURMAJIDIAN, M.

THE UNIVERSITY OF ADELAIDE

INTRODUCTION: Transcranial direct current stimulation (tDCS), a non-invasive neuromodulation technique, can be used to deliver continuous low intensity electrical currents, causing significant modulation in cortical excitability that mimic long-term potentiation (LTP) and long-term depression-like synaptic processes in humans (2). A recent study using tDCS reveal that priming the corticospinal system by lowering the threshold using cathodal-tDCS (ctDCS) for the induction of LTP-like plasticity during subsequent skill learning, augments corticospinal excitability and improves motor skill performance (1). However, the effect of priming ctDCS and subsequent anodal-tDCS (atDCS) coupled with cycling exercise on corticospinal excitability and working memory in young healthy individuals remain unknown.
METHODS: 11 subjects (21 ± 1 years) participated in two sessions receiving either priming cathodal-tDCS or sham stimulation, followed by anodal-tDCS (ctDCS-atDCS, sham-atDCS) while cycling at 1.2 times body weight (84 ± 20 W) in a counterbalanced double-blind design. Corticospinal excitability was measured with motor evoked potentials (MEP) elicited via transcranial magnetic stimulation intensity set to produce an MEP amplitude of 1 mV (S1mV) in a resting hand muscle. Executive cognitive function was measured using percentage correct (PC; %) and reaction time (RT; ms) in a 2-back short-term memory test. Both corticospinal excitability and cognitive function were measured at baseline (PRE), following priming tDCS (POST-PRIMING) and post atDCS combined with cycling exercise (POST-TEST).
RESULTS: There was no difference in RMT (sham-atDCS: 42 ± 1.7, ctDCS-atDCS: 41 ± 1.6) and S1mV (sham-atDCS: 53 ± 2.5, ctDCS-atDCS: 51 ±2.4) between sessions (P>0.5). There was a significant interaction between time and intervention ($P < 0.01$) and significant main effect of time ($P < 0.01$) and intervention ($P < 0.001$) on MEP. MEP increased at POST-TEST (1.3 ± 0.06) from PRE (1.0 ± 0.06) during ctDCS-atDCS ($P < 0.001$) but did not change across time during sham-atDCS (1.0 ± 0.06, $P > 0.7$). Furthermore, MEP was higher at both POST-PRIMING (sham-atDCS: 1 ± 0.06, ctDCS-atDCS: 1.1 ± 0.06) and POST-TEST (sham-atDCS: 1 ±0.06, ctDCS-atDCS: 1.3 ±0.06) in ctDCS-atDCS compared to sham-atDCS ($P < 0.01$). There was no interaction effect on PC ($F2, 147 = 1.7$, $P > 0.1$) and RT ($F2, 146 = 0.3$, $P > 0.7$), and no main effect of time ($F2, 128 > 2$, $P > 0.06$) on PC and RT. There was however, a main effect of intervention on RT ($F1, 52 = 9$, $P < 0.01$). RT at POST-TEST was shorter in ctDCS-atDCS (530.6 ± 27.3; $P < 0.01$), compared to sham-atDCS (597.7 ± 27.3).
CONCLUSION: The results demonstrate that priming cathodal tDCS can enhance corticospinal excitability and improve some domains of executive function following anodal tDCS applied in combination with cycling exercise. The outcomes suggest that priming tDCS protocols may potentially be used in sporting, clinical and defence settings to improve exercise tolerance and cognitive function.

ACUTE EFFECTS OF STATIC AND DYNAMIC STRETCHING ON SPINAL AND CORTICOSPINAL EXCITABILITY OF PLANTAR FLEXOR MUSCLES

OPPLERT, J., PAIZIS, C., PAPITSA, A., BABAULT, N.

INSERM UMR1093 CAPS

INTRODUCTION: The aim of the present study was to determine the acute effects of static and dynamic stretching on spinal and corticospinal excitability.
METHODS: On separate days, fifteen males completed three testing sessions on an isokinetic dynamometer. A control condition (CON), 5×20-s of static stretching (SS) and 5×20-s of dynamic stretching (DS) were randomly completed. Neurostimulation was firstly applied to investigate spinal excitability by using the Hoffmann reflex (Hmax/Mmax). Transcranial magnetic stimulation was secondly applied to investigate corticospinal excitability by recording the amplitude of the motor-evoked potential (MEP/Mmax) and the duration of the silent period (SP). These different responses were obtained during submaximal isometric contractions. Finally, neuromuscular properties were assessed using (i) the amplitude of the maximal M-wave (Mmax) and the corresponding peak twitch torque (PTT), (ii) the maximal voluntary isometric torque (MVIT) and the corresponding electromyographic activity (RMS values), and (iii) the V-wave (V/Mmax) elicited from a supramaximal stimulation during the maximal voluntary isometric contraction. These parameters were recorded before and immediately after each condition in the soleus (SOL), gastrocnemius medialis (GM) and gastrocnemius lateralis (GL) muscles.
RESULTS: Given that similar results were obtained for all triceps surae (TS) muscles, values from SOL, GM and GL were averaged. Statistical analyzes revealed an increase in MEP amplitude after SS and DS conditions (+30.2 ± 8.3% and +19.3 ± 9.5%, respectively; $P<0.05$) and no change was recorded after CON condition. Similarly, MEP/Mmax ratio was enhanced after SS and DS conditions (+30.9 ± 7.8% and +18.3 ± 7.7%, respectively; $P<0.05$) and was unaffected by the CON condition. No difference was obtained between SS and DS conditions for MEP amplitude and MEP/Mmax ratio. Hmax, Mmax and V-wave amplitude, Hmax/Mmax and V/Mmax ratios and the SP duration were unchanged. RMS/Mmax was significantly decreased after the DS condition (-16.7 ± 4.3%; $P<0.05$) but did not change after CON and SS conditions. Finally, PTT and MVIT were unaffected after all conditions.
CONCLUSION: As previously demonstrated, Hmax/Mmax and V/Mmax ratios were not modified after stretching. While spinal excitability was not altered after static and dynamic stretching, corticospinal excitability did increase, suggesting that neural modulations originated at a cortical level. This could be explained by a larger amount of sensory information to the brain from musculotendinous lengthening. Finally, neuromuscular properties were not affected after both stretching modalities. Nevertheless, such duration of dynamic stretching seems to induce fatigue which may alter central activation of motor unit of triceps surae.

EFFECTS OF AN EIGHT-WEEK DYNAMIC WHOLE-BODY ELECTROMYOSTIMULATION TRAINING ON STRENGTH AND POWER PARAMETERS OF THE LEG MUSCLES: A RANDOMIZED CONTROLLED STUDY.

MICKE, F., KLEINÖDER, H., DÖRMANN, U., WIRTZ, N., DONATH, L.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Whole-body electromyostimulation (WB-EMS) training is increasingly gaining importance in competitive sports. Despite a heterogeneous use of WB-EMS-specific stimulation patterns, a stimulation frequency of ≥60 Hz, a pulse width of 200-400 µs and a duty cycle of 50 % are recommended for improving strength and power parameters (Filipovic et al. 2012). However, in the context of WB-EMS, intervention studies have rarely been conducted so far. Therefore, the present study examined effects of dynamic WB-EMS training on maximal strength and power parameters of the leg muscles.
METHODS: Eighteen male sports students were randomly assigned to a WB-EMS intervention (INT; n=9; age: 22.8 ± 3.0 years; height: 179.4 ± 5.1 cm; body mass: 80.2 ± 6.6 kg; strength training experience: 4.6 ± 2.8 years) or traditional intervention (CON; n=9; age: 22.8 ± 2.5 years; height: 184.9 ± 9.1 cm; body mass: 77.6 ± 9.0 kg; strength training experience: 4.5 ± 2.9 years) group. Both training intervention programs had to be performed 2 times a week over a period of 8 weeks (adherence: INT & CON: 100%) with the only difference that INT performed all dynamic exercises (e.g. split squads, glute-ham raises, jumps, tappings) with superimposed WB-EMS. WB-EMS intensity was adjusted to 70% of individual pain threshold (RPE scale) to ensure dynamic movement. Before (PRE), after (POST) and two weeks after the intervention (FU), performance was assessed by maximal strength (Fmax) and maximal power (Pmax) tests on the leg extension (LE), leg curl (LC) and leg press (LP) machine. Additionally, squat jumps (SJ), counter movement jumps (CMJ), drop jumps (DJ), standing long jumps (SLJ), 30m linear sprint and 3x10m shuttle run tests were conducted as secondary endpoints.
RESULTS: Large within-group analysis showed significant improvements in all strength and power parameters (INT&CON: LE Fmax +5.0% , LC Fmax +5.1%, LP Fmax +17.9%, LE Pmax +12.8%, LC Pmax +13.5%, LP Pmax +7.8%; $p<0.05$; $0.13<\eta p^2<0.46$). A time x group interaction effect was merely observed for Fmax on the leg curl machine ($p=0.4$; $\eta p^2=0.18$) where post-hoc comparisons indicated higher improvements in the INT group from PRE to FU (INT: +9.1%, $p<0.01$; CON: +1.2%).
CONCLUSION: The findings of this study indicate that the combination of dynamic exercises and superimposed submaximal WB-EMS seems to be effective in order to improve leg strength and power, especially in hamstring muscles compared with dynamic training without WB-EMS. These EMS-specific improvements are relevant, because the knee flexor muscles play an important performance-determining role, not only in team and sprint sports with a high prevalence of hamstring injuries.

EXPLORING POWER-ATHLETE CIRCUITRY THROUGH TRANSCRANIAL AND PERIPHERAL STIMULATIONS

GROSPRETRE, S., MARTIN, A.

C3S - EA4660, INSERM U1093

INTRODUCTION: Extensively practicing the same activity during several years does not shape only the muscular system (e.g. muscle mass) but also the nervous networks, from the brain to the spinal cord. Particularly, power-type athletes are known to have lower spinal excitability of the lower limb than non-trained participants (1). However, several parameters remain unknown regarding the modulation of cortico-spinal networks with the practice of a power-type activity. The aim of the present study was to analyze cortico-spinal and spinal excitabilities of several muscles of the upper and lower limb. These responses were compared between a group of non-trained individuals and a group of particularly powered athletes (2) who practice Parkour, a modern physical activity that consists of jumping over obstacles in an urban landscape.
METHODS: A group of 10 non-trained participants (NT group; age: 24.5 ± 2 years old) and a group of 10 Parkour athletes (PK group; age: 23.4 ± 3.4 years old) were involved in the experiments. Transcranial magnetic stimulation was used to evoke motor evoked potentials (MEP) and peripheral stimulations to evoke H-reflexes and M-waves of the soleus (SOL) and flexor carpi radialis (FCR). Spinal and cortico-spinal responses were normalized by the maximal M-wave of the corresponding muscle (MEP/Mmax and H/Mmax). SOL and FCR MEP/H ratios were compared to measure the relative contribution of spinal and cortico-spinal modulations (3).
RESULTS: FCR MEP/Mmax was statistically ($p=0.04$) greater in PK (0.12 ± 0.1) than in NT (0.05 ± 0.05). FCR H/Mmax, 0.20 ± 0.1 in PK and 0.28 ± 0.2 in NT, were not statistically different (P=0.07). Opposite statistical trends were observed in SOL muscle: H/Mmax was statistically lower (P=0.02) in PK (0.32 ± 0.1) than in NT (0.41 ± 0.1) while MEP/Mmax, 0.07 ± 0.04 for PK and 0.05 ± 0.03 for NT, was not statistically different among groups (P=0.11). MEP/H was statistically lower in NT (0.20) than in PK (0.60) for both muscles.
CONCLUSION: Overall, greater cortical excitability and lower spinal excitability are observed in power athletes. Both are not similarly balanced between upper and lower limbs but lead to the same MEP/H ratio among muscles. The present study raised that the reduction of spinal excitability in such power athletes is counterbalanced by an increase of cortico-spinal excitability.

"YOU'RE TRYING TO BE HONEST BUT YOU'RE NEVER TRYING TO BE AT A DISADVANTAGE": QUALITATIVE EXPLORATION OF ATHLETE SELF-REPORT MEASURES IN ELITE GAELIC GAMES.

DUIGNAN, C.1,2, SLEVIN, P.1,2, CAULFIELD, B.1,2

1. INSIGHT CENTRE FOR DATA ANALYTICS, UNIVERSITY COLLEGE DUBLIN; 2. UCD SCHOOL OF PUBLIC HEALTH, PHYSIOTHERAPY & SPORTS SCIENCE

INTRODUCTION: Gaelic games are the national sports of Ireland, described as high intensity, multidirectional contact field games which require speed, strength and skill. Although amateur games, it has been recognized that the level of commitment shown in terms of the number of hours of training suggests a professional attitude to the game at the elite inter-county level (Cromwell et al., 2000).
Athlete self-report measures (ASRM) reflect changes in athlete well-being and provide a practical method for athlete monitoring (Saw et al., 2016). Short customised and commercial measures have been adopted in practice by many in elite Gaelic games; favoured by coaches for the reduced burden on athletes and the ease of use. However, insights regarding player's perceptions of using ASRM in elite Gaelic games is yet unknown.
METHODS: Semi-structured interviews were conducted with a cohort of elite Gaelic games players (n=10) to understand their perceptions of using ASRM. Interviews were audio recorded and transcribed verbatim. Data was inductively coded and a thematic analysis was applied.
RESULTS: For the purposes of this paper, the results focus on the factors influencing the integrity of the self-report data entered by players. Four sub-themes emerged from thematic analysis: (1) system factors; (2) reporting non-physical stressors; (3) apathy; (4) response distortion.
CONCLUSION: This study found four factors which influence the integrity of self-reported data from elite Gaelic games players. Insights relating to system factors and apathy were similar to those described by Saw et al (2015). However, the practice of response distortion was highly evident in the reporting of physical stressors by players. Distortion was influenced by the belief that appearing favourably would provide a competitive advantage in an elite team environment and raises the question of the reliability of these systems particularly in the lead up to team selection in Gaelic games. Another interesting concern is player's perceptions of the relative importance of reporting non-physical stressors to their management teams. This opens the discussion regarding team management's ability to appropriately address and react to measures of wellness outside the sports specific context.

SPORTS COACHES' MENTAL HEALTH LITERACY AND ROLE PERCEPTIONS FOR SUPPORTING YOUNG PEOPLE'S MENTAL HEALTH

MATTHEWS, J., DUFFY, J., ROONEY, B.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Sports coaches are in a prominent position to support young people and their mental health. However, sport coaches' knowledge of mental ill-health and the way in which they perceive their roles as coaches are likely to be key influences on such helping behaviour. Therefore, the purpose of this study was to examine how coaches' mental health literacy and their role-related perceptions effect their engagement in promotion, prevention, and early intervention behaviours with young people in the sporting environment.
METHODS: A cross-sectional design was employed. A sample of 296 Gaelic Football coaches (Mean age = 41.97; SD = 9.78; 14% female) were recruited and completed an online survey. Participants completed measures of: depression literacy, two types of role perception (i.e., role breadth and role efficacy) and engagement in prevention, promotion and early intervention behaviours.
RESULTS: Sports coaches' knowledge of the signs and symptoms of depression was moderate, reported at 55.2% (M = 12.15/22; SD =3.90). Path analyses demonstrated that depression literacy did not significantly predict helping behaviours. However, depression literacy did significantly predict role breadth for each of the helping behaviours (promotion: $p < 0.01$; prevention: $p < 0.01$; early intervention: $p < 0.01$) and role efficacy for prevention ($p < 0.05$) and early intervention ($p < 0.05$). In turn, role breadth and role efficacy both significantly predicted each of the helping behaviours.
CONCLUSION: This study revealed that role perceptions are influential in predicting coaches' involvement in supporting young people's mental health through promotion, prevention, and early intervention behaviours. Mental health literacy appears to strengthen coaches' beliefs and efficacy for these helping behaviours. Assisting coaches to engage in these helping behaviours, by developing their competence and clearly aligning these behaviours to the coaching role, may help reduce the burden of mental health problems among young people in Ireland.

HEALTH BEHAVIOURS OF POLISH AND CZECH AMATEUR LONG-DISTANCE RUNNERS

NOWAK, P.F.

OPOLE UNIVERSITY OF TECHNOLOGY

Organizing mass street running competitions is fashionable in Central and Eastern Europe and is still developing in the last decade. Especially in Poland, an increase in the number of organized competitions (marathons and other running events at different distances) is

being noted in recent years. The idea of these events is popularizing running as pro-health form of exercise for everyone and promoting a healthy lifestyle.
Determining the level of health behaviours of runners from Poland and Czechia was the aim of this study – in the context of their age, gender, training experience, a frequency of starting in running competitions and training load (number of trainings and number of kilometres running weekly).
The study included 765 amateur runners from Poland and 111 from Czechia, who have been training regularly at least for a year and have been participating in running events. The standardized research tool – Z. Juczyńskis adaptation of the Health Behaviour Inventory, was used to evaluate health behaviours of runners. In addition to the general indicator of health behaviours also four categories of behaviour were calculated to the test procedure: Proper Nutrition Habits, Prophylactic Behaviours, Positive Psychological Attitudes (PPA) and Health Practices (HP).
Researched runners from Czechia are characterized by a much longer training experience than Polish runners, but they train less than Poles (on average, run fewer kilometres during a week). As many as 48.6% of Czech runners received a low level of health behaviours (29,2% of Polish runners) and only 15,3% received high level (runners from Poland – 27%).
Runners from Poland obtained the slightly higher level of the general indicator of health behaviours than runners from Czechia. In the case of such categories of health behaviours as PPA and HP, Poles also obtained a higher level of indicators, statistically significant.
Gender is not a factor differentiating runners statistically significant – in context of the general indicator of the level of health behaviours. The number of kilometres covered each week, an average number of trainings a week and age positively correlate with health behaviours in the group of Polish runners. But in the group of Czech runners a statistically significant correlation was calculated only between indicator of health behaviours and number of kilometres running per week.
The organizers of running competitions should focus more on health education and popularize healthy lifestyle. It would be worth to examine what kind of values that organizers of sports and recreational events really popularize – if training experience and frequency of starting in running competitions do not affect the growth of healthy behaviours.

ASSOCIATIONS BETWEEN PHYSICAL ACTIVITY, SEDENTARY BEHAVIOR, DEPRESSION TENDENCY, AND SENSE OF COHERENCE IN EARLY ADOLESCENTS

SAKI, K.1,2, KOKUDO, S.1, KASANAMI, R.3, NAGANO, M.4, ISHII, K.5

1 KOBE UNIVERSITY,2 JSPS RESEARCH FELLOW ,3 NARA UNIVERSITY OF EDUCATION,4 FUKUOKA WOMENS UNIVERSITY,5 DOSHISHA UNIVERSITY

INTRODUCTION: To date, the appropriate intensities, amount and details of physical activity (PA) and sedentary behaviour for mental health remain partially elucidated for adolescents.This study aims to assess the structure of PA [intensity, time and activity details (ADs)]; sedentary behaviour (SB); depression tendency and sense of coherence (SOC) among early adolescents.
METHODS: We conducted a questionnaire survey with the International Physical Activity Questionnaire, including ADs, Birleson Depression Self-Rating Scale (DSRS) and Sense of Coherence Scale (SOC-13) for children, among 6481 adolescents (grades 5-8) in Japan. We log-transformed PA time/week, including vigorous intensity physical activity (VPA), moderate intensity physical activity (MPA) and walking (Walk), as well as sedentary behaviour on the weekdays (SBwd) and weekend (SBwe) for analysis. According to the characteristics of ADs and the degree of effect on the DSRS and SOC-13 factors, the classification of ADs was ranked in nine levels. We applied categorical exploratory factor analysis (categorical EFA; weighted least square mean and variance (WLSMV) estimation; oblimin rotation) to extract factors of both the DSRS and SOC-13. Furthermore, we performed structural equation modelling based on the correlation coefficients in the DSRS factors, SOC-13 factors, PA and SB variables.
RESULTS: We created a model comprising PA variables and four factors extracted by the EFA, including decline in activity and enjoyment (FDAE) and depression mood (FDM) from the DSRS and comprehensibility & manageability (FCO-MA) and meaningfulness (FME) from the SOC-13, based on the hypothesis that PA affects the four factors respectively. Considering the order of time, the path from the two DSRS factors to both the SOC factors was subtracted, respectively. Our model fitted the data significantly [χ 2(489), 5766.7; CFI, 0.902; RMSEA, 0.041]. In addition, the FDAE, FDM, FCO-MA and FME were mutually dependent, as expected. Although the estimates revealed a significant correlation, it was small in size as follows. ADs (-0.107), VPA (-0.093), MPA (-0.042), Walk (-0.089), SBwd (-0.036) and SBwe (0.072) affected the FDAE. In addition, ADs (-0.065), VPA (-0.039), SBwd (-0.056) and SBwe (0.085) affected the FDM. While ADs (-0.038) affected only the FME, ADs (-0.030) and SBwe (-0.040) affected the FCO-MA. Both the SOC factors were significantly affected by PA and SB mediate by the DSRS factors as follows: FDAE to FME (-0.729), FDM to FCO-MA (-0.673).
CONCLUSION: This study suggests that ADs, VPA and SBwe affect the FDAE in the early adolescence. In contrast, SBwe affects the FDM rather than PA. Furthermore, the SOC factors are affected by the mediation of the DSRS factors.

DRUG AND ALCOHOL USE AMONG CANADIAN RECREATIONAL SKIING AND SNOWBOARDING YOUTH

RUSSELL, K., SELCI, E., GOULET, C., MORRONGIELLO, B.

UNIVERSITY OF MANITOBA

Background: Skiing and snowboarding are popular activities among Canadian youth and are often done in the absence of parental supervision. While alcohol and drugs are suspected to contribute to injury risk among skiers and snowboarders, the prevalence and risk factors for drug and alcohol use among youth while skiing and snowboarding is unknown.
Methods: Using focus group methodology, a questionnaire examining high-risk behaviors while skiing and snowboarding was developed and rooted within the Theory of Planned Behavior. The questionnaire was assessed for validity and reliability. The questionnaire was administered to youth aged 14-18 during two winter seasons at a ski hill in Manitoba, Canada. No identifying data were collected. Logistic regression was used to determine factors that increased or decreased the use of drugs or alcohol while skiing or snowboarding.
Results: Overall, 735 youth completed the questionnaire. The mean age was 14.9 years , 82.1% were male, 83.0% were snowboarding that day, 11.5% self-identified as beginners, 40.2% as intermediate, 33.8% as advanced, and 14.6% as experts. The majority of youth were wearing a helmet <88.1%>. There were 101 <13.8%> youth who reported using drugs that day, 7.0% reported drinking alcohol, and 5.7% reported using both drug and alcohol. The most commonly used drugs were marijuana , amphetamines , and cocaine . Risk factors for drug or alcohol use were male , snowboarding instead of skiing , friends using drugs or alcohol when skiing or snowboarding , or sib-

lings using drugs or alcohol when skiing or snowboarding . Wearing a helmet and believing that using drugs or alcohol while skiing and snowboarding put their life at risk protected against drugs or alcohol use. Age or ability did not predict drug or alcohol use.
Conclusions: A notable proportion of skiing and snowboarding youth do so under the influence of drugs or alcohol. Prevention programs not only need to target the youth but also their friends and siblings. Promoting other safety behaviors like helmet use may also decrease drug and alcohol use.

PREVALENCE OF EATING DISORDERS AND RISK FACTORS IN THE SPORT ENVIRONMENT

TEIXIDOR-BATLLE, C., VENTURA VALL-LLOVERA, C., ANDRÉS, A.

GRUP DINVESTIGACIÓ SOCIAL I EDUCATIVA DE LACTIVITAT FÍSICA I LESPORT , INSTITUT NACIONAL DEDUCACIO FÍSICA DE CATALUNYA , UNIVERSITAT DE BARCELONA

INTRODUCTION: Due to the seriousness of eating disorders, and their frequent appearance in sports, it is important to examine and understand why athletes seems to be more at risk compared to non-athletes (Chapman & Woodman, 2015), and If there are agents that might explain the development of eating disorders (ED). Although physical activity provides great health benefits, when taken to an extreme, exercise can be a maladaptive behaviour associated with physical and psychological risks. Among the sport-specific weight pressures related with ED development, coach concerns about weight or strength, comments by coaches or teammates, revealing uniforms or performance expectations could contribute to body image disturbances. The aim of the present study was to examine the prevalence of ED symptomatology and risk factors for its development in elite athletes.
METHODS: Participants are 686 athletes, 332 male [Mage= 16.96; SD= 4.74] and 354 female [Mage= 16.29; SD= 4.15], competing in 34 different sports from Catalonia, Spain. Subjects were recruited from four sources: the Center of Training and High Performance (CEARE), the Sports Program for Catalonia (Pla de Tecnificació Esportiva), the Center of High Performance (CAR) or clubs playing in top-level competition. They were asked to complete an online self-reported questionnaire containing several sociodemographic items, the Weight Pressures in Sport (WPS) for Male or Female athletes' version and the Eating Attitudes Test (EAT-26).
RESULTS: Results from this study describe the prevalence of EDs among male and female athletes. A description of male and female weight pressure scores, such as coaches, peers, and team uniform, are described and compared between different sport groups. Moreover, the relationship between the sport-related weight pressures and disordered eating behaviours are examined in order to evaluate risk factors within the sport environment.
CONCLUSION: The present study findings are in the line of identifying possible sources of weight pressure within the sports setting as to prevent the vulnerability of developing a further eating disorder. These results must be considered in the designing of an educational program aiming to educate sport professionals and to prevent and cope body image and body weight pressures in athletes.

OP-SH20 Applications of self determination theory to sport and exercise

PERCEIVED DISEMPOWERING COACH-CREATED MOTIVATIONAL CLIMATE AND PERCEIVED EXERTION OF YOUNG FOOTBALL PLAYERS: THE MEDIATOR ROLE OF THE MALADAPTIVE INDIVIDUAL PSYCHOLOGICAL VARIABLES

PÉREZ-XIMÉNEZ, M.1, PARDO, A.1, TOMÁS, I.1, XIMÉNEZ-DE-EMBÚN, D.P.2, BALAGUER, I.1

UNIVERSITY OF VALENCIA <1>; UNIVERSITY OF ZARAGOZA <2>

INTRODUCTION: Based on the theoretical frameworks of Self-determination theory (Ryan & Deci, 2017) and Achievement Goals Theory (Ames, 1992; Nichols, 1989) the objective of this work is to analyse the mediation role of maladaptive individual psychological variables (external regulation, amotivation, and physical-emotional exhaustion) in the relationship between disempowering dimensions of coach-created motivational climate (controlling interpersonal style and ego-involving climate) and perceived exertion in young football players' legs when completing interval running training tasks.
METHODS: The participants were 77 male young football players (M = 15.17 years old; SD = 0.53), belonging to four different teams, with a relatively large competitive experience for their age (M = 6.39; SD = 2.04) and practising three or four times per week apart from the official game during the weekend.
Regarding the psychological variables, players completed the Spanish versions of a questionnaire package tapping the variables of interest. With respect to perceived exertion, players' RPE-legs was recorded in interval running training tasks at different intensity: aerobic capacity (A-Cap; 75%-84% HR) and aerobic power (A-Pow; 86%-92% HR). Players of the total sample who met the established criteria to be included in further statistical analysis for A-Cap and A-Pow running trainings were 36 and 30, respectively.
RESULTS: It was found that maladaptive individual psychological variables had a mediational role in A-Pow interval running training in the following four mediational models: (1) Controlling style – Amotivation – RPE (IE=.32; CI Bootstrap 95% [.01 to .77]); (2) Ego-involving climate – External regulation – RPE (IE=.38; CI Bootstrap 95% [.02 to 1.05]); (3) Controlling style – Exhaustion– RPE (IE=.54; CI Bootstrap 95% [.09 to 1.03]); (4) Ego-involving climate – Exhaustion – RPE (IE=.43; CI Bootstrap 95% [.06 to 1.09]).
CONCLUSION: The disempowering dimensions of coach-created motivational climate (controlling interpersonal style and ego-involving climate) lead to maladaptive individual psychological responses in young footballers (including lack of motivation, increment of external regulation and physical-emotional exhaustion). This causes a maladaptive response, with a rising perceived exertion in young football players' legs when completing interval training at aerobic power intensity (86%-92% HR).

INTRAPERSONAL GOALS, UNDERLYING REASONS AND EMOTIONAL WELL-BEING AMONG PARKRUNNERS: A PROSPECTIVE DESIGN

MULVENNA, M., ADIE, J.W., SAGE, L.

COVENTRY UNIVERSITY

INTRODUCTION: Integrating tenets of self-determination theory and the hierarchical model of achievement motivation (see Delrue et al., 2016; Vansteenkiste et al., 2014), the current study tested a temporal sequence of hypothesized relationships between intrapersonal goals and their underlying reasons > stress appraisals > emotional well-being among parkrunners. The mediational role of stress appraisals in the hypothesized model was also ascertained.
METHODS: Following ethical approval, 176 male and female runners (Mage=45.02; SD=10.76 years) responded to a series of online questionnaires 5 days prior to (T1), 24 hours before (T2) and immediately following (T3), a parkrun event in the UK. Data were collected for intrapersonal (i.e., self-approach/-avoidance) goals and their underlying (i.e., autonomous/controlling) reasons at T1, pre-parkrun challenge and threat appraisals were then captured at T2, and emotional well-being (indexed by pride) was measured at T3.
RESULTS: Multiple regression analyses confirmed autonomous reasons for intrapersonal goal adoption positively predicted self-approach and –avoidance goals. In turn, self-approach goals were positively associated with challenge appraisals. Additionally, autonomous reasons underlying self-approach goals and challenge appraisals both positively related to pride. Finally, self-avoidance goal adoption for controlling reasons was positively related to threat appraisals. Intrapersonal goal adoption and their underlying autonomous reasons were indirectly associated with pride via challenge appraisals.
CONCLUSION: The findings suggest the value of runners adopting self-approach goals for autonomous reasons if they are to view parkrun as a challenge and experience positive emotions. Further analyses aims to examine potential goal complexes (see Elliot, 1999) in moderating the prediction of intrapersonal goals on stress appraisals and subsequent emotional well-being among parkrun participants.

FEASIBILITY OF TRAINING EXERCISE CLASS INSTRUCTORS TO ADOPT A MOTIVATIONALLY SUPPORTIVE COMMUNICATION STYLE

NTOUMANIS, N.

CURTIN UNIVERSITY

This study examined the feasibility of a 10-week self-determination theory-based training programme delivered to 24 group exercise instructors. Feasibility of implementing the programme was explored in terms of 1> recruitment, 2> rates of adherence and retention, and 3> acceptability. Results revealed modest uptake <51%> and excellent workshop attendance and retention rates <96%>. Coding of the interview data revealed 9 main themes with regard to the acceptability of the training programme: satisfaction with content, challenging current motivational practices, perceived relevance of the motivational strategies, social support, mix of theory and practice, usefulness of learning resources, need-supportive delivery, multi-stage structure, and value for professional development. The findings can inform the development, design, and implementation of future research with the target population.

EXAMINING DECISION-MAKING AND CRITICAL THINKING IN A PHYSICAL-ACTIVITY-BASED POSITIVE YOUTH DEVELOPMENT PROGRAM FOR YOUTH FROM LOW-INCOME FAMILIES

KNISEL, E.1, MCDONOUGH, M.H.2, RUIZ, Y.3, SNYDER, F.J.4, MCDAVID, M.L.3

1: UNIVERSITY OF MAGDEBURG , 2: UNIVERSITY OF CALGARY , 3: PURDUE UNIVERSITY , 4: CENTRAL MICHIGAN UNIVERSITY

Introduction: The purpose of study was to analyze the associations between autonomy support from program staff and decision making and critical thinking among participants in a physical activity-based program for low-income youth. Additionally, demographic variables were examined. Self-determination theory offers a theoretical framework to explain how program staff behavior may be associated with youth decision making and critical thinking. SDT suggests that social contexts that are more autonomy supportive are more effective at meeting an individual's needs for competence, autonomy, and relatedness, which may be more conducive conditions for developing thoughtful decision-making skills and purposeful judgment .
Methods: 110 girls and 121 boys aged 7-14 participated in a physical activity-based positive youth development summer program providing opportunities in sports, health and fitness, and life skills development. Participants self-reported their decision making skills and critical thinking skills on the second and 17th day of the 20-day program, and rated their staff leader's autonomy supportive behavior on the 17th day
Results: There were significant increases in self-reported decision making =15.44, p=.000, η2=.063> and critical thinking =23.75, p=.000, η2=.094> over time. Results showed that the degree of change in decision making =10.59, p=.001, η2=.046> and critical thinking =7.71; p=.006, η2=.034> was associated with age. The younger group <7-10 years; n=141> increased their decision making skills compared with the older group < 11-14 years; n=83> . The younger group improved their critical thinking skills more than the older group . The enhancement of decision making skills and critical thinking skills was not associated with perceived autonomy-support or gender.
Discussion: The results suggest that the physical activity-based educational program has the potential to improve life skills such as decision making and critical thinking. There may be greater potential for change in these skills among children versus pre- and early adolescents, although whether these age differences are due to the program or are attributable to development needs to be examined in a controlled study. Furthermore, future interventions studies identifying the effects of an autonomy-supportive social context on youth life skills development is required.

MOTIVATION AND INTEREST: THE MEDIATORS OF THE RELATION BETWEEN SOCIAL SUPPORT AND PHYSICAL ACTIVITY AMONG ADOLESCENTS IN CHINA

FUBAIHUI, W.

CHINA INSTITUTE OF SPORT SCIENCE

Introduction: Most of the Chinese adolescent do not meet the moderate and vigorous physical activity (MVPA) 5 hours per week recommendation. The purpose of this study was to determine how motivation and interest mediate the relationship of social support with

physical activity by integrating available measures of personal characteristic including internal/external motivations for MVPA, MVPA interest, peer MVPA, parental support, and school support to better understand adolescent MVPA.
Methods: The data used in this paper came from the Survey on Physical Activity of Chinese adolescents in 2016, which investigated by General Administration of Sport of China. The structural equation model was used to verify the hypothesis model of the relationship among motivation, interest, social support and physical activity, which based on Self-Determination Theory (SDT).
Results: Adolescent MVPA was directly, significantly associated with MVPA interest (β= 0.209), peer MVPA (β= 0.213),and internal motivation (β= 0.079). Internal motivation was associated with peer MVPA (β= 0.264), parental support for MVPA (β= 0.748), and external motivation (β= 0.186). The indirect relationship between internal motivation and adolescent MVPA through MVPA interest as an intermediary (0.209, $p<0.01$) is stronger than the direct relationship between internal motivation and adolescent MVPA (0.0.079, $p<0.01$). The school support was not directly related to adolescent MVPA, but indirectly through mediation of internal/external motivation. It was verified that the importance of MVPA interest and intrinsic motivation in motivating adolescent MVPA behavior.
Discussion: Adolescents with MVPA interest are more likely to engage in MVPA, have greater internal motivation, and more active friends are more likely to engage in MVPA. Adolescents with higher MVPA interest are more likely to convert MVPA motivation into MVPA behavior. The rationality of Self-Determination Theory to explain adolescent physical activity behavior was verified. It is demonstrated the importance of MVPA interest and internal motivation for promoting adolescent MVPA.

IS-PM01 Dietary Nitrate as an Ergogenic Aid in Clinical Populations. What is it good for?

THE EFFECTS OF NITRATE SUPPLEMENTATION ON EXERCISE CAPACITY IN HEART FAILURE. HFPEF V HFREF: AN UPDATE FROM THE LITERATURE

WOESSNER, M.
VICTORIA UNIVERSITY

Low exercise tolerance is associated with increased morbidity and decreased quality of life in patients with chronic heart failure (CHF). Given this strong prognostic value, interventions targeting improvements in exercise tolerance have a significant clinical utility in this population.
Nitric oxide (NO) is essential for vascular health and function and has been implicated in exercise performance in humans. Patients with CHF display endothelial dysfunction and a have a diminished ability to endogenously produce NO. Recently, oral supplementation with inorganic nitrate has emerged as a novel intervention to exogenously increase vascular NO bioavailability and potentially improve exercise performance in patients with CHF.
There are relatively few published studies examining the effects of inorganic nitrate supplementation in patients with CHF, and the results are conflicting. One potential explanation for the discrepancies is that despite similar symptomology, there are two distinct classes of CHF, each with unique pathologies, differentiated by the cardiac ejection fraction (EF). Heart failure with reduced ejection fraction (HFrEF) is characterized by significant reductions in central systolic function (EF<40%) and pronounced chronotropic incompetence. In contrast those with preserved ejection fraction (HFpEF, EF>50%) are potentially more limited by peripheral tissue under-perfusion and a lower arteriovenous oxygen difference during exercise.
This talk will present new original data from the largest-to-date exercise study of inorganic nitrate supplementation in patients with HFrEF, including central and peripheral physiological parameters. There will also be a review of the current literature to compare and contrast the findings in patients with HFrEF and HFpEF.

WHAT'S DIFFERENT ABOUT DIETARY NITRATE AND DIABETES?

GILCHRIST, M.
UNIVERSITY OF EXETER

Type 2 diabetes has a limiting effect on VO2 at both maximal and sub-maximal exercise and endurance. Poorer cardio-respiratory fitness and inactivity are independent predictors of mortality in type 2 diabetes. The cause of the limitation on exercise tolerance in T2DM has been attributed to several potential factors during the transport of oxygen from the lung to its site of utilization in the muscles. These include impairments in cardiac function, peripheral blood flow, microcirculatory dysfunction, skeletal muscle glucose uptake, and mitochondrial dysfunction. Each of these physiological processes has a nitric oxide dependent component. People with type 2 diabetes have reduced bioavailability of nitric oxide. Strategies to enhance nitric oxide bioavailability would appear to be an attractive target to improve exercise tolerance and potentially the hallmark of type 2 diabetes, insulin resistance itself. Dietary nitrate supplementation has been shown to have beneficial effects on exercise tolerance and metabolic function in human studies in health and disease as well as in a range of animal models. We will review data from nitrate supplementation studies in subjects with diabetes. These data will be used to explore why people with type 2 diabetes do not appear to derive the same benefit from inorganic nitrate supplementation as healthy subjects and cohorts with a range of other pathologies. Reasons for discordant results between human trials and animal models will be examined.

CAN WE BEET THE BEST? - INORGANIC NITRATE, EXERCISE AND PERIPHERAL ARTERIAL DISEASE

ALLEN, J.D.
UNIVERSITY OF VIRGINIA

PAD is a form of cardiovascular disease caused by atherosclerotic occlusions that impair blood flow to the lower extremities. The most frequent clinical symptomatic manifestation of PAD is intermittent claudication defined as, pain in 1 or both legs during exercise that is

relieved with rest. This inability to match oxygen delivery to tissue demands during physical activity severely debilitates subjects. A primary goal of therapy for PAD+IC is increased ambulatory function.
Although the pathophysiologic mechanisms contributing to the functional impairment and functional decline in PAD are not fully delineated, current evidence suggests numerous peripheral tissue maladaptations in response to chronic under perfusion. These include vascular endothelial dysfunction, reduced NO bioavailability, capillary density rarefaction, increased reactive oxygen species, mitochondrial dysfunction, reduced aerobic enzyme activity, and a preferential loss of type I oxidative fibres. Overall this results in the uncoupling of skeletal muscle cellular metabolism from tissue perfusion and the exhibition of a glycolytic phenotype; which promotes the early onset of fatigue and exercise intolerance.
Nitric oxide (NO) is an important signalling molecule and essential for vascular function/health. In human exercise studies, increased vascular NO is associated with improved skeletal muscle perfusion, contractile efficiency and mitochondrial function. Unfortunately, in vascular pathologies, including PAD, a dysfunctional endothelium limits the ability to endogenously upregulate NO bioavailability and restricts the utility of eNOS-dependant therapeutics.
We will present data from the last 10 years of work outlining…
a) the discovery of the relationship between plasma nitrite concentrations and walking performance in PAD+IC
b) the role of exercise training in PAD+IC and its effects on nitric oxide metabolism
c) the effects of acute oral inorganic nitrate supplementation on walking performance in PAD+IC
d) The results of a double blind RCT of 3 months of exercise training plus chronic dietary provision of inorganic nitrate (EX+BR) or EX and placebo (EX+PL) on exercise performance in PAD+IC subjects.
Data will highlight changes in vascular function, gastrocnemius muscle tissue perfusion, muscle metabolism, and nitric oxide species signaling.

Invited symposia

IS-PM11 Muscle protein turnover – influencing factors

PHYSICAL (IN)ACTIVITY - INFLUENCE ON THE REGULATION OF MUSCLE MASS MAINTENANCE

VAN LOON, L.

MAASTRICHT UNIVERSITY MEDICAL CENTRE

INTRODUCTION: A period of muscle disuse due to sickness or injury can lead to substantial loss of skeletal muscle mass and strength in otherwise healthy individuals. The resulting health consequences, such as impaired functional capacity, decreased muscle strength, onset of peripheral insulin resistance, and a decline in basal metabolic rate, are of particular concern to older individuals, who are already functionally and/or metabolically compromised. Even a few days of disuse can already results in substantial loss of muscle mass and strength. These findings are of particular clinical relevance because hospitalization of (older) individuals with acute illness generally results in a mean hospital stay of 5–7 days. Such short successive periods of muscle disuse occurring throughout the lifespan may be instrumental in the progressive loss of muscle mass with aging. Loss of skeletal muscle mass due to disuse must be attributed to an imbalance between muscle protein synthesis and breakdown rates. A decline in basal (post-absorptive) muscle protein synthesis rates has been reported following both bed rest as well as limb immobilization. Furthermore, more recent work has shown that the muscle protein synthetic response to protein or amino acid administration becomes blunted following a period of disuse. Though declines in both post-absorptive and postprandial muscle protein synthesis rates seem to play the biggest causal role in the loss of muscle mass during a period of disuse, there is also some indirect evidence that increases in muscle protein breakdown rates occur during the first few days of muscle disuse.

METHODS: RESULTS: CONCLUSION: ENDOGENOUS AND EXOGENOUS DRIVERS OF MUSCLE HYPERTROPHY IN HUMANS

PHILLIPS, S.M.

MCMASTER UNIVERSITY

INTRODUCTION: Skeletal muscle growth and atrophy are the result, in part, of imbalances between the rates of muscle protein synthesis (MPS) and breakdown (MPB). Of the two, unless someone is pathologic, MPS predominates as the process that is stimulated to lead to accretion of muscle mass. Factors that we know stimulate MPS include: loaded contraction, ingestion of dietary protein (especially proteins rich in leucine), and some supplements. In this presentation, I will discuss the role of these anabolic factors and present the most recent data.
METHODS: The focus will range from short-term acute measurements of MPS, to longer-term measurements based on deuterated water ingestion, to training studies.
CONCLUSIONS
While there are claims for anabolic proteins, the leucine content of protein is still a driving factor. Supplements such as creatine appear to augment hypertrophy but this is through allowing greater work. Supplements to purport to suppress proteolysis are not likely to be beneficial. And despite our best efforts, endogenous factors that are muscle-derived supplant any known role of systemic hormones and exogenous supplements in determining hypertrophy.

INFLUENCE OF GENDER AND FEMALE SEX HORMONES ON MUSCLE PROTEIN TURNOVER

HANSEN, M.

AARHUS UNIVERSITY

INTRODUCTION: Women are characterized by a lower absolute and relative muscle mass than men. Differences in sex hormones coupled with localization of androgen and estrogen receptors in the skeletal muscle suggest a regulatory role of sex hormones on muscle mass.
METHODS: This presentation will specifically focus on the effect of endogenous and synthetic female hormones on the regulation on muscle protein turnover.

RESULTS: Estrogen deficiency is associated with changes in muscle protein turnover and the responsiveness to anabolic stimuli. In addition, an accelerated reduction in specific force is observed when women turn into the postmenopausal state. Young women experience comparable changes in muscle protein synthesis in response to anabolic stimuli. Nevertheless, use of oral contraceptives seems to influence muscle protein synthesis, but effect seems to depend on the type of oral contraceptives.
CONCLUSION: An enhanced knowledge is of importance since use of oral contraceptives use is widespread among young women and many elderly postmenopausal women are in great risk of losing independence due to sarcopenic fragility.

OP-PM17 Cardiovascular Physiology 2

EFFECTS OF ACUTE EXERCISE ON SKIN MICROVASCULAR FUNCTION

THOMAS, S.D., JONES, H., THIJSSEN, D., LOW, D.A.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Chronic exercise induces systemic vascular adaptations, yet less is known about acute changes to vascular function after exercise; the accumulation of which may provide the basis for long-term adaptations (1). After acute exercise conduit artery function may or may not be decreased, with potential changes seeming intensity-dependent (2). Skin microvasculature is a critical site for thermoregulation, blood pressure regulation and sensory function. Changes to skin microvascular function (SkMF) following acute-exercise, the repetition of which likely contribute to improved skin microvessel function with chronic exercise, are relatively unknown. The aim of this study was to examine effects of acute exercise on SkMF.
METHODS: Healthy participants (n=12, 1 female) had SkMF assessed via skin blood flux (perfusion units, PU) responses to fast local heating (0.1ºC/sec to 42ºC for 30 mins, 44ºC for 15 mins) using laser Doppler flowmetry before (PRE), immediately after (IMM) and 1-hour (1HR) after 30 minutes low (50% heart rate maximum, HRmax) or high (75% HRmax) intensity cycling (LOW, HIGH). Skin blood flow was indexed as cutaneous vascular conductance (CVC=flux/mean arterial pressure MAP, PU/mmHg) and percent maximal CVC (CVC%max, obtained from 44ºC response). Initial axon reflex peak/ nadir responses (sensory-nerve mediated) and plateau phase (endothelium-dependent) responses to local heating were analysed.
RESULTS: Exercise increased (PRE vs exercise) HR (LOW, 54±8 vs 104±6 BPM, p<0.001; HIGH, 55±9 vs 147±6 BPM, p<0.001), MAP (LOW, 82±8 vs 93±9 mmHg, p=0.001; HIGH, 81±5 vs 105±17 mmHg, p<0.001) and baseline skin blood flow (LOW, 6±1 vs 16±12 CVC%max, p<0.001; HIGH, 7±1 vs 47±17 CVC%max, p<0.001).
Local heating axon reflex peak increased after HIGH (PRE 56±10 vs IMM 73±17 CVC%max, p=0.001; PRE vs 1HR 74±15 CVC%max, p=0.003) and trended towards being increased after LOW (PRE 64±11 vs IMM 72±8 CVC%max, p=0.057). Axon response nadir increased after LOW (PRE 46±13 vs IMM 61±11 CVC%max, p=0.002; PRE vs 1HR 62±14 CVC%max, p=0.007) and HIGH (PRE 48±13 vs IMM 67±18 CVC%max, p<0.001). Neither exercise nor time affected endothelium-dependent plateau responses (LOW: PRE 85±9 vs IMM 92±7 CVC%max, p>0.05; PRE vs 1HR 90±11 CVC%max, p>0.05. HIGH: PRE 86±9 vs IMM 88±11 CVC%max, p>0.05; PRE vs 1HR 88±8 CVC%max, p>0.05).
CONCLUSION: Exercise increases cutaneous microvascular axonal response to local heating for up to 1-hour, suggesting an augmented sensory afferent function post-exercise. Acute exercise doesnt affect endothelial function in cutaneous jmicrocirculation, contrasting some findings in macrovessels.

CARDIOVASCULAR EFFECTS OF ISOMETRIC HANDGRIP TRAINING FOR PATIENTS WITH PERIPHERAL ARTERY DISEASE

CORREIA, M.1, OLIVEIRA, P.2, GERMANO-SOARES, A.1, WOLOSKER, N.2, CUCATO, G.G.2, RITTI-DIAS, R.3

1. UNIVERSITY OF PERNAMBUCO, RECIFE, BRAZIL; 2. HOSPITAL ISRAELITA ALBERT EINSTEIN, SÃO PAULO, BRAZIL; 3. UNIVERSITY NINE OF JULY, SÃO PAULO, BRAZIL.

INTRODUCTION: Patients with peripheral artery disease (PAD) have a high prevalence of hypertension, which contributes to a high mortality risk. Meta-analysis studies have demonstrated that isometric handgrip training (IHT) promotes reductions in blood pressure in normotensive, pre-hypertensive, and hypertensive individuals. However, the effect of this modality of training in individuals with significant impairment in cardiovascular function and regulation, such as patients with PAD, is unknown. Thus, the aim of the study was to analyze the effects of IHT on cardiovascular function of PAD patients.
METHODS: In this randomized clinical trial, 86 patients (66 ± 9 years) of both genders were randomized into two experimental groups: IHT and control (CG). The IHT group underwent three weekly sessions (four two-minute series of isometric of unilateral contraction at 30% of maximal voluntary contraction, with a four-minutes interval between sets). The CG patients received a compression ball to perform sham training, also three times a week, but without any isometric component. Before the beginning and after eight weeks of intervention, the following indicators of the cardiovascular function were obtained: brachial arterial pressure (OMRON, Japan) and central (pulse wave analysis, Sphygmocor, Australia), arterial stiffness (pulse wave velocity, Sphygmocor, Australia), heart rate variability (Polar, Finland) and vascular function (flow-mediated dilatation, Philips Healthcare, The Netherlands). For statistical analysis, models of generalized estimation equations were used, considering the group (IHT and CG) and time (pre and post intervention) as factors.
RESULTS: No effects on central and brachial artery pressure (P> 0.05), arterial stiffness (P> 0.05) and heart rate variability (P> 0.05) were observed. There was interaction effect group vs. time on flow-mediated dilation with significant increases of this parameter only in the IHT group (GC – pre: 8.4 ± 5.7 vs. post: 8.2 ± 5.2; IHT – pre: 5.8 ± 5.1 vs. post: 9.9 ± 5.4, P <0.05).
CONCLUSION: Despite the improvement in local vascular function, IHT did not alter blood pressure, heart rate variability and arterial stiffness in PAD patients.

BLOOD PRESSURE RESPONSES DURING AND AFTER HEAVY RESISTANCE TRAINING IN HEALTHY MALES

HEITMANN, K.A.1, DALEN, H.2,3,4, INGVALDSEN, R.P.5, WELDE, B.1

INTRODUCTION: Most recommendations are careful in advising heavy resistance training (HRT, 85-90% 1RM) for hypertensive individuals, due to earlier reports of acute excessive elevated blood pressure (BP) during resistance training (RT). In this population, RT with lighter weights (≤75% 1RM) have been recommended as a supplement to aerobic exercises. However, no association has been reported between the percent 1RM weight lifted and acute excessive elevated BT during HRT, if the Valsalva's manoeuvre is avoided. Therefore, the aim of this study was to examine the BP response during HRT with 3 and 5 repetitions (rep.), where both sessions were carried out at the 5RM load (i.e., 85% 1RM) and the Valsalva's manoeuvre was avoided. Also, we studied the BP response for 90 min resting post-exercise. We hypothesized that 3 rep. induced lower acute BP during training than 5 rep. and that both training sessions induced post-exercise hypotension (PEH).
METHODS: Seven healthy male students (23.8±1.4 years (mean and SD)) volunteered to seated leg press exercise for examination of their BP response to HRT in two different exercise sessions: 1) 10 x 5 rep. exercise session (5RES) and 2) 10 x 3 rep. exercise session (3RES), both at 5RM load and in a randomized, crossover within-subjects-design. Intra-arterial BP were measured before and during RT, as well as 15-90 min post-exercise.
RESULTS: At baseline there was no difference of the systolic and diastolic BP (SBP, DBP) between the exercise sessions (P=0.42). Mean (SD) SBP (3RES: 167.2 (13.8) mmHg; 5RES: 176.9 (17.4) mmHg, P=0.08), and peak SBP (3RES: 177.7 (15.5) mmHg; 5RES: 184.3 (16.8) mmHg; P=0.29), measured at the end of each training sets, did not significantly differ between 3RES and 5RES. Mean DBP (3RES: 79.2 (8.4) mmHg, 5RES: 88.4 (8.2) mmHg, P=0.01) and peak DBP (3RES: 88.1 (8.2) mmHg, 5RES: 95.3 (9.7) mmHg, P=0.02) were higher during training for 5RES vs. 3RES. In the rest periods during training, the mean and peak SBP and DBP did not differ between 3RES and 5RES (0.24≤P≤0.58). When compared to resting values before training, a significant PEH was found for SBP 30 min post exercise (mean difference: -11.8 (7.3) mmHg, P=0.01), with no difference between 3RES and 5RES and no hypotensive response for DBP.
CONCLUSION: The major findings in the present study were: 1) HRT could be performed without acute excessive elevated BP during training; 2) BP increased more during training for 5RES than for 3RES, however not significantly for SBP; 3) Ten sets of HRT induced systolic PEH.

SIMULTANEOUS ASSESSMENT OF INTRA- AND EXTRACRANIAL ARTERIAL RESPONSES TO SYMPATHETIC STIMULATION: IMPAIRED REACTIVITY IN HEALTHY OLDER SUBJECTS COMPARED TO YOUNGER PEERS.

SHKREDOVA, D.1, CLAASSEN, J.A.H.R.1, THIJSSEN, D.H.J.1,2

<1> RADBOUD UNIVERSITY MEDICAL CENTER <2> LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Impaired vascular health contributes importantly to the development of cardio- and cerebrovascular disease. Recent work found that common carotid artery (CCA) reactivity to the cold pressor test (CPT; a strong sympathetic stimulus) is closely related to coronary responses to the CPT and is impaired in older subjects. Given its close proximity to the brain, CCA reactivity to the CPT may also show similarity with blood flow velocity of the middle cerebral artery (MCA). Furthermore, in line with the CCA, MCA reactivity may be impaired in older humans. Therefore, the objectives of this study were to 1. Explore responses of extra- (CCA) and intra-cranial arteries (MCA, cortical) to the CPT, and 2. Examine the impact of age on these responses.
METHODS: Two groups were recruited for this cross-sectional study: healthy younger adults (YA; 18-30yrs) and healthy older adults (OA; ≥65yrs). Participants were free from cardiovascular and cerebrovascular disease, with no cognitive impairment (MoCA≥26). CPT consisted of a 3-min submersion of the left hand into cold water (<1°C), with continuous simultaneous assessment of CCA diameter (CCAd) and blood flow velocity (CCAv) by duplex ultrasound, MCA blood flow velocity (MCAv) by Transcranial Doppler, and cortical oxygenation (O2Hb) by Near Infrared Spectroscopy. Statistical analysis involved characterization of the vascular responses using 4th degree polynomial modelling. Between-group differences regarding the magnitude of vascular responses were assessed with unpaired t-Test (YA versus OA).
RESULTS: In n=15 YA (23.0±1.5yrs; 40% male), CPT produced a significant increase in CCA velocity (+8.9%, 74s), diameter (+5.2%, 89s) and blood flow (+67.7±16%). These responses in the CCA coincide with increased MCAv (+6.0%, 78s), subsequently followed by an increase in cortical oxygenation (O2Hb: +3.6µmol, 126s). Despite similarity in the magnitude of these responses, no significant correlations were observed between CCA versus MCA or cortical oxygenation (all P>0.05).
Compared to YA, the OA group (n=13, 71.8±4.6yrs, 62% male) showed an abolished dilator response in CCAd (0.8±4%, P=.002), whilst no differences were found in CCAv (P=.910) or blood flow (P=.601). OA subjects exhibited reversed MCAv responses to CPT (-13.2±28%, P=.005), whilst a trend for attenuated response was found for cortical oxygenation in OA compared to YA (P=.056). Time to reach peak was not different between YA and OA for CCAd, CCAv or O2Hb, although OA reached peak MCAv earlier than YA (P=.023).
CONCLUSION: In agreement with the extra-cranial CCA, we found that sympathetic stimulation leads to marked vascular reactivity of intra-cranial larger (i.e. MCA) and smaller vessels (i.e. cortical oxygenation). Furthermore, older age is associated with impaired and even reversed vascular responses in extra- and intracranial arteries, despite similar blood flow. Future research is warranted to better understand these responses and explore if physical activity interventions may be beneficial.

OP-PM20 Hydration / Dehydration

HYDRATION KNOWLEDGE, ATTITUDES AND PRACTICES OF OCEANIA ATHLETES PREPARING FOR THE 2018 GOLD COAST COMMONWEALTH GAMES: AN OBSERVATIONAL STUDY

IRWIN, C., DESBROW, B., BELLINGER, P., MINAHAN, C.

GRIFFITH UNIVERSITY

INTRODUCTION: Fluid and electrolyte balance are important considerations for athletes, particularly when undertaking regular training sessions separated by short recovery times (<24h). In these situations, rehydration between sessions is important, as hypohydration can increase physiological strain, decrease performance and contribute to heat illness. Relatively little is known about the hydration practices

of regional Oceania athletes (outside Australia and New Zealand), who typically train in hot environments and have variable access to sports science/nutrition advice and support. The aim of this study was to: (1) determine hydration knowledge and attitudes of Oceania region athletes; and (2) assess hydration status and fluid consumption practices of these athletes during a training camp based in Gold Coast, Australia for the 2018 Commonwealth Games.
METHODS: Fourty-six athletes (n = 29 male, age: 22.2±5.7 y) from different sports [Field (n = 3), Track (n = 8), Boxing (n = 8), Lawn Bowls (n = 2), Swimming (n = 9), Volleyball (n = 16)] attended the training camp. Nutrition knowledge and attitudes regarding hydration practices were assessed at commencement of the camp using a questionnaire. Hydration assessment (n = 33) involved urine measures of specific gravity (Usg), osmolality (Uosm) and colour (Ucol) at three times throughout a training day (upon waking and immediately pre- and post-training). Body mass (BM) was also measured and fluid intake during training was estimated.
RESULTS: The mean assessment score of nutrition knowledge was 43±13% correct responses. Females (45±12%) and field athletes (54±13%) scored slightly better than males (42±14%) and other groups (≤46%). However, no athlete obtained a pass score (≥80%), indicating a low level of hydration/fluid replacement knowledge. Most athletes agreed with statements suggesting positive attitudes towards personal hydration practices, with the exception of relying on thirst as an indicator of dehydration; where the majority of athletes indicated belief they could employ this strategy (n = 22, 51%). Most athletes were hypohydrated upon waking (Usg = 1.020±0.007; Uosm = 697±267; Ucol = 5.2±1.4) and commenced training sessions in a hypohydrated state (Usg = 1.022±0.009; Uosm = 795±261; Ucol = 5.4±1.3). Fluid intake during training was not sufficient to prevent further fluid losses (1.4±0.9% BM loss), irrespective of athlete group.
CONCLUSION: Results indicate that Oceania athletes have limited understanding of fluid replacement concepts and that this likely contributes to their poor hydration practices. Targeted information regarding pre-exercise hydration status and appropriate hydration practices during and between training sessions is required to support these athletes, particularly in preparation for major competition.

THE EFFECT OF SLOW, MODERATE AND FAST WATER DRINKING ON FLUID RETENTION FOLLOWING EXERCISE-INDUCED HYPOHYDRATION.

INTRODUCTION: Changing drinking rate has the potential to alter the fluid retention profile of a beverage (Jones et al 2010 & Kovacs et al 2002), but only slow or very slow ingestion rates have been examined. This study examined the influence of fast, moderate and slow drinking rates on fluid retention following exercise-induced hypohydration.
METHODS: Twelve active participants (9 males and 3 females: age: 28.3±6.3 y, height: 1.76±0.11 m, body mass: 74.0±10.2 kg, (Mean±SD)) undertook four exercise trials conducted 5-7 days apart to induce a body mass loss of 2.0±0.3%. After exercise, in a crossover randomised design participants ingested water in a volume equivalent to 100% of their body mass loss over either 15 min (DR15), 45 min (DR45) or 90 min (DR90), with a repeat trial of either DR15 or DR45 to assess test-retest reliability. Subjective sensations (thirst, nausea, fullness, bloating) and urine output were measured hourly for a total of 3-h after the onset of drinking.
RESULTS: Body mass loss was similar on all trials resulting in a total fluid intake of 1490±288 ml. Total fluid retention was significantly greater in DR90 (57.1±12.8%) compared to DR15 (49.7±10.9%, p=0.046), but not different to DR45 (51.5±21.8%). Thirst sensation peaked post exercise and decreased after water ingestion to similar levels regardless of the drinking rate. Perceived bloating and fullness was higher on DR15 trial ($p<0.05$) immediately after ingesting water, but not thereafter. Test-retest reliability assessment revealed that day to day variation in fluid retention was 7.3±8.8% (CV 17%).
CONCLUSION: Ingesting fluid at a fast drinking rate (DR15) reduced fluid retention compared to a slow drinking rate (DR90), however, this was just outside the range of normal day to day variation noted on repeated trials. Practically, there is no real difference between rapid or metered ingestion strategies on hydration, but a key benefit of staggering fluid intake during recovery would be to improve gastrointestinal symptoms compared to rapid ingestion.

EFFECT OF DRINKING RATE ON RETENTION OF MILK AND WATER FOLLOWING EXERCISE-INDUCED DEHYDRATION.

SAYER, L.1, RODRIGUEZ-SANCHEZ, N.2, RODRIGUEZ GIUSTINIANI, P.2, IRWIN, C.1, MCCARTNEY, D.1, COX, G.R.3, GALLOWAY, S.D.2, DESBROW, B.1

1: GRIFFITH UNIVERSITY , 2: UNIVERSITY OF STIRLING , 3: AUSTRALIAN INSTITUTE OF SPORT

INTRODUCTION: Changing drinking rate (Jones et al 2010) and altering nutrient composition (Maughan et al 2016) have independently been shown to change the fluid retention profile of a beverage, yet no study has examined the interaction of these factors. This study investigated the effect of drinking rate on the fluid retention properties of milk and water following exercise-induced sweat loss.
METHODS: Twelve male participants (23.5 y (SD 5.3), 178cm (SD 6), 77.3kg (SD 9.6)) lost 1.9% (SD 0.3) body mass (BM) through moderate intensity cycle exercise on 4 separate occasions. Following exercise, plain water or low fat milk equal to the volume of sweat lost during exercise was provided. Beverages were ingested at different rates (30 min or 90 min), resulting in the following four beverage treatments: (1) Water 30 mins (W30); (2) Water 90 mins (W90); (3) Milk 30 mins (M30); and (4) Milk 90 mins (M90). Nude BM, urine volume, urine specific gravity (USG), plasma osmolality (POSM) and ratings of gastro-intestinal (GI) tolerance were obtained pre-exercise and every hour for 3h after the onset of drinking.
RESULTS: Total fluid retention (%) was significantly greater when milk was consumed, as opposed to water (Water (both trials) 58.1% (SD 17.7) vs. Milk (both trials) 83.8% (SD 6.5), $p<0.001$). No significant effect of drinking rate was observed (W30 = 56.5% (SD 16.1); W90 = 59.7% (SD 19.7); M30 = 82.9% (SD 6.1); M90 = 84.9% (SD 7.1) at the end of the recovery period. Rapid drinking resulted in a peak in subjective bloating 30 mins post exercise and was not influenced by the type of beverage (p=0.28). Perceived fullness was higher at 90 mins following the M90 compared to W90 ($p<0.001$).
CONCLUSION: The nutrient composition of a beverage had a more pronounced impact on fluid retention than the beverage ingestion rate. Practically, total fluid intake and beverage choice are more influential than fluid ingestion rate in determining post-exercise rehydration. Personal preference, gastro-intestinal tolerance and post-exercise commitments can be considered when recommending drinking rates to athletes.
