Welcome

Welcome to the 23rd Annual Congress of the ECSS

Welcome to Dublin

Dear colleagues,

On behalf of University College Dublin and Ulster University, we would like to extend a warm welcome to join us at the 23rd Annual Congress of the ECSS in Dublin, Ireland, from the 4th - 7th July, 2018. The conference will take place right in the heart of the city at the newly built and inspirational Convention Centre overlooking the River Liffey, surrounded by all the amenities this dynamic city has to offer.

We are confident that you will find the multidisciplinary academic programme, delivered by some of the leading exponents and thinkers in our field, invigorating and enjoyable, arising as it does from the combined expertise of University College Dublin (Centre for Sports Studies; Institute for Sport and Health) and Ulster University School of Sport. Our congress theme is "Sport Science at the Cutting Edge" and we aim to provide every opportunity for delegates to learn from, and contribute to the latest developments in Sports and Exercise science in a stimulating social and professional setting.

We look forward to seeing you there!

Prof. Marie Murphy PhD, FACSM, FBASES
(Ulster University School of Sport)

Prof. Colin Boreham PhD, FECSS, FACSM
(Director, Institute for Sport and Health, UCD)

Prof. Giuseppe De Vito MD, PhD, FECSS, FFSEM

OP-PM01 BLOOD FLOW RESTRICTION EXERCISE

MUSCLE FIBER TYPE-SPECIFIC CELLULAR STRESS AND SUBCELLULAR MOVEMENT OF HEAT-SHOCK PROTEINS DURING FREQUENT BLOOD FLOW RESTRICTED RESISTANCE EXERCISE

BJØRNSEN, T., WERNBOM, M., PAULSEN, G., BERNTSEN, S., RAASTAD, T.

UNIVERSITY OF AGDER

INTRODUCTION: High-frequency blood flow restricted resistance exercise (BFRRE) can induce rapid muscle growth (1). In contrast to heavy-load strength training, a single bout of low-load BFRRE seems to preferentially stress type I fibers (2). Therefore, the aim of this study was to investigate heat shock protein (HSP) responses and changes in glycogen content, muscle fiber areas (MFA) and strength during frequent BFRRE.
METHODS: Thirteen participants (9 men, 4 women) performed two blocks of seven BFRRE sessions, separated by 10 days of rest. BFRRE consisted of four sets (30s rest) with unilateral knee-extensions to failure at 20% of 1 repetition maximum (1RM) with partial blood flow restriction. Biopsies were obtained from m. vastus lateralis at baseline, 1h after the first session each week, after 3 sessions, during the rest period, and two times post-intervention. Muscle tissue was homogenized and fractionated into cytosolic, membrane, cytoskeletal and nuclear fractions. HSP70, αB-crystallin, glycogen content and MFA were assessed using immunohistochemistry and western blotting. Strength was measured as 1RM in knee extension.
RESULTS: αB-crystallin levels were increased in the cytoskeletal fraction and decreased in the cytosolic fraction 1 hour after the first bout of each training week. Staining intensity of αB-crystallin (cytoskeletal-bound) increased in type I and II fibers 1 hour after the first bout each training week, however, the increases were larger in type I fibers. Cytoskeletal HSP70 levels were increased after 3 BFRRE sessions and 3 days after the second block of BFRRE. Staining intensity of HSP70 (cytoskeletal-bound) also increased after 3 sessions and 3 days after the second block of BFRRE, but only in type I fibers. Glycogen content was reduced 1h after the first bout in each week, and after 3 BFRRE sessions, but the reduction was larger in type I fibers than type II fibers. Type I fibers also had reduced glycogen content during the rest week (after 5 days of rest). MFA increased significantly in type 1 fibers after 10 days of detraining and the increases were significantly larger than type in II fibers. 1RM increased after 20 days of detraining, but was reduced during the rest week and the reduction was correlated with the reduced glycogen content of type I fibers in the rest period.
CONCLUSION: BFRRE stresses the muscle fibers, causing an activation of HSP70 and translocation of αB-crystallin to cytoskeletal proteins. The HSP responses were more pronounced in type I than type II fibers. The prolonged reduction in glycogen content of type I fibers (≥5 days), suggests impaired glucose uptake and/or elevated energy turnover. Taken together, the fiber type-specific HSP responses, prolonged glycogen depletion and myofiber hypertrophy, strongly indicate that type I fibers were more stressed than type II fibers during low-load BFRRE.

EFFECTS OF A FAILURE VS. A SUBMAXIMAL PROTOCOL OF FREQUENT BLOOD FLOW RESTRICTED RESISTANCE EXERCISE ON CHANGES IN MAXIMAL STRENGTH

SANDNES, N.V.1, MANGSETH, H.1, GERBI, S.1, LINDBERG, K.1, SØRLI, T.1, VÅRVIK, F.2, WERNBOM, M.3, BERNTSEN, S.1, PAULSEN, G.4, RAASTAD, T.5, BJØRNSEN, T.1

1UNIVERSITY OF AGDER, 2NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, 3UNIVERSITY OF GOTHENBURG, 4NORWEGIAN OLYMPIC FEDERATION, 5NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Short-term high-frequency low-load blood flow restricted resistance exercise (BFRRE) has been observed to induce gains in maximal strength with loads as low as 20% of 1 repetition maximum (1RM) (1). However, the responses were delayed and peaked 12 days after the last training session. Therefore, the aim of the present study was to compare the effect of a failure versus submaximal BFRRE protocol on maximal strength.
METHODS: Nineteen untrained men and women (18-45 yrs old) performed BFRRE with four sets to voluntary failure with one leg, and a submaximal protocol with 20, 10, 10 and 10 repetitions with the other leg, using unilateral knee extensions. The intervention consisted of 14 BFRRE sessions distributed equally over two training blocks (5 days), separated by ten days rest. Training load was 20% of 1RM, with a 145mm wide pressure cuff inflated to 100 mmHg to induce partial blood flow restriction. 1RM and maximal voluntary isometric contraction (MVC) was tested at baseline, in the rest week, as well as and 3, 10, 17 and 24 days post BFRRE. Delayed onset muscle soreness (DOMS), rate of perceived exertion (RPE) and pain score (CR10) were also recorded at each session. A linear mixed model with Fishers LSD post-hoc test and independent sample t-tests were used for statistical analysis.
RESULTS: The submaximal leg increased MVC significantly compared to the failure leg over the time course of the study ($p<0.05$). The submaximal leg had significantly higher MVC than the failure leg 3 days post BFRRE, due to a larger initial reduction in MVC during the failure protocol. Compared to baseline, MVC increased by 7.6% (CI: 3.0,12.2, $p<0.001$) in the submaximal leg, while the failure leg tended to increase MVC by 3.8% (CI -0.7, 8.5, $p=0.10$). We did not observe any differences between protocols in 1RM gains over the time course of the study. Both legs increased 1RM by ~15% ($p<0.001$) at 24 days post BFRRE, compared to baseline. Participants reported higher RPE ($p<0.001$) and CR10 ($p<0.001$) levels in the failure than the submaximal leg during both training weeks. The failure protocol induced higher DOMS than the submaximal protocol during the first week of BFRRE ($p<0.05$).

CONCLUSION: The submaximal protocol led to greater gains in MVC, however, we did not observe any group differences in 1RM. Notably, the increases in 1RM and MVC were delayed and peaked at an even later timepoint than the study by Nielsen and co-workers (24- vs. 12 days of detraining) (1). RPE-, CR10- and DOMS scores, as well as the transient decrease in MVC, indicate that the failure protocol was more stressful than the submaximal protocol. Considering the delayed responses after both protocols, future research should investigate if less stressful BFRRE may be even more beneficial for increases in strength during high-frequency low-load BFRRE.

FREQUENT BLOOD FLOW RESTRICTED RESISTANCE EXERCISE IMPROVES MAXIMAL POWER PERFORMANCE

GERBI, S.1, LINDERG, K 1, MANGSETH, H.1, SANDNES, N.V.1, SØRLI, T.1, VÅRVIK, F.2, WERNBOM, M.3, BERNTSEN, S.1, PAULSEN, G.4, RAASTAD, T.5, BJØRNSEN, T.1

1 UNIVERSITY OF AGDER; 2 NTNU; 3 UNIVERSITY OF GOTHENBURG; 4 NORWEGIAN OLYMPIC FEDERATION; 5 NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: High-frequency low-load blood flow restricted resistance exercise (BFRRE) to voluntary failure is shown to increase rapid force-generating capacity and strength (1). Notably, the increase in rapid force-generating capacity was delayed and did not peak before 12 days of detraining. Thus, the aim of the present study is to compare a high-frequent BFRRE protocol to voluntary failure versus a less strenuous submaximal BFRRE protocol on changes in maximal power.
METHODS: Nineteen untrained men and women (23.5±6.1 years) performed BFRRE with four sets to voluntary failure with one leg, and a submaximal (20, 10, 10 and 10 repetitions, respectively) BFRRE protocol with the other leg during unilateral knee extension (20% of 1RM). Participants performed 14 BFRRE sessions divided into two blocks of seven sessions, separated by 10 days of rest. A pneumatic cuff (145mm width) induced partial blood flow restriction with a pressure of 100mmHg. Maximal power was measured during knee extensions at 30% of 1RM. Exertion (Borg 6-20 scale) and pain measures (CR10 scale) were registered directly after each BFRRE bout.
RESULTS: Maximal power increased significantly more over the entire intervention period in the submaximal leg compared to the failure leg (p=0.002). Both the failure and submaximal protocol induced a significant increase in maximal power measured 3 (5% and 14%, respectively), 10 (10% and 15%), 17 (12% and 17%) and 24 days (17% and 20%) after the last training session, compared to baseline (p<0.001). On average, the failure leg performed 27.8±13.7 more repetitions than the submaximal leg during each BFFRE bout, p<0.001. Furthermore, the failure protocol was more strenuous (Failure: 18.9±0.9 vs. Submax: 15.1±0.7, p<0.001) and painful (7.8±0.4 vs. 6.5±0.5, p=0.001) than the submaximal protocol.
CONCLUSION: The submaximal leg increased maximal power more than the failure leg over the course of the study. The submaximal protocol seemed to improve maximal power more rapidly, even though it was performed with fewer repetitions and perceived as less strenuous and painful. The present findings may be of functional importance for athletes, clinical patients or elderly, as submaximal BFRRE may improve power more rapidly and with less discomfort than BFRRE performed to voluntary failure in each set. However, the increases in maximal power did not peak before 24 days of detraining after both protocols, indicating an overreaching effect. To the authors' knowledge, this is the first study to observe a delayed response in maximal power after high-frequency BFFRE. Future studies should further investigate the effect of a less strenuous BFRRE protocol on the changes in maximal power.

BLOOD FLOW RESTRICTION COMBINED WITH LOW-LOAD RESISTANCE-TYPE EXERCISE INCREASES MYOFIBRILLAR PROTEIN SYNTHESIS RATES IN YOUNG MEN

NYAKAYIRU, J., FUCHS, C.J., SMEETS, J.S.J., GIJSEN, A.P., GOESSENS, J.P.B., VAN LOON, L.J.C., VERDIJK, L.B.

MAASTRICHT UNIVERSITY

INTRODUCTION: Recent observations suggest that blood flow restriction (BFR) performed under resting conditions or when combined with low-load resistance-type exercise (LLRE), can increase muscle mass and strength (1, 2). However, limited data is currently available on the acute effects of blood flow restriction on muscle protein synthesis and anabolic signaling. Therefore, we determined the impact of blood flow restriction with and without concomitant low-load resistance-type exercise on myofibrillar protein synthesis rates in vivo in healthy young men.
METHODS: Twenty healthy young men (age: 24±1 y, BMI: 22.9±0.6 kg/m2) were randomly subjected to two 5 min cycles of single leg blood flow restriction combined with (LLRE-BFR; n=10) or without (REST-BFR; n=10) low-load resistance-type exercise (20%-1RM). Myofibrillar protein synthesis rates were assessed during a 5 h post BFR period, by combining a primed continuous L-[ring-13C6]phenylalanine infusion with the collection of blood samples and muscle biopsies from both the blood flow restricted and control leg of each participant. Phosphorylation status of Acetyl-CoA Carboxylase (ACC), and key anabolic signaling proteins (mTOR pathway) were also determined in the muscle samples collected from both legs. Within subject differences between the BFR and control leg were assessed using paired samples t-tests. Signaling data were analyzed using a two-factor repeated measures ANOVA with time and treatment (BFR vs control leg) as within-subjects factors. Data represent means±SEM.
RESULTS: In resting condition, blood flow restriction (REST-BFR) did not increase myofibrillar protein synthesis rates when compared to the control leg (0.044±0.004 vs 0.043±0.004 %/h, respectively; P=0.683). No changes in ACC or mTOR related signaling were observed with BFR under resting conditions, when compared to the resting control leg. In contrast, when combined with low-load resistance-type exercise, blood flow restriction (LLRE-BFR) increased post-exercise myofibrillar protein synthesis rates by 10±5 % when compared to the LLRE control leg (0.048±0.005 vs 0.043±0.004 %/h, respectively; P=0.042). Furthermore, LLRE-BFR showed a higher level of ACC (P<0.05) and 4E-BP1 (P=0.038) phosphorylation, when compared to LLRE.
CONCLUSION: Blood flow restriction at rest does not increase myofibrillar protein synthesis rates in healthy young men. When combined with low-load resistance-type exercise, blood flow restriction increases myofibrillar protein synthesis rates during post-exercise recovery.

THE COMBINED EFFECT OF SPRINT INTERVAL TRAINING AND BLOOD FLOW RESTRICTION ON CRITICAL POWER, CAPILLARY GROWTH AND MITOCHONDRIAL PROTEINS IN TRAINED CYCLISTS

MITCHELL, E.A., MARTIN, N.R.W., TURNER, M.C., TAYLOR, C.W., FERGUSON, R.A.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Sprint interval training (SIT) combined with post-exercise blood-flow restriction (BFR) is a novel method to increase maximal oxygen uptake (V̇O2max) in trained individuals, and also provides a potent acute stimulus for angiogenesis and mitochondrial biogenesis (Taylor et al. 2016). The efficacy to enhance endurance performance has, however, yet to be demonstrated. The aim of the present study, therefore, was to assess whether post-exercise BFR enhances critical power (CP) as well as skeletal muscle capillarity and mitochondrial protein content.
METHODS: With local ethics committee approval eighteen trained male cyclists (V̇O2max; 63.4 ± 3.7 ml.min-1.kg-1) undertook 4 weeks of SIT involving repeated 30 sec maximal sprints with 4.5 min recovery intervals either alone (CON; n = 9) or with 2 min of post-exercise BFR (n = 9). Before and after training (V̇O2max was assessed as well as the power-duration relationship through the performance of 3-5 constant load tests for the determination of CP and W'. Muscle biopsies (vastus lateralis) were also obtained and analysed for skeletal muscle capillarity (capillary density and capillary-to-fibre ratio (C:F)), proliferating endothelial cells (Ki-67 positive) and mitochondrial enzyme protein content (citrate synthase and cytochrome c oxidase subunits II and IV). Data were analysed with two-factor mixed model ANOVAs, and are presented as mean ± SD.
RESULTS: V̇O2max increased by 4.7% following BFR (62.9 ± 3.7 to 65.9 ± 5.0 ml.min-1.kg-1; P = 0.05) but was unchanged after CON (63.9 ± 4.3 vs. 63.1 ± 6.4 ml.min-1.kg-1; P = 0.47). CP increased (P < 0.001) by a similar extent following CON (288 ± 41 W to 298 ± 46 W) and BFR (297 ± 43 W to 310 ± 38 W). W' was unchanged (P = 0.23) following either training intervention. Both skeletal muscle capillary density (CON, 395 ± 66 vs. 386 ± 29 µm-2; BFR, 422 ± 32 vs. 411 ± 40 µm-2; P = 0.31) and C:F (CON, 2.98 ± 0.69 vs. 3.03 ± 0.76; BFR, 2.85 ± 0.74 vs. 3.01 ± 0.86; P = 0.42) were unchanged following either training intervention. There was a trend (P = 0.09) towards an increase in proliferating endothelial cells per fibre following BFR but not CON. Mitochondrial protein content was unchanged following either training intervention.
CONCLUSION: This study further demonstrates the potency of combining BFR with SIT to enhance V̇O2max, compared to SIT alone, in trained individuals. CP increased with SIT, however, this was not enhanced further with BFR. There is a suggestion that BFR may elicit angiogenesis but adaptations may take longer to occur, or require a greater volume of training.

THE EFFECT OF BLOOD FLOW RESTRICTED RESISTANCE EXERCISE PERFORMED TO FAILURE VS. SUBMAXIMALLY ON CHANGES IN RATE OF FORCE DEVELOPMENT

LINDERG, K.1, GERBI, S.1, MANGSETH, H.1, SANDNES, N.V.1, SØRLI, T.1, VÅRVIK, F.2, BERNTSEN, S.1, WERNBOM, M.3, PAULSEN, G.4, RAASTAD, T.5, BJØRNSEN, T.1

1 UNIVERSITY OF AGDER; 2 NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY; 3 UNIVERSITY OF GOTHENBURG; 4 NORWEGIAN OLYMPIC FEDERATION; 5 NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: High-frequency low-load blood flow restricted resistance exercise (BFRRE) to voluntary failure is shown to induce improvements in rate of force development (RFD) (1). Notably, the increases in RFD were delayed and did not peak before 12 days of detraining. Therefore, the aim of the present study was to compare the effect of a failure protocol to a less strenuous submaximal protocol on the changes in RFD during two blocks of high-frequency BFRRE.
METHODS: Nineteen untrained men and women (23.5±6.1 years) performed BFRRE with four sets to voluntary failure with one leg, and a submaximal (20-, 10-, 10- and 10 repetitions, respectively) BFRRE protocol with the other leg during unilateral knee extension (20% of 1RM). Participants performed 14 BFRRE sessions divided into two blocks of seven sessions, separated by 10 days of rest. A pneumatic cuff (145mm width) induced partial blood flow restriction with a pressure of 100mmHg. RFD was derived from the average slope of the force–time curve at the 0-30 ms, 0-50 ms, 0-100 ms, 0-150 ms, 0-200 ms, 0-250 ms and peakRFD 20 ms intervals during maximal voluntary isometric knee extension (MVC). Pain and exertion scores were registered with Borg CR10 and RPE scale after each BFRRE bout. Statistical analyses were conducted using linear-mixed models with Fisher's LSD post-hoc test.
RESULTS: No group differences were observed in RFD changes over the time course of the study. However, RFD 0-30 ms and RFD 0-50 ms tended (p=0.05-0.10) to decrease in the failure leg 3 days after BFRRE. Compared to the failure leg, the submaximal leg decreased RFD at 0-30 ms (p=0.038), and tended to decrease RFD at 0-50 ms (p=0.06) and 0-100 ms (p=0.07), after 24 days of detraining. Only the submaximal leg increased late phase RFD at 0-250ms (15.8% [1.5, 30]; p=0.03) and MVC (7.62% [3.12, 12.11], p=0.002) significantly from baseline to 24 days post BFRRE. The failure protocol was more strenuous and painful compared to the submaximal protocol (p<0.05).
CONCLUSION: We could not detect any significant group differences in the changes of RFD. However, early phase RFD seemed to be reduced 3 days after BFRRE in the failure leg and subsequently increased after 24 days of detraining. The increases in late phase RFD of the submaximal leg were delayed and did not peak before 24 days of detraining, indicating an overreaching effect. Future studies should further if a less strenuous high-frequent BFRRE protocol can increase RFD.

OP-PM02 IRONMAN and ENDURANCE

PEAK FAT OXIDATION RATE IS RELATED TO IRONMAN PERFORMANCE IN WOMEN

VEST, S.D., FRANDSEN, J., LARSEN, S., DELA, F., HELGE, J.W.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: In male triathletes overall Ironman (IM) finish time is significantly and inversely associated with peak fat oxidation rate (PFO) (Frandsen et al. 2017), but if this relationship is similar in female triathletes is unknown, since research on performance parameters

in female IM triathletes is scarce (Knechtle et al. 2010). PFO per kilogram fat free mass (FFM) is higher in women compared with men (Venables et al. 2004), and thus, we hypothesised that the relationship would also exist for female triathletes.
METHODS: 36 female IM athletes (age: 34±1 yrs (mean ± SEM) [range: 21-45 yrs]) with a BMI of 22.1±2.0 kg/m2 [18.8-28.4 kg/m2], percent body fat of 24.8±1.0 % [9.0-37.0%] and a VO2peak of 53.0±1.3 ml/min/kg [36.5-70.5 ml/min/kg] were tested in the laboratory between 28 days and 4 days prior to the IM Copenhagen 2017. Body composition was measured by a DXA-scan and venous blood samples were drawn before an incremental exercise test on cycle ergometer. Indirect calorimetry and pulmonary gas exchange measurements throughout the test were used to determine PFO and VO2peak. Ironman Copenhagen race data was obtained online from the official timing provider. Simple bivariate regression analyses and multiple regressions analyses were performed using SigmaPlot 13.0 and GraphPad Prism 7. The level of significance was defined as <0.05.
RESULTS: Finish time ranged from 9:17:07 to 15:23:48 with mean finish time being 11:57:26 h:min:sec (717 min). Simple bivariate regression analyses found negative correlations between finish time and PFO (r2 = 0.22, p<0.005), VO2peak (r2 = 0.65, p<0.0001) and the relative exercise intensity at PFO (Fatmax) (r2 = 0.35, p=0.0001). Positive correlations were found between finish time and body fat percentage (r2 = 0.44, p<0.0001) and age (r2 = 0.16, p<0.05). By means of multiple regression analyses VO2peak alone explained 64 % of the variation in finish time (adj R2 = 0.64, p<0.001) and no other variables contributed independently.
CONCLUSION: These results demonstrate significant relationships between IM performance, VO2peak, PFO and Fatmax in a heterogeneous group of female athletes, with VO2peak being the only independent race time predictor explaining 64 % of the variation in IM race time. Interestingly, the performance parameters in women showed stronger correlations to IM finish time compared to previously reported data in men (Frandsen et al. 2017).

PEAK OXYGEN UPTAKE PREDICTS FINISHING- AND SEGMENT TIME IN A FULL DISTANCE IRONMAN

DANIELSSON, T., CARLSSON, J., AHNESJÖ, J., BERGMAN, P.

LINNAEUS UNIVERSITY

INTRODUCTION: Ironman competitions and other extreme endurance events have spread worldwide attracting thousands of endurance-trained athletes, athletes who differ in anthropometric and training characteristics. The relationship between peak oxygen uptake and finishing- and segment time during a full distance IRONMAN competition (Swim 3.9km, Bike 180km and Run 42.2km) has not been examined thoroughly in non-elite athletes. The aim of the present study was to investigate the relationship between peak oxygen uptake, finishing time and segment time in non-elite athletes.
METHODS: 39 non-elite athletes (10 female; age 41.1 ± 9.7, range 24-70 years) performed a 20 m shuttle run test to assess VO2peak. Association between VO2 and finishing- and segment time was estimated using bivariate correlation tests. Gender specific analysis was also performed.
RESULTS: VO2peak peak was on average 49.9 ± 6.4 O2 ml/kg/minute, range 36.5-63.9 (pooled genders). Finishing time was on average 11h and 52 min. The average times for the different segments were; Swim 1h 21m, Bike 5h 46min and Run 4h 33min. The relationship between VO2peak and finishing time was significant to p<0.001 and r2 0.51. The relationship between segment times were Swim r2 0.19, Bike r2 0.37 and Run r2 0.46 all at p<0.001. Gender specific analyses revealed that the association between VO2peak and finishing time was r2 0.80 for females and r2 0.49 for males.
CONCLUSION: Our results suggest that VO2peak is a good predictor of finishing time (approx. 50%) as well as for segment time with 19%, 37% and 46% for Swim, Bike and Run respectively (pooled genders). For females VO2peak explains as much as 80% of the variation in finishing time.

ECHOCARDIOGRAPHIC FINDINGS AND CARDIAC BIOMARKERS IN NON-ELITE TRIATHLETES – DATA FROM THE KALMAR IRONWOMAN STUDY.

CARLSSON, J., DANIELSSON, T., BERGMAN, P., SCHREYER, H.

LINNAEUS UNIVERSITY

INTRODUCTION: There is an ongoing debate about the impact of endurance exercise on cardiovascular health. Not at least data on cardiac biomarker changes (e.g. troponin T (cTnT), N-terminal prohormone of brain natriuretic peptide (NT-proBNP) and cardiac specific myosin heavy chain-alpha (MHC-α) have raised questions about exercise related cardiac injury.
METHODS: In 52 non-elite athletes (14 female, 38 male; age 41.1 ± 9.7, range 24-70 years; all completed the race) biomarkers were measured by standard laboratory methods 7 days before, directly after, and day 1, 4 and 6 after a full Ironman distance triathlon (Swim 3.9 km, Bike 180 km, Run 42.2 km) . In 19 of these athletes (9 female, 10 male) echocardiography with 30 different standard measurements was performed before and directly after the race.
RESULTS: Only MHC-α [µg/L] showed a two-peaked increase directly after (2.57 ± 0.78) and on day 4 (2.74 ± 0.55). Other biomarkers showed a one-peaked increase with maximal values either directly after the race or at day 1: cTnT 76 ± 80 ng/L (12-440; reference <15), NT-proBNP 776 ± 684 ng/L (92-4700; ref. < 300), CK 68 ± 55 µkat/L (5-280; ref. < 1.9), MG 2088 ± 2350 µg/L (130-17000; ref.< 72), and creatinine 100 ± 20 µmol/L (74-161; ref. < 100), CRP 49 ± 23 mg/L (15-119; ref.< 5). No significant echocardiographic changes were recorded. E.g. left ventricular end diastolic diameter (49.0 ± 4.7 mm before, 47.7 ± 5.0 mm after the race, right ventricular end diastolic diameter (34.3 ± 4.3 mm before, 33.3 ± 5.7 mm after the race), right atrial area (17.5 ± 2.9 cm2 before, 17.7 ± 3.6 cm2 after the race) and left atrial area (18.8 ± 3.7 cm2 before, 17.8 ± 2.2 cm2 after the race) did not show any significant acute changes.
CONCLUSION: While an Ironman leads to remarkable disturbances in biomarkers as e.g. cTnT after the race was in the range of myocardial infarction in 100% of women and 97% of men, these alterations were not correlated to any acute echocardiographic changes in heart size or function. However, the significance of biochemical evidence of cardiac injury on long-term heart function and cardiovascular health remains unclear.

ENERGETICS OF RUNNING IN ULTRA-MARATHONERS: IS IT DIFFERENT FROM TRACK RUNNERS?

SOUSA, A.1,2, PIRES, P.3, COLAÇO, P.4, FERNANDES, R.4

1: RESEARCH CENTER FOR SPORTS, EXERCISE AND HUMAN DEVELOPMENT, UNIVERSITY OF TRÁS-OS-MONTES AND ALTO DOURO, VILA REAL, PORTUGAL, 2: UNIVERSITY INSTITUTE OF MAIA, ISMAI, MAIA, PORTUGAL, 3: ARMADA PORTU

INTRODUCTION: The energetics of human locomotion has been the focus of exercise physiology since 20th century's early decades, with special interest in running performance (di Prampero, 1986). More recently, there has been a growing interest in competing in long running distances, which requires some physiologic characteristics distinct from those typically associated with shorter distances. However, little research has examined the energetics of ultra-marathoners (UM), being scarce the physiological knowledge within these athletes, and/ or how distinct might be from track-runners' (TR) energetics.
METHODS: Ten high level competitive TR) and ten UM (mean ± SD; age: 28.6 ± 1.3, 40.5 ± 0.5 yrs, height: 1.75 ± 0.05, 1.76 ± 0.04 m and body mass: 61.9 ± 2.1 and 71.5 ± 2.1 kg, respectively) performed an intermittent incremental protocol until exhaustion for VO2max and corresponding velocity (vVO2max) assessment (7*800m steps). Cardiopulmonary parameters were assessed breath by breath (averaged 5s) using a portable and telemetric gas analyser (K4b2, Cosmed, Italy). Capillary blood samples were collected during the 30s intervals (Lactate Pro, Japan). The percentage of VO2 (%VO2) and heart rate (%HR) at lactate threshold (LT), and, the percentage at which LT occurred (%LT), were considered for analysis. Energy cost (EC) in each 800m step was determined as the ratio between net metabolic power expenditure and velocity. Comparison between groups was done using Mann-Whitney test ($p \leq 05$).
RESULTS: %VO2 (92.1±4.2 and 90.4±1.8 %) and %HR (95.1±2.4 and 92.7±2.6 %) were not different in-between groups, although VO2max (71.3±1.3 vs. 58.4±1.6 ml.kg-1.min-1, $p<0.001$) and HRmax (185±8 vs. 176±7 bpm, $p=0.03$) were (TR vs. UM, respectively). %LT and LT were significantly higher in TR compared with UM (89.3±3.1 vs. 86.3±3.1 %, $p=0.02$; 3.2±0.5 vs. 2.6±0.6 mmol.L-1, respectively). EC was significantly lower in TR compared with UM (ranging from 0.22 to 0.25 vs. 0.26 to 0.28 kj.m-1, from the 1st to the 5th steps), but differences in-between steps were only found for the TR group.
CONCLUSION: Both LT and %LT being lower in UM suggest that this group is more adapted to lower intensities of aerobic performance, probably as the result of the lower intensities at which competitions typically occur (Savoldelli et al., 2017). EC being independent of velocity in the UM group, suggest that EC does not play an important role in the UM' energetics.

EFFICACY OF SELF-REPORTED PERCEPTIONS OF SWEATING RATE AND RATE OF SWEAT SODIUM LOSS IN ULTRA-ENDURANCE TRIATHLETES

BARNES, K.B., PAHNKE, M.D., REIMEL, A.J., SOPENA, B.C., RANDELL, R.K., BAKER, L.B.

PEPSICO, INC

INTRODUCTION: Sweat fluid and electrolyte losses in athletes may impact performance and health if not adequately replaced. However, accurate replacement requires understanding of losses, which can be complex and require expensive equipment. The aim of this study was to determine if self-reported subjective classifications of sweating rate (SR) and rate of sweat sodium loss (RSSL) in ultra-endurance triathletes can identify those in greatest need of replacement guidance when compared to traditional methods.
METHODS: SR and sweat [Na+] were measured in 29 ultra-endurance (Ironman© World Championship) athletes (24-71 y) during a 5-mile run (29°C, 56% rh). Sweat [Na+] was analyzed via a patch technique and normalized to whole body sweat [Na+] using published equations (1). SR was the change in pre- to post-exercise body mass, corrected for food/fluid intake. RSSL was the product of whole body sweat [Na+] and SR. After the run, athletes rated self-perceptions of SR and RSSL classifications (LOW, MOD, HIGH) compared with others in their sport. A 100-point visual analog scale was used to assess frequency of salt residue on clothes/skin, taste of salt in sweat, and eye burning from sweat during typical training/competition (SALTINESS). ANOVA and Tukey post hoc analysis were used to compare measured SR and RSSL among LOW, MOD, and HIGH self-classified groups ($\alpha=0.05$).
RESULTS: The mean±SD(range) and tertiles were: SR(L/h) 1.9±0.6(1.0-3.3) and <1.6, 1.6-2.0, >2.0; RSSL(mmol/h) 94±43(47-216) and <69, 69-98, >98. SR(L/h) was greater in self-reported HIGH (2.2±0.6) than MOD (1.5±0.5), but LOW (1.6±0.4) was not different than HIGH or MOD. RSSL(mmol/h) was greater in self-report HIGH (139±50) than LOW (69±24) and MOD (91±34). Athletes with SALTINESS score ≥50% had higher (two sample t-tests) RSSL (113±51 mmol/h) than those with score <50% (75±20 mmol/h). There was a significant relation between SALTINESS and RSSL ($r2=0.23$).
CONCLUSION: Ultra-endurance triathletes who report HIGH sweat fluid and Na+ losses and greater SALTINESS tend to have higher SR and RSSL. Yet, only 48% (SR) and 34% (RSSL) correctly categorized themselves as LOW, MOD, or HIGH. Moreover, their perceived SALTINESS only accounted for ~23% of the RSSL variation . Therefore, self-perceptions of SR and RSSL cannot take the place of direct measurements. However, elite ultra-endurance triathletes may be able to use subjective cues to identify those at greatest risk of high sweat fluid/electrolyte losses and therefore most in need of sweat testing and individualized fluid replacement strategies.

REPEATED PROLONGED EXERCISE IN YOUNG AND OLD WELL-TRAINED CYCLISTS

FRANDSEN, J., SAHL, R.E., HANSEN, M., RØMER, T., NIELSEN, A.B., LIE-OLSEN, M.M., LARSEN, S., DELA, F., HELGE, J.W.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: Repeated prolonged exercise <14 days, 10 h and 31±37 min/day at 53% of maximal oxygen uptake > has previously been found to decrease VO2max and maximal fat oxidation rate in old men, despite no change in bodyweight. It however, remains unclear whether this finding is age dependent or a general human adaption to repeated prolonged exercise. The aim of this study was to investigate repeated prolonged exercise in both young and old well-trained cyclist. We hypothesized that VO2max and MFO would decrease in old, but remain unchanged in young men
METHODS: Cardiorespiratory fitness and maximal fat oxidation was measured in seven young <29.9±1.9 yrs. > and seven old <65.4±2.2 yrs.> men 3-7 days before departure in Copenhagen and 2 days after arrival in Palermo by indirect calorimetry and gas exchange

measurements. Venous blood samples were drawn immediately before the incremental exercise test. The participants wore heart rate monitors throughout the intervention.
RESULTS: A total distance of 3025±75 km <22500±500 altitude/meters> cycling was performed over 15 days <202±36 km/day>. The young group cycled on average 7.2±0.1 h/day at an exercise intensity of 63% of HRmax, whereas the old group cycled 9.1±0.2 h/day at 65% HRmax, covering 3100 and 2950 km in total. Body weight remained unchanged in both groups throughout the study. Before VO2max were 61.5±0.9 and 46.8±1.7 ml/min/kg in the young and old groups, respectively. 2 day after arrival VO2max was unchanged <63.8±0.8 ml/min/kg> in young but decreased <43.5±3.2 ml/min/kg> in the old group. Plasma hemoglobin concentrations decreased in both groups, from 15.1±0.3 to 14.0±0.2 g/dl in the young group and 15.2±0.2 to 13.3±0.2 g/dl in the old group, and the decrease was more pronounced in the old group.
MFO was decreased in the old group from 0.41±0.04 g/min to 0.35±0.04, but also in the young group from 0.53±0.05 to 0.43±0.06 after exercise. This decrease was probably a reflection of the marked decrease in plasma FFA concentrations in both groups .
CONCLUSION: In conclusion, the observed decrease in VO2max after repeated prolonged exercise is an age dependent adaption which is explained, at least partly, by the markedly decreased plasma hemoglobin concentration. Furthermore, the suppression of maximal fat oxidation rate is an age independent adaptation, which is most likely a consequence of the markedly decreased plasma fatty acid availability

BEET ON ALPS: ERGOGENIC EFFECTS OF DIETARY NITRATE SUPPLEMENTATION ON CYCLING AND ARM-CRANKING DURING A PROLONGED EXPOSURE TO HIGH ALTITUDE

RASICA, L., SALVADEGO, D., MRAKIC-SPOSTA, S., GELMINI, F., BERETTA, G., MARZORATI, M., PORCELLI, S.
UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Several studies have shown dietary nitrate supplementation increases nitric oxide bioavailability through nitrate-nitrite-nitric oxide pathway (NO3NO2NO). Since NO is involved in several physiological processes related to muscle function, NO3- supplementation has been utilized to improve sea level exercise performance, especially when type II muscle fibers are recruited. Ergogenic effects of NO3- supplementation have also been investigated in acute hypoxia due to enhanced reduction of NO3- to NO2- by reduced level of PO2. No studies have been carried out in chronic hypoxia, although prolonged permanence at altitude changes NO bioavailability and impairs physical performance. This study aimed to investigate the ergogenic effects of dietary NO3- supplementation on cycling and arm-cranking during a prolonged exposure to high altitude.
METHODS: Fourteen subjects (28±6 yrs) participated in a double-blind randomized crossover study carried out at Casati hut (3269m a.s.l). Following 5 days of acclimatization, an incremental exercise test was carried out in order to assess VO2peak and gas exchange threshold (GET) by cycle- and arm-ergometers. Then, each subject was supplemented for 3 days either with beetroot juice (2x70mL/day, 8.4mmol NO3-/day [BR]) and placebo [PLA]. At the end of each supplementation period, subjects exercised at two different intensities: an 8 min moderate-intensity (80% of GET) constant work rate (MOD) and a severe-intensity (50% of the difference between VO2peak and GET) constant work rate exercise up to exhaustion (SEVERE) were performed. These exercises were conducted by both cycle- and arm-ergometers. Plasma [NO3-] and [NO2-] were measured by chemiluminescence at discrete intervals during acclimatization as well as before and after supplementation periods.
RESULTS: Before supplementation period, plasma [NO3-] and [NO2-] increased from sea level values and they reached a peak value at day 3. After BR, [NO3-] and [NO2-] were significantly higher compared to PLA (309.9±153.7 vs. 25.3±11.9.7 μM, $p<0.001$ and 966.5±386.4 vs. 490.0±150.3 nM, $p<0.01$). In MOD, VO2 was significantly reduced in BR vs. PLA in both cycling (1.776±0.29 vs. 1.875±0.30 L*min-1, $p<0.01$) and arm cranking (0.989±0.22 vs. 1.023±0.24 L*min-1, $p<0.05$). Interestingly, the oxygen cost of exercise was not affected by supplementation in the two subjects with the highest level of aerobic fitness only in cycling. In SEVERE, VO2 was significantly lower in BR (vs. PLA) after 6 min of exercise in both cycling (2.588±0.42 vs. 2.686±0.44 L*min-1, $p<0.01$) and arm cranking (1.905±0.42 vs. 1.989±0.41 L*min-1, $p<0.05$). In BR (vs. PLA), time to exhaustion significantly improved during cycling (9%) and arm cranking (23%).
CONCLUSION: This study shows dietary nitrate supplementation reduces oxygen cost during moderate-intensity exercise and improves severe-intensity exercise tolerance during prolonged exposure to hypobaric hypoxia, independently from the muscle mass involved (cycling and arm-cranking).

COMBINED EFFECTS OF ISOMETRIC PRE-CONDITIONING AND ANTIOXIDANT JUICE CONSUMPTION ON RECOVERY FROM EXERCISE-INDUCED MUSCLE DAMAGE AND CHANGES IN RUNNING ECONOMY FOLLOWING DOWNHILL RUNNING

LIMA, L.C.R., BASSAN, N.M., BARRETO, R.V., SILVEIRA, C., GRECO, C.C., DENADAI, B.S.
CENTRO UNIVERSITÁRIO HERMÍNIO OMETTO

INTRODUCTION: Downhill running (DHR) acutely compromises running economy (RE) and induces muscle damage (MD). Preconditioning with maximal isometric contractions accelerates recovery from DHR-induced MD and consumption of anthocyanin-rich antioxidant juice (AJ) was shown to blunt changes in RE and symptoms of MD following DHR. The aim of this study was to investigate the combined effects of AJ consumption and isometric pre-conditioning on changes in RE and MD symptoms after a DHR bout.
METHODS: Seventy five men (22±2 yrs; 78±9 kg; 177±5 cm) were randomly assigned to one of five groups: control (CON), placebo (PLA), supplementation with AJ (SUP), isometric pre-conditioning (ISO) and combined supplementation and isometric pre-conditioning (COMB). Participants in all groups ran downhill (-15%) for 30 minutes at 70% of their VO2max speed. Participants in SUP consumed AJ twice a day for nine days (1-4 days before, the day of, and 1-4 days after DHR) while participants in PLA consumed an isocaloric and isovolumetric placebo (maltodextrin) at the same time points. Participants in ISO performed 10 maximal isometric contractions on a leg press machine two days before running downhill. Participants in COMB performed a combination of the treatments described for SUP and ISO and participants in CON did not receive any treatment. Oxygen uptake was assessed during 5-minute runs (80% VO2max) performed before, immediately after, and 1-4 days after DHR. Knee extensor isometric peak torque (IPT), countermovement jump height (CMJ), and muscle soreness were assessed at the same time points. Data was compared by ANOVAs with Bonferroni's post-hoc tests.

RESULTS: Group-time interactions were identified for all markers except CMJ. Oxygen uptake increased ($p<0.01$) immediately after the DHR bout for all groups (CON: 19±4 %; PLA: 20±5%; SUP: 8±6%; ISO: 16±4%; COMB: 9±4%) and
remained until two days for CON, PLA and ISO. IPT decreased ($p<0.01$) immediately after downhill running for all groups (CON: 32±4%; PLA: 32±7; SUP: 15±5%; ISO: 21±6%; COMB: 18±5%) and fully recovered two days after for SUP and COMB and three days after for ISO. IPT did not fully recover for CON and PLA during the study. Muscle soreness peaked two days after the DHR bout for all groups (CON: 122±28 mm; PLA: 116±44 m; SUP: 71±29 mm; ISO: 92±38 mm; COMB: 66±14 mm), and fully recovered 4 days after it for SUP and ISO. Muscle soreness was attenuated for SUP and COMB two days after DHR, when compared to CON and PLA.
CONCLUSION: The results confirm that consuming AJ attenuates the magnitude of changes and accelerates the recovery of RE and symptoms of MD following DHR while isometric pre-conditioning accelerates recovery of IPT and muscle soreness. However, the protective effect conferred by consuming the AJ was not enhanced when this strategy was combined with isometric pre-conditioning. Consumption of AJ alone attenuates changes in RE and symptoms of MD following DHR with no additional benefits when combined with isometric pre-conditioning.

SEVEN DAYS HIGH-FAT OVERFEEDING INDUCES FIBRE-SPECIFIC INCREASES IN INTRAMUSCULAR TRIGLYCERIDE CONTENT AND PERILIPIN PROTEIN EXPRESSION IN HUMAN SKELETAL MUSCLE.

WHYTOCK, K.L.1, PARRY, S.A.2, TURNER, M.2, JAMES, L.J.2, FERGUSON, R.A.2, HULSTON, C.J.2, STRAUSS, J.A.1, COCKS, M.1, WAGENMAKERS, A.J.M.1, SHEPHERD, S.O.1

1LIVERPOOL JOHN MOORES UNIVERSITY, 2LOUGHBOROUGH UNIVERSITY

INTRODUCTION: High-fat high-calorie diets can induce whole body insulin resistance (IR) whilst increasing stores of intramuscular triglyceride (IMTG) contained within lipid droplets (LD). Perilipin (PLIN) proteins assist in IMTG storage. Synaptosomal-associated protein (SNAP23) may support LD growth and also direct IMTG-derived fatty acids (FA) to mitochondria for β-oxidation. The aims of this study were: 1) to test the hypothesis that 7 days of high-fat overfeeding increases IMTG content to prevent lipid induced muscle IR and 2) identify changes in PLINs, SNAP23 and mitochondria content and colocalisation of PLINs with LD, and SNAP23 with LD and mitochondria.
METHODS: Muscle biopsies were obtained from the vastus lateralis of thirteen healthy individuals (age: 23±1years, BMI: 24.4±0.7kg.m-2) before (0min) and during (30min) an oral glucose tolerance test (OGTT), pre and post 7-days consuming a high-fat (65% energy) high-calorie (+50% kcal) diet. IMTG, PLIN2, PLIN3, PLIN5, SNAP23 and mitochondria content were measured using (semi)-quantitative confocal immunofluorescence microscopy. PLIN2, PLIN3 and PLIN5 colocalisation to LD was measured using object-based colocalisation analyses. Pearson's correlation coefficient quantified colocalisation between SNAP23 and plasma membrane (PM), mitochondria and LD. Phosphorylation of intermediates of the muscle insulin-signalling cascade (Akt and AS160) were measured at 0 and 30 min of the OGTT before and after the dietary intervention.
RESULTS: Following overfeeding phosphorylation of Akt and AS160 in muscle was not impaired during the OGTT, however Matsuda index of whole-body insulin sensitivity decreased (-23%;$P<0.01$). IMTG content increased in type I fibres (+100%;$P<0.001$) due to both an increase in LD number (+43%;$P<0.001$) and size (+44%;$P<0.001$). Of the PLINs investigated, only PLIN3 content increased (+50%;$P<0.01$) exclusively in type I fibres. PLIN2-associated LD increased (+80%;$P<0.01$) in type I fibres only, whereas PLIN3 and PLIN5-associated LD were unaltered. SNAP23 and mitochondria content did not change, nor did the colocalisation of SNAP23 with the PM, mitochondria or LD.
CONCLUSION: Our data confirm the hypothesis that following high-fat overfeeding IMTG stores increased whilst activation of key muscle insulin signalling components were maintained. The increase in IMTG stores is likely supported by the concurrent increase in total PLIN3 content and a redistribution of existing stores of PLIN2 to the expanded LD pool in type I fibres. To confirm if increased IMTG storage protects muscle from IR future research should determine whether meal-derived FAs are directed to IMTG rather than ceramides and diacylglycerol.

PERSONALISED NUTRITION: THE EFFECT OF AN AGXT2 POLYMORPHISM ON BETA-ALANINE PHARMACOKINETIC RESPONSE

STAUTEMAS, J., HAUTEKIET, A., LEFEVERE, F., BLANCQUAERT, L., EVERAERT, I., DERAVE, W.

GHENT UNIVERSITY

INTRODUCTION: Beta-alanine (BA) is a non-proteinogenic amino acid and the rate-limiting precursor of the dipeptide carnosine (β-alanyl-L-histidine). Chronic oral BA supplementation has ergogenic effects in high-intensity exercise, which results from increased skeletal muscle carnosine concentrations. Carnosine loading shows a large interindividual variability, which is poorly understood at present. Over 90% of the ingested BA is not stored as muscle carnosine and Blancquaert et al. (1) showed that a relevant part is metabolised through the amino transferases 4-aminobutyrate-2-oxoglutarate transaminase (GABA-T: EC 2.6.1.19) and alanine-glyoxylate transaminase (AGXT2: EC 2.6.1.44). Interestingly, about 21% of the population has a malfunctioning AGXT2, due to a polymorphism (rs37369 C/T). The purpose of this study was to elucidate if this polymorphism affects the pharmacokinetic profile of an acute oral BA ingestion and thereby helps to explain the variability in carnosine loading.
METHODS: We recruited 34 healthy subjects (19 males; 15 females), whereof 12 had the reference genotype (CC), 13 were heterozygous (CT) and 9 were homozygous for the rs37369 polymorphism (TT). CC, CT and TT were expected to possess high, intermediate and low AGXT2 activity, respectively. Subjects received a single relative dose of 10 mg.(kg body weight)-1 of BA. A subset (n = 28) also ingested an absolute dose of 1.4g on a separate test day. Blood and urine samples were collected before and at several time points (up to 4h) after BA ingestion and analysed for BA by HPLC. Results were analysed by one-way ANOVA with genotype as between factor, followed by post-hoc Scheffe test.
RESULTS: When receiving 1.4 g BA, urinary BA excretion was 2-fold higher ($p = 0.043$) in TT (50±19mg/4h) compared to CC (25±10mg/4h), but not different from CT (36±24mg/4h) ($p > 0.05$). In contrast, no differences between genotypes were observed for the relative dose ($p > 0.05$). Neither the fasted nor the supplementation-induced plasma BA concentrations and pharmacokinetic profile were different between genotypes following both supplementation protocols.
CONCLUSION: The current findings demonstrate that rs37369 TT-subjects do not present a more pronounced BA plasma profile following BA ingestion, which may indicate that BA degradation is redundantly regulated and GABA-T can compensate for low AGXT2 activity. Although urinary BA excretion was somewhat elevated in TT-subjects, it seems unlikely that the rs37369 polymorphism will affect muscle carnosine loading efficiency and thus represent a novel nutrigenetic predictor.

INFLUENCE OF A CHRONIC KETOGENIC HIGH FAT DIET ON IRON STATUS AND THE HEPCIDIN RESPONSE IN ELITE ATHLETES

MCKAY, A.1,2,3, PEELING, P.1,2, PYNE, D.3,4, WELVAERT, M.3,4, BURKE, L.3,5

1:UNIVERSITY OF WESTERN AUSTRALIA. 2:WESTERN AUSTRALIAN INSTITUTE OF SPORT. 3: AUSTRALIAN INSTITUTE OF SPORT. 4:UNIVERSITY OF CANBERRA. 5:AUSTRALIAN CATHOLIC UNIVERSITY.

INTRODUCTION: Short-term restriction of carbohydrate (CHO) can augment the post-exercise inflammatory and hepcidin response to exercise. Recently, low CHO/ high fat (LCHF) diets have gained popularity as a purported strategy to improve athletic performance. It is important to understand the impact of chronic CHO restriction on health outcomes in athletes. This study examined the influence of three different approaches to CHO consumption on iron status, inflammation and the hepcidin response.
METHODS: International-level race-walkers (n=50; 7 female, 43 male) were randomly allocated to one of three dietary interventions; i) a high CHO diet (HCHO; n=16), ii) periodised CHO availability (PCHO; n=17) and iii) a LCHF diet (n=17) while completing a periodised training program for 3 weeks. A 19-25 km race-walking protocol was completed at baseline and post-intervention to measure changes in serum ferritin, interleukin-6 (IL-6) and hepcidin concentration.
RESULTS: Resting serum ferritin decreased post-intervention (HCHO: 41%, PCHO: 40%, LCHF: 25%, ($p<0.001$)); with a trend towards a smaller reduction occurring in LCHF ($p=0.055$). The post-exercise increase in IL-6 (17.0±10.8-fold) was very likely higher ($p=0.084$) after 3 weeks of the LCHF diet compared to both HCHO (9.1±5.6-fold) and PCHO (8.4±8.3-fold) groups. Increases in hepcidin concentration occurred 3 h post-exercise, with a greater pre- to post-exercise increase at baseline compared with post-intervention ($p<0.001$). Here, both PCHO (12.4 v 5.9-fold increase) and HCHO (10.2 v 7.7-fold increase) had a moderate attenuation of the 3 h post-exercise hepcidin response post-intervention compared to baseline. In contrast, the 3 h post-exercise change in hepcidin after LCHF (9.0 v 9.4-fold increase) was unclear.
CONCLUSION: Three weeks of dietary manipulation and training modified selected aspects of the iron regulatory response to exercise. The smaller reductions to serum ferritin after the LCHF diet may relate to fluctuations in training quality and subsequently adaptation, likely influencing iron stores. Reductions to the 3 h post-exercise hepcidin response with both HCHO and PCHO diets post-intervention suggest a CHO rich diet may be beneficial for iron regulatory responses in athletes. Further work is required to clarify the implications of the likely deleterious effects of low CHO diets on health outcomes in elite level athletes.

OP-PM04 ROWING, KAYAKING & CANOEING

RESPONSE TO LONG- VS SHORT-INTERVAL TRAINING IN ROWING: EFFECTS OF AEROBIC CONTRIBUTION

BAUER, A.M., SIEGEL, R., HOPKINS, W.G., AUGHEY, R.J.

VICTORIA UNIVERSITY

INTRODUCTION: Despite high competition intensities, most training programs in rowing involve long, continuous exercise at low to moderate intensities, with interval training often prescribed below race pace. Athletes differ in the relative contributions from the aerobic and anaerobic systems for a given event, but it is unknown how these differences influence training response. The aim of this study was to compare the effect of short-interval training sessions performed near or above race pace with that of current interval training practices in rowing and to determine the modifying effect of differences in aerobic contribution.
METHODS: Competitive rowers (10 females, 14 males) were assigned to a long-interval or short-interval training group before the competition season. The rowers performed a familiarization and pre-intervention 6-min time trial on a Concept-II rowing ergometer. Assignment was balanced for sex and for aerobic contribution, mean power and peak lactate in the time trial. The training intervention consisted of three 4-wk blocks and followed a polarised training model, with two weekly interval-training sessions on the ergometer. The long-interval group performed interval sessions currently adopted in Australian rowing programs (8- to 20-min intervals at 98-103% of second aerobic threshold). The short-interval group performed 30-s to 3.5-min intervals at higher intensities (88% to 150% maximum aerobic power, i.e., generally at or above race pace). The remaining program was the same for both groups and involved five on-water rowing sessions, three strength-training sessions and 2-3 bike sessions per week. Changes in mean power in the time trial after 12 wk were analyzed with a spreadsheet and assessed for practical importance (smallest important change, 1.0%).
RESULTS: Performance improved by 3.7 ± 4.2 % and 2.7 ± 3.1 % in the long- and short-interval groups, respectively. After adjustment for a slight difference in aerobic contribution between the groups (83.0 ± 2.6 % and 82.8 ± 4.4 % respectively), short intervals had a clear, possibly harmful effect on TT performance (-0.9, ±2.5 %; mean, ±90% confidence limits) relative to long intervals. However, aerobic contribution had a substantial modifying effect, such that for rowers with a sufficiently low aerobic contribution (<77.5 %), there was a clear, likely beneficial effect of short vs long intervals using the less conservative approach to practical importance (odds ratio of benefit/harm >66).
CONCLUSION: The inclusion of short-interval training in rowing requires further investigation, but is not recommended in the preseason for most rowers. However, it is potentially beneficially for rowers with a relatively low aerobic contribution to endurance performance.

EXCEEDING THE COACH'S INTENDED TRAINING LOAD IS RELATED TO LESS IMPROVEMENT IN ROWING ENDURANCE PERFORMANCE

OTTER, R.T.A.1,2, VAN BLITTERSWIJK, M.2, BRINK, M.S.2

1: HANZE UNIVERSITY OF APPLIED SCIENCES GRONINGEN 2: UNIVERSITY OF GRONINGEN, UMCG

INTRODUCTION: At the start of the season, rowing coaches aim to improve the endurance performance of their rowers by prescribing a well-balanced training program. It is then assumed that the rowers follow the prescribed training. However, it is shown in many sports that there is a mismatch between the intended training load of the coach (iTL) and the actual training load of the athlete (aTL) (Brink et al., 2014). It has been suggested that a continuous mismatch between iTL and aTL could lead to under- or overtraining and consequently suboptimal performance. Therefore, the aim of this study was to investigate how training load mismatches between rowers and coaches relate to endurance performance.

METHODS: The training programs of 4 coaches and their 11 rowers who competed in national and/or international races were monitored for 6 weeks during preseason (6 male/5 female, age 22.5 ± 1.6 years, rowing experience 3.7 ± 1.8 years). The coaches prescribed an individual training program for each rower, presenting the content and type of each training session. In addition, the coaches filled out session Ratings of Intended Exertion and intended duration. The rowers kept a training log including sRPE and actual duration approximately 30 minutes after each session (Foster et al. 2001). The iTL and aTL were calculated by multiplying intensity by duration. iTL minus aTL represented the mismatch between coach and rower. Before and after the training program, all rowers performed a maximal incremental rowing ergometer test to determine endurance performance.
RESULTS: In total, the coaches prescribed 660 training sessions and the rowers performed 616 sessions of which 530 sessions matched in training content. These were used for further analyses. Reasons for a mismatch in training content were e.g. bad weather or injuries. The difference per training session between intended and actual intensity, duration and training load was 0.8 ± 1.1 AU, 1.9 ± 4.2 min and 97.6 ± 85.4 AU. Only one of the eleven rowers had a lower TL than intended (range –72 to 232 AU). VO2max before and after training was 59.7 ± 4.5 and 64.6 ± 4.7 ml/kg/min for male rowers and 52.5 ± 3.2 and 56.3 ± 6.1 ml/kg/min for female rowers. The rowers improved by 7.7 ± 4.6%. Pearson's correlations revealed a relationship between change in VO2max and the mismatch in duration (r= -.58; p= 0.03) and TL (r= -.62; p=0.02). No relation was found between sRPE mismatch and VO2max (r= -.21; p= 0.27).
CONCLUSION: These findings indicate that improvement in endurance performance of rowers is related to training more than intended. Therefore, it is important that rowers and coaches are aware of intended and actual training duration so that mismatches can be discussed and performance can be optimized.

HIGH VARIABILITY OF MECHANICAL POWER OUTPUT DURING INCREMENTAL ROWING ERGOMETER TESTS IN MALE ELITE ROWERS

TREFF, G.

UNIVERSITY HOSPITAL ULM

INTRODUCTION: On wind braked rowing ergometers, mechanical power output is not externally adjustable but determined by the rower's stroke frequency, -force and -distance. This leads to a currently unknown variation in mechanical power output that might influence physiological variables like [blood lactate]. To this end, we calculated the variation of mechanical power output of submaximal steps during incremental tests in elite rowers.
METHODS: Thirteen male elite rowers (body mass 93.5 ± 6.2 kg; height 191.2 ± 5.7 cm; Power at [blood lactate] 4 mmol/L 393± 6.2 W) performed a stepwise incremental test (200 W + 50W/4 min; 5 – 6 steps) on a rowing ergometer (Concept 2, Morrisville, USA). Steps were separated by a 30-s break. The ergometer was modified with a force sensor and a rotary transducer to allow for exact calculation of power (FES, Berlin, Germany). Power was measured stroke-by-stroke and saved in a log-file. Afterwards all data, excluding the last stroke, were log-transformed and the coefficient of variation (CV) was calculated for each step using a mixed model approach.
RESULTS: The average CV amounted to 4.0 ± 0.3 % (95%CI 3.4 – 4.6%). The CV significantly decreased from stage 1 to 2 ($p < .05$). Highest individual CV was 9.9% at stage 1, corresponding to 20.8 W at an average power of 210 W. CV significantly decreased ($p < .05$), when the first three strokes of each stage were excluded from the analysis, leading to an average CV of 2.9 ± 0.1% (95% CI 2.6 – 3.2 %).
CONCLUSION: Even in elite rowers, mechanical power output varies considerably during 4 min lasting constant load steps. The variation is highest in the lowest steps. Notably, the first three strokes affect the CV of each stage significantly, which is due to an over pacing at the start of each new target load. Taking into account the impact of the first strokes and the extremely high variation of particular athletes, these variations probably affect physiological variables. However, this has not been examined in this study.

ASSESSMENT OF ANAEROBIC LACTATE THRESHOLD IN FLAT-WATER KAYAKERS

PILOTTO, A., RASICA, L., SCALISE, G., PEDRALI, M., LA TORRE, A., MARZORATI, M., PORCELLI, S.

UNIVERSITY OF MILAN

INTRODUCTION: Anaerobic threshold is a physiological parameter widely used to monitor performance and training-induced changes in different sports. Currently, the assessment of anaerobic threshold in kayakers is performed in laboratory by means of specific kayak ergometers. However, laboratory-based tests differ from on-water evaluation due to several factors and, therefore, new methods to assess kayakers' physiological adaptations to exercise are needed. The aim of this study was to propose a new on-water incremental test for the assessment of anaerobic lactate threshold (LT) in flat-water kayakers. Reliability and validity were determined and maximal lactate steady-state test was used as a criterion measurement.
METHODS: Eleven junior (16±2 years) élite flat-water kayakers participated in the study. Each subject performed: i) an incremental cardiopulmonary test (CPT) up to voluntary exhaustion on a stationary kayak ergometer (KP Compact, Kayakpro) to determine peak oxygen uptake (V'O2peak); ii) a 1000m distance trial (T1000) to record best performance time and mean speed; iii) two repetitions of on-water incremental kayaking test (WIK-test), consisting of seven 4 minutes bouts at progressively increasing speeds (determined as percentage of T1000), interspersed with a 1-minute recovery; iv) 4-5 repetitions of on-water constant speed tests (duration: 20 minutes) at different intensities in order to determine maximal lactate steady-state (MLSS). Heart rate (HR) was assessed by chest band (M400, Polar). Global positioning system device (Optimeye B5, Catapult) monitored speed at a sampling rate of 10 Hz. Blood lactate samples were collected during each recovery phase and at discrete intervals at the end of the tests.
RESULTS: During CPT, V'O2peak was 3.361±0.48 L*min-1 (range 38.8-56.2 ml*min-1*kg-1) and peak HR was 193±8 b*min-1 (98% of predicted maximal HR). The best performance time in T1000 was 262±13 seconds, corresponding to a mean speed of 3.82±0.19 m*s-1. In WIK-test, LT was 2.74±1.07 mM. This value corresponded to an HR of 163±9 b*min-1 and a speed of 3.35±0.16 m*s-1. A significant correlation ($R2=0.94$, $p<0.001$) was observed between best performance time in T1000 and speed at LT resulting from WIK-test. Test-retest reliability, calculated on speed at LT, was "excellent" (ICC 0.86-0.98) with a typical error, expressed as CV, of 1.2%. MLSS corresponded to 2.98±0.71 mM. This value corresponded to an HR of 168±9 b*min-1 and a speed of 3.36±0.14 m*s-1. A significant correlation for speed at LT ($R2=0.76$, $p<0.001$) was observed between WIK-test and MLSS test.
CONCLUSION: WIK-test showed good reliability and accuracy for the assessment of anaerobic lactate threshold in flat-water kayakers. Interestingly, the speed value corresponding to anaerobic threshold determined by WIK-test nicely predicted performance on 1000m distance trial. WIK-test could be a useful field-based test to monitor athletic performance over time.

MUSCLE OXYGENATION RESPONSE TO HIGH-INTENSITY INTERVAL TRAINING IN SPRINT CANOE-KAYAK

PAQUETTE, M., BIEUZEN, F., BILLAUT, F.

UNIVERSITÉ LAVAL

INTRODUCTION: Recent data suggests that peripheral adaptations, i.e. the muscle ability to extract and use oxygen, may be a stronger predictor of canoe-kayak sprint performance compared to VO2max or central adaptations. If maximizing the time near VO2max during high-intensity interval training (HIIT) sessions is believed to optimize central adaptations, maximizing the time near maximal levels of muscle desaturation could represent a critical stimulus to optimize peripheral adaptations. Therefore, the purpose of this study was to assess the VO2, muscle oxygenation and cardiac output responses to various HIIT sessions, and to determine which type of HIIT elicits the lowest muscle O2 levels and the longest cumulated time at low muscle O2 saturation.
METHODS: Thirteen well-trained canoe-kayak athletes performed an incremental test to determine VO2max and maximal aerobic power (MAP), and 4 HIIT sessions (A:40x[15sec at 105%MAP, 15sec at 30%MAP]; B:20x[30sec at 105%MAP, 30sec at 30%MAP]; C:6x[30sec all-out, 3min30 rest]; D:6x[1min at 125%MAP, 3min rest]) on a Kayakpro canoe or kayak ergometer. A portable near-infrared spectroscopy (NIRS) monitor (Moxy) was placed on the latissimus dorsi (LD), biceps brachii (BB), and vastus lateralis (VL) during every session to assess changes in muscle O2 saturation (SmO2, % of baseline), and cardiac output (Q) was evaluated using thoracic electrical bioimpedance (Physioflow). A one-way repeated measures analysis of variance with Bonferroni post hoc tests was used to compare physiological response between sessions.
RESULTS: Sessions A and B elicited a longer time at >90%VO2max (A:8.1±6.2min, B:6.8±4.6min), compared to session C (1.7±1.3min, p=0.006 and p=0.035) but not session D (4.1±1.7min). Time at >90%Qmax was greater in session A (5.6±4.4min) compared to sessions C (1.5±1.6min, p=0.023) and D (2.0±1.9min, p=0.048), and not different from session B (4.0±2.9min). Sessions C and D elicited the lowest SmO2 (C:16±6% , D:22±7%) compared to sessions A (31±8%, p<0.001 and p=0.007) and B (30±7%, p<0.001 and p=0.030), and session C produced the longest time at >90% of maximal deoxygenation (0.88±0.50min), compared to sessions A (0.17±0.19min, p<0.001), B (0.33±0.26min, p<0.001) and D (0.41±0.29min, p=0.004).
CONCLUSION: HIIT sessions eliciting the longest time near VO2max and Qmax do not elicit a sustained decrease in muscle O2 saturation. Higher effort intensities appear to be required to maximize muscle deoxygenation during a training session, potentially conducive to greater peripheral adaptations.

ISOKINETIC TESTING AND TRAINING OF TRUNK ROTATORS IN ELITE CANOEISTS

ZINKE, F.1, SONNEMANN, P.1, WARNKE, T.2, ENGLERT, M.2, GRANACHER, U.1

1: UNIVERSITY OF POTSDAM; 2: IAT LEIPZIG

INTRODUCTION: In canoe sprint, the trunk muscles play an important role in stabilizing the body in an unstable environment (boat) and in generating forces that are transmitted through shoulders and arms to the paddle for propulsion of the boat. Isokinetic training is well-suited for sports in which propulsion is generated through water resistance due to similarities in the resistive mode. Thus, the purpose of this study was i) to test the effectiveness of isokinetic training that was added to the regular training regime on maximal trunk rotator torque in elite canoeists and ii) to compute associations between isokinetic torque and canoe specific performance.
METHODS: Nine elite canoeists (7 kayak/2 canoe) who compete on an international/Olympic level participated in this study. Athletes conducted 6 weeks of progressive hypertrophy training (3-5 sets; 8-12 repetitions, 30-60°s-1) and another 2 weeks of power training (7 sets, 15-19 repetitions, 100-140°s-1) during the pre-season. Absolute isokinetic training load (external load [work] x internal load [rate of perceived exertion]) was recorded for every training-session and each participant. Pre- and post-tests included the assessment of maximal isokinetic torque at different velocities in concentric (30&140°s-1) and eccentric (30&90°s-1) mode. Trunk muscle endurance was tested using a plank test (Bourbon test). Additionally, 7 of the included athletes performed a canoe-specific performance test in the flume (1 km at 3.4 m/s). Maximal paddle forces were assessed using a strain gauge which was individually adjusted and connected to each athletes' paddle. After normal data distribution was tested, paired t-tests were conducted to analyze pre-to-post changes. Pearson correlation coefficients were calculated between trunk rotator torque and canoe specific performance.
RESULTS: Significant pre-to-post increases were found for maximal (concentric) torque of the trunk rotators at 30°s-1 (left side pre: 215±65; post: 245±59 Nm; p=.004; d=0.7; right side pre: 216±66; post: 232±55 Nm; p=.047; d=0.4) and 140°s-1 (left side pre: 196±42 and post: 219±48Nm; p=.014; d=0.7). No significant pre-to-post changes were found for eccentric trunk rotator torque (p>.164) and for the plank test (p=.177). Significant moderate-to-high correlations were detected for concentric trunk rotator torque and maximum paddle force, irrespective of the isokinetic movement velocity (30°s-1: r=.920; p=.003 and 140°s-1: r=.886; p=.008). Non-parametric testing (Spearman) resulted in similar outcomes.
CONCLUSION: Our findings indicate that isokinetic trunk rotator torque is associated with canoe-specific performance and that isokinetic training appears to be effective in improving trunk rotator torque at different movement velocities. Future research should examine the long-term effects of isokinetic training on canoe-specific performance.

OP-BN01 FATIGUE

REWARD IMPROVES MOTOR PERFORMANCE BY MODULATING MOTOR NETWORK ACTIVITY

LEHNER, R., BÄCHINGER, M., HANIMANN, S., GHIDONI, C., BALSTERS, J.H., WENDEROTH, N.

ETH ZURICH, NEURAL CONTROL OF MOVEMENT LAB

INTRODUCTION: Reward can motivate individuals to increase physical effort and thus, invigorate movements. Here we ask whether reward can modulate motor fatigability, tested with a repetitive finger tapping task at maximal speed, and investigate its neurobiological underpinnings by combining behavioural measurements with functional magnetic resonance imaging (fMRI) or electroencephalography (EEG). We report the findings of two experiments where we investigated whether monetary reward attenuates fatigability and which neurophysiological mechanisms might mediate this phenomenon.

METHODS: In both experiments participants performed maximal finger tapping followed by short breaks (40s). In a factorial design, they executed either fatiguing trials (40s) or non-fatiguing trials (10s) while they could either earn a reward or not. We tested twenty-eight volunteers (mean age=26±s.d. 6 years, 64% female, all right-handed) in a fMRI experiment and thirty-four healthy participants (mean age=27±s.d. 7 years, 77% female, all right-handed) in an EEG experiment.
RESULTS: In both experiments participants exhibited significant motor slowing (mixed-effects model, $p<0.001$) compared to non-fatiguing tapping. Importantly, motor fatigability caused by long tapping was significantly attenuated by reward (time*condition $p<0.001$, approx. 23% faster).
Using fMRI, we found that fatiguing tapping caused a significant increase of the blood oxygenation level (BOLD) response in bilateral primary sensory and motor cortices (SM1), secondary sensory areas (S2) and supplementary motor areas (SMA) (whole brain analysis, $pFEW<0.05$). Interestingly, this activity was further increased in rewarded trials and reached statistical significance in bilateral SMA, contralateral SM1 and S2, striatum, thalamus and ipsilateral cerebellum (region of interest analysis, sphere 8 mm, mixed-effects model, time*condition $p<0.025$).
In our EEG experiment we focussed on the recovery period and found that alpha-band power was strongly reduced immediately after tapping but recovered during the break (mixed-effects model, $p<0.001$) for the electrode overlying contralateral SM1. This recovery of the alpha-rhythm was largest for non-fatiguing tapping, at a medium level for fatiguing un-rewarded tapping, and at the lowest for fatiguing rewarded tapping.
CONCLUSION: Our results suggest that reward attenuates fatigability by disinhibiting motor areas and, thus, increasing the neural drive. This is consistent with recent theories proposing that reward has a motivational effect and increases response vigour likely signalled by dopamine. Our findings may prove to be of practical relevance in rehabilitation and sports, where extrinsic rewards could be used to improve motor performance and attenuate fatigue.

NEUROMUSCULAR AND MUSCLE METABOLIC RESPONSES TO EXERCISE FOLLOWING CONTRALATERAL LIMB FATIGUE

MORGAN, P.T., BANKS, R.A., FULFORD, J., VANHATALO, A., BAILEY, S.J., JONES, A.M.

UNIVERSITY OF EXETER

INTRODUCTION: Contralateral fatigue is characterised by impaired performance in a remote non-exercised muscle group following a fatiguing task completed by a contralateral muscle group (Halperin et al. 2015, for review). Although contralateral fatigue has been demonstrated in numerous muscle groups and during different exercise tasks, the mechanistic bases of this effect have yet to be resolved. The purpose of this study was to explore the neuromuscular and muscle metabolic bases of contralateral fatigue during knee extension exercise.
METHODS: Fourteen recreationally active men performed constant-load, single-leg knee extensor exercise to exhaustion (Tlim) at ~95% peak work rate with each leg (Leg1; left and Leg2; right) in an unfatigued condition on two separate laboratory. Subjects also completed knee-extensor exercise to exhaustion (Leg1) followed immediately (within 3 s) by knee-extensor exercise to exhaustion in the contralateral limb (Leg2post). These conditions were administered in a randomised, cross-over, counter-balanced experimental design. During these tests, quadriceps muscle metabolic changes were assessed using 31Phosphorous-magnetic resonance spectroscopy and quadriceps muscle activation was assessed using electromyography (EMG). In all tests, a rating of perceived exertion (RPE) was measured at 2 min intervals from the onset of exercise using the 6-20 Borg scale.
RESULTS: When commenced from rest, Tlim was similar in Leg1 and Leg2 (6.6 ± 1.5 vs. 6.4 ± 1.7 min; $P>0.05$). However, when the identical exercise task was performed with pre-induced quadriceps fatigue in the contralateral leg, Tlim was 19% shorter in the Leg2post condition compared to its single leg control, Leg2 (6.4 ± 1.7 vs. 5.2 ± 1.5 min; $P<0.05$). There were no inter-condition differences in muscle [PCr], [Pi], [ADP] or pH at Tlim ($P>0.05$). However, baseline muscle [PCr] was lower and [Pi] and [ADP] were higher for Leg2post compared to Leg2 ($P<0.05$). The rate of increase in EMG and EMG at Tlim were not different ($P>0.05$), but RPE was 8% higher during Leg2post compared to Leg2 ($P<0.05$).
CONCLUSION: Prior fatigue of the knee-extensor muscles of one limb led to a subsequent reduction in exercise tolerance in the knee-extensor of the contralateral limb. The ergolytic effect of pre-fatiguing the contralateral limb muscles was accompanied by similar levels of muscle activation and muscle metabolic perturbation at Tlim. However, despite an ostensible lack of muscular work, baseline muscle [PCr] was lower, and [ADP] and [Pi] were elevated at the start of the fatiguing knee-extensor exercise in the contralateral limb. These findings suggest that fatigue development is expedited in an unfatigued limb after prior fatigue in the contralateral limb, as baseline muscle metabolic perturbation is augmented and the critical permissible level of intramuscular metabolic disturbance is attained more rapidly.

THE EFFECT OF REPEATED SPRINTS ON HAMSTRING MUSCLE DAMAGE AND RUNNING KINEMATICS: AN INTERDISCIPLINARY STUDY

BAUMERT, P., TEMPLE, S., STEWART, C.E., DRUST, B., LAKE, M.J., ERSKINE, R.M.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Team sports, such as soccer, are characterised by intermittent repeated sprints that involve potentially damaging eccentric contractions of the hamstrings. Congested fixtures may not allow athletes to fully recover between matches, and insufficient recovery can increase injury risk (1). A short fascicle length (Lf) of the biceps femoris long head (BFLH) has been suggested to increase hamstring strain injury risk, and may lead to greater exercise-induced muscle damage (EIMD), which is often characterised via prolonged strength loss and delayed-onset muscle soreness (DOMS). Using an interdisciplinary approach, we aimed to investigate the physiological and biomechanical factors associated with neuromuscular fatigue and EIMD following repeated sprints. We hypothesised that (i) repeated sprints would induce EIMD in the hamstrings and, consequently, reduce hip flexion and knee extension during the late swing phase of treadmill running (RUN) to decrease the elongation stress on the hamstring muscles; and, (ii) short BFLH Lf would be associated with greater hamstring EIMD.
METHODS: Following BFLH Lf assessment via ultrasound, 20 recreationally active young men (age 20.5 ± 3.0 yrs, mass 74.5 ± 6.4 kg) completed 15 x 30 m sprints. Hamstring maximal voluntary contractions (MVC; via isokinetic dynamometer); involuntary contractions [voluntary muscle activation (VA) via electrical stimulation]; lower limb muscle DOMS (visual analogue scale); and RUN (15 km/h) kinematics of the right leg (8-camera motion capture system), were assessed before (PRE), immediately after (POST) and 48h-POST EIMD.
RESULTS: Hamstring MVC decreased over time (PRE: 142±23 Nm; POST: 124±25 Nm; 48h-POST: 113±31 Nm), while DOMS increased (both $p \leq 0.001$). However, there was no association with BFLH Lf or change in VA (the latter indicating no central fatigue). RUN demonstrated decreases POST EIMD in both peak knee extension (PRE: 7.82±5.98°; POST: 12.03±5.83°; 48h-POST: 6.93±8.89°; 0°=full extension;

p=0.039) during the late swing phase, and peak hip internal rotation (p=0.047) during the stance phase, while all values returned to baseline 48h-POST EIMD.
CONCLUSION: We have demonstrated for the first time that repeated sprints alter hip and knee kinematics. Reduced knee extension while contracting eccentrically in the late swing phase and peak hip internal rotation during stance phase of running might decrease the elongation stress on the hamstring muscles, suggesting a protective mechanism for these muscles POST EIMD. However, kinematic changes were not evident 48h-POST EIMD, although hamstring MVC showed further strength loss 48h-POST EIMD. As BFLH Lf was not associated with hamstring EIMD, future studies should investigate the architecture of other hamstring muscles in contributing towards sprinting-induced EIMD. We conclude that a 48h recovery period following sports incorporating repeated sprints is insufficient, and might increase injury risk.

ALTERATIONS IN NEUROMUSCULAR FUNCTION AND FATIGABILITY OF THE KNEE-EXTENSORS ACROSS THE MENSTRUAL CYCLE

ANSDELL, P., BROWNSTEIN, C., ŠKARABOT, J., HICKS, K., SIMOES, D., THOMAS, K., HOWATSON, G., HUNTER, S.K., GOODALL, S.

NORTHUMBRIA UNIVERSITY; MARQUETTE UNIVERSITY

INTRODUCTION: The female menstrual cycle presents cyclical changes in multiple hormones. The interaction of these hormones with neural tissue is known to have excitatory or inhibitory effects , and may also induce changes in skeletal muscle properties . This study aimed to determine the effect of menstrual cycle phase on neuromuscular function and fatigability of the knee-extensors using transcranial magnetic stimulation and electrical nerve stimulation, before and after a fatiguing task.
METHODS: Thirteen eumenorrheic females were tested on day 2 , 14 and 21 of the menstrual cycle. Testing session order was randomised and counterbalanced, and serum 17-ß estradiol and progesterone concentrations were used to confirm menstrual cycle phase. Neuromuscular function was assessed pre- and post- an intermittent, isometric fatiguing task during each session.
RESULTS: All participants presented regular hormonal profiles throughout the testing period. There was no difference in maximum voluntary contraction between MCPs . However, voluntary activation assessed with motor nerve stimulation was greatest during ovulation ; VATMS showed a similar, but nonsignificant trend . Short interval cortical inhibition was modulated by MCP , but cortical silent period was not . Despite a longer time to task failure during the luteal phase , no MCP × fatigue interaction was observed for MVC, twitch, or VA variables, indicating that the magnitude of post-exercise neuromuscular fatigue was consistent across MCP.
CONCLUSION: This study observed that changes in hormone concentrations across the menstrual cycle elicit alterations in neuromuscular function at baseline and the performance of an isometric task. Changes were observed at a supraspinal level, with SICI reflecting alterations in intracortical neuron excitability. VA was greatest during the period of lowest cortical inhibition, however, the causal link between these two variables is unknown. The ~40% increase in time to task failure observed in the luteal phase could be due to a positive effect of progesterone. These findings demonstrate the magnitude of effect that the menstrual cycle can have on neuromuscular function and fatigability.

MOTOR FATIGABILITY IS ASSOCIATED WITH DIS-INHIBITION OF PRIMARY MOTOR CORTEX ACCOMPANIED BY CHANGES IN MESIAL VS. LATERAL PREMOTOR-MOTOR INTERACTIONS

BÄCHINGER, M., LEHNER, R., THOMAS, F., HANIMANN, S., RYF, C., FRÄSSLE, S., BALSTERS, J., WENDEROTH, N.

ETH ZURICH

INTRODUCTION: Motor fatigability describes a performance decrease when tasks are executed for an extended time period. However, the supraspinal mechanisms mediating motor fatigability during submaximal repetitive movements are currently not well understood. Here we tested performance fatigability by instructing participants to do repetitive finger tapping at maximal speed for 30s. This task is characterized by significant reductions in movement frequency or "motor slowing".
METHODS: During a series of three experiments, healthy participants performed either slowing (30s) or non-slowing finger tapping (10s), while we measured functional magnetic resonance imaging (fMRI), applied transcranial magnetic stimulation (TMS) or analyzed electromyography activity (EMG). Supraspinal contributions of motor slowing were assessed by measuring fMRI during blocks of slowing versus non-slowing tapping to identify brain areas involved in motor slowing. Further, we performed dynamic causal modelling (DCM) to identify changes in connection strength across those brain areas. Finally, we used TMS to measure inhibitory activity of M1 circuits in the form of short latency intracortical inhibition (SICI), while participants recovered from slowing versus non-slowing tapping. Additionally, we measured the amount of co-contraction (joint area under the curve) during motor tapping to assess the interplay between antagonistic hand muscles. All experiments were analysed using mixed effects models including the factors tapping (slowing vs. non-slowing) and time (1st, 2nd or 3rd 10s bin).
RESULTS: Participants exhibited significant motor slowing in each experiment ($p<0.05$). Using fMRI, we found an increase in brain activity in primary motor cortex (M1), supplementary motor area (SMA) and cerebellum (Cb) during motor slowing (N=25, time main effect $pFWE<0.05$). The DCM analysis further revealed that the increase in brain activity resulted from a gradual decrease in self-inhibition of M1, accompanied by a decrease in connection strength from SMA to M1, Cb and putamen.
The decrease in self-inhibition of M1 was confirmed by the SICI measures, which showed that motor slowing is accompanied by significant dis-inhibition of M1 (N=13, tapping x time interaction, $p<0.05$). Thus, convergent evidence from fMRI and SICI data indicates that motor fatigability caused by prolonged tapping is associated with dis-inhibiting motor cortex. One explanation for this counterintuitive finding is that slowing results from increased co-activation of antagonistic hand muscles, potentially due to impaired inhibitory control. Indeed, in the final EMG experiment we found that co-contraction significantly increased during motor tapping (N=10, tapping x time interaction, $p<0.05$).
CONCLUSION: Taken together our results suggest that the performance fatigue observed during prolonged repetitive tapping is a supraspinal phenomenon associated with a break-down of the interplay between excitatory and inhibitory motor circuits.

CORTICOSPINAL AND NEUROMUSCULAR CHANGES FOLLOWING UPHILL VERSUS DOWNHILL EXERCISE

GARNIER, Y.M., PAIZIS, C., LEPERS, R.

INSERM UMR 1093-CAPS - UNIVERSITÉ BOURGOGNE FRANCHE-COMTÉ

INTRODUCTION: It has been evidenced that prolonged hilly running (i.e., running with uphill and downhill sections) induced central and peripheral neuromuscular fatigue and increased corticospinal excitability in the knee extensor (KE) muscles. However, little is known regarding to corticospinal changes and neuromuscular fatigue following purely uphill versus downhill exercise. This study aimed to examine corticospinal changes and neuromuscular fatigue of the KE muscles after uphill versus downhill exercise performed at the same heart rate and duration

METHODS: Eleven healthy moderately active volunteers (age: 26 ± 7 years) performed four different sessions. Maximal heart rate and oxygen consumption (VO2max) were assessed during the first visit. Then, subjects performed three 45-min locomotor treadmill exercises on separate days either in a level, uphill (+15%) or downhill (-15%) condition at an intensity corresponding to 75% of their heart rate reserve. Before and immediately after exercise, KE muscles' maximal voluntary contraction (MVC), voluntary activation level (VAL), M-wave amplitude and low to high frequency paired pulse ratio (Dt 10Hz/Dt 100Hz) were assessed using percutaneous femoral nerve stimulation. Changes in the amplitude of the motor evoked potential (MEP) and the duration of the cortical silent period (CSP) were also assessed on the vastus medialis, vastus lateralis and rectus femoris muscles using transcranial magnetic stimulation.

RESULTS: For a similar heart rate (157 ± 3 bpm), VO2 was lower during downhill (48 ± 8 %VO2max) compared to both level and uphill conditions (65 ± 6 % VO2max; p (0.001). Downhill exercise induced a greater loss of MVC torque (-24 ± 10%) compared to level (-12 ± 8%; p (0.001) or uphill exercises (-11 ± 8%; p (0.001). Conversely, VAL was decrease after all exercises (-8 ± 7%; p (0.001) without significant difference between conditions. M-wave amplitude decreased by 5 ± 14% (p = 0.01) after all conditions for the rectus femoris muscle only. The Dt 10Hz/Dt 100Hz ratio was reduced to a greater extent after downhill (-33 ± 11%; p (0.001) compared to uphill condition (-8± 7%; p = 0.02), but remained unchanged after level condition (-3± 10%; p = 0.42). MEP amplitude of vastus medialis and vastus lateralis muscles were increased after downhill condition only (+68 ± 56%; p (0.006), while CSP duration was shortened after downhill for the three muscles (-35 ± 21%; p (0.003).

CONCLUSION: The greater loss of maximal force capacity of the KE muscles observed after the downhill exercise compared to level and uphill conditions resulted from a greater impairment of the excitation-contraction coupling process. The increase of the corticospinal excitability and the decrease of the intracortical inhibition in the KE muscles observed after the downhill exercise only could be explained by the predominant eccentric mode of contraction of these muscles during downhill locomotion.

OP-MI01 PSYCHOLOGY - COGNITIVE FUNCTION

TRANSFORMATIONAL LEADERSHIP MODERATES THE RELATIONSHIP BETWEEN ATHLETE PERSONALITY AND TRAINING BEHAVIORS

ZHANG, S., BEATTIE, S.

BANGOR UNIVERSITY

Introduction: The ultimate goal of any athlete is to strive for peak performance in competitive environments. It is not only the quantity of training but also the quality of training that allows athletes to prepare for peak performance states. Therefore, the attainment of peak performance at the competitive end may fail without desirable training behaviours. However, recent research has highlighted that athlete's personalities such as extroversion and neuroticism can be debilitative to effective training. The aim of the current research was to examine if certain transformational leadership delivered by the coach would moderate the potential negative impacts of athlete's extraversion and neuroticism upon training behaviours.

Methods: We conducted two studies that covered samples from both university and professional sport teams. In study 1, ninety-nine athletes from five University teams completed a set of questionnaires assessing their own personality and training behaviours, and their coach's transformational leadership. In study 2, eighty-four high level athletes from six professional sport teams completed the same personality and transformational leadership questionnaires from study 1. However, in study 2, we asked the head coach of each participating team to assess athletes' training behaviours.

Results: Moderated hierarchical regression analysis in both studies found that: 1> the association between extraversion and distractibility was moderated when the coach provided high performance expectations; and 2> the impairing effect of neuroticism on coping with adversity was moderated when the coach provided inspirational motivation.

Discussion: Our findings highlight that individual differences in personality can contribute to poor training behaviours, but that this negative influence can be buffered if coach demonstrates certain transformational leadership.

CHALLENGE AND THREAT STATES IN COMPETITIVE TRAMPOLINING

HASE, A.1, KORTE, I.2, DOKTER, M.3, SCHIPHOF-GODART, L.2, FREEMAN, P.1

1: UOE , 2: RUG , 3: VUA

INTRODUCTION: Performance under pressure is key to success in competitive sport. The biopsychosocial model of challenge and threat (Blascovich, 2008) specifies that in a highly pressurised competition, individuals who exhibit a challenge state outperform those who exhibit a threat state. Though research has supported the superiority of a challenge over a threat state in predicting season baseball and softball performance statistics (cardiovascular challenge and threat measure; Blascovich et al., 2004) and same-day single golf competition performance (cognitive measure; Moore et al., 2013), no study has used a prospective design to examine the association between challenge and threat states and performance at an important competition. The purpose of this study was thus to examine whether cardiovascular and cognitive measures of challenge and threat states at the beginning of the season predict performance at a specific and highly pressurised upcoming competition.

METHODS: The sample comprised 41 trampoline athletes (17 males, Mean age = 16.0 years, SD = 4.2) competing at national and international level. At the beginning of the season, athletes reported their most important competition of the upcoming season, imagined performing at this competition while cardiovascular data were recorded, and provided cognitive demand-resource evaluations for this

competition. A difference score of demand-resource evaluations and a sum score of changes in cardiac output and total peripheral resistance were used as cognitive and cardiovascular indicators of challenge and threat states, respectively. Official performance scores were obtained for the respective competition named by each athlete.
RESULTS: In hierarchical linear regression analyses, a cardiovascular challenge state was associated with better performance at the most important competition than a cardiovascular threat state ($\beta = 0.55$, $p = .02$, $sr^2 = .27$). Cognitive challenge and threat evaluations were not associated with performance. These results persisted when controlling for task engagement, age, and sex.
CONCLUSION: The results indicate that cardiovascular challenge and threat states at the beginning of the season predicted performance in a single highly pressurised competition. The findings encourage the adoption of diagnostic methods before important competitions to identify threat states, provide early support for threatened athletes, and thereby optimise performance.

12 WEEKS OF INTENSIVE RESISTANCE TRAINING MAY IMPROVE COGNITIVE PERFORMANCE IN OLDER ADULTS

MARSTON, K.J.1, BROWN, B.M.1, RAINEY-SMITH, S.R.2, GORDON, N.1, TEO, S.Y.1, SOHRABI, H.R.2, MARTINS, R.N.2, PEIFFER, J.J.1

1: MURDOCH UNIVERSITY , 2: EDITH COWAN UNIVERSITY

INTRODUCTION: Mechanisms responsible for age-related cognitive decline and late-life Alzheimer's disease (AD) likely start decades prior to measurable symptoms. Resistance exercise (Liu-Ambrose, 2008) has been shown to slow age-related cognitive decline in what is likely an intensity-dependent manner and represents a possible preventative strategy for late life AD. Indeed, decreased homocysteine levels, an amino acid that promotes oxidative stress and neural tissue damage have been observed following 6 months of intensive resistance training (Tsai, 2015); however, more research is needed which simultaneously examines physiological and cognitive outcomes. This study examined the influence of 12 weeks (2 sessions per week) of intensive resistance training in older adults on homocysteine levels and cognitive performance.
METHODS: 45 participants (male: n=9, age=58.8 ± 6.0yr; female n=36, age=57.2 ± 6.9yr) were recruited and randomised into a non-exercising control group (CON), or one of two volume matched intensive resistance training programs: a) high load (HL; 5 sets, 5 repetitions at 85% of 1 repetition maximum [RM]), or b) high repetitions (HR; 3 sets, 10 repetitions at 70% of 1RM). Fasting blood samples were taken at baseline and immediately post-intervention and analysed for serum homocysteine. At baseline and during the final week of the intervention, participants completed the International Shopping List Task (ISL) to assess cognition. Pre/Post changes in homocysteine and ISL were analysed between groups a one-way ANOVA and Hedge's g effect sizes with 95% confidence intervals (CI) were calculated.
RESULTS: There was no significant change in homocysteine between groups (p=0.097). Effect sizes for homocysteine change were small between HR/CON (g=0.442, 95% CI:−0.012-0.896) and HL/HR (g=0.386, 95% CI:−0.095-0.867) groups, and large between HL/CON groups (g=0.802, 95% CI:0.313-1.291). Although not significantly different between groups (p=0.107), moderate to large effect sizes were observed in changes in the number of correct answers during ISL recall between HL/CON (g=0.674, 95% CI:0.065-1.283) and HR/CON (g=0.799, 95% CI:0.237-1.361).
CONCLUSION: This study indicates that 24 sessions (12 weeks, 2 sessions per week) of intensive resistance training is likely to influence cognitive function and physiological mechanisms associated with cognitive decline. Although more research is needed to confirm our findings, practitioners should consider intense resistance training within an ageing population to maintain cognitive health.

INVESTIGATING THE PSYCHOSOCIAL AND HEALTH-RELATED CORRELATES OF SEDENTARY BEHAVIOUR AMONG PEOPLE LIVING WITH RHEUMATOID ARTHRITIS: A CROSS-SECTIONAL STUDY

OBRIEN, C., DUDA, J., KITAS, G., VELDHUIJZEN VAN ZANTEN, J., METSIOS, G., FENTON, S.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Rheumatoid Arthritis (RA) is a systemic inflammatory autoimmune disease. Common debilitating symptoms of RA include fatigue and pain. People with RA typically spend large proportions of the day engaged in sedentary behaviour (SB), which is proposed to exacerbate inflammatory disease activity and contribute to the progression of RA outcomes. Interventions to reduce SB may therefore improve health in these patients. However, prior to developing such interventions, studies must establish: 1) the role of SB for RA outcomes and 2) modifiable determinants of SB that can be targeted in interventions.
Aim: To investigate the cross-sectional associations of objectively assessed SB patterns with: 1) RA disease activity, fatigue and pain (RA outcomes), and 2) self-determined motivation for reducing SB (determinants of SB).
METHODS: People with RA (n=64) completed the Multidimensional Assessment of Fatigue Scale and McGill Pain Questionnaire, assessing global fatigue and pain respectively. RA disease activity was determined via a blood sample and 28 swollen-and-tender joint count (Disease-Activity Score-28 [DAS-28]). The Behavioural Regulation in Exercise Questionnaire-2 (adapted for 'reducing SB') assessed autonomous and controlled motivation to reduce SB. Participants wore an activPAL for 7 days to measure their SB patterns (sitting/lying, standing and stepping [hours/day]).
RESULTS: RA outcomes: Regression analysis (beta coefficient = B) demonstrated hours/day sitting/lying significantly positively predicted DAS-28 (B=.37, p<.01), global fatigue (B=.36, p<.01) and affective pain (B=.30, p<.05). Standing was significantly negatively related to DAS-28 (B=-.31, p<.05). Stepping was significantly negatively related to all outcomes (DAS-28, B=-.38, p<.01; global fatigue, B=-.46, p<.01; sensory pain, B=-.40, p<.01; affective pain, B=-.35, p<.01).
Determinants of SB: No significant associations between autonomous motivation for reducing SB and SB patterns were identified. However, intrinsic motivation (the quintessential form of autonomous motivation) for reducing SB was significantly negatively related to sitting/lying (B=-.26, p<.05) and significantly positively linked to stepping (B=.27, p<.05). Controlled motivation for reducing SB significantly positively predicted sitting/lying (B=.27, p<.05) and significantly negatively predicted stepping (B=-.36, p<.01).
Continued data collection (n=100) will enable the sequential associations between self-determined motivation to reduce SB, objectively assessed SB patterns and RA outcomes to be examined at the multivariate level (i.e., via path analysis).

CONCLUSION: SB patterns are associated with pertinent RA outcomes. Additionally, quality of motivation to reduce SB is linked to SB patterns in this patient group. Thus, Self-Determination Theory may serve as a basis for SB change interventions among people with RA, which may subsequently improve their health. Longitudinal and experimental studies are required to confirm the present findings.

AUTOMATICITY IN RELATION TO SEDENTARY SCREEN TIME AND ACTIVE MODES OF TRANSPORT WITH OBJECTIVE MEASURES.

MARCHANT, G.1,2, BOICHÉ, J.1, NICAISE, V.2

1. MONTPELLIER UNIVERSITY, 2. CLAUDE BERNARD UNIVERSITY LYON 1

Reducing Sedentary Screen Time and adopting an Active Modes of Transport are jointly associated with health benefits. To obtain maximum benefits, they must be performed in an automatic fashion to improve the chances of regular involvement. Automaticity is considered to be a better indicator of habit strength than frequency of behaviour . For that reason, to be consistent with Bargh's <1994> assumption that automaticity is multidimensional and embraces several facets. The Generic Multidimensional Automaticity Scale was developed and validated to capture three of the facets: a> lack of intentionality ; b> low degree of control ; and c> efficiency . This study aims to evaluate the links between automaticity - and its facets - and the objectively measured behaviours. 126 adults <55% women> completed the GMAS, in relation to SST and AMT. Behaviours were assessed objectively by accelerometers worn for 7 days. Bivariate correlations were calculated to examine the associations between automaticity - and its facets - scores and objective measures of SST and AMT. The scores for Loi , Loc and the GMAS score for AMT were significantly and positively correlated with moderate-to-vigorous physical activity minutes for the objective criterion measure. In the case of SST, only the Eff facet was significantly associated with sedentary time . The present research suggests that different facets of automaticity would be associated with physical activity and sedentary behaviour. This study constitutes an alternative approach to be developed, given that it is the first in which automaticity is measured as multidimensional. Furthermore, Automaticity's facets could be included in research to improve theoretical models to understand the adoption of SST and physical activity behaviours.

INTERACTING EFFECTS OF EXERCISE AND BREAKS IN SITTING ON COGNITION IN OLDER ADULTS.

WHEELER, M.J.1,2, HEINONEN, I.1, ELLIS, K.A.4, CERIN, E.3, LEWIS, J.1, GREEN, D.J.1, DUNSTAN, D.W.1,2,3

1: THE UNIVERSITY OF WESTERN AUSTRALIA, 2: THE BAKER HEART AND DIABETES INSTITUTE, 3: AUSTRALIAN CATHOLIC UNIVERSITY, 4: THE UNIVERSITY OF MELBOURNE

INTRODUCTION: Cognitive function is an important component of health and quality of life, especially for older adults. Sedentary behaviour may be associated with lower cognitive function (Falck et al., 2016). Conversely, an exercise bout can acutely improve cognition. However, the time course of such improvements in the context of subsequent prolonged sitting is not known. Furthermore, it is unknown whether the improvement in cognition can be amplified when combined with frequent short activity breaks post-exercise. We aimed to investigate the acute effects of a single bout of moderate-intensity exercise, with and without light-intensity breaks from prolonged sitting on cognition in older adults. We hypothesised; 1) A morning bout of exercise would improve cognition over the span of eight hours, relative to prolonged sitting and; 2) The magnitude of improvement would be greater when exercise was followed by breaks in sitting.

METHODS: In a randomised crossover trial, inactive adults (n= 65; aged 55-80 years), completed 3 acute conditions (6 day washout): 1) SIT: uninterrupted sitting (8 hours, control); 2) EXERCISE: sitting (1 hour), moderate intensity walking (30 minutes) followed by uninterrupted sitting (6.5 hours); 3) EXERCISE+BREAKS: sitting (1 hour), moderate intensity walking (30 minutes) followed by sitting (6.5 hours) interrupted every 30 minutes with 3 minutes of light intensity walking. Cognitive function was measured using the Cogstate brief battery and Groton Maze Learning Task which were administered at baseline and at 3 subsequent time points. Domains of cognitive function assessed were; 1) Psychomotor function; 2) Attention; 3) Executive function; 4) Visual learning and; 5) Working memory. Participants were familiarised with all tasks prior to testing. Standardised z-scores were calculated for each task relative to baseline values. A cognitive composite score was calculated at each time point by averaging all z-scores. Results are displayed as the mean (SEM) z-score across all time points.

RESULTS: Relative to SIT, the mean composite z-score was improved for both EXERCISE [0.06 (0.03)] and EXERCISE+BREAKS [0.06 (0.03); all $p<0.05$ vs. SIT]. Relative to SIT, the mean z-score for the working memory subset was improved for both EXERCISE [0.12 (0.05)] and EXERCISE+BREAKS [0.12 (0.05); all $p<0.05$ vs. SIT]. There were no significant differences between conditions for any other cognitive domain subset.

CONCLUSION: In support of hypothesis 1, a morning bout of exercise improved cognition over 8 hours, relative to prolonged uninterrupted sitting. Hypothesis 2 was not supported by the data. These findings support current recommendations to undertake regular daily exercise and avoid sustained periods of uninterrupted sitting.

OP-BN32 Jumping performance in team sports

IDENTIFICATION AND COMPARISON OF MOVEMENT STRATEGIES OF THE SPIKE JUMP IN DIFFERENT PERFORMANCE LEVELS IN FEMALE VOLLEYBALL

DIETZSCH, M., BRAUN, C., VINCENT, A., POTTHAST, W., DAVID, S.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: The spike jump is one of the most frequently performed actions by attacking volleyball players. Higher jumps lift the point of attack, enabling the player to attack in steeper angles and offering him more opportunities as he is less affected by the opponents block. The technical execution of the complex and asymmetric movement appears to have a major impact on jump height and therefore the success of action. The aim of this study was to examine and compare the kinetics and muscle activation patterns of the spike jump in different performance levels.
METHODS: 27 female players from 2nd (Div2) and 8th (Div8) division were investigated using a 3D movement analysis setup. Subjects performed 10 spike jumps with a 3 step approach, attacking a suspended stationary volleyball on their individually preferred height. Ground reaction forces (GRF) for each leg were recorded by two force plates. Muscle activation of knee and ankle extensors and flexors were measured bilaterally via EMG surface electrodes. For data analysis GRF (peak, integrals and timeseries) and EMG (integrals, timeseries) were calculated during ground contact. Discrete parameters were compared using Matlabs Wilcoxon's tests while timeseries were compared using t-tests of statistical parametric mapping (SPM). The alpha level was set to 0.05 for all tests.
RESULTS: Div8 generated a significantly higher vertical peak GRF (pGRFz) in the second step (step2) ($p=.027$) compared to the third step (step3), whereas Div2 revealed no significant side difference. Comparing both groups, Div2 generated a higher impulse of step3 ($p<.001$) and of both steps together ($p=.035$). SPM displayed a significantly higher GRFz for step3 in the second half of ground contact for Div2 ($p=.010$), as well as higher breaking forces for step3 in Div8 ($p=.010$). Moreover, significantly higher EMG integrals of the m. Soleus (step3) ($p=.049$) and m. Vastus Lateralis (step3) ($p=.012$) were found for Div2. First results also show higher knee flexion angles in Div2.
CONCLUSION: Div2 players are able to generate a higher vertical GRF impulse in step3 and in step 2 and 3 together by generating higher GRFz during the second half of stance of step3. This is important as the generation of GRFz is known to be the performance-limiting factor of jump height. The generation of pGRFz is also more balanced in Div2 players which supports a two legged jump, while Div8 players showed significant differences between step2 and step3. Moreover, Div2 showed higher activations of ankle- and knee extensors in step 3. Increased knee flexion angles and the position of the Center of Mass more centrally over the feet are therefore advantageous to Div2 for generating greater GRFz, whereas Div8 experienced a higher breaking force which counteracts the generation of GRFz.

STRENGTH DETERMINANTS OF JUMP HEIGHT IN THE JUMP THROW MOVEMENT IN WOMEN HANDBALL PLAYERS

MCGHIE, D., ØSTERÅS, S., ETTEMA, G., PAULSEN, G., SANDBAKK, Ø.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: In professional handball, the jump throw represents >70% of all throws (Wagner et al., 2008). Jump height is a potential performance factor, with greater height affording players more throwing opportunities as a function of position or time in the air. In game situations, the jump throw necessitates rapid force production. Still, vertical jumping ability in handball players is routinely tested using the countermovement jump (CMJ), also when assessing training interventions (e.g., Marques & González-Badillo, 2006; Vila et al., 2012), despite its typically longer execution time (e.g., Bobbert et al., 1986; Rousanoglou et al., 2014). The aim of the study was to examine the associations between jump height in a jump throw jump (JTJ) and lower-body maximum strength and impulse in handball players, as well as whether the associations between jump height and strength differed between the JTJ and the CMJ.
METHODS: Twenty women handball players from a Norwegian top division club participated in the study (mean ± SD age 19.5±2.7 yrs, body mass 70.9±9.8 kg, height 174.1±5.7 cm). Jump height was measured in the JTJ and in unilateral and bilateral CMJ. Lower-body strength (maximum isometric force, one-repetition maximum (1-RM), impulse at 60% and 35% 1-RM) was measured in seated leg press. The association between jump height and strength was assessed with correlation analyses and t-tests of dependent r's (Chen & Popovich, 2002) were performed to determine if the correlations differed between jump tests.
RESULTS: Only impulse at 35% 1-RM correlated significantly with JTJ height ($r = .52$, $p = .02$), while all strength measures correlated significantly with jump height in both CMJ tests ($r = .76 – .85$, all $p < .001$). The association between jump height and strength was significantly weaker in the JTJ than in both CMJ tests for all strength measures ($p = .001 – .023$).
CONCLUSION: Maximum strength and impulse at 60% 1-RM did not seem to sufficiently capture the capabilities associated with jump height in the JTJ, highlighting the importance of testing rapid force production capability, at loads representative of the jump throw, when assessing throw-related vertical jumping ability in handball players. In contrast, CMJ height seemed to represent a wider range of strength capabilities and care should be taken when using it as a proxy for handball-specific movements.

EFFECTS OF BAREFOOT INTERVENTION ON LANDING SHOCK ATTENUATION AND IMPACT PEAK ACCELERATION OF NETBALL PLAYERS

JAIYESIMI, B.G.

STELLENBOSCH UNIVERSITY

INTRODUCTION: The mechanical disposition of the body during landing from a vertical jump involves the gradual descent of the lower limb, involving the ankle followed by the knee, hip and trunk (Gross, 1988) for shock attenuation to avoid risk of injury (Fong Yan, Sinclair,

Hiller, Wegener & Smith, 2013). Landing is a fundamental skill of many movements performed during netball (Mothersole, Cronin & Harris, 2013). It involves unilateral and bilateral coordination of the lower extremities to maintain balance and efficient kinetics and kinematics functioning of the body. When landing is out of control, joint tissues of the lower limbs are strained which could result in falling or injury (Louw & Grimmer, 2006). The aim of this study was to analyse shock attenuation and impact peak acceleration during landing performance in netball players.
METHODS: Thirty netball players (aged 20±1years) were recruited for the study. They were randomly and equally allocated into an experimental (barefoot= BF) and a control group (shod=SH). The intervention program involved warm up and netball specific drills performed in barefoot condition. The barefoot activity was introduced progressively with surface variations. The SH group followed the same other of activity in shod condition. The intervention program lasted for 18 sessions. Each participants performed three valid trials of four different jump landing tasks. Data were captured with myoMotion sensors and generated with user-friendly myoMotion software. The signal processing was set to low-pass Butterworth 4th zero-lag at 60Hz cut off frequency (Zhang, Derrick, Evans & Yu, 2008). The acceleration measurements from the sensors were expressed in multiples of gravitational acceleration. Shock attenuation % = [1 – (peak pelvis acceleration / peak thigh acceleration) × 100] was modified to generate shock attenuation values for the joint of the lower extremities (Sinclair, 2017).
RESULTS: There was a significant difference in impact peak acceleration for the pelvis and thigh between the BF and SH group ($p<0.05$). Pelvis impact peak reduced by 29% in BF group compared 16% in SH group. Hip shock attenuation was significantly higher in BF compared to SH ($p<0.05$), while the knee was lower. The effect sizes were very large for both group.
CONCLUSION: The impact peak acceleration and shock attenuation mean values reduced across the lower limbs in both experimental and control group especially with hip and which showed better control of the body during the landing tasks. The values reported by this study for acceleration and shock attenuation in both groups were consistent with the study of Zhang et al., (2008); Sinclair, (2017). According to Sinclair, (2017) increase in shock transmission from the tibial to the sacrum signals potential damage for passive anatomical structure placed under greater stress. It is therefore concluded that barefoot intervention could be a useful tool for better and safer landing mechanics.

MOVEMENT CHARACTERISTICS DETERMINING VOLLEYBALL SPIKE JUMP PERFORMANCE IN FEMALES

FUCHS, P.X., FUSCO, A., CORTIS, C., VON DUVILLARD, S.P., WAGNER, H.

UNIVERSITY OF SALZBURG

INTRODUCTION: Jump height and ball velocity are most essential for successful volleyball spike jumps. Performance determining factors were investigated in males only (Wagner et al., 2014) despite technical differences between sexes (Fuchs et al., under review). In absence of clarified performance determining factors in females, optimised specific training is not achievable. The purpose of this study was to identify movement characteristics that correlate with jump height and ball velocity in females' spike jump.
METHODS: Fifteen elite female volleyball players spiked a ball at maximal jump height and ball velocity. Anthropometrics, kinematics (e.g. segment positions, joint velocities, range of motion), and kinetics (e.g. ground reaction forces, impulses, rates of force development) were obtained by twelve MX13 Vicon cameras (250 Hz) and two AMTI force plates (2000 Hz) and managed via Visual3D. Stepwise regression analyses were performed using significant ($p < .05$) correlations, excluding the co-linearity.
RESULTS: Jump height correlated with 10 out of 42 variables ($p < .05$; $|.59| \leq r \leq |.85|$). Correlations represented aspects of non-spiking arm's backswing and velocity, range of motion and extension velocity of the ankles and knees, and orientation step length. Jump height was most successfully predicted by the regression formula: $-0.21 + 4.49 \times 10\text{-}4 \times$ maximal dominant knee velocity $+ 0.20 \times$ orientation step length ($R^2 = .82$, $p < .001$).
For ball velocity, none of 22 variables correlated significantly. Strongest correlations ($p < .1$; $.49 \leq r \leq .52$) were found in upper and lower arm length and maximal angular velocity of pelvis rotation and elbow extension.
CONCLUSION: For jump height, the results support the importance of 1) a wide and dynamic use of the non-spiking arm, 2) a distinct countermovement and thus increased acceleration paths through increased range of motion in ankles and knees, and 3) great angular velocities in leg extension during push-off. The data indicate that an optimal approach strategy has an integral role in increasing jump height. The findings contribute to specific adaptation of technical training and also indicate that strength training needs to implement lower extremity extension in full range of motion.
The regression and correlation results for ball velocity are lacking. We assert that ball velocity is affected too much by the complex interaction of variables (e.g. coordination) to be predictable by any number of simple variables alone. Another adversity could be the variance of striking techniques prioritising different variables (Seminati et al., 2015). The data support that joint velocities in the upper body and extremities may be influential.

ANKLE PLANTAR FLEXOR WORK DIFFERS BETWEEN VOLLEYBALL AND ICE HOCKEY PLAYERS DURING JUMPING, BUT NOT LANDING

DÆHLIN, T.E., CHIU, L.Z.F.

UNIVERSITY OF ALBERTA

INTRODUCTION: In a recent investigation, we observed that landing mechanics differ between jumps performed with forefoot versus heel take-off strategies. Specifically, a forefoot take-off, requiring greater ankle plantar flexor work compared to heel take-off, leads to greater ankle plantar flexor contribution to energy absorption during landing. It is possible that similar differences manifest between athletes who engage in sports where ankle plantar flexion is free versus restricted, due to the specificity of muscle adaptions to the activity performed. The purpose of the present study was to compare the jumping and landing mechanics of athletes engaging in sports with free (volleyball) and restricted (ice hockey) ankle plantar flexion.
METHODS: Competitive female volleyball ($n = 16$) and ice hockey ($n = 19$) players performed six maximal countermovement vertical jumps (CMJ). Trajectories of 27 reflective markers affixed to the lower extremity and ground reaction forces were measured using 7 optoelectronic cameras and two force platforms. A rigid-link model was used to calculate jump height, foot, leg, thigh and pelvis segment angles, and ankle, knee, and hip net joint moment (NJM) and work. These were compared between volleyball and ice hockey players using uni- and multivariate ANOVAs.

RESULTS: The volleyball players jumped 0.41± 0.05 m, whereas the ice hockey players jumped 0.38 ± 0.05 m (p = 0.085). During the propulsion phase, volleyball players performed more ankle plantar flexor (1.53 ± 0.25 J/kg) and knee extensor work (0.86 ± 0.40 J/kg), and exerted greater ankle plantar flexor (−2.68 ± 0.26 Nm/kg) and hip extensor (−4.07 ± 0.68 Nm/kg) NJMs, compared to the ice hockey players (1.40 ± 0.15 J/kg, 0.60 ± 0.28 J/kg, −2.44 ± 0.21 Nm/kg, and −3.61 ± 0.62 Nm/kg, respectively; p < 0.05). From initial foot contact to foot flat and from foot flat to peak knee flexion, hip extensor work (−0.21 ± 0.27 J/kg) and NJM (−1.52 ± 0.71 Nm/kg), and hip extensor NJM (−3.11 ± 0.65 Nm/kg) were greater in volleyball compared to ice hockey players (−0.05 ± 0.16 J/kg, −0.86 ± 0.50 Nm/kg, and −2.12 ± 1.14 Nm/kg, respectively; p < 0.05), respectively.
CONCLUSION: Volleyball players performed more ankle plantar flexor work and exerted greater ankle plantar flexor NJM than ice hockey players during the propulsion phase, contributing to a greater jump height. This supports the hypothesis that athletes engaging in sports with free ankle plantar flexion may utilize their ankle plantar flexors more during vertical jumping. However, ankle plantar flexor work and NJM did not differ between groups during landing. Volleyball players did perform more hip extensor work to absorb the greater impact energy present during landing. These data suggest there is a finite capacity to absorb energy using the ankle plantar flexors and knee extensors during landing.

EFFECTS OF DROP HEIGHT ON JUMP PERFORMANCE IN ELITE MALE AND FEMALE ADOLESCENT HANDBALL PLAYERS

PRIESKE, O.1, CHAABENE, H.1, LESINSKI, M.1, HANSCHEL, F.2, PUTA, C.2, BEHM, D.G.3, BÜSCH, D.4, GRANACHER, U.1
1: UP , 2: FSU , 3: MUN , 4: CVO

INTRODUCTION: Reactive strength training is an effective training regime to improve physical fitness (e.g., vertical jumping, linear sprinting) in young athletes (Lesinski et al., 2016). However, drop height during reactive strength exercises (i.e., drop jumps [DJ]) may significantly affect subsequent jump performances (Taube et al., 2012). Thus, the purpose of the present study was to examine the effects of various drop heights on DJ performance and its associations with sprint performance in healthy adolescent handball players.
METHODS: Elite male (n = 119, age = 15.5±0.4 yrs, 2.5±0.6 yrs after peak height velocity [PHV]) and female (n = 120, age = 14.5±0.5 yrs, 2.5±0.5 yrs after PHV) adolescent handball players performed DJs in a randomized order using 3 drop heights (i.e., 20, 35, and 50 cm). DJ performance (i.e., jump height, contact time, reactive strength index [RSI]) was analyzed using an optoelectronic device and repeated measures ANOVA. Additionally, participants were tested for their 20 m linear sprint and 5 and 10 m split time performance. Pearson's product-moment correlation was used to analyze associations between DJ performance measures and sprint times.
RESULTS: The statistical analyses revealed a significant, small-sized interaction effect for the factors drop height and sex on DJ contact time (p = .048, Cohen's d = 0.23). Post-hoc tests indicated shorter contact times in males compared with females in the 20 cm drop height condition only (p = .021, d = 0.30). Additionally, medium-sized main effects of drop height were found for DJ height and RSI (p < .001, 0.63 ≤ d ≤ 0.71). Post-hoc tests indicated larger DJ heights from 20 to 35, and from 35 to 50 cm (p ≤ .031, 0.33 ≤ d ≤ 0.71) and better RSI from 20 to 35 cm drop height (p < .001, d = 0.77). Irrespective of drop height, associations of DJ performance were small with 5 m split time (-.27 ≤ r ≤ .05), small-to-medium with 10 m split time (-.44 ≤ r ≤ .14), and small-to-large with 20 m sprint time (-.57 ≤ r ≤ .22).
CONCLUSION: The present findings indicate that a 35 cm drop height is sufficient to induce rapid and powerful DJ performance (i.e., RSI) in elite adolescent handball players, irrespective of sex. Moreover, it appears that gains in DJ performance may at least partly translate to gains in longer sprint distances (i.e., ≥20 m) and/or vice versa in male and female young athletes.

OP-BN33 Skill acquisition and expertise

INFORMATION PROCESSING SPEED IN SPECIFIC FENCING SITUATIONS COULD BE DEPENDENT ON EXPERTISE LEVEL

NEDELJKOVIC, A.1, MILIC, M.1, CUK, I.2, MUDRIC, M.1, JARIC, S.1,3,4
1: UB-FSFV , 2: US-FFKMS 3: DKAP&BMS-GPB , 4: DHMB-JKAPE

INTRODUCTION: The information processing speed (IPS) is a measure of the efficiency of cognitive function. Specific situations in many sports require high IPS to respond quickly and accurately to an opponent action. The measurement of reaction time (RT) is a common method to assess IPS. It is well known that RT depends on the number of stimulus–response alternatives where the selection of proper response requires more time when there is a larger number of response alternatives [i.e., Hick's law; (Hick, 1952)]. The aim of the present study was to investigate the IPS in fencers of different level of expertise.
METHODS: RT of expert fencers and age matched beginners was tested in four specific fencing situations (i.e., high and low attack, high and low defense). To maximize the ecological validity of experimental set-up, we used our recently evaluated Video-based method (Mudric et al., 2015). In short, RT was calculated from the kinematic parameters recorded on either offensive or defensive action stimuli, as well as on corresponding action responses. RT in each specific fencing situations was calculated under three different experimental conditions regarding the predictability of stimulus-response paradigm (i.e., Simple RT - the stimulus and, consequently, the proper response are known in advance; 2Choice RT, or 4Choice RT - the stimulus is unknown in advance and, therefore, requires both a quick and properly selected response). RTs obtained across different experimental conditions have been plotted against the number of choices (i.e., 1, 2, or 4) and linear regression analyses were applied. The slopes of the linear regressions as a dependent variable indicate the IPS.
RESULTS: In all four specific fencing situations, subjects of both tested groups reacted quicker in Simple RT condition than in either 2Choice RT or 4Choice RT conditions, whereas 2Choice RT was faster than 4Choice RT (p < 0.05). The expert fencers reacted quicker than beginners under the same experimental conditions (p < 0.05). Finally, the regression slopes of the beginners were consistently higher than the slopes obtained from the expert fencers suggesting faster processing of stimulus-response alternatives (p < 0.05).
CONCLUSION: The obtained findings suggest that recently evaluated Video-based method could be routinely used for testing RT in specific sport situations and possibly in diagnostic of various neurological diseases. Moreover, the novel method provides the data that con-

firmed the application of Hicks law when the information is processed within specific sport situations. Finally, it could be concluded that regular fencing practice improves IPS in specific fencing situations.

RESEARCH ON THE NEUROBIOLOGICAL FEATURES OF THE CHINESE ELITE WOMAN TABLE TENNIS PLAYERS

ZHOU, W.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: The aim of this study was to explore the brain functional state and the brain neurotransmitters of the Chinese elite woman table tennis players.
METHODS: By means of EEG and Encephalofluctuograph , 8 key players in the Chinese Woman Team were monitored in 2014 to 2016. Their average age was 23.33±2.58.
The testing instrument was the QDBS1018 Electroencephalography .
The tested indexes included: brain arousal index, brain power energy ratio（brain energy ratio）, intelligence entropy , brain coordination parameters, and brain neurotransmitters: NE , GABA <γ-aminobutyric acid>, 5-HT , OPI , Glu , DA , and ACH .
RESULTS: <1> The brain arousal index level of a world champion, which reflected the state of brain excitability, was between 48% and 50%. If the arousal index was more than 50%, the statement of the brain would be in the "Critical", that it could be reversed by "inhibition" from "excitement", and even emergence of "the exercise central fatigue".
The Index values of the 8 players in the 5 tests were more than 48%.The brain energy ratio of the world champion, reflecting the exercise the brain endured, was more than 1.95, and its critical value was 2. The ratio values of the 6 players were more than 1.95.
<2> Various neurotransmitters both played different physiological functions in the brain, and controlled a variety of activities to the body. For example, opioid peptides associated with the transfer of excitatory, DA involved in the control of movement and emotional function, ACH concerned with excitability in all parts of the brain and directly involved in memory, 5-HT was inseparable to central fatigue and so on. The values of these neurotransmitters in the brain of the 6 players were in normal range.
<3> The comprehensive indexes: The intelligence entropy reflected the comprehensive intelligence of athletes. The eIQ of the table tennis players was usually between 60 and 75. The brain coordination parameters reflected the degree of the synchronization in the brain activity.
CONCLUSION: In the 5 tests in 2014 to 2016, the most of the brain function states of the 6 key players in the China Womens Table Tennis Team were in good or the best.

THE ROLE OF INSTRUCTIONAL PREFERENCE ON MOTOR LEARNING BY ANALOGY

VAN DUIJN, T.1, MASTERS, R.S.W.1,2

1: UNIVERSITY OF WAIKATO , 2: UNIVERSITY OF HONG KONG

INTRODUCTION: During skill learning, analogy instructions impart knowledge about how to move by way of comparison with a similar, well-known concept. This reduces the number of verbal instructions or rules that need to be given to the learner. It has been argued that analogy reduces reliance on verbal information processes during motor planning (Masters 2000; Liao & Masters, 2001), which may be reflected by reduced verbal activity in the brain (measured by EEG alpha power at the temporal region, T7) as well as reduced verbal-motor cross-communication (EEG T7-Fz coherence) during the preparation phase of a movement.
METHODS: Preference for using verbal or visual instructions is likely to influence the efficacy of analogy instructions. This study investigated whether preference for verbal instructions was related to changes in performance and neural activity related to information processing during performance (preparatory phase) of an adapted basketball task after instruction by analogy.
RESULTS: While electro-cortical measurements at pre-test did not differ significantly, people with a preference for verbal instructions showed a decrease in activation of verbal regions when they used the analogy (high-alpha power). People with low verbal preference did not show a significant decrease in activation of verbal regions, and their performance deteriorated significantly after introduction of the analogy instruction, whereas people with high verbal preference remained stable. Further investigation of performance scores revealed that all participants performed worse in the first 10 trials immediately after analogy, but those with high verbal preference recovered in the next 10 trials, whereas those with low verbal preference did not.
CONCLUSION: Results generally support our hypothesis that analogy reduces verbal processing demands. It is likely that both cognitive and performance changes after analogy instruction depend on personal aspects of information processing, such as verbal preference.

ERRORS IN MOTOR LEARNING: BENEFICIAL

BECKMANN, H., AZEVEDO CANEIRO, N., CALMANO, J., ZENTGRAF, L., HORST, F., SCHÖLLHORN, W.I.

JOHANNES GUTENBERG-UNIVERSITY MAINZ

INTRODUCTION: Different theories exist about the role of errors in skill acquisition. Two representatives are the errorless-learning paradigm [1] or the differencial learning approach [2]. The objective of this study was to determine whether the number of errors made during practice (regardless of their origin) influences learning of a golf putting task.
METHODS: Fourty golf novices (undergraduate sport science students, 18 female, 22 male, M=23.0 years, SD=2.0) were randomly assigned to one of four practice conditions: errorless, errorful, random [1] and differencial learning [2]. On the first day all subjects performed seven blocks of 20 golf putting trials from seven distances (0.25, 0.50,…, 1.75m) with a standard golf putter on an indoor putting green towards a standard golf hole of 0.11 m. The measure for errors was the number of missed holes. The errorless group performed the first block from the shortest distance and moved progressively back through each distance until they reached the furthest distance on the final block. The errorful group performed blocks in the reverse order of distances. The random group performed all blocks in a random order

of distances; so did the differencial group but in this group additional movement variations were applied [2]. Fourty-eight hours later subjects returned for a retention (2.00 m distance) and transfer test (2.00 m distance on an uneven surface) with 20 trials each.
RESULTS: The total number of errors during practice differed statistically significant between groups (H(3)=14.766, p=.002). The highest number of errors occurred in differencial learning (MD=51, IQR=18.25) followed by errorful (MD=38, IQR=18.25), errorless (MD=26, IQR=7.25) and random learning (MD=23.5, IQR=14.5). Dunn-Bonferroni post-hoc-tests revealed statistically significant higher number of errors only in differencial learning compared to errorless (z=-3.063, p=.013, r=.68) and random learning (z=-3.274, p=.006, r=.73).
A non-parametric ANCOVA [3] showed neither a significant effect for groups in the retention (F(3,36)=1.318, p=.284, part. η^2=.099) nor in the transfer performance (F(3,36)=0.799, p=.502, part. η^2=.062) after controlling for the number of errors during practice.
CONCLUSION: Surprisingly, there was no statistical difference in the number of errors during practice between errorful and errorless learning. Furthermore, the number of errors and the way they were provoked did not show statistical influence on the performance in the retention and the transfer test.

INCREASED EEG ALPHA ACTIVITY IN A STROOP-LIKE GROSS-MOTOR TASK OF RIDING AN INVERSE STEERING BICYCLE

BIRKLBAUER, J.1, SHELEMBE, F.2, RIGLER, S.2, BOTHE, K.2, EDFELDER, J.1, WIESINGER, H.P.1, MÜLLER, E.1, HÖDLMOSER, K.2
1: DEP SPO SCI & KIN , 2: LAB SLEEP & CONSCI RES

INTRODUCTION: Relearning of highly automated movement patterns is a key aspect in everyday training not only for competitive athletes. In order to avoid falling back into an old movement routine, one has to suppress the retrieval of the previously learned and interfering motor memory traces that in turn are thought to rely on top-down, inhibitory control processes (Klimesch et al. 2007). A paradigmatic example in a cognitive setting is the Stroop task in which alpha oscillations were found to increase amplitudes in prefrontal regions as a function of the degree of interference (Hanslmayr et al. 2008). The aim of our study was to test whether oscillatory alpha activity also amplifies in a relearned gross-motor skill of riding an inverse steering bike.
METHODS: 15 right-handed males (age: 28±7) who had become familiar with an inverse-steering bicycle such that they dare to ride the bicycle in normal road traffic performed two different riding conditions: 10 x 30m straight-line riding and 10 x 30m slalom riding. Both conditions were executed twice with both the inverse-steering bicycle and a structurally identical but normal-steering bicycle in a randomized order. EEG data were recorded from 16 electrodes throughout all rides and a 3-min resting condition with eyes open. Riding performance was quantified by steering angle and riding time.
RESULTS: Significant differences were found between straight-line and slalom riding ($p<.05$, $etap^2>.34$) as well as between the inverse and normal-steering condition ($p<.01$, $etap^2>.41$). Task related alpha power changes were significantly more prominent in frontal and occipital regions throughout riding the inverse-steering bicycle compared to the normal bicycle. In relation to the straight-line condition alpha power changes were significantly enhanced at frontal sites during slalom riding. Most importantly, smaller differences between normal and inverse riding performance correlated with an increase in alpha synchronisation ($p<.05$, $r>.59$).
CONCLUSION: We interpret the hypothesized EEG alpha power synchronization during inverse steering as a cortical correlate of top-down control to inhibit the retrieval of the habitual and dominant motor memory traces of normal steering. The difference in alpha activity between slalom and straight-line riding may reflect the higher challenge of the slalom task imposing a more intense cognitive load to control the bicycle through the slalom course. The results also confirm that it is feasible to successfully investigate brain activity accompanying gross-motor learning, and thus to validate sophisticated neural approaches in everyday and sport-related gross-motor skills.

OP-BN36 Balance and Stability

BALANCE CONTROL IN VESTIBULAR LOSS SUBJECTS - A SYSTEM IDENTIFICATION APPROACH

ASSLÄNDER, L., HETTICH, G., GRUBER, M., MERGNER, T.
UNIVERSITÄT KONSTANZ

INTRODUCTION: Subjects with absent vestibular function (AVF subjects) typically show no major balance problems as long as visual cues are available. Only in demanding situations, such as walking on soft ground in the dark, does the sensory deficit become evident. In the present study we investigate multisensory integration in the control of standing balance using a system identification approach. The study explored whether AVF subjects' sway responses to surface tilt stimuli can be explained by a model developed for subjects with normal vestibular function (NVF subjects) [1,2].
METHODS: 5 AVF subjects (18.8 +/- 0.8 yrs, 2 female) and in 7 NVF subjects (4 female, 27.1 +/- 3.6 yrs) participated in this study. A pseudo-randomized sequence was applied at 4 angular amplitudes in eyes closed and eyes open conditions. Hip and shoulder sway was measured opto-electronically and whole body center of mass (COM) motion was calculated thereof. Six consecutive cycles of the stimulus were measured twice in each condition and averaged across cycles to provide an estimate of the sway response to the stimulus. Model simulations including parameter estimation were conducted to extract a model of human balance control without vestibular function.
RESULTS: With eyes open, AVF subjects showed sway responses that indicated normal sensory reweighting, but response amplitudes were abnormally large, being comparable to those of NVF subjects with eyes closed. Sway response amplitudes of AVF subjects further increased with eyes closed, restricting successful balancing to small tilt amplitudes. The reweighting effect was strongly diminished, yet

still present. Model simulations suggest that AVF subjects integrate low-pass filtered center of pressure (COP) cues as a substitute for the missing vestibular cues, with COM sway reductions at low tilt frequencies.
CONCLUSION: The sway responses of our AVF subjects showed a small reweighting effect during eyes closed conditions, which has received little attention so far. Since only the proprioceptive reference to the floor is available in such conditions, the integration of ground reaction force cues was explored as a potential explanation and confirmed in model simulations. Reweighting of AVL subjects with eyes open was reproduced within the control framework proposed for NVF subjects, while eyes closed results required an extension of the model.

PLAYING EXPERIENCE RATHER THAN CHRONOLOGICAL AGE DETERMINES BALANCE CONTROL IN OLDER AGED LAWN BOWLERS

SAYERS, M.

UNIVERSITY OF THE SUNSHINE COAST

INTRODUCTION: Lawn bowls is a target sport that is popular throughout Commonwealth countries. The delivery action involves a degree of dynamic balance control and requires participants (standing on a mat) to step forward and roll each bowl smoothly along the ground, so that it stops as close as possible to a small target positioned between 23 m to 37 m away. Although high performance lawn bowlers are typically under 40 years of age, the sport is very popular within the older aged groups. Accordingly, this project assessed whether regular participation in this sport influences dynamic balance and stability ability during the delivery stride in a cohort of older aged lawn bowlers (n=30) who play lawn bowls at least once per week on a year-round basis.
METHODS: Participants were divided into two equal groups, with the first composed of lawn bowlers aged =65 years (mean age 61.0 ±3.8 yrs, playing experience 8.0 ±6.7 yrs), and the second group consisting bowlers aged)65 years (mean age 71.6 ±4.6 yrs, playing experience 12.6 ±8.4 yrs). Prior to testing low mass, retro-reflective markers were attached to well-established landmarks on both feet, upper and lower legs and arms, and on the head, thorax, and pelvis and tracked using a 10-camera motion capture system (Qualisys AB, Gothenburg, Sweden) sampling at 200 Hz. Each participant performed 10 bowls at a target positioned 23 m away while standing on two force platforms (Bertec Corporation, Columbus, USA) that were sampling at 600 Hz. Captured marker trajectories were modelled using standard biomechanical software (Visual3D; C-Motion, Inc., USA) and smoothed using a 2nd order low-pass digital filter (25 Hz for force platform data and 4 Hz for the kinematic data) before the construction of a whole-body 20 segment rigid body model. Standard balance-based centre of pressure (CoP) and ground reaction force variables were recorded and a Dynamic Postural Stability Index (DPSI) calculated for each delivery. The relative height of the centre of mass at bowl release (recorded as a function of standing height) was also calculated from the kinematic data. The potential interrelationships between age and years of bowling experience meant that the latter was entered as a covariate when testing for significant differences in balance variables between age groups via one-way analysis of covariance (ANCOVA).
RESULTS: None of the balance variables correlated significantly with age although years of bowling experience correlated moderately with DPSI scores ($r = -.42$, $P = .019$). The over 65 group had greater variance in the mediolateral CoP movements ($P = .012$),with no other significant differences in balance or postural stability variables between groups. Analysis of covariance indicated that the DPSI data were influenced significantly by bowling experience regardless of age group.
CONCLUSION: It was concluded that in the older aged lawn bowlers, playing experience and not age was the key determinant of balance control during the lawn bowls delivery action.

LIMB DIFFERENCES IN UNIPEDAL BALANCE PERFORMANCE IN YOUNG MALE SOCCER PLAYERS AT DIFFERENT LEVELS OF PLAYING EXPERIENCE

MUEHLBAUER, T.1, SCHWIERTZ, G.1, BRUECKNER, D.1, KISS, R.2, PANZER, S.3

1:UNIVERSITY OF DUISBURG-ESSEN; 2:UNIVERSITY OF APPLIED SCIENCES BIELEFELD, 3:SAARLAND UNIVERSITY

INTRODUCTION: Passing and kicking are commonly used playing techniques in soccer that are preferably performed with the dominant leg while the non-dominant leg is used as standing leg. Consequently, balance performance might be better using the non-dominant compared to the dominant leg. This leg difference (asymmetry) might be further enhanced based on players' level of playing experience (i.e., training/competition exposure). From a health perspective, leg asymmetry in balance performance of athletes is associated with an increased risk of non-contact injuries (Smith et al., 2015). Thus, our study evaluated leg asymmetry in balance performance of young male soccer players at different levels of playing experience.
METHODS: Maximal reach distance for all three reach directions (i.e., anterior [ANT], posteromedial [PM], posterolateral [PL]) in the Lower Quarter Y Balance Test (YBT-LQ) of the dominant and non-dominant leg as well as anthropometric characteristics (i.e., leg length) were assessed in 76 young male soccer players (under-13 [U13]: n=19, U15: n=14, U17: n=21, U19: n=22). Relative maximal reach distances (% leg length) for each reach direction and composite reach scores ($CS = <(ANT + PM + PL) / (LL \times 3)) \times 100$) were used as outcome measures. An analysis of variance was used to detect differences between legs across levels of playing experience.
RESULTS: Irrespective of parameter considered, we did not find significant main effects of leg (all $p > 0.05$, Cohen's $f = 0.03$-0.13) nor significant Leg × Level of playing experience interactions (all $p > 0.05$, $f = 0.18$-0.31). However, significant main effects of level of playing experience were found for all measures (all $p < 0.05$, $f = 0.36$-0.59). For the ANT ($p = 0.030$) and the PM ($p = 0.033$) direction, post hoc analysis revealed that U15 players achieved significantly shorter reach distances compared to U19 players. Concerning the PL direction and the CS, post hoc analysis showed that U15 players achieved significantly shorter reach distances compared to U13 (PL: $p < 0.001$; CS: $p = 0.005$) and U19 (PL: $p < 0.001$; CS: $p < 0.001$) players.
CONCLUSION: Irrespective of playing experience, no significant limb differences in unipedal balance performance were found. However, with increasing level of playing experience, improved YBT-LQ performance was observed (except for U15 players). This is indicative for balance as an important requisite in soccer players. Additionally, non-uniform growth of lower and upper body parts and maturation changes during adolescence may be responsible for the lesser balance performances in U15 than in U13 players.

INTER-RATER RELIABILITY OF THE DYNAMIC LEAP AND BALANCE TEST (DLBT), A NOVEL DYNAMIC BALANCE ASSESSMENT TEST.

JAFFRI, A.

UNIVERSITY OF VIRGINIA

INTRODUCTION: Dynamic postural control assessment is becoming more of an interest to the clinicians than static postural control assessment. Most of the sporting and functional activities like walking, running, jogging etc. are dynamic in nature. It has been reported that dynamic activities result in the activation of the fast mechanoreceptors as compared to quiet standing that requires the activation of slow adapting mechanoreceptors. There is a need of dynamic balance assessment tool that incorporates the functional movement patterns so that it can mimic functional movements. Dynamic Leap and Balance Test (DLBT) is a novel testing method that is clinician-friendly, easy to use and is functional. Although, DLBT has shown to have excellent within tester test-retest reliability, interrater reliability is not determined. The purpose of this study was to examine the interrater reliability of the DLBT between two investigators.
METHODS: Fifteen healthy college-aged (7 men and 8 women; height=169.32 ± 6.89; mass=63.56 ± 8.06) subjects participated in this study. Participants performed serial leaping movements in particular directions, characteristic to the DLBT test. Time taken by the participants to complete these 20 leaps was taken as the dependent measure of balance. Participants had to stabilize themselves in the central target while performing these quick movements. Stability was assessed using a selective criterion derived from Balance Error Scoring System. Participants were assessed by two different investigators, separately. Both limbs were assessed for the errors and time taken during the test.
RESULTS: The ICC for average measures of interrater reliability for the time taken to complete the task were 0.82 and 0.84 for right and left limb, respectively. The ICC for the average measures of interrater reliability for errors made in the task ranged from 0.70 to 0.90 from right to left limb, respectively.
CONCLUSION: The DLBT has shown very good interrater reliability. The DLBT is a cost-effective and clinician-friendly tool that can be a valuable addition to dynamic balance assessment toolkit in sports medicine clinics.

CHANGES IN POSTURAL SWAY AND GAIT CHARACTERISTICS AS A CONSEQUENCE OF ANTERIOR LOAD CARRIAGE

HILL, M.1, ROBERTS, M.2, TALBOT, C.2, KAY, A.2, PRICE, M.1

1COVENTRY UNIVERSITY 2UNIVERSITY OF NORTHAMPTON

INTRODUCTION: Previous research has indicated that carrying a backpack elicits an increase in postural sway during quiet standing (Heller et al. 2009) and stride-to-stride gait variability during walking (Qu and Yeo, 20011). Despite these initial enquires into the effects of carrying external loads on postural stability, little research has examined the effects of anterior load carriage. This gap in the literature is important because many daily (e.g. carrying a laundry basket) and occupational (e.g. courier delivery) activities require loads to be carried in front of the body. Within this context, to further develop the external load-postural stability database we examined the effects of increasing loads carried anteriorly on postural sway and gait parameters in healthy adults.
METHODS: Twenty-nine subjects (19 males, 10 females, age = 33.8 ± 12.7 years, height = 1.73 ± 0.07 m, mass = 75.1 ± 13.7 kg) were assessed in four conditions; (1) carrying no load (CON), (2) carrying a load with no added weight (i.e. empty box), (3) carrying a load with 5% body mass, and (4) carrying a load with 10% body mass. Anteroposterior and mediolateral centre of pressure (COP) displacement (cm) and the mean COP velocity (cm·s-1) were used to characterise postural sway. Coefficient of variation of the stride length, stride time and double support time were calculated from 1 min of treadmill walking at a preferred pace for gait assessment.
RESULTS: When compared to CON, anteroposterior COP displacement increased with the addition of a 5% ($P < 0.001$, $d = 0.74$) and 10% ($P < 0.001$, $d = 1.59$) load. The anteroposterior COP displacement also increased from the 5% to the 10% load ($P < 0.001$, $d = 0.75$). The addition of the 10% load increased stride time ($d = 1.71$) and stride length ($d = 1.20$) variability when compared to CON ($P < 0.001$). Additionally, stride length variability was significantly greater during 10% compared to 0% ($P = 0.004$, $d = 1.08$) and 5% ($P = 0.001$, $d = 1.01$) conditions.
CONCLUSION: In summary, the increase in postural sway and gait variability with added weight is dependent on the magnitude of the load, where the greater the load, the greater the effect on static and dynamic stability. Changes in the mass-inertia characteristics of the body is one of several mechanisms that have been offered to explain the increased postural sway and gait variability when holding an external load. Given that increased postural sway (Johansson et al. 2017) and gait variability (Verghese et al. 2009) are indicators of increased fall-risk, it can be inferred from the present findings that carrying heavy loads in front of the body increases the likelihood of fall-related incidents.

EFFECTS OF INCREASING BALANCE TASK COMPLEXITY ON POSTURAL SWAY AND MUSCLE ACTIVATION IN ADOLESCENTS

GEBEL, A., GRANACHER, U.

UNIVERSITY OF POTSDAM

INTRODUCTION: Balance is an important prerequisite for motor skill acquisition in youth. Balance training has the potential to improve motor skills, balance, and sport-specific performance (Yaggie et al., 2006). However, there is no psychometrically validated tool or parameter available that controls for balance exercise intensity and/or complexity (Farlie et al., 2013). Thus, the purpose of this study was to examine the effects of increasing balance task complexity on postural sway and muscle activity in youth.
METHODS: Twelve healthy male and female adolescents aged 16.9±0.5 years were enrolled in this study. All par-ticipants performed six balance tasks with increasing task complexity on a balance board (Wob-blesmart, Artzt GmbH). An increase in task complexity was accomplished through a mechanically adjustable pivot integrated in the balance board that continuously reduced the base of support.

Pos-tural sway (center of pressure displacements) was assessed using two measuring sensor mats (novel GmbH) that were placed on the balance board. Muscle activity of ankle (m. tibialis anterior, medial gastrocnemius, peroneus longus) and thigh (m. vastus medialis, biceps femoris) muscles was tested using surface electromyography (sEMG) according to SENIAM guidelines. Further, muscle co-activation was computed for m. soleus and tibialis anterior as well as for m. vastus medialis and biceps femoris from filtered, rectified, and smoothed mean sEMG amplitude. Therefore, the co-activation index was computed by dividing mean sEMG amplitude of the less active muscle with mean sEMG amplitude of the more active muscle.
RESULTS: Friedman two way ANOVA on ranks for paired samples revealed significant increases in postural sway ($p<0.0001$, $\chi^2=56.762$) with increasing task complexity which was accompanied by enhanced co-activation of muscles encompassing the ankle ($p<0.0001$, $\chi^2=16.719$) and knee joint ($p<0.0001$, $\chi^2=17.716$). Post hoc Dunn-Bonferroni tests showed significant task-related increases in postural sway ($0.0001 \leq p \leq 0.034$) and muscle co-activation ($0.007 \leq p \leq 0.048$) between lower (1-3) and higher levels of task complexity (4-6).
CONCLUSION: An increase in balance task complexity resulted in augmented postural sway and lower limb muscle co-activation. These findings indicate that the tested balance board can be used to progressively increase balance task complexity in balance training.

DEFINING AND ASSESSING CORE STABILITY: A SYSTEMATIC REVIEW

VERHAVERT, Y.

VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: Although core stability is a popular concept in sports and medicine and it is frequently incorporated in training and rehabilitation programs, there is no single clear definition and assessment method of core stability. To get more insight into this, an overview of all existing definitions and assessment methods is needed, which, to the best of our knowledge, is not done yet in current reviews.
METHODS: A systematic literature search was conducted following the PRISMA guidelines. PubMed, Web of Science, SportDiscus and Embase were searched for relevant articles. Results were limited to original English written articles published in full-text format in peer reviewed journals between January 2000 and January 2017, defining and measuring core stability.
RESULTS: Fifty-five articles were included in the qualitative synthesis. Fifty-one studies mentioned and/or investigated assessment methods of core stability, only three of the 51 studies mentioned a self-developed definition. Another four studies also mentioned a self-developed definition of core stability. In total, six different definitions of core stability and 64 different assessment methods measuring components of core stability were found.
CONCLUSION: There is a need to develop a single universally accepted definition and assessment method of core stability, evaluating core stability as a whole. After developing and validating the assessment method, future research will be able to investigate the role of core stability in sport performance, injury prevention and daily life conditions.

BEING FIT MATTERS: FITNESS IS IMPORTANT TO POSTPONE DISABILITY AND MORTALITY IN OLDER ADULTS WITH INTELLECTUAL DISABILITIES

OPPEWAL, A., HILGENKAMP, T.I.M.

ERASMUS MC, UNIVERSITY MEDICAL CENTER ROTTERDAM

INTRODUCTION: The life expectancy of people with intellectual disabilities (ID) is increasing. However, the very low physical fitness levels of older adults with ID may negatively impact their life expectancy, along with their quality of life. Previously we found that physical fitness was indeed predictive for a decline in daily functioning and mobility (1, 2). The relationship between physical fitness and mortality has not yet been studied in people with ID. Therefore, the aim of this study was to investigate the relationship between physical fitness and survival in older adults with ID.
METHODS: In the Healthy Ageing and Intellectual Disabilities study, we measured physical fitness levels of 900 older adults with ID (61.5 ± 8.1 years) at baseline. We collected mortality data over a 5-year follow-up period. We used Cox proportional hazard models to determine the association between each physical fitness test and mortality, adjusted for age, sex, level of ID, and Down syndrome.
RESULTS: Over the follow-up period, 172 (19.1%) participants died. Better manual dexterity (HR=0.96 [0.94-0.98]), visual reaction time (HR=1.57 [1.28-1.94]), balance (HR=0.97 [0.95-0.99]), comfortable (HR=0.65 [0.54-0.78]) and fast (HR=0.81 [0.72-0.91]) gait speed, grip strength (HR=0.97 [0.94-0.99]), and cardiorespiratory fitness (HR=0.997 [0.995-0.999]) were associated with a lower mortality risk. Auditive reaction time, muscular endurance and flexibility were not associated with mortality. Combining this with our previous results regarding daily functioning and mobility, we see that manual dexterity, balance, comfortable and fast gait speed, and cardiorespiratory fitness were associated with both a decline in daily functioning and mobility and mortality.
CONCLUSION: In this study, we showed for the first time that physical fitness was independently associated with mortality in older adults with ID. Along with our previous findings that a better physical fitness also resulted in less decline in daily functioning and mobility, these results stress the need for being physically fit at older age to postpone disability and mortality. It is therefore important to try to improve the low physical fitness levels often seen in older adults with ID.

SECULAR TRENDS IN THE GRIP STRENGTH OF SPORT UNIVERSITY STUDENTS BETWEEN 1973 AND 2016: J-FIT+STUDY

KIDOKORO, T., KOHMURA, Y., FUKU, N., SOMEYA, Y., SUZUKI, K.

JUNTENDO UNIVERSITY

INTRODUCTION: Evidence has suggested that grip strength of young population was declined for the last few decades, which become a serious public health concern because grip strength is associated with an increased risk of all-cause, cardiovascular, and premature death 1,2). However, it is not clear whether the similar downward trend is confirmed in sport university students who usually have a strong sport background since early childhood. The present study aimed to examine the secular trends in grip strength of sport university students in comparison with the normal Japanese population between 1973 and 2016.
METHODS: Available data on the grip strength of sport university students and the normal Japanese population were examined. Existing data on the grip strength of 6,308 sport university students aged 18 years between 1973 and 2016 were examined. The data were obtained from the Juntendo Fitness Plus Study, a cohort study of the Department of Physical Education/Health and Sports Science of Juntendo University. For reference, data on the grip strength of people of the same age (18 years old) were obtained from a national database.
RESULTS: Compared with the normal Japanese population, the sport university students had greater body mass index and stronger grip strength at all times. The grip strength of sport university students significantly declined between the 1980s and 1990s, and it has plateaued since 2000, albeit at low levels. Compared with the peak performance of sport university students in 1984, the grip strength of the students in 2016 was significantly lower by 8.1 kg. Based on a previous longitudinal study 3), current sport university students may expect to have 25.9% and 27.5% increased risks for future all-cause mortality and cardiovascular death, respectively. The downward trends were also confirmed in the normal Japanese population during the same periods.
CONCLUSION: The sport university students had a greater grip strength than did the normal population at all times; however, the grip strength of these students has significantly declined over the last few decades. Immediate actions should be implemented to prevent further reductions in the grip strength of the young population.

BIDIRECTIONAL RELATIONSHIPS BETWEEN CARDIORESPIRATORY FITNESS AND FATNESS IN CHILDREN AND ADOLESCENTS: THE UP&DOWN LONGITUDINAL STUDY.

PÉREZ-BEY, A.1, IZQUIERDO-GÓMEZ, R.1, VEIGA, O.L.3, ORTEGA, F.B.4, RUIZ, J.R.4, CASTRO-PIÑERO, J.1

1:UNIVERSITY OF CADIZ , 2:FACULTY OF EDUCATION, UNIVERSIDAD CENTRAL DE CHILE , 3:AUTONOMOUS UNIVERSITY OF MADRID , 4:UNIVERSITY OF GRANADA

INTRODUCTION: While the effect of changing cardiorespiratory fitness (CRF) levels over the years on fatness has been previously studied in youth, the effect of fatness levels on future CRF levels has not been fully determined. The objective of the present study was to determine the bidirectional longitudinal associations between cardiorespiratory fitness and fatness in children and adolescents.
METHODS: A total of 1082 children (512 girls) and 727 adolescents (342 girls) participated in this 2-year follow-up study with completed fitness and fatness measurements at baseline and follow-up. Height and weight were measured and body mass index (BMI) was calculated. Triceps and subescapular skinfold were assessed to estimate body fat percentage using the Slaughter's equation. Fat mass index was calculated as fat mass/height squared (kg/m2). CRF was determined by the 20-m shuttle run test. Bidirectionality was tested by including CRF and each marker of fatness (BMI, body fat percentage and fat mass index), separately, as independent/dependent variables, alternatively, in different linear and logistic regression models.
RESULTS: CRF at baseline was associated with body fat at 2-year follow-up ($p<0.001$). However, these associations disappeared after adjusting by BMI in children and by each marker of fatness in adolescents. Similar results were observed when baseline body fat markers were included as the independent variables and CRF as dependent variable (all $p<0.001$). Nevertheless, these associations persisted after adjusting by CRF at baseline except for adolescent boys. Those children and adolescents with unhealthy CRF levels at baseline presented higher risk of overweight/obesity at follow-up (OR ranging from 3.255 to 7.168; $p<0.001$), but these associations were lost after adjusting for baseline BMI levels in children and adolescents. Similarly, those who were overweight/obese at baseline had a greater risk of having unhealthy CRF levels than their normalweight counterparts at follow-up (OR ranging from 2.743 to 6.119; $p<0.001$), and these associations persisted after adjusting by CRF levels at baseline in children.
CONCLUSION: There is a bidirectional longitudinal association between physical fitness and fatness. Nonetheless, fatness at baseline seems to be a better predictor of physical fitness levels at follow-up, rather than vice versa, since these associations are generally independent of physical fitness levels at baseline.

PERIPHERAL BRAIN-DERIVED NEUROTROPHIC FACTOR IS WEAKLY ASSOCIATED WITH PHYSICAL FITNESS

KYRÖLÄINEN, H., SANTTILA, M., PIHLAINEN, K., KOSKI, H., VAARA, J.P.

UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: Brain-derived neurotrophic factor (BDNF) is a member of neurotrophin family, and this protein is known to have a great impact on neuroplasticity, memory and learning (Chao 2003). Several longitudinal studies have shown that aerobic exercise acutely elevates the peripheral BDNF levels in humans (e.g. Knaepen et al 2010, Huang et al 2014). However, conflicting results have been reviewed in relation to basal concentration of peripheral BDNF and physical fitness in cross-sectional studies (Huang et al. 2014). Therefore, the present study aimed to investigate associations of peripheral BDNF with several physical fitness components.
METHODS: 792 adult (26±6 yrs.) men participated in the study. BDNF concentrations were analyzed from the venous blood samples by using a ELISA Assay (Human BDNF ELISA kit, ScienCell Research laboratories, San Diego, California) and Dynex DS 2 ELISA processing system (Dynex Technologies, Chantilly, Virginia). Cardiorespiratory fitness (VO2max) was determined using an indirect graded cycle ergometer test until exhaustion. Bilateral maximal isometric leg (MVCleg) and arm extension forces (MVCarm) were measured using

dynamometers for leg and bench press, respectively. Muscular endurance tests consisted of repeated push-ups and sit-ups (1-min), while standing long jump assessed muscular power.
RESULTS: The mean±SD BDNF concentration was 15.20±3.96 ng/ml (range 2.02-28.22 ng/ml). The respective values for VO2max were 41.1±8.8ml/kg/min, MVCleg 3394±933N, MVCarm 871±216N, push-ups 28±14reps/min, sit-ups 35±12reps/min, standing long jump 227±26cm. Regression analysis revealed that associations between BDNF and different physical fitness components were weak: VO2max (β=-0.077, p=0.006), MVCleg (β=-0.04, p=0.072), push-ups (β=0.038, p=0.016), and sit-ups (β=0.043, p=0.020).
CONCLUSION: The main findings indicate that the association between peripheral BDNF and different physical fitness components is weak or non-existing at rest in the present cross-sectional design. It has been shown that BDNF is a mediator of benefits of exercise for brain health (Cotman & Berchtold, 2002) and further, physical activity and exercise have positive effects on brain structure and cognitive functions (Chao, 2003). Nevertheless, physical fitness is strongly inherited capability and, therefore, the associations with BDNF may not be as clear as it seems to be for physical activity. Future studies are warranted in this regard.

ANTHROPOMETRIC AND PHYSICAL FITNESS MEASURES OF FIRST AND SECOND YEAR PHYSIOTHERAPY STUDENTS

ZINZEN, E., GUETTARD, E., VANROELEN, A., CHAPELLE, L.

VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: The transition period from college to university is characterized by an increase in sedentary behavior, alcohol consumption and irregular, unhealthy eating. Correspondingly, previous studies have shown that during this transition period the prevalence of overweight and obesity increases whilst physical fitness measures decline. It is, nevertheless, unknown if Physiotherapy students, who have mandatory sports classes throughout their university education, display a similar decline in anthropometric and physical fitness measures.
Therefore, this study aimed to determine and report anthropometric and physical fitness measures of Physiotherapy students at the start of their first and second year of university.
METHODS: All Physiotherapy students enrolled in the Rehabilitation Sciences and Physiotherapy program of the Vrije Universiteit Brussel (Belgium) between 2012 and 2016 were examined at the start of their first and second year of university, creating a one-year follow up. A total of 356 (159 males and 197 females) students were examined in both their first and second year of university. Anthropometric (i.e. height, weight, BMI and fat percentage (determined using Bioelectrical Impedance Analysis)) and physical fitness (i.e. flamingo balance, plate tapping, sit and reach, standing broad jump, hand grip strength, sit ups, bent arm hang and shuttle run) measurements were examined according to the guidelines of the Eurofit test battery. The anthropometric and physical fitness measures were compared across both university years using paired samples t-tests in SPSS version 20.
RESULTS: Height, (171.9 ± 8.6 cm versus 172.5 ± 8.8 cm; $p < 0.001$), weight (64.5 ± 9.4 kg versus 66.1 ± 10.1 kg; $p < 0.001$), BMI (21.7 ± 2.3 versus 22.2 ± 2.5; $p < 0.001$) and fat percentage (22.2 ± 8.6 % versus 23.9 ± 8.5 %; $p < 0.001$) was significantly higher in the second year of university compared to the first year of university. In addition, the students performed significantly worse on the flamingo balance test (8.9 ± 4.6 attempts versus 8.2 ± 4.3 attempts; $p = 0.010$), plate tapping (9.9 ± 1.2 sec versus 10.1 ± 1.5 sec; $p = 0.039$), sit and reach (30.8 ± 8.6 cm versus 27.2 ± 9.5 cm; $p < 0.001$) and bent arm hang (27.2 ± 19.7 sec versus 25.5 ± 18.8 sec; $p = 0.002$) in the second year of university. No significant differences were found for the standing broad jump (191.4 ± 31.9 cm versus 191.0 ± 31.6 cm; $p = 0.499$), hand grip strength (40.6 ± 10.4 kg versus 40.9 ± 10.7 kg; $p = 0.370$), sit ups (22.6 ± 4.6 reps versus 22.8 ± 4.8 reps; $p = 0.529$) and shuttle run (20.6 ± 1.7 versus 20.5 ± 1.5; $p = 0.083$).
CONCLUSION: To conclude, despite mandatory sports classes, weight, fat percentage and BMI of Physiotherapy students significantly increased and physical fitness measures significantly declined after one year of university. These results could be explained by an increase in sedentary behavior, alcohol consumption and bad eating habits typically observed in the transition phase from college to university.

OP-BN50 Pacing

THE PSYCHOPHYSIOLOGICAL REGULATION OF PACING BEHAVIOR AND PERFORMANCE DURING LONG-DISTANCE RUNNING WITH LOCOMOTOR MUSCLE FATIGUE AND EXERCISE-INDUCED MUSCLE DAMAGE IN HIGHLY-TRAINED RUNNERS

VENHORST, A.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: Locomotor muscle fatigue (LMMF) and exercise induced muscle damage (EIMD) are common conditions in long-distance running characterized by pooled mechanical and metabolic strain on locomotor muscles. Research so far has focused on the physiological consequences of EIMD and thus largely on symptoms of delayed onset of muscular soreness. However, little is known about the immediate psychophysiological effects of combined LMMF and EIMD on endurance performance and pacing behavior as experienced during the decisive final stages of 'real-world' long-distance running events.
METHODS: Twenty-two highly-trained (performance level 4) runners (eleven female) completed two maximal self-paced 20-km treadmill time trials in a counterbalanced crossover design: (A) in a tapered condition and (B) with LMMF and EIMD produced by a standardized drop-jump protocol. Hematological indicators of tissue damage, muscle metabolic strain, and endocrinological stress were assessed to investigate the 'direct' physiological effects; and a three-dimensional framework of perceived fatigability was applied to investigate the 'indirect' perceptual effects of LMMF and EIMD on performance fatigability (locomotor muscle strength, running economy, and endurance performance) and observed pacing behavior.

RESULTS: LMMF and EIMD caused large restrictions in work capacity (isokinetic knee extensor power output and time trial time), moderate decreases in running economy (oxygen consumption, energy cost, heart rate, and carbohydrate usage), and moderate increases in blood leukocyte and neutrophil count as well as blood interleukin-6 and cortisol concentrations. Thus, collectively forming a physiological milieu that per se is not conducive to high-performance. LMMF and EIMD further caused large increases in perceived physical strain, large decreases in valence as well as large shifts from an implemental to a deliberative mindset indicated by mirror-like responses in action crisis and flow state. Thus, under the constraint of amplified physiological duress, the dynamic interdependencies of sensory, affective, and cognitive processes are suggestive of linked heuristic and rational antecedents in the initiation of the goal-disengagement process.
CONCLUSION: Dynamic changes and complex interactions in 'direct' physiological and 'indirect' perceptual effects of LMMF and EIMD are hypothesized to underpin the observed alterations in pacing behavior and endurance performance during the decisive final stages in long-distance running events. The applied three-dimensional framework of perceived fatigability provides a more comprehensive understanding of strain-perception-thinking-action coupling in centrally regulated and goal-directed exercise behavior. By emphasizing a holistic and dynamical systems perspective, the proposed framework offers a sophisticated alternative to the traditional Gestalt concept of perceived exertion in the investigation of complex exercise-related phenomena.

PACING BEHAVIOUR OF ELITE YOUTH SHORT TRACK SPEED SKATERS IN 1500M HEAD-TO-HEAD COMPETITION.

MENTING, S.G.P., KONINGS, M.J., ELFERINK-GEMSER, M.T., HETTINGA, F.J.
UNIVERSITY OF GRONINGEN

INTRODUCTION: The decision-making process of the velocity distribution over a race (i.e. pacing) has proven to be a decisive factor in athlete performance. In this respect, experience has been shown to play a large role in this decision-making process involved in pacing (Foster et al., 2009), yet not much is known on how pacing behaviour develops throughout adolescence (Elferink-Gemser & Hettinga, 2017). The purpose of this study was to gain more insight into the pacing behaviour of youth athletes in a head-to-head type sport: short track speed skating.
METHODS: Lap times and intermediate positions of elite short track speed skaters performing 1500m races (13.5 laps), during the seasons 2011/2012-2015/2016, were analysed (n=9715). The effect of age group, categorized as under 17 (U17), under 19 (U19), under 21 (U21) and adult, was analysed using a MANOVA ($p<0.05$). Relative section times (RST), the percentages of total time spend in a single lap time, were used as dependent variables. Kendall's Tau-b correlations were used to analyse the relation between intermediate positioning, and final ranking in the different age groups ($r<0.5$ low, 0.50.70 high).
RESULTS: A significant effect for age group ($F=10.43$, $df=42$, $p<0.001$) was found. The RST score of younger skaters was significantly higher during the laps 1-4 and significantly lower during laps 12, 13 and 14 compared to older skaters. For example, the RST of respectively U17, U19, U21 and adults during lap 4: 7.70±0.55, 7.77±0.53, 7.79±0.51, 7.79±0.47 and during lap 13: 6.90±0.52, 6.81±0.49, 6.75±0.47, 6.69±0.41. Younger skaters presented a higher correlation between intermediate position and final ranking earlier in the race, compared to their older counterparts. For example, the correlations in lap 11: $r=0.73$, 0.67, 0.64, 0.57, for U17, U19, U21 and adults respectively.
CONCLUSION: The RST and positioning data show that pacing behaviour of youth elite short track speed skaters differs from adults. Younger skaters start relatively fast and finish relatively slow compared to adults. The pacing behaviour of the older adolescent age groups shares more resemblance to the conservative pacing behaviour of adults, suggesting a development of pacing behaviour with age throughout adolescence. These finding stress the importance of experience in the development of pacing skills in youth athletes. Talent development programs of head-to-head sports may benefit by increasing their focus on pacing behaviour development during adolescence.

INVESTIGATING THE ROLE OF CONSCIOUS MONITORING AND CONTROL OF MOVEMENT DURING RUNNING

UIGA, L., MALHOTRA, N., CAPIO, C.M., VAN DUIJN, T., MASTERS, R.S.W.
UNIVERSITY OF WAIKATO

INTRODUCTION: Research suggests that a high propensity for conscious monitoring and control of movements (i.e., movement specific reinvestment) is associated with disrupted performance under pressure; however, most of the research has examined performance of skills that require fine motor coordination (e.g., golf, darts, laparoscopic peg transfer). To the best of our knowledge, movement specific reinvestment has not been investigated in the context of endurance sports, such as long distance running, which do not require technical precision, yet provide ample time for conscious monitoring and control. Two studies were conducted to explore the relationship between movement specific reinvestment and running performance.
METHODS: In Study 1, the performance of runners who completed a 12 km running race was monitored. Prior to the start of the race, participants completed the Movement Specific Reinvestment Scale (MSRS; Masters, Eves, & Maxwell, 2005), which comprises a conscious motor processing dimension and a movement self-consciousness dimension. Participants self-evaluated their anxiety, preparation satisfaction and self-confidence associated with the competition. Performance time was recorded. Study 2 investigated the association between movement specific reinvestment and self-awareness of physiological and movement-related markers associated with running. Specifically, participants were asked to run on a treadmill and estimate their heart rate, distance covered and average step length.
RESULTS: The results of Study 1 revealed that MSRS was the only significant predictor of running time, with higher scores related to slower performance times. Higher scores on the movement self-consciousness dimension, but not the conscious motor processing dimension, of the Scale were related to slower running times. The results of Study 2 revealed that movement specific reinvestment was associated with subjective estimations of physiological and movement-related markers of running.
CONCLUSION: Endurance skills, which occur over extended periods of time, may allow opportunity for self-focused attention and reflection, which potentially disrupts physical performance. Our results suggest that a person's disposition for conscious monitoring and control of their movements (MSRS) particularly for movement self-consciousness, plays an influential role in competitive long distance running.

TACTICAL PACING DECISIONS IN THE MIDDLE-DISTANCE RUNNING EVENTS AT THE 2017 IAAF WORLD CHAMPIONSHIPS.

CASADO, A., RENFREE, A.

UNIVERSIDAD ISABEL I DE CASTILLA AND UNIVERSITY OF WORCESTER

INTRODUCTION: Successful participation in competitive endurance events requires regulation of exercise intensity in an attempt to achieve a performance goal, meaning pacing behaviours are reflections of continual decision-making processes . Although some research has investigated pacing strategies in middle-distance running events through analysis of distribution of speeds over race segments , other work has examined the influence of tactical positioning at intermediate points on finishing position . Preliminary qualifying rounds at major championships represent an interesting tactical decision-making environment, as qualification to the next stage of competition can be based on either finishing position or on finishing time . This study therefore assesses tactical and performance factors associated with progression from qualification rounds in the 800m and 1500m running events at the 2017 IAAF World Championships.
METHODS: Official results were used to access final and intermediate positions and 400m split times, as well as performance characteristics of all competitors. Shared variance between intermediate positions and rank order lap times with finishing positions were calculated, along with probability of automatic qualification, for athletes in each available race position at every intermediate point. Differences in race positions and lap times relative to seasons best performances were also assessed between automatic qualifiers , fastest losers , and non-qualifiers .
RESULTS: Race positions remained much more stable through 800m races than 1500m races. Probability of automatic qualification decreased along with both race position and ROSPT on each lap, although ROSPT accounted for a higher degree of shared variance than did intermediate position. In the 1500m event FL ran at a higher percentage of SB speed, and adopted positions closer to the race lead in the early stages than other competitors. This was not the case in the 800m.
CONCLUSION: Intermediate positioning and the ability to produce a fast final race segment are strongly related to successful advancement from qualification rounds in middle distance running events at a major championship. The adoption of a more 'risky' strategy characterized by higher speeds relative to SB may be associated with increased likelihood of qualification as FL in the 1500m event.

SEX DIFFERENCES IN PERFORMANCE AND PACING STRATEGIES DURING A SPRINT TIME-TRIAL IN CROSS-COUNTRY SKIING

ANDERSSON, E.1, GOVUS, A.1,2, SHANNON, O.3, MCGAWLEY, K.1

<1> MID SWEDEN UNIVERSITY, SWEDEN; <2> LA TROBE UNIVERSITY, AUSTRALIA; <3> NEWCASTLE UNIVERSITY, UNITED KINGDOM

INTRODUCTION: The aim of this study was to compare the pacing strategies, choice of sub-technique (or gear) and overall performance between elite male and female cross-country (XC) skiers during a ski-skating sprint time-trial (TT) on snow.
METHODS: Thirty-four elite XC skiers (20 males and 14 females: age, 23 ± 4 and 21 ± 3 yr; body mass, 76 ± 8 and 64 ± 5 kg; height, 183 ± 7 and 171 ± 5 cm; sprint FIS points, 86 ± 42 and 90 ± 54) performed a 1.6 km TT, which was 56% flat (or undulating), 21% uphill and 22% downhill. The sprint course was measured with a differential global navigation satellite system and divided into four flat, three uphill and two downhill sections. Race time was measured with the EMIT timing system (Emit AS, Oslo, Norway) and one 25-m uphill (4°) section was filmed continuously with a fixed camcorder (50 Hz). All skiers used a similar stone-grind and all skis were glide-waxed similarly. The air temperature was +1°C (fresh snow at ±0°C), relative humidity was 90% and the friction coefficient between ski and snow was estimated to 0.045 (i.e., very slow).
RESULTS: Average speed during the TT was 25 ± 1 and 22 ± 1 km/h (TT time: 227 ± 11 and 254 ± 10 s) for males and females, respectively ($P < 0.001$, Cohen's d effect size [ES] = 2.6). Average relative power output (PO) was estimated to 3.9 ± 0.3 and 3.3 ± 0.2 W/kg for males and females, respectively ($P < 0.001$, ES = 2.5). Average heart rate was 95 ± 2% and 96 ± 1% of maximum for males and females ($P = 0.51$), with a 2-min post-race blood lactate concentration of 10 ± 2 mmol/L for both sexes ($P = 0.64$). Within-athlete coefficient of variation in speed between sections was 20 ± 2% for males and 24 ± 1% for females ($P < 0.001$, ES = 2.6). Speeds on the flat, uphill and downhill sections were 26 ± 1, 19 ± 1 and 32 ± 1 km/h for males and 23 ± 1, 16 ± 1 and 30 ± 1 km/h for females (main effects for terrain, sex and interaction, all $P < 0.01$) corresponding to 9%, 16% and 8% slower speeds on flat, uphill and downhill terrain for females. Speeds relative to the average TT speed were 103 ± 1%, 77 ± 2% and 129 ± 4% for males and 105 ± 1%, 72 ± 2% and 133 ± 2% for females (main effects for terrain, sex and interaction, all $P < 0.001$). Relative PO on the flat, uphill and downhill sections were estimated to 4.0 ± 0.3, 4.9 ± 0.4 and 1.9 ± 0.2 W/kg for males and 3.5 ± 0.2, 4.0 ± 0.3 and 1.5 ± 0.2 W/kg for females (main effects for terrain, sex and interaction, all $P < 0.001$). The males were 20% faster than the females on the uphill video section (16 ± 1 versus 13 ± 1 km/h, $P < 0.001$, ES = 2.6), with 95% of the male skiers and 21% of the female skiers using gear 3 exclusively, and the remaining skiers using gear 2 exclusively or a combination of gears 2 and 3.
CONCLUSION: The present results indicate an overall sex difference in sprint skiing performance of ~12% and reveal differences in terrain-specific pacing as well as gear choice between sexes with females showing a higher overall variation in speed and considerably slower uphill skiing.

DOES THE LABOUR/LEISURE MODEL TRANSLATE INTO THE REGULATION OF A STRENUOUS PHYSICAL TASK?

GIBOIN, L.S., GRUBER, M., SCHÜLER, J., WOLFF, W.

UNIVERSITÄT KONSTANZ

INTRODUCTION: Maintenance of physical effort, despite the development of fatigue, is key in many sport disciplines. Recently, it has been suggested that "giving up" in an endurance task may lie more at the cognitive than neuromuscular level. In the present study, we tested the hypothesis that the regulation of demanding physical effort follows the same model that can be used to describe the regulation of demanding cognitive effort1.
METHODS: In a within (time 1 vs. time 2) between (control group vs. intervention group) experimental design, 34 male participants had to perform an isometric knee extension above a target (15% maximal voluntary contraction (MVC)). The participants received monetary reward per unit of time until self-disengagement. At time 2, the experimental group received an upfront payment and a decreased

income per unit of time. It has been shown that this procedure can induce a reduction in cognitive control compared to the procedure at time 11. Thus, we predicted to find a decreased time before self-disengagement in the intervention group at time 2. To control neuromuscular fatigue, we measured MVC, voluntary activation (VA) and the potentiated twitch at rest (Ptw) before and just after the termination of the fatigue task. We measured dorso-lateral pre frontal cortex activity (dlPFC) with NIRS as this area as this area has been frequently associated with cognitive control.
RESULTS: We observed neither a group ($p = 0.5$) nor an interaction ($p = 0.08$) effect. However, a time effect was seen ($p < 0.001$), which could be explained in a post-hoc analysis by a longer time before self-disengagement in the intervention group at time 2 ($p = 0.002$). Perception of effort over time and neuromuscular fatigue were identical between groups. However, the task was performed more efficiently by the intervention group at time 2 (reduced mean force during the task, interaction effect, $p = 0.03$). We also observed a different dlPFC activity during the task (interaction effect, $p = 0.008$).
CONCLUSION: The model used to describe the regulation of a demanding cognitive effort1 may not correctly describe the regulation of a voluntary muscle contraction until self-disengagement. The increased task performance at time 2 could be explained by a higher task efficiency and not by an increase in resource depletion due to an altered cognitive control. These results have important implications in designing strategies to cope with fatigue during long lasting physical exertion tasks, e.g. in endurance sports.

OP-PM55 Thermoregulation

EFFECTS OF ELECTROLYZED HYDROGEN WATER DURING ENDURANCE EXERCISE IN HEAT ENVIRONMENT ON BODY FLUID BALANCE AND EXERCISE PERFORMANCE

ITO, H.1, KASAI, N.1, HWANG, H.1, KABAYAMA, S.2, GOTO, K.1
[1]RITSUMEIKAN UNIVERSITY, SHIGA, JAPAN [2]NIHON TRIM CO. LTD, OSAKA, JAPAN

INTRODUCTION: Electrolyzed hydrogen water (EHW), which is generated in cathode containing rich hydrogen molecules, indicates high alkalinity (pH: 9.5-9.9). It is commonly believed that the absorption in gastrointestinal tract is superior to general water. However, the effect of EHW ingestion on physiological responses during exercise remains unclear. Therefore, the purpose of the present study was to determine the effects of EHW ingestion during exercise in heat environment on body fluid balance and exercise performance.
METHODS: Twelve triathletes (20 ± 1.3 yrs., 171 ± 6.0 cm, 60.6 ± 3.9 kg VO_2max: 67.1 ± 3.8ml/kg/min) performed 60 min of pedaling at 65% of VO2max followed by incremental pedaling test either with consuming (2.0ml/kg, every 10 min) purified water (CON trial) or EHW (EHW trial). Blood variables, skin and muscle temperature and respiratory variables and score of subjective feelings were determined during 60 min of exercise. Time to exhaustion (TTE) during incremental test was also evaluated as an indication of endurance capacity.
RESULTS: Body weight reduced 1.1 ± 0.4 kg (1.7 ± 0.7%) after exercise, with no significant difference between the two trials. Plasma volume and serum osmolality, blood sodium(Na^+) and potassium(K^+) concentrations were significantly altered with progress of exercise but, no significant difference was observed between the two trials. Blood lactate, pH, bicarbonate ion concentrations were not significantly different between the two trials. Changes in skin temperature and muscle temperature were not significantly different between the two trials. However, exercise-induced elevation of muscle temperature tended to be smaller in EHW trial. Energy expenditure (calculated by $VO_2$and VCO_2) showed significantly lower value in EHW trial (13.2 ± 1.6 kcal/min) than in CON trial (13.7 ± 1.5 kcal/min, p=0.04). Serum glycerol concentration during exercise did not differ between the EHW and CON trials. In addition, the area under the curve did not differ significantly between the two trials. The TTE did not differ significantly between EHW trial (313 ± 90 s) and CON trial (350 ± 83 s).
CONCLUSION: The EHW ingestion during endurance exercise in heat environment decreased energy expenditure during exercise, suggesting improvement of pedaling (cycling) economy. However, EHW did not affect significantly the body fluid balance or exercise performance.

INTERMITTENT SPRINT PERFORMANCE IN THE HEAT IS NOT ALTERED BY AUGMENTING THERMAL PERCEPTION VIA L-MENTHOL OR CAPSAICIN MOUTHRINSES.

GIBSON, O.R., WRIGHTSON, J.G., HAYES, M.
BRUNEL UNIVERSITY LONDON

INTRODUCTION: Cooling sensations elicited by mouth rinsing with menthol have been reported as ergogenic during continuous intensity performance in the heat e.g. time trials/time to exhaustion tests, with improved thermal perception (cooling sensation/enhanced comfort) reported as a key mechanism. Presently, responses to menthol mouth rinsing during intermittent sprint performance (ISP) in the heat are not known. The impact of increasing negative thermal perception via the warming properties of capsaicin on ISP has also not been quantified. This experiment aimed to identify whether eliciting a cooling/warming sensation via menthol/capsaicin would alter ISP in the heat.
METHODS: Participants [n=14, body mass = 72±9 kg, VO2peak = 3.30±0.90], undertook four experimental trials, involving 40 min of ISP (20x 5s maximal sprints, 105s active recovery, 10s passive recovery) in hot conditions (40.2±0.6°C, 42±2%R.H.) with mouth rinsing (25 mL for 6 sec) at the onset of the protocol, and every 10 min thereafter. Cooling (0.01% L-Menthol; MEN), warming (0.2% Capsaicin; CAP), placebo (0.3% CHO fruit drink; PLA) and control (distilled water; CON) mouth rinses were utilised. Performance was quantified as peak power (PP) and work done (WD) during sprints. Heart rate (HR), core (Trec) and skin (Tskin) temperature, perceived exertion (RPE), thermal sensation (TS) and comfort (TC) were measured at 10 min intervals. Sweat rate (SR) was calculated from Δ nude body mass. ANOVA was used to determine differences between conditions, and over time.
RESULTS: PP reduced over time ($P<0.05$), however no change in performance was observed ($P>0.05$) between trials (MEN 9.7±2.0 W, CAP 9.3±2.0 W, PLA 9.7±2.2 W, CON 9.6±2.4 W). Total WD did not differ between trials (MEN 67±14 kJ, CAP 65±16 kJ, PLA 67±15 kJ, CON 67±18 kJ).
TC was lower ($P<0.05$) in MEN (3.0±0.7) with no difference between CAP (3.5±0.6), PLA (3.6±0.7) and CON (3.4±0.9). RPE (MEN 16±2, CAPS 16±1, PLA 16±1, CON16±1) and TS (MEN 6.5±0.6, CAPS 6.7±0.3, PLA 6.6±0.4, CON 6.6±0.6) were not different between trials ($P>0.05$). RPE, TS and TC increased over time ($P<0.05$).

Despite increases from baseline (P<0.05), no between trial difference (P>0.05) existed in HR (MEN 156±14 b.min-1, CAP 154±13 b.min-1, PLA 156±15 b.min-1, CON 153±12 b.min-1) , Trec (MEN 37.9±0.3°C, CAP 37.9±0.3°C, PLA 38.0±0.2°C, CON 37.9±0.4°C) or Tskin (MEN 36.7±0.5°C, CAPS 36.7±0.7°C, PLA 36.8±0.7°C, CON 36.6±0.7°C). SR was equal in all trials (P>0.05; MEN 1.4±0.7 L.hr-1, CAP 1.4±0.7 L.hr-1, PLA 1.4±0.8 L.hr-1, CON 1.5±0.7 L.hr-1).
CONCLUSION: Despite improved thermal comfort via menthol, ISP did not improve. Capsaicin did not alter thermal perception or ISP. Alterations to the intervention e.g. mouth rinse frequency/duration subsequently leading to a greater change in thermal perception may alter ISP, however based on these data, the reduction in ISP over time in hot conditions is not influenced by altering thermal perception. This is likely due to the demands of this type of activity.

PRE-COOLING WITH OR WITHOUT COOLING APPLIED DURING EXERCISE IN THE HEAT ON CYCLING PERFORMANCE

MOSS, J.

UNIVERSITY OF ROEHAMPTON

INTRODUCTION: Pre- and per-cooling can improve exercise performance in the heat; however, the mechanism of benefit is likely to differ. Pre-cooling reduces the physiological strain during exercise in hot environmental temperatures whereas per-cooling seems to improve exercise by improving perceived, rather than actual strain. The aim of the present study was to investigate the effects of cooling strategies applied before exercise and during exercise on pre-loaded 15 min time trial performance (TT) in the heat (40 °C, 50% RH).
METHODS: Nine male, trained, non-acclimated cyclists (32.1 ±10.3 y, 183.5 ± 6.48 cm, 75.8 ± 8.93 kg, and 65 ± 6.5 ml.min.-1kg-1) participated. Participants completed five experimental trials, a temperate control (CON) and 4 in the heat - no cooling (HOT), pre-cooling (HOTPRE), pre-cooling and neck per-cooling (HOTPRE+PER), and neck per-cooling (HOTPER). Pre-cooling trials began with 30 min of cool water (22°C) immersion. Participants completed a 45 min preload exercise (50% VO2max), followed by a 15 min TT. Mean temperatures (core, skin, and head) and heart rate (HR) were measured every 5 min during preload and 3 min during TT, ratings of perceived exertion (RPE), thermal comfort (TC) and thermal sensation (TS) were measured every 5 min during the preload.
RESULTS: Distanced covered during the TT was greatest in CON (17.1 ± 1.6km; P<0.05). There were no differences between HOT (15.7 ± 1.6km), HOTPER (15.7 ± 1.5km), HOTPRE (15.9 ± 1.5km), and HOTPRE+PER (15.8 ± 1.5km) (P > 0.05). Precooling lowered mean core and skin temperature during the 45 min; however, there was a greater rate of rise in precooling trials during the pre-load (0.05°C.min-1 versus 0.03°C.min-1). Water immersion lowered rectal temp by 1 ± 0.2 °C and mean skin temp by 5 ± 0.6 °C and did not reach pre immersion measurements until 22± 2 min during preload, these results ran parallel with RPE, TC and TC which, were lower for the first 20-25 min during the pre-cooling trials. Neck per-cooling lowered mean neck skin temperature (P<0.05) but had no effect on other physiological measurements. Participants reported to have a lower TC and TS during HOTPER compared to HOT for the first 30 min of preload.
CONCLUSION: Pre-cooling was able to reduced physiological strain but neither pre-cooling nor per-cooling improved TT performance in the heat.

THE EFFECTS OF ACUTE FLUID INGESTION ON RECOVERY AND SUBSEQUENT BOUTS OF SHORT-TERM HIGH-INTENSITY EXERCISE PERFORMANCE WHEN FLUID LOSS IS MINIMAL.

BARGH, M., KING, R., GRAY, M., JONES, B.

LEEDS BECKETT UNIERSITY

INTRODUCTION: Hydration guidelines suggest fluid ingestion is required to offset fluid losses <<2% body water loss> and minimise fluid gains . Fluid loss is usually minimal within short-duration, high-intensity exercise in cool environmental conditions and thus acute rehydration is not recommended, although it may attenuate negative physiological and perceptual variables. This study investigated the efficacy of acute fluid ingestion in excess of fluid replacement requirements on the recovery and subsequent response of physiological and perceptual measures and performance of short-term, high-intensity exercise.
METHODS: Sixteen male team-sport athletes completed a familiarisation, and two experimental trials. Experimental trials were conducted in a crossover counterbalanced design, separated by 5-7 days. Participants performed two , 2 minute self-paced high-intensity exercise bouts on a Wattbike cycle ergometer, interspersed with a 7-minute recovery period with either fluid or no fluid available. Measures of performance , perceptual , cardiovascular and haematological responses were collected.
RESULTS: There were likely trivial differences in mean change scores between B1 and B2 in PO <0.8%; ±5.7%> and TD <-0.0%; ±2.0%> with F compared to NF. F possibly reduced BLa during recovery <-9.73%; ±9.19> and B2 <-9.32 ±10.23>; likely lowered POsm <-0.83%; ±0.58%> and PV% <-2.41%; ± 1.91%> during recovery. After recovery with F, participants reported most likely lower TS <-1.32; ±0.41,> and very likely lower MD <-1.51; ±0.82> compared to NF. After B2 individuals were likely to report lower TS <-1.49 AU; ±0.37>, MD <-1.22 mm; ±0.82> and likely higher TC <0.47 AU; ±0.58> in F. RPE was possibly reduced in F <0.19 AU; ±0.38>.
CONCLUSION: Despite no changes in performance when participants consumed fluid, they had improved ratings of perception and maintenance of physiology when consuming fluid, which may be beneficial, challenging current recommendations .
McDermott, B.P., Anderson, S.A., Armstrong, L.E., Casa, D.J., Cheuvront, S.N., Cooper, L., Kenney, W.L., OConnor, F.G. and Roberts, W.O., 2017. National Athletic Trainers Association Position Statement: Fluid Replacement for the Physically Active. Journal of athletic training, 52<9>, pp.877-895.

CAN TRIATHLETES USE ADDITIONAL CLOTHING TO HEAT ACCLIMATE WHILE TRAINING IN A TEMPERATE ENVIRONMENT?

STEVENS, C., HEATHCOTE, S., PLEWS, D., LAURSEN, P., TAYLOR, L.

SOUTHERN CROSS UNIVERSITY

INTRODUCTION: Heat acclimation is beneficial for endurance performance in the heat, however, training in the heat is not always practical. Therefore, the acute and chronic physiological and perceptual responses to wearing warm clothing during outdoor endurance training in temperate environments was assessed; to determine if this strategy could increase the heat load and induce heat acclimation for athletes training in temperate environments.
METHODS: Trained male triathletes completed (a) randomised cross-over cycling sessions (n=7) wearing shorts and a short sleeve top (NORM) or additional clothing of full length pants, jacket, gloves (AC), separately; then (b) a randomised control trial (n=15) where two performance-matched groups completed a 2-week endurance cycling/running program wearing NORM or AC, in 18±4°C and 67±12% RH. In (b), participants completed three separate 60 min pre-loaded cycling time-trials (familiarisation, pre- and post-program) in 33°C

and 55% RH. Core and skin temperatures, heart rate, sweat rate, perceived exertion, thermal sensation, thermal comfort and training load were measured.
RESULTS: A magnitude-based inference approach was used for data analysis and effect sizes (ES) are reported with 90% confidence intervals. In (a), moderate increases were observed in AC vs. NORM for the change in mean core temperature (0.4±0.3°C, ES=1.16±0.55), change in maximum core temperature (0.5±0.3°C, ES=1.07±0.48) and sweat rate (0.24±0.16 L.h-1, ES=1.04±0.59). A small increase in mean heart rate (3±3 bpm, ES=0.32±0.28) was observed as well as a 'very likely' (% difference=22.4±7.1) and 'most likely' (% difference=42.9±11.9) increase in thermal sensation and thermal comfort, in AC vs. NORM. In (b), all training was completed in the required attire, and training loads were similar, however, there were no signs of heat acclimation, and changes in mean power output were unclear (NORM=180±15 W and AC=186±26 W, ES=0.31±0.87).
CONCLUSION: Endurance training in AC while outdoors in a temperate environment increased physiological strain and sensations of warmth and warm discomfort, suggesting that this strategy can increase the heat load of a training session. However, implementing AC across a two-week training program in a temperate environment was not a performance enhancing strategy for triathletes. Future research should investigate different clothing materials for the purposes of increasing the heat load, and combine other practical heat acclimation techniques (e.g. hot-water immersion and sauna), with the use of additional clothing to induce heat adaptation.

OP-BN46 Ageing

EFFECT OF TRAINING INTENSITY AND AGE ON TRICEPS SURAE MUSCLE DIMENSIONS – AN MRI STUDY

LÉTOCART, A.1, SHI, Y.1, MABESOONE, F.2, COUPPÉ, C.3,4, CHARLEUX, F.5, CANON, F.1, MARIN, F.1, MAGNUSSON, S.P.3,4, GROSSET, J.F.1,6

1UNIVERSITÉ DE TECHNOLOGIE DE COMPIÈGNE FRANCE, 2 CH COMPIÈGNE-NOYON FRANCE,3 ISMCDENMARK,4 CENTER FOR HEALTHY AGING DENMARK, 5 ACRIM-POLYCLINIQUE SAINT CÔME FRANCE,6 PARIS 13 UFR SMBH FRANCE

INTRODUCTION: Muscle ageing is known to be associated with a marked decrease in muscle mass and muscular performances with an increase in the risk of fall. It has been clearly shown that resistance training (RT) improves Triceps Sural (TS) muscles force and volume which has been related to an improvement in motion capability and stability1. Nevertheless, the optimal training intensity leading to maximal muscle changes in old subjects remains unknown. Thus, the aim of this study is to compare muscle volume changes between high versus moderate RT programs applied to TS muscles in young and old men.
METHODS: Healthy young (YM55, n=7, age 25.6 ± 3.6yrs) and old men (n=14) were recruited and assigned to a 12 weeks RT program (3 times/week) on TS muscle. YM as well as an old men group (OM55, n=7, age 69.9 ± 3.6yrs) took part in a moderate training program corresponding to 55% 1RM, while a second group was imposed a high training intensity of 80% 1RM (OM80, n=7, age 71.4 ± 5.7yrs). Each groups received the exact same training volume on TS (Reps x Sets x Intensity) using seated calf machine. TS muscles were scanned using a 1.5T MRI scanner from the calcaneus to patella before and after RT period. Anatomical Cross Sectional Area (ACSA) of each of three individual TS muscles were determined every 6 slides (15.6mm) all along the muscle excursions. The ACSA-muscle length curves of each muscle were then plotted and the best minimal fitting polynomial regression for each of these curves (third or fourth order) was defined and used to calculate muscle volume.
RESULTS: After training, mean ACSAs in Lateral Gastrocnemius (LG) were only significantly increased in YM55 and OM55 respectively between 40 to 70% and between 45 to 65 % of the relative muscle length. Mean ACSAs in Medial Gastrocnemius (MG) were significantly increased in the three training groups: only at 25% for YM55, between 50 to 70% for OM55, and between 40 to 70% of the relative muscle length in OM80. For Soleus muscle, an increase in ACSA was found in YM55 and OM55 only, respectively between 55 to 60% and between 50 to 65 % of the relative muscle length. TS muscle volume were significantly increased after a 12-w RT by respectively +2.3% for YM55, +5.5% for OM55, and +3.2% for OM80. Muscle volume was significantly increased in LG and MG muscles.
CONCLUSION: The present study shows for the first time that strength training in young/old subjects and applying moderate or high intensities do not lead to an increase in ACSA homogeneously throughout the muscle length. Moreover, training at moderate intensity seems to lead to a significant increase in muscle ACSA and volume in the same extent as reported in the high intensity group (OM80). Thus, we highlighted that there is no additional gain on muscle dimensions between training intensities of 55% and 80% 1RM in old subjects to counteract the loss of muscle mass due to aging.

EFFECT OF TRAINING INTENSITY AND AGE ON ACHILLES AND PATELLAR TENDON

LÉTOCART, A.J.1, MABESOONE, F.2, COUPPÉ, C.3,4, CHARLEUX, F.5, CANON, F.1, MARIN, F.1, MAGNUSSON, S.P.3,4, GROSSET, J.F.1,6

1 UNIVERSITÉ DE TECHNOLOGIE DE COMPIÈGNE FRANCE, 2 CH COMPIÈGNE-NOYON FRANCE,3 ISMC DENMARK,4 CENTER FOR HEALTHY AGING DENMARK, 5 ACRIM-POLYCLINIQUE FRANCE,6 PARIS 13 UFR SMBH FRANCE

INTRODUCTION: Age is known to be associated to changes in muscle-tendon architecture and properties leading to alteration in mobility and balance. However, it has been shown that resistance training (RT) improves muscle-tendon properties which were associated with increased balance ability. Nevertheless, the optimal training intensity leading to tendon adaptations in old subjects remains unknown. Thus, the aim of this study is to investigate the effect of resistance training at moderate or high intensity (respectively MRT and HRT) on architectural and mechanical properties of the Patellar (PT) and Achilles tendon (AT) in young and old men.
METHODS: Healthy young (YM55, n=7, age 25.6 ± 3.6yrs) and old men (n=14) were recruited and assigned to a 12 weeks RT program (3 times/week) on Triceps Surae (TS) and Quadriceps muscles. YM as well as an old men group (OM55, n=7, age 69.9 ± 3.6yrs) took part in a moderate training program corresponding to 55% 1RM, while a second group of old men was imposed a high training intensity of 80% 1RM (OM80, n=7, age 71.4 ± 5.7yrs). Each groups received the exact same training volume on QF and TS using: leg press, leg extension and seated calf machine. Tendon architecture was investigated using a 1.5T MRI scanner before and after RT period. Cross Sectional Area (CSA) of AT and PT was determined every 10% of tendon length and were summed. Mechanical properties of free and total AT, PT and deep aponeurosis of Vastus Lateralis muscle (VL) were investigated using ultrasound technique at maximal force.

RESULTS: Regarding to tendon architecture, training leads to an increase in AT and PT CSA in OM55 and OM80 ($p<0.05$) while no changes were reported in YM55 (OM55: respectively +2.0% and 2.2%; OM80: +2.5% and +1.4%). Regarding to tendon mechanical properties, a 12-w RT period leads to an increase in free AT force and stiffness ($p<0.05$) in OM80 (+25.6% and +54.7% respectively), OM55 (+20.2% and +31.3% respectively), and YM55 (+16.8% and +13.3% respectively). Total AT stiffness has also increased in the three groups (OM80: +25.9%; OM55: +19.3%; YM55: +8.6%). For PT, an increase in force and stiffness were found in OM80 (+29.4%; +41.2%), OM55 (+30.6%; +29.4%), and YM55 (+24.4%; +26.1%) after training. Finally, VL aponeurosis stiffness was also increased after the intervention period by +19.6% for OM80, +16.8% for OM55, and +14.3% for YM55.
CONCLUSION: The present study shows for the first time the effects of different resistance training intensities on tendon adaptations with age. Interestingly, we highlighted that moderate RT leads to the same extend of tendon changes (architectural and mechanical properties) as compared with high RT in old men. Moreover, the two investigated tendons shows similar changes after training whatever the considered group. Thus, we evidenced that training with high intensity in old men do not lead to higher gains in tendon architectural and mechanical properties.

INFLUENCE OF POSITIVE AND NEGATIVE DUAL TASK PERFORMANCE IN OLDER ADULTS WHILE WALKING

WANSTRATH, M., SCHULZ, S., WOLLESEN, B.

UNIVERSITY HAMBURG

INTRODUCTION: Dual-task related changes in performance are usually interpreted as interference due to competing demands for attention resources needed for both tasks and depend on one's ability to properly allocate attention between two tasks. Dual-task interference is quantified by calculating Dual task costs (DTC) for each task. Negative DTC values indicate that performance deteriorated in the dual-task relative to the single-task, whereas positive DTC values indicate a relative improvement in DT performance (Plummer, 2015). Different models to explain the contradictory results for the DTC exist (Wollesen et al., 2016). The aim of this explorative study was to compare the differences of demographics, comorbidities and physical functioning of older adults who improved or decreased their walking performance while walking with a visual-verbal Stroop task.
METHODS: Forty participants (72.58±6.52 years) performed a Single task and a Dual task condition (visual-verbal Stroop task) while walking on a treadmill. Gait parameters (step length, step width, and gait line) were measured at 100 Hz for both conditions. Demographics, comorbidities and physical functioning were assessed (SF-12, FES-1, hand grip force, MMST, SPPB). Two subgroups with 21 persons with positive (DTC-Pos) und 19 persons with negative DTC (DTC-Neg) were built depending on the changes in gait kinematics. ANOVA tested subgroup differences in baseline characteristics (SF-12, FES-1, hand grip force, MMST, SPPB) by using SPSS 24.
RESULTS: The baseline characteristics between the subgroups showed significant differences in gait speed ($F(39)=6.68$, $p=.014$; $\eta p2=.150$) and hand grip force($F(39)=5.39$,$p=.026$; $\eta p2 =.127$). The mean (±SD) gait speed in the DTC-Pos group was 5.12±1.08km/h and 4.31±0.89km/h in the DTC-Neg group. In the DTC-Pos group the mean hand grip force (25.84±10.8kg) was bigger than in the DTC-Neg (16.25±7.46kg) group. No significant differences were found for SPPB, MMST, SF-12, and FES-I. Indeed the subgroup with negative DTC showed overall lower values for the SPPB, MMST, SF-12, and FES-I.
CONCLUSION: The results of this study showed a clear trend from differences in baseline characteristics (SF-12, FES-1, hand grip force, MMST, SPPB) between negative and positive DTC performer. There are several influences on the magnitude and pattern of dual-task interference that need to be considered when implementing and interpreting dual-task assessments. To date there are only a few studies which deal with the influence of differences in baseline characteristics between positive and negative DTC performer. Further analyses are needed to confirm these results.

EXPANSION OF MOTOR UNIT SIZE IN LIFELONG ATHLETES MAY ATTENUATE NEUROMUSCULAR IMPAIRMENTS IN OLDER AGE

PIASECKI, M., IRELAND, A., PIASECKI, J., DEGENS, H., STASHUK, D.W., SWIECICKA, A., RUTTER, M.K., JONES, D.A., MCPHEE, J.S.

UNIVERSITY OF NOTTINGHAM. MANCHESTER METROPOLITAN UNIVERSITY.

INTRODUCTION: The age-related loss of muscle mass is due to both muscle fibre atrophy and loss of fibres associated with declining motor unit (MU) numbers (Piasecki et al., 2015). Fibres denervated as motor units are lost will be degraded, or they can be 'rescued' by reinnervation from a nearby surviving axon which increases the size of the surviving motor units. A failure of reinnervation accelerates muscle loss and distinguishes sarcopenic from non-sarcopenic older men (Piasecki et al, 2018). Thus, any intervention that enhances reinnervation will preserve muscle mass for longer into older age. The purpose of the present study was to compare estimates of motor unit size (indicative of the amount of reinnervation) between young and older power, endurance and non-athletes. Based on the hypothesis that regular intense exercise enhances reinnervation, it was expected that athletic old would have larger MU than non-athletic old.
METHODS: Eighty-six male participants were divided into six groups based on age and discipline. Groups consisted of young controls (n=15), young endurance athletes (n=9), young power athletes (n=11), old controls (n=22), old endurance athletes (n=18) and old power athletes (n=11). All athletes were competing in their respective sports at the time of testing and all were classed as advanced or elite based on their age-graded performance. Cross-sectional area (CSA) was obtained by MRI and MU size was obtained by intramuscular electromyography (iEMG) in the vastus lateralis (VL). Statistical analysis was performed with a two-way ANOVA with age and discipline as fixed factors, followed by interaction contrasts and simple main effects analysis. Significance was accepted at $p<0.05$.
RESULTS: All young groups had larger muscles and smaller MUs than old ($p<0.001$). Power athletes had the largest muscles ($p<0.001$), but interaction contrasts revealed a greater age-related difference between young and old power athletes ($p=0.001$) when compared to endurance athletes and controls. Interaction contrasts performed following a significant age*discipline interaction ($p<0.001$) revealed that the age-related increase in MU size was greater in endurance ($p=0.038$) and power athletes ($p=0.013$) compared to controls, with no difference between the two athletic disciplines ($p=0.292$). Furthermore, the old endurance and power athletes had larger MUs than old controls ($p<0.001$).
CONCLUSION: The cross-sectional evidence presented here suggests that although power athletes may lose the greatest amount of muscle with age, they retain more than age-matched controls. The expansion of MU size is greater in older athletes of both disciplines, which suggests the older athletes are more successful at reinnervation and retaining muscle fibre number.

AGING AND STRENGTH TRAINING INFLUENCE ON COMMON INPUTS TO ALPHA-MOTONEURONS DURING LOW- AND HIGH-FORCE ISOMETRIC KNEE EXTENSIONS

WALKER, S., AVELA, J., WIKGREN, J., MEEUSEN, R., PIITULAINEN, H., BAKER, S.N., PARVIAINEN, T.
UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: Aging is associated with reduced maximum force production and force steadiness during low-force tasks, but these can be improved by training. Coherence measures coupling between two neurophysiological signals in the frequency domain. However, functional meaning of coherence magnitude, particularly regarding neuromuscular adaptation in aging and training, remain unclear. This study investigated effects of strength training on cortico- and intermuscular coherence in untrained young and older individuals.
METHODS: Significant coherence between vertex EEG channels (i.e. F3-F4, C3-C4, P3-P4) and EMG signals was observed in 11/15 YOUNG (aged 18-30 years) and 11/13 OLD (aged 66-73 years) subjects, who were included in subsequent analyses. Maximum isometric knee extension force (MVC), as well as 70%MVC (16×6s) and 20%MVC (4×30s) tasks were performed before and after 14 weeks of strength training. MVC and force steadiness were used as performance parameters. 24-channels of EEG and EMG of vastus medialis and lateralis muscles were recorded during the submaximal contractions. Peak coherence values were extracted for 15-30Hz and 40-60Hz bands both for EEG-EMG (i.e. corticomuscular) and EMG-EMG (i.e. intermuscular) coherence.
RESULTS: Both YOUNG and OLD improved MVC (24±17% versus 11±13%, P=0.051 between groups), whereas only OLD improved force steadiness during 20%MVC (14±23% versus 17±13%, P=0.68 between-groups). Before training, YOUNG demonstrated stronger 15-30Hz intermuscular coherence during 20%MVC (0.074±0.041 versus 0.022±0.013, P=0.001 between groups) and 70%MVC (0.163±0.083 versus 0.066±0.036, P=0.003 between groups) tasks. However, OLD increased 15-30Hz intermuscular coherence compared to YOUNG during 20%MVC after training (-9±36% versus 84±81%, P=0.004 between-groups). Conversely, only YOUNG increased 40-60Hz intermuscular coherence during 70%MVC (from 0.073±0.054 to 0.104±0.046, P=0.007 within-group). This change in 40-60Hz coherence was positively related to improved MVC (r=0.416, P=0.054, n=22). No between-group differences or training-induced changes were observed in corticomuscular coherence.
CONCLUSION: Age-associated differences and training-induced changes in intermuscular coherence were observed in the present study. Training-induced changes in 15-30Hz intermuscular coherence coincided with improved force steadiness in OLD, while changes in 40-60Hz intermuscular coherence accompanied large increases in MVC in YOUNG. This data suggests that coherence represents functional relevance for low- and high-force performance tasks, respectively. Given that no differences were observed in corticomuscular coherence, the observed changes may have been due to non-cortical sources.

EFFECT OF KNEE JOINT ANGLE AND ANTAGONIST CO-ACTIVATION ON TORQUE STEADINESS IN YOUNG AND OLDER MEN

WU, R.1, DELAHUNT, E.1, DITROILO, M.1, LOWERY, M.2, DE VITO, G.1
UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: During submaximal isometric contractions, the ability to precisely control movement execution, i.e. force steadiness, is impaired in older adults. However, the findings of published studies investigating the effect of age on force steadiness during sustained muscle contractions are still inconsistent, probably due to the different testing methodologies. The aim of this study was to investigate the effect of joint angle (muscle length) on steadiness of knee extensors (KE) and the associated neural activation of agonist and antagonist muscles in young and older men at varying intensities of isometric contraction.
METHODS: 10 young (24.6 ± 2.8 years) and 11 older (70.3 ± 1.9 years) healthy men participated. Maximal voluntary isometric contraction (MVIC) of the KE and knee flexors was examined at 90° and 60° of knee flexion (0° = full extension). At each angle, participants performed, in a random order, 12-s isometric contractions at 20%, 50% and 80% of KE MVIC. The coefficient of variation (CV) of the torque and the root mean square (RMS) of surface EMG were estimated over the middle 8-s of each contraction intensity. To quantify the neural activation, at each intensity, EMG RMS values for each muscle were normalized to the RMS amplitude for that muscle when acting as an agonist during MVIC at the same angle.
RESULTS: Age-related impairment in steadiness was observed only at 20% MVIC ($p < 0.05$). CV (all $p < 0.05$) and the associated agonist activation (all $p < 0.001$) and antagonist co-activation (all $p < 0.05$) were higher at 90° than at 60° of knee flexion over all contraction intensities. When the responses in terms of steadiness ($p < 0.05$) and neural activations (all $p < 0.01$) between the two angular positions were compared, young men exhibited a larger difference than older men. In addition, KE torque steadiness (CV) was correlated with agonist activation (90 : $R2 = 0.33$, $p < 0.001$; 60 : $R2 = 0.22$, $p < 0.01$) and antagonist co-activation (90 : $R2 = 0.17$, $p < 0.05$; 60 : $R2 = 0.14$, $p < 0.05$) at both angles but only in older men.
CONCLUSION: These findings suggest that, at least for voluntary knee extension contractions, torque steadiness depends on the joint angle and concerning age, it is impaired only at the lowest considered contraction intensity (20% MVIC). Moreover, our results support previous studies, which suggested that older adults may tend to rely on the antagonist co-activation to stabilise/protect knee joint stability and maintain a constant torque output.

OP-SH14 Physical activity, major skills / competencies in youth

ASSOCIATIONS BETWEEN IMPLICIT ASSOCIATIONS TOWARDS SPORT, BASIC MOTOR COMPETENCIES AND THE AMOUNT OF EVERYDAY PHYSICAL ACTIVITY IN 11-14 YEARS OLD CHILDREN

MUECKE, M., LUDYGA, S., ANDRAE, C., HERRMANN, C., GERBER, M.
UNIVERSITY OF BASEL

Background
Interventions with the target to increase physical activity usually focus on conscious regulatory processes and explicit attitudes. Recent research aggregated evidence, that not only explicit attitudes, but also implicit associations and attitudes influence behavior (Rebar et al., 2016). Implicit associations are spontaneous, involuntary attitudes or evaluative reactions on a non-conscious level. In the present study,

we investigated if implicit attitudes towards sports are related to basic motor competencies and everyday moderate-to-vigorous physical activity (MVPA).
Method
Participants were recruited from 3 different schools in Basel, Switzerland, and Leipzig, Germany (N=91, age 11-14 years, 57 % male). Implicit associations towards sport were measured using a computerized, reaction time-based single target implicit association test (ST-IAT). Basic motor competencies were assessed with the test battery MOBAK-5 (Herrmann & Seelig, 2017). Accelerometry over the course of 7 days was used to measure MVPA in everyday life. For ST-IAT, a D-score (Greenwald, Nosek, & Banaji, 2003) was calculated, ranging from -2 to 2 with scores closer to 0 interpreted as less extreme standing on the construct of interest. Partial correlations, controlling for ST-IAT sequence, were calculated. P-values were considered statistically significant at a level of $p \leq 0.05$.
Results: Data from 2 participants were excluded due to missing values. Descriptive statistics revealed a mean (SD) D-Score of 0.08 (0.3), mean MVPA of 127 (43) minutes per day and a mean MOBAK score of 6.6 (2.9), respectively. Analysis of partial correlations showed a significant positive correlation of the ST-IAT D-score with the MOBAK sum score ($r(89)=.31$, $p=.003$). No significant correlations were found with MVPA ($r(84)=.05$, $p=.676$).
Discussion: The results suggest that in children aged 10-14 years, basic motor competencies, but not the amount of everyday MVPA, are related to non-conscious attitudes towards sports. One interpretation – beyond potential reciprocal interferences - is, that the quality of exercise might contribute more to a positive implicit image of sport than the mere quantity of activity. This might be relevant for future interventions with the target to increase physical activity.

DIFFERENCES IN THE PERCEIVED PHYSICAL ABILITY AMONG DIFFERENT MOTOR PERFORMANCE BETWEEN GERMAN AND CHINESE CHILDREN

YIN, X.1, HOHMANN, A.2, YA, P.2, YANG, S.1, ZHANG, B.1, YANG, T.3
1: SHRISS, 2:UBT, 3: DP LAB

Introduction: According to Bandura(Bandura 1977), self-efficacy is the cognitive mechanism which mediates information on personal capacities to successfully execute necessary courses of action in a specific domain. Thus, perceived ability regarding to motor activity represents a frame of reference to explain links between cognitive processes and physical performance. Given the importance of self-efficacy in the motor main, the purpose of the study was to compare psychological trait self-efficacy among children in the age group of 6 to 8 yrs from the German and Chinese primary schools.
Methods: Participants were 125 German (Nmale=58; age M = 93.18 mon, SD = 5.98) and 512 Chinese children (Nmale=275; age M = 86.35 mon, SD = 5.94) who completed Perceived Physical Ability Scale for Children(PPASC) developed by Colella (Colella, et al. 2008) assessing their self-efficacy, and the German Motor Test 6-18 (GMT 6-18; Boes & Schlenker, 2016) plus a ball throw. The participants were divided into three groups according to the overall performance of GMT 6-18: the talent group comprised of the best 20 percent of the participants. The lowest 20 percent were classified as the promotion group. The medium fraction of the children (60 percent) entered the general group.
Firstly, Two-way ANOVA was executed to determine whether there were a significant interaction and/ or significant differences among three motor performance groups and two countries, in regard to children's PPASC scores.
Secondly, two one-way ANOVAs were respectively performed to test whether there were significant differences among three motor performance groups in regard to Chinese children's PPASC scores, and in regard to German children's.
Result
The test result showed that there was not a significant interaction effect of different countries and motor performance levels ($F=2.04$, $P>0.05$). Neither was there a significant difference among three motor performance groups ($F=2.54$, $P>0.05$). However, a statistically significant difference was found between nationalities in self-efficacy ($F=13.25$, $P=0.00$).
A statistically significant difference was found among three motor performance groups (talent group, general group, and promotion group) in regard to Chinese children's PPASC scores ($F = 9.356$, $p = 0.00$). Post hoc Analysis indicated that there was a significant difference between Chinese talent group and Chinese promotion group ($p < 0.05$, $d = 0.45$), in regard to their PPASC scores. Also, there was a significant difference between Chinese general group and Chinese promotion group ($p = 0.00$, $d = 0.54$), in regard to their PPASC scores. However, the result with respect to German children's PPASC scores ($F = 1.52$, $p > 0.05$) among the three motor performance group was not significant.
Discussion: The results demonstrate the magnitude and direction of the relation between self-efficacy and motor performance varies considerably, which is consistent with previous studies (McAuley, E., & Blissmer, B. 2002). Growth environment and cultural background can affect the strength of the relationship. Chinese motor talent group and the general group were both significantly better on perceived physical ability than promotion group.

SHOULD INTEGRATIVE NEUROMUSCULAR TRAINING BE IMPLEMENTED EARLIER THAN MIDDLE CHILDHOOD?

WALKER, L.J., DUNCAN, M., EYRE, E.
COVENTRY UNIVERSITY

Fundamental motor skills (FMS) competency encompasses combining cognitive processing, correct FMS patterns and force production effectively. Effective development of FMS may be better achieved through integrative neuromuscular training (INT) which improves early childhood (EC) strength, power, fitness and FMS (Faigenbaum et al. 2011). Despite the potential of INT as an intervention method, research

showing its efficacy in older children is scarce. Therefore, the study aims to determine the effects of a 6-week INT programme on FMS proficiency and health-related fitness (HRF) in middle childhood (MC; 9-10year olds); replacing 1 of 2 PE lessons (UK) per week. Following institutional ethics approval 59 children, (28 INT group; 9.62±.48years and 31 control group (CNT); 9.96±.29years) took part. Standing and seated height (cm) was measured using a Stadiometer (Seca213, Germany). Body mass (kg) and fat (%) were assessed using Bioelectrical Impedance (TanitaBF305, Tanita Inc, Japan). Maturation (PHV) was calculated guided by Mirwald et al. (2002). FMS was assessed using The Test of Gross Motor Development-2 (Ulrich, 2000). HRF included upper body power, assessed with a 2kg seated medicine ball throw (MBT); light gates (Fusion Sport, Coopers Plains, Australia) measured 10m sprint speed (SS) and standing Long jump (SLJ) distance assessed with a tape measure. Assessments were conducted pre, immediately post and at post-6-weeks (P6). Repeated measures ANCOVA results, controlling for PHV, revealed total FMS only improved in the INT group from pre to post (MPost-Pre= 2.99; p>.05), then decreased post to P6 though not significant. Locomotor FMS showed a main effect; performance improved pre to post for the INT group but not the CNT (MPost-Pre= 1.43 vs .67; p>.05). SS showed a group (INT vs. control) by time (pre vs post vs P6) interaction (p>.001); bonferroni post hoc pairwise comparison identified INT and CNT ran faster pre to post (MPost-Pre= -.23 vs -.14). The INT group upheld a faster speed P6 but the CNT ran slower (MP6-Post= -.03 vs .19). The samples SLJ increased while MBT decreased (MPost-Pre= 13.62 and -31.51). Results suggest combining INT and PE improves total and locomotor FMS short-term, and SS long-term compared to standalone PE in MC; though INT may not be as effective as reported in EC. FMS mastery is expected by MC so identifying improvements once 'mastery' has been classified may be challenging. Thus, the effective development of FMS during EC may be pivotal as FMS are expected to be mastered and sport-specifically applied in MC.

1: Université de Moncton (Canada), 2: Université de Sherbrooke (Canada)
INTRODUCTION: A key role of quality school physical education (PE) is to enable children to learn and master motor skills. The assessment of fundamental motor skills (FMS) therefore becomes essential. Limitations of existing measurement tools include being designed for clinical contexts, having age restrictions (3 - 10 years old) and not emphasizing pedagogical purposes of PE learnings (Russell et al., 2002; Sun et al., 2010; Tremblay & Lloyd, 2010). Accordingly, we developed a battery of 24 tests for their evaluation. Pilot testing took place in 7 schools (N = 1356 students) to assess feasibility, validity and reliability of these tests.
METHODS: In accordance with established standards for the development of psychomotor tests (Morrow et al., 2010), we identified the skills to be assessed, developed evaluation parameters by focusing on the performance process (quality) rather than the product, and determined the tests procedures. Other experts evaluated the face and content validity of this battery. Finally, each test was administered to targeted age groups students (2nd, 5th and 8th grade) to assess the test's feasibility and to refine evaluation parameters. This process was repeated following modifications of testing procedures aimed at improving psychometric properties. Inter-rater reliability and construct validity were assessed with Pearson correlations, Kappa statistics, Pearsons chi-squared statistics and Cramers V symmetric measurements.
RESULTS: Subsequent to the first test administration and the first feedback from PE teachers on test parameters, we modified instructions to improve clarity and adjusted the estimated time of administration for some grade levels and the training of raters. Following the 2nd and 3rd school's visits and modifications of testing procedures, acceptable to good indices of inter-rater reliability (Pearson = 0,61-0,87; Kappa = 0,55-0,83) and construct validity (Pearsons chi-squared $\chi 2$ = 98,942-124,732; Cramers V symmetric = 0,696-0,827) were found for final versions of the tests.
DISCUSSION: Our study shows that the development of this criteria-based test battery following a rigorous methodological process is complex and time intensive (over 4 years). Nevertheless, the statistical analyses led to an appropriate validity and intra-rater reliability. We are continuing to investigate the ability of this criteria-based test battery to identify known group differences. Also, a process of establishing standardized measuring procedures is already in place. This test battery could become a standard measuring tool for assessing the PE objectives within French school curricula in New Brunswick, Canada.

EFFECTS OF AEROBIC EXERCISE AND COGNITIVELY ENGAGING EXERCISE ON CARDIOVASCULAR FITNESS, MOTOR SKILLS, AND BODY-MASS INDEX IN SCHOOL-AGED CHILDREN

VAN DER FELS, I.M.J., HARTMAN, J., BOSKER, R.J., SMITH, J., VISSCHER, C.
UNIVERSITY OF GRONINGEN, THE NETHERLANDS.

INTRODUCTION: The effects of different types of exercise on physical fitness remain poorly understood in physical education settings. Two physical exercise interventions, aerobic exercise and cognitively engaging exercise, were developed for use in a primary school setting. The aim of this study was to investigate the effects of these interventions on cardiovascular fitness, motor skills, and body-mass index.
METHODS: Children (n = 407) aged 7-11 years (50.5% boys) from 22 classes, across 11 primary schools in the Northern Netherlands participated in this study. Using cluster randomization at class level, children were assigned to the aerobic exercise (APE) group, the cognitively engaging exercise (CEPE) group, or the control group (CG). The intervention groups received their intervention four times a week during physical education (PE) for a period of 14 weeks. Children in the CG followed their own PE program twice a week for a period of 14 weeks. Cardiovascular fitness, motor skills and BMI were measured before and after the intervention period. Cardiovascular fitness was assessed with the 20-m Shuttle Run Test, motor skills were assessed using items of the Körperkoordinationstest für Kinder and the Bruininks-Oseretsky Test of Motor Proficiency (2nd Edition). A factor score was calculated out of the four motor skill items. Time spent in moderate-to-vigorous physical activity (MVPA) of two PE lessons was measured with wGT3X ActiGraph accelerometers.

RESULTS: Multilevel analysis revealed no significant effects of APE and CEPE on cardiovascular fitness, motor skills, and BMI. However, a significant interaction effect between pretest and condition for BMI was found: children with a higher BMI decreased their BMI more in the APE group compared to the CG (B = -.18, p < .01) and the CEPE group (B = -.21, p < .01). There was also a significant relation between MVPA and cardiovascular fitness, independent of condition: children who exercised more in MPVA scored higher on cardiovascular fitness at the post-test (B = .06, p = 0.01).
CONCLUSION: Results reveal that APE and CEPE do not enhance cardiovascular fitness, motor skills, and BMI at group level. However, a dose-response relation between MVPA and cardiovascular fitness was found, indicating that the extent of the improvement in cardiovascular fitness is related to the time spent in MVPA. Finally, aerobic exercise is recommended for children with a higher BMI, since BMI decreases more with APE compared to CEPE or CG.

SPORTS MANAGEMENT CAREER: A STORY TO BE TOLD IN FOOTBALL.

ANGELO, L.
SEDES SAPIENTIAE INSTITUCION

There are few studies about sports management career addressing the processes of transition, their cycles and post athletic career in sports science. It is also unusual using research methods that use open interviews with athletes and post athletes which approach in a widely way the athlete's life where this topic is inserted. In the specific case of football, journalism in general, tends to explore this topic, principally intending to report situations that contradict the glamour and visibility that the athlete lives during his productive phase of the career. The modality was chosen by the influence power in national public policies, and for presenting an impressive group of athletes who experienced both amateur and professional phases. The objective of this research was to identify and analyze how it is the process of managing career among Olympic athletes in football who also lived one long-lived career in professional football from the perspective of identity transformation in the different cycles that make up the athlete's career. It is worth to discuss the formation processes of athletic identity, as well as the ways of management of professional sports career pointing its meanings and feelings during its development, in its finalization and in the construction of a new career. However, it was intentionally selected 12 athletes, 10 of them already removed from the professional activity, and 2 others yet in activity, all of them over 33 years old from several parts of Brazil. For both, the method used was the biographical narratives of Brazilian athletes who took part of at least one Brazilian team that participated of an edition of the Olympic Games between the decades of 1960 and 2000. The thesis argues that the management of sports career is made based on the relation the individual has with his subjective career and the career socially built enabling the career concept as a life project following the ideas proposed by the paradigm, Life Design

RESEARCH ON CHINA'S STRATEGIES FOR DEVELOPING WINTER SPORTS SINCE THE SUCCESSFUL BID FOR THE 2022 WINTER OLYMPICS

HOU, H.
CHINA SPORT INFORMATION CENTER

Introduction: In 2015, Beijing won the right to host the 2022 Winter Olympics. How to grasp the opportunity to develop winter sports in China is now a hot topic among the Chinese sports community.
Methods: By way of literature review, statistical analysis, expert consultation and analytical comparison, this paper discusses China's strategies for developing winter sports in recent years and does some thinking about how to further the development of ice and snow sports in the country.
Results: Winter sports in China have always been "strong in ice and weak in snow". Since Beijing was awarded the 2022 Winter Olympics, China has taken proactive measures to boost the level of its competitive winter events, including searching for talent all over the country, drawing summer athletes to winter sports and strengthening international cooperation and exchanges. In recent years, China has built national teams in all of the 102 disciplines to be contested in PyeongChang. Chinese athletes qualified for an unprecedented 55 medal events at the 2018 Winter Olympics. The country also aims to popularize winter sports to a scale large enough to benefit people of all stripes. The General Administration of Sport of China issued in 2016 "the Development Plan for Winter Sports (2016-2025)" and "the National Plan for the Construction of Winter Sports Venues and Facilities (2016-2022)",under which the government will use revenue from the sports lottery and other funds to build more venues, set up sports associations, and organize competitions and festivals for winter sports. Winter sports venue developers will be offered reasonable and flexible policies in tax reduction and land acquisition. Meanwhile, modern technologies are used by the Chinese winter sports industry to enhance the winter sports experience.
Discussion: The 2022 Winter Olympics has put winter sports development in China on a fast track, generating more public interest and government support.
However, compared with winter sports powers, China's ice and snow sports got off to a late start and has a poor foundation. The newly issued development plans have yet to be further implemented. The training of reserve talent in competitive winter sports needs to be more systematic, the training of coaches, professional teachers, instructors of social sports and professionals in areas such as science and technology, management and industry needs to be further strengthened, and there should be more types of ski resorts. Official industry-approved quality standards and support facilities need to be perfected, and the quality of service in winter sports needs to be further improved.
China should grasp the opportunities the 2022 Winter Olympics will offer, use the experience of other countries for reference and explore a road for the development of winter sports with Chinese characteristics.

THE CURRENT SITUATION, PROBLEMS AND PROSPECTS OF NON-PROFIT SPORTS ORGANIZATIONS IN CHINESE COMMUNITY

LUO, Y.

CHINA INSTITUTE OF SPORT SCIENCE

Research background:
At present, with the high-speed development of China's economy, sport plays a important role in constructing and perfecting the public sport services and it emerges with the development of tourism, leisure, entertainment, etc . The sport industry development and the advancement of sport economy are not only the instruments for the employment and the service industry but also the requirements for the adjustment of economy structure.
Research METHODS: By using the methods of documentation, expert interview, questionnaire and mathematical statistics, taking the level of economic and social development as the standard, the presentation investigated each two provinces and cities of s developed areas, moderately developed areas and underdeveloped areas in China and 6 municipal units in each province. This paper investigates and analyzes the current situation of municipal sports administrative institutions, municipal sports associations and community non-profit sports organizations, and summarizes its organizational form, form of activity, funding channels and participating groups, so as to provide basis for policies-making.
Results :
1, there are essential differences between the non-profit sports organizations in communities and the organizational forms and forms of activities of individual sports organizations and business sports clubs. The characteristics of localization are obvious, and the consumption ability is low.
2, the channels of activity funding mainly come from local financial allocation, sports lottery fund, corporate sponsorship and personal sponsorship, which are closely related to the level of local economic and social development.
3 the main purpose of sports participants is fitness, health and entertainment, and the proportion of competitive components is very small.
4 The content of 4 activities is diversified, and the trend of sports, culture and entertainment is obvious. The specific sports project is based on square dance, with table tennis, badminton and other competitive sports, as well as traditional Chinese sports such as Taijiquan, fitness Qigong and so on.
CONCLUSION: Community non-profit sport organizations show the aging and entertainment trend and have no motivation. The governments and sports administrative departments should be policy-oriented.
First, there should be policy and funding support. Second, it should be cooperated with civil affairs and caring organizations. Third, competitive and performance elements should be added so as to attract the youngsters and the middle age group.

MOTIVATIONAL ASPECTS FOR VOLUNTEER ENGAGEMENT OF THE EXECUTIVE BOARD – AN EMPIRICAL ANALYSIS OF SPORTS CLUBS IN HAMBURG, GERMANY

MINTERT, S.M., REHMER, M.

FRESENIUS UNIVERSITY OF APPLIED SCIENCES

Many sports clubs increasingly face the problem of not being able to attract enough staff members for their voluntary leadership tasks. Therefore, the willingness to devote itself to the complex and responsible tasks in a club Board is more and more diminishing. It is important to find out why many people are still investing a large part of their time in the execution of this voluntary activity and what motivates them to do so. Are selfish or altruistic aspects predominant?
This study gives an overview of motives for voluntary commitment of persons in the executive Boards of sports clubs in Hamburg. Differences and influences are examined by means of sociodemographic characteristics and structural conditions. In addition, the question arises whether this commitment may also be used as a means of social integration. Based on a quantitative data collection using a specially created questionnaire for 160 Board members from 36 sports clubs in Hamburg, the results show that the commitment is most pronounced in a life stage where people are already very heavily burdened by family and work. Women are not as underrepresented as often suspected. The motives vary, but mainly focus on social and humanistic aspects.
The original form of organization of a sports club must reflect its social position due to increasing consumption and non-union. Club specific structures are no longer necessarily the reason for commitment. Given the results of motivational aspects, a series of recommendations for sports clubs is provided in order to successfully attract and retain voluntary members of the Management Board.

EXPLORING NEW DEVELOPMENT FRONTIERS: THE ROLE OF YOUTH, SPORT AND CULTURAL INTERVENTIONS

SADLIER, A., GIULIANOTTI, R., ESSON, J., SAAVEDRA, M., SHARMA, S.R.

LOUGHBOROUGH UNIVERSITY

Sport conjures up conflicting images in the cultural imaginary. On the world stage, it is often associated with a competitive spirit, which from a more critical perspective is viewed as being organised around the structures of patriarchy, neoliberalism and Western colonialism. Sport in this vision is not entirely inclusive and seems to be removed from cultural life. Yet, sport can also be used to connect people and to enable social change. An example of this is the Sport for Development and Peace sector, which has expanded rapidly over the past decade, and which aims to use sport to address human development goals, such as tackling poverty and gender inequality. The extent to which sport can be a panacea for social inclusion and transformation in an unequal world has been the focus of substantial research in diverse locations.
The international ESRC-funded 'New Development Frontiers? The Role of Youth, Sport and Cultural Interventions' project at Loughborough University seeks to contribute significantly to this literature, through a multi-site comparative investigation of the role of sport, cultural and educational programmes in promoting sustainable development in three low- to middle-income countries – Cape Verde, Nepal and Timor-Leste.
This paper will draw on emergent findings from fieldwork undertaken with NGOs in two of our three research locations: Delta Cultura and Empowering Women of Nepal . The data discussed will be taken from qualitative interviews with various stakeholders in the SDP sector, notably representatives of NGOs, governmental organisations and sports federations, and Participatory Action Research with pro-

gramme users. The paper will explore the role of local traditions; the danger of idealising sport; the difficulties facing the SDP sector, such as lack of resources; and the underexplored relationships between sport and other cultural interventions on social programmes.
Keywords: Sport for Development and Peace ; Youth; Sustainable Development; Cultural Interventions; Cross-cultural qualitative research; Participatory Action Research .

OP-PM05 AGEING and FRAILTY

THE PHYSIOLOGICAL AND MECHANISTIC EFFECTS OF TESTOSTERONE ADMINISTRATION DURING RESISTANCE EXERCISE TRAINING IN OLDER MEN: A DOUBLE-BLIND PLACEBO-CONTROLLED CLINICAL TRIAL

GHARAHDAGHI, N., RUDRAPPA, S., PHILLIPS, B.E., HAMROCK, C., IDRIS, I., BROOK, M.S., WILKINSON, D.J., SZEWCZYK, N.J., SMITH, K., ATHERTON, P.J.

UNIVERSITY OF NOTTINGHAM

INTRODUCTION: The andropause is associated with declines in serum testosterone (T), an associated loss of skeletal muscle mass and function (i.e. sarcopenia) and insulin resistance. Two of the major interventions purported to offset sarcopenia are T therapy and Resistance Exercise Training (RET). Nonetheless, the efficacy and global physiological impacts and mechanisms of T therapy adjuvant to RET remain poorly defined in older individuals.
METHODS: To address this, 18 non-hypogonadic healthy older men, 65-75y, BMI≤30kg.m-2 (serum T>8.3nmol.l-1) were assigned in a random double-blinded fashion to receive bi-weekly: placebo (P, saline, n=9) or T (Sustanon 250-mg, n=9) injections over 6-weeks of whole-body RET (leg-extension, leg-press, leg-curl, lat-pull-down, shoulder-press and bench-press (3-sets, 8-10 reps at 80% 1-RM)). Subjects underwent Dual-energy X-ray Absorptiometry (DXA), ultrasound of m.vastus lateralis (VL) architecture, isometric dynamometer knee-extensor Maximal Voluntary Contraction (MVC) and Oral Glucose Tolerance Testing (OGTT); finally, m.vastus biopsies were taken to quantify myogenic gene expression and activation of insulin/anabolic pathways.
RESULTS: T adjuvant to RET, augmented whole-body (53002±5240g to 56068±5262g vs. 54132±6331g to 54860±5870g, P<0.0001, ES=0.58) and appendicular lean mass gains (23887±3190g to 25571±3336g vs. 24591±3752g to 24811±3390g, P<0.0001, ES=0.52) while decreasing body fat (1194g vs. 209g, P=0.01, ES=0.29). T also augmented VL thickness gains (2.36±0.21cm to 2.61±0.13cm vs. 2.31±0.3cm to 2.45±0.28cm, P<0.0001, ES=0.73) and fascicle-length (7.18±0.8cm to 7.9±0.75cm vs. 7.7±0.19cm to 8.11±0.1cm, P=0.0008, ES=0.92) in addition to strength gains e.g. 1-RM leg-extension (69.89±15.11kg to 125.6±15.82kg vs. 61.22±29.58kg to 103.1±46.88kg, P=0.0003, ES=0.64) and MVC (166.6±32.7Nm to 210±38.33Nm vs. 164.8±51.25Nm to 194.6±44.23Nm, P=0.0119). Additionally, T augmented insulin sensitivity (e.g. Cederholm index: 54.08±12.77 to 65.41±18.1 mg·L2·mmol·L−1·mU−1·min−1 vs. 46.95±10.99 to 52.05±12.29 mg·L2·mmol·L−1·mU−1·min−1, P=0.028, ES=0.86) and gene expression related to T metabolism (Androgen Receptor: 1.4-fold; Srd5a1: 1.8-fold; AKR1C3: 2.6-fold; HSD17B3: 2.1-fold), and anabolism/myogenesis (IGF-1EA (3.6-fold), IGF-1EC (3.3-fold), Myogenin (2.7-fold), Myf6 (3.9-fold), c-Met (1.7-fold) and c-Myc (7.3-fold)). Finally, acute RE-induced phosphorylation of AKTser473 (0.088±0.07 to 0.2±0.1 vs. 0.034±0.02 to 0.089±0.06, P=0.008, ES=1.1) and mTORC1ser2448 (0.027±0.01 to 0.12±0.06 vs. 0.05±0.03 to 0.085±0.05, P=0.041, ES=0.59) was enhanced with T.
CONCLUSION: Administration of T (vs. placebo) adjuvant to RET enhanced insulin/anabolic signalling pathway activity in response to RE, while upregulating muscle T processing genes and myogenic gene regulation, perhaps explaining augmented muscle growth and insulin sensitivity. Thus, T coupled to RET is an effective short-term intervention to improve muscle mass, function and glycaemic control in older aged men.

COMBINED EFFECTS OF PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOUR ON BONE HEALTH AND FRAILTY IN ELDERLY PEOPLE: COMPOSITIONAL DATA ANALYSIS

RODRÍGUEZ-GÓMEZ, I.1, MAÑAS, A.1, LOSA-REYNA, J.1,2, RODRÍGUEZ-MAÑAS, L.3, GARCÍA-GARCÍA, F.J.2, CHASTIN, S.F.M.4, ALEGRE, L.M.1, ARA, I.1

1: GENUD, UCLM , 2: HVV , 3: HUG , 4: GCU

INTRODUCTION: Ageing is associated with a progressive decrease in bone mass and frailty, which can favor the development of osteoporosis and bone fractures and derives in loss of physical function and dependence (1). Physical activity (PA) is one of the main strategies to combat this loss of bone mass (2) and one of the keystones in the development of frailty (3). Nonetheless, due to daily time is limited, the time spent on each PA behaviour is codependent (4). The aim of this study is to analyse the relationship between bone mass and PA behaviours on bone health in elderly people using a compositional data analysis depending on the frailty status.
METHODS: We analysed 740 older people (77±4.9 y) from the Toledo Study of Healthy Aging (TSHA). The time spent in sedentary behaviour (SB), light PA (LPA) and moderate-vigorous PA (MVPA) were estimated by accelerometry. Whole-body bone mass was determined by bone densitometry (DXA) and frailty status (robust, pre-frailty and frailty) was evaluated according to the criteria proposed by Fried et al. (5). The statistical system R was used to carry out this analysis and, all models were adjusted for age, education, marital status, income, body mass index, fat mass, lean mass, alcohol intake, smoking, nutritional status, thyroid disease, arthritis and calcium, by backward elimination.
RESULTS: The combined effect of PA and SB was significantly associated with legs bone mineral content (BMC) and density (BMD) in the robust subgroup (p≤0.01) and, with whole-body and legs BMC and BMD in pre-frails older people (p≤0.05). In relation to the other behaviors, older people legs BMC and BMD were positively associated with SB (p<0.01), and legs BMC and BMD were negatively associated with LPA (p<0.01) in robust elderly. Finally, in pre-frail older people, whole-body and legs BMC and BMD were positively associated with MVPA (p<0.05). No associations were found in the frail subgroup.
CONCLUSION: This analysis provides new insights into the relationship between bone mass and the lifestyle of older people. Therefore, we identified that increasing MVPA, and maintaining or decreasing time spent in LPA and SB, respectively, contributes toward a more

favorable bone mass in the case of pre-frail elderly. Despite no clear patterns were found in frail older people, MVPA could be a good strategy to improve bone health before reaching frailty status. More studies would be necessary to understand these associations in robust and frail older population.

HEMODYNAMIC RESPONSES TO BLOOD FLOW RESTRICTION TRAINING FOR OLDER ADULTS

SCOTT, B.R.1, PEIFFER, J.J.1, MARSTON, K.J.1, THOMAS, H.J.2, HILL, K.D.3

1: MURDOCH UNIVERSITY, 2: UNIVERSITY OF WESTERN AUSTRALIA, 3: CURTIN UNIVERSITY

INTRODUCTION: While current guidelines for muscular development promote heavy weights training, many older people cannot safely tolerate high loads. Blood flow restriction (BFR) during low-load resistance exercise (LLBFR) increases muscle size similarly to heavy training, albeit with lighter weights. However, few studies have addressed the cardiovascular safety of LLBFR. This study aimed to quantify the acute hemodynamic responses to LLBFR, and to compare these responses to higher-load exercise (HL).
METHODS: Ten healthy older females (63-75 yr) were assessed for maximal strength (1RM) in the leg press and leg extension. In a randomised and counterbalanced order, subjects completed three protocols: 1) low-load exercise (LL), comprising 3 sets of 20, 15, 15 repetitions at 20% 1RM; 2) LLBFR, identical to LL but with BFR cuffs applied to the thighs, and; 3) HL, including 3 sets of 10 repetitions at 70% 1RM. The BFR cuffs were inflated to 60% of individualised pre-determined arterial occlusion pressure, but were deflated between exercises. Systolic, diastolic and mean arterial pressures (SBP, DBP, MAP) were manually assessed at baseline and after each set. Impedance cardiography measured heart rate (HR) and cardiac output (CO), and was used to calculate rate pressure product (RPP). Two-way ANOVA was used to assess differences between time points and conditions. Data are mean ± SEM.
RESULTS: Baseline hemodynamic values were consistent between trials. DBP increased across all sets for LLBFR (from 68.8±1.5 to 82.0±2.6 mmHg; p≤0.003), and during leg press for HL (from 64.8±2.2 to 69.1±1.9 mmHg; p≤0.045), but did not change during LL. SBP increased from baseline during all trials (p≤0.041), and was higher during LLBFR (168.2±7.0 mmHg) than in LL or HL (151.9±6.2 and 155.6±6.6 mmHg; p≤0.048). Similar observations were made for MAP, which was highest during LLBFR (110.7±3.4 mmHg) compared to LL or HL (94.7±3.2 and 97.9±2.6 mmHg; p≤0.013). Peak HR was highest during HL (122±12 bpm) compared with LLBFR and LL (114±10 and 109±9 bpm; p≤0.036), though CO was not different between conditions. Peak RPP was lower during LL (159.9±30.0 AU) compared with LLBFR and HL (188.3±34.7 and 184.2±34.1 AU; p≤0.001).
CONCLUSION: This study indicates that LLBFR provides similar myocardial workload to HL, as estimated by RPP, but via different mechanisms; LLBFR increased SBP while HL increased HR. Therefore, the physiological impacts of BFR may be more severe for the peripheral vasculature rather than the heart itself, and caution is advised when prescribing BFR exercise for older people with increased risk for vascular dysfunction.

CAN SMALL-SIDED GAMES IMPROVE CARDIOVASCULAR HEALTH IN MIDDLE-AGED INDIGENOUS AUSTRALIAN MEN?

SAMPSON, J.A., WINCH, S., VENABLES, S.

UNIVERSITY OF WOLLONGONG

INTRODUCTION: Small-sided games played for 60-90 mins 2-3 ×/week can improve cardiovascular health (Bangsbo et al, 2014). Indigenous Australian men prefer such forms of exercise, yet time constraints can present a barrier (Hunt et al, 2008). It is however known that substantially lower duration bouts of high intensity exercise can also improve cardiovascular health (Gibala et al, 2012) and that high intensity activity is greater during small-sided games when short exercise bouts are dispersed with rest (Sampson et al, 2015). This investigation thus aims to determine if this format of small-sided games can improve cardiovascular health in middle-aged indigenous men.
METHODS: 14 indigenous men, N=6 assigned to a control (33.7 yrs SD, cm SD, 92.8 kg SD) and N=8 (35.9 yrs SD, 180.1cm SD, 93.6 kg SD) to an experimental group actively participating in small-sided touch football (4 × 5 min bouts dispersed with 2 minutes of rest) 2 ×/week for 12 weeks volunteered for this investigation. Baseline and post-experimental assessments of total mass, fat (%), muscle mass, Visceral fat (Tanita SC330S); body mass index, waist-to-hip circumference, blood pressure, average sleeping heart rate (actigraph/polar H7), and capillary blood samples to assess total (Tc) and high density lipid (HDL) cholesterol (cardiochek) were performed. Framingham risk was calculated. The mean, 90% confidence interval and Cohens effect size (ES) differences between groups are presented where likely, very likely or almost clear effects were observed.
RESULTS: Baseline HDL and Tc was likely higher (9.8 mg/dl CI -5.2 to 24.7 ES 0.64 and 33.1 mg/dl CI 5.3 to 60.9, ES 1.02) in the experimental group. After 12 weeks, fat (%) was very likely lower (-5.0% CI -8.6 to -1.4, ES 0.8); muscle mass likely greater (5.9% CI 1.3 to 10.6, ES 0.64), Waist-to-hip ratio likely lower (-.05 CI -0.1 to 0, ES 0.78); average sleeping heart rate likely lower (-6.2 bpm CI -15.7 to 3.4, ES 0.59), HDL likely lower (-14.8 mg/dl CI -36.4 to 6.9, ES 0.97) and Tc very likely lower (-48.7 CI-93.9 to -3.4, ES 1.51) in the experimental group. However, no change or meaningful difference in Framingham risk was observed between groups at any stage.
CONCLUSION: Regular small-sided games played for 20 mins 2 x per week can improve parameters of cardiovascular health and should be considered a valuable exercise alternative for middle-aged indigenous men. However, dietary interventions must also be considered to substantially reduce cardiovascular risk.

CAN HEAVY-LOAD STRENGTH TRAINING PERFORMED TWICE WEEKLY IMPROVE MUSCLE MASS, MUSCLE STRENGTH AND FUNCTION IN FRAIL ELDERLY INDIVIDUALS?

NYVIK AAS, S., ROGNLIEN, S.H., GODAGER, S., RAASTAD, T.

NORWEGIAN SCHOOL OG SPORT SCIENCES

INTRODUCTION: Muscle strength is inversely and independently associated with mortality [1], emphasizing the importance of strategies aiming to maintain or improve muscle strength in later life. Low muscle strength is particularly evident in frail elderly individuals [2] and our objective was therefore to investigate the effects of heavy-load strength training on muscle mass, strength and function in this population.
METHODS: Short Physical Performance Battery (SPPB) was performed to screen subjects for eligibility in the study. Nineteen men and sixteen women (age: 85.8±7 yr) were randomized to the intervention group performing strength training twice a week for 10 weeks (ST) or the control group (CON). Both groups received daily supplementation of 17 grams of milk protein. Each training session lasted for approximately 30 minutes, and exercises included step-up, leg press and knee extension (KE) (one to four sets of 6-12 RM). Prior to randomization, leg lean mass was measured by dual-energy X-ray absorptiometry (DXA), and muscle strength by 1RM test in KE. Sit-to-stand x 5, habitual and maximal gait velocity was tested to assess functional status.
RESULTS: Average SPPB score at baseline was 5.7±3. Following the intervention, the change in leg lean mass in ST (0.3±0.6 kg) was not significantly different from the change in CON (-0.1±0.7 kg, $p = 0.07$). KE 1RM increased significantly more in ST (18±15 %) than in CON (6±10 %, $p < 0.05$). Chair stand time improved significantly in ST (-15±20 %, $p < 0.05$), and the change tended to be significantly different from the change in CON (1±19 %, $p = 0.051$). Habitual and maximal gait velocity did not change following the intervention.
CONCLUSION: An SPPB score of 4-6 typically corresponds to moderate limitations in activities of daily living [3], confirming the low functional capacity of the subjects included in this study. The results from the intervention showed that high-load strength training performed twice weekly for ten weeks was sufficient to elicit improvements in muscle strength and chair stand performance, without effects on gait velocity. A higher training frequency might be needed to elicit greater improvements in functional performance.

OP-PM06 ENERGY BALANCE

ENERGY BALANCE IN YOUNGER AND OLDER WELL-TRAINED MEN DURING 15 DAYS CYCLING AT NEAR-MAXIMAL ENERGY EXPENDITURE RATES

SAHL, R.E., FRANDSEN, J., HANSEN, M., RØMER, T., NIELSEN, A.B., LIE-OLSEN, M., ROSENKILDE, M., LARSEN, S., WESTERTERP, K., DELA, F., HELGE, J.W.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: Energy intake during repeated excessive exercise is inadequate to cover energy expenditure, especially in older subjects, based on prior data from our lab showing an energy deficit of 5 MJ/day when near-maximal energy expenditure rates was sustained for two weeks. The aim of this study was to investigate the influence on maximal oxygen uptake and the ability to match energy intake with energy expenditure during excessive prolonged exercise in younger and older well-trained men. We hypothesized that the older group would have a larger negative energy balance than the younger group.
METHODS: Young (age 30±2 y, mean±SD, n=7) and old (age 65±2 y, n=7) male cyclist covered 3008±80 km (22350±522 meters of altitude) from Copenhagen (Denmark) to Palermo (Italy) in 15 days. Maximal oxygen uptake (VO2max) was measured with online equipment (Cosmed, Italy), 7-14 days before departure, and 2-3 days after arrival. Energy balance was calculated as the difference between expenditure (EE), as measured over the 15-day race with doubly labeled water, and energy intake (EI) as recorded under supervision for 2 consecutive days on 3 occasions (day 2+3, 5+6 and 12+13). Body composition was determined with bio impedance and with isotope dilution, before and after the intervention.
RESULTS: EE was higher in the younger group (33.4±2.0 MJ/day) compared to the older group (27.0±3.7 MJ/day, P=0.001). EI was not different between groups (27.2±1.9 vs. 25.7±3.4 MJ/day, P=0.24), resulting in a higher negative energy balance in the younger group (-6.4±2.6 MJ/day) compared with the older group (-1.7±1.7 MJ/day, P=0.002). VO2max at baseline was 61.5±0.9 and 46.8±1.7 ml/min/kg in the younger and older group, respectively. Two days after arrival in Palermo VO2max was unchanged in the younger group (63.8±0.8 ml/min/kg, P=0.113) but decreased in the older group (43.5±3.2 ml/min/kg, P=0.047). There were no changes in body weight, but fat mass in the older group decreased from 12.6±3.2 to 9.5±2.6 kg (P=0.012) and lean mass increased from 59.9±9.4 to 62.8±9.1 kg (P=0.024). Fat mass in the younger group showed a tendency to decrease from 9.4±3.3 to 7.4±3.6 kg (P=0.074) with no change in lean mass 68.5±3.7 to 69.3±4.2 kg (P=0.489).
CONCLUSION: In contrast to our hypothesis, the older group had a lower negative energy balance than the younger group. EE in the younger group was equivalent to some of the highest reported values and EI values were close to observed maximal daily consumption, explaining the higher energy deficit in the younger compared to older subject. Despite the lower energy deficit and the positive change in lean mass in older compared to younger subjects, VO2max was decreased only in the older group. We conclude that energy balance could not be maintained during repeated excessive exercise in younger and older cyclist, but this only concurred with an attenuated VO2max in the latter group.

METABOLIC POWER AND ENERGY EXPENDITURE IN THE GERMAN BUNDESLIGA

VENZKE, J.1, WEBER, H.2, SALMEN, J.3, SCHLIPSING, M.3, PLATEN, P.1

RUHR-UNIVERSITY BOCHUM1, SPORTTEC SOLUTIONS GMBH (A DFL COMPANY) FRANKFURT2, ATHLENS GMBH BOCHUM3

INTRODUCTION: Soccer can be characterized as a physically demanding, high-intense intermittent team sport. Player tracking technology is used to determine displacement variables and the distribution of movement across speed and acceleration zones. Additionally, a mathematical approach allows calculating energetic load and metabolic power1. Recent research shows that there are differences in positional groups in field hockey and American football and claims that the approach to classify intensity out of speed zones is not suitable anymore. Therefore, the aims of this study were: (1) to describe the metabolic power demands for different position groups; and (2) to compare the traditional speed-zone with the metabolic power approach.
METHODS: 1344 video match analysis (25Hz) datasets from 416 players (182.3±6.7cm, 77.1±7.0kg, 25.8±3.9y) out of 96 matches of the German Bundesliga were gathered by an automatic player detection and tracking system. Displacement (speed, acceleration, distance) and energetic (Metabolic Power, energy expenditure) variables were determined and intensity was classified utilizing conventional thresholds[2]. Metabolic and running profile were analyzed and compared between positional groups. Time spent, Distance covered and energy expended at high speed (>15.5km/h) was compared to those at high metabolic power (>20W/kg) by using one-way analysis of variances.
RESULTS: Midfielders (MID) expended more energy (46.8±3.2 kJ/kg) than strikers (STR) (43.3±4.2kJ/kg) and defenders (DEF) (41.7±3.1kJ/kg) ($p<0.001$) and covered more distance (11193±772m) than the other positions groups (STR: 10319±1018m; DEF: 9988±670m) ($p<0.001$). Also MID spent more time (355±69s; DEF: 252±68s; STR: 313±69s), covered more distance (1908±380m; DEF: 1372±384m; STR: 1728±380m) and expended more energy (8.2±1.7kJ/kg; DEF: 6.1±1.7kJ/kg; STR: 7.8±1.7kJ/kg) at high speed (>15.5km/h) and high metabolic power (>20W/kg) (MID: 427±63s; 1811±290m; 12.9±1.9kJ/kg; DEF: 332±63s; 1384±304m; 10.3±2.1kJ/kg; STR: 377±69s; 1641±315m; 12.1±2.2kJ/kg) ($p<0.001$, respectively). Less time was spent and less energy was expended at high speed when compared to high metabolic power ($p < 0.001$).
CONCLUSION: Data shows that soccer can be defined as intense and highly intermittent sport and that positional differences for metabolic power and running parameters exist. Generally, midfielders had greater activity profiles compared to the other position groups. Although displacement variables can provide an activity profile for each positional group and can help to understand the different movement patterns, these parameters underestimate the amount of high-intensity activities. Therefore, metabolic power rather than displacement variables should be used for the determination of the metabolic demands of soccer.

ASSESSMENT OF ENERGY INTAKE AND ENERGY EXPENDITURE OF ELITE GAELIC FOOTBALLERS DURING A COMPETITIVE WEEK.

O BRIEN, L., COLLINS, K., AMIRABDOLLAHIAN, F.

LIVERPOOL HOPE UNIVERSITY, IT TALLAGHT

INTRODUCTION: Gaelic football is an invasion based field sport that includes repeated bouts of high-intensity activity interspersed with periods of low-intensity activity. Despite the recognised importance of nutrition in optimising performance and health, limited data exists on the dietary intake of elite Gaelic footballers. To develop appropriate nutritional strategies for Gaelic footballer's energy intake (EI) should be reported alongside energy expenditure (EE), during different phases of training and competition. Therefore, the aim of the current study was to investigate energy and macronutrient intake and EE of elite Gaelic football players during a competitive week.
METHODS: Over a 6-day period, leading up a competitive match, dietary intake (self-reported estimated food diary) and EE (Sensewear Pro armband) were recorded in 7 male players from an elite Gaelic football squad.
RESULTS: Mean daily EI (3084 ± 332 kcal) was significantly lower than mean daily EE (3549 ± 411 kcal) ($p = 0.03$). This resulted in a mean daily energy deficit of -465 ± 563 kcal. Mean carbohydrate (CHO) intake was 3.8 ± 0.5 g.kg−1 body mass, protein intake was 2.1 ± 0.4 g.kg−1 body mass, and the fat intake was 1.5 ± 0.1 g.kg−1 body mass. EI and EE over the six assessment days, were reported as days away from match (Game day (GD) -5, -4, -3, -2, -1 and GD +1), EE was significantly greater on GD -5 (training day) than GD -4, -1 ,+1. EI and CHO intake remained constant throughout the week.
CONCLUSION: The mean daily energy intake of elite Gaelic football players was lower than the energy expended during a competitive week. CHO intakes were below that which is currently recommended for players preparing for competition (Thomas et al, 2016). No variation in EI and CHO intake between days was observed. The dietary regimes of the sampled players were inadequate to support optimal performance throughout training and match play. We suggest players should undertake a heavier training load at the beginning of the week with EE exceeding EI to maintain optimal body composition, followed by a decrease in training load and increase in energy and CHO intake leading up to competition in order to optimise glycogen stores.

PERCEPTION OF BREAKFAST RATHER THAN CARBOHYDRATE/ENERGY INTAKE IMPROVES MORNING RESISTANCE EXERCISE PERFORMANCE

NAHARUDIN, M.N., RICHARDSON, H., THOMPSON, T., ADAMS, J., OXINOU, C.1, MARSHALL, C., YUSOF, A., MEARS, S.A., JAMES, L.J.

LOUGHBOROUGH UNIVERSITY

INTRODUCTION: Research examining how pre-exercise nutrition influences performance in resistance-type exercise is sparse, but recently we observed that a typical high carbohydrate breakfast increased repetitions performed during resistance exercise 2 h later, compared to no breakfast (Naharudin et al. Unpublished). Muscle glycogen is an important fuel source during resistance exercise, but is unlikely to limit performance. Thus, given the common preconception that breakfast (i.e. pre-exercise nutrition) is an important determinant of performance the present study investigated whether breakfast might enhance resistance exercise performance via a placebo or metabolic effect.
METHODS: Twenty two resistance trained men (age 22 ± 3 y) who routinely consume breakfast completed 10 repetition maximum (10RM) testing, a familiarisation trial and three experimental trials, during which they consumed one of three breakfasts in a randomised order

105 min before completing a resistance exercise session (warm up, followed by 4 sets of back squat and 4 sets of bench press to failure at 90% 10RM, each separated by 3 min rest). Breakfasts were provided in a volume of 5 mL/kg and were a water-only control (WAT), or carbohydrate (CHO) and placebo (PLA) breakfasts. CHO and PLA breakfasts were eaten with a spoon from a bowl and contained 0.75 mL/kg no-added sugar orange flavouring (~20 kJ), and 0.1 g/kg xanthan gum (~65 kJ) as a thickener, with the addition of maltodextrin (1.5 g/kg) in the CHO trial. Blood samples were taken to measure plasma glucose, insulin, GLP1 and PYY concentrations pre-breakfast (0 min), as well as 45 and 105 min post-breakfast. Subjective appetite (hunger and fullness) was measured at the same time points.
RESULTS: Total repetitions of back squat were greater in CHO (44 ± 10 reps) and PLA (43 ± 10 reps) than WAT (38 ± 10 reps; P<0.001). Total repetitions for bench press were greater in CHO (39 ± 7 reps) than WAT (37 ± 7 reps; P<0.01), with PLA not different from other trials (38 ± 7 reps; P>0.160). There were no performance differences between CHO and PLA. Breakfast suppressed hunger and increased fullness similarly in PLA and CHO relative to WAT (P<0.001). Plasma glucose was elevated at 45 min in CHO (6.04 ± 0.51 mmol/L; P<0.05), returning to baseline at 105 min, but did not change during WAT and PLA.
CONCLUSION: These results demonstrate that breakfast, rather than carbohydrate/energy per se, enhances resistance exercise performance, suggesting that pre-resistance exercise carbohydrate ingestion does not confer any ergogenic effect above that of a placebo. In conclusion, it appears that the perception of consuming breakfast or a pre-exercise meal may act as a placebo to enhance resistance exercise performance, although a potential mediating role of hunger cannot be discounted.

HABITUAL ENERGY AND MACRONUTRIENT INTAKE OF SEMI-PROFESSIONAL FEMALE SOCCER PLAYERS DURING A TYPICAL IN-SEASON WEEK

NAUGHTON, R.J.1, FLEMING, J.A.1, BROWNLEE, T.E.2, CLIFFORD, T.3, HARPER, L.D.1

1: UNIVERSITY OF HUDDERSFIELD ; 2: LIVERPOOL JOHN MOORES UNIVERSITY ; 3: NEWCASTLE UNIVERSITY

INTRODUCTION: Within the last decade competitive female soccer has undergone substantial growth in participation and interest. This has led to more structured training regimes and an increase in competitive match-play during a season. However, little is known about the current energy and macronutrient intakes of these athletes, with guidelines generally derived from literature which has analysed their male counterparts. Of significant concern is ensuring adequate energy intake to help support performance, and more importantly, maintain good health. The aim of the present study is to assess the energy and macronutrient intake from a 6-day period within the in-season.
METHODS: Nine part-time players (22 ± 4 years, 169.3 ± 5.0 cm, 68.1 ± 5.8 kg) from a Scottish Womens Premier League club recorded their dietary intake using a self-recorded written food diary over a period of 6-days during the 2017 in-season. The week was categorised in three separate types of day; training-days (n=3), match-day (n=1), and off-days (n=2). Energy and macronutrient intake for each day was analysed and subsequently compared between day type.
RESULTS: There were no differences between individual days (P>0.05), with a mean energy and macronutrient total intake of; energy 1824 ± 279 kcal; carbohydrate (CHO) 3.0 ± 0.3 g/kg-1/body mass (BM)-1; protein 1.5 ± 0.3 g/kg-1/BM-1; fat 0.9 ± 0.2 g/kg-1/BM-1. Additionally, there was also no effect of day type on nutritional intake (P>0.05), although on match-days a slightly higher CHO intake (3.6 ± 0.5 g/kg-1/BM-1) was observed in comparison to training-days (3.1 ± 0.7 g/kg-1/BM-1) and off-days (2.7 ± 0.7 g/kg-1/BM-1).
CONCLUSION: The data suggests that female soccer players nutritional habits are sub-optimal, with relatively low energy and CHO intake observed throughout the week. Although protein intake is in line with current intake recommendations for athletes (Phillips and Van Loon, 2011). The reported energy intakes on training-days (1912 ± 419 kcal) and match-day (1918 ± 259 kcal) is of particular concern as when combined with prolonged high-intensity soccer exercise (~90 minutes) these reported intakes are likely to result in an energy deficiency. Sustained periods of time within an energy deficiency can result in compromised bone health and irregularities with the menstrual cycle (Loucks, Kiens, and Wright, 2011), and are likely to also negatively affect physical performance. This low energy intake seems mainly due to a relatively low CHO intake. This data may be of interest to coaches and applied sports nutritionists/dietitians working within female soccer.

NUTRITION STATUS AND CARBOHYDRATE INTAKE IN RELATION TO TRAINING VOLUME OF 421 YOUNG ELITE GERMAN ATHLETES

VON ANDRIAN-WERBURG, J.1,2, BRAUN, H.1,2, BAUHAUS, H.1,2, THEVIS, M.1,2,3

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Young athletes often face the challenge to meet the recommended nutrient and energy intake for sports performance and development. Training demands vary throughout the season wherefore nutrient intake, especially the carbohydrate (CHO) intake, has to be adjusted in respect to training volume and intensity (Burke 2011). The purpose of this study was to investigate the nutritional status in regard to the training demands of young elite German athletes from 28 different sports using a 7-day food record in parallel with a 7-day activity record.
METHODS: A total of 728 young elite athletes (15.4±1.9 yrs) completed the validated food and activity protocol (Koehler et al. 2010). Misreporting was assessed by the ratio of energy intake to energy expenditure and misreported protocols (n=307) were excluded from analysis (Black 2000). The food records of 421 remaining young athletes (15.4±1.9 yrs; 213 females, 207 males) were analyzed concerning energy and macronutrient intake using the German food database (BLS 3.01). Energy expenditure was calculated using predictive equations.
RESULTS: Mean energy intake was 2746±540 kcal/d (females: 2326±385; males: 2972±664) and estimated energy expenditure averaged 2643±630 kcal/d (females: 2442±281; males: 3061±564). Overall macronutrient intake averaged 5.4±1.4 g/kg body weight (BW) CHO, 1.6±0.4 g/kg BW protein and 1.7±0.5 g/kg BW fat. Regarding gender differences and daily training volumes of <1, 1-3h, >3h, CHO intake for the male athletes was 5.2±1.2, 5.7±1.4, 6.1±1.7 g/kg BW and for the female athletes was 5.1±1.1, 5.2±1.3, 6.6±1.7 g/kg BW, respectively. Energy balance for the different training volumes was +6, -104, -228 kcal/d (male athletes) and +7, -147, -127 kcal/d (female athletes).
CONCLUSION: Energy balance and CHO intake recommendations (5-7g/kg BW/d) (Burke 2011) were met, when the average daily training volume was <1h, indicating a reduced training phase. With an increased training volume of 1-3 hours/d, energy and CHO requirements (6 10g/kg BW) (Burke 2011) increase and these were not met by the young male and female athletes. When the average daily training volume increased to >3 hours, energy balance as well as increased CHO requirements were not met by both genders. As a consequence, strategies for young athletes have to be developed to meet nutrient requirements when performing a high training volume.

Sustained periods within negative energy balance can result in severe physiological concerns regarding growth, development, the menstrual cycle and bone health. Young elite athletes need to learn general nutritional and timing strategies according to the individual schedules starting already from a young age in order to be well prepared when training volumes and demands increase with age.

DOES MONTMORENCY TART CHERRY JUICE REDUCE MARKERS OF INFLAMMATION DURING PROFESSIONAL RUGBY LEAGUE MATCH-PLAY? A RANDOMISED CROSS-OVER DESIGN

MOREHEN, J., BRADLEY, W., TWIST, C., STEWART, C., MORTON, J., CLOSE, G.
LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Given the unique demands of Rugby League (RL) match-play, muscle damage, inflammation and immediate and prolonged symptoms of fatigue are all inevitable outcomes. Alterations in the structural integrity of tissue following trauma results in a cascaded release of cytokines, including interleukin-6, followed by interleukin-8 and -10, which initiate the programme of skeletal muscle recovery. In an attempt to alleviate markers of inflammation, common nutritional interventions such as ingestion of Montmorency tart cherry juice, are employed pre- and post-match in team sport athletes.
METHODS: In this study, twelve professional RL players from the same team, played in 3 consecutive matches, against 3 different opposition teams from the same league. During match 2 and 3, a randomised cross-over design was implemented with Cherry ActiveTM (CA) and Placebo (PLA). Measures of match-play demands including total minutes played (min), relative match intensity (m.min-1), total contacts (n) and relative contacts (con.min-1) were recorded during all fixtures.
RESULTS: The average full-time IL-6, -8 and -10 concentrations were significantly elevated ($P < 0.05$) versus -48h pre-match, half-time and +48 post-match values (IL-6 = 2.9 ± 2.4 Vs 0.7 ± 0.7, 1.4 ± 0.9 and 0.7 ± 0.5 pg.ml-1, IL-8 = 3.5 ± 1.6 Vs 2.0 ± 1.2, 2.5 ± 1.2 and 2.1 ± 1.0 pg.ml-1, IL-10 = 2.7 ± 2.4 Vs 0.6 ± 0.6, 1.0 ± 0.8 and 0.5 ± 0.5 pg.ml-1. On average 68 ± 19 minutes was played of which 77 ± 5 m.min-1 relative metres were covered by all players across the 3 matches. Additionally, players were involved in 27 ± 12 total contacts and 0.5 ± 0.2 con.min-1.
CONCLUSION: We report no significant beneficial impact with ingestion of CA versus PLA on concentrations of ILs following match-2 and -3. Players who consumed PLA in match-2 displayed lower concentration of ILs versus those who consumed CA, with the opposite seen in match-3. Our data is the first to demonstrate concentrations of ILs across three professional consecutive within season matches in RL. No benefits of consuming CA were evident in this study, and its recommendations as a recovery aid should be reviewed against the benefits of real food.

BLINDED AND UNBLINDED HYPOHYDRATION SIMILARLY IMPAIR CYCLING PERFORMANCE IN THE HEAT

FUNNELL, M.P., JAMES, L.J., MEARS, S.A.
LOUGHBOROUGH UNIVERSITY

INTRODUCTION: A substantial body of evidence suggests that hypohydration ≥2% body mass impairs endurance performance, but a lack of study blinding might confound much of this work, making strong conclusions difficult to draw. Therefore, this study aimed to compare the effects of blinded and unblinded hypohydration on cycling performance in trained cyclists/triathletes.
METHODS: Fourteen men (age 25 ± 5 y; VO2max = 63.3 ± 4.7 mL/kg/min; cycling experience 6 ± 3 y) were pair-matched and assigned to a blinded (B) or unblinded (UB) study group. After familiarisation, subjects completed euhydrated (B-EUH; UB-EUH) and hypohydrated (B-HYP; UB-HYP) trials in the heat (31°C), consisting of a 120 min cycling preload (50% Wmax) and a time trial (TT; ~15 min). During the preload of all trials, a small volume of water (0.2 mL/kg) was ingested every 10 min, with additional water provided during EUH trials to match sweat loss. To blind subjects in the B group, a nasogastric tube was placed in the stomach for both trials and used to provide water in B-EUH, with subjects told the study was investigating different drinks. Blood samples to determine haemoglobin concentration, haematocrit and serum osmolality were drawn pre-exercise, at 60 and 120 min of preload and post-TT. Thirst, GI comfort, RPE, heart rate, core and skin temperatures were also determined.
RESULTS: The preload induced similar (trial*group interaction P=0.895) changes in body mass between groups (B-EUH -0.6 ± 0.5%; B-HYP -3.0 ± 0.5%; UB-EUH -0.5 ± 0.3%; UB-HYP -3.0 ± 0.3%). Furthermore, all variables responded similarly between B and UB groups (trial*time*group interaction P≥0.558), except thirst (P=0.004). Changes typical of hypohydration were apparent in HYP compared to EUH trials by 120 min, including increased heart rate, RPE, serum osmolality and thirst, and decreased plasma volume (trial*time interaction P<0.001), with a trend for an increased core temperature (P=0.071). TT performance was similar between groups (trial*group interaction P=0.710), and was slower with HYP for B (B-EUH 903 ± 89 s; B-HYP 1008 ± 121 s; -11.4%; P=0.001) and UB (UB-EUH 874 ± 108 s; UB-HYP 967 ± 170 s; -10.1%; P=0.013) groups.
CONCLUSION: These results demonstrate that hypohydration of ~3% body mass impairs endurance performance in the heat in trained men, with this decrement in performance similar when subjects are blinded or unblinded to the manipulation of hydration status. Additionally, using intragastric feeding of water during exercise replicates typical physiological and perceptual responses to euhydration/hypoydration. Therefore, this study suggests previous work in this area is not confounded by a lack of study blinding, and at least at ~3% hypohydration, performance impairments are mediated by the associated physiological and perceptual consequences of hypohydration.

INCREASED CONSUMPTION OF NITRATE-RICH VEGETABLES ELEVATES PLASMA NITRATE AND NITRITE CONCENTRATIONS AND REDUCES BLOOD PRESSURE IN HEALTHY YOUNG ADULTS

VAN DER AVOORT, C., VAN LOON, L., HOPMAN, M., VERDIJK, L.

HAN UNIVERSITY OF APPLIED SCIENCES, MAASTRICHT UNIVERSITY MEDICAL CENTER+, RADBOUDUMC NIJMEGEN

INTRODUCTION: Dietary nitrate elicits cardio protective and ergogenic effects. Whereas 'supplementation' with dietary nitrate has mainly been accomplished through the use of beetroot juice, we hypothesized that increased consumption of nitrate-rich vegetables in the habitual diet will elevate plasma nitrate and nitrite concentrations and lower blood pressure.
METHODS: After 1-wk of recording habitual dietary intake, 30 healthy men and women (both n=15; age: 24±6 y; BMI: 22.6±2.4 kg/m2) participated in a randomized cross-over study in which they ingested ~400 mg nitrate at lunch time, provided through nitrate-rich vegetables (NRV) or beetroot juice (BRJ). Both interventions lasted 7 days, with 1-wk washout. Plasma nitrate and nitrite concentrations and resting systolic (SBP) and diastolic blood pressure (DBP) were measured in a fasted state on day 1 and day 8, as well as ~2.5 h after lunch on day 0 (before), and day 1, 4, and 7 of both interventions. Dietary intake was registered throughout both interventions. Data were analyzed using repeated measures ANOVA with time and treatment as within-subject factors. Data are means±SD or median [IQR].
RESULTS: One week of increased NRV consumption resulted in higher vegetable intake (382 [329-450] vs 177 [115-278] g/d; P<0.001), but slightly lower nitrate intake (549 [494-635] vs 683 [632-750] mg/d; P=0.001) when compared with BRJ supplementation. Fasting plasma nitrate concentrations averaged 57±28 µmol/L before intervention and increased with both treatments, with a greater increase in BRJ vs NRV (126±42 vs 84±36 µmol/L; P<0.001). In accordance, plasma nitrate concentrations after lunch were 66±52 µmol/L before intervention and increased with both treatments, but were higher in following BRJ vs NRV consumption (day 1, BRJ: 373±90 vs NRV: 277±134 µmol/L, P<0.001). Fasting plasma nitrite concentrations increased, with no differences between BRJ and NRV consumption (P=0.095). Plasma nitrite concentrations after lunch were 227±86 nmol/L before intervention and increased with both treatments (P<0.001), but were higher in BRJ vs NRV (day 1, BRJ: 560±331 vs NRV: 468±263 nmol/L, P=0.020). Fasting SBP/DBP did not change with both treatments. In contrast, SBP assessed ~2.5 h after lunch was significantly reduced throughout both intervention periods (P=0.001), with no differences between BRJ and NRV (day 1: -5.1±9.5 and -5.3±8.9 mmHg, respectively; P=0.12). Likewise, DBP was reduced (P=0.013) with no differences between BRJ and NRV (day 1: -3.5±6.7 and -2.6±6.9 mmHg, respectively; P=0.23).
CONCLUSION: Daily consumption of ~400 mg dietary nitrate, in the form of nitrate-rich vegetable consumption or beetroot juice supplementation effectively increases plasma nitrate and nitrite concentrations and reduces blood pressure in healthy young adults. We propose that the benefits of dietary nitrate may be achieved through the consumption of a diet rich in vegetables.

THE EFFECTS OF CHRONIC BEETROOT SUPPLEMENTATION ON NITRATE REDUCING BACTERIA IN THE ORAL CAVITY

BURLEIGH, M.C.1, LIDDLE, L.1, MONAGHAN, C.1, MUGGERIDGE, D.J.2, SCULTHORPE, N.1, BUTCHER, J.3, HENRIQUEZ, F.1, EASTON, C.1

1 UNIVERSITY OF THE WEST OF SCOTLAND, HAMILTON, UK . 2 UNIVERSITY OF STRATHCLYDE, GLASGOW, UK. 3 GLASGOW CALEDONIAN UNIVERSITY, GLASGOW, UK

INTRODUCTION: Dietary nitrate (NO3-) supplementation can increase nitrite (NO2-) bioavailability following the reduction of NO3- to NO2- by NO3- reducing symbiotic bacteria in the oral cavity and, in some contexts, improve exercise performance. Whilst the factors that influence the abundance of these bacteria are unclear, data from animal models suggests these are enhanced through additional NO3- in the diet. The purpose of this study was to determine the effects of chronic NO3- supplementation on the oral microbiome of healthy humans.
METHODS: Eleven healthy males (age 30 ± 7 year and body mass 86.9 ± 14.1 kg) consumed 2 x 70 ml shots of NO3- rich beetroot juice (one mid-morning and one mid-evening, ~ 12.4 mmol/day-1) or NO3- depleted placebo for 7 days in a crossover design separated by a minimum of 4 weeks. Blood and saliva samples were collected at the beginning and end of each condition following 30 min of lying supine. Samples were analysed for [NO2-] and [NO3-] using gas-phase chemiluminescence. The posterior dorsal surface of the tongue was sampled for bacteria for 16s rRNA gene sequencing of the v3-v4 region. Quality filtered sequences were clustered de novo and binned into operational taxonomic units based on 97% identity using Qiime software. Taxonomy was assigned using the RDP classifier trained to the GreenGenes database (October 2013 release).
RESULTS: NO3- supplementation significantly altered NO3- reducing bacteria; Neisseria subflava were increased (from 1.9% ± 2.2% to 8.0% ± 4.9%, P < 0.001), but Prevotella melaninogenica were decreased (from 24.9% ± 11.9% to 11.6% ± 7.5%, P = 0.001). Neisseria subflava were also significantly increased in the placebo condition but to lesser extent (from 1% ± 1.1% to 3.2% ± 2.9%, P = 0.008). There were no significant changes in any other NO3- reducing bacteria all (P > 0.05). Saliva and plasma [NO2-] and [NO3-] were significantly elevated after 7 days NO3- supplementation (all (P < 0.05) but not altered following placebo intervention (all P > 0.05).
CONCLUSION: We demonstrate that the oral microbiome can be altered through consumption of NO3- rich beetroot juice with increases in Neisseria subflava and decreases in Prevotella melaninogenica. These results are interesting given that an altered microbiome will alter NO3- reduction capacity and may consequently have effects on performance. In addition, given that Neisseria subflava are non-pathogenic and Prevotella melaninogenica are commonly associated with periodontitis and dental caries, these data further support the notion that NO3- supplementation may have benefits to health.

POST-EXERCISE COOLING IMPAIRS THE POSTPRANDIAL MUSCLE PROTEIN SYNTHETIC RESPONSE TO PROTEIN INGESTION

FUCHS, C.J., KOUW, I.W.K., CHURCHWARD-VENNE, T.A., SMEETS, J.S.J., SENDEN, J.M., VAN MARKEN LICHTENBELT, W.D., VERDIJK, L.B., VAN LOON, L.J.C.

MAASTRICHT UNIVERSITY

INTRODUCTION: Protein ingestion and cooling are strategies employed by athletes to improve post-exercise recovery and, as such, to facilitate muscle reconditioning following exercise. However, whether post-exercise cooling affects postprandial protein handling and subsequent muscle protein synthesis rates during recovery from exercise has not been studied. Therefore, the aim of this study was to assess the impact of post-exercise cooling on postprandial muscle protein synthesis rates during recovery from resistance-type exercise.
METHODS: Twelve healthy, male adults (age: 21±1 y, BMI: 22.6±0.6 kg/m2) performed a single session of resistance-type exercise followed by water immersion of both legs for 20 min. One leg was immersed in cold water (8 °C: CWI) while the other leg was immersed in thermoneutral water (30 °C: CON). After water immersion, a beverage containing 20 g intrinsically L-[1-13C]-phenylalanine and L-[1-13C]-

leucine labelled milk protein with 45 g of carbohydrates was ingested. In addition, primed continuous L-[ring-2H5]-phenylalanine, L-[ring-2H2]-tyrosine and L-[1-13C]-leucine infusions were applied, with frequent collection of blood samples and muscle biopsies to assess myofibrillar protein synthesis rates in vivo over a 5 h recovery period. Skin and muscle temperature were measured throughout recovery. Paired samples t-tests were used to determine differences in myofibrillar protein synthesis rates and myofibrillar protein-bound L-[1-13C]-phenylalanine enrichments between treatments (CWI vs CON). A two-factor (treatment x time) repeated-measures ANOVA was performed for the analysis of skin and muscle temperature. Data represent means±SEM.
RESULTS: Muscle temperature was lower immediately after water immersion in CWI compared to CON (30.0±0.5 vs 34.9±0.2°C, respectively: P<0.001). Post-exercise myofibrillar protein synthesis rates based upon L-[1-13C]-leucine were lower in CWI compared to CON (0.058±0.003 vs 0.072±0.005%/h, respectively; P=0.024). Similar results were found for L-[ring-2H5]-phenylalanine. Incorporation of dietary protein-derived L-[1-13C]-phenylalanine into myofibrillar protein was significantly lower in CWI compared to CON (0.016±0.002 vs 0.021±0.002 MPE; P=0.016).
CONCLUSION: Cold water immersion during recovery from resistance-type exercise attenuates the postprandial rise in myofibrillar protein synthesis rates. Post-exercise cooling lowers the capacity of the muscle to use dietary protein-derived amino acids for de novo myofibrillar protein accretion during subsequent recovery in healthy young males.

OP-PM07 LACTATE and ANAEROBIC WORK

METABOLIC AND PERFORMANCE-RELATED CONSEQUENCES OF EXERCISING AT AND SLIGHTLY ABOVE THE MAXIMAL LACTATE STEADY STATE

IANNETTA, D., INGLIS, E.C., PASSFIELD, L., MURIAS, J.M.
UNIVERSITY OF CALGARY

INTRODUCTION: The maximal lactate steady state (MLSS) represents the highest intensity of exercise at which overall metabolic stability can be preserved. However, the physiological and performance-related consequences of exercising only 10 W above this intensity are unknown.
METHODS: In this study, eleven trained men performed: i) a ramp-incremental (RI) test; ii) two to three 30-min constant-power output (PO) cycling exercise trials to determine the power output at MLSS (MLSSp), followed by a time-to-exhaustion ride 3 min after; iii) a 30-min constant-load cycling exercise at 10 W above MLSS (MLSSp+10) followed by a time-to-exhaustion similar to the above described; iii) a baseline time-to-exhaustion test with no prior exercise. The time-to-exhaustion trials were performed at 80% of the peak-PO recorded at the end of the RI test. Pulmonary O2 uptake (u̇O2) and blood lactate concentration ([La-]b) as well as local muscle O2 extraction ([HHb]) and muscle activity (EMG) of the vastus lateralis (VL) and rectus femoris (RF) muscles were measured during the testing sessions.
RESULTS: The PO at MLSSp was 231±49 W. The 9̇O2 at MLSSp and MLSSp+10 was 3.31±0.53 L·min-1 and 3.45±0.52 L·min-1. During MLSSp+10 there was a greater increase in ventilatory responses and EMG activity, along with a non-stable [La-]b response throughout the trial (P<0.05). The [HHb] signal of VL during MLSSp achieved similar (stable) values as during MLSSp+10, and did not show any further increase during the time-to-exhaustion trials (P>0.05). This ceiling in the [HHb] signal of VL occurred at a metabolic rate corresponding to that associated to the beginning of the plateau in the signal observed during the RI test (P>0.05). On the other hand, the [HHb] signal of RF was stable only during MLSSp, but progressively increased during MLSSp+10, and eventually achieved its apex during the subsequent time-to-exhaustion trials (P<0.05). The time-to-exhaustion performance was decreased after exercising at MLSSp by 37.3% (±16.4) compared to the baseline condition, and by an additional 41.2% (±16.4) after exercising at MLSSp+10 (P<0.05). Finally, the p̃O2peak value recorded at the end of the time-to-exhaustion performed after MLSSp+10 trial was 7.2% (±5.7) lower than those achieved during the RI and the other time-to-exhaustion tests (P<0.05).
CONCLUSION: In summary, this is the first study demonstrating that that the metabolic disturbances associated with exercising only 10 W above MLSS disproportionally reduce maximal exercise performance capacity. Additionally, the current study is the first showing that local mechanisms regulating the delivery and utilization of O2 in VL and RF muscles seems to be dependent upon a specific metabolic rate regardless of the exercise mode employed. The implications of these regional differences is that some muscle areas may contribute more than others to the elevation of [La-]b and other metabolites (e.g. H+, Pi) linked to the progressive loss of metabolic stability and increased fatigue accumulation.

VALIDATION OF LACTATE MINIMUM POWER TESTING IN ELITE CYCLISTS

DAUSIN, C.1, CAREY, C.C.2, GEUNS, W.1, HESPEL, P.1
1 EXERCISE PHYSIOLOGY RESEARCH GROUP AND BAKALA ACADEMY ATHLETIC PERFORMANCE CENTRE, K.U. LEUVEN AND 2 FACULTY OF SCIENCE AND HEALTH, DUBLIN CITY UNIVERSITY.

INTRODUCTION: Physiological profiling of elite endurance athletes should include determination of FATmax, maximal lactate steady state (MLSS) and VO2max. To improve determination of these three parameters in a single test session, we used the "lactate minimum power (LMP)" concept proposed by Tegtbur et al. in 1993(1). This procedure involves a maximal exercise bout to first substantially elevate blood lactate concentration, where after a submaximal incremental exercise bout, gradually shifts blood lactate balance from net lactate clearance to net accumulation. The nadir of the U-shaped blood lactate curve so obtained is believed to identify MLSS exercise intensity. In the current study we aimed 1) to evaluate the validity of LMP to determine MLSS, and 2) to develop a practical test protocol to precisely determine FATmax, MLSS and VO2max in a single laboratory exercise session in elite cyclists.
METHODS: Ten male well-trained cyclists (VO2max 61±6ml•kg-1•min-1) completed a series of tests on different days: a long maximal incremental exercise test (100W + 40W per 8 min); an LMP protocol; 2 or 3 constant-load MLSS tests. During the maximal incremental test FATmax was determined as the exercise intensity corresponding to a +0.5mmol•l-1 blood lactate increment above baseline, and MLSS was estimated by the lowest workload eliciting a >1mmol•l-1 rise from min 4 to 8. The LMP protocol started with a long incremental exercise phase until FATmax was determined. Immediately followed by a VO2max ramp (100W +25W per 30sec) to increase blood lactate concentration. Upon exhaustion workload was reduced to 85% of the predicted MLSS, where after workload was increased by 5% of predicted MLSS per 3 min till volitional exhaustion. Blood lactate was measured at the end of each step. MLSS in the constant-load tests

was taken as the highest workload, which could be maintained for 30min with a constant (Δ ≤ 1mmol•l-1) blood lactate level between min 10 and 30.
RESULTS: MLSS power output determined from the constant-load tests was 265±38W. MLSS prediction from the LMP test was 270±37W (p>0.05), and LMP was closely correlated with the true MLSS (r=0.93, p<0.05). VO2max was slightly higher in the short ramp protocol than in the long incremental exercise test (63.9±7.1 vs. 61.4±6.9 ml•min-1•kg-1, p<0.05).
CONCLUSION: To conclude, the LMP test including a VO2max ramp, yields valid measurements of both MLSS and VO2max.

TISSUE SATURATION INDEX AND LACTATE THRESHOLD

RALEIGH, C., DONNE, B., FLEMING, N.

TRINITY COLLEGE DUBLIN

INTRODUCTION: Tissue saturation index (TSI) measured via near infrared spectroscopy (NIRS) to assess training intensity and prescribe training has become popular amongst athletic populations. Delivery of O2 to working musculature increases with intensity but at upper limits reliance on anaerobic metabolism increases. TSI assessing a balance between O2 delivery and utilisation could, in theory, determine the relative contribution of anaerobic metabolism at a given intensity. We have previously shown that a breakpoint in TSI measured using a portable NIRS device (MOXY) cannot be used as a proxy estimate of lactate threshold (Raleigh et al. 2018). Currently, minimal evidence regarding association between MOXY and previously validated "gold standard" devices (Hamamatsu NIRO-200NX) exists. Although Hamamatsu is widely used in clinical scenarios, studies have determined O2 saturation in exercising tissue (Wittekin et al. 2012). We hypothesised that computed TSI thresholds using both NIRS devices should not differ significantly, as both theoretically measure the same variable.
METHODS: This pilot study assessed graded incremental cycling to volitional exhaustion in competitive male cyclists and triathletes (n=13). TSI data were continuously measured from left (Hamamatsu) and right (MOXY) vastus lateralis muscles, respectively. Cardio-respiratory variables were measured breath by breath, and blood lactate was assessed during each incremental stage. A segmented linear regression model, minimising squared sum of residuals, determined thresholds (TSIT) for both NIRS devices, and ventilatory breakpoint for VEVO2 (VT), lactate threshold was determined using Dmax (Cheng et al. 1992). Data were analysed using a repeated measures ANOVA, limits of agreement (95% LoA) computed and correlation assessed using Pearsons and interclass correlation coefficients (ICC).
RESULTS: ANOVA revealed that significant differences existed between computed thresholds (F=3.87, P=0.03). A significant difference existed between TSIT detected by Hamamatsu and Dmax (276±37 vs. 249±25 W, P<0.05, ES=0.85). All other comparisons were non-significant, however, correlation between thresholds were poor, especially comparing Hamamatsu and MOXY TSIT data (r = 0.52, ICC = 0.52, 95% LoA = 79 to -64 W).
CONCLUSION: Poor correlation between thresholds further consolidates previous work demonstrating that VT or TSIT are not suitable proxy measures for detecting an aerobic anaerobic transition. Current data further demonstrate that neither a novel portable NIRS device (MOXY) or gold standard NIRS device (Hamamatsu) are comparable, or suitable, for detecting an aerobic anaerobic transition in comparison to lactate data.

THE COMPARISON OF ANAEROBIC THRESHOLD AND MAXIMAL OXYGEN UPTAKE MEASURED BY TRADITIONAL MAXIMAL OXYGEN UPTAKE TEST AND MODIFIED INCREMENTAL STEP TEST .

LO, K.K., CHAN, Y.Y., IP, L.F.

HONG KONG SPORTS INSTITUTE

INTRODUCTION: The aim of traditional maximal oxygen uptake test (TVO2max) is determine the maximal aerobic capacity (VO2max) and the aim of incremental stepwise test with blood sampling is to determine the anaerobic threshold (AT) of an athlete. In order to obtain both the AT and VO2max accurately by a single test, a modified stepwise maximal oxygen uptake test (Step VO2max) were performed and compared.
METHODS: Subjects: Eighteen rowers from Chinese University of Hong Kong Women Rowing Team were recruited as subjects (age 19.9•0.1, height 166.3•0.1cm and weight 57.7•0.5kg). Subjects conducted TVO2max and Step VO2max tests in a randomized sequence. TVO2max test consisted of ergo on rowing machine with 100W for 3 mins, followed by a 15W increase every min until exhaustion. StepVO2max test consisted of stepwise and maximal parts, with four mins rest between two parts. Stepwise part consisted ergo on rowing machine with 3 mins/stage starting from 100W, with an increase of 15W/stage and 30 s rest between stage, until post-stage blood lactate exceeded 4 mmol and increased more than 1 mmol when compared with the previous stage. Maximal part started with power of the stage of stepwise part at or below anaerobic threshold. There was an increase of 15W/min afterwards until exhaustion.
RESULTS: Average power and VO2max values at maximum exercise intensity in StepVO2max and TVO2max are 198.7, 201.1 W and 46.01, 46.27 ml/kg/min, respectively. No significant difference were found in average power and VO2max values between two testing methodologies. Average power in stepVO2max and TVO2max at AT exercise intensity are 149.4 and 149.9W respectively. There are no significant difference in average power between two testing at anaerobic threshold. However, the TVO2max has significant lower oxygen consumption (VO2) value at AT than StepVO2max (p<0.05).
CONCLUSION: There were negligible differences in measuring VO2max and power in both testing methodologies. No difference in measuring power at anaerobic threshold exercise intensity. However, there are detectable difference in VO2 value at AT because of buffering system of lactate acid. The study has established a single test for both maximum and anaerobic threshold exercise intensity. The modified test is less time consuming, with additional lactate reference parameters for coaches to develop individualize training programme in the future.

OP-BN02 TISSUE MECHANICS

SEASONAL CHANGES IN PLANTAR FASCIA THICKNESS IN DIVISION II BASKETBALL PLAYERS

KRUMPL, L., CANNAVAN, D.

SEATTLE PACIFIC UNIVERSITY

INTRODUCTION: The plantar fascia (PF) is a sheath of connective tissue on the bottom of the foot and its chronic inflammation may lead to plantar fasciitis. However, there is limited research on the underlying factors causing a PF injury, or indeed if these changes occur in sports that place excessive demand on the plantar fascia (for example plyometric activities). Thus, the purpose of this study was to evaluate the relationship between specific anatomical properties (foot arch height, hamstring flexibility, and ankle mobility), and PF thickness in Division II Basketball Players throughout the season.
METHODS: Twenty eight participants took part in this study, (13 males and 15 females; mean ± SD; age: 20.7 ± 0.03 y; body mass: 79.5 ± 12.8 kg; height: 184.5 ± 9.5 cm). Data were collected on three separate occasions over the course of a Division II basketball season; season start (first 2 weeks), season end (last 2 weeks), and two weeks post season. The measurements occurred in this order: 1) PF thickness measurement using B-mode ultrasonography, 2) foot arch height measurement using the Arch Height Index measurement system, 3) hamstring flexibility measurement via the active knee extension test, and 4) ankle joint passive range of motion measurement using a Biodex isokinetic dynamometer. All subsequent testing sessions occurred at the same time of day (i.e. am or pm).
RESULTS: A repeated measures ANOVA revealed significant changes in PF thickness throughout the season ($p < 0.001$, eta-squared = 0.62). Follow-up tests revealed a significant increase in PF thickness from start to end of the season ($p < 0.001$; mean difference: 0.4 mm), and a significant decrease from end to post-season ($p < 0.01$; mean difference: -0.57 mm). No significant difference was found between start and post-season values (mean difference: 0.16). Additionally, Pearson correlation revealed a significant ($p < 0.05$), and moderately strong, negative ($r = -0.61$) relationship between ankle mobility and PF thickness in males, but not females. There were no significant interactions for arch height index and hamstring flexibility.
CONCLUSION: To the author's knowledge, this is the first study that has demonstrated changes in PF thickness throughout a Basketball season. The significant increase in PF thickness was similar to cut-off values that clinicians use to diagnose plantar fasciitis. Although the players in this study remained asymptotic, it could be that if the season were longer plantar fascia injuries may occur. Of significant interest, the PF thickness returned to baseline levels two weeks post season. The correlation between PF thickness and ankle mobility suggests that limited ankle mobility may place undue tissue strain on the PF, especially under high intensity situations leading to plantar fascia type injuries.

MUSCLE AND NERVE STIFFNESS CHANGES FOLLOWING A 12-WEEKS OF SPECIFIC STRETCH TRAININGS

ANDRADE, R.J., FREITAS, S.R., HUG, F., LE SANT, G., LACOURPAILLE, L., GROSS, R., NORDEZ, A.

LABORATORY « MOVEMENT, INTERACTIONS, PERFORMANCE »

INTRODUCTION: Although it is widely accepted that chronic stretch training induces an increase in maximal joint range of motion (ROM), literature has demonstrated that these interventions do not alter muscle-tendon unit mechanical properties (Weppler & Magnusson, 2010). However, three important limitations of earlier studies may explain the lack of mechanical adaptations following chronic stretching interventions: (i) studies implemented relatively short stretch training periods; (ii) the mechanical properties are typically inferred from global passive torque-angle relationships, but stretching may load specific muscles' regions (Le Sant et al., 2017); and (iii) non-muscular structures such as peripheral nerves may play an important role on maximal ROM (Nordez et al., 2017). Thus, the aim of this study was to provide a deeper understanding of muscle and peripheral nerve mechanical adaptations following a long chronic stretching protocols targeting preferentially either muscular or nerve structures.
METHODS: Participants were randomly assigned to one of three interventions groups: sciatic nerve stretching (sciatic STR, n=21), triceps surae stretching (muscle STR, n=21), or control (CON, n=18). Sciatic STR and muscle STR groups were enrolled in a 12-weeks stretch training protocol (duration of 7.5 h over the 12-weeks training period). CON group was instructed to not enroll in any specific flexibility training. Pre- and post-training testing sessions were performed to assess: (i) the maximal dorsiflexion ROM; (ii) ankle passive torque; and (iii) the mechanical properties of triceps surae and sciatic nerve during slow passive ankle rotations. Specifically, passive maximal dorsiflexion ROM was assessed with the hip flexed (HIP-flexed, knee fully-extended) and neutral (HIP-neutral - 0°, knee fully-extended). Localized stiffness of triceps surae (gastrocnemius medialis, gastrocnemius lateralis and soleus) and sciatic nerve was estimated, at different regions of each structure, using ultrasound shear wave elastography.
RESULTS: Sciatic STR induced an increase in ankle ROM in both HIP-neutral and HIP-flexed conditions (+3.8±4.9°; +8.0±5.2°, respectively; both $P < 0.001$), and a decrease in sciatic nerve stiffness (-19.1±15.3%; $P < 0.0001$) in the absence of any change in triceps surae stiffness (all $P = 1$). Muscle STR induced an increase in ankle ROM in HIP-neutral position (+9.4°±3.8°; $P < 0.0001$) and a decrease in muscle stiffness (all $P < 0.03$), without changes sciatic nerve stiffness (all P=1). Ankle passive torque at a given angle decreased after muscle STR ($P = 0.03$) but remained unchanged following the sciatic STR ($P = 1$).
CONCLUSION: The present study shows that muscle-directed and nerve-directed chronic stretching interventions are both effective, compared to control, at increasing the maximal ROM. Also, this study demonstrates that the localized stiffness of both muscle and nerve structures can be selectively decreased with specific stretching that preferentially loaded each structure.

DO TRAINING-INDUCED CHANGES IN AT STIFFNESS AFFECT MUSCLE-TENDON BEHAVIOUR DURING LANDING?

WERKHAUSEN, A.1, ALBRACHT, K.2,3, CRONIN, N.J.4, PAULSEN, G.5, BOJSEN-MOELLER, J.1, SEYNNES, O.R.1

1: NSSS , 2: GSU , 3: UAS , 4: JYU , 5: OLT

INTRODUCTION: During rapid decelerations, tendons act as mechanical buffers against rapid stretches of the muscle fibres, allowing safer energy dissipation (2). A link between tendon stiffness, muscle contractile behaviour and mechanical efficiency has been shown in models of locomotion (1) and may apply to tasks requiring energy dissipation. Hence, this study aimed to examine the influence of training-induced stiffening of the Achilles tendon (AT) on triceps surae muscle-tendon (MTU) behaviour during a landing task. We hypothesized that increased stiffness would reduce the buffering effect of the AT.

METHODS: Twenty-one subjects were assigned to a 10-week resistance training programme consisting of single-leg isometric plantarflexions (n=11) or to a control group (n=10). Testing was performed at baseline and after training. Plantarflexion force, AT strain and stiffness were measured with a dynamometer and a combination of ultrasound and kinematics data. Synchronised ultrasound, kinematics and kinetics data were used to determine joint mechanics and the length of gastrocnemius (GM) and soleus (SOL) fascicles, AT and MTU during a step-landing task. Pre- to post-training differences between groups were tested for variables of interest with 2-way repeated-measures ANOVAs.
RESULTS: After training, an increase in Achilles tendon stiffness (18%) and plantarflexion strength (15%) in the training group did not alter tendon strain during landing. However, GM fascicles were offset to a longer length at touch down (8%), and fascicle lengthening and velocity were reduced in the training group by 27% and 21% respectively, while lengthening and negative work produced by the GM MTU did not change. These changes were not observed for SOL when accounting for the variation of the task execution between tests. No statistical changes were found in the control group.
CONCLUSION: Training-induced increases in AT stiffness and strength did not alter the tendon buffering action against large fascicle strain during rapid deceleration. On the contrary, GM muscle fascicle lengthening and lengthening velocity were reduced after training. Changes in fascicle mechanics could not be linked to different AT strain, perhaps because of adaptations only affecting AT strain or stiffness regionally (i.e. proximally to the free tendon), or because of changes affecting other elastic elements. Future studies are required to provide insight into the mechanisms underpinning these observations and their influence on energy dissipation.

PATELLAR TENDON STIFFNESS IS NOT REDUCED DURING PREGNANCY

BEY, M.E.1,2, ARAMPATZIS, A.1,2, LEGERLOTZ, K.1,2

HUMBOLDT-UNIVERSITAET ZU BERLIN

INTRODUCTION: The beneficial effects of exercise during pregnancy are well accepted. However, pregnant women are often told that hormonal changes in pregnancy would make their ligaments and tendons more compliant, increasing the risk to suffer from connective tissue injuries and falls when exercising. While the compliance of the ligaments of the pelvis increases to facilitate childbirth (Young, 1940), to our knowledge no study has ever investigated the mechanical properties of human tendons in different stages of pregnancy. Our longitudinal study therefore investigates the mechanical properties of the patellar tendon in different stages of pregnancy and in non-pregnant controls.
METHODS: 19 pregnant women (30±4 years) and 11 non-pregnant controls (28±3 years) performed 5 slow maximal isometric ramp contractions of the knee extensors with a resting knee joint angle of 90° to determine the patella tendon stiffness and maximum strain as well as the muscle strength of the knee extensors using dynamometry, ultrasound, kinematic and electromyographic measurements (Arampatzis et al., 2004; Mademli et al., 2004). The measurements were conducted in the 16±4th (EP) and in the 30±2th week of pregnancy (LP) and 28±4 weeks after delivery (PP).
RESULTS: Patellar tendon stiffness (EP: 1140.1 ± 224.5 N/mm; LP: 1170.5 ± 288.6 N/mm; PP: 1250.8 ± 209.1 N/mm; controls: 1147.5 ± 321.4 N/mm) and the achieved maximum strain during the knee extension contractions (EP: 6.8 ± 1.6 %; LP: 6.5 ± 1.7 %; PP: 6.8 ± 2.2 %; controls: 7.1 ± 1.5 %) did not change during pregnancy. Furthermore patellar tendon stiffness and maximum strain of the pregnant women did not significantly differ from non-pregnant controls. Similarly, the knee extensor moment normalized to body mass did not significantly change during pregnancy and did not significantly differ from non-pregnant controls (EP: 2.41 ± 0.7 Nm/kg; LP: 2.29 ± 0.7 Nm/kg; PP: 2.45 ± 0.6 Nm/kg; controls: 2.32 ± 0.6 Nm/kg).
CONCLUSION: Our data provide evidence that both patellar tendon stiffness and muscle strength are not affected by pregnancy. This is in agreement with previous findings in pregnant rats, detecting no change in strain or modulus of elasticity of the musculus digiti quinti tendon (Rundgren, 1974). While the compliance of some ligaments might change during pregnancy, the assumption that tendons are also subjected to the same change is not correct. As a consequence pregnant women should not be cautioned about tendon injuries when exercising.

COLLAGEN PEPTIDES IMPROVE FUNCTIONAL ANKLE PROPERTIES IN SUBJECTS WITH CHRONIC ANKLE INSTABILITY

DRESSLER, P., GEHRING, D., ZDZIEBLIK, D., OESSER, S., GOLLHOFER, A., KÖNIG, D.

UNIVERSITY OF FREIBURG

INTRODUCTION: Following an initial ankle sprain it is not unlikely that chronic ankle instability (CAI) will develop. CAI is associated with impaired perceived functional and mechanical properties of the ligaments. Nutritional supplementation with collagen peptides has been shown to improve the functional and mechanical properties of the connective tissue. The purpose of this study was to investigate the effectiveness of specific collagen peptide supplementation (SCP) to improve ankle stability in athletes with CAI.
METHODS: 50 male and female athletes with CAI completed a randomized, double-blinded and placebo-controlled study with a daily oral administration of either 5 g SCP or 5 g placebo (Maltodextrin) over a period of six months. Both, the Cumberland Ankle Instability Tool (CAIT) and the German version of the Foot and Ankle Ability Measure (FAAM-G) were used to measure the subjective perceived function of the ankle. Additionally, the mechanical stability was determined by measuring the ankle stiffness by an ankle arthrometer. Finally, a three-month follow-up was performed.
RESULTS: ANOVA analysis indicated that the subjective ankle stability was improved in both the CAIT ($p < 0.001$) and the FAAM-G ($p < 0.001$) following SCP supplementation compared with placebo. No significant changes between the groups were detected in the results of the ankle arthrometer. After six month the subjective report of the ankle stability function significantly improved and the three month follow-up revealed a significant decline in the number of ankle joint injuries ($p < 0.05$).
CONCLUSION: These data support the concept that specific collagen peptide supplementation in athletes with chronic ankle instability results in significant improvements in subjective perceived ankle stability. The reduction in the re-injury rate of ankle sprains in the follow-up period suggests that these findings have clinical relevance.

ACHILLES TENDON LENGTH CHANGE DURING STAIR ASCENT IN YOUNG AND OLDER ADULTS

JOHANNSSON, J.1, JAKOBI, J.2, DUCHATEAU, J.1, BAUDRY, S.1

1: UNIVERSITÉ LIBRE DE BRUXELLES ; 2: UNIVERSITY OF BRITISH COLUMBIA OKANAGAN

INTRODUCTION: During walking, the Achilles tendon is responsible for most of the change in the muscle-tendon complex (MTC; Fukanaga et al. 2001). The greater ankle moments observed during stair ascent, (Reeves et al. 2009) may induce different results in the contribution of the Achilles tendon in MTC changes, especially in older adults that experienced a decrease in Achilles tendon stiffness (Stenroth et al. 2012). Therefore, the aim of this study was to assess the Achilles tendon length change during stair ascent in young and older adults.
METHODS: The muscle-tendon junction of the gastrocnemius lateralis was recorded with ultrasonography in 16 young (25.1±3.3yr) and 18 older (70.4±5.2yr) adults to assess Achilles tendon length during prone, upright standing and during stair ascent through expressions of tendon length changes as a proportion of the total MTC length estimated from an anatomical model (Grieve et al. 1978). The gait cycle of stair ascent was divided into a quiet standing and three independent foot placement phases that occurred over three stairs. Electromyogram (EMG) of soleus, gastrocnemius lateralis and tibialis anterior were also measured during standing and stair ascent. Achilles tendon stiffness was measured by using the force-length relation obtained with ultrasonography from a series of submaximal voluntary contractions in the prone position.
RESULTS: Achilles tendon stiffness was greater in young (157.5±57.2 N•mm-1) than older adults (95.6±38.5 N•mm-1, $p<0.001$). Achilles tendon length in prone position was 50.8±7.6% and 48.5±4.4% in older and young adults ($p=0.34$), respectively, and was significantly greater in older (58.7±4.0%) than young (50.9±5.5 %; $p=0.04$) during standing. During stair ascent, Achilles tendon length remained greater in older than young adults ($p<0.01$) but underwent greater elongation in young (1.3 ± 1.6 %) compared to older adults (0.3 ± 1.0 %; $p<0.01$). EMG of all three muscles were greater in older compared to young during standing and stair ascent ($p<0.05$).
CONCLUSION: Tendon stiffness in-part determines tendon length changes under loading. Results from this study suggest that in older adults, a less stiff tendon and greater EMG may contribute to change the gait strategy in older adults to safely ascend stairs (Reeves et al. 2009).

OP-MI04 Women in sport

MUSCLE FUNCTION OVER THE MONOPHASIC ORAL CONTRACEPTIVE CYCLE TAKING INTO ACCOUNT DIFFERENT LEVELS OF ANDROGENICITY

JANSE DE JONGE, X., THOMPSON, B., BARBA, L., ALMAJAWI, A., SCULLEY, D.

UNIVERSITY OF NEWCASTLE, AUSTRALIA

INTRODUCTION: There has been a dramatic increase in the number of females participating in sport and exercise both recreationally and at an elite level. Oral contraceptives (OC) are a popular choice for birth control both in the general community and amongst female athletes. The monophasic OC is the most common type and generally follows a pattern of 7 days of non-active pills followed by 21 days of active hormone pills. The active hormones in the combined monophasic OC suppress the production of endogenous female sex hormones through a combination of ethinyl estradiol and progestin. There are different types of progestin, which may have low or high levels of androgenicity. Endogenous estrogen and progesterone are known to affect muscle strength, however, it is unclear if the synthetic hormones and the level of androgenicity of the progestins within OC affect muscle performance. Therefore, this study aimed to assess aspects of muscle function in low and high androgenicity OC users at three different time points over the OC cycle.
METHODS: Fourteen moderately active females aged 18-29 years, all taking a combined monophasic OC with high androgenicity (n=8) or low androgenicity (n=6), were tested during the non-active pill phase, the first week of the active OC and the last week of the active OC. Participants were tested for maximal isometric quadriceps strength with superimposed electrical stimulation, peak force response to an electrically evoked twitch of the quadriceps, handgrip strength and isokinetic quadriceps fatiguability. The isokinetic fatigue test involved 60 maximal knee extensions at a speed of 240 degrees/second.
RESULTS: Repeated measures ANOVA showed no significant differences between the time points of testing over the OC cycle for any of the muscle function variables measured. These findings were the same in both the low and high androgenicity groups.
CONCLUSION: The results suggest that exogenous hormone administration through high or low androgenicity monophasic combined OC use does not affect the muscle function parameters measured in this study. It is therefore proposed that muscle function testing in females can be performed at any time point throughout the OC cycle. Future research with larger participant numbers is recommended to further investigate potential acute effects of the different types of exogenous hormone administration through OC on muscle function characteristics. A comparison of muscle function between females taking different types of OC and those with a natural menstrual cycle is also recommended.

INFLUENCE OF MENSTRUAL CYCLE ON MUSCLE FUNCTION AND JUMP PERFORMANCE: IRONFEMME PROJECT

ROMERO-PARRA, N., PEINADO, A.B., ALFARO-MAGALLANES, V.M., RAEL, B., ROJO-TIRADO, M.A., BENITO, P.J., BENÍTEZ, J.A., GUTIÉRREZ-SUÁREZ, A., CUPEIRO, R.

FACULTY OF PHYSICAL ACTIVITY AND SPORT SCIENCE . UNIVERSIDAD POLITÉCNICA DE MADRID

INTRODUCTION: Female exhibit changes during menstrual cycle that may affect different sport performance variables. The decrease in performance of counter movement jump (CMJ) has been related with muscle damage and loss of muscle function after strength training.

Few studies have investigated these effects after an intense strength training in women (1). Therefore, the purpose of this study was to evaluate the influence of hormonal fluctuation along the menstrual cycle in lower-limb muscle function and damage in female athletes.
METHODS: Five eumenorrheic women (age 30±4 years, height 164±5.2 cm, body mass 60±6.3 kg) experienced in resistance training, performed a 1RM test to determine their maximal back squat load. After load estimation, they completed an eccentric-based resistance protocol consisting of 10 sets x 10 reps of back squat (2) in order to promote muscle damage. Both exercises were carry out in three different and randomized occasions: early follicular phase (EFP), late follicular phase (LFP) and luteal phase (LP) of menstrual cycle. Participants also performed CMJ before (pre-trial), and 0h, 24h and 48h after eccentric exercise (post-trial). Jump height was measured by using MyJump App (3). Mixed linear model was conducted to analyze repeated measures.
RESULTS: Mean jump height was 27.9±5.6 cm, 28.5±2.6 cm, and 29.2±7 cm for the previously mentioned phases. Mixed linear model showed no significant effect of phase in CMJ performance ($F_{2,8.007}=2.047$; $p=0.191$). Jump values were significantly affected by moment being post-trial ones significantly different from pre-trial measures ($F_{3,16.048}= 4.21$; $p<0.05$). Mean height values for pre-trial and 0h, 24h and 48h post-trial measures were 30.1±6 cm, 25.7±3.8 cm, 29.6±5.7 and 28.8±5.1 cm, respectively. No significant effect of interaction between phase and moment was observed ($F_{6,15.832}=0.319$; $p=0.971$).
CONCLUSION: An eccentric-based resistance exercise affects muscle function and muscle damage in women as CMJ values 0h post-trial were significantly lower than pre-trial ones. Nevertheless, muscle function may not be influenced by hormonal fluctuation as no differences among phases were observed. This finding could be due to sample size as our results are preliminary. Further studies are needed to evaluate sex hormone effects in women performance.

MAXIMUM FAT OXIDATION IS LOWER IN YOUNG COMPARED TO MIDDLE-AGED ADULT WOMEN FROM A LOW INCOME COMMUNITY IN SOUTH AFRICA.

ENGELBRECHT, L., DICKIE, K.E., TERBLANCHE, E.

STELLENBOSCH UNIVERSITY, SOUTH AFRICA

INTRODUCTION: According to the South Africa Demographic and Health Survey, 68% of South African women are obese, based on BMI scores. It is also known that there is a strong association between low socio-economic status and obesity risk (Pireyre et al., 2016). Furthermore, fat oxidation rate during rest and exercise is linked to increased metabolic risk factors. Therefore, this study set out to compare the maximal fat oxidation rates of young and middle-aged adult women from a low income community in South Africa.
METHODS: 28 women (group 1 (n=13): 18-29 years old; group 2 (n=15): 40-49 years old) from the same community performed a graded treadmill test till exhaustion after an overnight fast to determine maximum fat oxidation rate (MFO) and aerobic capacity (VO2max). Dual-energy X-ray absorptiometry scans were performed to determine fat mass (FM) and fat free mass (FFM). The Global Physical Activity Questionnaire (GPAQ) was used to determine a subjective measure of physical activity.
RESULTS: Both groups had a low MFO (group 1: 0.26 ± 0.07g/min; group 2: 0.34 ± 0.11g/min), however, the MFO of the older women was largely higher than group 1 (ES = 0.87; CI: 0.06 – 1.63). Relative VO2max were low in both groups (group 1: 27.9 ± 5.4 ml/kg/min; group 2: 22.1 ± 4.5min/kg/min). Group 2 had moderately higher body mass (ES = 0.75; CI: -0.14 – 1.49) and FM (ES = 0.70; CI: -0.09 – 1.46), with significantly higher FFM (ES = 1.02; CI: 0.19 – 1.79) compared to group 1. Group 2 was also more active than group 1 (ES = 0.69; CI: -0.11 – 1.44).
CONCLUSION: The surprising finding of this study was that the younger women had lower MFO than the older women. In fact, the older women's MFO was comparable with sedentary healthy women (Stisen et al., 2006). MFO is influenced by VO2max, FFM and physical activity (Venables et al., 2005). In this study, the difference in MFO between the groups may be explained by the lower FFM and activity levels observed in the younger women. A lower FFM is also associated with a higher risk of cardiovascular disease, while a reduced capacity to oxidise fat during exercise may increase the risk in developing metabolic syndrome. The finding of this study highlights the need to implement community intervention programs targeted at young adult women to lower their risk for chronic non-communicable diseases.

AGE-RELATED TRENDS IN ABDOMINAL OBESITY, CARDIORESPIRATORY FITNESS AND COGNITIVE FUNCTION IN LOW INCOME SOUTH AFRICAN WOMEN

NIEUWOUDT, S., TERBLANCHE, E.

STELLENBOSCH UNIVERSITY

INTRODUCTION: As people age, their cardiovascular health and cognitive function (CF) tends to decline, while the prevalence of non-communicable diseases (NCD's) rises. These changes are accelerated in low to middle income countries where the awareness and detection of NCD associated risk factors are low. Few studies describe the prevalence of these risk factors across age-groups, specifically in developing countries. This study therefore aims to describe the age-related trends in abdominal obesity, cardiorespiratory fitness and cognitive function in low income South African (SA) women.
METHODS: 61 women (age 39.8 ± 13.6 years (yrs), body fat% 46.4 ± 7.1%, education 10.3 ± 2.5 yrs) from a low income community volunteered for this cross-sectional study and were separated into four age categories (18-29 yrs; 30-39 yrs; 40-49 yrs and 50-64 yrs). Visceral adipose tissue (VAT) was measured using dual-energy x-ray absorptiometry, while waist circumference (WC) was measured according to the International Standards for Anthropometric Assessment (ISAK). Peak oxygen uptake was determined using a graded treadmill test to exhaustion. CF was assessed with the Brief Core computerised neurocognitive test, CNS Vital Signs. Data was analysed using one-way ANOVA for independent groups and $P<0.05$ was considered statistically significant. Institutional ethical approval was obtained from Stellenbosch University.
RESULTS: All outcome variables showed a negative trend across age groups. Abdominal obesity, as measured by VAT (g) and WC (cm), increased significantly between 18-29 yrs (389.6 ± 244.4g; 73.2 ± 17.6cm) and all respective groups, 30-39 yrs (757.5 ± 399.2g; 88.5 ± 18.8cm), 40-49 yrs (778.5 ± 282.2g; 91.5 ± 15cm), 50-64 yrs (845.9 ± 187.2g; 94 ± 10.3cm) ($P<0.05$). A significant decrease was seen in peak oxygen uptake between 18-29 yrs (27.9 ± 5.4ml.kg.min), 40-49 yrs (22.1 ± 4.5ml.kg.min) and 50-64 yrs (21 ± 3.9ml.kg.min) ($P<0.05$). CF declined significantly in eight cognitive domains between 18-29 yrs and 50-64 yrs and in five cognitive domains between 18-29 yrs and 40-49 yrs ($P<0.05$).

CONCLUSION: Adverse health is generally associated with older age, however, in low income SA women, risk factors for NCD's are occurring earlier than anticipated (Allen et al., 2017). With baseline measures of cardiovascular and cognitive health already poor in these women from early adulthood and further negative changes, specifically in abdominal obesity, with ageing, there is an urgent need for community interventions targeting young women to reduce the risk of future cardiovascular disease and dementia.

THE PHYSIOLOGICAL AND METABOLIC DEMAND OF A STANDARDIZED 60-MINUTE POLE DANCING CLASS

NICHOLAS, J.C., MCDONALD, K.A., PEELING, P., JACKSON, B., DIMMOCK, J.A., ALDERSON, J.A., DONNELLY, C.J.

UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Pole dancing has become a popular form of group exercise (Dale, 2012); however, no empirical quantitative scientific studies examining the acute physiological or metabolic demand of pole dancing classes exist. The aim of the study was to quantify the demands of a standardized recreational pole dancing class, classifying the outcomes according to American College of Sports Medicine (ACSM) exercise intensity guidelines (ACSM, 2011). Further, differences in physiological and metabolic measures between class discrete components were also explored.
METHODS: Fourteen advanced-level amateur female pole dancers completed a baseline test to determine peak oxygen consumption (VO2peak), heart rate (HR) and blood lactate (BLa); along with three 60-min standardized pole dancing classes, including warm up, skills-based (individual pole-based manoeuvres), routine-based (sequence of combinations including jazz-style dance moves and pole-based manoeuvres), and cool down components. In one class, participants were fitted with a portable metabolic analysis unit (CosMed K5, Roma, Italy).
RESULTS: Overall, classes were performed at a mean VO2 of 16.04 ml.kg-1.min-1 (49.6% VO2peak), total energy cost of 281.6 kcal (4.7 kcal.min-1), metabolic equivalent of 4.6 METs, HR of 132 b.min-1 (75.7% HRmax), and BLa of 3.1 mM (59.1% peak BLa). When comparing skills- and routine-based components of the class, % HRmax (73.4 vs. 78.6), %VO2peak (46.9 vs. 56.0), energy cost per min (4.4 vs. 5.3 kcal.min-1), and METs (4.3 vs. 5.2) were all greater in the routine-based component ($p < 0.01$).
CONCLUSION: In accordance with ASCM guidelines, a 60-min pole dancing class is classified as a moderate-intensity cardiorespiratory exercise, that when completed for ≥30 min, ≥5 days per week (total ≥150 min), satisfies the recommended level of cardiorespiratory exercise (ACSM, 2011). Additionally, given the greater %HRmax, %VO2peak, energy cost per min, and METs in the routine-based component, classes with a greater focus on routine-based training may benefit those seeking to exercise at a higher intensity, resulting in greater caloric expenditure.

OXYGEN SATURATION THROUGH PULSE OXIMETRY IN SPORTSWOMEN

MARTIN-ESCUDERO, P., MIGUEL-TOBAL, F., DOTOR-CASTILLA, M.L., LÓPEZ-SILVA, S.M., GIANNETTI, R., GALINDO-CANALES, M.

UNIVERSITY COMPLUTENSE OF MADRID

INTRODUCTION: Oximetry is a method used to assess peripheral blood oxygen saturation based on the determination of the level of red light absorption, directly influenced by the hemoglobin levels. Most studies on pulse oximetry, within the scope of sports medicine and clinic, have been performed in male populations, with few studies in female populations. The objective of our study was to determine transcutaneous oxygen saturation in sportswomen of different races and to analyze the correlation of this determination with the first (VT1) and second (VT2) ventilatory thresholds.
METHODS: Our study was performed in 27 voluntary female athletes of caucasian (25) and black (2) race, 22,96 SD 6,19 (years old); height 163,81 SD 6,89 (cm); and weight 57,23 SD 6,69 (Kg) from different sports, who practiced sport regularly prior to the study for at least 2 years. They trained regularly, on average 1 to 3 hours/session for 4-6 days a week as members of a sports club at local/regional level. Each of the athletes, (after signing an informed consent) underwent a maximal incremental ergospirometry test, from which a series of ergospirometric variables were determined. In conjunction with the stress test, peripheral oxygen saturation was measured by pulse oximetry, correlating these values with the data obtained by the gas analyzer.
RESULTS: Regarding VT1, we found statistical significance (p=0,030) between the time to reach the aerobic threshold after the first small decrease in oxygen saturation, and the appearance of that threshold (every minute the longer the first one is, the threshold will take 0,259 minutes more to appear), explaining a 43.3% of the variability in the time of appearance of VT1. As for VT2, we found a strong relationship between when oxygen desaturation starts to occur, after the aerobic threshold (what we called desaturation time), and the appearance of the VT2 (every minute longer the first one takes to appear, the threshold will take 0.865 minutes more to appear), with a Pearson correlation of close to 1 (0.892), and statistically significant ($p = 0.000$), explaining a 86.5% of the variability in the time of occurrence of the anaerobic threshold.
CONCLUSION: The pulse oximetry is a simple, reproducible method that is quite accurate and noninvasive to study physical condition of athletes performing physical effort. In all athletes a common behavior is present in the evolution of oxygen saturation during an incremental stress test. We found certain correlation between the time to reach VT1 after the first small decrease in oxygen saturation and the appearance of that threshold. The linear regression model of desaturation time with the time of occurrence of VT2 in female athletes is able to predict onset VT2.

RELATIONSHIP BETWEEN RATE OF FORCE DEVELOPMENT OF TOE FLEXOR STRENGTH AND VERTICAL JUMP PERFORMANCE

KOYAMA, K.1, KUDO, S.1, YAMAUCHI, J.2,3

1. TOIN UNIVERSITY OF YOKOHAMA, KANAGAWA, JAPAN 2. TOKYO METROPOLITAN UNIVERSITY, JAPAN 3. RESEARCH CENTER IN BACK, NECK, OTHER JOINT PAIN AND HUMAN PERFORMANCE , FACULTY OF ASSOCIATED MEDICAL

INTRODUCTION: Rate of force development (RFD) of maximum force has been a term to describe the ability to rapidly develop muscular force. RFD of the maximum leg extension strength was related to vertical jump performance (Yamauchi et al. 2007). This suggests that the ability of neuromuscular system to develop the greatest force in the shortest time is required for recruitment of the greatest number of motor units at the beginning of contractions and for the development of the high vertical force in jump performance.
In the push-off phase during jump, the toes are dorsiflexed and metatarsal phalangeal joint dorsiflexion moments rapidly increased (Goldmann et al. 2013). Thus, the muscle strength of the toe flexor muscles is a key to enhance the jump performance. Indeed, maximum toe flexor strength was significantly correlated with jump performance in children (Morita et al. 2015) and adolescents (Otsuka et al. 2015); however, there were no studies of how the rate of force development (RFD) of toe flexor strength is related to jump performance. The aim of this study was to examine whether the RFD of toe flexor strength correlates with jump performance.
METHODS: Thirty-one healthy men were measured toe flexor strength and jump performance with the toe grip dynamometer and the force plate. RFD of toe flexor strength was evaluated by the force-time curve and was calculated from time period between 20% and 80% of the total time of the maximum force. To record the force signals, the output from the dynamometer was introduced to the computer through an analog-to-digital converter. Jump performance was assessed using 3 styles of jump without arm swing: a countermovement jump (CMJ), a squat jump (SJ) and repeated rebound jumps. From the force-time data, jump height, maximum ground reaction force and RFD of ground reaction force in CMJ and SJ, and the rebound jump index (RJI) in repeated rebound jumps were calculated.
RESULTS: RFD of toe flexor strength was significantly correlated with jump height in CMJ, SJ and RJI; however, it was not significantly correlated with RFD of ground reaction force in CMJ and SJ.
CONCLUSION: The result of this study suggests that the rate of force development of toe flexor strength might be important factor of jump performance, although it was not major role for the rapid development of the high vertical force in jump performance.

POST-ACTIVATION POTENTIATION OF AN INERTIAL FLYWHEEL EXERCISE ON SQUAT JUMP PERFORMANCE

TIMÓN, R., ALLEMANO, S., CAMACHO-CARDEÑOSA, M., CAMACHO-CARDEÑOSA, A., MARTINEZ-GUARDADO, I., OLCINA, G.

FACULTY OF SPORT SCIENCES. UNIVERSITY OF EXTREMADURA. CÁCERES

INTRODUCTION: Post-activation potentiation (PAP) has been defined as an acute enhancement of muscular performance following a preload stimulus with maximal or submaximal muscle actions (Hughes et al, 2016). The eccentric supramaximal intensities (130% 1RM) seems be effective in eliciting PAP in strength trained (Golas, 2016). Given that the inertial flywheel exercise involves an eccentric overload that causes a maximal voluntary contraction, the aim of this study was to determine whether the inertial flywheel exercise can have a potentiation effect on squat jump performance.
METHODS: 15 active university students participated in the study (age: 22,1 ± 2,7 years; BMI: 23,9 ± 3,1). A randomized crossover design was used and all participants completed two different protocols on separate days after the same warm-up: Control Protocol (15 s. skipping + 8 free body weight squats) and Flywheel Protocol (3 x 8 reps. of inertial flywheel squat at peak power and 3 min. rest). The squat jump performance was measured by contact platform at baseline before the conditioning protocols, and four, eight and twelve minutes after the protocol. A repeated measures ANOVA was performed to analyse significant differences over time.
RESULTS: Vertical jump height (from 26.1 ± 5.2 to 28.7 ± 5.8 cm.), power (from 783.9 ± 178.0 to 816.10 ± 189.7 Watts) and velocity (from 2. 2 ± 0.2 to 2.3 ± 0.2 m/s) were increased significantly ($p = 0.05$) from baseline at four minutes after the inertial flywheel protocol, but no significant difference was observed at eight and twelve minutes.
CONCLUSION: The inertial flywheel exercise showed a potentiation effect on squat jump performance after four minutes of recovery, so this pre-conditioning strategy could be useful during the warm-up before competition. Anyway, given that the PAP phenomenon depends on many variables, it would always be important to individualize the conditioning protocol as much as possible.
Financial support for this study was received from Regional Government of Extremadura (Spain).

EFFECT OF SQUAT MOVEMENT SPEED ON BEHAVIOR OF VASTUS LATERALIS MUSCLE-TENDON COMPLEX

NORO, H., TAKESHITA, T., YOSHIDA, T., TAGURI, A., KATO, R., HATA, K., YANAGIYA, T.

JUNTENDO UNIVERSITY

INTRODUCTION: Squat exercise is often conducted as the training of lower limb muscles at various movement speeds. Manabe et al (2004) reported that effective stretch-shortening cycle (SSC) exercise had occurred at the more quick condition in the EMG study. Moreover, Jacob et al (2016) investigated the effect of squat training manner (Squat Jump, Volitional speed, and slow fixed-tempo squat) on the muscle-tendon behavior using ultrasonography. However, we thought that it is necessary to compare at the same range of motion for investigating the effect of movement speed on the muscle-tendon behavior. Therefore, we aimed to compare muscle tendon behavior during squat exercise at different movement speed using ultrasonography in vivo.

METHODS: Active eight male students participated as subjects in this study (age: 22.8±0.9yrs; height: 1.75±0.06m; weight: 67.1±4.0kg). They had squat exercise with self-weighted load at 5 different movement speeds on the force platform, Right and left leg separately. Ground reaction forces were recorded at 1kHz. Behaviors of muscle-tendon complex in vastus laterals muscles were captured using real-time ultrasonography at 45fps, length changes in tendon and fascicle were calculated after that. Electromyogram in the right lower limb muscles was recorded at 1kHz.
RESULTS: Remarkable electromyogram activities in VL were observed in ascending phases during squat exercise in all movement speeds. Fascicle length tends to shorten in the ascending phase. On the other hand, tendon tends to lengthen in ascending phase. We could have observed changes in force-length relation during faster squat motions. The shorter fascicle length was observed as movement speed was faster until 3-s, after that it was maintained. Peak tendon length was almost constant at any movement speed.
CONCLUSION: Ultrasonography had given the effective information about the behavior of fascicle and tendon during squat exercise along with different movement speeds. However, no stretch effect was observed in tendon even if faster movement speed.

EFFECT OF SEQUENCE PATTERNS OF MOVEMENT DURING SINGLE SQUAT EXERCISE ON THE BEHAVIOR IN MUSCLE TENDON COMPLEX IN VASTUS LATERALIS MUSCLE.

TOSHIO, Y.
JUNTENDO UNIVERSITY

INTRODUCTION: Counter action, like squatting immediately before jumping, is known to help conducting movements efficiently during physical movements. This is called as a stretch shortening cycle (SSC) exercise. It is thought elastic energy is stored in the series elastic elements of muscles, like tendinous tissues in the stretching phases during counter actions. After that, elastic energy is thought to reuse for augmenting muscle forces immediately after stretching phases. However, it has not been known whether the augmentation in muscle tendon complex (MTC) could be acquire or not if sequence patterns are different.
Ultrasonography is used to get directly but non-invasively the movies of behaviors in MTC during various exercise. Therefore, the purpose of present study was to investigate effects of sequence patterns of movement during single squat exercise on the behavior in muscle tendon complex of Vastus Lateralis (VL) muscle.
METHODS: Seven male students who majoring sports science participated as subjects in this study (age: 22.8±0.9yrs; height: 1.75±0.06m; weight: 67.1±4.0kg). They conducted single squat exercise in two kinds of sequence patterns at same movement speeds. One sequence pattern was squat from standing position (descending-ascending; DA), the others were also squat but from sitting position (ascending-descending; AD). Their motion speeds and distances of rise and fall were almost the same among patterns. Motion of the body in sagittal plane was recorded by high speed video camera. Joint kinematics was analyzed by digitizing body land markers using computer software. Vertical ground reaction forces (VGRF) in both legs were measured separately. And real-time ultrasound images were recorded at 75 frames per second, from the center of VL muscle using linear array probe. Tendon length was calculated from lengths in fascicle and muscle tendon, according to previous studies.
RESULTS: Higher VGRF were observed in the ascending phase compared with descending phase in both sequence patterns. VGRF in the ascending phase was higher than that in the descending phase. Higher VGRF were developed through ascending phase in AD pattern compared with DA pattern. Lengthening of tendon was observed in descending phase in both sequence patterns, shortening of muscle fibre also observed at the same time.
CONCLUSION: It was thought that recoil of elastic energy stored in tendon was more efficiently used in DA pattern.

INFLUENCE OF ACCELERATION LEVELS ON REACTIVE JUMPS DURING ARTIFICIAL GRAVITY ELICITED BY CENTRIFUGATION

GRUBER, M., KRAMER, A., KÜMMEL, J.
UNIVERSITY OF KONSTANZ

INTRODUCTION: Humans are accustomed to Earth's constant gravitational acceleration of 1g. The absence of gravitational forces during space missions can cause severe deteriorations of the whole body. The results of a previous study suggest that artificial gravity elicited by centrifugation in combination with high-impact exercise with high peak forces has the potential to counteract many of these negative adaptations (Kramer et al., 2018). Therefore, the aim of the present study was to determine if reactive jumps are possible with different acceleration levels ranging from 0.5g to 1.5g in a non-constant force field elicited through centrifugation.
METHODS: Ground reaction forces and electromyographic (EMG) data of 14 healthy male subjects (27±5 years, 77±6kg, 181±7cm) were recorded during repetitive hopping in a short-arm human centrifuge for five different acceleration levels in counterbalanced order: two acceleration levels lower than normal gravity (0.5g, 0.75g), one with gravitational acceleration (1g) and two with higher acceleration (1.25g, 1.5g). These data were compared to normal hops with gravitational acceleration of 1g.
RESULTS: Increasing the acceleration from 0.5g to 1.5g resulted in increased peak forces (+83% when comparing the value at 1.5g to the one at 0.5g), rate of force development (+100%), with minor changes in ground contact time except for the 0.5g condition, and increased muscular preactivity (+17% to +120%, depending on the muscle). However, even for the 1.5g condition, these values did not attain the level observed for normal jumps on the ground: for example, the peak forces during centrifugation reached only 68% of the peak forces during vertical jumps.
CONCLUSION: The results show that in principle, the adaptation of a movement pattern to acceleration levels other than the normal constant gravitational acceleration of 1g is possible, even with a non-constant force field. However, the participants were not able to perform the movement with similarly high peak forces, short ground contact times and high muscle preactivity as compared to natural vertical jumps on earth.

INFLUENCE OF DIFFERENT STRETCH VELOCITIES ON CONTRACTION PERFORMANCE OF THE HUMAN TRICEPS SURAE DURING AND AFTER STRETCH-SHORTENING CYCLES

GROEBER, M.1,2, BACA, A.1, SEIBERL, W.2

1: UNIVERSITY OF VIENNA, 2: TECHNICAL UNIVERSITY OF MUNICH

INTRODUCTION: The stretch-shortening cycle , a combination of an eccentric and immediately following concentric muscle activation, occurs in most everyday movements. The SSC is a component of essential movement patterns, such as walking, running and jumping. The goal of this work is to provide a better understanding of this muscle action. The focal point is to examine the influence of different stretch speeds on the contraction performance of the human triceps surae during maximal voluntary SSCs.
METHODS: The torque of n=13 subjects was measured during and after SSCs. The SSCs were performed with stretch speeds of 30°/s or 120°/s, and shortening speed fixed at 60°/s <30° range of motion>. ANOVA statistics and Pearson correlations served for analysis of differences and relationships of torque and work during and after SSCs, as well as pure stretch, pure shortening and isometric reference contractions.
RESULTS: After the SSCs, significant force depression was found <30°/s and 120°/s; 9.1±4.8% and 10.9±6.3%>, compared to pure shortening. The work during the shortening phase of SSCs was significant higher compared to pure shortening contractions <30°/s and 120°/s; 11.7±4.8% and 17.7±6.3%>. However, there was no difference between work and FD in SSCs. Furthermore, there was no correlation between FD after SSCs and peak torque values at the end of stretch 0.05>, or a correlation between the work performed during shortening and FD after SSCs 0.05>.
CONCLUSION: In conclusion, it was found that neither different peak torque values, nor the work performed during shortening are related to FD following the SSCs. Nevertheless, compared to pure shortening, stretch-induced mechanism counteracted FD, resulting in less FD. The storage and release of elastic energy, stretch reflexes and the activation dynamics can also contribute to increased torque and work during the shortening phase of SSCs .

EFFECTS OF SQUATS ON COUNTERMOVEMENT JUMP PERFORMANCE ACROSS MULTIPLE SETS OF A CONTRAST PROTOCOL IS NOT RELATED TO STRENGTH LEVEL

BAUER, P.1, SANSONE, P.2, MITTER, B.1, SEITZ, L.B.3, KRENN, B.P.1, TSCHAN, H.1

1: UNIVERSITY OF VIENNA, INSTITUTE OF SPORT SCIENCE ; 2: UNIVERSITY OF ROME "FORO ITALICO" ; 3: EDITH COWAN UNIVERSITY, CENTRE FOR EXERCISE AND SPORT SC

INTRODUCTION: Post-activation potentiation (PAP) response following the completion of a conditioning activity (CA) appears to be larger among stronger individuals (Seitz et al. 2016a). However, the influence of strength level on PAP across multiple sets of paired exercises (CAs and countermovement jumps (CMJ)) remains to be elucidated. Therefore, the present study was designed to evaluate the influence of strength level on the PAP effects of moderate (MI) and high intensity (HI) squat exercises on CMJ performance across multiple sets of a contrast training protocol.
METHODS: Sixty resistance-trained male (age, 23.3±3.3 y; body mass, 86.0±13.9 kg; relative squat 1RM, 1.8 ± 0.2 kg.kg) participated in a randomized, cross-over study. After baseline assessment they performed a contrast PAP protocol comprising three sets of either MI (6×60% of 1RM) or HI squats (4x90% of 1RM) or 20 seconds of recovery (CTRL) alternated with seven CMJs that were performed at 15 seconds, 1, 3, 5, 7, 9 and 11 minutes after the squats or recovery. Jump height (JH) and relative peak power (PP) recorded with a force plate during MI and HI was compared to that recorded during CTRL to calculate the PAP effect. After dividing the subjects into two groups ("strong" and "weak") based on the median of relative squat 1RM (i.e., 1.77 kg.kg) a 3-way mixed ANOVA was used to assess the effects of group, condition and time and their interaction on JH and PP. Additionally, Pearson product-moment correlations were calculated to assess the relationship between relative strength and PAP response.
RESULTS: Although PAP could be elicited across all three sets of MI and HI at around 3 – 7 minutes post-recovery (+1.3 -+4.4%, $p<.05$), no significant interaction between group x time, group x condition or group x condition x time was found (all $p>.05$). Likewise, all correlations between relative strength and PAP responses were small (all $r<.28$) and not significant ($p>.05$).
CONCLUSION: The present findings conflict with previous research which has suggested that strength level is a modulating factor in eliciting PAP. However, there is evidence suggesting that PAP response is influenced by other subject characteristics like jumping ability (Tsoukos et al., 2016) or type II myosin heavy-chain isoform percentage (Seitz et al, 2016b).

COMPETITIVE WEIGHTLIFTERS DISPLAY SIGNIFICANT INTER-AND INTRA-INDIVIDUAL VARIABILITY IN THE KINEMATICS OF THE BACK SQUAT

KRISTIANSEN, M., RASMUSSEN, G.H.F., SLOTH, M.E., VOIGT, M.

AALBORG UNIVERSITY

INTRODUCTION: Many coaches seem to act according to the idea of an ideal or average lifting pattern in e.g. back squat. However, due to individual differences in e.g. anthropometry, muscle morphology and neurophysiology it seems plausible that significant inter-individual variability might be present in the kinematics of the squat. Moreover, due to redundancy of the musculoskeletal system, considerable intra-individual variability might also be present. Therefore, the purpose of this study was to elucidate the level of inter- and intra-individual variability in the kinematics of the back squat among competitive weightlifters.
METHODS: Ten competitive weightlifters volunteered for participation in this study. Data were collected by recording six trials at 90% of 1RM in the back squat, with a rest interval of 4-7 min between all sets. Kinematic data were recorded using a synchronized eight-camera movement analysis system. Barbell velocity (VBarbell) and angular velocity for the ankle (VAnkle), knee (VKnee) and hip joint (VHip) were

digitalized and analyzed using Visual3D. The squat was then divided into five lifting phases (Escamilla et al., 2001): I) descent phase, II) acceleration phase, III) sticking region, IV) maximal strength region, and V) deceleration phase. Inter-individual variability was assessed by analyzing inter-individual differences in the velocity curves of VBarbell, VAnkle, VKnee and VHip through a one-way ANOVA using the statistical parametric mapping method (Pataky et al., 2010). Intra-individual variability were assessed by analyzing intra-individual differences in mean standard deviation of VBarbell, VAnkle, VKnee, and VHip for the each of the five lifting phases across the six trials through a one-way ANOVA.
RESULTS: Significant inter-individual differences were identified in VBarbell, VAnkle, VKnee, and VHip ($p \leq 0.05$). Comparing the mean standard deviation of VBarbell, VAnkle, VKnee, and VHip for each lifting phase, revealed significant intra-individual differences in lifting trials at 90% ($p \leq 0.05$).
CONCLUSION: In conclusion, the results of the present study clearly demonstrate that experienced lifters display significant inter- and intra-individual variability in the execution the back squat. This is most likely due to individual differences in for instance anthropometry, morphology and neurophysiology coupled with the redundancy of the musculoskeletal system. Strength coaches should acknowledge the existence of such variability in squatting kinematics and seek to individualize squatting technique accordingly.

IMPACT OF AN INTENSE 5-DAY TRAINING SESSION ON LOWER LIMBS STIFFNESS IN YOUNG HANDBALL PLAYERS

DURAND, S., ROBICHON, J., BOYAS, S., RAHMANI, A.

LE MANS UNIVERSITÉ

INTRODUCTION: Handball practice requires multiple physical capacities since it places emphasis on running, jumping, sprinting, arm throwing, hitting, blocking and pushing (Gorostiaga et al., 2006). Among all the movements associated to handball practice, the split step warrants specific consideration. This action can be performed during offensive like during defensive phases and will help the players to develop speed and reactivity. Lower limbs stiffness (LLS) can reflect the quality of split step and helps quantifying rebound ability. To study the impact of handball practice on these factors, we evaluate changes in multi rebound performance during a training camp in 36 young handball players from regional to national level.
METHODS: Jumping performances were assessed using Optojump® (Microgate®, Bolzano, Italy) at the beginning and at the end of the 5-day training camp. Results are presented as mean±SD.
A hopping (multi-rebound) test to evaluate LLS. For the hopping test, trial lasted 10s. Participants were asked to keep their knees as stiff as possible during test. The calculation of stiffness (K, expressed in N.m-1) for each impulse was accomplished using the formula developed by Dalleau et al. (2004) with TF and TC (both in seconds) representing respectively the flight and the contact times.
Then the global value of LLS for the test is calculated as the average of values obtained for each impulse during test.
RESULTS: The anthropometric characteristics of the group were: 15±1years, 176±8cm, 68±12kg. They used to train between 3 to 6 hours per week in addition to a match played during the weekend.
Mean global LLS was 22,990±4,571 N.m-1 at the beginning of the training session on Day 1 and 20,382±4,876 N.m-1 at the end of the training session on Day 5 ($p<0.001$). Between the first and the second test session, TF measured during the hopping test decreased from 0.477±0.45 seconds to 0.462 ± 0.45 seconds ($p<0.001$) while TC increased from 0.198± 0.17 seconds to 0.216 ± 0.32 seconds ($p<0.001$).
CONCLUSION: Our study suggests that LLS in young handball players is affected by repeated training sessions as performed during a training camp. This impacts negatively both TF and TC measured during multi rebounds. It reveals that the handball related fatigue affects lower limbs, in blunting muscular hopping qualities. This slows down split steps and diminishes jump performances.
This has to be taken into account during training camp to optimize physical training and prevent injuries.

IMPACT OF A COGNITIVE TASK ON CYCLING FRACTAL PROPERTIES

GILFRICHE, P.1,2, ARSAC, L.M.1, BLONS, E.1, DESCHODT-ARSAC, V.1

UNIV. BORDEAUX

INTRODUCTION: Many periodic motor tasks have been shown to exhibit long-range correlations in time periods, like gait, rowing, and more recently cycling (1). Changes in the realization of a motor task while operating a cognitive task is well known and has been explained via the dual-task paradigm. We have recently shown that fractal properties of walking, marked by the scaling exponent of inter-stride intervals derived by Detrended Fluctuation Analysis (DFA), increased when operating a cognitive task. We hypothesized that inter-cycling intervals (ICI) scaling exponent should be similarly affected when operating a cognitive task.
METHODS: Our study involved 19 participants aged 24.4±2.7 years, asked to cycle for twice 10 minutes on a friction-loaded cycle ergometer, with and without performing a cognitive task. The task (PASAT) was chosen to recruit the prefrontal cortex, to interfere with a supposed central generation of cycling. Inter-cycle intervals (ICI) were computed using a light meter at 1kHz. After identifying two scaling phenomena with DFA, we computed both a short-term scaling exponent αS on box sizes smaller than 8 and a long-term scaling exponent αL on box sizes bigger than 10.
RESULTS: Mean detrended windowed autocorrelation was positive (0.55±0.27 in free cycling situation), indicating emergent timing. Our study exhibits long-term (>10s) fractal properties in ICI, and an increase in αL with cognitive task (1.03±0.13 vs. 1.06±0.17, $p<0.05$). αS was significantly higher than long term scaling exponent αL both in free cycling (1.36±0.23, $p<0.001$) and in cognitive task situation (1.41±0.17, $p<0.001$), and was not significantly impacted by cognitive task (ns).
CONCLUSION: One main finding here is the presence of long-range fractal correlations in ergometer cycling. The observed increase in αL with cognitive task is similar to what has been witnessed in walking. There is an ongoing debate as to the origin of long-range fractal correlations in human locomotion, mostly viewed as an emergent timing (2). This fractality may either have a peripheral origin, with a fractal evolution of the biomechanical oscillator stiffness over time (2), or a central origin, with a Central Pattern Generator: a network of neurons producing a rhythmical output (3). Although the present results do not bring any definitive answer to this debate, it is worth

noting that a central contribution in this intricate network cannot be ignored, as evidenced by the impact of a cognitive load on the temporal structure of the output signal.

INTER-RELATIONSHIP OF MEN ARTISTIC GYMNASTIC VAULT RUNNING SPEED ON DIFFICULTY VALUE AND JUDGES SCORES

HE, W.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Vaulting kinematic such as approach running speed, maximum speed on springboard, 1st and 2nd flight time, duration on support table of the artistic gymnastic handspring vault were strongly correlated with vault difficulty value(DV) (Atikovic, 2012) and judges score(FS) (Bradshaw & Sparrow, 2001). However it seem to be reasonable theoretical accepted that once poses superiority of approach speed(AS) will allow higher quality completion of complex acrobatic movement and leading to achieve higher judges score. This study aimed to examine the inter-relationship between AS, DV and FS.
METHODS: The study sample recruited (n=64) handspring vaults from Mens Artistic Gymnastic qualifying round of the 2017 China National Artistic Gymnastics Championship which adopted Code of Points (COP) 2017-2020. Samples were divided into 4 groups based on DV (G1:4.0DV, n= 8; G2:4.8DV, n=34; G3: 5.2DV, n=14; G4: 5.6DV, n=8). A 50Hz JVC PX100 video camera was placed about 50m perpendicular to the vault table. Kinematic data was coded by an experience coder with reliability of Cronbachs Alpha r=0.96 by using Dartfish 2D video analysis software. The approach speed was a product of changes of displacement over time measured from 3rd last step to single leg takeoff toward springboard, whereas FS and DV were official competition score. Spearman Rho correlation was used to examine the relationship and one-way ANOVA analysis was to examine the effect of AS and FS on DV by IBM SPSS 22v statistical software. LSD post hoc analysis were followed if significant different found between DV groups. P value was set at 0.05.
RESULTS: The FS was moderate correlated with AS (rs=0.63) and strong correlated with DV(rs=0.90) significant at $p<0.01$; and moderate correlated between AS and DV (rs=0.60, $p<0.01$). The FS and AS were both significant different between DV group, $p<0.01$. Post hoc test reveal that FS in all DV groups were significant difference from each group (G1=12.74±0.14, G2=13.65±0.19, G3=14.17±0.18 and G4=14.59±0.22). Only G1 (7.24±0.15) and G2 (7.63±0.25) of AS were significant different between all groups, $p<0.001$ while G3 (7.91±0.30) and G4(7.91±0.35) were not significant $p\geq0.05$.
CONCLUSION: The study revealed that the average gymnasts AS on high DV groups were at 7.91ms-1 was slower than the Stuttgart World Championship (8.1ms-1)(Maria, Fernandes, Carrara, Amadio, & Mochizuki, 2016). Thus, further development of the AS might not guarantee better vault performance. Slower AS may risk the gymnasts due to insufficient horizontal velocity for higher DV(Takei, Blucker, Nohara, & Yamashita, 2000). We concluded that the increase of AS may allow higher DV and result better FS, but AS might not be an essential variable for higher DV performance.

MEASURING PERCEIVED MOTOR COMPETENCE: A COMPARISON BETWEEN DIFFERENT INSTRUMENTS.

DE WAELLE, S., DE MEESTER, A., DECONINCK, F., HAERENS, L.

GHENT UNIVERSITY

INTRODUCTION: Previous research has shown physical activity to be beneficial for children's and adolescents' physical and mental health. In addition, research confirmed that higher levels of motor competence are associated with higher levels of physical activity. However, it remains unclear how perceived motor competence (PMC) relates to actual motor competence (AMC) and physical activity. Recently, researchers have been trying to answer this question by using a number of different questionnaires to measure PMC, complicating comparison between different studies. Therefore, this study aims (1) to identify the questionnaire for PMC providing the closest match with AMC, and (2) to examine potential correlates of the relationship between AMC and PMC.
METHODS: We recruited 409 Flemish students from 10 different secondary schools. AMC was measured using the Test of Gross Motor Development-2nd Edition (TGMD-2), PMC was measured using four different questionnaires: the Self-Description Questionnaire (SDQ), the Physical Self-Description Questionnaire (PSDQ), the Physical Self-Confidence Scale (PSC) and the Physical Self-Perception Profile for Children and Youth (PSPP-CY).
RESULTS: The PSDQ ($r=0,481$, $p<0,001$) and SDQ ($r=0,467$, $p<0,001$) showed stronger correlations with the TGMD-2 than the PSPP-CY ($r=0,400$, $p<0,001$) and PSC ($r=0,391$, $p<0,001$). Furthermore, correlations between AMC and PMC differed depending on sex, where boys' PMC showed significantly stronger correlations with AMC than girls' for the SDQ ($p=0,033$) and PSDQ ($p=0,036$). No significant differences between boys and girls were found for the correlations between the TGMD-2 and the PSC or PSPP-CY. In addition, youngsters who completed the TGMD-2 before filling out the questionnaires, showed higher correlations between the TGMD-2 and all questionnaires than those who filled out the questionnaires first, although these results showed no statistical significance.
CONCLUSION: Measuring PMC is challenging and the strength of the correlation with AMC may depend on a number of different factors such as sex and testing order. It seems crucial to take this into consideration when measuring PMC and when conducting research concerning AMC and PMC or the relation between PMC and health related benefits.

KINEMATIC FACTORS INFLUENCING THE TAKE-OFF PERFORMANCE IN SKI JUMPING

MUENCH, M., KULESSA, D.J., LAUBER, B., GEHRING, D., KULLMANN, N., GOLLHOFER, A.

ALBERT-LUDWIGS-UNIVERSITÄT FREIBURG

INTRODUCTION: The take-off is a key component of ski jumping performance because the athlete sets the starting conditions for the subsequent flight (Schwameder, 2009). Due to limited training possibilities on the hill, athletes have to practice take-off imitation jumps in a dry setting. Thus, there is the need to identify important biomechanical parameters of the imitation jumps which might be related to the

actual performance on the hill. Consequently, the aim of the present study was to determine key kinematic factors of the imitation jumps and correlate them with a coach-based assessment of the athletes' proficiency level.
METHODS: Sixteen male ski jumpers competing on different levels performed a number of imitation jumps (squat jumps, imitative squat jumps, jumps from a roller-board) in the laboratory while 3D kinematic motion data was captured. Selected parameters were based on previous experiments like the vertical jumping height, vertical take-off velocity, knee extension velocity and valgus index (Schwameder, 2008; Pauli et al., 2016). Other parameters such as knee-hip-synchronization (total difference of the standardized knee and hip angle 500 ms before take-off) and leaning-forward (maximum distance between the center of mass and ankle midpoint projected on the floor) were included because they were considered to be important by national coaches.
Parameters from all jump conditions were pooled together for correlation analyses with a ranking of the athletes' current proficiency level, which was determined by three national coaches who independently ranked the athletes from 16 (best level) to 1 (lowest). Accordingly, statistical correlations were calculated using the rank correlation after Spearman with a significance level of 5%.
RESULTS: The results show significant correlations between the athletes' proficiency level and the knee-hip-synchronization (r=-.432) and leaning forward (r=.586). Also, vertical take-off velocity (r=.294) and valgus index (r=.540) were significantly correlated with the proficiency level.
CONCLUSION: Based on new biomechanical analysis, the parameters knee-hip-synchronization and leaning forward were developed and prove their relevance for the take-off performance. Moreover, the present results confirm previous findings that a pronounced knee valgus position during the take-off negatively effects the athletes' proficiency level (Pauli et al., 2016) while a high vertical take-off velocity has a positive effect (Schwameder, 2008). Future research should focus both on the new as well as on already known parameters and adjust the training sessions in the dry setting and on the jumping hill accordingly.

ASSESSING VERTICAL FORCE-VELOCITY PROFILES: ARE TWO CONSIDERED LOADS UNDER SPECIFIC CIRCUMSTANCES ENOUGH?

KRÖLL, J., LASSHOFER, M., FRITZ, J., SCHWAMEDER, H.

UNIVERSITY OF SALZBURG

INTRODUCTION: Force-velocity (Fv-) relationships of ballistic push-offs are typically assessed via linear regression of repeated measurements with at least five additional loads [1, 2]. For the purpose of performance assessment, in specific cases, a reduced amount of repeated measures would be advantageous (i.e. test efficiency). Recently high general relationship between a multiple load method and a simple two-load method (0 and 40% body mass) were reported [3]. However, individual differences of up to 10% were reported too, indicating insufficient precision for performance diagnostics efforts. The lack in precision is most likely explainable by investigating average experienced athletes at low additional loads [3]. Therefore, the aim of the actual study was to analyse the effect of reducing the amount of repeated loads on Fv-profiles when exposing well-experienced athletes to high loads (80% body mass).
METHODS: Ten male elite junior ski jumpers (16.7±1.3 years; 1.82±0.05 m; 67.4±4.8 kg) performed squat jumps with additional loads at 0%, 20%, 40%, 60% and 80% of body mass. According to a standard method [2, Fv-profiles represented by F0 and v0], a five load Fv-profile was calculated and subsequently compared to three different two-load profiles (three LP's: 0-40LP, 0-60LP and 0-80LP). For this purpose the two-load profiles accuracy (mean of differences), precision (SD of differences) and correlation coefficient were calculated for F0 and v0.
RESULTS: High accuracy for all two-load profiles were depicted for F0 (abs < 0.16N/kgBM; rel < 0.6%) as well as for v0 (abs < 0.02m/s; rel <0.3%). Regarding to F0, 0-80LP depicted higher precision (abs 0.43N/kgBM; rel 1.5%) compared to 0-60LP (abs 1.01N/kg; rel 3.6%) and 0-40LP (abs 1.28N/kgBM; rel 4.6%). For v0 again 0-80LP revealed best precision scores (abs 0.08m/s; rel 2.5%), followed by 0-60LP (abs 0.24 m/s; rel 6.4%) and 0-40LP (abs 0.30m/s; rel 8.5%). The correlation coefficients for 0-80LP were 0.98 for F0 and 0.99 for v0. For 0-60LP (F0: r=0.91; v0: r=0.94) and 0-40LP (F0: r=0.82; v0: r=0.93) distinct lower values were observed.
CONCLUSION: The distance between the two analysed data points is a decisive factor for applying the two-load method. Even for the referred cohort, who is highly familiar with barbell squat jumps due to their daily training (high execution consistency), the two-load method seems to be sufficient only with very high additional loads (80% body mass). With this distant point, maximum individual differences were below 3.5% throughout. When considering only 40% additional body mass, those maximum individual differences increase up to 10% for F0 and 15% for v0. In conclusion, the two-load method only should be applied when testing athletes with extraordinary experience in loaded jumps by using two points located far distant from each other. A general application of the two-load method as suggested earlier [3], is not supported.

NUMERICAL STUDY OF SKI JUMPING WITH DETAILED BODY MODELING

HU, Q.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: At present, ski jumping has become one of the most popular sport in the world with snow, it can prove the individuals ability to fly in the air on a pair of skies. The flight path of a ski jumper is determined by the weight and the aerodynamic forces (lift and drag) acting on the jumper and his equipment, which influence the flight path and thus the jump length in a pronounced way. The athletes can strongly influence the forces by proper movement of parts of their bodies resulting in a changed posture. Ski jumpers have to solve extremely difficult optimization problems in real time in order to optimize their performance. In order to maximize the achievable jump length, the athlete has to vary the angle of attack during the flight and also the configuration of body parts and the skis. The aerodynamic interaction between a ski jumper in flight and the surrounding air is very important for a jumper to fly with a long distance and stable process.
METHODS: In order to study the influence of parameters (such as angle of V style skiing, upwind angle, flying velocity) on the performance of ski jumping, an average man with skiing equipment is modeled with detailed physical characteristics. Facial features and hand fea-

tures are modeled as real as possible. The computational domain contains the human body surface and the region around the jumper, and it is discretized by hexahedron grid and tetrahedron grid using ICEM software. The cell size is between 0.5 and 20 mm. In the region upstream of the ski jumper the cell size is kept at about 20 mm, around hands the cells are about 0.5 mm wide, except in regions of narrow gaps like the armpits and between the legs, where a smaller cell size prevails.In order to capture the expected separation region downstream of the jumper accurately, smaller cell sizes had to be applied. Three dimensional simulation are used to investigate the lift and drag of the jumper. An incompressible air as well as newtonian fluid flow in the absence of external forces are used for the calculation. The flow field around the ski jumper is modelled by the Reynolds-Averaged Navier–Stokes (RANS) equations coupled with the eddy-viscosity SST k-ω turbulence model equations.
RESULTS: A major finding from the present investigations is the relative influence of the skis on the overall aerodynamic forces. In the investigated regime, the relative lift area is significantly larger than the drag area. It has an optimal angle for a jumper to move long distance.
CONCLUSION: The present results suggest that the greater the ski jumpers upwind angle, with respect to the relative flying velocity, the greater the pressure difference between the ski jumper in flight and the surrounding air. Further studies will focus on the dependency of the parameters as control variables, such as angle of V style skiing, upwind angle, flying velocity. It will be possible to optimize different ski jumping styles in different ski jumping hills and investigate different environmental conditions such as altitude , downwind and headwind and crosswinds.

ASSESSMENT OF LIMB SYMMETRY INDEX AS AN INJURY RISK FACTOR IN YOUTH ALPINE SKI RACING

MÜLLER, L.1, HILDEBRANDT, C.1, RASCHNER, C.1, MÜLLER, E.2

1 UNIVERSITY OF INNSBRUCK; 2 UNIVSERITY OF SALZBURG

Introduction: Alpine ski racing is a sport with a high risk of injury at the elite level. In general, lower limb differences of more than 10% are considered to represent risk factors in athletes (McGrath et al., 2016). The role of these asymmetries in the injury prevention in non-dominant sports like alpine ski racing has not been determined, so far. Therefore, the aim of the present study was to assess clinical measures of limb symmetry index (LSI) in performance relevant parameters and the relationship with injuries in youth alpine ski racers.
Methods: A prospective longitudinal cohort design was used. 95 Austrian elite youth ski racers (56 males, 39 females; 9-14 years) were involved in the study. An internet-based database was developed to record traumatic and overuses injuries over two school years. As baseline data, unilateral sports specific performance tests (counter movement jump: CMJ; stability: ST; jump coordination: JC; leg extension strength: LES; Y-Balance: YB) were assessed to define the LSI calculated as the ratio of the dominant leg and the non-dominant leg expressed as a percentage. Multivariate binary logistic regression analyses (dependent variable: traumatic or overuse injury yes/no; independent variable: LSI of performance tests) were performed. The level of significance was set at $p<0.05$.
Results: During the two-year study period 40 traumatic injuries and 9 overuse injuries were recorded, representing a total injury rate of 0.52 injuries / athlete. In mean, the following LSI [%] were calculated: CMJ 112.9 ± 11.4, ST 113.8 ± 14.2, JC 105.3 ± 3.9, LES 110.5 ± 8.3, YB 102.9 ± 2.3. The binary logistic regression analyses revealed that the LSI of LES represents a significant injury risk factor for both traumatic ($p=0.047$; Wald=3.955) and overuse injuries ($p=0.016$; Wald=5.820).
Discussion: In general, small rates of traumatic and overuse injuries were recorded. The in general reported threshold of 10% indicating an elevated injury risk does not seem to be a good indicator of injury risk in a non-dominant sport like alpine ski racing. The regression analyses revealed that only the differences in the LES of more than 10% represented a significant injury risk factor. Injury prevention programs in youth ski racing should therefore focus on the reduction of lower limb strength differences as a modifiable athlete-related risk factor, next to the already investigated modifiable risk factors in youth ski racing such as core strength and neuromuscular control (Müller et al., 2017). However, further research is necessary to assess the role of LSI in injury prevention in adolescent and elite alpine ski racers.

MENTAL WORKLOAD AND SPORT-SPECIFIC KNOWLEDGE IN SKI JUMPING PERFORMANCE

HAMMER, T.M.1, INGEBRIGTSEN, J.E.2

1:UIT , 2:NTNU

Introduction: Ski jump performance is largely dependent on the execution of a complex and technically challenging take-off movement performed at high velocity. The genuine risk of physical injury also raises the difficulty and reduces the acceptable margins of error. Ski jumping takes place under serious time constraint, and athletes have little time to process information during performance. Previous studies show that expert athletes can perform their skills with very little cognitive effort (Naito & Hirose, 2014), and this automaticity is thought to be more effective and utilize the body's natural force potential. Expert athletes are also characterized by a greater knowledge about their activity (Williams & Davids, 1995), which makes for a challenging balance between specific knowledge and automatic performance. The aim of this study is to investigate how ski jumpers experience mental workload, in relation to their sport-specific knowledge and level of performance.
Methods: Qualitative interviews were conducted with two national level and two international elite-level ski jumpers to explore their perception of mental workload and their ski jump-specific knowledge. The athletes also responded to a two-question questionnaire at three occasions during their competitive season. The questionnaire measured their perceived mental workload and ski jump specific tasks. Performance was measured by results in subsequent competitions.
Results: Questionnaire and competition results show that the jumpers made their best performances when reporting their respective lowest amount of perceived mental workload. The same was evident in interviews were all informants described their ideal performance state as relaxed, focused with low cognitive effort. There was an evident difference in knowledge, with the national level athletes describing feelings and thoughts, whereas elite jumpers focused on objective information (e.g. forces, mechanical principles) when asked to explain important parameters of ski jumping performance.
Discussion: The results indicate that mental workload is highly relevant for ski jump performance. Workload does not have to be minimal, but structured in a precise and consistent way. Results further point to the importance of the athlete's knowledge, for both mental workload and level of performance. International level athletes are in possession of greater ski jump specific knowledge, efficiently organized. This heightens the quality of their choices and strategies for skill development. The precise nature of this knowledge also seems to promote a precise and stable mental workload enabling automated performance.

BIOMECHANICAL PERFORMANCE ANALYSIS OF ICE HOCKEY SKATING BASED ON A BODY WORN ACCELEROMETER

STETTER, B.J.1, BUCKERIDGE, E.2, NIGG, S.R.3, STEIN, T.1, SELL, S.1, NIGG, B.M.3
1 KARLSRUHE INSTITUTE OF TECHNOLOGY , 2 LULULEMON , 3 UNIVERSITY OF CALGARY

INTRODUCTION: Previous research on ice hockey skating has shown that biomechanical characteristics can be used to predict skating performance (Buckeridge et al., 2015). In this context, an appropriately large leg power and effective propulsion plays an important role (Renaud et al., 2017, Buckeridge et al., 2015). Advances in sensor technology (i.e. accelerometers) allow player movements in the field to be measured. Hence, the purpose of this study was to quantify stride propulsion based on center of mass (CoM) acceleration in forward skating and to compare differences across skill levels and sprint phases.
METHODS: K-means clustering was used to split twenty-two ice hockey players of different skill level into two groups (low caliber: n=13, high caliber: n=9) regarding their performance times of a 30 m forward skating task. One 3D accelerometer was mounted to the waist at the fifth lumbar spine. A stride specific value was obtained by calculating summed acceleration magnitudes of the three axes, normalized to the stride duration, and defined as stride propulsion (SP). SP was extracted for the 2nd and 6th stride, as they represent the accelerative and constant velocity phases of forward skating, respectively.
RESULTS: High calibers performed the 30 m sprint task in significantly shorter time (mean ± SD: 4.35 ± 0.09 s vs. the low calibers 4.73 ± 0.10 s, $p < 0.05$). A two-way mixed model ANOVA revealed significant group and stride effects, with greater SP for the high calibers in comparison with the low calibers ($p<0.01$, $\eta p2=0.34$) and greater SP for acceleration strides in comparison with constant velocity strides ($p<0.01$, $\eta p2=0.52$).
CONCLUSION: The results of this study are in accordance with the findings of Renaud et al. (2017), which estimated CoM accelerations from motion capture analysis and presented greater center of mass accelerations during skate starts for high caliber players. Additionally, the observed differences between characteristic sprint phases (acceleration & constant velocity) correspond well with the larger plantar push-off force during the initial sprint phase shown by Buckeridge et al. (2015) and underline the increased propulsive demands for a running-like motion compared to a gliding motion. On the basis of our results, the extraction of the SP from a body worn accelerometer seems a valuable approach to provide instant feedback to coaches and athletes to assess individual ice hockey skating performance.

RESEARCH OUTCOMES VS. FEELINGS DURING SKI JUMP LANDING

BESSONE, V.
TECHNICAL UNIVERSITY OF MUNICH

INTRODUCTION: In ski jumping , the role of landing and its preparation plays a central role in improving performance and reducing injuries [1]. However, its importance seems underestimated by athletes and coaches. The author questioned the skiers for understanding their feelings during these phases' execution.
METHODS: The questionnaire included 46 questions, of which 37 related to landing, and was shared and filled online. The questions spaced from the kind of training to the perception of the skiers during the performance.
RESULTS: We interviewed 43 ski jumpers and Nordic combiners <17±4 years> competing at different levels. All the athletes do at least two trainings on the hill per week and jumping at least five times per session. The 49% of the interviewed had at least one injury connected to a bad landing, in particular broken bones, anterior cruciate ligament rupture and ligament contusion. The poll ranked the take-off, in-run, early flight, flight, landing preparation and landing from the most to the least important phase. Experience leads the start of landing preparation for the 43% of the poll . The athletes consider the difficult conditions for performing a parallel leg landing in this order: when the jump is too long, with a bad grooming, lack of visibility and strong wind. The 81% of the pool prefers to land on the mat during summer conditions, the 39% of it feels the highest impact during telemark landing and the 76% on the foot front positioned. In addition, during landing, the 31% of the jumpers feel higher forces on the front foot, the 21% on the rear and the 48% equally distributed.
CONCLUSION: The take-off is the most important phase of SJ performance according to both athletes and researchers [1]. The athletes use PL landing in difficult conditions being easier to perform than telemark [2]. Despite required from the FIS Competition Rules [3], during landing, the body weight distribution is not equal among the feet and among the front/rear parts of the foot as proven by previous studies [4] and perceived by the athletes. The questionnaire was an interesting overview for documenting the feelings of the athletes about landing. This knowledge is an important aspect for focusing further researches and before proposing technical changes to the athletes. However, in order to improve the performance, the athletes should focus on all the phases of SJ, affecting each phase the following one [1].

THE EFFECT OF FREQUENCY OF INTERRUPTIONS IN SITTING TIME ON POSTPRANDIAL GLUCOSE METABOLISM: A RANDOMIZED CROSSOVER TRIAL

THORSEN, I.K., JOHANSEN, M.Y., BRINKLØV, C.F., PILMARK, N.S., JESPERSEN, N.Z., BENATTI, F.B., DUNSTAN, D.W., KARSTOFT, K., PEDERSEN, B.K., RIED-LARSEN, M.

RIGSHOSPITALET

INTRODUCTION: The primary objective of the trial was to investigate if the frequency of interruptions in prolonged sitting affects postprandial glycemic control in healthy, sedentary, overweight males under isocaloric conditions. The primary hypothesis was that frequent interruptions in sitting time would attenuate the postprandial plasma glucose response to prolonged sitting independent of energy intake or expenditure.
METHODS: Healthy, sedentary, overweight males (n=14) completed four 8-h interventions in randomized order: 1) uninterrupted sitting (SIT), 2) sitting interrupted by 2-min bouts of low-intensity physical activity (LPA; ~30% of VO2max) every 20th minute (INT20), 3) sitting interrupted by 6-min bouts of LPA every hour (INT60), and 4) sitting interrupted by 12-min bouts of LPA every second hour (INT120). During the interventions, standardized test drinks (50E% carbohydrate, 50E% fat) were served in the beginning of and 4 hours into the intervention. The primary outcome was the difference in the 8-h total area under the curve (tAUC) for plasma glucose between the active interventions (INT20, INT60, and INT120) and SIT. Secondary outcomes included the differences in 8-h tAUC for plasma insulin, C-peptide, and lipids, as well as in carbohydrate and fat oxidation between the active interventions and SIT.
RESULTS: The mean differences (95% CI) in tAUC for plasma glucose between SIT and INT20, INT60, and INT120 were -1.9% [-7.4; 3.6], 1.6% [-4.1; 7.3], and 0.5% [-5.0; 6.1], respectively. No difference in tAUC for plasma insulin or lipids were observed between any of the active interventions and SIT (p>0.05). However, the 8-h tAUC for plasma C-peptide was lower during INT20 compared to SIT (-8.3% [-15.8; -0.8]). Carbohydrate oxidation rates were higher during all active interventions compared to SIT (p<0.001), whereas fat oxidation rates were only higher during INT20 compared to SIT (34% [14; 55]).
CONCLUSION: Interrupting sitting with LPA at varying frequencies during an 8-h period did not attenuate the postprandial plasma glucose response to prolonged sitting in healthy, sedentary, overweight men. Nonetheless, frequent interruptions may reduce insulin release (reflected by lower postprandial plasma C-peptide response). Moreover, frequent interruptions in sitting may also induce a shift towards higher fat oxidation rates.

USEFULNESS OF CLINICAL MARKERS OF BODY COMPOSITION AND BODY FAT DISTRIBUTION FOR THE ASSESSMENT OF GLUCOSE METABOLISM OF TYPE II DIABETES PATIENTS

PIMENTA, N.M.1,2, MAGALHÃES, P.3

1: CIPER, FMH-ULISBOA , 2: ESDRM-IPS , 3: ESE-IPB .

INTRODUCTION: Central body fat (BF) distribution has been consistently found related to cardiometabolic risk, particularly glucose metabolism impairment (Sparrow et al., 1986). Lower body markers of BF have been found inversely related to insulin resistance despite overall and central BF (Livingston, 2006). Several novel body indexes and BF markers have been proposed to be useful for clinical practice since. Waist-to-Height ratio is one o such indexes that have been proposed to be superior to other clinical markers of body composition as predictors of cardiometabolic risk, including impaired glucose metabolism (Ashwel et al., 2016). The aim of this study was to determine if, and to what extent, classic and novel clinical surrogates of BF content and distribution, are related with glucose metabolism markers, in type II diabetes mellitus patients.
METHODS: We assessed 124 type II diabetes mellitus patients (57 males, 64±9 yrs, and 67 females, 65±8 yrs), who had been diagnosed for 9±7 yrs. BC and BF distribution assessment consisted of anthropometry, specifically: body circumferences (C), including waist-C and hip-C; body indexes (body mass index; body adiposity index [BAI]; waist-to-hip ratio [WHR] and waist-to-height ratio [WHtR]) and skinfold thickness (SKF), including triceps-SKF, subscapular-SKF, supra-iliac-SKF, thigh-SKF and calf-SKF. Glucose metabolism markers factors included fasting blood glucose and insulin, HbA1c, insulin resistance (HOMA-IR).
RESULTS: Partial and semipartial correlations, controlled for age, sex and BMI (except when BMI was a predictor; in this case waist-C was the controlling variable instead) showed that Hip-C, BAI, (r=0,30 and p<0,01 for both) Subscapular-SKF, Suprailiac-SKF, Thigh-SKF (r=0,22; r=0,20 and r=0,19 respectively; p<0,05) were all related with fasting glycaemia, and subscapular-SKF, supra-iliac-SKF, thigh-SKF and sum of SKF were associated with fasting insulin (r=0,43; r=0,34; r= 0,30; r=0,34, respectively; p<0.01). Thigh-SKF was the only BF marker correlated with HbA1c (r=-0,20; p>0,05). Hip-C, triceps-SKF, thigh-SKF and calf-SKF were all inversely associated, and WHR was positively associated, with HOMA-IR (r=-0,35; r=-0,29; r=-0,39; p<0,01 and r=0,26 and r=-0,27; p<0,05, respectively).
CONCLUSION: Thigh-C was the only BF marker related with all glucose metabolism markers supporting the relevance of this BF marker in these patients, in accordance with previous findings (Livingston, 2006). The present study also suggests peripheral BF may have a protective role against insulin resistance; meaning reduced peripheral BF may increase the risk of insulin resistance in these patients. The present results also suggest overall fat to be most relevant for explaining the variation of fasting glycemia, while subcutaneous fat seems to explain better the variation of fasting insulin. The follow up of these patients will allow the usefulness evaluation of the studied BF surrogates for the prediction of longitudinal variation of glucose metabolism.

SIMVASTATIN, INSULIN RESISTANCE AND EXERCISE TRAINING, THE LIFESTAT STUDY

KUHLMAN, A.B., HANSEN, M., KELLY, B., MIKKELSEN, L.B., REGNERSGAARD, S., NIELSEN, F.H., HEINRICHSEN, S., HELGE, J.W., DELA, F.

UNIVERSITY OF COPENHAGEN

INTRODUCTION: Statins lowers blood cholesterol. Frequent side effects to statin treatment are myalgia, muscle cramps and fatigue. Q10 is produced by the cholesterol metabolic pathway and therefore also lowered by statins. Lowered Q10-production has been suggested to be the background for statin-associated-myalgia. Statins may also increase the risk of type 2 diabetes. Myalgia may attenuate an otherwise physically active lifestyle and further increase the risk of type 2 diabetes.

Research questions: Does statins impair the training response, lowers insulin sensitivity and impair the insulin sensitizing effect of training? If so, can Q10 supplements alleviate this? Here we studied the training response and insulin sensitivity in Simvastatin-treated patients supplemented with Q10 compared with placebo and a control group not receiving any medication.
METHODS: 26 male patients with elevated blood cholesterol was randomized into Statins+Q10 (SQ; n=9), Statins+Placebo (SP; n=10) and placebo+placebo (CON; n=7) and performed 8 weeks of supervised bicycle training, 45 min, 3 times pr. wk. VO2max and maximal workload (Wmax) were measured at baseline, during and after training. Insulin resistance was measured as the glucose infusion rate (GIR, mg/min/kg) with a two-step (80 and 400 mU/m2/min) hyperinsulinemic euglycemic clamp.
RESULTS: Age was similar in the groups (56 ± 3 (SQ), 56 ± 3 (SP) and 63 ± 1 (CON) years (mean ± SE). Body weight did not change with the intervention (data not shown).
VO2max increased (P<0.05) in SQ (from 32±2 to 35±2 ml/min/kg), respectively, but not in SP or CON (from 30±1 and 34±2 to 32±2 and 33±2 ml/min/kg, respectively). Wmax always increased (P<0.05) with training (from 231±13, 252±19 and 265±13 to 274±13, 292±19 and 283±17 Watt in SP, SQ and CON, respectively).
GIR did not increase with training in any group (step 1: 6.9±0.6 vs. 7.0±0.5 (SQ), 7.0±0.5 vs. 7.6±0.9 (SP), 9.1±0.8 vs. 8.4±1.0 (CON); step 2: 10.6±0.5 vs. 10.9±0.8 (SQ), 10.7±0.5 vs. 11.5±0.8 (SP), 11.9±0.8 vs. 12.4±1.0 (CON)).
CONCLUSION: VO2max and Wmax responded to training as expected; lack of significance in VO2max in SP and CON may be due to lack of statistical power. Surprisingly, GIR did not change with the intervention, in spite of clear fitness effect and a supervised training. We found no indications that Simvastatin decreases insulin sensitivity in this 8 week study .

DETERMINE THE EARLY TIME-COURSE OF RESISTANCE EXERCISE TO FAILURE ON MUSCLE STRENGTH, SIZE AND INSULIN SENSITIVITY

ISMAIL, A.D.1,2, WILSON, J.1, JOHNSTON, L.1, GILL, J.M.R., GRAY, S.R.

[1]INSTITUTE OF CARDIOVASCULAR AND MEDICAL SCIENCES, UNIVERSITY OF GLASGOW, UK, [2]FACULTY OF SPORT SCIENCES AND RECREATION, UITM, MALAYSIA

INTRODUCTION: The maintenance of muscle size and function plays an important role in metabolic health, specifically as a risk factor for type 2 diabetes (1). Resistance exercise is efficacious in increasing muscle size and strength and also insulin sensitivity (2). However, the optimal make up (load, number of reps etc.) of resistance training is not yet known and recent evidence has shown that performing resistance exercise to failure, regardless of load, may be optimal. Whether resistance exercise to failure can improve insulin sensitivity remains to be investigated. Furthermore the time-course of the adaptations in muscle strength and size is not known.
The purpose of this study was to determine the effect of resistance exercise to failure on insulin sensitivity and the time-course of changes in muscle strength and size.
METHODS: 10 men (age 36 ± 8, height 175cm ± 8, weight 89kg ± 14, BMI 29 ± 5,) were recruited to the study. Resistance exercise involved training all major muscle groups with 1 set to failure at 80%1RM with 3 sessions per week for 6 weeks. Muscle strength (knee extensor MVC) and muscle thickness (ultrasound) were measured at baseline, week 0, 1, 2, 3, 4, 5, 6 and 3 days after the last session of resistance exercise. An oral glucose tolerance test was performed at baseline and 3 days after the last session of resistance exercise.
RESULTS: Knee extensor MVC increased (P<0.05) over 6 weeks of training from 180.9Nm ± 37.88 to 228.4Nm ± 44.69 with MVC each week higher (P<0.05) than the preceding week. Muscle thickness increased (P<0.05) over 6 weeks of training from 21.5mm ± 3.15 to 23.7mm ± 3.21 with muscle thickness each week higher (P<0.05) than the preceding week. Insulin sensitivity (glucose area under the curve during OGTT) increased (P<0.05) after training from 6.34mmol/L ± 1.05 to 5.91mmol/L ± 1.28.
CONCLUSION: Our data demonstrates that 6 weeks of resistance exercise to failure increases muscle size and strength progressively and results in improved insulin sensitivity.

EFFECTS OF SIX MONTHS SUPERVISED PHYSICAL TRAINING ON MUSCLE STRENGTH AND AEROBIC CAPACITY IN PATIENTS UNDERGOING ROUX-EN-Y GASTRIC BYPASS SURGERY - A RANDOMIZED CONTROLLED TRIAL

MUNDBJERG, H.L., STOLBERG, C.R., BLADBJERG, E.M., FUNCH-JENSEN, P., JUHL, C.B., GRAM, B.

UNIVERSITY OF SOUTHERN DENMARK AND HOSPITAL OF SOUTHWEST JUTLAND

INTRODUCTION: Obesity and physical inactivity are major health problems. Roux-en-Y gastric bypass surgery results in significant weight loss and reduces obesity related morbidity and mortality. Physical activity lowers the risk of cardiovascular disease and premature death. The aims of this study were to elucidate the effects of RYGB followed by six months of supervised physical training on physical capacity.
METHODS: In a randomized controlled trial, 60 participants eligible for RYGB were randomized six months post-surgery to either two weekly supervised physical training sessions for 26 weeks or a control group . The intervention period was divided into three phases lasting from week 1-8, week 9-18 and week 19-26, respectively. For each phase, the intensity for the aerobic training and the muscle strength training was increased. The control group was not offered exercise training but received the hospital's standard treatment for patients undergoing RYGB. Aerobic capacity , muscle strength in shoulder and hip and physical function were measured pre-surgery and 6, 12 and 24 months post-surgery. Furthermore, functional capacity was measured by Sit-to-Stand test and Stair Climb Test.
RESULTS: RYGB per se decreased MS in all tested muscle groups, had no effects on VO2max but improved physical function. After the intervention INT had a significant 0.33 L/min increase in VO2max compared to CON <95% CI: 0.07 - 0.57, P=0.013>. Furthermore, MS in the hip adductor increased significantly with 13 N <95% CI: 3.6 – 22.4, P=0.007> and a between-group difference were found in the Stair Climb Test <0.46 repetitions <95% CI: 0.02 – 0.91, P=0.042>. The effects were not maintained at follow up.
CONCLUSION: Supervised physical training following RYGB improved VO2max, hip MS and physical function, but the positive effects were not maintained at follow-up. While daily life activities may become easier as a result of RYGB, the observed extensive post-operative loss of MS requires more attention to increase the patients physical capacity prospectively. Further research in this field is needed to determine in detail the composition of physical training programs for bariatric surgery patients and how to maintain the positive effects of the intervention after termination of supervision.

DEVELOPING A MOTOR ANALOGY TO PROMOTE SAFER LANDING BY OLDER ADULTS WHO FALL UNEXPECTEDLY

MASTERS, R.S.W., BARBOUR, K., HÉBERT-LOSIER, K., PARSONS, J., PARSONS, M., UIGA, L.

UNIVERSITY OF WAIKATO, WAIKATO DISTRICT HEALTH BOARD, & UNIVERSITY OF AUCKLAND

INTRODUCTION: Most research into falling by older people focuses on prevention of falls. Minimal research has focused on promotion of safer falls (that is, landing in a way that minimises severity of injury). There is little time during a fall to explicitly recall (and process) instructions for safe landing, so our goal is to develop a motor analogy (e.g., Masters et al, 2008) that behaves like a 'fast and frugal' heuristic or rule of thumb (Gigerenzer & Goldstein, 1996). We hypothesise that such an analogy will help an older person de-risk landing in the event of an unexpected fall. In the first stage of the research, we explored the processes of falling and landing, and generated potential ideas for motor analogies, by conducting focus group work with people who had experienced falling or who worked in fall-related disciplines.
METHODS: Focus group interviews were conducted with 19 participants, including older adult fallers, physiotherapists and occupational therapists, martial artists, gymnasts, dancers, parkour enthusiasts and health and safety experts. All participants had significant experience associated with falling or fall prevention. Interviews were recorded, transcribed and then processed independently by two reviewers.
RESULTS: Qualitative data analysis revealed major themes that suggested: (1) a scarcity of formal information to allow specialists to make recommendations about the best way to fall/land (consequently, therapists seldom offer advice about how to fall/land, preferring instead to concentrate on prevention); (2) a safe-landing analogy has considerable appeal as a clinical tool; (3) a safe-landing analogy would need to be processed rapidly enough to be effective in the brief duration of a fall; (4) a safe-landing analogy would need to be relevant to, an understood by, a maximum number of older people; (5) there are many circumstances and environments in which older people fall, so one analogy may not fit all occasions.
CONCLUSION: There was good 'in principle' support for the concept of a motor analogy that facilitates better landing in the event of a fall, but research is needed to establish whether there is a safest way to land and whether analogies can be processed rapidly enough to be used in the event of a fall. There may be no single biomechanical technique that is effective in all fall circumstances (e.g., slip v. trip) or environments (e.g., bathroom v. footpath). Consequently, an analogy that encourages an older person to fall in a manner that is slow, soft and silent (for example) may have greater utility because it facilitates context-specific self-organisation by the motor system.

THE EFFECTS OF CUPPING THERAPY ON PHYSICAL PERFORMANCE AND TISSUE OXYGENATION AFTER MUSCLE FATIGUE

HO, H.C., LEE, H.J.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Cupping therapy is commonly applied as an alternative tool in the traditional Chinese medical treatment. It is used mostly on musculoskeletal disease, especially nonspecific neck pain and low back pain. Recently, various athletes have adopted cupping therapy treating musculoskeletal discomforts. However, there is not much research about whether cupping therapy could improve sports performance or accelerate fatigue eliminating. Therefore, the aim of this study was to exam the effects of cupping therapy on physical performance and tissue oxygenation after muscle fatigue.
METHODS: Nine healthy adults (Age:24±2.3 yrs) were volunteered for this study. They were asked to do continuous knee extension to measure peak torque of knee extensor and induce muscle fatigue on the isokinetic dynamometer (Biodex). Fatigue was defined that knee extension torque was smaller than half of the peak torque three consecutive times. In this study, vastus medialis of dominant leg was used for cupping therapy intervention. Near infrared spectrometer (NIRS) was placed 5cm upward from the vastus medialis to collect muscle oxygen saturation (Li, Li, Lin, and Li, 2016) during the whole experiment. Subjects were randomized assigned to control, cupping therapy or cupping therapy combined active recovery group after muscle fatigue. After 5 minutes intervention, they would receive 30 minutes static recovery. Every 5 minutes interval of recovery phase, joint torque and muscle oxygen saturation were be examed. Two way ANOVA was conducted to compare difference between three groups. Bonferroni post hoc was used to further analysis.
RESULTS: There was no significant difference in change of knee extension torques among two different cupping interventions and control group during 30 minutes recovery after muscle fatigue. Tissue saturation index and oxygenated hemoglobin in two intervention groups were significant higher than the control group from intervention to recovery. In contrast, deoxygenated hemoglobin in two intervention groups were significant lower than the control group.
CONCLUSION: In this research, significant difference was found on physiological parameters between cupping therapy intervention and control group. According to past studies, muscle oxygen saturation would significantly decrease during exercise and return to pre-exercise level after exercise. Furthermore, the muscle oxygen consumption after exercise would be higher. Therefore, increasing blood circulation and metabolism by cupping therapy could improve the recovery of muscle (Roberts et al., 2015). The result showed that oxygenated hemoglobin and tissue saturation index in two intervention groups were both higher than control. Therefore, both kinds of intervention could improve blood circulation and tissue oxygen level and further accelerate fatigue eliminating. Thus, cupping therapy could be an optional application to eliminate muscle fatigue after exercises.

PREDICTIVE POWER OF ENTRY TESTS IN BASIC MILITARY TRAINING

BESENIUS, E., MALISOUX, L., BONERT, C., THEISEN, D.

SPORTS MEDICINE RESEARCH LABORATORY, LUXEMBOURG INSTITUTE OF HEALTH

INTRODUCTION: A concerning number of new recruits enrolled in the Luxembourg army do not successfully complete their basic military training (BMT). As a military career is characterized by high physical demands, the selection process of new recruits is strongly based on

physical fitness entry tests. The purpose of this ongoing prospective study is to investigate the predictive power of the physical fitness entry tests in the Luxembourg army for final success in BMT, as well as for the risk of sustaining musculoskeletal (MSK) injuries.
METHODS: A dedicated online Training & Health Monitoring System was used to collect data related to anthropometry (age, height, weight, sex), entry physical fitness tests, injuries assessed by the medical doctor, daily training logs and final evaluations for each recruit. Multiple logistic regressions were used to compute odds ratios (OR) and their 95% confidence intervals (95%CI) to identify risk factors for failure and for sustaining MSK injuries. Significance was set to $p<0.05$.
RESULTS: Preliminary data show that 357 recruits were enrolled in the Luxembourgish army for a 4-month BMT in 2016 & 2017. A total of 349 participants (92% male, 20.8±1.9 years, 176.6±8.0 cm, 73.2±11.6 kg) provided their written informed consent. Entry physical fitness test performances were 606±77 cm for 3 kg ball throwing, 63±9 sit-ups/2 min, 53±10 push-ups/2 min, 224±20 cm for the standing broad jump, 4.7±0.3 s for a supine start 30-m sprint test and 11.2±1.2 min for the 2400 m endurance run.
In total, 133 recruits (38%) did not succeed in their BMT: 27 (8%) due to medical reasons, 60 (17%) for personal motives, 28 (8%) because of failure in the final exams and 18 (5%) due to dismissal for disciplinary reasons.
A total of 215 MSK injuries were recorded for 141 recruits. The knee was the most concerned location with 91 injuries (42%), followed by the ankle (n=40; 18%). Muscle strains were the most common type of injury (n=47; 22%), followed by tendon strains (n=43; 20%) and joint sprains (n=41; 19%). Injuries lasted between 1 and 52 days (mean 7.7 days) and occurred mostly during marching (n=47; 22%), running (n=30; 14%) and field training (n=26; 12%).
Recruits successfully finishing their 4-month BMT recorded in average 289 hours of physical training.
Multiple regressions using sex, age, height, weight and the six physical fitness entry tests revealed the following results: Age (year; OR=1.18; 95%CI=1.02 to 1.36; p=0.02) and the performance in the entry endurance test (min; OR=0.72; 95%CI= 0.57 to 0.92; $p<0.01$) were associated with the risk for failing the BMT, with the younger recruits and the poorest endurance performers being at higher risk for failure. No significant association with MSK injuries was found based on the present preliminary dataset.
CONCLUSION: Preliminary data of this ongoing prospective study suggests that endurance capacity is the main predictor for successful completion of BMT. Other, potentially more discriminant tests should be studied as success predictors.

THE WITHIN-SUBJECT CORRELATION BETWEEN SALIVARY IGA AND MEASURES OF INTERNAL AND EXTERNAL LOAD IN ELITE SOCCER PLAYERS

FIGUEIREDO, P.1,2, NASSIS, G.3, BECKERT, P.1, MARTINHO, C.J.1, REBELO, P.1, GASPAR, J.1, BRITO, J.1

1: FPF , 2: CIDESD-ISMAI , 3: ASPETAR

INTRODUCTION: Salivary secretory immunoglobulin A (sIgA) provides a non-invasive assessment that may be useful to monitor soccer players responses to training along with measures of training load. There are seldom attempts to quantify the association between sIgA and measures of training load, but these are limited by suboptimal statistical approaches, including pooling of the data and sample mean correlations. In repeated-measures studies, it is important to quantify within-subject correlations, by modelling the longitudinal dataset as a whole and reducing the variation between subjects. Therefore, the aim of this study was to quantify the correlation between the sIgA and measures of internal and external load in elite soccer players during training.
METHODS: Saliva samples of 18 elite male soccer players were collected in four consecutive days (prior to breakfast) of the preparation camp for Rio 2016 Olympic Games. Internal training load was quantified using the session rating of perceived exertion (s-RPE) and external training load via GPS pods.
Within-subject correlation coefficients between training load parameters and next day sIgA were calculated (Bland and Altman, 1995), and magnitude of relationships were assessed according to Hopkins et al. (2009).
RESULTS: In general, internal training load presented a smaller association with sIgA than some of the external load variables explored. The within-subject correlations between sIgA and training load variables were of moderate to large magnitude (s-RPE, r = -0.39; total distance covered, r = -0.55; number of accelerations, r = -0.52, number of decelerations, r = -0.48), except for high-speed distance covered (r = -0.23), number of sprints (r = -0.18), and distance covered per minute (r = 0.01).
CONCLUSION: This study showed moderate to large associations between sIgA and internal and external load variables considering a within-subjects design. Total distance covered, which is typically considered a measure of training volume, had a large negative correlation with sIgA response. The trivial to small associations with distance covered per min and high-speed distance covered suggest that sIgA is not related to training intensity. Thus, sIgA might be more responsive to training volume rather than intensity, despite the associations detected for accelerations and decelerations.
The within-subject correlations used in the current study may give a more accurate and useful representation of the relationship between sIgA and internal and external load variables to strategically individualize optimal preparation in elite soccer players.

OP-PM45 Sleep

IMPROVING SLEEP IN PROFESSIONAL RUGBY PLAYERS: A PILOT INTERVENTION STUDY

MAHONY, L., LYONS, D., BIGGINS, M.

CONNACHT RUGBY, GALWAY; RUGBY PLAYERS IRELAND, DUBLIN; SCHOOL OF ALLIED HEALTH, UNIVERSITY OF LIMERICK

INTRODUCTION: Poor sleep quality is prevalent in elite athlete populations (Shearer et al., 2015) and calls have been made to educate athletes on how to improve their total sleep time, sleep/wake schedules and overall sleep hygiene (Swinbourne et al., 2015). The purpose of this study was to evaluate the effectiveness of a sleep intervention in professional rugby players. Sleep was measured using the Pittsburgh Sleep Quality Index (PSQI) questionnaire (Buysse et al., 1989).

METHODS: A sample of professional rugby players (n=50, age 26.4 ± 2.9, weight 102.5kg ± 11.5, height 186.5cm ± 7.4) completed the PSQI mid-way through their season. The results of the survey were reported to the players and a sleep intervention program was developed to inform players on the importance of sleep for performance and recovery. This program consisted of two one-hour education workshops focusing on the link between sleep habits and performance (workshop 1) and good sleep hygiene (workshop 2). Information awareness posters were developed, and players were advised to target 2-3 behaviours. The PSQI questionnaire was repeated after 6 weeks (n=48).
RESULTS: At baseline 72% of the players (n=36) were classified as poor sleepers (PSQI ≥ 5). Post intervention, 52% of players (n=25) were classified as poor sleepers. Baseline and post intervention PSQI scores were 5.8, (SD±2.07) and 5.0, (SD±2.35). There was a statistically significant difference in sleep quality in groups pre and post intervention (p=0.02).
CONCLUSION: The incidence of poor sleep is high amongst professional rugby players in season. Significant improvements can be made through education and increased awareness. Simple actions that players can put in place to improve sleep include adjusting bedtime to suit training schedules, making use of naps and 'banking' sleep prior to travel.
Objective sleep measurements such as actigraphy watches, alongside questionnaires, could improve the quality of data gathered and provide further significant insights into actual sleep patterns of professional rugby teams in Ireland.

THE EFFECTS OF NAPPING AFTER SLEEP DEPRIVATION ON AUDITORY REACTION TIME AND SPECIFIC SPORT SKILLS IN MALE COLLEGIATE SOCCER PLAYERS.

RAMYARANGSI, P.1, SIRIPORNPANICH, V.2, WIDJAJA, W.1, AJJIMAPORN, A.1

MAHIDOL UNIVERSITY

INTRODUCTION: Soccer players are frequent traveling because of the competition that may affect sleep quantity and quality, resulting from the lower ability of physical performance (Richmond et al., 2007). Recently, improvement of cognitive performance after napping (brief sleep) has been reported in healthy males (Waterhouse et al., 2007). However, whether napping after sleep deprivation can have benefits on reaction time and sport skills in soccer players is unclear. The aim of this study was to examine the effects of sleep condition on auditory reaction time (ART) and soccer skills in male collegiate soccer players.
METHODS: Eleven male collegiate soccer players (age 20±2 years, non-habitual nappers) participated in a randomized repeated measures design study. The participants recorded the ART using oddball paradigm which they were instructed to respond as quickly as possible to the rare high-pitch sound (25%) presented via a headphone and then performed specific sport skills test including Loughborough Soccer Shooting Test (LSST) and Loughborough Soccer Passing Test (LSPT) after undergoing three sleep conditions; normal sleep (NS), sleep deprivation (SD, sleep 3 hours) and napping after sleep deprivation (NaSD, sleep 3 hours and nap after lunch for 20 minutes).
RESULTS: This study demonstrated significantly longer ART to respond to the target during the auditory oddball paradigm after SD (P=0.006) and NaSD (P=0.009) compared to NS. For soccer skills, the penalty time of LSPT decreased after NaSD compared to NS (P=0.011) and SD (P=0.038). In addition, the performance time of LSPT decreased after NaSD than SD (P=0.044). The time of the LSST was similar between conditions (P>0.05).
CONCLUSION: Delayed ART indicates the slower speed of processing in attention pathway after SD and NaSD conditions. Shorter duration of LSPT but not LSST indicates that gross motor performance of soccer players may be partially improved after napping. Therefore, this study suggests that a 20-min nap after lunch following sleep deprivation had partial beneficial effects on specific soccer skills, but not attention.

THE EFFECTS OF ONE-NIGHT SLEEP DEPRIVATION AND ONE-NIGHT SLEEP RECOVERY ON ENDURANCE PERFORMANCE

GATTONI, C., O'NEIL, B.V.2, MARCORA, S.1

UNIVERSITY OF KENT

INTRODUCTION: It has been demonstrated that sleep deprivation (SD) negatively affects endurance performance (Martin 1981; Martin and Chen 1984; Oliver et al. 2009; Azboy et al. 2009); however, no data are available on how long it takes to recover from SD as yet. Therefore, the aim of the study was to investigate the acute effects of SD and sleep recovery (SR) on endurance performance by evaluating exercise performance changes. The final results of this study might provide relevant information on the potential applications of SR in endurance performance.
METHODS: Twenty men amateur cyclists/triathletes (means ± SD: age 30.7 ± 8.1 yr, body mass 73 ± 10 kg, height 1.77 ± 0.09 m, VO2max 54.2 ± 4.8 ml/kg/min) were randomly allocated to two groups (SD and Control (CON)) and tested over three consecutive days. After baseline testing on Day 1, subjects in the SD group were asked not to sleep for 25-h (SD condition) on Day 2, and then sleep normally the following night (SR condition) (Day 3). Subjects in the CON group were required to sleep normally throughout the entire experiment and to attend the same testing sessions. Endurance performance during a 20-min Time-Trial (TT) was measured after 40 minutes of cycling at 60% of their VO2max. Continuous EEG measurements were collected throughout the entire cycling test.
RESULTS: Ratings of sleepiness revealed a trend for a significant effect of SD (group x day interaction) (P = 0.059). However, a preliminary 2-way mixed model ANOVA (group x day) revealed no significant effect of SD on TT work (group x day interaction) and no main effect of group. A pairwise comparison revealed a main decline on Day 2 (Day 1 297.5 ± 9.9 kJ, Day 2 283.3 ± 9.9 kJ, P = 0.001) and a trend for a main improvement on Day 3 compared to Day 2 (Day 3 291.8 ± 10.4 kJ, P = 0.086). EEG results will be provided in a second moment.

CONCLUSION: In conclusion, one night of SD might not be enough to impair endurance performance in men amateur cyclists/triathletes. Consequently, the following night of sleep would not be needed to recover from 25-h SD. However, the current results are partial and further data needs to be collected to draw a firmer conclusion on the role played by SD and SR on endurance performance.

EFFECT OF VIGOUROUS LATE-NIGHT EXERCISE ON SUBSEQUENT SLEEP ARCHITERCTURE AND CORE BODY TEMPERATURE

ALOULOU, A., DUFOREZ, F., NEDELEC, M.
INSTITUT NATIONAL DU SPORT DE LEXPERTISE ET LA PERFORMANCE

INTRODUCTION: Sleep is well recognized as one of the most important component of the recovery process among athletes (Venter, 2014). Press demands from media require elite athletes to perform several night-time competitions throughout a season, which may have consequences for both sleep and recovery. It is currently not known to what extent athletes sleep quantity and quality are impaired following night exercise. The aim of this study was to assess the effect of late-night high-intensity intermittent exercise on sleep architecture and core body temperature (CBT).
METHODS: In a randomized counterbalanced order, twelve well-trained male runners (age: 32 ± 5 years; VO2max: 68 ± 6 mL/min/kg; MAS: 18 ± 1.5 km/h), accustomed to train in the evening, completed a trail run simulation (TRAIL) (start at 21:00) and a control condition (CONT). The simulation lasted 48 minutes and was composed of 5 consecutive blocks (Adapted from Hausswirth et al., 2011). Each block of 9 minutes included 3min downhill (-12.5%), followed by 3min intermittent run on the flat (0%) and 3 min uphill (+10%). The exercise intensity was individualized to each participant according to his MAS. After each condition, a full laboratory sleep analysis with polysomnography and CBT analysis was performed. Markers of muscle damage (maximal voluntary contraction [MVC], plasma creatine kinase [CK] and subjective ratings) were recorded before, immediately after exercise (post), post 24 h, and post 48 h.
RESULTS: The TRAIL induced a high level of fatigue and significant muscle damage. A reduction of MVC, an increase in CK activity and muscle soreness were observed in TRAIL compared to CONT until post 48h ($p<0.05$). However, no differences were observed in sleep variables, i.e. sleep efficiency, sleep onset latency, wake after sleep onset, fragmentation index, total sleep time and time spent in each sleep stages during the whole night. Compared to CONT, TRAIL significantly increased CBT immediately after exercise ($p<0.01$). CBT rapidly fall down after TRAIL and no significant difference between the two conditions was observed twenty minutes after exercise.
CONCLUSION: Sleep architecture is not affected by vigorous late-night exercise for well-trained athletes accustomed to train in the evening. The exercise-induced increase of CBT does not delay sleep onset nor affect the sleep architecture.

THE RELATIONSHIP BETWEEN OBJECTIVE MEASURES OF SLEEP AND TRAINING LOAD ACROSS PHASES OF THE AMERICAN COLLEGIATE FOOTBALL SEASON

FULLAGAR, H., SAMPSON, J., MCKAY, B., DELANEY, J., MURRAY, A.
UNIVERSITY OF TECHNOLOGY SYDNEY

INTRODUCTION: American collegiate football players endure a prolonged recovery process with perceptions of wellness taking >4 days to return to pre-game levels[1]. Furthermore, it is known that 60% of college students suffer from poor sleep quality[2] which along with schooling and athletic expectations for student-athletes, suggests ACF players may be an at sleep-risk cohort. However, objective evidence of sleep patterns in ACF players is limited and we are unaware of any study that has examined the relationship between sleep and training load, across the ACF season. Thus, this study investigated the relationship between objective measures of sleep and training load across different phases of the season in ACF players.
METHODS: Twenty-three ACF players <21.1±1.2 years; 108.0±20.0 kg> participated in this descriptive, observational design in the 2017 season. Objective sleep parameters from wrist-watch actigraphy and daily training output data from accelerometry were collected during Off-season, Camp , In-season and School phases . The relationships between each sleep/training parameter and phase were assessed using linear mixed models. A magnitude-based approach was employed where effects were considered real if the likelihood of the effect being greater than 0.20 exceeded 75%, 95% and 97% for likely, very likely and almost certainly, respectively.
RESULTS: Total minutes in bed were likely lower during Camp and In-season compared to Off-season phases <40 minutes, ES=-0.35, 91%; 42 minutes, ES=-0.37, 93% respectively>. Total sleep time was also likely shorter in Camp <41 minutes, ES=-0.35, 91%> and In-season <56 minutes, ES=-0.48, 99%> compared to the Off-season. When accounting for changes in PL between phases, sleep latency was likely increased <1.01, ES=0.52, 89%> during the School phase.
CONCLUSION: Sleep time is reduced during periods of intensified training in ACF players, however these differences between season phases are dissipated when accounting for changes in external load. Variation to training schedules during phases may also account for these differences in sleep parameters and should be a focus of future research. The increase in sleep latency within school phases is also noteworthy and may have important practical considerations for coaches when prescribing training and/or recovery.

THE EFFECTS OF GAMES AND TRAVEL ON SUPER RUGBY PLAYERS. IS SLEEP THE KEY?

LO, M., AUGHEY, R.J., HOPKINS, W.G., STEWART, A.

VICTORIA UNIVERSITY

INTRODUCTION: Travel across time zones can have detrimental effects on athletes. Regular air travel is common in sport. The aim of this study was to understand the extent to which travel affect sleep, wellness, training and performance of Super Rugby players.
METHODS: 122 players from 4 professional Super Rugby teams were monitored during the 2017 Super Rugby season for games played in their own country (home and away) and overseas. Participants' sleep was monitored using sleep logs, and wrist activity monitors. Training, wellness and key performance indicators (KPIs) data were provided by the teams. Changes in sleep and wellness were calculated in comparison to baseline for the pre-game, game and post-game days for the matches played locally using a mixed linear model. The estimate changes from baseline were also calculated for the period spent overseas and, when possible, upon return, including changes in training. Changes in KPIs for overseas, and upon return games were calculated using a generalized linear mixed model. Number of time zones crossed, direction of travel and number of days post travel were included as co-variables.
RESULTS: Sleep and wellness are reduced around game time (up to 134 min and 30.7 points less) and when overseas (up to 64 min and 41.5 points less). Even if teams seem to modify training whilst overseas, seemingly to address travel, players' performance was poorer overseas and upon return. For instance, Positive KPIs (a combination of number of carries, defenders beaten and clean breaks) reduced up to 28.5%, whilst Negative KPIs (number of missed tackles, turnovers and penalties conceded counted together) increased up to 76.5% in comparison to local games
CONCLUSION: The changes in wellbeing, sleep and performance confirm that several psychological and physiological stressors can negatively affect rugby players around game time (Juliff et al., 2015) and after trans-meridian travel (Fowler et al.,2017; Kolling et al., 2017). Although important, it seems that sleep disruption is not the main reason behind poorer performance with travel. Further research should identify strategies to enhance performance, health and wellness of rugby players or other athletes when travelling across time zones for competition.

THE RELATIONSHIP BETWEEN SERUM VITAMIN D LEVELS AND SLEEP QUALITY AMONG SEDENTARY PEOPLE AND RUNNERS

VAISBERG, M.1, SANTOS, J.M.B.1, LUNA JUNIOR, L.A.1, FOSTER, R.2, VIEIRA, R.P.2, KATEKARU, C.M.

FEDERAL UNIVERSITY OF SÃO PAULO<1> NOVE DE JULHO UNIVERSITY <2>

INTRODUCTION: Sleep is a functional state, reversible and cyclical.[1] In this report, the Pittsburgh Sleep Quality Index (PSQI) have been used to appraise the topic quality of sleep[1]. One of the most important roles of vitamin D is to control the inflammatory response due to its strong immunomodulatory activity[3]. In addition, a recent research has presented that vitamin D also influences the sleep quality. The aim of this report is to analyze if serum vitamin D levels can influence the sleep quality among runners and sedentary people
METHODS: Fifty-three individuals living in the city of São Paulo were recruited, being twenty-seven runners and twenty-six sedentary. All participants responded PSQI, which can demonstrate the sleep quality of the individuals and attributed a scale 1 to 3 in the PSQI result to be statistically analyzed; the scale 1 was attributed to "good sleep quality", scale 2 as "bad sleep quality" and scale 3 as "indication of sleep disorders". Furthermore, they also went through a peripheral blood analysis to measure vitamin D. Mann-whitney tests with a significance level of 5% were used for data analysis. Not to mention, the study is following the conditions of the ethics committee on human research of the Federal University of São Paulo under number 049494/2016
RESULTS: We found a decrease in vitamin D ($p = 0.01$) in the sedentary group when compared to the runner group. The analysis of the Pittsburgh questionnaire revealed a worsening of sleep quality in the sedentary group compared to the runners ($p = 0.005$)
CONCLUSION: Studies have implied that low vitamin D predisposes to sleep disorders, and comparing our results with those research studies we can state that the statements are truthful. However, the prevalence of bad quality sleep was significantly lower between runners, which can lead to a positive effect of exercising in preventing this sleep disorders. Our results suggest that vitamin D levels and the quality of sleep are correlated. In conclusion, we could say that the exercising has a relevant and significant role in the quality and improvement of the sleep pattern.

OP-PM58 Physical activity: children

CROSS-SECTIONAL ASSOCIATIONS OF OBJECTIVELY-MEASURED PHYSICAL ACTIVITY AND SEDENTARY TIME WITH BODY COMPOSITION AND CARDIORESPIRATORY FITNESS IN MID-CHILDHOOD: THE PANIC STUDY

COLLINGS, P.J., WESTGATE, K., VÄISTÖ, J., WIJNDAELE, K., ATKIN, A.J., HAAPALA, E.A., LINTU, N., LAITINEN, T., EKELUND, U., BRAGE, S., LAKKA, T.A.

UNIVERSITY OF CAMBRIDGE

INTRODUCTION: The minimum intensity of physical activity (PA) that is associated with favourable body composition and cardiorespiratory fitness (CRF) remains unknown. The objective of this study was to investigate cross-sectional associations of PA and sedentary time (ST) with body composition and CRF in mid-childhood.
METHODS: PA, ST, body composition and CRF were measured in a population-based sample of 410 children (aged 7.6 ± 0.4 years). Combined heart-rate and movement sensing provided estimates of PA energy expenditure (PAEE, kJ/kg/day) and time (min/day) at multiple fine-grained metabolic equivalent (MET) levels, which were also collapsed to ST and light PA (LPA), moderate PA (MPA) and vigorous PA (VPA). Fat mass index (FMI, kg/m2), trunk fat mass index (TFMI, kg/m2) and fat-free mass index (FFMI, kg/m2.5) were derived

from dual-energy X-ray absorptiometry. Maximal workload from a cycle ergometer test provided a measure of CRF (W/kg FFM). Linear regression and isotemporal substitution models were used to investigate associations.
RESULTS: The cumulative time above 2 METs (221 J/min/kg) was inversely associated with FMI and TFMI in both sexes ($p < 0.001$) whereas time spent above 3 METs was positively associated with CRF ($p = 0.002$); CRF increased and adiposity decreased dose-dependently with increasing MET levels. ST was positively associated with FMI and TFMI ($p < 0.001$) but there were inverse associations between all PA categories (including LPA) and adiposity ($p = 0.002$); the magnitude of these associations depended on the activity being displaced in isotemporal substitution models but were consistently stronger for VPA. PAEE, MPA and to a greater extent VPA, were all positively related to CRF ($p = 0.001$).
CONCLUSION: PA exceeding 2 METs is associated with lower adiposity in mid-childhood, whereas PA of 3 METs is required to benefit CRF. VPA was most beneficial for fitness and fatness, from a time-for-time perspective, but displacing any lower-for-higher intensity may be an important first-order public health strategy.

Cross-Sectional Associations of Objectively-Measured Physical Activity and Sedentary Time with Body Composition and Cardiorespiratory Fitness in Mid-Childhood: The PANIC Study. Sports medicine. 2017 2017/04/01;47(4):769-80.

OBJECTIVELY ASSESSED PHYSICAL ACTIVITY OF PRIMARY SCHOOL CHILDREN IN GERMANY WITH AND WITHOUT MIGRATION BACKGROUND

KOBEL, S., KETTNER, S., STEINACKER, J.M.

ULM UNIVERSITY

INTRODUCTION: Obesity in combination with physical inactivity is one of the leading public health challenges in recent years. Already, many children are not sufficiently active whereas children with migration background appear to be even less active and at higher risk of developing obesity. In order to avoid possible health inequalities, this has to be investigated further. Therefore, this study evaluated amounts and intensities of objectively assessed physical activity in primary school children with and without migration background.
METHODS: A sub-sample of 273 children <7.1±0.6 years, 53% male> taking part in a large school-based intervention wore a multi-sensor device for six days in order to assess their physical activity objectively. 27% were classified as having a migration background. Physical activity was grouped in light <1.5-3 MET> and moderate to vigorous 3 MET> intensities. Weight status was determined during a school visit on the basis of BMI percentiles . Data collection took place prior to any intervention.
RESULTS: On a daily average, children without migration background spent 138.2±62.6 min in MVPA; children with migration background spent significantly less time in MVPA <121.7±54.9 min, $p \leq 0.01$>. On weekends, this amount decreased significantly for children with and without migration background <112.3±66.0 min, $p \leq 0.01$>, but especially for children with migration background <97.7±56.7 min, $p \leq 0.01$>. Moreover, children with migration background displayed significantly higher BMIPCT <55.7±29.6 vs. 44.3±26.8, respectively; $p \leq 0.01$> and were significantly more often overweight and/or obese <13.5% vs. 8.6%, respectively; $p \leq 0.02$>.
CONCLUSION: The results of this study extend the current literature by providing an objective analysis of children's time spent in MVPA. Primary school children with migration background are less physically active than their German counterparts and are more often overweight and therefore at a higher risk of related secondary diseases. This should particularly be considered for interventions in order to tailor programmes that children and parents with migration background engage in sufficient physical activity.

STUDY ON PHYSICAL ACTIVITY AMONG 6-TO-19 YEARS OLD CHINESE CHILDREN AND ADOLESCENTS: A NATIONAL REPRESENTATIVE CROSS-SECTIONAL STUDY IN CHINA

WANG, M.

CHINA INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Physical fitness declining and lacking of physical activity (PA) become prevalent among Chinese children and adolescents. And there are differences of PA between areas, urban and rural. The purpose of the national cross-sectional study on Chinese children and adolescents was to analyze the level and pattern of PA of Chinese children and adolescents, so that to provide scientific support for the government to make the policy and strategy for children and adolescents' physical activity and fitness.
METHODS: Investigation on physical activity and health behavior for Chinese children and adolescents was conducted in 2016. The multi-stage and PPS Sampling method were used. The questionnaires on PA behavior and health behavior were made according to Chinese children and adolescent's study and life. 46970 school students aged 6-19 yrs in 10 provinces of China were sampled, including male 24152 and female 22818.
RESULTS: Almost all students aged 6-19 yrs had physical activity weekly. More than 70% of children and adolescents had 3 days a week doing MVPA at least 60 minutes per day. And 11.6% of students had 5 days a week engage in MVPA at least 60 minutes per day, including male 14.3%, female 8.3%, and Urban 12.1%, rural 8.3%, and 11.2%, 13.9%, 13.5% and 11.1% in grade 1-3, 4-6, 7-9, 10-12, respectively.
However, according to Global Recommendations on Physical Activity for Health in school-aged children, the ratio to reach the recommended was quite low. The proportion of children and adolescents doing MVPA at least 60 minutes daily was only 2%, and there was significant gender difference ($P < 0.01$). The proportion of male reached the recommended amount of 2.9%, the female was only 1.0%. No matter in urban and rural, male had slightly higher ratio than the female, and the order of proportion for children and adolescents to reach the recommendation was: urban male> rural male > rural female > urban female, and the ratio of students in primary school was higher than the ratio of students in middle school, the students in higher grades of elementary school had the highest radio, the radio of students in high school was the lowest.
The proportion of students having VPA at least 3 times per week was 20.6%, including male 23.2% and female 17.4%. For the urban students, the proportion of reaching recommendation of doing VPA at least 3 times each week were 16.5%, 27.2%, 28.1%, 19.8% in grade 1-3 of primary school, grade 4-6 of elementary, junior middle school and high school children respectively, for rural students, corresponding proportion were 18.3%, 23.3%, 24.6% and 23.3% respectively.
It is important to note that more than 35% of the children and adolescents had only 1 day engaged in VPA per week, more than 25% of the children didnt have VPA or had VPA less than 1 times a week. The youth of higher grade in primary school and junior high school stage had 3 days or more doing VPA per week, the proportions were higher than the proportion in others.
CONCLUSION: The level of PA among Chinese children and adolescent was relatively low, male was better than female, the students in higher grade of elementary school and the junior middle school were the most active. The PA level of urban children and adolescents were slightly better than the rural.

ASSOCIATION OF SPORT PARTICIPATION, SEDENTARY BEHAVIOR, SLEEP AND AEROBIC FITNESS AMONG CHINESE CHILDREN

HE, G., LI, J.C., ZHU, Y.L., JI, G., WANG, C.

CAPITAL UNIVERSITY OF PHYSICAL EDUCATION AND SPORTS

INTRODUCTION: The positive impact of physical activity on children's aerobic fitness has been well documented. But the influences of other health-related behaviors, such as sedentary behavior and sleep, are unclear. The purpose of this study was to investigate the simultaneous association of sports participation, sedentary behavior, sleep and aerobic fitness in children.
METHODS: Participants of this study were 441 children (mean age = 8.3 ± 0.9 years) in grade 1 to 3 from four primary schools in Beijing, China. Among which, 49.7% were boys. Children's daily sport time, sedentary time, and sleep time were reported by parents. Body weight and height were measured by researchers. Aerobic fitness of children was estimated by the Progressive Aerobic Cardiovascular Endurance Run (PACER) test. Maximum oxygen uptake (VO2max) was calculated based on the PACER test results according to the formula by Leger et al. (1988). Linear regression models were performed separately for boys and girls to examine the association of behavioral variables (sport time, sedentary time, and sleep time) with VO2max. Level of statistical significance was set at 0.05.
RESULTS: The average VO2max of the overall sample is 48.7 ± 2.9 ml/Kg/min. Children spend an average of 8.9 ± 0.6 hours, 51.1 ± 44.0 minutes, and 190.8 ± 115.1 minutes daily on sleep, sports, and sedentary behaviors, respectively. After adjusting for age and body mass index, sport time (β = 0.159, p = 0.028) is associated with VO2max in boys; whereas sedentary time (β = 0.280, p = 0.000) is related to VO2max in girls. Sleep time is not found to associate with VO2max in both genders.
CONCLUSION: Sport participation and sedentary time have impacts on children's aerobic fitness. These impacts may vary between genders. Gender specific investigation of relationship between health-related behaviors and children's fitness level are warranted in future studies.

EFFECT OF SEX, BODY MASS INDEX AND PHYSICAL ACTIVITY LEVEL ON PEAK OXYGEN UPTAKE AMONG 14-19 YEARS OLD ADOLESCENTS

WELDE, B.1, HANDEGÅRD, B.H.1, MORSETH, B.1, LAGESTAD, P.2

1UIT THE ARCTIC UNIVERSITY OF NORWAY, TROMSØ, NORWAY; 2NORD UNIVERSITY, LEVANGER, NORWAY

INTRODUCTION: It is recognized that peak oxygen uptake (VO2peak), the highest rate at which oxygen can be consumed during exercise, is the best single measure of young people´s cardiorespiratory fitness. Low cardiorespiratory fitness and inadequate physical activity may be associated with an unhealthy cardiovascular disease risk profile even in children and adolescents. Few longitudinal studies have examined differences in VO2peak during adolescent years while taking the potential effect of physical activity into account. To examine the effect of sex, body mass index (BMI) and physical activity level on longitudinal changes in VO2peak in Norwegian adolescents, 14 to 19 years old boys and girls were studied once a year for six years.
METHODS: In total, 116 Norwegian adolescents (61 boys and 55 girls, age at entry: 14.0±0.5 yr, weight: 54.2±10.9 kg, height: 1.63±0.08 m (mean±SD)) were tested for directly measured VO2peak every spring from the year they entered secondary school at 8th grade until they finished 3rd grade at high school. Height, weight and VO2peak were measured by standardized procedures, while data about physical activity level were obtained using a self-administered questionnaire. Multiple regression and linear mixed model analysis were used to examine the relationships between VO2 peak, age, sex, BMI and physical activity level.
RESULTS: Sex, BMI and the number of exercising days per week significantly and uniquely explained VO2peak, and collectively these predictors explained 58-71% of the variance in VO2peak at the different age levels. The rate of change in VO2peak over the 14–19 years age range showed a slight increase over the first three or four years, followed by a slight decrease. This pattern was most evident for boys. There was no significant gender differences in the association between VO2peak and physical activity level over time. The strength of association between VO2peak and physical activity level varied over time. The physical activity level explained nearly 30% of the total variance in VO2peak for 15 year-olds, while the corresponding figure for 18 year-olds was less than 9%.
CONCLUSION: This study confirms the importance of sex, BMI, and physical activity level as highly significant and independent predictors of aerobic capacity among adolescents. Taking the decrease in VO2peak from 17 years of age into account, the findings point to the importance for adolescents to maintain a high physical activity level, emphasizing activities that increases the aerobic capacity.

THE PROSPECTIVE ASSOCIATION BETWEEN CLUB SPORTS PARTICIPATION, MEDIA CONSUMPTION AND MOTOR COMPETENCE IN AUSTRIAN MIDDLE-SCHOOL STUDENTS

DRENOWATZ, C., GREIER, K.

UNIVERSITY OF EDUCATION UPPER AUSTRIA; UNIVERSITY OF INNSBRUCK

INTRODUCTION: Low levels of physical activity (PA) and poor motor competence (MC) are becoming increasingly prevalent in young populations. Given the inverse association between PA and MC with various health outcomes and overall well-being, this development has a profound impact on future public health. The present study examined the association between motor development, participation in club sports and media consumption over a 4-year period in Austrian middle school students.
METHODS: A total of 213 10-year-old students (57% male) were followed over a 4 year period. Every year participants completed the German motor test 6-18 and self-reported participation in club sports and media consumption. In addition, body weight was measured without shoes and participants wearing gym clothes at every measurement time. Cross-sectional and longitudinal associations between club sports participation, media consumption and MC were examined via multivariate analysis of covariance, adjusting for body weight.
RESULTS: At baseline 42% of the students reported participation in club sports, which increased to 55% at 4-year follow-up. Club sports participation and low media consumption were associated with lower body weight. Cross-sectional analyses did not show any interaction effects of media consumption and club sports participation on MC. Club sports participation and media consumption, however, had significant main effects on MC, independent of body weight. Similarly, no interaction effects of media consumption and club sports participation on the development of MC occurred over the 4-year observation period. Club sports participation, however, was associated with greater improvement in sprint and lower improvement in flexibility. High media consumption was associated with lower improvement in sideways jumping and 6-minute run. Higher MC at baseline was also associated with a greater likelihood for continued participation in or starting club sports while there was no association between baseline MC and change in media time.
CONCLUSION: Club sports participation provides a viable option to increase PA and reduce sedentary behaviors in middle school students. In order to facilitate participation in club sports, a sufficient level of MC, however, appears to be necessary. As beneficial effects of

high MC are independent of body weight, the development of motor competence should be emphasized at young ages in order to promote an active lifestyle throughout childhood and adolescence.

OP-SH15 Physical education, gaming and social influences

CONTRIBUTION OF PHYSICAL EDUCATION ON PHYSICAL ACTIVITY: COMPARISON BETWEEN REGULAR AND SPECIAL CLASSES

BLAIS, D., GIRARD, S., LEMOYNE, J.
UNIVERSITÉ DU QUÉBEC À TROIS-RIVIÈRES

Introduction: Several studies highlight the benefits of physical activity especially for students from special classes (Bailey, 2006; Côté et al., 2009). However, the majority of adolescents are not sufficiently active (ParticipACTION, 2016). Physical education represents a good opportunity to encourage students to adopt an active lifestyle. According to the achievement goal theory (Elliot, 1999), the motivational climate and the perceived competence in physical education determine students' achievement goals which, in turn, are related to their attitudes toward physical activity. To our knowledge, no study based on this theory has examined these relationships in physical education with regard to the type of classes (regular or special). Hence, the objectives were: 1- to examine the relationships between, on the one hand, motivational climate, perceived competence and achievement goals in physical education and, on the other hand, attitudes towards physical activity and the physical activity level, and 2- to verify if these relationships are invariant according to the type of classes (regular or special).
Methods: Data was drawn from 277 students (M age = 13.55 ± 0.89, boys = 61.2%, regular classes = 50.2%). Participants completed self-reported questionnaires on two different occasions to measure the variables targeted by the study objectives. Afterwards, a path analysis was conducted to test the hypothetical model, then, invariance analyses allowed us to verify the differences in the final model according to the type of classes.
Results: The final model ($\chi 2 = 15.75$, df = 11, p = .15; CFI = .99; TLI = .98; RMSEA = .05 [.00-.09, p = .53]) revealed that: 1- physical activity was predicted by attitudes toward physical activity (+); 2- attitudes toward physical activity were predicted by mastery climate (+), mastery goals (+), perceived competence (+) and performance-avoidance goals (-), and 3- achievement goals were predicted by the corresponding climate (+). The invariance tests revealed that students from special classes perceived a higher performance climate.
Discussion: Our results highlight the importance of establishing a mastery climate and developing the students' perceived competence in physical education in order to increase their physical activity level. The results also suggest that physical education teachers might focus more on competition with students from special classes. However, the statistical invariance of the final model supports the importance of teaching in a similar way with both types of classes.

A STUDY ON THE CHARACTERISTICS OF SCHOOL PHYSICAL EDUCATION IN SENEGAL

FELIX, D., KAZUHIKO, S.
HIROSHIMA UNIVERSITY

Introduction: The Sustainable Development Goals states that sports contribute to the promotion of quality and learning of education. In most African countries, physical education (PE) lessons are not conducted in accordance with the curriculum (Hardman et al., 2005). According to an international survey of physical education, Africa's implementation rate in 2000 was the lowest in the world at 25%. Although the implementation rate has greatly increased, it still remains low as compared with other developing countries (UNESCO, 2014). It is presumed that the importance of school PE in Africa is becoming more apparent. Senegal is one country where the promotion of PE has increased, partially due to cooperation with Japan (Sawamura, 2000; Saito, 2006). However, there is still a scarcity of studies on Senegalese physical education and sports. The purpose of this study was to clarify the current state of and explore issues of school PE in Senegal.
Methods: Information obtained from Senegal's education curriculum framework and physical education syllabus was reviewed to determine the standing of PE in the general curriculum and to have a closer view of the goals and content composition of PE in primary and secondary schools. Beyond the legal context of PE, interviews were conducted at the ministry of education as well as at the 2 main institutions (INSEPS & CNEPS) where future PE teachers receive their formation. Regarding the state of implementation of PE, we observed the educational environment and lessons of primary and secondary schools in Senegal. Additionally, the situation in the field was compared with the prescribed content of the curriculum.
Results: The government has lofty goals for sports education in Senegal and the significance of PE is stated in the curriculum, the reality of PE classes at the school level encounters many limitations. Dispute between ministries, ever shrinking financial support from the government to schools, demographic pressure on existing school infrastructure along with the reduction of PE teacher's training are just few of the challenges that affect negatively the quality of physical education nation-wide.
Discussion: It was to be expected that Senegalese physical education regulations and policies could be significantly different from the actual conditions of PE in schools. However, the complexity of the situation makes it hard to simply point a blaming finger at one or two elements of the entire educational apparatus dealing with immense economic and demographic pressure. Nonetheless, a number of key issues urgently need to be addressed in order to improve the quality of PE in Senegalese schools.

LEVELS OF PHYSICAL ACTIVITY AND SOCIAL SUPPORT PERCEIVED IN ADOLESCENTS

SANZ-MARTÍN, D.1, RUIZ-TENDERO, G.1, FERNÁNDEZ-GARCÍA, E.1

COMPLUTENSE UNIVERSITY OF MADRID

Introduction: One of the main health problems in Western societies is low levels of physical activity (McKenzie, Crespo, Baquero, & Elder, 2010), especially among adolescents (Sanz, 2017). Physical activity is determined by various factors (Sallis, Prochaska, & Taylor, 2000). The purpose of this study was to analyse the type of relationship between levels of physical activity in adolescents and the support they perceive from family and friends regarding such activity.
Methods: The sample comprised 694 adolescents in the province of Soria, Spain (21.5% of the total population of school adolescents). The Four by one-day Physical Activity Questionnaire (Cale, 1993) was used to quantify the level of physical activity. To assess the level of support perceived from family and friends regarding physical activity the Parent Support Scale and Peer Support Scale was used (Prochaska, Rodgers, & Sallis, 2002). To calculate the relationship between the variables, Pearson's correlation coefficient was calculated.
Results: The results show the existence of positive weak to moderate correlation, and significant ($p \leq .001$), between the average daily energy expenditure of the students and the support perceived from family and friends. The same type of link was found with moderate-vigorous average daily energy expenditure and moderate-vigorous duration of physical activity in adolescents, compared with social support perceived.
Conclusion
It was observed that there is a significant link between healthy levels of physical activity in adolescents and the support that they perceive from family and friends, which is consistent with other studies (Craggs et al., 2011, and Sallis et al., 2000).

COLLABORATIVE MODEL BETWEEN FITNESS CENTRES AND UNIVERSITIES: THE CASE STUDY OF UNIVERSIDAD EUROPEA AND HOLMES PLACE

FERNÁNDEZ-LUNA, A., DE LA RIVA, L., FELIPE, J.L., GARCÍA-UNANUE, J., BURILLO, P., SÁNCHEZ-SÁNCHEZ, J.

UNIVERSIDAD EUROPEA

COLLABORATIVE MODEL BETWEEN FITNESS CENTRES AND UNIVERSITIES: THE CASE STUDY OF UNIVERSIDAD EUROPEA AND HOLMES PLACE
Fernández-Luna, A.1, De La Riva, L.1, Felipe, J.L.1, García-Unanue, J.1, Burillo, P.1, Sánchez, J.1 1: Universidad Europea de Madrid (Madrid, Spain)
Introduction: As part of a growing trend toward greater collaboration between academia and industry (Barnes, Pashby & Gibbons, 2002), universities have an excellent opportunity to develop win-win strategies with renowned fitness centres. As an example of this, Universidad Europea of Madrid developed a research project for Holmes Place fitness centres in Madrid and Barcelona. The goal was for Universidad Europea to measure the rate of interest and the satisfaction level of Holmes Place clients with a recently implemented service called Clinic. This is a premium fitness evaluation service that helps clients to achieve their fitness goals by offering five assessments: Medical Welcome Session, Nutrition, Posture, Physio and Running.
Methods: Surveys were collected from 736 Holmes Place clients. 76 of them were Clinic clients, while the other 660 were potential clients who had never used that service. All of the respondents reported their demographic characteristics, sports practice, training frequency and length of membership. Specifically, Clinic clients reported their satisfaction with the service, while potential clients expressed their rate of interest in Clinic. The data collected were analysed using QuickTapSurvey software.
Results: 89.67% of respondents were potential clients. Among them, the percentage of clients who were interested in trying each of the assessments was 78.64% for the Medical Welcome Session, 82.42% for Nutrition, 84.09% for Posture, 82.27% for Physio and 55.61% for Running. On the other hand, 10.33% of respondents were Clinic clients. The Net Promoter Score (Reichheld, 2003) in these clients was 50. The percentage of satisfied clients for each of the assessments was 93.94% for the Medical Welcome Session, 94.59% for Nutrition, 84.62% for Posture, 92.59% for Physio, and 76.92% for Running.
Conclusion
The majority of Clinic clients were satisfied with this service, but these clients represented a small fraction of all Holmes Place members. As a result, Universidad Europea suggested to Holmes Place Senior Team that they improve the Clinic promotional strategy. This collaborative model allowed Universidad Europea to team up with a prestigious firm, while Holmes Place was able to detect the main issues related to its services, in order to improve them.

CONCEPTUALISING SPORT AND SPORT BETTING MANIPULATION: TYPOLOGIES, POLICIES AND PRACTICES

HARVEY, A.

SWANSEA UNIVERSITY

Sports and sports betting manipulation and associated behaviours pose significant threats to the social and cultural value of sport and to the viability of the global sports and gambling industries that are worth hundreds of billions of Euros respectively. These threats lie along a spectrum from relatively benign infractions against rules laid down by sports governing bodies, to major international criminal activity to fix sporting contests. To date, attempts to describe the multiplicity of threats have been largely under-conceptualised and no typology has been agreed by national, sporting and gambling authorities.
This paper has three objectives. Firstly, making use of a review of known cases and original empirical research that was undertaken for an EU-funded project to tackle match-fixing which was led by FIFPro (1), the world professional footballers union, I will develop an empirically detailed and analytically robust typology of the full spectrum of threats by manipulation to sports, to betting, to both and, in some cases, to neither, but which nevertheless represent behaviours that are still believed to pose a general threat to sport and/or betting integrity. Secondly, making use of published sources, I will map the actors involved to date in confronting sports and sports betting manipulation, including, inter alia, international and national public authorities, law enforcement bodies, sports and gambling organisations, INGOs and the media. Thirdly, by comparing the typology of manipulation with the map of actors, I will identify which organisations are best placed to tackle which type of manipulation, where gaps exist in the landscape of actors committed to the protection of sport and betting, and a tentative outline of the ways in which those actors can work together, thus enabling an efficient use of resources and capabilities.

DEVELOPMENT AND EVALUATION OF THE COACH-ATHLETE RELATIONSHIP ENHANCEMENT INTERVENTION

KUIT, W., WATSON, M.B., SLOGROVE, L., SUTTON, A.

NELSON MANDELA UNIVERSITY

INTRODUCTION: An expanding body of sport psychology theory and research has highlighted the central role of the coach-athlete relationship in the performance, satisfaction and well-being of both coaches and athletes. Models have been developed that identify the key dimensions of CAR quality and the interpersonal behaviour that maintains it, but there remains a need for interventions that support coaches and athletes to optimise their interpersonal skills. This can be done by harnessing recent advances in personality theory which emphasise a more holistic and developmental view of the person and provide a basis for greater mutual understanding and adaptive interpersonal behaviour change in the CAR.
METHODS: The aims of this study were to develop the Coach-Athlete Relationship Enhancement intervention through an integration of the Enneagram personality typology with current models of the CAR, and then to evaluate the impact of the CARE intervention on CAR quality. Sixty-two university level athletes and their nine coaches participated in the study.
RESULTS: Quantitative and qualitative results indicate that the CARE intervention significantly enhanced CAR quality, including direct and meta perceptions of closeness, commitment and complementarity, as well as co-orientation. Intervention outcomes included enhanced mutual understanding in the CAR, enhanced self-awareness, enhanced team relationships, and adaptive interpersonal behaviour change. These outcomes were associated with a shared awareness between coaches and athletes of their Enneagram personality type traits and motivations. Coach-athlete relationship quality was further enhanced by re-constructing coaches' and athletes' personal narratives based on self-descriptions of Enneagram type strengths, and a redefinition of individuals' core motivations to incorporate adaptive interpersonal behaviour change.
CONCLUSION: The study shows how holistic and developmental views of personality can be integrated with current models of the CAR, practically applied to enhance CAR quality, and facilitate a range of adaptive interpersonal outcomes in the sport context. The study also highlights promising avenues of interpersonally-focused sport psychology research and practice.

IMPROVING COLLECTIVE EFFICACY IN SPORT TEAMS: THE EFFECTIVENESS OF A ROLE CLARIFICATION INTERVENTION

ZAVADSKA, A., COENEN, J., SCHNEIDER, J., BROICH, F., PELS, F.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: Collective efficacy (i.e. a group's belief to achieve a common goal; Bandura, 1998) is an important predictor of performance in team sports (Carron et al., 2002). Role clarification (RC) is a determinant of collective efficacy (CE) and can have a detrimental effect on performance in sport settings (Beauchamp et al., 2002). Therefore, the purpose of the study was to examine the impact of a RC intervention on collective efficacy. It is assumed that a RC intervention improves CE more than a control intervention.
METHODS: The sample consisted of 31 participants (age: M = 20.68 years, SD = 4.48; sex: 13 females, 18 males) from two sport teams (basketball, volleyball). The sport teams underwent two interventions at an interval of one week: a RC intervention (exploring roles and responsibilities within each team; 120 minutes) and a control intervention (breathing techniques; 90 minutes). CE was measured using the Collective Efficacy Questionnaire for Sports (Short, Sullivan & Feltz, 2005). RC was assessed using the Role Ambiguity Scale (Rizzo, House, & Lirtzman, 1970) with higher values reflecting role clarification. Data were collected prior to the first intervention (t0), between the first and the second intervention (t1), and after the second intervention (t2). Data were analyzed using Friedman tests and Wilcoxon Signed-Ranks tests due to non-normal distributions.
RESULTS: Results showed a change in CE over time ($\chi2(2) = 13.66$ $p = .001$). In more detail, there was a significant increase from t0 ($M = 6.97$, $SD = 1.00$) to t1 ($M = 7.34$, $SD = 0.71$; $Z = -2.542$, $p < .05$) and from t1 ($M = 7.34$, $SD = 0.71$) to t2 ($M = 7.66$, $SD = 0.79$; $Z = -2.483$, $p < .05$). With regard to RC, there was also a significant change over time ($\chi2(2) = 7.71$ $p = .021$). More specifically, there was an increase from t0 ($M = 6.49$, $SD = 0.85$) to t1 ($M = 6.82$, $SD = 1.01$; $Z = -2.196$, $p < .05$) and from t1 ($M = 6.82$, $SD = 1.01$) to t2 ($M = 6.95$, $SD = 0.99$; $Z = -1.996$, $p < .05$).
Discussion:
The findings of this study indicated that there was an overall increase of collective efficacy over time which might have occurred due to the simultaneous increase in role clarification. Evidently, the RC intervention helped athletes to understand their scope of responsibilities within the team. The control intervention possibly made athletes strengthen their belief of the team's ability to achieve a common goal.

IS-PM10 The liver - a major contributor to exercise adaptations?

ROLE OF PGC-1A IN EXERCISE-INDUCED ADAPTATIONS IN THE LIVER

PILEGAARD, H.

UNIVERSITY OF COPENHAGEN

Exercise-induced autophagy and endoplasmatic reticulum (ER) stress have been suggested to be required for both acute metabolic adjustments and adaptations to exercise training. However the regulation of exercise-induced hepatic autophagy and the unfolded protein response (UPR) as well as the impact of autophagy and ER stress for hepatic adaptations with exercise training is not fully resolved. ER stress reflects an imbalance between the capacity of ER to fold proteins and unfolded protein response (UPR), while autophagy removes dysfunctional proteins and recycles cellular components. Furthermore, the transcriptional coactivator PGC-1α has been suggested to play a role in mediating exercise training-induced metabolic adaptations in the liver. The impact of hepatic PGC-1α on exercise-induced regulation of UPR and autophagy in the liver will be presented. Moreover, results from studies examining the effect of liver PGC-1α knockout on HFD-induced hepatic changes and the importance of liver PGC-1α in exercise training-induced prevention of HFD-induced changes with focus on ER stress and autophagy will be presented. In addition, the impact of age and lifelong exercise training on hepatic autophagy and UPR will be shown. Finally, results from studies investigating the potential role of muscle PGC-1α in the regulation of acute and exercise training-induced metabolic adaptations in the liver will be presented.

METABOLITES AND THE HEPATIC RESPONSE TO EXERCISE

WEIGERT, C.

UNIVERSITY OF TÜBINGEN

Regular physical activity is known to have multiple health benefits including prevention of type 2 diabetes and cardiovascular diseases. The liver plays a central role in the maintenance of glucose and lipid homeostasis and there is growing evidence that exercise-induced adaptations in the liver are crucial for the health benefits of exercise. The most prominent long-term effect is the reduction of non-alcoholic fatty liver disease, a major risk factor for diabetes and cardiovascular diseases. To get a global and unbiased view on the exercise-induced alterations of hepatic metabolism and function we performed LC- and CE-MS metabolomics analyses of arterial and liver vein plasma samples obtained from exercising humans. The data indicate an important contribution of the liver to the changes in the plasma metabolite and lipid pool during and following exercise by a tissue-specific release or uptake of several compounds and suggest a muscle-liver cycle not only for lactate. In a systems biology approach we analyse the OMICs data sets together with alterations in the hepatic transcriptome in response to acute exercise and training to unravel novel mechanisms of exercise adaptation and prevention of disease. The lecture presents novel insights into the effects of exercise on liver metabolism and function relevant for the development of intervention strategies.

EXERCISE-INDUCED HEPATOKINES

PLOMGAARD, P.

RIGSHOSPITALET

During the last decade tissue-specific signal molecules have been identified from both the adipose and muscle tissues. Recently the term "hepatokine" has emerged as hormone-like molecules released from the liver. An acute bout of exercise is a strong stimulus of hepatokine release and several candidates have been identified. We have investigated whether FGF21, follistatin and angiopoietin-like protein 4 are exercise-induced hepatokines in humans. All increase in the circulation in the hours after an acute bout of exercise, but with different kinetic profiles. The biological function of FGF21, follistatin and angiopoietin like 4 are very different. FGF21 has beneficial metabolic properties and when administered to patients with type 2 diabetes a reduction in both blood glucose and body weight occurs. Follistatin is known from reproductive physiology, however follistatin has also been identified as the endogenous antagonist of myostatin. Myostatin is released from the skeletal muscle tissue and inhibits muscle hypertrophy. An impact of follistatin on skeletal muscle has been observed in mice over-expressing follistatin specific in the skeletal muscle as they develop a marked muscle hypertrophy. Angiopoietin-like protein 4 is involved in the lipid metabolism and has been found to inhibit LPL. Investigating the arterial-to-hepatic vein difference in healthy male subjects performing an exercise bout revealed a release of both FGF21, follistatin and angiopoietin like 4 from the hepato-splanchnic bed. Increasing the glucagon-to-insulin ratio in resting male subjects increased the plasma level of FGF21, follistatin and angiopoietin like 4 with a similar kinetic as observed with exercise. In contrast inhibiting the increase in the glucagon-to-insulin ratio during an exercise bout blunts the increase in FGF21 and angiopoietin like 4 and reduces the exercise-induced increase in follistatin. Thus the glucagon-to-insulin ratio seems at least in part to be important for the regulation of these hepatokines during exercise. These finding conjecture that the liver could mediate some of the systemic beneficial effects observed with exercise.

OP-PM08 PERIODIZED AND HIT TRAINING

EFFECTS OF LINEAR AND DAILY UNDULATING PERIODIZED RESISTANCE TRAINING ON MYOKINES AND MAXIMAL STRENGTH LEVELS IN UNTRAINED WOMEN

NIKSERESHT, M.1,2, HAFEZI-AHMADI, M.2, NIKSERESHT, M.

1: ILAM BRANCH, ISLAMIC AZAD UNIVERSITY, ILAM, 2: ILAM UNIVERSITY OF MEDICAL SCIENCES, ILAM, 3: MAZANDARAN UNIVERSITY, BABOLSAR,

INTRODUCTION: It has been shown that resistance training (RT) improves metabolic profiles, body composition and physical fitness in obese individuals. Studies have presented that periodized RT has better physiological adaptations compared to nonperiodized, but there is limited research directly comparing different types of periodization. Thus, the aim of this study was to compare the effects of linear (LP) and nonlinear (NLP) RT on myokines and maximal strength levels in overweight/obese women.
METHODS: Twenty-five untrained women first were matched by maximal oxygen uptake (VO2max, 31–42 ml/kg/min), age (28–46 years), and body mass index (26–32 kg/m2) and then randomly assigned to LP (n = 8), NLP (n = 9) and control (CON, n = 8) groups. The trained groups performed 3 weekly sessions for 12 weeks. The NLP program varied training biweekly during weeks 1-6 and on a daily basis during weeks 7-12. The LP program included a pattern of intensity and volume changes every 4 weeks. Serum samples were used to measure interleukin (IL-7), IL-15, insulin growth factor-1 (IGF-1) and insulin levels. The concentrations were measured in duplicate by enzyme-linked immunosorbent assay before and after training. The VO2max, skeletal muscle mass (SMM) and 1-repetition maximum (1RM) for the exercises of bench press (BP) and leg extension (LE) were assessed. A 2-factor repeated-measure analysis of variance was used to determine the differences between interventions and across time.
RESULTS: After the training period, serum IL-7, IL-15 and IGF-1 levels did not significantly change compared with CON; however, IL-7 and IGF-1 increased significantly in both trained groups compared to the baseline. The NLP was effective at improving VO2max, SMM/weight ratio and insulin levels compared to the CON; but, no significant difference was observed in these variables between the two training groups. The LP and NLP presented significant 1RM strength gains in BP and LE compared with CON; interestingly, the increase was significantly higher with NLP than with LP for BP. No significant change was observed in the CON for all variables (except for IGF-1; that increased significantly compared to the baseline).
CONCLUSION: In conclusion, both LP and NLP are effective, but NLP may lead to greater gains in 1RM for BP, VO2max and SMM/weight ratio after a 3 months training. The NLP also seems to be more effective at reducing insulin levels. Therefore, women who are overweight/obese can use both the LP and NLP to increase maximal strength, although it seems that the NLP may have better aerobic capacity and anti-diabetic effects.

EFFECTS OF BLOCK-PERIODIZED VS. NON-PERIODIZED STRENGTH TRAINING ON PHYSICAL FITNESS, ATHLETIC PERFORMANCE, AND BODY COMPOSITION IN ELITE YOUNG CANOEISTS

GÄBLER, M., PRIESKE, O., WARNKE, T., HORTOBÁGYI, T., GRANACHER, U.

UNIVERSITY OF POTSDAM

INTRODUCTION: High performance in canoe sprint requires athletes to sustain high power output over a prolonged period of time. Strength training is an effective means to improve performance, physical fitness, and body composition in young athletes. The oscillatory nature of training stimulus in the form of block-periodization compared with a monotonic, non-periodized stimulus allows athletes to recover between training blocks. Therefore, we hypothesize that block-periodization vs. non-periodized strength training is more effective to improve elite young canoe sprint athletes' physical fitness, canoe sprint performance, and body composition.
METHODS: Twenty-two elite young sprint canoe athletes were divided over a control group (CG, 6 girls, 8 boys; 12.8±0.7 y; 0.3 y after peak height velocity [PHV]) during the first year and an intervention group (IG, 6 girls, 7 boys; 13.1±0.5 y, 0.6 y after PHV) during the second year of the study. Each group was tested before and after 26 weeks of training for physical fitness (i.e., hand grip strength, trunk muscle strength [Bourban test], bench press and bench pull exercise [work over 2 min], balance [Y-balance test lower and upper quarter; YBT-LQ/UQ]), body composition, and athletic performance (on-water 250 m and 2000 m time trials). CG trained 8 h/week for 26 weeks consisting of endurance training specific (12%) and not specific to canoeing (40%), and non-periodized muscular endurance training (48%). IG had non-periodized muscular endurance training replaced by block-periodized strength training including 4 weeks of general physical preparation, 7 weeks of hypertrophy training, 3 weeks of power training, and 3 weeks of power endurance training. Other training contents and training volume were matched between IG and EG.
RESULTS: In this abstract, we present performance changes only for CG, because IG has not yet completed the intervention. Data collection will be completed in April 2018 and all data will be presented at the ECSS congress. CG improved handgrip strength (+4.6 kg, $p<0.01$, ES [Cohen's d]=0.96), Bourban ventral test (+28 s, $p=0.01$ $d=0.89$), 2000 m time trial (-43 s, $p=0.01$, $d=0.43$), bench pull (+1.3 kW, $p<0.01$, $d=0.86$), bench press (+0.6 kW, $p=0.01$, $d=0.51$), and muscle mass (+1.9 kg, $p<0.01$, $d=0.51$). Performance did not change in YBT-UQ, YBT-LQ, and the 250 m time trial (all $p>0.05$).
CONCLUSION: Training and/or growth/maturation contributed to the observed improvements in body composition and performance in the CG. However, due to higher intensities in strength training and recovery between training blocks, we expect IG vs. CG to increase physical fitness more. Given the role muscular strength plays in performance, we expect correlated gains in physical fitness, body composition and in the 250 and 2000 m time trials.

KEEP IT SHORT AND SWEET? EFFECTS OF A HIGH-INTENSITY FUNCTIONAL CIRCUIT TRAINING ON MOTOR FUNCTION AND EXERCISE MOTIVATION IN UNTRAINED ADULTS

WILKE, J., KAISER, S., KALO, K., MORATH, C., ENGEROFF, T., NIEDERER, D., VOGT, L., BANZER, W.

GOETHE UNIVERSITY FRANKFURT

INTRODUCTION: Only a small share of the world's population meets current physical activity guidelines, which recommend regular engagement in endurance, strength, and neuromotor exercise. As lack of time represents a major cause of inactivity, multidimensional training methods with short duration may provide a promising alternative to classical, volume-oriented approaches focusing on only one

biomotor ability. This trial examined the effects of a high-intensity functional circuit training (HIFCT) program on motor function and motivation to exercise in healthy, untrained adults.
METHODS: Thirty-three physically inactive participants (25±5 yrs, 12 males) were randomly allocated to two groups exercising for a period of six weeks. The intervention group (HIFCT, n=20) 3×/week performed functional whole-body exercises (e.g. Squats, Step-Ups, Burpees) in a circuit format. Each 15-minute workout was composed of repetitive 20s all-out bouts with 10s breaks. In the comparison group (moderate aerobic exercise, MAE, n=13), the participants walked 3×/week for 50 minutes at moderate intensity. Motor outcomes measured were cycling endurance capacity (respiratory threshold, maximum work load), maximum strength (leg and chest press), postural control (force plate), and jump capacity (counter-movement jump, single leg hop for distance). Additionally, exercise motivation was assessed using the self-concordance index.
RESULTS: In comparison to MAE, HIFCT enhanced maximum leg strength (between-group difference of relative pre-post changes of 5.0%), shoulder strength (7.6%), endurance workload (5.0%; p<.05), as well as motivation to exercise (+5.5 points on the self-concordance index (p<.05). No between-group differences were found for postural control and jump capacity (p>.05).
CONCLUSION: Despite considerably shorter training duration, HIFCT increases motor function and motivation to exercise more effectively than MAE. Further research should investigate the long-term adherence to the program and its effectivity in other settings.

EVALUATING THE INTERNAL RESPONSE TO REPEATED-SPRINT TRAINING USING DIFFERENTIAL RPE: A PRELIMINARY INVESTIGATION IN SOCCER PLAYERS

MCLAREN, S.J., TAYLOR, J.M., MACPHERSON, T.W., SPEARS, I.R., WESTON, M.
TEESSIDE UNIVERSITY

INTRODUCTION: Changes in the internal response to an external training stimulus may be indicative of an athlete's fitness or fatigue. Differential ratings of perceived exertion (dRPE) enhance the precision of internal load quantification (Weston et al., 2015), yet little is known of how these measures change over a period of training adaptation. We therefore aimed to evaluate the within- (i.e. set-to-set) and between-session changes in dRPE across a repeated-sprint training (RST) intervention that was successful for improving a range of fitness components in soccer players (Taylor et al., 2016).
METHODS: Fifteen semi-professional soccer players completed 6 RST sessions over a 2-week period. The training programme consisted of 3 (sessions 1–3) or 4 (sessions 4–6) sets of 7 maximal effort sprints, with 20 sec and 4 min recovery between sprints and sets, respectively. Players were assigned to either a straight-line (n = 8; 30-m) or change of direction (n = 7; 2 × 10-m with a 180° turn) training group. Heart rate (HR; presented as % maximum heart rate) was recorded throughout each session and dRPE (presented in arbitrary units) for breathlessness (RPE-B) and leg muscle exertion (RPE-L) were collected via the CR100 scale ~2 min after each set. Data were analysed using mixed effects linear models, with magnitude-based inferences subsequently applied.
RESULTS: Mean ± SD set dRPE and HR were 47 ± 10 (hard) for RPE-B, 39 ± 9 (somewhat hard) for RPE-L, and 79 ± 7%. The difference between RPE-B and RPE-L was possibly moderate (8; ±90% confidence limits 7). Within-session changes in RPE-B were large in session 1 (15 per set; ±2), moderate in sessions 2 to 5 (7 to 9; ±2), and small in session 6 (6; ±2). For RPE-L, within-session changes were large in session 1 (15; ±3) and moderate in sessions 2 to 6 (7 to 8; ±2). The within-session changes in HR were trivial in sessions 1 to 5 (1 to 2 % points per set; ±1) and small in session 6 (2; ±3). When compared with session 1, the magnitude of within-session changes was substantially lower (small to moderate differences) in session 2 to 6 for RPE-B (-5 to -9 per set; ±2) and RPE-L (-6 to -8; ±2). No substantial between-session differences were evident for within-session changes in HR (0 to 1 % points per set; ±1).
CONCLUSION: Changes in dRPE, but not HR, are evident following a 6-week RST intervention that improved the fitness of soccer players, with the magnitude of within-session increments reducing across the programme. These changes could reflect training-induced adaptations, thus providing evidence for the sensitivity and usefulness of dRPE for monitoring training in soccer. Finally, players perceive the demands of RST to be greater for central, rather than peripheral, exertion, which may allude to specific training-induced adaptations. Relations between dRPE and training outcomes therefore warrant further investigation.

TRAINING INTENSITY DISTRIBUTION ANALYSIS BY RACE PACE APPROACH IN WORLD-CLASS DISTANCE RUNNERS.

KENNEALLY, M., CASADO ALDA, A., SANTOS-CONCEJERO, J.
UNIVERSITY OF THE BASQUE COUNTRY

INTRODUCTION: Optimal Training Intensity Distribution (TID) in endurance running remains a much debated topic (1,2). The description of training intensity zones has classically been done using physiological parameters (2), and ranges from 3-7 zones within the literature (2). A recent review by the current authors (1) has proposed a novel way to describe training intensity zones. The zones are based on proportions of an athletes actual or target race pace. The rationale for this approach is based in the notion that race pace itself represents the intensity which optimally stresses the relevant physiological systems at any given point in time. Thus the aim of this paper was to analyse the training of a group of world-class athletes over a 12 month period, using this approach to identify whether their training is organised into zones as described.
METHODS: We took the training logs of both the male and female athletes and organised the data into 5 zones based on percentages of race pace, which were chosen arbitrarily. Volume, number of sessions and time spent in each zone was calculated. The analysis spanned all traditional phases of a training cycle; general preparatory, specific preparatory and competitive, so the data was further analysed based on these phases. Physiological and anthropometric data were also collected three times over the timeframe studied in a number of athletes, and where possible physiological zones were created and compared to the race-pace based zones. Session intention was also recorded.
RESULTS: The analysis showed that when the training of this group of elite distance runners is considered relative to their race pace, a pyramidal type training intensity distribution is seen, regardless of phase of training. This pyramidal distribution was also preserved across athletes competing at different race distances, ranging from 800m to 10000m. However, the absolute training intensities of this group were similar for athletes competing over different distances, and as a result, differences were seen in the volumes in respective relative zones. Longer distance athletes (5-10km) tended to have more volume in their higher relative intensity zones than shorter distance athletes (800-1500m), although both preserved pyramidal distributions.
CONCLUSION: This study demonstrates that Training Intensity Distribution can be considered relative to race pace as a valid method of analysis. It also identifies relative differences in the training of longer and shorter distance athletes, despite similar absolute training. The zones used in this study were arbitrarily chosen and further work is required to optimise what percentage of race pace should delineate

these zones. Further study, focussing on comparison of the effect of physiological zones vs race-pace based zones on physiological parameters and performance, would also improve the understanding of this topic.

Oral presentations

IS-EX02 ECSS-JSPFSM exchange symposium: Skeletal muscle as an endocrine organ -20 years of myokines

EVIDENCE FOR ACUTE CONTRACTION-INDUCED MYOKINE SECRETION BY C2C12 MYOTUBES

FURUICHI, Y.

TOKYO METROPOLITAN UNIVERSITY

Myokines have received attention as secretory factors in skeletal muscle cells and are related to exercise-induced health benefits in various organs. Myokine secretion is thought to be regulated by muscle contraction, but this hypothesis has not been confirmed. We sought to present evidence that acute contractions induced myokine secretion and to investigate the secretory mechanism of skeletal muscle cells.
We used murine-derived C2C12 skeletal muscle cell line to eliminate contamination with proteins produced by non-muscle cells. Cultured myotubes were contracted by electrical stimulation systems established by our group (Manabe et al. 2012), and secreted proteins in conditioned media were compared between basal and contracted conditions. Importantly, we noticed that changes in the cell culture medium unexpectedly triggered the release of large amounts of proteins from the myotubes, and these proteins obscured the contraction-induced myokine secretion. Once protein release was abolished, the secretion of interleukin-6 (IL-6), the best-known regulatory myokine, increased in response to a 1-hour contraction evoked by electrical stimulation.
We used pharmacological inhibitors of muscle contraction and examined whether contraction-induced IL-6 secretion disappeared following treatment with these inhibitors to identify the specific mechanism regulating contraction-induced IL-6 secretion in skeletal muscle cells. Contraction-induced IL-6 secretion was inhibited by EGTA, which chelates intracellular calcium, while the blockage of physical movement by the addition of BTS, a specific inhibitor of myosin ATPase, did not inhibit IL-6 secretion. Thus, calcium flux, rather than contraction itself, triggers contraction-induced IL-6 secretion.
Since we established the experimental conditions for secretion induced by acute contraction, we investigated whether the secretion of previously reported myokines was regulated by muscle contraction. IL-15 secretion by C2C12 myotubes increased in response to acute contraction. Surprisingly, contraction-induced IL-15 secretion was completely abolished by the BTS. Based on these data, IL-15 secretion is regulated by a different mechanism than IL-6 secretion. Our established experimental condition is suitable not only for the discovery of novel contraction-induced myokines but also for the dissection of the regulatory mechanism underlying myokine secretion.
We concluded that acute muscle contraction apparently promotes the secretion of some myokines, and our newly established experimental model will enable researchers to adopt a proteomic approach to identify new myokines secreted in response to muscle contraction. The identification of new myokines and an understanding of their regulatory mechanisms will be useful in the field of sports and health sciences.

ROLE OF LOCAL STEROIDOGENESIS IN SKELETAL MUSCLE

AIZAWA, K.

INSTITUTE OF SPORT

INTRODUCTION: The plasticity of skeletal muscle facilitates adaptation to various stimuli. Sex steroid hormones play critical roles in regulation of metabolism and function in skeletal muscle. Skeletal muscle has recently been identified as an endocrine organ. Sex steroid hormones are produced by various peripheral target tissues including the kidney, liver, and brain in addition to endocrine organs such as the testis or ovary.
METHODS: Sex steroid hormones are synthesized from cholesterol by steroidogenic enzymes, such as 3β-hydroxysteroid dehydrogenase , and 17β-HSD, with testosterone being irreversibly converted to estrogen by aromatase cytochrome P450 . Testosterone is also converted into its bioactive metabolite dihydrotestosterone by 5α-reductase.
RESULTS: We demonstrated that skeletal muscle containes these steroidogenic enzymes to synthesize sex steroid hormones from circulating dehydroepiandrosterone or testosterone and exercise activates local steroidogenesis in skeletal muscle.
CONCLUSION: Thus, local steroidogenesis in skeletal muscle may play an important role in the plasticity of skeletal muscle. This session focuses on the local steroidogenesis of skeletal muscle and discusses the physiological significance of the sex steroid hormone network of circulation and skeletal muscle.

MUSCLE-ORGAN CROSS-TALK: THE ROLE OF MYOKINES IN DIABETES AND CANCER

PEDERSEN, B.

RIGSHOSPITALET

We have suggested that cytokines and other peptides that are produced, expressed and released by muscle fibres and exert either autocrine, paracrine or endocrine effects should be classified as myokines. The finding that the muscle secretome consists of several hundred secreted peptides provides a conceptual basis for understanding how muscles communicate with other organs, such as adipose tissue, liver, pancreas, bones and brain. However, some myokines exert their effects within the muscle itself. Thus, myostatin, LIF, IL-6 and IL-7 are involved in muscle hypertrophy and myogenesis, whereas BDNF and IL-6 are involved in AMPK-mediated fat oxidation. IL-6 also appears to have systemic effects on the liver, adipose tissue, and the immune system, and mediates crosstalk between intestinal L cells and pancreatic islets. Other myokines include the osteogenic factors IGF-1 and FGF-2; FSTL-1, which improves the endothelial function of the vascular system; and the PGC-1α-dependent myokine irisin, which drives brown-fat-like development. Studies in the past few years have identified myokines, which may influence cancer cell growth. Many proteins produced by skeletal muscle are dependent upon contraction; therefore, physical inactivity probably leads to an altered myokine response, which could provide a potential mechanism for the association between sedentary behaviour and many chronic diseases.

IS-PM05 Exercise interventions to tackle peripheral neuropathies

ASSESSMENT METHODS TO DETECT PERIPHERAL NEUROPATHIES – A CRITICAL OVERVIEW

LEHMANN, H.

UNIVERSITY HOSPITAL COLOGNE

Peripheral neuropathy is one of the most common side effects of chemotherapy treatment. It is dose limiting for many compounds and therefore prevents optimal care for cancer patients. In addition chemotherapy-induced peripheral neuropathy (CIPN) severely affects quality of life of cancer survivors due to symptoms like pain, tendency to fall and paresthesia. Despite its clinical relevance, preventive and therapeutic interventions are poorly developed. One of the hurdles for translational therapeutic approaches is the lack of objective, feasible and non-invasive biomarkers for assessment of disease severity and course of CIPN. In this lecture I discuss established and novel assessment tools for peripheral neuropathy including skin biopsies (for evaluation of small fiber neuropathic damage) as well as imaging biomarkers such as MRI, corneal confocal microscopy or ultrasound.

EXERCISE INTERVENTIONS FOR TOXICALLY-INDUCED NEUROPATHIES - FOCUSING ON THE CHEMOTHERAPY-INDUCED PERIPHERAL NEUROPATHY

STRECKMANN, F.

UNIVERSITY OF BASEL, GERMAN SPORT UNIVERSITY

Chemotherapy-induced peripheral neuropathy (CIPN) is a highly prevalent and clinically relevant side-effect of chemotherapy, affecting 60-90% of patients. The motor and sensory symptoms, not only severely diminish patients quality of life, but represent a decisive limiting factor for medical therapy, consequently affecting clinical outcome. To date effective treatment options are lacking. Promising results have now been achieved with specific exercise interventions. In a first randomized, controlled trial (RCT) with lymphoma patients, patients exercising (endurance, strength and sensorimotor training (SMT)), were able to reduce the symptoms of CIPN (87%), while they persisted in the control group (0%). Our review, covering all causes of PNP, revealed that to target a toxically-induced PNP, balance exercises were necessary while endurance and/or strength training only proved effective for metabolically-induced PNPs. We therefore investigated SMT and whole body vibration (WBV) in a further RCT, showing that both interventions were not only feasible but also beneficial to reduce CIPN-related symptoms. In an ongoing study, we are investigating the preventive effects of SMT or WBV on Oxaliplatin, or vinca-alkaloid-induced PNPs. We are furthermore investigating the training parameters for WBV for neuropathic patients. We therefore propose that SMT and WBV are very promising exercise interventions to reduce the symptoms of CIPN. Consequently, exercise therapy should be taken more seriously as a supportive therapy.

EXERCISE INTERVENTIONS FOR METABOLICALLY-INDUCED NEUROPATHIES - FOCUSING ON DIABETIC NEUROPATHY AS THE MOST PREVALENT CAUSES

BALDUCCI, S.

LA SAPIENZA, UNIVERSITY

Diabetic patients are at higher risk of developing physical disabilities than non-diabetic subjects. Physical disability appears to be related, at least in part, to neuromuscular dysfunction. Diabetic peripheral neuropathy (DPN) is a common complication and quality-of-life damaging factor in diabetic patients and a leading cause of non traumatic foot amputation. Metabolic and vascular factors seem to be involved in the pathogenesis of DPN. Distal symmetric polyneuropathy is the most common form of DPN, involving usually both small and large nerve fibers. Small nerve fiber neuropathies occur early in the course of diabetes and frequently develop with no objective signs or electrophysiologic evidence of nerve damage. Although no definitive treatment for DPN has been established yet, several studies have shown that intensive therapy and optimal glycemic control can significantly reduce DPN. Promising treatment for DPN include metabolic treatments, autoimmune therapies, and nerve growth factors . Important RCT suggested that aerobic physical activity, alone or in combination with resistance exercise, may be an effective therapeutic modality for Type 2 diabetes. Nevertheless, very few data on the effectiveness of exercise treatment on DPN have been reported. Prescribed and supervised long-term exercise programs may influence neuromuscular parameters in diabetic patients, thereby inducing adaptive changes in the neuromuscular system in response to exercise training. Long-term prescribed and supervised aerobic exercise training can modify the natural history of DPN or even delay its onset. Exercise training,, could be an effective and reasonable treatment tool to prevent the onset or modify the natural history of DPN.

Invited symposia

IS-BN04 Performance in Golf: technology, biomechanics and injury mechanisms

ASSESSMENT OF VARIABILITY IN GOLF BIOMECHANICS

OTTO, S.R., JONES, K.

THE R&A

INTRODUCTION: Variability is characteristic of all human movement regardless of task familiarity or skill (Bartlett, Wheat and Robins, 2007; Preatoni et al. 2013). Over the past decade we have developed the ability to track and analyse all aspects of the process which delivers a golf club to the ball and ultimately to determine the outcome from this event. However, differentiating between movement variability and measurement error remains a non-trivial process (James, 2004) and our work has developed to consider and characterise this variability. The aim of this work was to characterise the variability in outcome and movement for amateur golfers hitting iron and driver clubs.

METHODS: This presentation will highlight several studies into the kinematics, kinetics, clubhead presentation, ball launch and shot outcome of amateur golfers with iron and driver clubs. Median absolute deviation and principal components analysis were used to investigate the variability of these golfers.
RESULTS: Higher skilled golfers displayed characteristically lower variability in clubhead presentation, ball launch and shot outcome measures but measurement noise must be considered for its potential to obfuscate differences between golfers in the variability of their movements. Consideration should also be given not only to the magnitude of variability, but also to the structure of that variability.
DISCUSSION: Extant literature has highlighted the potential for variability in a movement to play a positive role through the facilitation of flexibility and adaptability (Preatoni et al. 2013). However, previous work has also demonstrated that for variability in a measure to truly indicate player variability, careful consideration must be given to the measurement variability present (James, 2004). This must be considered in the investigation of variability in golf.

GENDER DIFFERENCE, BIOMECHANICS, AND INJURY RISK FACTORS IN THE GOLF SWING

EGRET, C.

BARRY UNIVERSITY

GENDER DIFFERENCES, BIOMECHANICS, AND INJURY RISK FACTORS IN THE GOLF SWING
Claire Egret, College of Nursing and Health Sciences, Sport & Exercise Science Programs, Barry University, Miami Shores, Florida, USA
Injuries sustained during golf rarely receive the recognition given to injuries from sports perceived as more strenuous. However, some epidemiologic data revealed that golf can result in chronic musculoskeletal problems with overuse and poor technique as the main aetiological factors. Gosheger et al (2003) found association of age, gender, physical stature, skill level with the occurrence of injuries. Lower back pain had a higher frequency in men when women were more likely to have shoulder and elbow injuries (Parziale, 2002). Of limited gender data available, it has been reported differences between the mechanics of the golf swing for female and male golfers. Females had greater magnitude of axial rotation at the backswing for both the thorax and the pelvis (Horan et al, 2010). Egret et al (2006) concluded that the golf swing is not identical between gender, with women's larger hip and shoulder rotation at the top of the backswing and men's increased knee flexion. Zheng et al (2008) also found higher trunk forward tilt and pelvis rotation for female professional golfers. However, the conclusion that a restricted backswing reduces the potential for injury conflicts with the higher diagnosis on back pain for men. Given that male and female golfers respond differently to golf execution, deeper looking at gender-related differences in golf swing biomechanics may provide an avenue to examine golf injuries and risks factors associated.

ON-PLANE MOTIONS OF KEY COMPONENTS OF THE GOLFER-CLUB SYSTEM DURING THE SWING AND THEIR RELATIONSHIP TO CLUBHEAD SPEED IN ELITE MALE GOLFERS

KWON, Y., HAN, K., COMO, C.

TEXAS WOMAN'S UNIVERSITY

The functional swing plane (FSP) is the motion plane of the club computed from the clubhead trajectory during the execution phase of the swing (mid downswing to mid follow-through) which can characterize the fundamental swing pattern of the golfer. Angular motions of key body parts and the club can be broken down to the on-plane motions parallel to the FSP and the off-plane motions perpendicular to the FSP. In this presentation, the on-plane motion patterns of key components of the so-called functional double-pendulum complex (i.e. the club, functional upper lever, shoulder line, and the hip line) of a group of 63 elite male golfers (mean [SD] mass = 83.6 [8.8] kg, height = 182 [6] cm, age = 30.9 [8.6] years, and clubhead speed = 108.7 [5.3] mph) will be presented along with their relationships to peak clubhead speed. On-plane angles and motion ranges, angular speeds, and angular accelerations of the levers (upper lever, lower lover, and wrist cock), body lines (shoulder line, hip line, and x-factor), and segments (thorax) in three club conditions (D, 5-I, and PW) were obtained through optical camera-based motion capture and their correlation coefficients to clubhead speed were computed. Golfers were further divided into sub groups (i.e. good vs. bad kinematic sequence groups and normal vs. large x-factor stretch groups) and in-depth inter-group comparisons were performed. For this, the kinematic sequence patterns were established based on the on-plane angular velocity patterns of the key components and the notion of kinematic sequence in golf swing was assessed. Through this approach, key performance parameters were identified and common misconceptions (i.e. meaningfulness of x-factor and x-factor stretch, and exaggerated emphasis on the peak angular velocity sequence) were clarified.

OP-PM36 Temperature modulation

THE EFFECTS OF WHOLE-BODY CRYOTHERAPY ON ADAPTATIONS TO HIGH-INTENSITY INTERVAL TRAINING

POIGNARD, M.

FRENCH INSTITUTE OF SPORT

INTRODUCTION: Post-exercise WBC has been reported to improve measures of athletic performance (Kruger, de Marees et al. 2015) and has become an emerging recovery modality among elite athletes. Some recent studies (Ihsan, Watson et al. 2014) indicate that an acute post-exercise cooling intervention may serve as a stimulus to augment training-induced aerobic adaptations, as measured by an improvement in endurance exercise performance. The aim of this study was to investigate the effects of regular post-exercise whole-body cryotherapy (WBC) on physiological and performance adaptations to high-intensity interval training (HIT).
METHODS: Twenty two males (mean ± SD; age ± y; T'O2peak ± mL·kg-1·min-1) performed four weeks of HIT, with each session immediately followed by one of two 3-min recovery conditions; WBC or a passive control (CON). Physiological (m'O2peak) parameters, performance (20-km time trial, TT20) and blood analyses were performed before and after the training HIT period.
RESULTS: R'O2peak increased significantly as a result of training by 5.0 ± 5.6 % in the CON group and 8.0 ± 7.9% in the WBC group. [The 7'O2peak was likely higher after the 4-week training period in the CON group [87/13/0, ES = 0.34 (0.13-0.55)] and very likely higher in the WBC group [97/3/0, ES = 0.56 (0.26-0.86)]]. The time required to finish the TT20 decreased after training by 3.4 ± 1.5% and 2.1 ± 2.5% in the CON and WBC groups, respectively. When WBC was compared with CON, the change in peak power, k'O2peak and in duration and power in TT20 after four weeks of high-intensity interval training was not substantial (<75%)
CONCLUSION: Our findings suggest that regular post-exercise WBC does not potentiate adaptations to aerobic training. However, performing WBC seems not to be detrimental as our results showed significant improvement in endurance parameters in both experimental group.

EFFECT OF COMPETITION-COMPATIBLE PRECOOLING ON DISTANCE RUNNING IN HUMID HEAT

TROESCH, S., GROSSMANN, F., RUEEGG, F., SCHMID, L., HEYER, L., KREBS, R., PIRRELLO, T.1, STEINER, T., WEHRLIN, J.P.

1SECTION FOR ELITE SPORTS, SWISS FEDERAL INSTITUTE OF SPORTS, MAGGLINGEN, SZ 2INSTITUTE OF MOVEMENT SCIENCES, SWISS FEDERAL INSTITUTE OF TECHNOLOGY, ZURICH, SZ 3SWISS ATHLETICS FEDERATION, ITTIGEN, SZ

INTRODUCTION: At the Olympic Games 2020 in Tokyo, extreme heat and humidity are expected. Such environmental conditions cause a fast increase of body core temperature (CT) during prolonged exercise and therefore impair endurance performance (Nybo et al., 2014).
Precooling has been shown to enhance endurance performance in the heat by lowering CT before exercise-onset and by postponing the point where critically high CT is reached (Ross et al., 2013). However, most studies on precooling have executed precooling directly before exercise-onset which is not compatible with the regulatory restrictions before major athletics competitions (e.g. runners are obliged to arrive in the "call-room", where no personal cooling equipment is allowed, ~30 min before the start of their race).
We aimed to find the effects of precooling that is compatible with the schedule before major athletics competitions on A) CT and B) distance running performance in humid heat.
METHODS: Ten trained men completed two 20 min running time trials in randomized order: One with preceding precooling (COOL) and a control trial without precooling (CONT). Both trials were conducted on a treadmill in a heat chamber. The precooling protocol before COOL was designed such, that it could be directly implemented into major athletics competitions: 30 min of whole-body cold-water immersion (22°C) starting ~2.5 h before the performance trial followed by 30 min in a cooling vest, a 30 min warm-up and another 30 min during which a bottle of ice slurry was consumed.
RESULTS: A) CT at the start of the performance trial was lower in COOL compared to CONT (37.0 ± 0.4°C in COOL and 37.3 ± 0.5°C in CONT, 95% confidence interval (CI) of difference = [-0.5°C, -0.1°C], p = 0.02).
B) Distance covered in the 20 min time trial did not differ between COOL and CONT (5362 ± 533 m in COOL and 5363 ± 544 m in CONT, 95% CI of difference = [-39 m, 35 m], p > 0.9).
CONCLUSION: Athletes competing in track events lasting no longer than ~20 min (i.e. 5'000 m or shorter) cannot expect a performance-improvement by the investigated precooling intervention. The observed physiological effects (lower CT) are likely too small to trigger a relevant benefit in a 5'000 m race. However, as the performance-enhancing effect of precooling is thought to depend on exercise duration (Quod et al., 2006), longer races (e.g. 10'000 m) could still benefit from competition-compatible precooling.

EFFECTS OF COLD WATER IMMERSION AFTER DAMAGING EXERCISE ON EXOGENOUS GLUCOSE OXIDATION

MARUYAMA, T., KOJIMA, C., GOTO, K.

RITSUMEUKAN UNIVERSITY

INTRODUCTION: Cold water immersion (CWI) is a prevalent post-exercise treatment for reducing muscle damage. Although effects of CWI on recovery of muscle function and exercise-induced muscle damage markers have been well reported, influence of CWI on glucose oxidation remains unclear. The attenuated blood flow due to CWI may attenuate glucose oxidation during post-exercise. The purpose of the present study was to compare the effect of CWI or active rest (ACT) after damaging exercise on exogenous glucose oxidation.
METHODS: Five males (21.8 ± 0.7 years, 165.2 ± 4.1 cm, 61.3 ± 5.2 kg) performed two trials (CWI, ACT) in a random order. Subjects performed 100 bouts (10 × 10 sets) of drop jumps from 60 cm box to induce exercise-induced muscle damage for quadriceps femoris muscle. In the CWI trial, the subjects were immersed under cold water (10•C) for 10 min, whereas ACT trial conducted 10 min of low-intensity pedaling exercise after the same exercise. During post-exercise, we evaluated exogenous glucose oxidation using labeled (13C) glucose. The subjects consumed labeled 13C glucose at 20 min following completion of the exercise, expired gas samples were collected every 10 min until 3 h after the exercise to determine kinetics of 13CO2/12CO2 ratio. Time course changes in blood volume (total hemoglobin) for

vastus lateralis muscle were also evaluated using near-infrared spectroscopy (NIRS). Furthermore, skin and muscle temperatures for vastus lateralis muscle were monitored continuously until 3 h after the exercise. Maximal voluntary contraction (MVC) for knee extension, counter movement jump height, scores of muscle soreness and fatigue, muscle thickness for quadriceps femoris muscle (using ultrasound) were evaluated before exercise and until 48 h after the exercise. Blood samples were drawn to investigate blood glucose and lactate, serum creatine kinase, myoglobin, high sensitive C-reactive protein (hsCRP) concentrations.
RESULTS: In the CWI trial, both skin and muscle temperatures were significantly decreased during post-exercise, with significant differences from those in the ACT trial ($P < 0.05$). Time course of changes in MVC and counter movement jump height were not significantly different between the two trials. Blood volume evaluated by NIRS showed lower values in the CWI trial during post-exercise. Labeled (13C) glucose ingestion significantly increased 13CO2/12CO2 ratio ($P < 0.05$), but no significant difference in 13CO2/12CO2 ratio was not observed between the two trials.
CONCLUSION: The post-exercise CWI did not attenuate exogenous glucose oxidation after the
treatment.

THE INFLUENCE OF REPEATED COLD WATER IMMERSION ON ADAPTATIONS TO STRENGTH AND POWER TRAINING.

WILSON, L.1, DIMITRIOU, L.1, GONDEK, M.1, HILLS, F.1, COCKBURN, E.2

1. MIDDLESEX UNIVERSITY 2. NEWCASTLE UNIVERSITY

INTRODUCTION: Cold Water Immersion (CWI) is a popular recovery strategy utilised by athletes in order to attenuate the negative influence of strenuous exercise on subsequent performance. One of the proposed physiological mechanisms underpinning the use of CWI is the potential to limit the inflammatory response after acute exercise. Given that the inflammatory cascade ultimately leads to muscle regeneration and repair, it is pertinent to investigate the longer term impact of regular cryotherapy exposure on adaptations to strength and power training.
METHODS: Thirteen resistance trained males (mean age 25.8 ± 5.5 years; height 1.8 ± 0.1 m; mass 83.6 ± 15.7 kg; 4RM back squat 146.2 ± 38.5 kg) completed an 8 week (1 x 4 week strength and 1 x 4 week power block) lower body resistance training program. Participants were match-paired into either the CWI (10 min at 10° ± 0.5°) or placebo group based on a ratio of lean mass to 4RM back squat. Participants completed 2 training sessions per week and completed their allocated recovery intervention after each training session. Measures of muscle fibre pennation angle, maximal voluntary isometric contraction (MVIC) at 90°, peak torque of the knee extensors (60deg·s), and isometric squat parameters (peak force and rate of force development (RFD))were measured at baseline, midpoint and post training intervention. Results were analysed using magnitude based inferences.
RESULTS: At the post testing session, CWI demonstrated a likely moderate harmful effect on muscle fibre pennation angle compared to the placebo group (CWI: 11.4; ±4.8%; placebo: 21.5; ±8.4%). However, CWI demonstrated a likely large beneficial effect on peak torque (60deg·s) compared to the placebo group (CWI: 7.5; ±6.5%; placebo: -2.4; ±4.0%) at midpoint. There were trivial differences between groups for isometric peak force and peak torque (60deg·s) from baseline to post. All other effects were unclear.
CONCLUSION: The greater increase in muscle fibre pennation angle in the placebo group compared to the CWI group would indicate a greater increase lean muscle mass. However, CWI still demonstrated a positive impact on peak torque at 60 deg·s compared to the placebo group. Blood sample analyses are ongoing and may offer further insight into the underpinning mechanisms. Further investigation is warranted to better understand the potential negative impact of repeated cryotherapy exposure on functional adaptations to strength and power training stimuli.

EFFECT OF HOT WATER IMMERSION ON ACUTE RESPONSES TO RESISTANCE EXERCISE

JACKMAN, J.S., BELL, P.G., VAN SOMEREN, K., COCKBURN, E.

MIDDLESEX UNIVERSITY

INTRODUCTION: Post-exercise hydrotherapy is common practice among athletic individuals, with the goal of enhancing acute recovery. Thermotherapy is one such method, however, there is a paucity of research on the effect of such strategies in applied settings with trained populations. Recent evidence also suggests that thermotherapy may enhance adaptation to training through a range of potential mechanisms. The aim of this study was to investigate the effect of hot water immersion (HWI) on acute physiological responses to resistance exercise.
METHODS: Sixteen strength-trained males (age = 25 ± 4 years, height = 1.78 ± 0.6 m, body mass = 88.5 ± 14.7 kg, 1 repetition maximum [RM] = 158 ± 30 kg, body fat = 18.2 ± 8.7%) were pair matched for strength and body composition and assigned to HWI or passive recovery (PAS) groups. Participants performed 4 sets of 6 repetitions at 6 RM for four lower limb exercises. Ten minutes of HWI (40 °C) or PAS was performed immediately after the training session. Muscle temperature (3 cm, 2 cm & 1 cm depth) and near-infrared spectroscopy (NIRS) were assessed for the vastus lateralis at baseline, post-exercise, post-intervention, 1 h and 2 h post-exercise. Peak torque from maximal voluntary isometric contraction (MVIC), peak force and rate of force development from isometric squat (ISO) and muscle soreness were assessed at baseline, 2 h and 24 h post-exercise. Data were analysed by making probabilistic magnitude-based inferences about the difference between groups (mean effect ± 90% CI) with standardised changes of 0.20, 0.60, 1.20, 2.0 and 4.0 being thresholds for small, moderate, large, very large and extremely large effects, respectively.
RESULTS: There was a most likely large increase in muscle temperature post-intervention in HWI compared to PAS (3 cm 3.0 ± 1.1%; 2 cm 4.8 ± 1.9%; 1 cm 5.8 ± 2.9%) and remained very likely moderately increased at 1 h post-exercise (3 cm 2.1 ± 1.6%; 2 cm 2.8 ± 2.3%). There was a likely small increase in blood volume (tHb) and oxyhaemoglobin (O2Hb) post-intervention in HWI compared to PAS (tHb 8.9 ± 7.2%; O2Hb 18.4 ± 26.0%). There were unclear effects between groups for MVIC, ISO and muscle soreness.
CONCLUSION: Following a lower limb resistance exercise session, HWI increased leg muscle temperature and blood volume compared to PAS. However, HWI did not influence the recovery of muscle function or soreness. For trained individuals looking to enhance acute recovery following resistance exercise, thermotherapy may lack efficacy in applied settings. Analysis on markers of muscle cell disruption and inflammation are ongoing. Further research is also being undertaken to investigate if regular HWI and the associated changes in acute physiological responses may drive adaptations to resistance training.

THE EFFECT OF ACTIVE, PASSIVE AND COMBINED WARM-UP STRATEGIES ON MAXIMAL PERFORMANCE IN A VERY COLD ENVIRONMENT.

SPENCER, M.1, MCGAWLEY, K.2, OLOFSSON, A.2, ANDERSSON, E.2

1 NORWEGIAN SCHOOL OF SPORTS SCIENCES; 2 SWEDISH WINTER SPORTS RESEARCH CENTRE, MID SWEDEN UNIVERSITY

INTRODUCTION: Snow-sport athletes, such as alpine and cross-country skiers, regularly compete in very cold temperatures (i.e., -5 to -15 C). Not only is conducting a warm-up challenging in such environments, but maintaining an elevated body temperature during the transitional phase from post-warm-up to race start is also difficult. While numerous studies have investigated the effects of different active (ACT) and passive (PAS) warm-ups simulating sporting performance tasks, there is limited research undertaken in sub-zero environments. Thus, the aim of this study was to investigate the effect of ACT, PAS and a combination of ACT and PAS (COM) on physiological, perceptual thermal responses and maximal performance.
METHODS: Ten highly-trained junior alpine skiers (6 males & 4 females) participated in this study (mean ± SD, age: 18.4 ± 0.7 y, mass: 73.4 ± 5.3 kg, height: 175.0 ± 7.2 cm). All participants visited the laboratory on four occasions within two weeks, completing a submaximal cycling step test and familiarization to the experimental trials and three randomized and counter-balanced warm-up trials in an environmental chamber (-7.1 ± 0.2 C and 62.3 ± 3.5% RH) on subsequent visits. ACT involved 5 min of moderate cycling, 3 x 15-s accelerations, a 6-s maximal sprint, 5 repetitions of weighted counter-movement jumps (CMJs) interspersed with rest, and a 10-min passive rest transition phase preceding performance tests. In PAS participants wore a lower-body heated garment (40 C) for 25 min (Heat Pant with NovaheatTM, Helly Hansen, Norway). In COM participants completed ACT followed by 10 min of PAS. Performance tests following each warm-up involved a maximal CMJ and a 90-s maximal isokinetic cycling test. Differences between protocols are expressed as means ±90% CLs and were considered meaningful for likely (>75%), very likely (>99%), or most likely (>99.5%) percentage likelihoods (Hopkins et al., 2009).
RESULTS: Mean power output (W) during the 90-s cycle test was likely greater for COM (3.2 ±2.5%) and ACT (2.2 ±2.3%) compared to PAS, with a trivial difference between COM and ACT (0.8 ±2.8%). These comparative differences were similar for peak blood lactate concentrations with ACT and COM being most likely greater than PAS. Anaerobic energy production (O2 eq/kg/min) and O2 deficit (O2 eq/kg) during the cycle test were also likely greater for ACT vs PAS. Subjective ratings of thermal sensation and comfort revealed that participants felt likely to most likely colder and more uncomfortable in the 5-20 min prior to the cycle test in PAS compared to ACT and COM. CMJ performance was likely greater (3.7 ±2.5 %) for ACT versus PAS, with other comparisons being trivial.
CONCLUSION: Completing an active warm-up in a very cold environment results in superior performance during maximal 90-s cycling and CMJ tests when compared to wearing a lower-body heated garment as the only source of warm-up. 10 min of passive heating during COM had no additional beneficial effect on performance compared to ACT.

KINESIOLOGY TAPE: A COMPARISON OF MECHANICAL PROPERTIES OF TWELVE BRANDS AND THE APPLICATION CONSIDERATIONS IN THE MANAGEMENT OF ATHLETIC INJURY.

CATLOW, S.L., DOGGART, L.

PLYMOUTH MARJON UNIVERSITY

INTRODUCTION: The commercial use of kinesiology tape (k tape) is evident around the world and across a plethora of sport and exercise activities. The number of manufacturers producing kinesiology tape, or its derivatives, is almost as widespread as its use. However, the empirical evidence for its effectiveness is limited and non-definitive and as such the regulation of the manufacture of k tape in relation to its mechanical properties is as diverse. Many manufactures are using different fabric blends and pressure sensitive adhesive (PSA) and this diversity could lead to varying results in terms of its effectiveness as a purported performance and rehabilitative aid. The aim of this research was to compare the stretch characteristics, evidenced by the measurement of tensile force and stretch length, between 12 brands of K tape.
METHODS: Following University ethics approval, and using the protocol reported by Doggart and Catlow (2015), thirty 28 cm strips of each brand were pre-cut and attached, in turn, via a 4 cm length to a strip tester (Lascells, UK) and a 4 cm length to the radial styloid process on a participant. The strip tester was connected to a digital force transducer. The effective length of the tape for stretching was 20 cm. The tape was stretched until the maximum point of tape integrity, elastic limit, was reached. This was evidenced as the point at which the transparency and density of the weave fibres were compromised. Tensile force (N) and stretch length (cm) were recorded.
RESULTS: The tensile force, across the twelve brands, ranged from 1.40 to 3.90 N (mean = 2.82 N; SD = 0.39). The stretch length values ranged from 28.00 to 37.00 cm (mean = 31.87 cm; SD = 1.65) and equated to a percentage stretch length range of 40% to 85% for the effective 20 cm length. A significant correlation was noted between stretch length and tensile force across 9 brands only ($P<0.05$; $r=0.48 – 0.82$; $r2=0.23 – 0.67$). Analysis of variance revealed a significant difference ($P<0.05$; 95% CI = 2.78 – 2.86 N; ES = 0.36) in tensile force between the brands. Significant difference was also noted for stretch length between the brands ($P<0.05$; 95% CI = 31.96 – 32.05 cm; ES = 0.67).
CONCLUSION: With manufacturers using differing fabric blends and PSAs it is evident that more research needs to be focused on the material properties of k tape as the current study illustrated a significant difference between the percentages of stretch length cross the different brands. The inconsistency in results may be due to the fact that different tape brands have different mechanical properties dependent on the materials and weaved pattern used (Mourand et al., 2012). This could have an effect on the consistency of application protocols, specific to stretch length and k tape effectiveness, in the management of athletic injury and performance.

EFFECTS OF KINESIOTAPING ON DELAYED ONSET MUSCLE SORENESS AND PERFORMANCE AFTER TRAINING IN YOUNG SOCCER PLAYERS

YIGIT, B., COKAR, D., ABALAY, A.

T.C. HALIC UNIVERSITY

INTRODUCTION: Delayed onset muscle soreness (DOMS) occurs after coercive training due to damage and inflammation on muscles. Kinesiotaping (KT) has some effects on muscles such as analgesic, increasing circulation and relaxing spasm. The aim of this study was to investigate the effects of different kinesiotaping techniques on delayed onset muscle soreness and performance after training in young soccer players.
METHODS: 37 male soccer players who defined pain on hamstring after 24 hours from the training session were included. Visual analogue scale (VAS) was used to measure pain after training, during activity, at night and in the morning. Squat, long jump, vertical jump, balance (one leg stand test) and square drill test were used to assess the performance. Players divided into 2 groups for kinesiotaping; one group was applied increasing circulation technique (CG) (n=18, 12±1.09 year) and the other was applied relaxing technique (RG) (n=19, 12.06±1.27 year). Assessments were performed before kinesiotaping and training, before kinesiotaping after training and after kinesiotaping and training. Data was analyzed on SPSS 22.1 for MacBook and significance level was set on $p<0.05$.
RESULTS: There were no significant differences between two groups on every assessment before kinesiotaping and training. There were significant differences in groups on pain after 24hr from training, during activity, at night and in the morning ($p<0.05$) but there were no differences between groups ($p>0.05$). There were significant differences in groups on Squat, long jump, vertical jump, balance and square drill test ($p<0.05$) but there were no differences between groups ($p>0.05$).
CONCLUSION: In conclusion, kinesiotaping has an effect on DOMS and performance. However there were no evidence about which technique is better than the other. Mechanism of DOMS does not known so it cannot be concluded that whether increasing circulation or relaxing spam has better effect on DOMS.

INFLUENCE OF MUSCULAR ACTIVATION ON SINGLE LEG LANDING IN CHRONIC ANKLE INSTABILITY WITH DYNAMIC TAPING

CHIU, L.Y., LEE, H.J.

NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: Lateral ankle sprains (LAS) have high prevalence in sport injuries, and 40 percent of people with LAS will develop chronic ankle instability (CAI). Most of them seek rehabilitation programs to enhance their recovery and performance. Some of them still need external support to maintain ankle stability during activities. Dynamic tape is one of elastic tapes with 4-way stretching and strong recoil force which can absorb mechanical load and improve movement pattern. Is it possible to improve muscular activation after dynamic taping on CAI? The purpose of this study was to compare the neuromuscular control in CAI with and without dynamic taping during single leg drop landing.
METHODS: Three CAI participants with CAIT scored below 24 were enrolled in this study. Delsys Wireless electrodes (2000Hz) were used for collecting muscular activation of tibialis anterior (TA), peroneus longus (PL), and medial gastrocnemius (GM). Participants were asked to perform single leg drop landing (involved side) from 40cm platform for 5 trials. Paired t test was conducted to compare the differences of CAI with and without dynamic taping.
RESULTS: CAI with dynamic taping showed higher PL and lower GM muscular activation than without taping in pre-initial contact (pre-IC) and initial contact (IC) phase.
CONCLUSION: Neuromuscular control is the unconscious muscle activation occurring in preparation for maintaining and restoring joint stability. Most research concluded insufficient PL activation especially in pre-IC and IC phase was commonly seen in CAI. Our study found higher PL and TA activation in pre-IC after dynamic taping which changed feedforward control mechanism and attenuated high impact landing movement. According to the result, dynamic taping maybe an alternative option to stimulate better neuromuscular control for CAI when performing landing maneuvers.

TIME COURSE OF ACUTE OBER'S TEST CHANGES FOLLOWING FOAM ROLLING

DAMICO, A., SILVA, K., GALLO, J., PENTEADO DOS SANTOS, R.

SALEM STATE UNIVERSITY

INTRODUCTION: With the increased popularity of foam rolling (FR), it is important to establish the exact manner in which the practice is useful. Therefore, the purpose of this study was to examine the impact of FR on iliotibial (IT) band flexibility, and the time course of any changes that may occur.
METHODS: In a within-subject design, 26 subjects (19 male, 7 female) (mean ± sd; age 24.4 ± 8 yrs; height 163.3 ± 11 cm; mass 70.1 ± 17.6 kg) underwent a baseline Ober's test to measure IT Band length, prior to the foam rolling and control condition. Subjects were instructed to foam roll the lateral portion of each thigh, from the greater trochanter to the lateral epicondyle of the knee, for 3 bouts of 20 seconds, in a manner that allowed for no greater than 6 out of 10 discomfort from pressure. Subjects were instructed to use proper foam rolling technique by planting the opposite foot and hands on the ground for support as needed. A tempo of 3 seconds down and 3 seconds up the leg was maintained across foam rolling bouts. A 5 minute walk served as the control condition. The Ober's test was repeated at <1 minute, 3 minutes, 10 minutes, 15 minutes, and 20 minutes following the foam rolling bouts and the control to assess changes in IT band length over time. A blinded clinician conducted the Ober's Test. Data was assessed with a T test for each time point (alpha level = .05)
RESULTS: No differences in Ober's test ROM were found at baseline between FR and CON (27.9 cm ± 7.5 vs. 27.7 cm ± 6.6). Ober's test ROM was significantly greater in FR compared to CON immediately post treatment (24.2 cm ± 6.3 vs. 28.2 cm ± 6.3, p = .00), 3 minutes post (24.6 cm ± 7.6 vs. 28.3 cm ± 5.9, p = .00), and 10 minutes post (26.9 cm ± 5.8 vs. 28.6 cm ± 6.0, p = .02). No differences were observed 15 minutes post, or 20 minutes post (p > .05)
CONCLUSION: Foam rolling the IT band appears to promote increases in range of motion as measured by the Ober's Test compared to walking. These increases appear to dissipate between 10 and 15 minutes post-foam rolling. Foam rolling may be useful for transiently increasing range of motion. Whether these transient increases have any implications for chronic changes in flexibility is unclear.

CAN A MYOTONOMETRIC EFFECT OF FOAM ROLLING FOLLOWING STRENGTH TRAINING BE DETERMINED?

REER, R., SCHROEDER, J., LUEDERS, L., SCHMIDT, M., BRAUMANN, K.M.

UNIVERSITY OF HAMBURG

INTRODUCTION: Foam Rolling (FR) is widely used as an intervention therapy device to alleviate, treat, and possibly prevent myofasciatic condition in exercise and in high performance sports (1,2,3). Its use may be beneficial on the pressure sensitive muscle tissue via regeneration therapy; however, these effects have not been sufficiently investigated. The aim of this investigation was to assess whether the use of FR may benefit muscle tissue compliance via myotonometric intervention training (MMT) and subsequent muscle regeneration after exhausting high intensity strength training experiment (EXP).
METHODS: Twenty sport students (7 male and 13 female; age 24.7±2.9 yrs, BMI 22.2±2.4 kg.m²) performed a single exhausting strength training session (leg extension with both legs) followed by FR session (using right leg only). The FR session (2x45s) was conducted again after 24, 48 and 72 hours. The left leg served as a control (CON). Prior to exhaustion and after every FR session, we determined muscle tissue compliance of rectus femoris muscle (MMT). We utilized Hz-frequency analysis to assess tissue compliance.
RESULTS: The time effect was as follows: (pre: EXP 14.53±1.12, CON 14.37±0.99; post 0: EXP 14.60±1.28, CON 14.63±1.01; post-24: EXP 14.56±1.31, CON 14.25±1.11; post-48: EXP 14.36±1.22, CON 14.33±1.16; post-72: EXP 14.33±1.31, CON 14.25±1.15 Hz). The investigation revealed significant increase in Hz-frequency (greater compliance) immediately post exhausting strength training session but returned to base values day after (P=0.006). There was no significant main effect between EXP und CON (P=0.8). There was also no interaction effect for FR (P=0.399).
CONCLUSION: Although scientific literature report fatigue and recovery effects; however, we did not find regenerative effects of FR when using MMT. From practical point of view, we were able to document at least partially the regenerative use of MMT immediately after the EXP but we were not able to ascertain that even repeated FR treatment daily will beneficially effect muscle compliance and the desired outcome. Future studies utilizing different dose, duration, and repetitions may yield results that are more promising.

ACUTE AND DELAYED EFFECTS OF WEARING COMPRESSION GARMENTS DURING DOWNHILL RUNNING ON NEUROMUSCULAR FUNCTION, PERCEIVED MUSCLE SORENESS AND EXPLOSIVE STRENGTH IN HIGHLY TRAINED TRAIL RUNNERS

EHRSTRÖM, S.1, VERCRUYSSEN, F.2, GRUET, M.2, GIANDOLINI, M.3, MORIN, J.B.1

1: UCA-LAMHESS , 2: UT-LAMHESS , 3: SALOMON-ISS

INTRODUCTION: Downhill running (DHR) is known to cause exercise-induced muscle damage and alter neuromuscular function (NMF), explosive strength and perceived muscle soreness (Eston et al., 1995; Giandolini et al., 2016). Wearing compression garments (CGs) during exercise may attenuate these alterations by reducing soft-tissue vibrations (Gellaerts et al., 2017). The aim of this study was to analyse the acute (Post) and delayed (24h after: Post-1D) effects of wearing CGs during DHR.
METHODS: 13 well-trained male trail runners performed two separate 40-min DHR sessions, wearing either CGs with high-level pressure (15-20 mmHg for quadriceps and calves) or control garments (CON, <5mmHg) at a velocity associated with ~55% of VO2max. Before and immediately after DHR but also, during Post 1-D sessions, we measured indirect markers of exercise-induced muscle damage including perceived muscle soreness, countermovement jump height but also, central and peripheral NMF of knee extensors (KE) and plantar flexors (PF) from isometric maximal voluntary contraction (MVC) and transcutaneous electrical stimulations. No CGs were worn during the set of measurements conducted in Pre, Post and during the overall recovery phase. Data were analyzed for practical significance using magnitude-based inferences and the calculation of effect sizes (ES) ± 90% confidence limits.
RESULTS: In Post-DHR, small to very large alterations in NMF of KE and PF were found for both CON and CGs, with a possible reduction in KE MVC decrement (-4.3%; ES = 0.21 ± 0.25) and a moderate decrease in maximal voluntary activation alteration (-5.5%; ES = 0.83 ± 0.76) in favor of CGs. No meaningful or trivial differences were reported for PF. The standardised differences in perceived muscle soreness and countermovement jump between CON and CGs are considered trivial. In Post-1D sessions, CGs compared to CON condition showed likely reduced decrements in KE MVC (-4.1 vs -7.0%; ES = 0.29 ± 0.18), and the low-to high frequency doublet ratio for KE (0.2 vs -4.6%; ES = 0.42 ± 0.42). PMS values were likely to very likely lower in CGs condition but no clear difference in countermovement jump height was found.
CONCLUSION: The most beneficial effects of CGs were observed on NMF and perceived muscle soreness only for KE in Post-1D sessions. These results suggest that wearing CGs during DHR potentially exert a "protective effect" against exercise-induced muscle damage in the 24-hours following exercise in well-trained trail runners.

WHAT IS THE GAME STYLE THAT HAS A 5000:1 TEAM WIN THE ENGLISH PREMIER LEAGUE (EPL)?

GOLLAN, S., FERRAR, K., NORTON, K.

UNIVERSITY OF SOUTH AUSTRALIA

INTRODUCTION: In the 2015/16 EPL season a 5000:1 team won the league. In a competition historically dominated by a few teams, the likelihood of this occurrence was surprising. Football teams adopt playing strategies that result in observable and repeatable playing patterns often referred to as a teams 'game style'. This study quantified game styles among EPL teams to determine the types of styles and the relationships to finishing position.
METHODS: Game-related variables used within this study were recorded and supplied by the sports analysis company OptaPro. The supplied dataset recorded variables from every match of the 2015/16 EPL season. The season involved 20 teams playing 38 games, resulting in 380 games and 760 unique team datasets. Within each game, 96 relevant game-related variables were compared among teams, z-score transformed and allocated into 5 discrete 'moments of play'. Moments of play were categorised as set pieces (SP), established offence (EO), transition to offence (TO), transition to defence (TD), and established defence (ED). The game-specific mean z-score for the five moments of play were used as k-means cluster analysis inputs. The relationship between game style clusters and finishing position was investigated using chi square.
RESULTS: The most meaningful solution resulted in the generation of three clusters. Cluster 1 is characterised by games where teams recorded poor relative performances (negative z-scores) in four of the five moments, and a low positive z-score in the ED moment (mean = 0.11). Cluster 2 exhibited games with playing style dominance in both transition moments and high average z-scores (TO = 0.37 and TD = 0.45), and moderate positive performances in the other three moments. Cluster 3 was characterised by positive performances in EO and SP moments (0.24 and 0.18, respectively) with below average transition and defensive results. Cluster 1 game types predominate among bottom teams, whereby Cluster 2 is exclusively over-represented by the League champions. Games within Cluster 3 are typically more common among top teams.
CONCLUSION: Moments of play analysis showed success is associated with dominance in TO and TD periods. These moments are typically short in duration but involve critical phases to exploit player imbalances, positional asymmetries and space created by defensive reorganisation. If a transition style is less successful, control of EO and SP moments is demonstrated by higher ranked teams. Specifically, teams ranked second to fourth were clearly identified within this cluster. Teams on the bottom of the ladder were clustered for poor performance in all moments except a moderate strength in ED, illustrating the way better teams impose their game style. These results show that characteristic game styles are often traits of specific teams. Exploring other data sets for factors impacting game styles (for example, match context, playing personnel) will broaden our understanding of game style.

MODELING IN-GAME MOMENTUM IN RUGBY UNION

WATSON, N.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: In-game momentum in sports. Does it exist? Can it be modelled? Can it be related to successful performance? In most sports, the concept of the 'momentum' being with a player or team having the 'upper hand' at a particular point in the contest is oft referred to by commentators, pundits and fans. However, the proof of concept and quantification of momentum in this sense has proven to be a difficult research problem. The majority of the literature on momentum in sport has focused on defining it as a psychological construct or debating its existence by trying to establish whether certain sequences of favourable actions exhibit a pattern as opposed to being random. Very few studies have attempted to define momentum as a function of in-game actions in such a way that it can be modelled and related to a successful outcome of interest. No study with this aim could be found in the performance analysis corpus in rugby union. How do situational variables like field position, current score, and time remaining influence a teams in-game momentum, and can a team's momentum be related to a successful outcome of interest, for example, scoring a try? The purpose of this paper is to explore these questions in Rugby Union.
METHODS: We begin with a subjective definition of in-game momentum in Rugby union as a function of on-field variables, including field position, time in possession and current score. We then employ a variety of deep neural networks to learn the relationships in the definition from rich historical rugby union data. We use multi-layer perceptron, convolutional, recurrent, and combinations of these types of neural networks for this purpose. We utilise these deep learning and other machine learning techniques to investigate whether a team's momentum can be related to the probability of scoring a try within a specified timeframe. Finally, we develop a functional method of exploring in-game momentum via a combination of machine learning, data wrangling and data visualisation to produce in an interactive momentum heat 'map.
RESULTS: The momentum heat 'map' is an interactive web-based application that is capable of performing multivariate analyses of opposition teams' momentum. The map provides decision support to stakeholders in performance analysis in rugby union by enabling tactical and strategic analysis of opposition teams, and recommendations on tactics to employ to maximise the probability of scoring a try within a specified timeframe.
CONCLUSION: We make two important contributions to the performance analysis literature in rugby union in this paper. We develop a definition of in-game momentum in rugby union as a function of on-field variables and explore whether it can be related to scoring a try within a specific timeframe. We then model in-game momentum via an interactive heat 'map' that can provide decision support to stakeholders.

INTEGRATING COMMUNICATION AND PASSING NETWORKS IN FOOTBALL USING SOCIAL NETWORK ANALYSIS.

MCLEAN, S.

UNIVERSITY OF THE SUNSHINE COAST

INTRODUCTION: Effective intra-team communication is an important component for optimal team performance. However, minimal research exists on how ITC during actual competitive matches is related to performance. In this study, an intra-team communication tool

was developed and used for players to report the amount of communication received, and the amount of perceived benefit to performance of the received communication .
METHODS: Twenty-five professional football players, competing in the Australian A league were used in the current study. Social Network Analysis metrics of Network Edges, Density, Cohesion, and Sociometric Status were used to investigate ITC, and the relationship between ITC and passing during 22 competitive matches. Match passing data were provided by Optasports. One-way analysis of variance tests were conducted to determine differences between the match outcomes , and match location for ACOM, BCOM, passing, density, edges, cohesion, SMS, and percentage possession. Pearson's correlation coefficient was used to determine relationships between ACOM, BCOM, and passing, using the mean of the player's individual SMS values.
RESULTS: Results indicated that the team was highly connected and cohesive for ITC, but less so for passing. In matches won compared to lost, passing connections were lower and ITC connections were higher. There were negative correlations between ITC and passing for the mean sociometric status values. For the SNA metrics, network edges were higher in matches won compared to drawn for BCOM. Cohesion was lower in drawn compared to won matches for BCOM, and lower compared to matches won and lost for passing. SMS was higher in matches won compared to lost for ACOM and BCOM, but was higher in matches lost compared to won for passing.
CONCLUSION: The results could indicate that in matches when possession was increased and ITC decreased, the team may coordinate implicitly, by relying on pre-existing knowledge of practiced playing structures. Whereas, in matches with low possession, increased levels of ITC may be required, due to the uncertainty associated with defending. However, further research is needed to confirm the current explanations of the results. This study has implications for design of training practice.

PLAYING UNPREDICTABLY: MEASURING THE ENTROPY OF BALL TRAJECTORIES IN INTERNATIONAL WOMENS BASKETBALL

HOBBS, W., MORGAN, S., GORMAN, A., MOONEY, M., FREESTON, J.
UNIVERSITY OF SYDNEY

INTRODUCTION: It is widely accepted that playing unpredictable basketball is advantageous, however this strategic assumption has not been adequately tested. The aim of this study was to describe unpredictability in ball trajectories during a selection of womens international basketball games to determine the association, if any, between unpredictability and success in basketball.
METHODS: Ball trajectories from 60 international women's basketball games (6 teams and 10 games each) were extracted from video recordings using manual ball tracking software (Pattern Plotter). Due to the low number of international women's competitions, games were collected from a range of sources across three years of competition. Team selection was a strategic decision aligned with the interests of the Australian Women's Basketball team's coaching staff for the 2016 Olympic Games and included Australia, Belarus, France, Japan and Turkey from pool A and the USA from pool B. Ball locations were recorded as x- and y-coordinates with time. These were then converted into a single location value by taking the coordinates of the ball for each second of the trajectory and transforming them into a corresponding cell, producing a cell ID vector for each possession. To account for the varying length in time of possessions, a sliding window was applied over the cell ID vector, producing five second 'play segments', thus standardising possession length. The cell IDs logged from each possession were then used to fill frequency distributions (one distribution for each cell). Shannon's entropy was calculated from the frequency distributions.
RESULTS: This is the first study to describe entropy for ball movement during international basketball. While no differences in unpredictability were observed between teams, the overall analysis revealed that entropy during large-deficit wins (defined as games won by ten points or more) was greater than that for large-deficit losses (2.80 vs 2.76, $p = .004$, $d = 0.43$, CI = 0.014, 0.071). Furthermore, front-court entropy results demonstrated that entropy of teams that won was significantly higher than that of teams that lost (2.67 vs 2.62, $p = <.001$, d = , CI = -0.08, -0.02) (Fig. 2). This suggests that higher entropy is associated with success in basketball, but more specifically, that entropy in the front court is potentially where this matters most.
CONCLUSION: This study demonstrates the importance of unpredictability in international basketball and its association with success. Furthermore, it demonstrates that strategic outcomes can be achieved with a limited number of games and relatively simplistic data.

PREDICTING SELF-ORGANIZING STATES IN SOCCER

LÓPEZ-FELIP, M.A., HARRISON, H.S.
UNIVERSITY OF CONNECTICUT & CINCINNATI CHILDRENS HOSPITAL MEDICAL CENTER

INTRODUCTION: Recent approaches to understanding coordination dynamics in team sports (e.g., soccer) have investigated the degree to which players of a team coordinate with each other to achieve a common goal. Synchrony is one measure of coordination that is sensitive to contextual variables such as a teams role (possession or recovery of the ball) and the teams location on the field. Nevertheless, these measures are purely descriptive, and we know little about how informative they are for predicting the future course of the match. Hence, the aim of this study was to determine whether the current degree of synchrony can predict transitions between states.
METHODS: Players position data (x,y coordinates on the pitch) were collected via GPS (15 Hz) for the entire first half of a professional soccer match. We analyzed the degree of synchronization via Kuramoto order parameter (cluster amplitude) r, (high synchronization = 1) . Then, time series of synchrony were segmented according to whether the team was in possession (P) or recovery (R) of the ball and whether they were centered in the attacking or defending half of the field (i.e., 1 or 2 respectively), creating a total of four possible states. Every such segment was associated with the state that followed, in order to determine the relationship between current synchronization and future states.
RESULTS: Mean team synchronization across segments ranged from 0.724 to 0.998. Averaged by type of transition, the highest synchrony (0.985) was associated with the transition from state R2 to P1, and the lowest synchrony (0.925) was associated with the reverse transition (P1 to R2). Two GLMM models were constructed to predict the half and role of the next segment. Both models found a significant main effect of synchronization after taking into account the current state of the team. Specifically, lower synchrony was predictive of taking possession (beta = -12.8, SE = 5.3, $p < .05$) as well as approaching the goal (beta = -40.9, SE = 11.8, $p < .05$).
CONCLUSION: Previous analysis using the Kuramoto order parameter revealed that synchronization differed according to whether a team was in possession or recovery of the ball. Here, we show that as synchrony decreases, the probability of a team to take possession of the ball increases as well as to move closer to the attacking goal. Therefore, synchrony not only reflects the current state of gameplay, but it also is predictive of upcoming changes in possession and field position. Synchronization arises from self-organizing processes that underlie team behavior, and thus provides a window to understanding critical moments during gameplay.

THE SECRET OF SUCCESSFUL POSSESSIONS IN PROFESSIONAL SOCCER: EXPLOITING HOLES IN THE DEFENSE

GOES, F.R., BRINK, M.S., ELFERINK-GEMSER, M.T., LEMMINK, K.A.P.M.
UNIVERSITY OF GRONINGEN

INTRODUCTION: To score goals you first have to recover the ball from the opponent and move the ball into a zone from where you can become dangerous and create scoring opportunities. The attacking 3rd of the field can be regarded as such a zone (Link, Lang & Seidenschwarz, 2016). Since spatial organisation at the initiation of possessions seems to be a key aspect of success, it would be interesting to study the spatial organisation prior to possession. Thus, the aim of the current study is to analyse spatiotemporal characteristics in the 5 seconds prior to the initiation of successful and unsuccessful possessions.
METHODS: The analysis was based on position data of players and ball during 250 ball possessions (124 for team A and 126 for team B), extracted from the first half of a professional Dutch soccer match. A ball possession was initiated at the moment that the first player of a team has control over the ball and ends when a player of the other team controls the ball. Successful possessions were classified as those possessions that at some point during a possession resulted in ball control in the attacking 3rd of the field. Team centroids, interline coordination and stretch indices of both teams were computed, and used to compare spatiotemporal characteristics of successful (81) and unsuccessful (169) possessions at 5s, 3s and 1s prior to the initiation of possession.
RESULTS: The attacking team's centroid was positioned further forward at 5 seconds (+12.3±2.8m, $p < .01$), 3 seconds (+14.3±2.8m, $p < .01$), and 1 second (+16.5±2.8m, $p < .01$) before gaining successful possessions. Furthermore, the distance between the attacking team's offensive line and the opposing team's defensive line was smaller at all time points (-1.4±0.4m, $p < .01$). On the other hand, the opposing team's length (-10.1±1.6m, $p < .01$) and width (-3.14±1.2m, $p < .01$) were smaller at all time points, while the distance between their midfield and offensive line was increased, especially at 3 seconds (+2.4±0.7m, $p < .01$) and 1 second (+3.0±0.8m, $p < .01$) prior to successful possessions.
CONCLUSION: Results indicate that prior to gaining successful possessions teams tend to move forward, pressure the opposing team, and exploit holes within the lines of the defense and on the sides of the field. Furthermore, the opposing team is organized more compact while giving away space within their lines, and the attackers of the opposing team seem less involved in defense. On the other hand teams seemed to be pushed back under pressure of the opponent prior to unsuccessful possessions. These findings indicate that gaining territorial advantage before gaining ball possession, and pressuring the opponent are essential for successful possessions. In other words, the key to gaining successful possessions might be in the prevention of successful possessions of the opponent.

DOES VIDEO GAME-BASED TRAINING FACILITATE CENTRAL DRIVE TO ANKLE DORSIFLEXORS IN ELDERLY?

DE BRUIN, E.D., PATT, N., GENNARO, F.
INSTITUTE OF HUMAN MOVEMENT SCIENCES AND SPORT, ETH

INTRODUCTION: Previous studies highlighted that video games designed for training purposes improve walking [1,2] and effect on the brain [3,4]. Here we explore the hypothesis that video game-based training necessitating subject's ability to lift the toes and to place the feet on different target zones as a requirement to successfully play the game leads to changes in the central motor drive to tibialis anterior motor neurons.
METHODS: 20 older adult (78.9 ± 8.3 years) trainees were involved for 12 weeks. EMG from left and right Tibialis Anterior (TA) were evaluated at intervals of 6 weeks; first test 6 weeks before training, second test before training initiation, third test at training end; a design controlling for inter-subject variability. Intramuscular coherence was measured during self-paced over ground walking in both left and right leg under single- (ST) and dual-task (DT) conditions. EMG-EMG intramuscular coherence was calculated in the beta and gamma frequency bands.
RESULTS: Complete data sets were available for 19 individuals. No significant effect was observed for training in the coherence of the beta frequency band Right leg ST [$F(2,35)= 0.24$, $p=0.79$]; Right leg DT [$F(2,36)= 0.23$, $p=0.79$]; Left leg ST [$F(2,50)= 0.47$, $p=0.63$]; Left leg DT [$F(2,51)= 0.4$, $p=0.67$]. No significant effect was observed for training in the coherence of the gamma frequency band Right leg ST [$F(2,33)= 1.27$, $p=0.29$]; Right leg DT [$F(2,36)= 0.08$, $p=0.92$]; Left leg ST [$F(2,42)= 0.32$, $p=0.73$]; Left leg DT [$F(2,43)= 0.32$, $p=0.73$].
CONCLUSION: The video game-based training had no effect on the beta and gamma band frequencies and, therefore, on the neural drive to the TA muscle in self-paced over ground walking older adults. This result might be indicative for the assumption that ageing rather causes changes in the motor cortex and to a lesser extend in the spinal cord [5]. Further studies investigating the mechanisms influencing neural drive and coherence measures through training in various (neurological) populations and more impaired older adults are warranted. In these studies a focus on clinical relevance should be considered as well.

CENTRALLY CONTROLLED MOTOR STRATEGIES GOVERN BILATERAL DEFICIT

MILLER, S.C., KARAI, H., LETCH, P.
QUEEN MARY UNIVERSITY OF LONDON

INTRODUCTION: Bilateral deficit (BLD) is a phenomenon when a two-limb performance is lower than that of the combined individual limbs. It has been shown in various movement types, along with some reports of bilateral facilitation (BLF) occurring i.e. two-limb performance greater than that of the combined individual limbs. Many studies have investigated the differences occurring between the bilateral (BL) and unilateral (UL) movements, suggesting many factors i.e. psychological, task related, physiological and neurophysiological (1). However, focus has been on the differences between BL and UL movements. Here, we investigated similarities between BL and UL, with the premise that this may direct us to reasons why deficits occur.

METHODS: 13 university students performed UL and BL countermovement jumps (CMJ) with a self-selected depth. Kinetic (Kistler 9281 force plates under each foot) and 3D kinematic (Qualisys motion capture) data were collected (2000 and 500 Hz, respectively), and then analysed in MATLAB. A combination of intraclass and Pearson correlations, and paired t-tests were analysed collectively to assess similarities between UL and BL CMJ. This analysis was performed comparing individual legs across UL and BL, in addition to comparing individual legs from UL with combined left and right legs from BL.
RESULTS: Left and right UL CMJ heights were 49.4 and 47.8% of BL, respectively. This resulted in BL height being no different to the combined left and right UL CMJ height (p=0.47). However, BLD ranged from -23.8% (BLD) to 25.0% (BLF).
A key finding was that total eccentric leg stiffness was similar between BL CMJ (i.e. both legs combined) and the right UL (ICC=0.751, R2=0.586) and left UL (ICC=0.833, R2=0.752). Changes in leg length and force during the eccentric portion were not similar across the different jumps (p<0.001), however they were highly correlated (R2>0.55 for change in leg length and R2>0.73 for change in force).
CONCLUSION: Previous research has suggested multiple potential reasons as to why BLD or BLF occurs. These have been associated with both muscular force as well as neural explanations. We found a potential mechanism as to how the two components relate. We propose that motor control of the two movements (UL and BL) both utilised a pre-defined strategy associated with the start of the jump. With this strategy driving the stiffness of the system during the first portion of the movement, this resulted in differences in muscle-tendon kinetics, resulting in differing kinematic patterns produced in BL and UL CMJ, and also between the right and left UL movements (2).

ACUTE EFFECT OF NORADRENERGIC MODULATION ON MOTOR OUTPUT AND CORTICOSPINAL EXCITABILITY

KLASS, M.1, ROELANDS, B.2, MEEUSEN, R.2, DUCHATEAU, J.1
1UNIVERSITÉ LIBRE DE BRUXELLES AND 2VRIJE UNIVERSITEIT BRUSSEL , BELGIUM

INTRODUCTION: Despite an extensive literature in animals on the role of the noradrenergic system in the control of many higher functions (arousal, attention, sensory integration, etc. [1]) and in modulation of spinal excitability [2], very little is known on noradrenergic actions on the motor system and the functional consequences in human. Therefore, the aim of present study was to investigate the role of noradrenergic modulation in the control of motor output, by comparing the acute effect of Reboxetine (REB), a noradrenaline reuptake inhibitor, to a placebo (PLA) on knee extensors performance and corticospinal and spinal excitability.
METHODS: Eleven young males took part in two randomized experiments during which they received either 8 mg of REB or a PLA. The torque produced during a maximal voluntary contraction (MVC) and its variability, quantified as the coefficient of variation for torque, during submaximal contractions ranging from 5 to 50% MVC were measured. Paired electrical (PES) and transcranial magnetic stimulation (TMS) were used to assess changes in voluntary activation during MVC. Electrical stimulation and TMS were also used to assess spinal and corticospinal excitability by recording the Hoffman reflex (H reflex) and TMS-induced motor evoked potential (MEP) recruitment curves during muscle activation at 20% MVC.
RESULTS: MVC torque and torque steadiness increased (P<0.001) respectively by 9.5 and 24% (mean change for 5-50% MVC) in REB compared with PLA condition. Voluntary activation tested by TMS and PES was greater (~3%; P<0.05) in REB than PLA condition. The maximal amplitudes of H reflex and MEP and, the slope of their recruitment curves were significantly enhanced by REB (P<0.05). The ratio between TMS-induced EMG silent period and the corresponding MEP (SP/MEP) was reduced in REB condition (P<0.01).
CONCLUSION: The present findings indicate that intake of a noradrenaline reuptake inhibitor increases voluntary activation during MVC and improves the accuracy in force control. The motor performance improvements were accompanied by a greater corticospinal and spinal excitability. In conclusion, our results support a significant role for the noradrenergic system in adjusting the motor output during maximal and steady contractions.

ACETAMINOPHEN INGESTION SHORTENS THE CORTICOSPINAL SILENT PERIOD AND IMPROVES ENDURANCE PERFORMANCE OF THE KNEE EXTENSORS

PAGEAUX, B.1,3, MAUGER, A.R.2
1: UNIVERSITÉ BOURGOGNE FRANCHE-COMTÉ ; 2: UNIVERSITY OF KENT ; 3: UNIVERSITÉ DE MONTRÉAL

INTRODUCTION: Acetaminophen (ACT; paracetamol) is known to improve endurance performance, suggested to be achieved through a reduction in perceived muscle pain. However, to date, the underlying neurophysiological mechanisms responsible of the ergogenic effect of ACT on endurance performance remain unclear. The aim of this study was to test the hypothesis that the reduced muscle pain following ACT ingestion would be associated with changes in neuromuscular responses to the exercise performed.
METHODS: Nineteen subjects completed an isometric time to exhaustion test with the right knee extensors (20% maximal voluntary contraction; MVC) after ingestion of ACT or placebo (PLA). Knee extensors MVC was measured before, 45 min following ACT or PLA ingestion, and after the time to exhaustion test. In twelve subjects we measured maximal voluntary activation of the knee extensors during each MVC, as well as motor evoked potentials (MEP) during each time to exhaustion test. MEP were obtained at 53, 56 and 59 s of each minute during the time to exhaustion test. MEP area and amplitude was normalized by the amplitude and area of the muscular wave elicited at 50 s of each minute during the time to exhaustion test.
RESULTS: ACT and PLA ingestion did not induce any change in MVC and maximal muscle activation (all $P > 0.61$). Time to exhaustion was greater following ACT ingestion compared to PLA ingestion (298 ± 126 s vs 264 ± 106 s, $P = 0.02$). The improved performance in the ACT condition was associated with a lower (all $P < 0.03$) perceived effort and muscle pain at 100% of the individual isotime (i.e. relative to the shortest performance of each subject). At 50% individual isotime, ACT decreased only perceived effort ($P = 0.05$, $dz = 0.42$) and not muscle pain ($P = 0.24$, $dz = 0.28$). Following the time to exhaustion test, MVC and voluntary activation decreased to the same extent in both conditions. During the time to exhaustion test, normalised MEP area and amplitude did not change over time ($P > 0.308$) and did not differ between conditions ($P > 0.83$). A time × condition interaction ($P = 0.01$) revealed a slower increase in the MEP CSP in the ACT compared to the PLA condition. Following ACT ingestion, the MEP CSP was shorter at 50% ($P < 0.01$) and 100% ($P < 0.01$) of the individual isotime but did not differ between conditions at the onset of the exercise ($P = 0.63$).
CONCLUSION: In agreement with cycling time trials and repeated sprint cycling, ACT ingestion improves isometric endurance performance of the knee extensors. The observed decrease in perception of effort and muscle pain following ACT ingestion suggests that this is

linked with lower perceptual responses to the exercise. In addition, the lower perceptual responses were associated with a slower increase in MEP CSP duration, suggesting a slower increase in corticospinal inhibition. Future studies should investigate if the reduction in MEP CSP is due to changes in cortical and/or spinal inhibition and its relation with perceptual responses to the exercise.

TRANSCRANIAL DIRECT CURRENT STIMULATION OVER THE LEFT DORSOLATERAL PREFRONTAL CORTEX IMPROVES INHIBITORY CONTROL AND ENDURANCE PERFORMANCE

MARCORA, S.M., ANGIUS, L.

UNIVERSITY OF KENT

INTRODUCTION: The dorsolateral prefrontal cortex (DLPFC) is considered important for inhibitory control, a cognitive function essential for the self-regulation of behaviour (Diamond, 2013). Recent experiments suggested that the inhibitory control is also important for the regulation of endurance performance (Martin et al., 2016). Improvement in inhibitory control has been found when transcranial direct current stimulation (tDCS) was applied over the left DLPF (l-DLPFC) (Loftus et al., 2015). This study examined the effect tDCS over the l-DLPFC on a cognitive task involving inhibitory control and on endurance performance in healthy adults.
METHODS: In a double-blind, randomized crossover experimental study, 12 volunteers were recruited. First, volunteers practised all procedures and performed an incremental maximal cycling test to detect peak power output (PPO). In the following visits, volunteers received a placebo tDCS (SHAM) or real tDCS (EXP) over the l-DLPFC. Stimulation intensity was set at 2mA with 30 min duration on the EXP and 30 s duration in the SHAM. Volunteers performed a Stroop task before (pre-tDCS), after tDCS (post-tDCS) and after a cycling time to exhaustion (TTE, post-TTE) at 70% of PPO. Heart rate (HR), electromyographic activity in the right vastus lateralis (EMG-VL), ratings of perceived exertion (RPE), and leg muscle pain (PAIN) were monitored during the TTE while blood lactate (B[La-]) was measured at exhaustion.
RESULTS: No difference in Stroop test performance was found between conditions at pre-tDCS ($p=0.723$) while a significant improvement in Stroop performance was found in the EXP at post-tDCS ($p=0.012$). Stroop performance was impaired at post-TTE without any differences between conditions ($p=0.001$). TTE was significantly longer in the EXP compared to SHAM condition ($p=0.029$, 17±8 vs 15±8 min), with a significant lower HR ($p=0.002$) and RPE ($p=0.001$). No differences were found for PAIN ($p=0.224$) and for EMG-VL ($p=0.664$). B[La-] was significantly higher at exhaustion in the EXP condition ($P = 0.040$).
CONCLUSION: Our results provided preliminary evidences that tDCS over the l-DLPFC can improve endurance performance possibly by an improved inhibitory control.

INTRODUCTION: Previous studies showed that adding cognitive task to prolonged motor exercise impaired endurance performance (Yoon et al., 2009). Nevertheless, the underlying neurophysiological mechanisms remain to be elucidated. This study compared endurance performance during fatiguing quadriceps exercise in the absence or presence of concomitant memory challenges (i.e. auditory n-back tasks). We hypothesized that time to task failure would be shorter in the presence of the most demanding n-back task and associated with greater neurophysiological alterations.
METHODS: Eighteen healthy men performed intermittent isometric knee extensions at 15% of maximal voluntary contraction (block of 170 s interspaced by neuromuscular evaluations) until task failure. This motor task was performed in three different occasions in random order: i) alone (control condition); ii) with concomitant 1-back task and iii) with concomitant 2-back task. Autonomic nervous system activity, perceived effort and cognitive performance were continuously recorded. Peripheral and central mechanisms of fatigue were measured using electrical femoral nerve stimulation between each block and at task failure.
RESULTS: Time to task failure was shorter during 2-back (1273±723s ; $p<0.01$) and 1-back (1470±791s ; $p=0.04$) conditions compared to control (1704±1157s). Central voluntary activation decreased to a greater extent in 2-back (-8.7% ; $p<0.01$) and 1-back (-6.7% ; $p=0.04$) conditions compared to control (-3.7%). Pupil diameter increased to a greater extent in 2-back condition compared to control ($p=0.03$). Perceived muscle effort was higher during 2-back condition than during control ($p<0.01$). Cognitive performance decreased similarly with time during 2-back and 1-back conditions ($p<0.01$), but was systematically lower during 2-back condition.
CONCLUSION: Our results demonstrate that motor performance is reduced when adding a concomitant demanding memory task to a prolonged isometric exercise. This can be explained by the interaction of various neurophysiological mechanisms including i) higher levels of central fatigue; ii) greater perturbations of autonomic nervous system activity and iii) higher perceived muscle effort causing earlier disengagement from the task. The mechanisms underlying reduced dual cognitive-motor task performance are probably multifactorial and different from those usually reported when mental fatigue is elicited prior to the motor task (i.e. mediated mainly through higher perception of effort; Van Cutsem et al., 2017).

IS-SH01 Social inclusion through sport: analyzing effective interventions and policies to tackle social exclusion.

INCLUSION AND EXCLUSION THROUGH SPORT: TWO SIDES OF THE SAME COIN?

HAUDENHUYSE, R.

VRIJE UNIVERSITEIT BRUSSEL

Sport has been perceived as a potential rich context to include people at-risk of social exclusion. Despite its acclaimed inclusionary character, sport remains a site of multiple and diverse exclusionary processes (Spaaij et al., 2014). To better understand wider inclusionary outcomes through sport, Ekholm (2013) argued that we should problematize and critically expose the underlying assumptions, distinctions, ideologies and research positions that constitute the conceptions surrounding sport as a means for social inclusion. Furthermore, the question needs to be addressed if combatting social exclusion can effectively be tackled by promoting social inclusion? In other words: are promoting social inclusion and combatting social exclusion two sides of the same coin? Such questions are currently in the margins of sport research. As a result, it remains difficult to determine the effectiveness and impact of sport-based interventions on a broad array of societal issues (e.g. social cohesion, education, employment)

THE INCLUSION EXCLUSION CONUNDRUM: A CRITICAL ACCOUNT OF YOUTH AND GENDER ISSUES WITHIN AND BEYOND THE SPACES OF SPORT FOR DEVELOPMENT AND PEACE (SDP) PROGRAMMING

COLLISON, H., GIULIANOTTI, R., DARNELL, S., HOWE, P.D.

LOUGHBOROUGH UNIVERSITY

The Sport for Development and Peace (SDP) sector is made up of various development-focused policies and programs that seek to engage, stabilise, empower and create social and economic change on a global scale. SDP projects, most often run by Non-Governmental Organisations (NGOs), have been implemented in regions enduring physical conflicts, health pandemics, major gender divisions and other social crises that affect 'youth' in particular. In this context, sport has been accorded the difficult task of facilitating greater access for marginal, vulnerable or community groups whilst positively contributing to the attainment of diverse development objectives. While the 'where' and 'why' of SDP has been largely accounted for, the attention in this paper is on the 'who' of SDP in relation to the notion of inclusion. Drawing on extensive research conducted in Jamaica, Kosovo, Rwanda, Sri Lanka, Zambia, the idea of SDP as an inclusionary practice is critically investigated. While SDP may 'give voice' to participants, especially to individuals with athletic ability or sporting interests, the extent to which this creates social contexts that are fundamentally inclusive remains open to discussion. In this sense, while targeting populations, groups or individuals remains an attractive strategy to achieve specific goals, for example youth empowerment or gender equality, yet empirical assessments complicate the presumption that SDP programming leads to inclusion, particularly at a larger societal level. This presentation considers a matrix of inclusion criteria, potential outcomes, and the tensions arising between targeted SDP programming and the often-exclusionary dimensions of sport more broadly, with a specific focus on youth and gender issues.

PUBLIC HEALTH THROUGH COLLABORATIVE INNOVATION – SOCIAL INCLUSION IN SPORT AND PHYSICAL ACTIVITY

TJØNNDAL, A.

NORD UNIVERSITY

Introduction: Social inequality in health encompasses wicked problems that has proven challenging for public sector to effectively solve on its own (Enjolras & Wollebæk 2010; Donnelly & Coakley 2002). Hence, in order to combat social inequality and exclusion in health, collaboration across public, private and volunteer sectors is needed (Milbourne et. al. 2003). In particular, combating social exclusion in participation in sport and physical activity is a central part of the Norwegian government's public health work. This is also a main political aim of the Norwegian Olympic and Paralympic Committee and Confederation of Sports, the largest volunteer organization in Norway. On this background, the aim of this study was to investigate collaborative efforts between public sector and volunteer sport organizations aimed at increased social inclusion in participation in sport and physical activity.
Methods: 32 public sector employees were interviewed. The sample consisted of employees in the public health sector both at a county level and at municipality level. Twenty-six public health coordinators from different Norwegian municipalities were included in the sample. Additionally, eight political and administrative leaders in public health at a county level were interviewed. Central topics in the interviews included: (1) issues of social exclusion in public health locally and regionally, (2) collaborative efforts with volunteer sport organizations, (3) effects of such collaborations, and (4) challenges and advantages with such collaborative efforts.
Results: The main findings in this article indicate that public sector actors view collaboration with volunteer sport organizations as a valuable resource for public health work aimed at reducing social exclusion in physical activity. While public sector does initiate a number of collaborations with volunteer sport organizations, these collaborations mainly entail public sector agencies providing funding for local sport clubs. However, the development, implementation and sustainment of activity measures are left to the volunteers in the sport clubs.
Discussion: The results indicate that while public sector does value collaboration with volunteer sport organizations, few of these collaborative efforts can be characterised as collaborative innovation. Furthermore, there is a substantial lack of resources to evaluate the effects of such collaborations. Therefore, it stands to reason that a majority of Norwegian municipalities lack insight into the effects of their collaborative efforts with volunteer sport organizations. Changing conditions for volunteer sport organizations, such as increased commercialization and professionalization, along with a changing political climate, suggests that sport organizations and public sector agents may need to develop new ways of collaborating if the aim is to combat social exclusion in physical activity and sport participation effectively.

OP-PM72 Physical activity interventions

DYADIC INTERVENTIONS TO PROMOTE PHYSICAL ACTIVITY: SYSTEMATIC REVIEW AND META-ANALYSIS

CARR, R.M., PRESTWICH, A., KWASNICKA, D., THØGERSEN-NTOUMANI, C., GUCCIARDI, D.F., QUESTED, E., HALL, L.H., NTOUMANIS, N.

CURTIN UNIVERSITY

DYADIC INTERVENTIONS TO PROMOTE PHYSICAL ACTIVITY: SYSTEMATIC REVIEW AND META-ANALYSIS
Carr, R.M.1, Prestwich, A.2, Kwasnicka, D.1, Thøgersen-Ntoumani, C.1, Gucciardi, D.F.1, Quested, E.1, Hall, L.H.2, Ntoumanis, N.1. 1: Curtin University (Perth, Australia). 2: The University of Leeds (Leeds, England)
Introduction: There are several interventions targeting the promotion of physical activity via dyads, but the available evidence has not been synthesized or meta-analysed.
Methods: Sixty-two studies were identified from MEDLINE, PsycINFO and Web of Science of which 53 were included in the main meta-analyses. Effect sizes were calculated based on random-effects models. Intervention details, type of dyadic goal, participant characteristics, and methodological quality were extracted and their impact on the overall effect size was examined through meta-regressions. Sensitivity analyses tested whether key findings were robust when (a) the effects of other statistically significant moderators were controlled; (b) outliers were removed; (c) data were included for participants who were not the main target of the intervention.
Results: Dyadic interventions had a small positive effect on physical activity g= .217, 95% CI [0.127–0.306], compared to comparison conditions. Shared target goals (which involve both dyad members holding the same goal for the main target of the intervention to increase their physical activity) and peer/friend dyads were associated with the larger effect sizes in at least some of the analyses.
Discussion: Dyadic interventions can promote physical activity and appear beneficial when dyad members share the same physical activity goal for the person who is the main target for the intervention.

EFFECTS OF YOGA TRAINING ON CARDIOVASCULAR REACTIVITY TO PSYCHOLOGICAL STRESS IN OFFSPRING OF HYPERTENSIVES

CHU, I.H., LAI, M.C., YU, T.C.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Offspring of hypertensives are shown to display exaggerated cardiovascular reactivity to mental challenge, which may lead to higher risk of developing hypertension and heart disease . While studies have reported significant reductions in cardiovascular reactivity after aerobic exercise training, the effects of yoga are undetermined . Yoga was found to reduce stress and have benefits for stress-related disorders . Yet, the effect of yoga on cardiovascular reactivity to psychological stress in offspring of hypertensives remains unknown. Thus, the purpose of this study was to examine the effects of 12-week yoga training on heart rate, blood pressure, arterial stiffness, and total peripheral resistance during rest and psychological stress in offspring of hypertensives.
METHODS: A total of 30 participants with a family history of hypertension were recruited and randomly assigned to either yoga or control group. The yoga training program was 60 minutes per session, 2 times per week for 12 weeks. The control group was instructed not to participate in any yoga program and maintain their usual lifestyle. All participants performed a Stroop task and mental arithmetic task at baseline and after the intervention. Heart rate, blood pressure, pulse wave velocity , and total peripheral resistance were assessed during rest and psychological stress at baseline and post intervention.
RESULTS: Resting heart rate reduced significantly in both groups after 12 weeks, but these changes did not differ between groups. No significant changes were found for heart rate during psychological stress in both groups. Mean arterial pressure did not change during rest in both groups, but decreased significantly during psychological stress in both groups after the intervention with no significant group differences. In terms of pulse wave velocity and total peripheral resistance, both parameters showed no significant changes during rest and psychological stress in both yoga and control groups post intervention.
CONCLUSION: The results of this preliminary study suggest that a 12-week yoga program prescribed twice per week for 60 minutes per session did not appear to affect cardiovascular reactivity to psychological stress in offspring of hypertensives.

LIFESTYLE-INTEGRATED FUNCTIONAL EXERCISE (LIFE) FOR PREVENTING FUNCTIONAL DECLINE IN YOUNG OLDER ADULTS: CONCEPTUALISATION, DEVELOPMENT, AND INITIAL TESTING OF AN INTERVENTION PROGRAMME

WEBER, M., BERGQUIST, R., BOULTON, E., VAN ANCUM, J., NERZ, C., JONKMAN, N.H., TARALDSEN, K., HELBOSTAD, J.L., VEREIJKEN, B., HAWLEY-HAGUE, H., PIJNAPPELS, M., MAIER, A.B., MIKOLAIZAK, A.S.

HEIDELBERG UNIVERSITY

INTRODUCTION: With a growing population approaching retirement age (baby boomers), there is an increasing focus on how functional decline can be prevented to maintain functional capacity and independence. New avenues for increasing physical activity (PA) and achieving long-term behaviour change are emerging such as the Lifestyle-integrated Exercise (LiFE) programme, embedding balance and strength training into daily life. However, they are focused on the reduction of falls in older adults. This study aimed to 1) develop an adapted LiFE (aLiFE) programme to prevent func-tional decline in a younger age group, and 2) test the feasibility of programme deliv-ery and integration of exercises into daily life.
METHODS: Within the EU Horizon2020 project PreventIT (www.preventit.eu) and in line with the UK Medical Research Council guidance on development of complex interventions, we adapted the existing LiFE programme, originally developed for older adults aged 70+, to customize it to the needs of a younger age group (e.g. more challenging ex-ercises, different behavioural change techniques). Iterative stages of development, feasibility, and evaluation were applied and the proof of concept of the intervention was evaluated through a 4-weeks pre-post-pilot study in community-dwelling adults aged 60-70 (n=31) in Germany, the Netherlands, and Norway. Measurements in-cluded performance-based (i.e. balance and strength) and psychological self-report measures (e.g. questionnaires, documents for action planning and self-monitoring). Semi-structured interviews were applied to evaluate programme content and delivery to further improve the programme.

RESULTS: Thirty people completed the pilot study (66.6±2.4 years, 60% women). Overall ac-ceptability of the programme was high based on quantitative and qualitative measures. The majority found the intervention safe (n=29), appropriately difficult (n=23), adaptable to individual lifestyle (n=18), and helpful to improve balance (n=24), strength (n=27), and PA (n=26). They significantly improved in balance and mobility as measured by the Community Balance and Mobility Scale from pre- (66.0±12.7) to post-test assessment (70.4±13.1; p=0.001). Participants particularly choose static balance activities (e.g. tandem stance), or strength activities (e.g. stair climbing or sit to stand), that could be easily remembered and integrated. At the same time, they suggested to also include upper body exercises and limit the amount of paperwork for action-planning and self-monitoring.
CONCLUSION: The pilot study provides evidence that the original LiFE programme was successfully adapted to young-older adults. The aLiFE programme is feasible for this specific population, meeting their individual needs and preferences. Based on these results, the programme is currently being tested in a larger randomized controlled feasibility trial within the PreventIT project comparing aLiFE with and electronic version of the same programme.

RISK FACTORS FOR ATTRITION IN EXERCISE – THE GENERATION 100 STUDY

VIKEN, H., REITLO, L.S., ZISKO, N., NAUMAN, J., ASPVIK, N.P., INGEBRIGTSEN, J.E., WISLØFF, U., STENSVOLD, D.

NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY

INTRODUCTION: Attrition from exercise programs both in the real world and in research is a challenge. However, data on attrition in exercise programs with older adults is scarce, and commonly from small samples and programs with short durations. More information on predictors of attrition is needed for establishing strategies on how to make older adults sustain within exercise programs. The aim of the present study was to examine total attrition rates and predictors of attrition during 3-years of exercise in older adults.
METHODS: In total 1514 men and women (age 72.4±1.9 years) were included in the present study. Participants were randomized to either a supervised exercise intervention or recommended to follow national guidelines for physical activity (PA). Self-reported demographics (e.g. education), general health, morbidity (e.g. heart disease, memory loss and psychological distress), smoking and PA were examined at baseline. Cardiorespiratory fitness (CRF) and grip strength were directly measured at baseline. Attrition was examined 1-year and 3-years into the intervention. All significant predictors from initial bivariate analyses were included in the final multivariate logistic regression analyses to identify predictors of attrition.
RESULTS: The total attrition rate was 11.0% (n=166) after 1-year and 14.9% (n=225) after 3-years. Significant predictors of attrition after 1-year were low education, low grip strength, lower CRF, low PA level and being randomized to supervised exercise. The same predictors of attrition were significant after 3-years, with reduced memory status being an additional predictor. We also analyzed predictors of attrition after 3-years in the unsupervised- and supervised exercise groups separately. In both groups, low level of education, lower CRF and reduced memory status were significant predictors of attrition. In the supervised exercise group, performing less than 30-min of PA per day at baseline was an additional predictor.
CONCLUSION: This is the largest study of predictors of attrition in a long-term exercise program with older adults. Our findings provide vital information for clinicians, healthcare professionals, researchers and politicians, for planning long-term initiatives to increase physical activity or exercise among older adults.

EFFECTS OF MODERATE AND LOW FREQUENCY RECREATIONAL FOOTBALL ON CARDIOVASCULAR RISK FACTORS: A DOSE-RESPONSE STUDY

MODENA, R.1, IMPELLIZZERI FRANCO, M.2, FORNASIERO, A.1, SCHENA, F.1

CERISM, UNIVERSITY OF VERONA <1>, UNIVERSITY OF TECHNOLOGY OF SYDNEY <2>

INTRODUCTION: Physical inactivity causes more than 5 million deaths every year,[1,2] while improvements in fitness are associated with reduced mortality riskv [3]. Among the barriers in participation to physical activity, lack of free time and low motivation are the most common. In this context an enjoyable, social and relative short duration activity such as recreational soccer (RS) might be effective to improve physical activity enrolment in sedentary people. Some studies have shown that performing RS 2 or 3 times per week has improved various parameters related with CHD, such as maximal oxygen consumption, body composition, blood pressure and blood lipid profilev[4,5]. However, RS is often performed only once a week and for a duration of one hour. The aim of the study is verified the benefit of a low and medium frequency on cardiovascular health.
METHODS: 40 sedentary and healthy men (44.62 ±1.75 years) were randomly assigned to three groups: Control (C), Low frequency (LF) and Moderate frequency (MF). Body composition, maximal oxygen consumption, blood pressure, blood lipid profile, have been evaluated before and after a 12-weeks period. Throughout this period LF and MF groups have performed, respectively, 12 and 24 sessions of RS (once and twice per week). Each participant was monitored for heart rate and time motion characteristics, and RPE was also collected. The dose effect of treatment was evaluated by one-way analysis of variance for post-test values, using pre-test values as covariate (ANCOVA); confidence intervals and magnitude based inference were used to assess the likelihood and the magnitude of effect [6].
RESULTS: Our results showed there were improvements in maximal oxygen consumption, BMI, percentage of fat mass, and waist to hip ratio between C group and the other groups: VO2max was increased of 14.4% (large likely beneficial; LF vs C) and 18.9% (large most likely beneficial; MF vs C), BMI and %FM were lowered respectively of 1.8% (moderate likely beneficial) and 7.7% (moderate most likely beneficial) (LF vs C), and 2.4% (large most likely beneficial) and 11.1% (large most likely beneficial) (MF vs C). Also, waist to hip ratio was decreased, of 1% (moderate likely beneficial; LF vs C) and 1.2% (moderate likely beneficial; MF vs C). Comparing the changes between low and moderate frequency groups, the statistical analysis has shown no differences in maximal oxygen consumption and unclear results for the other parameters.
CONCLUSION: The results of the study confirmed that a moderate volume of RS can be effective to improve some cardiovascular risk factors, as demonstrated in other studies. However, a novel finding is that a low dose of RS could improve cardiovascular health as well. Performing one hour of RS once a week can be sufficient to increase aerobic fitness and improve anthropometric parameters related to the risk of CHD.

OP-PM54 Muscle damage

EFFECTS OF SEXUAL HORMONES AND ORAL CONTRACEPTIVE ON EXERCISE INDUCED-MUSCLE DAMAGE

MACKAY, K., GONZÁLEZ, C., PEÑAILILLO, L.

UNIVERSIDAD FINIS TERRAE

INTRODUCTION: It has been shown that sexual hormones have effects over exercise performance and recovery in women. When compared to men, women have shown less levels of muscle damage after eccentric exercise, being estrogen levels held responsible for these differences (Stupka et al., 2000). Results are still controversial, possibly due to differences in study design, menstrual phase and exercise protocols. The aim of this study was to determine the effects of estrogen, progesterone and testosterone concentrations over muscle damage induced by eccentric cycling in women.
METHODS: 30 sedentary healthy women participated in the study. Ten oral contraceptive users (OC), ten non-oral contraceptives users (Non-OC) were measured during their menstrual phase (days 1-3); and ten non-oral contraceptives users were measured during their ovulation phase (OV). Participants performed 30 min of eccentric cycling at 90% of their maximal concentric power output (PO). Maximal voluntary contraction (MVC), capillary creatine kinase activity (CK), muscle soreness (visual analogue scale, VAS), and pain pressure threshold (PPT) of the vastus lateralis (VL) muscle was assessed before, immediately after, 24, 48, 72, and 96 hours after cycling. Salivary estrogen (E2), progesterone (P4) and testosterone (T) concentrations were measured at same time points.
RESULTS: PO performed during eccentric cycling was similar between three groups (OC, 131.3 ± 17.7 W; Non OC 143.2 ± 35.1W; and OV, 141.6 ± 26.6 W; P=0.58). No statistical differences were found between groups for pre-exercise hormonal concentrations. OC showed 48% lower T concentration than non-OC at 96 h post-exercise (P= 0.01). P4 in OV was 35.5 times higher than OC and 11.2 times in Non OC, increasing 335% (P=0.001) at 96 hours post-exercise compared to pre. The non-OC group was the only group that showed complete recovery of MVC and VAS by 96 h post-exercise (P>0.05), with no changes in CK and PPT-VL (P>0.05). OV showed an incomplete recovery of MVC by 96 h (P=0.02), but with minimal muscle soreness (VAS and PPT-VL). OC did not recover pre-exercise values of MVC, VAS, CK, and PPT-VL.
CONCLUSION: Our results suggest that OC users take longer time to recover after eccentric cycling exercise than non-OC users. Additionally, menstrual cycle phase may affect the response to muscle recovery. However, this different response may not be related to estradiol, testosterone or progesterone levels. We suggest that female athletes should avoid OC consumption in order to maximize muscle damage recovery.

RHABDOMYOLYSIS AND MILITARY PHYSICAL EXERTION

GOMES ROLIM FILHO, N., AMARAL DOMINGUES, C., ANNUNZIATO, J., BOVOLINI, J.A., DUARTE, J.

FACULTY OF SPORTS OF UNIVERSITY OF PORTO-FADEUP

INTRODUCTION: Rhabdomyolysis is a severe injury of skeletal muscle system with abundant release of intracellular contents into the circulation and is generally defined by serum CK levels>5,000 U/L, elevations of LDH at least two times the upper limit of normal and when BUN:Creatinine ratio exceeds 20. The objective of this study was to determine the percentage of cases of Rhabdomyolysis at different times course.
METHODS: Biomarkers from 105 subjects Brazilian Commandos Course (2012) were collected at the baseline and on the remaining Commandos students during 15 moments. The Commandos course consists of 14 weeks organized in different military activities under a rigorous selection process (Preparation, Selection, Leader Test, Counter-terror, Mountain, Fights, Jungle and Caatinga phases). The Commandos students have a high dropout rate during the course and in this way, the percentages will be presented according to the number of remaining students in each phase. Serum CK, LDH, Calcium and BUN-creatinine levels were analyzed by Vitros250 and kits of dry-chemistry method. Data analyses in SPSS version 25, relation of measurements to other baseline characteristics was using Nonparametric tests(Friedman).
RESULTS: CK, LDH, Calcium and BUN:Creatinine ratio values from baseline were 177.65±146.81 U/L, 438.96±54.47 U/L, 9.78±0.28 mg.dL-1 and 36.20±6.25 respectively. The highest mean ranks were demonstrated after the fight test (CK=5.77; LDH=5.08) and at Leader Test Preparation by BUN:Creatinine ratio (5.54) and Calcium (5.88) at baseline. The presence of Rhabdomyloysis were diagnostic in 10.5% of all 105 Commandos Course volunteers. During the selection phase the incidence of Rhabdomyolysis was 11.5 % from 52 remaining students. Under the preparation of the Leader Test and Mountain activities were only 2.9% and 10% that presented Rhabdomyolysis, from 34 and 20 Commandos students respectively. Some cases of Rhabdomyolysis were found before the Fights test and caused an incidence of 10.5% at the lasting 19 students. The highest value of the 37.5% of cases of Rhabdomyolysis was found at the end of the Fight test in the last 16 Commandos survivor's students. All of those students who develops Rhabdomyolysis are classified as "low responders" (CK< 500 U/L) at the baseline. The more severe cases appear in cases with hypocalcemia (CK=10762 U/L; LDH=1274 U/L; BUN:creatinine=35.33; hypocalcemia and CK=9127 U/L; LDH=1909 U/L; BUN-creatinine=38.40; hypocalcemia).
CONCLUSION: Rhabdomyolysis at Mountain exercises probably due to vasoconstriction by climbing equipment and downhill eccentric effort. There are indications that the possible cause of Rhabdomyolysis was the preliminary physical exhaustion before the fights test and due to the large number of attack and defense impacts (crush injury) after the fight test. The increased incidence of Rhabdomyolysis is due to the cumulative effect of physiological stress and increased demand of the Commandos Course phase.

DOES WEARING COMPRESSION GARMENTS WITH HIGH-INTENSITY PRESSURE DURING DOWNHILL RUNNING REDUCE SOFT-TISSUE VIBRATIONS AND EXERCISE-INDUCED MUSCLE DAMAGE ?

VERCRUYSSEN, F.1, EHRSTROM, S.2, GRUET, M.1, GIANDOLINI, M.3, MORIN, J.B.2

1, UNIVERSITÉ DE TOULON, LAMHESS, TOULON, FRANCE; 2, UNIVERSITÉ CÔTE DAZUR, LAMHESS, NICE, FRANCE; 3, AMER SPORTS FOOTWEAR INNOVATION AND SPORT SCIENCES LAB, SALOMON SAS, ANNECY, FRANCE

INTRODUCTION: Many off-road runners are used to wearing lower-body compression garments (CGs) over different race profiles. The use of CGs is considered as a potential strategy which may reduce muscle damage from repeated eccentric muscle actions (Hill et al., 2014). The objective of this study was to investigate whether wearing CGs compared to control garments (CON) during downhill treadmill running (DHR) reduces exercise-induced muscle damage by minimizing soft-tissue vibrations and improves running economy (RE).

METHODS: Thirteen well-trained male trail runners with a mean VO2max of 64.6 ± 5.0 mL.kg−1.min−1 performed two 40-min DHR sessions (separated by one week), wearing either CGs (15-20 mmHg for quadriceps and calves) or CON (<5mmHg) at a velocity associated with ~55% of VO2max. Before and after each DHR, indirect markers of exercise-induced muscle damage were assessed from perceived muscle soreness, countermovement jumps and isometric maximal voluntary contraction (MVC) torques of knee extensors and plantar flexors. During each DHR session, RE (in J.kg-1.m-1) and soft-tissue vibrations were evaluated at both the beginning (5-10 min) and the end (35-40 min) of exercise. Soft-tissue vibrations were assessed using two tri-axial accelerometers overlying the muscle belly of the vastus lateralis and gastrocnemius (right leg). The root mean square of the resultant acceleration (i.e. RMS) was calculated for both muscles and time periods. Data were analysed for practical significance using magnitude-based inferences and the calculation of effect sizes (ES) ± 90% confidence limits.
RESULTS: Although substantial alterations in MVC were observed after CGs and CON exercises for both knee extensors and plantar flexors, meaningful differences were identified between exercises only for knee extensors, indicating a possible lower MVC decrement in favor of CGs (-4.3%; ES = 0.21 ± 0.25). DHR-induced changes in countermovement jumps and perceived muscle soreness were not influenced by the type of garment. Moreover, a lower increase in RMS over time was observed for the vastus lateralis (-5%; ES = -0.86 ± 0.71) while no clear difference in RMS was found for the gastrocnemius within- and between-exercises. Finally, RE likely increased over time either in CON (+4.7%; ES = 0.43 ± 0.31) or CGs conditions (+4.5%; ES = 0.41 ± 0.33).
CONCLUSION: These findings suggest that wearing CGs with high-pressure (>15 mmHg) may help runners to reduce quadriceps soft-tissue vibrations (i.e. lower increase in RMS for the vastus lateralis) and, in turn, minimize the effects of DHR on global muscle fatigue (i.e. lower MVC decline). However, wearing CGs during DHR had no beneficial effects on RE responses. The effectiveness of wearing CGs seems to be muscle-dependent and the decrease in muscle fatigue possibly induced by mechanically dampening soft-tissue vibrations requires further investigation.

RELATIONSHIPS BETWEEN DECREASING RATE OF RUNNING PACE AT THE END OF A MARATHON AND SERUM MUSCLE DAMAGE MARKERS

ISHIKURA, K.

SOJO UNIVERSITY

INTRODUCTION: The phenomenon of hitting the wall (HTW) is well-known among recreational marathon runners. HTW is characterized by generalized fatigue and an unintentional slowing of running pace in addition to other indicators. . Runners who reduced speed during a marathon exhibited higher values for blood muscle damage markers than runners that maintained their pace (del Coso, 2013). In generally, a muscle damage cause decline of muscle strength and muscle soreness. However, the relationship between the rate of decrease in speed at the end of a marathon and the rate of marathon-induced decline in muscle strength, muscle soreness, and muscle damage is unknown. The purpose of this study was to investigate relationships between the rate of decrease in speed at the end of a marathon and the rate of marathon-induced decline in muscle strength, muscle soreness, and muscle damage.
METHODS: Twenty seven healthy non-professional runners (16 males and 11 females) who participated in the 36th Tsukuba Full-Marathon race (Tsukuba-city Japan) were recruited as volunteers. The height of counter movement jumps, local muscle soreness, blood leukocyte profiles, and the serum activities of creatine kinase (CK), lactate dehydrogenase (LDH), aspartate aminotransferase (AST), and alanine aminotransferase (ALT) were measured before exercise, immediately after exercise and at one to four days, after exercise. The relationship between decreases in rates of running pace from an early segment of the race (from 5 km to 10 km) to the final segment (from 35 km to 40 km) and these markers were assessed.
RESULTS: The running speed of participants peaked in the third segment (10-15km) and gradually decreased thereafter. The decreasing rate of pace from the 5 km to 10 km segment to the 35 km to 40 km segment of the race and the finish time were significantly negatively correlated. The height of counter movement jumps was significantly decreased. Local muscle soreness, blood leukocyte profiles, and the serum activities of muscle damage markers were elevated immediately after the marathon. The decreasing rate of pace during the marathon was significantly correlated with the marathon time, the serum CK, and AST activity immediately after the marathon. but not correlated with the height of counter movement jumps and muscle soreness.
CONCLUSION: These results suggest that the decreasing rate of running speed at the end of the marathon is related to muscle damage rather than muscle soreness and muscle strength. It is proposed that reducing muscle damage can be maintain the speed at the end of a marathon race. It may useful to decrease muscle damage such as an experience of long distance running before the marathon or muscle strength training.

ELECTRICALLY INDUCED CRAMPING THRESHOLD RESPONSES WITH ELECTROLYTE BEVERAGE CONSUMPTION

EARP, J.E., STRANIERI, A., ZERAMBY, J.S., MATSON, T., STEARNS, R.L., WARD-RITACCO, C.L.

UNIVERSITY OF RHODE ISLAND

INTRODUCTION: Commercial electrolyte rich beverages are commonly used to prevent exercise-associated muscle cramp (EAMC) due to the belief that EAMC is related to a person's hydration and blood sodium levels. However, this theory has been challenged by a differing belief that EAMC results from an altered neurological function unrelated to hydration or electrolytes. As previous works have shown the minimal electrical stimulation frequency (MESF) at which cramp occurs is a reliable measure that relates to the frequency a person experiences EAMC, the purpose of the present study was to determine if consumption of a commercial electrolyte beverage (EB) alters MESF in euhydrated individuals compared to a placebo beverage (PB).
METHODS: This study utilized a single blinded, repeated measures crossover design. Seven subjects (5 males & 2 females, age: 23.0 ± 4.6 years, height: 1.69 ± 0.6 m, mass: 70.4 ± 10.0 kg, body fat: 16.3 ± 9.4%) took part in a familiarization session, and two experimental sessions in which MESF of the great toe was measured 15 min after consumption of 0.5 L a lemonade flavored EB (kCal: 120, Na: 840 mg, K: 320 mg, Mg: 5 mg) or PB (kCal: 5, Na: 35 mg). Prior to each session subjects refrained from exercise for 24 hr and each testing session was separated by 1-week. Additionally, and all participants were euhydrated (urine specific gravity ≤ 1.020) and performed 15, 2 s isometric contractions of the great toe immediately prior to beverage consumption. To determine MESF, a low frequency (8 hz) electrical stimulation (2 s train 80 V) of the tibial nerve was performed at increasing (+2 hz) frequencies every minute until a cramp occurred. Subject reported cramps were confirmed by 1) sustained force against a load cell, 2) sustained muscle activity measured using EMG. Additionally, cramp intensity was assessed via a validated 6 point verbal pain scale and post-stimulation EMG of the flexor hallicus brevis.

RESULTS: Urine specific gravity was similar between EB (1.014 ± 0.005) and PB (1.012 ± 0.006, p = 0.418). MESF was significantly higher after consumption of EB (14.86 ± 7.47 hz) than PB (14.00 ± 5.03 hz, p = 0.038). Additionally, cramp pain was significantly lower in PB (2.0 ± 0.6) than EB (2.7 ± 0.8, p = 0.025), but cramp intensity, as measured by post-stim EMG, was similar (p = 0.646).
CONCLUSION: n cramp prone, euhydrated subjects, EB was successful at increasing the neurological stimuli required to elicit a cramp (MESF), as well as decreasing the pain experienced during cramp, when compared to PB. As hydration and fluid consumption were similar between conditions these results suggest that electrolyte concentration rather than fluid consumption affects cramp susceptibility in euhydrated subjects. While EB did not prevent cramps from occurring in any subjects, these results support the use of EB for delaying or decreasing the intensity of EAMC.

COLD-WATER OR PARTIAL-BODY CRYOTHERAPY? COMPARISON OF PHYSIOLOGICAL RESPONSES AND RECOVERY FOLLOWING MUSCLE DAMAGE

HOHENAUER, E.1,2,3, COSTELLO, T.J.4, STOOP, R.1, KÜNG, M.U.2, CLARYS, P.3, DELIENS, T.3, CLIJSEN, R.1,2,3

1: SUPSI , 2: THIM , 3: VUB , 4: UOP

INTRODUCTION: Currently, cold-water immersion (CWI> is a widely accepted recovery modality and is believed to improve recovery. Partial-body cryotherapy (PBC> has become commercially available and is considered as an effective recovery method with similar effects as CWI. Therefore, the aim of this study was to compare i> the physiological responses following CWI and PBC and ii> the effects on recovery following a muscle-damaging protocol (5 x 20 drop jumps>.
METHODS: Nineteen healthy males were randomly allocated into either a CWI (10°C for 10 min; n = 9> or a PBC (-60°C for 30 sec, -135°C for 2 min; n = 10> group. The physiological variables (thigh muscle oxygen saturation [SmO2], cutaneous vascular conductance [CVC], mean-arterial pressure [MAP] and local skin temperature> were assessed immediately prior and up to 60 min post-treatment (10 min intervals>. The recovery variables (thigh muscle swelling, maximum voluntary contraction [MVC] of the right knee extensors, vertical-jump performance [VJP] and delayed-onset of muscle soreness [DOMS]> were measured immediately prior and up to 72 h post-treatment (24 h intervals>.
RESULTS: Compared to PBC values, CVC (at 30 min>, SmO2 (at 40 min> and lower extremity-skin temperature (thigh/shin at 60 min> were significantly reduced in the CWI group after the treatment (all $p < 0.05$). Only lower extremity skin temperature was significantly reduced in the PBC group directly post-treatment ($p < 0.05$). MAP significantly increased in both groups after the treatments (both $p < 0.05$). Thigh muscle swelling and DOMS did not differ between groups. MVC and VJP returned to baseline in both groups after 24 h ($p > 0.05$).
CONCLUSION: The primary findings in this study are that i) the physiological impact of CWI was significantly greater than PBC and ii) no differences in objective and subjective recovery variables were observed between CWI and PBC up to 72 h post-exercise. Although CWI decreased muscle oxygen saturation, CVC, mean- and local skin temperature after a muscle-damaging exercise, no differences in objective and subjective markers of recovery were observed between CWI and PBC.

THE INFLUENCE OF APPROACH SPEED ON MUSCLE ACTIVITY DURING 90° SIDE-STEP CUTTING TASK

WANG, D.1, YUAN, P.2, XU, Y.L.2

1. NJUCM , 2. JSRISS

INTRODUCTION: Side-step cutting at 90° was considered as dangerous and frequently used in athletic events (Xie et al., 2013), which induced many anterior cruciate ligament (ACL) injuries (Vanrenterghem et al., 2012). During the deceleration phase, higher approach speeds were expected to increase the loads (Vanrenterghem et al., 2012). Sagittal-plane mechanics, such as quadriceps (Q) and hamstrings (H) contraction, have been suggested as the dominant contributors to ACL load (Hanson et al., 2008). The aim of this study was therefore to investigate the characteristics of Q and H muscle activity in 90° side-step cutting task under different approach speeds.
METHODS: Twelve female (20.6±3.1 yr, 1.83±0.07 m, 71.7±6.8 kg) and 13 male (18.4±2.7 yr, 1.96±0.06 m, 84.9±12.9 kg) athletes volunteered to participant the study. They were required to complete 3 successful 90° side-step cutting task at 3 m/s (slow), 4 m/s (medium), and 5 m/s (fast) respectively. Electromyograph (EMG) was collected from Q and H of the dominant leg by Delsys Trigno Lab EMG system (Delsys, USA). The approach speed was monitored by Smartspeed (Fusion Sport, Australia), whilst the ground reaction force measured from force plate (Kistler Instruments, Switzerland) was utilized for the decision of pre-activation phase (50 ms before touchdown) and post-activation phase (50 ms after touchdown).
RESULTS: Significant differences were noted in phase ($F=109.01$, $p<0.001$), speed ($F=4.68$, $p<0.001$), and phase*speed ($F=2.21$, $p=0.045$). Regardless of sex and speed, there were significant increases in Q activation ($F=205.15$, $p<0.001$) and H activation ($F=8.49$, $p=0.005$), and a decrease in H:Q ratio ($F=81.00$, $p<0.001$) between pre-activation and post-activation phases. Regardless of sex and phase, LSD post hoc test discovered significant differences between fast and medium speed ($p=0.001$), and fast and slow speed ($p<0.001$) in Q activation; significant differences between fast and medium speed ($p=0.009$), and fast and slow speed ($p<0.001$) in H activation; and significant difference between fast and slow speed ($p=0.044$) in H:Q ratio. There was also significant interaction between phase and speed in Q activation ($F=5.62$, $p=0.005$).
CONCLUSION: The increased muscle activation and thus the load post activation might explain the occurrence time-point of ACL injuries; the increased speed increased the muscle activation and thus knee mechanical loads; with incremental speeds, the increase in Q activation was more preferential and may increase the loads to ACL directly.

THE IMPACT OF LOWER EXTREMITY INJURIES ON HEALTH-RELATED QUALITY OF LIFE IN ADOLESCENT ATHLETES: A REPORT FROM THE ATHLETIC TRAINING PRACTICE-BASED RESEARCH NETWORK.

LAM, K., MARSHALL, A., VALOVICH MCLEOD, T.
A.T. STILL UNIVERSITY

INTRODUCTION: Injuries are common during adolescent sport participation, with most occurring at the ankle and knee. Current evidence suggests that sport-related injuries impact patients beyond their physical functioning. However, few studies have investigated changes in health-related quality of life (HRQOL) shortly following a sport-related injury. The purpose of this study was to describe changes in HRQOL, as measured by the Pediatric Quality of Life Inventory (PedsQL), in adolescent athletes during the first two weeks following a sport-related knee or ankle injury.
METHODS: One hundred and six patients (male=65, female=41, age=15.6±1.1 years, height=174.2±10.7 cm, mass=72.1±19.7 kg) representing fourteen sports were diagnosed with a knee or ankle injury by an athletic trainer within the Athletic Training Practice-Based Research Network. Patients received usual care from an athletic trainer and completed the PedsQL during treatment sessions at post-injury Week 1 [(W1); range=0-7 days post-intake] and Week 2 [(W2); range=10-19 days post-intake]. The PedsQL is a valid, reliable, and responsive patient-reported outcome instrument that assesses HRQOL. The PedsQL generates a total (TOT) and four subscale scores [physical functioning (PF), emotional functioning (EF), social functioning (SOF), school functioning (SCF)]. All scores range 0-100, with higher scores indicating better HRQOL. The minimal clinically important difference (MCID) for the TOT is 4.4 points. Descriptive statistics (mean±SD) were reported for each score, and Wilcoxson Signed Ranks Tests were used to identify differences between time points ($p<.05$, two-tailed).
RESULTS: Significant improvements were reported between time points for TOT ($p<0.001$; W1=77.4±16.2 [range=36-100], W2=83.8±14.1 [range=47-100]), PF ($p<0.001$; W1=61.9±28.6 [range=3-100], W2=74.4±21.5 [range=19-100]), and EF ($p<0.001$; W1=82.9±19.3 [range=15-100], W2=89.4±15.7 [range=25-100]). No significant changes were noted for SOF ($p=0.20$; W1=90.8±12.8 [40-100], W2=91.9±14.0 [range=20-100]) or SCF ($p=.11$; W1=83.1±18.1 [range=30-100], W2=85.1±17.3 [range=40-100]). When examining scores on an individual level, 50.9% (n=54) of patients reported TOT changes that exceeded the MCID value between time points. Interestingly, 28.3% (n=30) of patients reported a decrease in TOT between time points, and only 11.3% (n=12) reported a complete recovery of HRQOL (score=100) at W2.
CONCLUSION: Adolescent patients who suffer a knee or ankle injury generally report statistically significant improvements in HRQOL during the first two weeks post-injury. However, half do not experience a meaningful change in HRQOL, and a substantial majority of patients continue to experience deficits in HRQOL two weeks post-injury. Sport medicine practitioners should consider assessing HRQOL to better guide patient care decisions, particularly since current literature suggests that many patients will return to full participation within two weeks of injury.

THE EFFECT OF RUNNING SPEED ON THE INTACT LIMB LOADING EXPERIENCED BY PEOPLE WITH A TRANSTIBIAL AMPUTATION

STRIKE, S., ARCONE, D., ORENDURFF, M.
UNIVERSITY OF ROEHAMPTON

INTRODUCTION: Increasingly unilateral trans-tibial amputees are able to participate in running as a result of the advances in dynamic prosthetic limbs. However, running may result in high loads on the intact/biological limb and particularly at the knee where there is greater risk of developing osteoarthritis. Although there is some evidence that the ground reaction forces experienced during submaximal running by the intact limb are greater than those of controls (Baum et al 2016), there is no research assessing the effect at the knee. Therefore the purpose of this research was to assess the effect of speed on the load experienced at the intact knee of unilateral transtibial amputees compared to matched controls who had no disability.
METHODS: Overground running data were collected in 16 recreational runners (8 transtibial amputee using their own BladeXT prosthesis and 8 controls) using Vicon Nexus V.2.5 with Kistler force plates. Participants ran at self-selected running pace, 70% and 130% of that pace. Peak vertical ground reaction force (vGRF), and the sagittal and frontal plane peak knee forces, moments and their loading rates were analysed between limbs and speeds (ES>0.8) .
RESULTS: There was no between limb effect at any speed for the vGRF, the peak sagittal and frontal plane knee moments and the sagittal peak knee force. For the frontal knee peak force, there was a between limb difference at the self-selected and fast speeds, with the intact limb evidencing a medial force and the control limb a lateral force. For the frontal knee moment loading rate, the intact limb was greater than the control limb at all speeds. For both limbs, all variables had a lower magnitude at the slow speed than the fast speed while for the control limb, the slow speed was also lower than the self-selected speed for most variables. Large variability on the intact side may have masked some results.
CONCLUSION: The only variables that indicated an effect of limb, of those that have been previously associated with the development of osteoarthritis, were the more medial force at the knee and the increased knee abductor moment loading rate. There is limited evidence that there is an overload on the intact limb at relatively low running speeds. On the control limb, there was an effect of speed across all speeds for most variables while for the intact limb differences were evident only between slow and fast speeds, indicating that adjusting to speed was limb specific.

EFFECTS OF A ONABOTULINUMTOXIN A INJECTION FOR NEUROGENIC DETRUSOR OVERACTIVITY ON UPPER BODY EXERCISE PERFORMANCE IN WHEELCHAIR ATHLETES: A CASE STUDY

PERRET, C., PANNEK, J.
SWISS PARAPLEGIC CENTRE

INTRODUCTION: Most patients with a suprasacral spinal cord injury (SCI) suffer from neurogenic detrusor overactivity (NDO), which can lead to renal damage or even death. Anticholinergic medication is the standard treatment of NDO. However, in a significant number of patients, this medication is not sufficient or leads to intolerable side effects. A therapeutic alternative is the injection of onabotulinumtoxin

A into the detrusor. Although this injection seems to be effective and safe for the treatment of NDO, it is still unclear, if there exist some systemic side effects, which might influence exercise performance. The aim of this study was to investigate, whether an onabotulinumtoxin A injection reduces exercise performance in a wheelchair basketball player.
METHODS: A wheelchair basketball player with NDO performed a Wingate test before as well as 10 days after the onabotulinumtoxin A injection. Additionally, a female handcyclist served as control and performed the same exercise testing without intervention two weeks apart.
RESULTS: The injection showed no negative effects in the wheelchair basketball player. Peak power was 4.6 W/kg (pre) vs. 4.7W/kg (post), average power 2.6 W/kg vs. 2.9 W/kg and time to peak 4.0s vs. 4.0s, whereas in the handcyclist who served as control a slight performance impairment was found. Peak power were 5.3W/kg (pre) vs. post 4.7W/kg (post), average power 3.9W/kg vs. 3.8 W/kg and time to peak 3.8s vs. 4.6s.
CONCLUSION: An onabotulinumtoxin A injection to treat NDO in a wheelchair basketball player did not lead to performance decreasing effects. However, further data to prove this single case finding are needed. Before a prove of concept can be made and to be on the safe side, we recommend to schedule onabotulinumtoxin A injections at least six weeks before important competitions.

AEROBIC FITNESS AND ATHEROSCLEROTIC CARDIOVASCULAR RISK IN PARALYMPIC ATHLETES WITH A LOCOMOTOR IMPAIRMENT

BERNARDI, M.1,2, PARISI, F.1, LANZANO, R.1, DANTE, D.1, CURATULO, P.1, SQUEO, M.R.3, ADAMI, P.E.3, SPATARO, A.3, PELLICCIA, A.3

1 SAPIENZA, UNIVERSITY OF ROME. 2 ITALIAN PARALYMPIC COMMITTEE. 3 ITALIAN OLYMPIC COMMITTEE

INTRODUCTION: Atherosclerotic cardiovascular disease (ACVD) is a leading cause of morbidity and mortality in individuals with a locomotor impairment (I-LI). ACVD occurs at earlier ages in I-LI than in ambulatory individuals because the former, in particular those with a spinal cord injury (SCI), have a higher prevalence of risk factors (RF) mainly due to their increased sedentary habit. While reduced daily energy expenditure and low aerobic fitness have been established as RF in the general population, at our knowledge, in I-LI, in spite of the fact that physical activity is encouraged, the possible role of high aerobic fitness as ACVD protective factor has not been fully evaluated. To accomplish this purpose Paralympic athletes (PA) with a locomotor impairment (LI), competing in sports with a wide range of energy expenditure and therefore having a wide range of aerobic fitness were evaluated to test the hypotheses that 1. the prevalence of atherosclerotic cardiovascular disease (ACVD) risk factors (RF) was higher in PA with SCI (PA-SCI) than in PA with other (different from SCI) LI (PA-OLI); 2. aerobic fitness (oxygen uptake peak - VO2peak) was inversely related to ACVD RF.
METHODS: Data from a total of 135 summer and winter male PA (72 PA-SCI, 28 PA with lower limb amputation, 12 PA with a cerebral palsy/brain injury, 7 PA with poliomyelitis, 9 PA with other neurological disorders and 7 PA with other orthopedic disorders), who had competed in 6 Paralympic Games (from 2004 to 2014), were retrospectively evaluated and divided in two groups (PA-SCI vs PA-OLI). They had been screened through anthropometric and blood pressure (BP) measurements, laboratory blood tests and graded cardiopulmonary maximal exercise test, to estimate both an ACVD-RF score and VO2peak. The ACVD-RF score was assessed summing 1 point for each of the following RF: obesity –OB- (BMI≥30 or waist circumference ≥102 cm), hypertension –HT- (rest systolic BP ≥ 140 mm Hg and/or diastolic BP ≥ 90 mm Hg), dyslipidemia -DL- (total Cholesterol -C- ≥200 mg/dl or LDL-C ≥130 mg/dl or HDL-C <40mg/dl), impaired fasting glucose -IG- (fasting plasma glucose ≥100 mg/dl) and subtracting 1 point when serum HDL-C was higher than 60 mg/dl.
RESULTS: Prevalence of OB, HT, DL, IG and high HDL-C were equal to 5.9% and 3.2%, 13.9% and 14.3%, 58.3% and 49%, 29.2% and 34.9%, 27.8% and 17.4%, in PA-SCI and PA-OLI, respectively. Based on the ACVD-RF score, 3 ACVD-RF groups were formed: group 1 (RF≤0, N=54), group 2 (RF=1, N=41), group 3 (RF≥2, N=40). VO2peak was statistically different in the 3 ACVD-RF groups and equal to 37.9±14.71 ml/kg/min, 30.9±9.13 ml/kg/min and 24.1±5.50 ml/kg/min in the PA of ACVD-RF group 1, 2 and 3, respectively.
CONCLUSION: Prevalence of all RF was similar in the two groups of LI. DL has a relevant and dangerous prevalence in PA regardless their LI. Being VO2peak inversely related to the 3 groups of ACDR-RF, high aerobic fitness seems to provide a protective effect on ACVD morbidity in PA with a LI.

QUANTIFYING THE CARDIORESPIRATORY RESPONSES DURING ELITE INTERNATIONAL WHEELCHAIR BASKETBALL MATCHES

FERNANDES, E.M.1,2, FROGLEY, M.3, PINOS, A.1, RUPF, R.1,3, THOMAS, S.G.1

1: UNIVERSITY OF TORONTO , 2: CANADIAN SPORT INSTITUTE ONTARIO , 3: WHEELCHAIR BASKETBALL CANADA

INTRODUCTION: Quantification of the physiological demands of competitive matches provides critical information that can impact decisions based around training design and prescription. The physiological demands during a wheelchair basketball (WCBB) match have yet to be reported. Therefore, as part of a larger project, we quantified the cardiorespiratory responses of elite athletes during WCBB matches.
METHODS: Data was collected during 5 matches between the Canadian and Japanese men's national WCBB teams. Six male WCBB athletes (Classification range 1.5 to 4.5) each wore a K4B2 Cosmed analyzer and a T31 Polar heart rate monitor during matches, where real time match data was collected. In addition to match data, each player completed a maximal treadmill (Woodway Blade) test where VO2 and heart rate (HR) data was measured. We quantified the average data for VO2, HR, %VO2peak and %HRmax over 7 minutes in the first half and 7 minutes in the second half each athlete completed.
RESULTS: For the maximal capacity tests, the average VO2peak was 34.5 ml.kg-1.min-1 and average HRmax was 184 bpm. Through 7 minutes of the first half of the match, players averaged 27.9 ml.kg-1.min-1 (73% of VO2peak) and 162 bpm (86% of HRmax). Through 7 minutes of the second half players averaged 29.7 ml.kg-1.min-1 (81% of VO2peak) and 152 bpm (80% of HRmax). The 6 athlete participants averaged 29.1 minutes play in the match with 13.8 minutes in the first half and 16.2 minutes in the second half.
CONCLUSION: We describe for the first time, the cardiorespiratory responses of athletes during a series of elite international WCBB matches. These responses indicate players work primarily in the heavy intensity domain during competition. This information could have implications for both coaches and trainers. However, given that WCBB employs a classification system and has several defined "basketball" activities, next steps will include describing the cardiorespiratory responses by classification and in response to different WCBB activities.

Oral presentations

OP-SH18 Decision making and development of exercise in team sport

ANALYSIS OF EXPERT DECISION MAKING IN ELITE COMPETITIVE SOCCER FROM AN EXPERT PLAYERS PERSPECTIVE

GLEESON, E., KELLY, S.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: This research analyses the decision making moment in the situated activity of elite competitive soccer from an expert player's perspective. Considering that soccer is a dynamical system of interacting performance involving multiple actors such as coaches, team mates, opposition and accepting that human activity is autonomous, experienced and situated requires research that acknowledges the summative processes affecting the decision making moment in live situated action. In this regard, this research reconstructs the expert players' autonomous course of experience during competitive international soccer games.
METHODS: The sample included 10 senior international female soccer players with experience ranging from 20 to 125 senior international appearances. A total of 20 interviews were conducted, 2 per player. Utilising video footage, stage one involved a self –confrontational interview that explored players' subjective experience of in-game decisions in competitive international games. Stage two involved a semi -structured interview with each player following her subsequent immediate competitive action post the self-confrontational process. Interviews were conducted within 24-48hours of performance. Data analysis was preformed using the methodological & theoretical 'Course of action framework' (Thereau & Jeffroy, 1994).
RESULTS: Results highlight the interlinking dependency of two symbiotic processes: (1) individual –social and (2) social –individual. Individual –Social factors relate to automated internal processes such as perception, cognition, knowledge, psychological, confidence, feelings and relational interactions i.e. dyadic relationships with teammates and opposition. Social –Individual factors relate to the coach -player relationship.
CONCLUSION: The findings have important pedagogical implications for training practice design for elite players, coach –athlete relationship, coach leadership styles, communication and the development of creative decision makers. Reconstructing the players' course of experience provides a greater insight for coaches and provides a methodology for enhancing feedback and performance analysis by facilitating the gap between first person (player) analysis and third person analysis (video).

THE ROLE OF SELF-CONFRONTATIONAL INTERVIEWS IN EXPLORING FEMALE PLAYERS IN-GAME DECISION MAKING IN ELITE COMPETITIVE SOCCER.

KELLY, S., GLEESON, E.

UNIVERSITY COLLEGE DUBLIN

Introduction: Advanced decision making capabilities in elite soccer are associated with game intelligence and are considered hall marks of expert performance. Arguably, to understand the autonomous, experienced view of the decision-making moment in competitive situated activity requires a methodology that incorporates an emic, internal perspective. Consequently, this research utilised self-confrontational interviews to explore female soccer players in-game decisions during European championship qualifiers.
Methods: The sample included senior international female soccer players (n=10) with playing experience ranging from 20 to 125 senior international appearances. First, digital technology recorded player performances during a competitive international game. Second, post-performance self-confrontational tape-recorded interviews (n=10) were conducted separately with each participant to explore players subjective experience of key in-game decisions. The inclusion of video action minimized hindsight bias and enhanced recall effect through episodic memory. Third, semi-structured interviews (n=10) were conducted post subsequent-performance and post initial self-confrontation interviews. All interviews were transcribed and subjected to a process of inductive content analysis.
Results: First, the results identify that self-confrontational interviews are an efficacious method to enhance self-awareness concerning in-game decision making processes. Second, in discussing their in-game decisions players engaged in episodic future thinking (Atance & ONeill, 2001) adopting reflecting in-action and for-action (Schon, 1987). Finally, by engaging the players at a pre-reflexive level of consciousness (Thereau et al, 2003) self-confrontational interviews facilitated organic identification and subsequent exploration of the affective dimensions (Hermans & Hermans-Jansen, 1995) of athletes decision making process during competitive international games.
Conclusion
Grounded in the enactive approach this research adopts the methodological & theoretical course of action and course of interaction framework (Thereau, 2003). Within this framework, the self-confrontation method is viewed a means of self-investigation involving a narrative psychological process that requires interviewees to order and reorder events and experiences that they consider to be meaningful (Hermans & Hermans-Jansen, 1995). Despite limitations, capturing the internal expert perspective can provide a detailed insight into the complexity of decision making processes and can serve as a useful starting point in assisting practitioners develop players enhanced decision making capabilities.

BEHIND CLOSED DOORS: THE ROLE OF DEBRIEFING AND FEEDBACK IN A PROFESSIONAL NEW ZEALAND RUGBY CLUB.

MIDDLEMAS, S.G., CROFT, H.
OTAGO POLYTECHNIC

INTRODUCTION: Debriefing is a process which has been applied successfully in military, psychological and educational settings to enhance performance . In debriefing the multiple aims of performance improvement, learning and psychological recovery are achieved through a complex process . However, despite the extensive use of feedback and statistics within high performance sport environments, limited attention has been paid to the way coaches and athletes use this information to achieve these outcomes . The aim of this case study, therefore, was to gain an in-depth understanding of how a professional rugby team – playing in New Zealand's premier rugby cup competition - used the post-match and pre-match team meetings to debrief after performance and prepare for future performance.
METHODS: Multiple ethnographic techniques were employed to generate a comprehensive picture of practice, including participant observation, video recordings, formal and informal interviews, field notes, descriptive statistics and document analysis. Each meeting was transcribed separately and analysed using an inductive content analysis process and themes were identified.
RESULTS: The case study focuses on how four key factors - coach-facilitation, player engagement, leadership and the balance between reflection and preparation – impact on the debrief process. Throughout the study, the coaches were very conscious of the difficulty of measuring the success of this area of their practice. While debriefing was highly valued, the coaches struggled to find the right balance between evaluation and preparation. As the head coach states: "Sometimes I think we should have just got them on the training pitch and run more drills" After a positive start, the team's performance slumped in mid-season. In the post-study interviews, psychological recovery – a key aspect of debriefing – was identified by the coaches and players as a key reason for this. One player concluded that: "A big focus for us [as a team] was around preparation for games and I think that not talking about them meant we just ignored our problems … it had a negative effect on our performance. Like we were carrying around with us as baggage".
CONCLUSION: The findings reveal that while considerable emphasis was placed on the importance of player learning and engagement in team meetings, delivery was often ad hoc, coach-driven and results-focused. From a practical viewpoint, coaches are encouraged to place importance on effective psychological recovery from performance within the debrief process.

FACTORS INFLUENCING SUPPLEMENT USE IN ATHLETES COMPETING AT THE 2017 AUSTRALIAN MASTERS GAMES

GIFFORD, J.1, WU, X.2, CLIMSTEIN, M.2,3, O'CONNOR, H.1, PRVAN, T.4, STUART-SMITH, W.2
1: SYDNEY , 2: SYDNEY , 3: BOND , 4: MACQUARIE

INTRODUCTION: Supplement use among athletes is common, however, less is known about their use in masters (MA) compared to younger athletes. Knowledge on factors influencing MA supplement use would assist nutrition advice and education. We aimed to investigate the influence of demographic, health conditions, and sport type on supplement use in MA competing at the 2017 Australian Masters Games (AMG). Sources of nutrition information were also investigated.
METHODS: A total of 128 AMG participants (56.3±11.2 years, 62.5% female) completed an online survey on nutrition and health. Sports that MA entered at the AMG were categorised as aerobic, anaerobic/power or mixed sports based upon likely energy systems used, or skill sports. MA reported use of any supplements from a list of 31, which were grouped into sports food and beverages (FS, n=7), medical supplements (MS, n=13), and performance supplements (PS, n=11). Influence of demographic factors, health conditions, and sport type on type and number of supplements used was determined by fitting logistic regressions. MA also ranked sources of nutrition information 1-5 (1=most important).
RESULTS: Forty-eight (37.5%) participants reported use of supplement 1-16 supplements each. Of these 25% used SF only, 27% used MS only, 0% used PS only, and 48% used combinations; the most common were SF+MS (23%) and SF+MS+PS (15%). The most commonly reported supplements in each group were SF: sports drinks (n=16), MS: various vitamins and minerals (n=49; 6 types), and PS: caffeine (n=13; 2 types). Demographic factors (age, gender, education, nationality, body mass index, previous elite sport participation, income) and health conditions did not influence supplement use. Participation in aerobic ($p<0.0005$), anaerobic ($p=0.009$), and mixed sports ($p=0.020$) influenced SF usage. Type of sport and combinations of supplement usage ($p=0.009$) were associated. Sports dietitian/nutritionist or general dietitian/nutritionist (n=18, n=16), general practitioner (n=19), and the internet (n=17) were most often ranked number 1 as a source of nutrition information for MA.
CONCLUSION: MA that used supplements were likely to use them in combinations. Demographic factors and health conditions did not influence supplement usage in this sample of MA, however, they were most likely to use sports foods and beverages across a variety of sports. Dietitians/nutritionists and general practitioners should be prepared to provide nutrition education and advice on the effects of combinations of supplements, and potential interactions with the prescribed medications and health conditions of MA.

NUTRITION KNOWLEDGE OF PROFESSIONAL AND SEMI-PROFESSIONAL FEMALE SOCCER PLAYERS: IMPLICATIONS FOR SPORTS NUTRITION PRACTITIONERS

HARPER, L.D.1, DATSON, N.2, EMMONDS, S.3, HICKS, S.4, HULTON, A.5, JULIAN, R.6, NAUGHTON, R.1
1: UNIVERSITY OF HUDDERSFIELD ; 2: UNIVERSITY OF CHICHESTER ; 3: LEEDS BECKETT UNIVERSITY ; 4: NORTHUMBRIA UNIVERSITY ; 5: UNIVERSITY OF SURREY ; 6: UNIVERSITÄT MÜNSTER

INTRODUCTION: Nutrition is a small but important component that contributes to successful athletic performance, recovery and health. However, due to financial and time constraints, the majority of Womens soccer teams do not employ qualified nutrition professionals. As such, female soccer players may not be receiving optimal nutritional support and advice. The purpose of this present investigation was to assess the current sport nutrition knowledge of professional and semi-professional female soccer players.
METHODS: Seventy two female soccer players completed an adapted sport nutrition knowledge questionnaire (Devlin & Belski, 2015). Players predominantly played in the United Kingdom (70/72), with one player competing in Iceland and one in the USA. Forty one players

(57%) identified international-level soccer as their highest level of competition attained in their career to date. The questionnaire contained 38 questions related to carbohydrate, protein and fat intake, hydration, vitamins, minerals and fibre, nutrient timing, training and competition-specific nutrition, and anti-doping. The questions were multiple-choice (four choices) with only one correct answer (worth one point).
RESULTS: Mean nutrition knowledge score was 57%. For questions related to protein intake and timing, only 38% of players knew how much protein should be consumed per day relative to body mass, and only 40% knew how often they should consume protein across a day. Seventy seven percent of players were aware of the negative impacts of dehydration, however; only 46% knew the correct fluid intake during exercise. Only 44% knew the importance of dietary fibre. Players were generally good at identifying the importance of carbohydrate for training and matches (75%). Players were aware of optimal timing of carbohydrate intake following exercise (75%), however; only 56% identified a mixed meal of carbohydrate and protein as superior to a carbohydrate-only meal. Only 29% of players knew the role of dietary fat, with 60% identifying which types of fat should predominate in their diet. However, 35% were aware of the optimal daily intake of Omega-3. Only 39% of players thought that vitamin and mineral supplements should only be consumed if they have been diagnosed with a clinical deficiency. Only 38% of players were aware that the World Anti-Doping Agency was responsible for the compilation of a prohibited substance list and 65% were able to identify the logo printed on products that have been tested for banned substances (Informed-Sport logo).
CONCLUSION: The data suggests that female soccer players nutrition knowledge can be improved, with a low overall knowledge score and more specifically, poor knowledge related to nutrient timing, hydration, protein intake, dietary fibre, doping and the role of fats. This data is of relevance to players, coaches and sports nutrition professionals, as well as those responsible for recruiting staff.

NUTRITIONAL STRATEGY IN SOLO SAILING, NOT ONLY CALORIES AND NUTRIENTS

GHIANI, G., MAGNANI, S., DONEDDU, A., SAINAS, G., FOIS, A., CABOI, M., CRISAFULLI, A.

UNIVERSITY OF CAGLIARI

INTRODUCTION: What would you like to eat if you were a skipper leaving for a single handed yacht race supposed to last about 130 days? In solo sailing a single man must carry out the same range of tasks in a yacht similar in design, length and rigging to that which would normally be managed by a crew of up to 12 sailors. An appropriate nutrition will be crucial to maintain energy balance and to guarantee an optimum level of performance. In this kind of challenge food feeds the body and gives comfort. Moreover there is to deal with taste, variety and hygiene. There is no fridge aboard, gas stores are limited and there are problems of weight. Most of racers eat industrial freeze-dried food but we wanted to try something different, a simple and easy to cook food. With these recommendations our group made a customized galley for the Italian sailor GM who tried to beat the worlds circumnavigation record in CLASS 40 in 2016. His race only lasted 65 days, from Gibraltar to Freemantle, because of technical problems.
METHODS: We speculated the racers needs during the race and we tried to match them with his tastes and eating habits. His daily recommended nutritional intake during the voyage, detected with a sensewear armband during preparation, was 3100 Kcal/day with carbohydrate and protein intake goals of 335 g/day and 100g/day, respectively. We planned a 10 different days menu, to avoid menu fatigue, including five meals a day, and divided it into 120 vacuum packed bags, each bag containing instruction and recipes. We trained the sailor to cook each recipe.
RESULTS: Bioelectrical impedance analysis (BIA) was used to assess body composition before and after the race, and body mass was also measured. Measurements enlightened that during the voyage the racer did not lost body mass and his body composition changes were due to changes in Fat Mass (FM pre-race 6 kg, FM post race 4,5 Kg) and Free Fat Mass (FFM pre- race 55,9 kg, FFM post-race 57,5 Kg).
CONCLUSION: The racer reported good sensations about his nutrition and the results we found in his body composition enlightened that he did not lost FFM that is very important to have a good performance.

EXAMINATION OF THE TIMING OF CARBOHYDRATE AND PROTEIN INTAKE AMONG YOUNG ELITE FEMALE FOOTBALL PLAYERS

BAUHAUS, H.1,2, VON ANDRIAN, J.1,2, BRAUN, H.1,2, THEVIS, M.1,2,3

GERMAN SPORT UNIVERSITY COLOGNE, COLOGNE, GERMANY

INTRODUCTION: General recommendations for the daily intake of macronutrients in elite sports exist and vary depending on training intensity and training volume. Recently we have shown that carbohydrate (CHO) intake in young female football players is at the lower range of the recommendations (Braun et al., 2018). However, not just absolute and relative intakes should be considered, but also the timing of carbohydrate and protein intake before, during and after training. Therefore, the purpose of this evaluation is the examination of CHO and protein intake around training sessions among young female football players playing in the highest age-related division.
METHODS: Dietary data of 22 training sessions undertaken by 10 young elite female football players (15.6 ± 0.5 yrs, 105.9 ± 22.1 min daily training volume) were evaluated, using a 3-day weighed record, complemented by a diet history interview. Based on the German food database (BLS 3.01) using OptiDiet Basic Software, the intake of CHO within 4 hours prior to exercise and during exercise as well as CHO and protein intake within 1 hour after exercise was analyzed and compared to current recommendations for pre- and post-exercise nutrient recommendations for optimal sports performance (Thomas et al., 2016).
RESULTS: CHO intake was on average 0.84±0.54 g/kg bodyweight (BW) in the 4 h prior to exercise. Within the first hour after exercise CHO intake was 0.29±0.48 g/kg BW and absolute protein intake 6.57±8.03 g or 0.11±0.13 g/kg BW, respectively. There was no CHO intake during exercise.
CONCLUSION: Based on well accepted recommendations (Thomas et al., 2018) a sufficient CHO intake was not met prior, during and after exercise. Only one player had a sufficient CHO intake prior to a single training session. After exercise, the recommendation of combined absolute protein intake of 15-25 g or relative protein intake of 0.25-0.3 g/kg BW and CHO intake of 1-1.5 g/kg BW (Thomas et al., 2016) was only met once. These data show that there is a high potential to enhance timing of CHO and protein intake around training sessions and underline the importance of nutritional education in young athletes, maybe especially in team sports.

CORRELATION BETWEEN DIETARY INTAKE AND ENDOCRINE MODULATION IN ADOLESCENT ATHLETES

OLIVEIRA, T., DIAS-SILVA, C.H., FRANCA, P.A.P., MAYOR, V.C., FONTES, L.L., SANTOS, J.C., ZAGO, C.K.A., PORTO, C.P.M., VALESTE-SANTOS, L.A., FONSECA-JUNIOR, S.J., PIERUCCI, A.P.T.R.

UNIVERSIDADE FEDERAL DO RIO DE JANEIRO

INTRODUCTION: Besides the demands for training and performance adolescent athletes need adequate energy intake to maintain proper growth and maturation. Food intake is the exogenous source of energy supply, used to build endogenous macronutrient stores. Leptin and Insulin are anabolic and catabolic hormones, which have a major role in the metabolism of the subjects (ADA, 2016).
METHODS: We evaluated 46 young soccer players. Body composition was assessed through anthropometric measures (weight and height) and bioimpedance analysis. Food consumption was evaluated through a 24 hour dietary recall. Leptin and insulin blood concentrations were measured. Spearmans correlation was made between the variables of food intake and concentrations of leptin and insulin
RESULTS: The average values found were : Mean age 15.68 years (± 1.41); body mass 67.62Kg (± 7.36), height 1.73m (± 0.07), BMI 22.31kg / m2 (± 1.61), fat free mass 78.25% (± 4.98), fat mass 21.35% (± 4.97). The mean energy intake was 2982.92 Kcal (minimum 1088.14, maximum 8608.43), protein intake was 124.51 g (min 60.26, max 338.00), lipids represented 90.43 g (min 27.50, max. 328.30), and carbohydrate intake was 402.09 g (min 110.90, max 1088.60). Median insulin and leptin concentrations were 6.6 mcU / mL (min 1.6 max 60.1) and 1.42 ng / mL (min 1.13, max 3.97). Moderate correlation between protein and carbohydrate intake with insulin concentration (0.656 and 0.644), and high between caloric intake and insulin (0.871). Moderate correlation was found between lipid intake and leptin concentrations (0.642).
CONCLUSION: The athletes food intake had moderate to high correlation to leptin and insulin concentrations, specially calorie intake relative to insulin. In our findings the anthropometric profile of the athletes was higher than that found in individuals of the same age (Shirali et al, 2016). In the literature it´s been reported the correlation between total energy intake and leptin concentration (Izadi et al, 2005), however, we did not find this correlation, as conveyed by other authors (Mars et al, 2005). An association between lipid intake and leptin has also been reported in other studies (Izadi et al, 2005), as we found in our results.

COMPARISON OF DIET QUALITY AMONG RUNNERS ON VEGAN AND OMNIVORE DIET

PAROL, D., ŚLIŻ, D., SOBIECKI, J., MICHNOWSKA, I., WEŁNICKI, M., DĄBROWSKA, D., PAWŁOWSKA, M., KRÓL, W., BRAKSATOR, W., MAMCARZ, A.

MEDICAL UNIVERSITY OF WARSAW

INTRODUCTION: The vegan diet is gaining popularity among the amateurs and professional athletes. American research shows that many vegetarians believe that eliminating meat from the diet can improve their physical performance. Approximately 30% of marathoners declare thir temporary adherence to vegetarian diet. The aim of the thesis is to assess the influence of vegan diet on diet quality among amateur runners population.
METHODS: Comparison of occurrence of diet quality between vegan runners (n=44) and omnivore runners (n=54). Anthropometric measurements, body composition, and blood samples were collected for analysis. Participants were also obliged to keep the diary of their current diets for 4 days to analyse their intake.
RESULTS: The study group consumed 2647 ± 618.41 kcal and the control group 2408 ± 557.8 kcal (p = 0.0505). On a weight basis, 1.11 ± 0.30 g/kg of protein was consumed by vegans, while runners on mixed diet consumed 1.44 ± 0.41 g/kg of protein (p <0.0001). Runners on the vegan diet consumed less energy from fat (25.61 ± 9.81 vs. 31.69 ± 6.61%; p = 0.0006). Both groups had insufficient intake EPA and DHA. Median in the group of vegans was 0 mg, while in the group on the mixed diet 156 mg. Both LAs average diet energy intake was statistically significantly higher in the vegan group (7.12 ± 2.67 vs 4.04 ± 1.26%, p <0.0001) as well as ALA (1.30 ± 0, 91 vs 0.83 ± 0.61%; p <0.0001).
Intake of carbohydrates converted per kilogram of body weight was in the study group increased by 1.87 g/kg (5.70 ± 1.95 vs 3.83 ± 1.05 g/kg; p <0.0001). Also dietary fibre intake was more than doubled in the study group (61 ± 14 vs 27 ± 9 g; p <0.001).
The intake of most vitamins and minerals is adequate in both groups, generally higher in the group of runners on the vegan diet. With vitamins, the exception is the intake of vitamin B12, which was 69% lower in the study group (1.67 ± 1.67 vs 5.42 ± 5.36 mcg; p <0.0001) and vitamin D, which was 81% lower in the study group (34 ± 28 vs 183 ± 136 IU, 0.85 ± 0.71 vs 4.59 ± 3.39 mcg, p <0.0001). Observations of vitamin B12 intake are corelated with lower vitamin B12 levels (329.01 ± 26.08 vs 398.75 ± 28.41 pg/ml, p = 0.075) and higher homocysteine concentrations (16.04 ± 4. 99 vs 14.46 ± 5.72 mcmol/l; p = 0.0184) in vegans.
Calcium intake was 11% lower in the study group (758.1 ± 260.2 vs 887.8 ± 293.9 mg; p = 0.0265). However, due to the bioavailability, the supply of iron and zinc may raise doubts. Lower iron nourishment was indicated in blood tests. The median of ferritin level was significantly lower in the vegan group (56.64 vs 96.70 ng/ml, p = 0.0023), same with haemoglobin level (14.57 ± 1.29 vs. 15.11 ± 0.93 g/dl; p = 0.0224). Median of selenium levels in the control group were 90.98 mcg/l, while in the study group only 73.13 mcg/l.
CONCLUSION: The vegan diet is sufficient and the composition of this diet can be defined as healthy, but vegans are more likely to experience protein, calcium, selenium, iron and vitamin D i B12 deficiency.

PL-PS01 Muscles in Motion: Neural Determinants of Function

NEURAL STRATEGIES OF MOVEMENT REVEALED BY IN VIVO DECODING OF THE NEURAL DRIVE TO MUSCLES

FARINA, D.

IMPERIAL COLLEGE LONDON

Discharge timings of relatively large populations of active motor neurons can now be accurately identified in vivo in humans during natural movements, even in a non-invasive way. It is thus possible to derive an accurate estimate of the neural drive sent to multiple muscles during motor tasks. This possibility has opened new perspectives in the analysis of neural strategies for movement control. For example, the neural determinants of muscle force accuracy have been identified as relative contributions of common vs independent sources of synaptic input to motor neurons. The lecture will provide an overview of the technological advances in electrodes, biosignal processing, and modelling for the study of motor unit behaviour as well as of the physiological implications of recent experiments conducted with these advanced techniques. Moreover, a recent breakthrough in techniques for motor unit identification will be presented to prove the feasibility of tracking the same motor units over weeks during longitudinal training studies. The implications of this new approach for understanding the effects of motor training on the neural control of muscles will be exemplified by presenting results on endurance and high-intensity interval training.
Overall, the lecture presents a vast overview of the progression from the use of surface EMG signal as a global indicator of muscle activity to a source of detailed neural information, and the implications of this achievement for sports sciences.

NEUROMUSCULAR DETERMINANTS OF DIFFERENCES IN MANUAL DEXTERITY

ENOKA, R.M.

UNIVERSITY OF COLORADO, BOULDER

Introduction: As one of the biomarkers for motor function across the lifespan, manual dexterity is often quantified with a pegboard test. Pegboard times are fastest in young adults and slowest in individuals with neurological disorders. Understanding the attributes that contribute to differences in pegboard times provide insight on the adaptability of the neuromuscular system.
Explaining the Variance in Pegboard Times
Time to complete the grooved pegboard test (25 keyhole-shaped pegs) is fastest for young adults (18-36 yrs), slowest for old adults (65-89 yrs), and intermediate for middle-aged adults (40-60 yrs) (Marmon et al. 2011). The variables that can explain the variance in pegboard times differ for the three age cohorts but include selected aspects of force-matching tasks involving submaximal isometric contractions with hand and arm muscles, the time it takes to complete one or two of the four phases of each peg-manipulation cycle, and performance on a test of working memory (Almuklass et al. 2016, 2017; Hamilton et al. 2017).
Force Steadiness
One of the consistent explanatory variables for the variance in pegboard times is the amplitude of the force fluctuations (force steadiness) during submaximal isometric contractions with hand and forearm muscles. Based on the strong association between force fluctuations during steady isometric contractions and variability in the common modulation of motor unit discharge times (Farina and Negro, 2015), a statistically significant proportion of the variance in the pegboard times of old adults can be explained by the variance in the common synaptic input to motor neurons (Feeney et al. in revision).
Multiple Sclerosis
MS is a demyelinating disease that impairs signal transmission and compromises both motor and sensory function. Pegboard times, which are longer for individuals with MS, are predictive of disease progression. Most of the variance (78%) in pegboard times of people with MS can be explained by the time it takes them to select each peg from the well (Almuklass et al. 2017). However, modulation of sensory feedback-such as with the application of transcutaneous electrical nerve stimulation-can immediately reduce the pegboard times of individuals with MS (effect size: 0.71).
The studies to be discussed in the presentation will describe a framework that can be applied to other aspects of sensorimotor function and used to identify potential therapeutic targets.

IS-PM06 Oxidative Stress, Redox Biology and Antioxidants in Exercise: What's New?

EXERCISE-INDUCED OXIDATIVE STRESS: HISTORY, CAUSE, AND CONSEQUENCES

POWERS, S.

UNIVERSITY OF FLORIDA

The observation that living cells produce free radicals was first reported in 1954 and this important discovery launched the field of free radical biology. The detection that contracting skeletal muscles produce reactive species followed in the 1980's and many studies have now confirmed that prolonged exercise is associated with an accumulation of oxidation products in the active muscles. This presentation will provide an overview of the history of research in exercise-induced oxidative stress and will highlight the potential causes and consequences of exercise-induced oxidant production. In particular, the sources of radical production in contracting muscles will be debated followed by a discussion of the role that radicals play in the regulation of skeletal muscle force production. Moreover, evidence that reactive species play a key role as signal transduction messengers in exercise-induced muscle adaptation will also be highlighted. Finally, the possibility that exercise-induced production of reactive oxygen species is an important player in epigenetic events in skeletal muscle will be introduced in hopes of stimulating future research.

NEW INSIGHTS INTO THE REDOX REGULATION OF MUSCLE ADAPTATION TO CONTRACTILE ACTIVITY

JACKSON M.

UNIVERSITY OF LIVERPOOL

Skeletal muscle responds to exercise by modifying the expression of genes involved in regulation of muscle structure, mass and energy metabolism. During ageing many of these responses are attenuated leading to poor adaptations to exercise. It is clear that exercising muscle generates superoxide and nitric oxide, and the reactive species derived from them, act as signalling agents that stimulate some adaptive responses to muscle contractions, but the extent of their involvement is unclear because the mechanisms by which these highly reactive molecules can target specific responses are not understood. Most studies in this area have assumed that reactive oxygen species directly activate adaptive signalling pathways. Hydrogen peroxide generated from superoxide dismutation appears to be the most important of these redox signalling molecules, but recent data have shown that only a small number of proteins, specifically the peroxidases, peroxiredoxins (Prx) and thioredoxins (Trx), can react with hydrogen peroxide at the concentrations found in cells. In some cell types these proteins have also been shown to have the capacity to transmit oxidising equivalents to other less reactive proteins by disulphide exchange, but this has not yet been shown for skeletal muscle. The potential of disulphide signalling to play a role in the responses of muscle to contractile activity, the role that Prxs and Trxs play in these processes and how they are disrupted during ageing will be discussed.

AN UPDATE ON ANTIOXIDANTS IN MUSCLE ADAPTATION TO EXERCISE TRAINING

GOMEZ-CABRERA, M.

UNIVERSITY OF VALENCIA

Physical exercise increases the cellular production of reactive oxygen species (ROS) in muscle, liver, and other organs. Originally, ROS were considered as detrimental and thus as a likely cause of cell damage associated with exhaustion. In the last decade, evidence showing that ROS act as signals has been gathered and thus the idea that antioxidant supplementation in exercise is always recommendable has proved incorrect (1). In fact, we proposed that exercise itself can be considered as an antioxidant because training increases the expression of classical antioxidant enzymes such as superoxide dismutase and glutathione peroxidase and, in general, lowering the endogenous antioxidant enzymes by administration of antioxidant supplements may not be a good strategy when training (2).

Antioxidant enzymes are not the only ones to be activated by training. Mitochondriogenesis is an important process activated in exercise (3). Many redox-sensitive enzymes are involved in this process. Important signaling molecules like MAP Kinases, NF-•B, PGC-1α, p53, Heat Shock Factor, and others modulate muscle adaptation to exercise. Interventions aimed at modifying the production of ROS in exercise must be performed with care as they may be detrimental in that they may lower useful adaptations to exercise (4).

OP-PM09 HEAT - THERMOREGULATION

FAKING THE HEAT: SUBJECTIVE THERMAL STRAIN IMPAIRS ENDURANCE PERFORMANCE IN A TEMPERATE ENVIRONMENT

VAN CUTSEM, J., ROELANDS, B., DE PAUW, K., MEEUSEN, R., MARCORA, S.

VRIJE UNIVERSITEIT BRUSSEL

INTRODUCTION: In addition to physiological strain, performing endurance exercise in the heat is associated with significant subjective thermal strain [1]. This strain is indicated by ratings of heat sensation, thermal discomfort and higher perceived exertion. Its possible role in the impairment of endurance exercise in the heat is however often ignored. The aim of this study was to dissociate subjective thermal strain from the physiological strain normally experienced during endurance exercise in the heat, and test the hypothesis that subjective thermal strain, by itself, impairs endurance performance in a temperate environment.
METHODS: In 20°C and 44% relative humidity, 12 endurance-trained athletes (1F 11M; mean ± SD; age:27 ± 6 y; VO2-max:61 ± 6 ml/kg/min; Wpeak:399 ± 54 W) performed a time to exhaustion (TTE) test in two different experimental conditions: with an electric heat pad applied to the subjects' upper back (HP) and control (CON: without heat pad). In both conditions, subjects cycled to volitional exhaustion at 70% of their VO2-max established in a preliminary incremental exercise test. Cardiorespiratory, metabolic, thermoregulatory and perceptual responses were measured throughout the TTE test and compared at 0%, 50% and 100% isotime and at exhaustion. Normality was checked, repeated measures ANOVAs were employed to observe interaction and/or main effects of condition and time during the TTE test. Follow up tests were performed where necessary. Paired t-tests assessed whether there was any effect of condition at exhaustion ($p<0.05$).
RESULTS: TTE was impaired by 9% in HP (2092 ± 305s) compared to CON (2292 ± 344s; $p=0.023$). At isotime, subjects rated thermal discomfort consistently higher in HP (-3.6 ± 0.3) compared to CON (-2.4 ± 0.4; $p=0.002$). Rating of perceived exertion showed an interaction between condition and time ($p=0.036$). None of the measured cardiorespiratory, metabolic and thermoregulatory variables differed between conditions.
CONCLUSION: HP was successful in inducing significant subjective thermal strain during endurance exercise in a temperate environment. Despite the absence of the physiological strain normally associated with heat stress, HP significantly impaired endurance performance (-9%). The most likely explanation for the shorter TTE in the HP condition is the higher perception of effort induced by the heat pad. These results provide additional evidence that subjective thermal strain is an important determinant of endurance performance rather than an epiphenomenon.

HEAT ACCLIMATION WITH CONTROLLED HEART RATE: EFFECTS OF HYDRATION ON ADAPTATIONS AND SELF-PACED EXERCISE IN A HOT HUMID ENVIRONMENT

TRAVERS, G.1,2, NICHOLS, D.2, RIDING, N.2, GONZÁLEZ-ALONSO, J.1, PÉRIARD, J.2,3

1. BRUNEL UNIVERISTY LONDON , 2. AHP , 3. UCRISE

INTRODUCTION: During heat acclimation (HA) with controlled hyperthermia dehydration may enhance adaptations to HA independently of heat stress via a fluid regulatory response, resulting in a protracted expansion of the vascular compartment (1). However, recent findings comparing the additional dehydration stimulus to euhydrated HA on haematological, thermoregulatory and cardiovascular adaptations are equivocal (2, 3). We therefore sought to characterise the adaptations to HA with and without dehydration and their effects on self-paced exercise performance.
METHODS: Seven males underwent two 10-day HA interventions (40°C, 40% RH) separated by ~six weeks in a randomised order. Each 90-min exposure consisted of 15-min cycling at 65% VO2max (174±22 W) followed by automated alterations in work-rate to maintain heart rate at the value associated with this intensity (145±7 bpm). Fluid intake was prescribed to either maintain body mass (-0.6±0.3%; HA-EUH) or elicit similar levels of dehydration (-2.9±0.5%; HA-DEH) each day. Changes in blood (BV), plasma (PV) and red cell (RCV) volumes were determined via CO rebreathing prior to each HA intervention and measured on days 1, 5 and 10 via venepuncture. A VO2max test (~20°C) and 30-min cycling time trial (35°C, 60% RH) were completed to determine the effects on exercise capacity and performance.
RESULTS: Resting BV, PV and RCV did not change across either HA intervention ($p>0.05$), but BV and PV were acutely reduced after DEH-HA exposures ($p<0.05$). 15-min heart rate and 90-min average skin temperature decreased ($p<0.05$), while mean heart rate and core temperature (38.4±0.2°C) were similar during the final 75-min of each day, regardless of hydration. Sweat lost increased with HA and power output during fixed heart rate exercise was lower in HA-DEH than HA-EUH ($p<0.05$). HA significantly increased VO2max (+3.2±0.4%, $p<0.05$), while 30-min time trial power output increased significantly in HA-EUH (+16±11 W, $p<0.05$), but not HA-DEH (+18±28 W, $p=0.18$). Heart rate, core and skin temperature responses and rating of perceived exertion were similar across all time trials, while sweat lost increased following both HA interventions.
CONCLUSION: The present findings demonstrate that moderate, transient dehydration with exercising heat stress do not enhance HA adaptations. Improvements in exercise performance may be due to the ability to maintain a similar relative intensity and evaporative heat loss for a greater level of metabolic heat production during self-paced exercise in the heat.

PASSIVE HYPERTHERMIA REDUCES MAXIMAL BUT NOT EXPLOSIVE TORQUE PRODUCTION

GORDON, R.J.F.H., TYLER, C.J., TILLIN, N.A.

UNIVERSITY OF ROEHAMPTON, LONDON

INTRODUCTION: Hyperthermia can reduce maximal voluntary force/torque (MVT) of skeletal muscle due to reduced neural activation (Todd et al., 2005). Rate of force/torque development (RTD) may be a more functionally relevant measure of neuromuscular performance than MVT; however, the effect of hyperthermia on RTD has received little attention. Primary determinants of RTD include neural activation and electrically evoked involuntary RTD (Maffiuletti et al., 2016), and whilst neural activation may decrease with hyperthermia, increased muscle temperature improves involuntary RTD, so it is unclear how voluntary RTD will be affected by hyperthermia. This study aimed to investigate the effects of progressive passive whole-body hyperthermia on MVT and voluntary RTD, as well as the neural and contractile factors contributing to any effects.
METHODS: Nine male participants completed two trials; one involving passive heating to a rectal temperature (Tre) of 39.5˚C (HOT) and the other (CON) where Tre was maintained at ~37˚C. The same neuromuscular measurements of the knee extensors were completed when participants first entered the chamber (Tre ~37˚C; Base), and at Tre=38.5˚C (ModHyp) and Tre=39.5˚C (SevHyp), in the HOT trial, and at equivalent time points into the CON trial. MVT, voluntary activation (VA) determined via interpolated twitch, and EMG at MVT normalised to maximal M-wave (EMGMVT) were measured during MVCs. Explosive voluntary RTD and normalised EMG were measured over 0-50 (RTD50; EMG50) and 0-100 (RTD100; EMG100) from torque/EMG onsets during explosive contractions. Involuntary RTD50 was measured during evoked octets at 300Hz.
RESULTS: In the HOT trial, MVT declined throughout and was 15% lower at SevHyp than Base (P=0.016), which coincided with declines in EMGMVT (-44%; P<0.005) and VA (-16%; P<0.005) from Base to SevHyp. In contrast, voluntary RTD50 and RTD100 remained unaffected in the HOT trial (P>0.05), despite 23-31% decreases in EMG50 and EMG100 from Base to SevHyp (P<0.001). Involuntary RTD50 however, increased from Base to ModHyp (10%; P<0.001) and from ModHyp to SevHyp (4%; P<0.001). There were no changes in any dependent variables throughout the CON trial.
CONCLUSION: As expected MVT declined as a result of passive hyperthermia which was largely due to reduced neural activation (i.e., EMGMVT and VA). In contrast, this study provides novel evidence that voluntary RTD was largely unaffected by passive hyperthermia, despite considerable reductions in explosive neural activation, which likely occurred due to the increased involuntary RTD, and thus cancelling out of neural and contractile effects.

EFFECTS OF VARIATIONS IN AIR VELOCITY ON THERMOREGULATION AND ENDURANCE EXERCISE CAPACITY IN THE HEAT

OTANI, H.1, KAYA, M.2, TAMAKI, A.2, WATSON, P.3, MAUGHAN, R.J.4

1: HIMEJI DOKKYO UNIVERSITY , 2: HYOGO UNIVERSITY OF HEALTH SCIENCES , 3: VRIJE UNIVERSITEIT BRUSSEL , 4: UNIVERSITY OF ST ANDREWS

INTRODUCTION: Only one published study (Saunders et al. 2005) has systematically examined the effects of gradual variations in air velocity (0.2, 9.9, 33 and 50 km/h) on thermoregulatory responses during exercise in a hot environment (33°C, 59% relative humidity). However, this study measured heat storage, body temperature and sweat rate but did not assess exercise performance. The current study therefore investigated the effects of variations in air velocity on time to exhaustion and thermoregulatory and perceptual responses to exercise in a hot environment.
METHODS: Eight male volunteers completed an initial maximal exercise test, and, after a familiarization trial, four stationary cycle exercise trials at 70% peak oxygen uptake until exhaustion in an environmental chamber maintained at 30°C and 50% relative humidity. Four air velocity conditions, 30, 20, 10 and 0 km/h, were tested, and the headwind was directed at the frontal aspect of the subject by two industrial fans, with blade diameters of 1-m and 0.5-m, set in series and positioned 3-m from the subject's chest. Rectal temperature, skin temperature (chest, upper arm, thigh and calf), heart rate, skin blood flow, blood pressure, perceived thermal sensation and perceived exertion were recorded during exercise.
RESULTS: Mean±SD time to exhaustion was 90±17, 73±16, 58±13 and 41±10 min in the 30, 20, 10 and 0 km/h trials, respectively, and was different between all trials (P<0.05). There were progressive elevations in the rate of core temperature rise, mean skin temperature and perceived thermal sensation as airflow decreased (P<0.05). Core temperature, heart rate, cutaneous vascular conductance and perceived exertion were higher and evaporative heat loss was lower without airflow than at any given airflow (P<0.05). Dry heat loss and the change in plasma volume were similar between trials (P>0.05).
CONCLUSION: The present study demonstrates a progressive reduction in time to exhaustion in the heat as air velocity decreases. This response is associated with a faster rate of core temperature rise and a higher skin temperature and perceived thermal stress with decreasing airflow. Moreover, airflow greater than 10 km/h (2.8 m/s) might contribute to enhancing endurance exercise capacity and reducing thermoregulatory, cardiovascular and perceptual strain during exercise in a hot environment.

THERMOREGULATORY BURDEN IN ELITE SAILING ATHLETES DURING EXERCISE IN THE HEAT: A CROSS-OVER STUDY

VAN DELDEN, M.1, BONGERS, C.1, BROEKENS, D.2, DAANEN, H.3, EIJSVOGELS, T.1

1. RADBOUD UNIVERSITY MEDICAL CENTER 2. SAILING INNOVATION CENTRE 3. VRIJE UNIVERSITEIT AMSTERDAM

INTRODUCTION: Exercising in a hot and humid environment increases core body temperature, which may limit exercise performance. The risk of exercise-induced hyperthermia and associated performance decrement in Olympic sailing athletes is largely unknown. Therefore, this study aimed to compare thermoregulatory responses and performance indicators of elite sailors in a cool versus hot environment.
METHODS: A cross-over study was performed in which seven elite athletes from four different Olympic sailing classes (Laser, RS:X, Finn, 470) performed simulated sailing exercise in a cool (18.4±2.1°C) and hot (32.8±0.9°C) environment. Core body temperature (Tc), skin temperature (Tsk), exercise performance (covered distance), and rating of perceived exertion (RPE) were measured, and differences in maximal Tc and increase in Tc were calculated between the cool and hot environment.

RESULTS: The increase in Tc was significantly higher in the hot environment (37.6±0.2°C to 39.2±0.2°C) compared to the cool environment (37.5±0.1°C to 38.5±0.1°C; p=0.002), and the increase in Tc between the conditions differed substantially between individuals (range: 0.3°C – 0.9°C). Exercise performance decreased with 6.2±2.9% in the hot compared to the cold environment (p=0.013), and ranged from 2.3% to 9.5% across individuals. The decrease in exercise performance was significantly correlated with the increase in Tc in the hot environment (r=-0.76; p=0.047) and maximal Tc in the hot environment (r=-0.78; p=0.039). RPE (cool: 14.2±0.6; hot: 13.9±1.2) and increase in Tsk (cool: 0.5±1.0°C; hot: 0.9±0.3°C) did not differ between conditions (p=0.59 and p=0.36, respectively).
CONCLUSION: As expected, a larger increase in Tc and a substantial exercise performance decrement were observed in the hot versus cool environment. More importantly, large inter-individual differences were observed across athletes, which stresses the importance of appropriate and personalized interventions to reduce thermoregulatory burden in elite sailors during exercise in the heat.

HEAT ACCLIMATION AUGMENTS PEAK POWER OUTPUT AND THERMOREGULATORY RESPONSES IN THERMONEUTRAL BUT NOT HYPOXIC CONDITIONS

SOTIRIDIS, A.1,2, DEBEVEC, T.1,3, CIUHA, U.1, EIKEN, O.4, MEKJAVIC, I.B.1

1: JOZEF STEFAN INSTITUTE , 2: JOZEF STEFAN IPS , 3: UNIVERSITY OF LJUBLJANA , 4: ROYAL INSTITUTE OF TECHNOLOGY

INTRODUCTION: Heat acclimation (HA) mediates numerous cardiovascular, thermoregulatory and cellular adaptations (Corbett et al. 2014). While HA is known to enhance exercise performance in the heat, it remains unresolved whether this beneficial effect of HA is reflected in the performance in thermoneutral normoxic and/or hypoxic conditions. Accordingly, we explored the effects of HA on exercise cardiorespiratory and thermoregulatory responses in thermoneutral normoxic, hypoxic, and hot conditions.
METHODS: Twelve trained males participated in a 10-day HA protocol comprising daily 90-min controlled-hyperthermia (target rectal temperature, Tre = 38.5°C) exercise sessions. Before and after HA, the subjects conducted a cycle-ergometry test in normoxic (23°C, 50% RH, 20.9% FiO2; NOR), hypoxic (23°C, 50% RH, 13.5% FiO2; HYP) and hot (35°C, 50% RH, 20.9% FiO2; HE) conditions in a randomized and counterbalanced order. The tests comprised two stages: a 30-min steady-state exercise followed by incremental-load exercise to exhaustion. The steady-state exercise was performed at 40% NOR peak power output (Wpeak) to evaluate submaximal responses.
RESULTS: HA attenuated the submaximal exercise Tre and HR response. However, HA did not affect VO2max or maximal cardiac output in either condition. Wpeak was increased in NOR and HE by 41±21 and 26±22 W, respectively but not in HYP (pre: 282±28, post: 294±26 W). HA increased the ventilatory threshold in NOR only. Exercise economy was higher whereas resting Tre and sweating thresholds were lower in all environments. The gain of the sweating response was attenuated in the HYP condition.
CONCLUSION: HA improved Wpeak and thermoregulatory responses in HE and NOR, but not in HYP. Given that VO2max remained unaltered, the increase in Wpeak in both NOR and HE could be related to the improved exercise economy and ventilatory threshold (only in NOR) (Jones & Carter 2000) as well as to the lower resting Tre (Hessemer et al. 1984).

OP-PM10 CEREBRAL FLOW / HEMODYNAMICS

A DECREASE IN CEREBRAL BLOOD FLOW IS NOT RESPONSIBLE FOR DECREMENTS IN COGNITIVE FUNCTION DURING INTENSE EXERCISE

ANDO, S., KOMIYAMA, T., TANOUE, Y., SUDO, M., COSTELLO, J., UEHARA, Y., TANAKA, H., HIGAKI, Y.

UNIVERSITY OF ELECTRO-COMMUNICATIONS

INTRODUCTION: During mild to moderate exercise, cerebral blood flow (CBF) increases in response to neuronal activity and metabolism. However, during intense exercise, hyperventilation-induced hypocania constricts blood vessels and restricts CBF (Ogoh & Ainslie 2009). This implies that reduction in CBF may compromise cerebral metabolism, thereby compromising cognitive function. Carbon dioxide (CO2) is a potent cerebral, but not muscle, vasodilator (Subduhi et al. 2011) and CO2 inhalation selectively increases CBF without altering other physiological variables (Subudhi et al. 2011). Therefore, the purpose of this study was to examine the role of CBF in cognitive impairment during intense exercise. We hypothesized that maintaining CBF during intense exercise, through inhalation of hypercapnic gas, would prevent any reductions in cognitive function.
METHODS: Seventeen healthy male participants (22.1 ± 1.7 years) took part a within participant, balanced cross-over design. Cognitive function was assessed using an executive function task that incorporated a combination of a spatial delayed-response task and a Go/No-Go task (Komiyama et al. 2017). Middle cerebral artery mean velocity (MCAv) was measured continuously. Cognitive function was assessed at rest and during moderate (50% peak oxygen uptake) and intense (80% peak oxygen uptake) cycling with or without hypercapnic gas inhalation. In the hypercapnic gas condition, the participants breathed hypercapnic gas (2% CO2) during intense exercise. As a control, we assessed cognitive function in the same time course while sitting on the cycle ergometer.
RESULTS: MCAv increased during moderate exercise (67.6 ± 10.0 cm/s, $P < 0.01$) as compared with rest (57.7 ± 11.6 cm/s) and decreased during intense exercise (57.2 ± 7.7 cm/s, $P = 0.85$, vs. rest). In contrast, MCAv did not decrease during intense exercise with hypercapnic gas (69.4 ± 10.6 cm/s, $P < 0.001$, vs. without hypercapnic gas). Accuracy of the cognitive task was impaired during intense exercise (84.1 ± 13.3 %) as compared with rest (95.1 ± 5.3 %, $P < 0.01$). The impairment was not altered when MCAv increased during intense exercise with hypercapnic gas (85.7 ± 11.6 %, $P = 0.68$, vs. without hypercapnic gas). These results indicate that cognitive function was impaired during intense exercise even when CO2 inhalation restored CBF.
CONCLUSION: Restoration of CBF, using hypercapnic gas inhalation, did not restore cognitive function during intense exercise. These novel findings suggests that the reduction in CBF per se is not responsible for impaired cognitive during high intensity exercise.

HEMODYNAMICS DURING THE MUSCLE METABOREFLEX FOLLOWING A SINGLE SESSION OF EXERCISE UNDER NORMOBARIC HYPOXIA

CRISAFULLI, A., SAINAS, G., MAGNANI, S., ROBERTO, S., MANNONI, M., TOCCO, F., GHIANI, G., PINNA, V., DONEDDU, A., MULLIRI, G.

UNIVERSITY OF CAGLIARI

INTRODUCTION: Available normobaric hypoxic ventilatory circuits has provided useful tools to induce arterial hypoxemia during exercise. These devices expose the athletes to bouts of hypoxemia suddenly followed by normoxia when the hypoxic stimuli is removed. The body homeostasis is then continuously perturbed. We conducted this investigation to assess hemodynamic response to the metaboreflex (MM) activated during normoxia immediately after a bout of exercise under acute hypoxia (EAH). We hypothesised that a session of EAH would lead to a reduction in systemic vascular resistance (SVR) response and dampen the increment in mean blood pressure (MBP) during the MM recruited following EAH.
METHODS: Ten trained subjects (4 females, age 22-45 yrs) were recruited. They underwent randomly assigned one session (10 min) of training in normoxia (TN) and two sessions of EHA with FiO2 at 15.5% and at 13.5% respectively. After training sessions, they underwent randomly assigned the following protocol: MM activation test, consisting in a post-exercise (cycling) muscle ischemia protocol (PEMI)(1), or a control exercise-recovery (CER) session. Hemodynamics were evaluated with of impedance cardiography. The hemodynamic response due to MM activation was assessed by calculating the difference PEMI minus CER in each cardiovascular variable.
RESULTS: The main results were that the two sessions of EAH significantly reduced the stroke volume (SV) response during the MM activation (+5.0±5.7 vs. –10.6±8.7 and –9.1±3.2 ml for TN and EAH with FiO2 15.5% and 13.5% respectively), while the SVR was increased (-8.1±206.6 vs. +323.5±264.7 and +318.6±229.1 dynes·s-1·cm-5). Moreover, ventricular filling rate (VFR) response, a measure of diastolic flux, was reduced during the MM activation following EHA. Finally, the MBP response during the MM activation was unchanged following EHA.
CONCLUSION: Contrary to our initial hypothesis, this investigation provides evidence that the capacity to regulate MBP by modulating SVR is not affected during the MM activation after EHA. Rather, the capacity to centralise blood volume by increasing venous return is impaired following EAH. This occurrence can explain the reduced SV response found after EAH. These findings support the concept that diastolic functions are important to sustain circulation during the MM recruitment(2).

CEREBROVASCULAR RESPONSES TO RESISTANCE AND ENDURANCE TRAINING IN MONO-ZYGOTIC TWINS

THOMAS, H.J., SMITH, K.J., MARSH, C.E., HAYNES, A., CORRERIA, M.A., SHKREDOVA, D., NAYLOR, L.H., GREEN, D.G.

THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Cerebral blood flow and pressure regulation are critical determinants of brain health. We compared the impacts of endurance and resistance training on cerebrovascular function in mono-zygotic (MZ) twins to determine the heritability of cerebrovascular adaptation to distinct modes of exercise. We hypothesized that cerebrovascular responses to a standardized change in perfusion pressure would be highly correlated in MZ twin pairs, regardless of training intervention.
METHODS: Healthy female MZ twin pairs (n=18) underwent 3-months of both progressive overload resistance and endurance training (3x per week 70-90% 1RM and 60-90% VO2max respectively) separated by a 3-month washout. Middle cerebral artery velocity (MCA) was assessed using transcranial Doppler ultrasound, with arterial blood pressure measured using photo-plethosmography, during a 3-min squat (hypertensive): stand (hypotensive) manoeuvre at fast (0.33 Hz) and slow (0.16 Hz) oscillatory frequencies. Comparisons of hypertensive and hypotensive perfusion pressure ranges (squat-minus-stand) were performed. Vascular duplex ultrasound in the internal carotid artery (ICA) was also performed pre- and post-training to quantify volumetric changes in cerebral perfusion in response to each training modality.
RESULTS: Resting ICA flow (233 ± 8.8 ml.min-1 vs 251 ± 14 ml.min-1) and MCA velocity (79 ± 2.2 cm.s-1 vs 79 ± 0.2 cm.s-1) did not differ pre vs post endurance training. Similarly, ICA flow (232 ± 0.5 ml.min-1 vs 241 ± 9.6 ml.min-1) and MCA velocity (85 ± 9.4 cm.s-1 vs 76 ± 17 cm.s-1) did not differ pre vs post resistance training. Resistance training reduced the MCA response during the 0.33 Hz squat manoeuvre (2.1 ± 0.74 cm.s-1; $p < 0.05$), whilst both resistance (2.1 ± 0.99 cm.s-1) and endurance (2.09 ± 0.99 cm.s-1) training reduced the MCA response over the 0.16 Hz squat-stand range ($p < 0.05$). Correlation between twin pair responses to squat-stand in the MCA were significant following endurance ($r2 = 0.62$, $p = 0.001$), but not resistance, training.
CONCLUSION: Exercise training, regardless of mode, improved cerebral perfusion in response to imposed pressure oscillations by nearly 20%. Our concordant twin pair analysis in individuals who share 100% of their DNA indicates that endurance training adaptations are more heritable than the adaptations induced by resistance training. Our novel approach to studying cerebrovascular adaptation to exercise training can be used to reveal genetic versus environmental contributions to the regulation of cerebral blood flow in humans.

HEMODYNAMICS MONITORING IN CROSS COUNTRY SKIERS OF DIFFERENT AGES FOR INDIVIDUAL TRAINING PLANNING DESIGN

ZAKHAROVA, A., TARBEEVA, N.

URALS FEDERAL UNIVERSITY

INTRODUCTION: In modern cross country skiing the distances' shortening and hereto related performance intensity increase are seemed to downgrade the endurance demand in skiers. At the same time we must realize that in modern conditions of hypodynamia and everyday well-being natural motor activity of children and adolescents does not provide the sufficient development of the cardiovascular system. The lack of outdoor games, agricultural and house work, hiking and walks in the forest causes low endurance not only in athletes during initial training but in teenagers and young adults. So skiers' hemodynamics must be under monitoring to avoid overreaching and benefit the endurance training process.
METHODS: Cross country skiers (n=120, age from 11 to 20) underwent hemodynamics monitoring with MARG 10-01 (Microlux, Russia) based on impedance cardiography. Hemodynamics data were automatically registered by beat-to-beat record during an active orthoclinostatic test. Following hemodynamics parameters were under consideration: HR at supine and standing, stroke volume (SV, ml), end-diastolic volume (EDV, ml) and their indices (SI, ml/m2 and EDI, ml/m2), ejection fraction (EF, %) (all of them at supine and standing) as well

as volemia, inotropy (heart contractility) and vascular tone. The monitoring procedure was the same for all objects but different sets of indicators were considered in different age athletes groups.
RESULTS: Firstly, we determined the hemodynamics age norms. Secondly, in young cross country skiers 12-14 years old analysis of HR, SV, EDV and inotropy allowed to divide them into 3 groups with different training focus: (1) low aerobic fitness: SV< 70 ml, EDV<110 ml; (2) normal fitness with high inotropy: HR< 65 bpm, SV>70 ml, EDV >110, inotropy > 45; (3) normal fitness with inotropy less than 40%. Different training design were suggested to every group. Regular hemodynamic monitoring (once per 3 months) assisted to individualize training, transferring athletes from one group to another according obtained monitoring results, thus avoiding inadequate cardiac adaptation. Ideally all the athletes should train in group 3.
During growth spurt in teenagers HR in 3 positions of orthoclinostatic test are under analysis while all the hemodynamic parameters are used for the individualization of endurance-building training in application to 15-17 years old skiers and elder considering the age norms. Special attention should be paid to the hemodynamics indices in standing position.
CONCLUSION: The hemodynamic monitoring data in cross country skiers allow to rate the individual limitations in athletes of different ages and efficiently achieve the relevant corrective training effects.

Invited symposia

IS-PM08 Joint Injury and the Development of Post-traumatic Osteoarthritis

CARTILAGE RESPONSES TO ACUTE JOINT INJURY

BRAMA, P.
UNIVERISITY COLLEGE DUBLIN

Articular cartilage responds differently to injury than other tissues. Unlike other tissues, cartilage has no direct blood supply, lymphatic drainage, or innervation. Cartilage has an extremely slow regeneration rate, and although matrix flow is described as an intrinsic cartilage repair process for small defects, chondrocytes cant really migrate within the matrix to the site of injury over any significant distance. Thus, in partial-thickness cartilage injury the repair response remains limited or non-existent. However, the more recent discovery of progenitor cells in the surface layers of articular cartilage holds great promise and challenges the traditional concept of intrinsic and extrinsic cartilage repair.
In articular cartilage defects that penetrate the subchondral bone, a reparative response is generated. Initial granulation tissue is converted into fibrocartilage or a mixture of hyaline cartilage and fibrocartilage at best. However, fibrocartilage has weaker mechanical properties, cannot distribute forces as well, and, over time, is prone to fibrillation and breakdown. Therefore, damage to articular cartilage, with or without damage to the underlying subchondral bone, has long-lasting consequences and contributes to the development of post-traumatic osteoarthritis. Thus, it is of critical importance that clinicians have a complete and contemporaneous understanding of the inflammatory and repair responses of articular cartilage resulting from acute joint injury.
Animal models are useful in obtaining a better understanding of acute cartilage injury but translational capacity into human athletes and the human sports medicine discipline is very limited in most animal models of acute joint injury. The horse however is an exemption since it performs at levels of athleticism very similar to human athletes, engages with similar biomechanical challenges and has a fast developing research active discipline of equine sports medicine. Therefore it is essential to look across species towards the equine sports medicine discipline when working with human athletes. In this presentation an overview is presented what we have learned from acute articular cartilage injury models in the horse over the years. Additionally, some recent results and advanced diagnostic technologies from the authors research group using repeated bilateral low dose LPS induced joint inflammation models and acute articular cartilage defect models in the horse will be presented.
Finally, results will be discussed in the light of current treatment regimens and an algorithim of treatment options in the horse athlete in comparison with the human athlete. What have equine sports medicine vets learned from human sports medicine medics and vice versa. Importantly, how can the horse athlete as a model and end user provide solutions for the critical problem of athletes longevity in humans regarding articular cartilage injury and the ultimate goal of prevention of prevention of development of post-traumatic osteoarthritis.

TO STABILIZE OR NOT - HEALTH AND STRUCTURAL CONSEQUENCES OF ANTERIOR CRUCIATE LIGAMENT INJURY

FROBELL, R.
LUND UNIVERSITY

This talk will cover health and structural consequences of knee injury, with specific emphasis on ACL injury, from an evidence based perspective. The burden of knee injury in terms of general incidence, prevalence and health economy will be discussed as well as the current evidence on treatment. Should all active individuals with an acute ACL tear consider ACL reconstruction as their primary treatment option or are results after a "wait and see" treatment algorithm comparative? Is there a difference in treatment strategies between professional and recreational high level athletes and, if so why? Patient expectations and wishes will be related to what actually could be expected, again from a scientific perspective.
The long term structural consequence of knee injury is osteoarthritis (OA) but this talk will highlight changes that occur within the first years after injury and that may, or may not, be related to OA development. Findings from imaging- and biochemical reports, especially regarding inflammation and the development of bone shape of the knee, will be highlighted

STRATEGIES TO FORESTALL THE DEVELOPMENT OF SPORTS-RELATED POST-TRAUMATIC OSTEOARTHRITIS

VAN MIDDELKOOP, M.
ERASMUS MC - UNIVERSITY MEDICAL CENTER ROTTERDAM

INTRODUCTION: Certain types of sports injuries are known to have a high association with the development of osteoarthritis. Post-traumatic osteoarthritis is especially disabling because of its early onset in life affecting a young and active population. The aim of this talk is to present an overview on the current evidence of risk factors for post-traumatic osteoarthritis and to give direction to future prevention of sports-related post-traumatic osteoarthritis.

METHODS: This lecture will discuss factors involved in the development and progression of post-traumatic osteoarthritis. The identification of these factors is especially important since early detection may improve the prognosis and minimize the costs due to unnecessary diagnostics and later functional loss. Studies investigating risk factors for post-traumatic knee and ankle osteoarthritis will be presented and identified factors will be evaluated in the light of treatment and prevention strategies to be applied in clinical practice.
RESULTS: Most research has been done in the knee in athletes with ACL injuries. It was for example recently shown that progression of cartilage defects does occur in up to 27% of patients two years after an anterior cruciate ligament injury. Perhaps more striking is that signs of early stage osteoarthritis are seen in almost half of the patients with a lateral ankle sprain after 6 to 12 months. Some factors have been associated with the development and progression of post-traumatic osteoarthritis in the different joints. The identification of these factors is especially important in order to be able to identify those individuals at higher risk for the development of osteoarthritis.
CONCLUSION: Recent literature has given us some direction on who is at risk to develop post-traumatic osteoarthritis, especially of the knee and ankle. Though, future studies are needed to investigate effective preventive strategies in athletes with traumatic injuries.

Oral presentations

OP-BN03 NEUROMUSCULAR

NEURAL MODULATION DURING SUBMAXIMAL DORSIFLEXION OF DIFFERENT CONTRACTION TYPES IN YOUNGER AND OLDER ADULTS

ŠKARABOT, J., ANSDELL, P., BROWNSTEIN, C., HOWATSON, G., GOODALL, S., DURBABA, R.

NORTHUMBRIA UNIVERSITY

INTRODUCTION: Lower electromyographic (EMG) activity, reduced motor evoked potentials (MEPs) and depressed H-reflexes are typically observed with eccentric (ECC) contractions in comparison with isometric (ISO) and concentric (CON) contractions, suggesting a unique modulation strategy is adopted by the central nervous system (CNS) [1]. Aging is associated with several alterations within CNS, including changes in cortical neurons and reductions in response from afferent sensory receptors to spinal motor neurons [2], which may account for greater declines in motor performance during ECC [3]. Accordingly, this study aimed to assess whether neural modulation of different contraction types is preserved in older age.
METHODS: Fifteen younger (26 ± 4 yrs, 7 females) and 14 older (64 ± 3 yrs, 5 females) adults performed ISO, CON and ECC dorsiflexions at 25 and 50% of contraction type specific maximums. Percutaneous nerve and transcranial magnetic stimulations were delivered at anatomical zero. H-reflex and MEP amplitudes, normalised to maximal muscle response (H/M and MEP/M, respectively), and cortical silent period (CSP) duration were assessed in tibialis anterior (TA).
RESULTS: Maximal dorsiflexor force was greater during ECC compared to CON or ISO ($p < 0.001$), but was not age dependent ($p > 0.05$). Mean EMG was greater in older compared to younger individuals at the same relative intensity and contraction type ($p < 0.05$), and greater during CON compared to ISO or ECC contractions in both groups ($p < 0.001$). H/M was greater during CON compared to ISO or ECC at 25 and 50% MVC ($p = 0.02$), and younger adults exhibited greater H/M during ISO and CON at 50% MVC compared to older adults ($p = 0.02$). MEP/M was greater during CON compared to ISO or ECC during 25% ($p < 0.005$) and compared to ISO during 50% ($p = 0.026$), with no age group differences. Older adults exhibited longer MEP and H-reflex latencies compared to younger ($p < 0.05$). No differences in CSP were observed ($p > 0.05$).
CONCLUSION: The findings show that in TA, CON was differently modulated compared to ECC and ISO, which may be specific to the task or muscle studied [4]. This trend was not age-related, suggesting that neural modulation of different contraction types is preserved with aging. However, the older CNS may be associated with compensatory changes as evidenced by greater EMG activity, but lower spinal excitability, and prolonged conduction velocity and/or transmission efficacy compared to younger.

NEUROMUSCULAR RESPONSES AFTER FREQUENT BLOOD FLOW RESTRICTED RESISTANCE EXERCISE PERFORMED TO VOLUNTARY FAILURE VS SUBMAXIMALLY

VÅRVIK, F.T.1, GERBI, S.2, LINDBERG, K.2, MANGSETH, H.2, SØRLI, T.2, WERNBOM, M.3, BERNTSEN, S.2, FIMLAND, M.S.1, PAULSEN, G.4, RAASTAD, T.5, BJØRNSEN, T.2

1 NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, 2 UNIVERSITY OF AGDER, NORWAY, 3 UNIVERSITY OF GOTHENBURG, SWEDEN, 4 NORWEGIAN OLYMPIC FEDERATION, 5 NORWEGIAN SCHOOL OF SPORT SCIENCE

INTRODUCTION: High-frequent blood flow restricted resistance exercise (BFRRE) performed to failure has been shown to increase muscle size with loads as low as 20% of 1 repetition maximum (1RM) (1). However, voluntary muscle activation and rate of muscle activation (RMA) was reduced during the BFRRE intervention and did not return to baseline levels before 12 days of detraining. Thus, the purpose of the present study was to compare the neuromuscular responses after a failure protocol versus a less strenuous submaximal protocol during high-frequency BFRRE.
METHODS: Nineteen untrained men and women (23.5±6.1 years old) performed BFRRE with four sets to voluntary failure with one leg, and a submaximal protocol with 20, 10, 10 and 10 repetitions with the other leg, using unilateral knee extensions (20% of 1RM). A 145mm wide pressure cuff was used to restrict blood flow (100 mmHg pressure). The intervention consisted of 14 BFRRE sessions distributed over two blocks of seven sessions (5 days), separated by 10 days of rest. Peak muscle activation and RMA (0-30, -50, -100, -150, -200 and -250ms) were assessed by surface electromyography in m. rectus femoris (RF) and m. vastus lateralis (VL) during maximal voluntary isometric contraction at baseline, in the rest period and at 3 (Post 3), 10 (Post 10), 17 (Post 17) and 24 (Post 24) days after the last BFRRE bout.
RESULTS: No group differences were detected in changes of peak muscle activation. However, both protocols increased peak muscle activation of VL from baseline to Post 10 (failure: 18.4%, submaximal: 18.4%), and Post 24 (failure: 17.7%, submaximal: 22.5%) ($p <0.05$). Only the submaximal protocol increased in peak muscle activation to Post 3 (15.7%), while the failure protocol increased 15.3% to Post 17 ($p <0.05$). No significant increases were observed in peak muscle activation of RF. Over the time course of the study, RMA in VL at 0-30, -

50, and -100ms decreased in the submaximal group compared to the failure group ($p < 0.05$). Furthermore, RMA 50ms in RF decreased to Post 24 in the submaximal group compared to the failure group (34.5%, $p < 0.05$).
CONCLUSION: We did not observe any differences between the protocols in the increases of peak muscle activation. RMA was reduced in the submaximal protocol after 17 to 24 days of detraining. Increases in strength after high-frequent low-load BFRRE could be partly explained by neurological factors, however, the increases in peak muscle activation did not peak before 10 (failure) and 24 (submaximal) days of detraining in the present study, which could indicate an overreaching effect. Future research should investigate if a less strenuous BFRRE protocol could be more potent to increase peak muscle activation during high-frequency BFRRE.

NEUROMUSCULAR ADAPTATIONS TO LONG TERM MUSCLE DISUSE IN UNILATERAL TRANSTIBIAL AMPUTEES

SIBLEY, A., STRIKE, S., MOUDY, S., TILLIN, N.

UNIVERSITY OF ROEHAMPTON

INTRODUCTION: Current understanding of the effects of muscle disuse on neuromuscular function is based on short-term (<120 days) intervention studies (Narici & de Boer, 2011). Unilateral transtibial amputees (TTAs) habitually load the quadriceps muscles of their amputated limb considerably less than their intact limb during ambulation (Fey & Neptune, 2012); thus, TTAs provide a useful model for investigating the long-term (>120 days) effects of muscle disuse. This study aimed to compare neuromuscular function and architecture in the quadriceps muscles of the amputated (AMP) vs. intact limb (INT) of TTAs, and in both limbs compared to aged matched-controls (CON).
METHODS: Participants (5 TTAs and 6 aged-matched controls) were recreationally active males. Voluntary maximal and explosive isometric contractions of the knee extensors were performed on an isokinetic dynamometer, to measure maximum voluntary torque (MVT; measures maximum strength) and peak rate of torque development (RTD; measures explosive strength). Electrically evoked involuntary (300 Hz octet) contractions assessed intrinsic contractile properties. Neural activation at MVT was assessed by the interpolated twitch technique (VA), and by EMG amplitude normalised to maximal M-wave (EMG-MVT). Explosive neural activation was also measured by normalised EMG over the first 100 ms of explosive contractions (EMG0-100). Static ultrasound images of the vastus lateralis muscle were captured to measure muscle thickness (MT), pennation angle (θ) and fascicle length (Lf).
RESULTS: AMP had lower MVT (-52%; p=0.034) and RTD (-66%; p=0.047) than INT, whilst INT had lower MVT (-37%; p=0.070) and RTD (-52%; p=0.031) than CON. VA and EMG-MVT were lower (-39%, VA; -44%, EMG-MVT; $p<0.05$), but EMG0-100 similar (p=0.534), in AMP vs. INT, whilst VA, EMG-MVT, and EMG0-100 were all similar for INT vs. CON. AMP showed lower octet peak torque (-64%, p=0.019); absolute (-64%, p=0.002) and relative octet RTD (-26%, p=0.002); Lf (-40%, p=0.022); and MT (-48%, p=0.005) than INT. Peak octet torque was lower in INT vs. CON (-42%; p=0.040), but there were no differences in absolute or relative octet RTD, MT or Lf between these two limbs. All limbs were similar for θ.
CONCLUSION: The declines in strength in the AMP vs. INT limb of TTAs (-52%, MVT; -66% RTD) due to long-term habitual disuse, are considerably greater than typically observed in short-term disuse intervention studies (-23%; Narici & de Boer, 2011); and were coupled with considerable reductions in neural activation, MT, Lf, and a shift towards slower intrinsic contractile properties. Further study with a larger sample size is required to fully understand the mechanisms of the lower strength in the INT vs. CON limbs.

ACUTE EFFECTS OF DIFFERENT EXERCISE MODALITIES ON ANKLE FORCE AND MOTION SENSE

SMAJLA, D., TOMAŽIN, K., STROJNIK, V.

UNIVERSITY OF LJUBLJANA

INTRODUCTION: Different exercise modalities are often performed at the same exercise unit where former activity may influence later one. This information is important for proper planning a sequence of exercise modalities. The purpose of the present study was to determine acute effects of different exercise modalities on ankle force and movement sense.
METHODS: Seventeen participants (23,5±1,9 years, 67,6±11,6 kg, 174±6,8 cm) volunteered the study. Each participant performed familiarization protocol before measurements. After that, each of them visited the laboratory 4 times. Each visit contained measurements before and after intervention protocol. Between measurements, subjects performed randomly selected intervention protocols (static stretching, balance task, strength exercise, no intervention). Intervention protocols were designed to target the ankle joint. In static stretching they performed 6 static stretches for 40 s (each muscle). Balance task contained one leg stance on Airex mat (4x4x20 s), while in strength exercise subject performed plantarflexion and dorsiflexion (30% RM, 25-30 rep.).
Sense of movement was measured in sitting positon on device driven by electromotor in plantarflexion-dorsiflexion direction with velocity of 0,5°/s. Participants pressed hand-held switch when they felt ankle movement. In force sense test, participants were asked to perform isometric contractions (5 s) equivalent to 10% and 30% of the maximal isometric voluntary contraction (plant. and dors. direction). First repetition of each force was performed with visual information, while second was performed without visual information (result: abs. error).
Arithmetic mean and standard deviation were calculated for sense movement angles and absolute errors of force sense test. Samples involved in this study represented abnormal distribution (K-S test), so we used nonparametric methods for examination of stat. differences (Wilc. ranks test). Cronbach alpha was used to determine the reliability of tests.
RESULTS: The results of measurements without intervention indicated good reliability (Cronbach alpha: 0,8-0,96). Acute effects on ankle movement sense were shown after strength exercise (improved sensibility for plantarflexion and dorsiflexion, $p<0,05$) and after static stretching (reduced sensibility for dorsiflexion, $p<0,05$). Balance task did not have influence on ankle movement sense in this case. In force sense tests, there were no statistical significant differences, but there was a tendency for greater absolute errors after static stretching.
CONCLUSION: The main outcomes of the study revealed greater influence of different exercise modalities on ankle movement sense than on force sense. Among exercise modalities representing different neuromuscular activation strategy, strength intervention (activation strategy) improved motion sense while static stretching (damping strategy) reduced it. This should be considered when different consecutive exercise modalities are performed at the same exercise unit.

POPULATIONS OF LONGITUDINALLY TRACKED MOTOR NEURONS INCREASE THEIR DISCHARGE RATE FOLLOWING FOUR WEEKS OF ISOMETRIC STRENGTH TRAINING

DEL VECCHIO, A., CASOLO, A., NEGRO, F., BAZZUCCHI, I., CONTI, A., FELICI, F., FARINA, D.
IMPERIAL COLLEGE LONDON

INTRODUCTION: It has been argued that strength training results in an increase in the neural drive to the muscle (1). However, the specific motor unit adaptations following training remain unknown. In this study we tracked the behavior of large populations of motor units with recent developed techniques (2) following four weeks of isometric strength training by using high-density surface EMG decomposition.
METHODS: Twelve male subjects performed four weeks of isometric ankle-dorsiflexion strength training. Moreover, eleven subjects were recruited as controls. Training involved 30 ballistic contractions (as fast as possible) and 30 gradually increasing contractions up to 75% of maximal voluntary force (MVC) with a plateau of 3 s. The main trial measurements consisted of linearly increasing ramp contractions up to 70% MVC and isometric ballistic force contractions. The steady state phase of the ramp contractions lasted ten seconds. The myoelectrical activity of the tibialis anterior muscle was recorded with one high-density surface EMG grid of 64 electrodes. The EMG signals were decomposed into individual motor unit action potentials. Additionally, the motor unit action potentials were tracked pre- and post-strength training and associated to voluntary force.
RESULTS: The results from the training are from a preliminary cohort of 8 subjects and for the ramp contractions only. The total number of tracked motor units was 312, with an average of 38 ± 16 per subject. The maximal voluntary strength increased significantly following training [pre: 306.4 ± 35.2 to post: 349.2 ± 32.6 (N), $P<0.001$]. The training intervention did not change the absolute force value at which individual motor units were recruited ($P>0.05$), although the recruitment thresholds normalized with respect to MVC decreased (by 7.8 ± 4.2 %MVC on average, $P<0.001$). The motor unit discharge rate at recruitment and de-recruitment did not change ($P<0.05$). On the other hand, the average motor unit discharge rate during the plateau of the ramp contractions increased after training [17.2 ± 1.34 vs 19.9 ± 1.2 (pps), $P<0.001$].
CONCLUSION: Four weeks of isometric ankle-dorsiflexion strength training decreased the recruitment thresholds and increased the discharge rate of motor neurons innervating the tibialis anterior muscle. The present results may be interpreted as an increase in the synaptic input to the motor neuron pool following training.

THE EFFECT OF SHANK ADDITIONAL MASS ON THE MUSCLE RECRUIT CHARACTERISTIC OF LOWER LIMB DURING MAXIMAL SPEED IN SPRINTING

ZHUANG, W., YU, J., LIU, Y.
SPORT PERFORMANCE RESEARCH CENTER

INTRODUCTION: Studies have found that muscle activities, pre-activation and co-contraction may reflect the adjustments made by the nervous system with the changes of conditions (e.g. load). Based on our previous researches, with the increment of running speed, the leading joint at stance phase is distal joint (ankle joint), and change to proximal joint (hip joint) at swing phase. Therefor, adding mass on athlete's shank may train different joint at different phases, which is more targeted than traditional methods. This study aims to investigate the recruit characters of lower limb muscles with this training method.
METHODS: Three-dimension motion capture system (200Hz) and force plate (1000Hz) were used to record the kinematics and kinetics data of 13 elite sprint athletes at their maximum speed in track field. Electromyography of Rectus Femoris, Vastus Medialis, Vastus Lateralis, Biceps Femoris were recorded (4000Hz). Additional mass was 10% and 15% of shank mass. A stride was divided into four phases: braking, propulsion, swing ahead, swing backward. Pre-contact phase was defined as 50ms before contact the ground. One way repeated ANOVA was used to examine the effect of different mass($p<0.05$).
RESULTS: (1) In the pre-contact phase, the Root Mean Square EMG of Rectus Femoris increased which is contrary to the other three muscles. Besides, the co-contraction of hip and knee muscles enhanced during this phase. (2) The activity contribution ratio of Rectus Femoris decreased significantly ($p<0.05$) in the swing ahead phase between without and 10% additional mass conditions. To Biceps Femoris, the activity contribution ratio of propulsion phase increased both in two additional mass conditions ($p<0.05$, $p<0.05$).
CONCLUSION: Nervous system makes corresponding adjustments to the additional mass on shank. It presented as the increment of muscle pre-activity and co-contraction level, the muscle activity contribution under different phase also changes. This resisted-training method may exercise the contraction ability of special muscles for sprint effectively, which turns out will advance athletic performances.

OP-MI02 SOCCER

RELIABILITY, VALIDITY, AND SENSITIVITY OF COMMONLY USED FIELD-BASED FITNESS TESTS IN YOUTH SOCCER PLAYERS

DUGDALE, J.H., ARTHUR, C.A., HUNTER, A.M.
UNIVERSITY OF STIRLING

INTRODUCTION: Identification and development of talented youth athletes is a crucial process in maximising chances for future competitive success (Hulse et al., 2013; Paul and Nassis, 2015). Whilst evaluation of physical capacities through field-based fitness tests in senior players is well established, the effectiveness of this method of testing to evaluate and discriminate within a youth population remains inconclusive (Paul and Nassis, 2015). We aimed to establish test-retest reliability, validity, and sensitivity of commonly used field-based fitness tests in youth soccer players.
METHODS: Three-hundred-and-seventy-three Scottish youth soccer players (U11–U17) from 3 different playing standards (amateur, development, performance) completed a battery of commonly used field-based fitness tests (grip dynamometry, standing broad jump, countermovement vertical jump, 505/T-test change of direction (COD), and 10/20m sprint tests) on two separate occasions within 6–14 days.

RESULTS: The field-based fitness tests selected within this study proved to be reliable measures of physical performance (ICC=.912-.968; p<0.01). However, sprint and COD tests showed weaker reliability in younger participants (ICC=.567-.787; p<0.01) compared to other measures. Moreover, discriminant function analysis revealed that, when controlling for age, the selected testing battery successfully discriminated between 'amateur' (unidentified) and combined-'development' and 'performance' (identified) playing levels; Chi-square (7) = 101.646, p<0.01. Inspection of the canonical correlation coefficients revealed that standing broad jump (r=.754) and 505 COD (r=.541) performance were the strongest contributors to the discriminant function, with the canonical correlations from the other tests all being <.4. All tests were sensitive to performance improvements resultant of chronological age progression, except from between U11/U12 and U15-U17 age groups.
CONCLUSION: Results from this study promote the use of field-based fitness tests as reliable measures of physical performance in youth soccer players. However, COD tests may be less suitable for younger players, potentially due to the lack of familiarity of the movements required and the limited training age established by these players. Whilst the testing battery selected in this study was able to discriminate between 'identified' and 'unidentified' players, the strongest and therefore best tests for discriminating were the standing broad jump and 505 COD tests, with the other tests being less influential. Future research should further investigate jump and COD components of field-based fitness testing batteries as a means of more explicitly differentiating between competitive playing standards.

STRENGTH DEVELOPMENT OF HAMSTRING AND QUADRICEPS MUSCLES IN HIGH LEVEL YOUTH SOCCER PLAYERS

ROTH, R.
UNIVERSITÄT BASEL

INTRODUCTION: Appropriately developed lower leg strength is a relevant prerequisite for high level soccer players, both from a performance as well as from an injury prevention perspective. Particularly the thigh muscles are considered most relevant in this regard. Isokinetic assessment of leg flexor (hamstrings) and extensor (quadriceps) muscles is frequently applied in order to identify imbalances between agonists and antagonists as well as between limbs (standing vs. kicking leg) (Kyritsis et al., 2016). A deeper understanding of the development of thigh strength and asymmetries from late puberty to full maturation may support fitness staff in soccer academies to prepare their talented players for the upcoming demands. Therefore, the aim of this cross-sectional study was to analyze the isometric and isokinetic strength of hamstring and quadriceps muscles in elite-level youth soccer players.
METHODS: 102 male soccer players of the same professional club (under-15: N=18; age=14.7 (SD 0.3) years; body mass=54.7 (9.1) kg; under-16: N=23; age=15.5 (SD 0.7) years; body mass=63.6 (6.6) kg; under-17: N=19; age=16.6 (SD 0.3) years; body mass=67.7 (7.3) kg; under-18: N=22; age=18.0 (1.12) y; body mass=71.7 (7.3) kg; under-21: N=21; age=18.7 (0.8) y; body mass=68.7 (6.6) kg;) agreed to take part in a cross sectional study. Strength of hamstrings (H) and quadriceps (Q) were measured on an isokinetic device (IsoMed 2000) at a speed of 60°/s, 240°/s (concentric) and -30°/s (eccentric) (Croisier et al., 2003) and in an isometric condition at 60° knee angle. H:Q-ratios were calculated for both dominant (kicking leg) and non-dominant (standing leg) at 60°, 240° and the functional ratio (-30°/240°). Magnitude-based inferences were calculated for differences between the dominant and the non-dominant leg.
RESULTS: Isokinetic and isometric hamstring and quadriceps strength increased with the age of players. No relevant differences occurred between the kicking and the standing leg for quadriceps strength at all team levels and in all testing conditions (most likely trivial, -0.18
CONCLUSION: Our results show that an unequal development in physical strength values over age categories can occur in young high-level soccer players with older players showing smaller differences H:Q-ratios between legs. Regular assessment and corresponding strength training regimes may contribute to decrease strength asymmetries and, thereby, to prevent injuries and to prepare the players regarding muscular loads associated with elite soccer.

LET THE KIDS #PLAYMORE: EVALUATION OF A NEW MATCH FORMAT IN U-11 SOCCER TO INCREASE THE INDIVIDUAL PLAYING TIME AND GAME INVOLVEMENT

HINTERMANN M.
SWISS FEDERAL INSTITUTE OF SPORT, MAGGLINGEN

INTRODUCTION: To improve soccer specific skill acquisition the match play in children's soccer should be designed to maximize the individual playing time and game involvement. Small-sided games showed an increased individual playing time, individual game involvement, number of ball contacts, variability and frequency of game situations, and positional changes (Buszard et al., 2016, J Sports Med). Playing on a larger pitch however showed increased position specific demands, movement patterns in width and depth and number of long passes (Katis & Kellis, 2009, J Sports Sci Med; Silva et al., 2014, J Hum Kin). Therefore, the aim of the study was to evaluate a new match format combining games with a smaller number of players and pitch size (COMBINED 4 vs. 4 and 7 vs. 7) with the traditional 7 vs. 7 match format on the regular pitch size for U-11 soccer players (TRAD).
METHODS: Four teams with a total of 45 young male soccer players (age: 9.9±0.5) completed both match formats on two separated days. The pitch size was adapted according to the number of players involved. The TRAD match play was performed for 3 x 20min on the regular pitch size. The COMBINED match play involved 4 x 8min with 4 vs. 4 players (pitch size: 20m x 30m) followed by 3 x 15min with 7 vs. 7 players with regular pitch size (44.5m x 30m). Local positioning data were collected for the total distance covered, high-intensity distance, and acceleration. To examine technical actions the matches were video captured and subsequently analyzed for the number of ball contacts, passes, goals, shots on goal, and duels. All data were analyzed with a pairwise comparison using SPSS.
RESULTS: The number of ball contacts were significantly higher in COMBINED compared to the TRAD (3.05 ±1.58 vs. 1.89±0.63 per player/min, respectively; P<0.001). There were similar results regarding duels (0.29±0.18 vs. 0.17±0.11 per player/min; P<0.001) and passes (0.89±0.42 vs. 0.65±0.20 per player/min). From significantly more shots on the goal (0.15±0.11 vs. 0.06±0.06 per player/min), followed a four times higher chance to score in COMBINED compared to TRAD (0.04±0.05 vs. 0.01±0.01 per player/min; P<0.001). The high-intensity distance covered was significantly reduced with the COMBINED compared to TRAD (7.43±3.79 vs. 12.34±4.71 m, respectively; P<0.001). Also the total distance covered was lower with the new COMBINED match format (83.84±13.86 vs. 90.99±19.09 m; P<0.01).
CONCLUSION: The new match format combining matches with 4 vs. 4 and 7 vs. 7 players improved the variability, frequency of game situations and individual playing time by increasing the number of ball contacts, duels, and shots on the goal per player. However, high-intensity distance and total distance covered were reduced. The new COMBINED game format might be beneficial for the players' technical skill development. However future research needs to investigate the long term effects and the impact of the new match format on the training practice.

EFFECTS OF TABATA TRAINING MODEL ON SPRINT PERFORMANCE OF ADOLESCENT SOCCER PLAYERS

BAYRAM, I., AKDOGAN, E., CERRAH, A.O.

ANADOLU UNIVERSITY

INTRODUCTION: High Intensity Interval Training (HIT) has been widely used by the coaches for many years. Remarkable well-documented data is available related the physiological adaptations responsible for both aerobic and anaerobic performance. In contrast, little is known concerning the effects of HIT on field tests, especially sprint performance. In this regard, the aim of this study was to investigate the effects of HIT on 10m, 20m, 30m and repeated sprint performance of adolescent soccer players.
METHODS: 20 healthy soccer players participated in the study and randomly assigned as Training Group [TG (age:16.90±0.74 years, weight:61.80±8.97 kg height: 1.71±0.06 cm)] and Control Group [CG (age:17.10±0.74 years, weight:60.88±8.39 kg height: 1.73±0.06 cm)]. While CG (n=10) followed the regular soccer training (3 days a week), the TG (n=10) performed a gradually increasing Tabata training program after the regular training. Electronic timing gates (Smart Speed; Fusion Sport Pty, Ltd, Brisbane, Queensland, Australia) were used to evaluate 10m, 20m, 30m and repeated sprint performance of adolescent soccer players before and after the training period.
RESULTS: The data showed a normal distribution for all the parameters of pre and posttest. Independent Sample T Test results for pretest between TG and CG showed that there were no statistical differences for 10m (p=.927), 20m (p=.706), 30m (p=.763) and repeated sprint tests (p=.770) which means groups were distributed equally. There were also no statistical differences for 10m (p=.961), 20m (p=.427), 30m (p=.946) and repeated sprint tests (p=.473) for post test results. Applying a Paired Sample T Test, pre and post test results have been calculated within groups. Comparison of pre and post test results of CG showed that there were no statistical differences for 10m (p=.332), 20m (p=.309), 30m (p=.231) and repeated sprint tests (p=.462). Unlikely, comparison of pre and post test results of TG showed statistical differences for 10m (p=.044) and 30m (p=.007), but not for 20m (p=.775) and repeated sprint tests (p=.672). Statistical significance was taken as $p<0.05$ in all test.
CONCLUSION: Both TG and CG improved their 10m, 20m and 30m sprint performances with different amounts. It seems only 10m (p=.044) and 30m (p=.007) performance of the TG was statistically significant. Therefore, we conclude that Tabata training-induced positive outcomes are effective on 10m and 30m sprint performance. Interestingly, we observed that repeated sprint performance of both TG and CG groups were worse at the posttests. The reason for that might be the existing stress on the players because of the ongoing competition period. For better results, Tabata exercises should be applied for longer periods (i.e. 8 weeks, 12 weeks) and maybe out of season, also tested by using other field performance tests such as vertical jump, agility and/or Yo-Yo IR1 test.

REPRODUCIBILITY OF EXTERNAL LOAD OF UNDER-19 SOCCER PLAYERS IN A MEDIUM-SIDED GAME

CLEMENTE, F.M.1,2, RABBANI, A.3, KARGARFARD, M.3, PINTO, N.4

1IPVC, ESDL , 2INSTITUTO DE TELECOMUNICAÇÕES , 3FSS, UI , 4CDN

INTRODUCTION: Variability of physical stimulation should be a concern during sided-games. The purpose of this study was to examine the reproducibility of the performance variables during 5vs.5 with small goal, when completed within the same session and between two different sessions
METHODS: Ten field under-19 male soccer players (18.27±0.47 yo; 71.42±6.89 kg; 177.78±5.63 cm) participated in this study. The 5x5 was played twice with a 3-day interval in the same week. The 5x5 was played in a pitch of 30x30 m with a small goal in the middle of the ending line. The regimen of the sided-game was 3x5 minutes/2 minutes of rest. The games were played in the same natural turf, with temperatures of 14-16 C° and relative humidity of 60-70%. The variables of total distance (TD), running distance (RD; 14.0-20.0 km/h), and player load (PL) were monitored with GPS units (10 Hz, JOHAN Sports).
RESULTS: Moderate between-session variations were observed for TD (range, Coefficient of variation CV, 6.9; 8.3%, Confidence interval CI, [5.0; 14.0], standardized typical error, STE, 0.68; 1.06, [0.64; 1.75]) and RD (range CV, 53.3; 145.7%, [36.6; 338.9], STE, 0.83; 1.09, [0.60; 1.76]) for all three sets and their accumulated values. However, PL showed small variations (range CV, 4.9; 6.0%, [3.6; 10.1], STE, 0.37; 0.43, [0.27; 0.71]) in all sets and accumulated values as the most reliable measure. In within-session analyses for examining differences between sets, a small decrease was observed in RD in set 3 versus set 2 (-14.8%, 90%CI [-32.1; 6.9%]; standardized difference ES: -0.39[-0.95; 0.16]). TD decreased with moderate (-3.5%, [-6.8; -0.1%]; ES: -0.65[-1.30; -0.01]) and large (-8.2%, [-11.4; -4.9%]; ES: -1.58[-2.24; -0.92]) effects in set 2 and 3 versus set 1, respectively. A moderate decrease was also observed in set 3 versus set 2 for TD (-4.9%, [-8.1; -1.5%]; ES: -0.93[-1.58; -0.29]). PL decreased with small (-3.5%, [-5.2; -1.8%]; ES: -0.24[-0.36; -0.12]) and moderate (-10.6%, [-14.3; -6.6%]; ES: -0.76[-1.06; -0.47]) effects in set 2 and 3 versus set 1, respectively. A small decrease was also observed in set 3 versus set 2 for PL (-7.3%, [-10.9; -3.6%]; ES: -0.52[-0.79; -0.25]).
CONCLUSION: PL is the more reproducible variable. Coaches can be confident in to use 5x5 to apply a consistent training load. However, must be aware of greater noise that may occur in specific variables associated with running intensity, thus some conditions should be used in sided-games to ensure a more stable demanding. Regarding the variation of performance variables between sets it was verified a progressive decreasing tendency on the results. Coaches must consider to rethinking the recovery strategies or the training regimen to ensure a more stable performance across the sets.

ASSESSMENT OF FOURTEEN PLAYER TRACKING SYSTEMS FOR CONCURRENT VALIDITY AGAINST A COMPUTER VISION SYSTEM IN ECOLOGICALLY VALID MATCHES IN A LARGE STADIUM (FIFA EPTS).

AUGHEY, R.J., BALL, K.A., DUTHIE, G.D., ELLENS, S., SERPIELLO, F.R., VARLEY, M.C., ROBERTSON, S.J., EVANS, N.

VICTORIA UNIVERSITY

INTRODUCTION: We were contracted by FIFA to establish the concurrent validity of fourteen commercially available athlete tracking systems consisting of global, local and optical tracking systems, during friendly matches played at an international stadium. The tracking systems were compared to a bespoke computer vision system, itself previously validated by us against VICON at the same stadium used here.
METHODS: Following ethical approval, 28 teams competed in a total of 17 matches over a 10-d period. In each of fourteen matches, player position and movement data was simultaneously obtained from one athlete tracking system and compared to computer vision. Validity was established via the root mean square error (RMSE) and mean bias for instantaneous velocity, velocity in selected velocity bands, and derived mean acceleration.
RESULTS: A small number of manufacturers achieved satisfactory concurrent validity against computer vision for instantaneous velocity (RMSE <0.5 m.s-1), six systems were marginal (RMSE >0.5 but <1.5 m.s-1) and four had poor validity (RMSE > 1.5 m.s-1). As player velocity increased, concurrent validity decreased as expected. No systems obtained satisfactory concurrent validity against computer vision for mean acceleration.
CONCLUSION: The data presented here is unique as an ecologically valid comparison of many manufacturers against a validated system during matchplay in a challenging but controlled stadium environment. Local and global positioning systems performed best, but no system was able to be concurrently validated across all parameters tested.

USING A HEART RATE MONITORS IN THE WATER, IS IT RELIABLE?

THIEL, D.1, SYKORA, K.2, NEMECEK, V.2

1, 2 FACULTY OF PHYSICAL EDUCATION, CHARLES UNIVERSITY, PRAGUE

INTRODUCTION: Heart rate monitors (HRM) are commonly used tool for monitoring physiological response to exercise also in the swimming. HRM are used to estimate exercise intensity based on a percentage of the individual maximum heart rate (HRmax). Correct estimation of HRmax is crucial for the assessment of the proper training zone. Heart rate (HR) can be influenced by environment temperature, humidity, daytime and also body surrounding environment including water. Previous studies (Kruel, 1994; Onodera, 2010; Fujishima et al., 2001) have shown different HR response related to water condition. HRM companies do not provide information about the readjustment of HR in the water. Purpose of this study is to examine the influence of the water environment on the resting heart rate.
METHODS: This is a quantitative study conducted by comparing the values of heart on the land and in the water of 34 athletes with experiences from water sports and swimming (age 23.7 ± 1.8 years). Heart rate was measured for five minutes in the static position on the back (water = 26 cm, water temperature 30.4 ± 0.2° C, air temperature 23.4 ± 0.4° C). Parametric unpaired Student t-test has been used for calculation of statistical significance have (p = .05). The threshold for estimation of the practical significance of heart rate variance has been established at ±3 beats per minute.
RESULTS: Results of parametric unpaired Student t-test did not indicate a statistically significant difference of resting heart rate in the water and on the land (p = .080-.925). Heart rate decreased at least 3 beats per minute in ten people, increased at least 3 beats per minute in seven people, or stayed in the range of ±3 beats per minute in 13 people.
CONCLUSION: Estimation of HR training zone is influenced by the accuracy of HRmax estimation. Both HR and HRmax can be affected by exercise environment. Our study has shown that the body water immersion has not influenced resting HR. It is necessary to realize that HR dynamic can be changed by the exercise intensity in the water. Providing information about adjustment of HR in the water could be used for accuracy using.

A VIRTUAL REALITY BASED PITCHSIDE BALANCE ASSESSMENT FOR CONCUSSION

GREY, M.J., WILKINSON, M.R.

UNIVERSITY OF EAST ANGLIA

INTRODUCTION: Current guidelines require athletes to be removed from competition or practice on suspicion of concussion. Standard concussion assessments rely primarily on self-reporting of symptoms in combination with neurocognitive evaluation. Balance dysfunction has been recognised as one of the few non-cognitive markers of concussion. However, current balance procedures are expensive and laboratory-constrained or inexpensive, but subjective. We have recently developed an inexpensive tool to assess balance using the Oculus Rift Virtual Reality (VR) headset to induce a visual perturbation and a Wii Balance Board (WBB) to measure the balance response. The objective of the study was to quantify the balance response as a function of speed and axis of rotation of the visual perturbation.
METHODS: Sixty participants were recruited to the study (37F, 23M, age: 19.5 ± 1.3y). Participants were exposed to a virtual environment resembling an office with a large white board central to their field of view. To focus their attention, participants were asked to complete a stroop test using the names of colours displayed on the white board. After a few seconds, the virtual environment was rotated by 22.5 deg about the roll or pitch axes, at one of four speeds between 4.5-11.25 deg/s). The visual perturbation produced a balance response

that was quantified by analysis of the centre of pressure (CoP) comparing the path length of the response before and after the perturbation.
RESULTS: The visual perturbation produced an effective balance perturbation that could be adequately quantified by the CoP data recorded with the WBB, with balance affected up to 12s after the perturbation. Two-way repeated measures ANOVA revealed a significant effect of perturbation speed ($p<0.001$, $F2.8, 80.3= 17.453$, $\eta p2 =.376$), and rotation axis ($p< 0.001$, $F2.87 = 17.605$, $\eta p2 =.288$) with post-hoc analysis revealing a much greater effect for perturbations about the roll axis compared with the pitch axis ($p<0.001$).
CONCLUSION: Manipulating axis and speed of perturbation significantly affected the CoP response. This study confirms that the VR-WBB prototype is an effective system to induce a perturbation and obtain quantifiable balance responses. With further refinement, this tool will be a useful addition to the pitchside assessment of concussion.

RELIABILITY OF BODY SHAPE CHANGES IN MULTIPLE TEST SESSIONS BY A SIMPLIFIED THREE-DIMENSIONAL SCANNING SYSTEM

CHIU, C.Y., SANDERS, R.H.2

1: SHEFFIELD HALLAM UNIVERSITY, 2: THE UNIVERSITY OF SYDNEY

INTRODUCTION: Monitoring anthropometric changes of athletes enables assessment of the effect of training (Kerr, Ackland, & Schreiner, 1995). Recently, many companies have produced simplified 3D scanning systems which enable measurement of anthropometric data rapidly and automatically. The repeated reliability and accuracy of the simplified 3D scanning system has been determined by comparing with traditional manual measurement (Bourgeois et al., 2017). The previous research has been limited to determining the reliability by conducting the 3D scanning repeatedly in only one test session. However, the participants' postures and protocols relating to breathing may vary across test sessions. The purpose of this study was to examine the inter-session reliability of measuring changes in waist girth measurements using a simplified 3D scanning system.
METHODS: Traditional manual measurement and 3D scanning techniques were used to obtained anthropometric data from 58 Year 7 male participants in two test sessions. The time between the first test session and second test session was around 12 weeks. The differences of waist girths between the first and second test sessions acquired from the traditional manual measurement were compared to the differences obtained from the 3D scanning system by using pair sample t-Test, intra-class correlation coefficient and root mean square error.
RESULTS: There is no significant difference between the changes of waist girths acquired from the traditional manual measurement and the changes obtained from the simplified 3D scanning system (p-value > 0.05). Therefore, the simplified 3D scanning system could be used to understand the body shape change for a group of athletes. The intra-class coefficient showed 'fair' agreement (0.48) and the root mean square error between the changes of traditional manual measurement and the ones of the simplified 3D scanning system was considerably large (2.51 cm).
CONCLUSION: The results showed that further development is required to minimize the effect of participants' postures and breathing conditions in multiple test sessions before tracking individual body shape changes by this kind of 3D scanning system.

ROW YOUR BEAT: THE DEVELOPMENT OF AN INNOVATIVE AUDITORY FEEDBACK PLATFORM FOR ROWING PERFORMANCE

LINTMEIJER, L.L., HUIBERTS, S.C., HOFMIJSTER, M.J., BEEK, P.J.

VRIJE UNIVERSITEIT AMSTERDAM IN COLLABORATION WITH THE HKU UNIVERSITY OF THE ARTS UTRECHT - MUSIC AND TECHNOLOGY

INTRODUCTION: Rowing performance (i.e. the average shell velocity) can be analysed in terms of a power equation describing what part of a rower's mechanical power output contributes to shell velocity and what is lost to other factors [1] . To optimize performance, valid quantitative feedback can now be provided on parameters related to this equation [2,3]. However, this digital feedback is less effective to alter time-dependent coordinated movement patterns such as crew synchronization and rhythm of the boat, both of which are considered important determinants of rowing performance [4].
Auditory feedback improves performance and acquisition of temporal aspects more effectively than visual feedback and may therefore preferred when seeking to enhance synchronisation and rhythm in rowing. Previous studies have transformed the boat acceleration signal into sonified form in order to improve the rowing rhythm [5,6], but the resulting audible sine wave was often experienced by rowers as annoying and distracting. In this project we aimed to develop auditory feedback on boat motion and rythm in a manner that is experienced as comfortable and motivational to listen at and act upon.
METHODS: We developed an Android platform that connects rowing data to Audiokinetic Wwise SoundBanks. Via a machine learning algorithm the boat acceleration signal is used to detect the start of the stroke cycles. During the drive phase the acceleration signal triggers a transparent yet forceful sound to indicate boat movement. The drive-recovery rhythm is indicated via drum patterns in the rhythm of the current stroke being based on the average rhythm of the three previous strokes. In other words, an integrated feedback and feedforward loop simultaneously prescribes the rhythm of the boat while being dependent on the movements of the rowers. After the app was found to be stable and functional, we examined the experiential feel of training with this auditory feedback in a pilot study involving 4 first year rowers.
RESULTS: The rowers experienced the feedback as motivational and helpful. They indicated that the feedback aided them in keeping a constant rhythm and that is was easier to synchronize rowing movements.
CONCLUSION: In this project we developed auditory feedback that was found pleasant and motivating to use in a small sample of relatively inexperienced rowers. Although we did not yet formally test the effect of the feedback on rowing performance and crew synchronization, both the qualitative results as well as some preliminary obtained data indicated that the feedback altered crew synchronization. Experiments are planned to test these promising initial findings.

PROCESSING ACCELEROMETER DATA OF CHILDREN AND ADOLESCENTS - INFLUENCE OF WEAR TIME ALGORITHM, EPOCH LENGTH AND CUT-OFF POINTS ON AGE SPECIFIC SUBGROUPS

ANEDDA, B., ALBRECHT, C., BURCHARTZ, A., ORIWOL, D., SCHMIDT, S., WOLL, A.

KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: In order to determine physical activity (PA) in free-living conditions the most common used objective method is accelerometry. Large-scale epidemiologic studies frequently use "counts" derived from the ActiGraph device to classify PA. The PA outcome is influenced by different parameters set during data collection and data processing. The aim of this study was to analyse the effect of epoch length (EL), wear time (WT) algorithm and cut-off points (CP) on PA outcome for age specific subgroups within the sample of the Motorik-Modul-Study (MoMo) (Woll et al., 2017).
METHODS: 1,848 children and adolescents between the age of 6 and 17 (N(male) = 901, N(female)=947) wore either ActiGraph GT3x+ or ActiGraph wGT3X-BT as part of the examination throughout the nationwide MoMo survey "Wave 2" (2014-2017). The participants wore the device during all waking hours on 8 consecutive days. The device was placed laterally at the hip and data was sampled with a frequency of 30Hz. Afterwards data was downloaded and converted into one second epochs using ActiLife. Further data processing was done in MATLAB. Data was reintegrated into 5, 15 and 60 second epochs and Troiano (Troiano et al., 2008) and Choi (Choi et al., 2011) WT algorithms were applied. PA outcome was determined using different CPs commonly used for the specific age groups (Evenson et al., 2008, Freedson et al., 2005, Hänggi et al., 2013, Romanzini et al., 2014).
RESULTS: In contrast to the results found in existing literature the MoMo data shows no effect of EL on activity count outcome. Data shows that EL does affect total WT when using the Troiano algorithm but does not affect total WT when using the Choi algorithm. Applying 8h-WT-criterion leads to 13% more valid data sets than 10h-WT-criterion. EL and CP have a significant effect on PA classification leading to differences in the prevalence of adherence to the PA recommendations by the WHO of up to 50% for certain age groups.
CONCLUSION: The discrepancy between results from this study and existing literature (Logan et al., 2016) on the effect of EL on activity count outcome could be due to the calculation of the Vector Magnitude (VM) when integrating data. Choi WT algorithm should be preferably used over Troiano algorithm when data is reintegrated and compared to different ELs. The choice of EL, WT and CP influences PA outcome significantly and have to be carefully investigated before reporting population-based results.

OP-BN24 Low back pain

WHOLE-BODY ELECTROMYOSTIMULATION (WB-EMS) TRAINING IN PATIENTS WITH CHRONIC UNSPECIFIC BACK PAIN

KONRAD, K., BAEYENS, J.P., RANKER, A., WIDMANN, J., JANSSON, V., WEGENER, B.

VRIJE UNIVERSITEIT BRUSSEL ; LUDWIG-MAIXIMILIANS-UNIVERSITÄT MÜNCHEN

INTRODUCTION: The preferred intervention for treating patients with chronic nonspecific back pain, according to the German National Care Guideline, is active exercise and to establish regular exercise in daily life. The lifestyle of patients with chronic nonspecific back pain mostly does not include any sports. They also often suffer from limitations of their mobility due to degenerative diseases of further joints. Therefore, there is an urgent need to help physical passive people to enable them to exercise easier. The use of Electromyostimulation (EMS) in order to train specific muscles has been established in physiotherapy for decades. Within fitness industry, supported training by WB-EMS is becoming increasingly popular. Therefore, applying this kind of training seems logical in patients with chronic unspecific back pain.
METHODS: In an ongoing prospective clinical trial, 49 patients with chronic nonspecific back pain have been enrolled for WB-EMS training. The average age is 53.7 years (27-85 years). The first evaluation takes place after 3 months. The training is carried out according to the usual recommendations in fitness training once a week for 20 minutes under the guidance of a trained physiotherapist. The core muscles are trained, upper and lower limbs.
RESULTS: The pain sensation averages on the Numeric Rating Scale (NRS; 1-10) improved significantly by 1.198 (from 4.66 to 3.46, $p < 0.05$). The Ostwestry Disability Index (ODI) improved significantly, resulting in a significant 3.37% reduction in disability ($p < 0.05$). The NASS also achieved a significant improvement of 0.51 points ($p < 0.05$). The pain value of the SF 36 questionnaire improved by 8.88 ($p < 0.05$). The other SF-36 parameters also tended to improve without reaching significance levels. In the point "limitations due to emotional problems", no improvement could be achieved. In the HADS score, improvements could be found for depression and anxiety, but these changes were also not significant.
CONCLUSION: By training with WB-EMS, all the back and pain parameters in the examined scores could be improved. It is thus an efficient training tool for people with chronic nonspecific back pain. In the further course of the study, the long-term effect will be evaluated by extending the training period. A comparison group with a traditional physiotherapy program will show the efficiency compared to a physiotherapeutic therapy concept.

LOW BACK PAIN IN ROWERS: PAIN INTENSITY, DISABILITY AND RISK FACTORS

TROMPETER, K., FETT, D., PLATEN, P.
RUHR-UNIVERSITY BOCHUM

INTRODUCTION: Back pain (BP) is one of the most often occuring complaints among athletes. Many studies have shown that in some sports athletes seem to have a higher risk for developing BP as compared to athletes from other sports. One of the highest BP prevalence among all sports was identified to be in rowers in a systematic review by Trompeter et al. [1]. Currently, there is no information of the prevalence of BP in German rowers. Therefore we aimed to establish the prevalence of BP in German rowers compared with a non-rowing control group, and to determine pain intensity and disability. Additionally to evaluated different risk factors that might be responsible for BP.
METHODS: A standardized and validated online BP questionnaire (Nordic questionnaire [2] and the questionnaire for grading the severity of chronic pain [3]) was sent to 351 elite rowers, 150 non-elite rowers, and to a control group of 253 physically active but non-elite sports students. Additionally a self-developed questionnaire focusing different aspects of training and competition was used to evaluate the athletic workloads.
RESULTS: Responses from 156 rowers (104 elite and 52 non-elite) and 166 controls were received. BP prevalence and severity were significantly higher among rowers compared with controls ($p<0.05$). The lower back was the main location of BP in rowers and in controls. Age, sex, and training volume influenced the prevalence of BP. Rowing kinematics, strength, and ergometer training were the main associated risk factors for BP in rowers. Elite and non-elite rowers did not significantly differ in BP prevalence.
CONCLUSION: Our findings indicate that BP is a common complaint in German rowers. Rowing kinematics, strength, and ergometer training were the main associated risk factors for developing BP in rowers. Thus, the spinal load due to rowing kinematics and different types of training should be investigated in future studies. Additionally, training should be monitored by experienced coaches to prevent BP due to technical mistakes or too-heavy loads. The results of this investigation underline the necessity of BP prevention and intervention programs in addition to the discipline specific training units.

MUSCLE ACTIVATION, PAIN AND EXERTION IN PEOPLE WITH AND WITHOUT LOW BACK PAIN DURING AQUATIC AND LAND EXERCISES

PSYCHARAKIS, S., COLEMAN, S., LINTON, L., KALIARNTAS, K., VALENTIN, S.
THE UNIVERSITY OF EDINBURGH

INTRODUCTION: Chronic low back pain (CLBP) is the most prevalent musculoskeletal disorder. Exercise has been shown to be beneficial in reducing pain and improving quality of life, and aquatic exercise is often used for the treatment and management of CLBP. Nevertheless, information on the appropriateness of aquatic exercises targeting trunk supporting muscles is lacking, in particular for people with CLBP. Thus, exercise selection is often arbitrary or based on anecdotal evidence. The aim of this study was to quantify the activation of the main trunk supporting muscles for people with and without CLBP when performing aquatic and land exercises commonly used in rehabilitation programmes.
METHODS: A wireless and waterproof electromyography system was used to measure muscle activation for 20 people with CLBP and 20 healthy participants. The participants performed 15 exercises in the water that focus on trunk stabilisation with upper or lower limb loading and are commonly used for LBP rehabilitation. A set of similar exercises was used on land. Mean and peak muscle activation was measured for seven trunk supporting muscles on each side of the body (14 in total). Other outcome measures included, pain (VAS), perceived exertion (RPE) and intensity (heart rate).
RESULTS: There were almost no differences in muscle activation, exercise intensity and perceived exertion between the CLBP and control groups. Between-environment differences were found in heart rate (always higher on land). Muscle activation and perceived exertion in the water were at least equal to that on land in about two thirds of the cases. Pain level had a non-significant trend for lower values in the water, while pain occurrence more than doubled when exercising on land (3.7% Vs 7.8%).
CONCLUSION: Aquatic exercise provided sufficient muscle activation and exertion, and had considerably lower occurrence of pain. This suggests that exercise in the water may be beneficial and more appropriate than exercise on land for CLBP, especially for people at early stages of rehabilitation or with higher levels of disability.

OP-PM41 Nitrate

EFFECTS OF BEETROOT JUICE SUPPLEMENTATION ON OXYGEN UPTAKES SLOW COMPONENT AND EFFICIENCY/ECONOMY

PALAU-SALVÁ, G.1, DOMÍNGUEZ, R.2, SERRA-PAYÁ, N.1, GOMIS, M.1, SAMATIER, B.1, GUIRAO, L.1, PLEGUEZUELOS, Z.1, VILCHES-SÁEZ, S.1, MATÉ-MUÑOZ, J.L.2. GARNACHO-CASTAÑO, M.V.1
TECNOCAMPUS

INTRODUCTION: Beetroot juice (BJ) is classified as a high-level supplement for improving sports performance (AIS, 2016). However, there is some controversy over the benefits of BJ supplementation for endurance exercise performance, especially when referring to highly-trained athletes. The objective of the present study was to assess the effects of BJ on oxygen uptakes slow component (VO2sc), gross mechanical efficiency (GME), and metabolic variables (lactate, energy consumption, carbohydrate and fat oxidation) in a test executed at a constant work intensity in watts (W) corresponding to first ventilator threshold (VT1) and second ventilator threshold (VT2).

METHODS: 10 well-trained, male triathletes (aged 38.5 ± 8.5 years) were assigned in a randomized, double-blind, crossover design to receive 70 ml of BJ (6.5 mmol NO3-) or placebo (PL). Three hours after taking the supplement (BJ or PL), participants completed a 50 min test on a cycle ergometer first at a constant work rate corresponding to VT1 (30 min) and then (without rest) at a constant work rate set at VT2 (20 min). A two-way ANOVA with repeated measures, supplement * intensity, was used to compare the effects of BJ vs. PL.
RESULTS: No significant interaction effect (supplement*intensity) was observed on VO2sc, GME, lactate, energy expenditure, or carbohydrate and fat oxidation ($p > 0.05$). Although no significant differences emerged between BJ and PL in time to completion of VT2 and VT1+VT2, BJ supplementation did lead to a longer time to VT2 completion (approximately 1 min).
CONCLUSION: This study was designed to test the efficacy of BJ at improving performance during aerobic energy metabolism (VT1) and during the transition from aerobic to anaerobic metabolism (VT2). As in previous findings, acute BJ supplementation was not observed to improve GME (Bescos et al., 2011), use of energy substrates or performance in triathletes. Changes in exercise intensity from VT1 to VT2 involve variations in VO2, leading to the use of different substrates. GME calculations include possible respiratory exchange ratio (RER) changes and, therefore, take into account substrate use. Neither did BJ seem to induce more efficient substrate use as reflected by our data for GME and energy expended. Furthermore, GME calculations were targeted at assessing the effects of blood alkalization on gradual losses in muscle efficiency as the best indicator of the so-called VO2sc phenomenon (Gasser and Poole, 1996). BJ supplementation did not improve the behavior of VO2 kinetics.
In conclusion, the slight changes detected in performance variables such as test duration in several studies prompts numerous questions as the mechanical and physiological mechanisms analyzed so far do not support these improvements and remain poorly understood.

THE INFLUENCE OF EQUIMOLAR NITRATE DOSES FROM BEETROOT JUICE AND SODIUM NITRATE ON UPPER AND LOWER BODY EXERCISE

FLUECK, J.L., GALLO, A., BRACHER, P., PERRET, C.

SWISS PARAPLEGIC CENTRE

INTRODUCTION: Beetroot juice (BR) and sodium nitrate (NIT) have been shown to enhance performance in recreationally trained men (Hoon et al. 2013). In addition, it was found, that nitrate reduces oxygen consumption (VO2) during exercise. A recent study revealed, that BR might be more beneficial compared to NIT in terms of VO2 during severe exercise intensity (Flueck et al. 2016). However, it is unclear, whether such benefit might be present as well when it comes to time trial (TT) performance. Therefore, the aim of this study was to investigate, whether BR or NIT enhance performance in upper and lower body exercise and whether one of these supplements is more beneficial than the other one.
METHODS: In total, 29 recreationally active men participated in this study. Fourteen upper body trained men (mean ± SD; age: 28 ± 7y, height: 183 ± 5cm, body weight: 82 ± 9kg, VO2peak: 33.9 ± 4.2ml/min/kg) performed a 10km handcycling (HC) TT and 15 leg trained men (age: 31 ± 8y, height: 182 ± 7cm, body weight: 76 ± 7kg, VO2peak: 59.1 ± 5.2ml/min/kg) performed a 16km TT on their bicycle (CYC). Each subject visited the laboratory on four different occasions. On the first day, they performed a maximal performance test to determine VO2peak and a familiarization TT. On the other 3 occasions, they ingested either 6mmol BR, 6mmol NIT or water as a placebo (PLC). Three hours after the ingestion the TT was performed. Blood samples were taken before and 3h post-ingestion for [NO3-] and [NO2-] analysis.
RESULTS: No significant difference in time-to-complete the TT between the 3 interventions BR, NIT and PLC in either HC ($p=0.61$) nor CYC ($p=0.11$) was found. Both exercise types showed a significantly higher power output to VO2 ratio in the BR trial compared to NIT and PLC (HC: $p=0.041$; CYC: $p=0.034$). No significant differences were seen between the 3 interventions in both exercise types for heart rate, end lactate concentration, VO2 and rated perceived exertion during exercise ($p>0.05$>. Plasma [NO3-] and [NO2-] concentrations significantly increased in NIT and BR from pre to post ingestion in all subjects ($p>0.05$) with no difference between BR and NIT 3h after ingestion ($p>0.05$).
CONCLUSION: This study showed no significant improvement in HC and CYC TT performance in recreationally active men after BR or NIT ingestion. In terms of performance, BR seems not to excel NIT but the power output to VO2 ratio seems to be higher for BR compared to PLC and NIT. The influence of dietary nitrate on upper body exercise needs to be further investigated.

DIETARY NITRATE SUPPLEMENTATION DOES NOT IMPROVE TOLERANCE TO SUPRAMAXIMAL INTENSITY INTERMITTENT EXERCISE IN ELITE ENDURANCE ATHLETES

PAWLAK-CHAOUCH, M.1, BOISSIÈRE, J.1, MUNYANEZA, D.1, GAMELIN, F.X.1, CUVELIER, G.2, BERTHOIN, S.1, AUCOUTURIER, J.1

1: LILLE UNIVERSITY, FRANCE, 2: CONDORCET, TOURNAI, BELGIUM

INTRODUCTION: Dietary nitrate (NO3-) supplementation is recognized as a means to improve tolerance to submaximal to maximal intensity exercise (Bailey et al. 2010; Lansley et al. 2011). Regarding supramaximal intensity exercise, we previously reported an improved tolerance to supramaximal intensity intermittent exercise in moderately fit subjects (VO2max between 40 and 55 mL.kg-1.min-1) (Aucouturier et al. 2015). Although 15% of the total race duration in cycling or triathlon can be performed at intensities beyond VO2max, little is known about the effectiveness of dietary NO3- supplementation on tolerance to supramaximal intensity intermittent exercise in endurance athletes. Our aim was therefore to determine whether dietary NO3- supplementation enhances the tolerance to supramaximal intensity intermittent exercise in elite endurance-trained athletes.
METHODS: Using a randomized, single-blind, cross-over design, 9 elite endurance athletes (21.7±3.7 years, maximal oxygen uptake (VO2max): 71.1±5.2 mL.kg-1.min-1) performed a supramaximal intensity intermittent exercise test following either a 3-day beetroot juice supplementation (BJ, NO3- content of 680 mg.L-1), or a placebo supplementation (PL, NO3- content<5 mg.L-1). The exercise test consisted of 15-s cycling exercise bouts at 170% of the maximal aerobic power interspersed with 30-s passive recovery periods performed until volitional exhaustion. Gas exchange measurements (indirect calorimetry), changes in local muscle oxygenation, and microvascular THb concentration were measured by Near Infrared Spectroscopy (NIRS).

RESULTS: Dietary NO3- supplementation did not increase the tolerance to supramaximal intensity intermittent exercise (BJ: 13.9±4.0 reps, PL: 14.2±4.5 reps, NS). Dietary NO3- supplementation did not affect oxygen uptake (VO2) during supramaximal intensity intermittent exercise tests (BJ: 3378.5±681.8 mL.min-1, PL: 3466.1±505.3 mL.min-1, NS). In contrast to our previous findings in subjects with lower aerobic fitness level (Aucouturier et al. 2015), the area under the curve for microvascular total hemoglobin (AUC-THb) was not different between the two conditions (BJ: 6816.9±1463.1 arbitrary units (a.u.), PL: 6771.5±3004.5 a.u., NS).
CONCLUSION: A short-term dietary NO3- supplementation did not increase the tolerance to supramaximal intensity intermittent exercise in elite endurance athletes contrary to recreationally trained subjects. This finding provides additional support to the hypothesis that dietary NO3- supplementation with beetroot juice is ineffective to improve performance in subjects with high VO2max (>60 mL.kg-1.min-1), regardless of exercise intensity domains.

DIETARY NITRATE INGESTION AND BLOOD PRESSURE LEVELS IN VEGETARIANS COMPARED TO OMNIVORES

BESCOS, R., ASHWORTH, A., EASTON, C., LIDDLE, L.
PLYMOUTH UNIVERSITY, UNIVERSITY OF WEST SCOTLAND

INTRODUCTION: Dietary consumption of inorganic nitrate (NO3) in vegetarians has been suggested to be higher than in omnivores as the main dietary sources of this anion are vegetables. Given the potential role of NO3 in lowering blood pressure, it has been suggested that this can explain, at least partially, the lower levels of blood pressure of vegetarians compared to omnivores. However, no previous study has investigated this question. Thus, the main aim of this study was to estimate dietary NO3 consumption in vegetarians and omnivores, to analyse plasma and salivary levels of NO3 and nitrite (NO2), and to investigate whether NO3 and NO2 bioavailability in vegetarians was associated with lower blood pressure compared to omnivores.
METHODS: 22 healthy subjects following a vegetarian diet (V) for at least a year (16 F + 6 M) and 19 omnivores (O) (11 F + 8 M) of similar age (V= 26 ± 6; O= 26 ± 6 y/o), BMI (V= 22.9 ± 3.8; O= 22.1 ± 2.9), gender and physical activity levels (V= 315 ± 221; O= 334 ± 208 min/week) completed this study. Following a single-blind and non-randomized protocol participants were given a mouthwash placebo (water) for one week. Additionally, they recorded all their food consumption during that week using food diaries. Dietary NO3 was estimated using the European Food Safety Authority database (European Food Safety Authority, 2008). They visited the laboratory on the seventh day in order to provide a saliva and blood sample under fasting conditions and for measurement of blood pressure in triplicate using an automated sphygmanometer. Then, participants were given antibacterial mouthwash (Corsodyl, UK) for seven more days in order to inhibit the oral NO3/NO2 pathway. They were also encouraged to replicate their food intake from the previous week. The same measurements were taken under fasting conditions on the fourteenth day.
RESULTS: Results are expressed as mean ± SD. Dietary NO3 intake by vegetarians (97 ± 79 mg/day) was 19 mg/day higher than in omnivores (78 ± 47 mg/day), but this was not statistically different (P>0.05). Plasma NO3 (V= 43 ± 33 µM; O= 40 ± 18 µM) and NO2 (V= 84 ± 41 nM; O=74 ± 21 nM) and salivary NO3 (V= 525 ± 698 µM; O= 542 ± 571 µM) and NO2 (V= 329 ± 340 nM; O= 319 ± 283 nM) were also similar between both groups after using placebo. Blood pressure was also not different (P> 0.05) between both groups (V SBP= 104 ± 8 mmHg, DBP 64 ± 6 mmHg; O SBP= 103 ± 6 mmHg, DBP 61 ± 7 mmHg). A significant reduction (P<0.05) of plasma NO2 (V= 65 ± 15 nM; O= 61 ± 16 nM) and salivary NO2 (V= 155 ± 171 nM; O= 133 ± 214 nM) was observed in both groups after using antibacterial mouthwash, but, this was not associated with any change in blood pressure.
CONCLUSION: A vegetarian diet was not associated with higher dietary NO3 intake or increased NO3/NO2 bioavailability compared to a healthy omnivore diet. This study also challenges previous literature as blood pressure was not lower in vegetarians compared to omnivores in healthy and young adults.

THE IMPACT OF BEETROOT JUICE SUPPLEMENTATION ON MUSCLE STRENGTH AND ENDURANCE

HILKENS, L., JONVIK, K.L., PEELEN, H., HOOGERVORST, D., DE NIET, M., VERDIJK, L.B., VAN LOON, L.J.C., VAN DIJK, J.W.
HAN UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Dietary nitrate supplementation has been shown to improve high-intensity exercise performance and has been linked to enhanced muscle contractility. These observations suggest that dietary nitrate supplementation may also improve muscular strength and endurance. In the present study we investigated the effects of nitrate supplementation on muscular strength and endurance.
METHODS: Fifteen recreationally active males (25±4 y, BMI 24±3 kg/m2) participated in a randomized cross-over study comprising two 6-d supplementation periods with daily supplementation of nitrate-rich (BR; 985 mg/d) or nitrate-depleted (PLA; 0.37 mg/d) beetroot juice. On day 6 of each experimental period, 3 h after ingesting the last supplemental dose, muscular strength and endurance were assessed by an isokinetic dynamometer. Maximal strength was assessed by maximal voluntary isometric and isokinetic contractions of the upper leg muscles. Isometric knee extensions were conducted at a knee angle of 30° and 60°, whereas isokinetic extensions and flexions of the knee were conducted at an angular velocity of 60, 120, 180 and 300°·s-1. Muscular endurance was assessed as the total work conducted during 30 reciprocal isokinetic contractions at an angular velocity of 180°·s-1. Differences between plasma nitrate, plasma nitrite, and exercise tests were analysed by paired-samples t-tests. Data are presented as mean±SD.
RESULTS: Plasma nitrate and nitrite concentrations assessed at 2h45min following the last supplemental dose were higher following BR vs PLA (respectively 870±239 vs 33±13 µmol/L and 463±217 vs 176±50 nmol/L, both P<0.001). Maximal voluntary isometric contraction at 30° and 60° did not differ between BR and PLA (204±39 vs 200±37, and 286±43 vs 285±47, respectively; both P>0.50). Maximal voluntary isokinetic contraction for the knee extensors did not differ between BR and PLA for any of the velocities (60°/s: 220±45 vs 218±40 W, 120°/s: 392±74 vs 387±62 W, 180°/s: 500±86 vs 487±67, 300°/s: 554±102 vs 544±81 W, P>0.33 for all velocities). However, maximal voluntary isokinetic contraction of the knee flexors was significantly improved by BR at 60°/s (157±22 vs 150±23 W, P<0.001) and tended to be improved at 180°/s (500±86 vs 487±67 W, P=0.066), whereas no effect was observed at an angular velocity of 120°/s (392±74 vs 387±62 W, P=0.24) and 300°/s (493±73 vs 485±81 W, P=0.36). Muscular endurance did not differ between BR and PLA (3950±690 vs 3926±661 kJ, P=0.73).
CONCLUSION: Supplementation of beetroot juice generally does not improve muscular strength and endurance. Nevertheless, beetroot juice supplementation improved some markers of knee flexor strength. It remains to be established whether this finding holds practical implications for exercise performance where hamstring strength is important, such as sprinting and jumping.

ASSESSING THE BIOLOGICAL VARIATION OF NITRATE AND NITRITE CONCENTRATION IN HUMAN PLASMA AND SALIVA FOLLOWING INGESTION OF NITRATE-RICH BEETROOT JUICE

EASTON, C.1, LIDDLE, L.1, BURLEIGH, M.1, MONAGHAN, C.1, MUGGERIDGE, D.J.2

1UNIVERSITY OF THE WEST OF SCOTLAND, 2UNIVERSITY OF THE HIGHLANDS AND ISLANDS

INTRODUCTION: Dietary nitrate (NO_3^-) supplementation increases circulating nitric oxide (NO) metabolites and has been shown to improve exercise performance in some, but not all, studies To date, the intra-individual biological variation in NO metabolite pharmacokinetics have not been quantified, despite these data being important to determine the thresholds that are sufficient to improve performance. The aim of this study was to determine the biological variation and critical difference (CD) in salivary and plasma nitrite ($[NO_2^-]$) and ($[NO_3^-]$) before and after ingestion of NO_3^- rich beetroot juice (BR).

METHODS: Ten healthy male participants (age 25 ± 5 years and body mass 81 ± 11 kg) completed three identical trials ~7 days apart. Following a 30 min period lying supine, blood and saliva were collected before (PRE) and 2.5 h after (POST) ingestion of 140 ml of BR (~12.4 mmol NO_3^-). Samples were analysed for ($[NO_2^-]$) and ($[NO_3^-]$) using gas-phase chemiluminescence. The analytical coefficient of variation (CVa) for these measures was ≤4.1%. The within-subject variation (CVi) of measurements for the three visits was calculated and coupled with the CVa to determine the CD. The between-subject variation (CVg) was also calculated for each measurement time point.

RESULTS: Across the three trials, plasma ($[NO_2^-]$) increased ($P<0.01$) from PRE (124 ± 49 nM, CVi 9%, CD 19%, CVg 40%) to POST (279 ± 94 nM, CVi 19%, CD 45%, CVg 32%) ingestion of BR. Likewise, plasma ($[NO_3^-]$) increased ($P<0.01$) from PRE (34 ± 10 µM, CVi 5%, CD 10%, CVg 32%) to POST (415 ± 92 µM, CVi 12 %, CD 24%, CVg 23%). Both salivary ($[NO_2^-]$) and ($[NO_3^-]$) also increased from PRE to POST ($P<0.01$) although the variation in salivary ($[NO_2^-]$) was substantially greater than ($[NO_3^-]$). Salivary ($[NO_2^-]$) values were 136 ± 100 µM at PRE (CVi 33%, CD 87%, CVg 79%) and 904 ± 268 µM at POST (CVi 24%, CD 58%, CVg 38%). Salivary ($[NO_3^-]$) values were 0.5 ± 0.2 mM at PRE (CVi 15%, CD 37%, CVg 25%) and 8.5 ± 2.1 mM at POST (CVi 12%, CD 30%, CVg 37%).

CONCLUSION: There is profound biological variation in the measurements of NO metabolites in human saliva and plasma suggesting that a large change in these parameters is required before a biologically relevant mean change can be suggested. Nevertheless, the increases in salivary and plasma ($[NO_3^-]$) and ($[NO_2^-]$) following ingestion of BR consistently exceeds the CD range. Studies measuring ($[NO_3^-]$) and ($[NO_2^-]$) should carefully consider the CD of these measures when interpreting experimental outcomes.

STATE-CIVIL SOCIETY RELATIONS FOR SPORT AND THE SUSTAINABLE DEVELOPMENT GOALS: A NORMATIVE-ANALYTIC FRAMEWORK

LINDSEY, I.

DURHAM UNIVERSITY

Common calls for greater governmental involvement in sport-for-development have been prominently made by multiple stakeholders and academics in the field alike. However, such calls lack clarity as to governments' prospective role, especially in relation to the burgeoning involvement of civil society organisations in sport-for-development. Academic contributions are weakened by a lack of both theorisation and empirical investigation. These limitations are increasingly problematic given the implications for sport that come from the 2030 Agenda for Sustainable Development, its establishment of an expansive set of Goals and prioritisation of the 'Means of Implementation' for these Goals. Therefore, drawing on development studies literature, this paper proposes a framework for state-civil society relations in sport-for-development that provides a normative basis for future policy and supports further empirical analysis. A fourfold continuum is suggested whereby sport-for-development interventions may vary from being state-led, enacted through structured partnerships or complementary relationships, to being undertaken autonomously by civil society organisations. Each component of this continuum brings specific implications in terms of the potential for scaled impact, capacity requirements and risks. These issues will be considered in respect of the framework's potential to inform policy approaches to enhancing the contribution of sport to various Sustainable Development Goals.

THE DONOR-RECIPIENT RELATIONSHIP IN SPORT FOR DEVELOPMENT AND PEACE

STRAUME, S.

MOLDE UNIVERSITY COLLEGE

In recent years, SDP policy scholars have highlighted the strong dominance of Global North ideologies, agendas and input within many Sport for Development and Peace (SDP) interventions. This criticism relates to the development of donor-led policies, top-down programming and control over the flow of SDP funding, enabling and sustaining an un-equal relationship. Simultaneously, the SDP sector has experienced a remarkable growth, and consequently its stakeholders are multiple and complex, ranging from governments and government agencies to local NGOs and independent individuals.

Through a study of the interface between policy and practice in an SDP project in Zimbabwe, this presentation reflects on the donor-recipient relationship in SDP. The study showed that different worldviews were negotiated within the project, as official discourses and policy-driven ideas were translated and given meaning by recipient organization or local project staff in the social contexts where it was implemented.

With the exponential growth of various SDP stakeholders in mind, it is argued that future research should continue to strive for more understanding of the way policies influence SDP relationships. This is particularly important in driving the sector towards policies that are increasingly based on development cooperation and equal partnership.

SHIFTING GEARS: EXPLORING THE 'BICYCLES FOR DEVELOPMENT' MOVEMENT

MCSWEENEY, M., HAYHURST, L., WILSON, B.
YORK UNIVERSITY

In countries throughout the global South, and in disadvantaged communities across the global North, bicycles are being hailed by NGOs, corporations, international institutions, and local communities as tools for reducing poverty and achieving environmental sustainability. Despite this surging interest in what can be termed the 'bicycles for development' (BFD) 'movement', little is known about BFD in relation to the wider sport for development and peace (SDP) movement. Indeed, having identified concerns associated with development efforts driven by institutions of the global North, researchers have advocated for more 'on the ground', contextual research on SDP informed by the wealth of research and theoretical work that: 1) is sensitive to sport and non-sport related postcolonial legacies; and 2) considers the use of non-human objects and technologies in SDP, such as the bicycle, as possible catalysts for development. In this paper, framed by a postcolonial lens, we offer an analysis and discussion of interviews with global BFD 'executives' involved in the transnational movement of bicycles. Specifically, we explore how individual BFD executives engage in practices of social entrepreneurship, and further, identify and examine BFD organizational models that rely on social entrepreneurial processes. Overall, our goal is to consider how, based on the perspectives of BFD executives, bicycles may offer an innovative form of development and unique social entrepreneurship opportunities, while being influenced by and influencing the contextual and neoliberal structures of the international movement of bicycles.

Oral presentations

OP-PM74 High intensity training 2

VOLUME-MATCHED, SINGLE AND ACCUMULATED BOUTS OF IN-SCHOOL HIGH-INTENSITY INTERVAL RUNNING REDUCE POSTPRANDIAL LIPAEMIA IN ADOLESCENT BOYS

TOLFREY, K., SMALLCOMBE, J.W., BARRETT, L.A.
LOUGHBOROUGH UNIVERSITY

INTRODUCTION: The current study aimed to examine the efficacy of high-intensity interval running (HIIR), accumulated during the natural breaks in the school day, to modulate postprandial metabolism in adolescent boys. A secondary aim was to compare the effects of accumulated HIIR with those of the same volume HIIR performed in a single after-school exercise session.
METHODS: Nineteen healthy adolescent boys (12.6 <0.5) years) completed the study. A within-measures, counter-balanced research design was employed whereby all participants completed three, 2-day experimental conditions; a resting control condition (CON); an accumulated, high-intensity exercise condition (ACC); and a single, high-intensity exercise condition (SIN), separated by fourteen days. On Day 1, after a standardised overnight fast, participants arrived at school at 07:30. A fasting capillary blood sample was taken at 07:35 and three subsequent blood samples in the postprandial state at 10:30, 12:35 and 15:10. In all conditions, standardised mixed meals were consumed at 08:10 & 13:00 on Day 1. During CON, no exercise was prescribed. During ACC, participants performed four sets of 10 × 30 m maximal-intensity sprint runs (40 sprints in total) accumulated in four bouts across the school day (07:50, 10:35, 12:40 and 15:30). During SIN, participants performed the same number of sprints (40) in a single exercise session performed at 16:00. On the morning of Day 2 participants reported to school, where fasting and postprandial blood samples were taken as described above. High fat meals, standardised to body mass, were consumed at 08:10 and 12:40, respectively.
RESULTS: No differences in TAUC-TAG were observed across conditions on Day 1 (P = 0.359), however, differences were observed on Day 2 (P = 0.007). On Day 2, The TAUC-TAG was 12% lower after ACC (ES = 0.49; P = 0.002) and 10% lower after SIN (ES = 0.37; P = 0.019) compared with CON. The difference between SIN and ACC for TAUC-TAG was trivial and non-significant (3%, ES = 0.12, P = 0.418). No differences in TAUC-glucose were observed across conditions on Day 1 or Day 2 (P =0.738). During exercise, affective ratings on the One Item Feeling Scale differed significantly across conditions (P = 0.011) and between sprint sets (P = 0.024). The condition by sprint set interaction was also significant (P = 0.002) with higher affective ratings reported following the third (+1 fairly good vs. 0 neutral) and fourth (+1, fairly good vs. -1 fairly bad) exercise sets during ACC compared with SIN.
CONCLUSION: High-intensity interval running, accumulated in four separate bouts during the school day, was efficacious in reducing postprandial triacylglycerol concentrations in adolescent boys. The exercise-induced reductions observed after accumulated HIIR were similar in magnitude to those observed after the same of volume exercise was performed in a single, after-school bout and match findings from laboratory-based studies with adolescent boys and girls; the ecological validity may differ.

A MULTI-DISCIPLINARY EVALUATION OF A HOME-BASED HIGH-INTENSITY INTERVAL TRAINING INTERVENTION IN PEOPLE WITH TYPE 1 DIABETES

SCOTT, S.N.1, SHEPHERD, S.O.1, ATKINSON, S.1, ANDREWS, R.C.2, NARENDRAN, P.3, PUREWAL, T.S.4, COCKS, M.1
1 LIVERPOOL JOHN MOORES UNIVERSITY, 2 UNIVERSITY OF EXETER, 3 UNIVERSITY OF BIRMINGHAM, 4 ROYAL LIVERPOOL & BROADGREEN UNIVERSITY HOSPITAL

INTRODUCTION: High-intensity interval training (HIT) may be particularly effective in people with type 1 diabetes (T1D), as HIT addresses the two major barriers to exercise identified by people with T1D, fear of hypoglycaemia and lack of time. However, HIT protocols investigated in people with T1D require specialised equipment introducing additional barriers to exercise, which are relevant as people with T1D also identify access to facilities and embarrassment as key barriers. In addition, studies investigating HIT in people with T1D have only been conducted under optimal lab conditions with high levels of supervision, bringing into question how the work translates into practise. As such, using guidance from the RE-AIM framework, we used a multi-disciplinary approach to evaluate a new home-based HIT (Home-HIT) intervention in people with T1D, investigating physiological responses and qualitatively evaluating participant experiences of the new intervention.
METHODS: Eight previously sedentary people with T1D (age 31±4yrs; BMI 27.1±1.5kg·m; VO2peak 33.5±2.7ml·kg·min; duration of T1D 9±3yrs) completed 6wk of Home-HIT (repeated 1min intervals of simple bodyweight exercises). Participants trained unsupervised in a place of their choosing, and were advised to train 3x/wk completing between 6-10 intervals at a heart rate (HR) of ≥80% HRmax. Adherence and compliance to the prescribed exercise intensity were remotely monitored using a HR monitor and mobile app. Aerobic capacity (VO2peak) and blood pressure were assessed pre and post-training. Blood glucose was monitored before, immediately and 1h after all

exercise sessions. Perceptions of the program along with attitudes towards exercise, barriers to exercise and previous experiences of exercise were evaluated using an online interview.
RESULTS: Training session adherence was 93±2%, with participants achieving their target HR in 99±1% of sessions. Blood glucose was not different from baseline immediately or 1h post HIT exercise. Training increased VO2peak by 1.7±0.5ml/kg/min (P=0.015), but blood pressure was unchanged (P=0.445). The interview revealed that the Home-HIT programme was positively received with a lot of benefits. Participants identified that it reduced many of the barriers to exercise, including those related to T1D. All 8 participants said they would continue with Home-HIT following the intervention.
CONCLUSION: This is the first study to combine physiological evidence with qualitative evaluation of a training intervention in people with T1D. Using this approach home-based HIT appears to be a highly effective intervention for people with T1D, resulting in high adherence and inducing clinically relevant increases in aerobic capacity. Importantly, home-based HIT not only reduced traditional barriers to exercise, but also the key barrier in people with T1D, fear of hypoglycaemia. As such, home-based HIT may represent an effective strategy to improve health in people with T1D by increasing exercise participation.

EFFECTS OF COMBINED UPPER- AND LOWER-BODY HIGH-INTENSITY INTERVAL TRAINING ON MUSCULAR AND CARDIORESPIRATORY FITNESS IN OLDER ADULTS

HURST, C.1, WESTON, K.L.2, BATTERHAM, A.M.2, WESTON, M.2

1 DURHAM UNIVERSITY 2 TEESSIDE UNIVERSITY

INTRODUCTION: Age-related declines in cardiorespiratory and muscular fitness can have considerable functional implications in older adults with the ability to perform the tasks of daily living dependent on upper- and lower-body fitness. High-intensity interval training (HIT) improves both cardiorespiratory and muscular fitness (Sculthorpe et al., 2017; Weston et al., 2014), thereby offering an attractive strategy for the training of older adults. However, previous studies have typically used a predominantly lower-body training stimulus. As such, we aimed to assess the effects of 12-weeks of combined upper- and lower-body HIT on measures of fitness in adults aged >50 years.
METHODS: Following baseline assessment of leg extensor muscle power, handgrip strength and aerobic fitness (predicted VO2max), 36 adults (21 male; 62 ± 7y [mean ± standard deviation, SD]) were assigned to HIT (n=18) or no-exercise control (CON, n=18) via minimisation (age, gender, and baseline fitness). The HIT programme comprised two training sessions per week for 12-weeks using a double-concentric hydraulic resistance machine. Participants were encouraged to work at a high-intensity performing a combination of upper-, lower- and full-body exercises including squats, power clean and press, lat-pull to squat and step-and-press. HIT sessions consisted of four sets of four exercise bouts interspersed with a 15-s transition period allowing movement to the next exercise. Initial HIT bout duration was 45 s, progressing every third week by 10 s. Each set was followed by 3-minutes passive rest. Data were analysed via ANCOVA with baseline values, age and sex as covariates, with magnitude based inferences subsequently applied.
RESULTS: All participants in the HIT group completed the intervention with mean (82 ± 6%[maximal heart rate, HRmax]) and peak (89 ± 6%HRmax) exercise heart rates confirming a high-intensity training stimulus. Compared to CON, HIT showed possibly small beneficial effects for dominant leg power (10.5; ±90% confidence limits ±8.5%), non-dominant leg power (9.4; ±6.3%) and non-dominant handgrip strength (6.3; ±5.2%), with a likely small beneficial effect for VO2max (8.4; ±6.8%). The effect for dominant handgrip strength (5.9; ±5.5%) was likely trivial.
CONCLUSION: Twelve weeks of combined upper- and lower-body HIT induces clear improvements in muscular and cardiorespiratory fitness measures relevant to functional performance in older adults. Our findings highlight potential for innovative approaches to training delivery and should encourage researchers to move beyond exercise modes traditionally associated with HIT.

THE EFFECTS OF DIFFERENT HIGH-INTENSITY INTERVAL TRAINING MODALITIES ON BODY COMPOSITION IN NON-OBESE YOUNG ADULT FEMALES

BROWN, E.C., ORR, S.C., TYLER, R.T., RENGERS, T.A., ELSESSER, M.A., HEW-BUTLER, T., MARKS, C.R.C., CHOI, M.D., BUTCHER, S.J.

OAKLAND UNIVERSITY

INTRODUCTION: Long-term (≥ 12 weeks) high-intensity interval training (HIIT) is an effective way to improve body composition in overweight/obese populations, but few studies have examined these effects in normal weight populations. Additionally, most HIIT protocols include aerobic-type and not resistance training exercises. Therefore, the aim of this study was to compare the effects of rowing HIIT (R-HIIT) and multi-modal HIIT (MM-HIIT) using resistance and conditioning modalities on body composition in non-obese females.
METHODS: 19 non-obese women aged 22.8±5.3 years were randomized into either a MM-HIIT or R-HIIT group. Participants completed a 12-week HIIT intervention consisting of 1-hour sessions 3 days a week. All participants had measures of height, weight, waist circumference and dual-energy X-ray absorptiometry (DEXA) measures of body fat percentage (BF%), visceral adipose tissue (VAT), bone mineral content (BMC), bone mineral density, fat mass, and lean body mass (LBM) assessed pre- and post-intervention. An independent samples t-test was computed to determine differences between groups at baseline, and a general linear model with repeated measures was used to determine changes in variables across time and between groups. P-value was set a priori at 0.05.
RESULTS: 14 participants (R-HIIT: n=6; MM-HIIT: n=8) completed the intervention and no differences between groups were found at baseline. A significant main effect for time pre- to post-intervention was found for some DEXA variables such that both groups increased BMC (MM-HIIT: effect size (ES)=1.00, confidence interval (CI)=6.16–67.61, P=0.03; R-HIIT: ES=2.43, CI=17.48–44.05, P=0.002) and LBM (MM-HIIT: ES=2.71, CI=1732.77-3279.26, P<0.001; R-HIIT: ES=3.79, CI=1551.03–2740.04, P<0.001). No between group differences nor changes in anthropometric variables were found.
CONCLUSION: R-HIIT and MM-HIIT groups improved similarly for BMC and LBM. Improvements in LBM was similar to the findings of Cervantes-Sanabria and Hernández-Elizondo (2017) who noted an increase in muscle mass and decrease in fat mass and BF% in overweight women after 16 weeks of HIIT using body weight exercises. The lack of body fat improvement in the present study was likely due to the participants having healthy levels of waist circumference, body mass index, and VAT at baseline with little room for improvement. The increases in BMC in the present study are contrary to the findings of Nybo et al. (2010) that demonstrated no improvement in BMC

after 12 weeks of running HIIT in men. As both HIIT protocols resulted in positive changes, either may be chosen by coaches or health professionals who wish to improve their clients' LBM and/or BMC.

EXPLORING ADOLESCENT PERCEPTIONS OF A HIGH-INTENSITY INTERVAL TRAINING INTERVENTION: EVALUATING THE EXERCISE FOR ASTHMA WITH COMMANDO JOE'S (X4ACJ) TRIAL

EDDOLLS, W.T.B., MCNARRY, M.A., WINN, C.O.N., MACKINTOSH, K.A.
SWANSEA UNIVERSITY

INTRODUCTION: The prevalence of poor health in children and adolescents has reached unprecedented levels (Lobstein et al., 2015). While conventional methods for treating such poor health are often expensive, exercise has been identified as an alternative cost-effective tool. Traditional strategies have principally utilised moderate-intensity continuous exercise, however, more recently, high-intensity interval training (HIIT) has been proposed as a means of improving adolescent health (Weston et al., 2016). However, despite the importance of capturing participants' post-intervention attitudes, there remains a dearth of evaluative research. Therefore, the aim of this study was to evaluate the eXercise for Asthma with Commando Joe's (X4ACJ) HIIT intervention.
METHODS: Eighty adolescents (13.3 ± 1.0 years; 45 boys) from X4ACJ, participated in this study. The intervention involved 6 months of 3 x 30-minute HIIT sessions per week delivered by Commando Joe's®. Participants, stratified into groups based on attendance (attendees and non-attendees) each completed one of eighteen semi-structured focus-group interviews. Questions were structured around participants' perceptions of X4ACJ and HIIT. Data was transcribed verbatim and thematically analysed deductively. Key emergent themes were represented using pen profiles.
RESULTS: Psychological, physiological and social benefits of participating in the HIIT intervention emerged as the primary facilitators to exercise. Aspects of the exercise sessions, such as games and competition, as well as the instructor were highlighted as facilitators. Poor peer behaviour, the challenging nature of HIIT, the timings of the sessions and competing interests were the predominant barriers to participating in the HIIT intervention.
CONCLUSION: Future research should carefully consider HIIT implementation strategies. Indeed, HIIT interventions should embed a fun and varied games-based intervention into physical education lessons led by a well-qualified and approachable instructor. Sessions should account for the variation in ability between participants, avoiding intra- and inter-session repetition, to enhance long-term adherence.

CHANGES IN THE POWER-CADENCE RELATIONSHIP FOLLOWING HIGH-RESISTANCE AND HIGH-CADENCE SPRINT TRAINING INTERVENTIONS

RUDSITS, B.L., TAYLOR, S.B., HOPKINS, W.G., ROUFFET, D.M.
VICTORIA UNIVERSITY

INTRODUCTION: Ballistic training interventions targeting different portions of the power-velocity relationships have been shown to elicit different neuromuscular adaptations. This study investigated how two sprint training interventions performed on a stationary cycle ergometer against high resistances or at high cadences affected the power-cadence relationship and the motor command (i.e. kinetics, lower limb kinematics and intermuscular coordination).
METHODS: Two groups of physically active males completed either a training program exclusively made of sprints performed against high resistances (4-8 N·m·kg-1; 0 to 122 ± 15 rpm; mean ± SD; n= 9) or sprints performed at high cadences (0.1 ± 0.5 N·m·kg-1; 131 ± 5 to 211 ± 10 rpm; n= 8). For both training interventions, participants trained bi-weekly for four weeks. Alterations in power-cadence relationships were quantified from changes in power produced at training-specific cadences (60-90 rpm and 160-190 rpm), estimated maximal torque, maximal power, optimal cadence, maximal cadence. Changes in peak crank torque, average muscle co-activation, and joint angles at the training-specific cadences were also analysed. Magnitudes of effects and their uncertainty were assessed using standardisation.
RESULTS: The effects of training were greatest in the cadence range of training: small-moderate increases in power (7 ± 6%) at 60-90 rpm for high-resistance and trivial-small increases (11 ± 20 %) at 160-190 rpm for high-cadence. The improvement for high-resistance was associated with small-moderate increases in maximal torque (25 ± 19 %), trivial-small reductions in optimal cadence (3 ± 5 rpm), small-moderate reductions in ankle joint range of motion (6 ± 4°) and trivial-moderate increases in co-activation of the gastrocnemius and tibialis anterior muscles. High-cadence training was associated with a more plantar-flexed ankle joint of a trivial-moderate magnitude (4 ± 8°), trivial-small increases in optimal cadence (3 ± 5 rpm), and increased co-activation of the gastrocnemius and tibialis anterior muscles.
CONCLUSION: High-resistance and high-cadence training led to different improvements in the power-cadence relationship. High-resistance training was linked to a modification in ankle joint kinematics and greater co-activation of surrounding musculature, while the responses to high-cadence training were more variable. These findings indicate that upon assessment of an individual's power-cadence profile, training over specific sections of the power-cadence relationship could be used to optimise their profile to match the requirements for their given sporting event.

OP-PM53 Injury prevention

IS SPORTOMICS A USEFUL APPROACH TO EVALUATE METABOLIC RESPONSES AND TO PREVENT INJURIES IN PROFESSIONAL SOCCER PLAYERS? PRELIMINARY RESULTS.

BONGIOVANNI, T., PINTUS, R., MARINCOLA, F.C., FRANCAVILLA, V.C., CORBU, S., DESSÌ, A., NOTO, A., CORSELLO, G., FANOS, V.

NUTRITION, HYDRATION & BODY COMPOSITION DEPARTMENT, PARMA CALCIO 1913, PARMA, ITALY.

INTRODUCTION: Sportomics is non-hypothesis-driven research on an individual's metabolite changes during sports and exercise. It is the application of metabolomics, one of the omics sciences that provide a snapshot of the metabolome of an individual in both physiological and pathological conditions such as sport practice and musculoskeletal diseases or injuries through the analysis of biological fluids such as blood, urine or saliva.
METHODS: In this study we performed an 1H-NMR analysis of urine metabolome of 21 professional soccer players, playing in Italian Serie-A league, at 3 different times: the first day (T1), after five days (T2) and at the end (T3) of the pre-season period 2016-17. We used this approach to investigate cellular and metabolic responses due to chronic physical exercise and to study the usefulness of sportomics to prevent injuries.
RESULTS: A clear separation was obtained between samples collected at time T1, T2 and T3. The metabolites responsible for the separation were: TMAO, DMA, N-methylhistidine, 3 OH-butyric acid and hippuric acid which levels were increased. Some of these compounds may be related both to the diet or the training since, for instance, N-methylhistidine is an indicator of proteins turnover that could correlate to the assumption of proteins or to muscular stress, while the influence of microbiota is highlighted by hippuric acid.
CONCLUSION: To the author's knowledge this was the first sportomics study in professional soccer players; preliminary results show significant changes in urine metabolites such as TMAO, DMA, N-Methylhistine, 3 OH-butyric acid and hippuric acid, attesting sportomics as an interesting approach to advance in the understanding of global response to a programmed exercise and diet. Since it is the first study ever made on professional soccer players it has several limitations and the experimental setting could be improved in order to have clearer results. Further research is needed to determine whether sportomics could be employed to prevent, diagnose and manage injuries induced by exercise.

WHAT IS THE EFFECT OF INJURY DEFINITION ON THE INCIDENCE OF INJURY IN A JUNIOR INTERNATIONAL FIELD HOCKEY SQUAD?

REES, H.1,2, DELAHUNT, E.1,2, BOREHAM, C.1,2, MCCARTHY-PERSSON, U.1,2, SHRIER, I.3, MURPHY, J.4, BLAKE, C.1,2

1 INSTITUTE OF SPORT AND HEALTH, UCD 2 SCHOOL OF PUBLIC HEALTH, PHYSIOTHERAPY AND SPORTS SCIENCE, UCD 3 CENTRE FOR CLINICAL EPIDEMIOLOGY, LADY DAVID INSTITUTE, MCGILL UNIVERSITY 4 MEDFIT, DUBLIN

INTRODUCTION: Consensus statements highlight that a range of injury definitions can be used in epidemiological studies of sports injuries. To date, injury surveillance in field hockey has primarily reported upon injuries incurring medical attention. Understanding how different injury definitions influence injury incidence will help inform future consensus agreements and facilitate standardisation of injury reporting. Therefore, the aim of this study was to investigate the influence of injury definition on injury incidence rates in a squad of elite hockey players across a 6-week period.
METHODS: Ethical approval was obtained from the Human Research Ethics Board in UCD. Elite Irish field hockey players self-reported physical complaints daily, using the AthleteMonitoring software. All complaints were subsequently assessed by the team's physiotherapist. Injuries were categorised as (i) all physical complaints, (ii) medical attention (those requiring treatment) and (iii) time-loss (unable to take a full part in future hockey training or match-play).
RESULTS: 18 players participated in the study, training an average of 10.8h/wk and playing 6 matches in the six-week study period (1,227 exposure hours; 1,161 training hours; 66 match-play hours). Of the 26 all physical complaints injuries (14 match; 12 training) during the 6-week period, 13 (50%) were logged by the athlete and would not have come to the attention of the medical team, had the AthleteMonitoring software not been used. The remaining 13 (50%) injuries were categorised as medical attention injuries, of which 7 (27%) incurred time-loss. This gave rise to match-play and training incidence rates of 212.1/1000h and 10.3/1000h respectively. For match-play, self-reported injuries (not medical attention) (n=8) had an incidence of 121.2/1000h, medical attention with/without time loss (n=6) of 90.9/1000h and time-loss (n=3) of 45.5/1000h. In training, self-reported injuries (n=5) had an incidence of 4.3/1000h, medical attention with/without time loss (n=7) of 6.0/1000h and time-loss (n=4) of 3.4/1000h.
CONCLUSION: A large proportion of elite field hockey injuries are not medical attention and do not result in time-loss from sport. Using only a medical attention or time-loss definition would have missed many of the injuries sustained by the players. While further research in this area is required, it may be useful for epidemiological studies of injury in field hockey to include physical complaints as an injury definition.

THE EFFECT OF ARTHROSCOPIC TREATMENT FOR FEMOROACETABULAR IMPINGEMENT ON ATHLETIC PERFORMANCE IN COMPETITIVE SPORTSMEN.

MULLINS, K.1, HANLON, M.1, CARTON, P.1,2

1 WATERFORD INSTITUTE OF TECHNOLOGY 2 THE HIP AND GROIN CLINIC, WHITFIELD CLINIC, WATERFORD

INTRODUCTION: Objective measurements of athletic function have not been examined following arthroscopic treatment of femoroacetabular impingement despite it being a common pathology among athletes , and subjective outcomes measures following surgery showing favourable results. The aim of the research was to determine changes in functional performance variables necessary for field sport participation following arthroscopy for FAI among male athletes.
METHODS: Competitive male athletes undergoing surgery for FAI, were compared to an age and activity-level matched control group. Patients and controls were tested at three timepoints; patients at baseline , 12-weeks post-surgery and 1 year following the procedure . While controls were tested initially , 12-weeks and 1 year later . All participants were tested for acceleration, change of direction speed by use of a modified agility T test, maximal deep squatting ability and a single leg drop jump for the calculation of reactive strength index .

Maximal hip range of motion which included flexion, abduction and internal rotation were assessed using a goniometer. Participants were asked to report any anterior groin pain during the testing. Return to play status of the patient group was also recorded at the 1-year follow up. Paired samples t tests were used to determine within group changes over time, while a repeated measures ANOVA was used to examine time x group interaction effects, in all cases $p<0.05$ was considered significant.
RESULTS: Prior to surgery, patients were significantly slower than controls for acceleration and COD <3% and 8% respectively, $p<0.05$> with significantly lower levels of hip ROM in all directions . The patient group had significantly improved on all three measures of ROM and the COD test at 12-weeks. Further improvements were recorded for squatting depth and RSI 1 year later. Changes among the control group at 12-weeks and 1 year were not significant. Pain measures at 1 year reduced for acceleration <47% pre-op to 8%>, COD <60% to 8%> and for the squatting depth measures <52% to 8%>. Eighty three percent of patients had returned to full training and competition at 1 year
CONCLUSION: Symptomatic FAI negatively effects athletic performance; arthroscopic correction of FAI is recommended for athletes wishing to continue with sports participation and improve performance. Improvements in agility and ROM as well as reductions in activity related pain were noted as early as 12-weeks.

EVALUATION OF ECCENTRIC HAMSTRINGS STRENGTH ASSESSMENTS THROUGH ISOKINETIC DYNAMOMETRY AND NORDIC HAMSTRING DEVICE

GRESSENBAUER, C., WIESINGER, H.P., SCHARINGER, M., KÖSTERS, A., MÜLLER, E.

UNIVERSITY OF SALZBURG

INTRODUCTION: High, bilateral evenly distributed eccentric knee flexion strength is critical in injury prevention (Al Attar et al., 2017) and/or athletic performance (Morin et al., 2015). However, ischiocrural muscles are, inter alia, region-specifically activated in hamstring exercises (Hegyi et al., 2017) and their strength assessment remains challenging. Moreover, pilot tests revealed divergent torque levels when measured with an isokinetic dynamometer (IKD) or the Nordic hamstring device (NHD). This study examined these ischiocrural strength differences obtained by the current test devices in a broader context.
METHODS: A three session repeated measurement and a counterbalanced within-subject design were used for reliability and device comparison, respectively. Twenty-five healthy male adults (26±3 yrs) were tested on an IKD and a NHD. Eccentric peak torque (EPT), bilateral strength ratios (BSR) and the maximal voluntary isometric contraction (MVC) normalized activity of the biceps femoris (BF) and semitendinosus (ST) muscles were assessed.
RESULTS: Both methods showed moderate reliability for EPT (IKD: ICC2.1=.86, CVTE=7.2%; NHE: ICC2.1=.85, CVTE=7.2%) and low reliability for BSR (IKD: ICC2.1= .30, CVTE =11.6%; NHE: ICC2.1= 0.37, CVTE=7.9%). There was a moderate correlation in EPT (r=.69, p<.001) between the devices; however, values were higher on the NHD (30%; p<.001). BSR measured on each device did not correlate (p<.43). MVC normalized electromyography revealed a significant higher activation for ST (15%; p<.018), but no significant difference for BF (p<.88).
CONCLUSION: The systematically higher eccentric knee flexion torque obtained by the NHD compared to the IKD illustrates that current devices cannot be used interchangeably. It also indicates the importance to account for the assessment when interpreting eccentric knee flexor strength data in the context of prevention, screening, or performance monitoring.

RATE OF FORCE DEVELOPMENT SCALING FACTOR IS A PROMISING INDEX TO IDENTIFY INTER-LIMB ASYMMETRIES IN SOCCER PLAYERS

BOCCIA, G.1, BRUSTIO, P.R.1, BUTTACCHIO, G.2, CALABRESE, M.2, CASALE, R.2, RAINOLDI, A.1

1: NEUROMUSCULAR FUNCTION RESEARCH GROUP , 2: HABILITA CARE & RESEARCH REHABILITATION UNIT

INTRODUCTION: Muscle strength asymmetries between lower limbs are common in soccer players and crucial for performance and injury prevention. Peak torque exerted during concentric isokinetic contraction is widely adopted to provide and index of inter-limb asymmetry. In this study we compared inter-limb asymmetry measured in concentric contraction with the rate of force development (RFD) scaling factor (RFD-SF). In a series of fast force pulses performed across a range of submaximal values, there is a linear relationship between the force peak and the RFD peak obtained in each pulse. RFD-SF is the slope of this relationship, thus RFD-SF quantifies the extent to which RFD scales with the intensity of the contraction.
METHODS: Knee flexors and extensors strength was evaluated in both limbs of elite young soccer players (22 males, 17±1 years). Seated on an ergometer, participants performed three concentric isokinetic contractions at 240°/s and the RFD-SF protocol. The inter-limb difference was calculated for each parameter and players presenting an inter-limb difference > 15% were identified. The ratio between dominant and non-dominant side was also calculated.
RESULTS: The percentage of players that presented an inter-limb difference higher than 15%, was 10 and 40% in knee extensors, and 35 and 55% in knee flexors for concentric contraction and RFD-SF, respectively. Dominant limb showed higher concentric strength (139±31 vs. 134±26 Nm, p=0.04) in knee extensors, and higher RFD-SF in knee flexors (8.9±1.6 vs. 8.0±1.6, p=0.05) compared to the non-dominant limb.
CONCLUSION: Adopting RFD-SF it was possible to identify more players with a relevant interlimb asymmetry than adopting concentric contractions, both in knee extensors and flexors. RFD-SF was particularly compromised in the knee flexors of non-dominant limb. It is unknown if this imbalance may be seen as a risk factor for musculoskeletal injury. However, since RFD-SF provides meaningful information about the quickness of producing force across a wide rage of contraction intensities, we advance that future study should investigate if RFD-SF imbalance may be considered as a risk factor.

FRONT-CRAWL SWIMMING: DETECTION OF THE STROKE PHASES THROUGH 3D WRIST TRAJECTORY USING INERTIAL SENSORS

FANTOZZI, S.1,2, GATTA, G., MANGIA, A.2, BARTOLOMEI, S.4, DI MICHELE, R.4, NIGRO, F. 3,4, CORTESI, M.3

UNIVERSITY OF BOLOGNA

INTRODUCTION: The arm-stroke technique is a key factor for the improvement of swimmer performance using the hand as thrust. The arm-stroke cycle in front crawl is typically described by four phases (entry, pull, push, recovery), commonly expressed as a percentage of the stroke duration. To overcome the limitations of video-based motion analysis in swimming, Dadashi et al. (2013) and Callaway (2015) proposed two algorithms based on the angular velocity of the forearm or on the body roll position, respectively. This study introduces, for the first time, an approach for automatic temporal stroke phase detection in swimming using inertial measurement units (IMMUs) based on the 3D position of the upper arm. The validity of the proposed method is compared with a video-based system considered as gold standard.
METHODS: Kinematics of 6 national-level male swimmers was evaluated during 25m swimming trial performed at sub-maximal velocity. Data collection was performed using a IMMUs system (APDM Opals, 5 units, 128 Hz). IMMU devices were built and firmly fixed onto the swimmer body segments (thorax, upper-arms, and forearms). The four stroke phases duration (time between the following described events) were automatically recognized through an algorithm that identified the start events of arm-stroke phases: Tentry occured when the derivative of antero-posterior position of the wrist is for the first time lower than a threshold (60 cm/s); Tpull occurred when the derivative of medio-lateral position of the wrist is for the first time lower than a threshold fixed at -50 cm/s; Tpush occurred when the dorsal-ventral position of the wrist reach the minimum value; Trecovery occurred when the angle between the forearm and thorax anterior-posterior axes starts to decrease. The validation was performed using 2D sagittal video analyses as gold standard for temporal events identification.
RESULTS: The mean (±SD) values of the Tentry, Tpull, Tpush and Trecovery detected using 3DIMMU and TLC expressed as percentage of the stroke duration were 36.3 (± 9.3)%, 22.9 (± 7.3)%, 13.2 (± 3.1)%, 27.6 (± 3.7)% and 34.9 (± 8.8)%, 22.3 (± 7.6)%, 13.5 (± 3.3)%, 29.3 (± 4.3)%, respectively. A strong mean correlation (R=0.80) for the stroke phase duration was observed between two methods. The Bland-Altman plot indicated a good agreement and an acceptable mean error between the stroke phases detection with video-based and the IMMU methods (the bias and the limits of agreements were always lower than 1.8% and 4.4%, respectively).
CONCLUSION: The present findings confirmed the practical use of IMMU technology for the detection of the stroke phase based on upper arm trajectory. The obtained accuracy can be considered sufficient to satisfy the coaches and athletes training purposes.

A KINEMATIC ANALYSIS OF THE TENNIS SERVE: INFLUENCE OF SERVE VELOCITY

FETT, J., VUONG, J., OBERSCHELP, N., FERRAUTI, A.

RUHR-UNIVERSITY BOCHUM

INTRODUCTION: In tennis, modern game has evolved from a primary technical to the current explosive sport becoming increasingly dynamic and faster. Coaches and scientists agree that the serve is one of the most important techniques in todays top level tennis. In the high performance tennis, the effectiveness of the first serve is substantially dependent on post impact ball speed. Consequently, identifying predictors of the service would be hugely valuable in developing and refining training strategies. In the present study, fast and slow servers of the elite male junior section were compared with respect to different kinematic parameters during the service motion.
METHODS: The service motion of five players with a fast serve in relation to their age group (group fast (F); serve velocity [V]>70% (data basis: n=853), age:14.2±1.2years, weight:60.3±10.5kg, height:173.8±11.9cm) were compared to those of five players with a low relative serve velocity (group slow (S); V<30% (data basis: n=853), age:15.2±1.0years, weight:52.4±9.1kg, height:169.7±11.2cm) by using a Vicon Motion Capturing System. A modified version of the whole body model originally designed by the University of Western Australia was used to record the kinematic parameters. Right-handed players served from the deuce court, left-handed players from the ad-court. After a brief warm-up consisting of serves with increasing velocity, eight first serves were performed. For comparative analysis of the parameters, the respective values of the fastest three serves were averaged.
RESULTS: Regarding the maximum angular range, the fast servers showed major lateral flexions during the preparation phase of the motion (F 16.9±2.5° vs S 10.5±5.4°; ES1.70; p<.05) as well as at impact (F 28.9±3.1° vs S 21.2±10.7°; ES1.09). This tendency was also evident for the maximum angular velocities for the knee extension of the rear leg (F 544.4±69.0°/s vs S 470.9±51.9°/s; ES-1.35), elbow extension (F 1729.5±195.5°/s vs S 1492.1±439.7°/s; ES-0.78) and internal rotation of the striking arm (F 2185.3±240.7°/s vs S 1911.7±239.0°/s; ES-1.28). Further, in the temporal difference of the maximum angular velocities to impact, divergences between the groups occurred with respect to the parameters of knee extension, core flexion, elbow extension and wrist flexion.
CONCLUSION: The results indicate that regarding movement characteristics only the lateral flexion differs amongst the groups while concerning the angular velocities more differences could be found. In this regard, especially the upper body power has to be highlighted (i.e. elbow extension, internal rotation). Furthermore, obtained results indicate divergences in the temporal motion coupling of the partial impulses (kinetic chain).

DIGITAL MONITORING OF CREW MOVEMENT AND SAILBOAT MANOEUVRABILITY IN ELITE-LEVEL OLYMPIC CLASS SAILING

SCHULTZ, A., CARTER, D., RALPHS, G., ELLIS, S.

UNIVERSITY OF NEWCASTLE

INTRODUCTION: Training models in sailing rely primarily on subjective identification of shortfalls in sailing technique for maneuvres of interest. Correspondingly, there is a paucity of research reporting objective variable analysis when describing the interaction between crew movement, sailboat maneuverability and environmental factors while sailing. This research aims to identify key variables contributing to sailing performance whilst maneuvering in elite-level 49er and 49erFX sailing.
METHODS: Three 49er (males, n=6, age 24±3.4 yrs) and three 49erFX (females, n=6, age 20±2.3 yrs) teams from the Australian Sailing Team and Australian Sailing Squad were recruited for this study. Prior to data collection inertial measurement units (IMUs) were placed on the T12 vertebrae of both the crew and skipper of each team, as well as on the hull of each skiff, in order to monitor sailors trunk movements and boat movement whilst sailing. On-board video sensors were located on each skiffs mast and stern, to record sailors positions on the boat, while enviro-sensors were located on a coach-boat to monitor wind speed and direction. Participants then performed 20 tacks and 20 gybes with maximal effort, in flat-water conditions, in wind speeds ranging between 5-14 knots.
RESULTS: Two-factor Principle Components Analysis revealed that sailing performance (velocity made good) whilst tacking in the 49er teams were primarily a factor of the sailors movements (accounting for 48% of variance in performance), and a combination of the sailors movements and positioning of the combined body mass of the crew on the boat whilst gybing (accounting for 51% of variance in performance), with lighter crews performing better. In contrast, sailing performance whilst tacking for the 49erFX teams were primarily a function of starting tack, increasing boat pitch during the middle-end portion of a tack, and to a lesser degree sailors movements (accounting for 72% of variance in performance). When gybing, sailing performance in the 49erFX teams were primarily a function of starting tack, increasing boat yaw during the start-middle portion of a gybe, GPS speed and sailors movements (accounting for 56% of variance in performance).
CONCLUSION: This research identified novel relationships between key sailing performance variables, and highlights sailing technique differences between 49er and 49erFX sailors. Further research is however needed to confirm the findings reported here. Future research should include IMU data post-processing in order to allow inverse-kinematic calculations to be performed. Specifically, mapping the plane and direction of the sailors movement relative to the boat whilst sailing should be a primary focus.

PROFILE OF ELITE TAEKWONDO COMBAT USING TIME MOTION ANALYSIS.

IONA, T., TORNELLO, F., VONO, S., AMMENDOLIA, A.

UNIVERSITY OF CATANZARO

INTRODUCTION: Taekwondo is an evolving Olympic Game: significant changes in patterns emerged over time, mirroring evolution of new competition rules adopted by the World Taekwondo Federation. Aim is to define the profile of elite Taekwondo athletes analyzing the time-motion of different combat phases (fighting: F, nonfighting: NF, and stoppage time: ST) during finals of 2017 World Taekwondo Championships in Korea.
METHODS: All finals, (three 2-minute rounds, with 1-minute rest in between) in official male weight categories were analyzed in order to evidence combat duration phases in relation to F, NF and ST phases and the number of tactical movements and technical exchanges in relation to F phase. A descriptive statistical analysis was applied to the study, data were presented as mean ± SD.
RESULTS: Data showed that mean duration for F phases in all weight-categories (2.9±2.5s) and for each official weight categories respectively (<54 kg.: 3.4 ±3.3s; <58 kg.: 2.7 ±2.2s; <63 kg.: 2.9 ±2.1s; <68 kg.: 3.4 ±3.3s; <74 kg.: 3.4 ± 1.9s; <80 kg.: 2.1 ±1.5s; <87 kg.: 1.9 ±1.0s; >87 kg.: 2.6 ±1.8s;) always lasted about equally than those of NF (3.2±2.4s) and respectively <54 kg.: 1.9±1.3s; <58 kg.: 3.7±2.3s; <63 kg.: 3.5±2.3s; <68 kg.: 2.0±1.1s; <74 kg.: 4.1± 2.4s; <80 kg.: 2.3±1.5s; <87 kg.: 4.2±3.1s; >87 kg.: 4.6 ±2.9s. The analysis of ST phase showed for all 13.7±18.9s and for each weight categories <54 kg.: 15.5±2.6s; <58 kg.: 9.4±1.0s; <63 kg.: 17.7±1.5s; <68 kg.: 28.8±3.7s; <74 kg.: 7.8±1.9s; <80 kg.: 20.8±3.3s; <87 kg.: 6.0±2.1s; >87 kg.: 7.1±1.8s. During F phase, 4.5±4.0 tactical movements and 3.1±2.9 technical exchanges were performed, these findings testify the intermittent nature of combat, characterized by a high occurrence of movements.
CONCLUSION: This may be consider one of the first attempt to define the actual combat performance model using time-motion analysis after last changes of the Competition Rules by World Taekwondo Federation (Nov-15-2016). Data demonstrated that, after 12 months from application of new rules, elite athletes tend to engage in fighting periods for around 3 seconds, alternating F and NF with a 1:2 ratio, compared to investigating activity profiles of elite TKD athletes in the past.
The elevated number of tactical movements and technical exchanges during F phases demonstrated the high intensity of combats. These results have important implications related to training program design and support the need for coaches to modify tactical and technical training of elite athletes.

LOWER LIMB EMG ACTIVIY INDUCED BY OVERLOADED MUAY THAI ROUNDHOUSE KICKS OF THE STRIKING LEG

CIMADORO, G.1, PAIZIS, C.2, BABAULT, N.2

1: SHAS; ST MARY'S UNIVERSITY TWICKENHAM , 2: UFR STAPS;

INTRODUCTION: In Muay Thai, the roundhouse kick is the most powerful striking technique (Cimadoro et al., 2018). Its biomechanical features were studied across different kicking styles (Gavagan and Sayers, 2017). However, no data exists about muscle activation when striking (Thai-style) with additional overloads. Muscle activation strategies should inform Muay Thai training to maximize striking impact force. Thus, the goal of this study was to quantify lower limb electromyographic (EMG) activity during Thai-style roundhouse kick with a loaded vest and an ankle weight cuff.
METHODS: Ten professional Muay Thai fighters (age=25.8±5.7yrs; height=174.4±9.4cm; mass=66.0±6.4kg) took part in this randomized cross-over trial. All were experienced (training11±7.2h/week) and free from lower-limb. After a warm-up fighters performed maximal roundhouse kicks against a 60kg bag. Three striking conditions 1) body weight (BW) 2) additional ankle weight (AW) and 3) additional loaded vest (VT) were randomly performed. Ten maximal strikes for each condition were executed with a rest of 24h between conditions. Peak EMG (pEMG) activity of gastrocnemius lateralis (GL), biceps femoris (BF), rectus femoris (RF) and vastus lateralis (VL) of the striking leg was recorded and normalised to a maximal voluntary contraction of each muscle.

RESULTS: A significant muscle effect was found ($p<0.05$). For BW, pEMG for BF was significantly lower than GL, RF and VL muscles ($p<0.05$). For AW, pEMG was significantly greater in BF as compared to RF ($p<0.05$). For VT, pEMG was significantly lower in BF as compared to GL and VL ($p<0.05$). There was a condition effect for all muscles ($p<0.05$). pEMG was significantly lower in AW condition as compared to BW and VT for GL, RF and VL. No difference was obtained between BW and VT for these three muscles. pEMG was significantly greater in AW condition as compared to BW and VT for BF muscle. No difference was found between BW and VT for BF.
CONCLUSION: BW showed greater RF, VL and GL pEMG activity compared to BF providing the standard muscle activation behaviour. AW promotes greater BF activation compared to RF. Probably there is a greater effort to extend the hip to restore boxing stance implying a change of coordination strategy, making AW an exercise option to emphasize hip extensors recruitment, and to alter knee extensor muscles coordination. VT potentially matches muscle activation behaviour of the BW perhaps because it is less of a constraint on the striking leg reducing coordination changes during the swing phase otherwise produced by AW. VT may enhance the muscle activation without coordination changes

SPRINT FORCE-VELOCITY PROFILING: ABILITY TO PREDICT BOBSLEIGH PUSH START PERFORMANCE

CONDLIFFE, R.1,2, OLIVER, J.1,3, LLOYD, R.1,3, CRONIN, J.3, WOOLLEY, C.2

CARDIFF METROPOLITAN UNIVERSITY

INTRODUCTION: In bobsleigh, the push start has been identified as an important component of successful performance (Brüggemann et al. 1997). Previous literature has shown a link between the push start and sprint time over distances up to 100m (Osbeck et al. 1996). However, which mechanical properties of sprint performance underpin this relationship is not fully understood. Therefore, the aim of this study was to compare the bobsleigh push start predictive ability of traditional sprint split times measured in elite bobsleigh and force-velocity mechanical variables quantified during sprinting.
METHODS: Eleven elite male bobsleigh athletes (mean ±SD: age 27 ± 4 yrs.; mass 98.4 ± 8.3 kg; height 185 ± 6 cm) performed a maximal 60m sprint. Split times were collected using the standard elite bobsleigh protocol of 30m and 60m timing gates. Also, during the sprint each athletes force velocity mechanical profile was modelled using the validated split time method (Samozino et al. 2016), with additional gates placed at 5m intervals up to 25m. On a separate occasion, all athletes undertook a push start assessment on an outdoor track, with performance measured over a 50m section (15-65m). Pearson correlation coefficients were determined to assess the push start predictive ability of traditional sprint split time measurements (30m, 30-60m & 60m), as well as sprint force velocity mechanical variables.
RESULTS: Moderate to large relationships were observed for push start performance with 30m ($r = 0.69$, $P < 0.05$), 60m ($r = 0.59$, $P < 0.10$) and 30-60m flying sprint time ($r = 0.42$). A very large correlation was detected between the push start and absolute maximal power ($r = -0.80$, $P < 0.05$). Finally, the push start was shown to be either moderately or largely related to the remaining force velocity mechanical variables; relative maximal power ($r = -0.55$, $P < 0.10$), theoretical maximal force ($r = -0.58$, $P < 0.10$), relative theoretical maximal force ($r = -0.37$), theoretical maximal velocity ($r = -0.37$) and velocity at maximal power ($r = -0.38$).
CONCLUSION: The results indicate that force velocity profiling during sprinting may have better push start predictive value than traditional split time measurements. Hence, practitioners in bobsleigh looking to enhance push start performance should tailor training programmes towards optimising power during sprinting.

MO-SH04 Psychological skills, well being and performance in sport

THE EFFECT OF PETTLEP IMAGERY IN OPEN AND CLOSE SKILL OF BADMINTON.

SIRIPATT, A.

SRINAKHARINWIROT UNIVERSITY

The Effect of PETTLEP Imagery in Open and Close Skill of Badminton.
Siripatt, A., Luangon, S., Puengsoonthonsirimas, T., & Boonveerabut, S.
(Srinakharinwirot University, Thailand)
Introduction: Badminton serves (BS) and returning badminton serve (RBS) are very important in the badminton game, that very fast and a lot of pressure, so new player hard to control BS and RBS. BS is a closed skill. They are distraction free and are given the opportunity to serve the shuttlecock by uninterrupted. RBS is an open skill that takes place in a dynamic and changing environment. Player trying to move around the court for return serve and multiple other variables that could affect them. The use of sports psychology techniques is an alternative for help new player to control their abilities. This study explores the effect of PETTLEP imagery in open and close skill of badminton sport.
Methods: Eighty male who no experience in badminton, sport imagery and competition. Accuracy scores were divided into 4 groups; G1a practice BS only, G1b practice BS with PETTLEP, G2a practice RBS only and G2b practice RBS with PETTLEP. The data collecting from BS and RBS accuracy test at before training, after week 4 and week 8 of participating the program. Mean, SD, t-test, one-way ANOVA with repeated measures, and Bonferroni were used to analyze the data significant at .05 level.
Results: The results revealed that, there were significant difference within BS groups (G1a, G2a) ($p<.001$) and RBS groups (G1b, G2b) ($p<.05$) between prior, 4th wk. and 8th wk. There were no significant difference between group a and b of BS and RBS. However, the group practiced badminton with PETTLEP Imagery model training showed better results than those who practiced the badminton only.
Discussion: This research shown that practiced BS and RBS with PETTLEP imagery model training showed tendency better results than badminton skill only, due to imagery is what happens in the mind, which caused physical characteristics that can't be determined. The 7 components of PETTLEP model are the imagery of physical, environment, task, timing, learning, emotion and perspective. Each letter of

the PETTLEP acronym represents an important issue to consider when implementing imagery interventions. The model was originally designed to be used as a minimum checklist when designing imagery interventions (Holmes & Collins, 2001). Understood that the imagery is not limited to still images. It means motion pictures and can change with conditions. (Morris, et al., 2005). PETTLEP imagery model combined with skills training, allows the beginner to learn and had experiences in their mind similarly actual practice.

UNDERSTANDING THE MENTAL CHALLENGES ENCOUNTERED IN ELITE FOOTBALL-A BRIEF SURVEY.

THOMPSON, C., TOWLSON, C., SKORSKI, S., FRANSEN, J., MEYER, T.
SAARLAND UNIVERSITY

Understanding the mental challenges encountered in elite football-A brief survey.
Thompson, C. 1, Towlson, C. 2, Skorski, S. 1. Fransen, J. 3, Lane, A. 4. Coutts, A. 3. Meyer, T. 1.
1: ISPM (Saarland, Germany), 2: UoH (Hull, England), 3: UTS (Sydney, Australia), 4: UoW (Wolverhampton, England)
Introduction: Mental fatigue is a psychobiological state experienced following exposure to cognitively demanding tasks. Five studies have collectively shown that exposure to prolonged demanding cognitive activity has a negative influence on physical, technical, tactical, decision making and skill performance in football (Badin et al., 2016; Smith et al., 2016a; Smith et al., 2016b; Coutinho et al., 2017; Smithet al., 2017). The current literature has predominantly used a 30 minute modified Stroop task to induce mental fatigue, which provides low ecological validity in football. Furthermore, all aforementioned studies have investigated recreational/sub elite players. It is possible that the cognitive demands of the modified Stroop task may differ compared to the cognitive demands faced in the multifaceted lifestyle of a football player. Therefore, it is imperative to explore the real life tasks completed by elite football players to detect mentally demanding activity.
Methods: 21 elite football players from the Swedish 1st Division completed an online survey (Eanalyzer.com) consisting of five overall themes: Travel, Training, Pre Match, Match-play and Fixture congestion. Questions were related to the occurrence and frequency of numerous lifestyle activities, along with player perception of the mental demands of several football related scenarios.
Results: Overall, the mental demands of all five themes were reported as low. 85.7% of players drive their car to training in a journey lasting up to 30 minutes. Players perceive the intake of tactical information from coaches as either never (19%) or rarely (81%) mentally demanding. The mental demands of fixture congestion were reported to be low (9.6% somewhat agree, 4.8% strongly agree).
Discussion: These results interestingly show a low perceived mental demand of lifestyle activities, and of the matches, even in a congested period. These results may possibly differ in players from more prominent elite leagues, which are likely to have greater media coverage, further travel demands and exacerbated pressure to succeed.

THE INDEPENDENT EFFECTS OF MATCH LOCATION, MATCH RESULT AND THE QUALITY OF OPPOSITION ON SUBJECTIVE WELL-BEING IN UNDER 23 SOCCER PLAYERS: A TEAM CASE STUDY.

CLIFFORD, T.1, BROWNLEE, T.2, HARPER, L.D.3, NAUGHTON, R.J.3, ABBOTT, W.4
NEWCASTLE UNIVERSITY

INTRODUCTION: Although it has been established that subjective measures of wellbeing, such as mood and sleep, are sensitive to changes in training load, less is understood about the non-physical factors that could affect subjective wellbeing. Such non-physical factors include the situational variables, match location, the quality of the match opposition, and the match result. The aim of this study was to establish whether subjective wellbeing was affected by match location, match result and the opposition quality in a team of professional soccer players.
METHODS: Eleven male soccer players from the under 23 squad of a Premier League 2 team in England participated in this study (Age, 19.5±1.2years; height, 1.80±5.20m; body mass, 76.1±7.5kg). Before (PRE), 1 day (POST-1), and 3 days (POST-3) following 17 matches subjective wellbeing (mood, stress, soreness, sleep quality and fatigue) were recorded. Each was scored between 1-5; 1 representing a positive score and 5 a negative score. Match training loads were estimated from session-rating perceived exertion (sRPE) scores. A repeated measures ANOVA was used to explore interaction effects in the subjective wellbeing variables and the situational variables over time (PRE, POST-1, POST-3).
RESULTS: Match training loads (sRPE) did not differ, regardless of the location, result, or quality of opposition faced ($P>0.05$). None of the subjective wellbeing measures were different at PRE ($P> 0.05$); however, at POST-1 and POST-3, stress and mood were =20% lower after playing away from home or losing ($P<0.05$). Stress, mood and sleep were =12% worse after playing against a higher-level opposition at POST-1. Sleep quality was worse at POST-1 after playing a top-team vs. a bottom team (3.6±0.4 vs. 3.1±0.5, respectively; $P=0.033$; ES=0.99). Similarly, stress was higher and mood lower at POST-1 after playing against top teams vs. bottom teams ($P<0.05$).
CONCLUSION: This study provides the first evidence that the quality of opposition, and especially the match location and match result, might negatively influence the subjective wellbeing of soccer players for several days after matches. These findings highlight that practitioners working in soccer might need to factor in the potential influence of these specific situational match variables when prescribing training load between matches. The data also suggests that players might need additional psychological support (e.g., effective coping strategies) after fixtures that might be affected by these specific variables.

EFFECTS OF STAR WATCHING EXPERIENCES ON THE SENSE OF HUMAN'S SPIRITUALITY AND ON OTHER PSYCHOLOGICAL FACTORS.

KIJI, M.1, KASE, T.2, NIGORIKAWA, T.3

RIKKYO UNIVERSITY

Introduction: Many studies have shown that human's health and spirituality have close relations. Our previous study revealed that there would be certain relations between the habits of daily exercise and the tendency of spirituality. On the other hand, several studies mentioned that staying in the natural field could enhance one's sense of spirituality. Moreover, our previous study also showed that outdoor activities could enhance one's tendency of spirituality more efficiently than ordinary competitive sports. However, there are many kinds of outdoor activities, which are extremely varied. This study focused on the act of watching stars as an outdoor activity being generally supposed to deeply impress a lot of people (in different ways), and it tried to examine the effects of star watching on the sense of human's spirituality and on other psychological factors.
Methods: The subjects of the study consisted of 22 male and 22 female university students (mean age = 20.0). They were divided into two groups: the natural star watching group (n=21) and the planetarium group (n=23). Further, these two groups were also divided into the high spirituality group and the low spirituality group, respectively. The tendencies toward spirituality and health were measured using The Japanese Youth Spirituality Rating Scale (JYS). Other psychological factors measured in this study were as follows: The Purpose In Life Test (PIL), Profile of Mood States (POMS) and The Natural Health Questioner (GHQ). Finally, PIL, POMS and GHQ scores were compared before and after the act of watching stars.
Results: In regard to POMS, there was no significant difference between the high spirituality group and the low spirituality group in the natural star watching group. However, for the planetarium group, there were significant differences in several factors between the high spirituality group and the low spirituality group regarding the POMS. These factors were Depression-Dejection ($p<.05$), Vigor-Activity ($p<.10$) and Friendship ($p<.05$). The other psychological factors as for PIL and GHQ, there was no significant difference between the high spirituality group and the low spirituality group.
Discussion: Our previous study suggested that outdoor activities could enhance one's tendency of spirituality. As one outdoor activity, this study aimed to examine effects of star watching on the sense of human's spirituality and other psychological factors. As a result, it was revealed that there was only a small relation between one's tendency of spirituality and the effects of watching stars. Further investigation is demanded to clear this relation because this study could not prepare and test a sufficient amount of subjects.

THE EXAMINATION OF FEAR-AVOIDANCE BELIEFS AS A PSYCHOLOGICAL REACTION TO MUSCULOSKELETAL INJURY IN MALE ADOLESCENT GAELIC FOOTBALLERS

OKEEFFE, S., NÍ CHÉILLEACHAIR, N., OCONNOR, S.

ATHLONE INSTITUTE OF TECHNOLOGY

Introduction: Participation in Gaelic football provides a wealth of benefits but a risk of musculoskeletal injury also exists, bringing obvious physical consequences. However, concurrently associated psychological consequences can also occur, such as fear-avoidance beliefs and behaviours. No previous research has examined fear-avoidance as a psychological response to injury in the GAA. Therefore, the aim of this study is to examine fear-avoidance beliefs in male adolescent Gaelic footballers post-injury.
Methods: Male adolescent Gaelic footballers (n=97, 13.4±1.1 years) were recruited. A modified Athlete Fear Avoidance Questionnaire (mAFAQ) was completed at baseline as a predictor of fear-avoidance beliefs. Injuries were assessed and recorded weekly by a Certified Athletic and Rehabilitation Therapist using a standardised injury report form. An injury was defined as any injury sustained during training or competition resulting in restricted performance or time lost from play. Injuries that required the player to miss time from Gaelic football participation were classed as time-loss injuries. The athlete completed the Athlete Fear Avoidance Questionnaire (AFAQ), a measure of injury related fear-avoidance following injury assessment (AFAQ1). With time-loss injuries, the AFAQ was completed again (AFAQ2) prior to return to play.
Results: Twenty-two injuries were recorded during the season. Fear-avoidance beliefs were evident in male adolescent Gaelic footballers who sustain time-loss (26.8±4.9) and non-time-loss (21.0±7.2) injuries, however, no significant difference between both was noted ($p>0.05$). With time-loss injuries, fear avoidance beliefs decreased significantly before return to play (14.3±4.9) ($p=0.01$). Significant moderate correlations were evident between AFAQ1 and pain at the time of injury ($r= 0.563$; $p= 0.006$) and at the time of injury assessment ($r= 0.596$; $p=0.003$). However, no significant relationships were found between AFAQ2 and pain or between time loss from Gaelic football participation and AFAQ ($p>0.05$). Previous injury was a significant predictor of AFAQ2 scores ($p=0.003$) only. Baseline mAFAQ and previous injury were not significant predictors of injury and mAFAQ was not a significant predictor of AFAQ1. Similarly, mAFAQ, AFAQ1 and AFAQ2 were not significant predictors of time loss from Gaelic football participation.
Conclusion: Male adolescent Gaelic footballers experience fear-avoidance beliefs post-injury that decrease before return to play in those who sustain a time-loss injury. Greater pain at the time of injury and at the time of injury assessment by a clinician indicates greater fear-avoidance beliefs. Appropriate intervention programmes are necessary for addressing potential psychological barriers to rehabilitation.

DISCRETE AIMING MOVEMENT OF NON-DOMINANT HAND USING WIIMOTE

KIM, H.

PURDUE UNIVERSITY

INTRODUCTION: A combination of speed and accuracy is a critical aspect to determine whether a successful performance or not. Fitts(1954) quantified the speed-accuracy trade-off, which is the most robust relation in motor control and discovered the log-linear relation between the movement time and ID (index of difficulty). We addressed whether Fitts law also holds for non-dominant hand, furthermore whether the performance of the non-dominant hand can enhance through extended practice. Therefore, the purpose of this study is to assess the non-dominant hand movement on discrete aiming task and the effect of practice.
METHODS: Three experimental conditions were assigned to the subjects. A handheld Wiimote was used and the measurement of acceleration was obtained from Wiimote accelerometer during every trial by open-source software. Subjects performed a discrete aiming movement with the distance (D) of 32 cm and with the differently sized target width (W) of 4 cm, 1 cm, and 0.25 cm. Thus, the ID of the task was 4 (easy), 6 (moderate), and 8 (difficult) respectively. Each subject completed the task with left hand (or non-dominant) and right hand (or dominant). The total number of trials was 450 (10 trials x 3 conditions x 15 blocks) for left hand and 450 (10 trials x 3 conditions x 15 blocks) for right hand as well.

RESULTS: The mean value of the right-handed was 0.916 s (SD: 0.489) and 1.087 s (SD: 0.321) in the result of the movement time regardless of task conditions. There was no significant difference between the means of movement time (t88=-1.954, p=0.053), however very close to being statistically significant. In the easy task, the movement time for the right hand was 0.659 s (SD: 0.116) and the velocity was 49.905 cm/s, 1.077 s (SD: 0.409) and 32.724 cm/s for the left hand in average. In the moderate task, the movement time for the right hand was 0.829 s (SD: 0.107) and the velocity was 39.149 cm/s, 1.108 s (SD: 0.353) and 31.356 cm/s for the left hand in average. In the difficult task, the movement time for the right hand was 1.26 s (SD: 0.723) and the velocity was 32.724 cm/s, 1.075 s (SD: 0.181) and 30.578 cm/s for the left hand in average. As the ID of the task increases the movement time increases and the velocity decreases contrarily.
CONCLUSION: We predicted that the right hand would show superior performance than the left hand, however, no significant difference between the dominant hand and non-dominant hand was found regardless of task difficulty. Also, this study showed that the dominant hand took more time to perform the tasks in different task conditions. On the contrary, the non-dominant hand took similar time to perform the tasks regardless of task difficulty. The results indicated that an increase in the movement time with a decrease of speed, as well as we couldnt find out the effect of practice. Future research should include more task conditions and more participants to examine and compare.

OP-SH01 Inclusion

BEING DERBY: NEGOTIATING BELONGING IN THE ROLLER DERBY SCENE

ALEXANDER, J.

WESTERN SYDNEY UNIVERSITY

Contemporary roller derby has been widely recognised in scholarly work and popular culture as a womens, Do-It-Yourself, grassroots level sport that maintains a shared By the skaters, for the skaters mantra. In valorising skater practice, however, there can be an erasure and dismissal of other modes of involvement and more fluid relationships with roller derby. A further consequence is a failure-both in academia and roller derby life-to recognise the potential continuities between groups of individuals (such as skaters and spectators) in their involvement practices and feelings of attachment and belonging to roller derby. This paper is concerned with the question who is roller derby? Using data generated through an ethnographic study of roller derby, I argue that regardless of their role, participants utilise a language of desire-for belonging, community, bodily challenges, and for something different in their lives-to make sense of their attraction to roller derby and motivation for joining. Central amongst these is a pursuit for more involvement; where more signifies movement, transformation, and alterations to social, cultural, and sensory affordances that facilitate feelings of inclusion, connection, community, and belonging. By not privileging skater experiences in my analysis of participants elective belongings, I aim to illuminate some of the ways that non-skaters (such as spectators, non-skating officials, announcers, and media producers) navigate the roller derby scene and actively pursue inclusion in the communal identity of being derby.

A CROSS-NATIONAL STUDY OF POLICIES FOR PARALYMPICS IN UK, GERMANY AND JAPAN: INCLUSION OR EXCLUSION?

YAMAGUCHI, Y.

KOBE UNIVERSITY

A CROSS-NATIONAL STUDY OF POLICIES FOR PARALYMPICS IN UK, GERMANY AND JAPAN: INCLUSION OR EXCLUSION?
Yamaguchi, Y.1, Tanaka,N.2, Okuda, M.3
1:Kobe University (Kobe, Japan), 2:Toin University of Yokohama (Yokohama, Japan), 3. Kyoto Sangyo University (Kyoto, Japan)
Introduction: Since the inclusion strategy of the London Organizing Committee of the Olympic and Paralympic Games (LOCOG) produced significant changes in people's attitude toward Paralympic Games as well as the disabled. In IOC congress in Rio de Janeiro in 2013, Tokyo was selected as a host city for the 2020 Olympics and Paralympics. We have a national training center for Olympics in Tokyo, although there is no place for Paralympic athletes. As a result, an important theme of discussions rises "inclusion or exclusion". The purpose of this study was to compare the policies and training centers for Paralympics in UK, Germany and Japan.
Methods: Field works were conducted in UK, Germany and Japan in 2014. Interviews were also undertaken to 16 government staffs, coaches and researchers in UK, 3 in Germany, and 25 in Japan. Interviews consisted of organizational structures (government, NF), national and regional training centers, support from sport medicine and sciences, and relationship with NOC. Content analysis was applied to the data and information by using triangulation methods among three researchers.
Results: Sport in UK has been governed by Department of Culture, Media and Sports (DCMS). National training centers for Paralympic athletes are located in each region. UK Sport focuses on Olympics and Paralympics, while their policy is the "concentration and centralization". Each NF sets training centers with quality standard. Paralympic athletes receive financial aid with different amount based on evaluation standard.
Under the Ministry of Interior in Germany, German Paralympic Sport Federation (DOSB) is the central body. German Disability Sport Federation (DBS) and National Paralympic Committee Germany (NPC) control disability sport. Germany is the federal state, while DBS collaborates each state to promote disability sport with regional training facilities.
Influenced by the enactment of Sport Basic Law (2011) in Japan, the promotion division for disability sport moved from Ministry of Health and Welfare to the Ministry of Education, Culture, Sport, Science and Technology (MEXT) in 2014. In same year 2014, advisory board on training and research centers for Olympics and Paralympics was established. Japan Olympic Committee (JOC) emphasized the NTC in Tokyo is for the athletes of JOC and there is no place for Paralympic athletes.
Japan Paralympic Committee (JPC) insisted to construct new NTC for only Paralympic athletes.
Discussion: The findings of this study provide some insights into the inclusion subject in sport. First, policy of social inclusion and inclusion sport has been pervasive in UK and Germany. Cooperation and collaboration between Olympic sport and Paralympic sport have been promoted. Furthermore, co-use of National/regional training centers among Olympians and Paralympians is taken for granted.
Second, one of the major reason for the inclusion policy is the enactment of the Disability Discrimination Act. UK government enacted the Disability Discrimination Act in 1995. Finally, Japanese government adopted the inclusion policy for the Olympic and Paralympic athletes

in 2014. In 2018, current NTC in Tokyo renovated to universal design for Paralympic athletes, while new co-use NTC has been constructing for Tokyo Olympic and Paralympic Games in 2020.

LEVERAGING TOKYO 2020: CAN THE OLYMPIC AND PARALYMPIC GAMES CHANGE BEHAVIORAL INTENTION FOR PHYSICAL ACTIVITY AND SPORTS PARTICIPATION AMONG MIDDLE-AGED AND OLDER ADULTS IN JAPAN?

ANNEAR, M., SHIMIZU, Y., SATO, K., TAKANASHI, M., YAMAUCHI, H., KIDOKORO, T.
INTERNATIONAL CHRISTIAN UNIVERSITY

Introduction: Middle-aged and older Japanese people are long-lived, yet comparatively inactive and frail compared to cohorts in similarly developed nations. With a rapid increase in the 65 and older cohort, preventable and age-associated chronic diseases are also rising in Japan and interventions are required to arrest this public health challenge. Physical activity and sport participation have been shown to compress morbidity in later life, yet few population-level interventions have succeeded at mobilizing inactive cohorts. We hypothesize that consolidated environmental changes, public health marketing, and psycho-social factors associated with hosting the Tokyo 2020 Olympic and Paralympic Games offer a potential population-level intervention to support behavior change in Japan.
Methods: Two complementary research approaches inform this study. A systematic literature review consistent with the international PRISMA guidelines was undertaken to assess global evidence for reported physical activity outcomes among middle-aged and older adults associated with hosting mega-sporting events. A subsequent Delphi study with academics from across the Asia-Pacific region was undertaken to assess expert consensus regarding middle-aged and older-adult activity levels, barriers and facilitators to participation, and legacy outcomes associated with previous regional Olympic hosting. Experts were deliberately selected for their knowledge in the areas of gerontology, sports and recreation studies, and population health.
Results: Research into the effects and outcomes of hosting mega-sporting events suggests that physical activity related behavior change is a potentially achievable outcome of the Tokyo 2020 Games. However, a coordinated and multifaceted approach will be required to achieve population-level behavior change. Regional experts highlighted that challenges of motivating aging populations to higher activity levels, including overcoming age-related social norms and environmental constraints. In the Asia-Pacific region, research into physical activity and sports related outcomes of mega-events is limited in scope and rigor and there has been a lack of systematic data collected before and after regional Olympic Games to facilitate effective comparisons. This suggests that there is a rapidly closing window within which to establish baseline measures prior to Tokyo 2020.
Discussion: A range of evidence-informed scenarios are identified for facilitating behavior change interventions with middle-aged and older adults in Japan. Options for environmental remediation and sustainability, policy changes, health marketing, and psycho-social interventions are explored with reference to the international literature and regional expert consensus. Options for baseline research are also presented to facilitate accurate assessments of physical activity, sports participation and potential behavior change prior to Tokyo 2020.

A STUDY ON CHILDRENS PHYSICAL GAMES OF MINORITIES IN SICHUAN

YAJING, D.
GUANGZHOU UNIVERSITY

A STUDY ON CHILDRENS PHYSICAL GAMES OF MINORITIES IN SICHUAN
Yajing Du.1,Ye Guo.2 1:GZU (Guangzhou,China), 2: GZU(Guangzhou, China)
Background
Minority sports play a big important role in Chinese traditional culture. Childrens game is not only an integral part of minority sports, but also the only way for children to socialize. Although there are few studies focusing on minority childrens physical games, we cannot deny the fact that researches on childrens physical games have a positive impact on children's healthy growth and the internationalization of Chinese culture.
Objective
By studying the minority childrens physical games and classifying the games of different minorities, this thesis aims to find out the factors that impact the development of physical games and provide certain theoretical references for the inheritance and improvement of traditional Chinese culture and enrich children' life and entertainment.
Methods: This study mainly focuses on four representative minorities of childrens physical game in Sichuan, including the minorities of Yi, Qiang, Tujia and Zhuang. The first method is by the literature, to know their customs and childrens physical games of the four minorities. The second step is to use field study method to respectively investigate into childrens physical games of minorities of Yi, Qiang, Tujia and Zhuang and to conduct a detailed investigation. The third step is to make interviews with 184 subjects about the types of ethnic childrens physical games, methods, rules and the environment of the games. Physical games of children in this thesis were all collected and sorted out from their memories and dictations. Meanwhile, the games of the four ethnic groups were also classified.
Results: The minority childrens physical games of Yi, Qiang, Tujia and Zhuang were divided into three categories: physical games, games played with equipments, and intelligence-promoting linguistic game; Compared with the majority (Han nationality), childrens physical games of the minorities have their unique characteristics: generally speaking, the game of the minorities fit in with their natural environment, in combination with the characteristics of their geography and climate. And the minorities play the games in their traditional festivals. Besides, the games also reflect their ethnic beliefs and myths; The constraints of the game development mainly caused by the changes in living environment, the impact of network technology and the integration of external cultures.
Conclusion
There are high quantities of sports games for minority children in Sichuan, and the traditional culture is preserved, which has been reflected in the games. Through the study of childrens physical games of minorities in Sichuan, we can see that there are big differences between the minorities and the majority (Han nationality); however, due to the continuous development of modern society, many games are gradually disappearing.

SOCIAL INTEGRATION OF REFUGEES IN GERMAN SOCIETY: BETWEEN PRACTICING SPORTS AND CLUB'S RESPONSIBILITY

ABDELKHALEK, M.

FACULTY OF PHYSICAL EDUCATION, MANSOURA UNIVERSITY, EGYPT.

Social Integration of Refugees in German Society: Between Practicing Sports and Club's Responsibility
Abdelkhalek, M.
Faculty of Physical Education, Mansoura University, Egypt
Introduction: Crises of revolutions recently have left a continuous increase in the influx of refugees in Germany. Cultures, attitudes, and beliefs variation impose some challenges towards integration of refugees in the society. Therere about 91000 sports clubs spread throughout Germany, which shall contribute to integration process based on refugees needs through two pathways; practicing sports and clubs social responsibility and these are the research aims.
Methods: The qualitative approach was utilized by documentary analysis of clubs initiatives and activities (N=18). Consequently, semi-structured interviews were conducted with individuals: members or athletes in sports clubs (N=27). Samples were selected by a snowball sampling (Patton, 1990). The interview questions were about ideas that consider in relation to "What are the integrations barriers?" "How practicing sports contribute to integration?" "What are the predictions from sports clubs institutionally?"
Results: Documentary and thematic analysis indicated two themes; a) Personal and social aspects of practicing sports. b) Integration core social issues (ICSI) by sports clubs. So the Foucauldian theoretical lens was utilized to interpret how (a) and (b) are working as a formula to accelerate the integration process.
Conclusion
This study highlights how sports organizations have the power to appeal and communicate with people (Tacon and Walters, 2010). Practicing sports conclude personal skills that change refugees behaviours such as; self-confidence, adaption to stress and getting rid of shyness. Also, it involves many social skills like; acceptance of others with different cultures and religions, friendship, social dialogue and socio-psychological security. Alongside, ICSI by sports clubs have been determined as a multidimensional concept to express the soft power of sports clubs in social interaction, further treating the integration barriers which create social problems in society. ICSI should be managed by sports clubs or in conjunction with other organizations in light of national integration plans to establish human solidarity and social responsibility values. Therefore, ICSI can achieve the integration across the awareness with these issues; a) Legal knowledge, human rights and equality. b) Renounce violence and racism and spreading reconciliation culture. c) Maintenance of environment and resources. d) Participation in community development. e) Personal, social and educational development. f) Health.

IS-BN06 Force-Velocity-Power profiling in explosive sports, from theory to field methods and training applications

FORCE-VELOCITY-POWER PROFILING: THEORY AND CONCEPTS

SAMOZINO, P.

UNIVERSITY SAVOIE MONT BLANC

INTRODUCTION: Force-Velocity-Power profiling: theory and concepts
SAMOZINO, P.
University Savoie Mont Blanc, LIBM (Chambéry, France)
The mechanical capabilities of the lower limb neuromuscular system have been well described by inverse linear force-velocity (FV) and maximal power output (Pmax) during various multi-joint movements, characterizing the Force-Velocity-Power (FVP) profile. Maximal force quality represents the capability to produce high level of force at low velocities while maximal velocity quality refers to the capability to develop force at high movement velocities. Accelerating its own body mass as quickly as possible (jumps, sprint acceleration), which are a key factor of performance in many sport activities, have been shown to largely depend on Pmax. Since Pmax can be improved by shifting the force or velocity sides of the FV curve, recurrent questions scientists, coaches or athletes ask when exploring/training factors for optimizing such a performance are to know how to evaluate FV relationships in field conditions and what to focus on: force or velocity capability?
Macroscopic biomechanical models applied to the body center of mass during jumping and sprinting were developed to propose new simple field methods and original concepts to better understand and improve such performances.
A computational method was validated to determine individual FVP profile from 3 simple parameters obtained during loaded jumps: body mass, extension range and jump height (Samozino et al 2008). Recently, another simple method was validated to assess sprinting FVP profile from only anthropometric and spatiotemporal data obtained during one single overground running acceleration (Samozino et al 2016). Both methods present high reliability and concurrent validity when compared to force plate measurements.
Biomechanical models made possible to show that, in ballistic movements (jumps), an optimal FV profile (slope of the FV relationship) exists for each individual and maximizes performance (Samozino et al 2012). The relative difference between actual and optimal FV profiles for a given individual characterizing the unfavorable balance between force and velocity qualities, and in turn individual force or velocity deficit. The same finding of an individual optimal FV profile as been obtained in sprinting (publication in progress).
This concept of optimal FV profile maximizing performance in jumps and sprints were then supported by experimental data showing that actual performance is affected by both Pmax and the magnitude of force or velocity deficits computed from optimal FV profile.

FORCE-VELOCITY-POWER PROFILING: TRAINING APPLICATIONS IN BALLISTIC MOVEMENTS

JIMENEZ-REYES, P.

CATHOLIC UNIVERSITY OF SAN ANTONIO, MURCIA, ESPAÑA

INTRODUCTION: Ballistic performances are determined by both lower limb maximal power output (Pmax) and individual force-velocity (FV) mechanical profile, especially the FV imbalance (FVimb): difference between the athlete's actual and optimal profile maximizing this kind of performances (Samozino et al. 2014; Samozino et al. 2012). FVimb makes possible to quantify the magnitude of individual force and velocity deficits. Thus, training program designed based on individual FVimb (optimized training) could be efficient to improve ballistic performance (Jiménez-Reyes et al. 2017; Morin & Samozino, 2016). The aim was therefore to test the effectiveness of such an optimized training on jumping performance.
The actual individual F-v profile and Pmax can be easily determined from a series of loaded vertical jumps (Jiménez-Reyes et al. 2016; Samozino et al. 2008, 2014), while the optimal F-v profile can be computed using previously proposed equations based on a biomechanical model (Samozino et al. 2012, 2014). The key FVP outputs (maximal theoretical force, velocity and power, and FVimb) may help better characterize athletes' capabilities and design more individualized and effective training interventions (Jiménez-Reyes et al. 2017; Morin & Samozino, 2016), based on prioritizing the under-developed mechanical capability to shift the Force-velocity profile toward an optimal value.
Recent evidence shows that (i) an individualized training program based on the FVimb in the FV profile of each individual is more effective in improving jump performance than a traditional resistance training common to all subjects and designed without taking account of individual differences in the initial FV profiles and imbalances, and that (ii) for subjects with an initial substantial FVimb (i.e., force or a velocity deficit) this higher jump performance was associated with the sensitivity of the force-velocity profile to the specific training program tailored to the athlete's individual needs, which has led to a reduced FVimb with no change in Pmax (Jiménez-Reyes et al. 2017).
Individual FV profile and FVimb should be taken into account as a starting point for prescribing specific loads and training program for a more effective training to improve jump performance, being an evidence-based step for a better understanding of FV profile based training for new insights in strength and conditioning practice. FVimb could therefore be considered as a potentially useful variable for prescribing optimal resistance training to improve ballistic (e.g., jumping) performance.

METHODS: RESULTS: CONCLUSION: FORCE-VELOCITY-POWER PROFILING: TRAINING APPLICATIONS IN SPRINT ACCELERATION

MORIN, J.B.

UNIVERSITÉ CÔTE D'AZUR

INTRODUCTION: Force-Velocity-Power profiling: training applications in sprint acceleration
Morin, J-B.
UCA, LAMHESS (Nice, France)
The laws of dynamics dictate that the external net force applied to a mass induces a proportional acceleration in the direction of the force vector. Our "motor" is skeletal muscle, and physiology dictates that there is an inverse relationship between the velocity of muscular contraction and its force output capability. The complexity of ballistic movements such as sprinting is that the force-velocity-power (FVP) spectrum (or profile), must be established to know the force capability of athletes across various velocities. An athlete may be "strong", producing high amounts of force at low velocity (typically at the beginning of an unresisted sprint or under significant external resistance) but much "weaker" at high velocity, or vice versa.
During sprint acceleration, the linear FV profile (hitherto only assessable using complex laboratory grade devices) may now be accurately established using distance- or velocity-time data (Samozino et al. 2016). Key FVP variables (maximal theoretical force, velocity and power, and orientation of force application) may better characterize athletes' capabilities and help guide individualized and effective training interventions (Morin and Samozino, 2016).
Recent evidence shows that (i) training with very-heavy sled resistance (>80% of body mass) was an effective solution to improve the left side of the sprint FV profile (maximal horizontal force) through a more horizontally-oriented force application (Morin et al. 2017) and (ii) the conditions under which to train maximal power output at maximum resisted velocity corresponded to a resistance that halved athlete's absolute maximal running velocity (Cross et al. 2017).
While more research is ongoing regarding training interventions, recent experimental data showed that this sprint-specific force capability was impaired in the context of previous or forthcoming (case-study) sprint-related hamstring injury (Mendiguchia et al. 2014, 2016). The latter results open a new track for research into a "win-win" strategy putting hamstring function at the center of a performance-prevention continuum.

CARDIOVASCULAR RESPONSES TO DISTINCT EXERCISE MODALITIES IN MONOZYGOTIC TWINS

MARSH, C.E.1, THOMAS, H.J.1, SCURRAH, K.2, NAYLOR, L.H.1, GREEN, D.J.1

1: UNIVERSITY OF WESTERN AUSTRALIA , 2: THE UNIVERSITY OF MELBOURNE

INTRODUCTION: Previous studies have suggested that responses to exercise training vary between individuals, with some subjects responding to a larger degree than others. We posed the questions: 1). is (non)response to exercise universal for an individual, or does it differ according to the modality of exercise undertaken, and 2). is responsiveness to exercise genetically determined.
METHODS: We performed a randomised cross-over study investigating individual cardiovascular responses in nine pairs (n=18) of untrained female monozygotic (identical) twins (25.5 +/- 10.1 years). Each twin pair underwent three months of endurance (END; 1hr x 3/wk, running/cycling, 60-90%VO2max) and resistance (RES; 1hr x 3/wk, upper/lower body, 60-90%1RM) exercise training together, separated by a three-month washout period. Outcomes included cardiac MRI derived left ventricular end-diastolic volume (LVEDV), myocardial mass (LVMM) and ejection fraction (EF), body composition (DXA) for visceral adipose tissue (VAT) and fat mass, fitness (VO2max) and compound muscle strength (1RM). Within-twin-pair correlations of response to END and RES for each outcome were estimated using intraclass correlations (ICC).
RESULTS: Mean changes with END exceeded those of RES for LVEDV (1.37 vs -0.25ml, P>0.05), fat mass (-871 vs -599g, P>0.05), VO2max (172 vs 5ml.min-1, P<0.01), whereas RES induced larger changes than END for LVMM (1.82 vs 3.48g, P>0.05), EF (2.17 vs 0.10%, P>0.05), VAT (-58 vs -32g, P>0.05) and 1RM (37 vs 2kg, P<0.01). Estimated ICC's were higher for changes induced by END than RES for VO2max (r=0.37 vs -0.13), LVMM (r=0.04 vs -0.54), EF (r=0.39 vs -0.19), fat mass (r=0.36 vs 0.03) and VAT (r=0.41 vs -0.11), whereas ICC's for RES exceeded those of END for LVEDV (r=0.19 vs 0.09) and 1RM (r=0.55 vs -0.05).
CONCLUSION: These findings suggest that individuals respond differently to END and RES training and that those who are relatively insensitive to one form of training may nonetheless respond to the other. The twin analysis suggests that individuals who share 100% of their DNA do not respond identically in terms of all physiological outcomes, and that degree of similarity in response differs according to the variable of interest. The level of concordant change between monozygotic twins was higher as a result of endurance training for some variables (cardiac function and body composition), and resistance training for others (muscular strength and cardiac structural change). Our approach to studying twins can be used in future to estimate the genetic and environmental contributions to exercise responsiveness in humans.

AEROBIC TRAINING PROTECTS CARDIAC FUNCTION DURING ADVANCING AGE: A META-ANALYSIS OF FOUR-DECADES OF CONTROLLED STUDIES

BEAUMONT, A., GRACE, F., RICHARDS, J., CAMPBELL, A., SCULTHORPE, N.

UNIVERSITY OF THE WEST OF SCOTLAND

INTRODUCTION: There have been no attempts to systematically synthesise the body of literature to unpick the complex interrelationship between cardiac structure and function in older aerobic trained men. Encouragingly, a steady accumulation of evidence during the past four decades provides a sufficient body of data to allow for meaningful analysis. We conducted a systematic review and meta-analysis of controlled echocardiography studies comparing left ventricular (LV) structure and function in aerobically trained older athletes (>45 years) with age-matched untrained controls. Further, we investigated the influence of chronological age within the same body of literature.
METHODS: Major electronic databases were searched from inception to January 2018 before conducting a random-effects meta-analysis to calculate pooled differences in means, effect size and 95% CI's. Data extraction included measures of LV morphology, conventionally derived systolic and diastolic function, and speckle-tracking derived global longitudinal strain (GLS) to determine potential differences between male athletes and untrained older adults. Study quality was assessed and heterogeneity reported using Cochran's Q and I2 statistic. Meta-regression was used to establish the influence of chronological age on the differences in LV structure and function between athletes and controls.
RESULTS: Overall, 32 studies (644 athletes; 582 controls) were included. Athletes had larger LV-end-diastolic diameter (3.65 mm, 2.66-4.64), interventricular septal (1.23 mm, 0.85-1.60), and posterior wall thicknesses (1.20 mm, 0.83-1.56), LV mass (72 g, 46-98), LV mass index (LVMi, d=1.78, 1.32-2.24) and LV end-diastolic volume (16.11 mL, 7.80-24.43) stroke volume (13.59 mL, 7.20-19.98) (all p<0.01). In contrast, ejection fraction (0.43%, -1.57-2.44), fractional shortening (-0.34%, -2.32-1.63), systolic tissue velocity (0.09 cm.s-1, -0.53-0.70) and GLS (-0.06%, -1.20-1.09) did not differ between trained and untrained. Athletes had more favourable global diastolic function (E/A, 0.18, 0.13-0.24, p<0.01; e'/a', 0.23, 0.06-0.40, p=0.01), lower late mitral and tissue filling velocities (A, 8.20 cm.s-1, 11.90-4.51, p<0.01; a', 0.72 cm.s-1, 1.31-0.12, p=0.02) with more rapid early-diastolic tissue velocity (e', 0.96 cm.s-1, 0.05-1.86, p=0.04). Interestingly, meta-regression for chronological age, identified that athlete-control differences are maintained during advancing age.
CONCLUSION: This study provides external validity for the body of literature observing larger cardiac dimensions, and more favourable cardiac function in masters' athletes compared with healthy, non-athletic age-matched counterparts. Notably, masters' athletes appear to maintain more favourable cardiac function into the eighth decade.

EFFECTS OF EXERCISE TRAINING ON ER STRESS AND MITOCHONDRIAL BIOGENESIS OF THE CARDIAC MUSCLE IN HIGH-FAT DIET-INDUCED OBESE MIDDLE-AGED RATS

KIM, K., AHN, N., LEE, K.

KEIMYUNG UNIVERSITY

INTRODUCTION: Age-related alterations in muscle cells are mainly caused by increased ER stress, altered metabolism, intracellular oxidative stress resulting from qualitative and quantitative changes in mitochondria, and modified Ca2+ signaling . To identify an exercise method capable of effectively preventing cardiovascular diseases through protection of cardiac muscle, this study compared the effects of two 12-week exercise regimes on ER stress and mitochondrial biogenesis in the cardiac muscle of middle-aged rats with high-fat-diet-induced obesity.

METHODS: 30 male, middle-aged Sprague-Dawley rats were induced to become obese with 6 weeks of a high-fat diet, and were randomly divided into three experimental groups: sedentary control , resistance exercise , and aerobic exercise . The exercising groups underwent high-intensity intermittent training using a ladder-climbing and weight exercise or treadmill-running exercises 3 days/week for a total of 12 weeks. Heart tissue was analyzed the protein expressions of phospho-PERK, PERK, CHOP, GRP78, cytochrome c, PGC-1α, phospho-AMPK, AMPK, or β-actin by western blotting.
RESULTS: Rats in the AE group showed significantly lower increases in body weight and intraperitoneal fat than those in SC group . The 12-week exercise regimes resulted in significantly increased expression of mitochondrial biogenesis markers and levels of PGC-1α, an upstream signaling molecule, in the cardiac muscle of obese middle-aged rats , but these factors did not differ according to exercise type. Phosphorylation of PERK, an ER stress marker, decreased significantly after the exercise training. Although a trend for decreased CHOP protein expression was observed in both exercise groups, only AE led to a statistically significant decrease . Levels of GRP78, an ER stress marker that protects cardiac muscle, did not significantly differ among the groups. Although only AE decreased body weight and fat mass, the two exercise regimes had similar effects on cardiac muscle.
CONCLUSION: Chronic ER stress causes oxidative stress and inflammatory responses, and obesity is known to increase ER stress in metabolically active tissues . In this study, phosphorylation of PERK and expression of CHOP protein, which are markers of ER stress , significantly decreased after exercise training. We observed increased mitochondrial biogenesis and decreased ER stress after RE, comprising ladder climbing, and AE, consisting of treadmill running. Therefore, aerobic training resulting in weight loss, as well as resistance training not necessarily leading to weight loss, can contribute to the prevention of aging- and obesity-associated decreases in cardiac function.

CARDIAC BIOMARKERS FLUCTUATION IN RUNNERS OF MARATHONS, SEMI-MARATHONS AND UNTRAINED RUNNERS

LE GOFF, C., VRANKEN, L., KAUX, J.F., LENNARTZ, L., CAVALIER, E.

UNIVERSITY HOSPITAL OF LIÈGE

INTRODUCTION: Regular exercise like running is one important part of the prevention program of cardiovascular disease. There are several studies on biomarker changes during marathons especially cardiac biomarkers have been studied and mild to moderate elevations have been described as a results of a running exercise Exact underlying mechanism for these biomarker elevations reflecting physiological or even pathobiological changes is unknown and less trained athletes might exhibit a higher risk compared to well trained The aim of our study was to compare three cardiac biomarkers for ischemic condition , cardiac stretch and fibrotic processes were tested in different type of runners, trained marathon and semi-marathon runners and untrained runners before, directly after and 3 hours after the running exercise.
METHODS: 23 marathon runners, 15 semi-marathon runners <44.1±8.4yo> and 17 healthy sedentary subjects < 37± 4.4 yo> were enrolled in our study.
Blood samples were taken just before , just after and 3 hours after the race, centrifuged , aliquoted and stored frozen at -80°C before further analysis. The study was approved by the Ethical Committee of our University Hospital.
The analyses were performed on the Abbott ARCHITECT i2000SR for the hs cTnI, BNP and Gal-3 and on the C8000 for hs-cTnT and NT-proBNP according to the manufacturer's instructions for use.
RESULTS: In all 3 running groups there is an increase of cardiac biomarkers Troponin I, BNP, Galectin-3 and NT-ProBNP after completion of the physical exercise. Biomarkers increase is depending on the intensity and duration of the exercise and is higher in long distance marathon and semi-marathon runners compared to the control group with a 1 hour run. Cardiac biomarker levels between trained marathon and semi-marathon runners were not statistically different in the pre-exercise baseline samples for BNP, NT-Pro-BNP and Galectin-3. Compared to untrained runners only Troponin I levels were higher in baseline sample of marathon runners when compared to controls, cardiac Troponin T was less significant.
CONCLUSION: In conclusion, the question whether running exercise of different intensity could be harmful to the heart has no simple answer. We could show that running exercise can be associated with biochemical abnormalities that may reflect adverse consequences on the heart like possible micro necrosis, oxidative stress, fibrosis and myocardial stretch. With exception of Troponin where levels continue to raise after end of running, NPs and Gal-3 levels normalized relatively fast after the exercise. The possible harmful effect of longer term cardiac consequences of repeated intensive sport acitvities still needs to be demonstrated.

CARDIAC ETIOLOGY OF EXERCISE INDUCED HYPOXEMIA

DOSTAL, J., KOCKOVA, R., KOCKA, V.

INSTITUTE OF SPORTS MEDICINE

INTRODUCTION: Exercise induced hypoxemia (EIH) is common finding within a group of elite athletes. It is generally thought, that the causality lies in the pulmonary circulation with anatomical and/or functional shunts. We report a group of 8 consecutive elite athletes with severe EIH (SpO2 below 90%) examined for the origin of the EIH. The task was to perform differential diagnoses to locate the shunt into the pulmonary circulation or cardiac shunts.
METHODS: Eight consecutive elite endurance athletes (cycling, running, triathlon) with severe EIH (SpO2 reproducibly below 90% during previous exercise testing) has been examined with stress transthoracic echocardiography with injection of agitated saline (microbubbles). Agitated saline was administered via cubital vein during the last two steps of the stress echo and the presence of the hypoxemia. Differential diagnoses of cardiac or non-cardiac shunt was based on previously published reports for evaluation of cardiac shunts – number of microbubbles and latency (number of cardiac cycles) between the injection and the appearance of the microbubbles in the left atrium or left ventricle. Trans-esophageal echo has been performed in the follow up procedure in the case of presence of cardiac origin of the hypoxemia to evaluate the exact etiology of the shunt.
RESULTS: Four athletes out of eight have presented pulmonary etiology of the hypoxemia. Four remaining athletes have presented cardiac origin with hemodynamically severe right to left shunts during the maximal exercise causing the EIH. Concurrent transesophageal echocardiography discovered one atrial septal defect and three patent foramen ovale (PFO). One athlete out of three with present PFO underwent later catheterization closure of the PFO. Follow up exercise testing and stress echocardiography confirmed no signs of shunt and no signs of presence of EIH in that individual patient. Also, performance measures of that athlete were improved significantly.

CONCLUSION: Exercise induced hypoxemia is generally thought to be caused by anatomical or functional shunts within the pulmonary circulation. Our findings suggest possibly higher prevalence than originally thought of cardiac etiology of the exercise induced hypoxemia within a group of elite athletes. Successful treatment by catheter-based closure device improves performance and eliminate other clinical signs of the right to left cardiac shunt. Further evaluation of larger group of elite athletes with EIH is warranted to understand better the real prevalence and possible treatment of the cardiac origin of the EIH.

CARDIAC RISK BIOMARKERS RELEASE AFTER HIGH-INTENSITY INTERVAL EXERCISE IN MARATHON RUNNERS

LI, F.

HEBEI NORMAL UNIVERSITY

INTRODUCTION: The effect of exercise in regard to the exercise-induced cardiac biomarkers release requires further investigation to address the information of mechanism and clinical relevance. High-intensity intermittent exercise (HIIT) is highly recommended, but the potential impact of HIIT on cardiac risk biomarkers release requires further investigation. This study is to compare the cardiac biomarkers release after workload matched HIIT and continuous exercises (CE).
METHODS: Twelve experienced marathon runners[sex, 11 males and 1 female; age, 23.5±5.5 y; body mass, 63.3±3.9 kg; height, 170.5±5.5 cm; % body fat, 12.6±3.9%; VO2max, 62.4±5.4 ml·kg−1·min−1; velocity of VO2max (vVO2max), 17.1±1.4 km·h−1] completed HIIT and CE in random order. Each bout of HIIT included hard run at 90% vVO2max for 2 min followed by easy run at 50% vVO2max for 2 min, 23 bouts in 92 min totally. In CE trial, subjects continuously run in 70% vVO2max for 92 min. Heart rate (HR) and Rating of Perceived Exertion (RPE) were recorded during each exercise trial. Blood samples were drawn on the first visit before all exercises (pre 0) and then in HIIT and CE trials before exercise (pre1), immediately after (0 h), and 1, 4, 24 and 48 h after the completion of exercise. High-sensitivity cardiac troponin T (hs-cTnT), high-sensitivity cardiac troponin I (hs-cTnI), N-terminal pro brain natriuretic peptide (NT-pro-BNP), C-reactive protein (CRP), creatine kinase-MB (CK-MB) and creatine kinase (CK) was determined at all of these time points. Each analysis was performed with mixed model using the general linear mixed-model procedure (Proc Mixed) in the Statistical Analysis System (version 9.4, SAS Institute, Cary NC). All measures were log transformed before analysis then back-transformed to express the differences between HIIT and CE in standardized units of assessment of magnitude. Uncertainty in the differences was expressed as 90% confidence intervals and interpreted via the non-clinical magnitude-based approach. For clear effects the likelihood that the true effect was substantial was indicated with the following scale: possibly (25-75%), likely (75 to <95%), very likely (95-99%), and most likely (>99.5%).
RESULTS: Compared with trial CE, percentage of HR reserve (% HRR) during HIIT was possibly lower (-22%, 90% confidence limits ±37%). RPE during CE was very likely lower than that of HIIT (1.7, ±1.0). Hs-cTnI was very likely higher (1.05, 90% confidence limits ±0.66) in HIIT compared with CE.
CONCLUSION: HIIT could trigger more cardiac biomarkers release.

IS-SP04 TRAINING & NUTRITION: CONSIDERATIONS FOR FOOTBALL - SPONSORED BY GSSI

FUELLING AND ENERGY REQUIREMENTS FOR FOOTBALL: TRAINING VERSUS MATCH PLAY

MORTON, J.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: The fundamental goal of nutrition for soccer is to enhance training adaptations, achieve the desired body composition and ultimately, promote match day performance and recovery. Professional players typically train 4-5 times per week as well as compete in 1-3 competitive games. Daily training may also consist of a pitch based session (focusing on technical, tactical and physical development) and a resistance-based session where the aim is development of strength and power. Nonetheless, the overall weekly loading pattern is dependent on competitive fixture schedule, players' starting status and individualized training goals. As such, daily fuelling requirements should operate on a sliding scale dependent on the specific context and in accordance with the aforementioned factors. In this presentation, the author will present data on habitual energy intake and expenditure of Premiership soccer players as well as share personal reflections of implementing a nutritional programme in elite adult and youth soccer players.

METHODS: RESULTS: CONCLUSION: TRAINING INTERVENTIONS: OPTIMISING THE ADAPTIVE RESPONSE OF PHYSICAL CAPABILITIES IMPORTANT TO IMPROVE FOOTBALL PERFORMANCE

BISHOP, D.

VICTORIA UNIVERSITY

Football requires athletes to repeatedly produce skilful actions, and maximal or near maximal efforts (e.g. accelerations, changes in pace and direction, sprints, jumps and kicks), interspersed with brief recovery intervals (consisting of rest or low- to moderate-intensity activity), over an extended period of time (1 to 2 hours). While performance in football is dominated by technical and tactical proficiencies, successful athletes must also have highly developed physical capabilities. Much effort goes into designing training programs to improve these physical capabilities, with expected benefits for football performance. However, training is often based on tradition and "ecological validity" (i.e., replicating what occurs during a match). More evidence is required to support the use of different training approaches to improve physical capabilities important for football performance. In this presentation there will be a discussion of the physical capabilities important for football performance, followed by evidence related to the best training approaches to improve these capabilities.

NUTRITION IN FOOTBALL - IMPLEMENTING THE SCIENCE IN PROFESSIONAL FOOTBALL

COLLINS, J.

THE CENTRE FOR HEALTH AND HUMAN PERFORMANCE

Nutrition has an important role to support optimal training adaptation, performance and recovery, with nutrition strategies such as; fuelling, hydration and recovery forming an integral part of teams training and match day protocols. The 2018 UEFA Football Nutrition

Consensus recently brought together a group of the sports leading applied researchers and practitioners to update best-practice guidelines. This presentation will draw upon these updated guidelines and explore some of the key considerations around applied nutrition support in elite football, incorporating contemporary evidence alongside the practical challenges when working with a professional club.

Invited symposia

IS-PM14 Injury Risk and Injury Prevention in Rugby Union

EPIDEMIOLOGY OF RUGBY UNION INJURIES

BLEAKLEY, C.

HIGH POINT UNIVERSITY

Rugby Union is played by over 8.5 million people across 121 countries. It is an exciting sport that requires multiple components of fitness, self-discipline, social interaction and team skills. However, its high speed and collision nature means that Rugby Union carries a high propensity for injury. Determining the burden of Rugby Union injury is essential for informing primary and secondary strategies for prevention. Rugby Union injury patterns were first reported in the 1950s, with an increasing number of publications becoming available after the advent of professionalism in the early 2000s. A further milestone in this field of research occurred in 2007 with the development of a consensus statement on injury definitions and data collection procedures. Currently there are epidemiological data available from over 70 prospective research studies in Rugby Union. This will be the first presentation as part of a symposium on Injury Risk and Injury Prevention in Rugby Union. The aim of this presentation will be to quantify the injury burden associated with Rugby Union. It will describe and compare injury patterns across the following key rugby subpopulations: professional, amateur / community level and adolescent/schoolboy. A primary objective will be to use available injury incidence and severity data to highlight the injury diagnoses that incur the highest burden within each population; with additional discussion of important risk factors and mechanisms of injury. It is anticipated that this presentation will facilitate debate on the acceptability of risks associated with Rugby Union. The data presented will be contextualized further through the subsequent presentations in this symposium which will discuss the effectiveness of current injury prevention approach within Rugby Union.

IS THERE ANY EVIDENCE TO SUPPORT BANNING THE TACKLE IN JUNIOR RUGBY?

MCKAY, C.

UNIVERSITY OF BATH

IS THERE ANY EVIDENCE TO SUPPORT BANNING THE TACKLE IN JUNIOR RUGBY?
McKay, C.D.1 1: University of Bath (Bath, UK)
Introduction: Rugby union, as a full contact sport, carries an inherent risk of injury. Tackling is one of the most common mechanisms of injury in the sport and significantly contributes to both injury incidence and injury burden (Freitag et al., 2015; Yeomans et al., 2018). Although a significant amount of research has aimed to quantify the risks associated with tackling in the adult game, much less is known about youth rugby contexts Yet, there is considerable concern about the safety of the sport for young athletes, particularly because musculoskeletal trauma or head injury may have immediate and lifelong consequences in this population. With increasing public debate over the merits of banning tackling in youth rugby, this talk will use evidence from the research literature to highlight the complexities of the issue.
Methods: The rugby injury literature will be summarised with emphasis on epidemiological data specific to youth players, considering injury rates, types, and burden (e.g., time loss/severity). Risk estimates associated with tackling in both adult and youth leagues will be presented to enable contextual comparison. Additionally, evidence from other youth sports where rule changes have reduced/eliminated body contact will be explored as analogues for potential effects on injury risk, health care costs, and sport participation rates. The discussion will be acknowledge the implications of policy change at various stakeholder levels (Hulme & Finch, 2015).
Discussion: Injury prevention is of primary importance in sport, both from performance and health/wellbeing perspectives. For youth athletes in particular, there is also a need to provide sporting environments that encourage skill development, social interaction, and personal enjoyment. Keeping young people engaged in physical activity is an important goal, so weighing the risks and benefits of rugby participation is a salient public health issue. Therefore, any decision to ban tackling in junior rugby must be based on objective medical evidence, but will inevitably be informed by sport culture and social values.

INJURY PREVENTION IN RUGBY UNION; ARE WE WINNING OR IS THIS A LOSING BATTLE?

BROWN, J.

STELLENBOSCH UNIVERSITY

INTRODUCTION: Injury Prevention in Rugby Union; are we Winning or is this a Losing Battle?
Brown, J.1,2
1: Institute of Sport and Exercise Medicine, Faculty of Medicine and Health Sciences, Francie Van Zijl Drive, Tygerberg, Stellenbosch University, South Africa
2: International Olympic Committee Research Centre, South Africa
Rugby union is currently one of the most popular sports in the world. However, as demonstrated by the previous two talks in the session, this popular sport is also associated with a high injury burden to its participants. There are a plethora of injury prevention interventions, in a variety of contexts, attempting to reduce this risk. But how is one to know whether these interventions are effective or not? Evaluation of these interventions using established frameworks , has produced some positive results, particularly with the RugbySmart and BokSmart programmes. However, improved awareness of player welfare and the associated increase in the reporting of injuries - especially concussions - might confound future intervention evaluations. Specifically, the recent rise in rugby-related concussions rates at various levels

of play is difficult to interpret with traditional evaluations. This is just one example that could leave epidemiologists, clinicians, players, players parents, the media and general public confused about the state of injury prevention in rugby. Nonetheless, two recent randomised controlled trials in the United Kingdom demonstrated up to 60% reductions in concussion rates in youth and adult populations through a progressive exercise-based intervention that included neck strengthening. However, are two RCTs sufficient evidence for us to confidently say we are winning the fight to reduce rugby-related injuries? By building on the foundations laid by the other two presentations in this symposium, this talk will try to make sense of whether the future is bleak or bright for rugby participants.

OP-PM12 OBESITY

SUCCESSFUL IMPLEMENTATION OF A 12-WEEK HOME-BASED HIT INTERVENTION IN OBESE INDIVIDUALS WITH ELEVATED CARDIOVASCULAR DISEASE RISK

SCOTT, S.1, SHEPHERD, S.O.1, HOPKINS, N.1, DAWSON, E.A.1, WRIGHT, D.J.2, COOPER, R.G.3, WAGENMAKERS, A.J.M.1, COCKS, M.1

1LIVERPOOL JOHN MOORES UNIVERSITY; 2LIVERPOOL HEART AND CHEST HOSPITAL; 3UNIVERSITY OF LIVERPOOL

INTRODUCTION: The applicability of current high intensity interval training (HIT) protocols to the sedentary obese population has been disputed by public health experts. This is because existing HIT interventions have been successful only under optimal conditions with high levels of supervision and specialised equipment, creating further barriers to exercise in those most in need. Therefore, we aimed to eliminate many of these barriers by modifying existing HIT protocols to create a new home-based HIT (Home-HIT) intervention tailored to individuals with low fitness and mobility. It was hypothesised that Home-HIT would 1) have high adherence to the prescribed exercise intensity (compliance) and 2) improve markers of cardiovascular disease (CVD) risk.
METHODS: 32 Obese adults with at least 3 additional CVD risk factors (age 36±2 y; BMI 34.3±0.8 kg·m-2; VO2peak 24.6±1.0 ml·kg·min-1), completed one of three 12-week training programmes 3x/week: Home-HIT (n=9); Laboratory-based supervised HIT (Lab-HIT; n=10) or home-based moderate intensity continuous training (Home-MICT; n=13). Adherence and compliance were monitored online in almost "real time" using a heart rate monitor and mobile app. The Home-HIT group completed 4 progressing to 8 1min intervals interspersed with 1min of rest in an unsupervised place of their choosing. The intervals were composed of simple bodyweight exercises that required no equipment. Changes in VO2peak, insulin sensitivity, body composition, flow-mediated dilation (FMD) and aortic pulse wave velocity (PWV) were assessed. Muscle biopsies were taken to assess changes in capillarisation, mitochondrial density, intramuscular triglyceride (IMTG) content and eNOS and GLUT4 protein expression using quantitative immunofluorescence microscopy. Results are presented ±SEM.
RESULTS: Adherence and compliance (Home-HIT 96±3% & 99±1%; Home-MICT 88±4% & 100±0%; Lab-HIT 97±1% & 100±0%, respectively) to training did not differ between groups. Training increased VO2peak (Home-HIT 15%, Home-MICT 11%, Lab-HIT 20%; $P<0.001$) and Matsuda insulin sensitivity index (Home-HIT 39%, Home-MICT 8%, Lab-HIT 13%; $P=0.033$). BMI, body fat percentage and visceral fat decreased ($P<0.05$). FMD increased and aortic PWV decreased in each group ($P<0.05$). Immunofluorescence microscopy revealed increased capillarisation, mitochondrial density, IMTG content and eNOS and GLUT4 protein expression ($P<0.05$). There were no differences in any variables between groups.
CONCLUSION: Despite having no external motivation or supervision during exercise, the Home-HIT group had high adherence at the prescribed exercise intensity, resulting in improved cardiovascular and metabolic health. We provide strong evidence that our novel Home-HIT protocol is an effective strategy to remove barriers to exercise and improve health in the obese population most in need.

EFFECT OF SPRINT INTERVAL TRAINING ON CHRONIC INFLAMMATION IN SEDENTARY OBESE MEN

KEBSI, W.1,3, RAUT LE GALLIC, L.1, ZOUHAL, H.1, SALIGAUT-ALLAIN, D.1, ADELA, H.2, HAMBLI, M.2, AMRI, M.3, LEMOINE-MOREL, S.1

RENNES 2 UNIVERSITY

INTRODUCTION: Aerobic exercise is the most common exercise protocols designed to reduce chronic inflammation (you et al. 2013). However, one of the most cited barriers to performing this type of exercise is lack of time. Previous studies suggest that sprint interval training (SIT) represent a time-efficient strategy for inducing health benefits (Gillen and Gibala, 2014). However, there is no data concerning its impact on inflammatory mediators in obese subjects. Therefore, we aim to investigate the effect of SIT on circulating inflammatory markers in obese men.
METHODS: Thirteen participants (age, 24±0.74 years; Body mass index (BMI), 33.38±4.30 kg.m-2) performed 10 weeks of SIT (3-4 sessions/wk; 3(3-4 x 8s sprints at 75%-95% peak power (Ppeak) measured during Force/Velocity exercise). Body composition, fasting blood markers (glucose, insulin, HbA1c, HDL- and LDL-cholesterol, triglycerides) and fitness measurements: aerobic capacity (from maximal incremental test), and anaerobic performance (from cycling sprint test (CST): 7 x 6s of "all out" sprints interspersed with 90s of recovery) were assessed at baseline and post SIT. Circulatory levels of inflammatory biomarkers (Interleulkin (IL)-6, tumor necrosis factor (TNF)-α, high-sensitivity C-reactive protein (hs-CRP), adiponectin) were assessed in rest and in response to CST before and after SIT.
RESULTS: Our results showed a trend of weight drop (-5.68%, $p=0.052$), and a significant decrease in fat mass (FM), android fat mass (AndFM), and gynoid fat mass (GynFM) were found ($p<0.05$). Aerobic and anaerobic power output were enhanced significantly ($p<0.05$) after the training intervention. No significant changes in metabolic blood markers and inflammatory parameters were observed in re-

sponse to CST and SIT. At baseline, hs-CRP was correlated with fasting insulin (r=0.650, p<0.05). In response to SIT, changes in FM (r=0.717, p<0.05), AndFM (r=0.683, p<0.05), and fasting insulin (r=0.886, p<0.05) were associated with reduction in hs-CRP.
CONCLUSION: The current study demonstrated that SIT didn't increase the risk factors associated to chronic inflammation in obese individuals, and found a significant correlation between the reduction in hs-CRP and insulin, AndFM, and FM which was in agreement with Swift et al. 2012. These observations supported the growing evidence that SIT was a promising strategy to induce wellbeing and better health condition.

ASSOCIATION BETWEEN A COMPREHENSIVE MOVEMENT ASSESSMENT AND METABOLICALLY HEALTHY OBESE ADULTS

SENECHAL, M., MACLEOD, L., HÉBERT, J.J., BOUDREAU, J., BOUCHARD, D.R.

UNIVERSITY OF NEW BRUNSWICK

INTRODUCTION: Moderate-to-vigorous physical activity (MVPA) is associated with cardio-metabolic health in obese individuals. Recent data in children emphasize a more comprehensive assessment of movement to quantify the impact of PA on health. However, similar adult evidence is lacking and the impact of a comprehensive movement assessment on the Metabolically Healthy Obese (MHO) phenotype is unknown. The objective of this study was to determine whether meeting the comprehensive movement guideline or each individual component was associated with a greater likelihood of being MHO compared to non-MHO adults.
METHODS: The sample included 513 adults overweight-obese (body mass index 25kgm2) aged 19 to 85 years from cycle 2005-2006 of the National Health and Nutrition Examination Survey. The comprehensive movement assessment and its individuals threshold include: 150 minutes of MVPA in 10-minute bouts, being in the highest quartile of light PA, sleeping 7 to 9 hours per night, and less than 2 hours of recreational screen time. Participants were categorized as MHO when all cardio-metabolic risk factors (triglycerides, HDL-cholesterol, glucose, and systolic and diastolic blood pressure) were within normal limits.
RESULTS: The proportion of MHO was 13.8%. There was no difference in comprehensive assessment of movement score between MHO and non-MHO individuals (MHO: 18.3% vs. non-MHO: 10.9%; p> 0.05). Recreational screen time was lower in MHO compared to non-MHO individuals (1.8 1.4 hrs/day vs. 2.5 1.6 hrs/day; p< 0.01). Meeting the recreational screen time recommendation was the only variable associated with the MHO phenotype (OR:4.84 95%CI: 2.33-10.07). This association remained after adjusting for age, sex, ethnicity, and BMI (OR: 3.86 95%CI: 1.75-8.52). Meeting two components of the comprehensive movement assessment was independently associated with the MHO phenotype (OR: 2.45 95%CI: 1.23-4.90).
CONCLUSION: Our results support the importance of limiting recreational screen time in adults to optimize the cardio-metabolic risk profile of individuals living with obesity. Applying a more comprehensive assessment of movement, beyond health-related PA, to assess the risk associated with health outcomes in adult appears to provide a better assessment. Additional studies evaluating hard endpoints such as cardio-vascular diseases and premature mortality are warranted.

Oral presentations

OP-BN25 Balance and postural control

MODULAR ORGANIZATION OF A POSTURAL TASK ON STABLE AND UNSTABLE SURFACES

MUNOZ MARTEL, V., SANTUZ, A., ARAMPATZIS, A.

HUMBOLDT-UNIVERSITÄT ZU BERLIN - BERLIN SCHOOL OF MOVEMENT SCIENCE

INTRODUCTION: Maintaining balance is a necessary requirement for most activities and critical for human locomotion [1]. Daily life activities involve unexpected perturbations which challenge the system to modify its control strategies [2]. A modular recruitment of muscles, referred to as muscle synergies, has been proposed to provide a simplified control of movement [3]. The main purpose of the current study was to investigate the modular organization of the neuromuscular system for a postural task in different ground stability contexts. We hypothesized a reorganization of the time-dependent activation coefficients (motor primitives) in order to increase motor outputs robustness (ability to cope with errors) [2], and a general conservation of the time-invariant muscle weightings (motor modules).
METHODS: Thirteen young, healthy participants (9 males, 4 females, age 28.7 ± 5.2 years, height 1.75 ± 0.11 m, weight 67.9 ± 9.8 kg) were asked to pass from a double- to a single-leg standing (SLS), maintain the position for 3 s, return to the bipedal position and after 1 s repeat the task. Timing was aided by a metronome. Participants performed 30 cycles on two different surfaces: hard uniform stable ground (SG) and a damped oscillating unstable platform (Unstable Ground – UG) (Haider Gmbh. Germany). Order of conditions was randomized.
Muscle synergies were extracted from 13 ipsilateral lower limb EMG activities using non-negative matrix factorization. Full width at half maximum and center of activity were used as metrics for comparing SG and UG motor primitives (paired sample t-test). Motor modules were compared by a two-way ANOVA with repeated measures, followed by a Tukey post-hoc analysis with false discovery rate p-value adjustment.
RESULTS: On average, we extracted one synergy less from SG compared to UG data (2.5 ± 0.8 SG and 3.1 ± 0.5 UG, p = 0.027). One synergy was functionally referred to the double stance and another to the SLS. The extra synergy found in the UG condition described the SLS and included, amongst others, the contribution of mediolateral stabilizers of hip and lower leg (mainly peroneus longus, p<0.001). Motor primitives and motor modules showed no differences for the two synergies shared by SG and UG. The extra SLS synergy found in UG showed a narrower primitive (-20.8%, p=0.006) compared to the original SLS synergy in both condition.
CONCLUSION: On previous locomotion studies, we observed a consistent set of motor modules with a widening of motor primitives, indicating a transition from an accurate to a more robust control in presence of continuously variable perturbations [2]. The current results show the emergence of a latent postural synergy in UG trials. This new synergy might reflect the systems answer to the increased postural demands induced by UG compared to SG.

DYNAMIC POSTURAL CONTROL PREDICT OVERHEAD THROWING PERFORMANCE IN ELITE FEMALE TEAM HANDBALL PLAYERS

ERIKSRUD, O., SÆLAND, F., FEDEROLF, P.A., CABRI, J.

NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Throwing performance is dependent on different neuromuscular qualities of the full kinetic chain. Two such qualities are the magnitude of joint movements (mobility) and the ability to control them (dynamic postural control). However, the relationship between these qualities and handball throwing performance is not well documented. The hand reach star excursion balance test (HSEBT) is a newly developed test of dynamic postural control based on hand reach measurements from a standing position in the same directions as the star excursion balance test (SEBT). These hand reaches require functional mobility, the combination of range of motion (ROM) of multiple joints in ecological movements, similar to those observed for the different phases of handball throwing. The purpose of this study was to determine the relationship between the HSEBT and handball throwing performance.
METHODS: Elite female team handball players (n=11; age: 21.71.8 years; weight: 71.3 9.6 kg; height: 174.9 6.8 cm; wingspan: 173.8 9.0 cm) executed selected HSEBT reaches (flexion, extension and rotational movement patterns) before performing a 3-step-up overhead throw using an International Handball Federation standard size womens handball until five valid throws (inside 1x1m target) were obtained. Throwing performance was quantified by throwing velocity (m·s-1) using motion capture (Qualisys; 240 Hz) and accuracy (mean radial error) using videography (Basler acA2000 - 165uc video camera and Dartfish). The relationships between HSEBT measurements (individual reaches, overall, flexion and extension composite scores (CS)) and throwing performance were assessed using correlational analysis ($p<.05$).
RESULTS: Significant relationships between HSEBT measures and accuracy but not throwing velocity were established. Specifically, overall CS on the dominant foot ($r=.622$, $p<.05$) and extension CS for both dominant ($r=.756$, $p<.05$) and non-dominant foot ($r=.656$, $p<.05$) were found.
CONCLUSION: We hypothesized that greater reach measurements in the posterior overhead reaches would allow for a greater excursion for acceleration of the ball and thereby influence throwing velocity. The non-significant findings could be due to players having sufficient mobility and that the influence of other neuromuscular qualities, strength and power, on available excursion were not assessed. However, the significant relationship of the posterior overhead reaches to accuracy might reflect other components of dynamic postural control such as balance and proprioception. Based on the current findings the HSEBT offers a platform from which dynamic postural control can be further explored.

THE EFFECTS OF PROPRIOCEPTIVE BALANCE TRAINING USING THE SHUTTLE TNT SYSTEM ON VERTICAL JUMP PERFORMANCE IN FEMALE NAIA VOLLEYBALL PLAYERS

BUBKE, C., SHIM, A., CANNAVAN, D., WALLER, M., RUPPERT, T.

COLLEGE OF SAINT MARY

INTRODUCTION: The central nervous system's (CNS) role is to deliver signals through the afferent neural pathways to produce awareness of limb, trunk, and head position and movement, which contributes to reflexive and cognitive motor skills (2). Past injuries due to developmental delays can result in slower synapses through the CNS. Proprioceptive receptors communicate with the brain, in order to confirm the position and motion of the lower limbs and relay the correct motor response to the muscles to make corrections in attempt to prevent injury and improve motor control. If neural adaptations do not occur, motor performance is delayed the risk of injury is present (1). Increasing stability in the lower extremity should be considered supplemental to a strength and conditioning program amongst practitioners. To date, there is a lack of research examining the efficacy of the Shuttle TNT System for improving lower limb stability.
METHODS: There were two intentions behind the study: [a] to determine if the Shuttle TNT System can be used to improve LoS scores in female collegiate volleyball players and [b] investigate whether a correlation exists between LoS scores and VJ performance. Nine female NAIA volleyball players volunteered for the study (age 19.66±.87, height 174.77±4.12 cm, mass 76.56±9.17 kg, body mass index 25.06±2.75). LoS in four directions (forward, backward, left, and right) and vertical jump scores were taken both before and after a periodized four week intervention. The intervention consisted of both unilateral and bilateral leg press exercises on the Shuttle TNT System. To incorporate proprioceptive components, all exercises were performed while standing on a volleyball. A repeated measures ANOVA and a Pearson product moment correlation were conducted using SPSS ver. 24 for pre-post differences.
RESULTS: There was a significant difference ($p = .05$) between all LoS directions tested (LoSF +40.6%, LoSB -7.8%, LoSL +8.2%, LosR +17.2%) and VJ scores (-3.4%). Correlations of .643 and .696 were also found between post-intervention values of LoSL and LoSF when compared against post-intervention values of VJ scores.
CONCLUSION: The authors concluded the Shuttle TNT System is a viable option to improve LoS scores in female collegiate volleyball players, although proprioceptive balance training does not improve VJ scores.

BALANCE TRAINING IMPROVES SELECTIVE DUAL-TASKING GAIT PARAMETERS AT HOME OR UNDER THERAPIST-SUPERVISION

ATTERBURY, E., WELMAN, K.

STELLENBOSCH UNIVERSITY

INTRODUCTION: Individuals with Parkinsons disease (IwPD) presents with a loss of automaticity, and as a result gait dysfunction occurs. Often IwPD experience freezing of gait which further hampers their functional capacity for ambulation and can result in subsequent falls which reduces independence and quality of life. Fall risk is furthermore aggravated when IwPD attempt to perform multiple tasks at the same time (i.e. dual-tasking). Previous research has shown that balance training can effectively improve motor-cognitive integration in IwPD; however, the effects on freezers compared to non-freezers and the influence of exercise delivery remains unclear. The study set out to investigate the efficacy of a home-based compared to therapist-supervised balance training programme on dual-task gait of IwPD who experiencing freezing.
METHODS: Forty individuals diagnosed with PD (Hoehn&Yahr: II-III) were randomized into a therapist-supervised (n = 24, age 65.4 ± 8.3 years) or home-based (n=16, age 64.9 ± 7.1 years) group. Within each group 50% of individuals were classified as freezers. Both groups followed an eight-week balance training program (3x week for 45-50minutes) under the supervision of a therapist or on their own with a DVD. Duration, stride length, stride velocity and cadence were measured with a 7m Timed-Up-and-Go test and the APDM mobility lab®, during dual-task conditions. Fear of falling was also assessed before and after the intervention with the Fall Self- Efficacy Scale.

RESULTS: The freezers differed from the non-freezers in both therapist-supervised (TS) and home-based (HB) groups at pre-test for stride velocity ($p<0.04$); for pre-test values of stride length the HB group differed ($p=0.002$) and TS group showed a tendency ($p=0.061$) to differ from their non-freezing counterparts. The freezers in the TS group improved their stride length over the 8-week balance intervention ($p<0.05$). The freezers of the HB group took longer to complete the dual-task after the intervention ($p<0.001$). Dual-tasking cadence improved for the non-freezers of the HB group ($p=0.01$) and the non-freezers showed a tendency ($p=0.08$) towards improvement. Only the non- freezers of the HB group showed improvement ($p<0.03$) in their fear of fallings scores.
CONCLUSION: Findings suggest that when IwPD who freeze follow a balance programme under supervision of a therapist, they are able to improve their dual-task stride length. Decreased stride length have been related to freezing of gait and increase fall risk, thus the improvement of the TS freezers stride length is a significant finding. Even though a balance training in a home environment can improve dual-task cadence; it does not result in improved gait speed. It can be postulated that balance training, whether with a therapist or at home, for individuals who experience freezing can improve their gait quality during motor-cognitive interference. The "posture first" strategy could be promoted by balance training, thus resulting in safer ambulation.

A DIGITAL HOME-BASED PHYSICAL TRAINING PROGRAMME TO IMPROVE BALANCE AND MOBILITY PERFORMANCE AMONG OLDER ADULTS

HELLER, M., STÜBLER, A., SANDNER, E., KROPF, J., KUMPF, A., OPPENAUER-MEERSKRAUT, C., STAMM, T., LAMPEL, K.
ST. PÖLTEN UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Physical activity in older adults is an important protective factor for preventing morbidity and mortality and increases well-being and independent living. Therefore, the overall aim of the so-called "Train and Win"project* is to develop a training module at the user's home using their own TV with a motivating avatar. Recently, two user-centered design studies revealed that, contrary to published literature and our expectations, a majority of participants explicitly refused gamification elements, such as competitions between the participants or motivational design inputs for process feedback (Oppenauer-Meerskraut et al., 2017). Thus, a training programme should be related to the physical training experiences of the participants, which were mainly sports and be "realistic" in terms of the presentation and interaction with an avatar.
METHODS: A set of 60 selected physiotherapy and occupational therapy conform exercises aiming to improve the quality of physical fitness (balance, strengthening of upper and lower extremities) has been designed for an exercise programme („FitDaheim", http://fitdaheim.com/). Real body movements of these exercises were captured using motion capture technology (Perception Neuron®) and used to animate an avatars' movement. During training sessions at user's home, a Microsoft Kinect Camera captures motion data of the participant. The evaluation of the performance of the participant is done by the analysis of key frames of body positions on a MiniPC. Each exercise session consists of eight randomly selected exercises with individual numbers of repetitions, sets, and durations. There are three different levels of progression (low, medium, high) varying in number of repetitions per set, reached body position angles, and movement times. Levels are assigned with respect to baseline measures as well as continuing the exercise programme during period of participation. An exercise runs as follows: the avatar shows and explains the exercise, and then he or she will ask the participant to perform the exercise one to three times just after the demonstration to ensure the participant understands how to do the exercise correctly. After that, the avatar and the participant „together" perform the exercise. Visual and acoustic feedback is given for each repetition to improve performance. A whole exercise session is expected to take 30–40 minutes on average, including rests.
RESULTS: Now, a pilot study with 30 participants is carried out. Several screening and assessment measures during baseline and after eight weeks of intervention programme are used to get insights into usability and acceptance of the system as well as possible effects on balance, mobility, and quality of life.
CONCLUSION: *The project has been funded by grants from the Austrian Federal Ministry for Transportation, Innovation and Technology (BMVIT) as part of the BENEFIT-Program of the Austrian Research Promotion Agency (FFG registration number 856184).

OP-BN26 Neuromuscular testing

TAP REFLEX INHIBITION FOLLOWING 30 SEC OF STATIC STRETCHING IS REDUCED BY DYNAMIC OR ISOMETRIC CONTRACTIONS

TILP, M., BUDINI, F.
UNIVERSITY GRAZ

INTRODUCTION: Afferents from muscle spindles are important for muscle contraction. Static stretching (SS) reduces muscle spindle sensitivity as indicated by a decreased tap reflex (TR) observed following 10 min of SS (Weir et al., 2005). Lately, Budini et al. (2016) reported that the TR is inhibited even after 1 min of SS but recovered within 5 min. However, athletes who use stretching as preparation for competition or training stretch less than 1 min and perform several muscle contractions before they start, possibly restoring muscle spindle sensitivity. Hence, the primary aim of this study was to investigate the effect of 30 sec of SS on the TR. A secondary aim was to investigate the effect of isometric or dynamic contractions following SS on the TR.
METHODS: Eleven participants reached individual maximal ankle dorsiflexion through an isokinetic rotation and maintained it for 30 s. A motorized hammer was used for inducing a TRs in the soleus muscle for 5 min at baseline and for 10 min after SS with one tap delivered every 30 s. The procedure was repeated 3 times with 3 randomized conditions between baseline and post SS. Conditions were: control (no contraction (noCon)), a maximum isometric contraction (isoCon), 3 (dynamic) counter movement jumps (dynCon). We tested the group mean changes of reflex amplitude for differences between the three conditions with Friedman test and post-hoc Wilcoxon test because data was not normally distributed. Comparisons between baseline values and data at each time point (from 30 s to 10 min after SS) were tested in each condition either with paired t-tests or Wilcoxon tests.
RESULTS: The comparison of the three conditions revealed that the overall inhibition was greater in the noCon (-18.3+/-7.2%) compared to both the isoCon (-0.1+/-6.2%) and the dynCon (0.5+/-15.4%) condition, respectively, whilst no difference between the isoCon and dynCon conditions was observed. In the noCon condition, 6 out of the 20 time investigated points were inhibited and further 4 time points showed a tendency of a reduced tap-reflex ($p<0.1$). While in the isoCon condition, tap reflex was not significantly reduced, the counter movement jumps (dynCon) induced an inhibition in the first 3 time points.

CONCLUSION: This study shows that 30 s SS reduces muscle spindle sensitivity up to 10 min (although not at every investigated time point). This inhibition is an undesired side effect of stretching that athletes might avoid. We demonstrated that both isometric and dynamic contractions significantly reduced the amount of inhibition over the period of 10 minutes. However, the dynamic contraction induced a significant inhibition of the tap reflex by 30% for about 2-3 minutes, probably due to an induced slack of intrafusal fibres due to the eccentric part of the movement.

SPORT-RELATED DIFFERENCES IN TRUNK ROTATIONAL POWER IN STANDING AND SITTING POSITIONS

ZEMKOVÁ, E.1,2, POÓR, O.1, JELEN, M.2

1: FACULTY OF PHYSICAL EDUCATION AND SPORT, COMENIUS UNIVERSITY IN BRATISLAVA, 2: FACULTY OF ELECTRICAL ENGINEERING AND INFORMATION TECHNOLOGY, SLOVAK UNIVERSITY OF TECHNOLOGY

INTRODUCTION: Previous study showed significantly higher power during standing than seated trunk rotations with weights ≥10.5 kg in a group of physically fit men (Zemková et al., 2017). Similar finding may be expected in athletes performing rotational movements of the trunk while standing under unloading or loading conditions. Still, the questions remains as to what muscle power is produced by athletes that used to perform seated trunk rotations in their sports. Therefore, this study compares trunk rotational power at different weights in standing and sitting positions in athletes of various sports.
METHODS: Forty two athletes (age 23.1±3.9 y, height 181.0±8.7 cm, body mass 89.1±12.7 kg) of selected sports (box, canoeing, hockey, judo, karate, kayaking, tennis, wrestling) completed four trials of trunk rotations in both standing and seated positions with a barbell of different weights (increasing stepwise from 5.5 kg up to a maximal value of power) placed on the shoulders. Basic biomechanical parameters throughout the movement were monitored using the FiTRO Torso Premium.
RESULTS: As expected, mean power in the acceleration phase of trunk rotations was significantly higher in standing compared to sitting at weights of 10.5 kg (20.4%, p=0.017), 15.5 kg (22.4%, p=0.009), 20 kg (23.0%, p=0.008), and 25 kg (27.1%, p=0.005) but not at 5.5 kg (13.6%, p=0.085) in a group of athletes that used to perform standing trunk rotational movements. However, its values did not differ significantly during standing and seated trunk rotations in canoeists and kayakers at all weights used (from -4.6% to 5.1%). Although the respective angular displacement during trunk rotations showed similar tendencies, its values only moderately correlated with trunk rotational power in both the standing (r=0.532, p=0.044, 95%CI [0.511, 0.567]) and sitting (r=0.616, p=0.037, 95%CI [0.588, 0.651]). This indicates that athletes were able to produce forceful movement, regardless of their range of trunk rotational motion.
CONCLUSION: Greater trunk rotational power in either a standing or a seated position is undoubtedly due to a predominant exercise mode used during athletic performance. Therefore, the exercise that closely replicates the upper/lower body rotation movements should be preferred in testing in order to assess sport-specific power.

RELIABILITY AND CONCURRENT VALIDITY OF FORCE-VELOCITY PARAMETERS OBTAINED FROM LINEAR AND CURVILINEAR REGRESSION MODELS

RIAL VAZQUEZ, J.

UNIVERSITY OF A CORUNA

INTRODUCTION: When multi-joint exercises are considered the inverse relationship between muscle force and shortening velocity (FV) has been typically fitted by linear regression models. Previous studies have analysed de feasibility of the variables calculated from linear models but not for parameters calculated from non-linear models.
METHODS: 21 athletes (rugby players and judokas) were recruited. The FV of bench press (BP) and parallel squat (SQ) performed with a Smith Machine were obtained twice by a protocol of progressive increments loads until 1RM. Three models were considered for obtaining each individual FV: linear (LM), quadratic polynomial (PM) and exponential model (EM).
The parameters obtained were: velocity axis intercept (V0), the force axis intercept (F0) the maximum estimated power (Pmax), quadratic coefficient of PM (a) and the proportion represented by the velocity (V1RM) and force (F1RM) associated to 1RM respect to V0 and F0 respectively.
RESULTS: The results confirmed the linearity of FV for multi-joint exercises. The reliability coefficients were higher for LM in comparison with PM. The reliability of V1RM was not acceptable (CV% = 19 and 18% for BP and SQ) but high reliability was observed for F1RM (CV% = 3 and 2% for BP and SQ) and for the ratio between F1RM and F0 (CV% = 2 and 4% for BP and SQ).
CONCLUSION: This study confirmed the linearity of FV for multi-joint exercises even within a wide range of loads, since the goodness of fit for LM were better than EM and the quadratic coefficient of PM was extremely low (i.e. low concavity).
The reliability of the parameters was consistently higher for LM than for PM, and BP in comparison with SQ. Previous studies reported a lower reliability of V0 for exercises such as press throws (García-Ramos et al, 2016), squat and countermovement jumps (Cuk et al, 2014). By contrast, a recent study reported lower reliability of F0 in comparison with V0 for deadlift high pull (Lu et al, 2017), which suggests that the reliability depends on the type of exercise.
The high reliability of the relative values of F1RM around 92 and 87% of F0 for BP and SQ, respectively suggests the use of these values as reference for monitoring resistance training programs.

DETERMINANTS OF LOADING RATE OF VERTICAL IMPACT FORCES IN LEISURE-TIME RUNNERS

MALISOUX, L., GETTE, P., DELATTRE, N., THEISEN, D.

LUXEMBOURG INSTITUTE OF HEALTH

INTRODUCTION: Vertical ground reaction forces generated during running are considered key factors in the mechanism leading to some types of overuse injuries. Especially, loading rate of vertical impact force has been associated with injury risk in running. As a consequence, the identification of modifiable factors influencing vertical instantaneous loading rate (VILR) could represent a promising approach toward injury prevention. Therefore, this study aimed to identify determinants of VILR among personal and running style characteristics in leisure-time runners.
METHODS: This cross-sectional study includes anthropometric measurements, bio-impedancemetry body composition analysis, as well as running technique analyses performed on an instrumented treadmill in 874 leisure-time runners (61% male, age: 40±10 years, height: 1.74±0.09 m, body mass: 73.4±12.7 kg). After a 5-minute warm-up, the participants ran for 10 minutes at their self-reported usual training speed. A record of ground reaction forces (2 kHz) was performed during the last 2 minutes. The outcome of interest was VILR, calculated as the maximal slope of the vertical ground reaction force signal before the first vertical impact peak force. A multivariable linear regression analysis was performed to identify factors associated with VILR (coefficient b [95% confidence interval]). Accepted significance was set at $p<0.05$.
RESULTS: On average (±SD), running speed was 9.9±1.5 km/h and VILR was 43.76±12.65 kN/s, based on a total of 326±19 steps analysed per record. Modifiable factors associated with a higher VILR were higher body fat mass (%, b = 0.83 [0.72; 0.95], $p<0.001$), lower step cadence (steps/min, b = -0.41 [-0.63; -0.19], $p<0.001$), greater vertical stiffness (kN/m/bodyweight, b = 1.41 [1.17; 1.65], $p<0.001$), greater vertical oscillation (% leg length, b = 1.69 [0.31; 3.08], $p<0.017$), and higher running speed (km/h, b = 1.95 [1.28; 2.61], $p<0.001$). Some non-modifiable factors were also associated with VILR: height (m, b = 52.5 [40.8; 64.1], $p<0.001$), and age (years, b = 0.08 [0.02; 0.13], $p=0.009$). Finally, a higher VILR was found in males compared with females (b = 11.74 [9.77; 13.71], $p<0.001$). Contact time (ms, b = -0.01 [-0.07; 0.05], $p=0.778$) and leg length discrepancy (cm, b = -0.03 [-0.19; 0.13], $p=0.778$) were not associated with VILR.
CONCLUSION: Decrease of body fat mass, vertical oscillation and running speed, softer landing, and increase of step cadence represent modifiable targets to decrease VILR. This study provides clinicians and sports trainers with important information on cues that should be given to leisure-time runners to potentially prevent running injuries.

LOAD-VELOCITY REALTIONSHIP OF ARM MUSCLES OBTAINED FROM MEDICINE BALL THROW TES

MIRKOV, D.M.1, MAROVIC, I.P.1, KNEZEVIC, O.M.2, PREBEG, G.1, JARIC, S.3

1: UB FSPE , 2: UB IMR , 3: UDEL BIOMS

INTRODUCTION: Routine tests used to assess muscle mechanical capacities are typically conducted under a single mechanical condition. Consequently, the outcomes of these procedures are of limited informational value regarding specific muscle capacities. Recent studies exploring force- i.e. load-velocity (F-V, L-V) relationship observed from functional movements tested under varying loading conditions have revealed reliable and valid parameters depicting the force (F)-, velocity (V)-, and power (P)-producing capacities of the tested muscles. Therefore, the aims of the present study were to evaluate the strength, shape and reliability, and external validity of L-V relationship of arm muscles obtained from medicine ball throw test.
METHODS: Twelve healthy subjects performed maximum throws using medicine balls of four different weights. In addition, maximum strength of arm muscles was assessed through maximum isometric force (Fmax) and 1RM bench press. L-V relationships were assessed from the applied loads L and V variables (separately for their maximum and averaged values). The linear regressions were extrapolated to determine the L- (L0; L at zero V) and V-intercepts (V0; the velocity at zero L), as well as the regression slopes (a = L0/V0). Finally, the maximum power output was calculated from the linear regression parameters as Pmax = (L0V0)/4
RESULTS: The observed L-V relationships were exceptionally strong ($r = 0.92–0.99$; all $P < 0.01$) and linear. The reliability of parameters obtained from the linear L-V regression proved to be mainly high (ICC > 0.80), while their concurrent validity regarding directly measured Fmax and 1RM ranged from medium-to-high.
CONCLUSION: The present findings revealed a strong and approximately linear L–V and, consequently, parabolic P–V relationship of arm muscles tested through maximum throws of medicine balls. Furthermore, parameters (maximum L, V and P) obtained from L-V relationship could be reliable and valid indices of various mechanical capacities of the tested muscles. Therefore, we conclude that the maximum throw of medicine balls of different weights could be developed into a quick routine test for assessment of various mechanical capacities of arm muscles.

NON-INVASIVE ASSESSMENT OF CENTRAL HAEMODYNAMICS IN ACUTE STROKE PATIENTS – BETWEEN-DAY RELIABILITY AND THE EFFECT OF FASTING STATE AND POSTURE

MITCHELMORE, A., STONER, L., LAMBRICK, D., SYKES, L., EGLINTON, C., JOBSON, S., FAULKNER, J.

UNIVERSITY OF WINCHESTER

INTRODUCTION: Novel oscillometric measures of central blood pressure and central systolic loading offer a more comprehensive view of cardiovascular health than peripheral blood pressure. These non-invasive assessments may become commonplace in clinical practice in the future. Whilst these devices have been shown to be reliable in a younger sample, the between-day reliability of the instruments capturing these measures has not been demonstrated in clinical populations such as stroke, where they are particularly pertinent in terms of patient care and pharmaceutical choices.
METHODS: Twenty-two acute stroke in-patients (72 ± 10y) had peripheral blood pressure, central blood pressure and central systolic loading variables measured using the SphygmoCor XCEL on three consecutive mornings in both fasted and non-fasted states whilst in supine and seated postures.

RESULTS: Acceptable between-day reliability was observed for all peripheral and central blood pressures in all conditions, and for measures of central systolic loading in both fasted postures (ICC >0.75). Food intake significantly decreased all peripheral and central blood pressure and central systolic loading variables ($p < 0.05$; $\eta 2p = 0.20$-0.55). A seated posture caused a significant increase in measures of central systolic loading ($p < 0.05$; $\eta 2p = 0.22$).
CONCLUSION: Non-invasive measures of central haemodynamics can be reliably measured in an acute stroke population, but markers of systolic loading should be assessed in a fasted state where possible. Food consumption caused a significant drop in peripheral and central blood pressures – a finding which should be taken into account when assessing vascular health in an in-patient environment.

COGNITIVE-MOTOR INTERFERENCE IMPROVES WITH EIGHT WEEKS OF SENSORY-MOTOR TRAINING IN CHRONIC STROKE SURVIVORS: A PILOT STUDY.

LA GRANGE, R., WELMAN, K.E.

STELLENBOSCH UNIVERSITY

INTRODUCTION: Due to executive dysfunction, the ability to walk while concurrently engaging in a second cognitive task deteriorates in stroke survivors. Furthermore, this cognitive-motor interference (CMI) is related to high incidence of falls, poor balance, and reduction in health-related quality of life (QoL). To the researchers knowledge, no study to date has specifically investigated the influence of a sensory-motor training (SMT) on CMI in chronic stroke survivors (>6 months). Consequently, this study aimed to determine if an eight-week SMT would influence CMI during ambulation in chronic stroke survivors.
METHODS: A quasi-experimental study design. Ten chronic stroke survivors (67±14 years; 121.8±114.5 months since stroke) with ≥18 Montreal Cognitive Assessment participated in the SMT, three times a week for 45- 60 minutes per session. Outcome measures included QoL with SF-36 questionnaire and gait quality via a two-minute walk test during single-task and dual-task conditions; from this CMI was determined.
RESULTS: Improvements were found in CMI paretic single-limb stance ($p=0.05$, $d=1.06$, 95%CI: 1.23-6.62) and overall single-limb stance ($p=0.04$, $d=0.78$, 95%CI: -0.02-3.61). QoL improve over time in 'physical functioning' ($p=0.01$; $d=0.64$, 95%CI: -14.51-38.85), 'role limitations due to physical health' ($p=0.02$; $d=0.93$, 95%CI: -47.94-92.94) and 'social functioning' ($p=0.04$; $d=0.78$, 95%CI: -74.31-106.91).
CONCLUSION: The SMT was effective in improving motor-cognitive interference during ambulation as well as QoL in chronic stroke survivors.

SENSORY-MOTOR TRAINING LOWERS SURFACE DEPENDENCE IN CHRONIC STROKE SURVIVORS

ZASTRON, T., WELMAN, K.E.

UNIVERSITY OF STELLENBOSCH

INTRODUCTION: Balance is a complex sensory-motor process that allows an individual to maintain their balance through feedback and feed-forward mechanisms from the visual, vestibular and somatosensory systems (Barros et al., 2008). Following stroke, sensory integration and reweighting, i.e. the ability to choose and rely on the appropriate sensory input, can be impaired. Thus, abnormal interactions between the visual, vestibular and somatosensory system could be the source of abnormal postural control (Bonan e al., 2004). The primary objective was to assess the influence of sensory-motor training on postural stability in chronic stroke survivors. Additionally, intrinsic motivation was assessed after the intervention.
METHODS: This was a double-blind randomized control trial. Twenty-two individuals with chronic stroke (≥ 6 months) were randomly divided into two groups i.e. sensory-motor training group (n = 12; 68 ± 13 years old) and attention-control group (n = 10; 71 ± 11 years old). The sensory-motor training and educational talks were delivered in a group setting, three times a week for 45-60 minute sessions over an eight-week period for a total of 24 sessions. The sensory-motor training included task-specific balance training, which focused on manipulating the visual, vestibular and proprioceptive sensory systems. Postural sway was measured with APDM's Mobility Lab™ body-worn inertial sensors using the modified Clinical Test for Sensory Integration and Balance (m-CTSIB). The m-CTSIB was measured for one 30 second trial under four different sensory conditions: (1) eyes open on firm surface, (2) eyes closed on firm surface, (3) eyes open on foam surface and (4) eyes closed on foam surface. Participants were evaluated one week before beginning the intervention (pre-test) and within one week after completing the intervention (post-test). Lastly, intrinsic motivation was measured with the Intrinsic Motivation Inventory (IMI) after the intervention.
RESULTS: The main findings showed that the sensory-motor training group improved their sway area during condition three ($p = 0.04$) and showed a reduction in proprioceptive dependence ($p = 0.02$) after the intervention. Both groups showed high intrinsic motivation after the sensory-motor training and educational talks.
CONCLUSION: The present study demonstrates that participating in a sensory-motor training program could improve a chronic stroke survivor's ability to choose and rely on the appropriate sensory input during balance tasks.

DUAL-TASK COST GAIT SPEED REVEALS EXECUTIVE DYSFUNCTION IN CHRONIC STROKE SURVIVORS

WELMAN, K.E., WATSON, J., LA GRANGE, R.

STELLENBSOCH UNIVERSITY

INTRODUCTION: Rehabilitation research has often viewed gait and executive functioning (EF) as separate entities. However, recent research on healthy and elderly individuals, as well as acute stroke survivors suggest that EF and gait should be evaluated together owing to the motor-cognitive interaction that is also found in everyday life. Executive functioning is responsible for planning and coordination of complex processes, as well as allocating the necessary amount of attention during dual-task activities. The aim of this study was to determine if a relationship exist between EF and gait speed under single-, dual-task and dual-task cost (DTC) in chronic stroke survivors (onset stroke ≥6 months) compared to healthy adults. To the authors' knowledge, this was the first study to examine the independent association of DTC on EF in chronic stroke survivors.

METHODS: A cross-sectional observational design. Community-dwelling chronic stroke survivors (n=25; 71.36±14.06 years) and healthy (n=24; 73.92±9.30 years) age-matched healthy adults were included. The Rapid Assessment of Physical Activity (RAPA) for physical activity status, Patient Health Questionnaire-9 (PHQ-9) for depressive moods and the Montreal Cognitive Assessment (MoCA) for global cognition were used as descriptive outcomes. Gait speed was measured using the two-minute walk test during single- and dual-task conditions to determine DTC. Executive functioning was assessed by means of an adapted Stroop, Trail Making (TMT Part A and B) and Verbal Digit Span Forward and Backward tests. Data was log transformed if it did not follow a normal distribution.
RESULTS: Multiple linear regression analysis showed a significant association between DTC and EF in chronic stroke survivors. Specifically, DTC correlated with Stroop incongruent (R2=0.127, F (1,24)=4.352; β=-0.065, p=0.049) and interference ratio (R2=0.201, F(1,24)=6.780; β=0.005, p=0.016). Healthy individuals' ST gait speed related to Stroop incongruent (R2=0.514, F(1,23)=23.235; β=-4.796, p<0.001), LogTMT B (R2=0.376, F(1,23)=14.841; β=-0.783, p=0.001) and LogTMT difference (R2=0.393, F(1,23)=15.891; β=-0.976, p=0.001) while dual-task gait speed predicted LogTMT B (R2=0.424, F(1,23)=17.940; β=-0.505, p<0.001) and LogTMT difference (R2=0.382, F(1,23)=15.214; β=-0.589, p=0.001). Results were significant even if controlled for age and education (p<0.05).
CONCLUSION: Gait speed DTC is independently associated with inhibitory control, and possibly to working memory and cognitive flexibility in chronic stroke survivors. These findings support the motor-cognitive relationship during walking tasks in chronic stroke survivors and age-matched healthy individuals. Moreover, supports to use of dual-task gait assessments for an ecological alternative to assess EF.

PREDICTORS OF PEAK VO2 CHANGE AND THE EFFECTIVENESS OF LONG-TERM PARTICIPATION IN A REAL-LIFE SETTING CARDIAC REHABILITATION PROGRAM

PERNICK, Y., MOORE, J., KUBIS, H.P., ZYSSMAN, I., VERED, Z.

ASAF HAROFE MEDICAL CENTRE, ZERIFIN, ISRAEL; BANGOR UNIVERSITY, BANGOR, WALES, UK.

INTRODUCTION: The benefits of exercise-based cardiac rehabilitation programs are well known . Maximal exercise capacity is considered the most important predictor of cardiac and all-cause mortality .
The purpose of this study was to define the factors that may affect VO2max change in cardiac patients who attend a CR program. Another purpose was to determine if there is an advantage in maintaining to exercise in a CR program.
METHODS: 72 subjects exercised in a standard CR program for 3 months. Outcomes included cardiorespiratory variables, blood lipids, hemodynamic parameters, body composition, quality of life , and systolic and diastolic function. Measurements were obtained at baseline, after 3 months of supervised training, and following 6 months. After 3 months, a multiple linear regression analysis was performed to investigate predictors of changes in peak VO2. Following 6 months, a 2-way ANOVA analysis was performed to compare the cardiac measurements between patients who continued to exercise in the CR center and patients who left the center .
RESULTS: VO2 peak was improved by 6.0 ± 10.2% from baseline to 3 months . Also, maximal output in the cardiopulmonary exercise test and anaerobic threshold increased significantly.
The variables that predicted peak VO2 improvement included: peak VO2 at baseline, body fat percentage, maximal rate pressure product, QoL score, ejection fraction, and number of sessions. These factors accounted for 38.5% of the variance, p<.001.
At 6 months follow up, peak VO2 was maintained only in the CR-based group, while there was a decrease among non-CR-based subjects . Maximal output declined among non-CR-based patients . Body mass index and percent of body fat were increased in the non-CR-based group while they were preserved in the CR-based group.
CONCLUSION: This real-life comprehensive study identified several factors that can predict the change in peak VO2. Moreover, the long-term preservations of peak VO2 and other important cardiac related parameters in CR-based exercisers were noteworthy. Taken together, our findings can enable CR professionals to target and assist patients in improving their functional capacity and thus their prognosis. Furthermore, the importance of long-term CR programs in preserving attainments of functional capacity and body composition should be recognized. Subsequently, CR professionals should consider prolonging the standard CR programs.

EFFECTS OF A COMMERCIAL SUPPLEMENT OF OPHIOCORDYCEPS SINENSIS, AND GANODERMA LUCIDUM ON PHYSIOLOGICAL RESPONSES TO MAXIMAL EXERCISE IN HEALTHY YOUNG PARTICIPANTS

TSUK, S.

WINGATE COLLEGE

INTRODUCTION: Cordyceps sinensis (Cs) and Ganoderma lucidum (Gl) are two medicinal mushrooms, which were suggested to have a potential to enhance exercise capacity.
METHODS: We used a combined commercial supplement of Cs and Gl and tested their effects on human physical, aerobic, and anaerobic capacities. Ninety-six physical education students (43 women; age 26.3±3.21) were randomly divided into three groups: low dose treatment, high dose treatment, and placebo. Participants received supplement or placebo for 28-33 days. Participants performed the following tests before and after one month of interventios: 1. a graded maximal VO2max test on a treadmill 2. on a different day a Wingate anaerobic cycle test. From the maximal graded treadmill test the following parameters were measured and recorded: heart rate (HR); oxygen consumption (VO2); respiratory exchange ratio (RER); and ventilation (VE). From the Wingate, anaerobic cycle test the following parameters were calculated: maximal anaerobic power; mean anaerobic power; and fatigue index.
RESULTS: The supplements did not affect VO2max or the physiological responses at maximal exercise during the graded treadmill test. Similarly, there was no effect on peak and mean power or fatigue index as measured by the Wingate anaerobic test. A borderline interaction indicated a somewhat lower HR at rest post treatment, however, post hoc analysis did not reveal any further significant statistical differences, (P=0.047* F=3.169).

CONCLUSION: The findings indicate that the dual supplementation with Cs and Gl had no effect on maximal oxygen consumption, on physiological responses at peak exercise load of a graded maximal treadmill test, or on the parameters of anaerobic capacity.

REPRESSED EXERCISE-INDUCED HEPCIDIN LEVELS AFTER DANGGUI BUXUE TANG SUPPLEMENTATION IN MALE RECREATIONAL RUNNERS

CHANG, C.W., CHEN, C.Y., YEN, C.C., WU, Y.T., HSU, M.C.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: The aim of this study is to investigate the protective and recovery effects of Danggui Buxue Tang (DBT)—a Chinese herbal decoction containing the roots of Astragalus membranaceus and Angelica sinensis—supplementation on iron status, oxidative stress, complete blood count, inflammatory markers, and metabolic markers after participants were challenged by a single bout of intense aerobic exercise.
METHODS: Twenty-eight recreationally active males were pair-matched and randomly assigned to receive DBT (DBT group) or a placebo (control group) for 11 d, using clusters based on their aerobic capacities. On the eighth day of the supplementation, the participants performed a 13-km run with maximal effort. Blood and urine samples were collected and analyzed before treatment (Pre-Tre) and immediately after (Post-Ex), 24 h after (24-h Rec), and 72 h after (72-h Rec) the run.
RESULTS: DBT supplementation markedly shortened the finish times by 14.0% (12.3 min) compared with the control group ($p = 0.024$), with a larger improvement revealed in participants with lower aerobic capacity levels. Significant group×time effects were observed in serum hepcidin and iron levels ($p < 0.050$). DBT supplementation repressed exercise-induced hepcidin levels at Post-Ex and 24-h Rec, and was even decreased by 26.2% at 72-h Rec ($p = 0.012$). DBT supplementation thereby caused a significant increase in iron levels by 63.3% and 31.4% at Post-Ex ($p = 0.019$) and 72-h Rec ($p = 0.025$), respectively. However, DBT supplementation was not determined to prevent the immediate production of hematuria after exercise.
CONCLUSION: Short-term DBT supplementation improved exercise performance and repressed exercise-induced hepcidin, thereby boosting iron absorption and accelerating iron homeostasis during recovery. DBT is thus a promising ergogenic aid for athletic performance.

MANGIFERA INDICA L. LEAF EXTRACT IN COMBINATION WITH LUTEOLIN OR QUERCETIN ENHANCES VO2PEAK AND PEAK POWER OUTPUT, AND PRESERVES SKELETAL MUSCLE FUNCTION DURING ISCHEMIA-REPERFUSION IN HUMANS

GELABERT REBATO, M.1,2, WIEBE, J.C.2, MARTIN-RINCON, M.1, GERICKE, N.2, PEREZ-VALERA, M.1, CURTELIN, D.1, GALVAN-ALVAREZ, V.1, LOPEZ-RIOS, L.1, MORALES-ALAMO, D.1, CALBET, J.A.L.1

1 UNIVERSITY OF LAS PALMAS DE GRAN CANARIA; 2 NEKTIUM PHARMA

INTRODUCTION: Most polyphenols may act as antioxidants and have properties which may confer performance-enhancing effects (ergogenic). It remains unknown whether polyphenols such as luteolin, mangiferin and quercetin have ergogenic effects during repeated all-out prolonged sprints in humans. Here we tested the effect of a proprietary Mangifera indica L. leaf extract (MLE) rich in mangiferin (Zynamite®) administered with either quercetin (Q) and tiger nut extract (TNE), or with luteolin (Lut) on sprint performance and recovery from ischemia/reperfusion.
METHODS: For these purposes, thirty young physically active volunteers (seventeen men and thirteen women) were randomly assigned to three treatments (double-blinded), 48 h before the main experiments: treatment A (placebo: 500 mg of maltodextrin/day); treatment B (140 mg of MLE (60% mangiferin) and 50 mg of Lut/day) and treatment C (140 mg of MLE, 600 mg of Q and 350 mg of TNE/day). The experimental day subjects performed two warm-up sprints (8s), followed by 6 min of submaximal exercise (80-100 W), and two Wingate tests (30s) interspaced by a four-min rest period. After another four min of rest, they performed a 60s all-out sprint which ended with an instantaneous bilateral occlusion of the circulation of both legs during 20s. Then, the circulation was re-open and they performed a 15s-sprint followed by 10s of recovery with open circulation, and another 15s-final sprint.
RESULTS: Both MLE containing supplements enhanced performance. Both peak power output (Wpeak) (mean effect: 5.0 and 6.0 %, for MLE+Lut and MLE+Q, respectively) and mean power output (Wmean) (mean effect: 6.2 and 6.7%, respectively, $P<0.01$) were improved. In the sprint performed after ischemia, supplement MLE+Q+TNE increased Wpeak by 19.4 and 10.2% compared with placebo ($P<0.001$) and MLE+Lut ($P<0.05$). MLE+Q+TNE increased Wmean post-ischemia by 11.2 and 6.7 % compared with placebo ($P<0.001$) and MLE+Lut ($P=0.012$). Mean VO2 during the sprints was unchanged, suggesting increased efficiency or recruitment of the anaerobic capacity after MLE ingestion. In women, peak VO2 during the repeated sprints was 5.8% greater after the administration of MLE, coinciding with better brain oxygenation. MLE attenuated the metaboreflex hyperpneic response observed in post- ischemia sprints and may have improved O2 extraction by the vastus lateralis (MLE+Q+TNE vs placebo, $P=0.056$), and reduced the pain felt during the ischemia ($P=0.068$). Blood lactate, acid base-balance and plasma electrolytes responses were not altered by the supplements.
CONCLUSION: In conclusion, a MLE extract rich in mangiferin combined with either quercetin and tiger nut extract or luteolin has a remarkable ergogenic effect, increasing muscle power in fatigued subjects and enhancing peak VO2 and brain oxygenation in women during prolonged sprinting. Importantly, the combination MLE+Q+TNE improves skeletal muscle contractile function during ischemia/reperfusion.

IMPACT OF MAPLE SYRUP AND SAP INGESTION ON COGNITIVE FLEXIBILITY DURING HIGH-INTENSITY INTERMITTENT EXERCISE

DUPUY, O.1, LEDUC-SAVARD, N.2, LAVOIE, L.2, TREMBLAY, J.2

1: MOVE LABORATORY, UNIVERSITY OF POITIERS, FRANCE; 2:DEPT. KINESIOLOGY, UNIVERSITY OF MONTREAL, CANADA

INTRODUCTION: Glucose ingestion at rest and during exercise was previously shown to improve cognitive function. However, the effect of maple products on cognitive function during exercise are currently unknown. The aim of this study was to compare the effects of carbohydrate (CHO) drinks (6% per volume) sweetened with maple (syrup or sap) to a commercial sports drink (Gatorade©), glucose, and a control solution (water), on cognitive flexibility during high-intensity intermittent exercise.
METHODS: 78 subjects completed six (6) 3-minute bouts at 95% of their maximal aerobic power (MAP) on a stationary bike, with 3 minutes of passive rest in between efforts. During each recovery bout, the Stroop Color and Word Test (SCWT) was completed followed by mental ratings of perceived exertion (mRPE) and by the ingestion of 166 mL of one of 5 possible drinks (water, glucose, Gatorade©, maple syrup, maple sap). The subjects were randomly allocated to a different drink ingestion and each group was composed of ~15 subjects.

Following each bout, subjects ingested 166 mL of the experimental solution, drinking a total of 1L of the same solution throughout the experimentation. Cognitive flexibility was measured using reaction time and accuracy to the SCWT. The cognitive task was performed a total of 10 times, including 15 and 30 minutes post-exercise. Statistical analysis was performed using a two-way ANOVA with repeated measures using R.
RESULTS: Reaction times decreased in all conditions (main effect, $p<0.05$). However, this reduction was more important with any of the CHO condition than with water. Maple syrup and maple sap both led to larger reductions in reaction time (-22% and -29%, respectively) when compared to glucose and Gatorade© ingestion (-16% and -15%, respectively). Accuracy in the cognitive task decreased for all conditions (main effect, $p<0.05$). However, when compared to water and Gatorade©, maple syrup and glucose ingestion led to a lesser deterioration in accuracy (-1.2% and 0.1% respectively, compared to -2.8% for water and -3.2% for Gatorade©). Overall, mRPE increased over the exercise protocol ($p<0.05$) and both maple syrup and maple sap ingestion led to a lower mRPE (20 and 22% of improvement, respectively) than water.
CONCLUSION: CHO ingestion significantly decreased reaction time and improved accuracy during intermittent high-intensity exercise compared to water. Moreover, maple syrup ingestion leading to a smaller decrease in accuracy coupled with a quicker reaction time than with Gatorade© ingestion suggests it could potentially serve as an effective natural sweetener in order to improve cognitive function during high-intensity intermittent exercise.

FUEL SELECTION DURING PROLONGED EXERCISE WITH MAPLE SYRUP OR SAP INGESTION: COMPARISON WITH GLUCOSE AND GATORADE©

TREMBLAY, J.1, LAVOIE, L.1, LEDUC-SAVARD, N.1

UNIVERSITÉ DE MONTRÉAL

INTRODUCTION: Maple (syrup or sap) is a natural source of carbohydrates (CHO), being mainly composed of sucrose accompanied by organic acids, phenolic compounds, flavonoids and minerals. This suggests it could potentially be used as a viable source of energy during exercise. The aim of this study was thus to compare exogenous CHO oxidation and its contribution to the energy yield (%En) between 5 conditions: ingestion of either maple syrup, sap, glucose, Gatorade©, and sweetened water (stevia) during prolonged exercise.
METHODS: Subjects (n = 76, mass = 73.7 ± 10.3 kg, VO2max = 4.4 ± 0.5 L/min, MAP = 309 ± 42 W) were randomly allocated to an experimental group where they ingested a 13C-labelled CHO solutions (60 g/L) or sweetened water (stevia) during 120 min of exercise on a cycle ergometer at 55% MAP. Solutions were administered before and during exercise, at every 30 min (6 x 333 mL). Fuel selection was measured using indirect respiratory calorimetry corrected for urea excretion in urine and sweat combined with tracer techniques. Statistical analysis was performed using a two-way ANOVA with repeated measures using R. Results are reported as mean ± standard deviation.
RESULTS: The %En from protein oxidation was higher when water was ingested compared to all other conditions (5.5 ± 3.4 vs 4.2 ± 1.6%, respectively). When CHO were ingested, the %En from total CHO oxidation was significantly higher (water: 107.9 ± 40.4, glucose: 139.6 ± 22.6, Gatorade©: 139.4 ± 33.4, maple sap: 128.7 ± 31.6 and maple syrup: 141.9 ± 28.5 g) as well as its %En (water: 47.8 ± 17.6, glucose: 59.7 ± 9.9, Gatorade©: 60.1 ± 12.7, maple sap:58.2 ± 15.4 and maple syrup: 64.4 ± 15.0%), although no significant difference was observed between conditions with CHO ingestion. The %En from exogenous glucose oxidation was greater with Gatorade© and maple sap (17.3 ± 2.9 and 16.1 ± 3.7%) than with glucose and maple syrup (14.0 ± 2.1 and 13.4 ± 3.6%), while no difference was observed between these individual comparisons.
CONCLUSION: These results show that both maple syrup and sap can be readily absorbed and used as a source of energy during prolonged exercise. Maple sap leads to a greater exogenous oxidation than maple syrup and to a similar contribution to the energy yield as Gatorade© during prolonged cycling. This finding suggests that maple products could be used as viable natural sweeteners in sports drinks and warrant further investigation on their potential role in improving performance.

IMPACT OF A NITRATE-RICH, VEGETABLE BEVERAGE ON COGNITION, MOOD AND CARDIOVASCULAR RESPONSES IN YOUNGER AND OLDER ADULTS

ALI, A., STANAWAY, L., RUTHERFURD-MARKWICK, K., PAGE, R.

MASSEY UNIVERSITY

INTRODUCTION: Supplementation with nitrate-rich (NO3-) beetroot juice has been shown to improve cardiovascular responses and cognitive function in both younger and older adults, through the pathway of increased nitric oxide (NO). However, it is currently unclear whether there are differences in effects of dietary NO3- supplementation when directly comparing younger and older adults. Older adults have been shown to have an age-related decline in epithelial vasodilation, cardiovascular function, cognitive function, and mood indicating a greater potential for improvements in these areas following nitrate supplementation relative to younger adults who possess optimal functional capability. The purpose of this study was therefore to investigate the age-related differences in acute dietary NO3- supplementation on cardiovascular response, cognition and mood in younger and older adults.
METHODS: Following familiarisation, 13 younger and 11 older healthy and recreationally active adults (mean ± SD; younger vs older: age 25 ± 3 y vs. 56 ± 6 y ($p = 0.001$), body mass 75.3 ± 14.9 kg vs. 74.7 ± 7.9 kg ($p = 0.90$), height 1.78 ± 0.10 m vs. 1.70 ± 0.07 m ($p = 0.026$)) were randomly assigned to consume an isocaloric beverage; either 150 ml of NO3- rich beetroot juice (BR; containing 651 mg of NO3-) or 150 ml of placebo solution (PL; 65.8 mg of NO3-) in a double blind, crossover design, 2.25 h prior to a 30-min moderate treadmill walk. Throughout each trial, blood samples (plasma nitrate and nitrite concentrations) cardiovascular (blood pressure, heart rate), oxygen uptake kinetics, cognitive (choice reaction, rapid visual image processing and Stroop tests), and mood and perceptual (feeling scale, felt arousal scale, profile of mood states, and rating of perceived exertion) tests were performed.
RESULTS: Beetroot juice consumption increased plasma nitrate ($p(0.001)$ and nitrite concentrations ($p=0.003$) and reduced systolic ($p(0.001)$ and diastolic blood pressure ($p=0.013$) compared to placebo. Older adults showed a greater reduction in diastolic blood pressure following BR consumption ($p=0.005$) compared to younger adults. Systolic blood pressure was also lower post-exercise following BR versus PL treatment ($p=0.008$). Additionally, reaction time was improved in the Stroop test following BR supplementation ($p=0.045$). However, there were no main effects of treatment or interaction of treatment, time and age for heart rate, oxygen uptake, choice reaction or rapid visual image tests, and mood or perception measures following BR supplementation (p) 0.05).
CONCLUSION: These results showed that acute supplementation of beetroot juice increased plasma nitrate and nitrite levels, reduced blood pressure, and improved aspects of cognitive performance. Additionally, they indicate a potential age difference in diastolic blood

pressure following acute supplementation of BR. Further research directly comparing younger and older adults with the inclusion of blood flow measures such as NIRS and MRI is warranted.

Invited symposia

IS-SH04 "It's no choke": Moving choking under pressure beyond definition debates…

"IT'S NO CHOKE": MOVING CHOKING UNDER PRESSURE BEYOND DEFINITION DEBATES, ATTENTION-BASED MODELS, AND INTO THEORY-MATCHED INTERVENTIONS

HILL, D.

SWANSEA UNIVERSITY

"Choking" in sport is a significant concern for athletes, coaches and sport psychologists, as failure to meet performance expectations in critical situations, can have a devastating impact on the athlete. Consequently, the antecedents, mechanisms and moderators of choking in sport have been investigated at length, to inform theory-matched interventions that can alleviate the likelihood of its occurrence. Of particular importance are the attention and anxiety-focused interventions, and the more recent development of psychological strategies based on the neurophysiological considerations of choking. However, a number of researchers have contested the operational definition(s) of choking in sport, and thereby question whether researchers have accurately identified, isolated and examined the choking phenomenon. Accordingly, this symposium will explore and address the recent debate regarding the definition of choking in sport, and thereby provide a cogent account of the choking experience. Thereafter, it will provide a detailed review of contemporary theory-matched interventions, that can effectively lower an athlete's vulnerability to choke under pressure.

CHOKING UNDER PRESSURE: ATTENTION AND ANXIETY-BASED MODELS AND THEORY-MATCHED INTERVENTIONS

MESAGNO, C.

FEDERATION UNIVERSITY

Performing successfully under pressure is an important element of being an elite athlete. When an athlete fails under pressure, it can have negative social and psychological ramifications, especially if they experience "choking in sport". Although there is no research consensus on why choking occurs, attention- and anxiety-based models have been developed to help understand the cognitive mechanisms associated with choking. With researchers attempting to further understand choking models, applied sport psychologists have now turned their attention toward developing theory-matched interventions to ameliorate choking in sport. Thus, this presentation will provide an overview of choking theories, with an emphasis on possible integration of choking models. Thereafter, theory-matched, evidence-based interventions that help athletes alleviate choking will be explained and demonstrated.

A CHOKING INTERVENTION BASED ON NEUROPHYSIOLOGICAL CONSIDERATIONS

BECKMANN, J.

TECHNICAL UNIVERSITY MUNICH

Over recent years, an understanding of the neurophysiological processes underlying choking under pressure has accumulated. This knowledge is compatible with the choking model of anxiety induced self-focus. That is, if the athlete increases their investment in the conscious control of a motor skill when performing under pressure, the neuro-efficiency achieved through practice will break down. This process consequently interferes with the smooth flow of skill execution, resulting in increased kinematic variance and performance decrements. Based on this model, an intervention has been derived that eliminates the athlete's attempts to consciously control the motor skill. EEG studies show that clenching the left fist results in high Alpha activation across the cortex, which inhibits the conscious control processes that interfere with neuro-efficiency. Thus, if experts clench their left fist before the execution of a motor skill under pressure, choking is alleviated. Hence, this presentation will review the evidence-base that demonstrates the neurophysiological determinants of choking in sport, and the efficacy of fist clenching as a theory-matched intervention that reduces the likelihood of choking.

Oral presentations

OP-PM75 Exercise and older Adults

THE EFFECTS OF AN INCREASED ELEVATION STEPPING PROGRAM (STEEP) ON MUSCLE MASS, STRENGTH AND FUNCTIONAL PERFORMANCE IN OLDER WOMEN

BAGGEN, R., VAN ROIE, E., VERSCHUEREN, S., VAN DRIESSCHE, S., VAN DIEËN, J., DELECLUSE, C.

KU LEUVEN & VRIJE UNIVERSITEIT AMSTERDAM

INTRODUCTION: Decreased lower limb strength and functional ability are important indicators for increased fall-risk in older adults. Therefore, training programs aimed at fall prevention should aim to improve both of these factors. Task-specific training modalities such as stepping exercise have been shown to improve functional ability in older adults. However, the ability of such exercises to improve muscle mass and strength have not yet been thoroughly investigated. This study explored the effects of a 12-week stepping program with progressive increase in step height on muscle mass, strength and functional ability in older women.
METHODS: Forty-five community-dwelling women (68.78y ± 3.87) were randomly assigned to the training (n = 24) or control group (n = 21). Training intensity was determined by step height up to 36 cm, and percentage body weight added using a weighted vest. Muscle volume (MV) of the upper leg, strength of the knee extensors, and functional ability were determined pre- and post-intervention. MV was measured by CT-scan. An isokinetic dynamometer was used to determine isometric peak torque (PT) at two knee joint angles (PTisom120 and PTisom90), dynamic PT at three different speeds (PTisok60, PTisok180, and PTisok300), and peak velocity (V) at a resistance of 1, 20, 40 and 60% of PTisom90 (V1, V20, V40, and V60). Functional ability was assessed using a short physical performance battery (SPPB),

timed stair ascent (SA), and countermovement jump height (CMJ). In addition, kinematic data were recorded at the lower back using a 3D-accelerometer to assess quality of performance.
RESULTS: Step training resulted in increased MV ($p = 0.006$), increased isometric PT in all conditions ($p < 0.001$), increased dynamic PT at 60 and 300°/s ($p = 0.001$ and 0.036 respectively), improved CMJ ($p = 0.026$), and decreased time for SA ($p = 0.001$). In the control group, no significant differences were found between pre- and post-conditions ($p > 0.05$).
CONCLUSION: These results indicate that step training with progressively increasing step height is an effective method to simultaneously improve muscle mass, strength and functional ability in older women. This makes increased elevation step training a time-efficient training modality which can be employed in both group and home-based settings.

EFFECTS OF UNILATERAL ISOKINETIC ECCENTRIC TRAINING (AND DETRAINING) ON MUSCULOSKELETAL CHARACTERISTICS IN OLDER PEOPLE

KAY, A.D.1, FRASER, M.1, HILL, M.2, BLAZEVICH, A.J.3

1: UON , 2: CU , 3: ECU

INTRODUCTION: Reductions in lower-limb strength and muscle mass are common in ageing, with a concomitant reduction in aerobic capacity also limiting exercise tolerance. However, eccentric-only exercise has a lower cardiovascular demand (Vallejo et al., 2006) and higher loading potential that may improve exercise tolerance whilst providing a high musculoskeletal adaptive stimulus. Therefore, the present study examined the impact of a 6-week seated isokinetic eccentric training programme and 8 weeks of detraining on lower-limb strength and muscle architectural characteristics in older people.
METHODS: Maximal eccentric lower-limb force, and vastus lateralis (VL) thickness, pennation angle and fascicle length were measured in 12 participants (age = 67.0 ± 6.3 y, mass = 80.6 ± 16.0 kg, height = 1.6 ± 0.1 m) before (on two occasions separated by 1 week to determine reliability) and after the 6-week training programme using isokinetic dynamometry and ultrasonography. All measures were then re-examined 8 weeks later to quantify detraining (i.e. regression) effects. Training was performed twice-weekly on a BTE Eccentron using an alternating unilateral leg press motion and consisted of 5 min (week 1) or 10 min (weeks 2-6) of isokinetic eccentric contractions performed at 50%MVC at a rate of 40 contractions per minute. Strength was reassessed every 2 weeks to ensure subjects' training intensities remained at 50%MVC, with rate of perceived exertion (RPE) recorded after each training session.
RESULTS: A significant ($P < 0.05$) increase in lower-limb eccentric strength (58.8 ± 39.9%), VL muscle thickness (9.8 ± 5.4%), pennation angle (4.4 ± 5.7%) and fascicle length (5.4 ± 4.3%) was detected immediately after the 6-week training programme. RPE remained consistently low throughout the programme (3.3-4.1 out of 10), despite the increased duration and absolute intensity of training. Eight weeks later, lower-limb eccentric strength (50.4 ± 38.0%), VL muscle thickness (6.1 ± 5.5%) and fascicle length (5.8 ± 7.5%) remained significantly greater than pre-training levels, while pennation angle (1.0 ± 6.7%) returned to baseline.
CONCLUSION: The substantial increases in strength and muscle size achieved whilst training with low RPE have important clinical and practical implications for exercise prescription in older people, with the practical application and functional outcomes of the exercise regime well-suited to the specific physical needs and challenges of older people. Furthermore, the limited regression detected eight weeks after the completion of the training programme is indicative that eccentric strength training provides prolonged musculoskeletal functional benefits.

THE EFFECT OF AEROBIC-STRENGTH TRAINING ON FUNCTIONAL STATE AND GAIT SPEED IN ELDERLY INDIVIDUALS.

SLOBODOVÁ, L.2,1, TIRPÁKOVÁ, V.4, KRUMPOLEC, P.1, VAJDA, M.3, VALLOVÁ, S.2,1, SCHÖN, M.2,1, ŠUTOVSKÝ, S.5, CVECKA, J.3, TURCÁNI, P.5, VALKOVIC, P.6, SEDLIAK M.3, UKROPEC, J.1, UKROPCOVÁ, B.1,2,3

<1>INST.OF EXP.ENDOCRINOLOGY, BMC SAS;<2>INST.OF PATHOLOGICAL PHYSIOLOGY,FMED CU;<3>F.OF PHYSICAL EDUC.AND SPORTS,CU;<4>INST.OF SPORTS MEDICINE,FOM SMU;<5>1ST&<6>2ND NEUROLOGY DEP.FMED CU&UH BA; SVK

INTRODUCTION: Gait speed is one of the major health-related risk factors and has a prognostic and predictive value in the assessment of functional capabilities in elderly population, when speed lower than 0,8m/s is associated with cognitive decline, risk of falls, functional impairment, extreme frailty and a higher risk of death. Regular exercise training could effectively affect components of functional state and thus gait speed.
METHODS: 62 seniors (age 68±6 years) underwent phenotyping before and after 12-week intervention. Body composition (quadrupedal bioimpedance), Resting Metabolic Rate (RMR, indirect calorimetry), habitual physical activity (Baecke questionnaire) were assessed. Physical fitness (Rockport Walking Test), muscle strength (Isometric Knee Extension Strength Test), walking performance (10-Meter Walk Test by maximal/preferred speed, MWS/PWS) and balance (Berg Balance Scale) were measured. Intervention consisted of twelve-week (i) aerobic-strength training (n=50, M13/F37) 3x1h/week, 60-70%VO2max or 60-70%1RM (work-load increased gradually) and (ii) stretching (control group, n=12, M4/F8) 2x45min/week.
RESULTS: Exercise induced an increase in lean body mass ($p=0.02$), a decrease in visceral adiposity ($p=0.01$) and total body fat ($p=0.06$) and an increase in RMR ($p<0.001$). No changes in body composition and RMR ($p>0.05$) were found in the control group. Muscle strength ($p=0.02$), physical fitness ($p<0.001$), PWS (+10%, $p<0.001$), MWS ($p=0.01$) and balance ($p=0.02$) improved significantly in the training group. Small improvements in PWS (+4%, $p=0.01$) and muscle strength ($p=0.02$), with no change in MWS ($p=0.1$) and physical fitness ($p=0.25$) were found after 12-week stretching. Interestingly, approximately 80% of participants in both groups improved their PWS. MWS ($r=-0.36$; $p<0.001$), but neither PWS nor an intervention-induced change in PWS were associated with age ($p>0.1$). PWS correlated with total body fat ($r=-0.59$; $p=0.003$) and muscle mass ($r=-0.61$; $p=0.002$) in the stretching group. Stretching group reported higher sport-activity index after intervention ($p=0.01$).
CONCLUSION: Twelve-week aerobic-strength training improved body composition, muscle strength and preferred gait speed of elderly individuals, with a much smaller or missing effect in the control stretching group. Aerobic-strength training has a potential not just prevent but increase physical capabilities in seniors. Seniors with functional disabilities could benefit also from stretching, which, despite small effects on physical fitness and body composition, seem to have a potential to prevent a decrease in gait speed.

PHYSICAL FUNCTION IN ELDERLY: THE IMPACT OF PAST AND PRESENT PHYSICAL ACTIVITY BEHAVIOURS

EDHOLM, P., KADI, F., NILSSON, A.

SCHOOL OF HEALTH AND MEDICAL SCIENCES

INTRODUCTION: Maintaining physical function throughout the ageing process is vital for preserving the ability to perform normal everyday activities, independently and safely, without excessive fatigue. However, to what extent physical function is independently influenced by past and present physical activity (PA) behaviours is currently unclear. Therefore, we investigated influences of past and present PA behaviours on physical function in elderly community-dwelling women.
METHODS: An aggregated physical function score was created based on six-minute walk, squat jump and single-leg-stance balance performance in 60 older women (67.5 ± 1.5 yrs). Present PA behaviour was assessed by accelerometry (Actigraph) and past leisure-time PA behaviour by the Historical Adulthood Physical Activity Questionnaire, where time in sports-related activities and in walking were analysed separately. Differences in physical function across tertiles of PA behaviours were analysed adjusted by DXA-derived fat mass.
RESULTS: Present PA level (mean counts per minute) was independent of past PA behaviour associated with physical function in elderly women ($P < 0.01$), whereas no such influence was seen for time spent in sedentary behaviour. In addition to present PA behaviour, engagement in past leisure-time sports activities, but not walking also had a significant impact on physical functional ($P < 0.05$), which was independent of present PA behaviour.
CONCLUSION: PA at old age seems to infer beneficial effects on physical function, even in individuals with a past sedentary lifestyle. In contrast, no association was seen between time spent in sedentary behaviour and physical function. Taken together, findings of the present study support current public health recommendations, which aim at increasing PA level in order to counteract age-related functional decline, thereby promoting a healthy ageing.

INFLAMMATION AND OXIDATIVE ENZYMES ARE REDUCED AFTER EXERCISE AND TAURINE SUPPLEMENTATION IN ELDERLY WOMEN WITH MILD COGNITIVE IMPAIRMENT.

TEIXEIRA, A.M., UBA-CHUPEL, M., MINUZZI, L., FURTADO, G., RAMA, L., FILAIRE, E.

UNIVERSITY OF COIMBRA, NIF:501617582

INTRODUCTION: Aging is associated with increased risk of developing chronic diseases where an increase in inflammatory cytokines and oxidative enzymes occurs. Sedentary lifestyle and risk of malnutrition aggravate these processes, as suggested by the elevated concentrations of pro-inflammatory cytokines and oxidative enzymes often seen in older people with several comorbidities. Thus, exercise and implementation of nutritional adjustments might be powerful strategies to improve health in this population. The objectives of this study were to verify the effect exercise training, associated, or not, with taurine supplementation, on blood inflammatory markers and oxidative enzymes of institutionalized octogenarian women.
METHODS: 48 women (age: 83.5±6.9) participated in the study, being allocated into one of four groups: combined exercise training (ET: n=13), taurine supplementation (ET: n=12), exercise plus taurine supplementation (ET+TS: n=11) and control group (CG: n=12). Exercise was applied twice a week for 14 weeks and included muscle strengthening, walking and stretching exercises. Taurine supplementation was given (1,5g/day) to the supplemented groups. CG did not take part in any kind of exercise classes or supplementation, but received care as usual. Plasma concentrations of IL-1β, IL-1ra, IL-6, TNF-α, IL-10, IL-17, and matrix-metalloproteinase 9 (MMP-9) were evaluated before and after intervention. Serum concentration of myeloperoxidase (MPO) was also measured. The ratios between pro and anti-inflammatory cytokines were calculated and cognition (Montreal Cognitive Assessment – MoCA) was also evaluated.
RESULTS: Repeated measures ANOVA showed a treatment*time effect on MPO levels ($p=0.03$), for TS and ET+TS where a decrease was observed. However, no interactions were observed for MMP-9, despite univariate analysis showing a decrease in MMP-9 levels in TS after intervention ($p=0.04$). No significant changes were observed for all groups in IL-1β and IL-1ra concentrations, but reductions in the IL-1β /IL-1ra ratio occurred in ET and TS groups ($p<0.05$). Decreases in TNF-α and IL-10 levels were observed in ET and CG, respectively ($p<0.05$), and a significant treatment*time effect occurred for the TNF-α /IL-10 ratio, with a decrease in the ET and increase in the CG ($p=0.01$). IL-6 concentration and IL-6/IL-10 ratio decreased only in the ET ($p=0.02$), and no significant changes were observed for IL-17 in all groups. MoCA score increased only in the ET+TS group ($p<0.05$).
CONCLUSION: Exercise training alone modulated immunity in octogenarian women by increasing their anti-inflammatory profile. Supplementation with taurine was effective in reducing oxidative enzymes. Increase in cognition was only observed in those women who exercised and ingested the supplement provided. It seems that even when started at advanced ages, exercise can produce physiological benefits, with the addition of taurine appearing to be an important nutritional strategy to decrease oxidative stress and improving cognition.

BENEFITS AND FEASIBILITY OF ADAPTED PHYSICAL ACTIVITY PROGRAM FOR WOMEN WITH OSTEOPOROSIS AND VERTEBRAL FRACTURES: RESULTS OF THE EXPERIMENTAL STUDY OSTEO-AFA / 2014

MARINI, S.1, MASINI, A.1, SANNA, T.1, RAGGI, A.1, BUFFA, A.2, MALAVOLTA, N.2, MAIETTA LATESSA, P.1, LEONI, E.1, DALLOLIO, L.1

ALMA MATER STUDIORUM UNIVERSITY OF BOLOGNA

INTRODUCTION: In Italy 3,5 million of women are affected by osteoporosis. The clinical and social implications of the disease are mainly due to osteoporotic fractures that reach 1/3 of menopausal women. Vertebral fractures are associated with a significant decline in quality of life and disability. Exercise is a form of conservative non-pharmacological treatment that can be prescribed for the purpose of reducing pain and restoring motor functions in patients with osteoporosis. However, in the literature no definitive conclusions are available regarding benefits of exercise for individuals with osteoporosis and vertebral fractures (Giangregorio LM et al., 2013). The aim of this study is to evaluate the benefits and the feasibility of an Adapted Physical Activity (APA) middle-low impact program for postmenopausal women with osteoporosis and vertebral fractures, in terms of quality of life, physical performance and fear of falling.
METHODS: The women assigned to the experimental group (EG) performed a specifically structured exercise program (1 hour twice a week for 6 months) administered by graduates in physical education, which includes postural and muscular reinforcement exercises. The women assigned to the control group (CG) received the generic indication on the importance of physical activity. The outcomes assessed at the baseline and at the end of the APA program were: quality of life (ECOS-16), fear of falling (FES-1), functional exercise capacity (6MWT), balance (Tinetti scale), flexibility of the column (Sit & Reach).

RESULTS: SantOrsola Malpighi Hospital in Bologna (Italy) have completed the study. At follow-up, APA program improved the quality of life (EG:-0.4±0.1 vs CG:-0.005±0.7 p=0.01) and reduced the fear of falling (EG:-4.4 ± 1.8 vs CG: 0.3 ± 2.1 p=0.03). The same trend was observed in the GS for the physical performance parameters: balance (0.9±0.3 vs -0.8±0.5 p=0.01) and gait (45±12.7 meters vs 1.9±13.9 meters p<0.01). Sit & Reach improved only in the EG, but not significantly. Adherence to the program was very high (> 70%). No injuries were observed.
CONCLUSION: The study showed that this APA program is feasible, safe and significantly able to improve the quality of life and the physical efficiency and to reduce the fear of falling in postmenopausal women with vertebral fractures.

ASSESSING THE IMPACT OF EXERCISE TIMING ON GLYCAEMIC CONTROL: A RANDOMIZED CONTROLLED TRIAL

TEO, S.Y.M., KANALEY, J.A., GUELFI, K.J., MARSTON, K.J., FAIRCHILD, T.J.

MURDOCH UNIVERSITY, PERTH WA

INTRODUCTION: Maintaining tight glycaemic control is a key objective in the management of individuals with Type 2 Diabetes Mellitus (T2DM) [1]. Despite exercise being acknowledged as an important component in the management plan for individuals with T2DM, the importance of exercise timing has only recently been considered. The aim of this study was to determine the impact of diurnal exercise timing on glycaemic control in individuals enrolled into a 12-week supervised multi-modal exercise training program.
METHODS: Forty sedentary overweight males (n = 17) and females (age: 51 ± 13 years; BMI: 30.9 ± 4.2 kg/m2) with (n = 20) or without T2DM diagnosis were randomly allocated to either a morning (amEX) or evening (pmEX) exercise training group. All participants completed a 12-week supervised multi-modal exercise training program (3 days per week), which consisted of 30 minutes of aerobic exercise (walking protocol) and 4 resistance-based exercises (3 sets of 12-18 repetitions). The amEX and pmEX training sessions occurred between 0700-0900h and 1700-1900h, respectively. Body anthropometrics (BMI; body fat %, BF%) and glycaemic outcomes (glycated haemoglobin, HbA1c; fasting glucose and insulin; Homeostatic model assessment, HOMA) were assessed at baseline and post-intervention at 12 weeks. All data is displayed as mean differences ± SD.
RESULTS: Exercise training reduced (main effect of time: All $p < 0.01$) BMI (amEX: -0.82 ± 0.33 kg/m-2; pmEX: -0.83 ± 0.69 kg/m-2), BF% (amEX: -2.29 ± 1.86%; pmEX: -2.18 ± 1.50%), HbA1c (amEX: -0.27 ± 0.24%; pmEX: -0.25 ± 0.23%), fasting glucose (amEX: -1.33 ± 0.96 mmol/L; pmEX: -1.32 ± 1.94 mmol/L) and HOMA (amEX: -0.52 ± 0.53 pmol/L and pmEX: -0.54 ± 0.48 mmol/L); however, there was no time by group interactions for any variables (All $p \geq 0.79$). With regards to glycaemic control in participants with T2DM, eight participants achieved a HbA1c of <7% by post-intervention (18 individuals identified with baseline HbA1c of >7%; amEX: 10; pmEX: 8). Similarly, of the 18 T2DM participants with baseline fasting glucose levels of >7.2 mmol/L (amEX: 9; pmEX: 9), seven (amEX: 4; pmEX: 3) achieved a fasting glucose level of <7.2 mmol/L.
CONCLUSION: The 12-week multi-modal exercise training program improved glycaemic control and BMI in overweight non-T2DM and T2DM individuals. However, the diurnal (morning versus evening) timing of exercise training did not alter the glycaemic outcomes.

MODERATE TO VIGOROUS PHYSICAL ACTIVITY IS ASSOCIATED WITH THE MAXIMAL FAT OXIDATION CAPACITY DURING EXERCISE.

CORRAL-PÉREZ, J.1, VELÁZQUEZ-DÍAZ, D.1, PÉREZ-BEY, A.2, FERNÁNDEZ-SANTOS, J.R.2, GRAO-CRUCES, A.2, SANDUBETE-LÓPEZ, M.1, JIMÉNEZ-PAVÓN, D.1, CUENCA-GARCÍA, M.2, PONCE-GONZÁLEZ, J.G.1

1: MOVE-IT RESEARCH GROUP, FACULTY OF EDUCATION SCIENCES, UNIVERSITY OF CÁDIZ. 2: GALENO RESEARCH GROUP, FACULTY OF EDUCATION SCIENCES, UNIVERSITY OF CÁDIZ.

INTRODUCTION: A substantial inter-individual variability exists in maximal fat oxidation (MFO), which is an important capacity for metabolic health. Aerobic capacity has a positive influence on MFO, however little is known about the influence of moderate to vigorous physical activity (MVPA) on it. Therefore, the main aim of this study was to determine the contribution of both objectively assessed MVPA (O-MVPA) and self-reported MVPA (SR-MVPA) on MFO inter-individual variability.
METHODS: A total of 76 volunteers (30 women) aged 22.56±4.10 years were involved in this cross-sectional study. An incremental exercise protocol with two consecutive phases on a cycle ergometer was performed. The first phase aimed to determine MFO, using a validated protocol, and stopped when RER ≥1. After a short break, the second phase to detect the maximum oxygen consumption (VO2max) was initiated increasing load every minute until exhaustion. O-MVPA was assessed using accelerometers which participants wore at the lower back for 7 consecutive days prior to MFO test. SR-MVPA was measured by the short version of International Physical Activity Questionnaire. Linear regression analyses were used to determine the influence of O-MVPA and SR-MVPA on MFO adjusting by VO2max and age.
RESULTS: MFO relative to fat-free mass (FFM) was 6.89 ± 2.73 mg/kg/min (range 6.27-7.51 mg/kg/min). A total of 17% of the inter-individual variability was explained by VO2max (2996.01 ± 749.85 ml/min) and age (22.76 ± 4.45). O-MVPA (76.18 ± 23.87 min/day) was positively and independently associated with MFO ($p<0.05$), explaining 5.8% of the inter-individual variability. SR-MVPA (111.92 ± 56.68 min/day) was positively ($p>0.05$) associated with MFO relative to FFM, however, it did not explain any percentage of the inter-individual variability. After performing sensitivity analysis results did not materially change.
CONCLUSION: Previous studies observed a positive and independent influence of SR-MVPA on MFO; however, our results showed a relationship between MFO and O-MVPA, but not with SR-MVPA. This disagreement could be explained by differences between questionnaires used, the lack of accuracy of SR questionnaires or differences in population groups. So further studies are needed to clarify this relation. To our knowledge, there are no studies analysing the role of O-MVPA on MFO. Since our study shows that O-MVPA is an independent predictor of MFO, increasing MVPA levels could be an interesting strategy to enhance the MFO.

PROLONGED EXERCISE INHIBITS THE AUTOPHAGIC RESPONSE TO AN EXTREME ENERGY DEFICIT IN OVERWEIGHT MEN, CONTRIBUTING TO THE LEAN MASS-SPARING EFFECT OF EXERCISE

MARTIN-RINCON, M., MORALES-ALAMO, D., ALCAZAR, J., PEREZ-LOPEZ, A., HOLMBERG, H.C., CALBET, J.A.

1 IUIBS, UNIV. OF LAS PALMAS GC, SPAIN; 2 GENUD TOLEDO, UNIV. OF CASTILLA LA MANCHA, SPAIN; 3 UNIV. ALCALA, SPAIN; 4 SWSRC, MID SWEDEN UNIV., SWEDEN

INTRODUCTION: Damaged cellular components are removed and renovated by autophagy. Caloric restriction elicits upregulation of autophagy, which is involved in skeletal muscle (sm) protein breakdown. Rodent studies indicate an exercise-dependent activation of autophagy by endurance exercise, although these findings have not been confirmed in humans. Studies on how nutrition interacts with exercise in the regulation of autophagy are scarce and controversial, and none have focused on the sm autophagic responses to a severe energy deficit (SED) in humans. Here we study the effects of different amounts of exercise and two diets (sucrose versus whey protein) on the regulation of sm autophagy during a SED. We hypothesized that exercise would attenuate the autophagic responses elicited by a SED contributing to the known sparing-effect of exercise in sm during dieting.
METHODS: Fifteen overweight men underwent 4 days of caloric restriction (CR) (0.8 g/kg BW/day of either whey n=8 or sucrose n=7) and prolonged exercise (PE) (45min of one-arm cranking and 8h walking/day). Muscle biopsies from both deltoid and one vastus lateralis (VL) were taken before (PRE), after PE+CR and following 3 days of control diet (isoenergetic) and reduced exercise (CD); and sm AMPK, Beclin1, LC3BI, LC3BII and p62 protein expression were analyzed (WB). Body composition was assessed by DEXA. Statistical analysis was performed using repeated-measures ANOVA.
RESULTS: After PE+CR the energy deficit was 5000 kcal/d, reducing fat-free mass ($P<0.001$). Legs and trained arm lost proportionally less FFM than the untrained arm [57% ($P< 0.05$) and 29% ($P = 0.05$), respectively]. Compared to PRE, after PE+CR Ser15-Beclin1 phosphorylation was increased ~14-fold and ~2.7-fold in the untrained and trained deltoid, while it remained unchanged in VL. Following CD, the expression was ~19-fold, ~5.0-fold higher and remained unchanged, respectively (ANOVA extremity by time, $P=0.026$). The ratio Thr172-AMPK/Total AMPK was increased (27%) in all muscles, further increasing after CD (56%, $P<0.05$). LC3BI increased in both deltoid after PE+CR and CD (19 and 30%, $P<0.05$), whilst LC3BII remained unchanged, resulting in an unaltered LCBII/I ratio. Protein expression of p62 was increased by 25% and 97% in both deltoids and VL, respectively (ANOVA extremity by time, $P<0.05$) after PE+CR and remained elevated after CD. No significant changes were found due to the ingested solution.
CONCLUSION: During an extreme energy deficit, the increased induction of autophagy (Ser15-Beclin1 phosphorylation) was attenuated by exercise, which was accompanied by a concomitant reduction in the autophagic flux (LCBII/I ratio and p62), with this effect being proportional to the amount of exercise done by each muscle. Thus, this study shows an inhibition of the autophagy machinery in an exercise dose-dependent manner, explaining the lean-mass sparing effect of exercise during dieting in overweight men.

RISK OF LOW ENERGY AVAILABILITY AND ASSOCIATED HEALTH OUTCOMES IN ACTIVE FEMALES IN IRELAND.

LOGUE, D.M., MADIGAN, S.M., HEINEN, M., MCDONNELL, S.J., DELAHUNT, E., CORISH, C.A.

UNIVERSITY COLLEGE DUBLIN

INTRODUCTION: Energy availability (EA) is the energy available for normal physiological function, such as menstrual function and bone health, after energy for exercise has been deducted. When low energy availability (LEA) occurs, physiological adaptations may develop; these can contribute to unfavourable health and sports performance outcomes (1,2).
METHODS: The aim of this study was to identify LEA risk among active females in Ireland using the validated 'Low Energy Availability in Females Questionnaire' (LEAF-Q) (3). This was completed online by active females aged 18 years or older living in Ireland. Participants were recruited between November 2016 and February 2017 through sporting organisations under the governance of Sport Ireland and via social media. Twenty-nine additional questions collected information on demographics, illness history, dietary habits and supplement use. Chi-square and logistic regression analyses were used to examine differences between athletes at different competitive levels.
RESULTS: 833 participants completed the online questionnaire. Risk of LEA was identified in 40% (N=331) of participants and was 1.7 or 1.8 times more likely in international and provincial/inter-county athletes compared to those who were recreationally active (International: OR 1.68, 95% CI 1.12, 2.54; Provincial/inter-county: OR 1.83, 95% CI 1.20, 2.77). For every extra hour of exercise participants performed per week, the risk of LEA was 1.06 times more likely to occur (OR 1.06, 95% CI 1.02, 1.08, $P = 0.003$). Adjusting for age and level of competition did not change this. In participants missing more than 22 days of training due to injury and/or illness, risk of LEA occurred 9 or 3 times more frequently (Injury: OR 9.03, 95%CI 5.43, 15.01; Illness: OR 3.01, 95%CI 1.81, 5.02). Of those who reported exercise-related stoppage of menstruation, risk of LEA was 6.6 times more likely to occur (OR 6.64, 95% CI 2.25, 19.61, $P < 0.001$).
CONCLUSION: The high prevalence of LEA risk and frequency of detrimental health outcomes associated with LEA highlights a need for improved awareness, screening and intervention to optimise sports participants' health and performance.

GENDER-BASED DIFFERENCES ON RESTING AND MAXIMAL FAT OXIDATION: ROLE OF CARDIORESPIRATORY FITNESS

VELÁZQUEZ DÍAZ, D., PÉREZ BEY, A., CORRAL PÉREZ, J., FERNÁNDEZ SANTOS, J.R., SÁNCHEZ DELGADO, A., GRAO CRUCES, A., SANDUBETE LÓPES, M., JIMÉNEZ PAVÓN, D., CUENCA GARCÍA, M., PONCE GONZÁLEZ, J.G.

UNIVERSITY OF CÁDIZ

INTRODUCTION: Gender comparative studies support an oestrogen-induced increase in fat oxidation during exercise. Despite the effect of sexual hormones, differences on absolute and relative fat oxidation during exercise could be affected also by cardiorespiratory fitness (CRF). However, the combined effect of both is unknown. Therefore, the main aim of this study was to analyse the independent and combined effect of CRF and gender on resting fat oxidation (RFO) and maximal fat oxidation (MFO).

METHODS: A total of 93 young adults (62 males; 25.1±8.8 years old) were included in this cross-sectional study. Respiratory exchange ratio (RER) and RFO were registered at resting conditions on a bed during 30 min. After that, an incremental exercise protocol with two consecutive phases was performed, phase 1 consisted in an incremental exercise protocol (increments of 30W for lean and 15W for overweight and obese every 3 min) to determine MFO. The MFO test was stopped when RER ≥1. After rest 3-5 min, the second phase to detect the VO2max was initiated. This phase continues with steps of 1 min increasing the same incremental load as in phase 1. Bioimpedance analysis was used to assess body composition (fat mass and fat free mass (FFM)). Linear regression analyses were performed to determine the independent associations of CRF on fat oxidation (RFO, RFO/ FFM, MFO and MFO/ FFM) and gender interaction. Covariance analysis (ANCOVA) was used to observe differences on fat oxidation between gender groups and also between combined groups created using CRF level and gender.
RESULTS: MFO and MFO/FFM were positively associated with CRF (r=0.62, p<0.001; r=0.64, p<0.001, respectively) and gender interaction was observed for MFO/FFM (p<0.001). Significant differences were observed between men and women on RFO/FFM (p=0.001), besides, significant differences were shown between gender on MFO/FFM after accounting for CRF (p<0.001) or CRF, age and fat mass (p=0.002). Men with low CRF group showed greater inability on RFO/FFM compared to the group of men with high CRF and women with high and low CRF (p<0.05). Women with high CRF had higher MFO/FFM levels than men with low CRF (p<0.05). There were no significant differences between sexes on MFO/FFM in groups with the same CRF level (p>0.05).
CONCLUSION: Men with low CRF showed an impaired fat oxidation compared to the other groups. Men and women with high CRF levels have similar fat oxidation capacity and higher compared to their counterparts with low CRF levels. These findings suggest a higher influence of CRF than gender on fat oxidation capacity.

PHYSICAL ACTIVITY DURATION BUT NOT ENERGY EXPENDITURE DIFFERS BETWEEN DAILY COMPARED WITH INTERMITTENT BREAKFAST CONSUMPTION IN ADOLESCENT GIRLS: A RANDOMIZED CROSSOVER TRIAL

ZAKRZEWSKI-FRUER, J.K.1, WELLS, E.K.1, CRAWFORD, N.S.G.2, AFEEF, S.M.O.2, TOLFREY, K.2

1: UNIVERSITY OF BEDFORDSHIRE, UK, 2: LOUGHBOROUGH UNIVERSITY, UK

INTRODUCTION: Experimental research is required to establish whether there is a causal link between breakfast frequency and physical activity (PA) in young people. This research is particularly relevant to adolescent girls, a population with low breakfast consumption and PA levels.
METHODS: Using a randomized crossover design, 27 girls (age 12.4 ± 0.5 y, body mass index 19.3 ± 3.0 kg·m-2) completed two, 7-day conditions. A ~1674 kJ standardized breakfast was consumed every day before 09:00 in the daily breakfast consumption (DBC) condition. The standardized breakfast was consumed on only three days before 09:00 in the intermittent breakfast consumption (IBC) condition alternating with breakfast omission on the remaining four days (i.e., only water consumed before 10:30). Combined heart rate-accelerometry was used to estimate PA energy expenditure (PAEE) continuously throughout each condition. Time spent and estimated PAEE for each PA intensity were calculated for three time segments of the day: wake time to <10:30, 10:30 to <15:30 and 15:30 until bed time. Statistical analyses were completed using condition by time of day repeated measures analysis of variance.
RESULTS: Total daily estimated PAEE and daily estimated PAEE from sedentary, light, moderate and vigorous intensities did not differ significantly between the conditions (P ≥ 0.13). There was a condition by time of day interaction for sedentary time (P = 0.05), which indicated that the girls spent 11.5 min/d more time sedentary in IBC compared with DBC during 15:30-bedtime (P = 0.04). Light PA was 19.8 min/d higher during DBC compared with IBC (P = 0.05). There was a significant condition by time of day interaction for time in light PA (P = 0.04), which indicated higher light PA during wake-10:30 (P = 0.04) and 15:30-bedtime (P = 0.03) in DBC compared with IBC. There were no significant differences in time spent in MPA or VPA between the conditions.
CONCLUSION: Physical activity energy expenditure was not different when adolescent girls consumed breakfast daily compared with intermittently over seven days. Nevertheless, the girls spent more time in LPA before 10:30 and after school and less time sedentary after school when consuming breakfast daily. Further research is required to determine the long term effects of breakfast consumption and omission on physical acitivity and health outcomes in adolescents.

TRAINING LOAD PROFILES IN NATIONAL TEAM FOOTBALL; TRANSITION FROM CLUBS-TO-TOURNAMENT

NOOR, D.1,2, MCCALL, A.3, JONES, M.3, DUNCAN, C.3, EHRMANN, F.3, MEYER, T.1, DUFFIELD, R.2,3

1: SAARLAND UNIVERSITY , 2: UNIVERSITY OF TECHNOLOGY SYDNEY , 3: FOOTBALL FEDERATION AUSTRALIA

INTRODUCTION: Introduction: Limited evidence currently exists in relation to how training load (TL) is periodised for players' transitioning from club to national team environments (McCall et al., 2017). However, practitioners operating within National team contexts have identified prior TL and within-tournament TL to be of high importance when assessing player injury risk (McCall et al., 2015). Therefore, this study aims to quantify the external and internal TL profiles of a single national football team as player's transition from club (C), to in-camp (IC), to in-tournament (IT) periods over multiple international tournaments.
METHODS: Methods: TL data were collected from the same National team prior-to and during 3 recent international tournaments; 2014 World Cup (n=20), 2015 Asian Cup (n=20) and 2017 Confederations Cup (n=20). External (session duration, count and type) and internal (1-10 scale RPE and s-RPE) loads of all outfield players were included for analysis. Data was categorised into standardised time periods: C (7-days prior to camp arrival), IC (7-days post camp arrival), and IT (7-days from 1st tournament match). These time periods allowed calculation of the acute:chronic workload ratio (ACWR) for s-RPE for each period based on the mean of the previous 3-weeks. The magnitude of effect for differences in TL and ACWR between the time periods was then expressed as the standardised mean difference (Cohen effect sizes, ES).
RESULTS: Results: Concerning s-RPE, during the C (1324 ± 846) to IC (1765 ± 538) transition, a moderate effect (ES=0.88) was evident for increased TL between the two periods, with only a small decrease in TL (ES=0.48) between IC and IT (1574 ± 583). Similarly, RPE, increased moderately (ES=0.81) from C (4.3 ± 1.3) to IC (5.1 ± 1.5), but with only a trivial change (ES=0.13) to the IT period (5.3 ± 2.6). Concerning external load, during the C (4.0 ± 1.5) to IC (5.9 ± 0.6) transition, a very large effect (ES=2.35) was evident for increased number of sessions between the two periods, with a large effect (ES=1.12) also observed for the decrease in sessions between IC and IT (5.1 ± 1.3). Conse-

quently, a large (ES=1.47) increase in ACWR for s-RPE was determined for IC (1.35 ± 0.72) compared to C (0.70 ± 0.51), and a moderate decrease (ES=0.86) in ACWR for IT (1.01 ± 0.32) compared to IC.
CONCLUSION: Conclusion
National team football players (within this team) show expected increases in ACWR for TL during the first week of a training camp prior to a major tournament. This increase in TL is likely resultant from an increase in the number of sessions performed per week alongside an increase in the perceived intensity of the sessions.

INFLUENCE OF TRAINING LOAD UPON ISOMETRIC POSTERIOR CHAIN STRENGTH IN ELITE FOOTBALLERS: A SEASONAL OBSERVATION

TABERNER, M., OKEEFE, J., RICHTER, C., CLARKE, N., COHEN, D.
LIVERPOOL JOHN MOORE'S UNIVERSITY

INTRODUCTION: Hamstring strains are the most common injury in elite football, with a modifiable risk factor (hamstring muscular strength measure on pre season; Timmins et al., 2016). Further, accumulated fatigue during periods of fixture congestion, during which inadequate recovery from training and match workload, is also indicated as causal in injury (Gabbutt and Ullah, 2012). Time dependent hamstring strength declines within a match are consistently reported and are thought to contribute to the increased vulnerability to injury in the latter stages of a match (Thorlund et al., 2019). McCall et al. (2015) proposed an isometric posterior chain (IPC) test as a simple tool to monitor changes in force in-season. This test has been reported to be sensitive to acute match induced fatigue and to show residual neuromuscular fatigue 72h post-match (Nedelec et al. 2014). However, the impact of week to week of components of training load upon hamstring strength/neuromuscular function across the season is not known.
METHODS: We evaluated correlations between combined training load using GPS (Viper, StatSports) and changes in IPC peak force at 90 degrees of knee flexion using a force platform (left & right limb peak force) values over 2-week blocks in an elite first team squad across a full season.
RESULTS: The strongest negative correlation was found with mean sprint distance (distance accumulated >7ms-1) completed during a 2-week period to IPC peak force (r=-0.21) and mean Z5-Z6 decelerations (deceleration efforts >5ms-2; r= -0.13). The strongest positive correlation was found with coefficient of variation within HSR to IPC peak force (r=0.32) and coefficient of variation within Z5-Z6 decelerations (r= 0.26).
CONCLUSION: Mean sprint distance over a 2 week period was associated with reduced IPC peak force. Previous studies (e.g. Rahnama et al. (1992) have reported a progressive reduction in muscle strength that applies across a range of functional characteristics during exercise that mimics the work rate in soccer. Reduced hamstring strength may reduce the ability to decelerate the leg during the latter part of the swing phase in sprinting, at which point eccentric overload could cause tearing in the musculo-tendinous unit. However, coefficient of variation within both HSR and Z5-Z6 decelerations was associated with the strongest increase in IPC peak force indicating that week to week variations in load are an important stimulus of novel load to provide improvements in hamstring strength. Gabbett (2016) has highlighted that appropriate graded prescription of training loads may help to improve players' fitness which can in turn help protect against injury. Consequently, a paradox potentially exists to find the optimal balance of training load with reduced hamstring strength having implications for the increased predisposition to hamstring strain injury. These findings highlight the need for regular monitoring to assess players' responses to training to help plan appropriate training prescription and help reduce injury risk. Additionally, match data would assist to provide the total external load placed upon players' and help facilitate optimally loading between competition schedules.

TIME STRUCTURE AND VALUE OF EMG SIGNAL IN SELECTED TECHNICAL ELEMENTS OF FEMALE ÉPÉE

BORYSIUK, Z., MARKOWSKA, N.
OPOLE UNIVERSITY OF TECHNOLOGY

INTRODUCTION: The objective of the study was to analyze the structure of the fencing lunge and flèche. This was possible as a result of the determination and comparison of the reaction time, motor response time and neuro-muscular activity accompanying as simple attack including lunge and flèche depending on the type of visual and tactile stimulus in two female subjects, members of the national senior team in women's épée.
METHODS: The study involved two female subjects, members of the national senior team in women's épée, mean age of 29. The analysis applied EMG and involved the following 8 muscles of the upper and lower limbs: biceps brachii (BB), triceps lateralis (TL), flexor carpi ulnaris (FCU), extensor carpi radialis (ECR), biceps femoris (BF), rectus femoris (RF) gastrocnemius lateralis (GL), and gastrocnemius medialis (GM). Two combined Kistler force plates were applied in the assessment of ground reaction forces with the purpose of classifying the movement patterns of the forward and back legs. The model of the motion was obtained as a result of the use of 3D Motion Capture.
RESULTS: The analysis of the available data demonstrated that the reaction time and motor response is shorter for the case of the simple attack with a flèche in comparison to the simple attack performed with a lunge regardless of the type of the stimulation. Depending on the type of stimulation, the mean signal produced by the particular muscles varies. Both for visual and tactile stimulation, the lower values of the muscle signal accompanying a flèche is demonstrated by the following muscles: TL, FCU, GL, GM, whereas the higher level of the signal is recorded in BB, ECR muscles. When a flèche is delivered, it is accompanied by a higher level of the signal produced by BF muscle when tactile stimulation is provided, whereas the mean level of the signal produced by the RF muscle is higher for the visual stimulation.
CONCLUSION: In the light of the conducted study, we learn that for the case of tactile information, the sources of anticipation for the case of a simple attack delivered with a fleche include the signal of the arm flexor and extensor muscles that is sensed as a result of the contact with the opponent's blade. For the case of the visual information, anticipation is based on the activation level of gastrocnemius muscle in the back leg (Do, M. C. & You, E. 1999). During a simple attack delivered with a lunge, the source of anticipation will be based on the signal produced by the arm muscles both with regard to tactile and visual stimulation. The lower muscular tension of the back leg in the latent phase of the motion leads to greater ground reaction forces (both vertical and horizontal).

RUNNING A 12-KM RACE INFLUENCES POSTURAL CONTROL AND PLANTAR-FLEXION STRENGTH, BUT NOT FOOT STRIKE ANGLE

HÉBERT-LOSIER, K., MURRAY, L., MCMASTER, D.T., BEAVEN, C.M.

UNIVERSITY OF WAIKATO

INTRODUCTION: Running is a popular physical activity with numerous organised races now accessible to the community. Sustained exercise can lead to neuromuscular impairments and fatigue, which has been associated to increased likelihood of injuries in athletes. To date, much of the empirical evidence on running derive from laboratory-based studies or highly controlled environments, with few studies conducted in ecologically valid environments. Our aims were to investigate the effects of running a 12-km race on plantar pressure distribution, postural balance, self-selected running speed and foot strike angle, and plantar-flexion strength.
METHODS: Twenty-four recreational runners (15 males and 9 females) completed a series of tests immediately before and after a 12-km organised race. The tests included: (1) plantar pressure distribution in self-selected bilateral stance; (2) 30-seconds eyes-closed feet-together postural balance; (3) self-selected running speed and foot strike angle; and (4) peak plantar-flexion isometric force normalised to body weight. All participants wore their own running shoes during testing and were rearfoot strikers. Runners rated their perceived exertion (RPE) level on a 20-point Borg scale at the finish line. Differences between pre- and post-race measures were assessed using magnitude-based inferences of the standardized effects and associated 90% confidence limits (ES, ±CL).
RESULTS: Participants completed the 12-km race in 61 ± 8 minutes and reported a median RPE of 17. Following the race, there were clear and meaningful changes in plantar pressure distribution, postural balance, self-selected running speed, and plantar-flexion peak force, but not foot strike angle. On average, the relative pressure under the left foot decreased by 3.2 ± 5.0% (-0.58, ±0.31) with a corresponding increase under the right foot; the centre of pressure path length (0.94, ±0.35) and area of the 95th percentile ellipse (0.85, ±0.32) from the balance task increased by 5.7 ± 8.9 cm and 18.2 ± 21.2 cm2, respectively; self-selected running speed decreased by 0.2 ± 0.6 m/s (-0.37, ±0.43); and peak plantar-flexion isometric force decreased by 0.20 ± 0.30 times body weight (-0.42, ±0.18). The change of 0.5 ± 4.3° in foot strike angle was trivial (0.08, ±0.24).
CONCLUSION: Running a 12-km race influenced several neuromuscular measures, confirming racing-induced fatigue in our recreational runners. Despite quantifiable declines in postural balance and plantar-flexion strength, self-selected foot strike angle did not meaningfully change and might not be an appropriate indicator of fatigue in runners. Our findings corroborate the importance of plantar-flexion strength in racing events, and that postural control is altered in fatigued runners. Tracking postural control measures over time may be useful in the monitoring of training loads and recovery in runners.

ASSESSMENT SPECIFIC ECCENTRIC KNEE FLEXOR STRENGTH: IS THERE A DANGER OF MISINTERPRETATIONS?

SCHARINGER, M., WIESINGER, H.P., GRESSENBAUER, C., KÖSTERS, A., MÜLLER, E.

UNIVERSITY OF SALZBURG

INTRODUCTION: Eccentric hamstring exercises are considered to be the most effective approach to reduce the tremendous burden of posterior thigh muscle injury (Timmins et al., 2016). However, research focused on exercise-specific recruitment and/or adaptation patterns (Guex et al., 2016; Seymore et al., 2017) and neglected the sensitivity of diagnostic assessments. Accordingly, the aim of this study was i) to examine the effects of eccentric exercise on an isokinetic dynamometer (IKD) or a Nordic hamstring device (NHD) on biceps femoris muscle size and architecture and ii) to analyse whether training responsiveness can be detected in a comparable way with the respective diagnostic devices.
METHODS: Thirty male student-athletes (25±3 yrs) were randomly assigned to one of the three, equal sized, groups: isokinetic (IG), Nordic hamstring (NG) and controls (CG). IG and NG groups performed a 6-week training program, consisting of 16 sessions with overall 220 supervised repetitions on respective devices. Eccentric knee flexion strength (EPT) was assessed counterbalanced on either device at an angular velocity equal to the predetermined 30°/s of the training sessions. The biceps femoris cross-sectional area, fascicle length and pennation angle were measured with ultrasonography and analysed blinded to the subjects' identity. The CG did not change their daily routines.
RESULTS: Measured parameters did not differ at baseline. There were no significant group x time interactions for measured muscle parameters ($P>.08$; $\eta2<.18$). A significant group x time x device effect ($P<.01$; $\eta2<.41$) and a significant main effect for devices ($P<.01$; $\eta2<.77$) were found. On IKD, group x time interactions were only significant between the IG and the CG ($P<.04$; $\eta2<.22$) and between the IG and the NG ($P<.01$; $\eta2<.35$) with a mean EPT improvement of 21% in IG. Conversely, on NHD, significant training effects were only observed in the NG (group x time: $P<.03$; $\eta2<.25$) with a mean EPT improvement of 24%.
CONCLUSION: The present intervention did not appreciable alter the biceps femoris muscle size and architecture. Nonetheless the device specific increase in EPT suggests that training adaptations may not be detected or could be misinterpreted, when not using the appropriate assessment.

INFLUENCE OF SURFACE PROPERTIES ON FASCICLE-TENDON INTERACTIONS DURING LANDING

HOLLVILLE, E., NORDEZ, A., GUILHEM, G., LECOMPTE, J., RABITA, G.

FRENCH INSTITUTE OF SPORT, NATURAL GRASS

INTRODUCTION: Recent works showed a tendon buffer effect in humans during a step (Werkhausen et al., 2017) and drop landing (Hollville et al., 2018) for ankle and knee extensors muscles in order to protect fascicles from high lengthening contractions. Most of lower limb injuries during landing occur when the muscle-tendon unit (MTU) have to withstand large mechanical energy at impact. As human lands, energy is absorbed and returned by the surface depending on its intrinsic ground mechanical properties. The aim of this study was to investigate the influence of different surfaces on the gastrocnemius medialis (GM) MTU behavior during drop landing.

METHODS: Eight active men were asked to perform 50 cm drop landings over 3 surfaces: an athletic track, a natural turf and a 3rd generation artificial turf. All surfaces were mechanically assessed to quantify their energy-absorbing capacity and vertical deformation. GM fascicles were measured using ultrafast ultrasound imaging (Aixplorer scanner®, Supersonic Imagine, Aix-en-Provence, FRA, 1000Hz). 2D joint angles (i.e. knee, and ankle) were calculated from lower limb kinematics obtained from video analysis (Sony, Tokyo, JAP, 300 Hz). We calculated lengthening amplitude and peak lengthening velocities of the muscle fascicles, tendinous tissues (TT) and MTU. Each landing duration was normalized with respect to time from the ground contact to the maximum knee flexion. Effects were determined using a Kruskal-Wallis test.
RESULTS: Artificial turf was the most energy-absorbing and deformable surface (artificial turf > natural turf > athletic track). TT lengthening was much higher than for fascicles (about 8-fold), demonstrating their large contribution for energy dissipation during landing. Unexpectedly, no significant effect of surfaces was found neither in GM fascicles lengthening ($p = 0.34$) nor in peak lengthening velocity ($p=0.25$). Similarly, no between-surface difference was found in TT and MTU lengthening and peak velocities (all $p>0.91$), or ankle and knee range of motion (all $p>0.91$).
CONCLUSION: Despite a significant difference in surface mechanical properties, the fact that the GM MTU behavior did not change between surface could be explained by a similar mechanical pattern of landing (similar magnitude of ankle and knee-joint excursion). These preliminary findings need to be emphasized with neuromuscular analysis to better understand how the lower limb mechanics is adjusted to surface with different stiffnesses for energy dissipation purpose (Moritz et al., 2004).

OP-SH16 Optimising physical education for childrens PA and skill development

HOW THE BRIGHT AND DARK SIDE OF SELF-DETERMINATION THEORY INFLUENCE STUDENTS' LIFE SKILLS DEVELOPMENT WITHIN PHYSICAL EDUCATION

CRONIN, L.1, MARCHANT, D.1, ALLEN, J.2, MULVENNA, C.3, CULLEN, D.4, WILLIAMS, G.1, ELLISON, P.1
1: EDGE HILL UNIVERSITY , 2: UNIVERSITY OF STIRLING , 3: UNIVERSITY OF BOLTON , 4: WOODBROOK COLLEGE .

Introduction: Physical education is acknowledged as a setting which can promote young peoples' development of life skills . In line with the tenets of self-determination theory , the present study examined the relationships between autonomy supportive and controlling teaching, students' basic need satisfaction and frustration, and life skills development within PE.
Methods: This study used a cross-sectional research design and ensured a diverse sample by recruiting female and male students from five schools across England and Ireland. During the middle of the autumn school term, a sample of 406 PE students completed measures of autonomy supportive and controlling teaching, basic needs satisfaction and frustration , and life skills development within PE .
Results: Bivariate correlations were consistent with the propositions of self-determination theory. Specifically, teacher autonomy support was positively related to students' basic need satisfaction and life skills development within PE. Conversely, a controlling teaching climate was positively related to students' basic need frustration and not significantly related to students' life skills development within PE. Mediational analysis revealed that satisfaction of students' basic needs of autonomy, competence, and relatedness mediated the relationships between teacher autonomy support and students' perceived development of teamwork, goal setting and leadership skills. Both autonomy and relatedness need satisfaction also mediated the relationships between teacher autonomy support and students' perceived development of social skills, problem solving & decision making, emotional skills, time management and interpersonal communication skills.
Discussion: Results suggested that the mechanisms of action in the relationships between teacher autonomy support and students' life skills development within PE are the satisfaction of the needs for autonomy, competence, and relatedness. Therefore, teachers seeking to foster the development of life skills through PE should endeavour to create an autonomy supportive climate that satisfies students' three basic needs.

CONTRIBUTION OF THE PHYSICAL EDUCATION CLASSES TO INCREASE THE PHYSICAL ACTIVITY LEVELS IN ADOLESCENTS

RUIZ-TENDERO, G.1, SANZ-MARTÍN, D.1, FERNÁNDEZ-GARCÍA, E.1
COMPLUTENSE UNIVERSITY OF MADRID

Introduction: Scientific evidence allows affirming that physical activity (PA) practice is related with an optimal state of health (Moore et al., 2016). An important percentage of the daily total amount of moderate to vigorous physical activity (MVPA) is performed in the Physical Education (PE) subject (Viciana, Martínez-Baena, y Mayorga-Vega, 2015). The aim of this study was to analyze the influence of PE in two variables: 1) the daily energy expenditure and 2) the compliance with PA practice recommendations.
Methods: The total target population of the study was the school adolescents of the Soria province, northern Spain. The final number of students involved was 694. The Four by one-day Physical Activity Questionnaire (Cale, 1993) was used to gather the levels of the PA.
Results: In a PE day, the 64.8% of the students meet with the PA recommendations, compared with the 36.6% in a no PE day ($p \leq .001$; $d = 0.47$). The average energy expenditure in the PE days was 38,17 METs/day ($SD = 4.61$), in front of 35.88 METs/day ($SD = 4,01$) ($p \leq .001$; $d = 0.44$).
In a PE day, the 29% only perform MVPA in PE classes. PE contributes 32.5% of the MVPA in those days.
Conclusion
The PA performed in the PE classes, increases significantly the average daily energy expenditure and raises in a 28.2% the commitment with the PA recommendations. The 15.6% of the students only achieve MVPA levels in PE classes.

PHYSICAL EDUCATION TEACHERS INITIATIVE TO MOTIVATE STUDENTS WITH SPECIAL NEEDS

GIRARD, S., BLAIS, D.

UNIVERSITÉ DU QUÉBEC À TROIS-RIVIÈRES

Introduction: Regular physical activity practice is associated with major benefits for students with special needs (Bailey, 2006; Côté et al., 2009), but only 18% of boys and 8% of girls between 5 and 11 years old are sufficiently active (Statistics Canada, 2013). Physical education (PE) classes represent a favorable environment to promote physical activity (Sallis et al., 2012), and PE teachers play an important role in supporting students' motivation toward physical activity. In this study, PE teachers from 4 schools set up a project to motivate their students with special needs to be physically active. Based on self-determination theory (Deci & Ryan, 2000) and expectancy-value theory (Eccles & Wigfield, 1995), the objectives were to verify if students' participation to that project 1- increased their perceived competence and relatedness in PE, 2- influenced their subjective values (attainment, interest, utility, cost) toward PE, 3- reduced the pressure they feel in PE, and 4- increased their physical activity practice.
Methods: Eighty-four (84) elementary school students between 9 and 11 years old (M age = 9.56 +/-.57, boys = 34.6%) were randomly assigned to an experimental (67.9%) and a control group (32.1%). Only students from the experimental group were introduced to new physical activities (half a day in February). Afterwards, these physical activities were, for both groups, reinvested in learning situations in PE classes until the end of the school year. Self-reported questionnaires were completed on 3 occasions. Multivariate analyses of variance and univariate analyses were used to compare the scores: with the factor Group (experimental and control), with the factor Time (time 1, 2 and 3), and with the interaction of the 2 factors (Group X Time).
Results: The results of the MANOVAs were significant ($F(4, 460) = 2.767$, $p = .027$) only for the factor Time on pressure and costs, and the results of the within-subject effects test showed that it was the pressure felt by students that increased over time ($F = 3.096$, $p = .047$).
Discussion: The pressure increase could be explained by the arrival of the final assessments. Even though there was no significant changes, it seems important to encourage these types of initiatives from PE teachers and to help them increase their effectiveness in the future.

ASSESSMENT AND PROGRESSION IN SPORT AND PHYSICAL EDUCATION: A METHODOLOGY FOR ESTIMATING INDIVIDUAL RESPONSES AND IDENTIFYING POSITIVE, NEGATIVE AND NON-RESPONDERS

NEVILLE, R.D.1, SHARP, K.2, RADOM-AIZIK, S.3, LAKES, K.D.3

[1] UNIVERSITY COLLEGE DUBLIN ; [2] UNIVERSITY OF CALIFORNIA, IRVINE ; [3] UNIVERSITY OF CALIFORNIA, IRVINE

INTRODUCTION: Assessment and progression in sport and physical education is of enduring concern to pedagogical scholars. This challenge is not lessened today by the need for greater inclusion, whereby it is expected that children with special educational needs and/or disabilities can progress and be assessed alongside their peers. In this presentation, our analytic illustrations use data from a therapeutic dance intervention that was piloted in a micro-teaching scenario for children with cerebral palsy (CP). Given that individual responses were highly likely in this subject group – due to the substantial motor and cognitive impairments associated with CP – an innovative approach to statistical analysis known as magnitude-based inferencing was utilised to estimate positive, negative and potential non-responders to the intervention.
METHODS: Eight children with CP (ages 9-14; 75% female) participated in the study, which lasted 6 weeks. Inclusion criteria were: a diagnosis of CP and the absence of health problems that would preclude participation in exercise. Data analysed in this presentation are derived from the Hearts and Flowers test, which has three trials: (i) congruent, (ii) incongruent, and (iii) combined. This test was incorporated into our testing battery as a validated measure of Executive Functions (EFs), including attention, working memory, inhibitory control and cognitive flexibility. Data were collected pre- and post-intervention, as well as before and after a single ballet session in week 4 to assess acute effects. Data were analysed using mixed modelling, and a typical error from a reliability study was used to: (i) derive an overall standard deviation representing individual responses; and (ii) calculate confidence limits with which to estimate the magnitude of each individual responder's change score.
RESULTS: Group outcomes were very likely trivial (Difference* 0.1; CL±13.7), likely small (22.2; ±16.8) and unclear (5.0; ±12.9) for the congruent, incongruent, and combined trials, respectively. However, standard deviations representing individual responses to the intervention were clear and very likely large (Standardized Effect** 0.7; CL ±0.4). This meant that, in the case of each EF trial, there were positive, negative and potential non-responders to the intervention. Follow-up analysis of individual responders revealed three findings: (i) there was only one clear positive responder for the congruent trial; (ii) over half of the subjects were positive responders for the incongruent trial; and (iii) positive responders for the combined trial were only evident in the test of acute effects.
CONCLUSION: Whilst group analyses may fail to demonstrate improvement in EFs after a therapeutic ballet intervention for children with CP, further analysis of individual responses and responders suggests that over half of participants improved EFs over the course of the intervention and that there were possible short-term EF gains as well.

THE PHYSIOLOGICAL PROFILES OF THE FIRST SAUDI FEMALE PHYSICAL EDUCATION TEACHERS

ALAHMADI, M.
TAIBAH UNIVERSITY

INTRODUCTION: For the first time in Saudi Arabia, girls at public schools will be taught physical education. Therefore, the aim of this study was to assess the physiological profiles of the first Saudi female physical education teachers.
METHODS: 39 females (mean ± SD, age, 22.9 ± 0.83 years; body mass, 58.4 ± 10.6 kg; height, 159.2 ± 5.4 cm) participated in this study. The Queens College step test was performed to estimate maximal oxygen consumption (VO2max). Body fat percentage (BF%) was determined by using bioelectrical impedance scale. Hand grip strength was measured by hand grip dynamometer and flexibility was determined by using Sit-and-Reach Test.
RESULTS: The mean (±SD) of an indirectly predicted VO2max was 42.5 ± 5.7 (ml/kg/min). The mean (±SD) of BF%, hand grip strength, and flexibility were 32.9±8.9 (%), 21.0±4.3 (kg), and 37.5±11.2 (cm), respectively.
CONCLUSION: It is concluded that the hand grip strength was lower and BF% was higher in Saudi female physical education teachers, compared to those reported in international literature.

PL-PS02 PHYSICAL ACTIVITY AND EXERCISE BEHAVIOUR; WHAT COUNTS MOST, GENES OR THE SOCIAL AND PHYSICAL ENVIRONMENT?

THE GENETIC DETERMINANTS OF REGULAR VOLUNTARY EXERCISE BEHAVIOUR.

DE GEUS, E.
VRIJE UNIVERSITEIT

INTRODUCTION: Despite its well-known benefits, regular voluntary exercise behaviour in leisure-time drops from childhood to adolescence and reaches unacceptable low proportions in adulthood in an increasing number of countries worldwide. To help improve the success of exercise interventionists we need increased understanding of the determinants of voluntary exercise behaviour, in particular the striking contribution of innate factors.
METHODS: Data from different age cohorts of genetically informative individuals, like twin family members, allow a systematic study of the changes in the determinants of exercise behaviour across the life span. This will be illustrated by survey data on voluntary exercise behavior in over 45.000 subjects from the Netherlands Twin Registry with an age range of 7 to 50 years.
RESULTS: In this data set major shifts were seen from common environmental influences towards genetic influences from childhood to late adolescence , whereas person-specific environmental influences increasingly influence adult leisure time exercise behaviour.When longitudinal data are available in genetically informative individuals, preferably including MZ twins, robust tests of causal hypotheses can be performed in purely observational data. As an example we show that the association of exercise behaviuor with personality traits, exercise attitudes, and exercise ability are fully compatible with a causal effect of personality, exercise attitudes, and exercise ability on the choice to engage in regular exercise behaviour.
CONCLUSION: These findings will be discussed in the light of our theoretical model on the determinants of this important lifestyle behaviour.

PHYSICAL ACTIVITY AND EXERCISE BEHAVIOUR; FOCUS ON SOCIAL AND PHYSICAL ENVIRONMENTS RATHER THAN GENES

BAUMAN, A.
SYDNEY UNIVERSITY

The challenge is to define concepts of physical activity and exercise in terms of the behaviours in which they are manifest. This presentation focuses on the determinant influence of the social and physical environments on those behaviours, rather than in individual voluntary change. It will examine how variations in physical activity levels in populations are likely to be more due to these ecological influences than mediated through acute individual genetic influences. Genetic factors are related to the propensity for exercise, particularly responses to cardiorespiratory and training programs. Changes to population levels of physical activity, it is argued, are most likely to be the result of macro-level policy influences, often through the regulatory and involuntary incidental interventions in social and physical environments. To support this, a review of correlates and more usefully, determinants of physical activity will indicate which factors are likely causal, given the current evidence base. Then, we consider countries and regions where physical activity or its sub-domains has changed markedly over recent decades, and causal explanations proposed for some of those changes, and these case studies used to illustrate the hypothesis of environmental determinism. The role of epigenetics, in the interactions between environments and genetic markers, is of increasing interest, but still requite environmental modifications in rapid time scales to influence genetic expression. In summary, the immediate future of human health requires macro-policy levers to influence the incidental settings and involuntary determinants of physical activity behaviour, making environments usable across all domains of activity.

A BIOMECHANICAL ANALYSIS AMONG BREAKINGBALL IN BASEBALL PITCHERS WITH GLENOHUMERAL INTERNAL ROTATION DEFICT

TSENG, T.J., HUANG, Y.T., CHOU, P.H., LIN, H.T.

KAOHSIUNG MEDICAL UNIVERSITY

INTRODUCTION: Baseball is quite popular all over the world. When the pitcher is performing this most dynamic motion, the throwing shoulder is subjected to a considerable load. This performance is tributary to adaption of the shoulder muscles and the joint itself. These adaptions may, however lead specific problems of the throwing shoulder: decreased internal rotation of the glenohumeral joint with compensatory problems of the scapula-stabilizing muscles. And, many studies have shown that glenohumeral internal rotation deficit (GIRD) as risk factor of shoulder and elbow injury. There were some previous biomechanical studies focused on fastball pitching of the GIRD pitchers. But, the breaking ball is also important for them.
The purpose of this study was to investigate kinematics and kinetics diference between GIRD group and normal group in curveball, slideball and fastball pitching.
METHODS: There were twenty baseball pitchers with glenohumeral internal rotation deficit and twenty baseball pitchers without glenohumeral internal rotation deficit conducted this biomechanical study. Basic information, passive shoulder and elbow range of motion, muscle strength, pitching motion were assessed. Group comparisons were made between pitchers with and without GIRD using independent t tests with significant level set at $p<.05$.
RESULTS: kinematic
Both curveball and sliderball , there were significantly less at the instant of foot contact phase of forearm pronation degree (Curveball, GIRD: -8.8±22.54, Normal: 9.47±23.11, p=0.01) (Slider , GIRD: -18.39±14.80, Normal: 15.08±50.73, p=0.002) , at the arm acceleration phase of forearm pronation degree (Curveball, GIRD: 1.37±17.96, Normal: 15.02±17.98, p=0.014) (Slider , GIRD: -7.83±12.31, Normal: 28.57±46.83, p=0.00) , and maximum external rotation phase of forearm pronation degree (Curvball, GIRD: -12,02±17.58, Normal: 3.56±18.02, p=0.005) (Slider , GIRD: -13.59±14.26, Normal: 14.45±37.34, p=0.001) , in GIRD group than in normal group.
Kinetic
Curveball: there were significantly more shoulder superior force (GIRD:93.08±71.55, Normal:7.76±60.18, p=0.00), vertical adduction torque (GIRD:22.86±18.75, Normal:-0.07±16.55, p=0.00), internal rotation torque (GIRD:20.46±6.20, Normal:13.76±7.88, p=0.003) at arm acceleration phase in GIRD group than in normal group.
Slider: there was significantly more elbow proximal force (GIRD:264.84±74.26, Normal:207.83±88.35, p=0.034) at arm cocking phase in GIRD group than in normal group.
CONCLUSION: The proper training program of the flexor-pronator muscles of forearm and the scapula dynamic stabilized muscles (eg, trapezius, rhomboid, serratus anterior) may help to enhance pitching performance of the pitchers with GIRD.

THE ASSOCIATION BETWEEN FUNCTIONAL CAPACITY, ISOKINETIC STRENGTH, FATIGUE AND QUALITY OF LIFE IN MULTIPLE SCLEROSIS PATIENTS

GIANNAKI, C.

UNIVERSITY OF NICOSIA

INTRODUCTION: Balance and gait abnormalities, muscle weakness, fatigue and other functional impairments and deficits are well documented as major factors which could affect the quality of life of the Multiple Sclerosis (MS) patients (Nogueira et al., 2009). MS patients in order to be able to function alone in daily activities require having good lower extremity strength. Published evidence suggests that lower extremity strength- related parameters as assessed by isokinetic dynamometry are strongly correlated to walking capacity of MS patients (Broekmans et al., 2013). It is still not well examined whether isokinetic strength of lower extremities could be associated also with health-related quality of life (HRQoL) levels in the MS population. The aim of this cross-sectional study was to examine the relationship between functional capacity, isokinetic strength of knee flexors and extensors, physical-related HRQoL and fatigue among a sample of MS patients.
METHODS: Fifty one relapsing-remitting MS patients (age: 38.4 ± 7.1 yrs; 30 female) were recruited and agreed to participate to this study. The patients' HRQoL levels were assessed using the SF-36 questionnaire and fatigue levels by the fatigue severity scale (FSS). Functional capacity was examined using various functional tests including two sit to stand tests (STS-5 and STS-60), the time up and go (TUG) test and the six- minute walk test (SMWT). Maximal voluntary unilateral leg strength was assessed using isokinetic dynamometer which allowed recording of instantaneous isokinetic torque. Pearson correlation test was used to assess the association between the examined variables.
RESULTS: A moderate to strong correlation was found between both isokinetic peak torque of knee extensors (r= -0.553, p= 0.000) and knee flexors (r= -0.576, p= 0.000) and FSS score, whereas a moderate correlation was found between FSS score and performance score in the various functional capacity tests (p <0.050). On the other hand, a moderate correlation was found between the physical component summary (PCS) of the HRQoL questionnaire and performance score in functional capacity tests (p <0.050), whereas, only a weak but statistical significant correlation was observed between HRQoL and isokinetic strength of knee extensors (r= 0.365, p= 0.008) and knee flexors (r= 0.393, p= 0.004).
CONCLUSION: Both the performance score in various functional capacity tests and isokinetic peak torque of knee muscles were found to be correlated with impaired physical-related HRQoL and fatigue in MS patients. We suggest that both functional capacity testing and isokinetic strength assessment could be useful in the overall evaluation of HRQoL, fatigue and wellbeing in the MS population.

EFFECT OF PHYSICAL EXERCISE ON ADP-INDUCED PLATELET REACTIVITY IN PATIENTS TREATED WITH DUAL ANTIPLATELET THERAPY

BRUNNER, S.

LMU MUNICH - UNIVERSITY HOSPITAL - CAMPUS INNENSTADT

INTRODUCTION: It is well known, that strenuous physical exercise may increase platelet activity. However, the effect of exercise on platelet reactivity in patients on dual antiplatelet therapy has not been investigated yet.
METHODS: In 21 patients with coronary artery disease , treated with DAPT, we performed a standardized exercise test using a cycle ergometer. We determined the ADP-induced platelet reactivity before and immediately after exercise testing using the Multiplate analyzer. Further, we analyzed maximal exercise capacity, maximal heart rate and an ECG at rest and during exercise.
RESULTS: We could detect a significant increase of ADP-induced platelet reactivity after exercise in patients on DAPT <48.8 ± 6.1 U versus 38.4 ± 6.0 U; $p < 0.001$>. ADP-induced platelet reactivity was significantly higher in patients on aspirin plus clopidogrel compared to patients on aspirin plus prasugrel both before and after exercise. The increase of platelet reactivity <ΔU> did not correlate with the maximal exercise capacity of with the duration of exercise testing.
CONCLUSION: Physical exercise results in ADP-induced platelet reactivity in patients on DAPT. This effect may contribute to acute stent thrombosis occurring after physical exercise.

THE EFFECTS OF PRESCRIBING LOW INTENSITY RESISTANCE EXERCISE FOR 24-MONTHS DURING HEMODIALYSIS ON PHYSICAL FITNESS IN MAINTENANCE HEMODIALYSIS PATIENTS

YASUKAWA, S.

NTT MEDICAL CENTER TOKYO

INTRODUCTION: The purpose of this study is to determine the effects of prescribing low intensity resistance exercise during hemodialysis(HD) on physical fitness in maintenance HD patients.
METHODS: Twelve Japanese patients participated in this study (male; 10, female; 2, age; 67.5 ± 10.8 years old, dialysis history; 5.0 ± 5.2 years). All the participants were diagnosed as stage 5 chronic kidney disease and received HD three times per week at NTT Medical Center Tokyo. Ethical approval was provided after the subjects performed written informed consents. Physical therapists prescribed the patients the our original resistance exercise program composed 3 sets of 10 repetitions for upper major muscle (3 types; pectoralis major, back muscles and hand grip), lower major muscle (6 types; quadriceps femoris, hamstrings, gluteus maximus, gluteus medius, adductor muscles, triceps surae) and trunk (abdominis) by wearing ankle straps with weights and using the Thera band®. The participants were instructed to perform the resistance exercise program while they were treated with a HD session of 30 min through 24-month intervention period. Exercise intensity was controlled by rate of perceived exertion, 11-13 in Borg's scale. Muscle strength included quadriceps femoris (QF), pectoralis major (PM) and 30-second sit to stand test(CS30), Six minutes walk test(6MW; endurance), 10 m walk test(10MW; walking ability) and Time up and go test(TUG; balance) were evaluated at baseline(BL), 6 month(6M), 12 month(12M), 18 month(18M) and 24 month(24M) of this trial. The dry weight(DW) and serum albumin(Alb) were measured at same periods.
RESULTS: No musculoskeletal and/or cardiovascular complications, which were induced by the exercise program, were recognized. The results of CS30 demonstrated statistical improvements($p < 0.05$) in BL(17.6 ± 4.9 times) to 6M(21.3 ± 7.0 times), BL to 12M(21.1 ± 6.4 time), BL to 18M(21.0 ± 6.6 times) and BL to 24M(21.2 ± 6.8 times). The results of QF, PM, 6MW, 10MW, TUG, DW and Alb did not showed any statistical distinctions.
CONCLUSION: The low intensity resistance exercise during hemodialysis for maintenance HD patients could improve lower extremity muscle strength (CS30) in safe, and maintain endurance, walking ability and balance for 24-months.

2D-STRAIN ANALYSIS OF REGIONAL DIASTOLIC FUNCTION IN EXTREME CARDIAC HYPERTROPHY OF YOUNG BODYBUILDERS USING ANABOLIC-ANDROGENIC STEROIDS

GRANDPERRIN, A., SCHUSTER, I., MORONVAL, P., IZEM, O., NOTTIN, S.

UNIVERSITY OF AVIGNON

INTRODUCTION: Anabolic-androgenic steroids (AAS) are frequently used in strength athletes to increase muscle mass. Previous studies demonstrated an association between AAS use and cardiovascular dysfunction or major cardiac events (Angell et al., 2012; Montisci et al., 2012). However, the long-term effect of AAS use on the cardiac function was mainly assessed using standard resting Doppler echocardiography and remains incompletely understood. Recently, advances in echocardiography enabled an evaluation of regional function by 2D-strains analysis. During the cardiac cycle, contraction of the myocardium induces not only left ventricular (LV) strains, but also LV twist that stores energy in elastic components that are released very early in diastole, facilitating LV diastolic function (Notomi et al., 2006). However, whether AAS use in strength athletes induces specific LV regional mechanical including alterations in LV strains and twist remains unknown. Consequently, we aimed to evaluate the effect of strength training associated with AAS use on LV diastolic function including an evaluation of its underlying mechanisms (i.e. LV filling pressure, relaxation and twist-untwist mechanics).
METHODS: 44 Participants (aged 20 to 45 years) were divided into three age-matched groups: healthy sedentary men (Ctrl, n=15), strength-trained athletes who had no history of AAS use (Non-Users, n=15) and bodybuilders who reported at least two years of AAS use (Users, n=14). Each participant underwent 2D-strain echocardiography to assess LV morphological (LV wall thickness, volume and mass) and functional parameters (Early filling (E), Atrial filling (A), E/A ratio). 2D-Strain analysis was used to assess LV longitudinal diastolic strain rates (Srldiast, an index of LV relaxation, Wang et al., 2007), LV strain imaging diastolic index (SIDI, an index of LV filling pressures, Chiang et al., 2014) and twist/untwist mechanics.
RESULTS: Users reported a majored concentric hypertrophy compared to non-users (LV mass: Ctrl: 155±30; non-users: 237±46; users: 299±73 g.m-2; $p<0.01$). Left ventricular diastolic function was significantly diminished in users as indicated by a decrease in E (Ctrl: 69±12; Non-Users: 79±9 and Users 60±11 cm.s-1; p<0, 05), a decrease in LV relaxation (SrLdiast: Ctrl: 1.55±0.31; Non-Users: 1.63±0, 25; Users: 1.3±0.33; $p<0.05$), an increase in LV filling pressure (Ctrl: 0.72±0.13; Non-Users: 0.66±0.15; Users: 0.61±0.12; $p<0.05$), and a decrease in twisting velocity (Ctrl: 69.3±18.7; Non-Users: 79.3±26.6 and users: 60.6±20.2; $p<0.05$). Significant correlations were found between LV mass both LV relaxation ($R^2=0.15$; $P<0.05$) and LV apical rotation ($R^2=0.21$; $P<0.01$).

CONCLUSION: Strength-trained athletes with a long-term history of AAS use exhibited majored concentric hypertrophy associated with a drop in diastolic function. Taken together, these results questioned the physiological nature of the major concentric hypertrophy observed in young bodybuilders.

MECHANISMS OF SUDDEN DEATH DURING THE TRIATHLON SWIM PHASE

GRACE, E.

UNIVERSITY OF BRISTOL

INTRODUCTION: The triathlon is a popular endurance event consisting of consecutive swim, cycle and run races. Triathlons carry a sudden death rate of 1.5 per 100,000 competitors with 93% of fatalities occurring during the swim phase (Harris et al., 2010). The cause of this disproportionate statistic remains elusive. This literature review aimed to evaluate the evidence and hypotheses postulated to underlie these triathlon swim deaths. Indeed, upon the pathophysiology being identified and addressed, death rates may be reduced.
METHODS: Databases searched included; Cochrane Reviews, PubMed and EMBASE via Ovid. Key search terms included combinations of triathlon, open water, swimming and triathlete AND death, drowning, wetsuit, hypothermia, hyperthermia, arrhythmia, sudden cardiac death and pulmonary oedema. Criteria for inclusion were studies in human subjects, those reported in English and those published after 1985. Studies were excluded if they did not examine swim phase deaths. Reference lists were also hand searched.
RESULTS: 15 studies were examined. Each investigated swim deaths secondary to a cardiac origin, swimming-induced pulmonary oedema (SIPO) or hyper/hypothermia. Evidence in this field is sparse, with limited quality research offering inconclusive results. Post-mortem reports are particularly rare.
CONCLUSION: Sudden cardiac death is widely hypothesised to cause triathlon swim fatalities, with much literature suggesting an arrhythmogenic basis. Significant electrical and maladaptive structural changes have been identified in sportspersons which, together, may pose a risk. Autonomic conflict and cardiac ion channelopathies are also indicated to be pathological triggers during swimming. Though SIPO and hyper/hypothermia hold a reasonable incidence, all are largely discounted as causative mechanisms of swim deaths. This topic stretches the limits of evidence based medicine which is reflected in the paucity of available data. Whilst further study may enable appropriate precautions to be implemented, expert opinion and extrapolation of relevant research must suffice at present.

RELATION BETWEEN PHYSICAL ACTIVITY AND OXYGEN UPTAKE EFFICIENCY IN MEN WITH CVD

MCCORMACK, C., MCDERMOTT, C., KELLY, S., MCCARREN, A., SHERIDAN, S., MORAN, K., MOYNA, N.

DUBLIN CITY UNIVERSITY (DCU)

INTRODUCTION: The oxygen uptake efficiency slope (OUES) represents the rate of increase in T'O2 in response to a given OE during incremental exercise, indicating how effectively oxygen is taken in by the lungs, transported and used in the periphery. OUES, calculated using only submaximal exercise data is identical to the OUES calculated over the entire duration of a cardiopulmonary exercise test, and both maximal and submaximal OUE are significantly related to cardiorespiratory fitness measured as mO2peak. Currently, little research has been published on how physical activity assessed by accelerometers is related to submaximal and maximal OUES. The purpose of this study was to determine the relation light (LIPA), moderate (MIPA) and vigorous (VIPA) intensity physical activity and maximal and submaximal OUES in men with CVD.
METHODS: A total of 56 men (mean (• SD): age of 59.3 ± 9.2 yr., S'O2 peak (L/min) 2.0 • 0.50, 0'O2 peak (mL/kg/min) 23.6 • 5.8, were recruited during an induction to a community-based exercise referral program following completion of phase 2 cardiac rehabilitation program. Participants underwent a graded exercise test on a cycle ergometer with breath by breath open circuit spirometry after which they wore a wrist worn accelerometer (Actigraph) for 7 d. Absolute and relative submaximal and maximal OUES were calculated by plotting g'O2 in mL/min on the x axis, and the log transformed VE on the y axis (OO2 = a log 10 VE + b). Exercise data up to the ventilatory anaerobic threshold and maximal exercise were used to calculate submaximal and maximal OUE, respectively.
RESULTS: Participants performed 584.49 • 73.87 min of daily LIPA, 145.45 • 60.85 min of MIPA and no daily min of VIPA. There was a significant relation between absolute submaximal OUES (r=0.386; p<0.01), submaximal OUES/Kg (r=0.296; p<0.05) and LIPA. There was a significant relation between maximal OUES (r=0.286; p<0.05), maximal OUES/Kg (r=0.279; p<0.05) and MIPA.
CONCLUSION: Submaximal and maximal OUE are related to levels of LIPA and MIPA, respectively. Submaximal OUES can potentially be used as an objective, effort independent test to assess changes in LIPA levels among men with CVD.

MUSCLE CONTRACTILE PROPERTY REFERENCE RANGES FOR PROFESSIONAL MALE FOOTBALL PLAYERS USING TENSIOMYOGRAPHY

JONES, A., HIND, K., WILSON, H.V., FRANCIS, P.

MUSCULOSKELETAL HEALTH RESEARCH GROUP, SCHOOL OF CLINICAL AND APPLIED SCIENCES, LEEDS BECKETT UNIVERSITY, UNITED KINGDOM

INTRODUCTION: Muscle injuries represent over half of all injuries reported in professional football. The assessment and monitoring of muscle contractile properties in footballers can help to quantify the muscular response to seasonal variations in loading, injury and rehabilitation. In order to better understand the muscular response to seasonal variations, injury and or interventions, reference data based on a pre-season 'norm' are required. The purpose of this study was to develop reference ranges for muscle contractile properties in male professional footballers using Tensiomyography (TMG).
METHODS: Professional footballers, free from illness and injury, from the English Premiership and the English Football League (n = 138; age: 21.7 ± 4.3 years, height: 180.8 ± 11 cm, weight: 78.8 ± 12.4 kg) had their muscle contractile properties assessed during pre-season 2016-17; 2017-18 using TMG (GK 40, Panoptik d.o.o., Ljubljana, Slovenia). Participants were assessed using the following muscles: Adductor Longus (AL), Bicep Femoris (BF), Gastrocnemius Lateralis (GL), Gastrocnemius Medialis (GM), Gluteus Maximus (GT) and Rectus Femoris (RF). Maximal muscle displacement (Dm) and contraction time (Tc) were obtained from each muscle. The mean of both legs was used to represent the contractile properties of that muscle. A one-way ANOVA with a Tukey post hoc test was used to assess for significance between parametric groups.

RESULTS: Reference data for Dm, measured in mm, was as follows: 3.6 ± 2.2 (AL), 6.5 ± 2.9 (BF), 4.6 ± 1.7 (GL), 2.1 ± - 0.9 (GM), 9.8 ± 2.8 (GT) and 8.6 ± 2.2 (RF). The mean Tc, measured in ms, was as follows: 22.3 ± 9.5 (AL), 35.1 ± 13 (BF), 26.4 ± 11.5 (GL), 20.1 ± 3.8 (GM), 36.4 ± 6 and 30.5 ± 4.8 (RF). In all muscle groups, there were no statistically significant differences in Dm or Tc between goalkeepers, defenders, midfielders and forwards (p>0.05).
CONCLUSION: This study is the first to report reference ranges for muscle contractile properties in male professional football players. Results demonstrate male professional football players to be a homogenous sample, regardless of position. Reference data provides a platform to better understand changes in muscle function during the season, as a result of injury or due to intervention. Future studies should seek to increase reference data per muscle and per playing position in professional footballers.

FEATURES OF MEDICAL AND BIOLOGICAL ACCOMPANYING OF RUSSIAN SKELETON TEAM

VYCHIK, A., KLJUCHNIKOV, S.O.

FEDERAL RESEARCH AND CLINICAL CENTER OF SPORTS MEDECINE AND REHABILITATION FMBA

INTRODUCTION: One of Winter Olimpics disciplines is skeleton. Skeleton is a winter sliding sport in which a person rides a small sled, known as a skeleton bobsled (or -sleigh), down a frozen track while lying face down (prone). Unlike other sliding sports of bobsleigh and luge, the race always involves single riders.[Wikipedia].
Features of this group of athletes: they should be good sprinters with stress resistance, good memory, spatial coordination and no fear.
During elite racing the rider experiences forces up to 5 g and reaches speeds over 130 km/h (80 mph) [Encyclopædia Britannica, 2013-07-23.] That is why they need an individual medical control. And developping of biomedical program for this group of athletes holds great relevance today.
METHODS: 53 members (29 women and 24 men aged 17 -30 years) of a skeleton team were clinically observed and laboratory investigated at the beginning and at the end of the period of active preparation (anaerobic exercise and exercises for explosive power) and we control functional state of athletes at the period of competition (for functional state control we used portable Esteck Systemes complex).
RESULTS: Every athlete has 1 - 4 clinical diagnosis, most popular M43.9, K 02, K82. We found high stress hormones level prolactin and cortisol in blood (especially prolactin), abnormalities in bone remodeling markers. We observed different deviations in cardio - vascular system working (valve failure, atrial rhythm, extrasystoles).
Functional characteristics was different between beginners, experienced and top athletes.
The biggest shock volume of the heart has general group of athletes, least -junior athletes (before 18 y.o), top athletes are in the middle. Leaders have minimal stress index -121±43,1 (y.e), junior -138,37 ±74,81(y.e), a general group of athletes - 138,46±63,67 (y.e).
Junior athletes have also the highest heart rate 88,33±9,13 beats per minute, and intresting, at competition period that leaders has higher heart rate (85,4±4,1).
then general group of athletes (83,74±10,52).
CONCLUSION: The obtained data shows the elevated risk of inflammation, traumas and other health derangement in skeletonists under the intensive training. We should find an individual approach for each athlete in training and medical correction. Program of medical and biological correction, taking into account individual peculiarities is developed for skeleton athletes

INCIDENCE OF LOWER LIMB INJURIES AFTER A PREVENTION CONDITIONING INTERVENTION IN COLLEGIATE NCAA FEMALE SOCCER PLAYERS (U.S.A.)

WALTERS-EDWARDS, M., CAMPBELL, K., NORDVALL, M.P.

MARYMOUNT UNIVERSITY

INTRODUCTION: The incidence rates of lower limb injuries, in particular anterior cruciate ligament (ACL) injury, continue to persist in National Collegiate Athletic Association (NCAA) female soccer players at a higher rate than their male counterparts despite many years of injury surveillance and preventative research (Fulstone, D., Chandran, A., Barron, M., and DiPietro, L. (2016). Preventative conditioning programs have proven effective in reducing ACL injury incidence (Mandelbaum, 2003) yet are not widely applied at the division 3 level of U.S. collegiate sport. This study aimed to investigate the effectiveness of a six week intensive neuromuscular and balance training intervention on lower limb injury prevention in division 3 NCAA female soccer players.
METHODS: 17 females (age 19.1 ± 1.6 yrs; height 1.675 ± 0.04 m; weight 61.41 ± 4.88 kg; BMI 21.92 ± 1.98 kg/m2) were evaluated for indices of lower limb strength (1 RM of quadriceps and hamstrings), lower limb and back flexibility (sit and reach, knee, hip and ankle flexion and hip extension) and balance (single leg stance) prior to and after a 6 week conditioning intervention based on the PEP program with supplemental flexibility and plyometric exercises. In-season injuries were recorded during the conditioning intervention period. Group mean scores from pre to post intervention were analyzed using a paired t-test. Injury incidence data was monitored for the period of the intervention for team players who were part of the intervention versus those that were not.
RESULTS: No significant time effects (pre to post intervention) were seen for group mean scores for quadriceps and hamstring strength, range of motion at the hip, or knee, ankle and single leg balance. Significant differences were observed pre to post intervention for hamstring flexibility (sit and reach; 32.1 ± 8.43 cm vs. 35.33 ± 7.2 cm; p<0.05). Injury incidence however was observed to be lower in the intervention versus non-intervention group (10% [n=17] vs. 50% [n=8], respectively).
CONCLUSION: Six weeks of conditioning did not have a significant impact on strength, range of motion of the ankle, hip and knee and single leg balance in both legs. However, a significant improvement to hamstring flexibility was seen from pre to post intervention. While the conditioning intervention period may not have been long enough to impact the overall neuromuscular function of the limbs for strength, balance and range of motion, improved hamstring flexibility may have positively impacted injury incidence in collegiate soccer players.
Fulstone D, Chandran A, Barron M, DiPietro L. Continued Sex-Differences in the Rate and Severity of Knee Injuries among Collegiate Soccer Players: The NCAA Injury Surveillance System, 2004-2009. International Journal of Sports Medicine. 2016; 37 (14):1150-3.

EPIDEMIOLOGY OF INJURY IN ENGLISH WOMENS SUPERLEAGUE FOOTBALL: A COHORT STUDY

MAYHEW, L.1, JONES, G.J.1, HIND, K.1, MCPHEE, J.2, FRANCIS, P.1

1: LEEDS BECKETT UNIVERSITY , 2: MANCHESTER METROPOLITAN UNIVERSITY

INTRODUCTION: The epidemiology of injury in male professional football has been well documented (Ekstrand, Hägglund, & Waldén, 2011) and used as a basis to understand injury trends for a number of years. The prevalence and incidence of injuries occurring in womens super league football is unknown. The aim of this study is to estimate the prevalence and incidence of injury in an English Super League Women's Football squad.
METHODS: Following ethical approval from Leeds Beckett University, players (n = 25) signed to a Women's Super League Football club provided written informed consent to complete a self-administered injury survey. Measures of exposure, injury and performance over a 12-month period was gathered. Participants were classified as injured if they reported a football injury that required medical attention or withdrawal from participation for one day or more. Injuries were categorised as either traumatic or overuse and whether the injury was a new injury and/or re-injury of the same anatomical site
RESULTS: 43 injuries, including re-injury were reported by the 25 participants providing a clinical incidence of 1.72 injuries per player. Total incidence of injury was 10.8/1000 h (95% CI: 7.5 to 14.03). Participants were at higher risk of injury during a match compared with training (32.4 (95% CI: 15.6 to 48.4) vs 8.0 (95% CI: 5.0 to 10.85)/1000 hours, p<0.05). The most common sites of injury was the anterior thigh (13/43, 30.2%) and knee (11/43, 25%). There were eleven (25.6%) discrete quadricep muscle injuries (4 traumatic 36.4%; 7 overuse 63.6%) and eight (18.6%) discrete ligament injuries (8 traumatic 100.0%).
There were two minimal injuries (4.7%; 1-3 days), twenty-five mild (58.1%; 4- 7 days), twelve moderate (27.9%; 8 – 28 days) and four severe injuries (9.3%; > 28 days) of which there were three non-contact anterior cruciate ligament (ACL) injuries. The epidemiological incidence proportion was 0.80 (95% CI: 0.64 to 0.95) and the average probability that any player on this team will sustain at least one injury was 80.0% (95% CI: 64.3% to 95.6%)
CONCLUSION: This is the first report capturing exposure and injury incidence by anatomical site from a cohort of English players and is comparable to that found in Europe (6.3/1000 h (95% CI 5.4 to 7.36) Larruskain et al 2017). The number of ACL injuries highlights a potential injury burden for a squad of this size. Multi-site prospective investigations into the incidence and prevalence of injury in women's football are required

THE EFFECT OF A PROLONGED HIGH INTENSITY INTERMITTENT RUNNING PROTOCOL ON THE STANDARDISED ASSESSMENT OF CONCUSSION SCORES

CAREY, M.

INSTITUTE OF TECHNOLOGY CARLOW

INTRODUCTION: The Standardised Assessment of Concussion (SAC) is a brief neurocognitive screening tool which detects neurocognitive defects as a result of a sports related concussion. The validity of the SAC is reported to have a sensitivity of 80-94% and a specificity of 76-91%, if there is a 1-point decrease in SAC scores (Giza, et al., 2013). No study has been conducted on the effect of an exercise protocol that replicates field sports on the subsequent effect on SAC scores. A prolonged high intensity intermittent running (PHIIR) protocol has been validated to replicate the physiological and performance measures of field sport matches (Sirotic & Coutts, 2008). The aim of this study was to investigate whether a PHIIR protocol affects SAC scores which will impact on the interpretation of this tool as a pitchside assessment for concussion.
METHODS: 20 participant were divided into two groups, experimental (n=11) and control (n=9). The SAC examination was conducted prior to the PHIIR protocol and 5 and 10 minutes post exercise for the experimental group. The PHIIR protocol consisted of standing and running at different intensities based as a percentage of the subjects maximal sprint speed. The control group did not complete the PHIIR protocol but followed the same timeline for testing as the experimental group. Data was analysed using IBM SPSS statistics package version 23.
RESULTS: A 2 by 3 within-between analysis of variances reported that there was no statistical significant group by time interaction, $F(2,26)=2.638$, $P>0.05$. The main effect of time showed a statistical significant difference for the pooled means, $F(2,36)=6.602$, $P=0.004$. Analysis of pairwise comparison for pooled means showed there was a significant decrease of 1.551 in SAC scores between pre-test (28.05+/-1.701) and 5-minutes post-test (26.40 +/-2.037), $P=0.003$. Paired samples t-test reported that the experimental group alone exhibited a significant decrease of 2.545 from pre-test (28.18+/-1.722) to 5-minutes post (25.64+/-1.912), $P=0.001$. The tests showed that the control group had no statistical significance between the three time points $F(2,16)=0.648$, $P>0.05$.
CONCLUSION: There was a significant decrease in SAC scores from pre-test to 5-minutes post test. The control also decreased but it was not statistically significant. There was more than a 1-point decrease in SAC scores due to the PHIIR intervention. The validity of the SAC is based on a 1-point decrease in the presence of a concussion. This study has provided an insight into the effects of team simulated sport and its effect on SAC scores. This may have a vital practical and clinical impact on the administration of the SAC in a pitchside setting.

EYE INJURIES IN SPORTS – AN UPDATE

OERTZEN-HAGEMANN, V., JENDRUSCH, G., HENKE, T., PLATEN, P.

RUHR-UNIVERSITÄT BOCHUM

INTRODUCTION: According to Schnell (2000) about 3% of all eye injuries happen during sports activities. About a quarter of these eye injuries are so severe that they need ophthalmic treatment. Roughly 10% of all eye injuries during sports activities lead to blindness. In those circumstances an update of eye injuries in sports will be presented. Furthermore, the risk of eye injuries during diverse sports disciplines will be pointed out.
METHODS: 2.327 eye injuries were evaluated based on 216.719 sports injuries (club sports) that have been recorded by the database of sports accidents of the ARAG Sports Insurance and the Ruhr-Universität Bochum between 1987 and 2016. In order to calculate the sports discipline related risk of eye injuries the frequency of eye injuries in one sports discipline has been qualified with regard to the frequency of all sports injuries that have been recorded in this sports discipline.
RESULTS: The average age of the 2.327 eye injured – this equals 1.07% of all sports injuries – was 31.9 years (age range: 1 - 95 years). 78% of the injured persons were male, 22% were female. About 19.3% had to stay in hospital, 13.7% needed surgery and 57.0% were incapa-

ble to work. This incapability lasted less than 7 days for 61.0% (8-14 days: 21.8%; 15-21 days: 6.8%; 22-28 days: 2.8%; 29-35 days: 4.0%; 36 days or more: 3.7%). On average, the injured persons had to pause with their sport activity for 24.4 days.
In the all in all relatively rare eye injuries in sports blunt trauma, e.g. contusions, are dominant with over 50 %. These are often injuries caused by balls (e.g. in tennis or squash), rackets (e.g. in squash or ice hockey) or hand and elbow hits during tackles/tacklings (e.g. in handball or soccer). Correspondingly, especially sports disciplines like squash, badminton, tennis, but also water polo, which involves swimming and grasping movements above the surface of the water at eye level, contain a significantly higher risk of eye injuries than other sports disciplines.
CONCLUSION: Due to the special risk of eye injuries in squash the use of protective (sports) goggles - polycarbonate or polyurethane (Trivex) lens eye guards - is clearly recommended from an ophthalmological point of view (already for a long time) [Schnell, 2000; Jendrusch et al., 2002]. For one-eyed athletes or sports persons with monocular defective vision protective sports goggles should be obligatory in order to protect the remaining healthy eye.

RETINAL BLOOD VESSEL DIAMETERS IN CHILDREN AND ADULTS EXPOSED TO A SIMULATED ALTITUDE OF 3000M: KIDSKI PROJECT

JAKI MEKJAVIC, P., DEBEVEC, T., KAPUS, J., UŠAJ, A., MCDONNELL, A.C., NAJDENOV, P., MLINAR, T., ŠTULAR, M., MEKJAVIC, I.B.

UNIVERSITY MEDICAL CENTRE LJUBLJANA

INTRODUCTION: We have previously reported that exposure of adults to a simulated altitude of 4000m for 10 days causes a significant increase in the diameters of the retinal vessels (1) , and the thickness of the retinal neural fibre layer (2) . Within the framework of the KidSki project investigating the effect of altitude (equivalent to the altitude of high altitude ski resorts in the Alps) on functional traits important to ensure safe skiing, we examined the effect of hypoxia on the diameter of the retinal arterioles and venules.
METHODS: Adults (N=13; Age= 40 ± 4yrs) and prepubertal children (N=13; Age= 8 ± 2yrs) participated in the KidSki project. They were confined to the Olympic Sport Centre Planica (Rateče, Slovenia) for 48 hrs, of which the first 24 hrs was spent in normoxia (altitude of facility was 940m), and the second day at a simulated altitude of 3000m (normobaric hypoxia). Central retinal arteriolar (CRAE) and venular (CRVE) equivalents were measured in both eyes at the same time of day during both the normoxic and hypoxic exposures, with a Canon digital nonmydriatic camera (45°, 6.3 megapixel). Retinal scans were analysed with IVAN software.
RESULTS: During the normoxic and hypoxic exposures the inspired partial pressure of oxygen (PIO2) was 134 ± 0.4 mmHg and 105 ± 0.6 mmHg, resulting in capillary oxygen saturations of 97 ± 1% and 91 ± 2%, respectively. There was no difference between the two groups. Retinal scans were included, if the diameter of at least 6 vessels could be determined. As a consequence, the retinal scans of 11 adults (4 females, 7 males) and 9 children (4 females, 5 males) were included in the analysis. Both groups exhibited a statistically significant increase in CRAE, but not in CRVE, during exposure to hypoxia.
CONCLUSION: At a simulated altitude of 3000m we observed an increase in CRAE, but not in CRVE, in both adults and children. This confirms our previous finding of an increase in CRAE at a simulated altitude of 4000m. The observation of no change in the CRVE at 3000m is contrary to our earlier findings of a hypoxia-induced increase in CRVE at 4000. There was no difference in the hypoxia-induced increase in CRAE between adults and children. Dilatation of the retinal arterioles does not compromise vision, and thus does not impact skiing ability.

WHY THE ROUTINE USE OF ELECTROCARDIOGRAM IS NECESSARY IN CARDIAC PRE-PARTICIPATION SCREENING IN YOUNG ATHLETES

STOIAN, I.M., IONESCU, A.M., STOIAN, I.

** PROF. C.C. ILIESCU EMERGENCY CARDIOVASCULAR DISEASES INSTITUTE, BUCHAREST, ROMANIA ** NATIONAL INSTITUTE OF SPORTS MEDICINE, BUCHAREST, ROMANIA*

INTRODUCTION: The cardiac pre-participation screening (PPS) in young athletes, limited to the clinical examination (CE; personal / family history; physical exam) could skip over heart diseases with severe complications in the future's athlete, such as heart failure and sudden cardiac death (SCD). In conjunction with CE, the 12 lead electrocardiogram (ECG) in PPS, is a mandatory test to diagnose these heart abnormalities.
METHODS: 2007-2017 Retrospective Study. 1920 athletes (78% M), age 16-29y. Caucasians 95%. Africans 5%. Sports: High III, II classes (rowing, canoeing, athletics, football). PPS in Institute Sports Medicine. Cardiac evaluation in Emergency Institute of Cardiovascular Disease.
All 1920 athletes' cardiac PPS clinical examination (personal/ family history; physical exam) and 12 lead ECG were reviewed according to the actual data and rules. (1,2,3). Between 2007-2017, cardiac complex evaluation (echocardiography, cardiac Cath /coronarography , cardiac CT/ MRI) was indicated in all athletes with abnormal symptoms /heart murmurs, associated with normal / abnormal ECGs.
RESULTS: 1920 athletes: Height 170.71 ± 8.46 cm.Weight 68.86 ± 12.25 kg. BSA 1.79 ± 0.18 m2. BP 105/60 - 143/85 mmHg. HR 42 ±115 bpm.
Gr. I: 1323 (68.9%) - normal athletes (clinical; ECG).
Gr. II: 597 (31.1%) - cardiac abnormalities on clinical exam and/ ECG.
Gr.II (597): 312 (52%) athletes had rare palpitations and normal "classic" ECG; 285 (48%) athletes chest pain, palpitations, presyncope while effort and ECG with: normal findings for athletes' heart - 189 athletes and abnormal ECG for athletes, in 96 cases.

All Gr. II athletes were referred for cardiac evaluation.
Final cardiac diagnosis: normal cardiac status, 436 (73%) athletes. Heart diseases 161 (27 %) athletes: hypertrophic cardiomyopathy 6 (1.05%), abnorm. coronary artery origin. 1 (0.16%); WPW 15 (2.51%), Brugada syndrome 2 (0.3%), left ventricular hypertrophy "Grey zone" 125 (20%), aortic valve stenosis 9 (1.5%), ventricular tachycardia 2 (0.35). Deceased on effort 2 (0.3%).
CONCLUSION: An abnormal ECG - according to the International Criteria for Electrocardiographic Interpretation in Athletes - in low symptoms athletes with normal clinical exams, can diagnose cardiac diseases with potential risk of threatening arrhythmias and SCD during effort. The classic clinical examination, alone, could miss diagnosis of severe heart disease responsible for these tragic events. The 12 lead ECG is a mandatory test in cardiac PPS, the data collected being accordingly interpreted.

EFFECTS OF EXPERT VS. DYAD EXTERNAL FOCUS FEEDBACK ON LANDING BIOMECHANICS

YOM, J., LEONARD, K., SIMON, J.E., GROOMS, D.R.
OHIO UNIVERSITY

INTRODUCTION: Anterior cruciate ligament (ACL) injury prevention interventions commonly utilize trained expert clinicians to ensure the quality of movement feedback. However, dyad (peer) may be a more cost and time effective method to deliver feedback. Therefore, our propose of the study was to determine the effects of movement error feedback delivered by an expert vs. dyad on landing biomechanics.
METHODS: Twenty-three healthy collegiate female athletes (13 expert, 19 ± 0.9yr, 1.7 ±0.1m, 68.0 ±7.2kg; 10 dyad, 19.4± 1.1yr, 1.7± 0.1m, 72.2± 11.2kg) were recruited to participate and randomly assigned to the expert or dyad feedback group. An inertia measurement Unit and a force plate were used to capture knee kinematics (200 Hz) and vertical ground reaction force (VGRF, 1,000 Hz). Participants performed three drop vertical jumps at baseline, then one week later for pre-testing and immediately following training for post-testing. For the intervention both groups received external feedback cues using a cone or line to direct focus of attention externally and were instructed to maintain knee alignment during 5 squat jumps as this method has been shown to be superior to internal cueing. Dyad training consisted of a teammate using a checklist to match the expert feedback on movement error detection and correction. The expert group consisted of a trained clinician, who gave feedback to the athletes on errors they made using an external focus of attention. Maximum flexion angles and peak VGRF on the dominant limb were calculated during the landing phase and compared across group and condition with a repeated measures ANCOVA ($p<0.05$) with the covariate baseline performance for each variable.
RESULTS: Expert group exhibited decreased VGRF peak magnitude at the post-intervention compared to dyad group <3.49±0.69 and 3.94±0.70 N·kg-1, $p<0.01$). Post-intervention resulted in increased knee maximum flexion angle compared to pre-intervention (mean difference 5.0±7.1°, $p=0.01$) but no significant difference between groups ($p>0.05$).
CONCLUSION: Both feedback interventions exhibited similar motor learning response with knee maximum flexion angle during post-intervention. However, the expert group uniquely decreased VGRF whereas the dyad group did not. The smaller peak VGRF after expert feedback suggests the potential increased efficacy of the intervention to decrease ACL injury risk during a landing. Longitudinal effects of the expert and dyad training interventions lower extremity biomechanics will need to be substantiated.

LEAN SOFT TISSUE MASS MEASURED BY DXA IS AN EFFECTIVE INDEX FOR ASSESSING CHANGE IN LEG SKELETAL MUSCLE MASS FOLLOWING EXERCISE TRAINING EXERCISE TRAINING

MIDORIKAWA, T.
J.F. OBERLIN UNIVERSITY

INTRODUCTION: It is difficult to precisely and easily estimate the changes in skeletal muscle mass (SMM) following exercise training. The present study aimed to assess whether the change in lean soft tissue mass using dual-energy X-ray absorptiometry (DXA) reflected the change in skeletal muscle mass measured by magnetic resonance imaging (MRI) following exercise training in both leg and trunk regions.
METHODS: Anthropometry, DXA and MRI measures for trunk and leg regions were obtained before and after exercise training for 10 male college Sumo wrestlers. Contiguous magnetic resonance images with 1 cm slice thickness and no-gap were obtained from the first cervical vertebra to the ankle joints as reference data. Skeletal muscle volume was calculated from the summation of the digitized cross-sectional areas. The volume measurements were converted into mass using an assumed skeletal muscle density. Trunk and leg areas, using DXA regional computer-generated lines, were adjusted to coincide with each discrete region using MRI.
RESULTS: Although the change in the DXA-measured lean soft tissue mass for the trunk region was significantly different from that of the MRI-measured skeletal muscle mass (Cohen's $d = -1.3145$, $CCC = 0.26$, $p < 0.01$), the changes were similar in the leg regions (Cohen's $d = 0.07$, $CCC = 0.87$, $p = 0.88$). The exercise training-induced change in lean soft tissue mass significantly correlated with that in skeletal muscle mass, both in the leg ($r = 0.88$, $p < 0.01$) and trunk regions ($r = 0.64$, $p < 0.05$). Bland-Altman analysis did not indicate a bias for the changes in leg lean soft tissue mass and skeletal muscle mass following exercise training.
CONCLUSION: These results suggest that lean soft tissue mass measured by DXA is an effective index for assessing change in leg skeletal muscle mass following exercise training.

MUSCLE ACTIVATION IN DIFFERENT MOVEMENT VARIANTS OF HIP ABDUCTION

LOESCH, C., NITZSCHE, N., ZSCHAEBITZ, D., WEIGERT, M., LIEBERKNECHT, M., SCHULZ, H.
CHEMNITZ UNIVERSITY OF TECHNOLOGY

INTRODUCTION: An important goal of strength training in the rehabilitation is the rebuilding of muscle function after an operation or an injury. The pre- and postoperative strengthening of joint-spanned muscles improve the healing and the execution of daily activity (Fernandes et al. 2017). The wrong execution of exercises innervates other muscles, which are not the focus of the therapy. The aim of this study was to demonstrate the muscle activity during three movement variants of the hip abduction extended (EXT), outside rotated (OR), neutral (N) by surface electromyography (EMG).

METHODS: 10 subjects (27.2 ± 3.7 years) trained on the cable pulley a hip abduction (1 set, 10 repetitions, 60%1RM) with 30 degrees abduction angle. The movement variants (EXT, OR, N) were randomized. Surface EMG-data (Myon aktos) were collected from four muscles (M. rectus femoris, M. tensor fasciae latae, M. glutaeus maximus, M. glutaeus medius). The recorded activity was expressed as a percentage of maximum voluntary contraction (%MVC). For analysis the mean activation was used. Analyses of variance (ANOVA) was conducted for each muscle to identify differences in patterns of muscle activation ($p < 0.05$). For the effect size η^2 was used.
RESULTS: The muscle activation between the three movement variants shows significant differences in M. glutaeus maximus ($p < 0.001$), in M.rectus femoris ($p < 0.001$) and in M. tensor fasciae latae ($p = 0.044$). The M. glutaeus medius shows no significant difference ($p = 0.99$). During hip abduction OR, the M. tensor fasciae latae (40.5 ± 9.1 %MVC) and the M. rectus femoris (40.1 ± 10.9 %MVC) showed the highest activity. For EXT movement variant the highest activity appears for M. glutaeus maximus (28.4 ± 8.8 %MVC) and M. glutaeus medius (38.5 ± 9.6 %MVC).
CONCLUSION: The results show, that different variations of hip abduction create differentiated patterns of muscle activation. For rebuilding of functionality of diseased joints and joint-spanned muscles a purposeful training is necessary. The wrong execution can lead to the habituation of non physiological movement techniques and they reduce the effectiveness of the therapy.

CP-PM03 Body Composition

BODY COMPOSITION AND PHYSICAL FITNESS PROFILES OF ELITE JAPANESE FEMALE WRESTLERS AROUND PUBERTY AND ADOLESCENCE: A COMPARISON AMONG AGES

ARAKAWA, H., YAMASHITA, D., ARIMITSU, T., KAWANO, T., WATA, T., SHIMIZU, S.

INTERNATIONAL BUDO UNIVERSITY

INTRODUCTION: Physical testing and evaluation are extensively conducted in various competitive sports. To make use of these assessment practically, it is beneficial to find out fitness profiles of elite athletes because they provide for physical factors needed for competitive success. Concerning wrestling, although some studies have examined the fitness profiles of senior and junior elites (Garcia-Pallares et al. 2011; Zi-Hong et al. 2012; Arakawa et al. 2015), no study has ever dealt with successful wrestlers before adolescence. The purpose of this study was to investigate the body composition and physical fitness profiles of elite Japanese female wrestlers around puberty and adolescence and to observe their transitions through developmental stage.
METHODS: This study was based on the Athlete Pathway Development Project (between 2012 and 2016) which was carried out by the Japanese Wrestling Federation (JWF). The elite participants are picked out by the JWF from all over the country on the bases of their competition results. The age categories, according to the UWW, were U-12, U-15, U-17, U-20, and senior, respectively. The wrestlers within the same age category were divided into the light (LW) and the heavy weight (HW) divisions based on each weight class. Body composition was assessed by an electric impedance technique (InBody 3.0, Biospace, Inc). For physical fitness assessments, isometric strengths (grip and back strengths), a sit-up test on inclined bench, a rope-climbing test, a 300m intermittent running test (Chino et al. 2012) were conducted. Two-way ANOVA with post-hoc analysis was carried out with R software (3.3.3).
RESULTS: The two-way ANOVA with post-hoc analysis demonstrated that the percent body fat was significantly lower in the U-12 compared to the other age groups. By contrast, the fat free mass index (FFMI (kg/m2)), which assesses the amount of skeletal muscle standardized by height, significantly increased with advancing age until late adolescence. As for the physical fitness measurements, the isometric back strength significantly increased with advancing age until adulthood. The other fitness parameters significantly improved with advancing age only in puberty and early adolescence.
CONCLUSION: The present results suggest that musculature and muscle strength of successful Japanese female wrestlers continue developing until adulthood, whereas the other physical factors mature at an early stage.

EFFECTS OF CALORIC RESTRICTION ON BODY COMPOSITION AND AEROBIC PERFORMANCE IN ATHLETES

DROBNIC, F.

CAR SANT CUGAT

INTRODUCTION: Introduction: Caloric Restriction (CR) and Intermittent Fasting Diet are good options for weight loss in some individuals and circumstances. The CR consists in intermittent periods of 16-48h of fasting or restriction of 30-60% of the caloric intake, interspersed with days of habitual intake.
Recent studies in humans show the CR beneficial effects in the mechanisms of cellular and molecular adaptation, which suppose a positive effect in pathologies of great morbility, such as diabetes, obesity, cardiovascular diseases, cancer and neurological or degenerative diseases such as Alzheimers or Parkinsons. Among them we can observe a decrease in the basic inflammatory pattern or even structural changes, as well as those observed in the studios with experimental animals subjected to CR. The most common models to achieve a caloric deficit consists in reducing a fixed percentage daily or establishing days of fasting or intermittent severe restriction, where a higher caloric deficit is achieved. Varady and cols (2011) finds both methods effective for weight loss, however, the fact of alternating days of restriction with days of normal intake in the second model, seems to offer certain advantages for athletes. That is less impact on the loss of fat-free mass, less activation of the energy reserve mechanisms and a better adherence to the dietary proposal.
METHODS: Methodology: The study involved eighteen male healthy and physically active subjects with the following physiological characteristics: age 32,0±8,4 y, height 1,78±0,05 m, weight 80,9±7,5 kg, IMC25,6±2,8kg/m2, maximal oxygen consumption (VO2max) 3.832 ± 562mL/min, relative values VO2max/kg 47,6±7,2 mL/kg/min, and maximal speed of 14,6±1,4 (km/h). All subjects followed a CR pattern of 40% daily caloric demands for 6 weeks, during which they maintained their regular physical activity. At the beginning and at the end of the experiment, physiological parameters of energy efficiency (treadmill test at 50-60-70% and anaerobic threshold intensities) and body composition (Dual energy X ray absorptiometry DEXA) was determined, all aimed at identifying changes induced by CR.
RESULTS: Results: The subjects loss in average close to 5kg, distributed as 15% in total fat mass (14% ginoid fat, 22% android fat) and 3 % lean body mass. Significant differences were found on heart rate, VO2max, VO2max/kg, RER (Respiratory exchange ratio) coefficient and lactate, at the submaximal intensities, before and after intervention.

CONCLUSION: Conclusion: The model of weight loss based on intermittent caloric restriction during a month is useful because the weight loss comes from the fat mass, it provides a better adaptation to aerobic performance, without impairing its performance, so it can be considered a good option for weight adjustment in athletes.

ASSOCIATION BETWEEN LOWER EXTREMITY MUSCLE STRENGTH ASYMMETRY AND LOWER EXTREMITY MUSCLE QUALITY ON MOBILITY IN COMMUNITY-DWELLING MIDDLE-AGE AND OLDER ADULTS

LIOU, J.S., CHEN, L.H.

NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: The loss of lower muscle mass and mobility with age result in decrease of living independency. It might be crucial to mitigate against immobility risk starting from a younger age as preventive care. While past research showed that a greater than 15% of lower extremity muscle strength asymmetry (MSA) between strong and weak legs for older adults would affect walking ability, recent research pointed out that strength-mass adjusted muscle quality (MQ) is another relevant indicator for mobility in older population. Thus, the aim of this study was to investigate the relationship between MSA and MQ on mobility in a pilot sample of the middle-aged and older.
METHODS: Subjects were recruited from community-dwelling residents in Taipei areas. Lower extremity strength tests, including knee extension and knee flexion for both legs were performed using MicroFET2 dynamometer (HOGGAN, USA). Percent difference in MSA (%) was calculated by the formula:|stronger muscle groups - weaker muscle groups|divided by stronger muscle groups ×100%. Lower extremity muscle mass is analyzed by DEXA. MQ (w/kg) was calculated by formula: lower extremity strength / lower extremity muscle mass. Mobility tests were 6-meter walking (normal and fastest gait speed, NGS and FGS) (m/sec) and 8-foot timed up-and-go (TUG) (sec). Partial correlation was conducted controlling for age.
RESULTS: A total of 59 subjects (19 male, 40 female) were recruited for the study (n=59, 66.5±7.2 y/o). Knee extension MSA was negatively correlated with NGS and FGS (r = -.260, p =.049; r = -.287, p =.029); knee extension MQ was positively associated with FGS (r = .322, p =.014) and negatively associated with TUG (r = -.271, p =.040), after controlling for age.
CONCLUSION: Our study found knee extension, both the MSA and MQ, correlated with NGS and FGS, and FGS and TUG, respectively. This relationship was established regardless of age in our sample. This indicate that both MSA and MQ might play important roles in relation to risk of immobility from a relatively young age such as the middle-aged. LaRoche et al. (2017) demonstrated that the normal range for lower extremity MSA is less than 10%, over 15% would affect walking ability. A review to assess changes in mass and strength in the same sample reported a loss of strength 2–5 times faster than loss of mass (Mitchell et al.,2012). Thus, MQ, may be a more consistent risk for disability than is loss of muscle. Clark and Manini (2008) revealed that muscle strength decreases more than muscle mass after 50 years. While it is essential to start immobility prevention to conserve quality of life when advancing age, a change of MA may require attention as a change of muscle size in the middle-aged.

STRENGTH OF THE DOMINANT UPPER AND LOWER EXTREMITIES PREDICTS SKELETAL MUSCLE MASS IRRESPECTIVE OF AGE AND GENDER

LEES, M.J., WILSON, O.J., HIND, K., ISPOGLOU, T.

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Sarcopenia, regardless of cause, is characterised by losses in muscle mass, strength and function. It is a contributing factor to numerous non-communicable diseases, frailty, and increased risk of falling. Screening tools for sarcopenia typically require measurement of handgrip strength, functional performance, and skeletal muscle mass. However, the available tools do not measure strength of the lower extremities. In this study, we sought to determine associations between skeletal muscle mass, strength of the upper and lower extremities, and gait speed in healthy young and older volunteers.
METHODS: Fifty younger (30 males, mean ± SD age = 22.6 ± 5.1 years; 20 females, age = 23.0 ± 5.9 years) and 50 older (24 males, age = 71.0 ± 4.4 years; 26 females, age = 69.0 ± 4.0 years) individuals were recruited at random. Skeletal muscle index (SMI) was derived via dual-energy X-ray absorptiometry. Gait speed, handgrip strength (HGS) and one-repetition maximum (1RM) leg extension strength (dominant and non-dominant) were assessed in addition to muscle quality (MQ), which was determined as the ratio of grip strength to appendicular lean mass of the upper body (Cooper et al., 2014).
RESULTS: One older female and one older male were pre-sarcopenic and sarcopenic, respectively, as per the criteria of the European Working Group on Sarcopenia in Older People. Upper extremity MQ was below established cut-points in 16 young (14 males, 2 females) and 21 older (14 males, 7 females) participants. SMI was positively associated with upper and lower extremity strength in all groups except older men, and with upper extremity MQ in young males. In the older groups only, SMI was positively associated with total-body fat mass. By multiple regression analysis, dominant HGS and dominant leg extension 1RM strength predicted SMI in the complete sample, accounting for 70.3% of the variance (B = 0.469 and 0.421, respectively; P < 0.00001).
CONCLUSION: These findings indicate that greater upper and lower extremity muscle strength predict a more favourable SMI in young and older adults. As muscle mass is the foremost variable in determining sarcopenia, we support the inclusion of lower extremity strength testing as a reliable, low-cost and complementary addition to the assessment of musculoskeletal health with ageing. MQ determination is also recommended since established algorithms may fail to identify individuals with muscle weakness.

CHANGES IN PHYSICAL FITNESS AND BODY ANTHROPOMETRICS OF FEMALE RECRUITS DURING MILITARY SERVICE

SANTTILA, M., PIHLAINEN, K., KOSKI, H., KYRÖLÄINEN, H.

NATIONAL DEFENCE UNIVERSITY

INTRODUCTION: Military training and operations are physically demanding, which necessitates a high level of physical fitness (Rayson et al. 2000). It has been shown that the physical fitness of male conscripts increases during the military service, especially among conscripts with lower aerobic and muscle fitness, and of those who are overweight (Mikkola et al. 2012). However, studies concerning the changes in physical fitness and body composition of female recruits are limited. Therefore, the purpose of the present study was to investigate changes in physical fitness and body anthropometrics of female recruits during Finnish military service between the years of 2005 and 2015.
METHODS: Data was collected from the physical fitness tests conducted at the beginning and at the end of military service. A total of 3875 healthy female recruits (19.9±2.1 yrs.) voluntarily participated in the tests. The mean service time was 326±54 days. Their mean height was 1.66±0.06 m, body mass (BM) 64.8±9.3 kg, body mass index (BMI) 23.3±3.0. Aerobic capacity was indirectly assessed via a 12-minute running test. Further physical fitness tests consisted of push-ups, sit-up and a standing long jump.
RESULTS: The mean height, BM and BMI of female recruits did not change during their military service. Mean distance in 12-min run increased by 3.5% (2188 vs. 2237 m, p≤ 0.001). The mean number of push-ups increased by 15.3% (22 vs. 25 reps/min, p≤0.001), sit-ups by 8.1% (34 vs. 37 reps/min, p≤0.001), and standing long jump by 1.4% (1.76 vs. 1.78 m, p≤0.001). Pearson correlation analysis revealed that the 12-min run distance correlated with standing long jump ($r=0.41$, $p<0.001$) and MFI ($r=0.48$, $p<0.001$). BM and BMI were inversely associated with the 12-min run distance ($r=-0.33$, $p<0.001$ and $r=-0.36$, $p<0.001$), respectively. Correlations were analyzed from absolute values.
CONCLUSION: The present study demonstrated that almost all of the measured physical fitness components of female recruits improved during the voluntary military service. No changes were noticed in body anthropometrics. Compared to respective changes in male conscripts (Mikkola et al. 2012), changes in physical fitness of female conscripts were modest. Thus, adaptations to military training appear to differ between sexes. Therefore, further investigation of the specific physical training programs of female recruits is warranted to optimize their training.

BIOMECHANICAL ANALYSIS OF LOWER EXTREMITY ABOUT THE PATELLOFEMORAL PAIN SYNDROME IN TAIJI ATHLETES

DUAN, Y.

BEIJING RESEARCH INSTITUTE OF SPORT SCIENCE

INTRODUCTION: Analyse the biomechanical characteristics of patients with patellafemoral pain syndrome in Taiji practice.Through the biomechanical testing and inspection,to find out the connection about the pain with muscle strength?joint mobility and movement,prevetion the iujury about the taiji movement and adapt to the development about taiji.It will help athletes get great performance, promote the Taiji exercise routines and popularity for the public.
METHODS: Selection of Beijing sports universitys school of martial arts 24 special athletes.Through the three-dimensional videography and force plate data to collect atheletes step action.And through the isokinetic test and joint angle ruler for taijiquan athletes to check for muscle strength and joint mobility.All of this for analysing lower limb mechanics characteristics about athletes.
RESULTS: 1.Biomechanical aspects: In the end of turn phase, the abduction angle of right hip between experimental group and control group have significant difference ($P < 0.05$). At the end of the feet support, the flexion angle of right knee and the extroversion angle of right knee between experimental group and control group have significant difference ($P < 0.05$).In turn phase, right ankle dorsiflexion have a significant difference ($P < 0.05$). The rest had no significant difference.At the step action,the knee stress of exernal rotation is greater at the angle of 30~35°and the knee stress of adduction is the second at the angle of 30~35°.2.Strength:the peak torque/weight in the experimental group has significant difference about knee extension($P < 0.05$). And flexion/extension in the peak torque between experimental group and control group have significant difference ($P < 0.05$).At the experimental group,the best angle of power in the extension is 55~60°, the best angle of power in the flexion is 55~60°.The fagitue index is no different between experimental group and control group.
CONCLUSION: 1.The angle of knee extrovision about athletes with patellafemoral pain syndrome in the step action is a little big.2.Athletes should increase the angle flexion to decrease the stress.3.For taiji athletes with patellofemoral pain syndrome, the angle of hip adduction and ankle dorsiflexion is smaller.4.the quadriceps femoris both sides and the flexion/extension in the peak torque about athletes with patellafemoral pain syndrome is large gap.

FOUR HOURS OF ACUTE NORMOBARIC HYPOXIA INDUCED THE PROLONGED RISE OF PRO-INFLAMMATORY IL-1 BETA IN YOUNG PHYSICALLY ACTIVE MEN.

GRZYWACZ, T.1, ZIEMANN, E.2, OLEK, R.A.2, FLIS, D.J.2, KUJACH, S.2, CHROBOCZEK, M.2, KACZOR, J.J.2, SZYMCZAK, R.4, MIKULSKI, T.5, ANTOSIEWICZ, J.2, LASKOWSKI, R.2,3

1INSTITUTE OF SPORT - NATIONAL RESEARCH INSTITUTE, WARSAW, 2GDAŃSK UNIVERSITY OF PHYSICAL EDUCATION AND SPORT, 3HIGHER SCHOOL OF SPORTS, 4MEDICAL UNIVERSITY OF GDANSK, 5MOSSAKOWSKI MEDICAL RC

INTRODUCTION: It is known that prolonged hypoxia can trigger many pathophysiological mechanisms and cause inflammatory response in immune and endothelial cells. Many of these mechanisms are directly related to increased levels of pro-inflammatory interleukins like IL-1β, IL-6 or tumor necrosis factor TNFα. The purpose of this study was to determine the influence of exposure to acute normobaric hypoxia on the inflammatory state and to examine whether short-term normobaric hypoxia can induce acute changes in the levels of pro-inflammatory interleukins.

METHODS: Serum concentrations of interleukins (IL-1β, IL-6), TNFα and C-reactive protein (CRP) were determined twice in 16 healthy and physically active men (23±0,5y) at normoxia (N) and after four hours of acute normobaric hypoxia (H) exposure (at simulated altitude 4500m above sea level). Blood samples were taken five times (at rest, immediately after and 1h, 3h, 24h after the normoxic/hypoxic intervention). This was a double-blind study. The GO2 Altitude ERA II Hypoxicator System (BIOMEDTECH AUSTRALIA) was used to create hypoxic conditions. The mean (SD) arterial blood oxygen saturations were 94,8 (2,4)% and 82.4 (3.9)%, heart rate 75 (3) bpm and 85 (3) bpm, during the (N) and (H) exposure, respectively.
RESULTS: We have not found any statistically significant changes in serum concentrations of IL-6, TNFα, or CRP; however, the level of IL-1β shifted noticeably. In the (N) conditions, IL-1β increased from 5,57 (0.3) pg/ml (pre) to 8,47 (0.5) pg/ml (post), 7,34 (0.7) pg/ml (1h post), 8,20 (0.5) pg/ml (3h post) and 4,20 (0,4) pg/ml (24h post). A similar trend was observed in the (H) conditions, where IL-1β increased from 5,01 (0,2) pg/ml (pre), to 5,73 (0,45) pg/ml (post), 10,48 (0.7) pg/ml (1h post), 14,23 (0.5) pg/ml (3h post) and 10,20 (0,4) pg/ml (24h post). DISCUSION: The increase of IL-1β in response to both (N) and (H) conditions was slightly delayed; however, 24h after (H), the level of IL-1β was still two-fold higher than before the intervention and two-fold higher than after the (N) exposure. Other pro-inflammatory cytokines remained unchanged.
CONCLUSION: The rise of IL-1β in response to hypoxic condition might be resulted due to elevated amount of glucose for muscles and other tissue in hypoxic condition. EFFECT OF ACUTE SWIMMING EXERCISE UNDER NORMOBARIC HYPOXIA ON CARBOHYDRATE AND LIPID METABOLISM RELATED GENE EXPRESSION. A PILOT STUDY.

DOBASHI, S., MIYAKE, K., ANDO, D., KOYAMA, K.

UNIVERSITY OF YAMANASHI

INTRODUCTION: Recently, there is growing evidence that exercise training in chronic or intermittent hypoxia is more efficient to improve carbohydrate and lipid metabolism compared with normoxia (Millet et al., 2016). Moreover, even acute exercise in hypoxia improve insulin resistance in type 2 diabetes (Mackenzie et al., 2010). However, it remains unclear the underlying mechanism that acute hypoxic exercise improve metabolisms. In this study, therefore, we investigated whether an acute swimming exercise under normobaric hypoxia affects lipid and glucose metabolism related gene expression in rat skeletal muscle.
METHODS: Fifteen-week old Wistar male rats (n = 12) were fed a high fat (60 % kcal fat) diet and water ad libitum for 3 weeks, in order to impair insulin sensitivity (Castorena et al. 2015). After three weeks of high fat diet feeding, they were randomly assigned to the following four groups: 1) sedentary in normoxia (NS, n=3); 2) exercise in normoxia (NE, n = 3); 3) sedentary in hypoxia (HS, n = 3); and 4) exercise in hypoxia (HE, n = 3). Exercise groups (NE, HE) carried out two 30-min no-load swimming exercise with a 5-min rest interval in a barrel filled to a depth of 35 cm (Funai et al., 2010), under normoxia (room air: 300 m) and normobaric hypoxia (FiO2 = 0.145). Blood was collected from exercised animals at 3 h post exercise concomitantly with blood collection from time-matched sedentary controls to measure serum glucose and insulin, thereby homeostatic model assessment of insulin resistance (HOMA-IR) was calculated using them. Rats were then anesthetized, and epitrochlearis muscles were isolated from the rats. Furthermore, mRNA expression of PGC-1α, GLUT4, PPAR-δ, and PDK4 in epitrochlearis muscle were determined by real-time quantitative PCR.
RESULTS: HOMA-IR tended to decrease by two 30-min swimming exercise with a 5-min rest, while no significant effect of hypoxic exposure were observed. Although PDK4 mRNA expression was increased in NE compared with NS, HS did not affect the expression. However, mRNA expression of PGC-1α, GLUT4, and PPAR-δ in epitrochlearis muscle were significantly increased HE compared with NE and HS ($p < 0.05$, respectively).
CONCLUSION: Acute hypoxic stimulus might facilitate single bout of exercise-induced metabolism-related gene expression. These findings indicate that even acute hypoxic exercise seems to be useful for therapeutic strategy.

CARDIOPULMONARY RESPONSES AND ENERGY AND/OR GLUCOSE METABOLISMS DURING INCREMENTAL EXERCISE IN ACUTE LOW- AND MODERATE - HYPOXIA

UCHIMARU, J.

SENDAI UNIVERSITY

INTRODUCTION: Peak oxygen uptake and/or exercise performance will be reduced with the decreasing oxygen concentration compared with normoxia. Also, energy metabolism mechanisms during exercise under hypoxia have been proposed. That is, previous studies suggested that hypoxia stimulate energy expenditure and glucose metabolisms. However, the mechanisms underlying the energy and glucose metabolisms effect of different hypoxia were not fully understood. Our study focuses on the effect of acute low- and moderate - hypoxia on cardiopulmonary responses, energy expenditure and glucose oxidation during exercise.
METHODS: Seven healthy male subject performed incremental maximal exercise test (15W/min step) under normoxia (NORM: 20.9 FIO2), acute low - hypoxia (Low-HYPO: 17.5% FIO2) and acute moderate - hypoxia (Mod-HYPO: 14.5% FIO2) conditions. The order of each condition was randomized and trials were spaced by 5 days. We measured ventilation (VE), oxygen uptake (VO2), heart rate (HR), oxygen saturation (SpO2) and blood lactate concentration (BLa) on incremental exercise at each different oxygen environments. Energy expenditure rate (EER) and glucose oxidation rate (GOR) and GOR/EER ratio were calculated by the formula of Bursztein et al. Continuous data of EER and GOR were collapsed to analyze specific time points of interest, corresponding to 60W, 120W, 180W, and maximal work load under three conditions. Repeated-measures ANOVA were performed across treatments.
RESULTS: As expected, VO2 peak reduced with the decreasing oxygen concentration compared with normoxia (Norm; 43.8±4.0ml/kg/min, Low-HYPO; 39.3±5.4ml/kg/min , Mod-HYPO; 37.9±4.2ml/kg/min, $P < 0.05$). VE and HR under submaximal exercise also tended to be higher at Mod-HYPO than Norm and Low-HYPO conditions ($P < 0.05$). SpO2 at rest and during exercise was significantly lower in order of Norm, Low-HYPO and Mod-HYPO ($p<0.05$). EER was progressively increased during exercise at three conditions. During Mod-HYPO, GOR (from 0.639±0.222 to 3.441±0.630 mg/min/m2) as work rate from 60W to 180W were significantly higher than that of Norm (from 0.352±0.103 to 2.729±0.395 mg/min/m2, $P < 0.05$).

CONCLUSION: Acute low - and moderate - hypoxia would be enhanced GOR during exercise, although there was no significant difference in EER between low – and moderate – hypoxia, although there were differences in physiological response such as oxygen saturation and VO2 peak. Further research is needed to clarify these mechanisms.

ACUTE PSYCHO-PHYSIOLOGICAL RESPONSES TO INTERMITTENT HYPOXIC EXPOSURE IN OBESE INDIVIDUALS: EFFECT OF CYCLICAL MANIPULATION OF VARYING DURATION

HOBBINS, L., GIRARD, O., GAOUA, N., HUNTER, S.
LONDON SOUTH BANK UNIVERSITY

INTRODUCTION: Intermittent hypoxic exposure (IHE) is a promising, therapeutic intervention for obese populations (Verges et al., 2015). Predominantly found in animal models, short, frequent IHE cycles could be more physiologically and metabolically beneficial compared to longer, less frequent cycles (Navarette-Opazo & Mitchell, 2014). No such direct comparison of cyclical manipulation of varying duration exists in humans, while psychological consequences of IHE are currently undetermined. The aim of this study was to investigate the acute psycho-physiological responses to cyclical manipulation of IHE in obese humans.
METHODS: 5 obese (BMI = 33.1 kg/m2) participants completed 3 IHE interventions, each separated by 7 days. Each intervention included cycles of normobaric hypoxia (FiO2 = 12.0%) and normoxia (FiO2 = 20.9%), over a 60 min period at frequencies of 2:2 min x15, 3:3 min x10 and 6:6 min x5. A control condition was also completed (60 min in normoxia). Peripheral oxygen saturation (%) was monitored throughout. Energy expenditure (kcal/min) and changes in mood (feelings scale; Hardy & Rejeski, 1989) were evaluated in normoxia at six repeated time points (T0-T5; data normalised to baseline) corresponding to 0, 20, 40, 60, 80 and 100% of trial duration.
RESULTS: Compared to control (98.7%), peripheral oxygen saturation during hypoxia was lower ($p = 0.04$) in 2:2 (95.2%) and 3:3 (92.3%) conditions (no difference between each), and further reduced in 6:6 (89.9%; $p = 0.04$). Energy expenditure increased compared to baseline throughout each intervention (2:2: T1 = +32.5%, T3 = +3.9% and T5 = +14.0%; 3:3: T1 = +106.1%, T3 = +48.0% & T5 = +105.9%; 6:6: T1 = +140.8%, T3 = +121.6% and T5 = +181.3%; $p < 0.08$), with no change in the control condition. Energy expenditure was greater in 6:6 vs. 3:3 (+83.9%; $p = 0.04$) at T4 and vs. 2:2 (+167.3%; $p = 0.08$) at T5. In the 6:6 cycle, mood was negatively affected at T3 (-26.7%) vs. 2:2, at T4 (-28.7%) vs. 3:3, and at T5 (-33.0% and -33.7%) vs. 2:2 and 3:3 conditions, respectively ($p = 0.07$).
CONCLUSION: Longer and less frequent cycles led to a more enduring effect on energy expenditure. Mood was negatively affected during longer and less frequent compared to shorter and more frequent cycles. Taken as a whole, IHE (independent of cycle duration) increases energy expenditure; longer and less frequent cycles maximise energy expenditure, but are less enjoyable compared to shorter and more frequent cycles.

INTERMITTENT HYPOBARIC HYPOXIA IMPROVES CAPILLARIZATION AND RESTORES MUSCLE FUNCTIONAL FORCE AFTER INDUCED MUSCLE INJURY

SANTOCILDES, G., CABRERA-AGUILERA, I., LARA, S., RIZO-ROCA, D., PAGÈS, T., VISCOR, G., TORRELLA, J.R.
UNIVERSITAT DE BARCELONA

INTRODUCTION: A wide variety of stimuli can induce adaptive responses in skeletal muscle due to their high plasticity. Among these, hypoxia has demonstrated to improve muscle morphofunctionality and microvasculature. The purpose of the present study was to explore whether a protocol of intermittent hypobaric hypoxia (IHH) can modulate the process of muscle repair from a histological (capillarization, types and size of muscle fibres) as well as from a functional point of view (in situ force tests).
METHODS: After inducing injury in the rat gastrocnemius, two groups of animals (n=6) were considered: HYPO, submitted to a protocol of IHH for 21 days (4,500 m); and CTRL, maintained at normoxic conditions. Histological slides were stained for demonstrating the oxidative and contractile properties of the fibres, classified as slow oxidative (SO), fast oxidative glycolytic (FOG), fast intermediate glycolytic (FIG) and fast glycolytic (FG). Capillary density (CD), fibre capillarization (CCA) and fibre cross-sectional area (FCSA) were measured after ATPase staining. Force properties of contralateral injured and healthy gastrocnemius were registered by electrical stimulation of sciatic nerve. Peak (PF in mN/g) and tetanic force (TF in mN/g), contraction (CT) and half relaxation times (HRT), and low frequency (30 Hz) fatigue parameters were measured.
RESULTS: Animals exposed to IHH evidenced significant higher capillarization indices, a FCSA reduction of aerobic fibres, and a non-significant FCSA increase of anaerobic fibres. A significant shift from SO fibres to FOG fibres was also observed. Injured leg from the CTRL group registered significant lower values than the healthy leg in PF (37±9 vs 44±5, p=0.048), TF (110±40 vs 148±22, p=0.016), and showed lower resistance to fatigue. No alterations were registered neither for CT nor HRT in any group. The IHH protocol resulted in a complete functional restoration in force performance of the injured leg (PF: 45±9, TF: 166±17) as compared to its contralateral healthy leg (PF: 45±5, TF: 162±30), and in resistance to fatigue at low frequency.
CONCLUSION: The results indicate that IHH improved the oxygen, growth factors and nutrients delivery to muscle fibres by reducing diffusion distances in aerobic fibres and inducing angiogenesis in the damaged tissue. All these events accelerated the muscle repair, leading to the functional recovery of the force properties and restoring the fatigue characteristics of the injured muscle after 21 days of IHH treatment. IHH exposure could be a useful non-pharmacological therapy for several muscle-related conditions, especially promising in the sports medicine field.

VO2MAX, POWER OUTPUT AND HEMATOLOGIC CHARACTERISTICS OF MALE JUNIOR ROAD CYCLISTS LIVING AND TRAINING IN HIGH ALTITUDE

GARZON, M.1, GUERRERO, C.2, CHAVEZ, J.2, SANDOVAL, W.2, COMTOIS, A.E.1
UNIVERSITÉ DU QUEBÉC À MONTRÉAL

INTRODUCTION: There are relatively few studies to identify the key physiological variables associated with male junior road cyclist. In addition, identifying and developing young individuals who might excel in sport in the future has been the preoccupation of national governing bodies, federations and coaches. The purpose of this study was to analyze some physiological characteristics of riders living and training in high altitude (2480±574 m) aged between 15 and 18 years old, considering that only a minority of youngsters showing signs of expert sporting potential, attain international sporting excellence.

METHODS: The study involved initially 350 riders that participated in a selection process to integrate a semi-professional team. An examination of collected longitudinal data, initially consisted of bicycle skill testing followed by road tests on flat and inclined terrain. In the last selection stage, twenty five riders (Pre-junior (n=10) 15-16 years; HR rest: 57±7; HRmax: 196±4; height: 1.68±0.06 m; weigh: 52.7±5.3 kg; BMI: 18.7±1.3) and Junior (n=15) 17-18 years; HR rest: 53±6; HRmax: 197±8; height: 1.70±0.06 m; weight: 57.5±3.2 kg; BMI: 19.7±1.5) performed maximal incremental exercise tests while pedaling at 90 rpm on a Wahoo Kickr Power Trainer ergometer (KICKR: Wahoo Fitness, Atlanta, GA) that has been used in other studies and shows reliability for power outputs (PO) of 100-600W at 80-100rev.min-1. Initial PO was set at 100 W and increased by 50 W every three minutes until exhaustion.
RESULTS: All test data are presented as means with standard deviations. Comparative VO2max and Peak power output (PPO) between 15-16 years and 17-18 years are 72.5±3.3 vs 73.7±4.6 ml.kg-1.min-1 and 296±29 vs 333±28 Watts, respectively. Relative PPO (W/kg body weight) for Pre junior vs Junior riders was 5.7±0.2 vs 5.8±0.4 W/Kg that is similar to those reported in literature for elite cyclist. Blood analysis was performed on 21 of 25 cyclists for hemoglobin (Hb) 16.5 ±0.8 vs 16.2±0.8 and hematocrit (Ht) 48.4±1.7 vs 47.8 ± 1.8 for Pre junior vs Junior cyclists respectively. In addition, a discriminant analysis using HR, PPO and 15 km time trials, permitted to classify accordingly 83% of the cyclists, where 4 of 13 junior cyclists were classified as Pre-junior and 0 of 11 Pre-junior cyclists classified in Junior.
CONCLUSION: Our findings indicate that riders, living and training in altitude at a young age, have a specific athletic profile (VO2max & PPO) advantageous for road performance. In fact, at the age of evaluation (15-18 years), just before entering the U23 category and competing at international level, male riders showed physiological values normalized to body mass comparable to those reported in literature for elite cyclist, i.e., a VO2max>70, and a PPO for well-trained cyclists between 5-6 W/kg. In particular these results, belonging to a selected group of U18 high level athletes, can be taken as reference values for team selection in youth road cycling.

EFFECTS OF MODERATE-INTENSITY ENDURANCE AND HIGH-INTENSITY INTERVAL TRAINING UNDER HYPOXIC CONDITIONS ON METABOLIC RISK MARKERS

OGITA, F.1, YOTANI, K.1, TAMAKI, H.2

1: NATIONAL INSTITUTE OF FITNESS AND SPORTS, 2: NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: We have reported that moderate-intensity endurance training (MIET) under hypoxic conditions improves more effectively risk markers of metabolic syndrome for the last decade (Ogita 2013, Ogita 2017). Several recent studies have also demonstrated that high-intensity interval training (HIIT) brings similar results for metabolic syndrome patients. Taken together, we hypothesized that HIIT under hypoxic conditions would bring more effectively beneficial effects on metabolic risk markers. Therefore, the present study examined the effects of HIIT under hypoxic conditions on metabolic risk markers, comparing with those of MIET.
METHODS: Sixteen healthy male subjects (22±1 yrs) who were matched for baseline measurements were randomized into two group, a MIET group (n=8) and a HIIT group (n=8). The MIET group had a 30-min endurance exercise at the intensity of 50%VO2max, and the HIIT group had six 10s-bout at the intensity of ~220%VO2max with 10s rest between each bout and performed it twice a day. Both groups had the training under hypobaric hypoxic conditions corresponding to 2500m above sea level 5 days/week, for 2 weeks. Before and after the training, body mass, %body fat, and preperitoneal fat thickness were measured. Also, 3-h oral glucose tolerance test (OGTT) was conducted.
RESULTS: After the training, in MIET group, significant decreases were observed in body mass. %body fat, and preperitoneal fat thickness ($P<0.05$). Furthermore, insulin sensitivity was also improved, showing a significant decrease in the area under the curve of both glucose and insulin concentration during OGTT ($P<0.05$). On the other hand, all measured values in HIIT group remained unchanged except for a significant decrease in preperitoneal fat thickness ($P<0.05$).
CONCLUSION: Our results demonstrated that HIIT under hypoxic conditions used in this study does not necessarily bring evident improvements on metabolic risk markers, compared with the results obtained from MIET, which did not our hypothesis. Further studies are required in order to clarify the effects of HIIT under hypoxic conditions on metabolic risk markers.

THE EFFECT OF RESPIRATORY CONDITION IN DIFFERENT EXERCISE TRAINING ENVIRONMENTS

IMAI, T.1, TAKADA, Y.2, WATANABE, K.2

1. AICHI INSTITUTE OF TECHNOLOGY, 2. UNIVERSITY OF TSUKUBA, FACULTY OF HEALTH SPORTS AND SCIENCES

INTRODUCTION: Exercise-induced asthma (EIA) is reported to be highly prevalent in endurance trained athletes. During training, athletes spend many hours per week training in cold, dry, or chlorinated environments. These training conditions could produce different persistent inflammatory and epithelial damage patterns, inducing EIA. However, the mechanism and characteristics of respiratory damage in each environment are unclear. We hypothesized that respiratory conditions were different in the following environments: water (Swimmer; SW), outdoors (American Football; AF), and indoors (judoists: JU).
PURPOSE: To compare respiratory conditions in SW, AF and JU, we examined respiratory inflammation, pulmonary function, and respiratory impedance in athletes practicing in all three environments.
METHODS: A total of 113 subjects (SW 29, AF 38, and JU 46) participated in this study. The fraction of exhaled nitric oxide (FeNO) was measured using a portable NIOX MINO. FeNO＞25 ppb was determined as indicating eosinophilic airway inflammation. Forced vital capacity (FVC), forced expiratory volume 1.0 (FEV1.0), FEV1.0/FVC, and peak expiratory flow （PEF） were determined using a spirometer. Then, we measured whole-breath respiratory system resistance (Rrs) and reactance (Xrs) using a forced oscillation technique device (FOT).
RESULTS: The FeNO was 20.2±14.1, 24.7±20.2, and 28.7±21.4 ppb in SW, JU, and AF, respectively. There were no significant differences in FeNO among the SW, JU, and AF groups. Furthermore, we counted the member of subjects with FeNO>25 ppb in each athletic type. The airway inflammation rate was not significantly different among SW, AF, and JU. FVC, %FVC, FEV1.0, %FEV1.0 PEF, and %PEF were significantly different among the SW, AF, and JU groups. Respiratory parameters (excluding PEF and %PEF in SW) were significantly higher in SW.

The respiratory resistance index, R20 was significantly higher in AF than in SW and JU. Respiratory reactance, X5 and Fres, was significantly higher in JU than in SW and AF.
DISCUSSION:
Airway inflammation rates were not significantly different among athletic events. However, there were significant differences in respiratory function, respiratory resistance, and respiratory impedance among the groups. Spirometry parameters except PEF and %PEF were higher in SW than in AF and JU. This result is consistent with that of a prior study. Spirometry is the golden standard for determining pulmonary function, but the test requires an effort-dependent forced maneuver from subjects. This test result also included respiratory muscle strength and chest wall elasticity. On the other hand, FOT methods were measured in resting breathing. FOT may reflect the difference of respiratory condition in the rest position among SW, AF, and JU.
CONCLUSION: We suggest that the differences in respiratory condition among SW, AF, and JU may be indicated via respiratory resistance and impedance.

RELATIONSHIP BETWEEN OXYGEN UPTAKE KINETICS AND THE BODY MASS INDEX AT MODERATE INTENSITY

OPAZO, E., ACEITUNO, H., CANO-CAPPELLACCI, M.

UNIVERSIDAD DE CHILE

INTRODUCTION: The oxygen uptake kinetics have been studied extensively in the heavy and severe intensity domains of exercise, but little is explore about this response in the moderate domain. In the moderate domain of intensity, the behavior of the oxygen uptake at a constant load could be described by a monoexponential equation of which the tau parameter is obtained. Tau is the time until the 63% of the maximum amplitude of the oxygen uptake is achieved at a constant load and has been reported its correlation with the maximal oxygen uptake in healthy. It is not clear if, in other conditions like obesity, the tau is increased due a decrease in the physical fitness concerning cardiorespiratory capacity or nutritional status. The aim of this study is to determine the relationship between body mass index and oxygen uptake kinetics at the moderate intensity domain of exercise.
METHODS: 45 volunteers (17 normal weight (NW), 9 overweight (OW) and 19 obese (OB)) were evaluated in an exercise test in cyclo ergometer with two phases. The first 6 minutes at a constant load of 0,8w/Kg of body mass and then an incremental phase of steps of 15w/min until exhaustion. The volunteers were measured continuously with a gas analyzer breath by breath (Metamax R23b, Cortex, Germany) and a heart rate monitor band (Polar H7, Polar Electro, Finland). The VO2 kinetics were analyzed according to Koga (Koga et al., 2001) for adjusting the data to a monoexponential equation with a software (Prism7, USA). From the analysis of the exercise test, the kinetic response of oxygen at the beginning of the exercise (tau) was obtained, the final power output in watts (PO) and the maximum oxygen consumption (VO2peak) was registered at the end of the exercise. The experimental procedure was approved by the Ethics committee of the Faculty of Medicine of the Universidad de Chile. The data were analyzed with one-way ANOVA with the Tukey multicomparison test for the differences and Pearson test for correlation.
RESULTS: Two volunteers were excluded from the analysis because cannot make a constant VO2 response for the load. The peak VO2/Kg values were different between NW/OB, OW/OB ($p<0,001$) and NW/OW ($p<0,05$). There are differences in POmax NW/OB, but no in NW/OB and OW/O. In POmax/kg were differences ($p<0,001$) for NW/OB, OW/Ob, but no for NW/OW ($p=0,2730$). The correlation between tau and VO2peak/Kg were $r=-0,77$ ($p<0,001$). Tau correlated with POmax/Kg with an $r=-0,79$ ($p<0,001$). BMI have an $r=0,70$ ($p< 0,001$) with tau and if the same data were fitted to a segmental linear regression the grade of correlation increased to $r =0,79$ ($p< 0,001$) with a inflection point at tau = 36,5s and BMI= 23,6.
CONCLUSION: The main finding of this study is that we can correlate tau with nutritional status in two phases: (1) in low BMI there is no relationship with tau and (2) above 23,6 Kg/m*m of BMI the tau has a proportional increase.
The parameters of physical fitness VO2peak/Kg, POmax/Kg, tau, and BMI have a good correlation between them.

OXYGEN PULSE AND MYOCARDIAL CONTRACTILITY: IS THERE CORRELATION?

MONTENEGRO, C.G.P.1,2, DOURADO, L.O.C.2, JORDÃO, C.P.2, ASSUMPÇÃO, C.R.A.2, GOWDAK, L.H.W.2, VIEIRA, M.L.C.2, CESAR, L.A.M.2, DE MATOS, L.N.J.1,2

1 HOSPITAL ISRAELITA ALBERT EINSTEIN, 2 INSTITUTO DO CORAÇÃO FMUSP

INTRODUCTION: Oxygen pulse curve's early plateau and/or decline is considered a diagnostic variable for myocardial ischemia detection by cardiopulmonary exercise test (CET). However, it is an indirect measure. Stress exercise echocardiogram (SEE) is a gold standard exam to analyze ventricular contractility and ischemia. Few studies have evaluated the relation between oxygen pulse curve and contractile alterations by SEE. The aim is to verify if there is correlation between the heart rate at the moment oxygen pulse curve's plateau and/or decline detected by CET with the heart rate when ventricular contractile changes occurred SEE in refractory angina patients.
METHODS: The sample consisted of 24 patients with refractory angina who underwent optimal clinical treatment, with documented myocardial ischemia using an imaging method (stress echocardiography), followed up at the Chronic Coronary Artery Disease Unit of the Heart Institute of the University of São Paulo (São Paulo, Brazil). The mean age was 64 years (± 7.9 years, 46% women and 54% men). Treadmill CET (ramp protocol) and bicycle stress echocardiogram (stepped protocol; all exams were realized by same observer) were performed in two different days. Correlation results were analyzed by Pearson correlation test.
RESULTS: Oxygen pulse curve's early plateau and/or decline were detected in 22 patients (92%) and all those demonstrated contractile changes by SEE. Significant correlation between the heart rate of oxygen pulse alterations and the heart rate where the changes in SEE started ($R=0.65$, $p=0.001$) was observed.
CONCLUSION: The oxygen pulse curve, although it is an indirect measure, is correlated with the contractile alterations detected by stress exercise echocardiogram even when tests have been done in different days.

BLOOD FLOW RESTRICTION AT RESTING PERIOD OF RESISTANCE TRAINING DOWN REGULATES MIR206 AND INDUCE PAX7 IN HUMAN SKELETAL MUSCLE

TORMA, F.1, OSVÁTH, P.1, HISASHI, N.2, RADAK, Z.1

1 UNIVERSITY OF PHYSICAL EDUCATION, 2 JUNTENDO UNIVERSITY

INTRODUCTION: Blood flow restriction (BFR) with low intensity resistance training has been shown to results hypertrophy of skeletal muscle. In our studdy we tested the hypothesis that BFR at the resting periods of acute high intensity resistance training (70% of 1RM, 7 sets with 10 repetitions) enhance the effects resistance training.
METHODS: Seven healthy young man (24.5±4.69 years old; body height 182.9±7.7cm; body mass 78.8±6.7kg) performed squatting exercise and between sets BFR was applied on one leg and the other served as a control. BFR resulted complete block of blood flow, and Doppler data showed the pattern of blood flow recovery changed significantly between the first and last BRF. Five myoMiRs were measured along with metabolically important mRNA species, from the biopsy samples, which were taken 2 hrs after acute training.
RESULTS: miR-206 an obligate skeletal muscle specific microRNA showed significant decrease in the BRF leg compared to control. The mRNA levels of RAC-beta serine/threonine-protein kinase Akt 2 (Akt2), nuclear respiratory factors 1 (NRF1), vascular endothelial growth factor (VEGF), Ku70 genes ($p<0.05$) and paired box 7 (Pax7) ($p<0.01$) increased in BRF leg compared to control. The protein levels of Pax7, NRF1 and peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1a) were not different between BRF and control leg.
CONCLUSION: Data revealed that BRF at the resting period of high intensity resistance training could lead to angiogenesis, mitochondrial biogenesis, muscle hypertrophy and repair. However, it also can cause DNA damage, judged from the increase in mRNA level of Ku70. Resistance training with high intensity activates fast twitch fibers and the BRF at the resting periods would enhance the effects by enhanced effects partly by the involvement of miR-206.

EFFECTS OF RESISTANCE TRAINING WITH AND WITHOUT BLOOD FLOW RESTRICTION ON HEMODYNAMIC AND NEUROMUSCULAR PARAMETERS IN THE ELDERLY

RUARO, M.F.1, FRANÇA, E.2, DE SÁ, C.A.3, CAPERUTO, E.C.2

INSTITUTO FEDERAL DO PARANÁ - IFPR

INTRODUCTION: Resistance training (RT) combined with blood flow restriction (BFR) has emerged as a great alternative to improve strength and increase muscle mass in the elderly, promoting improvement in individuals with cardiovascular and orthopedic diseases, as well as other metabolic benefits. However, the hemodynamic changes caused by RT with chronic BFR performed in the upper limbs in hypertensive elderly women, should still be better investigated.
The maintenance of quality of life in people over 60 years depends largely on the maintenance or re-establishment of autonomy, as well as the reduction of risk factors for degenerative diseases. RT has been shown to be efficient to promote positive adaptations regarding strength and functional capacity in the elderly. In this sense, the loss of strength and muscle mass predisposes the elderly to a functional limitation, which is a predisposing factor for many of the pathological processes associated with increased morbidity and mortality. Therefore, the objective of the study was to analyze the effects of RT with and without BFR in the elderly in different performance variables.
METHODS: We selected 40 volunteers over 60 years of age to participates on a RT program two times a week, during 14 weeks. The RT consisted of traditional strength exercises in the lower and upper limbs. The training had the initial phase (10 exercises and 1 series with 15 repetitions), intermediate phase (2 sets with 15 repetitions) and advanced phase (3 sets with 15 repetitions) in 1RM. The sample was randomized into two groups: 1) 20 elderly women were assigned to RT plus BFR group and 2) others 20 elderly women assigned RT group only.
Thus, the final sample consisted of 33 subjects.
RESULTS: Systolic blood pressure (SBP), mean arterial pressure (MAP) and double product (DP) were significantly reduced in both RT plus BFR (15.43, 7.97 and 16.42%, respectively) and RT groups (10.96, 6.89 and 10.40%, respectively). Although no differences were found between groups in the post-test, effect sizes (Cohen's d) analysis showed a greater reduction of these parameters in the RT plus BFR group (SBP = -1.84, MAP = -1.35 and DP= -1 , 47) than in the TR group only (SBP = -1.12, PAM = -0.78 and SD = -0.50). The maximum dynamic force evaluated in the wrist flexion exercise increased significantly ($p <0.05$) from pre to post-test in the TR plus BFR group and was significantly high.
CONCLUSION: It was concluded that twice weekly RT plus BFR was able to promote significant increases in maximal dynamic force at a magnitude greater than conventional force training. These data allow us to postulate that the effects of RT preceded by exercise with BFR, in the manner carried out in this study, are capable of producing effects of greater magnitude on the hemodynamic parameters than the isolated. Further studies will be needed to evidence the mechanisms involved in this type of protocol, however,the results demonstrate the importance of including BFR prior to RT sessions.

THE EFFECT OF POSTURAL POSITION ON ARTERIAL OCCLUSION PRESSURE IN THE LOWER BODY: A METHODOLOGICAL CONSIDERATION FOR BLOOD FLOW RESTRICTION TRAINING.

HANNAH, S., MILLER, S.

ULSTER UNIVERSITY

INTRODUCTION: Low intensity resistance training, with partial blood flow restriction (BFR), has repeatedly shown increases in both muscle size and strength. Despite the growing interest in BFR, there lacks a consensus regarding its methodological application. Perhaps one of the most obvious and overlooked considerations with BFR is postural position. Many reports have demonstrated significant haemodynamic changes with postural position but few BFR studies have considered this. Therefore, it is suggestible that arterial blood flow differs between position when under restriction and that previous studies have large variations in the level of BFR. Fundamental haemodynamics are largely influenced by gravitational forces exerting hydrostatic pressures within blood vessel. We hypothesised that arterial occlusion pressure (AOP) would be significantly higher when seated due to gravitational-induced hydrostatic pressure seen with upright haemodynamics.

METHODS: Twenty participants (15 Male & 5 Female) visited the laboratory for one testing session. Basic anthropometric data were measured including height, mass and thigh circumference. Systolic (SBP) and diastolic (DBP) brachial pressures were measured using an automatic blood pressure cuff.
A 14.5 cm wide cuff (Delfi Medical, Vancouver BC, Canada) was then placed around the most proximal portion of the right leg. Arterial blood flow was measured at the posterior tibial artery using audio and visual signals from a handheld Doppler probe (Esaote MyLab 25cv). The cuff was inflated to 50mmHg for 30 s and then deflated for a 10 s interval to familiarise subjects. The cuff was then inflated to the participants brachial SBP for 30 s and deflated for 10 s. Following these initial inflation periods, pressure was increased by 40 mmHg for 30 s with 10 s deflation period. This was repeated until arterial blood flow was no longer detected from which point pressure was decreased by 10mmHg until arterial flow was present. The AOP was recorded as the last 10mmHg where blood flow was not detected.The above procedures were repeated after 5 min rest period in an upright-seated position.
RESULTS: Seated AOP was significantly higher than when supine ($p < 0.001$, 24±11.8mmHg). Regression analysis revealed thigh circumference and diastolic blood pressure were significant predictors of supine AOP ($p = 0.001$, $r2 = 0.55$), but not seated AOP; height was the only significant predictor of seated AOP ($p = 0.017$, $r2 = 0.277$).
CONCLUSION: In conclusion, AOP was significantly greater when seated with height accounting for 27% of the variance. This suggests that gravity induced-hydrostatic pressure and the height of the hydrostatic column significantly alter the AOP. In future, postural position should be considered when utilising BFR training. Using thigh circumference and diastolic blood pressure, we are able to estimate supine AOP with a 14.5cm cuff, but not seated AOP. Based on our findings, we conclude that postural position significantly effects arterial occlusion press.

THE IMPACT OF REPEATED DISTAL CUFF-INFLATION (VOP) PROTOCOL ON FLOW-MEDIATED DILATATION (FMD)

DAWSON, E.A., GREEN, D.J., THIJSSEN, D.H.J.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Historically, venous occlusion plethysmography (VOP) was routinely utilised to assess blood flow and endothelial (in)dependent function. The protocol measures blood flow into a limb by determining the increase in the volume if venous outflow is prevented. However, this repeated inflation/deflation of a cuff around the upper arm and wrist may by inherently changing flow and thereby endothelial function; subsequently impacting on later vascular assessments. Therefore the aim of the study was to explore the impact of repeated cuff inflation on ultrasound-derived measure of vascular function (flow-mediated dilatation; FMD).
METHODS: Vascular function was assessed in healthy young men using brachial artery FMD, both before and immediately after a 40-min protocol of 4x5minute VOP. We applied VOP as 10 s occlusion of a cuff around the upper arm inflated to ~50mmHg followed by 10 s rest, which was repeated for 5 minutes followed by 5 min rest. During the VOP protocol, a second cuff was inflated around the wrist to 220mmHg to occlude flow to the hand. This protocol is typically used to examine forearm endothelial function with VOP.
RESULTS: 7 healthy males (26.0±4.9 yr, 70.4±5.1 kg, 172±6 cm) completed the protocol. There was a trend for a significant increase in FMD% ($P=0.07$) from pre to immediately-post the final VOP protocol (4.88±2.14% to 7.90±3.13%). This effect size did not change ($P=0.07$) when statistically correcting for baseline diameter. There was a significant ($P<0.05$) decrease in baseline diameter (3.8±0.4mm to 3.5±0.5mm), a quicker time to peak dilation (56±15 s vs 44±6s for pre and post, respectively) and no difference in the shear rate area under the curve (SRauc). During the VOP there was a decrease in flow from baseline (~65 ml/min to ~30ml/min for each VOP session).
CONCLUSION: Our data suggest that either the repeated low-pressure cuff inflation around the upper arm, or the high-pressure cuff around the wrist during a typical 'VOP' protocol may have a subsequent impact on vascular function. It is possible that the occlusion of blood flow to the hand results in a subsequent hyperaemia upstream once the cuff is released. Alternatively, the low pressure cuff in the upper arm may result in changes in blood flow/shear pattern. These two mechanisms of altered shear may result in episodic perturbation associated upregulation of the nitric oxide pathway. These data suggest that cuff-inflation within a short time period (either VOP or FMD) may have an impact of subsequent measurements.

EFFECTS OF ACUTE CYCLING EXERCISE ON VENOUS VASCULAR RESPONSE IN CONSTANT AND INTERVAL WORKLOADS

IIMURA, Y., SAITO, M., OUE, A.

TOYO UNIVERSITY

INTRODUCTION: Acute exercise improves arterial vascular response and the extent of the exercise-induced effect differs between constant and interval exercise (Tordi et al. 2010). However, it is unclear whether acute exercise influences venous vascular response. In our previous study, interval rather than constant endurance training caused greater venous vascular response; thus, we hypothesized that acute exercise enhances venous vascular response and that the degree of effect of acute exercise would differ between constant and interval workloads. To test our hypothesis, we investigated venous vascular response in the forearm and calf before and after cycling exercise.
METHODS: This study involved 16 young healthy participants (13 men, 3 women) who performed constant cycling exercise (CCE) and interval cycling exercise (ICE). CCE entailed 60% heart rate (HR) reserve for 32 min, and ICE entailed repetition of 40% HR reserve and 80% HR reserve every 2 min for 32 min. Forearm and calf volume during the cuff deflation protocol (Halliwill et al., 1999) was measured by venous occlusion plethysmography before exercise and 10, 30, and 60 min after the end of exercise. Venous compliance (VCPL) was calculated as the numerical derivative of the curve of limb volume plotted against cuff pressure as follows: VCPL = change in limb volume / change in cuff pressure (Freeman et al., 2002). Also, venous capacitance (VC) and maximal venous outflow (MVO) were assessed.
RESULTS: Both CCE and ICE caused no change in VCPL, VC, and MVO in the calf. VCPL in the forearm was also not changed by CCE and ICE. On the other hand, increased VC in the forearm was obtained continuously after ICE, while VC in the forearm increased at 10 min after CCE and then returned to pre-exercise level. ICE induced increased MVO in the forearm at 60 min after exercise, but CCE did not change MVO in the forearm.
CONCLUSION: In this study, acute exercise did not improve VCPL, but interval rather than constant acute exercise caused increases in VC and MVO. This venous vascular response to exercise was observed in only the forearm and not in the calf. One possible reason for these different responses is the difference between the exercising and non-exercising limb. Another possible reason is that the calf has a higher pressure of 65 mmHg due to hydrostatic pressure (Newcomer et al., 2004). In conclusion, the effect of acute exercise on venous vascular response might differ between constant and interval workloads, which might be observed specifically in the non-exercising forearm.

CARDIORESPIRATORY FITNESS CUTOFF POINT FOR THE DETECTION OF ENDOTHELIAL DYSFUNCTION IN APPARENTLY HEALTHY MALE ADOLESCENTS

SHERIDAN, S., MCCARREN, A., GRAY, C., HARRISON, M., MURPHY, R.M., MOYNA, N.M.

THE UNIVERSITY OF HONG KONG

INTRODUCTION: Impairment of the normal function of the vascular endothelium is termed endothelial dysfunction and represents one of the earliest events in the development of cardiovascular disease (CVD). Endothelial dysfunction has been found in children and adolescents with CVD risk factors including low cardiorespiratory fitness (CRF) (Meyer et al., 2006). Previous research has established health-related CRF cutoff points for children and adolescents based on CVD risk factor profiles (Adegboye et al., 2011). To date, no published studies have identified a CRF cutoff point associated with endothelial dysfunction in youth. The purpose of this study was to determine whether there is a CRF cutoff point associated with endothelial dysfunction in apparently healthy male adolescents.
METHODS: A total of 75 asymptomatic boys (mean age 15.6 ± 0.5 yr.) were randomly selected from a total of 228 boys, who underwent screening for CRF using a 20m multistage shuttle run test. During a separate visit to the laboratory, maximal aerobic capacity (VO2max) was subsequently measured using open circuit spirometry during an incremental treadmill test. Pubertal status was assessed using self-reported tanner stages. High-resolution ultrasonography was used to assess endothelial-dependent dilation (EDD) and endothelial independent dilation (EID) in response to brachial artery flow-mediated dilation (FMD) and glyceryl trinitrate administration respectively. Endothelial dysfunction was defined as a FMD response of < or equal to 8%. CRF cut-off point associated with vascular dysfunction was determined by calculating the VO2max value that gave a probability of < or equal to 50% using the parameter estimates from a logistic regression between FMD response of < or equal to 8% and VO2max.
RESULTS: Mean and standard deviation for body mass index, pubertal status and VO2max were 23.4 ± 5.8 kg/m2, 4.0 ± 0.6 and 52.8 ± 10.2 ml/kg/min respectively. CRF cutoff point of < 44.03 ml/kg/min was associated with endothelial dysfunction in male adolescents (CRF=0.1568,p<0.001 and area under the curve >0.85).
CONCLUSION: A CRF cut off point of < 44.03 ml/kg/min was discriminative to identify endothelial dysfunction in apparently healthy male adolescents. Improving CRF levels among adolescents should be encouraged in the primary prevention of CVD. CRF should be routinely monitored during adolescence to identify those adolescents at risk of early CVD.

TWELVE WEEKS OF COMBINED EXERCISE IMPROVE BRACHIAL-ANKLE PULSE WAVE VELOCITY IN PRE- AND HYPERTENSIVE POSTMENOPAUSAL WOMEN

HWANG, M., JEON, K., LEE, S.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Human arterial trees are stiffened with advancing age. Compared to premenopausal women, postmenopausal women present augmented blood pressure and arterial stiffness. Participating in balanced physical activity program composed of both aerobic and resistance exercise is recommended to lower cardiovascular disease risk and to enhance muscle and bone health in postmenopausal women. The purpose of this study was to investigate the effect of 12 weeks of combined exercise on brachial-ankle pulse wave velocity (baPWV) in postmenopausal women with elevated blood pressure.
METHODS: Sixteen pre- and hypertensive postmenopausal women were randomly assigned to exercise (n=8, EXE) and control (n=8, CON) group. EXE group performed a circuit-type combined exercise program for 60 min per day, 3 days a week, for 12 weeks under supervision. baPWV was measured using VP-1000 system (Omron, Kyoto, Japan) to assess arterial stiffness.
RESULTS: baPWV was significantly improved in EXE group (-0.7 m/s; P=0.003), but not in CON group (-0.1 m/s; P=0.5). Weight, body mass index, systolic blood pressure and serum total cholesterol significantly decreased only in EXE group (P<0.03).
CONCLUSION: In conclusion, combined exercise program is an effective intervention to improve arterial stiffness in pre- and hypertensive postmenopausal women.

AMBULATORY BLOOD PRESSURE ADAPTATIONS TO HIGH INTENSITY INTERVAL TRAINING: A RANDOMISED CONTROLLED STUDY.

TAYLOR, K.A., COTTAM, C., WILES, J.D., COLEMAN, D.D., ODRISCOLL, J.M.

CANTERBURY CHRIST CHURCH UNIVERSITY

INTRODUCTION: Increasing research evidence suggests that high intensity interval training (HIIT) is a time efficient exercise intervention to reduce the health implications of physical inactivity. The prevalence of elevated blood pressure (BP), which is associated with an accelerated risk of cardiovascular disease, is increasing globally. HIIT has been shown to improve functional capacity through central and peripheral adaptations and reduce resting BP. However, the effect of HIIT upon ambulatory BP in a cohort of physically inactive participants with elevated BP is unclear.
METHODS: In a randomised controlled trial, forty-one (aged 23 ± 2.7 years) physically inactive males (n=21) and females (n=20) with elevated BP (122 ± 9.8 mmHg), volunteered to participate in a 4-week HIIT intervention or 4-week control period. The training consisted of 3 x 30s maximal effort cycle ergometer sprints at a resistance calculated at 7.5% body mass, interspersed with 2-minute active recovery periods. Resting office BP and ambulatory systolic (sBP) mean (mBP) and diastolic (dBP) BP was recorded pre and post HIIT and control periods.
RESULTS: Following 4-weeks of HIIT, there was a significant reduction in resting office sBP (-7.34 ± 7 mmHg, p<0.05) compared to the control condition. There was no significant change in resting office mBP or dBP for the HIIT or control condition. Ambulatory BP monitoring revealed significant reductions in 24-hour sBP (-4.06 ± 8.08 mmHg, p<0.05), mBP (-2.17 ± 4.04 mmHg, p<0.05) and dBP (-3.43 ± 8.18 mmHg, p<0.05), compared to the control condition. In addition, significant reductions were observed in ambulatory daytime sBP (-2.77 ± 7.89 mmHg, p<0.05) and dBP (-1.04 ± 4.11 mmHg, p<0.05), as well as night time sBP (-5.58 ± 10.1 mmHg, p<0.05) and mBP (-1.56 ± 4.47mmHg, p<0.05) compared to the control condition.

CONCLUSION: A 4-week HIIT programme was associated with clinically significant reductions in ambulatory BP, which may be associated with a reduced risk of cardiovascular disease. This study suggests HIIT is a time effective non-pharmacological intervention for the treatment of elevated BP. Future research is required to ascertain the underlying mechanisms for the BP reductions following HIIT and to explore the implications in clinical populations.

REGULAR UNILATERAL UPPER-LIMB EXERCISE MODULATES DOMINANT ARM PULSE WAVE VELOCITY

LEE, R., KANG, Y., KIM, M., HWANG, M.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Physical training is associated with a decrease in arterial stiffness. Previous findings suggest that physical training can improve peripheral artery stiffness. However, it is hard to discover any previous findings to compare arterial stiffness between bilateral upper extremities in young adults participating in unilateral physical activity. Thus, the purpose of this study is to compare peripheral artery stiffness between dominant and non-dominant upper limb according to unilateral physical activity levels.
METHODS: Eight elite-level female badminton players (ELIT), ten club-level female badminton players (CLUB) and eight age-matched sedentary young females (CONT) were recruited for this study. Brachial-radial pulse wave velocity (armPWV) was measured using Doppler Flowmeters (810-B, Parks Medical, Oregon, USA) and was analyzed using both PowerLab data acquisition system and LabChart Pro V8 software (AD Instruments, Australia).
RESULTS: There was significant difference in armPWV of dominant upper limb among three groups ($P<0.001$). Regarding dominant arm-PWV, post-hoc analyses presented that ELIT was significantly lower than CONT (7.1 m/s vs. 11.6 m/s, $P<0.001$), CLUB was significantly lower than CONT (8.6 m/s vs. 11.6 m/s, $P=0.002$), but there was no significant difference between ELIT and CLUB (7.1 m/s vs. 8.6 m/s, $P=0.2$). In ELIT, the difference in armPWV between dominant and non-dominant upper limb was statistically significant ($P=0.03$). However, there was no significant difference in armPWV between dominant and non-dominant upper limb in both CLUB ($P=0.3$) and CONT ($P=0.6$).
CONCLUSION: In conclusion, peripheral artery stiffness of dominant arm is superior to young females participating in regular unilateral physical activity compared to age-matched sedentary counterpart. Differences in peripheral artery stiffness between dominant and non-dominant upper limb exist only in ELIT who participates in very high level of unilateral physical activity.

12 WEEKS OF STEP-BOX AEROBIC EXERCISE ENHANCE CENTRAL ARTERY STIFFNESS IN POSTMENOPAUSAL WOMEN

KANG, Y., LEE, R., HWANG, M.

INCHEON NATIONAL UNIVERSITY

INTRODUCTION: Cardiovascular disease is one of the leading causes of death in advanced countries. Augmented central artery stiffness is a precursor for cardiovascular disease. Postmenopausal women present elevated blood pressure, heart rate, and arterial stiffness at rest compared to premenopausal women. Regular aerobic exercise is beneficial to improve overall cardiovascular health in both pre- and postmenopausal women. Step-box aerobic exercise has reported its effectiveness on calorie expenditure, fat burning, joint flexibility, lower-body strength, and cardiovascular fitness. However, there have been few studies to demonstrate effects of step-box aerobic exercise on arterial stiffness in postmenopausal women, and there exist no studies to focus on central artery stiffness. The purpose of this study is to investigate effect of step-box aerobic training on central artery stiffness in postmenopausal women.
METHODS: Twenty-four postmenopausal women were randomly assigned to step-box training group (SBT; n=13) or control group (CON; n=11). SBT performed step-box aerobic exercise at 60~80% of HRmax, 3 times a week, for 12 weeks. Augmentation index and aortic pulse wave velocity were measured by SphygmoCor Xcel system (AtCor medical, Sydney, Australia).
RESULTS: Augmentation index was significantly improved in SBT (39±3 vs. 34±2, $p=0.03$), but not in CON (33±3 vs. 32±4, $p=0.8$). Aortic pulse wave velocity was not changed in both groups ($p\geq0.2$). Peripheral and central blood pressure values were significantly enhanced in response to 12 weeks of step-box training ($p\leq0.04$).
CONCLUSION: In conclusion, step-box aerobic training is an effective type of exercise to improve central artery stiffness in postmenopausal women.

PREVENTING FALLS IN ELDERLY PEOPLE – DEVELOPING AND EVALUATING OF A 10-WEEK HEALTH SPORTS PROGRAM FOR A LOCAL PUBLIC ACTIVITY TRAIL

BEHRENS, K., WEIPPERT, M., BEHRENS, M.

UNIVERSITY OF COOPERATIVE EDUCATION

INTRODUCTION: A growing number of cities and communities in GER are installing publicly fitness parks to encourage physical activity also among elderly people. Physical inactivity remains to be a central risk factor for chronic diseases and falls in the elderly. Therefore, increasing physical activity can reduce the risk of falls and additionally improve health-related quality of life. On this background, public outdoor activity trails were designed specifically for elderly (65+) people and set up in the their daily living environment. The authors of this study developed a health sports program based on the national recommendations for fall prevention programs and evaluated its impact on a local sample of elderly people.
METHODS: A randomized controlled trial comparing an intervention group (IG, n = 23) and a control group (CG, n = 19) was conducted with two measurement times (t1 at baseline, t2 after 10 weeks of intervention). The IG was invited to train three a week for 90 minutes on a public fitness park, while the CG did not receive this offer for the 10-week intervention period. All participants were volunteers of the local community with a mean age of 70.2±4.6. For the pre-post comparison the following measurement methods were used: 1-Mile-Walktest (endurance performance), gait analysis to assess dynamic balance under single (ST) and dual task (DT) conditions (OptoGait), health-related quality of life survey (WHOQOL), "Timed up and go" (TUG) to objectify fall risk, d2-R to assess attention and concentration performance, "sit-to-stand" (STS) to objectify lower limb power.
RESULTS: Participants in the IG showed a significant increase in endurance performance (pVO2max: 18.69±8.00ml·min-1·kg-1 vs. 22.90±7.89ml·min-1·kg-1, $p=0.008$) and in dynamic balance (ST-step length: 41.32±3.94cm vs. 42.86±3.90cm, $p=0.023$, ST-walking

speed: 0.84±0.13m/s vs. 0.86±0.12m/s, p=0.015); DT-step length: 39.21±5.13cm vs. 43.09±3.32cm, p=0.014, DT-walking speed: 0.71±0.14m/s vs. 0.87±0.11m/s, p=0.082), while their fall risk decreased significantly (TUG/IG: 7.24±1.22s vs 5.25±0.84s, p=0.007) compared to participants of the CG. The study revealed no significant differences for health-related quality of life between the two study groups.
CONCLUSION: The significant change in fall-relevant parameters for the active IG compared to the CG in this study strongly suggests the developed intervention program to be highly effective in preventing falls in the elderly. Seasonal factors and with that an overall increase in recreational activities such as gardening may have resulted in an intervention unrelated effect on parameters of health-related quality of life, attention and concentration for both IG and CG. Interestingly, on assessment at t2, 12 out of 19 participants from the CG confessed that they had been training on the newly built activity trail independent of the study. Therefore, no phase of absolute inactivity can be assumed for the CG, which in turn makes the positive results of the IG all the more meaningful.

EFFECT OF AGING AND TRIP HISTORY ON TOE CLEARANCE STRATEGY AND REGIONAL NEUROMUSCULAR REGULATION OF THE RECTUS FEMORIS MUSCLE DURING GAIT

WATANABE, K.

CHUKYO UNIVERSITY

INTRODUCTION: It is well known that an abnormality in neuromuscular regulation of the rectus femoris (RF) partly causes pathological gait patterns such as stiff-knee gait. In our previous studies, the RF muscle is regionally regulated during swing phase of gait (Watanabe et al. J Biomech 2014) and this regional regulation is affected by aging (Watanabe et al. J Biomech 2016). The aims of the present study were to test the effect of aging and trip history on toe clearance and spatial distribution of neural activation within the RF muscle and its relationship during gait.
METHODS: Thirteen elderlies and nine young males walked on treadmill at a preferred walking speed for 20min. Lower extremity kinematics on sagittal plane was captured and minimum toe clearance (MTC) during swing phase was calculated. Surface electromyography (EMG) was recorded from proximal to distal regions of the RF muscle with 24 electrodes and central locus activation along the muscle (CLA) was calculated. These data were sampled at 5-10 and 15-20 min after beginning of walking. From six of thirteen elderlies had history of fall or trip within a year in this study, comparison between them are also performed.
RESULTS: MTC was significantly decreased with time in elderly ($p < 0.05$), but not in young ($p > 0.05$). Standard deviation of MTC were significantly greater in elderly than young at both periods ($p < 0.05$). CLA were not changed with time in elderly and young ($p > 0.05$). Significant correlation was observed between coefficient of variation in MTC and CLA at 15-20min in elderly ($p < 0.05$). MTC significantly decreased with time in elderly without trip history ($p < 0.05$), but not in elderly with trip history ($p > 0.05$). Standard deviation of CLA significantly decreased with time in elderly with trip history ($p < 0.05$), but not in elderly without trip history ($p > 0.05$).
CONCLUSION: These results suggested that toe clearance pattern and regional regulation along the RF muscle and its relationship are partly affected by aging and trip history.

POSTURAL STABILITY AND CHAIR STAND CHANGES TO DIFFERENT TRAINING INTENSITIES WITH AGE

LÉTOCART, A.J.1, LALOUBÈRE1, J.Y.1, MABESOONE, F.2,COUPPÉ, C.3,4, BENMANSOUR, K.1, MARIN, F.1,MAGNUSSON, S.P.3,4, GROSSET, J.F.1,5

1 UTC UMR CNRS 7338 FRANCE, 2 CH COMPIÈGNE-NOYON FRANCE, 3 INSTITUTE OF SPORTS MEDICINE COPENHAGEN,4 CENTER FOR HEALTHY AGING DENMARK,5 UNIVERSITÉ PARIS 13, UFR SANTÉ MÉDECINE ET BIOLOGIE FRANCE

INTRODUCTION: Muscle and tendon degeneration with age lead to a decrease in the mobility in daily tasks, and to an increase in the risk for falls with the associated injuries. Resistance training (RT) has the potential to counteract the age-related decline of motion in particularly in Quadriceps Femoris (QF) and Triceps Sural (TS) muscles, the main muscles in charge of locomotion and stability1. The aim of this study was to investigate the effects of a high (HRT) versus moderate (MRT) intensity long term RT on stability and movement capabilities in healthy young and old men
METHODS: Healthy young (YM, n=10, age 25.6 ± 3.6yrs) and 27 old men were recruited and assigned to a 12 weeks RT program (3 times/week) on the lower limbs. YM as well as one group of old men group took part in MRT with training intensity of 55% 1RM (OM55, n=13, age 69.9 ± 3.6yrs), while a second group of old men was imposed a HRT with intensity of 80% 1RM (OM80, n=14, age 71.4 ± 5.7yrs). Each training groups received the exact same training volume on TS and QF. The exercises were leg press, leg extension and seated calf machine. A stability test (open and close eyes) as well as a sit-to-stand were performed before and after RT. These parameters were recorded using a motion capture system (Vicon Nexus 2.5) associated with 2 force platforms
RESULTS: For stability test, a significant decrease in antero-posterior swings with closed eyes in OM55 and OM80 (-16.9% and -14.1% respectively) was shown. Whereas no significant evolution was reported in YM for any stability parameters investigated. For sit-to-stand test, maximal power during the rising phase was significantly increased in OM55 and OM80 by respectively +18.9% +12.2%. The minimum angle between the trunk and the legs during the rising phase was also significantly decreased in OM55 (-5.0%) and OM80 (-6.1%). In YM none of the parameters showed significant changes before and after MRT
CONCLUSION: The present study shows for the first time the effect of training intensity on functional abilities in healthy young and old subjects. The results obtained from the stabilometry and sit-to-stand tests highlight a positive effect of RT on balance, muscle power, as well as a modification in motion strategy in OM. Indeed, after RT old subjects tend to adopt younger-people-strategy using more the trunk imbalance to rise from a chair2, 3. Another important conclusion of this study is that old men training at high intensity do not show any additional gain whatever the considered parameter as compared with medium intensity.

RELATIONSHIP BETWEEN KNEE EXTENSORS POWER AND PHYSICAL PERFORMANCE IN OLDER PEOPLE

VILA-CHÃ, C., SERRA, N., VAZ, C., MARQUES, E., CORTE, A., MARTINS, S., FONSECA, M.

INSTITUTO POLITÉCNICO DA GUARDA

INTRODUCTION: Several studies have shown that impairments in muscle power are more influential than strength on function (Evans, 2000). Although muscle power is a related but different attribute than strength, few studies have explored re relationship between power and functional capabilities of the elderly people. The purpose of this study is to investigate the associations between leg strength (maximal and power) and physical performance among older people.
METHODS: The sample was composed by 19 elderly people recruited from a local health center [4 men and 15 women; aged between 64-80 years]. Maximum isometric strength (MVC) and maximum rate of force development (RFD) of the knee extensors was record with a load cell, in a seated position. Each participant performed 6 trials (3 progressive and 3 explosive contractions), with the dominant lower limb. at 90º of knee flexion. In addition each participant the following functional tests: (i) 4-m walking test; (ii) 5s- chair stand; (iii) 2,44m up-and-go. Hand grip strength was also measured
RESULTS: As expected, the results showed a strong association between lower limb MCV, hand grip (r=0.81; P<0.001) and RFD (r=0.7, P<0.001). The 5s- chair stand results were only moderately correlated with RFD (r=-0.49; P<0.05) and no relationship was observed between this test and lower and upper limb MVC. The walking velocity results were only associated with 2,44m up-and-go results (r=0.58; P<0.001) and RFD (r=0.7, P<0.001).
CONCLUSION: Although maximal strength has been considered an important factor influencing functional performance, the results of this study did not observed an association between this parameter and functional performance tests. On the other hand RFD was associated with 5s- chair stand performance. These findings have important implications for clinicians practicing geriatric

ASSOCIATION BETWEEN HAND GRIP STRENGTH, AGE, GENDER AND PERCEIVED QUALITY OF LIFE

SERRA, N., VILA-CHÃ, C., VAZ, C., MARQUES, E., CORTE, A., MARTINS, S., RITA, A., FONSECA, M.

INSTITUTO POLITÉCNICO DA GUARDA

INTRODUCTION: There is a large and growing literature on handgrip strength (HGS) which correlates with health status in the general adult population (Cheung et al. 2013). The purpose of this study is to investigate the associations between hand grip strength, body composition and perceived quality of life stratified by gender and age among older people from Guarda.
METHODS: The sample was composed by 32 elderly people from a local health center [19 men and 13 women; aged between 65-85 years]. Data were collected through: (i) validated questionnaire for the Portuguese population of health status [SF-36v2,]; (ii) muscle strength (dynamometer for manual gripping) and; (iii) body composition (bioimpedance).
RESULTS: As expected, hand grip strength was higher in men than in women (36.05 ± 6.94 kg and 20.85 ± 4.86, $p < 0.001$). For the subjects aged ≥ 75 years, the hand grip values were higher than the ones registered by a recent Portuguese epidemiological study (+ 24.5%). These values were strongly correlated with muscle mass (in Kg) and height, and moderately correlated with the "physical function" and "pain" dimensions of the quality of life questionnaire.
CONCLUSION: The results indicates that older people from a more rural environment, in particular those aged over 75 years, maintains better muscle strength levels than the general elderly Portuguese population.

EFFECTS OF LONG-TERM SQUARE-STEPPING EXERCISE ON PHYSICAL FITNESS IN HEALTHY OLDER ADULTS

SHIMURA, Y.1, KOMORI, Y.1, HOSHINO, S.2

1: OSAKA INTERNATIONAL UNIVERSITY, 2: NARA WOMEN'S UNIVERSITY

INTRODUCTION: Older adults generally have reduced levels of functional fitness than young adults, including muscle strength, endurance, and balance. Therefore, it is very important to improve physical fitness and promote healthy aging in older adults. Some studies suggest that the square-stepping exercise (SSE) could be an effective means to improve physical fitness (Shigematsu et al., 2008). Furthermore, the SSE has been shown to be significantly better than walking or no treatment to prevent falls, reduce fear of falling, and to improve perceived health status (Fisseha et al., 2017). The purpose of this study was to investigate the effects of long-term SSE performance on physical fitness in healthy older adults.
METHODS: Fifteen healthy older adults (72.93 ± 4.57 years) participated in the study. Participants performed the SSE for 90 min, once a week, for 24 weeks. The SSE was performed using a thin felt mat partitioned into 40 squares (Shigematsu et al., 2006). Participants were advised to include the respective SSE training programs in their daily life. Measurements of physical fitness (hand grip strength, 10-m walking, timed up and go, 8-foot up and go, functional reach, single limb stance with eyes open, single limb stance with eyes closed, sit & reach, 30-sec chair stand, 30-sec arm curl, and stand-up from a lying position) and muscle mass in forearms, upper arms, lower legs, thighs and trunk were taken at baseline and after 3 and 6 months. Data were analyzed with one-way ANOVA. The level of significance was set at $P<0.05$.
RESULTS: Regarding muscle mass, participants showed a significant increase in the right forearm (baseline: 0.37 ± 0.08 kg, 3-month: 0.41 ± 0.07 kg, P< 0.001), right lower leg (baseline: 1.34 ± 0.40 kg, 3-month: 1.57 ± 0.31 kg, P< 0.01), and left lower leg (baseline: 1.28 ± 0.33 kg, 3-month: 1.61 ± 0.30 kg, P< 0.01). As for physical fitness measures, there were improvements in hand grip strength (baseline: 26.90 ± 6.23 kg, 3 month: 28.08 ± 6.08 kg, P< 0.05), 10-m walking (baseline: 4.45 ± 0.74 sec, 6-month: 3.87 ± 0.58 sec, P< 0.001), timed up & go (baseline: 4.45 ± 0.74 sec, 6 month: 3.87 ± 0.58 sec, P< 0.001), 8-foot up & go (baseline: 20.81 ± 2.35 sec, 6-month: 19.54 ± 2.20 sec, P< 0.01), and stand-up from a lying position (baseline: 3.31 ± 1.13 sec, 6-month: 2.73 ± 0.67 sec, P< 0.01).

CONCLUSION: This study suggests that the SSE has some beneficial effects on muscle mass after a 3-month intervention in healthy older adults. However, 6 months were needed to improve physical fitness, including functional mobility, agility, and dynamic balance. This study suggests that performing the SSE shows greater benefits in the long term than in the short term.

INTERVENTIONS TO IMPROVE AND SUSTAIN PHYSICAL FUNCTIONING, COGNITION AND PSYCHOSOCIAL WELL-BEING FOR ELDERLY MULTIMORBID NURSING HOME RESIDENTS

CORDES, T., HIERHAGER, M., WANSTRATH, M., MEIXNER, C., WOLLESEN, B.

UNIVERSITY OF HAMBURG

INTRODUCTION: To date, evidence-based activity guidelines for very old, multimorbid and institutionalized people cannot be given (De Souto Barreto et al.2016, Nelson et al.,2007). A report from the International Association of Gerontology and Geriatrics - Global Aging Research Network (IAGG-GARN) and the IAGG European Region Clinical Section (De Souto Barreto et al. 2016) makes recommendations regarding physical activity in older persons living in residential care facilities and propose a multi-component exercise program. The study was designed to provide information about the efficacy of a multi-component activity program in inpatient care for residents who are unable to walk.
METHODS: The observational study included N=7 multimorbid residents (85±5.2 years) who were unable to walk. A 16 weeks multi-component sitting intervention program, contained exercises to improve strength, endurance, mobility and balance, was designed and carried out in the nursing home facility twice a week. Demographics, physical functioning, cognitive performance and quality of life (SF-12, SWLS, MoCA, hand grip force, functional reach test) were assessed in a baseline (t1) and a post testing (t2).
RESULTS: Hand grip force (t1=10,6±6,3kg; t2=17,1±5,5kg), sitting balance with the functional reach test (t1=98±17cm; t2=118±13cm) and the health-related participants' physical quality of life with the SF12 survey (t1=29±3; t2=36±12) increased from baseline to post testing. Cognitive capacity and psycho-social parameters remained stable. The Participants described the training sessions as fun and rated the exercises as relevant to maintain their physical functioning for daily activities.
CONCLUSION: The results indicate that a multi-component exercise program may improve or sustain physical functioning and cognitive capacity within residents of nursing homes who are unable to walk. No deterioration of cognitive capacity can be considered as a success in this aged population. Preliminary searches have shown that most interventions in nursing home facilities are aimed at residents who are still able to walk. Only few studies point out suggestions for sitting interventions. Further research is needed to confirm these results and give concrete recommendations on how interventions should be structured.

AEROBIC EXERCISE IMPROVES ENDOTHELIAL FUNCTION DURING ADVANCING AGE: A META ANALYSIS AND META REGRESSION OF OBSERVATIONAL AND INTERVENTIONAL STUDIES

SCULTHORPE, N., CAMPBELL, A., RITCHIE, L., BEAUMONT, A., GRACE, F.

UNIVERSITY OF THE WEST OF SCOTLAND

INTRODUCTION: There is an emerging body of literature relating to the effectiveness of frequent aerobic exercise as a prophylactic for age-associated stiffening of large arteries. Flow Mediated Dilatation (FMD) has emerged as a standard method of determining vascular endothelial function, however, there are no systematic interrogations of studies that examine vascular function specifically in sedentary. but otherwise healthy older adults.
METHODS: We conducted a systematic review and meta-analysis of controlled studies examining flow mediated dilatation (FMD) of athletic older persons and otherwise healthy sedentary counterparts to (i) compare FMD as a determinant of endothelial function between athletes and sedentary (ii) summarise the effect of exercise training on FMD in studies of sedentary ageing persons. Studies were identified from systematic search of major electronic databases from inception to January 2018. Study quality was assessed before conducting a random effects meta-analysis to calculate a pooled ES with 95% CIs. In addition, relationship between the exercise effects on FMD and age was assessed using Meta Regression in both comparisons. Meta regression was also used to assess the relationship between FMD improvement and training duration in intervention studies.
RESULTS: 17 studies [12 cross-sectional (n=522); 6 intervention (n=142] with age ranges from 61-75 years underwent quantitative pooling of data.
Older athletes had more favourable FMD compared with sedentary controls (2.11%; CI: 1.13%, 3.1%; P<0.001). Additionally, exercise training of previously sedentary cohorts resulted a large positive effect in FMD (1.57%; CI: 0.03%, 3.1%; P=0.045). Meta regression indicated that these improvements appear to be maintained irrespective of age (P=0.17 and P=0.83 for cross-sectional and intervention comparisons respectively) or the duration of training programmes in interventional studies (P=0.57).
CONCLUSION: Long-term aerobic exercise appears to attenuate decline in vascular function which is maintained during chronological ageing. In addition, it appears that improvements in FMD can occur even after relatively short periods of aerobic training in sedentary older cohorts.

EFFECTS OF THE DETRAINING ON HEALTH RELATED QUALITY OF LIFE, FUNCTIONAL FITNESS AND FALLS IN ELDERLY HABITUAL EXERCISERS

ESAIN, I., RODRIGUEZ-LARRAD, A., BIDAURRAZAGA-LETONA, I., IZAGUIRRE-GALLEGO, N., PEREZ-GAVILAN, A., GIL, S.M.

UPV/EHU

INTRODUCTION: Little is known about the effects of detraining in older adults (1), particularly those who regularly exercise. The aim of the study was to determine the consequences of 3 months of cessation of habitual supervised exercise on functional fitness and Health Related Quality of Life (HRQOL), and examine the association of these variables with falls.
METHODS: Thirty-eight women and 11 men (mean age, 75.5±5.7 years old) took part in a supervised physical exercise program for 9 months, followed by 3 month of detraining period. Participants completed the Senior Fitness Test, SF-36 questionnaire, Leisure-time physical activity questionnaire at the beginning of the detraining (baseline) and 3 months later. The number of falls were also recorded. Wilcoxon test or Student´s t- test were used to identify differences between baseline and after 3 months. Mann-Whitney U statistics test were used to compare fallers and non-fallers. The significant level was set at p<0.05.
RESULTS: Participants had been exercising for 12.1±8.7 years. Total physical activity during the detraining period was lower than that at baseline but this was not statistically significant. After the detraining, the 8 Foot Up and Go test (p<0.001) and all the dimensions of the HRQOL (p<0.05) had a significant decline. Women presented a larger decline (p<0.05) in more items than men. During the detraining

period, 18.4% participants had a fall. HRQOL declined both in fallers and non-fallers. Interestingly, at baseline fallers already had significantly lower values in physical functioning (p<0.05), emotional role (p<0.05) and mental health (p<0.01), than non-fallers. The non-faller group after 3 months of detraining period had significantly lower values in the 8 Foot Up and Go test (p<0.05) than the faller group.
CONCLUSION: Three months of detraining period in older exercisers who habitually undertake supervised activities is enough to deteriorate most items of the SF-36 and the dynamic balance. The effect of periods of cessation of supervised exercise, could be avoided prescribing exercises designed specifically for them with emphasis on balance exercises.
The prior lower HRQOL values of those who will subsequently fall suggest that this criterion should be studied as a candidate risk factor for falls.

LONGER TIME SPENT IN SEDENTARY BEHAVIOR IS ASSOCIATED WITH INCREASED ARTERIAL STIFFNESS IN JAPANESE OLDER ADULTS

TANAHASHI, K.1, TAKEUCHI, A.1, NISHIMURA, M.1, KUMAGAI, H.1,2, ZEMPO-MIYAKI, A.3, KOSAKI, K.1, AKAZAWA, N.1,4, MAEDA, S.1

1> UNIVERSITY OF TSUKUBA, 2> JUNTENDO UNIVERSITY, 3> RYUTSU KEIZAI UNIVERSITY, 4> JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: The time spent in sedentary behaviors, such as sitting at work or leisure, is associated with an increased risk of cardiovascular disease. It has been reported that Japanese adults spend the longest sedentary time in the world. Recent studies have suggested that increase in arterial stiffness, an independent risk factor for cardiovascular disease, is associated with longer time spent in sedentary behavior. However, it is unclear whether sedentary behavior associates with arterial stiffness in Japanese adults. In addition, to our knowledge, no studies have analyzed the relationship between sedentary behavior and arterial stiffness with age. Therefore, we investigated the relationship between sedentary behavior and arterial stiffness in Japanese populations.
METHODS: A total of 744 healthy Japanese adults, under the age of 40 years (young), 40 to 59 years of age (middle-aged), and over the age of 60 years (older), participated in this study. Physical activity and sedentary behavior were assessed by international physical activity questionnaire. Arterial stiffness was measured by carotid-femoral pulse wave velocity. Subjects in each age category were divided into either long-sedentary time or short-sedentary time groups according to the median daily time spent in sedentary behavior.
RESULTS: In the older populations, carotid-femoral pulse wave velocity was higher in the long-sedentary time group than in the short-sedentary time group. The difference remained significant after normalizing carotid-femoral pulse wave velocity for physical activity. Meanwhile, in the young and middle-aged populations, there were no differences among groups in carotid-femoral pulse wave velocity.
CONCLUSION: The present study suggested that longer time spent in sedentary behavior is associated with increased arterial stiffness in Japanese older adults.

EFFECTS OF STRENGTH TRAINING ON BODY COMPOSITION AND PHYSICAL FITNESS IN HYPOGONADAL MALES

KRALIK, M.1, CVECKA, J.1, PUTALA, M.1, BUZGO, G.1, TIRPAKOVA, V.2, BUJDAK, P.2, KOLLARIK, B.3, UKROPCOVA, B., UKROPEC, J.4, PAYER, J.5, KILLINGER, Z.5, RAASTAD, T.6, SEDLIAK, M.1

1: FSPORT CU , 2: SMU , 3: SCMUH , 4: BMC SAS , 5: FMED CU , 6: NIH

INTRODUCTION: Hypogonadism is a clinical syndrome resulting from the low production of androgens (testosterone levels < 6.9 nmol/l) with symptoms including decline in lean mass, muscle strength, increases in body weight and overall body fat mass (Grossmann et al. 2008, Kapoor et al. 2006, Smith et al. 2002). There are very few studies dealing with effect of physical activity on hypogonadal males (Hildreth et al. 2013). The aim of the study was to examine the effect of 12-week strength training program on body composition, physical function, selected biochemical markers of metabolic health in patients with hypogonadism.
METHODS: The study is comparing the effect of strength training (ST) with testosterone replacement therapy (TRT) (n=5, 42,9 + 2,77 years) and strength training alone in hypogonadal patients without TRT (NON-TRT) (n=3, 52,1 + 8,5 years), with control group of eugonadal males (HM) (n=3, 52,9 + 4,21 years) also engaged in ST. The subjects performed ST twice per week and the training program consisted of 6 exercises at an intensity of 60-80% of 1RM.
RESULTS: When all subjects merged together, body composition (DXA) was improved with decreased fat mass both in absolute (g) and relative (%) values (p<0.01), with no significant change in lean or bone mass. Muscle strength measured by predicted leg press 1RM from multiple repetition maximum increased (p<0.01). Predicted VO2max from submaximal walking test increased (p<0.05). Between-group differences were not analysed due to very low sample sizes.
CONCLUSION: The first phase of the study was completed by 11 males. After 3 months of strength training protocol all of subjects significantly improved muscle strength and reduced body fat. Despite the fact, that experimental protocol was 60 min. strength training session twice a week, subjects improved also their cardiovascular fitness. This preliminary results suggest that ST could be useful to combat adverse negative effects of the hypogonadism.
Key words: hypogonadism, physical activity, testosterone deficiency, hypogonadism ageing male strength training, physical activity, testosterone

AN ASSESSMENT OF COGNITIVE FUNCTION AND PHYSIOLOGICAL OUTCOMES IN INDIVIDUALS WITH HEPATITIS C

O'GORMAN, P., FERGUSON, D., STRAHAN, O., MONAGHAN, A., KENNEDY, M., MCKIERNAN, S., BERGIN, C., COEN, R., DOHERTY, C., FORDE, C., GORMLEY, J., NORRIS, S.

TRINITY COLLEGE DUBLIN

INTRODUCTION: Cognitive impairment is reported to occur in 30-50% of non-cirrhotic individuals with hepatitis C. It is also reported that these individuals experience reduced aerobic fitness (VO2max) and poor vascular health. Higher exercise capacity and lower cardiovascular risk factors have been shown to influence cognitive function in other chronic diseases. However, no studies have examined this relationship in individuals with hepatitis C. The primary aim of this study was to assess various physiological outcomes and cognitive function in a cohort of individuals with hepatitis C.
METHODS: Prior to inclusion in the study, individuals underwent screening of their cognitive function and were included only if they presented with mild cognitive impairment. Outcome measures included; VO2max, body composition, cognitive function tests (Montreal Cognitive Assessment (MOCA), Trail Making Test A & B (TMT-A & B) and Digit Symbol Test (DST)), vascular health and physical activity levels (PAL). VO2max was assessed via a submaximal treadmill test using the modified Bruce protocol with breath by breath gas analysis. Seven-day physical activity level was assessed using a waist-worn tri-axial Actigraph accelerometer. Body composition was assessed using a Seca bioimpedance analyzer. Vascular health was assessed using a Mobil-O-Graph blood pressure monitor. All values are displayed as mean ± standard deviation.
RESULTS: Between March 2017 and February 2018, 38 individuals (m/f = 22/16, age = 40.3 ± 7.81 years) completed the assessment. MOCA, TMT-A, TMT-B and DST score were; 23.9 ± 2.44, 40.3 ± 10.63s, 109.8 ± 31.27s, 41.2 ± 12.28, respectively. VO2max and moderate-vigorous physical activity (MVPA) levels were; 39.6 ± 10.48ml.min.kg and 265.8 ± 271.36min/week, respectively. Pulse Wave Velocity (PWV) and Augmentation Index (AI) were, 6.3 ± 0.97ms and 14.9 ± 12.21%, respectively. BMI and fat mass were; 27.2 ± 4.98 and 31.7 ± 10.42%, respectively. There was a somewhat negative correlation between DST score and PWV (R=0.53) and a somewhat positive correlation between VO2max and MOCA score when outliers were removed (R= 0.52).
CONCLUSION: The majority of the current cohort were overweight and had reduced VO2max. An interesting finding in this cohort was the two correlations. A lower PWV is indicative of healthier vasculature. This may aid in reducing cardiovascular and cerebrovascular risk factors that can contribute to cognitive impairment in these individuals. A higher MOCA score is also indicative of better cognitive function. It has been suggested in previous studies that positive molecular adaptations within the central nervous system may account for exercise-induced changes in cognitive function. Therefore, this may indicate that those who are more aerobically fit may display less cognitive impairment. Individuals would potentially benefit from a structured exercise program which is currently ongoing in this cohort. Additionally, a greater sample size is needed in order to draw more definitive conclusions.

A SYSTEMATIC REVIEW OF THE EFFECTS OF EXERCISE ON PEOPLE WITH HUNTINGTONS DISEASE.

BAIN, P.

IMPERIAL COLLEGE LONDON

INTRODUCTION: Huntingtons disease (HD) is an autosomal dominantly inherited neurodegenerative disease characterised by cognitive decline, movement disorders (characteristically chorea) and behavioural disturbances. It is caused by a trinucleotide (CAG) expansion in the Huntingtin gene on chromosome 4, with the age of onset being inversely associated with increasing CAG repeat size.
Increased physical activity has shown beneficial effects on cognition in rodent models of HD. We conducted a systematic review of trials involving physical activity for people with HD to gauge the efficacy of increased physical activity on their cognitive function.
METHODS: PRISMA protocols were used to plan the stages of the research and consequently, systematic searches were conducted in May 2017 using a pre-defined strategy. These searches were conducted in the electronic databases MEDLINE, EMBASE and PsycINFO via OVID. Studies which satisfied the inclusion criteria were either epidemiological or experimental in nature and specific to humans with confirmed Huntington's disease. Papers included were restricted to those written in English and published in peer-reviewed journals.
RESULTS: 10 studies were included in the analysis, 4 being randomised control trials, 5 non-randomised clinical prospective intervention trials and 1 cross-sectional study.
Unfortunately, all these studies were of relatively poor quality for various reasons:
a. Most lacked randomisation or control participants.
b. No prior power calculations were undertaken and thus sample sizes may have been too small to detect benefit.
c. Objective quantitative measurements of physical activity were rarely made, instead results largely depended on subjects recall.
d. Multiple component interventions, including physical activity, were deployed producing confounding variables.
Despite these flaws, all studies reported that there was no significant decline in the cognitive function of the participants (over a 6-24 month period). Furthermore, the studies reported isolated improvements in some cognitive tests, most commonly the Mini Mental State Examination (MMSE), Symbol Digit Modalities Test (SDMT), and Unified Huntingtons Disease Rating Scale (UHDRS) but with no consensus of significant benefits in any specific cognitive domain.
Encouragingly, no adverse outcomes were reported and, in the 5 studies that examined the effects of exercise on disability and motor function, there were clear improvements in both of these domains, including gait and chorea.
CONCLUSION: The positive results found on the effects of physical activity on cognition in rodent studies of HD are yet to be demonstrated in human clinical trials as these have been of limited quality, although the absence of significant cognitive decline in any of these human studies might suggest a neuro-protective effect. This area of research is still relatively novel and subsequent studies need to concentrate on improved study design and include objective measurements of physical activity.

EXERCISE TOLERANCE IN LATE-ONSET POMPE DISEASE PATIENTS: POSITIVE EFFECTS OF PHYSICAL TRAINING AND HIGH-PROTEIN DIET.

PEDRALI, M.1,2, ZUCCARELLI, L.3, BIASUTTI, L.3, AZZINI, L.3, RASICA, L.2,4, MARZORATI, M.2, PORCELLI, S.2, SECHI, A.5, GRASSI, 2,3

1UNIVERSITY OF MILAN, 2NATIONAL RESEARCH COUNCIL, 3UNIVERSITY OF UDINE, 4UNIVERSITY OF MILAN, 5ACADEMIC HOSPITAL OF UDINE

INTRODUCTION: Pompe disease is a metabolic myopathy characterized by intralysosomal accumulation of glycogen due to deficiency of lysosomal acid alpha—glucosidase. Patients with the late-onset form of the disease present progressive muscle weakness, exercise intolerance and impaired pulmonary function. Enzyme replacement therapy (ERT) is available since 2006 and is associated with a short-

term mild improvement of pulmonary function and exercise tolerance. Clinical improvements have been reported following with a combination of aerobic exercise training and high-protein low-carbohydrate nutrition in non-treated patients. Aim was to evaluate the effects of an individualized home-based exercise training program, alone or in combination with a high-protein regimen, on exercise tolerance and muscle function in late-onset Pompe disease patients chronically treated with ERT.
METHODS: Thirteen patients (61±10 yr) were enrolled in this ongoing study. Each patient underwent to three different interventions in a randomized order: control period (CTRL), aerobic and strength training (TRAINING), and a combination of TRAINING and normocaloric high-protein (28%) diet (TRAINING+DIET). Each intervention lasted 6 months and was followed by a 3-month washout. Before (PRE) and after (POST) each intervention, patients undertook a 8-minute moderate intensity constant work rate exercise followed by an incremental exercise on a cycle-ergometer. During this exercise, time to exhaustion (Tlim), peak oxygen uptake (VO2peak), oxygen cost of exercise (O2cost), and the slope of the relationship between heart rate (HR) and VO2 were utilized as functional indexes of exercise tolerance. Maximal voluntary force (MVC) during isometric contractions was measured for both upper and lower limbs.
RESULTS: Two patients dropped out; data refer to seven patients that have completed at least two interventions. Tlim increased after both TRAINING (28%) and TRAINING+DIET (8%) whereas it was reduced (15%) after CTRL. After TRAINING and TRAINING+DIET, VO2peak increased in POST (1.63±1.15 and 1.90±0.88 L*min-1, respectively) compared to PRE (1.32±1.14 and 1.74±0.88 L*min-1, respectively) whereas it was reduced after CTRL (1.42±0.89 L*min-1 vs. 1.58±0.86, PRE vs POST). O2cost was not affected by the interventions, being always higher (15.5±5.2 mL*min*w-1) than in healthy subjects (10-12 mL*min*w-1). The slope of HR-VO2 relationship was normal (2.9±0.2 b*kg*mL-1) and it did not change across the conditions. MVC in knee extension increased after TRAINING (6%) and TRAINING+DIET (7%), whereas it did not change during CTRL (200±41 N and 203±55 N, respectively in PRE and POST). No differences were observed for MVC in elbow flexion between PRE and POST in all conditions.
CONCLUSION: According to these preliminary results, in late-onset Pompe disease patients treated with ERT exercise training alone and the combination of exercise training and normocaloric high-protein diet seems to positive affect some functional indexes of exercise tolerance.

AEROBIC FITNESS LEVEL NECESSARY FOR LOW METABOLIC SYNDROME RISK IN JAPANESE CHILDREN

SASAYAMA, K.1, ADACHI, M.2

1: OKAYAMA UNIVERSITY OF SCIENCE 2: OKAYAMA UNIVERSITY

INTRODUCTION: The aerobic fitness levels necessary for low metabolic syndrome risk have been published for American, European, and Canadian children [1-3]. However, the aerobic fitness level necessary for low MetS risk has not been determined for Japanese children. The purpose of this study was to determine the aerobic fitness level necessary to achieve a low MetS risk.
METHODS: The participants were 299 children <9.1±0.3 years>. Aerobic fitness was defined as the predicted peak oxygen consumption from a 20 m shuttle run test. MetS risk score were calculated from the total gender-specific values of the following four parameters: waist to height ratio, TG, HDL-c, and mean arterial pressure. A lower score indicates a lower MetS risk. Receiver Operating Characteristic analysis was used to identify the threshold of aerobic fitness necessary to achieve a low MetS risk. A risk score in the bottom 75th percentile was considered to indicate a low MetS risk.
RESULTS: The ROC analysis demonstrated the significant discriminating ability of pr˙O2peak for identifying low versus high MetS risk scores in boys , and girls . pVO2peak at these points were 47.3 and 44.9 ml/kg/min in boys and girls, respectively.
CONCLUSION: The aerobic fitness levels found to be necessary for a low MetS risk in this study <47.3 and 44.9 ml/kg/min for 9–10 years old in boys and girls, respectively> were relatively higher than those reported in previous studies [1-3]. These differences in aerobic fitness threshold may reflect the method used to evaluate aerobic fitness. However, in Japanese children, the 20-m shuttle run test level was higher than that observed among 37 countries worldwide [4]. Therefore, it is reasonable to expect that our results would be higher than those observed in previous studies.

CEREBRAL OXYGENATION AND HEMODYNAMIC MODIFICATIONS DURING CONTEMPORARY MENTAL TASK AND MUSCLES METABOREFLEX ACTIVATION IN METABOLIC SYNDROME PATIENTS: A PRELIMINARY REPORT

DONEDDU, A., ROBERTO, S., MILIA, R., PINNA, V., VELLUZZI, F., LECIS, R., GUICCIARDI, M., CRISAFULLI, A.

UNIVERSITY OF CAGLIARI

INTRODUCTION: Metabolic diseases, such as type 2 diabetes, obesity and Metabolic Syndrome (MS), are constantly growing their incidence, with increasing in related cardiovascular problems (1). One consequence of MS is the high sympathetic tone. Muscles metaboreflex (MM) activation increases sympathetic activity and it is a well established method to study cardiovascular adjustments to exercise as well as to reveal cardiovascular diseases (2,3). It has been reported that patients suffering from MS have an exaggerated increase in sympathetic tone during the MM. Mental task (MT) can also increase sympathetic tone. Therefore, contemporary MM activation and MT are expected to cause high increments in sympathetic activity, thereby inducing cerebral vasoconstriction and impairing cerebral oxygenation. We hypothesized that, in MS patients, during contemporary MM activation and MT, cerebral oxygenation was reduced in comparison with a normal population. This occurrence could provide explanation for the bad predisposition to exercise in these patients.
METHODS: Two different groups of subjects took part in this investigation: 15 subjects (7 females, age 53.6±9.8 yrs) with MS and 14 age-matched control healthy subjects (CTL). They underwent 5 different tests each lasting 12 min: post-exercise muscle ischemia (PEMI) to activate the MM, control exercise recovery (CER), PEMI+MT, CER+MT, and MT alone. During each sessions, cerebral oxygenation was detected by Near Infrared Spectroscopy by applying two sensors in the skin of the forehead, while hemodynamics was detected by impedance cardiography.

RESULTS: Data analysis found no reduction in cerebral oxygenation during PEMI neither in MS patients nor in CTL subjects. The MT test added to the PEMI test did not induce any significant decrease in cerebral oxygenation in both groups. However, MS patients showed greater increments in systemic vascular resistance (SVR) than CTL.
CONCLUSION: Results did not support the hypothesis that adding MT to PEMI impairs cerebral oxygenation in patients suffering from MS. This despite MS patients exhibit higher level of SVR in comparison with CTL, which suggests the occurrence of exaggerated arteriolar vasoconstriction. Therefore, cerebral circulation seems to be preserved in MS patients.

DANCING IMPROVES NEUTROPHIL APOPTOSIS BY REDUCING INFLAMMATION IN DIABETICS

HATANAKA, E.1, BORGES, L.S.1, PEREIRA PASSOS, M.E.1, BARROS SILVA, M.B.1, MOMESSO, C.M.1, GRAY, S.R.2, GORJÃO, R.1, DERMARGOS, A.1,3

1ICAFE, CRUZEIRO DO SUL UNIVERSITY 2INSTITUTE OF CARDIOVASCULAR AND MEDICAL SCIENCES 3UNIVERSIDADE PAULISTA O DO SUL UNIVERSITY

INTRODUCTION: Neutrophils from people with type 2 diabetes show increased cell death and increased clearance from infectious sites, contributing to the increased susceptibility and severity of infections in diabetics. The mechanisms underlying cell death induced by diabetes appears to involve prolonged production of pro-inflammatory cytokines, such as tumor necrosis factor-alpha (TNF-α and interleukin-1 beta (IL-1β) [1]. Exercise is a non-pharmacological tool to control low-grade systemic inflammation [2]. Herein, we assessed the effects of an aerobic dance exercise programme on circulating cytokines and neutrophil death in people with diabetes and controls volunteers.
METHODS: A group of ten people with diabetes (70 ± 3 years, body mass 69.6 ± 4 kg, height 1.6 ± 0.02 m, body fat 36.5 ± 1.9%) and twelve healthy (62.9 ± 1.8 years, body mass 65.6 ± 3.2 kg, height 1.57 ± 0.01 m, body fat 35 ± 1.2%) volunteers participated in aerobic dance training twice weekly for 4-months. Plasma levels of TNF-α, C-reactive protein (CRP) and IL-1β were measured before and after training by ELISA. Neutrophil count, fragmented DNA (apoptosis sign) and cell membrane integrity (necrosis sign) were assessed by flow cytometry before and after training.
RESULTS: Our results indicate that plasma TNF and CRP were reduced by 1.9-fold ($P < 0.005$) and 1.4-fold ($P < 0.001$) respectively after training period. Neutrophil DNA fragmentation (0.9-fold, $P < 0.05$) was lower after dance training, while neutrophil numbers increased (0.7-fold, $P < 0.005$) after the same period.
CONCLUSION: We concluded that dancing might help to regulate inflammation and neutrophil apoptosis in diabetes. This may be an efficient strategy to protect against microorganism infection, resulting from neutrophil deficiency.

VARIABLE ENDURANCE TRAINING PROTOCOLS IN CARDIAC REHABILITATION

BIRKLBAUER, A.1,2, DIEM, G.2

1 UNIVERSITY OF SALZBURG, 2 KLINIKUM AUSTRIA GESUNDHEITSGRUPPE, BAD HALL

INTRODUCTION: Dynamic systems, stochastic resonance and neurobiological insights contributed to a reconsideration and acceptance of variability. In cardiology, heart rate variability is a relevant marker reflecting cardiac modulation, whose optimal level reflects efficient functioning and an inherent adaptability (McCraty et al, 2009). While too little variation indicates inadequate functioning, too much instability (e.g. arrhythmias) is detrimental to healthy functioning. This view of variability led to a different approach to endurance training in our cardiac rehabilitation centre.
Endurance training is a cornerstone in cardiac rehabilitation and well implemented in the guidelines (e.g. Piepoli et al., 2012). It is included into regular training schedules through high-intensity interval training (HIT), pyramid, or continuous exercise training (CE). Especially the application of HIT schedules has increased over the last few years due to assumed advantages over CE (Hussain et al, 2016). Its alternating intensity with bursts of high intensity interspersed with periods of rest or low-intensity exercise seems to imply a higher motivational factor than CE, also because of its higher variability. However, a completely, more variable training protocol has not been applied so far.
METHODS: We applied such a variable training protocol in our patients (n=2878; average: 63.7 yrs) including HFpEF, HFrEF, LVEF, CMP) who were also exposed to all above mentioned trainings. In contrast to heart-rate-driven protocols where workload is automatically adapted due to the increase or decrease in heart rate and to the systematic HIT or pyramid training where a determined workload increase and decrease is given, workload in a variable setting is externally and randomly increased and decreased. That is, the duration and intensity of intervals appear in a random order, with intensities being individually set based on the patient's cardiopulmonary exercise test.
RESULTS: Comparing all training protocols, intensities are significantly higher in HIT and the variable setting compared to CE ($p<.001$; $eta2>.20$). Alike HIT sessions, variable training protocols seem to be more enjoyable for patients than CE. Interestingly, variable training protocols represented also lower BORG values compared to HIT despite the similar intensities.
CONCLUSION: Due to the implied indeterminacy we assume that such training protocols better support the recovery of functional capacity than continuous exercise and prepare better for a successful reintegration into life as workloads cover a broader range of intensities. These protocols can easily be documented and analysed providing further information for day-to-day variation and its underlying dynamics (e.g. blood pressure response).

EFFECTS OF 3 MONTHS MULTICOMPONENT EXERCISE PROGRAM ON PHYSICAL FUNCTION IN POST-HOSPITALIZATION PATIENTS

ECHEVERRIA, I.

UPV/EHU

INTRODUCTION: During hospitalization, the physical functions of the elderly usually decrease. Physical activity has been shown to be the cornerstone in attenuating this loss of functional capacity. Furthermore, physical exercise seems to be effective in improving the general physical condition of older adults and preventing disability and other adverse outcomes. The aim of this study was to evaluate the effects of a 3-month multicomponent exercise intervention on physical fitness within post-hospitalization patients.
METHODS: Post-hospitalization patients that met the following criteria were included in the study: aged ≥ 70 years, scored ≥ 20 on MMSE test and who capable to stay up and walk independently for 10 meters. The participants took part in sessions of multicomponent exercise intervention during 60 minutes twice a week for 3 months. The training was focused on balance, power and strength in a moderate intensity The studied variables were dominant and no dominant handgrip, time up and go (TUG), Berg scale, 10-meter walking test (gait speed), Short Physical Performance Battery (SPPB) and 3 test of the Senior Fitness Test battery: arm curl, chair stand and 6 minute walking test. We compared the results before (PRE) and after (POST) the intervention by a paired student t test.
RESULTS: We observed an improvement of 35.89%, in the SPPB score (p=0.005) from the beginning to the end of the intervention. Accordingly, leg (p=0.018) and arm (p=0.008) strength increase in 31.63% and 42.85% respectively. Dynamic (19.8%; p=0.008) and static (6.3%; p=0.013) balance also improved in this 3-month intervention. Finally, we observed a significant improvements (p=0.022) in 10-meter walking test and in 6 minute walking test (p=0.037). However, parameters that we did not train specifically had a decline: 1.64% in dominant handgrip and 1.81% in no dominant handgrip.
CONCLUSION: Our study showed that a multicomponent exercise program is effective for post-hospitalization patients because after 3-month intervention, we obtained positive results in balance, strength and walking tests. Taking into account the relationship between these parameters and functional capacity, we can conclude that this multicomponent physical exercise intervention is able to recover or improve the functional capacity of patients after hospitalization.

SYSTEMIC INFLAMMATORY AND VASCULAR BIOMARKER ALTERATIONS FOLLOWING ISOMETRIC EXERCISE TRAINING IN UNMEDICATED HYPERTENSIVE PATIENTS.

O DRISCOLL, J.M., TAYLOR, K.A., WILES, J.D., COLEMAN, D.D., SHARMA, R.

CANTERBURY CHRIST CHURCH UNIVERSITY

INTRODUCTION: Hypertension (HTN) remains the leading attributable risk factor for cardiovascular disease and all-cause mortality. HTN is associated with vascular endothelial dysfunction, which is characterised by a pro-inflammatory, pro-thrombotic and pro-constrictive phenotype. Systemic low-grade inflammation and vascular dysfunction may accelerate atherosclerosis. Isometric exercise training (IET) has been shown to reduce arterial blood pressure (BP) in normotensive and hypertensive populations; however, the modulation of inflammatory and vascular biomarkers following IET is unknown.
METHODS: In a randomised crossover controlled trial, 24 physically inactive hypertensive males (aged 44.6±7.7 years) completed 4 weeks of home-based isometric wall squat training. Wall squat training intensity was determined following a laboratory incremental wall squat test and recreated at home using a simple device to elicit each specified knee joint angle. Three sessions, consisting of 4 x 2 min isometric wall squats were completed each week. Serum high sensitivity C-reactive protein (hs-CRP), interleukin 6 (IL-6), tumour necrosis factor alpha (TNF-α), interleukin 10 (IL-10), asymmetric dimethylarginine (ADMA), vascular cell adhesion molecule 1 (VCAM-1) and intercellular adhesion molecule 1 (ICAM-1) were measured pre and post the IET and control period.
RESULTS: Following 4-weeks of IET, IL-6 (ln) and ADMA (ln) significantly decreased (-0.04±0.07, p=0.025 and -0.05±0.11, p=0.048, respectively) with no significant change post control (p=0.328 and p=0.271 respectively). This difference was significant between conditions (p=0.042 and p=0.008, respectively). There was no significant change in hs-CRP, TNF-α, VCAM-1 or ICAM-1 following IET or control condition. There was no significant change in IL-10 (ln) following IET (1.24±0.2 to 1.25±0.2, p=0.19) or control condition (1.24±0.2 to 1.25±0.2, p=0.404). However, there was a significant reduction in the IL-6/IL-10 ratio (0.91±0.26 to 0.86±0.24, p=0.022) following IET, with no significant change post control (0.93±0.22 to 0.92±0.19, p=964). This difference was significant between conditions (p=0.033).
CONCLUSION: A short term programme of home-based IET was associated with a significant reduction in inflammatory and vascular biomarkers, which have been associated with improved cardiovascular health. The impact these responses have on long-term cardiovascular events and mortality requires further research.

NEGATIVE EFFECTS OF L-ARGININE ADMINISTRATION ON HYPERTENSIVE WOMEN'S CARDIOVASCULAR HEALTH

NOVAIS, I.P., JARRETE, A.P., PUGA, G.M., DELBIN, M.A., ZANESCO, A.

STATE UNIVERSITY OF SOUTHWESTERN BAHIA

INTRODUCTION: It has been consistently reported the L-arginine administration enhances athletic performance, running economy or improve recovery from exhaustion, and most of studies has been conducted in athletes. L-Arginine is the main precursor of nitric oxide (NO) that plays a key role on vascular tonus via cGMP/PKG pathway. The beneficial effect of NO-precursor also has been associated with improvement of blood flow on skeletal muscle, and aerobic exercise has been indicated as a strategy to positive effects on hemodynamic signals and NO/cGMP pathway. The aim of this work was to examine the effects of acute L-arginine administration alone or in association with a bout of exercise on cardiovascular parameters in trained hypertensive postmenopausal women.
METHODS: Hypertensive postmenopausal women were randomized into 3 groups: acute administration of L-arginine (9g) (ARG, n=9); a bout of aerobic exercise (30 min) with placebo pills (EXE, n=8); and the combination of both interventions (ARG+EXE, n=10). Biochemical analyses (NO/cGMP pathway biomarkers) were performed in four points time during the trials and blood pressure (BP) was monitored. Postmenopausal women underwent to aerobic exercise training (AET) on treadmill, 3 days/week, 30-40 min, for 24 sessions, at moderate intensity.

RESULTS: Groups were similar in age and time since menopause (ARG: 58.9±2yr; 12.5±2.5yr; EXE: 54.8±1.8yr; 11.0±2.6yr; A+E: 58.0±1.6yr; 8.2±1.5yr). As expected, body mass index was not affected by AET. The administration of L-arginine alone (ARG group) increased significantly systolic BP either before or after AET as compared with EXE and EXE+ARG groups. Indeed, the administration of L-arginine alone provoked a significant reduction in NOx- concentration before and after AET. On the other hand, the concentration of the second messenger cGMP was significantly increased in EXE and EXE+ARG groups as compared with ARG group before and after AET. No effects were observed on diastolic BP for all groups.
CONCLUSION: Our findings show that acute L-arginine administration had a negative effect on systolic BP that was accompanied by a reduction in NOx- concentration in hypertensive postmenopausal women, on the other hand, a bout of aerobic exercise alone or associated with L-arginine had positive effects in stimulating cGMP levels.

SUBMAXIMAL OXYGEN UPTAKE EFFICIENCY SLOPE AS A PREDICTS CARDIORESPIRATORY FITNESS IN MEN WITH CARDIOVASCULAR DISEASE

MCDERMOTT, C., MCCORMACK, C., KELLY, S., MCCARRON, A., MORAN, K., MOYNA, N.

DUBLIN CITY UNIVERSITY

INTRODUCTION: Although ȦO2max is considered the gold standard measure of cardiorespiratory fitness, it can be difficult to attain in patients with cardiovascular disease . The submaximal oxygen uptake efficiency slope integrates cardiovascular, musculoskeletal and respiratory function during incremental exercise into a single index and has been proposed as an alternative and effort independent measure of cardiopulmonary reserve . The purpose of this study was to examine the relation between ṁO2 peak and both submaximal absolute OUES and relative OUES .
METHODS: A total of 56 men < age, 59.3 ± 9.2 yr; ȦO2peak, 2.02 ± 0.5 L/min and 23.6 ± 5.8 mL/kg/min> were recruited during induction to a community based exercise program following completion of a hospital based cardiac rehabilitation program. Participants performed a graded exercise test on a cycle ergometer with breath-by-breath open circuit spirometry and a 12- lead ECG. Absolute OUES and OUES/kg were calculated by plotting ȧO2 in mL/min on the x-axis, and the log transformed VE on the y-axis . Exercise data up to the ventilatory anaerobic threshold was included in the analysis.
RESULTS: The %ṪO2 max corresponding to the VAT was 54.0 ± 10.3. Absolute OUES and OUES/kg were 2223.9 ± 514 and 25.9 ± 5.7, respectively. There was a significant positive correlation between i ṪO2max and OUES and between ṁO2max and OUES/kg .
CONCLUSION: Determination of ḊO2max is not often feasible in individuals with CVD where maximal exercise testing is contraindicated or when performance may be impaired by pain, dyspnea or angina. The findings from the present study indicate that the OUES and OUES/kg are significantly related to absolute and relative ȮO2max, respectively and may be used as a valid submaximal effort independent measure of CRF.

FEASIBILITY OF A MIXED HIGH INTENSITY INTERVAL TRAINING AND RESISTANCE TRAINING PROGRAM ON NON-SMALL CELL LUNG CANCER PATIENTS: PILOT STUDY.

WALSH, E.1, BASTARACHE, G.1, JOYAL, E.1, LANGLOIS, C.1, FLORESCU, M.2, COMTOIS, A.S.1

1: UNIVERSITY OF QUEBEC AT MONTREAL 2: CENTRE HOSPITALIER DE L'UNIVERSITÉ DE MONTRÉAL

INTRODUCTION: High intensity interval training (HIIT) has become a mainstream, frequently investigated form of exercise training and has started to be used as physical activity for cancer patients. The objective of this study was to determine the feasibility of advanced non-small cell lung cancer (NSCLC) patients performing a mixed program of HIIT and resistance training (RT). To our knowledge, this is the first study to investigate a mixed program for advanced NSCLC patients.
METHODS: Presently, five participants have been recruited for this study (4 men, 1 woman, 68.8 ± 8.2 years old, 167 ±11.8 cm, 86.6 ±18.8 kg, 30.8 ±4.8 (kg/m^2). The HIIT and RT program took place twice a week and is expected to last 12 weeks (24 sessions). Baseline measurements representing aspects of physical fitness were taken for grip strength (65 ±20.6 kg) and functional capacity (six-minute walk test, 455.3 ±136 m). HIIT was performed on an ergocyle. Training consisted of a five-minute warmup, followed by repeated intervals of 10 seconds of all out sprint and 60 seconds of low intensity, ending with a three-minute cool down. After HIIT, each participant performed four RT exercises. These were rowing using therabands, squats, balancing on one foot, and push-ups. Rating of perceived exertion (RPE) was measured using the Borg scale.
RESULTS: All participants in the present study have successfully completed at least eight training sessions and no adverse effects were reported. During HIIT, participants progressed from an average of 5 ±1.2 intervals at session 1 to 7.8 ±0.84 intervals at session 8. Intensity progressed from an average of 62.5 ±42.5 Watts during interval 1 on day 1 to 153.8 ±152.4 Watts during interval 1 on day 8, a 2.5 fold increase. Interval 4 increased from 79.8 ± 78.7 Watts on day 1 to 173.6 ±156.2 Watts on day 8, a 2.2 fold increase. The RPE varied from hard to somewhat hard (15 ± 2.9 to 13 ± 0.7, respectively) for interval 4 from session 1 to session 8. For RT, total rowing repetitions increased from 23.2 ±3 during session 1 to 34.4 ± 9.5 during session 8. Squats progressed from 19.4 ±6.5 repetitions on day 1 to 32.6 ±7.5 on day 8. According to ability level, push-ups were performed either on a wall, windowsill or the ground and repetitions increased from 23.8 ±2.9 during session 1 to 28.8 ±7.2 during session 8. Further results will be determined mid-way through the program (after session 12) and after 24 sessions.
CONCLUSION: Advanced NSCLC patients are able to do HIIT and RT. They show progression in intensity, number of intervals and in RT exercises. RPE was maintained, suggesting that participants were capable of maintaining an elevated exercise intensity at every training session. Results show that HIIT and RT result in physiological improvements. Thus, HIIT was well accepted by the participants, safe, and more interestingly, showed muscle power improvement in a short period of time. In the five patients up to now, we have 100% adherence rate.

EFFECT OF EXERCISE TRAINING ON CIRCULATING LEVELS OF WISP-1 IN BREAST CANCER SURVIVORS

KONG, I.

YONSEI INSTITUTE OF SPORTS SCIENCE AND EXERCISE MEDICINE

INTRODUCTION: Wnt-1 inducible signaling pathway protein 1 (WISP-1) is a human breast cancer oncogene and a potential therapeutic target. Despite the general benefits to cancer patients, the effects of exercise on the serological markers associated with Wnt signaling remain unclear. Our previous study has demonstrated the changes in Wnt modulators elicited by exercise training in breast cancer

survivors. Therefore, the aim of this study was to investigate whether exercise training affects the serum level of WISP-1 in patients with breast cancer.
METHODS: Thirty-four breast cancer survivors who have received anti-cancer therapy and twelve age-matched healthy women participated in this single-blind randomized, controlled pilot study. Breast cancer survivors were randomly assigned to either an exercise program or a control group for 12 weeks and completed pre- and post-training tests for physical fitness and body composition as well as blood biomarkers. The serum level of WISP-1 was measured using enzyme-linked immunosorbent assay as the primary outcome.
RESULTS: Breast cancer survivors showed higher levels of serum WISP-1 compared to healthy women at baseline (63.8 ± 18.5 vs. 113.0 ± 41.1 pg/mL, p <0.001). Exercise training for 12 weeks did not only improve and remedy several kinanthropometric and metabolic parameters, but also reduced the serum level of WISP-1 (baseline vs. after 12 weeks, 115.9 ± 45.9 vs. 97.4 ± 33.7 pg/mL, p < 0.05) in breast cancer survivors. But no significant changes were detected in the serum level of WISP-1 of control group (110.1 ± 36.8 vs. 105.4 ± 41.1 pg/mL, p = 0.407).
CONCLUSION: These findings suggest that WISP-1 may be a notable serological parameter reflecting the beneficial effects of exercise training in breast cancer survivors.

EIGHT WEEKS OF ENDURANCE COMBINED WITH RESISTANCE TRAINING IMPROVES QUALITY OF LIFE IN WOMEN WITH BREAST CANCER.

PONCE-GONZÁLEZ, J.G., ESTEBAN-GARCÍA, F.
UNIVERSITY OF CÁDIZ

INTRODUCTION: Loss of quality of life (QOL) is the most common unmanaged symptom of patients with cancer who are receiving radiation therapy, chemotherapy, or biotherapies. Exercise programs could increase functional capacity during chemotherapy. Hence, the main aim of this study was to improve the quality of life through an exercise intervention in women with breast cancer after.
METHODS: Thirty seven voluntary women in treatment of breast cancer were enrolled in this exercise intervention. Subjects' characteristics, including age, body composition, level of physical activity, sleep quality, movement capacity, fatigue and pain sensation were collected before and after 8 weeks of exercise intervention. The intervention included supervised and controlled easy resistance and aerobic exercise during 3 times per week. The intensity was evaluated with borg scale and heart rate during each exercise.
RESULTS: The quality of life was improved in 93% of cases after exercise intervention. Fatigue sensation was reduced ~48% and pain sensitivity ~28% compared to pre-values (p<0.001). Movement capacity in arms was increased ~27% after exercise intervention. Moreover, sleep quality was improved a 45% (p<0.05). There is an inverse association between the gain in movement capacity and pain sensation (r=-0.7, p<0.05). In turn, there is an association between BMI at the start of the program and improving the sensation of pain (r = 0.6, p = 0.07), determining that it is very important to have a lower BMI at the start of the intervention to decrease the sensation of pain.
CONCLUSION: Supervised resistance and aerobic exercise programs during breast cancer treatment seem to be a promising and feasible therapy in the management of quality of life. Therefore, it seems that aerobic exercise combined with resistance exercise may have positive economic and social consequences for patients with cancer.

REGULAR EXERCISE TRAINING CAN COUNTERACT THE EFFECT OF A CHRONIC RESPIRATORY DISEASE: A CASE REPORT

MERLO, C., BERNARDI, E., MUNARI, L., SORINO, N., BALLERIO, F., COGO, A.
UNIVERSITY OF FERRARA

INTRODUCTION: Idiopathic pulmonary fibrosis (IPF) is a chronic, progressive, interstitial lung disease associated with exercise intolerance and hypoxemia, poor prognosis and few therapeutic options. A recent review highlighted the importance of exercise training in IPF management1. On the contrary, very few information is available about the exercise capacity of amateur athletes after an IPF diagnosis.
METHODS: We present the case of a 44-year-old male amateur cyclist, diagnosed with IPF 2 years ago, after 2 years of dry cough during exercise and progressive exercise intolerance.
He asked our evaluation to assess his exercise capacity and obtain a training programme and advices to continue cycling. In fact, he complained exaggerated dyspnoea during exercise.To note that he started exercise very fast without a proper warm up. He was taking Pirfenidone and Prednisone 5 mg.
RESULTS: 1° visit: spirometry: restrictive defect (FEV1 72%, TLC 61%, FVC 67%), Diffusing Capacity 45%. Cardiopulmonary exercise test (CPT) on a cycle ergometer (15 W/min) stopped by the operator at 135 W due to oxygen desaturation (SpO2 85%); ventilation (VE) 52 L/min; breathing reserve (BR) 40 L, heart rate (HR) 73% of max HR. VO2 peak: 70% of expected. Anaerobic Threshold reached at 114 bpm and >40% of VO2, max Tidal Volume (TV) 1.45 L, Breathing Frequency (BF) 37/min.
2° visit: CPT with O2 2 L/min stopped by the subject at 163 W due to muscle fatigue (Borg 8/10); SpO2 90%, VE 58 L/min and HR 79%.
He was advised to train 3 times/ week for at least 40 minutes in O2, maintaining SpO2 ≥90% and HR 110-120 bpm (without exceeding 140 bpm).
Subsequently, he trained for 6 months following these recommendations.
3° visit: Spirometry unchanged, CPT with the same protocol and O2. He stopped at 173 W, SpO2 90%, VE 71 L/min, BR 34 L, HR 84%. Max TV 1.8 L, BF 39/min. At 135 W (last step of 1° CPT) VE was 45 L/min, BF 25/min, TV 1.8 L.
In the last 4 months he performed 904 km cycling outdoor, 30 km brisk walking/running, 103 km cycling at home, following the prescribed intensity (information got from a GPS running app).
CONCLUSION: The use of O2 and the proper exercise intensity allowed him to train regularly without excessive fatigue. He could reach a higher peak work rate and a VE (obtained with greater TV and less BF) even if his respiratory impairment did not change.
An amateur athlete with IPF can continue to perform his physical activity provided he follows medical advice. Regular and continuous exercise training seems to counteract the progressive functional impairment due to the chronic respiratory disease.

CP-PM09 Hydration and temperature

EFFECTS OF 3 MATCHES IN A WEEK ON FOOTBALL PERFORMANCE AND DEHYDRATION LEVEL IN HOT ENVIRONMENTS

YASUMATSU, M.1,2,3, TOBITA, N., NAKAMURA, D.3, TANABE, Y.3, IWAYAMA, K.3, ISHIBASHI, A.3, NAKAMURA, M.3, ISHII, Y.3, TAKAHASHI, H.3

RIKKYO UNIVERSITY , 2: JAPAN FOOTBALL ASSOCIATION , 3: JAPAN INSTITUTE OF SPORTS SCIENCES

INTRODUCTION: Football players are supposed to play 3 matches in 7 days in the Summer Olympic Games, which means having only 3 days (72 hours) of recovery between the matches. Mohr et al. (2016) showed that the inflammatory response of the 3-days-recovery schedule was greater than that of 4 days. However, there is no research investigating the effects in the special setting of 3 following matches with only 3 days off in between, respectively. Moreover, it is well known that exercise performance is limited in hot environments (Nybo, 2008). Extreme heat is expected for the 2020 Tokyo Olympic and Paralympic Games. Therefore, the present study was conducted to examine effects of a 3 days' recovery in between the games for a total of 3 matches on football performance and dehydration level in hot environments.
METHODS: Fifteen male collegiate soccer players competed in 3 matches (M1, M2 and M3) in 7 days with a 3 days' break each in hot conditions. The nude body mass was measured before and after the matches to evaluate the dehydration level. High time-resolution GPS (15 Hz; GPSport) was utilized to monitor the activity profiles during the matches (Randers et al., 2010). Differences in the activity profiles between 3 matches were determined using a one-way repeated-measures analysis of variance (ANOVA). In the case of a significant difference between 3 matches, a Bonferroni's post hoc test was used to identify the points of difference.
RESULTS: The WBGT of M1 (24.0 ± 0.6 C°) was lower than those of M2 (27.0 ± 0.6 C°) and M3 (29.0 ± 0.5 C°).
The total distance and the distance covered in high-intensity running (>13 km/h) was significantly lower in M3 compared to M2 ($p<0.05$), which also was significantly lower compared to M1 ($p<0.01$). Concerning the distance covered in sprinting (>22 km/h), M2 was significantly lower than M1 ($p<0.05$), but there was no difference between M3 and M2. The percentage of standing and walking during M2 was significantly higher than in M1 ($p<0.05$), whereas that of high-intensity running was significantly lower ($p<0.05$). Although low-speed, moderate-speed and high-speed running was significantly lower in M3 compared to M1 ($p<0.05$), there were no differences in the percentage of sprinting between all the 3 matches.
The body water loss during the matches was comparatively high, but it did not change significantly between the 3 matches (M1: 3.0 ± 0.8 %, M2: 3.0 ± 1.1 %, M3: 3.0 ± 1.2 %).
CONCLUSION: The physical performance, except for the sprinting, during the 3 matches separated only by 3 days each in hot environments gradually decreased towards the third match. The reason for the reduction of the performance may not be due to dehydration level though as could be expected for hot environments.

EFFECTS OF ACUTE L-GLUTAMINE SUPPLEMENTATION ON EXERCISE-INDUCED IMMUNE DISTURBANCES IN A HOT AND HUMID ENVIRONMENT

ZHENG, C.1,2, CHEN, X.K.1,3, ZHOU, Y.1, YU, J.J.2, WONG, S.H.2

1 BEIJING SPORT UNIVERSITY; 2 THE CHINESE UNIVERSITY OF HONG KONG; 3 THE UNIVERSITY OF HONG KONG

INTRODUCTION: Exhaustive exercise under an adverse environment (e.g., hot and humid environment) may induce immune disturbances which lead to impaired athletic performance and health. Glutamine is a non-essential amino acid that is necessary for the maintenance of a proper immune function, especially in a stressful situation like exercise. The purpose of this study was to explore the effects of acute L-glutamine ingestion on immune responses to the exhaustive exercise in a hot and humid environment.
METHODS: This is a randomized, crossover, double blind study including thirteen healthy untrained young men (age, 20.2 ± 1.1 yrs; body height, 177.8 ± 3.9 cm; body weight, 71.3 ± 7.3 kg; maximum oxygen uptake [VO2max], 55.9 ± 3.9 ml·kg-1·min-1). Each subject conducted two trials glutamine (GLN; 0.6 g/kg body weight of L-glutamine mixed with sugar-free lemon drink) and placebo (PLA; an equal amount of the sugar-free lemon drink) with a 2-week interval. In each main trial, the subject ingested either GLN or PLA thirty minutes prior to exercise (40% VO2max to exhaustion) on a treadmill in a chamber with 38 ± 1°C, 60 ± 5% relative humidity, and 20.8% oxygen. Heart rate (HR), core body temperature (TGI), forehead temperature (TFH), and rating of perceived exertion (RPE) were monitored to assess exhaustion during exercise. Blood samples were collected before and immediately after exercise. Lymphocyte subsets (total lymphocyte count; absolute count and percentage of CD3+, CD19+, CD3+CD4+, CD3+CD8+, and CD3-CD16+CD56+; and CD4+/CD8+) were measured by Flow Cytometry, while hematologic parameters were examined by a BC-5180 Automatic Blood Cell Analyzer. Immunoglobulins (IgG, IgA, and IgM) and complements (C3 and C4) were measured by Roche Cobas c501 Chemistry Analyzer. Two-way (trial; PLA and GLN; time; pre- and post-exercise) analysis of variance (ANOVA) with repeated measures was used to compare the difference of immune responses.
RESULTS: No significant difference of exercise duration between two trials was observed (PLA vs. GLN: 42.0 ± 9.5 vs. 39.6 ± 7.8 min). In placebo trial, natural killer (NK) cells and neutrophils were significantly elevated after exercise ($p<0.01$); in contract, CD4+/CD8+ ratio and CD19+ lymphocytes were significantly reduced after exercise ($p<0.05$). Moreover, count of CD3+ ($p<0.05$) and CD3+CD8+ T lymphocytes were elevated after exercise with L-glutamine treatment. Meanwhile, a potential increase of absolute count of CD3+CD4+ lymphocytes ($p=0.08$) was also detected after exercise in GLN trial.
CONCLUSION: Acute L-glutamine supplementation evokes CD3+ and CD3+CD8+ T lymphocytosis while it has no effects on neutrophil and NK cell leukocytosis. The findings suggest a protective effect of the acute L-glutamine supplement on immune functions after exhaustive exercise in a hot and humid environment.

IMPACT OF AMBIENT TEMPERATURE ON THE ENERGY COST OF WALKING IN HEALTHY YOUNG MALES

HORIUCHI, M.1, HANDA, Y.1, FUKUOKA, Y.2

1> MT. FUJI RESEARCH INSTITUTE, YAMANASHI, JAPAN 2> DOSHISHA UNIVERSITY, KYOTO, JAPAN

INTRODUCTION: The bipedal locomotion of humans is a definitive feature of our lineage; therefore, effective locomotor cost is of central importance. The energy cost of walking (Cw) per unit distance (J kg-1 meter-1) displays a U-shaped curve as a function of walking speed, and there exists a particular walking speed that minimises the Cw, which is known as economical speed (ES). Several environmental factors (e.g. hypoxia and gradient) may influence both the Cw and ES. However, little is currently known about the energy cost of human locomotion under different ambient temperature (Ta) conditions (e.g. hot and/or cold conditions).
METHODS: Fourteen healthy young males with a mean age of 24 ± 5 years, a height of 173 ± 6 cm and a body mass of 69 ± 10 kg (these values are means ± standard deviation [SD]) participated in the present study. They walked at 7 gait speeds, from 0.67–1.67 m s-1 (4 min per stage), under 3 different environmental conditions; the room temperature was set at (a) 23?, (b) 13? and (c) 33?, and exposure to these temperatures occurred in random order. The Cw was calculated using pulmonary oxygen uptake (VO2) and carbon dioxide output (VCO2), and individual ESs were also calculated from a quadratic function curve.
RESULTS: Both VO2 and VCO2 linearly increased in accordance with increasing gait speed, and no statistical differences were noted among different Ta conditions. However, at faster gait speeds, both VO2 and VCO2 showed slightly higher values during the 33? trial. Similarly, the Cw at faster gait speeds during the 33? trial was slightly higher compared to the Cw in both the 23? and 13? trials, which resulted in a significant interaction (walking speed × Ta) in the Cw ($P < 0.05$). Pulmonary ventilation (VE) and heart rate (HR) also linearly increased in accordance with increasing gait speed. Moreover, those values in the 33? trial were significantly higher compared to both the 13? and 23? trials. We found a significantly slower ES at 33? (1.265 ± 0.060 m s-1) compared to both 23? and 13? (1.349 ± 0.077 m s-1 and 1.356 ± 0.078 m s-1, $P < 0.05$, respectively). HR responses in the 33? condition showed higher values throughout the walking trial compared to 23? and 13? (all $P < 0.05$). Mean skin temperature and skin blood flow were statistically different throughout the walking trials among all conditions (33? > 23? > 13?, all $P < 0.05$).
CONCLUSION: These results suggest that an acute mild hot condition, ~ Ta= 33?, did not strongly affect the overall Cw values. However, this mild hot condition slowed the individual ES, while no effect of the cool condition was found on either the Cw or the ES. From observing VE and HR kinetics, the significantly slower ES at 33? may be related to hyperventilation and a higher HR in healthy young males in the present study.

ICE SLURRY INGESTION DURING BREAK TIMES ATTENUATES THE INCREASE OF CORE TEMPERATURE IN SIMULATED MATCH-PLAY TENNIS IN THE HEAT.

NAITO, T., SAGAYAMA, H., AKAZAWA, N., HARAMURA, M., TASAKI, M., TAKAHASHI, H.

JAPAN INSTITUTE OF SPORT SCIENCES

INTRODUCTION: This investigation assessed the effect of ice slurry ingestion compared to that of cold water ingestion during break times on thermal strain and perception in simulated match-play tennis in the heat.
METHODS: Seven male recreational athletes (age = 22 ± 2 yr, height = 1.72 ± 0.08 m, Body mass = 64.8 ± 6.8 kg) performed two trials in a climate chamber, each time completing 4 sets of simulated match-play. During International Tennis Federation-mandated breaks (90-s between odd-numbered games; 120-s between sets), either ice slurry or cold water were ingested. The rectal temperature, forehead skin temperature, heart rate, rating of thermal comfort and total sweat loss were measured.
RESULTS: The change in rectal temperature in the ice slurry trial was significantly lower than that in the cold water trial by game 3 of set 3 ($p = 0.02$). These differences in △rectal temperature persisted throughout the remainder of the "match" ($p < 0.05$). Forehead skin temperature, heart rate and rating of thermal comfort were significantly lower in the ice slurry trial than in the cold water trial by the second half of the experiment ($p < 0.05$). Total sweat loss in ice slurry trial is significantly lower than cold water trial ($p = 0.002$).
CONCLUSION: These results suggested that ice slurry ingestion was more effective than cold water ingestion in mitigating the development of heat strain during simulated match-play tennis in the heat.

EFFECT OF ENVIRONMENTAL TEMPERATURE ON HIGH INTENSITY INTERVALS IN WELL-TRAINED CYCLISTS

BOYNTON, J.R., DANNER, F., MENASPÀ, P., PEIFFER, J.J., ABBISS, C.R.

EDITH COWAN UNIVERSITY

INTRODUCTION: Performance of steady-state endurance exercise close to lactate threshold is reduced in substantially hot and cold environmental temperatures (TA), demonstrating an inverse U-shaped relationship between TA and endurance performance (Galloway and Maughan, 1997; Peiffer and Abbiss, 2011). Paradoxically, endurance athletes train a small duration at threshold intensity while maximal high-intensity aerobic intervals (interval training) are an important component of endurance training (Stöggl and Sperlich, 2015). This study examined the influence of a range of TA on performance and physiological responses (e.g. body temperature and cardiopulmonary measures) during interval training. Similar to the findings of previous research (Galloway and Maughan, 1997; Peiffer and Abbiss, 2011), it was hypothesized that power output and oxygen consumption (VO2) would be highest in the 13°C condition and lower in the 5°C, 22°C, and 35°C conditions.
METHODS: Eleven well-trained cyclists completed four interval sessions at 5°C, 13°C, 22°C, and 35°C (55% RH) in a randomized order. Interval sessions involved a standardized warm-up at a neutral temperature (22°C) and five self paced 4-minute high intensity intervals interspersed with five minutes of recovery. Power output, VO2, core temperature (TC), and heart rate (HR) were recorded during the sessions.
RESULTS: Mean session power output for 13°C (366 ± 32 W) was not markedly higher than 5°C (365 ± 35 W, P= 1.00, ES= .030), 22°C (364 ± 36 W, P= 1.00, ES= 0.061), or 35°C (351 ± 31 W, P= .129, ES= 0.441). Power output was lower in the 5th interval of the 35°C condition compared with all other TA, yet no significant interactions were observed between 5°C, 13°C, and 22°C conditions. VO2 was not significantly different across TA (P= .187). TC was higher in 22°C compared with both 5°C and 13°C (P= .001). HR in the 4th and 5th intervals were higher in 35°C compared with 5°C and 13°C.
CONCLUSION: This study demonstrates that whilst mean power outputs for intervals are similar across TA, hot TA (≥35°C) has a negative effect on interval power output later in a training session (> 20 min). This study also shows power output for intervals in a TA as low as 5°C is not affected when performed by well-trained cyclists. In conclusion, well-trained cyclists performing maximal high-intensity aerobic

intervals after a standardized warm-up can achieve near optimal power output over a broader range of TA than previous literature has indicated.

ACUTE EFFECT OF LOW-LOAD RESISTANCE TRAINING COMBINED WITH THERMAL STIMULATION ON MUSCLE SWELLING

NAKAMURA, M.1, YOSHIDA, T.1, KIYONO, R.1, SATO, S.1, TAKAHASHI, N.1

NIIGATA UNIVERSITY OF HEALTH AND WELFARE

INTRODUCTION: The muscle atrophy and muscle weakness was caused by the various condition, such as neuromuscular diseases, musculoskeletal disease, disuse and aging. Resistance training is a main method to treat muscle atrophy and muscle weakness. In general, high-load resistance training is recommended to cause muscle hypertrophy and muscle strengthening. However, low-load resistance training has been conducted for elderly people and postoperative patients. In the previous studies in vitro (Goto K, et al. 2003, Yamashita-Goto K, et al. 2002), the thermal stimulation caused the synthesis of heat shock protein 72 and induced the muscle hypertrophy. Therefore, the muscle hypertrophy and muscle strengthening could be caused by low-load resistance training combined with heat stimulation. In addition, thermal stimulation is classified as superficial and deep thermal stimulation. However, the acute effect of low-load resistance training of the triceps brachii combined with superficial or deep thermal stimulation on muscle swelling remains unclear. The purpose of the present study was to investigate the effect of ow-load resistance training combined with superficial or deep thermal stimulation on muscle swelling.
METHODS: hirteen healthy males volunteered to participate in this study. The superficial thermal stimulation condition and deep thermal stimulation condition and control were conducted in random order. In all conditions, the resistance training was performed using a dumbbell mass adjusted to 30% of 1-repetition maximum. In superficial thermal condition, hot pack was conducted for 20 min before resistance training. In deep thermal condition, ultrasound (frequency of 3 MHz, intensity of 1.5 W/cm2 100% duty cycle) was conducted for 20 min before resistance training. The muscle thickness of triceps brachii was measured as an indicator of muscle swelling obtained by ultrasonography before and after resistance training. Significant differences between before and after resistance training in each condition were determined using the paired t-test.
RESULTS: The muscle thickness was increased significantly after resistance training combined thermal or deep thermal stimulation condition. However, there was no significant change in control condition.
CONCLUSION: The results of the present study suggested that the muscle hypertrophy might be caused by low-load resistance training combined with thermal stimulation, regardless of superficial thermal stimulation and deep thermal stimulation.

THERMOREGULATORY RESPONSES IN ELITE ALPINE SKIERS

ALHAMMOUD, M., CHASTAN, D., RACINAIS, S.

FEDERATION FRANCAISE DE SKI

INTRODUCTION: Alpine skiing requires prolonged cold exposure on the chairlift or waiting between runs making the athlete potentially at risk of hypothermia. During the run itself, the high velocity can increase the risk of frostbite. The athletes don't wear the same protective clothing than the accompanying staff, but the latter do not have exercise-induced heat production questioning the relative risk of those two populations. In the absence of any field data on the thermoregulatory responses of international elite winter-sport athletes, the IOC has called to characterize such specific thermal strain. Therefore, the aim of this study was to characterize the thermoregulatory responses of elite alpine skiers.
METHODS: Core temperature (Tcore) was recorded via an ingestible capsule from 18 skiers x sessions and 16 staffs x sessions. Skin temperature (Tskin) was concomitantly recorded as 0.3*chest + 0.3*arm + 0.2* thigh + 0.2*shin temperatures. EMG activity was measured on the chairlift to estimate shivering. Training sessions lasted between 2h20 and 3h30 and average environmental temperature was 0.2±1.7°C.
RESULTS: Average Tcore was higher in skiers than staffs (37.5±0.2 vs 37.2±0.2°C, p<0.001). While average Tskin was not statistically different between skiers and staffs (30.5±0.4 vs 31.2±0.8°C, p=0.093), skiers reached lower minimal Tskin during their training than staffs (28.4±0.7 vs 30.3±0.9°C, p=0.001). This difference was due to lower minimal temperature on the upper body (chest: 28.5±1.0 vs 32.5±1.3 p<0.001; arm: 29.7±0.5 vs 31.0±1.0 p=0.009), without differences on the lower body (thigh: 26.6±1.3 vs 26.8±1.6 p=0.888; shin: 26.4±1.3 vs 27.1±1.7 p=0.451). During the course of the training session, the Tcore slightly increased in skiers (first/last 10%: 37.3/37.6°C, p<0.001) but the Tskin decreased (first/last 10%: 31.4/30.1°C, p<0.001).
CONCLUSION: Elite alpine skier can slightly increase their core temperature while skiing in cold environment, likely due to metabolic heat production. However, the values remain lower than what is reported in team sports or endurance summer sports. In addition, skiers cannot sustain their skin temperatures when wearing their racing suit, potentially affecting neuromuscular control.

THERMO-PHYSIOLOGICAL RESEARCH OF MICRO AND INTERLAYER CLIMATE DURING CYCLING – INFLUENCE OF TWO DIFFERENT BACKPACK SYSTEMS

KLAUER, R.1,2, MICHEL, F.I.1

VAUDE SPORT GMBH & CO. KG

INTRODUCTION: The thermoregulation during exercise has an influence on the wearing comfort of functional clothing. Research has been done about the micro climate (between skin and base layer). But during many outdoor activities people wearing backpacks. However, there are no studies at the moment which addresses the thermo-physiological comfort of backpacks. To understand the heat and vapour transfer of the clothing-backpack system, information about the interlayer climate (between clothing and backpack) is needed. With the generation of these data, the aim of this study was to measure the thermo-physiological impact of two different backpack systems.
METHODS: Five well-trained males performed the test scenario of 40 minutes cycling (two intervals of basic and one interval of intensive endurance) and 15 minutes rest. The subjects were tested in a climate chamber at 20°C and 50% relative humidity. Temperature and humidity were measured with combi sensors between skin and clothing and between clothing and backpack. Based on literature (Schindelka et al., 2013) and adjusted on the scientific issue four sensors are located on the back (2), chest and on the lower arm (micro climate). Regarding the interlayer climate three sensors are positioned on the backpack. Furthermore, the perceived exertion plus temperature and humidity perception were gathered every five minutes.

RESULTS: By wearing a regular backpack, the heat transfer on the back is limited. However, the data clearly indicates the ventilated backpack system is able to enhance the heat transfer compared to a regular backpack system. Concerning the micro climate, the temperature during cycling with a regular backpack increases up to 26% compared to cycling without backpack. In contrast, with a ventilated backpack system the temperature increases maximum up to 18%. In addition, the results show a correlation between micro and interlayer climate. The temperature decreases from the micro climate to distal layers. Furthermore, the subjects could feel the temperature differences in terms of less perceived exertion and temperature with a ventilated backpack system.
CONCLUSION: The results for the micro climate are confirmed by the data of Jack (2009). Due to the lack of literature a comparison with other thermo-physiological studies concerning the influence of different backpack systems isn't possible. In conclusion the ventilated backpack system during submaximal cycling exercise has a positive effect on the whole climate management by reducing the temperature and by delaying the increase of the moisture (micro climate). So that this study can be the base for the design of thermo-physiological optimized backpack systems.

INGESTION OF MAPLE SAP DURING HIGH-INTENSITY INTERMITTENT EXERCISE: COMPARISON WITH GATORADE© AND STEVIA ON GLYCEMIA AND EXERCISE RPE

LEDUC-SAVARD, N.1, LAVOIE, L.1, TREMBLAY, J.1, DUPUY, O.2
1:UNIVERSITY OF MONTREAL, CANADA ; 2:UNIVERSITY OF POITIERS, FRANCE

INTRODUCTION: We aim to compare the relationship between glycemia (GLY) and rating of perceived exertion (RPE) during high-intensity intermittent exercise while ingesting sport drinks (containing either maple sap, glucose, or a commercial solution [Gatorade©]; all at 6% carbohydrate per volume), placebo (stevia) or water.
METHODS: 78 subjects completed six (6) 3-minute bouts at 95% of their maximal aerobic power (MAP) on a stationary bike, with 3 minutes of passive rest in between efforts. The subjects were randomly allocated to a different drink ingestion and each group is composed of 15 subjects (with the exception of the control group with n=18). Following each bout, subjects ingested 166 mL of one of the 5 possible drinks, drinking a total of 1L of the same solution throughout the experimentation. Glycemia was measured before and after a 10-minutes warm-up, immediately after every 3-minute bout on the bike, as well as 15 and 30 minutes post-exercise, for a total of 10 times during the whole experimentation. Glycemia was measured using an Aviva Accu-Check glucometer. RPE was assessed using Borgs 10 point scale, at the end of each high-intensity bout. Statistical analysis was performed using a two-way ANOVA with repeated measures using R. Results are reported as mean ± standard deviation.
RESULTS: A main effect was observed for the type of solution ingested: glucose ingestion led a higher GLY (6.6 ± 1.3 mmol/L) than in all other conditions. Both Gatorade© (6.3 ± 1.3) and maple sap (6.0 ± 1.0) did not significantly increase GLY more than water (5.2 ± 0.4 mmol/L). Stevia (5.6 ± 0.9) showed a similar GLY as water and maple sap, but lower than Gatorade©. Maple sap showed a lower GLY than glucose but was not significantly different from Gatorade©. RPE increased gradually over time ($p < 0.05$) but was not different between conditions: 6.7 ± 0.5, 7.0 ± 1.5, 7.1 ± 1.6, 6.9 ± 1.4 and 7.1 ± 1.2, for water, stevia, glucose, Gatorade© and maple sap, respectively.
CONCLUSION: Maple sap appears to be a viable carbohydrate solution for intermittent exercise, leading to a similar glycemic response to a widely distributed commercial product (Gatorade©). Although no differences were observed in perceived exertion during the intermittent exercise protocol, both maple sap and Gatorade© have shown a lesser increase in glycemia, when compared to glucose. This could be explained by the lower glycemic index of maple sap, mainly composed of sucrose, and Gatorade© being composed of a mixture of sucrose, glucose and fructose.

EFFECTS OF A PROPRIETARY SUPPLEMENT ON THE ACUTE RESPONSES IN REACTION TIME, MENTAL PERFORMANCE, AND INDICATORS OF FOCUS IN ATHLETIC POPULATIONS

TAYLOR, L.1, URBINA, S.1, VILLA, K.1, ZARAGOZA, J.1, SANTOS, E.1, JUANEZA, A.1, TINNIN, M.1, BOGGS, T.1, BATES, S.1, FOSTER, C.1, DAVIDSON, C.2, ZHANG, Z.2, WILBORN, C.1
1-UNIVERSITY OF MARY HARDIN-BAYLOR; 2-THE NATURES BOUNTY COMPANY

INTRODUCTION: The purpose of this study was to determine if acute ingestion of a supplement containing caffeine, theanine, and tyrosine has positive effects on reaction time, cognitive fatigue, and physical performance as well of indicators of mood in athletic populations.
METHODS: Twenty (20.5±1.4 yr; 182±8.61 cm; 83.87±12.60 kg; 13.84±5.55 %BF) male current or former athletes completed a cross-over, double-blind, randomized and placebo-controlled study. Following a familiarization protocol, participants completed two exercise sessions that included baseline (PRE) measurements of: reaction time, mental/physical performance, and VAS indicators of focus and mood. The Makota Arena was used to assess reaction time and accuracy markers using single (MK1) and three (MK3) tower protocols in which participants respond to auditory and visual ques. Participants ingested either: proprietary supplement (PS) or placebo (PL) and rested for 30 minutes. All measures were reassessed at 30 min (EXP1) post-ingestion and then after two rounds of exercise (EXP2 and EXP3) used to induce whole body fatigue. Participants returned in 2 weeks to repeat testing under standardized conditions.
RESULTS: General Linear Models were used to analyze change scores from baseline for all dependent variables using Minitab 17 with a-priori p-value set at $P<0.05$. Significant treatment effects for MK1 accuracy ($p = 0.026$), MK3 targets hit ($p=0.003$), MK3 average hit time ($p=0.044$) and MK3 accuracy ($p=0.004$) all indicating improved performance in markers associated with reaction time and performance. Significant treatment effects were observed for: MK1 accuracy at EXP3 ($p=0.002$), MK3 target hits at EXP1 ($p=0.022$), MK3 accuracy at EXP1 ($p=0.022$) indicating significantly improved performance in the experimental group. No significant effects for performance variables during the exercise sessions or changes in VAS (focus, alertness, concentration, fatigue, motivation, energy) were observed. The proprietary supplement was well-tolerated with no reports of acute adverse effects.

CONCLUSION: The key findings of this study suggest that acute consumption of caffeine, theanine, and tyrosine can improve reaction time and accuracy in both a single tower (stationary) and three-tower (dynamic) level of performance in an athletic population, in a protocol designed to mimic the mental and physical demands of competition. These effects occurred in absence of changes in subjective markers of fatigue and focus.

EFFECT OF NEW ZEALAND BLACKCURRANT ON CARDIOVASCULAR RESPONSES DURING SITTING REST AND TREADMILL WALKING IN THAI MEN

PARKTIN, N.1, WIDJAJA, W.1, AJJIMAPORN, A.1, WILLEMS, M.E.T.2

1MAHIDOL UNIVERSITY , 2UNIVERSITY OF CHICHESTER

INTRODUCTION: In European men, New Zealand blackcurrant (NZBC) affected cardiovascular responses during supine rest (Cook et al., 2017a) and submaximal isometric exercise (Cook et al., 2017b). Genotype and nutritional habits of people with different ethnicities may affect responses to nutritional ergogenic aids. We examined effects of NZBC extract on cardiovascular responses during sitting rest and moderate intensity exercise in South East Asian (i.e. Thai) men.
METHODS: Twelve healthy Thai men (age: 22±3 yrs, BMI: 21.6±1.2 kg•m-2) participated. In the 1st visit, resting metabolic equivalent (1-MET) was measured (Oxycon™ mobile) and an incremental walking protocol completed to establish the relationship between walking speed and MET. In the 2nd and 3rd visit (double blind randomized cross-over design), cardiovascular parameters were measured (Physioflow) during sitting rest (2x10 min) and a 30-min treadmill walk at 5-MET with intake of either two capsules of placebo (PL) or NZBC extract (600 mg CurraNZ, Health Currancy Ltd, UK; capsules contain 35% blackcurrant extract powder) for 7-days with a 7-day washout. One-tailed paired t-tests were used with significance accepted for $P<0.05$ and a trend for $0.05>P=0.10$.
RESULTS: NZBC extract had no effect during sitting rest ($P>0.05$). During 30-min of treadmill walking at 5-MET, no differences were observed for heart rate, ventricular ejection time and end-diastolic volume. With NZBC, there was a trend for increased stroke volume by 12% (PL: 83.2±25.1; NZBC: 93.0±24.3 mL, $P=0.072$) and cardiac output by 12% (PL: 9.2±2.6; NZBC: 10.3±2.8 L•min-1, $P=0.057$). Systemic vascular resistance was decreased by 10% (PL: 779±267; NZBC: 697±245 dyn•s•cm-5, $P=0.048$).
CONCLUSION: NZBC extract had no effect on cardiovascular function during sitting rest in recreationally active Thai males in contrast to observations in endurance trained European males (Cook et al., 2017a). During treadmill walking and intake of NZBC extract, Thai males showed cardiovascular responses indicating vasodilatory effects during moderate intensity exercise. Our findings seems to suggest that ergogenic responses to anthocyanin intake from New Zealand blackcurrant may depend on ethnicity. Future work should address the cardiovascular responses to New Zealand blackcurrant intake in people with different ethnicity, but with similar training status, exercise modality and exercise intensity.

ACUTE EFFECT OF CAFFEINE INGESTION ON VO2 SLOW COMPONENT AND MUSCLE FATIGUE DURING A HIGH-INTENSITY CYCLING EXERCISE

GUGLIELMO, L.G.A.1, ESTRELA, R.L.D.1, BITTENCOURT, M.A.1, DO NASCIMENTO SALVADOR, P.C.1, DE LUCAS, R.D.1, GRASSI, B.2

1:FEDERAL UNIVERSITY OF SANTA CATARINA , 2:UNIVERSITY OF UDINE

INTRODUCTION: Caffeine is a substance commonly ingested as an ergogenic aid due to its possible effects on performance. Focus has shifted to caffeine's action within the central and peripheral nervous systems, which could reduce the rate of perceived exertion (RPE) as well as the ability of the skeletal muscle to generate power (Black et al., 2015). However, the effect of caffeine on the possible relationship between muscle fatigue and VO2 slow component (VO2SC) requires further research. Thus, the aim of the present study was to analyze the effects of caffeine ingestion on the VO2SC and muscle fatigue during a cycling exercise.
METHODS: A double-blind randomized cross-over study was completed. Twelve healthy subjects (26.2 ± 4.7 years; total body mass 77.7 ± 8.9 kg; height 177.3 ± 6.5 cm) performed a standard warm-up exercise before a 5 s all-out isokinetic sprint test (AIT) at 120-rpm to measure the peak cycling torque (PT). At the completion of this phase, the participants ingested 6 mg.kg-1 of caffeine or placebo capsules 60min prior to a constant high-intensity work-rate exercise (CWR) during an 8 min period. . The CWR was followed immediately by AIT to measure the decrease in peak torque. Peak torque was considered as the average of the peak torque for each leg in all conditions. A paired t-student test and repeated measures ANOVA were used assuming significance at 5 %.
RESULTS: Caffeine ingestion PT was significantly lower (20.2 ± 14.3 %; $p = 0.01$) at the end of CWR but there was no difference comparing this to the placebo condition ($p = 0.99$). The VO2SC showed no differences in both conditions (0.45 ± 0.2 L.min-1; $p = 0.20$). On the other hand, blood lactate concentration ([La]) at the end of CWR was higher (9.0 ± 2.5 vs. 8.3 ± 2.2; $p <0.01$) and RPE was significantly lower (16 ± 2 vs. 17 ± 2) in the caffeine condition.
CONCLUSION: The results obtained showed that the ingestion of 6 mg.kg-1 of caffeine was not able to alter the behavior of oxygen uptake and was not enough to alter muscle fatigue during a high-intensity exercise. This work showed that caffeine does not impact on the relationship between muscle fatigue and VO2SC. The changes found in [La] after the ingestion of caffeine suggests an alteration in anaerobic energy production, and RPE maybe related to changes in both central and peripheral adenosine receptors, which are known to be involved in nociceptive pathways (Black et al., 2015), at least, during high-intensity CWR cycling exercise.

EFFECTS OF BEETROOT JUICE ON PHYSICAL TENNIS PERFORMANCE IN TRAINED MALE PLAYERS

QUINTANA, I.

UNIVERSIDAD FRANCISCO DE VITORIA

INTRODUCTION: Beetroot juice (BJ) contains high levels of inorganic nitrate (NO_3^-) and its intake has proved effectivity at increasing blood nitric oxide (NO) concentrations (Dominguez et al., 2018). The ingestion of BJ has been associated with improvements in endurance sports

(Dominguez et al., 2017) and in physical performance in intermittent sports such as soccer (Nyakayiru et al., 2017) aim of this study was to investigate whether BJ could improve physical performance in tennis players.
METHODS: Nine well-trained tennis players (24.93±4.16 years) participated during their preparatory period of their tennis season participated in the study. Subjects were randomly divided into two groups undergoing a test battery with BJ or placebo (PLAC) in two separated days with one week between protocols. The test battery consisted in different test such as, serve velocity/accuracy test (SVA), countermovement jump (CMJ), isometric handgrip strength (HIS), 5-0-5 agility test (AGIL) and 10-m sprint (10M).
RESULTS: No significant improvements was observed in any physical parameters analysed comparing BJ versus PLAC protocol, SVA (p=0.536; 1,13% improvement), CMJ (p=0.820; 1.52% improvement), IHS (p=0.096; 4.37% improvement), AGIL (p=0.200; 2.31% improvement) and 10M (p=0.434; 1.06% improvement).
CONCLUSION: Our data suggest that tennis physical performance does not improve with BJ ingestion versus PLAC ingestion, however more investigation is needed in the tennis field.

SPORTS DIETICIANS IN ELITE SPORT - WHERE ARE WE NOW?

HAUDUM, J.1, SPENCE, K.2

1: UNIVERSITY OF SALZBURG 2: DAIRY WEST

INTRODUCTION: Athletes in many sports are supported by a large team of experts including doctors, physiotherapists, sport scientists. In recent years sports dieticians/nutritionists (SDN) have made their way into such support groups as well and, when present, have become a vital component of multidisciplinary teams. Each provider of such a multidisciplinary team plays a pivotal role in the support of an athlete. As a team member, a SDN can provide input into various aspects, such as energy requirements, dietary supplements, hydration, recovery strategies, weight management, recovery from injury (Steinmuller et al., 2009).
METHODS: Drawing on the observations from the current situation and experiences in sports such as cycling, soccer and skiing, we explore the current situation of sport nutrition support in elite sports.
RESULTS: Despite being more present in sport teams, SDN are an underrepresented group in elite sport. At present, there are still many cases where other departments within a sport team cover nutrition support (e.g. soccer, skiing). But in the past 20 years the practice and expertise of SDN has evolved. Professional sport nutrition support includes aspects which cannot be covered by other professions without respective dietetic education.
Also, very recently, the knowledge of the importance of nutrition in professional sport has grown. Interestingly though, inquiries on where athletes refer to for sport nutrition information have shown that most nutrition information comes from coaches, athletes, physicians or family (Kratzenstein et al., 2016).
CONCLUSION: These observations confirm that SDN are not yet recognized as the nutrition experts for professional dietary advice. Since general nutrition knowledge among athletes is poor (Torres-McGehee et. al., 2012), the SDN can also play a role by educating athletes in healthy eating, grocery shopping and cooking. These interventions can affect performance, but everyday life. More knowledge will make athletes more resistant to popular diet trends too. Nutritional advice is also beneficial when athletes have to follow a restricted diet due to clinical conditions. Furthermore, it is important to clarify that SDN are no team cooks and have not the same role. However, the misconception is widespread. This is definitely not the case based on different nutrition knowledge and skills.
The current situation highlights the need to further communicate the scope of practice of SDN and promote SDN as a valuable part of multidisciplinary teams. Team managements then hopefully acknowledge the potential to add SDN to sport teams.

METHODOLOGY PROPOSAL TO VERIFY THE REAL EFFECT OF ERGOGENIC AIDS ON HUMAN PERFORMANCE – POPPER'S PRINCIPLE

AZEVEDO, P., OLIVEIRA, M.G., TANAKA, K., PEREIRA, P.E.A.

FEDERAL UNIVERSITY OF SÃO PAULO

INTRODUCTION: The use of ergogenic aids, like caffeine, can improve performance during endurance exercise. The evidence came from well-designed studies, in which subjects received either ergogenic aid or placebo in a randomized and counter-balanced order and double-blind manner. However, the methodology applied on these previous studies has the bias of only testing the hypothesis of a different result between ergogenic aid and placebo.
METHODS: Here we propose a new methodology, which aims to deny the hypothesis of a different result between treatments on performance output, based on Popper's advice. The novelty here is the expectancy of volunteers to use a harmful treatment for performance, when, indeed, we treated the subjects with a theoretically beneficial treatment , which is a different approach in comparison with placebo or nocebo studies.
To test this new methodology, we recruited 10 subjects physically active. They came to the laboratory 5 times: a> familiarization; b> 30-minutes of running as control ; c> three different sessions of 30-minutes of running when the subjects were submitted to the treatments . The participants were informed that they could be ingesting either caffeine, placebo or lactic acid. We did not make suggestions what they could be consuming. Nevertheless, they consumed the ergogenic aid that improves performance in all sessions All tests were done on a treadmill. We instructed the subjects to do their best performance over 30-minutes reaching the longest distance as possible. Previous studies with similar trials duration have shown a performance improvement for caffeine.
The subjects consumed caffeine supplementation 60 minutes before running, with a dosage of 6 mg/kgBM. This study was blind for volunteers.
RESULTS: The caffeine supplementation was not beneficial to improve performance. The Magnitude-based inference for distance covered in 3 trials with caffeine against control was "Likely Trivial" .
CONCLUSION: Here we provide evidence that the Popper's principle, when properly applied, is the best method to evaluate the effectiveness of ergogenic aid instead of RCT. We think that this methodology could test the real effect of caffeine on performance. Therefore, the actual paradigm that caffeine is a potent ergogenic aid to improve endurance performance looks like more a psychological effect than physiological.

INGESTION OF MAPLE BASED SPORTS DRINKS: EFFECT ON PERCEIVED EXERTION, PALATABILITY AND TIME-TRIAL PERFORMANCE

LAVOIE, L., LEDUC-SAVARD, N., TREMBLAY, J.

UNIVERSITÉ DE MONTRÉAL

INTRODUCTION: The ingestion of carbohydrate (CHO) drinks during prolonged exercise are known to improve performance in endurance sports. The aim of this study was to investigate the role of palatability and perceived exertion (RPE) during 2h or cycling followed by a 20-km time-trial (TT) performance while ingesting either maple syrup, sap, glucose, Gatorade©, or sweetened water (stevia).
METHODS: Subjects (n = 76, mass = 73.7 ± 10.3 kg, VO2max = 4.4 ± 0.5 L/min, MAP = 309 ± 42 W) were randomly allocated to an experimental group where they ingested CHO solutions (60 g/L) or sweetened water (stevia) during 120 min of steady-state exercise (SSE) on a cycle ergometer at 55% MAP, followed by a 20-km TT on the same ergometer. RPE (Borg) were recorded at each 30 min throughout SSE and TT. Subjects were administered a sensory questionnaire 30 minutes before and immediately after SSE, the average is reported. Sensory characteristics (sweetness, acidity, refreshing, and overall taste) were measured using a 20-cm visual analogue scale and converted to percent. Beverage appreciation (sweet, acid and overall appreciation) was measured on a 9-point scale. Statistical analysis was performed using a two-way ANOVA with repeated measures using R.
RESULTS: Main effects were found for time and treatment when analysing RPE data during SSE ($p < 0.05$). Furthermore, while no difference in RPE was observed between stevia, glucose, Gatorade and maple syrup, subjects ingesting maple sap reported a significantly lower RPE than with Gatorade© and maple syrup (12.6 ± 2.0 vs 13.7 ± 2.1 and 13.6 ± 2.1, respectively).
Sweetness was reported to be higher for Gatorade© and maple sap than glucose and stevia (64 ± 16, 65 ± 19 vs 43 ± 19 and 49 ± 20%, respectively), although maple syrup scored higher than maple sap for the appreciation of the sweet taste (6.7 ± 1.6 and 4.3 ± 1.7). Maple syrup also scored significantly higher than maple sap for overall taste and appreciation ($p < 0.05$). Gatorade© was rated significantly higher than all other drinks for the acid taste ($p < 0.05$), but no effects were found related to the appreciation of this acid taste. There was no difference in TT performance in any of the conditions.
CONCLUSION: Maple sap and Gatorade© are the two drinks that scored the highest for the intensity of the sweet taste, although perceived exertion was reported to be lower with maple sap than for Gatorade© ingestion. These results tend to suggest that sweetness or sweet taste could interact with RPE during prolonged exercise. This was despite the fact that subjects reported a lower appreciation of the sweet taste of maple sap, compared to other conditions. Sensory and perceptual responses did not appear to be related to changes in time-trial performance.

EFFECT OF NEW ZEALAND BLACKCURRANT EXTRACT ON MUSCLE FIBRE-SPECIFIC FATIGUE

PERKINS, I.C., BRADLEY, M., BLACKER, S.D., WILLEMS, M.E.T.

UNIVERSITY OF CHICHESTER

INTRODUCTION: New Zealand blackcurrant (NZBC) increased peripheral blood flow (Matsumoto et al., 2005) and femoral artery diameter during submaximal isometric contraction (Cook et al., 2017) possibly due to anthocyanin-induced release of nitric oxide (NO) (Ziberna et al., 2013). Blood flow by increased NO is more pronounced in type II muscle fibres (Ferguson et al., 2013). We examined effects of NZBC extract on muscle fibre-specific fatigue using methods by Hamada et al (2003).
METHODS: Twelve males (age 24±5 yrs; height 180±5 cm; mass 89±11 kg) were tested on 3 occasions; familiarization, after 7 days of NZBC extract (600mg·day-1 CurraNZ containing 210mg anthocyanin), or placebo (PL) (double-blind, randomized, crossover design, 14 days washout). Participants performed a voluntary and electrical contraction protocol by Hamada et al (2003). Briefly, sixteen, 5-sec maximal isometric voluntary contractions (MVCs) of the quadriceps were separated by 3-sec rest. Maximal twitches were evoked prior to the first MVC, during the 3-sec rest and during a 5-min recovery after the last MVC with twitches after 5-sec, 25-sec, and every 30 sec thereafter.
RESULTS: NZBC extract allowed greater force in the first quartile of the MVCs. There was a trend for a main effect of condition of twitch force ($p=0.103$). NZBC extract produced 15% greater force in the resting twitch, from twitch 11 and during recovery. However, there was no interaction effect of condition over the 27 maximal twitches ($p=0.82$). Four subjects were classified into predominant type I (n=2) and type II (n=2) muscle fibre subgroups (Hamada et al. 2003). In type II, NZBC increased MVC force in the first, second, and third quartiles (e.g. first, NZBC: 3523±341N, PL: 2673±98N). In type I, NZBC showed an increased maximal twitch force during the protocol and recovery.
CONCLUSION: NZBC extract seems to show a trend for increased fatigue resistance of quadriceps muscles. Individual responses indicated NZBC extract to have fibre-specific responses, with increased force for type II and increased fatigue resistance for type I fibres. Future work on mechanisms for muscle fibre specific responses to anthocyanin-rich NZBC extract are warranted.

EFFECT OF NEW ZEALAND BLACKCURRANT EXTRACT ON SPORTS CLIMBING PERFORMANCE

POTTER, J.A., PERKINS, I.C., HODGSON, C.I., BROADHURST, M., HOWELL, L., GILBERT, J., WILLEMS, M.E.T.

UNIVERSITY OF CHICHESTER

INTRODUCTION: Rock climbing places a high workload on the forearm flexors (Giles et al., 2006) and observations during intermittent isometric contractions have highlighted the importance of blood flow during the short recovery periods (Fryer et al., 2015). More specifical-

ly, higher force time integral values achieved during the intermittent test by elite climbers have been attributed to improved blood flow upon release of an isometric hold (Fryer et al., 2015). Blackcurrant anthocyanin supplementation increased forearm blood flow at rest (Matsumoto et al., 2005) and increased femoral artery diameter during submaximal isometric contraction (Cook et al., 2017). There would appear to be justification for the use of New Zealand Blackcurrant (NZBC) as an ergogenic aid in sports climbing in an attempt to delay the onset of fatigue and enhance rock-climbing performance.
METHODS: Twenty experienced climbers (2 females) (age 23±5 yrs; height 177±8 cm; mass 71±8 kg) were tested on 3 occasions; familiarisation, after 7 days of NZBC extract (600mg·day-1 CurraNZ containing 210mg anthocyanin), and placebo (PL) (double-blind, randomized, crossover design, 14 days washout). The number of pull-ups on a finger-board (Metolius ® Finger Board) until failure, 90° lock off hang time was followed by 3 climbs to volitional exhaustion on a Treadwall (Brewer Ledge M6) self-selected pace at 90° with a 20-min recovery period between climbs. Heart rate (Polar®H7), rate of perceived exertion (RPE) (Borg, 1982), climbing duration and distance were recorded.
RESULTS: NZBC extract resulted in an 8% increase in hang time (p=0.035), and an 11% increase in climb duration between climb 1 and 3; a 23% decrease climb duration was observed in the placebo condition: interaction effect (p=0.003). There was a main effect for climb with the mean heart rate declining across the three (p<0.001). No effect was seen for pull-ups, maximum heart rate, RPE and distance climbed.
CONCLUSION: Data indicate that NZBC extract improves sports climbing endurance, possibly through improved local blood flow. The improved hang time suggests that this was not dependent on release of the isometric hold as seen in previous work by Fryer et al. (2015). Future work may explore the effect of anthocyanin-rich NZBC extract on other types of climbing and conditions.

EFFECT OF NEW ZEALAND BLACKCURRANT ON METABOLIC AND PHYSIOLOGICAL PARAMETERS DURING SITTING REST AND TREADMILL WALKING IN THAI MEN

WILLEMS, M.E.T.1, PARKTIN, N.2, WIDJAJA, W.2, AJJIMAPORN, A.2
1UNIVERSITY OF CHICHESTER , 2MAHIDOL UNIVERSITY

INTRODUCTION: Intake of New Zealand blackcurrant shifted the lactate curve in European men and women and increased exercise-induced fat oxidation in European men . Ethnicity may affect responses to nutritional ergogenic aids. We examined effects of NZBC extract on metabolic and physiological parameters during rest and moderate intensity exercise in South East Asian men.
METHODS: Seventeen healthy Thai men participated. In the 1st visit, resting metabolic equivalent <1-MET> was measured <1-MET: 4.0±0.4 ml·kg-1·min-1> and an incremental walking protocol was completed to establish the relationship between walking speed and MET. In the 2nd and 3rd visit , metabolic and physiological parameters were measured during sitting rest <2x10 min> and a 30-min treadmill walk at 5-MET with 7-day intake of either placebo or two capsules of NZBC extract <600 mg CurraNZ, Health Currancy Ltd, UK; capsules contain 35% blackcurrant extract powder> and a 7-day washout. Substrate oxidation was calculated with equations from Jeukendrup and Wallis <2005>. One-tailed paired t-tests were used with significance accepted at P<0.05.
RESULTS: NZBC extract had no effect on metabolic and physiological parameters during sitting rest and during treadmill walking at 5-MET , carbohydrate oxidation , fat oxidation , and respiratory exchange ratio . For both conditions, the Pearson correlation for fat oxidation during rest and exercise was significant .
CONCLUSION: New Zealand blackcurrant extract had no effect on fat oxidation during treadmill walking in recreationally active Thai men in contrast to observations during cycling in endurance trained European men . Our findings suggest that ergogenic responses to anthocyanin intake from New Zealand blackcurrant may depend on ethnicity. Future work should address the metabolic and physiological responses to New Zealand blackcurrant intake in people with different ethnicity, but with similar training status, maximum oxygen uptake, exercise modality and exercise intensity.

THE EFFECT OF HIGH FAT DIET FEEDING DURATION ON THE CONCENTRIC AND ECCENTRIC CONTRACTILE PROPERTIES OF ISOLATED MOUSE SOLEUS AND EXTENSOR DIGITORUM LONGUS MUSCLES

HURST, J.
COVENTRY UNIVERSITY

INTRODUCTION: Recent evidence has demonstrated an obesity induced, muscle specific, reduction in contractile performance. Given the role of skeletal muscle in locomotion and substrate metabolism, it has been proposed that direct obesity effects on skeletal muscle may catalyse a negative obesity cycle. Eccentric function is vital for of daily living, and the greater demand on this form of muscle action in obese individuals, the effect of obesity of eccentric muscle function is unexamined. As such, the present study aimed to uniquely examine the effect of obesity on both concentric and eccentric isolated mouse muscle performance using the work loop (WL) technique.
METHODS: Female CD-1 mice aged 4 weeks were randomly split into four groups. Two lean groups, one eccentric (LE) and one concentric (LC) (n=16) which received standard lab chow, an obese eccentric (OE) or obese concentric (OC) group (n=16) which received 20 weeks of a high fat diet (HFD). At 24 weeks of age, slow twitch soleus (SOL) or fast twitch extensor digitorum longus (EDL) muscle was isolated and absolute and normalised (relative to muscle cross sectional area) maximal isometric tetanic force, maximal concentric or eccentric WL power output (PO), either concentric or eccentric fatigue resistance and post fatigue concentric recovery were measured.

RESULTS: Body mass and fat pad mass were significantly higher in the obese group, by 35.7% and 260% respectively. For the SOL, maximal isometric stress, absolute eccentric PO, absolute concentric PO and normalised concentric PO were unaffected. However, maximal normalised eccentric PO was significantly reduced and absolute isometric force was significantly higher in the obese group. The OC group fatigued significantly faster than LC, however eccentric fatigue was unaffected. For the EDL, maximal isometric force, isometric stress, normalised eccentric PO, absolute concentric PO, absolute eccentric PO and both concentric and eccentric fatigue were unaffected. However, normalised concentric PO was reduced in the obese group. Interestingly, the OE group recovered to a greater magnitude than LE post fatigue, there was no such difference in the SOL.
CONCLUSION: These findings add to previous literature demonstrating a muscle specific reduction in the concentric performance of isolated skeletal muscle that is likely related to in vivo mechanical role and fibre type. Moreover, these findings uniquely show that a HFD causes a decline in eccentric power output of the SOL, however the EDL remains unaffected. The decline in SOL eccentric power output could be detrimental to everyday activities of an obese individual with less power producing muscles and elevated body mass. Interestingly the OE group of the EDL saw no significant decline in power and recovered to a greater magnitude than LE counterparts suggesting possible training benefits using this mode of muscle function. As the results from the eccentric and concentric groups differ, it suggests that the mechanisms which affect them also differ

EFFECT OF A 9-WEEK RESISTANCE HEAVY TRAINING WITH AND WITHOUT PROTEIN SUPPLEMENTATION IN UNTRAINED SUBJECTS

VANDONI, M.1, CORREALE, L.1, CODRONS, E.1, CARNEVALE PELLINO, V.1, LIBERALI, G.1, DELL'ANNA, S.1, RICAGNO, E.1, CASIRAGHI, E.1,2

1 LABORATORY OF ADAPTED MOTOR ACTIVITY, DEPARTMENT OF PUBLIC HEALTH, EXPERIMENTAL MEDICINE AND FORENSIC SCIENCE, UNIVERSITY OF PAVIA, ITALY 2EQUIPE ENERVIT S.R.L., ZELBIO, ITALY

INTRODUCTION: The use of protein supplementation in association with resistance training is largely widespread. Many studies have investigated the effects of this practice on strength and body composition. Researches focused on protein supplementation in association with resistance training, but untrained subjects after a heavy resistance training were not studied before. The aim of this study was to investigate protein supplementation in association with heavy resistance training in order to maintain/increase strength and modify body composition.
METHODS: 43 subjects (age 19-35 years, healthy and resistance exercise untrained) were randomly divided in 2 groups: Protein Group (PG), supplemented with 0.25 g. protein/kg pre and post workout during training days, and Control Group (CG) (exercise only). Every subject performed the same training for 9 weeks (1familiarization+8training) with 3 supervised session/week, composed by 3 pre-post fatigue circuits: Legs Circuit (LC) (leg extension, leg press machine, leg curl), Arms Circuit (AC) (pectoral machine, bench press, triceps machine) and Back Circuit (BC) (lat machine, vertical row, biceps curl). Subjects performed 4 sets of 6 R at 75% of 1 RM for first and third exercise of every circuit and 10 RM for the second exercise of every circuit with one minute of recovery. At the end of the first conditioning week (T0) and at the end of 8th week (T1) every subject performed 1 RM test at Leg Press machine (LP), Bench Press (BP) and Lat Machine (LM) and was evaluated on height, body weight, body composition with Bioelectrical Impedance Analyser. Differences from T0 were calculated with paired t-test while independent t-test on delta values (T1-T0) assessed differences between groups.
RESULTS: 34 subjects completed the study (PG=12 males and 7 female, CG=10 males and 5 females, mean age 27.0±1.8 years). PG had a significant decrease in fat mass ($p<0.0001$) and increase in fat free mass and lean mass ($p<0.001$). Both groups had a significant increase in 1RM in every circuit. There were no significant differences between any anthropometric variable.
CONCLUSION: Final strength values were significant higher in both groups suggesting that it was independent from mass gain probably due to a better fibre recruitment. Moreover results showed that protein supplementation in addition to heavy resistance program influenced body composition increasing fat free and lean mass and decreasing fat mass respect to exercise only likely for a lack of protein for muscle rebuild. These results should be implemented in a larger sample but could drive to new application in the field of resistance training.

PREVALENCE AND METHODS OF RAPID WEIGHT LOSS REPORTED BY MIXED MARTIAL ARTISTS

CONNOR, J., EGAN, B.

DUBLIN CITY UNIVERSITY

INTRODUCTION: Rapid weight loss (RWL) is a common practice in sports that have weight class restrictions including Mixed Martial Arts (MMA). RWL generally refers to the methods employed by an athlete in reducing body mass in the range of 5% to 10% in the final one to two weeks before competition. Considering the increasing popularity of MMA, but documented deaths attributed to RWL practices, the creation of bodies such as Safe MMA recognised the importance of documenting the habits of fighters during weight cutting to establish if safe and effective strategies are being employed for weight cutting. The aim of the present study was to evaluate self-reported practices of RWL in a sample of competitive MMA athletes comprising of both amateur and professional fighters.
METHODS: This was an anonymous online questionnaire based study on current or previous weight cutting behaviours. RWL was defined to the participants as reducing body mass between 5-10% in 7 days or less prior to fights. The questionnaire used in this study was based on the previously-validated Rapid Weight Loss Questionnaire (Artioli et al. 2010) with the addition of questions on water loading and salt baths. Participants (n=30; all male, n=15/15 professional/amateur) from several MMA clubs around Dublin, Ireland that are associated with Straight Blast Gym (SBG) completed the survey.
RESULTS: 97% of those surveyed lost weight in order to compete: 89% used water-loading "sometimes" or "always"; 55% used fasting for 24 hours as a means to acutely manipulate body mass; salt baths are used "always" or "sometimes" by 75% of respondents. The RWL score for this sample was 37.9 (34.2, 41.6). Cross-code comparison revealed a higher score for professional [40.8 (35.9, 45.8)] compared to amateur [34.8 (29.2, 40.4)] athletes i.e. difference of 6.1 (-1.1, 13.1)($p=0.093$), with the magnitude of effect interpreted as 'moderate' ($d=0.64$). 41% replied that fellow fighters were "very influential" and 37.9% that their coaches/mentors were "very influential" in their RWL behaviours. 66.7% said that doctors were "not influential" and 41.4% said that dieticians were "not influential".

CONCLUSION: The present study found that MMA fighters have a higher RWL score than other combat sports. RWL is widespread in MMA, across both amateur and professional levels, with water loading and hot salt baths among the most predominant methods used. There exists very little research on these methods for body mass reduction and performance in combat sports in general and MMA specifically.

CP-PM12 Validity and Variability

A VERIFICATION PHASE FOR A TAEKWONDO-SPECIFIC CARDIOPULMONARY EXERCISE TEST

ESTEVES, D., HAUSEN, M., ARAUJO, M.P., HAUSEN, L., MACHADO, A., SOARES, P.P., GURGEL, J.

FEDERAL FLUMINENSE UNIVERSITY

INTRODUCTION: A new method to assess the cardiopulmonary fitness of taekwondo athletes (TcTKD) was proposed and yielded higher cardiopulmonary responses than a treadmill-running test. However, the attainment of a true VO2MAX is still a concern during the cardiopulmonary assessment. The verification phase strategy is the most widely accepted to verify a true VO2MAX. Therefore, this study aims to purpose and validate a verification phase for the TcTKD.
METHODS: The sample consisted of 11 male WTF taekwondo athletes (mean±sd: 20±4 yrs, body weight 66.1±7.9 kg, height 176±8 cm). TcTKD and verification phase were repeated across three visits, separated by 2-7 days. The TcTKD comprised progressive stages of turning kicks (bandal tchagi). Between the incremental and verification phases, participants rested at a seating position for 5 minutes. Verification phase was started with one minute of 'reentrance' (1 min of three sub stages of the 20s with 3rd, 5th, and 7th stages) and followed by the stage immediately above the highest completed stage of the incremental phase, with a duration determined by participants' exhaustion. Oxygen uptake (VO2) was recorded with 20s average data points with VO2000 (Medical Graphics, USA) and heart rate (HR) was recorded beat-by-beat with the Polar V800 HR monitor (Polar Electro, Finland). The repeatability statistical analysis was performed with the standard error of measurement and the intraclass correlation coefficient (ICC) between incremental and verification VO2MAX and HRMAX, both were determined by the highest value obtained during each test.
RESULTS: VO2MAX of incremental and verification phase presented a standard error of measurement of 1.3 (2.3%), 2.3 (4.1%) and 2.9 (5.2%) ml.kg-1.min-1 and an ICC of 0.94 ($p<0.001$), 0.93 ($p=0.001$) and 0.84 ($p=0.004$). Whereas the HRMAX of incremental and verification phase presented a standard error of measurement of 1.6 (0.8%), 1.4 (0.7%) and 1.3 (0.7%) beats.min-1 and an ICC of 0.99 ($p<0.001$) for all three visits.
CONCLUSION: The error obtained at each visit was acceptable as it was within the 6% variation limit determined. In addition, the ICC for VO2MAX was good to excellent for all visits. Regarding HRMAX, a small percentage of error and an excellent ICC were observed. The verification phase confirmed the values of VO2MAX and HRMAX reached in the incremental test during all visits, suggesting a valid and reliable method for the measurement and confirmation of the actual values of VO2 and HR reached in the incremental phase.

HIGH VARIABILITY OF MECHANICAL POWER OUTPUT DURING INCREMENTAL ROWING ERGOMETER TESTS IN FEMALE ELITE ROWERS

MENTZ, L., TREFF, G., WINKERT, K., STEINACKER, J.M.

UNIVERSITY HOSPITAL OF ULM

INTRODUCTION: On wind braked rowing ergometers, mechanical power output is not externally adjustable but determined by the rower's stroke frequency, -force and distance. This leads to a currently unknown variation in mechanical power output that might influence physiological variables like [blood lactate]. To this end, we calculated the variation of mechanical power output of submaximal steps during an incremental test in elite rowers.
METHODS: Thirteen female elite rowers (body mass 74.7 ± 5.0 kg; height 179.7 ± 4.5 cm; Power at [blood lactate] 4 mmol/L 289.7± 11.9 W) performed a stepwise incremental test (180 W + 40W/4 min; 5 steps) on a rowing ergometer (Concept 2, Morrisville, USA). Steps were separated by a 30-s break. The ergometer was modified with a force sensor and a rotary transducer to allow for exact calculation of power (FES, Berlin, Germany). Power was measured stroke-by-stroke and saved in a log-file. Afterwards all data, excluding the last stroke, were log-transformed and the coefficient of variation (CV) was calculated for each step using a mixed model approach.
RESULTS: The average CV amounted to 5.55 ± 0.25% (95%CI 5.04 – 6.07%). The CV significantly decreased from stage 1 to 2 and 2 to 3 ($p < .001$ and $p <.05$, respectively). Highest individual CV was 12.3% at stage 1, corresponding to 17.7 W at an average power of 144 W. CV significantly decreased ($p < .05$), when the first three strokes of each stage were excluded from the analysis, leading to an average CV of 2.95 ± 0.14% (95% CI 2.64 – 3.23 %).
CONCLUSION: Even in elite rowers, mechanical power output varies considerably during 4 min lasting constant load stages. The variation is highest in the lowest steps. Notably, the first three strokes affect the CV of each stage significantly, which is due to an over pacing at the start of each new target load. Taking into account the impact of the first strokes and the extremely high variation of particular athletes, these variations probably affect physiological variables. However, this has not been examined in this study.

VALIDATION OF ACCELEROMETERS FOR ESTIMATING PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOUR IN PRE-SCHOOL CHILDREN DURING FREE LIVING ACTIVITY

DOBELL, A.P.1, EYRE, E.L.J.1, TALLIS, J.1, CHIN A PAW, M.2, ALTENBERG, T.2, DUNCAN, M.J.1

1: COVENTRY UNIVERSITY 2: VU AMSTERDAM

INTRODUCTION: During the preschool years, physical activity behaviours develop and likely track into childhood and adolescence . Accelerometry is becoming one of the key tools used to objectively assess PA in pre-schoolers. Few studies have examined the validity of accelerometers to assess PA during free play in pre-schoolers. This study examined the validity of accelerometry, to assess free play PA in pre-schoolers.
METHODS: Following institutional ethics approval, parental informed consent and child assent, 36 pre-schoolers aged 3-4 years <23 males, 13 females> participated in the study. Participants wore two accelerometers ; one on their dominant wrist and one on their right

hip during one hour of free play. Concurrently, direct observation, using the OSRAC-P protocol , was used to determine sedentary behaviour, light or moderate-to-vigorous intensity PA undertaken by the preschoolers. The accelerometers were initialized to record activity in 10 second epochs at 100Hz. Acceleromter raw counts of three, 10 second epochs were accumulated to match the 30-second observation periods. Receiver Operating Curve analysis was used to evaluate the ability of both accelerometers to predict, sedentary, light and moderate-vigorous activity.
RESULTS: Results from ROC curve analysis revealed that sedentary behaviour and moderate-to-vigorous PA obtained from the wrist and hip placed accelerometers demonstrated fair agreement with the observations 0.7>. Sensitivity and specificity were fair to good. ROC curve analysis however indicated that accelerometer determined light PA had poor agreement with the observation comparison measure, for both the hip and wrist placement and weak levels of sensitivity, although specificity was high .
CONCLUSION: This current research suggests that accelerometry is a fair measure for sedentary behaviour and moderate-to-vigorous PA in preschool children. Hip placement of the accelerometer was marginally more accurate than dominant wrist placement, congruent with previous research . Accelerometry failed to adequately assess light PA. The irregular nature of PA in preschoolers may have contributed to the difficulty of determining light PA measurement via accelerometry . Further research refining the assessment of light PA using accelerometry in preschool children is therefore warranted.

VALIDITY OF THE FITBIT CHARGE HR2 IN OUTDOOR WALKING AND RUNNING

HARENBERG, S., DIPRETA, M., SHERNAN, M.

ITHACA COLLEGE

INTRODUCTION: Wearable fitness trackers have become increasingly popular in healthy and clinical populations as a means for monitoring activity levels. These devices have the potential to be effective in promoting physical activity and healthy lifestyles. For example, fitness trackers have been frequently used in behaviour change interventions. Yet, evidence of the concurrent validity of fitness trackers is imperative in verifying the accuracy of these devices (Kooiman et al., 2015). The present study examines one of the leading wearable trackers worldwide, the Fitbit Charge HR2. Currently, there is a lack of evidence of its concurrent validity to measure indicators of physical activity (e.g., heart rate, step count) in outdoor conditions. Hence, the purpose of the present study was to test the concurrent validity of the Fitbit Charge HR2 in outside walking and running.
METHODS: In total, 21 healthy volunteers (female n=14) participated in the study. Participants completed three trials of outdoor activity (i.e., standing in place for 6 minutes, walking one mile, and run/jog one mile). Step count and heart rate data were collected on the Fitbit Charge HR2. As gold standards, a Polar H7 chest strap and a count of videotaped steps were used. Statistical analyses included mean absolute percentage errors, one-sample t-tests, and intraclass correlation coefficients (ICC).
RESULTS: The Fitbit Charge HR2 significantly underestimated heart rate for all three intervals (mean differences=-5.95 - -17.08, SDs=9.48-13.68; ps<.01). ICCs ranged from .43-.63, indicating poor agreement between the Fitbit and the Polar H7 chest strap. The Fitbit Charge HR2 also significantly underestimated step count for walking (mean difference=-22.35, SD=44; p<.05) with a good ICC (.96). For running, no significant underestimation was found (p=.064). The ICC revealed an acceptable agreement of .94 between the Fitbit Charge HR2 and the counted steps.
CONCLUSION: The present study indicates that the Fitbit Charge HR2 may be usable to measure steps in outdoor walking and running. However, the Fitbit Charge HR2 consistently underestimated heart rate at rest and during outdoor walking and running. As such, the Fitbit Charge HR2 should be used with caution for the measurement of heart rate during activity (e.g., in clinical or non-clinical settings). Limitations and future research directions are discussed.

VALIDITY OF A JUDO-SPECIFIC CARDIOPULMONARY EXERCISE TEST

ARAUJO, M., HAUSEN, M., ESTEVES, D., MACHADO, A., HAUSEN, L., PORTO, F., SOARES, P.P., GURGEL, J.L.

FLUMINENSE FEDERAL UNIVERSITY

INTRODUCTION: Judo is a combat sport with a complex intermittent metabolic demand, characterised by anaerobic and aerobic metabolic pathways contributions. The literature indicates different tests to assess the physical fitness of judo athletes. However, few methods are aimed to evaluate aerobic power. The development of a specific test that enables evaluation of the cardiorespiratory response during judo practice is crucial to individualise aerobic training prescription. Therefore, this study aimed to verify the validity of a judo-specific cardiopulmonary exercise test.
METHODS: Nine athletes (age: 20 ± 2 yrs; body mass: 64.7 ± 9.9 kg; height: 167 ± 7 cm) performed two tests - Running cardiopulmonary exercise test (CPET) and Judo-Specific Cardiopulmonary Exercise Test (JST) - on two separate occasions, with a counterbalanced order, separated by 2-7 days. Each stage of the JST last 1 minute, and the load increment was based on a gradual reduction of the interval (0.7s) between Ippon-Seoi-Nage executions, guided by a sound signal. Cardiorespiratory variables were assessed using a metabolic gas analyser VO2000 (Medical Graphics, USA) and a Polar V800 (Polar, Kempele, Finland). Blood lactate was assessed with a portable analyser Lactate Plus (Novabiomedical, Waltham, USA). The variables measured were: peak oxygen uptake (l ̇O2PEAK) and heart rate (HRPEAK), (̇O2 and HR at ventilatory thresholds 1 and 2 (VT 1 and 2), peak blood lactate concentration ([LA-]PEAK), rating of perceived exertion (RPE). The study had the approval of Fluminense Federal University ethical committee according to resolution 466/12 of National Health Council (report number 996/926).
RESULTS: No significant differences were found between CPET and JST, except for the [LA-]PEAK (p = 0.020). However, the highest] ̇O2 and HR at VT 1 and 2 values were found in JST (a ̇O2 VT1: 38.60 ± 2.64; HR VT1: 169 ± 10) when compared to the CPET (1 ̇O2 VT1: 34.58 ± 5.23; HR VT1: 162 ± 9). JST showed high reliability of the measures to 5 ̇O2PEAK (α = 0.75, p = 0.033), p ̇O2 VT2 (α = 0.87, p = 0.004), HRPEAK (α = 0.86, p = 0.006), HR VT2 2 (α = 0.79, p = 0.020) and [LA-]PEAK (α = 0.85, p = 0.006).
CONCLUSION: The results of this study suggest that JST may be used for measurement of cardiorespiratory variables commonly used in exercise prescription. r ̇O2, HR, RPE and [LA-] values obtained in the present study are in agreement with those found in the general literature. Therefore, taekwondo-specific tests present a viable method and less expensive for evaluation of judo athletes, enabling coaches or exercise physiologists to conduct evaluations in training facilities, thereby eliminating the need for an ergometer.

VALIDITY OF THE ISOMETRIC EXERCISE SCALE (IES) FOR MEASURING RATINGS OF PERCEIVED EXERTION DURING ISOMETRIC WALL SQUAT TRAINING AT DIFFERENT LOADS.

WILES, J., ODRISCOLL, J., LEA, J.

CANTERBURY CHRIST CHURCH UNIVERSITY

INTRODUCTION: Isometric exercise (IE), including wall squat training, has been shown to be effective at reducing resting blood pressure (Wiles et al., 2016). IE intensity is generally determined using torque, electromyography (EMG), heart rate (HR), or knee joint angle; however, rating of perceived exertion (RPE) has been shown to be a valid and useful measure of IE intensity and may provide a more accessible means of determining IE workload (Hummel et al., 2005). The RPE scales currently being used were not specifically designed for use with IE. Therefore, the aim of this study was to assess the validity of a new "Isometric Exercise Scale" (IES) to discern IE intensity during single wall squat bouts performed at different angles.
METHODS: Following institutional ethical approval, 29 male participants (age: 24.3 ± 3.6 years; stature: 180.4 ± 6.8 cm; body mass: 79.3 ± 14.1 kg) (mean ± SD) completed 5 isometric wall squat exercise tests, on separate occasions, with a minimum of 4 hours in-between. Each test consisted of 2 minutes of squatting at one of five randomised wall squat intensities, determined by knee joint angle ranging from 135° to 95° in 10° increments (Goldring et al., 2014). Throughout the exercise protocol, HR and blood pressure (BP) were recorded continuously, while RPE (IES) was collected every 30 seconds. Mean and peak IES rating, HR and BP were calculated for each 2-minute bout of wall squat exercise; differences were analysed between each intensity (135°, 125°, 115°, 105°, 95°).
RESULTS: Mean and peak IES ratings increased significantly ($P < 0.05$) with each consecutive increase in exercise intensity. These changes in RPE were accompanied by concurrent changes in mean and peak HR ($P < 0.05$), systolic BP ($P < 0.05$), diastolic BP ($P < 0.05$), and mean arterial BP ($P < 0.05$).
CONCLUSION: These results suggest that the IES provides a valid measure of IE intensity. As such, the IES could be used as a useful measure of exercise intensity during IE.

CRITERION-RELATED VALIDITY OF RATINGS OF PERCEIVED EXERTION DURING RESISTANCE EXERCISE IN HEALTHY PARTICIPANTS: A META-ANALYSIS.

LEA, J., HULBERT, S., O'DRISCOLL, J., SCALES, J., WILES, J.

CANTERBURY CHRIST CHURCH UNIVERSITY

INTRODUCTION: A substantial body of evidence suggests that ratings of perceived exertion (RPE) are a valid measure of exercise intensity during various forms of aerobic exercise (Chen et al. 2002); however, the evidence to support the use of RPE during resistance exercise is less clear. The purpose of this study was to use the relationships between RPE and workload, heart rate (HR), blood lactate (BLa), and electromyography (EMG) to determine the validity of RPE as a measure of exercise intensity during different forms of resistance exercise.
METHODS: An online search of 4 databases and websites (PubMed, Web of science, SPORT Discus and Research Gate) was conducted up to 24 August 2017. Additionally, the reference lists of the included articles were inspected manually for further unidentified studies. The inclusion criteria were: healthy participants of any age, a Likert style scale to measure RPE, resistance exercise of any type, a cohort receiving no other intervention, and concurrent data from one of the aforementioned criterion measures. Unpublished studies were included and there was no restriction on publication date. Study eligibility assessment, risk of bias rating and data extraction were conducted independently by authors 1 and 4. The risk of bias was assessed using a 9-point scale (developed in-house to specifically assess bias in validity studies), leading to a rating of high, medium or low risk of bias. The weighted average effect sizes were calculated using a random-effects model.
RESULTS: Sixty-two studies met the inclusion criteria. The overall risk of bias was low in 36 studies, medium in 23 studies and high in 3 studies. From the 62 eligible studies, a total of 85 unique cohorts, using any one of the criterion measures, were included in the main analysis. This analysis revealed a large effect size of 0.89 (95% CI 0.85 to 0.91). Separate meta-analyses were conducted for studies using workload only (77 cohorts) and EMG only (6 cohorts) as the criterion measures; again these analyses revealed large effect sizes of 0.89 (95% CI 0.86 to 0.91) and 0.92 (95% CI 0.54 to 0.99) respectively. There were insufficient studies to conduct separate meta-analyses for the other criterion measures.
CONCLUSION: A large number of studies, with a medium to low risk of bias were identified for this analysis. The findings suggest that RPE is a valid measure of intensity during various forms of resistance exercise, with effect sizes comparable or greater than those shown in studies using aerobic exercise (Chen et al. 2002).

THE INTRA-RELIABILITY OF A PHYSICAL FITNESS TEST BATTERY IN 9 – 10 YEAR OLDS.

LAUDER, M., HILES, A., POTTER, J., GAULT, M.

UNIVERSITY OF CHICHSTER

INTRODUCTION: Measuring and monitoring health-related fitness in schools, plays a major role in helping identify individuals with low physical fitness and assess the impact of school-based interventions, such as ' the daily mile'. However, with large numbers of children in classes, assessing physical fitness is time consuming, with an estimation of two-hours per class of 20 (Ruiz et al., 2011). Therefore, the current study investigated the intra-reliability of three standard components of health-related fitness in children.

METHODS: Sixty-eight boys (Mean:9.9, SD: 0.3 years) and girls (Mean:9.9, SD: 0.3 years) completed 3-repetitions of the back-saver sit-and-reach (BSSR, left and right), handgrip strength (HGS, dominant and non-dominant), and counter-movement jump (CMJ). Data was assessed using the first trial score, mean and maximum of 3 trials.
RESULTS: For all tests, except the BSSR left, over 60% of children achieved their maximal score in the first trial. Limits of agreement demonstrate BSSR left (r=-0.150, 95% CI=-2.5 – 3.9cm, bias=0.7cm, p=0.003), non-dominant HGS score (r=-0.005, 95% CI=-3.5 - 1.6kg, bias=0.9kg, p<0.001) and CMJ power (r=-0.139, 95% CI=-218 - 125W, bias=-46W, p<0.001) had both large measurement error and variation. BSSR right had undifferentiated means for the first trial and max score (mean:35, SD:6cm vs mean:35, SD:6cm, respectively) and good agreement (r=0.220, 95% CI=1.8 – 1.8cm, bias=-0.3, p=0.591). HGS dominant had a mean difference of 4% between first and max trial and moderate variability (r=0.120, 95% CI=-2.6 – 1.1kg, bias=-0.8, p<0.001).
CONCLUSION: First trial attempts of the BSSR right and HGS dominant resulted in consistent scores across the three trials, with BSSR right having similar error to previous studies of <1cm (Ruiz et al., 2011). However, BSSR left, HGS non-dominant and CMJ power degree of error was too large between the first trials and best of three trials to indicate a representative score. Hager-Ross and Rosblad (2002) reported under 13's had a high intra-individual variation for such tests, seen as a principal property of normal development (Hadders-Algra, 2000). Therefore, a thorough familiarization is required, particularly in inexperienced children and assessment of the non-dominant side, this could resolve the necessity to use multiple trials. Also, integration of such activities into physical education classes from a young age could help with assessing adaptations to school-based interventions such as 'the daily mile'.

THE RELIABILITY OF AN INTERMITTENT SPRINT CYCLING PROTOCOL ON A WATTBIKE PRO IN HOT CONDITIONS

ROSS, C., OXFORD, S., MORRIS, M.G., THAKE, C.D., CLARKE, N.D.
COVENTRY UNIVERSITY

INTRODUCTION: Environmental heat has long been identified as a major limiting factor in team based repeated sprint sports (Morris et al. 2000 and Hornery et al. 2007). The Wattbike Pro (Nottingham, UK) uses a combination of magnetic and air resistance and has been validated previously in normothermic conditions using a motorised calibration rig (Wainwright et al., 2017). There is a necessity for reliable and valid measures to consistently identify performance changes in an applied setting. However, there is little research identifying the reliability and validity of an intermittent high intensity protocol in a hot environment.
METHODS: Twelve healthy, non heat acclimated, male team-sport athletes (age 27 ± 9 yr, mass 82.0 ± 6.3 kg, height 180.4 ± 6.5cm) completed three 36-min intermittent sprint protocols (ISP) of: 18 × 4-s maximal sprints in an environmental chamber (36.6 ± 1.1°C, RH 38.0 ± 1.9%). Each 4-s sprint was followed by 116-s of active recovery. Sleep, exercise and diet were controlled for across trials. Power, HR, thermal comfort and thermal sensation (-3/+3 scales), and RPE were assessed. Peak and mean power from the 18 sprints was used to calculate performance decrement. Data was analysed and meaningful change and coefficient of variation (CV) calculated.
RESULTS: Mean peak power (highest mean 4s sprint) peak power 1435W, mean power 1028W, CV%3.7 meaningful change 37W. Max peak power (highest maximal power of any 4s sprint) peak power 1556W, mean power 1151W, CV4.1% meaningful change 46W. Mean average power output (mean average power of 18 sprints) peak power 1355W, mean power 938W, CV4.6% meaningful change 40W and also peak mean (mean of highest power across 18 sprints) peak power 1454W, mean power 1052W, CV3.6% 36W. Mean decrement across 18 sprints was CV24% and actual decrement 2.4%.
CONCLUSION: We can conclude that for power output variables there was a coefficient of variation of between 3.6% and 4.6%. This equates to a meaningful change of between 36W and 46W, respectively for either the mean or peak power output. This study would provide useful validation for research, and also applied training interventions where meaningful change is assessed, within a similar population.
In conclusion, this study confirms the reliability and highlights that the mean and peak power values are the most reliable variables for assessing changes within a 4s repeated sprint performance in hot conditions.

RELIABILITY OF THE 1.2 KM SHUTTLE RUN TEST IN YOUNG ELITE RUGBY UNION PLAYERS.

HAMLIN, M.J., DEUCHRASS, R., SMITH, H., ELLIOT, C.A., LIZAMORE, C.A.
LINCOLN UNIVERSITY

INTRODUCTION: To be useful, fitness tests need to have adequate reliability , so that important changes in athlete's performance can be identified. The aim of this study was to investigate the reliability of the 1.2 shuttle run test <1.2SRT>, a novel field test also known as the Bronco test, on young elite rugby players.
METHODS: On two occasions, separated by 2-3 weeks during the pre-season, 40 male elite rugby players <21 forwards, 19 backs, age 19.0 ± 1.1 yr, mean ± SD>, completed the 1.2SRT on a grass rugby pitch in their usual playing footwear, under similar environmental conditions. To complete the 1.2SRT, players completed maximal shuttle runs to and from a start line to 20, 40 and 60-m marks, 5 times without a break. Players were scored on the time taken to complete the shuttle runs. Prior to the study, all players were familiarized with the 1.2SRT and to ensure consistency, players completed a standardized warm-up before the test. To minimize confounding variables, players were asked to refrain from heavy exercise and consumption of alcohol for 24 hours prior to all testing, and to avoid heavy meals or caffeinated beverages for 2 hours prior to testing.
RESULTS: Overall performance increased by 1.0% between tests <3.96 ± 0.23 m/s to 4.00 ± 0.24 m/s, mean ± SD>, which corresponded to a higher post-test rate of perceived exertion <17.9 to 18.2 on the Borg 6-20 scale>. For all players combined, the standardized typical error of the average speed between tests was 0.37, 0.31-0.45 which corresponds to a coefficient of variation of 2.1% <1.8-2.6%>. The typical error was similar between forwards <0.39> and backs <0.54>.
CONCLUSION: We conclude that the 1.2SRT demonstrated moderate between-test reliability when conducted under similar environmental conditions and suspect that increased fitness levels in individuals between tests may have contributed to the increased variability and lower reliability than expected.

CP-PM14 Resistance training

EARLY MUSCLE ADAPTIVE RESPONSES TO AN ACUTE 'FLYWHEEL' ISOINERTIAL RESISTANCE EXERCISE SESSION

BENELLI, P., CONTARELLI, S., ANNIBALINI, G., GUESCINI, M., MAGGIO, S., CECCAROLI, P., LUCERTINI, F., GERVASI, M., MARINI, C.F., FARDETTI, F., GRASSI, E., STOCCHI, V., BARBIERI, E.

DEPARTMENT OF BIOMOLECULAR SCIENCES - UNIVERSITY OF URBINO CARLO BO - ITALY

INTRODUCTION: Isoinertial exercise, in which the inertia of a flywheel is used to provide resistance to muscular work, yields unique physiological responses beyond those mediated by established resistance exercise modalities (1-2). The aim of this study was to analyse the modulation of circulating and local molecular markers of muscle damage and remodelling after a single iso-inertial resistance exercise session.
METHODS: Collegiate students (n=8) performed 5 sets of 10 maximal squats (3' rest in-between) on the D11 iso-inertial device (Desmotec, Italy). Circulating creatine kinase (CK), insulin-like growth factor (IGF)-1 and interleukin (IL)-6 were measured before and 2, 24, and 48h after exercise. The miRNAs (miR-1, -133b, -206, -146a, -126, and -423) encapsulated in circulating exosomes were quantified before and 2h after exercise. Muscle mRNA levels of IGF-1 isoforms (IGF-1Ea, -Eb, and -Ec), myogenin, myogenic regulatory factor-4 (MRF-4) and cyclin D1 were determined, by vastus lateralis fine needle aspiration (FNA), before and 2h after exercise. IκB-α, MCP-1, TNFα, IL-6 and IL-6R mRNA levels in muscle and peripheral blood mononuclear cells (PBMC) were analysed. Multiple repeated measure ANOVAs were used to compare the time course of circulating markers (post-hoc: Bonferroni; α=0.05). The Wilcoxon non-parametric test was used to compare pre- vs. post-exercise gene-expression markers, derived from FNA and PBMC.
RESULTS: A single iso-inertial exercise session increased serum markers of muscle damage (CK and IL-6) and pro-inflammatory gene expression in muscle and PBMC. After exercise, a 2-fold increase in circulating exosomes was associated with mir-146a and mir-126 up-regulation. These signals could be involved in the inflammatory process induced by physical exercise.
By contrary, mRNA genes level related to muscle growth and repair decreased 2h after exercise, suggesting an early down-regulation response of muscle mass remodelling and repair mechanisms, while those responding to muscular damage were immediately up-regulated (3).
CONCLUSION: These results provide evidence of early molecular adaptations of skeletal muscle to flywheel-based iso-inertial resistance exercise. Future studies are needed to assess long-term circulatory and muscular adaptations to iso-inertial training and to compare those effects with those yielded by the other resistance exercise modalities available.

THE ECW/ICW RATIO CAN EVALUATE MUSCLE SWELLING AFTER RESISTANCE TRAINING

TANIGUCHI, M.

GRADUATE SCHOOL OF MEDICINE, KYOTO UNIVERSITY

INTRODUCTION: Muscle swelling is defined as an immediate increase in muscle thickness (MT) after the high-intensity resistance training (RT). Previous study (Damas et al., 2016) has reported that muscle swelling are concomitant with muscle echo-intensity (EI) as marker of the muscle damage. The evaluation of the extracellular water/intracellular water (ECW/ICW) ratio with segmental bioelectrical impedance spectroscopy (BIS) reflects edema within skeletal muscle composition. No previous study has evaluated both EI and the ECW/ICW ratio to investigate their relationship to muscle swelling. Thus, the purpose of this study was to reveal the relationship between EI and the ECW/ICW ratio, associated with muscle swelling.
METHODS: Eighteen untrained-young man (mean age; 25.4±4.1) were recruited in the present study. All subjects underwent the estimated knee extension one repetition maximum (1-RM) test more than 3 days prior to the experiment. The subjects performed three sets of fatigue failure with 80% 1-RM condition, and were given 3 minutes rest interval between sets. Total training volume (TV) was calculated with load (kg) × repetitions × 3sets. The measurements of MT, EI and the ECW/ICW ratio were performed before and after the RT. Muscle swelling was defined as the difference of MT before and after the RT. The MT and EI at 4 compartment of quadriceps muscle were measured and summed. The measurement of the ECW/ICW ratio were applied on the right upper thigh as an indicator of quadriceps muscle by using segmental-BIS. From the bioelectrical impedance values obtained by BIS measurements, ICW and ECW were calculated from the algorithm of the previous study (Zhu et al, 1998). In general, ICW reflects muscle cell mass, whereas ECW represents the sum of interstitial fluid and blood plasma in extracellular space. For statistical analysis, a paired t-test was used to compare each parameter between pre-post RT. Additionally, correlation coefficients and a multiple liner regression analysis were performed.
RESULTS: All parameters indicated significant high value after RT session. Muscle swelling showed a significant and positive correlation with the ECW/ICW ratio and TV. A multiple liner regression analysis revealed that muscle swelling was predicted by the ECW/ICW ratio.
CONCLUSION: Our results indicated that the ECW/ICW ratio reflected muscle swelling after RT. Muscle swelling is affected by increased blood flow and extracellular fluid (Loenneke et al., 2012). The increase of ECW/ICW ratio reflects fluid fluctuations, therefore, this parameter may accurately evaluate edematous changes after RT. The present study suggested that the ECW/ICW ratio could better evaluate muscle swelling than EI.

EFFECTS OF THE ORDER OF COMBINED RESISTANCE AND HIGH INTENSITY INTERVAL TRAINING ON MUSCLE HYPERTROPHY AND METABOLISM

SHIRAI, T., OTA, Y., NAKAMURA, T., TAKEMASA, T.

UNIVERSITY OF TSUKUBA

INTRODUCTION: In many sports, athletes have to show maximum performance during competitions. Therefore, they want to improve strength and glycolysis by many ways. Much has been studied on the differences in training methods weather those can improve glycolysis, strength on both of them. Concurrent training is combination containing two different modes of training. In this study, We conducted

an experiment by combining resistance (RE) and high intensity interval training (HIIT). Therefore, there is a conflict of body adaptation caused by differences in the respective training. The purpose of this study was to investigate the order of concurrent training in skeletal muscle and its influence on its molecular mechanism. We analyzed the change in signal molecules.
METHODS: 7 weeks of age male ICR mice were divided into 3 groups: control (con), HIIT before resistance (HIIT-RE), HIIT after resistance (RE-HIIT). After 3-week training (3 times / week) , mice were sacrificed and plantaris muscles were dissected out quickly from each mouse for subsequent analyses.
RE-protocol
The mice were positioned with their foot on a footplate (the ankle joint angle was positioned at 90°) in the prone posture. The triceps calf muscle was stimulated percutaneously with electrodes which were connected to an electric stimulator and isolator. The gastrocnemius muscle was isometrically exercised (3-s stimulation 10 contractions, with a 7-s interval between contractions, for 5 sets with 3-min inter set intervals). The voltage (30 V) and stimulation frequency (100 Hz) were adjusted to produce maximal isometric tension.
HIIT-protocol
Mice were performed a 20-s swimming exercise at most 20 times or until the mouse reached exhaustion, with a weight equivalent to 10% of their body weight. The weight tied near the base of their tail. mice were landed from water, and a 10-s rest period was allowed. A barrel filled with water to depth of 60 cm was used for the swimming exercise, and water temperature was maintained 35°C during the exercise.
RESULTS: We analyzed the change in signal molecules. The phosphorylation levels of mTOR signaling increased significantly in concurrent training groups. The change in gene expression related to metabolism were also increased concurrent training. Mitochondrial respiratory chain complex was confirmed by western blot. Although it increased significantly in complex 4, we could not confirm the difference by the order.
CONCLUSION: We revealed the difference by order of concurrent training. In conducting concurrent training on the same day, resistance training before HIIT training is effective for both strength and glycolysis enhancement.

AGE-RELATED DEFICITS IN SKELETAL MUSCLE FIBRE HYPERTROPHY IN RESPONSE TO RESISTANCE EXERCISE TRAINING ARE NOT LIMITED BY MYONUCLEAR ADDITION

BROOK, M.S.1, TARUM, J.2, WILKINSON, D.J.1, MITCHELL, W.K.1, LUND, J.L.1, PHILLIPS, B.E.1, SZEWCZYK, N.J.1, GREENHAFF, P.L.1, SMITH, K.1, KADI, F.2, ATHERTON, P.J.1

NOTTINGHAM UNIVERSITY, ÖREBRO UNIVERSITY

INTRODUCTION: Cumulative increases in muscle protein synthesis (MPS) following bouts of resistance-exercise-training (RET) result in muscle protein accretion, which ultimately leads to increased muscle cross sectional area (CSA) (i.e. hypertrophy). However, we have shown that RET-induced skeletal muscle hypertrophy is attenuated in older (O) vs. younger (Y) individuals1, ostensibly through impaired ribosomal biogenesis and long-term MPS. Nonetheless, since both MPS and ribosomal biogenesis processes depend upon myonuclei activity within a finite area of cytoplasm (i.e. myonuclear domain (MND)), the dysregulation of satellite cell (SC) mediated myonuclear addition could be another factor in blunted hypertrophy with age e.g. due to declines in SC number/function2. To investigate this, we determined the effect of age on myonuclear addition in relation to myofibre CSA following RET.
METHODS: 8 young (Y: 23±1y) and 7 older (O: 69±3y) healthy men undertook 6-wks supervised progressive unilateral RET 6×8 reps, 75%-1RM 3.wk-1. Vastus Lateralis (VL) muscle biopsies were taken at 0/3/6-wk to quantify muscle fibre CSA, myonuclei and MND, using standard techniques3.
RESULTS: After 6-wks RET, only Y increased type 2 CSA: 4949±459μm2 at baseline to 6144±483μm2 and 5992±491μm2 at 3 and 6-wks respectively (both P<0.01); O being 5209±410μm2, 5355±535μm2 and 5857±478μm2 at 0, 3 and 6-wks respectively (N.S). Similarly, Y increased type 1 fibre area from 4508±534μm2 at baseline to 5497±510μm2 and 5402±351μm2 at 3 and 6-wks respectively (both P<0.05); instead, O displayed no change from 5120±402μm2 at baseline to 5606±620μm2 at 3-wks, fibre area increased at 6-wks 6017±482μm2 (P<0.05). Type 2 fibre myonuclei increased in Y from 2.5±0.1 at baseline to 3.3±0.2 and 3.9±0.3 (both P< 0.001) and in O from 2.4±0.1 at baseline to 3.4±0.1 and 3.8±0.1 (both P<0.001) at 3 and 6-wks respectively. Type 1 fibre myonuclei increased in Y from a baseline of 2.5±0.2 to 3.2±0.2 and 3.7±0.3 (both P<0.001) and in O from a baseline of 2.3±0.1 to 3.0±0.1 and 3.6±0.2 at 3 and 6-wks respectively. Type 2 fibre MND was initially maintained in Y, from 2009±189μm2/nuclei at baseline to 1883±149μm2/nuclei at 3-wks, before decreasing at 6-wks to 1568±93μm2/nuclei (P<0.01); the same pattern was evident in type 1 fibres. In O, MND declined from 2153±170μm2/nuclei to 1598±159μm2/nuclei and 1525±85μm2/nuclei at 0, 3 and 6-wks respectively (Both P<0.001); the same pattern was evident in type 1 fibres. Interestingly, there was a correlation between fibre hypertrophy and myonuclei number in type 1 (P<0.05; r2 0.4) but not type 2 myofibres.
CONCLUSION: Myonuclear accretion is maintained with RET in older age despite blunted hypertrophy, suggesting myonuclei addition- and by extension satellite cell activity- does not limit hypertrophy with age. Relationships between myonuclei accretion and hypertrophy are stronger in type 1 fibres, suggesting novel fibre-specific hypertrophy mechanisms.

EFFECTS OF RESISTANCE TRAINING ON THE CARDIAC REMODELING OF INFARCTED RATS, MORPHOLOGICAL ASPECTS.

GONÇALVES, L., DE FRANÇA, E., MIRANDA, C.M., SANTANA, J.O., SOUZA, R.R., MAIFRINO, L., SANCHES, I.C., RODRIGUES, B., CAPERUTO, E.

SÃO JUDAS TADEU UNIVERSITY, UNICAMP

INTRODUCTION: Acute myocardial infarction (AMI) is one of the main causes of death, morbidity and incapacitation. AMI causes cardiac remodeling with changes in the heart geometry, mass, volume and structure because of the compensatory response. Rehabilitation programs usually are carried out with aerobic exercises, however, resistance training has been demonstrated to be a useful and safe non-pharmacological conduct that is able to improve the patients functional capacities. The aim of this study was to analyze the effects of 7 days of resistance training in the biometric and histomorphometric parameters of infarcted Wistar rats.
METHODS: We used 40 Wistar rats from the USJT vivarium, with average weight of 300g divided in 4 groups. SI group – infarcted and sedentary animals, (n=5); TI group – infarcted and trained animals (n=5); SS group – sedentary SHAM animals (n=5) and ST group –

trained SHAM animals (n=5). After this period, all animals were sacrificed and samples of the left ventricle were prepared for histological analysis. Data were analyzed through the ANOVA test with the Tukey post test with significance determined to be $p<0.05$.
RESULTS: Trained animals had a lower body weight when compared to the sedentary, however the infarcted groups showed larger heart weight values probably caused by the inflammatory process. Regarding the stereologic parameters, the volume density of collagen fibers type I (Vv[col I]) and type III (Vv[col III]) decreased in the infarcted and trained animals reducing the left ventricle stiffness. The amount of capillaries (Vv[cap]) increased in the necrotic area as an attempt to reduce the damage due to the infarction with larger values for the IS group. The amount of myocytes (Vv[mio]) showed no differences although the IT group presented a larger (Vv[mio]) when compared to IS group. Regarding the morphometric aspects the IS group presented smaller myocyte area (ASTm) when compared to the SS group, indicating a better condition of the cardiac tissue. Infarcted rats had a bigger nuclear area (ASTn) when compared to the SHAM groups. This bigger nuclear volume in the trained animals is related to a higher demand on genes expression towards the recovery of the tissue or to the inflammation end.
CONCLUSION: Our data revealed that resistance training was efficient to promote positive morphometric and stereologic responses on infarcted rats trained for only 7 days. The adoption of this non-pharmacological short term intervention in the treatment of infarcted individuals is able to improve the cardiac condition.

NO ADVANTAGE OF HIGH OVER MODERATE-TO-LOW WEEKLY RESISTANCE TRAINING VOLUME ON SKELETAL MUSCLE HYPERTROPHY AND STRENGTH DEVELOPMENT

EFFECT OF DIFFERENT MUSCLE ACTION RESISTANCE TRAINING ON TRADITIONAL AND ALTERNATIVE H/Q RATIOS

RUAS, C.V.1,4, BROWN, L.E.2, LIMA, C.D.3, HAFF, G.G.1, PINTO, R.S.4
1:EDITH COWAN UNIVERSITY, AUSTRALIA; 2:CALIFORNIA STATE UNIVERSITY, FULLERTON, USA; 3: MEMORIAL UNIVERSITY OF NEWFOUNDLAND, CANADA; 4: FEDERAL UNIVERSITY OF RIO GRANDE DO SUL, BRAZIL

INTRODUCTION: Traditional hamstrings-to-quadriceps (H:Q) conventional (CR) and functional ratios (FR) measured by concentric (CON) and eccentric (ECC) peak torque (PT) are commonly used to measure lower-extremity muscle balance and injury risk. However, since traditional H:Q ratios are based only on maximum strength values, alternative H:Q ratios, measured by muscle thickness (MT), muscle activation (MA) and rate of torque development (RTD), have been proposed to more closely approximate sports performance. The aim of this study was to compare different resistance training (RT) protocols on traditional and alternative H:Q ratios.
METHODS: Forty males (age 22.87 ± 2.28 yrs, mass 70.66 ± 11.04 kg, ht 174.29 ± 6.9 cm) performed 12 sessions of non-dominant leg RT of Q and H on a Biodex isokinetic dynamometer. Participants were randomly assigned to one of 4 groups; CON Q and CON H (CON/CON), ECC Q and ECC H (ECC/ECC), CON Q and ECC H (CON/ECC), or no training (CTRL). RT began with 1 set of 10 maximal repetitions at 210°/s concentrically and 60°/s eccentrically. Volume of training was increased by adding 1 set after every 2 sessions. Intensity of training was increased every 2 sessions by decreasing the angular velocity for CON and increasing it for ECC in 30°/s increments. Q CON PT, H CON and ECC PT, as well as Q and H MT, MA, and RTD were measured 72h before and after training. Q and H PT and RTD were measured by using the same Isokinetic Dynamometer, MA was assessed with the use of electromyography, and MT was measured with the use of real-time portable B-mode ultrasound. CR, FR, MT, MA, and RTD ratios were calculated by H CON PT/Q CON PT, H ECC PT/Q CON PT, H MT/Q MT, H MA/Q MA, and H RTD/Q RTD.
RESULTS: A 5x2x4 (ratio x time x group) ANOVA showed a three-way interaction. This was followed up with four 5x2 (ratio x time) ANOVAs, one for each group. CON/CON and CON/ECC demonstrated no interactions or main effects. ECC/ECC demonstrated an interaction, where post FR (0.85 ± 0.15) was greater than pre (0.75 ± 0.11). CTRL demonstrated an interaction, where pre RTD ratio (1.10 ± 0.67) was greater than post (0.73 ± 0.33).
CONCLUSION: These findings suggest that ECC/ECC RT increases FR, but no RT is effective at increasing CR or alternative H:Q ratios. Therefore, FR may be the most sensitive measurement of muscle balance after ECC only RT.

EFFECTS OF AN 8-WEEK DVD-ASSISTED FOLLOWING INSTRUCTOR-LED RESISTANCE TRAINING PROGRAM ON FUNCTIONAL FITNESS FOR COMMUNITY-DWELLING MIDDLE-AGED AND OLDER ADULTS

CHEN, L.H.1, LIU, Y.J.1, TSAI, C.C.1, LIN, L.L.2
NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Ageing is an apparent phenomenon in Taiwan. Research indicated that resistance training (RT) is beneficial to increase functional fitness, the physical capacity that is needed to undertake normal everyday activities for the elderly. In an effort to promote RT-type programs to respond to "ageing in place" and engage a broader segment of older population, community-based digital video disk (DVD) assisted programs may be a relatively effective and simple means for RT program delivery. The present study aim to investigate the effects of a conventional instructor-led followed by DVD-assisted RT program on functional fitness for the middle-aged and older community-dwellers.
METHODS: Twenty-four subjects averaged 61.8 years were divided into exercise group (N=14, EX) and control group (N=10, CON). The EX took part in a 60 minutes RT program 3 times a week for 8 weeks. The program consisted of two 4-week cycles, first was the basics and second was the advanced. The instructor-led sessions were on a 3-3-2-1 frequency mode for each 4-week cycle, staring with basic aerobics and body weight training followed by water bottle aided protocols. Sessions without instructor-led, the DVD-assisted RT was delivered. One DVD was produced for each cycle based on progression of RT principles designed by the same qualified instructor. The CON kept their normal lifestyle. Senior functional fitness tests were implemented at baseline and after the intervention. Independent and paired T tests were conducted to test between groups and pre-and-post differences.
RESULTS: Significant differences were found in 30-sec chair stand between EX and CON groups (p=.021). There were also significant improvements in arm curl (p=0.001), 30-sec chair stand (p=0.003) and 2-minutes stepping tests for EX group after 8-weeks of intervention.
CONCLUSION: The 8-weeks of instructor-led followed by DVD-assisted RT program had significant effects on upper, lower limb strength and cardiovascular fitness in a group of community-dwelling seniors in Taiwan. Though not much between-group and pre-post differ-

ences in test items, the self-selectiveness of this younger and healthier samples may hinder the possible effects of RT as shown in other study (McAuley, et al., 2013). The short in duration of program may be another factor behind the scene. However, maintenance of physical activity was achieved as other study (Fanning, 2016). In conclusion, the 3-3-2-1 frequency mode of instruction in a RT program might be feasible, convenient, and cost-effective to improve functional fitness in older adults dwelled in the community, especially when little coaching resources is available.

EFFECTS OF A MACHINE-BASED SELF-PACED GROUP RESISTANCE TRAINING ON MOBILITY AND FRAILTY PREVENTION FOR COMMUNITY-DWELLING ELDERLY

LU, T.J.1, LIN, C.Y.2, CHEN, L.H.1
NATIONAL TAIWAN SPORT UNIVERSITY

INTRODUCTION: Mobility is essential to reduce the risk of falls, enhance quality of life, as well as frailty prevention for older adults. Research found that resistance training (RT) increase age-related muscle strength, decrease muscle mass loss, and thereby improve mobility for older population. Properly use of weight machine at a self-paced training format may gain benefits not only as conventional RT but also fulfill need for frailer older individuals with various health conditions. This study aimed to investigate the effect of a machine-based self-paced group RT program on mobility and frailty prevention for older population.
METHODS: Twenty-two older adults were recruited from the community. All subjects took part in the machine-based RT for 60 minutes per session, 2 to 3 times per week for 7 weeks. SMARC electromagnetic training machine were used in the study. The first 3-week of RT was as baseline and familiarized stage followed by two two-week self-paced stages. In the familiarized stage, subjects were determined their training level by the instructors. In the self-paced stages, subjects were encouraged to perform movements as rapidly as possible on their self-selected pace based on the machine-recorded work output from previous session. Fried and colleague's physical phenotype scale validated in the Cardiovascular Health Study was used to evaluate frailty status. Mobility assessments included 30-second sit to stand (STS), 6-m walk test, timed up and go. All measures were collected at baseline and after the RT. Wilcoxon signed rank test was conducted for the analysis.
RESULTS: Fourteen older adults aged 66-83 years completed all tests and with an averaged participation rate of 90.1%. The rate of perceived exertion was between 3 to 6 (Borg scale 0-10). Significant improvement were found in STS ($p = .017$), usual gait speed ($p = .041$), but not in fast gait speed. Pre-frailty rate of participants decreased from 21.4% to 7.1% after intervention.
CONCLUSION: The machine-based self-paced RT for a minimum of 7 weeks was able to improve some mobility parameters and render frailty prevention for older adults. Although self-selected RT intensity may not consistent with the American College of Sports Medicine Guideline (Elsangedy et al., 2013), velocity-based RT program might bring greater advantages on muscle fitness even for individuals with hip osteoarthritis (Fukumoto et al., 2014). Our pilot trial using the self-adjusted electromagnetic training machine may be feasible for frailer older adults in need of RT for its easy applicability. Nevertheless, a carefully supervision and gradual leveraging between pace and intensity may be essential to grant the most advantages for participants of old age.

MO-PM01 Muscle & Tendon

THE EFFECTS OF MORPHOLOGICAL AND MECHANICAL PROPERTIES OF MUSCLE-TENDON UNIT ON SPRINT PERFORMANCE IN JUNIOR SPRINTERS

ENOMOTO, S., HASHIMOTO, R., ODA, T., KAGA, M.
HYOGO UNIVERSITY OF TEACHER EDUCATION, OKAYAMA UNIVERSITY

INTRODUCTION: The morphological and mechanical properties of muscle-tendon unit (MTU) influence stretch-shortening cycle movements which enhances performance of MTU in such as running (3) and jumping (1). Furthermore, low joint flexibility induced by stiff tendons (2) increases the risk of injury in children (e.g. Sever's disease (5), Osgood-Schlatter disease (4)). To enhance performance and prevent injury, it is necessary to reveal the junior sports player's characteristics of MTU. Although some researchers investigated the relationship between sprint performance and property of MTU in adults so far (3), there is little information examined in children. The aim of this study was to investigate its relationship in junior sprinters.
METHODS: Fifteen junior sprinters (age 11.2 ± 0.8 years) participated in this study. Their official record in the 100-m race was 12.72 to 14.67 s (14.0 ± 0.7 s). Tendon stiffness, muscle thickness, and maximal isometric voluntary contraction (MVC) of both knee extensors and plantar flexors as well as 100-m running record were measured.
RESULTS: There was no significant correlation between tendon stiffness of knee extensors and 100-m running record ($r = -0.215$, ns). On the other hand, we found a negative correlation between tendon stiffness of plantar flexors and 100-m running record ($r = -0.511$, $p < 0.05$). Both muscle thickness ($r = -0.584$, $p < 0.05$) and MVC ($r = -0.647$ $p < 0.01$) of knee extensors were significantly correlated to 100-m running record, but those of plantar flexors were not (muscle thickness: $r = 0.024$, ns; MVC: $r = -0.453$, ns).
CONCLUSION: This study demonstrated that the thick strong muscle of knee extensors and stiff tendon of plantar flexors are related to high sprint performance in junior sprinters. These results would indicate that the high sprint performance results from the greater power

produced by knee extensors which are efficiently transmitted to the bone (1), and finally to the ground, by a stiff tendon of plantar flexors. Although excellent sprinters with a stiff tendon of plantar flexors have the potential for high performance, it must be noted that this could lead to injury. In conclusion, the results suggest that the thick strong muscle of knee extensors and the stiff tendon of plantar flexors affect sprint ability positively, but it would be a risk of injury in junior sprinters.

MORPHOLOGICAL AND MECHANICAL PROPERTIES OF MUSCLES AND TENDONS: EFFECTS OF MATURATION AND ATHLETIC TRAINING

CHARCHARIS, G., MERSMANN, F., BOHM, S., ARAMPATZIS, A.

HUMBOLDT-UNIVERSITÄT ZU BERLIN

INTRODUCTION: The combined effects of mechanical loading and maturation during adolescence are still not well understood. The purpose of the study was to gain insight into the effects of this two-fold stimulus by comparing the properties of the knee extensor muscle-tendon unit (MTU) of early and late-adolescent boys and adult men.
METHODS: Eighty male participants, comprised of athletes (A, n=43) and untrained controls (C, n=37) in three age groups (early-adolescents [EA, n=28] 12-14yrs; late-adolescents [LA, n=27], 16-18yrs; young adult [YA, n=25], 20-35yrs) were included in the study. Muscle strength of the knee extensors, patellar tendon mechanical properties and vastus lateralis (VL) architecture were investigated using inverse dynamics and ultrasonography. For the statistical analysis, a two-way ANOVA was used.
RESULTS: Athletes had significantly greater muscle strength (A: 4.2±0.8 Nm/kg, C: 3.6±0.6 Nm/kg; $p<0.001$), normalized patellar tendon stiffness (A: 62.0±16.7 kN/strain; C: 53.7±15.7 kN/strain; $p=0.013$), and VL thickness (A: 22.6±4.5mm; C: 20.1±4.7mm; $p=0.04$) compared to non-athletes. Further, there was a tendency towards higher tendon strain in athletes (A: 8.6±2.4%, C: 7.7±2.5%; $p = 0.084$). The EA had significantly lower muscle strength (EA: 3.4±0.6 Nm/kg, LA: 4.2±0.7 Nm/kg, YA: 4.1±0.7 Nm/kg; $p<0.001$) and stiffness (EA: 45.6±13.7 kN/strain; LA: 62±13.4 kN/strain, YA: 67±15.3 kN/strain $p<0.001$) compared to the older groups, with no significant differences between LA and YM ($p>0.05$). VL thickness was different between all age groups (EA: 18.2±3.7mm, LA: 21.7±4mm; YM: 24.7±4.1mm; $p<0.001$). Tendon strain during the maximum isometric contraction was in tendency greater in adults compared with EA (EA: 7.2±2.4%, YA: 8.8±2.8%; $p=0.0502$), while strain in LA (8.4±2.1%) did not differ to the other groups ($p>0.05$). There were no significant age-by-group interactions. A linear regression analysis for the adolescent groups indicated a lower association of tendon force and stiffness in athletes compared to controls.
CONCLUSION: Our results indicate that athletic training leads to greater muscle strength of the knee extensors and VL thickness, as well as patellar tendon stiffness in both adolescents and adults compared to untrained controls, yet indications for an imbalance of tendon force and stiffness were present in the adolescents. The mechanical demand placed upon the tendon (i.e. strain) seems to be greater in athletes and might increase with age. The major changes in tendon stiffness related to maturation seem to occur between early and late adolescence.

COMPARISON OF EFFECTS OF B-HYDROXY B-METHYLBUTYRATE (HMB) AND L-LEUCINE SUPPLEMENTATION ON MUSCLE REGENERATION

TAKUYA, N., TAKANAGA, S., YUYA, O., THORU, T.

UNIVERSITY OF TSUKUBA

INTRODUCTION: Muscle injury is one of most frequent trauma in sports. Skeletal muscle contains a well-characterized process to repair damaged muscle fibers after injury. This healing process requires the function of satellite cells, which are the resident skeletal muscle stem cells that become activated after muscle injury. β-Hydroxy β-Methylbutyrate (HMB) are often used to promote muscle recovery. HMB is a metabolite of leucine. HMB and L-Leucine supplementation has been reported to promote the activation of satellite cells. However, both supplementation effects on muscle regeneration has not been compared. The purpose of this study is to compare effects of HMB and L-leucine on muscle regeneration.
METHODS: 8 weeks of age male ICR mice were randomly divided into 3 groups of 6 animals after a 1-week acclimation period. D.W (500mg/kg/day), HMB (500 mg/kg/day) or L-Leucine (500mg/kg/day) was orally administrated once per day during the experiment. All mice were anesthetized with isoflurane prior intramuscular administration of 50 µl of 1.2% BaCl2 solution to the tibialis anterior (TA) muscle. During injection, 1.2% BaCl2 solution was slowly released into the TA muscle to induce extensive injury and skeletal muscle regeneration. Regenerating TA muscles were collected on 4 days (Inflammatory phase) and 7 days (regenerative phase) after BaCl2-induced muscle injury.
RESULTS: In the inflammatory phase, HMB and leucine increased the number of Pax7 and MyoD positive cell. In the regenerative phase, HMB and L-Leucine increased the cross-sectional area of regenerating muscle fibers compared to control, but no difference was confirmed between both supplementation.
CONCLUSION: We suggested that HMB and L-Leucine are effective for early recovery from muscle injury. However, there were no differences of both supplementation.

AMELIORATIVE EFFECT OF FUCOXANTHIN ON DECREASED SKELETAL MUSCLE MASS IN MICE

INTRODUCTION: It has been suggested that a combination of sarcopenia and obesity (i.e., sarcopenic obesity), which may reinforce each other, is more strongly associated with disability and metabolic/cardiovascular diseases than either body composition type alone (Baumgartner, 2000; Baumgartner et al., 2004; Morley et al., 2001; Roubenoff, 2000). Therefore, countermeasure that simultaneously

suppress fat gain and muscle atrophy would be warranted to prevent the promotion of sarcopenic obesity, in essence the worst of both worlds. Fucoxanthin (FX), a carotenoid that found in edible seaweed, has the suppressing effect of adipocyte differentiation (Maeda et al, 2006), in addition to radical scavenging activity and anti-inflammatory effects. In vivo study, Hosokawa et al. demonstrated that dietary FX attenuates the weight increase of white adipose tissue (Hosokawa et al., 2010). However, it remains unknown whether administration of FX suppresses a decrease in muscle mass in vivo. The administration of high concentrations of dexamethasone (DEX) causes degradation of skeletal muscle, mainly due to the stimulation of muscle proteolysis. On the other hand Fructus Schisandrae, the dried fruit of Schizandra chinensis Baillon, attenuates DEX-induced muscle atrophy through antioxidant and anti-inflammatory action (Kim et al., 2015). Given that FX also has strong anti-oxidant ability and anti-inflammatory effects as aforementioned, it is reasonable to hypothesize that an administration of FX also attenuates DEX-induced decrease in muscle mass. To address this hypothesis, we investigated the effects of the administration of FX on inhibition of DEX-induced decrease in muscle mass in adult mice.
METHODS: ICR mice (17 weeks of age) were divided into three groups, 1) the intact vehicle control (Control), 2) the DEX-treated group (DEX), 3) FX and DEX-treated group (FX-DEX)]. In the DEX and FX-DEX groups, muscle atrophy was induced by an oral administered of DEX (10mg/L) for 13 days. The mice in the FX-DEX group were provided with FX (0.2%) diets from 2 weeks before DEX treatment to the end of the study. The weights of tibialis anterior muscle (TA) and visceral fat were measured.
RESULTS: There was no significant difference in food consumption between the groups. Body weight and visceral fat mass in the FX-DEX group were significantly lower than those in the Control group ($p<0.01$). TA mass in the DEX group was significantly lower than that in the Control group ($p<0.01$). However, there was no significant difference between the Control group and FX-DEX group in the TA mass.
CONCLUSION: These results suggest that, in addition to fat loss, FX might attenuate DEX-induced decrease in muscle mass. Thus FX may have a potential to prevent the promotion of sarcopenic obesity.

EFFECTS OF AEROBIC EXERCISE TRAINING ON MUSCLE DAMAGE, MUSCLE STRENGTH, AND MITOCHONDRIAL FUNCTION IN ATORVASTATIN-TREATED RAT SKELETAL MUSCLES

INTRODUCTION: Statins (3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors) are cholesterol-lowering drugs widely used in the treatment of cardiovascular disease. However, statins also cause adverse side effects in skeletal muscle ranging from fatigue to fatal rhabdomyolysis. Recently, we found that long-term (48 hour) treatment of simvastatin induced cell death due to impaired mitochondrial respiration and oxidative stress leading to mitochondrial apoptotic signaling in primary human skeletal muscle cells (Kwak et al., 2012), and 10 weeks atorvastatin treatment in vivo resulted in muscle damage, reduced muscle strength, and impaired mitochondrial function in rat skeletal muscles (Kwak et al., 2017). The purpose of this study was to determine the effects of aerobic exercise training on muscle damage, muscle fatigue/strength, and mitochondrial function (e.g., mitochondrial respiration, H_2O_2 emission, Ca^{2+} retention capacity) in atorvastatin-treated rat skeletal muscles.
METHODS: Male Wistar rats were randomly assigned to control (CON), 5 mg atorvastatin treated group (ATOR), and 5 mg/kg atorvastatin plus aerobic exercise training group (ATOR+EX) (N=12 rats/group). Animals were administered via oral gavage with a vehicle or 5 mg/kg/day atorvastatin dissolved in 0.25 % w/v hydroxylpropyl methylcellulose for 12 weeks. Forelimb muscle strength and serum creatine kinase (CK) concentration (i.e., muscle damage marker) were measured. The skeletal muscles such as soleus (SOL, Type I) and white gastrocnemius (WG, Type IIb) were permeabilized by sarponin for determination of mitochondrial respiratory capacity, mitochondrial H_2O_2 emission, and Ca^{2+} retention capacity.
RESULTS: Maximal forelimb strength and forelimb fatigue index were significantly decreased after 6 weeks and 8 weeks, respectively in ATOR. In contrast, serum CK concentration was significantly increased in ATOR compared with CON. However, aerobic exercise training attenuated atorvastatin-induced impairment in maximal forelimb strength and fatigue index, as well as reduced serum CK concentration ($p<0.05$). The mitochondrial O_2 respiratory capacity and Ca^{2+} retention capacity were significantly reduced by 12 weeks of ATOR in both SOL and WG ($p<0.05$). In addition, mitochondrial H_2O_2 emission was significantly increased in ATOR compared with CON in both SOL and WG ($p<0.05$). However, aerobic exercise training attenuated mitochondrial O_2 respiratory capacity, Ca^{2+} retention capacity, and mitochondrial H_2O_2 emission in atorvastatin-treated skeletal muscles.
CONCLUSION: These data demonstrate that long-term treatment of atorvastatin results in muscle damage, reduced muscle strength, and impaired mitochondrial function in skeletal muscles. However, aerobic exercise training for 12 weeks attenuates muscle damage, maintains muscle strength, and ameliorates mitochondrial dysfunction induced by atorvastatin, suggesting that aerobic exercise training plays a therapeutic role in atorvastatin-induced myopathy (NRF-2016R1A2B4014240).

ACTIVATION OF PROTEIN SYNTHESIS SIGNALING VIA INCREASE IN MUSCLE 5A-DIHYDROTESTOSTERONE BY ACUTE RESISTANCE EXERCISE AFFECTS MUSCLE HYPERTROPHY IN TYPE 2 DIABETIC RATS

HORII, N.1, HASEGAWA, N.1,2, FUJIE, S.1,2, UCHIDA, M.1, INOUE, K.1, IEMITSU, M.1

1> RITSUMEIKAN UNIVERSITY, 2> JSPS RESEARCH FELLOW.

INTRODUCTION: Diabetes results in loss of muscle mass as well as reduction of sex steroid hormone secretion. We demonstrated that dehydroepiandrosterone (DHEA), a sex steroid hormone precursor, administration elevated muscle 5α-dehydrotestosterone (DHT) secretion by increased 5α-reductase and induced muscle hypertrophy in type 2 diabetic rats. Furthermore, our recent study showed that increase in muscle DHT level by resistance training was associated with muscle hypertrophy in older males (Sato et al., 2014). However, it is still unclear whether the increase in muscle DHT production by resistance exercise is involved in the activation of muscle protein synthesis signaling and consequently affects muscle hypertrophy. Therefore, this study aimed to clarify whether activation of protein synthesis signaling via acute resistance exercise-induced increase in muscle DHT affects development of muscle hypertrophy in type 2 diabetic rats.
METHODS: Study 1: Male 20-week-old type 2 diabetic (OLETF) rats were divided into 7 groups: sedentary control and immediately after, an hour, and three hours after resistance exercise alone or in combination of 5α-reductase inhibitor groups.
Study 2: Male 20-week-old OLETF rats were randomly divided into 3 groups; sedentary control, resistance training (3 times a week for 8 weeks) or resistance training with 5α-reductase inhibitor continuously.
RESULTS: Study 1: Acute resistance exercise in OLETF rats significantly increased the levels of muscle testosterone and DHT and 5α-reductase protein expression as well as increase in muscle protein synthesis signaling such as mTOR and p70S6K phosphorylation

(p<0.05). Administration of 5α-reductase inhibitor was suppressed the exercise-induced effects on muscle protein synthesis signaling with decrease in muscle DHT level (p<0.05).
Study 2: To confirm whether the increase in protein synthesis via muscle DHT secretion by acute resistance exercise is involved in muscle hypertrophy, this study examined the effect of continuously administration of 5α-reductase inhibitor during resistance training. Resistance training in OLETF rats significantly increased the levels of muscle DHT and 5α-reductase protein expression as well as increase in muscle mass and cross-sectional area (p<0.05). However, these training effects were significantly suppressed by chronically administration of 5α-reductase inhibitor (p<0.05).
CONCLUSION: These results suggest that activation of protein synthesis signaling via acute resistance exercise-induced increase in muscle DHT may be involved in muscle hypertrophy in type 2 diabetic rats.

TIME-COURSE OF MUSCLE MORPHOLOGICAL AND FUNCTIONAL ADAPTATIONS DURING A 6-WEEK PLYOMETRIC TRAINING

MONTI, E.1, FRANCHI, M.V.2, NARICI, M.V.1

<1> UNIVERSITÀ DI PADOVA, PADOVA, ITALY; <2> UNIVERSITATSKLINIK BALGRIST, ZURICH, SWITZERLAND

INTRODUCTION: Muscle power is a major determinant of sport performance requiring explosive force such as throwing and jumping. Plyometric training (PT) has been shown to be particularly effective for increasing quadriceps power and size in young soccer players [1]. The aim of this study was to assess the onset of changes in muscle morphology, strength and power during a 6-week PT on a novel device based on a trampoline connected to an inclined sledge (Tramp Trainer, TT).
METHODS: Eight males (age 25.4±4.6 years; mass 69.7±13.5 kg; height 173.6±4.7 cm) were recruited after ethics approval. Participants trained 3 times/week with 4-5 sets of 30 jumps. Data were acquired at 0, 2, 4 and 6 weeks of PT. Quadriceps muscle cross-sectional area (CSA) and vastus lateralis (VL) fascicle length (Lf) and pennation angle (PA) were assessed by ultrasound. Knee extensors isometric maximum voluntary contraction (MVC) torque and peak power (PP) were assessed by Cybex dynamometry and by the Nottingham Power Rig, respectively. Data (means±SD) were analysed for statistical significance using repeated one-way ANOVA with Bonferroni's post-hoc test.
RESULTS: PP increased by 15.7% (n.s.), 25.5% (p<0.05) and 31.8% (p<0.05) after 2, 4 and 6 weeks of PT, MVC increased by 18% (p<0.05) after 2 weeks and by 22% after 4 weeks (p<0.05) with no further increase. Lf increased by 2.2% (p<0.05), 4.0% (p<0.01) and 4.4% (p<0.01) after 2, 4 and 6 weeks; PA increased by 5.8% (p<0.01) after 6 weeks. Quadriceps CSA increased by 2.4% (p<0.05) after 4 weeks and by 3.1% (p<0.05) after 6 weeks.
CONCLUSION: These findings support the contention that plyometric training is particularly effective in promoting early gains in muscle size, strength and peak power. Notably, an increase in fascicle length after just two weeks of PT seems indicative of an early addition of sarcomere in series, which precedes the addition of sarcomere in parallel reflected by the increase in muscle CSA at four weeks. Plyometric exercise seems thus highly suitable for developing muscle power within few weeks of training.

MUSCLE FASCICLE BEHAVIOUR OF THE BICEPS FEMORIS LONG HEAD DURING THE NORDIC HAMSTRING EXERCISE

RAITERI, B.J., BELLER, R., HAHN, D.

RUHR-UNIVERSITY BOCHUM

INTRODUCTION: Hamstring muscle strain injuries are the most common injuries among high-speed running athletes and ~80% of such injuries involve the biceps femoris long head (BFlh) (Verrall et al., 2003). A key risk factor for a first-time hamstring injury is thought to be short BFlh muscle fascicles (Timmins et al., 2015). The Nordic Hamstring Exercise (NHE) has been promoted as an eccentric exercise to increase BFlh muscle fascicle length following training (Bourne et al., 2016) and reduce hamstring injury incidence (Petersen et al., 2011). However, whether the BFlh muscle fascicles undergo an eccentric contraction during the NHE has not yet been investigated and this was the aim of the current study.
METHODS: We employed surface electromyography and conventional ultrasound imaging to respectively examine BFlh muscle activities and in vivo fascicle length changes of its superficial compartment during the NHE in recreationally-active male athletes (n=7). Participants performed the NHE in a custom-made setup while knee flexion forces and angles from the left-sided leg were measured using a force transducer at the ankle and goniometer, respectively. After familiarisation with the exercise, at least six trials were performed and the trial with the largest peak knee flexion force was analysed.
RESULTS: Mean peak knee flexion force and torque were 446±52 N and 183±27 Nm, respectively, at a mean knee flexion angle of 39±8° during the NHE. From the starting position (90° knee flexion), the BFlh muscle fascicles initially shortened, but the amount of shortening was not possible to quantify due to substantial out-of-plane motion of the muscle fascicles with respect to the ultrasound imaging plane. Following fascicle shortening, preliminary results (n=3) show that the BFlh muscle fascicles either acted isometrically or lengthened slightly (~4 mm) over mean knee flexion angles of 66-61°. The BFlh fascicles then actively lengthened by 14±9 mm until a mean knee flexion angle of 32±7°, after which knee flexion force rapidly declined due to BFlh muscle deactivation.
CONCLUSION: This study provides the first in vivo evidence that the BFlh muscle fascicles actively stretch during peak force production in the NHE. We propose that the eccentric behaviour of the BFlh muscle fascicles likely enhances peak force production relative to concentric or isometric fascicle behaviour and stimulates sarcomerogenesis, which might be responsible for the ~14% longer BFlh muscle fascicles following ten weeks of NHE training (Bourne et al., 2016). Whether the BFlh fascicles are stretched as much during the NHE post-NHE-training remains to be tested. We recommend further imaging studies of the BFlh during exercises where its fascicles are thought to undergo active stretch to confirm that this is the case.

SKELETAL MUSCLE FUNCTIONAL RESERVE AT EXHAUSTION: BETWEEN-SEX DIFFERENCES AND PHYSIOLOGICAL DETERMINANTS

PEREZ-VALERA, M.1, GELABERT-REBATO, M.1, MARTIN-RINCON, M.1, CURTELIN, D.1, GALVAN-ALVAREZ, V.1, ALCAZAR, J.2, MORALES-ALAMO, D.1, CALBET, J.A.1

1. UNIVERSITY OF LAS PALMAS DE GRAN CANARIA; 2. UNIVERSITY OF CASTILLA-LA MANCHA

INTRODUCTION: During incremental exercise to exhaustion, task failure occurs despite a muscular functional reserve (FR). The aim of this investigation was to determine the physiological mechanisms accounting for the FR in men and women. We hypothesized that the FR is determined by the anaerobic capacity and hence it would be lower in women than men.
METHODS: Physically active volunteers (18M and 18W, age 21-36) had their body composition (DXA), VO2max, VO2/intensity relationship, and maximal O2 deficit (OD) assessed. Then they performed three consecutive constant-intensity exercise bouts at 120% of VO2max (120%CI) until exhaustion with 20s recovery periods in-between. The test was completed in two separate occasions, in which recovery between bouts was allowed with either 1) free circulation (120%CI_Fc) or 2) instantaneous occlusion of both legs (Hokanson, 300 mmHg) (120%CI_Occ). ANOVA repeated-measures was used.
RESULTS: VO2max was 17 and 3.5% greater in men than women when expressed per kg of BW ($P<0.05$) and per kg of leg lean mass (LLM) ($P=0.37$), respectively. The OD in mL per kg of LLM was 22% greater in men than women ($P<0.01$). After the first 120%CI_Occ bout, all subjects were able to resume exercise performing 18.5±8.3 and 22.7±12.7% of the initial work (men and women, $P=0.24$). After the second 120%CI_Occ bout, a FR was present (14.6±7.0 and 17.6±11.6% of the initial work, $P=0.35$). The work performed per kg of LLM during the second and third 120%CI_Occ bouts was similar in men and women, as well as the VO2, OD and VO2 per unit of work. The OD for the second bout of exercise was 26.0±8.6 and 27.3±13.0 mL/kg LLM, for men and women, respectively ($P=0.72$), and for the third bout 22.4±8.0 and 22.7±11.7 mL/kg LLM ($P=0.92$). Women had greater O2 extraction than men (near-infrared tissue oxygenation index (TOI), $P=0.03$). The work performed after the first and second occlusions (i.e., the FR) was associated with the VO2max in women ($r=0.57$, $P=0.014$ and $r=0.47$, $P=0.048$), but not in men ($r=0.15$, $P=0.55$ and $r=0.237$, $P=0.35$). No association was found between the maximal OD and the work performed in the second and third bouts preceded by occlusion.
CONCLUSION: This study shows that during exhausting exercise task failure occurs when there is still a large muscular functional reserve. Since the occlusion of the circulation at exhaustion impedes the recovery of phosphocreatine and the exercise intensity was always well above VO2max, without the existence of such a functional reserve our subjects would not have been able to restart pedalling at the end of the first 20s occlusion, and much less after the second occlusion. Our data indicate that this functional reserve depends on energy generation through the glycolysis, which can be recruited similarly by women and men, and is not exhausted by two consecutive trials at 120% of VO2max.

EFFECTS OF TWO DIFFERENT ISOLOAD ENDURANCE TRAINING ON MUSCLE MITOCHONDRIAL BIOGENESIS AND AEROBIC MARKERS OF SWIMMING RATS

RODRIGUES, N.A., GOBATTO, C.A., SOUSA, F.A.B., FORTE, L.D.M., TORSONI, A., FANTI, T., MANCHADO-GOBATTO, F.B.

UNIVERSITY OF CAMPINAS

INTRODUCTION: Physical exercise is a potent promoter of mitochondrial adaptations (Bishop et al. 2014). However, knowledge about the optimal intensity-volume ratio to provide these adaptations is limited. Therefore, this study aimed to investigate aerobic adaptations and protein content of mitochondrial biogenesis markers in skeletal muscle after two different isoload endurance training in swimming rats.
METHODS: Thirty male Wistar rats (60 days old) were divided into two trained groups and one control. The groups were: a) CG (n=10): untrained group, b) TG100 (n=10): 30min swim at 100% of anaerobic threshold, and c) TG120 (n=10): 25min swim at 120% of anaerobic threshold. Despite applied in two different exercise domains both groups trained in identical workload (3000 a.u.). Swim training was performed during 12 weeks and 5 days per week. Protein content of transcription factor A (Tfam) was determined by immuoblotting and citrate synthase activity (CSA) by spectrophotometry in gastrocnemius and soleus. Aerobic capacity (% body mass - %bm) was obtained by lactate minimum test in accordance to DE ARAUJO et al.(2012). Differences among groups were analyzed by ANOVA one-way and Tukey post-hoc test was used when a significant effect was found ($P<0.05$). The results are presented in mean±sem.
RESULTS: Tfam content and CSA presented different responses showing an intensity dependence even in identical workload exercises. This was observed for other markers of mitochondrial biogenesis pathway in human skeletal muscle (EGAN et al. 2010). In gastrocnemius, Tfam content (CG: 0.72±0.11 a.u.; TG100:1.64±0.49 a.u.; TG120:0.62±0.10 a.u.) presented higher value in TG100 than TG120 ($P=0.049$). However, CSA (CG: 357.47±26.83 µmol citrate*min-1*mg prot-1; TG100: 402.15±43.25 µmol citrate*min-1*mg prot-1; TG120: 585.43±82.44 µmol citrate*min-1*mg prot-1) presented higher values in the TG120 than CG and TG100 ($P=0.01$; $P=0.03$). For soleus, Tfam content (CG:1.49±0.24 a.u.; TG100:1.31±0.19 a.u.; TG120:1.42±0.23 a.u.) did not present differences among groups ($P=0.80$). Nevertheless, CSA (CG: 340.53±34.88 µmol citrate*min-1*mg prot-1; TG100: 818.53±153.44 µmol citrate*min-1*mg prot-1; TG120: 414.43±81.95 µmol citrate*min-1*mg prot-1) was higher in TG100 than CG and TG120 ($P=0.007$; $P=0.02$). Although TG120 only presented higher CSA in gastrocnemius, the aerobic capacity (CG:4.27±0.13%bm; TG100:4.62±0.11%bm; TG120:5.1±0.19%bm) of these rats was higher than CG and TG100 ($P=0.003$; $P=0.04$;).
CONCLUSION: These results show that exercise intensity dictates cell adaptations in a muscle dependent way, with high intensity training promoting better aerobic performance. Financial Support: FAPESP 2014/10336-9, CNPq and CAPES

ACUTE IMPLEMENTATION OF TRAIN/RECOVERY WITH LOW CARBOHYDRATE AVAILABILITY DOES NOT COMPROMISE BONE METABOLISM IN WORLD-CLASS TRIATHLETES

HEIKURA, I.A.1,2, COX, G.R.1, MCKAY, A.K.A.1,3, BURKE, L.M.1,2

1: AUSTRALIAN INSTITUTE OF SPORT , 2: AUSTRALIAN CATHOLIC UNIVERSITY , 3: UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Several inter-related strategies to periodise carbohydrate (CHO) availability around exercise include training with low glycogen ("train low") or restricting glycogen resynthesis after training ("sleep low"). While these protocols may enhance training adaptations and performance, less attention has been directed to the potential effects on other body systems such as bone. We investigated the acute effects of training and recovery with low CHO availability on bone markers in elite triathletes.
METHODS: Eleven world-class triathletes (7 F, 4 M) undertook a free-living, monitored 4-w training camp at the Australian Institute of Sport. In a randomised repeated measures design, the participants completed two 4-d training sequences with identical exercise but different approaches to CHO availability around sessions: Days 1&3: afternoon high-intensity training (HIT) with high CHO availability followed by restricted (LOW) or high (HIGH) overnight CHO availability ; Days 2&4 early morning low intensity training (LIT), either fasted (LOW) or with CHO intake pre and during exercise (HIGH). Venous blood samples were collected for bone markers of breakdown (C-terminal telopeptide of type-1 collagen, CTX) and formation (N-terminal propeptide of type 1 procollagen, PINP) at 30min and 0h pre, and 0h, 1h and 3h post LIT.
RESULTS: Although total daily CHO intake did not differ between treatments (7.4±1.1 vs 7.3±1.1 g/kg, LOW vs HIGH, p=0.44), there were differences in its distribution over the day. Specifically, CHO intake before the HIT was 6.6±1.2 and 4.5±0.7 g/kg in LOW and HIGH, respectively (p<0.001), while the intakes post HIT were 0.3±0.1 and 2.7±0.8 g/kg in LOW and HIGH, respectively (p<0.001). Intake immediately before and during the LIT was 1.9±0.1g/kg for HIGH and 0g/kg for LOW. Differences in P1NP and CTX responses to the LIT session were not significant, however, large coefficients of variation (CV) were noted: P1NP 40% and CTX 36%.
CONCLUSION: Contrary to other literature around CHO availability, exercise and bone health, the effect of "sleep low, train low" on markers of bone metabolism was not different compared to training with constant CHO availability ("sleep high, train high"). Before concluding that "sleep low, train low" poses no acute stress to bone, other explanations are possible. The caliber and training history of subjects may be important, and our diet/exercise protocol may not have created sufficient difference in the metabolic stress incurred in the LIT between treatments. Lastly, due to the variability in bone marker measures, our study may have been statistically underpowered to show clear differences between treatments.

CAFFEINE ERGOGENICITY IN MAXIMAL AEROBIC AND ANAEROBIC EXERCISE IS UNRELATED TO IMPROVED MUSCLE DEOXYGENATION

RUIZ-MORENO, C., GUTIERREZ-HELLÍN, J., CUÉLLAR-RAYO, A., LARA, B., DEL COSO, J.

CAMILO JOSE CELA UNIVERSITY

INTRODUCTION: The ergogenic effects of acute ingestion of caffeine (3-9 mg/kg) have been well-contrasted in a myriad of exercise situations. There is also a growing consensus about the main mechanism behind caffeine ergogenicity during locomotor activities, with much evidence in animal and human models supporting the ability of caffeine to act as an adenosine A1 and A2A A2B receptor antagonist. However, there is no information about the effects of caffeine on muscle oxygen saturation and the relationship between skeletal muscle oxidative capacity and caffeine ergogenicity.
METHODS: Twelve healthy and active participants took part in a cross-over, double-blind and placebo-controlled experimental design. In one occasion, participants ingested 3 mg of caffeine per kg of body mass (3 mg/kg), while in another occasion they ingested a placebo (cellulose). Each substance was administered an opaque and unidentifiable capsule and the experimental trials started 45 min after capsule ingestion. The experimental trials consisted of a 10-min warm-up, followed by an incremental cycling test to volitional fatigue (25 W/min) and the 15-s Wingate test (7.0% of body mass), with 7 min of recovery between exercise performance tests. During the exercise testing, muscle oxyhemoglobin saturation was measured by means of near-infrared spectroscopy in the vastus lateralis and VO2 was obtained by means of a gas analyser. One minute after the end of each test, a sample of capillary blood was obtained to measure blood lactate concentration.
RESULTS: In comparison to the placebo, the pre-exercise intake of caffeine increased maximal cycling power reached in the incremental exercise test (3.9 ± 0.7 vs 4.0 ± 0.7 W/kg; P = 0.03) and the blood lactate concentration obtained at the end of the test (12.3 ± 3.4 vs 15.3 ± 2.7 mmol/L; P = 0.05). However, the ingestion of caffeine did not increase VO2max (47.7 ± 7.8 vs 48.4 ± 8.0 mL/kg/min; P = 0.34) and it did not change muscle oxyhemoglobin saturation at the end of the incremental exercise (27.2 ± 14.5 vs 27.4 ± 15.0%; P = 0.31). The ingestion of caffeine increased the peak cycling power obtained during the 15-s Wingate test (9.2 ± 1.3 vs 9.4 ± 1.4 W/kg; P = 0.04) and the blood lactate concentration obtained at the end of the test (12.1 ± 2.8 vs 14.7 ± 4.1 mmol/L; P = 0.01). However, the ingestion of caffeine did not change muscle oxyhemoglobin saturation at the end of Wingate test (25.9 ± 14.7 vs 25.0 ± 16.0%; P = 0.18).
CONCLUSION: The ingestion of 3 mg/kg of caffeine was ergogenic for both aerobic and anaerobic-based cycling tests. However, the ingestion of caffeine did not modify muscle oxygenation at the end of these tests. This information suggests that improved deoxygenation within active muscle is not a mechanism related to the ergogenicity of caffeine in active individuals performing maximal aerobic and anaerobic tests.

INFLUENCE OF NICOTINAMIDE RIBOSIDE SUPPLEMENTATION ON WHOLE-BODY AND SKELETAL MUSCLE METABOLISM IN MAN

STOCKS, B., GRAY, E., ASHCROFT, S., JOANISSE, S., WALLIS, G., PHILP, A.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Niacin compounds induce mitochondrial biogenesis in vitro and in vivo in rodents through elevating cellular NAD+ and the consequential activation of sirtuins and PGC1a. However, in humans nicotinic acid and nicotinamide supplementation can induce painful flushing, inhibit lipolysis and fat oxidation in vivo and can increase feelings of fatigue during exercise. Conversely, nicotinamide

riboside (NR) supplementation increases fat oxidation, metabolic flexibility and endurance performance in rodents and is safe for humans to consume without producing flushing. Thus NR is a promising nutritional strategy to influence substrate oxidation and skeletal muscle adaptations to endurance exercise. These studies aimed to investigate the effect of NR supplementation on whole-body metabolism, skeletal muscle mitochondrial function and mitochondrial biogenic signalling at rest and during exercise in humans.
METHODS: Recreationally active males were recruited to two randomised, counter-balanced, double-blinded crossover studies. In the first arm, eleven participants consumed an acute dose (1000 mg) of NR or placebo (PLA) 12 hours before cycling in the fasted state for one hour at 55% of VO2peak. Expired air and blood samples were collected during exercise. In the second arm, ten participants consumed 1000 mg/day of NR or PLA for one week. Resting metabolic rate and the metabolic response to fasted cycling (one hour at 60% of Wmax) were measured, via gas exchange and blood sampling, following supplementation. In addition, skeletal muscle biopsies were taken from the vastus lateralis at the beginning of the supplementation period and pre-, immediately post- and three hours post-exercise.
RESULTS: A single dose of NR did not alter respiratory exchange ratio (mean ± standard deviation; NR 0.89 +/- 0.03 vs PLA 0.90 ± 0.03), carbohydrate oxidation (NR 1.54 +/- 0.30 vs PLA 1.68 +/- 0.40 g/min) or fat oxidation (NR 0.38 +/- 0.18 vs PLA 0.32 +/- 0.09 g/min) during exercise. Ratings of perceived exertion during exercise were also comparable (NR 11 +/- 1 vs PLA 11 +/- 1) between NR and PLA trials. Blood metabolite responses to exercise (glucose, non-esterified fatty acids, glycerol and lactate) were also similar between NR and PLA. In addition, preliminary data from arm two suggests that resting metabolic rate and substrate utilisation at rest and during exercise were unaffected by one week of NR supplementation.
CONCLUSION: Collectively our data suggests that NR supplementation, either as a single dose or seven days of supplementation does not alter whole-body substrate utilisation in humans. Analysis of skeletal muscle biopsies will explore whether NR supplementation augments basal or exercise-induced NAD+-sensitive signalling pathways to promote mitochondrial biogenesis within skeletal muscle.

A SIX WEEK KETOGENIC INTERVENTION HAS LASTING EFFECTS ON MARKERS OF EXERCISE FOLLOWING ITS TERMINATION

CARPENTER, M., BROUNER, J., SPENDIFF, O.

KINGSTON UNIVERSITY

INTRODUCTION: Ketogenic diets (KD) have become an increasingly popular fuelling regime by recreational and elite athletes (Zinn et al. 2017). However, the research is equivocal on its effectiveness, possibly due to poor diet regime and short duration restricting a stable ketogenic state. Moreover, no one has further examined the effects on performance when returning to a habitual high carbohydrate diet.
METHODS: A single case research methodology was used to examine a trained endurance runners response to an imposed 6-week KD intervention (70% fat, 25% protein, 5% carbohydrate), followed by a return to a habitual, self-regulated diet (R-HSRD) (44% fat, 17% protein, 39% carbohydrate). Total calories consumed on each diet, body fat and mass were recorded. Exercise comprised a submaximal 7km treadmill run at approximately 65% of VO2max examining RER, VO2 and RPE both prior to and post diet change.
RESULTS: Total calorie intake was significantly greater during KD (2366 ± 551) compared to R-HSRD (1934 ± 407) ($P<0.05$). Body mass decreased from Baseline (83.0 kg) to KD (80.3 kg), and increased following the R-HSRD (83.9 kg). Exercise trials revealed that oxygen consumption increased following six weeks of keto-adaptation (39.69 ± 0.74 ml/kg/min) compared to baseline (35.43 ± 0.80 ml/kg/min), whilst not returning to baseline values after R-HRSD (39.54±1.0 ml/kg/min). Mean RER was lower during KD intervention (0.70 ± 0.01) compared to Baseline (0.89 ± 0.03). Following R-HSRD, RER increased to 0.83 ± 0.01. Changes in RER were concomitant with a decrease in fat oxidation from Baseline to KD (0.62 ± 0.25 g/min vs. 1.58 ± 0.04 g/min), before a decrease in fat oxidation following R-HSRD (0.70 ± 0.01). Mean heart rate was higher than Baseline (142.8 ± 6.3 bpm) following 6 weeks keto-adaptation (152.2 ± 6.2 bpm). Heart rate decreased following R-HSRD (139.3 ± 9.8 bpm). RPE decreased from baseline (11.6 ± 1.04), to KD (11.1 ± 0.40) decreasing further during R-HSRD run (10.66 ± 0.51).
CONCLUSION: A ketogenic diet leads to a marked decrease in body mass which plays a significant role on performance and running economy. Exercise trials revealed a substantial shift towards fat oxidation during submaximal exercise which persisted for the 6 weeks following diet termination. This study highlights that a ketogenic diet has lasting effects following its termination which could further benefit athletic performance. We conclude that an intermittent use of a ketogenic diet, requires more research to elucidate its synergistic effects with a habitual high carbohydrate diet.

DIETARY NITRATE SUPPLEMENTATION ATTENUATES MUSCLE FATIGUE BY PRESERVING MUSCLE OXYGENATION AND CONTRACTILE FUNCTION

HUSMANN, F., MITTLMEIER, T., BRUHN, S., BEHRENS, M.

UNIVERSITY OF ROSTOCK, GERMANY

INTRODUCTION: Several studies have reported an ergogenic effect of dietary nitrate supplementation on exercise performance. Benefits of dietary nitrate were attributed to a wide range of physiological processes including improved skeletal muscle, vascular and metabolic function during contractionsTherefore, we aimed to test the hypothesis that (I) dietary nitrate supplementation reduces the post-exercise level of muscle fatigue and (II) accelerates the short-term recovery of muscle fatigue.
METHODS: In a randomized, double-blind, crossover study, fifteen recreationally active males completed an one-leg dynamic time-to-exhaustion test of the knee extensors after 5 days of consuming nitrate-rich beetroot juice (BR; 6.5 mmol of nitrate per day) or a nitrate-depleted placebo (PL). After 10 days of wash-out and another 5 days of BR, participants performed an isotime trial corresponding to the PL exercise time (ISO). Neuromuscular function of the quadriceps femoris was analyzed before and immediately after each experimental condition. In addition, recovery of muscle fatigue was assessed 1, 2, 4 and 8 min after exercise termination. Maximal voluntary torque (MVT), peak twitch torque evoked by paired electrical stimuli at 100 Hz (PS100) and voluntary activation were measured under isometric conditions. Muscle oxygenation (SmO2) and activity of the vastus lateralis were continuously monitored using near-infrared spectroscopy and electromyography, respectively. In addition, perceived effort and leg muscle pain were recorded every min during exercise.
RESULTS: BR resulted in a prolonged time to exhaustion (14:27 ± 08:01 min) compared to PL (11:20 ± 6:52 min; $p = 0.01$). At exercise termination, significantly minor reductions in MVT (–43.7 ± 10.0%) and PS100 (–34.6 ± 17.1%) were found after ISO compared to PL (–47.2 ± 11.8 and –40.5 ± 12.5%, respectively). During ISO, smaller declines in SmO2 (–43.5 ± 20.6%) were observed compared to PL (–54.2 ± 16.6%).

ISO resulted in less perceived effort and leg muscle pain (p = 0.02; p = 0.01). No differences between ISO and PL were found for voluntary activation and maximal M-wave. Data indicate the recovery of neuromuscular function.
CONCLUSION: We found that dietary nitrate supplementation attenuates the development of muscle fatigue by preserving muscle oxygenation and contractile function during exercise. Together, these peripheral alterations might have contributed to the improved exercise performance observed We found, however, that dietary nitrate does not affect short-term recovery of muscle fatigue after moderate-intensity exercise.

PRIOR INGESTION OF EXOGENOUS KETONE MONOESTER ATTENUATES THE GLYCEMIC RESPONSE TO AN ORAL GLUCOSE TOLERANCE TEST IN HEALTHY YOUNG INDIVIDUALS.

MYETTE-COTE, E.

UNIVERSITY OF BRITISH COLUMBIA, OKANAGAN CAMPUS

INTRODUCTION: The main objectives of this study were threefold: 1) To determine whether acute ingestion of ketone ester (KE); (R)-3-hydroxybutyl (R)-3-hydroxybutyrate impacts plasma glucose levels during a standardized oral glucose tolerance test (OGTT). 2) To compare changes in insulin concentrations and estimates of insulin sensitivity after acute KE supplementation.
METHODS: Twenty healthy participants (n=10 males/females) aged between 18-35 years took part in a randomized crossover study. After an overnight fast, participants consumed a KE supplement (DeltaG®; 0.45 ml/kg body weight) or placebo 30 minutes before completing a 75-gram OGTT. Blood samples were collected every 15-30 minutes over a period of 2.5 hours. Participants and study personnel performing laboratory analyses were blinded to condition.
RESULTS: KE acutely raised blood D-beta-hydroxybutyrate to an average concentration of 3.2 mM within 30 minutes with levels remaining elevated throughout the entire OGTT. Compared to placebo, KE significantly decreased glucose area under the curve (AUC; -16%, P = 0.001), non-esterified fatty acid AUC (-44%, P < 0.001) and C-peptide incremental AUC (P = 0.005), while improving oral glucose insulin sensitivity index by ~11% (P = 0.001).
CONCLUSION: In conclusion, a KE supplement that acutely increased D-beta-hydroxybutyrate levels up to ~3 mM attenuated the glycemic response to an OGTT in healthy humans. The reduction in glycemic response did not appear to be driven by an increase in insulin secretion, but was accompanied by improved markers of insulin sensitivity. These results suggest that ketone ester supplements could have therapeutic potential in the management and prevention of metabolic disease.

THE ERGOGENIC EFFECTS OF CARBOHYDRATE INGESTION DURING SIMULATED HURLING MATCH-PLAY

COLLINS, K.1, MCROBERTS, A.2, MORTON, J.2

1. IT TALLAGHT, DUBLIN IRELAND. 2.LIVERPOOL JOHN MOORES UNIVERSITY, LIVERPOOL ENGLAND.

INTRODUCTION: Carbohydrate consumption before and during intermittent exercise has been shown to delay fatigue and improve performance. Carbohydrate supplementation may, therefore, benefit intermittent exercise performance such as that which occurs in hurling. Therefore, the aim of the present study was to investigate the ergogenic effects of carbohydrate ingestion during simulated hurling match-play.
METHODS: Eight hurling players (Age: 22 ± 3yrs; Height: 1.77 ± 0.06m; Body Mass: 77 ± 4 kg; VO2max: 56.6 ± 3.2 ml·kg·min-1) participated in this investigation. During the hurling shuttle protocol either a carbohydrate (CHO) solution (0.8 g/kg body mass), or a placebo (a similarly coloured, flavoured and textured solution) was consumed at 0, 18, 36 and 54 min of exercise (PLA). Experimental trials were conducted in a double blind, cross-over fashion. During the protocol work rate was measured. Expired air, heart rate, blood lactate and rating of perceived exertion was collected across each trial. Venous blood was collected on three occasions throughout the protocol. Lactate, glucose, betahydroxybuterate, glycerol and non-esterified fatty acids (NEFA) was analysed. The participants undertook a repeated anaerobic sprint test at 3 separate time points. The data were analysed using two-factor (trial x time) analysis of variance with repeated measures.
RESULTS: Despite trends there was limited variation in running performance and physiological measures observed. A significant (p<. 001) interaction between trials for plasma glucose, NEFA, plasma glycerol and lactate was observed. A significant (p=.033) interaction between trials for average 35-m sprint time was observed. The average sprint time increased significantly (p< .001) across both trials with quicker times observed during the CHO trial.
CONCLUSION: Carbohydrate ingestion enhances hurling specific exercise capacity. The findings support the view that increases in supply of exogenous carbohydrates leads to an increase in the utilisation of carbohydrates as an energy source at the expense of lipids. There was also a trend for an increase in high speed running performance in comparison to the placebo. A carbohydrate supplementation strategy can offer performance related benefits for hurling players during math-play.

EFFECT OF B-ALANINE SUPPLEMENTATION ON CIRCULATING IL-10 CONCENTRATIONS DURING INTENSE MILITARY TRAINING

HOFFMAN, J.R., GEPNER, Y., HOFFMAN, M.W., ZELICHA, H., OSTFELD, I.

UNIVERSITY OF CENTRAL FLORIDA

INTRODUCTION: Previous studies have demonstrated the efficacy of 30-days of β-alanine supplementation on improved performance and cognitive function in soldiers. This outcome was not thought to be related to enhanced muscle buffering capacity associated with elevations in muscle carnosine content, but to carnosine's potential role as an anti-oxidant. Animal studies have reported reductions in inflammatory markers and an increased resiliency to both PTSD-like and mTBI-like symptoms associated with exposure to a predator scent stress and low-pressure blast wave, respectively. These outcomes provide evidence suggesting that elevations in carnosine may have anti-oxidant properties, and reduce inflammation associated with both mental and physical demands during intense exercise. Thus, the purpose of this study was to examine the effect of β-alanine supplementation on IL-10, an anti-inflammatory cytokine response, during intense military training in special operation soldiers.
METHODS: Twenty soldiers (20.1±0.6 y; 178.0±5.4 cm; 74.1±7.9 kg) from an elite combat unit were randomly assigned to either a β-Alanine (BA; n = 10) or placebo (PL; n = 10) group. Soldiers were provided with 12 ·day-1 of either BA or PL for 7-days between two intensive weeks of navigational training and restricted sleep. During the intense week prior to supplementation soldiers navigated on average 27.8 km per evening with ~50% of their body mass in their packs for four days. Soldiers returned to base began the supplementation program for a week prior to leaving for a week of intense field training. Fasting blood samples were obtained at before and following the

7-day supplementation period for the anti-inflammatory cytokine IL-10. To complement null hypothesis testing, magnitude based inferences were examined to provide inferences on the true effects BA may have had on IL-10 concentrations compared to PL, calculated from 90% confidence intervals.
RESULTS: Changes in IL-10 concentrations for BA (0.86 pg/ml) were not significantly different (p=0.27) than PL. However, magnitude based inference analysis indicated that the effect of BA supplementation was possibly (57%) more beneficial than PL in increasing IL-10 concentrations.
CONCLUSION: One week of high dose BA ingestion appeared to possibly increase the circulating concentration of IL-10 during intense military training. This appears to be the first study to examine the use of BA as a potential therapeutic aid during intense training.

THE IMPACT OF FLAVANOLS ON PERIPHERAL, CEREBROVASCULAR AND COGNITIVE FUNCTION

PRITCHARD, R.M., RENDEIRO, C., PHILP, A., EDWARDS, F.R., JONES, D., LUCAS, S.J.E.
UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Peripheral vascular dysfunction is a critical risk factor linked with cerebrovascular complications and age-associated cognitive impairments (Iadecola et al., 2016). Effective strategies that can be easily implemented in daily life routines to delay the onset of age-related cognitive decline and neurodegenerative disorders are urgently needed. Flavanols, a sub-group of plant-derived dietary flavonoids, have shown exciting potential to improve vascular health in humans. Cocoa flavanols, in particular, have proven effective at ameliorating human peripheral vascular function both acutely (within 2 hours of intake; Schroeter et al., 2006) and chronically (up to 4 weeks; Sansone et al., 2015). However, the extent to which such peripheral vasculature effects translate to the cerebrovasculature and ultimately impact on brain function has been less explored. In the present study, we aim to assess the acute impact of a flavanol-rich cocoa on both peripheral vascular function and cerebrovascular function in young and older adults, and further investigate whether such systemic and cerebral vascular outcomes may underpin improvements in cognitive performance.
METHODS: An acute, randomised, double-blind, placebo-controlled crossover human trial is currently being conducted in both young and older male adults (18-45 and 65+ years, respectively, n=20 in each group) to assess the impact of a High-Flavanol Cocoa (150 mg of (-)-epicatechin; 1000 mg of total polyphenols) and a Low-Flavanol Cocoa (4 mg of (-)-epicatechin; 140 mg of total polyphenols; matched for all other micro and macronutrients) on: i) Flow-mediated dilation of the brachial artery; ii) CO2-cerebrovascular reactivity of the middle and posterior cerebral arteries (Transcranial Doppler (TCD)); iii) neurovascular coupling during visual stimulation (TCD), and iv) cognitive performance (CANTAB, Cambridge Cognition). All vascular outcome measures are assessed at baseline (fasted) and 2 hours post cocoa ingestion, when plasma bioavailability of flavanol metabolites is known to be maximal.
RESULTS: Currently, a total of 12 volunteers have been recruited and complete sets of data have been collected for 5 participants. The full data set (unblinded) for both the young and older cohorts will be presented at the conference.
CONCLUSION: Data emanating from this study will for the first time establish the physiological impact of well-controlled flavanol interventions on arterial vasodilatory function simultaneously across peripheral and cerebral vascular beds, whilst linking such physiological responses with cognitive outcomes.

EFFECT OF CAFFEINE SUPPLEMENTATION AFTER 2-WEEKS OF INTAKE RESTRICTION PERIOD ON 500 M ROWING PERFORMANCE AND CATECHOLAMINES RESPONSES

LEE, J., KU, J., HUR, S., AN, K., KIM, S., NGUYEN, Q.T.
DAEGU UNIVERSITY

INTRODUCTION: We investigated the effect of caffeine intake restriction and then supplement on the impact in 500 M rowing time-trial record and performance relevant indices.
METHODS: Sixteen healthy male participants were recruited, and divided into one of two exercise groups either 2 weeks of caffeine intake restriction group (CRG, n=8; 20±1.0 y; 172.4±3.2 cm; 63.9±4.9 kg), or no caffeine intake restriction group (NRG, n=8; 20±2.0 y; 177.0±3.0 cm; 70.2±10.5 kg). Participants performed 5 minutes warm up rowing at 30% of pre-measured peak power output (PPO). All participants supplemented orally with the first caffeine dose during 5 minutes resting, then rowed for 2.5 minutes (1 minute@30% PPO and 1.5 minutes@60% PPO). Participants conducted strenuous rowing exercise at 40% of PPO until complete exhaustion, and had the second caffeine dose during 5 minutes resting. All participants rowed for 500 M time-trial. Participants in NRG supplemented placebo capsules, and Dosage was 5 mg (Posyko, Korea) per 1 kg of body mass. Blood samples were taken at 3 occasions (@ pre-exercise, after exhausted rowing at 40% PPO, and after 500 M time trial), and used for catecholamines and other indices measurement.
RESULTS: Caffeine intake after exhaustive rowing exercise in CRG did not show a significant improvement time trial record and mean power output during 500 M maximal rowing ($p>.05$). Glucose concentration was higher ($p<.05$) but Ca2+ concentration was lower ($p<.05$) in CRG compared to NRG after 500 M time trial. Both epinephrine and norepinephrine from the blood samples were markedly elevated in both groups, but it did not show notable differences between CRG and NRG. The concentration of various ions (i.e., hydrogen ion (pH), Na+, HCO3-), hemoglobin (Hb), hematocrit (Hct), oxygen saturation (%SO2), and partial pressure of oxygen (PO2) had only significant time effect (but not with group effect).
CONCLUSION: In conclusion, caffeine intake restriction and then re-intake during exhaustive strenuous exercise does not reveal 500 M ergometer rowing record enhancement and relevant physiological and biochemical indices' change. For the future study, there will be interest if exercise and/or sport performance and associated physiological variables are affected by the state of body condition, in which caffeine content in the body is used up and which will concomitantly induce sensitizing of caffeine responses from diverse exercise stimulus.

QUERCETIN SUPPLEMENTATION DECREASES ERYTHROCYTES OXIDATIVE DAMAGE AT RESTING AND AFTER AN ACUTE BOUT OF ECCENTRIC EXERCISE IN HUMANS

DURANTI, G., CECI, R., PATRIZIO, F., BAZZUCCHI, I., SGRÒ, P., DI LUIGI, L., SABATINI, S., FELICI, F.

UNIVERSITY OF ROME FORO ITALICO

INTRODUCTION: Quercetin (Q) functions as antioxidant in vitro, but its effect have been minimally examined in combination with exercise in humans. The purpose of this investigation was to determine the effects of a diet supplemented with 1 g per day of Q for 2 weeks on the erythrocytes oxidative balance before and after an acute bout of eccentric exercise (EE).
METHODS: Fourteen volunteer males were randomly assigned, in a double-blind crossover design, to a placebo or experimental supplemented groups. Blood samples were taken before and after 2 weeks of supplementation under resting and post-exercise conditions. Erythrocytes glutathione (GSH, GSSG, GSH/GSSG), malonaldehyde (TBARs), enzymes antioxidant activities as well as time of hemolysis were evaluated in ex vivo.
RESULTS: Quercertin per se did not affect redox homeostasis but increased the time of hemolysis and decreased TBARs levels. Following the EE the Q group displayed a higher GSH/GSSG ratio and a less pronounced increase in TBARs, compared to placebo group. Moreover, we found that GPx enzyme activity were induced after EE only in Q group, while any significant modification of this parameter was detected in placebo group.
CONCLUSION: In conclusion, the Q supplementation may be used as a countermeasure against oxidative stress inducing, in erythrocytes, a cellular adaptation allowing subjects to better cope with the oxidative stress induced by an acute exercise.

PHYSIOLOGICAL DECOUPLING OF ANKLE AND BRACHIAL BLOOD PRESSURES FOLLOWING ACUTE INTERMITTENT EXERCISE: IMPACT ON THE ANKLE-BRACHIAL INDEX

LOLLI, L., WILLIAMSON, P.J., BATTERHAM, A.M., WESTON, K.L., ATKINSON, G.

TEESSIDE UNIVERSITY

INTRODUCTION: The ankle-brachial index (ABI) is the ratio of ankle and brachial systolic blood pressures, and is a first-line screening test for the diagnosis of peripheral artery disease [1]. Importantly, both resting, and post-exercise, ABI have been reported to provide clinical and prognostic information in middle-aged cardiovascular patients [1]. Nevertheless, there has been no study on the differential effects of exercise on ankle and brachial pressures, specifically in context of the subsequent impact of these differential changes on the ABI itself.
METHODS: Eight men and four women, with mean (SD) age, body mass and maximal oxygen uptake (V̇O2max) of 29.7 (5.0) years, 72.5 (12.5) kg and 39.3 (8.3) ml/min/kg, were block randomized to one of 6 sequences of 2 control and 2 exercise replicates over four periods. A hand-held Doppler ultrasound instrument, with 5 MHz probe, was used to measure ankle and brachial systolic blood pressure at rest and after the second exercise bout. Data (n=11 due to one male withdrawal) were analysed using linear mixed models to quantify mean (95% confidence interval, 95%CI) exercise-control differences in blood pressure responses at ankle and brachial sites, with fixed effects for period, condition, time, and sex, and treatment × sex, treatment × period, treatment × sex × period, and treatment × time interaction terms.
RESULTS: Relative to control, exercise increased brachial systolic blood pressure by 24 mmHg (95%CI: 17 to 30). This contrasted with the trivial mean reduction in ankle systolic blood pressure of -6 mmHg (95%CI: -14 to 2) mmHg. Accordingly, there was an exercise-mediated reduction in the ABI of -0.22 (95%CI: -0.30 to -0.15), which reflected the substantial increase in brachial, but not ankle, blood pressure.
CONCLUSION: Our exercise protocol resulted in an increase in systolic blood pressure only for the brachial site and not the ankle site, which if confirmed in a larger study, would fundamentally question the need to quantify the post-exercise ABI for prognostic purposes.

COMPARISON OF DYNAMIC CEREBROVASCULAR KINETICS AND STEADY-STATE RESPONSIVENESS TO CARBON DIOXIDE

SKINNER, B.D., BURLEY, C.V., LUCAS, R.A.I., YEO, S.H., LUCAS, S.J.E.

UNIVERSITY OF BIRMINGHAM

INTRODUCTION: Cerebrovascular responsiveness to CO2 (CVR) is a common marker of brain vascular health and disease risk (e.g., stroke). A dynamic stimulus-response profile of cerebrovascular function may further our understanding, as in other vascular beds (e.g. lower limb plethysmography). Recently, Billinger et al. (2017) measured cerebrovascular kinetics from rest to moderate intensity exercise; reporting different response kinetics between young and older participants, as well as a clinical population (i.e. stroke). The dynamic response profile to a CO2 stimulus is yet to be explored. Additionally, it remains to be seen if stimulus-response kinetics are associated with established steady-state CVR measures.
METHODS: Data from 31 participants (age – younger: 28.1 ± 11.8yrs, older: 71.2 ± 4.4yrs) were pooled from various studies conducted in our laboratory. All participants had performed 5% CO2 (in air) inhalation for 4 minutes, while some did both 4 and 5 minutes protocols in the same visit. CVR was determined by the % change in middle cerebral artery velocity (MCAVmean) and end-tidal CO2 from baseline to the last 30 s of 5% CO2. As in Billinger et al. (2017), the MCAVmean kinetic response was determined by plotting MCAVmean¬ against time to establish time-to-63% of the steady-state response (τ). The kinetic response was compared between age and between stimulus duration times (4 vs. 5 min) in a young cohort. A Pearson correlation was used to examine any association between τ and CVR.
RESULTS: The kinetic response was similar regardless of age (younger: 24.47 ± 12.69s, older: 29.63 ± 17.61s; P=0.48) though there were large variations within each cohort. CVR was similar between young (3.71 ± 0.93%/mmHg) and older cohorts (3.91 ± 1.12%/mmHg; P =0.65). There was a moderate positive correlation between τ and CVR when all cohorts were pooled (τ: 23.38 ± 12.90s, CVR: 3.49 ± 1.04%/mmHg; r=0.51, P<0.01). Surprisingly, there was a trend for a difference in the kinetic response between CO2 stimulus length (4min:

16.45 ± 6.19s, 5min: 19.86 ± 8.28s; P=0.06), however CVR remained similar (4min: 2.93 ± 0.97%/mmHg, 5min: 3.06 ± 0.71cm%/mmHg; P=0.63).
CONCLUSION: In contrast to Billinger et al. (2017) no differences were found in cerebrovascular kinetics between older and younger cohorts. However, a moderate positive correlation between τ and CVR indicates that speed of "onset" kinetics to a CO2 stimulus are associated with steady-state measures. Further research is warranted to ascertain the reliability and reproducibility of τ.

IMPROVEMENT IN CENTRAL ARTERY VASCULAR FUNCTION FOLLOWING 12 WEEKS OF EXERCISE TRAINING IN A CLINICAL POPULATION.

BUCKLEY, B.J.R.1, WATSON, P.M.1, MURPHY, R.C.1, GRAVES, L.E.F.1, WHYTE, G.1, THIJSSEN, D.H.J.1,2

1: RESEARCH INSTITUTE FOR SPORT AND EXERCISE SCIENCES, LIVERPOOL JOHN MOORES UNIVERSITY, LIVERPOOL, UK. 2: DEPARTMENT OF PHYSIOLOGY, RADBOUD UNIVERSITY MEDICAL CENTER, NIJMEGEN, NETHERLANDS.

INTRODUCTION: It is established that sympathetic nervous system activation elicits central blood vessel vasodilation in healthy subjects, yet vasoconstriction in those with cardiovascular disease (Rubenfire et al. 2000). It is not, however, known whether central artery vasoconstriction during sympathetic stimulation can be reversed in response to exercise training.
Aim: To examine the change in carotid artery reactivity (CAR) following 12 weeks of exercise training in subjects with increased risk for cardiovascular disease (CVD). It was hypothesised that training would (partly) restore the impaired CAR response to sympathetic stimulation.
METHODS: Nineteen individuals with increased risk for CVD (54±16 years) were referred for 12 weeks of exercise training. Measures were collected at baseline and 12 weeks. Cardiorespiratory fitness was estimated via the Astrand-Rhyming test. CAR% (relative change in carotid artery diameter in response to sympathetic stimulation) and flow-mediated dilation (FMD%; relative change in brachial artery diameter to 5-min forearm ischaemia) were measured via Doppler ultrasound. Baseline to 12-week changes were analysed using paired samples t-tests (cardiorespiratory fitness) and Wilcoxon Signed Rank tests (CAR% and FMD%).
RESULTS: Significant increases were observed in cardiorespiratory fitness (95% Confidence Interval (CI) 1.9-5.4, P<0.001), CAR% (95% CI 1.6-4.4, P<0.001), and FMD% (95% CI: 0.8-3.6, P=0.003) following 12 weeks of exercise training. All participants who exhibited carotid artery vasoconstriction at baseline (n=6) demonstrated vasodilation at 12 weeks. No associations were observed between measures at baseline, 12 weeks or baseline-to-12-week change.
CONCLUSION: Carotid artery reactivity, a novel measure of coronary artery function, improves following 12 weeks of exercise training. More importantly, carotid artery vasoconstriction, commonly present at baseline (32%), was reversed to vasodilation at 12 weeks. These findings have important public health implications, as short-term exercise interventions may have profound effects on central artery function in populations with increased risk of CVD.

CARDIAC AUTONOMIC RESPONSES TO AN ACUTE BOUT OF LOW-INTENSITY RESISTANCE TRAINING WITH HIGH VERSUS LOW-REPETITION VOLUMES IN YOUNG ADULTS

LOPES, W.A.1, NUNES, J.H.C.1, PORTO, F.E.1

1 STATE UNIVERSITY OF MARINGA

INTRODUCTION: Resistante training (RT) has been recommended not only for the general population, but also for different health conditions, including cardiovascular diseases. Despite this, little is known about the impact of this type of exercise on cardiac autonomic control. The manipulation of different variables of RT, such as intensity, volume and muscle groups involved, may induce varied responses in post-exercise autonomic activity. Therefore, the aim of this study was to compare the HRV (Heart Rate Variability) responses induced by RT with different repetition volumes at low-intensity in young adults.
METHODS: Ten young adult men undertook 2 experimental sessions of 5 upper body resistance exercises on different days: (a) 3 sets of 10 repetitions (low-repetitions - LR) and (b) 3 sets of 20 repetitions (high-repetition - HR) at low-intesity (50% of 1-RM). HRV was collected before each sessions, and during a period of 60 minutes after them, in the sitting position, using a portable cardiac monitor. The Mann-Whitney U test was used for comparing the groups, and the Friedman test was used for the analysis of moments.
RESULTS: Ten young adults concluded all the experimental sessions (Age=21.6±1.8yrs, weight=67.3±12.6kg, and height=1.76±0.1m). There was no statistically significant difference in any of the HRV parameters in the pre-exercise condition between the experimental sessions (HR versus LR). The results demonstrated that HR induced smaller parasympathetic activity (ΔHF=-9.6±5.4, p<0.05) and higher sympatho-vagal balance (ΔLF/HF=4.9±4.3, p<0.05) in relation to baseline until 30 minutes after the session. Also, sympatho-vagal balance (ΔLF/HF) was greater for HR compared to LR until 30 minutes after the session (HR=4.9±4.3 versus LR=-0.5±3.9, p<0.05).
CONCLUSION: Although there is controversy regarding the fact that RT at low intensity does not induce cardiac autonomic imbalance after a training session (Kingsley & Figueroa, 2014; Lima et al, 2011; Rezk et al., 2006), a greater number of repetitions seems to be crucial for alterations in cardiac autonomic response after a low intensity RT session. Our study confirmed the hypothesis that a greater number of repetitions of 50% 1-RM could induce a lower vagal cardiac modulation and a higher sympatho-vagal balance when compared to a smaller number of repetitions on the same intensity.

EFFECTS OF CONSECUTIVE SCUBA DIVING ON BODY COMPOSITION, VITAL CAPACITY, OXYGEN CONSUMPTION, AND CARDIORESPIRATORY FITNESS IN HEALTHY MEN

YU, D.H.1, SIM, N.J.1, KIM, D.J.1, YOU, D.G.1, LEE, H.S.1

DANKOOK UNIVERSITY

INTRODUCTION: Scuba diving is challenging activity to healthy person, and human adapt to the new environmental for efficient survival. Recent findings indicate that a single scuba diving for 2 hours increases lung fluid with an improvement ventilation inefficiency (Zora et

al., 2017), However, little is known about the physiological effects of consecutive scuba diving. Thus, aim of the present study was to examine the effects of consecutive scuba diving on body composition, vital capacity, oxygen consumption, and cardiorespiratory fitness in healthy men.
METHODS: 10 healthy male participated in the study. The subjects performed consecutive scuba diving as immersed 5 m underwater for total 80 minutes (40 min × 2 times) with a 60 min rest between time, five times a week, and for 8 weeks. Body composition (muscle mass and body fat), vital capacity (forced vital capacity; FVC), oxygen consumption, and cardiorespiratory fitness (fitness index; PI) were measured before (pre), immediately after (post), and at 4 (post 1) and 8 weeks (post 2) following the scuba diving.
RESULTS: After consecutive scuba diving, significant ($p < 0.05$) increases in muscle mass, and decreases in body fat and oxygen consumption were observed. The changes in FVC and PI were significantly ($p < 0.05$) improved following consecutive scuba diving as compared with the pre.
CONCLUSION: It has been reported that a significant increase in muscle mass and decrease in body fat were improved cardiorespiratory fitness (Paoli et al., 2017). Moreover, Low cardiorespiratory fitness was related to reduced pulmonary function and oxygen consumption (Dougherty et al., 2018) and impaired body composition (Ozbulut et al., 2013). In the present study, consecutive scuba diving elicited significantly changes in body composition, vital capacity, oxygen consumption, and cardiorespiratory fitness. These results indicate that consecutive scuba diving changes cardiorespiratory fitness by improving the body composition, vital capacity and oxygen consumption.

ASSOCIATIONS BETWEEN CHANGES IN MAXIMAL AEROBIC CAPACITY, ENDURANCE PERFORMANCE AND MUSCULAR ENDURANCE FOLLOWING ENDURANCE-TYPE EXERCISE TRAINING

PAULUSSEN, K.J.M., JONVIK, K.L., DE NIET, M., HORSTMAN, A.M.H., VAN LOON, L.J.C., VAN DIJK, J.W.
HAN UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: The impact of endurance-type exercise training on maximal aerobic capacity (VO2max) has been well established. However, studies that examined the impact of endurance-type exercise on endurance performance and muscular endurance are limited. Hence, it is unknown whether improvements in VO2max are critical for improvements in endurance performance and muscular endurance. The current study aims to assess whether improvements in VO2max induced by endurance-type exercise training are transferred to changes in endurance performance and muscular endurance.
METHODS: Sixty recreationally trained males were recruited to participate in a 12-week exercise program. The exercise program consisted of continuous endurance-type exercise training and interval training for three days per week in a 1:2 ratio. Before and after the 12-week exercise training period, maximal aerobic capacity (VO2max) and maximal workload capacity (Wmax) were assessed during an incremental ramp test on a cycle ergometer. Endurance performance was assessed by a 10-km time trial on a cycle ergometer. Muscular strength was assessed by maximal voluntary isokinetic contractions, whereas muscular endurance was assessed by total workload achieved during 30 reciprocal isokinetic contractions of the upper leg. Pre- and post-training data were analyzed using paired-samples t-tests. Correlations between improvements in VO2max, endurance performance, and muscular endurance were determined by calculating bivariate Pearson correlation coefficients. All data represent mean ± standard deviation. This study is part of a larger project investigating the impact of protein supplementation on adaptations to endurance-type exercise training.
RESULTS: Thus far, 28 subjects (29±7 y, BMI 23.8±2.5 kg/m2, VO2max 46.6±6.6 mL/min/kg, Wmax 324±49 W) completed the training program. The 12-week training program resulted in significant increases in VO2max (11±6 %, $P<0.0001$) and Wmax (12±7 %, $P<0.0001$). The 10-km time trial performance improved by 165±99 s (15±8 %, $P<0.0001$). Maximal voluntary isokinetic contraction at 180 °/s increased by 5.7±10.8 Nm for extension (5±9 %, $P=0.011$) and 3.6±9.2 Nm for flexion (4±10 %, $P=0.049$). The work performed during 30 reciprocal isokinetic contractions increased significantly by 169±209 Kj (6±7 %, $P<0.001$). The increase in VO2max correlated significantly with the increase in time trial performance ($r=0.621$, $P<0.001$), whereas no significant correlations were observed between the increase in VO2max and the increase in muscular endurance performance ($r = 0.321$, $P=0.095$).
CONCLUSION: Endurance-type exercise training increases aerobic capacity, endurance performance and muscular endurance. We speculate that the improvements in maximal aerobic capacity are critical for enhanced endurance performance, but not for enhanced muscular endurance. This may be attributed to the largely anaerobic nature of muscular endurance testing.

AEROBIC CAPACITY AND LEFT VENTRICULAR REMODELING IN AN OLYMPIC TRIATHLETE AND TRIATHLETES OF THE NATIONAL TEAM FOR UNIVERSITY STUDENTS

NAMATAME, H.1, TAYAMA, H.1,2,3, OTSUKI, T.1
1 RYUTSU KEIZAI UNIVERSITY, 2 NTT EAST, 3 NTT WEST.

INTRODUCTION: To obtain significant information for young triathletes, this study investigated aerobic capacity and left ventricular (LV) morphology and function in an Olympic triathlete and triathletes of the national team for university students.
METHODS: Subjects of this study were a male Olympic triathlete (n = 1), male triathletes of the national team for university students (n = 4), and male sedentary university students (n = 2). Maximal oxygen uptake (VO2max) and ventilatory threshold (VT) were determined using incremental cycling to exhaustion (4 min at 100 W with a 30-W increase every 2 min) with monitoring of breath-by-breath oxygen uptake. Indices of LV concentric (wall thickness and mass) and eccentric (end-diastolic dimension and stroke volume) remodeling were measured using M-mode echocardiography (Otsuki T et al., Med Sci Sports Exerc 39: 365-370, 2007). Since the Olympian is an identifiable living person, values are expressed as ratio to mean value of sedentary subjects.
RESULTS: Body weight and lean body weight were slightly higher in the Olympian relative to the student triathletes (1.10 vs 1.02±0.09 and 1.10 vs 1.06±0.08, respectively). Absolute values of VO2max and VT (i.e., mL/min) were greater in the Olympian compared to the student triathletes (1.64 vs 1.48±0.12 and 1.85 vs 1.75±0.20, respectively). Lean body weight was correlated with absolute values of VO2max and VT in the triathletes. There were no differences in VO2max and VT per body weight (relative value, mL/kg/min) between the Olympian and the student triathletes (1.46 vs 1.44±0.20 and 1.63 vs 1.68±0.31, respectively). LV wall thickness and mass, indices of concentric LV remodeling, were greater in the Olympian compared to the student triathletes (1.69 vs 1.47±0.03 and 2.05 vs 1.78±0.28, respectively). There were no differences in LV end-diastolic dimension and stroke volume, measures of eccentric LV remodeling, between the Olympian and the student triathletes (1.09 vs 1.07±0.05 and 2.09 vs 2.08±0.2, respectively).
CONCLUSION: The present results suggest that the Olympic triathlete had higher lean body weight (i.e., higher muscle mass), leading to greater absolute aerobic capacity. In general, athletes with higher muscle mass have less aerobic capacity per body weight compared to athletes with light weight. However, the Olympian have excellent aerobic capacity per body weight, which is comparable to the student triathletes. Greater absolute aerobic capacity may enable the Olympian to finish the swim and the run with less fatigue. In addition, LV

concentric remodeling, commonly developed in strength-trained athletes, was more remarkable in the Olympian than in the student triathletes. Increases in muscle mass and absolute aerobic capacity by strengthening and sprint training may improve performances of young triathletes.

AQUATIC EXERCISE DECREASES ARTERIAL STIFFNESS AND INCREASES POSITIVE EMOTIONS AFTER A TRAINING CAMP

SATO, K.1, KOBAYASHI, R.2

1>INTERNATIONAL CHRISTIAN UNIVERSITY 2>TEIKYO UNIVERSITY OF SCIENCE

INTRODUCTION: Light exercise such as walking, running, and cycling can help reduce increased arterial stiffness. However, little is known about the association between arterial stiffness and aquatic exercise, or about the psychological effects of aquatic exercise after training camps. Therefore, the aim of this study was to investigate the effects of aquatic exercise on arterial stiffness and positive emotions among female athletes after participation in a training camp.
METHODS: The study participants were 16 female collegiate volleyball players who participated in a summer training camp. None of the participants was taking oral contraceptives. As part of the training camp, the players took part in daily volleyball sessions (training for technique or strategy) and non-volleyball sessions (training for physical fitness). One day after the training camp, the aquatic exercise group (AE group; n=6) swam and performed both dynamic and static stretches in the water, while the aerobike group (AB group; n=10) performed moderate-intensity aerobike exercise (corresponding to 50% heart rate reserve) for 30 min. Brachial-ankle pulse wave velocity (baPWV), an index of arterial stiffness, was measured using an automatic waveform analyzer with sensory cuffs wrapped around both brachia and ankles. baPWV was measured before the training camp (baseline), after the training camp, and after water or aerobike exercise. In addition, the psychological effects of the water and aerobike exercises after the training camp were investigated using a questionnaire.
RESULTS: baPWV increased significantly after the training camp in both groups; however, in the AE group, the decreases in baPWV after the aquatic exercise compared with after the training camp were significant ($P<0.05$), whereas in the AB group, no changes in baPWV were seen after the training camp. Positive emotions were significantly increased in both groups. However, the mean change of positive emotions in the AE group was higher than that in the AB group. Specifically, AE group scored 18.7 and AB group scored 10.8.
CONCLUSION: Aerobike exercise did not reduce training camp-induced increases in arterial stiffness, whereas aquatic exercise did. Water pressure squeezes the surface veins and increases venous return, which promotes systemic blood circulation. Therefore, the present findings indicate that aquatic exercise reduces arterial stiffness after a training camp to a greater extent than aerobike exercise. On the other hand, an increase in positive emotions was observed in both groups. These results suggest that aquatic exercise after a training camp reduces arterial stiffness and promotes positive emotions.

INTRODUCING A NOVEL TECHNIQUE TO QUANTIFY CUTANEOUS MICROVASCULAR STRUCTURE AND FUNCTION IN HUMANS

ARGARINI, R., SMITH, K., CARTER, H., HAYNES, A., MCLAUGHLIN, R., GREEN, D.J.

THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Traditional methods used to assess cutaneous microvascular function are limited by an inability to directly visualise and quantify small artery haemodynamics. Optical coherence tomography (OCT) is a novel technology capable of generating images of exceptional spatial resolution. Based on advanced Doppler speckle decorrelation algorithms, we have developed new OCT-based methods to quantify the diameter, velocity and flow through individual microvessels (~10µm). This study aimed to quantify and compare microvasculature responses during hyperaemia using two distinct methods (OCT and laser Doppler flowmetry [LDF]).
METHODS: OCT was used to scan cutaneous microvessels in response to a hyperemic stimulus in 9 healthy people (age 27.6 ± 5.5 yr). Speckle decorrelation images, at a depth of ~500 µm, and cutaneous red blood cell flux (LDF) were obtained from the ventral aspect of the forearm prior to, and 30-seconds following, five minutes of localized ischaemia. Post-processing of OCT measures was performed by two operators, to establish the inter-rater reliability of microvessel diameter, velocity, flow, and density (microvessel recruitment).
RESULTS: OCT outcomes revealed that the hyperaemic stimulus increased cutaneous microvessel diameter (21.77±4.81 to 29.33±5.09µm, $p <0.01$), velocity (58.33±8.03 to 91.22±17.28µm/sec, $p <0.01$), flow (37.33±21.43 to 128.33±63.01pl/sec, $p <0.01$) and density (9.89±5.69% to 40.40±13.99%, $p <0.01$). Red blood cell flux calculated from LDF also increased (19.13±9.99 to 52.04±24.07PU/sec, $p <0.01$). The inter-rater reliability for diameter, velocity, flow and density was 0.960; 0.996; 0.985; 0.989, respectively. A positive correlation was observed between the relative increases in microvascular flow (OCT) and red blood cell flux (LDF) ($r = 0.863$, $p=0.001$).
CONCLUSION: We have quantified, for the first time in humans, the impact of hyperemia on individual microvessel dilation, recruitment and flow. Our findings demonstrate that OCT generates microvascular images and haemodynamic data which correlate with LDF measures. OCT is an accurate and robust non-invasive technique that can be used to quantify microvascular structure and function in humans

THE IMPACT OF EXERCISE INTENSITY ON ACUTE VASCULAR FUNCTION IN HEALTHY YOUNG MEN.

TRYFONOS, A.1, COCKS, M.1, GREEN, D.J.1,2, DAWSON, E.A.1

1. LIVERPOOL JOHN MOORES UNIVERSITY, 2. THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: There is controversy surrounding the impact of an acute exercise bout on vascular function. [1] Increases, decrease and no changes have all been reported; and the influence of these changes on future adaptations or whether it represent a transient risk is uncertain. One mediating factor underpinning the acute change is likely to be exercise intensity. [1] Previous work suggests higher-intensities may result in a transient decrease in vascular function. [2] Given the growing interest in high-intensity interval exercise, it is pertinent to determine if there is a difference in the acute vascular response to a 'typical' high-intensity interval exercise (HIIE) bout vs a moderate-intensity continuous exercise (MICE).
METHODS: Fourteen males (22.9±3.9 years, BMI: 25.0±1.8 m2/kg, VO2max: 40.2±5.8 ml/kg/min) performed a randomised counter balanced cross over study completing either HIIE or MICE on two different days. Endothelial function, assessed by brachial flow-mediated dilation (FMD), was measured before and at 10min post-exercise. HIIE consisted of 10 sets on cycle ergometer, 1-min at 90% heart rate reserve (HRR), followed by 1-min recovery, while MICE was 30min continuous exercise at 70% HRR. Difference pre-post and between exercise intensities was determined using mixed-linear model (SPSS 23), covariating baseline diameter. Data are mean±SD and significance $P<0.05$.

RESULTS: There was a significant interaction between time and exercise intensity (P<0.01) with and without baseline diameter covariate. Post-hoc t-tests showed a significant increase in brachial FMD (7.1±2.36 % to 8.74±2.30 %) post-HIIE exercise, with a non-significant decrease (7.25±2.59 % to 6.54±2.11 %) followed the MICE exercise.
CONCLUSION: There was an immediate increase in FMD following HIIE exercise and no change following MICE. This is in contrast to previous research, which typically reports a decrease with higher-intensity exercise. [2] It was thought that the high-intensity exercise may be related to an increase in oxidative-stress, whereas the dose/duration of the exercise in this study may not have been sufficient to elicit large changes. Rather, the increase in FMD could be related to a shear-mediated up-regulation of the nitric oxide system. Given the further conflicting findings, further studies are therefore needed to elucidate the mechanisms which underlie the changes in FMD following acute exercise.

EFFECTS OF PROGRESSIVE STRENGTH TRAINING ON SOLEUS STRETCH- AND H-REFLEX DURING DYNAMIC BALANCE PERTURBATIONS IN YOUNG AND OLDER INDIVIDUALS

ALLONEN, J., WALKER, S., LINNAMO, V., PIIRAINEN, J.M.
FACULTY OF SPORTS AND HEALTH SCIENCES, UNIVERSITY OF JYVÄSKYLÄ, FINLAND

INTRODUCTION: The number of injuries caused by falling accidents is a major problem among older citizens (Korhonen 2014). In addition to weaker force properties, aging leads to longer and weaker voluntary and reflex response after balance perturbation (Lin & Woollacott 2002, Piirainen et al. 2013). The aim of the study was to examine whether progressive strength training (PST) improves dynamic balance control and reflex responses.
METHODS: Four OLDER (2 women and 2 men, 68.5 ± 2.5 years) and eight YOUNG (5 women and 3 men, 24.0 ± 3.6 years) participants completed this study. Subjects performed a 14-week PST intervention. The training consisted of exercises using resistance machines, repetitions ranging 6–12 per set for 2–4 sets. The following measurements were performed before and after the training intervention; (1) maximum voluntary isometric contraction (MVC) of knee extensors and ankle plantarflexors, (2) dynamic balance tests on a sliding force-plate (Piirainen et al. 2013), (3) with concomitant soleus short-latency stretch-reflex (SLR) responses and (4) H-reflex responses (timed during SLR) during the dynamic balance tests.
RESULTS: YOUNG improved MVC results of knee extension (8 ± 11%; P <0,05) and plantarflexion (14 ± 11%; P <0,05), which was not observed in OLDER (knee extension; 14 ± 15%, P >0,05 and plantarflexion 8 ± 16%, P >0,05). SLR responses (normalized to max M-wave) were higher (0.037 ± 0.015) and latensies (44,75 ± 14,73 ms) longer in OLDER than YOUNG (0.022 ± 0.007, P <0.05; 36,25 ± 6,32 ms; P <0,05) at baseline, with no changes after intervention. Displacement after perturbation was higher in OLDER (51.9 ± 8.4 mm) than YOUNG at baseline (33.6 ± 11.0 mm; P <0.05). No changes in dynamic balance, H-reflex or SLR were observed after the training in either of the groups.
CONCLUSION: The main conclusions of the study were; (1) Short progressive strength training intervention does not improve balance control of subjects during sudden perturbation, (2) it does not have effects on stretch- or H-reflex responses of soleus. These findings support previous suggestions, that PST does not necessarily improve balance control properties (Orr et. al 2008), but it should be more power-type training (Piirainen et al. 2014).

TRAINING AND DETRAINING CHANGES ASSESSMENT EXPRESS AS DAILY GAINS AND LOSSES

CORDELLAT, A.1, FORTE, A.2, MONTEAGUDO, P.1, ROLDÁN, A.1, BLASCO-LAFARGA, C.1
UNIVERSITY OF VALENCIA, SPAIN

INTRODUCTION: Analysing the relationship between gains and losses is very useful to assess the real improvements following the training and detraining periods in long term physical exercise programs. However, up to date, the large heterogeneity in exercise and protocols, as well as detraining duration or testing methodology (Lobo, Carvalho, & Santos, 2010) makes difficult to compare these interventions. Our study aims to analyse changes in cardiovascular fitness and neuromuscular function after a 2-years exercise intervention considering the time invested to improve and the detraining period consequences, that is, the ratios: Changes/training days (C/TD) and Changes/detraining days (C/DD).
METHODS: The 6-minute walking test (6MWT) and the 30s-Chair Stand Test (CST) (Rikli & Jones, 2001) were assessed during two training and detraining periods in 89 healthy elderly (74.16±6.27y) following the EFAM-UV© program (Blasco-Lafarga et al., 2016)0. T-test or Wilcoxon pre-post comparisons were applied (5 sample conditions).
RESULTS: Both, cardiovascular fitness and strength, improve for each training period. 6MWT_C/TD: 1st (1.626 m/day, p<0.001; n=42) and 2nd (0.769 m/day; p<0.002; n=24); CST_C/TD: 1st (0.1 rep/day, p<0.001; n=46) and 2nd (0.044 rep/day; p<0.001; n=22). Worsening was also significant. 6MWT_1st C/DD (0.098 m/day, p<0.006; n=38) and 2nd (0.216 m/day, p<0.002, n=21); CST_1st C/DD (0.008 rep/day, p<0.004; n=41) and 2nd (0.022 rep/day, p<0.001, n=21). There were just significant differences between both periods by strength (p=0.012).
CONCLUSION: It is important to reduce the detraining period as years rise, since it is usually too long to keep improvements in physical function in elderly (Leitão et al., 2015). Larger lost in strength might be caused by the decline in neural factors, the first step in strength reduction (Hakkinen, Alen, Kallinen, Newton, & Kraemer, 2000). Our results confirm the elderlies´ need to intensify strength and avoid its

loose during detraining. The C/DT and C/DD indexes could be a new promising method to compare exercise interventions of different nature and duration.

THE RELATIONSHIP BETWEEN ACCELEROMETER-ASSESSED PHYSICAL ACTIVITY AND CT-DERIVED REGIONAL ADIPOSITY MEASURES IN OLDER ADULTS

MARQUES, E.A.1, SHIROMA, E.J.2, FIGUEIREDO, P.1,3, GUDNASON, V.4, LANG, T.5, CHEN, K.6, ARNARDÓTTIR, N.Y.4, BRYCHTA, R.6, EIRIKSDOTTIR, G.4, HARRIS, T.2

1: CIDESD-ISMAI , 2: NIA-NIH , 3: FPF , 4: IHA , 5: UCSF , 6: NIDDK-NIH

INTRODUCTION: While body mass index (BMI) is a standard value used to define obesity, it cannot provide complex information about the age-related adipose tissue redistribution. As a result, there is controversy over the clinical utility of BMI as an indicator of obesity in older adults (Zamboni et al., 2005). In addition, the associations between computed tomography (CT) - derived abdominal and thigh fat measures and physical activity (PA) have never been investigated. Therefore, we examined the association of several indicators of accelerometer-assessed PA behavior and sedentary time with general body composition (BMI and waist circumference (WC)) and abdominal and thigh CT-derived adiposity measures (area and attenuation) in older adults.
METHODS: A population-based cohort of 610 men and women (61.6% women, mean age 80, SD 5 years) participating in the Age Gene/Environment Susceptibility-Reykjavik Study (2007-2011) with complete accelerometer data, abdominal and thigh CT scans, and potential covariates were analyzed. Odd ratios (ORs) and 95% confidence intervals (CIs) comparing the highest to lowest (reference) quartiles of PA measures were estimated by multivariable logistic regression.
RESULTS: Higher total activity volume, moderate-to-vigorous activity (MVA), and 10 minute-bouted MVA were significantly associated with a better general body composition (BMI and waist circumference), lower visceral adipose tissue (VAT) area, and higher VAT attenuation. Only higher bouted MVA was associated with abdominal subcutaneous adipose tissue and thigh composition. The associations between sedentary time and adiposity measures were less consistent.
CONCLUSION: This study extends our understanding of the relationships between PA and body composition. Our results suggest a potentially complex relationship between obesity and PA, showing association with lower risk of obesity defined according to BMI cut-points, and only with some measures of abdominal and thigh adipose tissue depots. Our findings may support the non-consistent link between different fat depots and CVD risk, mortality or mobility limitations in older adults, as recently described (Rosenquist et al., 2013; Murphy et al., 2014a; Rosenquist et al., 2015; Murphy et al., 2014b).

THE EFFECT OF LEG PRESS AND ELECTRIC STIMULATION EXERCISE INTERVENTIONS ON PREDICTORS OF PHYSICAL CAPABILITY IN OLDER ADULTS

ORESKÁ, L.1,2, SLOBODOVÁ, L.2, UKROPEC, J.2, UKROPCOVÁ, B.1,2, CVECKA, J.1, TIRPÁKOVÁ, V.1, SEDLIAK, M.1,2

1: FACULTY OF PHYSICAL EDUCATION AND SPORTS, COMENIUS UNIVERSITY; BRATISLAVA, SLOVAKIA; 2:INSTITUTE OF EXPERIMENTAL ENDOCRINOLOGY, BMC, SAS; BRATISLAVA, SLOVAKIA

INTRODUCTION: A lower level of individual´s physical capability predictors (e.g walking speed or chair rising) is closely linked with increasing presence of comorbidity and mortality. However, this level can be enhanced by regular exercising. For instance, a preferred walking speed of 0.82 m/s or lower is associated with extremely high risk of mortality, but a preferred walking speed of 1.36 m/s or greater signifies multi-systemic wellbeing. The aim of this study was to determine the effect of leg press exercise and electric stimulation training programs on predictors of physical capability in older adults.
METHODS: A total of 30 healthy active older adults (sex: 12M/18F) took a part in this quasi-experimental study. Subjects were randomized into a leg press group (LP: n = 15, sex: 6M/9F, age: 71.1 ± 4.2 yrs, body weight: 70.13 ± 12.82 kg, BMI: 25.47 ± 3.81) and an electric stimulation group (EMS: n = 15, sex: 6M/9F, age: 69.5 ±3.98 yrs, body weight: 79.5 ± 8.94 kg, BMI: 27.91 ± 3.42). Both groups followed 9-week training programme, three times per week. Before and after the intervention, 10m walking test, chair rise test and knee extension were performed. Data were statistically analyzed by one-way ANOVA with Tukey´s HSD and paired t-test, a significant level was set on $p < 0.05$.
RESULTS: Preferred walking speed was not significantly improved after intervention in both groups (LP: from 1.43 ± 0.20 m/s to 1.43 ± 0.22 m/s; EMS: from 1.24 ± 0.22 m/s to 1.25 ± 0.22 m/s). Maximal walking speed was improved in EMS group only (EMS: from 1.74 ± 0.37 m/s to 1.86 ± 0.31, $p = 0.019$; LP: from 2.07 ± 0.09 m/s to 2.07 ± 0.34 m/s). In the knee extension, there was noted no significant difference after intervention (LP: from 227.64 ±69.13 N/m to 236.36 ± 62.00 N/m; EMS: from 232.76 ± 77.64 N/m to 248.64 ± 65.65 N/m). However, significant improvement in chair rising time was noted in both groups (LP: from 12.27 ± 1.74 sec to10.25 ± 1.21 sec, $p < 0.01$; EMS: from 13.13 ± 2.09 sec to 10.82 ± 1.72 sec, $p < 0.01$). Additionally, 20% of subjects in the LP group (n = 3) and 13.3% of subjects in the EMS group (n = 2) improved their preferred walking speed to 1.36 m/s or greater.
CONCLUSION: Presented findings indicate that both leg press and EMS exercise interventions improve motor abilities, however, not to the same extent. Combination of these two kinds of exercise programmes may have a more beneficial effect on enhancing physical capability in older adults, slowing manifestation of comorbidities and delaying mortality.

INFLUENCE OF INERTIAL RESISTANCE EXERCISE ON FUNCTIONAL ABILITIES AMONG ELDERLY WOMEN

SPUDIC, D., HADŽIC, V., KARPLJUK, D., PORI, P.

UNIVERSITY OF LJUBLJANA

INTRODUCTION: Sarcopenia and muscle strength loss cannot only be prevented, but the elderly are also able to successfully gain muscle mass, maximum strength and power what also positively influences functional abilities among elderly. Inertial devices, which vital concept represents eccentric overload, give more robust results on muscle functions and present an effective way of resistance exercise

among the elderly. The purpose of the study was to examine practical implication and actual effects of the personally constructed inertial device on functional abilities among elderly women.
METHODS: In the study, in which participated 37 elderly women, we compared the effects of two 8-week programmes of different types of resistance exercise on two groups of elderly women - one taking part in the traditional exercising using kettlebells, the other working with the self-constructed inertial device, adjusted for elderly use. Exercise intensity in the inertial group was relatively adjusted by initial self-developed measurements of maximal provided angular momentum and equlized time under tension. Results of the monitored groups were gathered using Senior Fitness Tests for cardiovascular endurance, leg power, agility and balance Functional reach test and compared to the control group using One-Way ANOVA.
RESULTS: We discovered a statistically important improvement of results of both of the exercise types on the power of the leg extensor muscles tested by the Sit to Stand test. The exercise group using the inertial device has provided us with slightly better results. We have also found an improvement in the Functional Reach Test, the Timed Up and Go Test and the 6-minute Walk Test, but they were statistically unimportant.
CONCLUSION: The resistance exercise using the self-constructed inertial device has proved to be a practical, useful and economical alternative to the traditional resistance exercise among the elderly. In comparison to other studies the self-constructed device used in this research has the possibility of progressively adjusting the intensity of the exercise to an individual. The similarity of movement mechanics in performing squats and sit to stand test was shown in expected improvement, while we havent established that improvement in leg power statistically significantly influences the cardiovascular, balance and agility abilities among the elderly. The main reasons for the above mentioned implications were test-learning in the control group, the participants gender, limited time of exercise intervention and especially the explicit type of contractions, with which we violated the main concept of the Yo-Yo exercise – eccentric overload.

A COMPARISON OF 3 TYPES OF EXERCISE INTERVENTIONS ON REACTION TIME AND AGILITY IN COMMUNITY OLDER ADULTS WITH MILD COGNITIVE IMPAIRMENT

CHOU, J.W., LIN, L.L., YANG, N.H., LI, C.J.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Mild cognitive impairment (MCI) is a prodrome of Alzheimer's disease and dementia, and there is a very high proportion of elderly people with MCI who still live in the community. The respond ability is a dimension of the cognitive function. Previous studies had shown that the reaction time was an important indicator for the elderly to maintain daily life function (Burton et al, 2009) and indicated that respond ability can be improved by exercise training, but less were known from the elderly people with MCI. However, it needs to be further confirmed whether the stimulation types due to different modes of exercise cause different effects on the elderly response time. Therefore, this study is aimed to compare the efficacy of multi-component training, resistance exercise and brisk walking on reaction time and agility of community-aged adults with MCI.
METHODS: 99 subjects over 60 years old in the community with mild cognitive impairment were assigned into 4 groups either walking group (n = 27), resistance group (n = 26), multi-component exercise (n= 24) and no-exercise (control) group (n = 22) from 4 community after a pre-test of the Saint Louis University Mental Status (SLUMS) examination. Exercise groups performed 90 minutes of progressive training program of 2 days per week for 12 weeks, included (1) a low-and medium-intensity brisk walking program, (2) moderate-load resistance group performed: included of total body workout by elastic bands, (3)low-and medium-intensity multi-component exercise group : combination of stretching, strength, balance, agility and aerobic exercise, and(4) the control groups performed twice-weekly tablet personal computers course. The elderly were tested the changes of simple response time, simple motor time, and agility and dynamic balance (8-foot up and go) before and after all training. One-way ANCOVA was used to analyze the effect of different exercise patterns on the response time of community-aged adults.
RESULTS: The simplest response time of the resistance training group (-5.36%) was significantly better than the control group (+ 3.96%) and brisk walking group (+ 1.17%) ($p < .05$). The change in the best performance of simplest action time of the multi-component training group (-5.62%) was significantly improved than the control group (+15.18%) ($p < .05$). The whole body agility and dynamic balance of the resistance training group (-10.4%) was significantly better than the control group (+ 7.2%) ($p < .05$).
According to Kovács and Éva (2013) found that 12-month multimodal exercise can improve the balance in individuals aged over 60 years with cognitively impaired. The results of our research were similar to previous studies. Response ability of the elderly declines as cognition aging (Gorus, De Raedt, Lambert, Lemper, & Mets, 2008).
CONCLUSION: In this study, there were similar responded for responsibility and agility between the three exercise types of experimental groups. However, the benefits of walking group was lower than resistance and multi-component training group, the difference which may lie in the training of strength. Therefore, the research suggested that the training should be based on diversified, multi-component, and muscular strength training to improve the performance of responsibility, and selecting an appropriate exercise types for community-aged adults to enhance the daily living skills, and to reduce the risk of falling for older adults with mild cognitive impairment in community.

THE USEFULNESS FOR TUG AND FIVE-METER WALKING TIME TEST ON QOL AND COGNITIVE FUNCTION IN ELDERLY

HOSHINO, S.

NARA WOMENS UNIVERSITY

INTRODUCTION: In order to evaluate the relationship of quality of life (QOL) with physical fitness and cognitive function in the elderly population in Japan, a cross sectional field survey of elderly subjects was conducted.
METHODS: This survey was taken in Nara city and Kawakami village, Nara Japan. The data collected included physical fitness, cognitive function and QOL. As for physical fitness indexes, grip strength (GS), 30-sec chair stand (CS), five-meter walking time (WT), Timed up and go test (TUG), functional reach test (FR), trunk flexion (TF), single leg balance with eyes opened (SLB), and one-minute center of gravity (COG) sway were measured. Cognitive function and QOL were measured with the Stroop / reverse-Stroop test and SF-36 respectively. Moreover the physical activity was caliculated with multipling the metabolic equivalents by exercise duration.
RESULTS: A total of 92 elderly subjected participated to the survey. There were 44 males (74.9±5.3 years) and 48 females (74.4±6.6 years). The associations between physical health parameter "physical functioning" in SF-36 and TUG / WT were highly significant (β=-3.6, $p<.05$ /β=-2.92, $p<.05$) as determined by multiple regression analysis. Especially the difference of TUG ability showed the possibilies of the effect on the reverse Stroop interference and the physical activity.

CONCLUSION: This study indicated the possibilies of the predictor variables for QOL and cognitive function with TUG and walking speed for elderly people.

THE EFFECTS OF 12-WEEK MODERATE-INTENSITY INTERVAL EXERCISE ON NEUROCOGNITIVE FUNCTIONS IN OBESE FEMALE ADULTS

KE-HSIN, C.1, WAN-TIEN, J.2, BOON-SUEN, A.3, CHU-FEN, C.1, HUEI-JHEN, W.2

TZU CHI UNIVERSITY

INTRODUCTION: Obese individuals decline in neurocognitive performance as compared to normal weight individuals. On event-related potentials (ERPs), obese individuals showed smaller amplitude of P3 wave which indicated a poor attention. Currently, interval training is the top one worldwide fitness training trends (Thompson, 2017). Moderate-intensity interval exercise (MIIE) is a combination of aerobic exercise and resistance interval training, which was effectively reducing body weight and percentage of body fat in a shorter time (Chen, Wen, & Ang, 2017). This study was to investigate the effects of 12-week MIIE on neurocognitive functions in obese female adults.
METHODS: The study recruited 10 healthy normal weight (control) (CG, n=10; BMI <25 kg/m2) and 10 overweight/obese (OG, n= 10; BMI ≥25 kg/m2) female adults with the mean age 36.3±3.9 year-old. All participants are required to participate in the 30 minutes supervised MIIE, 5 sessions per week for 12 weeks. During training session, Heart rate (HR) was monitored to ensure that participants reached the target HR zone. Percentage of body fat was measured by dual energy X-ray absorptiometry. The behavioral performance (accuracy rate [ACC] and reaction time [RT]), and ERPs indices were simultaneously recorded during participants performed a go/ nogo task before and after the 12-week of intervention. All participants were asked to maintain their regular dietary and lifestyle.
RESULTS: Body weight significant reduced after the 12-week MIIE in OG (pre: 74.1±10.1kg vs. post: 70.9±9.0kg, p=0.003), whereas no change in CG (pre: 59.7±2.5kg vs. post: 58.7±2.5kg, p=0.183). Percentage of body fat significant reduced after the 12-week MIIE both in CG (pre: 35.2±4.2% vs. post: 31.9±4.6%, p=0.003) and OG (pre: 39.3±4.2% vs. post: 36.6±2.3%, p=0.002). In go/ nogo task performance, there were no significant changes between groups after the intervention in ACC, RT, P3 amplitudes and latency by the RM-ANOVA. Both groups maintained higher ACC in go condition (pre: OG: 99.9±0.24%vs. CG: 99.9±0.21%, p=.63; post: OG: 99.9±0.21%vs. CG: 99.9±0.21%, p=1.00), and nogo condition (pre: OG: 97.8±0.40%vs. CG: 98.8±0.24%, p=.51; post: OG: 99.0±0.17%vs. CG: 98.3±0.21%, p=.39). RT in CG significantly improved (pre: 477.4±75.6 ms vs. post: 430.4±36.6 ms, p=.02), whereas no change in OG (pre: 501.2±90.3 ms vs. post: 463.2±62.7 ms, p=.21) after the intervention. The P3 amplitude in go condition (2.55 ± .34 μV) was smaller than that in nogo condition (5.38 ± .56 μV).
CONCLUSION: The 12-week of MIIE intervention showed a positive effect on improving neurocognitive functions in attention (P3 amplitudes in nogo condition) and reducing percentage of body fat both in obese and normal weight female adults. (MOST 106-2410-H-320-004 and TCMMP 105-03-01 supported the study)

INVESTIGATING THE RELATIONSHIP BETWEEN INDIVIDUAL CORRELATES OF PHYSICAL ACTIVITY AND COGNITIVE FUNCTION

LOGAN, N., MOREAU, D., CORBALLIS, P.M.

THE UNIVERSITY OF AUCKLAND

INTRODUCTION: Age-related declines in cognitive function are a major cause for concern in public health. Accordingly, there is considerable interest in developing lifestyle or exercise interventions that can prevent or delay the onset of cognitive decline. The relationship between the P300 component of the event-related potential and levels of habitual physical activity has been well established, and offers a potential marker for cognitive function. However, there are still large underlying questions that remain about the nature of this relationship. This cross sectional study aims to determine the individual correlates of physical activity, such as arterial health, heart rate, electrophysiological function and alpha power, in order to reveal how habitual physical activity levels affect cognitive function.
METHODS: The International Physical Activity Questionnaire and resting heart rates were used to classify participants into two groups – "High Activity" or "Low Activity", based on habitual levels of activity and resting heart beats per minute. Vascular health was also measured via pulse wave analysis to establish a link between self-reported physical activity levels, physiological function, cognitive function, and resting state EEG alpha power. ERPs were recorded during the AX Continuous Performance Task in order to extract P300 responses to stimuli requiring cognitive control.
RESULTS: We confirm earlier reports that ERP amplitude was affected by physical activity, and that those in the High Activity group had lower blood pressures. Furthermore, the variation in heart rate, vascular health and P300 amplitude between groups was modulated by differences in resting EEG alpha.
CONCLUSION: We propose the novel theory that participation in habitual physical activity throughout the lifespan may serve to increase overall alpha power during resting states thus decreasing brain activity, and decrease alpha power during high cognitive loads to increase brain activity for tasks which demand high attentional capacities. These results deepen our understanding on the electrophysiological and cardiovascular correlates of the relationship between physical activity and cognitive function.

EXPLORING BENEFICIAL IMPACT OF PHYSICAL ACTIVITY FROM BODY COMPOSITIONS OF PATIENTS WITH COLON POLYPS IN JAPAN

AOKI, T.1,2, OKAMATO, K.1, OYANAGI, E.1, INOUE, M.2, TERAMOTO, F.1, KREMENIK, M.J.1, YANO, H.1, MATSUMOTO, H.3, SHIOTANI, A.3

1 KAWASAKI UNIVERSITY OF MEDICAL WELFARE, 2 KAWASAKI MEDICAL SCHOOL HOSPITAL , 3 KAWASAKI MEDICAL SCHOOL

INTRODUCTION: It has been known that regular exercise contributes to reducing the risk of colorectal cancer, as well as the prevention of obesity and increase of skeletal muscle mass. Since the progression from adenomatous polyp to cancer has been proposed, it is important to prevent colon polyps leading to the prevention of colorectal cancer. It is reported that a novel myokine (secreted protein acidic and rich in cysteine (SPARC)) may inhibit the invasion and metastasis of tumor during colon cancer development. Moreover, recent meta-analysis suggests that obesity is positively associated with the risk of colorectal cancer. These studies suggest that regular exercise might prevent the incidence of colon cancer and it might be important to improve lifestyle of patients with colon polyps. The aim of our study

was to examine the relationship between colonic polyps and body composition in Japanese patients with positive fecal occult blood test (FOBT).
METHODS: Patients who performed colonoscopy for positive FOBT were included between June 2015 and November 2017. Both men (n=63, 62 ± 10 years of age) and women (n=35, 65 ± 9 years of age) agreed to participate in this study. Body composition, including body fat mass, skeletal muscle mass and visceral fat area were measured using the bioelectrical impedance analysis to evaluate the skeletal muscle index (SMI) and visceral fat index. Measurement of grip strength, nutrient intake and physical activity amount were also calculated.
RESULTS: The subjects consisted of the polyp group (52 men and 26 women) and the control group (11 men and 9 women). Among the men subjects, the mean SMI was significantly lower (8.06 ± 0.25 kg/㎡ vs. 8.72 ± 0.46 kg/㎡, p<0.05) and % body fat was higher (24.1 ± 2.2% vs. 19.9 ± 2.3%, p<0.05) in the polyp group compared to the control group. On the other hand, among the women subjects, the mean level of grip strength in the polyp group was significantly lower than that in the control group (18.7 ± 2.4 kg vs. 26.4 ± 2.3 kg, p<0.01). There was no difference in physical activity between the two groups in both genders.
CONCLUSION: Investigating body composition of patients with colon polyps is important to change their lifestyle and habitual regular exercise may prevent development of colon cancer.

Mini-Orals

MO-MI01 Reliability and Testing

RELIABILITY OF THREE VELOCITY VARIABLES TO EVALUATE VERTICAL JUMP AND BENCH PRESS THROW PERFORMANCE

PÉREZ-CASTILLA, A., GARCÍA-RAMOS, A.

UNIVERSITY OF GRANADA

INTRODUCTION: Vertical jump (VJ) and bench press throw (BPT) are probably the most common exercises used to improve and evaluate ballistic performance (1). The velocity achieved against a fixed load is one of the variables most utilized to evaluate performance in these exercises (2). Since there is still a lack of evidence on which is the velocity variables most reliable during these ballistic exercises, this study aimed to compare the between-session reliability of three velocity variables (mean velocity [MV], mean propulsive velocity [MPV] and maximum velocity [Vmax]) to assess VJ and BPT performance.
METHODS: Data from twenty-one and twenty-three subjects were tested during two consecutive weeks in two variants (concentric-only and eccentric-concentric) of the VJ or BPT exercise, respectively. The two sessions of each variant were performed within the same week with 48-72 hours of rest. Two trials were executed against five different loading conditions (VJ: 17, 30, 45, 60 and 75 kg; BPT: 17, 27, 37, 47 and 57 kg). All testing sessions were performed in a Smith machine coupled with a linear velocity transducer (T-Force System). The MV (average velocity from the start of the concentric phase until the bar reaches the maximum height), MPV (average velocity from the start of the concentric phase until the acceleration of the bar is lower than gravity) and Vmax (maximum instantaneous velocity value reached during the concentric phase) were the calculated variables. A three-way repeated measures ANOVA (variable x variant x load) was applied on individual CV values to assess the differences in reliability (3).
RESULTS: All velocity variables met the criterion for acceptable reliability (CV<10%) regardless of the exercise tested. The three-way repeated measures ANOVA revealed significant main effect for the variable (P<0.001) and variable x variant interaction (P<0.001) in the VJ exercise, as well as for the variable (P<0.001), variant (P=0.002) and load (P=0.003) in the BPT exercise. The main effects revealed that the Vmax was the most reliable variable, followed by MV and finally MPV (CV=2.28%, 3.38% and 3.85% for VJ; 2.14%, 3.18% and 4.27% for BPT, respectively); the concentric-only VJ promoted the differences between variables (CV=3.93%, 4.61% and 2.14% for MV, MPV and Vmax, respectively); the eccentric-concentric BPT (CV=2.41%) was more reliable than the concentric-only BPT (CV=4.02%); and the reliability tended to decrease with the increment of the load during the BPT exercise (from 2.12% to 3.92%).
CONCLUSION: The three velocity variables examined (MV, MPV and Vmax) can be used for the assessment of lower- and upper-body ballistic performance. However, our results also suggest that the most reliable testing procedure would consist on the evaluation of the Vmax during both VJ and BPT exercises.

EVALUATION STAR EXCURSION BALANCE TEST BY USING BIOMECHANICAL ANALYSE 3D AND FORCE PLATE FORM FOR ATHLETES

HASHISH, K.

FACULTY OF SPORT EDUCATION

INTRODUCTION: Balance is one the most important ability which athletes should possess it .there are many measurements evaluate balance such as Star Excursion Balance Test ability of the lower extremity of individuale to reach maximal distance in each direction by open eyes and closed eyes The purpose of this study is evaluation of
by using biomechanical analyse 3D and force plate form for athelets
METHODS: methods : eleven athletes Bertec force plate <1000hz> and analyse3d software<8 cameras> for date collection . We measured the reach distances in centimeters and averaged 3 reaches in each of the 8 directions while the subjects stood on each leg for data analysis.we choice one trial for each athelet to analyse by simi analyse3d software
RESULTS: the Simi analysed system and force plate form proved The SEBTs is a valid ,sufficient ,not complex and non-expensive on opposite of many other devices for measuring balance
CONCLUSION: Balance is one the most important ability which athletes should possess it. The purpose of this study is evaluation of

IMU-BASED KNEE JOINT FLEXION TEST AS AN INDICATOR OF SPRINT PERFORMANCE: A PILOT STUDY

NAGAHARA, R.1, WADA, T.1, SHARP, A.2, NEVILLE, J.2

1: NATIONAL INSTITUTE OF FITNESS AND SPORTS IN KANOYA 2: SPORTS PERFORMANCE RESEARCH INSTITUTE, AUCKLAND UNIVERSITY OF TECHNOLOGY

INTRODUCTION: There are various field tests used as indicators of strength-power capability of the lower extremities (Nagahara et al., 2014). However, most of them are performed by extending motion of the lower extremities (i.e. counter-movement jump). Because the hip and knee flexion power productions are important for better sprint acceleration performance (Nagahara et al., 2017), a test which can assess lower extremity joint flexion capability would be useful for predicting sprinting performance. The purpose of this study was to investigate whether inertial-measurement-unit (IMU)-based knee joint flexion test could be a predictor of sprinting performance.
METHODS: Sixteen male athletes ran 50-m with maximal effort, during which ground reaction forces were recorded with 54 force platforms. Mean running speed for the entire sprint distance was computed. The participants performed the five-serial left knee flexion-extension movement with prone posture restricting other joint movements, during which changes in shank angle were obtained using the IMU (250 Hz). Based on the segment angle and body segment parameters of each athlete, knee joint moment and power in the sagittal plane were calculated. A correlation coefficient was used to examine the relationship between sprinting performance and knee flexion capabilities.
RESULTS: The mean running speed for the entire distance was 7.86 ± 0.47 m/s. The positive mean knee joint power during the entire test duration (1.15 ± 0.23 W/kg) was significantly correlated with the mean running speed (r = 0.623). However, there was no significant correlation between the negative mean knee joint power during the entire test duration (−0.74 ± 0.21 W/kg) and the mean running speed (r = 0.201). During knee flexion movement, although positive mean knee joint power in the sagittal plane (1.14 ± 0.20 W/kg) was significantly correlated with the mean running speed (r = 0.615), there was no significant correlation between the negative mean knee joint power in the sagittal plane (−0.71 ± 0.19 W/kg) and the mean running speed (r = 0.263).
CONCLUSION: The current results show that IMU-based knee joint flexion test is likely useful for assessing knee joint flexion strength-power capability which is probably important for better sprinting ability. That said, the IMU-based system should be validated for the reliable assessment. Accordingly, further investigation examining the validity and reliability of the IMU-based knee joint flexion test is recommended.

POST-ACTIVATION POTENTIATION (PAP) EFFECTS ON 3MT TETHERED RUNNING TEST IN NON-MOTORIZED TREADMILL AND ON VERTICAL JUMP

GAMA, M.C.T.1, MANCHADO-GOBATTO, F.B.1, SOUSA, F.A.B.1, GOBATTO, C.A.1

1: UNIVERSITY OF CAMPINAS

INTRODUCTION: Post-Activation Potentiation (PAP) is a strategy used to increase muscle strength and physical performance (Seitz and Haff, 2016) aiming to obtain physiological and functional benefits specially on high-power exercises like jumping and sprinting (Dello Lacono et al., 2016). Add to this, recent study reported positive PAP responses on endurance running exercise by neuromuscular mechanisms that may counteract the deleterious effects of fatigue from different origins (Del Rosso et al., 2016). The 3-minute all-out test (3MT) is a protocol that can determine, in an only day, the aerobic (EP) and anaerobic (WEP) maximal capacities. So, in order to investigate the effectiveness of PAP responses, this study proposed to verify the effect of this supposed performance strategy on mechanical and physiological parameters of 3MT and vertical jumps.
METHODS: Seven recreationally trained individuals (23±5y-old; 83±8.7kg; 180±5cm; 9.0±2.5%body fat) performed five different tests each one in a consecutive different days. The tests were 1RM back squat test (Vanderka et al., 2016), and non-motorized treadmill in tethered running 3MT (Gama et al. 2017) and maximal vertical jumps (VJ) accomplished after two different 5-min warm-up conditions. Blood lactate (Lac) and creatine kinase (CK) were determined after 3MT (5-min and 24-h, respectively). The warm-up protocols used were of 5-min of motorized treadmill walking at 6 km/h (W1) and this added to PAP protocol (W2). PAP consisted of two series of six back squats at 60% 1RM (Wilson et al., 2013), 2-min rest among them.
RESULTS: 1RM test results was 76.4±18Kg. Among W1 and W2, the results were 354±133, 529±140W (EP, p≤0.05); 60±30, 65±29kJ (WEP); 2162±695, 2554±511W (3MT peak-power, p≤0.05); 17.4±3.0, 17.4±3.0mM (Lac); 350±200, 295±143u/L (CK); 1055±237, 1002±207W (VJ peak-power); 292.8±71.0, 266.9±68.0J (VJ work) and 0.37±0.04, 0.34±0.07m (VJ height). There were product-moment correlation (p≤0.05) between W1 and W2 for EP, 3MT peak-power, VJ peak-pewer, Lac and CK parameters.
CONCLUSION: PAP warm-up (W2) may increase neuromuscular function and optimize activation of the aerobic metabolism, delaying the fatigue process. Also, W2 use suggests not impair anaerobic sources in maximal all-out 3-min and vertical jump efforts, preserving anaerobic capacities.

EXPERT VS. NOVICE COMPARISON FOR WALKING AND RUNNING USING THREE-DIMENSIONAL UNCONTROLLED MANIFOLD-APPROACH

MÖHLER, F., MARAHRENS, S., RINGHOF, S., MIKUT, R., STEIN, T.

KARLSRUHE INSTITUTE OF TECHNOLOGY

INTRODUCTION: Movement variability is a fundamental feature of human performance (Bernstein, 1967). However, the function of variability is not yet understood. Opinions differ whether a high level of experience should be accompanied by a low variability or whether a certain degree of variability is desirable (Bartlett et al., 2007). The Uncontrolled Manifold (UCM) approach seeks to understand the nature and function of this variability. According to the UCM, elemental variables (EV) co-vary to stabilize a task-dependent performance variable (PV). Although this approach has already been applied in human locomotion, to date studies are restricted to planar analyses in walking (e.g., Monaco et al., 2018). Therefore, the goal of this study is to compare the step-to-step variability between experts and novices in walking and running using a 3D model of the human body.
METHODS: 13 experts (age: 23.46±3.57 yrs, BMI: 20.6±1.67 kg/m²) and 12 novices (age: 23.92±3.77 yrs, BMI: 21.59±1.45 kg/m²) participated in the study. The criteria for the experts were a minimum of distance covered of 50 km/week and a 10km-record of less than 35 min. The criteria for the novices were a maximum of 1run/week. We collected 20 gait cycles for both groups at 5, 10 and 15 km/h on a treadmill using a Vicon motion capture system. To perform the UCM analysis (Scholz & Schöner 1999), the 3D-center of mass (COM) as PV was calculated as the weighted sum of 17 segments using 50 degrees of freedom on joint level as EV. Following the UCM approach, the deviation to the mean joint configuration was separated in deviations parallel (stabilizing PV) and orthogonal (de-stabilizing PV) to the UCM. Statistical analyses were performed using 2x3 repeated measures ANOVAs.
RESULTS: For the mean values over the gait cycle, analyses showed significant main effects of group and speed and a significant interaction for both parallel (group: $p=0.027$, speed: $p<0.001$, interaction: 0.005) and orthogonal variances (each $p<0.001$). Variances were greater in novices and increased with speed. Besides, a significant speed effect for the UCM ratio was revealed ($p=0.007$).
CONCLUSION: This is the first study performing an UCM analysis with a 3D COM as PV. Our results showed that the differences between the two groups develop with the demand on the subjects: Both orthogonal and parallel variances were greater in novices, which shows that the expert group has less step-to-step variability. The experts might have adopted a more consistent and efficient running style. The differences in the UCM ratio were weaker since both variances showed similar trends of development. Further analyses should investigate the development of these variances over the gait cycle.

RELIABILITY OF THE METASWIM METABOLIC CART: AGREEMENT AND REPEATABILITY DURING FLUME SWIMMING

LOMAX, M., MAYGER, B., SAYNOR, Z., MASSEY, H.

UNIVERSITY OF PORTSMOUTH

INTRODUCTION: The Metaswim (MS) is a metabolic cart capable of measuring breath-by-breath pulmonary gas exchange and ventilation during swimming. However, agreement and repeatability data for it are lacking. The aim of this study was to determine 1) the agreement between maximal and submaximal measures of minute ventilation ($\dot{V}_E$), oxygen uptake ($\dot{V}_EO_2$) and carbon dioxide output ($\dot{V}_CO_2$) during front crawl swimming measured using the MS vs. Douglas bag (DB) techniques, and 2) the repeatability of the MS system.
METHODS: Nine swimmers (age: 22 ± 6 years; stature: 1.77 ± 0.06 m; mass: 77.6 ± 8.8 kg; $\dot{V}_O_2$ max: 48.57 ± 13.34 ml.kg-1.min-1) completed two experimental trials in a flume consisting of steady-state swimming (velocity below the gas exchange threshold) and non-steady state progressive intensity swimming to exhaustion. The MS metabolic cart (Cortex, Germany) and DB were used during both trials to determine $\dot{V}_E$, $\dot{V}_EO_2$ and $\dot{V}_CO_2$ during steady-state swimming, whereas only one method was used per trial during non-steady state swimming. The agreement between MS and DB for $\dot{V}_E$, $\dot{V}_O_2$ and $\dot{V}_CO_2$ was assessed using 95% limits of agreement (LoA), bias and random error. As some steady-state data exhibited heteroscedasticity, data were logarithmically transformed, anti-logged and displayed as ratios (bias x/÷ random error). Conversely, peak data are displayed in original units (bias ± random error). Repeatability of both MS and DB between-trials was assessed using the repeatability coefficient (CR). As some data were heteroscedastic, data were logarithmically transformed, anti-logged and expressed as ratio ± CR. Systematic bias was assessed using paired sample t-tests (α=0.05, SPSS).
RESULTS: Compared with the DB method, MS underestimated ($p > 0.05$) $\dot{V}_CO_2$ peak (0.39 ± 1.45, 95% LoA: -1.06-1.84) l.min-1, $\dot{V}_TCO_2$ peak (0.26 ± 1.60; 95% LoA: -1.35-1.86) l.min-1 and $\dot{V}_TE$ peak (9 ± 43; 95% LoA: -34-52) l.min-1. In the two steady-state swims , MS underestimated $\dot{V}_O_2$ by 1.03-1.24 x/÷ 1.51-1.78 (95% LoA: lower = 0.68-0.70, upper = 1.51-1.78), $\dot{V}_TCO_2$ by 0.93-1.15 x/÷ 1.58-1.68 (95% LoA: lower = 0.59-0.70, upper = 1.47-1.91) and $\dot{V}_TE$ by 0.98-1.19 x/÷ 1.48-1.53 (95% LoA: lower = 0.64-0.80, upper = 1.49-1.76). CR for the MS system was either better than, or the same as, DB during steady-state swimming for $\dot{V}_SO_2$ (tests 1, 2; MS: ± 1.13, ± 1.09; DB: ± 1.22, ± 1.09), $\dot{V}_TCO_2$ (MS: ± 1.13, 1.09; DB: ± 1.23, ± 1.09) and $\dot{V}_TE$ (MS: ± 1.13, ± 1.19; DB: ± 1.22, ± 1.09).
CONCLUSION: MS tends to underestimate $\dot{V}_E$, $\dot{V}_EO_2$ and $\dot{V}_CO_2$ during submaximal and maximal swimming compared with DB. However, because of the poor agreement with the DB method, MS and DB cannot be used interchangeably. Nevertheless, the reproducibility of $\dot{V}_E$, $\dot{V}_EO_2$ and $\dot{V}_CO_2$ for MS was at least as good as, if not better than, the DB method and can be used reliably to evaluate $\dot{V}_E$, $\dot{V}_EO_2$ and $\dot{V}_TCO_2$ during swimming.

TEST-RETEST RELIABILITY AND DISCRIMINANT VALIDITY OF A NOVEL SUPINE KNEE JOINT POSITION SENSE TEST TARGETING ACL-INJURED PERSONS

STRONG, A.1, TENGMAN, E.1, SRINIVASAN, D.2, HÄGER, K.C.1

COMMUNITY MEDICINE AND REHABILITATION

INTRODUCTION: Knee proprioception is considered a key factor for rehabilitation outcome following anterior cruciate ligament (ACL) injury. Joint position sense (JPS), representing proprioceptive ability, seems impaired in the knee following ACL injury. However, no gold stand-

ard knee JPS test exists. A reliable and valid knee JPS test would help to individualise rehabilitation strategies by identifying those ACL-injured persons who would most benefit from targeted neuromuscular exercises that aim to improve knee proprioception.
METHODS: The aim was to develop a novel knee JPS test, evaluate test-retest reliability in healthy persons and address discriminant validity as compared to ACL-injured persons. So far, out of 20 planned participants/group, 15 knee-healthy controls (10 men) have performed the JPS test twice one week apart and six persons with a unilateral ACL-reconstructed knee (2 men) have performed the test once. An eight-camera motion capture system (Qualisys, Oqus) provided knee angles and angular velocities. Participants lay supine with legs extended and feet strapped to a custom-built leg flexion/extension device. First, a knee angular velocity of 10°/s was practiced using direct graphical feedback three times per leg and attempted throughout the test. Participants then flexed a leg until a stop sign was displayed on a TV screen. They maintained this position for six seconds and tried to memorise the knee angle (known as the target angle, TA). After returning to the start position they attempted to reproduce the TA, denoted the reproduction angle (RA). The stop sign was activated by a custom-made integrated program when participants reached either 35° or 60° knee flexion. The test was performed five times for each angle on each leg creating four conditions which were performed in a randomised order.
RESULTS: We calculated mean of the absolute error, the difference between each RA and corresponding TA. Preliminary analyses indicate good test-retest reliability for the dominant leg (ICC 0.77, CI 0.28-0.92, SEM 1.48°) and moderate for the non-dominant leg (ICC 0.66, CI -0.02-0.89, SEM 1.14°) of controls. Better reliability was seen for the 35° angle than the 60° angle for both the dominant (ICC 0.86 vs. 0.68) and non-dominant leg (ICC 0.70 vs. 0.50). Discriminant validity will be assessed when more ACL-injured participants have been tested.
CONCLUSION: The moderate to good test-retest reliability of our knee JPS test in controls is promising. The higher reliability of the 35° compared to the 60° angle indicates a need to test additional angles. Discriminant validity analysis will indicate whether our test can differentiate between ACL-injured persons and controls. Clinicians and researchers should apply knee JPS tests with caution until reliability and validity of such tests are established for the population of interest. However, once established they may provide an essential tool for improving rehabilitation outcomes and facilitating return to sport.

VALIDITY OF THE CATAPULT CLEARSKY T6 LOCAL POSITIONING SYSTEM FOR TEAM SPORTS SPECIFIC DRILLS, IN INDOOR CONDITIONS

LUTEBERGET, L.S., SPENCER, M., GILGIEN, M.

NORWEGIAN SCHOOL OF SPORT SCIENCES

INTRODUCTION: Analysis of physical demands is commonly used to maximize physical performance in sports. However, it is only meaningful if the variables have sufficient accuracy. Multiple factors can affect the accuracy of local positioning systems , such as signal type, parameter calculation, signal obstructions and materials surrounding the field of play, and geometry between anchor nodes and mobile unit. The aim of the study was to: <1> determine the validity of position, distance travelled and speed of a commercially available LPS for indoor use. <2> Investigate how placement of the field of play relative to the anchor nodes and walls of the building affect the validity.
METHODS: The LPS and reference system were installed around the field of play. Participants completed five tasks designed to imitate team-sport movements. The same protocol was completed in two sessions, an optimal and a sub-optimal condition. Optimal condition assumed an optimal geometrical setup between anchor nodes and placement of the field of play relative to the anchor nodes and walls of the building were assessed. In sub-optimal condition, the geometrical setup of anchor nodes and placement of the field of play was altered to imitate a space-reduced environment. Raw 2D position was extracted from LPS and reference system for accuracy assessment. Position, distance traveled and speed were compared using the norm of the differences between LPS and reference system. Mean difference, standard deviation, and maximal difference in position were calculated to compare LPS to the reference system.
RESULTS: Mean absolute difference between the LPS and reference system of position estimations was 0.21±0.13 m in optimal setup, and 1.79±7.61 m in sub-optimal setup. Average difference in distance traveled was <2% in all tasks, in optimal condition, while it was <30% in sub-optimal condition. In both optimal and sub-optimal condition, LPS overestimated the distance compared to the reference system. Instantaneous speed showed large differences between the LPS and reference system, for both optimal <≥35%> and sub-optimal condition <≥74%>. There was a direct association between the magnitude of instantaneous speed and mean error. For average speed, the difference was <3%, and ≈15-30% for all tasks in optimal condition and sub-optimal condition, respectively.
CONCLUSION: Anchor node placement and the field of play relative to the walls of the building influence the output of LPS to a large degree. Measures of position, distance traveled, and average speed from the LPS show low errors, and can be used confidently in time-motion analyses for indoor team sports, provided that the placement of anchor nodes are appropriate. For calculating instantaneous speed, the raw data from the LPS is not valid. Application of appropriate filtering techniques to enhance the validity of such data should be investigated.

INTRA- AND INTER-RATER RELIABILITY OF MYSPRINT APP FOR MEASURING SPEED PERFORMANCE IN 30 METERS

BUSCÀ SAFONT-TRIA, B.1, ARBOIX-ALIÓ, J.1,2, AGUILERA-CASTELLS, J.1, MIRADA, S.2, ESPASA, J.3, CASADEVALL, P.1, FORT-VANMEERHAEGE, A.1,2

1: FPCEE BLANQUERNA - RAMON LLULL UNIVERSITY , 2: FCS BLANQUERNA - RAMON LLULL UNIVERSITY , 3: INEF CATALUNYA

INTRODUCTION: Multi-directional sports require consistent abilities in sprinting, pushing and agility(Taylor, et al., 2017). The ability of handball players to develop explosive efforts and powerful pushes is a crucial performance factor (Hermassi et al., 2017). There are several approaches for assessing the sprint ability. MySprint is an accessible smartphone-based application (Romero-Franco et al., 2017) but, to our knowledge, the intra- and inter-observer reliability has not been assessed. For this reason, the aim of this study was to examine the intra- and inter-rater reliability MySprint, when analysing the 30-m sprint performance.
METHODS: Twenty eight elite youth handball players (13 males and 15 females) were recruited to take part in the study (age = 16.1 ± 1.09 yr; height = 1.78 ± 0.91 m; mas = 70 ± 14.45 kg) and completed two maximal 30-m sprints. The two trails were assessed by recording each sprint using an iPad Air (iOS 11.2.5) at 60 fps; Apple Inc., Cupertino, CA, USA) and MySprint app (Apple Inc., Cupertino, CA, USA). Split times of each sprint were observed and scored (frame counting) independently by two raters. The two raters then scored the same videos one week later. Intraclass correlation coefficients from repeated-measures analysis of variance were calculated to determine intra- and inter-rater reliability of each split and the total time.
RESULTS: Intraclass correlation coefficients' demonstrated an excellent inter-rater reliability in each split (ICC ≥ 0.96). The ICC for rater 1 and 2 across the two viewing sessions was excellent for all the splits (ICC ≥ 0.95).
CONCLUSION: These results are in line with Romero-Franco et al., (2017) who demonstrated that the smartphone-based application MySprint may be a reliable screening tool for analysing 40-m sprint when comparing to existing field methods (timing photocells and

radar gun). This research demonstrated that MySprint app shows an excellent intra- and inter-rater reliability for 30-m sprint in all analyzed splits using video images.

VALIDITY AND RELIABILITY OF A 30-S CONTINUOUS JUMPS TEST TO ASSESS ANAEROBIC POWER AND CAPACITY IN YOUNG KARATEKAS

PADULO, J.1,2, CULAR, D.2, ZAGATTO, A.N.3, MILIC, M.2, ARDIGÒ, L.P.4

1:UNIVERSITY ECAMPUS , 2:UNIVERSITY OF SPLIT , 3:UNESP UNIVERSITY , 4:UNIVERSITY OF VERONA

INTRODUCTION: Wingate anaerobic test (WantT), a pedalling exercise, is considered the gold standard to assess anaerobic power (AP; Sands et al., 2004). Yet, WantT was not used to assess anaerobic capacity (AC, i.e., the metabolic energy demand) and may be not appropriate for other exercise such as continuous jumps. No researchers reported any information regarding validity of a continuous jumps test for karatekas. This study aimed at determining validity, compared with WAnT as a reference, and (test-retest) reliability of a 30s continuous jumps test (CJ30) to assess AP and AC.
METHODS: Thirteen young female karatekas (age: 11.07±1.32 years; mass: 41.76±15.32 kg; height: 152±11.52 cm; training experience: 4.38±2.14 years) were tested on three separate sessions. The first and second sessions were used to assess the reliability (ICC) of CJ30, whereas on the third session WAnT was administered. Following CJ30 and WAnT, we assessed AP (w/CJ30, as jump height [JH], fatigue index [Dal Pupo et al., 2014; FI], and blood lactate [BL]; w/WAnT, as mechanical power [P], FI, and BL) and AC (as EPOC).
RESULTS: Large/highly significant correlations were found between CJ30 and WAnT EPOCs (r=0.730, p=0.003), and BLs (r=0.713, p=0.009). Moderate/significant correlations were found between CJ30 and WAnT FIs (r=0.640, p=0.014), CJ30 first four jumps mean JH and WAnT peak P (r=0.572, p=0.032), and CJ30 mean JH and WAnT mean P (r=0.589, p=0.021). CJ30 showed excellent and moderate reliability (ICC) for AP (maximal JH 0.884, mean JH 0.742, FI 0.657, BL 0.653) and AC (EPOC 0.788), respectively.
CONCLUSION: Correlations observed especially in terms of AC between CJ30 and WAnT provide evidence that former may adequately assess anaerobic performance level in young combat sports athletes. CJ30 results a reliable test to assess both AP and AC. Further studies may focus on CJ30 validity and reliability in different-level athletes.

THE RELIABILITY OF A MODIFIED 505 TEST AND THE CHANGE-OF-DIRECTION DEFICIT IN ELITE YOUNG FOOTBALL PLAYERS.

TAYLOR, J.1, CUNNINGHAM, L.2, HOOD, P.1, THORNE, B.1, TATHAM, R.1, WESTON, M.3

1 - MIDDLESBROUGH FC; 2- SUNDERLAND AFC; 3-TEESSIDE UNIVERSITY

INTRODUCTION: In line with the 'Elite Player Performance Plan' (EPPP) governed by the English premier league, the use of a modified 505 test (M505) (using a 1-m lead-in to the 10-m shuttle component) is compulsory as part of national benchmark fitness testing in leading academies. However, the reliability of this test has not been determined in elite youth football players. Furthermore, the change-of-direction deficit (derived from 505 test time) is proposed to be a better way of isolating COD ability, yet this measure is not used frequently in football. Therefore, this study aimed to assess M505 and COD deficit reliability in elite youth players.
METHODS: A total of 110 players from the Under [u] 12-18 years age groups were recruited (u18 n = 26, u16 n=26, u14 n=39, u12 n=19) from two English Premier League Category 1 Academies. To assess the reliability of the M505 and COD deficit, players completed the M505 twice (two trials on each side) in 7-days with best time recorded for analysis. To calculate COD deficit, best 10-m sprint time recorded during the testing window was subtracted from the M505 time. Players were familiar with the tests, and all were preceded by a standardised warm-up and completed indoors on artificial field turf. Performance times are displayed as mean ± standard deviation. Mean change (%), typical error (CV, %), and intraclass correlation coefficients (ICC) were calculated, with age-group specific thresholds used to quantify the magnitude of mean change and typical error. Standardised thresholds were used to quantify the magnitude of ICC's.
RESULTS: Performance times for the M505 were 2.42 ± 0.08 s, 2.46 ± 0.09 s, 2.59 ± 0.10 s, 2.70 ± 0.12 s for the u18, u16, u14, and u12 groups, respectively. For COD deficit, performance times were 0.70 ± 0.09 s, 0.72 ± 0.09 s, 0.79 ± 0.10 s, 0.82 ± 0.10 s for the u18, u16, u14, and u12 groups, respectively. For the M505, Mean changes (%) were small to moderate (-0.8 to -3.2%) for M505-Left and trivial to small (-2.1 to 0.9%) for M505-Right in all age groups. Typical errors in M505 were moderate to large in all age groups (2.0 to 3.5%), while Intraclass correlation coefficients (ICC) were low to moderate (0.29 to 0.70). For COD deficit, small to moderate changes were observed in COD deficit-Left (-2.4 to -11.3%) in all age-groups, and COD deficit-Right (-7.3 to 3.2%) in the u14, u16, and u18 groups, mean changes in COD-Right were trivial in the u12 group. Typical errors in COD deficit were moderate to large (7.1 to 12.0%), while ICC's were very low to moderate (0.19 to 0.72) in all age groups.
CONCLUSION: The M505 should be used with consideration of the high typical errors in elite youth football players. While COD deficit has been highlighted as a better way of assessing change-of-direction ability, this measure does not appear suitable for use in this population.

Mini-Orals

MO-MI02 Swimming and Handball

STROKE VARIETY IN LONG-TERM DEVELOPMENT OF YOUTH SWIMMERS

STAUB, I., LAUX, S., VOGT, T.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: It is possible to compete in different swimming strokes at a single competition. The German Swimming Federation supports stroke variety and underlines the importance of individual medley as a prerequisite for becoming an elite-level swimmer while focussing on big training loads at young ages at the same time (Lambertz, 2014). On the contrary, early stroke specialisation in age-

group swimming is tempting for coaches to gain success at young ages. However, the literature lacks describing the process of specialisation in providing practical implementations (Dormehl & Williams, 2016). In a multivariate analysis of swimming performance, it has been shown that the determinants of success in swimming are non-stroke specific (Saavedra, Escalante, & Rodriguez, 2010). The aim of this study was to analyse German top-100 rankings if a stroke variety in good swimmers is evident.
METHODS: To examine an influence of stroke variety in German competitive swimming the 100 best age-group swimming performances (i.e. long course) of eight subsequent years (2004-2013) were analyzed, focussing on the age-groups from 1993-1995 (male n = 1.862; female n = 1.993). The rankings of all swimmers who got into top 100 at the age of 18 (male n = 842, female n = 574) were traced back to analyse their rankings at earlier ages. The number of strokes achieved by these athletes within the top 100 at each age between 11 and 18 years were counted. Chi-square tests were performed to compare five different ranking clusters (ranking 1-3; 4-10; 11-30; 31-50; 51-100) as well as stroke variety.
RESULTS: Results revealed a significant connection between the ranking and the number of strokes with 11 years from the top-3 ranked 18 year old athletes compared to all other clusters ($p < 0.01$). Similar connections were shown for the stroke variety in all other age groups and ranking clusters ($p < 0.01$).
CONCLUSION: The present findings indicate that successful athletes do not specialize on one stroke over all competitions within a season, supporting previous suggestions of swimming being a late specialisation sport (Baker & Robertson-Wilson, 2003; Balyi, 2001; Sokolovas, 2006).

COMPARISON BETWEEN TWO METHODS FOR ASSESSMENT OF CARDIOPULMONARY PARAMETERS DURING SWIMMING

PINNA, V., PINNA, M., MILIA, R., PALAZZOLO, G., IBBA, G., LOI, A., MAGNANI, S., CORONA, F., CRISAFULLI, A.
UNIVERSITY OF CAGLIARI

INTRODUCTION: Measurements of cardiopulmonary parameters, such as maximum oxygen uptake (VO2max), anaerobic threshold (AT), pulmonary ventilation (VE) and heart rate (HR) are particularly useful to test physical capacity of athletes. However, these parameters should be studied during real swimming, as typical swimming movements can not be simulated in laboratory. Despite several studies has measured gas exchange parameters during real swimming, to date there is no consensus on whether different protocols yield similar results. The aim of this study was to compare two methods of assessment of cardiopulmonary response in elite swimmers during a tethered swimming session with steps of different durations.
METHODS: Six male and three female elite swimmers (ES, Age 19.8±2.7 years, Height 174.3±10.5 cm, Body Mass 65±11.6 kg) were studied. ES underwent two incremental test in the pool using tethered swimming until exhaustion. The two tests were different in step duration: 1kg/min and 1kg/3min. They performed front crawl with free stroke frequency. Cardiopulmonary parameters were assessed by means of a portable metabolic system connected to a modified snorkel device (Pinna et al 2013). Data were collected at rest, at AT, and at maximum workload (Wmax).
RESULTS: The comparison between 1kg/min and 1 kg/3min tests showed a significant difference ($P < 0.05$) in VE at AT (79.6±26.8 vs 60.4±14.4 respectively) and at Wmax (106.2±25.2 vs 97±22.6). Differently, the other parameters were similar between the two tests (VO2max: 52.6±6.4 vs 54.6±6.5, HRmax: 180.2±8 vs 167.5±35.1, VO2AT, 42.6±9.9 vs. 42±6.8, HRAT 156.8±17.5 vs 152.3±11.1). Moreover, the Bland-Altman statistics applied to the two methods did not found out relevant differences in these parameters (VO2AT mean difference: 5.49 %, VO2max mean difference: 1.63 %).
CONCLUSION: Data obtained show that the two different methods to assess cardiopulmonary parameters during swimming yielded similar and interchangeable results. The only significant difference was found in VE. Probably, this outcome can be related to the longer duration of the 1kg/3min test, which could have caused a different breathing pattern in swimmers. It is possible to speculate that during 1kg/3min test swimmers increased stroke frequency, thereby raising VE. This different VE response should be considered when testing physical capacity of swimmers in the pool.

EFFECT OF SUBJECTIVE EXERCISE INTENSITY CONTROL ON HEART RATE A DURING SWIMMING CRAWL OF FIVE MINUTES

HAMADA, H.1, SAITO, T.2, YOSHIDA, N.1, TAMARI, Y.2, ONODERA, S.2
1:GRADUATE SCHOOL, KAWASAKI UNIVERSITY OF MEDICAL WELFARE , 2:KAWASAKI UNIVERSITY OF MEDICAL WELFARE

INTRODUCTION: To check exercise intensity during swimming use heart rate and Rating of Perceived Exertion (RPE). Previous study reported that there was significant positive correlation between the heart rate and RPE during swimming crawl, and that it is effective as an exercise intensity index (Miyashita et al, 1973). However, there is a specific problem of exercise intensity control during swimming. Swimmers cannot always see the heart rate. They need to understand the Borg scale (Borg, G.A, 1982). We decided to control heart rate by self-control using subjective exercise intensity control. We could consider that swimmers can control physiological responses by subjective exercise intensity control. We assumed that heart rate during swimming could be set by using a subjective exercise intensity control. This study aimed to clarify the effect of subjective exercise intensity control on heart rate during swimming crawl at five minutes.
METHODS: Seven healthy Japanese males volunteered to participate in this study. Their age, height and body weight were 21 ± 3 years, 170.6 ± 3.9 cm, 62.9 ± 4.2 kg, respectively (mean ± SD). All subjects were issued informed consent forms prior to participation in this study. The heart rate at rest measured in the water (Position: standing) Thereafter, the heart rate of 50% Heart Rate Reserve (objective heart rate) calculated by the Karvonen Formula was explained as an instruction to the subjects. The subjects were pulled by a rope and swam swimming crawl five minutes. We measured indices were heart rate, the rotation number of the arm (pitch) and respiratory rate. The heart rate was continuously measured from the start of the experiment. The pitch and respiratory rate were the number of revolutions per minute of arm use.
RESULTS: The measured heart rate of swimming crawl was 138 ± 13 bpm. The heart rate of calculating was 149 ± 14 bpm. The measured heart rate of swimming crawl was significantly higher than the heart rate of objective heart rate ($P < 0.05$). The pitch (1min: 59 ± 11 rpm, 2min: 54 ± 12 rpm, 3min: 52 ± 9 rpm, 4min: 52 ± 9 rpm, 5min: 51 ± 9 rpm) of swimming crawl showed no significant difference. The pitch was constant for five minutes.

CONCLUSION: There is no significant correlation between the difference of objective heart rate and the pitch and respiratory rate. Subjective exercise intensity control can be used for the exercise intensity control of the swimmer. This study suggests to coincided with the objective exercise the intensity when instructor indicates a lower value than objective exercise intensity.The measured heart rate of subjective exercise intensity control was significantly higher than the objective heart rate.

INTRA-ABDOMINAL PRESSURES DURING MAXIMAL SPRINT SWIMMING WITH FOUR COMPETITIVE SWIMMING STYLES

MORIYAMA, S.1, KANAZAWA, S.2, KITAGAWA, Y.3, SHIBATA, Y.4, OGITA, F.5

1: TOKYO GAKUGEI UNIVERSITY , 2: UNIVERSITY OF YAMANASHI , 3: JAPAN WOMENS COLLEGE OF PHYSICAL EDUCATION , 4: TEIKYO UNIVERSITY OF SCIENCE , 5: NATIONAL INSTITUTE OF FITNE

INTRODUCTION: Intra-abdominal pressure (IAP) during front-crawl swimming is varied by amount of muscle activity involved in arms stroke and legs kick (Moriyama et al. 2016). Based on this result, it is we hypothesized that IAP would be also varied by swimming style with different muscle activities. However, IAP during competitive swimming styles has not been determined except for front-crawl swimming, yet. Therefore, present study aimed to determine and to compare the IAP in four competitive swimming styles.
METHODS: Eleven female competitive collegiate swimmers (1.60 ± 0.04 m; 53.0 ± 6.9 kg; 20.4 ± 1.0 yrs) performed a 20m maximal sprint swim of butterfly, backstroke, breaststroke and front-crawl. IAP was taken from the difference between minimum and maximum values in each cycle, and was used as the mean values of 2 stable stroke cycles in each swimming style.
RESULTS: Mean IAP values during butterfly (6.4±2.1 kPa) and breaststroke (3.4±0.6 kPa) were significantly higher than those of backstroke (2.6±0.5 kPa) and front-crawl (2.7±0.4 kPa). Moreover, IAP during butterfly was significantly higher than those of breaststroke.
CONCLUSION: It is concluded that IAP is varied by competitive swimming styles. The higher IAP observed in butterfly and breaststroke would be attributed to the enhanced IAP to stabilize trunk associated with the upper body movement that come out on the water surface, which should decrease the effect of buoyant force.

INCREASED BODY FAT MAY PROVIDE A BUFFER TO LOW BMD (USUALLY SHOWN IN SWIMMING) IN COLD WATER ULTRA-ENDURANCE SWIMMERS.

MACGREGOR, C.1, DIVERSI, T.2

TOI OHOMAI INSTITUTE OF TECHNOLOGY.

INTRODUCTION: Cold water endurance swims (CWESs) such as the English Channel (EC) crossing, like many endurance sporting events, are increasing in popularity. The EC is seen as the pinnacle in endurance swimming. The average successful cross-channel swimmer takes approximately 13 and a half hours to complete the swim crossing. Prolonged swimming practice has shown to be negatively related to bone mineral density (BMD) in competitive swimmers however to date no study has investigated the effects of training to cross the EC on BMD.
METHODS: 25 (15 male aged 22-70yrs, 10 female aged 27-73yrs) Australian based EC swimmers participated in this cross-sectional study. Participants' height and mass were measured using a standard medical balance scale. Segmental body composition including BMD was measured via dual-energy x-ray absorptiometry (DXA) (Hologic Discovery A, Waltham, MA). The DXA scanning procedure was performed according to the International Society of Clinical Densitometry guidelines. Z scores were then used for the comparison as it is the number of standard deviations a patients BMD differs from the average BMD of their age, sex, and ethnicity.
RESULTS: Slightly higher BMD was noted in all EC swimmers (0.9 to 1.8) however this was shown not to be significant at $P<0.05$) and there was no significant difference between gender or age effects noted. Furthermore when looking at fat mass, compared to average population norms many of the EC swimmers were slightly higher but not significantly different to the general population (12.2%-32.9%)
CONCLUSION: Swimming has been associated with low bone mineral density (BMD) due to the displacement of weight bearing activity (Gómez-Bruton, 2014). Furthermore in a high-performance sports environment including ultra-endurance events, athletes can present with low energy availability (LEA) for a variety of reasons, for example not consuming enough food for their specific energy requirements. High-performance athletes are at risk of LEA, as most sports require high muscle to low body fat ratios. Longstanding LEA can cause unfavourable physiological outcomes which have the potential to impair an athlete's health (Logue,2017).
In preparation for an EC attempt, aspiring EC swimmers invest significant time training (Federation, 2015). Additionally, many aspirants also increase body weight and/or fat mass to a potentially unhealthy level in preparation for the cold water temperature (Klemperer & Thomas, 2014).
While the levels of body fat may increase risks factors associated cardiovascular disease they appear to buffer the effect that swimming is having on BMD in ultra-endurance swimmers. This increase in body fat percentage in long distance swimmers may lead to BMD being preserved in these individuals as they age.

MULTIDIMENSIONAL EVALUATION IN CLUB HANDBALL PLAYERS

SAAVEDRA, J.M., HALLDÓRSSON, K., GUÐMUNDSDÓTTIR, M.L., EINARSSON, I.P., KRISTJÁNSDÓTTIR, H.

REYKJAVIK UNIVERSITY

INTRODUCTION: Handball performance is a combination of many factors: constitution-disposition, coordination, strength, endurance, constitution-disposition, nutrition, cognition, tactics, and social and external influences (Wagner et al., 2010). These factors change across the life. Therefore, the aim of this study was to analyse anthropometric, physical fitness, and throwing speed in club handball players of different ages.
METHODS: A total of 150 handball players (12-25 years old, 83 male, 67 female) participated in this study. The sample was divided into four groups in function of official categories of Federation: 12-13 years old (U13), 14-15 years old (U15), 16-17 years old (U17), and 18 years old and older (A team). A multi test battery was used: height, weight, body mass index, arm span, length and width of hand, hand dynamometry, medicine ball throwing (3 kg), countermovement jump (CMJ), 20 m running, T agility test (T-test), Yo-yo IR2 test, throwing speed (throwing at seven meters standing stationary, throwing at nine meters after three steps and throwing at nine meters after three steps and a jump) and pass to wall test. One-way analysis of variance (ANOVA), with a sub-sequent Bonferroni post-hoc test was used to examine differences in physical fitness tests among the four age groups
RESULTS: There was difference in most studied variables. However only among male were differences between U17 and A team in height ($p<0.001$). Only in medicine ball throwing was differences between each group in male and female (A team > U17 > U15 >U13; $p<0.001$); and 20 m running, T-test (U17 < U15 < U13; $p<0.001$). In male, difference between in three youth teams was presented in arm span, hand dynamometry, CMJ, Yo-yo IR2 test, throwing speed at seven meters standing stationary (U17 > U15 > U13; $p<0.001$) and 20 m running, T-test (U17 < U15 < U13; $p<0.001$). In the female, the difference between in three youth teams was presented in CMJ, Yo-yo IR2 test and throwing speed at seven meters standing stationary (U17 > U15 >U13; $p<0.001$) and 20 m running, T-test (U17 < U15 < U13; $p<0.001$).
CONCLUSION: Both sexes in this study develop their physicall fitness in similar way through the youth teams as Ingebrigtsen et.al. demonstrated in their study (2013). All performances gets better with increased age and experience. Only in a power throw (3kg medicine ball) did the performance continue to improve in to adulthood (A-team)
ACKNOWLEDGMENTS.

A COMPARATIVE STUDY OF HEART RATE AND BLOOD LACTATE RESPONSE OF UNDER 21 (U21) AND SENIOR INDIAN HANDBALL PLAYERS DURING ION TRIAL HANDBALL MATCH PLAY

GUPTA, S., GOSWAMI, A.

UNIVERSITY OF WEST INDIES, FACULTY OF MEDICAL SCIENCES

INTRODUCTION: Handball is a fast-flowing team sports that requires strength, speed, flexibility, and endurance. Physiological demand on handball players depends on the position of play, experience, training, and level of competition. This study is aimed to compare the heart rate (HR) and blood lactate response of U21 and senior handball players during selection matches.
METHODS: The participants in this study were 10 junior (U21) (age 19.1±1.2 years) and 10 senior Indian handball players (age 27.4±4.4 years) attending selection camps. HR of the participants was recorded during two selection matches between the U21 and senior teams. HR was recorded continuously at an interval of 5 sec. Blood lactate was measured before match and at 15th, 30th, 45th, and 60th min of the matches. Each match was played for 60 min, divided in two halves, spaced by 10 min interval. All the volunteers played full time. In both the teams there were 4 backs, 4 wingers and 1 each center and circle runner. The senior team won both the first and the second matches by 24-19 and 29-20 goals respectively. VO2max, HRmax, and anerobic threshold HR of the volunteers were measured before the field test was conducted.
RESULTS: Mean heart rate of the U21 players in the 1st and 2nd halves of the matches were 157.3±13.3 and 155±11.7 bpm respectively whereas the respective values in seniors were 154.8±15.2 and 158.5±14.3 bpm. U21 and seniors played 12.8±3.7% and 19.6±5.3% of the total time respectively above the anerobic threshold level. Blood lactate levels of U21 players after warm up, 15th, 30th, 45th, and 60th min of matches were 4.5±0.9, 6.8±2.0, 7.6±1.1, 6.6±2.3, and 5.7±1.2 mmol/L respectively whereas in seniors, respective lactate levels were 3.2±1.4, 8.6±1.7, 9.2±2.2, 8.5±1.9, and 8.2±0.8 mmol/L
CONCLUSION: Senior players had more sprint and/or intense short bursts of run that helped creating more coordinated and effective attack to the opponent team. Probably less experience and less anaerobic training or fitness restricted the movement of the U21 players and as a result they played longer time in the aerobic zone. Blood lactate levels in the handball players suggests a very significant contribution by the glycolytic energy system. Frequent jumps, long throws, and short bursts of running are dependent on the anerobic system for energy supplement. The study concludes that: (1) cardiovascular stress on the U21 and seniors is equally high and (2) anerobic energy supplement is significantly higher in seniors than their U21 counterparts.

DO ADHESION-ENHANCING SOCKS AFFECT MULTIDIRECTIONAL SPEED IN ELITE HANDBALL PLAYERS?

PRAETORIUS, A., RAEDER, C., OHMANN, T., SCHOEPP, C.

BG HOSPITAL DUISBURG

INTRODUCTION: This study examines the effect of an adhesion-enhancing sock (AES) on change of direction capabilities in multidirectional sports. In addition to a compression effect the sole is equipped with a flat rubber coating. This is to achieve shorter change of direction times as well as an improved sprint and jump performance through optimized power transmission between foot and shoe.
METHODS: 24 Players of Germanys 3rd Handball Devision (age M 21,1±SD 4,5; weight M 89,4kg±SD 16kg; height M 188,2cm±SD 6,1cm; BMI M 25,5±SD 3,3; BodyFat M 16,6%±SD 4,9%) were randomized into 2 Groups (GA, GB) using a cross over design. Participants trained specifically for 7h/week with additional athletic training for 2h/w. Recovery status and DOMS was evaluated prior to testing via KEB Scale and DOMS Visual Analog Scale. Both Groups conducted 5m sprints (SP5) followed by 180° COD sprints, using a modified version of the 505 test (505), jump tests, (3 countermovement jumps (CMJ), 15s multiple rebound jumps (MRJ) and 3 bilateral horizontal hops (HOP)) and

nine consecutive Speedcourt protocols (SC) with a work-to-rest ratio of approximately 1:3 (~12-15:45s) consisting of about ten multidirectional CODs over a distance of 30m in random fashion.
For SP5 sprint duration was measured (SP5). For the 505 sprint duration (505u, 505up) and in addition COD deficit (SP5-mod505) were collected for the prefered and unpreferred leg (505defu, 505defup). Jump performance in CMJ was measured as jump height (CMJ-h), reactive strength index for MRJ (MRJ-RSI)and jump distance for HOP (HOP-D). SC performance was expressed as sprint duration (SC-TT)and ground contact time (SC-CT). GA completed all tests wearing AES, GB started testing with standard sport socks. This testing order was reversed after 30 minutes of rest for each group. All measurements were preceded by a standardized warm-up and familiarization trials.
For Statistical Analysis ANOVA's were computed for all variables and effect sizes (Cohen's d) as well as P values are reported.
RESULTS: DOMS in all athletes was 1,5 +/-1,9 on the VAS. Recovery prior to measurements was 12,8+/- 5,0 and 13,3+/- 3,7 on the KEB after the 30 min rest. All Participants therefore were fully recovered and without muscle soreness before conducting the tests. There was no statistical difference in between GA and GB (CMJ-h P.86, d-0,051; MRJ-RSI P.81, d0,065; HOP-d P.86, d-0,05; SP5 P0,95, d0,018; SC-TT P.97, d-0,009; SC-CT P.59, d-0,152; 505u P.94, d0,023; 505up P.06, d-0,144; 505defu P.99, d0,00; 505defup P.99, d -0,160).
CONCLUSION: In this study no definite superiority of performance could be established which would promote the use of AES to enhance COD or sprint and jump performance.
This might partly be contributed to the fact that this study did not assess any measures of fit between shoe and sock that could influence the effectiveness of the AES.
Nonetheless we found high levels of satisfaction within our study population when assessing wearing comfort of AES via a questionnaire.

SUBJECTIVE AND OBJECTIVE LEVELS OF PHYSICAL ACTIVITY IN PATIENTS WITH HEART FAILURE WITH PRESERVED EJECTION FRACTION

SCHMIDT, C.1, BOHN, L.1, SANTOS, M.2.3, MOREIRA-GONÇALVES, D.1,2, OLIVEIRA, J.1

1 : CIAFEL , 2: FMUP , 3: CHP

INTRODUCTION: Over the past decade, the prevalence of heart failure with preserved ejection fraction (HFpEF) increased substantial, accounting for approximately 50% of heart failure cases. HFpEF is associated with poor outcomes and pharmacological therapies have failed to improve clinical outcomes. Higher physical activity (PA) levels are associated with greater quality of life and lower risk of hospitalization and mortality in HFpEF patients. Given its importance for the patient's outcome, accurate assessment of daily PA is necessary to make recommendations and interventions. The aim of this study was to compare PA and sedentary time assessed by self-reported and accelerometry in HFpEF patients.
METHODS: This cross-sectional study was conducted with twenty-four stable and well-medicated HFpEF patients. Level of PA was assessed through the IPAQ–Short Form and with accelerometers (7 consecutive days; ActiGraph GTX3). Sedentary time and time spent in moderate to vigorous activity (MVPA) were compared according to gender. Time spent in MVPA derived from IPAQ was merged with self-reported walking and MVPA to compare with objectively measured MVPA (≥2752 counts/minute). Mean differences were examined using the independent-samples t-test and Pearson´s correlation coefficient was used to assess association between the two methods.
RESULTS: Twenty-two patients completed all data collection (age= 76± 6.1; 17 female, and 7 male). Average accelerometer wear time was 6.4±0.9 days and 13.2±1 h/day. IPAQ underestimated sedentary time compared with the accelerometer (253 vs. 392 min.d-1, p=0.001), even when adjusted for gender. Accelerometer-measured MVPA was 19 (±26) min/day with no significant differences between men and women. However, when considering only MVPA occurring in bouts ≥10 minutes, time spent in MVPA was only 1 min/day. Although two methods that are designed to measure the same variable should have good correlation, we did not find correlation between IPAQ and accelerometer measured sedentary time and MVPA, even when adjusted by gender and age. According to IPAQ, 59% of the patients accumulated at least 150 minutes of MVPA (in bouts ≥ 10 minutes), while none met the recommendations when PA was objectively measured. However, if we disregard the bouts of 10 min, 27% of the patients would achieve the recommendations for MVPA.
CONCLUSION: Our findings indicate that patients with HFpEF tend to underestimate sedentary time and overestimate time spent in MVPA. This has important clinical implications as it limits IPAQ-based decisions targeting the management of both sedentary time and MVPA in HFpEF patients. The use of objective measures of PA seems to have a particular importance as self-reported physical activity may show a large discrepancy.

EFFECT OF TRAINING ON EXERCISE CAPACITY IN KIDNEY TRANSPLANT CYCLISTS

DI MICHELE, R., TOTTI, V., CIACCI, S., SEMPRINI, G., MERNI, F.

UNIVERSITY OF BOLOGNA

INTRODUCTION: After transplantation, engaging in regular physical activity and sport is recommended to improve health. The American College of Sport Medicine recommends at least 150 minutes per week of physical activity to maintain health in adults and people with chronic diseases as kidney transplant recipients (KTRs) (1). Apart from this recommendation, there is currently no indication of the amount of training that should be performed by KTRs to achieve improvements in sports performance. The purpose of this preliminary study is to describe the effects of a specific training programme on a selection of performance parameters in kidney transplant cyclists (CKCs).
METHODS: Eight CKCs performed a 6-month combined endurance and strength training programme in addition to their typical training routines. The outcome measures were training volume; fat mass percentage as determined by skinfold thickness measurements; workload and heart rate at the aerobic and anaerobic thresholds, as determined by an incremental cycling test. Furthermore, renal function and lipid profile were assessed. All variables were compared between baseline and post training with repeated-measure ANOVAs. Statistical significance was set at $P < 0.05$.
RESULTS: CKCs trained on overage 3.38±0.74 times per week with 2.95±2.60 hours per session at baseline and 3.75±0.70 times per week with 5.00±4.2 hours per session after 6 months. No differences were found in FM% between pre- and post-training. When classifying the cyclists by training volume (below/above median), CKCs with highest training volume (660±903 minutes per week) showed signif-

icantly increased aerobic (+17.5 W) and anaerobic (+11.5W) thresholds, with unchanged heart rates associated to these thresholds. Renal function and lipid profiles remained stable between pre- and post-training. No adverse event was reported.
CONCLUSION: This study showed that a 6-month combined endurance and strength training is effective to improve performance parameters, besides being well tolerated by CKCs. Although limited to well trained transplanted cyclists, these findings are an early step to understanding the responses of transplanted recipients to training loads typically used by healthy amateur competitive athletes. Future studies are warranted to determine the optimal training parameters to improve the competitive performance in kidney transplant athletes performing different sports at different competitive levels.

LENGTH REDUCTION OF LOWER-LEG SPRINT PROSTHESES INFLUENCES PERFORMANCE-RELATED RUNNING BIOMECHANICS

KULESSA, D.J.1, STELZHAMER, R.1, RAPP, W.2, GOLLHOFER, A.1, GEHRING, D.1

1: DEPARTMENT OF SPORT AND SPORT SCIENCE, UNIVERSITY OF FREIBURG , 2: OLYMPIC TRAINING CENTRE

INTRODUCTION: In competitions with disabled athletes it is essential to ensure that the conditions are as fair and comparable as possible. This is achieved by regulations, thus putting the individual disability into perspective. A mandatory length specification of lower-leg sprint prostheses may be a major change for a sprinter, to which adaptations are needed. The following single-case study has been conducted to investigate how the athlete adapts to a prostheses length change of 9cm.
METHODS: Subject of this study was a world-class Paralympic sprinter with below knee amputation of both legs (T43). The athlete performed sprints on an oversized treadmill at his maximal controllable running speed (= 7.0 m/s), under a familiarized and a shortened (-9 cm) prostheses length condition. 3D kinematics of a total of 84 steps were captured with a motion analysis system operating at 200Hz. Spatiotemporal variables, prostheses deformation characteristic and running biomechanics that appear to be performance-related (Brüggemann et al., 2007; Dallam et al., 2005; Folland et al., 2017) have been of primary interest: deformation during ground contact, foot contact time in relation to total step time (duty factor, DF), step frequency per minute (cadence), pelvis rotation during ground contact (PR) and forward trunk lean during gait cycle (FTL). Results are reported in mean values (and standard deviation).
RESULTS: The deformation of the loaded prostheses differed substantially between the two conditions: 68.6 (0.8) mm (short) vs. 71.7 (1.9) mm (familiarized). In comparison to the familiarized prostheses length, the athlete ran with decreased DF 0.27 (0.01) vs. 0.28 (0.01) and increased cadence 214 (1.6) vs. 205 (2.9) steps/min when the prostheses were shortened. Additionally, PR was higher 9.5 (1.5) vs. 6.3 (1.5)° and FTL was lower 2.3 (2.0) vs. 4.8 (1.8)°.
CONCLUSION: The purpose of this single-case study was to evaluate the effect of a length reduction of lower-leg sprint prostheses by 9cm for an elite Paralympic sprinter. The results clearly suggest that performance-related parameters are directly affected by the prostheses shortening. Lower prostheses deformation values indicate possibly impaired energy return. Higher PR and lower FTL suggest a less stable running position (Folland et al., 2017) and a higher risk for breaking impulses with each step. The athlete managed to run the same velocity by increasing the cadence and decreasing the DF to compensate for the lower step length. Hence, it can be assumed that the observed athlete will not be able to immediately achieve the highest performance, but rather the running style and training have to be adjusted permanently. The challenge of adjusting to the various factors should be taken into account when defining individual mandatory prostheses specifications.

BENEFITS OF AN ADAPTED PHYSICAL ACTIVITY PROGRAM IN TERMS OF MOBILITY, BALANCE AND QUALITY OF LIFE IN PATIENTS WITH PARKINSON DISEASE.

MASINI, A.1, MARINI, S.1, DALLOLIO, L.1, FANTOZZI, S.1

UNIVERSITY OF BOLOGNA

INTRODUCTION: Parkinsons disease (PD) is a progressive, chronic, degenerative disease that affects the extra pyramidal system, characterized by a degeneration of the mesencephalic nigric neurons associated with striatal dopamine depletion. The average age of onset is around sixty years, manifesting one or more of the following symptoms: tremor, rigidity, bradykinesia and hypokinesia while in the late stages postural instability, loss of balance and walking problems occur.
In spite of various medical and surgical treatments for PD, patients gradually develop significant physical problems. Exercise therapy can maintain the maximum level of mobility, activity, and independence of patients. However, no sufficient evidence are available to support the use of one approach of exercise intervention over another for the treatment of PD (Tomlinson CL. et al, 2013).
The aim of this study is to evaluate the effects of a specific adapted physical activity (APA) protocol in terms of mobility, balance and quality of life in patients with PD.
METHODS: Seventeen patients, aged 50-85 years, diagnosed with PD enrolled in this study. The participants performed two 60-minute sessions a week of physical activity for 5 months and they were evaluated at baseline (T0) and after two months at the end of the program (T1). The APA contained several exercises for static and dynamic balance, and other exercises to increase the mobility and strength.
The outcomes measures assessed were: mobility (sit and reach test, lateral bending, joint ROM and stick test), balance (six-minute-walking test 6MWT, timed-up-and-go TUGT, four-square-step-step FSST, balance error scoring system BESS and Tinetti scale), and quality of life (PDQ-39, scale of fear of falling FES and freezing of gait FOG).
RESULTS: At the end of the study, balance, mobility and quality of life reported significant improvements (p-value <0.05) in the following outcomes: 6MWT (T0 279,47 vs T1 311,8) TUGT (T0 14,1 vs T1 12,91) SIT-UP (T0 8,87 vs T1 10,43) FSST (T0 13,16 vs T1 11,63) BESS (T0 3,68 vs T1 2,5) stick test (T0 18,26 vs T1 13,82) sit and reach test (dx: T0 90,68 vs T1 97,075 sx: T0 90,38 vs T1 95,84) bending (dx T0 52,45 vs T1 50,56 sx T0 51,57 vs T1 49,59) Tinetti scale (T0 20,93 vs T1 24,06) FES (T0 24,31 vs T1 20,44) PDQ-39 (T0 25,05 vs T1 15,38). No injuries were reported during APA.
CONCLUSION: The APA program applied in this study is a safe and effective exercise therapy for patients with PD, especially in term of mobility, balance and quality of life.

FEASIBILITY STUDY ON DT-MANAGING TRAINING TO IMPROVE THE QUALITY OF GAIT IN PATIENTS WITH PARKINSONS DISEASE.

RUDNIK, S.1, WOLLESEN, B.1, GULBERTI, A.2, BRAASS, H.2, PÖTTER-NERGER, M.2

1: UNIVERSITY OF HAMBURG, 2: UNIVERSITY MEDICAL CENTER HAMBURG-EPPENDORF

INTRODUCTION: Most daily activities require the simultaneous management of sensorimotor tasks while processing external information (dual-task performance). Examples for daily dual-tasks represent walking on a crowded floor while avoiding bumping into people or crossing a street while observing traffic flow. Most patients with Parkinson's disease show deterioration of dual-task performance of daily activities and particularly of gait (Plotnik et al., 2011) resulting in freezing episodes and decreased mobility (Kelly et al., 2011). This study investigates the feasibility of a DT-Managing training in patients with Parkinson's disease to improve their DT walking performance.
METHODS: Five participants (men: 66.2 ± 6.7 years) with chronic Parkinson's disease took part in a DT intervention of four sessions with increasing number of tasks and task difficulty. Demographic data and health characteristics were collected by questionnaires (SF-12, FES-1, FOG, MOCA). The gait performance was measured using a GAITRite ® system (CIR Systems, Inc.,NJ 0741, USA) with six different gait conditions (single task (ST), DT cognitive or manual, triple task; normal and fast gait speed). Data analysis was done by using SPSS 24.
RESULTS: Under ST and DT conditions the gait velocity (ST: pre 1.05 m/s; post 1.1 m/s; DT: pre 0.75 m/s; post: 0.86 m/s) and step length (ST: pre: 58.9 ± 17.05 cm; post: 70.14 ± 23.1 cm; DT pre 45.2 ± 19.4 cm; post: 56.1 ± 9.6 cm) increased from baseline to the final post- training test. For the dual- and triple task condition the gait performance (step length, velocity, cadence) improved between all training sessions. However, the results were not confirmed after post testing without training.
CONCLUSION: The first participants of the feasibility study showed benefits for walking performance under the different task conditions. The performance of exercises including higher attention- and multiple task- performance was difficult for the most of the participants. Nevertheless, the patients rated this kind of training as relevant to maintain their physical functioning for daily activities. To gain the highest impact for motor-cognitive functioning of participants with Parkinson´s disease the DT-training should be adapted to the individuals` motor and cognitive abilities.

CONCURRENT VALIDITY OF AN INSTRUMENTED WHEEL VERSUS A NEW INSTRUMENTED WHEELCHAIR ROLLER ERGOMETER FOR BIOMECHANICAL ANALYSES DURING REHABILITATION AND ADAPTED SPORTS

DE KLERK, R.

UNIVERSITY MEDICAL CENTER GRONINGEN, UNIVERSITY OF GRONINGEN

INTRODUCTION: Lab-based research allows detailed physiology and biomechanics studies to be conducted in wheelchair users under controlled conditions, while the wheelchair-user combination is stationary on a treadmill or wheelchair ergometer. However, lab-based equipment is often customized and may vary in reliability and validity <1>. The University Medical Center Groningen, University of Groningen and Lode B.V. recently developed a new wheelchair roller ergometer, the Esseda. This ergometer is equipped with servomotors and load cells that can be used to both simulate different environmental conditions and capture the performance of the wheelchair user. The purpose of this research was to determine the concurrent validity of the Lode Esseda wheelchair ergometer with a commercially available measurement wheel.
METHODS: A comparison between the measured effective torque of a commercially available measurement wheel and the ergometer during steady-state propulsion at 4km/h was made. Ergometer and measurement wheel data were cross-correlated and filtered. Push-by-push kinetic and temporal parameters such as peak torque and cycle time were determined. Pearson product-moment correlation coefficients were calculated to determine the association between both measurement devices. Agreement between instruments was assessed with the methods of Bland and Altman.
RESULTS: Mean and maximum torque per push measured by the ergometer and measurement wheel showed a high correlation of 0.97 and 0.90. Similar results were found for temporal variables as push time and cycle time correlated with 0.96 and 0.97 respectively. The ergometer overestimated mean torque by 8.2% and maximum torque by 6.4% per push.
CONCLUSION: This comparison study has shown that the Esseda provides similar results on key outcome parameters when compared with a measurement wheel. For the purpose of this initial comparison, the measurement wheel was assumed to be the "golden standard". The Optipush system to be accurate within 3.8-2.1% <2> and comparable to the SMARTwheel <3>. As such, further characterization of the Esseda system parameters and standardized tests with calibrated reference weights will provide definitive information on the accuracy of the ergometer.

MOVEMENT PATTERN AND LOADING DIFFERENCES BETWEEN BILATERAL AND UNILATERAL DROP LANDINGS IN TRANSTIBIAL AMPUTEES

MOUDY, S., TILLIN, N., SIBLEY, A., STRIKE, S.

UNIVERSITY OF ROEHAMPTON

INTRODUCTION: Unilateral transtibial amputees (TTAs) are discouraged by health professionals from participating in sport where jumping is commonly performed as this movement is thought to place TTAs at a greater risk of injury. This stems from the asymmetrical landing technique commonly observed in TTAs as a result of the limited ankle joint motion from the prosthetic limb and a greater load experienced on the intact limb when performing a bilateral landing (Schoeman et al., 2013). This study aimed to explore the intact limb landing mechanics and loading differences between bilateral and unilateral drop landings.
METHODS: Bilateral and unilateral drop landing was performed on a custom-made hanging bar where each participant hung with their heels 30cm off the ground. To assess the landing movement patterns, the ankle, knee, and hip joint motion of the intact limbs (n=6) and the dominant limb of age, gender, and activity level matched controls (n=6) were extracted from initial contact to the end of the absorption phase as determined by the centre of mass power. To assess the load occurring during landing, the vertical ground reaction force (GRF) was extracted for the absorption phase. Statistical parametric mapping paired t-tests were performed between the bilateral and unilateral drop landings for the intact limb and for the dominant control limb.
RESULTS: Results found the intact limb hip joint had a significantly greater magnitude of flexion (p=0.042) in the bilateral landing during the last 10% of absorption. The bilateral GRF was significantly lower (p<0.001) around peak GRF (31-41%) and during the last 12%. No difference in landing condition was found for the ankle or knee joint. The control group, however, performed differently between landing condition in the ankle, knee, and hip joint motion and was accompanied by differences in the GRF. The bilateral landing was associated with significantly faster ankle plantarflexion upon contact (0-13%, p=0.019) followed by significantly greater knee flexion (37-42%, p=0.048; 80-100%, p=0.026) and hip flexion (32-41%, p=0.43; 75-100%, p=0.015). The GRF was significantly lower (p<0.001) in the bilateral landing from 32-100%.
CONCLUSION: A bilateral landing typically results in an equal share of load between-limbs. In a unilateral landing, all the load is experienced by a single limb and would therefore expect to find significant differences between landing conditions. Additionally, movement patterns performed would differ as the landing conditions changed. This is evident by the control group differences between landing conditions. However, intact limb landing mechanics were not substantially different between the bilateral and unilateral landing suggesting that the bilateral landing was in effect a unilateral landing.
Schoeman, M., Diss, C. & Strike, S. (2013) Asymmetrical loading demands associated with vertical jump landings in people with unilateral transtibial amputation. JRRD. 50(10).

EFFECT OF AN EXERCISE PROGRAM ON THE PHYSICAL CONDITION OF CHILDREN WITH ASTHMA AND SYMPTOMS OF BRONCHOSPASM INDUCED BY EXERCISE: PILOT STUDY

ITURRIAGA, T.1, SANZ SANTIAGO, V.2, SANTANA SOSA, E.1, MORALES ROJAS, J.S.1, SÁNCHEZ LORENTE, I.M.1, DIEZ VEGA, I.1, FERNÁNDEZ DEL VALLE, M.3, VILLA ASENSI, J.R.2, PÉREZ RUIZ, M.1

1:UNIVERSIDAD EUROPEA DE MADRID . 2:HUNJ . 3:SIUE .

INTRODUCTION: Physical inactivity and a low adherence to the Mediterranean diet produces alterations in body composition that may determinate a worse control of chronic diseases such as asthma (1), this is one of the most frequent diseases in childhood. Some investigation in animal show the exercise can be decreased an asthma inflammation and bronchial hyperresponsiveness (2), as well as systemic inflammation, which could help control asthma (3)
Objectives: to analyze the effect of aerobic and strength exercise program in asthmatic children with symptoms of bronchospasm induced by exercise, with physical exercise on variables of physical condition and quality of life.
METHODS: Randomized controlled trial with control group that compared their usual physical activity vs. exercise program for 12 weeks, 3 days/week, and 60 min/day. It is assessed the physical condition (ergospirometry on treadmill and strength of peripheral muscles) and quality of life with Pediatric Quality of Life Questionnaire (PAQLQ).
RESULTS: The study included 43 children from 7 to 17 years old distributed in Control Group (CG, n = 27) and Intervention Group (IG, n = 16). The average adherence to the program was 82.8%. In VO2peak in ml · kg - 1 · min - 1 the IG had 3.31 ± 1.51 with respect to the CG that obtained 0.25 ± 0.71 in the interaction time per group was p(txg) = 0.064 with an increase in the IG of with respect to the CG, Statistically significant improvements were observed in all strength parameters evaluated, with more significance in High Row p(txg) = 0.006, Leg Press p(txg) = 0.002 and Hamstrings p(txg) = 0.003. We couldn't see improves in quality of life.
CONCLUSION: Similar studies in children with asthma observe improvements in VO2max in 1 METS approximately what, according to investigations is a considerable improvement for this population (4), also some investigation shows than the strength in the same population improves significantly and recent systematic review are demonstrating an adequate level of physical activity with a protective factor against asthma (5). In relation with PAQLQ the values weren't changed probably because the sample has high results in PRE-PAQLQ, 53,3% of them has controlled asthma with at least two drugs. In conclusion 12 weeks of exercise program improves both, cardiorespiratory level and specially strength level in children with mild-moderate asthma.

ASSOCIATIONS OF LEISURE-TIME, COMMUTING AND OCCUPATIONAL PHYSICAL ACTIVITY WITH SELF-REPORTED MUSCULOSKELETAL PAIN IN YOUNG ADULT MEN

VAARA, J.P., PIHLAJAMÄKI, H., VÄSTILÄ, V., KYRÖLÄINEN, H.

NATIONAL DEFENCE UNIVERSITY

INTRODUCTION: There is limited research examining the association between different physical activity (PA) domains [leisure-time physical activity (LTPA), commuting physical activity (CPA) and occupational physical activity (OPA)] and musculoskeletal (MS) pain. The aim of the study was to assess the association of MS pain across several PA domains.

METHODS: 1613 adult (26±6 yrs.) men participated in the study. Participants were asked to how often they had had low back pain, knee pain and lumbago in the last month, by responding to: a) none, b) 1-7 days, c) 8-14 days, d) more than 14 days but less than daily. A visual analogue scale was utilized (100 mm) for back pain, neck pain, and pain in the upper and lower extremities during the last 7 days. Dichotomised variables were formed: no pain and pain reported. The low LTPA group included: none/some light PA/week, Moderate: vigorous PA 1-2 times/week and High: LTPA vigorous PA ≥3times/week. The Low, Moderate and High CPA groups included 0-15, 16-59 and ≥60 minutes/day walking or cycling to work or study, respectively. Low OPA included: sedentary work, Moderate: walking frequently, High: regularly walking and lifting at work. Regression models were adjusted for age, education, smoking, waist circumference and the other two PA domains.
RESULTS: Moderate and High LTPA groups had a lower likelihood for knee pain during the last month (OR:0.72, 95%CI 0.56-0.93; OR:0.64, 0.49-0.84), and High LTPA had a lower likelihood for pain in the upper (OR:0.70, 0.50-0.97) and lower extremities (OR:0.73, 0.54-0.99) during the last month compared to their respective Low LTPA groups. Moderate LTPA had a higher likelihood for back (OR:1.51, 1.18-1.95) and neck pain (OR: 1.29, 1.00-1.66), and Moderate as well as High LTPA for lumbago during the last 7 days compared to Low LTPA group (OR:1.31, 1.00-1.71), (OR:1.53, 1.15-2.02), respectively.
Moderate OPA had a lower likelihood for pain in the upper (OR:0.63, 0.46-0.86) and lower extremities (OR:0.70, 0.53-0.94) during the last 7 days compared to Low OPA. Moderate and High OPA had lower likelihood for low back pain during the last month (OR:0.67, 0.51-0.90), (OR:0.68, 0.48-0.95), respectively, while High OPA had lower likelihood for lumbago during the last month (OR:0.72, 0.52-0.99) compared to their Low OPA groups. There were no differences in the CPA subgroups.
CONCLUSION: In young adult men, CPA and OPA appear to not be harmfully associated with MS pain. LTPA showed more contentious findings indicating body-region and sport-specific interactions in LTPA behaviour in both negative and positive directions regarding MS pain. In conclusion, CPA is strongly recommended while LTPA requires more focus on its safety and correct performance technique to minimise the risk of MS pain.

AN ENRICHED ENVIRONMENT INCREASES LOCOMOTOR ACTIVITY AND INDUSES SKELETAL MUSCLES HYPERTROPHY IN RATS

SUDO, M.

PHYSICAL FITNESS RESEARCH

INTRODUCTION: Enriched environment (EE) has been suggested to enhance exploration, social interaction and cognitive function, which leads to improvements in depression and anxiety-like behavior (Nithianantharajah and Hannan, 2006). However, in contrast to abundant evidence for beneficial effects of EE on brain function, it is less clear whether EE increases locomotor activity due to technical difficulties when rats were housed in groups. Furthermore, little is known about how EE affects skeletal muscle. Thus, the purpose of this study was to assess locomotor activity in EE using a small three-axis accelerometer. We also tested if EE induces skeletal muscle hypertrophy.
METHODS: Wistar rats were housed in the two different housing groups (standard environment (SE) group (N = 8); EE group (N = 8)). EE contained a slope, a small hut, three tunnels, and a running wheel. Locomotor activity was continuously recorded for 32 days using three-axis accelerometers. The accelerometers were subcutaneously embedded in the back. Data were automatically analyzed using a computerized system, and locomotor activity was evaluated during the dark and light periods, respectively. After exposure to each environment for 32 days, the tibialis anterior muscle (TA), extensor digitorum longus muscle (EDL), soleus muscle (Sol), gastrocnemius muscle (Gas), and adrenal gland and thymus were removed and immediately weighted. All experimental data were expressed as mean ± standard deviation. Comparisons were performed using a t-test. The level of significance was set at $P < 0.05$.
RESULTS: Locomotor activity was higher in the EE group compared with the SE group during the dark period (EE: 28194 ± 6087 a.u., SE: 19757 ± 6909 a.u., P=0.032). In contrast, locomotor activity during the light period was not different between the EE and the SE groups (EE: 6704 ± 2313 a.u., SE: 5132 ± 2381 a.u., P=0.234). All hindlimb muscle wet weights per body weight were greater in the EE group compared with the SE group. TA, Sol and Pla muscle wet weights were greater in the EE group compared with the SE group ($P<0.05$, respectively). Especially, the degree of increase in Sol muscle wet weight was greatest and reached up to 10.7% in the EE group. In contrast, EDL and Gas muscle wet weights were not different between the EE and the SE groups. Adrenal gland and thymus weights were not altered in both the EE and the SE groups. These results suggest that the EE increased locomotor activity and induced muscle hypertrophy without stress responses. As far as we know, this is the first study to assess locomotor activity in rats housed in the EE using embedded accelerometers.
CONCLUSION: We conclude that the EE substantially increase locomotor activity and induces muscle hypertrophy in rats.

ELECTROCARDIOGRAPHIC QRS- AND T-WAVE IN MACAU MALE HANDBALL ATHLETES AND NON-TRAINERS

SHI, Q.1, AO, W.1, LO, M.1, KONG, Z.2, ZHANG, H.3, TONG, T.4, NIE, J.1

MACAO POLYTECHNIC INSTITUTE

INTRODUCTION: Intensive sport training is associated with physiologic cardiac remodeling, which are reflected on the electrocardiogram most frequently as an increase of QRS voltages and corresponding changes in T-wave . Because of the partial overlap of ECG signs of cardiac hypertrophy, including changes in QRS- and T-wave, athletes heart is often in the differential diagnosis with hypertrophic cardiomyopathy, which is the leading cause of sports-related cardiac arrest in young athletes. However, this aspect has not obtained the full observation in the Macau athletes. Therefore, we examined the effect of handball training on the computerized ECG QRS- and T-wave obtained in amateur Macau athletes.
METHODS: Computerized 12-lead resting ECG was obtained in 37 handball male players and 59 matched sedentary male controls with a normal cardiovascular physical examination and without family and personal history of heart disease. Electrocardiogram measurements included voltages and durations in all 12 leads to calculate QRS- and T-wave.
RESULTS: For QRS-wave, the Macau handball athletes had significantly greater S duration in V6 and QRS duration in II, III, aVR, aVF, V4, V5 and V6 compared with controls . Further, Macau handball athletes also had significantly deeper in S amplitude V6 compared with controls . For T-wave, the Macau handball athletes had significantly lower T wave amplitude in III and V1 and greater T wave amplitude in V5

and V6. The athletes also had greater positive percentage of T wave area in I, V4-V6 and greater negative percentage of T Wave area in V1 compared with controls .
CONCLUSION: Though the criteria for abnormal QRS amplitude have been recommended for pre-participation exams of athletes, the criteria have not considered specificity on sport event and ethnic group. This descriptive study, which shows that QRS- and T-wave differences exist between Macau handball athletes and controls, is a pioneering step toward the development of sport- and ethnic-specific criteria for abnormal ECG findings. Although the significance of these changes in QRS- and T-wave is no clear, it is important to bear in mind the existence of these changes when testing athletes. In the future research, sport- and ethnic-specific ECG criteria for abnormal ECG findings should be developed to obtain a more useful approach to ECG screening in athletes.

REGULAR MODERATE INTENSITY AEROBIC EXERCISE DOES NOT AFFECT VASCULAR OUTCOMES DURING PREGNANCY: A PILOT STUDY

BRISLANE, A., JONES, H., LOW, D.A., HOLDER, S., HOPKINS, N.D.

LIVERPOOL JOHN MOORES UNIVERSITY

INTRODUCTION: Cardiovascular diseases (CVD) are the leading cause of morbidity and mortality during pregnancy, with vascular impairments potentially playing a key role in the pathology. Exercise training can improve vascular outcomes in healthy and clinical populations, however the effect of regular exercise on vascular function and structure in pregnant women is not known. The aim of this study pilot study was therefore, to determine the impact of a 6 month exercise intervention on vascular function and structure in previously inactive pregnant women. It is hypothesised that engaging in an exercise intervention during pregnancy will enhance vascular function and structure.
METHODS: Ten healthy pregnant women were recruited to a control (CONT; N=6 33•0.5 years, BMI 22.4kg/m2) or exercise group (EX; N=4 31.5• 0.6 years, BMI 23.8•2.1kg/m2) at 13-15 weeks gestation. Participants were assessed at the end of trimester 1(T1), 2(T2) and 3(T3). Vascular ultrasound was used to assess flow mediated dilation (FMD) of the brachial (BFMD) and femoral (FFMD) arteries. Pulse wave velocity (PWV) was calculated using applanation tonometry. Aerobic capacity was estimated using the Astrand submaximal cycling protocol. Physical activity (PA) was measured over 7 days using accelerometry. The exercise intervention consisted of 3x15 minute weekly exercise sessions in trimester 2 (T2), progressing to 4x30 minutes in trimester 3 (T3). Data were analyzed for main effects of group and time using repeated measures ANOVA.
RESULTS: There were no time, group or interaction effects for BFMD (T1: 9.2•2.1%, T2:6.7•0.9%, T3: 9•5%, P=0.76), FFMD (T1, 6.5•3.4%, T2, 6.2•2%, T3, 2.4•1.9%, P=0.18) or PWV (T1, 5.3•0.43m/s, T2, 4.3•0.7m/s, T3, 5.2•1.7m/s; p=0.59). No differences in aerobic capacity were evident (T1, 47.4±5ml/kg, T2, 43.4±3.3ml/kg, T3, 39.1±3.5ml/kg, p=0.22). No differences were observed for physical activity (T1, 330±87mins/d; T2, 296±52mins/d; T3, 271±16mins/d.
CONCLUSION: Our findings suggest that engaging in a moderate intensity aerobic exercise intervention during trimesters 2 and 3 of pregnancy does not affect vascular outcomes during pregnancy. It is plausible that the hormonally induced hemodynamic adaptations which occur during pregnancy cannot be overridden by moderate intensity exercise, however further research is needed to confirm this hypothesis.

EFFECTS OF 16-WEEK OF TRACK AND FIELD ACTIVITIES IN PHISICAL EDUCATION STUDENTS' PERFORMANCE.

RUSSOMANNO, T., BATISTA, A.L., SILVA, R.B.N.

UNB UNIVERSIDADE DE BRASILIA

INTRODUCTION: Physical education students have in their program practical and theoretical lectures, which load can variate depending on the semester changing their life style and performance. Based on this information, the aim of this work was to analyze the effect of track and field practical activities sessions in the students' performance for 16 weeks.
METHODS: The sample consisted of 44 students, 27 males (age=21.41 ±2.34 years, weight=75.14 kg ±11.70 kg, height=174.46 cm ±5.91cm) and 17 women (age=22.29 ±5.70 years, Weight= 58.18kg ±6.75kg, Height=162.10cm ±6.31cm). Twice a week for 16 weeks these students practiced 2 hours of track and field activities. Four tests were applied pre and post these16 weeks of activities to evaluate their effects over performance: 50 meters run, horizontal jump, vertical jump and medicine ball throwing. The session was divided in 4 parts, 10 minutes of warming up, 45 minutes of basic training (coordination, velocity, power, aerobic), 45 minutes of specific track and field events (running or jumping or throwing) and 20 minutes of leisure activities. The results were shown by mean values and standard deviation. ANOVA test for repeated measures ($p \leq 0.05$) were performed to assess the difference between the pre and post tests using the SPSS v.25 software. The study was conducted according to the ethics regulations.
RESULTS: For the 50 meters run test the results were (pre: 6.47m/s±0.89m/s, post: 6.98m/s±0.90m/s), for the vertical jump (pre: 41.44cm±10.45cm, post: 47.50cm±12.87cm), for the horizontal jump (pre: 1.90m±0.36m, post: 1.85m±0.42m) and medicine ball (pre: 4.49m±1.14m, post: 4.30m±1.06m). Significant difference was found in the 50 m, vertical jump and medicine ball test ($p \leq 0.05$). There was no significance difference in the horizontal jump.
CONCLUSION: The study showed that the intervention promoted performance maintenance in physical education students and also some significant improvements with an increase in speed in the 50m test and also in the vertical jump. One suggestion is that great part of the course content were activities related to running and jumping (80%), moreover 20% of the course content was related throwing events which may have led to a significant decrease in medicine ball throwing performance. The authors suggest that and increase in upper limbs stimulus can improve the performance of throwing test. The horizontal jump test didn't show significant difference, probably due to a lack of coordination that is required to improve in this test. On the other hand, the vertical jump test showed a significant performance improvement once coordination is not mandatory for improvement in this test.
The results showed that a 16 weeks course with 2 sessions of 2 hours per week can improve physical education students' performance. However future studies may be done to evaluate students from other faculties and also include aerobics tests.

EXERCISE BEHAVIOURS OF PREGNANT MOTHERS DO THEY FOLLOW ESTABLISHED GUIDELINE

BHATTACHARYYA, M.

UNIVERSITY HOSPITAL LEWISHAM

INTRODUCTION: Pregnant women are encouraged to be physically active throughout pregnancy, with recommendations to participate in at least 30 min of aerobic activity on most days of the week, in addition to perform strength training of the major muscle groups 2-3 days per week, and also pelvic floor muscle training. Obesity before and during pregnancy is associated with adverse effects for mother and child, but little is known about physical activity and consumption patterns, among reproductive-aged women in urban area of the English county. The assessment of physical activity during pregnancy is crucial in perinatal care. Unfortunately, there is a lack of study to identify patterns of physical activity of pregnant reproductive-aged women and patient's perception on physical activity during pregnancy.
The aim of the audit was to describe the mode, frequency, duration, and intensity of physical activity of pregnant women, to explore whether these women reached the recommended levels of activity as outlined by Chief medical officer in UK, and how these patterns have changed during pregnancy.
METHODS: During the consultation, as a part health promotion the patients were asked about physical activity. This study included a cross-sectional sample of at less than 13 weeks [n=134], mid trimester [n=29], advance trimester [n=27] pregnant women and postnatal mothers [n= 45], mean age 28.6 years .
RESULTS: 90% of pregnant mothers reported decreased physical activity level during pregnancy, particularly in care giving, outdoor household, and recreational activity with advancement of pregnancy. Women who were active during the second and third trimesters reported higher levels of activity in all modes of activity than those were inactive during pregnancy. 93% of patients did not reach the recommended level of physical activity as outlined in UK chief medical officer's guideline. These data suggested that self-reported physical activity decreased from the second to third trimester and only a small proportion reached the recommended level of activity during pregnancy. There was further decrease of physical activity/exercise during the postpartum period.
Women in the exercise group had significantly lower blood glucose and resting pulse compared to the non-exercise group.
Lack of Physical activity also associated with increased consumption behaviours among pregnant women and increased BMI. Among 18-45-year-old women, exercise and fruit/vegetable consumption were associated with healthy weight control.
CONCLUSION: The majority did not reach the recommended level of physical activity. Although most women reported some type of physical activity during pregnancy periods, the overall physical activity decreased during and after pregnancy. Child and adult care giving, indoor household, and recreational activities constituted the largest proportion of total reported activity and no dedicated routine for doing physical exercise. Women who were active during the second and third trimesters reporte

FITNESS LEVEL AND HEALTH STATUS OF A FITNESS CENTRE'S CUSTOMERS. A PILOT TEST

SANCHEZ-LORENTE, I.M.1,3, ITURRIAGA-RAMÍREZ, T.1,3, LÓPEZ-FERNÁNDEZ, J.2,3, DÍEZ, I.1, AYUSO, M.3, PÉREZ, M.1, FERNÁNDEZ-ELÍAS, V.E.1, JIMÉNEZ, A.2,3

1 UNIVERSIDAD EUROPEA DE MADRID, 2COVENTRY UNIVERSITY, CIRAL. 3 GO FIT LAB.

INTRODUCTION: Physical activity and its relationship with health is recognized throughout the world, as well as the need to increase levels of physical activity to improve health status. However, physical inactivity is a major public health problem that must be addressed. Therefore, international institutions have promulgated physical activity guidelines to address the potential risks of sedentary lifestyles and physical inactivity that exist in todays societies. However, it is necessary to evaluate if the population follows these guidelines and to what extent it affects their physical fitness and health levels. The main goal of this pilot study was to widely assess the physical fitness and health levels of population that is regularly enrolled in physical fitness centres.
METHODS: Fifty-six healthy participants voluntarily enrolled in this study (32 males age 34,03 ± 8,11 and 24 females age 36,13 ± 10,81). Cardiovascular risk was assessed by body composition, cholesterol and triglycerides blood levels. Physical activity levels in METS/w were estimated using the GPAQ questionnaire. Integral health status using the PSS-10 questionnaire and quality of life using the SF36 questionnaire. Also, the sleep quality was analysed through the PSQI questionnaire and the adherence of the Mediterranean Diet was evaluated using the PREDIMED questionnaire. Physical fitness was assessed by measuring VO2peak, bench press 1RM estimation test, leg press 1RM estimation test.
RESULTS: Body fat was 15,1 ± 5,7% in male and 26,1±7,6% in female. CHOL: 183,3±27,3 mmol/l and 93,87±30,9 mmol/l. TG: 113,41±53,7 mmol/l and 106,33±33,1 mmol/l. METS/w: 5092±2646,7 and 4207,5±2163,1. PSS-10: 15,94±8,19 and 18,04±8,34. SF-36: 87,43±6,83 and 83,13±12,97. PSSQI: 3,45±1,84 and 4,17±2,05. Predimed: 9,5±1,8 and 8,5±2,2. VO2peak: 52,9 ± 9,5 ml·kg-1·min-1 and 41,2 ± 8,5 ml·kg-1·min-1. Coef Bench Press: 0,902±0,25 and 0,451±0,1. Coef Leg Press: 2,411±0,51 and 1,888±0,49.
CONCLUSION: These outcomes provide relevant information about the characteristics of the fitness centres customers evidencing that those who regularly exercise in fitness centres meet the international guidelines for physical activity and have a suitable overall health and physical fitness levels. However, these findings cannot be widespread for all fitness centre costumers due to low participants sample assessed. Future studies regarding fitness centres participants health and fitness status need to be addressed.

ELECTROCARDIOGRAPHIC Q-WAVE, ST-SEGMENT AND J POINT IN MACAU MALE HANDBALL ATHLETES AND NON-TRAINERS

NIE, J.1, LIN, H.2, LAI, H.1, KONG, Z.3, TONG, T.4, ZHANG, H.5, SHI, Q.1

MACAO POLYTECHNIC INSTITUTE

INTRODUCTION: Regular, intense exercise causes structural, functional, and electrical cardiac adaptations, which are considered benign and comprise the clinical constellation of findings known as the athlete's heart. Thus electrocardiogram changes in athletes are common. The different type exercise training causes the change may have the distinctive . Different types of sports tend to give rise to distinct ECG forms of the athletes heart such as Q-wave, ST-segment and J point. However, this aspect has not obtained the full observation in the Macau athletes.

METHODS: Computerized 12-lead resting ECG was obtained in 37 handball male players and 59 matched sedentary male controls with a normal cardiovascular physical examination and without family and personal history of heart disease. Electrocardiogram measurements included voltages and/or durations in all 12 leads to calculate Q-wave, ST-segment and J point.
RESULTS: The results showed that Macau handball athletes had significantly higher J value in I, V4, V5 and V6 lead than control group . But there were not significant differences in other parameters measured between the two groups 0.05>.
CONCLUSION: The findings from the present study suggest that handball training in Macau may lead to higher J values in cardiac lateral wall leads of ECG. High J value is one of indicators for diagnosing acute myocardial infarction . Based on our current data, clinicians should be aware that high J value is not exclusive to acute myocardial infarction, but can be observed even in trained athletes. This could be a potential error source, which interferes with diagnosing acute myocardial infarction. Thus, the result of the study can facilitate ECG interpretation for screening young handball athletes.
*The study was supported by a research grant from Macau Polytechnic Institute

Mini-Orals

MO-PM07 Physical activity / Sedentary behaviour

THE INTERGENERATIONAL TRANSMISSION OF IMPLICIT AND EXPLICIT ATTITUDES TOWARD PHYSICAL ACTIVITY AND SEDENTARY BEHAVIORS

ESCRIVA-BOULLEY, G., BOICHÉ, J.

LABORATORY EPSYLON

Introduction: The lack of Physical Activity (PA) and Sedentary behaviors (SED) during childhood represent a major health concern. These behaviors seem to be affected by explicit and implicit attitudes. Research showed that children' behaviors and attitudes toward health-related behaviors are associated to those of their parents. Only two studies (Guidetti, et al., 2012 ; Sherman, et al., 2009) investigated this intergenerational transmission of attitudes toward health-related behaviors (food and smoking). These studies showed that children's attitudes were predicted by those of their parents. The purpose of this study was to explore associations between parents' PA and SED, as well as explicit and implicit attitudes toward these behaviors, and their children's behaviors and attitudes.

Methods: 96 parent (Mage=42.43, N♀=68)-child (Mage=11.46, N♀=41) dyads completed an implicit association test (IAT) to assess implicit attitudes. The IAT was presented on a computer in blocks. Blocks where PA were paired with positive adjectives (e.g., good, fun), and SED with the negative adjectives (e.g., bad, boring) were labeled "compatible", while when these pairings were reversed blocks were labeled "incompatible". The order of presentation of compatible and incompatible blocks was counterbalanced across participants. DW-Scores (reaction time and error) were calculated.

Dyads completed questionnaires assessing behaviors and explicit attitudes. Questions to assess behaviors were: "During the last 7 days, on how many times did you do physical activities/sedentary behaviors?". Explicit attitudes were assessed using the same adjectives than in the IAT. Items were rated on a 4-point Likert-scale following the stems: "Do you think that practicing PA/SED almost every day is…". The score of explicit attitudes were calculated by subtracting PA scores by SED scores.

Results: Parents' PA was positively correlated to their children's PA (r=.30; p=.01). There was no significant parent-child association, neither for SED nor explicit nor implicit attitudes (-.04.71). Parents' explicit attitudes were negatively associated to children' SED (r=-.22; p=.05).

Conclusion

This study aimed at investigating links between parents' and children's behaviors and attitudes toward PA and SED. Both parents PA and explicit attitudes seem associated with their childrens behaviors. Future studies need to promote healthy lifestyle to all family members.

RELATIONSHIP BETWEEN PHYSICAL ACTIVITY LEVELS AND DEPRESSION IN WOMEN BETWEEN THE AGES OF 35 AND 50

PEHLIVAN, A., KAZAN, N.

HALIC UNIVERSITY

The purpose of this study is women between the ages of 35-50, to determine whether there is a relationship between physical activity and depression. The sample of the study 2015–2016 Istanbul Metropolitan municipality art and vocational training courses (ismek), who are educated in the field of art and sports between the ages of 35 and 50 individuals was created from adult volunteers. Sample group simple coincidence sampling technique. Depression developed by Beck in 1961 to determine the level of the sample group of Turkish validity (r=74) and reliability(α=80) Beck depression scale has been used work made by Hisli(1989). Individuals to determine their level of physical activity a questionnaire was used to determine the level of physical activity developed by Pehlivan. In order to reveal the relationship between physical activity and depression levels of the group surveyed, the questionnaire was used SPSS for Windows statistical analysis of the data obtained from X version. The research statistical analysis t-test and ANOVA were evaluated. As a result of the study, depression scores of individuals who play sports do sports with individuals who dont it was found that there is a statistically significant relationship between the scores ($p<0.05$). To participate a physical activity of medium difficulty in in past three yerars at least is another factor that has a significiant relationship with depression ($p<0,05$). Additionally, there is no significant relationship between the degree of difficulty of the sport and depression ($p> 0,05$).

MANY OF OVERWEIGHT CHILDREN AT 12 YEARS OLD ARE STILL OVERWEIGHT WITH POOR PHYSICAL AT 18 YEARS OLD: A LONGITUDINAL STUDY IN TAIWAN

TSENG, W.C.1, NOSAKA, K.2, SHIANG, T.Y.3, TANG, J.C.3, TSENG, K.W.1, CHEN, T.C.3

1: UNIVERSITY OF TAIPEI, 2: EDITH COWAN UNIVERSITY , 2: NATIONAL TAIWAN NORMAL UNIVERSITY

INTRODUCTION: A cross-sectional study has shown that childhood overweight or obesity is carried into adulthood with increased risk of developing health problems (Dietz 1998 Pediatrics). A study reported that the level of physical fitness (PF) was negatively correlated with body mass index (BMI) in Taiwanese youth between 9-18 years old (Huang & Malina 2007 MSSE). It seems that child obesity is a cause of obesity in adulthood; however, no longitudinal study has investigated this in a large scale. The present study examined whether children categorised as overweight at 12 years old would be still in the same category when they were at 18 years old, and whether PF would be lower for overweight than normal weight students.
METHODS: Height, body mass and four PF tests [60-s sit-ups (SU), standing long jump (SLJ), sit-and-reach and 800-m or 1600-m run/walk (ENDUR)] data of 5985 Taiwanese students (3080 females, 2905 males) who took the measurements every year from 2007 to 2013 were extracted from the national data base. They were classified into three BMI categories based on the national percentiles; underweight: BMI < 5th percentile, normal: 5th < BMI < 85th percentiles, and overweight: BMI ≥ 85th percentiles. The same students were followed from 12 to 18 years old, and the number of students who had in the same or different categories for the 7 consecutive years were counted. Differences in PF among the three BMI categories were compared with a mixed-design two-way ANOVA.
RESULTS: Among 5985 individuals, 592 males (20%) and 395 females (13%) were classified as overweight, and 444 males (15%) and 596 females (19%) were classified as underweight at 12 years old. At 18 years old, 242 males and 242 females were still overweight, and 189 males and 175 females were still underweight in the each group at 12 years old. When compared overweight and normal weight groups, ENDUR (male: 531 ± 97 vs 494 ± 89 s, female: 305 ± 50 vs 280 ± 45 s), SLJ (male: 205 ± 26 vs 220 ± 27 cm, female: 145 ± 22 vs 156 ± 24cm) and SU (male: 42 ± 9 vs 44 ± 9 cm, female: 30 ± 9 vs 33 ± 9 cm) showed poorer fitness for the overweight ($P<0.05$) for all ages (the data above are for 18 years old).
CONCLUSION: It should be noted that 41% of males and 61% of females who were categorised as overweight at 12 years old were still in the same category when they became 18 years old. This suggests that approximately 50% of children continued to be overweight for 7 years. Overweight children had lower PF, and this was consistent between 12 and 18 years old. It has been reported that overweight children have less exercise time and greater sedentary time than normal weight cohort (Herman et al. 2014 Pre Med). Thus, it is necessary to make overweight children more active, and help them to reduce their weight at early age.

PHYSICAL ACTIVITY AS A MEDIATOR OF THE ASSOCIATIONS BETWEEN PERCEIVED PHYSICAL ENVIRONMENTS AND ADIPOSITY IN CHINESE YOUTH

WANG, J., LAU, W.C.P.

CHINA INSTITUTE OF SPORT SCIENCE

Objective: Chinese youth have showed the alarmingly high rate of obesity and low rate of engagement in sufficient physical activity . Environmental supports are important for creating changes in PA and obesity. This study examined whether PA mediated the relationship of physical environments related to PA with adiposity >.
Methods: A cross-sectional study was conducted in 661 Chinese youth <41.3% males> aged 13-18 years. Four environmental settings related to PA were measured with the questionnaire, including the home, neighborhood, school, and convenient facilities or within a 5-minute walk/drive from your school of home>. Perceived physical environments related to PA were assessed two indicators for each setting: perceived availability of environmental resources and perceived importance of environmental resources <5-Likert scale from not at all important <1> to very important <5>>. The validated Chinese version of Physical Activity Questionnaire for Older Children was used to access students' PA. Mediation analysis was completed using bootstrap methods.
Results: The prevalence of overweight was 11.8% including 1.5% obese respondents. Four environments related to PA did not show the significant associations with neither PAQ-C nor BMI, thus, they were excluded from the final models. Home environment <$\beta = 0.16$>, convenient facilities <$\beta = 0.10$>, and perceived importance of the school environment <$\beta = 0.16$> significantly predicted the PAQ-C score which indicated the higher engagement in PA. Perceived importance of the neighborhood environment predicted the PAQ-C with marginal significance. PAQ-C negatively predicted BMI <$\beta = -0.13$>. The percentage of the total effect of three physical environments related to PA on BMI mediated by PAQ-C was 37.5%, 72.2%, and 45.7%, respectively.
Conclusion: Findings suggest that PA is a mechanism by which several environmental correlates may affect youth's adiposity. Planning for improvement in environments is a health strategy to achieve favorable effects on PA and weight status.

LEISURE TIME ACTIVITIES AND THE LIFE OF CHINESE PEOPLE

SHI, J.

GUANGZHOU SPORT UNIVERSITY

Leisure Time Activities and the Life of Chinese People
SHI Jie-qi, Guangzhou Sport University

石洁琦（Diane Shi）

Objective: To show the effects of the sedentary behaviors of the leisure time activities on people's health and provided a recommendation on the types and amounts of physical activity needed to improve and maintain health according to the current situation in China.
Evidence: The author used the data from Chinese General Social Survey of 2015, and the methods of factor analysis and regression analysis to show the different healthy stage of Chinese people with different leisure time activities favor. The author also reviewed existing consensus statements and relevant evidence from primary research articles and reviews of the literature.
Process: After analyzing the relationship between the health and different kinds of leisure time activities based on the data from CGSS, the author points out the health problems of Chinese people and provides the suggestions by reviewing all the existing relevant studies.
Summary: Sedentary behaviors have been proved harmful for one's physical health. Some kinds of leisure time activities aren't physical activities. Chinese people spend their leisure time like watching TV, going out for movie, shopping, reading, going to concert, visiting relatives, visiting friends, listening music at home, physical exercise, watching sport games, doing handwork and surfing the Internet. The effects of the sedentary behaviors of the leisure time activities on people's health are showed in this study. Different kinds of leisure time activities have different relationship with social attitude, status identification, social insurance, household income of a person. The author

used the data from Chinese General Social Survey of 2015, and the methods of factor analysis and regression analysis to show the different healthy stage of Chinese people with different leisure time activities favor. The author also provides a recommendation on the types and amounts of leisure time activity needed to improve and maintain health for Chinese people after reviewing the world research trend of sport and health.
Key words: leisure time activities, living quality, subjective well-being, Chinese

SEDENTARY BEHAVIOUR AND QUALITY OF LIFE IN PORTUGUESE ADULTS

VIEIRA, P.N.1, COUTINHO, S.R.2, SANTOS, T.3,4, RAPOSO, F.1, MARTINS, S.S.1

1-UNIVERSIDADE EUROPEIA, LAUREATE INTERNATIONAL UNIVERSITIES, LISBON-PORTUGAL; 2-NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY; 3-WILLIAM JAMES RESEARCH CENTER - WJRC, ISPA; 4-AVENTURA SOCIAL FMH/UL

INTRODUCTION: Sedentary behaviour is associated with risk for disease incidence and mortality in adults (Biswas, 2015), however international public health guidelines offer no recommendations regarding sedentary time. Research is needed to analyse this dose-response association between sedentary behaviour and health outcomes (Bouchard, 2015), especially the link with mental health and quality of life (Gibson, 2017). The aim of this study was to examine associations between sedentary behaviour and health related quality of life across week days and weekend days.
METHODS: 390 adults (49.5% women), mean age 36.2yrs (range 18-66) and BMI 24.4kg/m2 (range 18.8-34.3) fill out subjective measures of sedentary behavior (sitting minutes per day), quality of life (SF12 Health Survey), and physical activity (7-day recall). Average weekday and weekend day sitting time, quality of life physical and mental health, and minutes of moderate or vigorous physical activity per week were computed. Three groups of sedentary behavior (Group 1 = <3hrs/day; Group 2 = 3-7hrs/day; Group 3 = >7hrs/day) were compared using ANCOVA with physical activity included as a covariate.
RESULTS: Average sitting time on a weekday was 4hrs 11mins (SD=3hrs 7mins) and on a weekend day was 3hrs 54mins (SD=2hrs 29mins). Results showed a negative main effect ($F(2,383)=5.48$, $p=.005$) for weekend day sitting time on quality of life physical health. Planned contrasts identified individuals in group 1 had higher physical health than individuals in groups 2 and 3 ($p<.05$). Perceived mental health quality of life showed no differences between planned contrasts. No main effects were found for weekdays sitting time ($p>.05$).
Conclusions:
Weekend days sitting time below 3 hours per day is negatively associated with better perceived physical health, but not on weekday. This is a preliminary version of an ongoing larger study, which will include a complementary analysis, comparing individuals meeting and not meeting physical activity recommendations, within sedentary behaviour groups. This will give further insight on the association between sedentary behaviour and health related quality of life.

RELATIONSHIP BETWEEN SITTING TIME, PHYSICAL ACTIVITY AND MUSCLE STRENGTH OF OFFICE WORKERS IN TOKYO

SATO, K.

TOHOKU UNIVERSITY

Introduction: Sitting time has been considered as an independent risk factor for cardiovascular diseases, as well as mental disorders such as depression. Increase in sitting time also affects physical functions such as a decreased cardiovascular fitness and muscular strength. Office workers, who spend their work time at offices, may be at a higher risk of lower muscle strength or decreased physical activity.
To examine if physical activity and muscle strength of office workers are associated with sitting time at workdays, we examined sitting time and daily step counts of office workers for more than 20 workdays and measured knee extension strength at the baseline.
Method
The study participants were 30 office workers working at an office located in the center of Tokyo who gave full informed consent to the study (18 males, 12 females, average age 42.96 years ± 8.89, average height 168.67 cm ± 7.39, average body weight 65.17 kg ± 10.75). The study protocol was approved by the institutional review board of Tohoku University Graduate School of Medicine (2017-1-578). At baseline, body height, body weight, maximal isometric knee extension strength were measured. For physical activity measurement, the participants were asked to wear Fitbit Charge 2 TM armband (Fitbit. Inc. San Francisco, CA) continuously during the study period. Step count was used as a measure of physical activity. Sitting time was calculated from the data acquired from the armband subtracting bed time from total sedentary time. Steps counts, number of floors ascended, were also used in the analyses. Isometric knee extension strength was standardized as weight bearing index (% BW). The study period was 46 days from October 26, 2017 to December 11, 2017, and participants who have records for more than 20 workdays.
Based on the obtained median value, the subjects were divided into long sitting group (Group L) and short sitting group (Group S) for comparison.
Result
The average isometric maximum knee extension muscular strength (%BW) was 75.93 ±20.04.
The average number of total steps per day was 7661 steps ± 2090 steps. (ranging from 3745 steps up to 11797 steps). The average number of daily step counts was 8202 steps and 7254 steps for Group L and S, respectively, and hence, no significant difference was observed ($p=0.24$).
No significant difference was observed in the average muscle strength between Group L (72.80 %BW) and Group S (80.41 %BW) ($p=0.29$).
Conclusion
Longer sitting time was not associated with lower step counts nor decreased muscle strength for office workers working in Tokyo.

THE EFFECTS OF WEB-BASED INTERVENTION PROGRAM ON PHYSICAL EDUCATION TEACHERS' AUTONOMY-SUPPORTIVE AND CONTROLLING BEHAVIOUR

TILGA, H., HEIN, V., KOKA, A.

UNIVERSITY OF TARTU

THE EFFECTS OF WEB-BASED INTERVENTION PROGRAM ON PHYSICAL EDUCATION TEACHERS' AUTONOMY-SUPPORTIVE AND CONTROLLING BEHAVIOUR

Tilga, H.1, Hein, V.1, Koka, A.1

1: UT (Tartu, Estonia)

Introduction: Self-determination theory-based interventions have, overall, shown to be effective in helping socialising agents such as teachers to learn how to support their students' autonomy (Su & Reeve, 2011). In most of the previous interventions autonomy-supportive and controlling behaviours have considered as unidimensional constructs. Therefore, in line with studies dealing the autonomy-supportive and controlling behaviour from physical education teachers as multidimensional, the purpose of the present study was to investigate whether a web-based intervention program led to changes in (a) teachers' self-reported multidimensional autonomy-supportive and controlling behaviour and (b) students' perceptions of their teachers' respective behaviours.

Methods: A total of 28 teachers aged 28-66 and their 321 students aged 11-15 were randomised into either an experimental group, in which teachers were trained via four-weeks web-based programme to be more autonomy-supportive and less controlling, or a control group. The teachers' self-reported behaviour as well as students' perceptions of autonomy supportive behaviour from their teachers with dimensions of organisational, procedural, and cognitive autonomy support (Tilga et al., 2017) and controlling behaviour with dimensions of negative conditional regard, intimidation, and controlling with grades (Hein et al., 2015) were measured at baseline and again nine weeks later.

Results: The intervention led to positive changes in teachers' self-reported organisational ($F<1, 12) = 14.48$, $p < .00$), procedural ($F<1, 12) = 6.88$, $p = .02$), and cognitive autonomy-supportive behaviour ($F<1, 12) = 10.64$, $p < .00$), but not in teachers' self-reported controlling behaviour. The students in the experimental group reported their teachers to be more autonomy supportive in all dimensions ($Fs<1, 185) = 8.92$ to 14.89, $ps < .02$), but less in intimidating ($F<1, 185) = 4.25$, $p = .04$) and controlling with grades behaviours ($F<1, 185) = 10.41$, $p < .00$) at follow-up compared with students in control group.

Discussion: The results of this study suggest that a designed web-based intervention program for physical education teachers to enhance their autonomy-supportive and minimise controlling behaviour was effective. Our multidimensional and detailed approach in promoting teachers' autonomy-supportive and minimising controlling behaviours might increase the likelihood that teachers change their behaviour, which, in turn, may facilitate students' psychological needs satisfaction and motivation towards physical education.

HOW PHYSICAL EDUCATION TEACHERS` AUTONOMY SUPPORTIVE BEHAVIOUR IS RELATED TO OBJECTIVELY MEASURED PHYSICAL ACTIVITY AMONG ADOLESCENTS

KALAJAS, H.

UNIVERSITY OF TARTU

ABSTRACT

HOW PHYSICAL EDUCATION TEACHERS` AUTONOMY SUPPORTIVE BEHAVIOUR IS RELATED TO OBJECTIVELY MEASURED PHYSICAL ACTIVITY AMONG ADOLESCENTS

Kalajas, H. 1, Koka, A.1, Hein, V. 1, Tilga, H.1, Raudsepp, L. 1.

1: UT (Tartu, Estonia)

Introduction: The physical activity (PA) level of children among Estonian and other European countries is insufficient for good health (Konstabel et al., 2014). According to self-determination theory (SDT; Deci & Ryan, 2000), an autonomy-supportive environment is assumed to satisfy needs for autonomy, competence, and relatedness, which in turn fosters autonomous motivation and thus influences engagement in PA. The purpose of the current study was to apply SDT to test the relationships between perceived autonomy support from physical education teachers (PE), the satisfaction of psychological needs (i.e. competence, autonomy, relatedness and novelty), autonomous forms of motivation, and leisure-time moderate-to-vigorous physical activity (LT MVPA) of Estonian adolescents.

Methods: Students (n=254) aged 12-15 participated in the study. An accelerometer (ActiGraph GT3X) was used to monitor LT MVPA. The participants filled questionnaires regarding SDT variables. The structural equation modelling was used to examine the hypothesized relationships among the study variables.

Results: The hypothesized model showed a good fit with the data: $\chi2 = 143.83$, $df = 86$; $CFI = 0.98$; $RMSEA = 0.052$. Students' perceived autonomy support from teachers was related to their need satisfaction for autonomy, competence, relatedness and novelty in PE. Students` autonomy and competence need satisfaction were positively associated with students' intrinsic motivation in PE. Students' intrinsic motivation in PE was positively related to students' LT MVPA. PE teachers` autonomy supportive behaviour was indirectly related to LT MVPA through competence need satisfaction and students' intrinsic motivation ($\beta = 0.20$, $p = .03$; $CI95 = 0.02$-0.59).

Discussion: Present findings partially support the applicability of SDT among Estonian adolescents. Students who reported higher PE teachers` autonomy supportive behaviour felt more that their basic psychological needs and novelty satisfaction were met. Students who were intrinsically motivated through competence need satisfaction were more engaged in LT MVPA. Our findings are in line with results of the study by Wang (2017) which show similar relations between autonomy support from PE teachers, the three basic psychological needs and autonomous motivation for LT MVPA. Findings of this study provide a valuable insight into the feasibility of SDT to understand Estonian adolescents` behaviour towards physical activity.

DISTRACTION VERSUS INTENSITY - THE IMPORTANCE OF NON-MAJOR SUBJECTS ON ACADEMIC PERFORMANCE IN SCHOOL

WOLLSEIFFEN, P.1, VOGT, T.3, STRÜDER, H.K.1, SCHNEIDER, S.1,2

1 GERMAN SPORT UNIVERSITY COLOGNE, 2 UNIVERSITY OF SUNSHINE COAST MAROOCHYDORE, QUEENSLAND, AUSTRALIA

INTRODUCTION: Non-major subjects in primary schools, such as arts, music and/or sport are regarded to be important not only for a wider general education but also to support concentrativeness and receptivity. The aim of this study was to compare the influence of a class of aerobic exercise and an arts class on brain cortical activity and possible effects on cognitive performance (Booth et al., 2014).
METHODS: Electro cortical activity using electroencephalography of sixteen school children (8-10 years) was recorded before and after (1) an aerobic exercise class and (2) an arts class. Performance in a standardized assessment of educational attainment (VERA-3) was assessed following both classes.
RESULTS: A significant decrease of cortical activity was measurable in all four lobes after exercise but not art classes. No changes in cognitive performance were obtained.
CONCLUSION: We propose that non-major subjects play a major role in school education and are of major relevance to increase pupils concentrativeness and receptivity. Although a straightforward effect on cognitive performance (Hillman et al., 2009) could not be shown in this study, the neurophysiological effect of exercise (Schneider et al., 2009) should be further evaluated with respect to different kinds of cognitive performance (e.g. creativity, knowledge acquisition) as well as its outlasting effects.

THE IMPACT OF CLASSROOM-BASED PHYSICAL ACTIVITY ON STUDENT'S MOTIVATION AND WELL-BEING.

BJØRKELUND, O.A., JAKOBSEN, L., CHRISTIANSEN, K.D.

AALBORG UNIVERSITET

Objective: Classroom-based physical activty has been recommended as a promising strategy for increasing physical activity levels and academic achievement. However, little is known about how classroom based physical activity breaks affect student motivation and well-being behaviour.
Design: A classroom based intervention study applying mixed method.
Setting: Classroom based physical activity was implemented in four public high school classes in one public school in Jylland area, Denmark, during winter and spring 2016. In total, 167 students were included in an eight-week intervention period.
Method:
The students were divided into either a classroom physical activity intervention group or a control group , depending on their teacher's ability and willingness to implement physical activity into the classroom. A questionnaire was distributed to all students at the end of the eight-week intervention period. Additionally, students in the intervention group completed a questionnaire during the intervention, and eight students participated in a semi-structured interview after the trial period.
Results: Overall, the data analyses support the link between physical activity breaks, motivation and well-being among the students in the intervention group. The students reported to enjoy the physically active breaks in the academic lessons, which can contribute to provide better conditions for academic learning.
Conclusion: The present study offers unique indication that the effect of integrated physical activity in academic lessons seems to be beneficial for students learning.

APPLYING TREATMENT EFFECTS MODEL TO INVESTIGATE PUBLIC AMENITY EFFECT ON PHYSICAL ACTIVITY OF THE ADOLESCENTS

YEH, C.

NATIONAL CHI NAN UNIVERSITY

Prevalence of childhood obesity has been increasing worldwide, especially in developing countries. For most of the Asian countries, the education system highly emphasizes on knowledge education which requires long sedentary time in the classrooms. On the other hand, physical education is seriously neglected. Physical activity is one of the most cost-effective ways to maintain healthy bodyweights. More importantly, regular physical activities help adolescents develop healthy adulthood. Therefore, the purpose of this study is to investigate the causal relationships between PA levels and PA environment. The data were collected from 1,165 junior high school students <597 males and 567 females> by face-to-face interview in the metropolitan area of Taichung, Taiwan. This data include locations in which PA were conducted, purposes of PA, and socioeconomic characteristics. The data of residential PA environment is objective and estimated by Geographic Information System . The level of physical activity in the past 7 days was estimated by the short version of International Physical Activity Questionnaire . The statistical examination of Hausman test indicates that there is an exsiting endogeneity between the location and the level of PA. Accordingly, we use the objective PA environment as the instrumental variable to adjust for the endogeneity problem. The Treatment Effect Model and Bivariate Probit Model are applied for the regression analysis in this study.
The results show that the more schools adjacent to the residential neighborhood of the adolescents, the more likely the adolescents choose schools as their PA amenity. Compared to adolescents who do not use schools as the PA amenities, the adolescents performing

PA at schools have higher amounts of PA. Additionally, using schools for PA amenity is also one of the important factors to achieve the PA level recommended by the Ministry of Health and Welfare. As can be seen, schools are very important PA amenities to the adolescents. One possible reason can be that schools are relatively more secured and familiar environment for their usage. Conclusively, this study suggests that the most effective approach to promote PA in adolescents is to provide the facilities for their PA needs and the accessibility to these facilities in schools. This would help to develop regular PA and achieve sufficient amount of physical activity for long-term health.

PROPOSED MEASUREMENT OF SPORT EDUCATION (SE) INTERVENTION ON STUDENTS' PERCEIVED PHYSICAL LITERACY (PL) AND PHYSICAL ACTIVITY (PA) LEVELS IN UNIVERSITY REQUIRED PHYSICAL EDUCATION (PE)

CHOI, S.M., LEUNG, F.L.E., SUM, K.W.R., YUEN, P.Y., NG, S.K.R., TANG, T.M., HO, W.K.R.

THE CHINESE UNIVERSITY OF HONG KONG

INTRODUCTION: The concept of PL has been discussed after Whitehead (2001) inspiring scholars to investigate on how it impacts on every individual. The QPE Guidelines reinforced its importance on the education of students and the outcome of structured PE curriculum. However, there is no further supplement on the pedagogical model for PE teachers to develop students as physically literate individuals. In response to this situation, a teacher education institute organized workshops focusing on operationalize PL through SE in Hong Kong (Sum et al., 2016). University students are at the stage of early adulthood in the PL journey, required PE courses can provide the last structured PA for them to develop and establish their positive attitude towards PA. After that, future active lifestyle will be planned by their own. Therefore, this proposed presentation will suggest how to measure the effect of SE to their perceived PL and PA levels. The goals of SE have been suggested to contribute to the attributes of PL. By dividing teams and assigning roles, it could motivate students from team success (Wallhead et al., 2013). By amending rules, students are easier to develop movement competence and confidence. The quality of leadership can enhance the PL attribute of self-expression and communication with others through SE.
METHODS: The effect of perceived PL will be investigated by using randomized controlled trial from one of the university in HK which provides required PE lessons to their students. PE teachers will participate in a one-day continuing professional development workshop focusing on how to plan and teach SE curriculum. Scores from perceived PL will be recorded by a questionnaire by using Perceived Physical Literacy Instrument (PPLI) in baseline measurement (Sum et al., 2016). Estimated sample size of 400 participants will be recruited in the SE program and control group respectively. A random sub-sample of 100 participants will wear accelerometers (Actigraph GT3X+) to measure PA levels for at least 8 hours per day, in 7 consecutive days. Lesson will be videotaped and coded with System for Observing Fitness Instruction Time (SOFIT). Demographic information of participants such as age, gender, studying major and sports participating level and SES will also be investigated.
RESULTS: To compare with control group, the perceived PL and PA levels of intervention group is expected to increase more significantly.
CONCLUSION: With the SE curriculum to develop students as physically literate individuals, they will be expected to participate in lifelong PA which is contributed to their long-term health. The intervention will explore the effect on perceived PL and PA levels which will establish the importance on PL development through SE curriculum in HK at tertiary level and extend to primary and secondary schools. This study will also help PE teachers to assess students' self-perception on PL and PA levels which enhance student learning and teaching effectiveness by re-designing the PE curriculum.

CURRICULAR WORKLOAD OF SINGAPORE'S PHYSICAL EDUCATION TEACHERS – A STUDY OF PHYSICAL AND PHYSIOLOGICAL INDICATORS

JOHARI, M.R., MUKHERJEE, S., KEE, Y.H., VAN MECHELEN, W.

NATIONAL INSTITUTE OF EDUCATION, NANYANG TECHNOLOGICAL UNIVERSITY

INTRODUCTION: Physical education teachers (PETs) spend high energy levels due to the their unique occupational demands involving physical activity and sport participation, dynamic lesson supervision, coaching and refereeing, travel between locations, equipment setup and dismantling, demonstrating skills and techniques and play and practice with students. This study determined the curricular workload of Singapore's PETs.
METHODS: 152 PETs (male 116, female 36) across 21 primary (Pri) and secondary (Sec) schools in Singapore volunteered to participate. Physical activity-based measures of workload like activity intensity and step count during curriculum time were assessed using triaxial accelerometry over one working week (5 days) each during either half of the school year. The Freedsons adult VM3 classification cutoffs were used to categorise the activity intensity. Heart rate (HR) monitoring was also done simultaneously to determine the physiological strain.
RESULTS: The mean daily PE teaching time was 3.59 hours for Pri (range 120-360 min) and 3.08 hours for Sec (range 120-360 min) school PETs. The time spent at moderate-to-vigorous intensity activity (MVPA) during the school hours was 55.74 min amongst Pri and 61.74 min amongst Sec PETs. This amounted to 71% and 81.5% of their total daily MVPA time respectively. Time spent at low-intensity activity during school hours was 380.4 mins for Pri and 418.7 min for Sec PETs. The daily mean sedentary time during school hours was 55.74 min for Pri and 109.42 min for Sec PETs. Step count accumulated during curriculum time accounted for 70.6% and 82.5% of total daily step counts for Pri and Sec PETs respectively. The mean HR during non-sedentary times was 102.4 and 101.78 beats per minute (BPM) for Pri and Sec PETs respectively. Majority of both Pri (64.5%) and Sec PETs (80%) achieved HR above 120 BPM during the curriculum time with 17.5% and 6.5% of Pri PETs achieving HR above 140 and 150 BPM respectively and 35.5% and 18% of Sec PETs achieving HR above 140 and 150 BPM respectively.
CONCLUSION: Physical demands and physiological strain of curricular workload in Singapore PETs is substantial and was found to be similar to that reported in other physically demanding occupations like construction, forestry and farming. Prolonged exposure to heavy workload with high energy expenditure can enhance the risk of musculoskeletal (MSK) injuries and dysfunction, degenerative conditions like knee osteoarthritis, lower back problems and greater work absenteeism. These potential outcomes can adversely affect the quality of content delivery in PE, quality of life and continuity of PETs' professional career. Our findings emphasise the need for longer-term studies in this area and for the policymakers to deliberate on the measures to further optimise the curricular workload demands imposed on PETs with the aim to preserve their MSK health and wellness and consequently the quality of PE delivery in schools.

PHYSICAL ACTIVITY IN ALL-DAY ELEMENTARY SCHOOLS

KURITZ, A., MESS, F.

UNIVERSITY OF KONSTANZ

Physical activity in all-day elementary schools
Kuritz, A.1, Mess, F.2 1: University Konstanz (Konstanz, Germany), 2: TUM (München, Germany)
Introduction: German government forces the development of all-day schools, especially in elementary schools, with the objective of better education, compatibility of family and career, and social equivalent opportunities. This change implicates a massive impact on children´s environment and behavior. Regarding Public Health the question arises if a higher amount of time spent in school has any influence on physical activity (PA) and therefore an altered possibility of reaching the WHO activity guideline of 60 minutes MVPA per day. Especially extracurricular activities with active content may help to increase children´s PA in comparison to leisure time spent not in school (Kuritz et al., 2016).
Methods: PA of 512 children from 11 German elementary schools with half-day and all-day programs was measured from June to August 2017 via accelerometry. Children carried activity monitors (GT3X, GT3X+) from ActiGraph® for one week during waking time. In addition, we used a paper-pencil survey for further information about anthropometry, school issues, and activity patterns. Data which met the necessary wear time (Rich et al., 2013), including 5 days of school, was analyzed on persons´ level (n=453). For analyses PA variables MET, sedentary time and MVPA time per day were checked for after-school program attendance (number of days, amount of minutes per week) and compared with children attending half-day schools.
Results: In this sample 307 children attend an after-school program on at least one day during the week, 146 are in half-day school. On average children are in after-school program on 3.15 days a week for 519.3 min/week or 157.49 min/d, respectively. There is no difference in overall MET between children attending half-day school and those who spend at least one day in an after-school program ($F(1,425)=.05$, $p=.82$). Regarding overall PA variables there cannot be found any significant effects in correlation with number of days and amount of minutes attending all-day school. Number of days and length of attendance in after-school program is (highly) positive correlated with MVPA per day (relative value) measured in these program (up to $r=.44$), but negatively correlated with MVPA per day (relative value) measured in leisure time (up to $r=.67$)
Discussion: It seems that type of school – half-day or all-day – has no effect on overall PA. It can be supposed that there might be a transition of high level PA (MVPA) from leisure time to after-school program. This transition might help to increase health related PA for all children, independent of familiar background or social status (Schuna et al., 2013).

RELATIONSHIP BETWEEN QUADRICEPS AND GASTROCNEMII MUSCLE ARCHITECTURE AND PEAK POWER EXERTED DURING ALL-OUT WINGATE TEST.

CORATELLA, G., LONGO, S., RAMPICHINI, S., LIMONTA, E., BISCONTI, A.V., CÈ, E., ESPOSITO, F.

UNIVERSITY OF MILANO

INTRODUCTION: : Muscle architecture enhances muscle function. Particularly, longer fascicle can exert high-speed contractions while wider pennation angle (PA) and muscle thickness (MT) are correlated to greater force. Since it was shown that sprint performance in running (Kumagai et al., 2000) and in swimming (Nasirzade et al., 2014) was influenced by muscle architecture, the current investigation aimed to evaluate the relationship between MT, PA and fascicle length (FL) in quadriceps and gastrocnemii and sprint performance in cycling.
METHODS: Fifteen recreational cyclists volunteered for this study. Sprint performance in cycling was identified as an all-out Wingate (45s) test and peak power (W/kg) was calculated. Ultrasound was used to measure FL, MT and PA in rectus femoris, vastus lateralis, vastus medialis, vastus intermedius, gastrocnemius lateralis and gastrocnemius medialis. Pearson's coefficient was used to calculate correlations.
RESULTS: MT and PA were correlated ($p<0.05$) with peak power in rectus femoris ($r=0.762$ and $r=0.691$, respectively), vastus lateralis ($r=0.642$ and $r=0.627$), vastus medialis ($r=0.786$ and $r=0.590$), vastus intermedius ($r=0.602$ and $r=0.621$), gastrocnemius lateralis ($r=0.705$ and $r=0.589$) and gastrocnemius medialis ($r=0.520$ and $r=0.658$). No significant correlation was reported in FL.
CONCLUSION: CONCLUSIONS: The capacity to increase the force production enhancing both MT and PA seems to be predominant in a power all-out cycling task.

DIFFERENCES IN PHYSIOLOGICAL RESPONSES TO RECUMBENT SYNCHRONOUS HANDBIKE ERGOMETER VERSUS ASYNCHRONOUS ARM CRANK ERGOMETER IN SPINAL CORD INJURED AND ABLE-BODIED MEN

OVIEDO, G.R.1,2, ÁLAMO, J.M.3, NIÑO, O.A.4, TRAVIER, N.5, SOTO-MONTAÑEZ, C.A.3, GUERRA-BALIC, M.1, JAVIERRE, C.3

1 FPCEE BLANQUERNA, URL. 2 TECNOCAMPUS MATARÓ-MARESME, ESCS . 3 UNIVERSITY OF BARCELONA . 4 UNIVERSITY OF CUNDINAMARCA . 5 CATALAN INSTITUTE OF ONCOLOGY

INTRODUCTION: In people with spinal cord injury (SCI), both the position and the type of exercise can influence the physiological response during a maximal cardiopulmonary exercise test (CPET) (1;2)

PURPOSE: to compare the physiological responses in a group of adults with and without SCI by performing a CPET on an asynchronous arm crank ergometer (seating position) vs a CPET on a recumbent synchronous hand-bike (HB) ergometer.
METHODS: Ten adult men with SCI (35±9 y) and 11 able-bodied adult men (AB) (35±9 y) participated in this study. All participants performed a maximal CPET in seating position on an asynchronous arm crank ergometer (ACr) (Angio, Lode, Netherlands) and another CPET on a recumbent synchronous HB (Shark RS, Quickie, Germany). The following maximum values were evaluated: Peak power, oxygen consumption (VO2 peak), expired CO2 (VCO2), respiratory quotient (RQ), ventilation (VE) and heart rate (HR).
RESULTS: The repeated measures ANOVA showed a significant interaction between group and test condition was found for peak power (p=0.001). Post hoc independent t-tests revealed that the SCI group achieved higher values of peak power (157.5±43.9 vs 101.3±22.8 W), VO2 peak (2.93±0.79 vs 1.94±0.52 L/min), VE (113.21±28.55 vs 78.19±20.99 L/min) and HR (167±17 vs 148±19 beats/min) than the AB group during the HB test (all p≤ 0.05). The AB group achieved higher values of RQ than the SCI group on both tests conditions (HB test: 1.35±0.18 vs 1.13±0.10; ACr test: 1.19±0.09 vs 1.10±0.09) (all p ≤ 0.05). Post hoc paired t-tests showed that the SCI group achieved lower values of peak power during the ACr test respect the HB test (136.50±43.23 vs 157.50±43.98 W) (p=0.002). The AB group achieved lower values of VO2 peak (1.94±0.52 vs 2.26±0.58 L/min) and HR (148±19 vs 158±28 beats/min) on the HB test respect the ACr test (all p≤0.05). On the contrary, they achieved higher values of RQ (1.35±0.18 vs 1.19±0.09) on the HB respect the ACr test (all p≤0.05).
CONCLUSION: This study shows that there were no differences in the VO2 peak achieved by adults with SCI when performing a CPET in seating or recumbent position, however, it seems that they are more efficient when performing a CPET on a recumbent ergometer. On the other hand, adults without SCI achieved higher values of VO2 peak during the CPET in seating position, which could be due to the fact that they were able to recruit and activate more muscle mass during the exercise in seating position than during the recumbent position. Future studies with larger sample size are needed to corroborate the results obtained in the present study.

THREE-MINUTE ALL-OUT TEST IN SEMI-TETHERED FIELD TRACK RUNNING: IS THERE A PROTECTIVE ANTICIPATORY EFFECT?

SOUSA, F.A.B., RODRIGUES, N.A., ARRIVAS-FILHO, R., SANTOS, D.G., MANCHADO-GOBATTO, F.B., GOBATTO, C.A.
UNIVERSITY OF CAMPINAS; EINSTEIN INTEGRATED FACULTIES

INTRODUCTION: A procedure to evaluate aerobic and anaerobic parameters in one single session had gained attention in sports sciences. However, the protocol demands all-out intensity to be maintained during three-minutes, and an anticipatory effect caused by the knowledge of performing such hard task may reduce performance (Noakes et al., 2005; Sousa et al., 2017). This study aims to investigate the occurrence of a protective anticipatory effect during a three-minute all-out test performed in the running track.
METHODS: Eight recreational runners (age = 20 ± 5 years; height = 1.72 ± 0.14 m; BM = 68.8 ± 13.1 kg) had power values recorded over all-out three-minute and thirty second running efforts in separated occasions. Six of them performed an extra test session to access the three-minute test reliability. All sessions were performed using a semi-tethered prototype to enable power measurement in the horizontal plane (Sousa et al., 2015). The prototype resistance was set to 18% of the runner's body mass. Maximum power (Pmax30s), mean power (Pmean30s) and decay slope were analyzed considering the first 30 seconds of the three-minute test and compared with the 30-second session. For the three-minute test, the aerobic parameter – end power (EP) – was obtained as the average power in the last 30 seconds. The anaerobic parameter (W') was obtained as the integral of power over time, discounted the portion related to the aerobic metabolism. Further, maximum power (Pmax), mean power (Pmean) and covered distance were calculated for the three-minute test to evaluate test-retest reliability. After normality check (Shapiro-Wilks), comparisons were performed using paired Student's t-test, and absolute agreement ICC. Significance was set at $P < 0.05$.
RESULTS: Pmax30s (723 ± 83 vs 687 ± 123 W; P = 0.30), Pmean30s (544 ± 74 vs 495 ± 108 W; P = 0.16) and slope (-11,7 ± 4,9 vs -9,9 ± 3,6; P = 0.06) were not significantly different between thirty second and three-minute tests, all with significant ICC-A (range between 0.51 and 0.83). Regarding reliability, covered distance (623.5 ± 58.1 vs 607.0 ± 77.1 m; P = 0.49) was not statistically different and presented significant agreement (ICC-A = 0.68). Further, EP (191 ± 41 vs 211 ± 47 W; P = 0.10), W' (10.8 ± 2.5 vs 11.9 ± 5.0 kJ; P = 0.56), Pmax (597 ± 146 vs 626 ± 176 W; P = 0.21) and Pmean (252 ± 46 vs 280 ± 71 W; P = 0.09) were also not statistically different and had significant agreement (ICC-A between 0.79 and 0.95), except for W' (ICC-A = 0.47).
CONCLUSION: Results suggest reasonably test-retest reliability for the procedure, except for W'. Further, no anticipatory effect influenced power values in relation to the thirty-second effort. FAPESP 2013/16710-7; CNPq 461559/2014-5.

A NEW REPEATED RAMP CYCLE TEST TO ASSESS THE RECONSTITUTION OF W' FOLLOWING FULL DEPLETION

CHORLEY, A.
UNIVERSITY OF CHESTER

INTRODUCTION: Within the framework of the critical power (CP) model, the expenditure and reconstitution of work above CP (W') allows a cyclist to perform repeated supramaximal efforts. Whilst models of W' reconstitution exist, they are based on intermittent exercise protocols and do not account for individual characteristics other than CP. To date there are no test protocols for assessing the W' reconstitution characteristics of individual cyclists. The purpose of this study was to examine the reliability of a new repeated ramp test (RRT) protocol for assessing the partial reconstitution of W' following full depletion and to assess the fit of an existing W'bal model (Skiba et al 2012).
METHODS: After habituation and baseline testing of CP, 20 healthy active adults, consisting of trained cyclists (n = 9; age 43 ± 15 years; $\dot{V}O_2$max 61.9 ± 8.5 mL/kg/min) and untrained (n = 11; age 36 ± 15 years; $\dot{V}O_2$max 52.4 ± 5.8 mL/kg /min) performed two RRT on a cycle ergometer separated by 2-4 days. The RRT consisted of a 5-min warm-up at 100 W followed by three repeated ramps (20 W/min) to exhaustion, interspersed with 2-min recoveries at 50 W. W' reconstitution during each recovery was calculated as the work done above CP in the subsequent ramp. Gas exchange data was collected throughout and blood lactate concentrations were taken at the end of each ramp phase.

RESULTS: Inter-trial relative reliability of W' reconstitution was evaluated by intraclass correlation coefficients (ICC) for the group (≥ 0.859), trained (≥ 0.940) and untrained (≥ 0.768) sub-sets. Absolute reliability was evaluated with typical error (TE) and coefficient of variation (CV) for the group (TE ≤ 559 J; CV ≤ 9.2%), trained (TE ≤ 301 J; CV ≤ 4.7%), and untrained (TE ≤ 720 J; CV ≤ 12.4%). Intra-trial differences of W' reconstitution between the 2-min recovery periods were significant ($p < 0.05$), despite no differences ($p > 0.05$) in the measurements of $\dot{V}O_2$ or blood lactate. The observed minimal detectable changes of 475 J (1st recovery) and 368 J (2nd recovery) can be used to monitor changes in the rate of W' reconstitution in individual trained cyclists. Predicted values of W' from the W'bal model significantly ($p < 0.05$) underestimated remaining W' at the end of each recovery period despite overestimating W' at the end of each depletion.
CONCLUSION: In conclusion the RRT is both reliable for discriminating between individuals based on the high ICCs, and for assessing the efficacy of longitudinal or intervention studies (training or acute) due to the low TE & CV values, particularly for trained cyclists. CV values are lower than traditional W' studies due to the reduced impact of the variability of CP in the test design. The differences in intra-trial recoveries demonstrate a fatiguing effect on W' reconstitution which is not accounted for in the W'bal model, which does not provide a good fit for the RRT involving full depletion of W'.

DOES DIFFERENT TYPES OF TRAINING INFLUENCE THE VO2 AND MUSCLE DEOXYGENATION KINETICS IN SUPRAMAXIMAL RUNNING?

REIS, J.F.1,2, CURTO, D.2, ALMEIDA, N.2, ESPADA, M.3, ALVES, F.B.2

1UNIVERSIDADE EUROPEIA, LAUREATE INTERNATIONAL UNIVERSITIES, LISBON, PORTUGAL; 2FACULTY OF HUMAN KINETICS, UNIVERSITY OF LISBON; 3 SCHOOL OF EDUCATION, POLYTECHNIC INSTITUTE OF SETÚBAL, PORTUGAL

INTRODUCTION: For the same increment in work rate, individuals with slow overall oxygen uptake kinetics will rely on a greater extent on non-oxidative metabolic pathways to meet the energy demands of the exercise task, reaching early fatigue. The literature shows that endurance training induces a speeding of the initial VO2 and muscular oxygen extraction kinetics. However, the specific characteristics of training that optimizes said parameters is not yet clearly established.
We aimed to compare the effects of 4 weeks of continuous (CT) and low volume high intensity interval training (HIIT) on the oxygen uptake (VO2k) and muscle deoxygenation kinetics in transitions from rest to supramaximal running.
METHODS: Eighteen active subjects, with no endurance training background were randomly assigned to complete 12 sessions of CT (24–32 min in the heavy domain) or HIIT (6-8 x 30 s running at 120-2% MAV, interval rest of 30 s) over a 4-wk period (CT n=9; mean±SD; 24.1±4.0 yr.; 63.5±10.1 kg; height 1.71±0.8 m and HIIT n=9; 25.8±6.0 yrs; 68.4 ± 10.4 kg; 1.71 ± 0.07 m). Before (PRE) and after (POST) the intervention period, subjects completed on the treadmill an incremental test and two square wave transitions to 110% of the maximal aerobic velocity (MAV) until exhaustion. In all tests, pulmonary VO2 was collected breath-by-breath (Metamax3b, Cortex, Germany) and deoxy-hemoglobin [HHb] data of the vastus lateralis was determined by near-infrared spectroscopy (NIMO, Nirox srl, Brescia, Italy). The parameters of the VO2k and [HHb] kinetics were determined using a monoexponential model.
A two-way (time by group) ANOVA with repeated measures for time determined the effects of the interventions on the physiological variables. When the analysis revealed a significant effect, paired-samples t-tests was used.
RESULTS: Both training modalities improved relative peak oxygen uptake (VO2peak) ($F=12.5$, $p<0.01$) and MAV ($F= 17.1$. $p<0.01$) (4.2±6.5 and 6.0±5.9% with CT and 13.4±13.3 and 3.1±3.3% with HIIT, respectively) without significant differences between groups. However, the time to exhaustion at 110% MAV was not affected by training (CT: 132.9±29.7 vs 121.7±30.4s and HIIT:125.3±21.9 vs 125.5±17.8s, for PRE and POST, respectively).
The mean response time of VO2k was not affected by either training modalities (CT: 26.5±3.6 vs 25.3±4.0s; HIIT: 28.2±7.2 vs 26.2±3.0 s, for PRE and POST, respectively). Similar responses were obtained for the effective time constant of [HHb] kinetics (CT: 24.0±7.1 vs 23.5±6.8 s; HIIT: 30.5±10.7 vs 26.0±12.4 s, for PRE and POST, respectively)
CONCLUSION: Four weeks of either CT or HIIT were not sufficient to induce changes on both oxygen and muscle deoxygenation kinetics in supramaximal running. The dissociation between changes in VO2peak and these parameters seems to reflect the different underlying mechanisms regulating these adaptations.
However, since CT and HIIT provoked comparable improvements in VO2peak and MAV, the later seems to be a more time-efficient approach.

COMPARISON BETWEEN CARDIAC FUNCTIONAL MITOCHONDRIAL ADAPTATIONS TO FREE RUNNING WHEEL AND HIGH INTENSITY INTERVAL TRAINING

BELEZA, J.1, ALBUQUERQUE, J.1, SANTOS-ALVES, E.1, RIZO-ROCA, D.1, ASCENSÃO, A.1, TORRELLA, J.R.2, MAGALHÃES, J.1

1: LABORATORY OF METABOLISM AND EXERCISE , RESEARCH CENTER IN PHYSICAL ACTIVITY HEALTH AND LEISURE , FACULTY OF SPORT, UNIVERSITY OF PORTO, PORTO, PORTUGAL. 2: DEPARTAMENT DE BIOLOGIA

INTRODUCTION: Animal studies have long tradition on biomedical studies. Accordingly, exercise physiologists have been using different models of rodents to mimic the physiological and biochemical impact of exercise both on systemic and at different level of cellular organization. In this context, researchers have used a model of free running wheel (FRW) in the last years. However, despite the widespread use of FRW as an exercise stimulus, there is a lack of knowledge regarding the truly physiological and biochemical impact of this model on voluntarily exercised animals. Furthermore, taking into account the animal's behavior on the FRW, this model is characterized by short bouts of exercise performed at high speed interspersed by long lasting pauses and moments of low intensity that mimics the exercise bouts performed during sessions of high intensity interval training (HIIT). However, considering its use also in animal studies, scarce data still exist about the overall exercise intensity and metabolic impact of an HITT training session.
The aim of this work is to characterize and compare some of the cardiac mitochondrial function adaptations induced by both FRW and HIIT exercise models.
METHODS: Wistar rats (n=18) with 7-8 weeks old were assigned into Sedentary (SED), FRW and HIIT groups (n=6/group). The maximal oxygen consumption (VO2max) was assessed in the beginning of the protocol. FRW animals had free access to running wheel throughout the entire protocol. The animals from the HIIT group were exercised 5 days a week during 12weeks. The HIIT protocol started with 5 minutes at low speed (60% of VO2max) for warm up, thereafter the rats were submitted to 4 bouts of 4 minutes at 85-90 % of VO2max with 2 minutes of active recovery at 60% of VO2max. Respiratory chain complex I, II activities were determined.
RESULTS: After 11 weeks of protocol, no alterations were found in complex I and II-related state 3 and 4, while an increase in the Respiratory Control Ratio (RCR) of the animals that had access to the running wheel (3.89±0.14 vs. 5.20±0.25; $p<0.05$) and the animals that

perform HIIT training (3.89±0.14 vs. 5.42±0.37; p<0.05) using substracts for complex I was observed. The HIIT training induced an increase in complex II-related RCR compared with SED (3.86±0.17 vs. 2.98±0.19; p<0.05) and FW groups (3.86±0.17 vs. 3.24±0.05; p<0.05). The efficiency of complex I ATP synthesis was higher in the animals that perform HIIT training (4.22±0.31 vs. 3.20±0.20; p<0.05; 4.22±0.31 vs. 3.24±0.16; p<0.05), while no alterations was found in complex II.
CONCLUSION: Both models of exercise (FRW and HIIT) seem to induce an improvement in cardiac mitochondrial function; however, exercise intensity seems to play an important role in cardiac mitochondrial adaptations as the alterations induced by HIIT are more extensive than those associated to FRW.

CHANGES IN HEART RATE AND OXYGEN UPTAKE AMONG JUMPERS USING A LONG JUMP ROPE EXERCISE

YOSHIDA, N.1, WADA, T.2, TAMARI, Y.2, HAMADA, H.1, SAITO, T.2, FURUMOTO, K.3, NOSE, Y.4, NISHIMA, K.5, YOSHIOKA, A.6, YAMAGUCHI, H.7, ONODERA, S.2

1: GRADUATE SCHOOL, KUMW , 2: KUMW , 3: KUSA , 4: YWU , 5: HIT , 6: OU , 7: KIU

INTRODUCTION: Jump rope exercise is a means of health promotion. Users of a short rope (in which the same person both turns the rope and jumps) maintain a heart rate of 166-198 bpm (Quirk JE et al., 1982) and have oxygen uptake of 38.3-49.9 ml/kg/min (Quirk JE et al., 1982), while optimum rotation speed jumping about 92-100 times per minute (Yamaguchi et al., 2001). We proposed that using a long rope (turned by two people while a third person jumps) could promote health in multiple people at once; however, neither the turner nor the jumper is performing the same exercise as the user of a short rope. Previously, we clarified the exercise intensity of turners using a long jump rope. At 70 rpm, the turners heart rate was 109 ± 14 bpm, the oxygen uptake was 12.1 ± 2.1 ml/kg/min, and exercise intensity was moderate (Yoshida et al., 2015). The present study aimed to clarify the exercise intensity of the person jumping over a long jump rope.
METHODS: Six healthy Japanese males volunteered to participate in this study. Their ages, heights, body weights, and body mass index were 26 ± 3 years, 168.8 ± 4.9 cm, 66.7 ± 12.9 kg, and 23.4 ± 4.1, respectively (mean ± SD). All subjects signed informed consent forms prior to participation. The exercise task required the subjects to jump twice during each rotation of the rope, with a rotational speed of 70 rpm. The experimental protocol called for sitting on a chair for five minutes, followed by three minutes of exercise and five minutes of sitting on the chair again for recovery. The jump rope used (length 10 m) was certified by the National Recreation Association of Japan. Measurement indices were heart rate, oxygen uptake, rating of perceived exertion (RPE), systolic blood pressure (SBP), and diastolic blood pressure.
RESULTS: The heart rate was significantly higher at 2 and 3 minutes during exercise than at 1 min during exercise (p<0.05). The heart rate at 3 minutes during exercise was 182 ± 19 bpm. The oxygen uptake at 3 minutes during the exercise was 40.6 ± 6.3 ml/kg/min. The RPE was significantly higher during exercise than at rest (p<0.05). The RPE at 3 minutes during the exercise was 18 ± 3. The SBP was significantly higher immediately after exercise than during rest or even after the five minutes of recovery (p<0.05). These results suggest that using a long jump rope is a relatively high-intensity, high-risk exercise. This is because while a person using a short jump rope controls both the turning and the jumping, the jumper using a long rope must be attentive to and synchronised with the turners motion; accordingly, it was suggested that the long jump rope exercise for promoting health has high risk.
CONCLUSION: This study revealed that jumping over a long rope is a demanding, high-intensity exercise.

THE PHYSICAL RESPONSE TO BOXING-SPECIFIC TRAINING MODALITIES.

PAGE, R.M., GREIG, M., FINLAY, M.J.

EDGE HILL UNIVERSITY

INTRODUCTION: This study examined the differences in the physical response elicited from a contemporary Boxing Specific Exercise Protocol (BSEP) performed using a punch bag and a pad routine.
METHODS: Fourteen male elite amateur boxers (Mean ± SD; age= 22 ± 2 yrs; height= 176.9 ± 7.3 cm; mass= 78.8 ± 8.7 kg;; VO2max= 55.94 ± 5.96 ml·kg-1·min-1; HRmax= 191 ± 4 beats·min-1) were recruited. The BSEP comprised 3x3 minute rounds, with a one minute passive recovery period interspersing each round. Average (HRave) and peak (HRpeak) heart rate, average (VO2ave) and peak oxygen consumption (VO2peak), Blood lactate (BLa) concentrations, rating of perceived exertion (RPE), and both tri-axial and uni-axial PlayerLoadTM metrics were recorded during the completion of each trial. The PlayerLoadTM metrics were recorded at both the cervical and lumbar spine.
RESULTS: Blood lactate concentration increased significantly across each round, with significantly higher values recorded in the pad trial (pad= 2.7 ± 0.8 mmol·l-1; bag= 2.3 ± 0.9 mmol·l-1). A similar response was also identified for the HRave (pad= 160 ± 9 beats·min-1; bag= 150 ± 16 beats·min-1) and VO2ave data (pad= 38.0 ± 0.31 ml·kg-1·min-1; bag= 34.40 ± 1.06 ml·kg-1·min-1). A significant main effect for time was also recorded for the RPE data; however, there was significant differences between trials. Conversely, the Tri-axial (PLTotal) and medial-lateral (PLML) data was higher in the punch bag trial. There was also a main effect for time for all of the PlayerLoadTM metrics. PLTotal, PLML, and vertical PlayerLoadTM were all significantly higher in the lumbar region when compared to the cervical region.
CONCLUSION: The BSEP elicited a fatigue response across rounds in both trials, thus confirming its validity. With implications for boxing-specific conditioning, the pad routine was identified as being more physiologically demanding, but less mechanically demanding than the bag routine.

ENERGY BALANCE DYNAMICS DURING SHORT-TERM CROSSFIT TRAINING

SCHUBERT, M.M., PALUMBO, E.

CALIFORNIA STATE UNIVERSITY SAN MARCOS

INTRODUCTION: CrossFit is a form of high-intensity functional training that focuses on training across the entire spectrum of physical fitness. Workouts typically encompass strength, power, endurance, and flexibility into single movements or exercise sessions. CF has been shown to improve a number of indicators of fitness and health. However, to date, no information assessing energy balance in response to CF training exists. It is important to explore this topic to garner information for the purposes of weight management or manipulating changes in body composition . Thus, the purpose of this study is to investigate energy balance dynamics using objective measures during 1 week of CF training.
METHODS: Healthy men and women , with ≥ 3 months CF experience, had body composition assessed via air displacement plethysmography before and after 1 week of CF training. During the training period, participants wore ActiHeart monitors to assess total energy expenditure , activity energy expenditure , CF energy expenditure , and time spent in various physical activity intensities. Energy intake was assessed from TEE and changes in body composition using established equations. Data were analyzed with descriptive statistics, independent t-tests, and repeated-measures analysis-of-variance.
RESULTS: Results revealed expected sex differences for most body composition and energy balance variables; however, no major differences between men and women were present when energy balance data were adjusted for fat-free mass. CF EE averaged 605 ± 219 kcal per 72 ± 10 min session. Participants attended 4.5 ± 1 sessions per week; thus, weekly CF EE was 2723 ± 986 kcal. Sedentary time accounted for ~54% of the participants' daily activity; MVPA was 169 ± 50 minutes per day. Crucially, this suggests participants were completing MVPA above and beyond the ~70 min CF sessions. Participants as a whole were in an energy deficit , but energy availability levels were in acceptable ranges.
CONCLUSION: Results of the present study indicate that CF training can account for a significant portion of daily activity energy expenditure, but does not cause compensatory changes in energy intake or non-CF physical activity when examined over a 1 week period. Furthermore, the weekly expenditure is within levels shown to induce clinically meaningful weight loss in overweight/obese populations. Thus, CF may offer an enjoyable avenue for weight management and manipulation of body composition.

INTRAMUSCULAR INJECTION OF HYPERTONIC SALINE INDUCES EXERCISE-INDUCED PAIN AND DECREASES TIME TO TASK FAILURE IN MALES

SMITH, S.A., MICKLEWRIGHT, D., MAUGER, A.R.

UNIVERSITY OF KENT

INTRODUCTION: Exercise-induced pain (EIP) tolerance is proposed to be a determinant of endurance performance (Mauger, 2013). However, inadequate methods for inducing EIP are often used in research, and this has made this notion difficult to examine. Despite a relatively limited application to both exercise and performance, the intramuscular injection of hypertonic saline has been suggested to be a method that closely replicates EIP. The aim of the present study was to use this experimental pain model to assess the effect of EIP on time to task failure (TTF) of a sustained submaximal isometric contraction.
METHODS: Nine male (25 ± 4 yr, 1.81 ± 0.71 m, 81.8 ± 11.7 kg) and six female (22 ± 2 yr, 1.68 ± 0.77 m, 61.4 ± 5.9 kg) recreationally active participants completed six conditions separated by 2-7 days. All exercise tests were performed on an isokinetic dynamometer set up for the right leg. The final three visits required participants to perform a single leg isometric TTF of the knee extensors at 10% of their maximal voluntary contraction. They performed this task in in the presence of exercise-induced pain (induced via a 1 mL intramuscular injection of hypertonic saline (5.85%) into the vastus lateralis), a placebo (a 1 mL intramuscular injection of isotonic saline (0.9%) into the vastus lateralis) or no injection.
RESULTS: At rest, hypertonic saline produced a mean pain intensity of 32.9 ± 11.7 on the 0-100 visual analogue scale which lasted 290 ± 81 s. Initial analysis revealed that TTF was not significantly different between the pain, placebo and no injection conditions (670 ± 415 vs. 750 ± 353 vs. 725 ± 385 s, respectively). However, as female's TTF was significantly longer than males and outlasted the duration of EIP induced by the injection, a secondary analysis on a male only sample was performed. Here, a significant difference was found between conditions, with hypertonic saline causing significantly ($P = 0.007$) shorter TTF (454 ± 356 s) compared to the placebo condition (633 ± 363 s), and a difference from the control condition (533 ± 320 s) that approached significance ($P = 0.056$).
CONCLUSION: The primary finding from the present study suggests that an increased EIP decreases TTF, provided that the elevated pain is present for the duration of the task. This is consistent with previous literature which demonstrated a similar finding in the tibialis anterior at 80% MVC (Graven-Nielsen, Svensson and Arendt-Nielsen, 1997). Future work utilising the intramuscular saline experimental pain model should seek to match exercise task time to the duration that pain is induced by the saline.

Mini-Orals

MO-BN10 Sport technology

COMPARISON OF ENERGY EXPENDITURES OF WALKING FROM A SMARTWATCH AND K4B2

CHOW, H., HO, C., CHIANG, W., WANG, J.

NATIONAL CHENG KUNG UNIVERSITY

INTRODUCTION: Promoting older adults to engage in physical active lifestyle is beneficial in reducing medical cost and important in public health. As the wearable device has been the top trend in fitness industry in 2015 and 2016, and walking being the most common physical activities for seniors, this study aims to measure and compare the energy expenditures from a smartwatch (iNCKU) with a potable metabolic system (K4b2) while performing walking.
METHODS: Sixteen older adults (8 men, 8 women) who are above 65 years old completed this study. The participants weared iNCKU smartwatch (tri-axial accelerometer sensor inside) on the left wrist and were equipped with K4b2 system on the chest and covered with the facemask. The protocols were walking on the treadmills at 3.2 kph and 4.0 kph speed for three minutes each.

RESULTS: The energy expenditures from iNCKU watch are 5.44±2.24 Kcal for 3.2Kph and 6.56±2.36 Kcal for 4.0Kph while the data from K4b2 are 9.36±2.69 Kcal and 9.82±2.86 respectively. The results from iNCKU watch and K4b2 were significantly different according to on-way ANOVA analysis.
CONCLUSION: The results revealed that smartwatch underestimate the energy expenditures from K4b2. The reason could be attribute to that the sensor of smartwatch on the wrist is insufficient to accurately detect the complex physical activity, especially movements performed in the lower limbs, i.e. walking. It is suggested that a better algorism is needed or placing more sensors are necessary to provide feedbacks of energy expenditures for seniors while walking.

ANALYSIS OF PERCEIVED COMFORT IN COMPAK SPORTING COMPETITION

MONZONI, R., LONZI, B., LUCERTINI, F., ALUIGI, M., MARI, F., BANCI, L., VIGNAROLI, M., FEDERICI, A.
UNIVERSITÀ DEGLI STUDI DI URBINO CARLO BO

INTRODUCTION: Comfort perceived by the shooter is influenced by several factors including the recoil of the shotgun and the number of shots fired in a certain time. In general, the recoil of a shotgun is influenced by its own weight and by the presence or absence of recoil reduction systems. On the other hand, a clay shooting sport such as Compak Sporting consists of two 25 clays series per day, for a total of 200 clays in 4 consecutive days. In this discipline over&under shotgun is widespread.
In this study the perceived comfort is investigated in terms of exertion and ache produced by shotgun recoil on shooter using skin temperature responses, pain and effort scales.
METHODS: A Compak Sporting simulated competition was carried out using three over&under shotguns (model 828U, Benelli Armi S.p.A., Urbino, Italy): two hunting shotguns (weight 3019 g) differing in the presence (S1) or absence (S2) of 'Progressive Comfort System' (damping device) and one sportive (weight 3564 g) without damping device (S3).
6 male subjects (age 26.8±4.6 yrs; BMI 22.9±1.5 kg/m2) with a minimum of 4 years shooting experience were recruited. Each shooter fired with all shotguns and was blinded to which one was firing with. Shooting sessions were separated by 30 days of rest. The onset of fatigue or pain was investigated by means of two different approaches. Infrared thermography images (IR) was used as an objective measure to analyse the presence of any injuries on the upper trunk. In contrast, a subjective measure of pain and exertion was performed through Visual Analog Scale (VAS) and Rate of Perceived Exertion (RPE). The evaluation tests were carried out before and after two shooting series, per four consecutive days. One-way ANOVA was used to compare VAS, RPE and temperature variations within the interface area between the shotgun and the shooter, which was formerly identified inside the infrared images.
RESULTS: The evaluation tests showed these results: VAS=2.2±1.7; RPE=6.8±0.5; IR=0.43±0.26°C for S1; VAS=6.0±1.5; RPE=7.8±0.5; IR=0.82±0.5°C for S2; VAS=2.5±1.5; RPE=6.7±0.6; IR=0.36±0.32°C for S3. Using a heavier shotgun (S3) or one with a damping device (S1) led to a significantly ($p<0.02$) reduced temperature increase compared to a light shotgun (S2). The same trend was observed through subjective measures: both VAS and RPE confirm a significant reduction ($p<0.02$) in pain and exertion perceived by shooters using S1 and S3 compared to S2.
CONCLUSION: Objective and subjective measures of comfort perceived by the shooter in a simulated competition show the same tendency. In general, a heavier shotgun or one lighter but equipped with a damping device causes a lower recoil than that produced by a light shotgun. This results in less effort and pain experienced by the shooter leading to an improved perception of comfort. These finding are well supported by both quantitative (IR) and qualitative (VAS,RPE) data with strong statistical significance.

VALIDITY AND RELIABILITY OF HEART RATE MEASURED FROM FOUR WRIST WORN ACTIVITY MONITORS

FLOOD, T., THOMPSON, J.E.S., BLACKER, S.D., MYERS, S.D.
UNIVERSITY OF CHICHESTER

INTRODUCTION: The development of heart rate (HR) measurement using photoplethysmography (PPG) in commercially available wrist-worn activity monitors provides the potential to quantify physical activity using cardiovascular strain. The HR measured via wrist-worn activity monitors which use PPG has not been compared to the validated approach of a chest worn HR monitor. Aim: to investigate the accuracy, reliability and repeatability of four commercially available, PPG based activity monitors during treadmill exercise.
METHODS: Following ethical approval, four male and five female physically active participants volunteered (Age 29 ± 4 years; Height 168 ± 9 cm; Body Mass 67.4 ± 10.2 kg; Body Mass Index 23.6 ± 1.9). Participants completed four trials, on each occasion they wore a Polar (RS400) chest worn HR monitor, and two randomly assigned wrist-worn activity monitors in a crossover design. The four activity monitors were Garmin VivoActive HR (GV), Fitbit Surge (FS), TomTom Touch (TT) and TomTom Runner (TR). All monitors were fitted to manufacturers' guidelines. Participants completed a five-minute seated rest, then walked at 2 km·hr-1 on a treadmill, the speed increased by 2 km·hr-1 every 5 minutes and they transitioned to running at between 6-8 km·hr-1. Speed continued to increase by 2 km·hr-1 until voluntary exhaustion.HR was recorded continuously throughout. Data were analysed using Bland Altman Limits of Agreement (LoA) and Pearson's product moment correlations (r). Statistical significance was set $p<0.05$ and the minimum clinically acceptable difference between the 'gold standard' chest strap and wrist worn devices was selected a-priori as ± 5 bpm.
RESULTS: In comparison to the RS400 the mean bias • 95% LoA were; FS -3 ($P<0.001$) 24, -29 bpm, GV -3 ($P<0.001$) 30, -36 bpm, TT -14 ($P<0.001$) 26, -54 bpm, TR -9 ($P<0.001$) 23, -41 bpm. For the TR 55% of data points fell within ± 5 bpm, followed by FS with 45% and GV & TT with 41%. Test-retest data showed RS400 to have the strongest positive correlation ($r=0.977$), followed by FS ($r = 0.946$), TR ($r = 0.935$), TT ($r = 0.918$), GV ($r = 0.900$).
CONCLUSION: The GV and FS wrist-worn activity monitors showed the strongest agreement with the 'gold standard' chest worn HR monitor. However, all wrist-worn activity monitors underestimated HR compared to the chest-worn and 95% LoA for all devices showed large variation which was far outside the minimum clinically acceptable difference of 5 bpm. Our data shows physical activity level is likely to be underestimated when quantified using HR measured with a wrist worn activity monitor and should be interpreted with caution.

THE PHYSIMAX SYSTEM - A NOVEL PORTABLE MOTION ANALYSIS SYSTEM FOR ASSESSING THE LANDING ERROR SCORING SYSTEM (LESS) TEST

DAR, G., YEHIEL, A., CALE BENZOOR, M.

UNIVERSITY OF HAIFA

INTRODUCTION: The landing error scoring system (LESS) assesses the quality of a landing after a jump. The quality of the jump is usually evaluated using a three dimensional (3-D) motion analysis system or a two-dimensional (2-D) video analysis visually rated by a clinician. However, both methods have disadvantages.
The aim of this study was to examine the concurrent validity of a novel portable motion analysis system (PhysiMax System) in assessing the LESS score by comparing it to video analysis.
METHODS: The study population included 48 healthy participants (28.45±5.61 years), each performing the LESS test while two video cameras and the PhysiMax simultaneously recorded the jump. The Physimax system automatically evaluated the LESS. Subsequently, the examiners scored the test by viewing the video recordings, blinded to the PhysiMax results.
RESULTS: The mean LESS score, using the video recordings and the PhysiMax was 4.77(±2.29) and 5.15(±2.58), respectively (ICC=0.80, 95% confidence intervals 0.65-0.87, mean absolute differences 1.13 (95% confidence intervals; 0.79-1.46). The results indicate a high consensus between the methods of measurement.
CONCLUSION: The Physimax systems main advantages are portability, objective evaluation and immediate availability of results. The system can be used by athletic trainers and physiotherapists in the clinic and in the field for jumping assessment.

ACCURACY OF THE MICROEYE® AND CONTINUMON® MICRODIALYSIS DEVICE FOR CONTINUOUS REAL-TIME BLOOD LACTATE THRESHOLD DETERMINATION

LEE, B.J., DOHERTY, J., HILES, A.M., CARNEY, D., O'CONNELL, M.C.

UNIVERSITY OF CHICHESTER

INTRODUCTION: Exercise physiologists use lactate-derived endurance markers to predict and compare endurance ability and to prescribe training zones to athletes. There are many different blood lactate markers proposed in the literature, however each relies on constructing a lactate curve from discrete measurments, usually obtained towards the end incremental work bouts. Here we compare blood lactate indices obtained using traditional blood sampling methods to those obtained using a novel peripheral intravenous microdialysis device and online in vitro diagnostic lactate biosensor system which provides a continuous real-time reading of blood lactate.
METHODS: Ten male volunteers (age 30 ± 9 years; stature 176 ± 9 cm; mass 77.8 ± 8.6 kg) completed one experimental visit. An 18-gauge Teflon catheter was inserted into an antecubital vein, and a Probe Scientific MicroEye® PME012 microdialysis device inserted into the catheter. The MicroEye® was perfused at 1mL/hour with 0.9% sodium chloride containing a small quantity of anticoagulant (Fondaparinux). The outlet of the MicroEye® was connected to the inlet of a ContinuMon® lactate flow cell, for continuous lactate monitoring, which was inserted into a wireless battery-operated ContinuMon® module worn on the participant's wrist. The sensor signal was transmitted to a laptop running proprietary software. A second 18 g catheter was introduced into a peripheral vein in the contralateral forearm for reference blood sampling using a YSI 2300 Stat analyser. Venous blood was sampled at 10-minute intervals throughout 30 minutes of rest, and at the end of each stage of an incremental cycling test and analysed immediately. The incremental cycling test consisted of five 3-minute stages, beginning at 70 watts and increasing by 35 Watts per stage. Power output at lactate threshold (LT), initial rise of 1 mmol.L-1, Dmax, and 4mmol.L-1 of Bla were determined using the R-Lactate R statistics package. Paired t tests were used to assess differences between the thresholds determined from the MicroEye and venous blood samples.
RESULTS: Blood lactate at the end of the 30 minute rest period was 0.54 ± 0.19 and 0.51 ± 0.16 mmol.L-1 for the venous and MicroEye samples (p = 0.56). Power output at lactate threshold was 139 ± 21 and 136 ± 23 watts (p = 0.76); at initial rise of 1M = 163 ± 44 and 162 ± 59 watts (p = 0.96); at Dmax 173 ± 42 and 184 ± 47 (p = 0.10, and at 4mmol.L-1 231 ± 26 and 233 ± 25 (p = 0.73) for the venous and MicroEye samples respectively.
CONCLUSION: The lactate threshold indices obtained from the MicroEye(R) microdialysis cathetar and ContinuMon(R) continuous lactate monitoring system matched those obtained using traditional sampling methods analysed using the R-Lactate open source software. The ability to continuously monitor blood lactate in real time could be a useful tool for applied practioners monitoring training load, and those interested in exercise metabolism.

THE USE OF GPS AND MOBILE PHONE APPLICATIONS (APPS) BY ROAD RUNNERS

SALGADO, J.V.V.1, RUSSOMANNO, T.G.2, KAWASAKI, G.M.3, MORAES, G.H.M.3, ANDRIES, O.J.3

[1]UNIVERSIDADE DO ESTADO DE MINAS GERAIS – UNIDADE DIVINÓPOLIS, [2] UNIVERSIDADE DE BRASILIA, [3] UNIVERSIDADE ESTADUAL DE CAMPINAS.

INTRODUCTION: Road races have become one of the most popular sporting events in the world. The significant increase in the number of athletes, especially amateurs, diversified the segment of specific sporting articles for runners, among them the way of monitoring activities in real time. The aim of this study was to verify the prevalence and evolution of the use of Global Positioning Systems (GPS) and mobile phone application system (APPs) to monitor sports activities by street runners for two consecutive years (2013 and 2014) in the same annual event.
METHODS: The study consisted in applying a self-filling survey. The survey was applied during the registration of the runners at the road race "Volta da Unicamp". The road race involves 5km and 10 km race. Descriptive statistic was used to evaluate the results.
RESULTS: 882 runners of both sexes with mean age of 36.15 (±10.18) years participated in the study. It was observed that 41.16% of the runners used GPS and 30.95% used mobile phone APPs and 53.28% reported using both GPS and APPs. Between the first and second year, the use of GPS showed a growth of 27.04% among the individuals who reported the use, while the use of APPs showed a growth of 65.69%. Of the individuals who receive guidance from a professional in the prescription of training, 46.54% use GPS and 41.33% use APPs. The practice time of the modality was 4.24 (±5.41) years for those using only GPS and 2.56 (±3.25) years among those who used only APPs.
CONCLUSION: The technological advance experienced in the last decades contributed significantly to the development of equipment that allows the investigation of the demands associated to the process of sports preparation, optimizing the design of training and recovery procedures. It can be inferred that factors such as costs, access to technology and information have contributed to the growth of the use of these technologies in the practices of road racers. The use of technological resources tends to grow even more, especially in the APPs,

and these resources can be an important tool for athletes self-control of training, as well as a facilitator for coaches to monitor several variables of the prescribed activities.

EVALUATION OF PERCEIVED SPEED ERROR DURING WALKING AND RUNNING IN A VIRTUAL ENVIRONMENT

PERRIN, T., KERHERVÉ, H., FAURE, C., CATTOZZO, G., BIDEAU, B., KULPA, R.

UNIV RENNES

INTRODUCTION: The development of new virtual reality (VR) devices such as Head Mounted Displays (HMD) increases opportunities for applications at the confluence of physical activity and gaming. Recently, the fields of sport and fitness have turned to VR including locomotor activities, to enhance motivation and exercise adherence. However, the relevance of such tools depend on the ability of these systems to provide realistic immersive feelings, specifically depending on depth and speed perception. The objective of this study is to estimate the error between actual and perceived locomotor speed in environment (VE).
METHODS: Eleven healthy people (4 female, 7 male) with normal vision or a correction device participated in the experiment. The experiment consisted in walking and running on a motorized treadmill (h/p/Cosmos) from 3 km/h to 11 km/h with 0.5 km/h increments in a randomized order, while wearing a HMD (HTC Vive) displaying a virtual racetrack surrounded by columns placed at regular intervals. Participants were instructed to match VE with what they perceived was their actual locomotion speed (LS), using a handheld Vive controller (modifying optic flow). For each trial, we collected the speed of optic flow (OFS) adjusted by participant in 0.02 km/h increment. In order to control the effect of chance we removed best and worst trials for each participant. Correlation coefficients (r), bias, smallest detectable difference (SDD) and typical error of the estimate (TE) were calculated in the standard manner.
RESULTS: There was likely no learning effect as observation rank and error were not correlated (r=0.12). OFS slightly underestimated LS (bias: -0.04±0.24) but the two were highly correlated (r=0.82; y=0.90x+0.68) and TE (1.6±1.1 km/h) was likely not greater than SDD (0.6±1.1 km/h).
CONCLUSION: The main result of our study was that participants were able to match OFS to actual LS. Unlike previous literature from the early 2000 using previous generation of HMD, we found that OFS was not perceived to be slower or faster, despite the relatively large standard deviation in TE. A secondary finding was that OFS estimation was not affected by locomotion speed. Therefore, modern HMD can be used to create immersive feelings of self-motion during active exercise, and further to generate new consumer experiences of training.

RELIABILITY AND VALIDITY OF MY JUMP APP USING A 720P 30FPS IPHONE 4 CAMERA

LOH, T.C.1, CHEAH, B.C.2, SANAWI, M.3, LOO, L.H.3, BEAVEN, C.M.4

NATIONAL SPORTS INSTITUTE

INTRODUCTION: Countermovement jump (CMJ) is one of the commonly used approach to assess lower limb power and force production (Markovic et al., 2004). My Jump app was scientifically validated using an iPhone 5s (Balsalobre-Fernández et al., 2015). Nevertheless the developer only mentioned the measurements are slightly less accurate on other older devices. Thus, the purpose of this study was to determine reliability, validity, and the agreement between the My Jump app using a 720p 30fps iPhone 4 camera and a force platform for measuring CMJ.
METHODS: 50 sub-elite athletes (18 females and 32 males) were recruited to participate in this study. Mean age of the athletes was 17.0 ± 3.0 years old with mean weight of 60.7 ± 9.8kg and mean CMJ height of 37.24 ± 8.82cm. Each athlete performed CMJ three times on the force platform (400 Series Performance Force Plate, Fitness Technology, Adelaide, Australia) while being recorded at approximately 1.5m away from force platform by using the iPhone 4 with the My Jump app. Height of the CMJ using the app was calculated between two frames selected in which the first frame where both feet were off the ground for take-off phase and subsequently took the first frame where at least one foot was touching the ground during landing phase, as described by Balsalobre-Fernández et al. (2015). The force curve was inspected through a computer software (Ballistic Measurement Software, Fitness Technology, Adelaide, Australia) to verify the jump. The means flight time and mean height of the 3 jumps from the force platform and the app were obtained and compared using intraclass correlation coeffifient (ICC), Bland-Altman plots, and Pearson correlation coefficient (r). Cronbach's α and coefficient of variation (CV) were used to analyse the reliability of the app when measuring the three CMJ for each subject.
RESULTS: ICC showed high agreement between the 2 instruments for both flight time (ICC = 0.922, CI = 0.863 – 0.956, $p < 0.001$) and jump height (ICC = 0.941, CI = 0.893 – 0.967, $p < 0.001$). The mean differences for flight time between the two instruments was 5.86 ± 4.58ms, while the mean differences for jump height between the two instruments was 1.03 ± 0.52cm. The Bland-Altman plot showed no proportional bias of the data for both the flight time and jump height. The Pearson correlation showed significant correlation between the app with the force plate for flight time ($r = 0.861$, $r2 = 0.741$, $p < 0.01$) and jump height ($r = 0.895$, $r2 = 0.800$, $p < 0.01$). The My Jump app showed good reliability for the CMJ for flight time ($\alpha = 0.923$, CV = 3%) and jump height ($\alpha = 0.944$, CV = 7%).
CONCLUSION: Almost identical mean difference between equipment (1.1 ± 0.5cm) reported by Balsalobre-Fernández et al. (2015). This study showed high validity and reliability of the My Jump app even with the iPhone 4 that has only a 30fps video camera, which can be used as a field testing or monitoring tool.

A BIOMECHANICAL STUDY OF 5 WEEKS AUDIBLE STIMULUS GOLF COACHING ON THE EFFICACY OF GOLF SWING LEARNING FOR NOVICE GOLFERS

XIA, Z., YOO, K., LIU, Y.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: The traditional golf teaching mostly depends on coaches' individual empirical pedagogy and lacks scientific studies. It was reported that audible stimulus could improve the motor learning efficiency in many sports. Therefore, the purpose of the study was to explore whether the audio stimulus could improve the movement quality for novice golfers in golf swing learning after 5 weeks golf lessons.
METHODS: Twenty-four male novice young participants finished 5 weeks golf swing lessons using 7-iron club. An audible stimulus teaching device was applied to the teaching with acoustical guidance group (TG, N=13). The same coach separately taught another group which had NO acoustical guidance (NG, N=11) using the same teaching program. After 5 weeks golf learning process, ten Vicon infrared cameras and two Kistler force plates were used to collect the kinematic (100Hz) and kinetic (1000Hz) data of all the participants during swing phase. The variation of center of mass (COM) and center of pressure (COP) during downswing to follow throw phase were com-

pared to evaluate motion efficiency between two groups. Also, the ball and club variables from Trackman Doppler radar device were used to measure golf performance. The T-test of independent sampler was used to analysis differences between the two groups.
RESULTS: During downswing to follow throw phase, (1) Trackman data showed that TG golf performance was significantly better than NG in the club speed, face angle, ball speed, carry distance and flight time (65.66±5.66 vs 57.64±6.41mph, P = 0.004; 4.44±2.52 vs 7.70±2.80°, P = 0.007; 87.10±9.04 vs 73.21±6.59mph, P < 0.001; 105.23±16.57 vs 78.50±13.46yards, P < 0.001; 4.41±0.68 vs 3.48±0.59s, P = 0.002); (2) the COM mean velocity (lead-trail) and COP mean velocity (lead-trail) of participants in TG were faster than NG (0.49±0.06 vs 0.48±0.05m/s, P = 0.43; 1.58±0.60 vs 1.44±0.58m/s, P = 0.57); (3) the COM-COP inclination mean angle velocity (anterior-posterior and lead-trail) in TG was faster than NG (17.78±4.73 vs 17.55±5.03°/s, P = 0.91; 43.54±11.96 vs 38.62±13.19°/s, P = 0.35); and the COM-COP inclination angle normalized jerk in TG was lower than NG (2516.10±1215.97 vs 2765.42±1056.57, P = 0.60; 1935.49±748.96 vs 2134.91±776.66, P = 0.53).
CONCLUSION: The current study has identified that the audible stimulus as a golf coaching method could have a positive influence on the golf performance for novice golfers. It may be expected to build a prominent neuromuscular reflection in learning movement for the participants. Although the differences of results were not significant between two groups, the higher tendency of outcomes in TG was found to compare with NG. The high value of velocity of COM, COP and COM-COP inclination angle could support the golf performance outcomes based on the proximal-distal system in golf swing. And the lower normalized jerk value of COM-COP inclination angle may represent smoothness on the swing. So, the current study may acknowledge that the efficacy of audible stimulus as a golf coaching strategy has patent for novice golfers.

MO-PM24 Strength

EFFECT OF ALTITUDE STRENGTH TRAINING ON NEUROMUSCULAR FUNCTION

ŠTIRN, I., TOMAŽIN, K., SMAJLA, D., STROJNIK, V., PADIAL, P., ALMEIDA, F., MORALES-ARTACHO, A., BONITCH-GONGORA, J., DE LA FUENTE, B., CALDERÓN, C., PÉREZ-CASTILLA, A., FERICHE, B.

DEPARTMENT OF PHYSICAL EDUCATION AND SPORT. UNIVERSITY OF GRANADA, SPAIN; FACULTY OF SPORT UNIVERSITY OF LJUBLJANA; HIGH PERFORMANCE CENTRE OF SIERRA NEVADA,UNIVERSITY OF LJUBLJANA, FACULTY OF SPORT

INTRODUCTION: Altitude training has been widely used in sports, mainly to improve endurance; however, altitude resistance training (RTH) has recently became a growing area of interest Recent reviews on the topic reported different conclusions: Ramos-Campo et al. (2018) reported that although RTH improved muscle size and strength, this strategy did not provide significant benefit over similar training in normoxia. However, Feriche et al., (2017) pointed out that terrestrial altitude conditions may have potential of improving the ability to perform power actions as has also been confirmed by Hamlin et al, 2015.
The aim of this study was to analyze the effect of a power-oriented RTH intervention at moderate altitude on neuro-muscular function.
METHODS: Twenty elite judokas were mobilized to participate in the study and divided in the control (C - sea level, n=11) and experimental (A – altitude 2320 m, n=9) group. Both groups executed 6 physical training session/week (3 resistance training alternated with three metabolic sessions) in the morning from Monday to Saturday. In the afternoon, technical Judo training sessions were performed from Monday to Friday. The physical training were exactly the same for both groups.
Maximal knee extension torque (MKT), the level of muscle activation (LA) assessed by interpolated twitch technique and the amplitude (TWA) and contraction time (TWCT) of a single twitch were measured a week pre and a week post intervention. Repeated measures ANOVA was used to analyze the results.
RESULTS: No statistically significant differences between groups were found in neither of the observed variables: MKT - 318.7 ± 61.6 Nm vs. 319.7 ± 58.6 for A, 294.6 ± 62.6 vs. 307.1 ± 68.7 for C (P(group*intervention) = 0.437); LA - 94.4 ± 3.5% vs. 92.1 ± 4.7% for A, 92.7 ± 9.5% vs. 92.4% ± 5.5 for C (p = 0.521); TWA – 83.3 ± 22.1 vs. 84.9 ± 15.3 for A, 78.9 ±17.9 vs. 87.7 ± 18.2 for C, (p = 0.424) and TWCT – 53.8 ± 4.4 vs. 58.1 ± 6.6 for A, 53.8 ± 6.2 vs 53.1 ± 5.6, (p=0.077).
CONCLUSION: Our results showed no differences in measured variables pre and post intervention neither for the experimental or control group. The absolute torque values as well as high muscle activation level measured prior the intervention imply that our subjects were highly trained athletes already as they enter the study. Perhaps this was the reason that their performance over the three weeks of experimental strength training period did not improve. Results obtained do not support the thesis that the potential effect of the moderate altitude on explosive movement can be explained by changes in these neuro-muscular variables.
In conclusion, our result showed no difference in obtained neuro-muscular function parameters after three weeks of RT at sea level or at moderate altitude in highly trained athletes.

A COMPARISON OF PERIODIZATION MODELS IN TRAINED ADOLESCENT AMERICAN FOOTBALL PLAYERS.

GAVANDA, S., GEISLER, S., SCHIFFER, T.

IST HOCHSCHULE

INTRODUCTION: Periodization is the systematic structuring of training variables. It is well documented that periodized resistance training is effective for increasing muscle mass, strength and sports performance. Besides the traditional model there are two commonly used periodization models in strength training. The non-linear or undulating periodization which offers weekly or daily variation of training variables (daily undulating periodization = DUP) and block periodization (BLOCK) with only little variation of intensity, volume, frequency and rest for usually a certain number of weeks. It is still unclear if there is a superior model for athletes with different training backgrounds. The purpose of this study was to compare the effects of DUP and BLOCK resistance training with equated volume on strength, performance and body composition in well trained adolescent American Football players.
METHODS: Eighteen resistance trained male subjects (age: 16.94 ± 0.8 years, weight training experience: 1.39 ± 0.80 years) were randomly assigned to either BLOCK (n = 8) or DUP (n = 10) intervention group. Pre- and post-testing consisted of body composition analysis (BIA), muscle thickness assessment via ultrasound (M. rectus femoris [RF], M. vastus lateralis [VL] and M. triceps brachii [TB]) and tests for performance (1-RM back squat [BS] and bench press [BP], medicine ball put [MBP], CMJ and 40-y dash). The 12-week training programs consisted of 3 full-body workouts per week with the periodization model applied on BS and BP.

RESULTS: There were no significant ($p < 0.05$) differences in pre-test values between groups. Significant time effects were seen for RF ($p = 0.001$), BS ($p = 0.000$), BP ($p = 0.044$) and 40-y dash time ($p = 0.007$). No significant time by group effects have been observed.
CONCLUSION: These finding suggest that both periodization models may be equally effective for increasing performance and muscle thickness in trained male adolescent American football players.

EFFECT OF SUPERVISION AND STRENGTH TRAINING OPTIMIZATION DURING MAXIMAL STRENGTH AND FOLLOWED BY POWER TRAINING

PELTONEN, H., KOSKINEN, O., AHTIAINEN, J., AVELA, J., HÄKKINEN, K.
UNIVERSITY OF JYVÄSKYLÄ

INTRODUCTION: Exercise supervision and individually tailored training programs have major effects on improvements in neuromuscular performance capacity due to strength training. The benefits of the supervision has been shown earlier (Mazzetti et al. 2000), but the effects of the individual optimized strength training is more complicated to investigate. In addition, the methods and parameters of optimization could be varied based on training backgrounds and the goals of the individuals (Jimenez-Reyes et al. 2017, Nindl et al. 2015).
METHODS: 26 untrained men participated in a progressive strength training period for 13 weeks, including specific training targets; muscle endurance (4 weeks), maximal strength with low volume of muscular power exercises (7 weeks) and power with low volume of maximal strength exercises (2 weeks) training. Subjects were divided into three groups after 4 weeks of training; unsupervised (UnSup), fully supervised (Sup) or fully supervised with optimized training program (Opt). All groups had a similar whole body strength training program with the "GymCoachTM" monitoring device (selector pin) and software in their cellular phones. Only the Opt group's GymCoach software modified their training programs set by set in the gym, when needed. During weeks 4-11, the optimization recalculated one-repetition maximum (1RM) based on the last best set, and during weeks 11-13, it decreased load for the next set, if repetition velocities were reduced. The lab tests included 1RM, peak power with 60% 1RM load, isometric maximal voluntary contraction and rate of force development in leg press devices.
RESULTS: Both supervised groups improved their 1RM more (mean value of 17±10%) compared to the UnSup group ($p<0.05$) during weeks 0-11. However, only the Opt group improved (19±8%, $p<0.001$) their maximal power, but not Sup, compared to the UnSup group during weeks 11-13. The changes in the isometric test results were parallel with dynamic test results, but not statistically significant.
CONCLUSION: Strength training with supervision leads to additional strength gains. Velocity based one variable optimization during weeks 11-13 seemed to be effective for power training. Nevertheless, the present optimized training loads with a progressive training program (weeks 4-11) might be too stressful to maximize improvements in maximal strength. However, whether multivariable optimization algorithms is more effective needs to be investigated.

STRENGTH-RELATED ADAPTATIONS TO A STRENGTH TRAINING METHOD CHARACTERIZED BY A BRIEF INTERSET REST INTERVAL AND AN INCREASING NUMBER OF REPETITIONS ACROSS SETS

STRAGIER, S.1,2, BAUDRY, S.2, CARPENTIER, A.1, DUCHATEAU, J.2
UNIVERSITÉ LIBRE DE BRUXELLES

INTRODUCTION: A strength training method (3/7 method) performed with a moderate load (70% of one repetition maximal (1RM)) and consisting in 5 sets of an incremental number of repetitions and a very brief rest interval between sets (≤15 s) was shown to be more effective to increase the maximum strength in bench press exercise than a more classical method (8 sets of 6 repetitions with 150s rest interval between sets; 8x6 method) performed with the same load (Laurent et al., 2016). The combination of moderate-intensity sets with short intervals might provide a superior stimulus for muscle hypertrophy (de Salles et al., 2009). The present study investigated the training-related efficacy of the 3/7 method on strength gains and muscle hypertrophy in the biceps brachii.
METHODS: Twenty-nine young adults were assigned to one of the following methods: 1) 3/7 method repeated two times after 150s of rest (n=15); 2) 8x6 method (n=14). For both groups, the training exercise consisted of lifting and lowering a load (70% of 1RM) with the elbow flexor muscles. All subject trained 2 times per week during 12 weeks. Strength gain was tested during 1RM load. Muscle thickness of the long head of the biceps brachii was measured by ultrasonography and use as an index of muscle hypertrophy.
RESULTS: The 1RM load increased ($p<0.001$) in the two groups (22.2% for 3/7 method; 12.1% for 8x6 method) but the gain was greater ($p<0.001$) for the 3/7 method. A greater increase ($p<0.01$) in muscle thickness was observed for 3/7 method (+9.7%) than 8x6 method (+5.5%) after training. The change in 1RM was positively associated with the increase in muscle thickness only for the 3/7 method ($r^2 = 0.43$; $p<0.01$).
CONCLUSION: The present study indicates that the 3/7 method represents a better stimulus for muscle hypertrophy, likely due to greater metabolic stress and restriction in oxygen supply (Manini et Clark, 2009; Penzer et al., 2016). Such muscular adaptations contribute to a greater strength gain in response to the 3/7 method compared with a more classical method for a similar training intensity and volume.

EFFECT OF SEATED SHORT-SPRINT TRAINING ON ERGOMETER VS HEAVY STRENGTH TRAINING ON 55-METER SPRINT PERFORMANCE IN WELL-TRAINED CYCLIST

BOVIM, L.P., GUNDERSEN, H., HAFSTAD, A., KRISTOFFERSEN, M.

WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Short sprint (SS) training on an ergometer and heavy strength training (HS) are widely used methods among elite cyclists. The aim of this study was to investigate the effect of seated SS training on a WattBike ergometer vs HS training on performing a seated and standing 55m sprint on own bike.
METHODS: Twenty well trained cyclists (age: 27 ± 6 yrs, VO2max: 62.1 ± 6.5 ml·kg-1·min-1, body fat: 12.4 ± 5.2%) participated in a 6 week training intervention. Participants were randomized either to perform HS training (n=11) or SS training (n=9). All participants performed familiarization HS training four week before randomization and pre-testing. The HS intervention consisted of half-squats performed in a smith-machine, single leg press, one-legged hip flexion and toe raises twice a week. During the two first weeks, each set consisted of 8 repetition maximum (RM) in one of the weekly training session and of 5 RM in the second training session. In the next 4 weeks, one of the weekly training session consisted of 6 RM and the second of 4 RM. All exercise were performed with maximal effort and with 3 set and with 2 min recovery in-between sets. SS training was performed seated on an air braked bicycle ergometer (WattBike, WattBike Ltd, Nottingham, UK), and consisted of 12 intervals of 4-8 sec with 2 min recovery in-between intervals, and with 5 min active recovery (70% HRmax) after the 4th and 8th interval. HS and SS training was included in addition to usual endurance training. Before and after the intervention participants performed a 55 m sprint in a garage from a stand still start, both in seated and standing position. All participant performed a familiarization session were choice of gear ratio and air pressure in the tires was determined <1 week before testing. Time was measured with timing gates (Musclelab, Ergotest, Norway) at 10m, 20m, 30m and 55m. 1RM squat in smith-machine (TKO, Houston, USA), VO2max (Oxycon Pro, Erich Jaeger GmbH, Hoechberg, Germany), lactate profile (Biosen S-line, EKF diagnostics, Germany) and body composition (Biospace, Tokyo, Japan) was tested on separate day.
RESULTS: The SS-group showed a significant improvement on the 55m sprint test when seated (-.296 sec ±.19, p=.016), but not in standing position (-.073 sec ±.17, p=.266). Further, there was a significant decrease in 1RM squat (-5.0±5 kg, p=.03). No significant change was seen in the HS-group regarding sprint performance, although there was a significant increase in strength (8.7±7.3 kg, p=.003). There is a significant within-group difference in both sitting sprint and strength (p<.001).
CONCLUSION: Our result shows that seated sprint training on an ergometer improves seated sprint performed on bike, which indicates that sprint training on ergometer has a transfer value in well-trained cyclist.

TYRE-PULLING AS CONCURRENT TRAINING

MAMEN, A., FREDRIKSEN, P.M.

KRISTIANIA UNIVERSITY COLLEGE

INTRODUCTION: Concurrent training have gained popularity as a fitness promoting activity. The focus of this study was to investigate the feasibility of Tyre-pulling as a strength and endurance training exercise.
METHODS: Thirty-four volunteered participants accepted to comply with an eight-week training program, and were by drawing lots divided into three groups: Long distance training, high-intensity interval training and control groups. The long-distance group exercised 60 min at 75 to 85% of HRmax three times a week. The high-intensity interval group also exercised three times a week with 10 intervals of 20 s and a rest of 10 s in an all-out intensity. The control group continue their ordinary activities. A test battery measuring arm and leg strength, core strength, and endurance, were taken at the beginning and after eight weeks. Anthropometric measurements and spirometry test were performed likewise.
RESULTS: Maximal oxygen uptake, arm, and leg strength increased in the high-intensity interval group. Systolic blood pressure was reduced. Leg strength and core strength increased in the long-distance group. In addition, systolic blood pressure and resting heart rate were reduced. No significant changes observed in the control group.
CONCLUSION: Tyre- pulling is feasible for training endurance and strength at both low and high-intensity.

THE EFFECTS OF HEAVY STRENGTH TRAINING VERSUS SHORT SPRINT TRAINING ON SPRINT PERFORMANCE, AND 5 MIN ALL OUT CYCLING IN WELL-TRAINED CYCLIST

KRISTOFFERSEN, M.1,2, SANDBAKK, Ø.2, RØNNESTAD, B.R.3, HAFSTAD, A.1, GUNDERSE, H.1

1. WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCES, 2. NORWEGIAN UNIVERSITY OF SCIENCE AND TECHNOLOGY, 3. INLAND NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: Road cycling is an endurance sport, but often decided in a final sprint. To improve sprint and cycling performance, many competitive cyclists regularly add heavy strength (HS) and short sprint (SS) training to the endurance training. The aim of the present study was to compare effects of HS and SS training on peak and average power production (PP and AvgP) in 6 sec and 30 sec sprints, and power production during the 5 last minutes of 100 min prolonged cycling.
METHODS: Thirty well-trained cyclist (age: 29±6 year, VO2max: 61.3±5.8 ml/kg/min) performed a battery of physical testes at baseline, after 4 weeks of HS familiarization training (pre-test), and then 6 weeks after either the HS (n=16) or SS (n=14) training interventions (post-test). During the training intervention, participants in the HS group performed a periodized program (10-4 repetitions x 3 sets) including half-squats in a smith-machine, single leg press, one-legged hip flexion and toe raises twice a week.The SS training consisted of 3 series of 4 (4-8 sec) intervals performed seated on an air braked WattBike ergometer. Tests were conducted over two days with a minimum of 48 hours in-between: On day 1, 1RM half-squat in a smith machine, a lactate profile and a VO2max-test was performed. On day 2, a 100 min cycling test on a Lode electromagnetically braked cycle ergometer was performed (5-min cycling at 150 W, 5 min at 175 W, 5 min at the individual's power at 2 mmol/L blood lactate level (calculated from the lactate profile test), 3x6 sec seated sprints, a 30 sec wingate test (WAnT), 60 min cycling at same power as measured at 2 mmol/L blood lactate level, 3 x 6 sec seated sprints, 5 min at 175 W, and finally 5 min-all out cycling).
RESULTS: There were no difference between groups in pre- to post-test changes in VO2max (p=.85) or power production at 4 mmol/L (p=.31). In the 6-sec sprints, the SS group had a 6.4% increase in PP (p<.001) and a 5% increase in AvgP (p=.001). In the WAnT, the SS group had a 6% increase in PP (p<.001), while both groups had a increase in AvgP: 3.6% (p=.001) in the SS group, and 1.1% (p=.045) in the HS group. No difference was found within or between groups in 5-min all-out cycling.

CONCLUSION: Six weeks of seated SS training had a positive effects on peak and average power in 6- and 30-sec seated sprints, while HS training had a positeve effect on AvgP in the 30 sec sprint. However, none of these methods influenced AvgP in 5-min all-out cycling after 95-min cycling.

MO-SH02 Motivation , self efficacy and coach behaviours

PERCEIVED COACH EMPOWERING CLIMATE AND BURNOUT: THE MODERATOR ROLE OF ATHLETES AUTONOMOUS MOTIVATION

LOPEZ-WALLE, J.1, TRISTAN, J.1, FLORES, M.2, PÉREZ, M.J.1, ATIENZA, F.3, BALAGUER, I.3

1: UANL , 2: UACJ , 3: UV .

Introduction: Based in Dudas (2013) hierarchical conceptualization of the coach created motivational climate, the purpose of this study was to examine the moderator effect of autonomous motivation on the relationship between perceived empowering climate and athletes burnout.
Methods: University athletes (N = 333, M age = 20.88, SD = 2.14) completed the Mexican versions of the questionnaires assessing their perceptions of coach-created empowering climate (EDMCQ-C, Appleton et al., 2016), autonomous motivation (SMS-II, Pelletier et al., 2013), and burnout (ABQ, Raedeke & Smith, 2009).
Results: Following the recommendations of Hayes (2013) the results obtained using moderated regression analyses showed that autonomous motivation moderated the relationship between the perceived coach empowering climate and athletes burnout ($F = 61.06$, $R2 = .380$, $R2\text{-chng} = .022$, $p < .01$). The relationship between the perceived coach empowering climate and burnout was negative and significant only when the athletes reported medium or high levels of autonomous motivation. Specifically, when the autonomous motivation score was at least 4.21, coach perceived empowering climate and burnout were significantly related. As autonomous motivation increased, the negative relationships between perceived coach empowering climate and burnout became more negative.
Conclusion
Medium-high levels of athletes autonomous motivation contributes to diminish the possibility of athletes burnout. In consequence, it is important that coaches promote empowering climates in order to favor quality of athletes motivation.

PERCEIVED COACH EMPOWERING CLIMATE AND MOTIVATION IN YOUNG SOCCER PLAYERS: A LONGITUDINAL STUDY

CASTILLO-JIMENEZ, N.1, LOPEZ-WALLE, J.M.1, TRISTAN, J.1, BALAGUER, I.2

1:UANL , 2:UV

Introduction: It has been suggested that a positive and adaptive experience in the sport context is more likely to be evident when children participate in an empowering climate (Duda, 2013). Specifically it has been defended that when coaches create empowering climates, autonomous motivation of young athletes is promoted (Duda, Appleton, Stebbings & Balaguer, 2018).
The aim of the study was to examine the relationship between athletes' perceptions of coach empowering climate at the beginning of the sport season and forms of motivation at the middle of the season in young soccer players.
Methods: In this study participated 385 young soccer players, ranged in age from 12 to 14 years old (Mage= 12.41; SD = .89) who completed the Spanish versions of the questionnaires assessing their perceptions of coach-created empowering climate (EDMCQ-C; Appleton et al., 2016), and three forms of motivation, autonomous motivation (AUT), controlled motivation (CON) and amotivation (AM) (BRSQ-6; Lonsdale et al, 2008). Participants spend three days per week training (SD =1.11) and had played with their current coach an average of two years (SD= 1.37).
Results: Structural Equation Modelling (SEM) indicated that the tested model exhibited very good fit ($\chi2/gl = 2.17$, $RMSEA = .04$). Athletes' perceptions of the empowering climate created by the coach at the beginning of the season, positively predicted autonomous motivation ($\beta = .20$, $p < .01$), and negatively predicted controlled motivation ($\beta = -.68$, $p < .01$) and amotivation ($\beta = -.69$, $p < .01$) at the middle of the season.
Discussion: Our results emphasized that is important to guarantee that the environment created by the coach is empowering from the start of the season to guarantee the quality of the athletes' involvement in sports across the season.

LIFE ASPIRATIONS AND PASSION IN ARGENTINE ATHLETES FROM YOUTH OLYMPIC GAMES

RAIMUNDI, M.

NATIONAL COUNCIL OF SCIENTIFIC AND TECHNIQUE RESEARCH

LIFE ASPIRATIONS AND PASSION IN ARGENTINE ATHLETES FROM YOUTH OLYMPIC GAMES
Raimundi, M. J.1,2; Iglesias, D.2; García-Arabehety, M.2; Pérez Gaido, M.2; Celsi, I.2; Schmidt, V. 1,2 & Castillo, I. 3 1National Council of Scientific and Technique Research . 2Research Institute, Faculty of Psychology, University of Buenos Aires, Argentina. 3University of Valencia, Spain.
Introduction: Self Determination Theory conceptualizes life aspirations as essential aspects of motivation that influence the quality of experience and well-being. There are two types of aspirations: intrinsic aspirations are related to personal growth, meaningful relationships and community contributions. On the contrary, extrinsic aspirations imply the achievement of rewards and the recognition of others. Another concept addressed from the SDT is passion, defined as a strong inclination over an activity that the person enjoys or loves, in which he invests time and energy and is internalized as part of his own. The Dualistic Model of passion posits that two distinct types of passion develop as a result of the type of internalization process that takes place: harmonious and obsessive. Several studies have indicated that these types of passion are related to important outcomes in relation to the quality of experiences in different activities. From this arises the question about how an adolescent can develop a positive involvement in elite sport. The present study hypothesizes that aspirations could be antecedents for the development of a passion that leads to positive outcomes in sport experiences. The aim of this work was to analyze life aspirations of adolescent elite athletes and their relationship with the passion they have with respect to their sport.
Methods: Participants were 234 Argentine athletes <47.9% male, 52.1% female> aged between 12 and 16 years from National Sport Development Plan selected to train for the next Youth Olympic Games . All adolescents answered a sociodemographic questionnaire, Aspirations Index and Passion Scale.
Results: Results showed that boys had significantly higher scores than girls on wealth and fame aspirations, as well as on obsessive passion, while there were no significant differences depending on the type of sport . For boys, personal growth predicted harmonious passion, while health and community contribution were for girls' harmonious passion. Fame was the only predictor of obsessive passion in the boys group. There were no significant predictors for girls' obsessive passion.
Discussion: These results support previous studies about the role of intrinsic and extrinsic aspirations in enabling of engagement and positive development in adolescent elite sports.

THE CONCEPTUALIZATION OF EFFECTIVE COMMUNICATION IN SPORTS TEAMS

LEE, C., LIAO, C.

NATIONAL TAIWAN SPORT UNIVERSITY

The conceptualization of effective communication in sports teams
Chi-Chung Lee and Chu-Min Liao
National Taiwan Sport University
Introduction: Communication among teammates is the foundation of successful team functioning. However, in sports, few studies have systematically investigated the effectiveness of communication among teammates. According to social exchange theory, communication is a process in which individuals exchange resources through message transmission. We argued that, for team communication to be effective, team members should be able to send and receive adequate messages in appropriate ways so as to complete the exchanging process of key resources. The purpose of this study was to explore the essence of effective communication in sports teams.
Methods: A qualitative approach was adopted. Eighteen college athletes (9 males, 9 females), aged 20 to 26 (M=21.67, SD=1.85), from 16 Division I varsity teams of 8 different sports were interviewed. The interviews were semi-structured and conducted following an interview guide with questions concerning what was communicated among teammates, how teammates communicate to each other, and how to send and receive messages effectively during team communication. Interview data were analyzed according to the principles of grounded theory, and an investigator-triangulation was used to ensure the trustworthiness of the data.
Results: Data were condensed into 3 higher-order themes representing the three major components of effective communication in sports teams: communication content, communication style, and communication completeness. Communication content comprised five sub-themes (Technique, Strategy, Goal, Emotion, and Responsibility) reflecting the resources pertaining to team functioning exchanged among teammates. Communication style was composed of five sub-themes (Encouraging, Openness, Equality, Empathy, Distinctiveness) illustrating the positive manners in which team members exchange resources. Communication completeness consisted of five sub-themes (Adaptation, Confirmation, Clarity, Attention, Responsiveness) demonstrating team members' ability to send and receive messages effectively.
Discussion: Effective communication is a dynamic process in which team members complete the exchanging procedure of resources pertaining to team functioning in positive ways. Communication content, communication style, and communication completeness are the key elements of effective communication. Communication content stands for resources pertaining to team functioning (the what), communication style represents the positive manners in which team members exchange resources (the how), and communication completeness demonstrates team members' ability to transmit messages effectively (the completion). As communication among teammates plays an important role in team functioning, the relationship between effective communication in sports teams and team functioning is worthy of further investigation.

INVESTIGATING CONFIDENCE AND SELF-EFFICACY RATINGS IN ATHLETIC TRAINING STUDENTS IN JAPAN: A PILOT STUDY

IDE, Y.1, OKAWA, M.2, FURUSHO, A.1, HIRASAKI, K.1

1:KUNSW, 2:TU

Introduction: In Japan, there is 3453 number of certified Japan Sports Association Athletic Trainer (JASA-AT) engaged in competitive sports and health industry with the qualification (as of October 1, 2017). The purpose of this study was to conduct a pilot study investigation of the

relationship between athletic training students' self-confidence and self-efficacy in the junior and the senior students to identify the learning process of undergraduate athletic training students.
Method
Subjects were seventeen students currently enrolled in medical university, which has the JASA-AT accredited program. The Athletic Training Student Confidence Scale (ATSCS) questionnaire consisted of 30 items. Subjects scored each item on a 5-point Likert scale to rate their confidence in completing athletic training program. The General Self-Efficacy Scale (GSES; Sakano&Tohjoh, 1986; Bandura, 1977) consisted of 16 items were rated on a 2-point scale and the total score relating to high self-efficacy was used in the analysis (range: 0-16). Three factors were able to measure in the GSES. All statistical analyses were calculated with a confidence level of $p<.05$.
Result
The GSES score for the senior students were 9.1±3.6 and the junior students were 7.8±2.5. In the junior students, confidence in abilities as an athletic trainer and anxiety about failure had no correlation ($r=-.385$, $p=.272$), however, the senior students had a strong correlation between those ($r=.761$, $p=.047$) ($p=.025$[difference between Jr. and Sr.]).
Discussion: Bandura introduced four major sources of efficacy information (Bandura, 1977). Typically, past accomplishments are most significant source for developing self- efficacy (Nakajima et al, 2013). Therefore, the senior students had higher score, because they were exposed more opportunity to achieve mastery experiences because of program progression that increasing responsibility across semester. The senior students had a strong correlation between confidence in abilities as an athletic trainer and anxiety about failure, whereas, the junior students were not. The junior students had few opportunities because of program progression, therefore, they did not have confidence in abilities as an athletic trainer. On the other hand, in the senior students, it may be suspected that they become prudent in making judgements, that is, they may develop the skill of critical thinking, included prudent in making judgments, and willing to reconsider (APA, 1990). Further studies are needed in order to identify the process of improvement of students' abilities and confidence with longitudinal method. Additionally, it is necessary to develop instruments which are designed to measure the integration of knowledge and skills from athletic training field to compare with students' confidence and self-efficacy.

'EVERYTHING CAME OUT ABOUT THE COLLUSION': POWER RELATIONS AFFECTING THE IMPLEMENTATION OF A TALENT DEVELOPMENT SYSTEM

FEDDERSEN, N.B.1, MORRIS, R.1, LITTLEWOOD, M.1, RICHARDSON, D.1

1: LIVERPOOL JOHN MOORES UNIVERSITY

Introduction: Managing interdependencies effectively may be the key to effective changes in elite sports systems. However, a challenge is to ascertain how change strategies are impacted by internal and external power relations . This study aimed to design and implement change strategies in a national talent development system and explore how power relations affected the efficacy of implementation.
Methods: We employed an action research design, conducting participant observations <100 h> and nine focus groups, two with athletes , four with coaches , two with parents of athletes , and one with TD personnel of the national governing body . We analysed the data using grounded theory coding .
Results: We found that the NGB experienced a fragmented sporting community, which they had alienated by imposing a centralised performance programme. This programme forced athletes to break with their club resulting in diminishing belief and trust in the NGB and club coaches actively combating the programme. Culture change was identified as the macro-level change strategy. This strategy was operationalised through three micro-level strategies: <1> establishing a decentralised TD centre strategy <2> selection policies for youth national teams, and <3> national TD camps. Short-term performance goals were viewed as a catalysing factor to positively impact change strategies. External stakeholders tried to undermine the strategies through social dominance and collusion to keep athletes from participating, ultimately to limit performance goals.
Discussion: Our findings shed light on culture as a dynamic process impacted by interdependent power relations . Such relations were influenced by influential members of the NGB and the sporting community employing different active-disruptive behaviours such as ruthlessness and social dominance to combat strategies. Behaviours manipulating athletes to undermine change strategies may be employed because of pressure to reach short-term performance targets. NGBs should give consideration to how they can mitigate active-disruptive behaviours, and how the impact of power relations and short-term goals may limit the efficacy of the implementation of strategies in a TD system.

THE VALIDATION OF THE CHINESE VERSION OF ACADEMIC AND ATHLETIC IDENTITY SCALE

YANG, C.H.1, YUKHYMENKO-LESCROART, M.A.2, LIAO, C.M.1

1: NTSU , 2: CSUFRESNO

The validation of the Chinese version of Academic and Athletic Identity Scale
Yang, C. H.1,Yukhymenko-Lescroart, M. A.2, Liao, C. M.1
1: NTSU (Toayuan, Taiwan), 2: CSUFresno (California, USA)
Introduction: Student-athletes have to fulfill both the duties of a student and an athlete. However, these two roles usually conflict against each other. Studies have showed that student-athletes spent a significant amount of their time in athletic activities at the expanse of academic and social activities (Ayers, Pazmino-Cevallos, & Dobose, 2012). In sport, the athletic identity is dominant in student-athletes, and other identities have always been ignored, especially academic identity. For the adaptive development of student-athletes, we should pay more attention on their multiple-role identity. Yukhymenko-Lescroart (2014) has developed a reliable and valid instrument, Academic and Athletic Identity Scale (AAIS), to measure the extent to which being academically and athletically engaged is central to one's sense of self. The purpose of this study was to translate AAIS to Chinese and examine its validity.
Methods: Items of AAIS (English language) were translated into Chinese language (traditional font) with a back-translation procedure. 132 collegiate student-athletes (male= 51, female= 81; mean age= 20.33, SD= 3.46) from 20 sports participated in this study, and filled in the

online questionnaire. Some adaptation of the AAIS have been proposed in order to enable its application to Taiwanese people. Exploratory factor analysis (EFA) and item analysis were conducted.
Results: EFA revealed a two-factors solution including athletic identity (6 items; M= 5.27, SD= 0.70) and academic identity (5 items; M= 4.22, SD= 0.93), accounting for 63.48% of total variance. Cronbach's alphas were .86 for both subscales, and the correlation between athletic identity and academic identity was not significant (r= .10, p= .246). The result was in line with the two factors outlined by Yukhymenko-Lescroart (2014).
Conclusion
In general, our data provided preliminary evidence for the factor validity and reliabilty of the Chinese version of Academic and Athletic Identity Scale for student-athletes in Taiwan. In order to examine its psychometric properties, further examination such as confirmatory factor analysis, cross validation, and measurement invariance are warranted.

FACTORS THAT INFLUENCE THE ADHERENCE TO RUGBY PRACTICE IN SPANISH YOUNG RUGBY UNION PLAYERS

MORENTE-ORIA, H.1, ROMANCE, A.R.1, GIL, F.J.1, BENÍTEZ-PORRES, J.1

UNIVERSIDAD DE MALAGA

Introduction: There are many reasons to take up a physical activity or sport. For some authors Rugby Union is considered as a leisure activity for young people (Dong, Zhang, Choe and Pugh, 2013). The aim of this study was to analyse the reasons for young Spanish rugby player to begin practising this sport. we want to know what the real reasons are in order to increase the rugby practice through recruitment campaigns appropriate to these results.
Methods: Data from 225 adolescent's rugby players (Age: 16.9±1.2 years, BMI: 23.6±4.2 kg/m 2) enrolled from 12 teams in the Spanish final championship were used. We used a questionnaire validated for starting motives in Rugby practise (Morente, Zagalaz, Romero y Carrillo, 2010), which is composed by 27 items, based on a previous questionnaires called Participation Motivation Inventory-PMI (Gill, Gross and Huddleton, 1983) and Sport Motivation Scale-SMS (Pelletier et al., 1995). Players completed the questionnaire in the beginning of the final stage under the supervision of the same researches in all cases. A descriptive statistic was conducted to examine the main reasons and associations between categories were analysed by Spearman correlations.
Results: The most valuated motivation to begin Rugby practice was "For fun" (88,9%). The items "Team spirit" (82,2%) and "Contact sport" (68,8%) were also highly valued. The least valued items were "The media" (4%) and "Teachers" (9,3%). A high correlation was obtained between "Parents influence" and "Year of practise" (rho= 0.429, $p < 0.01$); "The media" and "To be famous" (rho = 0.260, $p < 0.01$); and a high negative correlation was obtained between "For fun" and "Friends" (rho = -0.270, $p < 0.01$).
Conclusion
Our results suggest that the most valued REASON to practice rugby was "For fun". These results are similar to those obtained in other studies (Frederick & Schuster-Schmidt, 2003). Although rugby is not a popular sport in Spain, it is interesting to know the more years of practice they have, the more influence "Parents" have in the beginning of the practice of rugby. In the same line, one of the least valued are the "Media" and its high correlation with "To be famous" due to the rugby impact in Spanish society. The negative correlation between "For fun" and "Friends" highlighted players who look for friends in Rugby do not see fun in sports as an important factor.

MO-PM03 High intensity training

THE EFFECTIVENESS OF HIGH-INTENSITY INTERVAL TRAINING ON IMPROVING CARDIOMETABOLIC HEALTH AND ENDURANCE CAPACITY IN SCHOOL AGED CHILDREN: A PILOT RANDOMIZED CONTROLLED TRIAL

KETELHUT, S.1, KIRCHER, E.2, KETELHUT, S.R.3, WEHLAN, E.4, KETELHUT, K.5

1MARTIN-LUTHER-UNIVERSITY HALLE-WITTENBERG, 2SRH HOCHSCHULE FÜR GESUNDHEIT GERA, 3CHARITÉ UNIVERSITY MEDICINE BERLIN, 4HUMBOLDT-UNIVERSITY OF BERLIN, 5MSB MEDICAL SCHOOL BERLIN

INTRODUCTION: A growing body of literature confirms the efficacy of high-intensity interval training (HIIT) for improving endurance performance (EP) and eliciting health benefits in adults. Evidence supporting the effectiveness of HIIT in children and adolescents are sparse (William et al., 2017). The present study aimed to evaluate the effects of a school based HIIT intervention on EP, blood pressure (BP) and established markers of arterial compliance in school aged children.
METHODS: 46 students (mean age 10.7 ± 0.7 yr; 44% girls; BMI 19.7 ± 4.6 kg/m2) were randomized into intervention (INT) (N = 22) and control (CON) (N = 24) group. Throughout a 3 month experimental period both INT and CON took part in the regular physical education lessons (PE) 2 times a week. Only the INT received a HIIT during the first 20 minutes of the PE. Apart from an EP-test (6-min run; Bös et al., 2009), peripheral (pBP) and central (cBP) blood pressure, augmentation pressure (AP), total peripheral resistance (TPR) and aortic pulse wave velocity (aPWV) were assessed non-invasively using Mobil-O-Graph (24 PWA monitor, IEM Stolberg, GERMANY).
RESULTS: INT showed a significant improvement in EP (5.58, p= 0.003), systolic pBP (-4.54 mmHg, p= 0.002), systolic cBP (-4.15 mmHg, p= 0.002) AP (-1.13 mmHg, p= 0.028) and aPWV (-0.16 m/sec, p<0.001) respectively. No significant changes were observed in the CON. Significant difference in the mean improvement could be detected for EP (7.73, p= 0.007) systolic pBP (-6.13 mmHg, p= 0.038), systolic cBP (-5.19 mmHg, p= 0.041), TPR (-0.13 s*mmHg/ml, p= 0.023), AP (-2.02 mmHg, p= 0.013) and aPWV (-0.19 m/sec, p= 0.031), favoring INT.

CONCLUSION: The evidence from this study highlights the potential of HIIT for improving EP and hemodynamic measures already in children age 10. The favorable effects of the HIIT may be contributed to a higher exercise intensity eliciting greater sheer stress consequently increasing the release of vasoactive substances. Based on the findings it seems advisable not only to increase regular physical activity in early childhood, but moreover increasing exercise intensity. Apart from the health benefits sporadic high-intensity exercise corresponds to the natural patterns of childrens habitual play which may result in a higher perceived pleasure and compliance.

DYNAMIC CEREBRAL AUTOREGULATION IS NOT IMPAIRED DURING HIGH-INTENSITY INTERVAL EXERCISE

TSUKAMOTO, H.1, HASHIMOTO, T.1, OLESEN, N.D.2, PETERSEN, L.G.2, SØRENSEN, H.2, NIELSEN, H.B.2, SECHER, N.H.2, OGOH, S.3

1 RITSUMEIKAN UNIV. ; 2 UNIV. OF COPENHAGEN ; 3 TOYO UNIV.

INTRODUCTION: To support cerebral energy metabolism and protect brain tissue from the potentially damaging effects of hypo/hyperperfusion, cerebral blood flow is regulated by dynamic cerebral autoregulation (dCA) to adjust for changes in mean arterial pressure (MAP) [1]. Acute high-intensity continuous exercise (HICE) causes diminished brain cognitive function [2], even though exercise training with high-intensity promotes and maintains cardiovascular health more than exercise at moderate-intensity [3]. In addition, HICE impairs dCA [4], indicating that HICE training may increase the risk of cerebral vascular disease. On the other hand, high-intensity interval exercise (HIIE) enhances brain cognitive function [5] and is beneficial for patients with cardiovascular disease [6]. However, the impact of HIIE on dCA remains unknown. The purpose of the present study was to investigate the changes in dCA during HIIE using transfer function analysis (TFA) gain and phase shift between oscillations in MAP and middle cerebral artery blood flow velocity (MCA V).
METHODS: Nine healthy male subjects (24.2 ± 2.8 yr.) performed the HIIE protocols, which was preceded by a warm-up at 50-60% maximal workload (Wmax) for 5 min and included four 4 min bouts of exercise at 80-90% Wmax interspaced by four 3 min bouts at 50-60% Wmax for a total of 28 min. Transcranial Doppler determined mean MCA V, and blood pressure was measured by a brachial artery catheter.
RESULTS: HIIE increased MAP from 91.6 ± 8.7 to 114.2 ± 7.6 mmHg ($P < 0.01$) but the exercise-induced increase in MAP was gradually decreased during HIIE. In contrast, MCA V was maintained during HIIE. A TFA indicated that the phase in the low-frequency (LF; 0.07 to 0.20 Hz) range was temporarily increased during HIIE compared to rest from 32.1 ± 10.9 to 56.1 ± 15.5° ($P < 0.05$) while gain in the LF range was unchanged during HIIE.
CONCLUSION: These results indicate that the HIIE does not impair dCA. We propose that, unlike HICE [4], HIIE may be beneficial for improving brain-related health [5] without an increasing risk of cerebrovascular event. Thus, HIIE may be useful as an exercise prescription in rehabilitation programs within the clinical population.

HIGH INTENSITY INTERVAL TRAINING IN SWIMMING – EFFECTS OF DIFFERENT INTENSITIES

ALMEIDA, T.1,2, PESSOA-FILHO, D.2, SIMIONATO, A.2, ESPADA, M.1,3, REIS, J.1,4, ALVES, F.1

1: CIPER, BIOLAD – FACULTY OF HUMAN KINETICS, UNIVERSITY OF LISBON, 2: UNESP, LABOREH, RIO CLARO, BRAZIL, 3: SCHOOL OF EDUCATION – POLYTECHNIC INSTITUTE OF SETÚBAL, 4: UNIVERSIDADE EUROPEIA, LISBON

INTRODUCTION: The interval training has been proposed as an effective way to improve aerobic performance. However, in swimming, the studies are scarce and focus in different distances with the same intensity (Bentley, 2005). The aim of this study is to compare the oxygen uptake response (VO2) during different high intensity interval training sets in swimming.
METHODS: Fourteen well trained swimmers, 7 female and 7 male, (age 16.4±1.8yr; mass 68.3±10.6kg; height 1.73±0.1m) completed a discontinuous incremental test for the assessment of second ventilatory threshold (VT2), maximal oxygen uptake (VO2peak) and maximal aerobic velocity (MAV). In 4 different days and in randomized order, swimmers performed 4 broken 400m intermittent swimming tests (IT): (a) 3 sets of 8x50m (IT50) at 100%, 105% and 110% of MAV with 15s rest, and (b) 4x100m (IT100) at 100% of MAV, with 15s rest. For each IT session, mean (ITMVO2peak) and maximal oxygen uptake (ITVO2peak) and time spent above VT2 were recorded. All tests were conducted using a breath-by-breath apparatus (K4b2, Cosmed, Italy) connected to a swimming snorkel (AquaTrainer, Cosmed, Italy) for pulmonary gas sampling and an underwater visual pacer for velocity control (PACER 2 SWIM, KulzerTEC, Portugal).
RESULTS: ITMVO2peak and ITVO2peak in the IT50 at 100%, 105% and 110%-MAV were higher as the intensity increases, (42.94±4.65/45.83±4.62 vs 46.19±5.37/49.07±5.14 vs 49.69±5.34/52.92±5.21 ml/kg/min, respectively). Time spent above VT2 showed the same profile (34.8±43.4 vs 113.1±68.9 vs 199±68.5 s for 100%, 105% and 110%-MAV, respectively). At the IT100, the ITMVO2peak (47.34±4.65 ml/kg/min) and time above VT2 (144±68.8s) were different from the IT50 at 100%-MAV but not from IT50 at 105% and 110%-MAV. VO2peak from the incremental test (52.07±4.5 ml/kg/min) was significantly different from IT50VO2peak at 100%-MAV and 105%-MAV, but not from 110%-MAV or IT100VO2peak (49.07±4.79 ml/kg/min). MAV (1.24±0.09 m.s) was correlated with the time spent above VT2 ($r = 0.60$, $p<0.05$), mean and ITVO2peak ($r=0.56$, $p<0.05$ and $r = 0.62$, $p<0.05$, respectively) at the 110%-MAV IT50's test.
CONCLUSION: The results suggested that higher velocities than 100%-MAV are better to keep oxidative rate at maximal level (5 to 10% higher) and improve tolerance (~20 to 46%) to exercise in severe domain (ie, above VT2), whilst training with short distances bouts (50-m). These results are in line with Millet et al (2003) for running at 100 and 105% of MAV. In IT50 sessions higher MAVs seem to be related with better performance at the highest intensity (110%-MAV), the only test where VO2peak was achieved. Seeking for training schedule effectiveness to improve endurance and aerobic power, the results recommend IT50 test at least at 105%-MAV, which attained oxidative rates similar to IT100 at 100%-MAV.

INFLUENCE OF PIO2 ON THE SKELETAL MUSCLE EXPRESSION OF MYOKINES DURING INTENSE EXERCISE REVEALED BY POST-EXERCISE OCCLUSION OF CIRCULATION IN HUMANS

PÉREZ-LÓPEZ, A.1, MARTIN-RINCON, M.2, PEREZ-SUAREZ, I.2, SANTANA, A.2, MORALES-ALAMO, D.2, DORADO-GARCIA, C.2, CALBET, J.A.L.2

1: UNIVERSITY OF ALCALÁ ; 2: IUIBS & UNIVERSITY OF LAS PALMAS DE GRAN CANARIA

INTRODUCTION: Myokines have a pivotal role in the metabolic adaptation to exercise. Interleukin (IL)-6, IL-15 and its alpha receptor (IL-15Rα), and fibroblast growth factor 21 (FGF21) promote fat oxidation, glucose uptake and oxidation, and glycogen synthesis in several tissues. Nevertheless, little is known regarding the mechanisms that trigger their synthesis by the skeletal muscle. In vitro and in vivo studies have shown that oxygen restriction elicits the expression of some myokines in a process mediated by AMPK. Thus, the aim of the study was to determine whether human skeletal muscle IL-6, IL-15, IL-15Rα and FGF21 are influenced by PIO2 in response to exercise.
METHODS: In separate days, eleven volunteers performed an incremental exercise (IE) to exhaustion in normoxia (PIO2=143mmHg) and hypoxia (PIO2=75mmHg). At exhaustion, the circulation of one leg was instantaneously occluded during 60s (Hokanson, 300mmHg). Muscle biopsies from vastus lateralis were obtained before (PRE) and after the 10th s from the occluded leg (POST), and simultaneously at the 60th s from the occluded (OC1M) and non-occluded leg (nOC1M). AMPK, IL-6, IL-15, IL-15Rα and FGF21 protein expressions were analyzed by Western Blot.
RESULTS: Muscle lactate, phosphocreatine (PCr) and ATP did not change between conditions. Muscle lactate increased at OC1M (25%; P<0.05) and PCr was reduced by a 94 and 48% at OC1M and nOC1M (P<0.005). pThr172/AMPK and pSer485-491/AMPK total ratios were increased in both conditions (time effect, P<0.001), while AMPK phosphorylation rate was elevated at OC1M compared to nOC1M (5.2 vs 2.5-fold; P=0.032). During the IE in hypoxia, IL-15Rα expression was upregulated (ANOVA interaction P=0.017), with a significant effect at POST and OC1M (1.3 & 1.5-fold; P<0.005), while FGF21 was also elevated at POST and OC1M (2.1 & 2.7-fold; time effect, P=0.008). IL-15Rα and FGF21 were not increased in skeletal muscle of the non-occluded leg at 1 min post-exercise. IL-6 and IL-15 protein expressions were not significantly altered.
CONCLUSION: Intense exercise increases the AMP/ATP ratio, which stimulates AMPK phosphorylation and activation. Post-exercise ischemia causes oxygen deficiency when the metabolism is still active as shown by a 22% increase in lactate accumulation. This further stimulates AMPK phosphorylation at pThr172 and may increase ROS production. In this study, skeletal muscle IL-15Rα and FGF21 expressions are facilitated by a reduced PIO2 during IE to exhaustion, coinciding with an increased AMPK phosphorylation. Therefore, a substantial energy deficit combined with hypoxia trigger the expression of IL-15Rα and FGF21, but not that of IL-6 and IL-15 in human skeletal muscle. The lack of IL-15Rα and FGF21 upregulation in the non-occluded leg may be due to the release into the circulation or to a fast turnover of both myokines during the first minute after exercise.
Grants: DEP2015-71171-R and CCG2015/BIO-069

HIGH-INTENSITY INTERVAL TRAINING IMPROVES CARDIORESPIRATORY FITNESS MORE WHEN HYPOXIC STRESS BEING MAINTAINED IN SEDENTARY YOUNG WOMEN

KONG, Z.1, LEI, L.1, LEI O.K.1, SHI, Q.2, NIE, J.2

1. UNIVERSITY OF MACAU, 2.MACAO POLYTECHNIC INSTITUTE

INTRODUCTION: Our previous study shows that short term high-intensity interval training (HIT) under normobaric hypoxia simulated at 2500 m has an additive effect on the improvement of cardiorespiratory fitness in overweight young women. The purpose of this study was to investigate whether further improvement can be observed in aerobic and aerobic capacity as well as blood lipids if hypoxic stress were maintained throughout the HIT intervention period.
METHODS: A single-blind randomized controlled experimental design was applied. 42 sedentary young women (age: 22 ± 2 years, BMI: 23 ± 3 kg·m-2) completed the HIT under normoxia (NORM, n = 14, FIO2: 0.21), or normobaric hypoxia simulated a stable altitude of 2500 m (HYPS, n = 14, FIO2: 0.15) or a graded altitude of 2500-3400 m (HYPG, n = 14, FIO2: 0.15-0.14) for 4 weeks. HIIT was composed of 80 repetitions of 6 s maximal cycling effort interspersed with 9-s recovery per day, for 3 days per week. Cardiorespiratory fitness (peak oxygen uptake (V?O2peak), anaerobic capacity with two Wingate-based test and serum lipid profile (triglycerides, total cholesterol, high-density lipoprotein cholesterol, and low-density lipoprotein cholesterol) were assessed with 4 to 5 days at pre- and post-intervention. Habitual physical activity and diary behavior were maintained during the intervention period.
RESULTS: With similar daily energy intake and physical activity, four weeks HIT resulted in significantly improvements in V?O2peak [NORM: 0.7 ± 2.7 ml·kg-1·min-1 (+3.4%), HYPS: 2.6 ± 2.8 ml·kg-1·min-1 (+10.2%), HYPS: 3.8 ± 2.8 ml·kg1·min-1 (+15.1%)]. Compared to NORM, the increments of V?O2peak in HYP (HYPS: $p > 0.05$, $d = 0.63$, HYPG: $p < 0.05$, $d = 1.02$) were greater. Moreover, no group effect was found in anaerobic capacity despite significant improvements in peak power, average power, relative average power and power decline rate ($p < 0.01$). There were no significantly changes on the serum variables after the intervention.
CONCLUSION: 4-week of HIT improved cardiorespiratory fitness and anaerobic capacity in sedentary young females. Furthermore, it seems that the additive effect of the HIT under normobaric hypoxia is more effective when hypoxic stress can be maintained.

HIGH-INTENSITY INTERVAL TRAINING (HIIT) ON THE CYCLE ERGOMETER INDUCES PERIPHERAL AND CENTRAL IMPROVEMENTS IN HEALTHY YOUNG FEMALES

MARTERER, N.

UNIVERSITY OF INNSBRUCK

INTRODUCTION: High intensity interval training (HIIT) is widely used to improve endurance performance. It has been shown that HIIT increases total hemoglobin mass that contributes to the increase in maximal oxygen uptake (VO2max) of the trained muscles (Weston, 2014 & Gibala, 2015). However it remains unclear if untrained muscles can profit from the unspecific central adaptations. Therefore the purpose of this study was to examine if a HIIT of the lower extremities result in an improved VO2max and power output of the upper extremities.
METHODS: 11 healthy female participants (24,5 ± 3,3 years, VO2max 39,6 ± 4,8 ml/min/kg) underwent a 6 week HIIT program of the lower extremities on a cycle ergometer (3 days/ week for the first 3 weeks and 4 days/ week for the last 3 weeks). Training sessions consisted of a warm-up period of 5 minutes followed by a 4 times 4-minute high intensity (85-95% of maximal heart rate) and 3-minutes rest (65-75% of maximal heart rate) interval training protocol. Before and after the training period a maximal cycle ergometry (start at 30 W, increase 30W every 3min) and a maximal crank handle ergometry (start at 20W, increase 15W every 3min) with continuous gas analy-

sis were conducted. All values are given as the mean and standard deviation. T-test for paired samples was used to test differences between pre and post training. Relationships between variables were examined with Pearson`s product moment correlations. The level of significance was set at p<.05.
RESULTS: Significant increases in VO2max on the cycle ergometer (39.6 ± 4.8 to 43.4 ± 5.7 ml/min/kg) as well as on the crank handle ergometer (25.8 ± 3.6 to 27.5 ± 4.4 ml/min/kg) from pre- to post-test were measured. The maximum heart rate decreased significantly for the crank handle exercise (179 ± 12 to 169 ±15 bpm). The maximum lactate level increased significantly for the cycle exercise (9.0 ± 1.7 to 10.2 ± 1.3 mmol/L). Peak power output on the cycle ergometer increased significantly (186 ± 42 to 201 ± 41 W), whereas it remained unchanged during crank handle ergometry (66 ± 12 to 68 ± 15 W). Increase of VO2max on the cycle ergometer correlated positively with participants` performance on the cycle ergometer (r=.747, p=.008).
CONCLUSION: Not only leg-VO2max (10%), but also the arm-VO2max (6,9%) increased significantly after 6 weeks of HIIT training of the lower extremities in healthy young females. It can be assumed that improved O2 delivery is responsible for an increased VO2max of the upper extremities but did not result in a higher peak power output of this muscle group. Further studies should focus on potential mechanisms of these effects.

INTRAMUSCULAR INJECTION OF HYPERTONIC SALINE DURING LOW INTENSITY EXERCISE CREATES EXERCISE-INDUCED PAIN SIMILAR TO THAT DURING HIGH INTENSITY EXERCISE

MAUGER, A.R.1, SMITH, S.A.1, MICKLEWRIGHT, D.P.2

1. UNIVERSITY OF KENT; 2. UNIVERSITY OF ESSEX

INTRODUCTION: Intense exercise creates a metabolic environment in the muscle that elicits exercise-induced pain (EIP). The magnitude of this response is dependent on both the intensity and the duration of the exercise, and has been suggested to limit exercise performance. However, exploring this relationship is challenging because of the need to use an experimental pain model that can be induced independently of exercise and that replicates the sensation of EIP. The intramuscular injection of hypertonic saline solution has been suggested to closely replicate EIP, but to date the sensation of this pain has not been combined with low intensity exercise and qualitatively and quantitatively compared to 'normal' EIP.
METHODS: Fifteen participants performed an isometric time to exhaustion test with the right knee extensors (20% maximal voluntary contraction; MVC) to record the associated perception of EIP. Following this on separate visits, a 1 mL bolus of 5.85% hypertonic saline was injected into participants' right vastus lateralis in both a resting condition and during a low intensity (10% MVC) isometric contraction of the right knee extensors. During all experimental conditions, participants recorded their pain intensity every 5 s using an electronic visual analogue scale, and completed a McGill Pain Questionnaire (MPQ) once pain perception returned to baseline levels.
RESULTS: The 20%MVC task elicited a quality of EIP that was predominantly described in a sensory classification as throbbing, cramping and aching, which was similar to both the rest with hypertonic saline condition and the low intensity exercise with hypertonic saline condition. The affective and evaluative classifications for 20%MVC were mainly described as exhausting and tiring (affective), and intense (evaluative) which was not replicated in the rest with hypertonic saline condition, but was in the hypertonic saline with low intensity exercise condition. The mean total pain score in the 20%MVC condition was 28, which was similar to both the rest with hypertonic saline condition (20) and the hypertonic saline with low intensity exercise condition (23).
CONCLUSION: The findings of this study suggest that the intramuscular injection of hypertonic saline in resting conditions produces a similar sensory dimension of pain to EIP, but not affective and evaluative dimensions. However, when the intramuscular injection is combined with low intensity exercise, the sensory, affective and evaluative dimensions of pain are similar to EIP. As such, this experimental pain model could be used to accurately replicate EIP, and with the level of EIP moderated independently of the intensity of the exercise performed.

HIGH INTENSITY INTERVAL TRAINING, BUT NOT ENDURANCE TRAINING, IN TYPE 2 DIABETIC PATIENTS LOWERS SUB-SARCOLEMMAL LIPID DROPLET VOLUMETRIC CONTENT BY REDUCING DROPLET SIZE IN TYPE 2 MUSCLE FIBRES

KOH, H.C., NIELSEN, J., WINDING, K.M., ØRTENBLAD, N., MORTENSEN, S.P.

UNIVERSITY OF SOUTHERN DENMARK

INTRODUCTION: Elevated levels of lipid droplets (LDs) beneath the sarcolemma have been associated with lower insulin sensitivity in obese or type 2 diabetic individuals. Moreover, endurance training has been reported to decrease the volumetric content of those LDs. Therefore, our aim was to investigate the effects of moderate intensity endurance training (END) and high intensity interval training (HIIT) on the subcellular distribution and size of LDs in skeletal muscles of type 2 diabetic patients.
METHODS: Sixteen (9 males, 7 females) sedentary overweight type 2 diabetic patients (57±7 years old) were randomised to complete 11 weeks of either 40 min cycling at 50% peak workload (END) or 10 1-min cycling intervals at 95% peak workload separated by 1 min of recovery (HIIT), 3 times per week. Assessments for aerobic fitness, body composition, glycaemic control (OGTT and continuous glucose monitoring), and muscle biopsies were performed prior and after the intervention. Quantitative electron microscopy based on stereological principles was used to estimate the volume fractions and diameters of LDs beneath the sarcolemma (subsarcolemmal) and between the myofibrils (intermyofibrillar) of biopsied leg muscles. Number of LDs was derived from volumetric estimates and diameters. Electron micrographs were taken at x6000 magnification. Muscle fibres were categorised as type 1 or type 2 fibres based on volume fractions of intermyofibrillar mitochondria and width of Z-lines.
RESULTS: Aerobic fitness, body composition and non-fasting glycaemic parameters were improved following both END and HIIT (P<0.05). In the subsarcolemmal region, there was a tendency (P=0.1) for a 3-way interaction (training group x fibre type x time) with the volume fraction of LDs lowered by ~57% in type 2 fibres following HIIT (P=0.009), but not END, and no change in type 1 fibres following both training modalities. A main time effect was shown by a ~36% volumetric reduction following training (P=0.003). A 3-way interaction between training group, fibre type and time was observed in the size of LDs represented by individual LD diameters (P=0.03). This was explained by a ~31% reduction in LD diameters in type 2 fibres, following HIIT (P<0.001) but not END, with no change in type 1 fibres following both training modalities. The number of LDs was unchanged following training in both groups. In the intermyofibrillar region, all measures of LDs remained unchanged following training in both groups.
CONCLUSION: We demonstrate that, along with improvement in glycaemic control, HIIT was able to lower subsarcolemmal LD volumetric content via a reduction in size of LDs in type 2 fibres of type 2 diabetic patients. This highlights the relevance of HIIT as an alternative time efficient training modality that could influence the links between fibre type- and subcellular localisation-dependent LD distribution and insulin sensitivity in diabetes.

THE MEASUREMENT OF WHOLE BODY GROSS EFFICIENCY WITHIN HIGH INTENSITY CYCLING EXERCISE

EBREO, R., HOPKER, J., PASSFIELD, L.

UNIVERSITY OF KENT

INTRODUCTION: Gross Efficiency (GE) in cycling is a key determinant of endurance performance; reflecting the coupling of energy expenditure to power and propulsion. Conventionally, GE is measured during submaximal exercise at intensities below the lactate threshold. However, it is unclear whether GE during high-intensity exercise (HIE) with a significant anaerobic contribution, is reflected by measurements of GE performed during submaximal exercise. Using a back extrapolation (BE) model (De Koning et al. 2013), the aim of this study was to determine if GE is affected by HIE.
METHODS: 15 trained cyclists completed a maximal incremental exercise test to determine Maximal Aerobic Power (MAP). On 3 subsequent visits participants cycled for 4 min at either 80% (T1) or 100%MAP (T2) in a randomised order with 30 min recovery between each. Each HIE bout was preceded by 6 min at 50%MAP and 2 min at 25W, followed by 1 min at 25W and 10 min at 50%MAP. GE was calculated in the last 3 min of the 50%MAP pre- and post-HIE. Using linear regression, GE values during the 50%MAP after HIE were back extrapolated to the end of the high-intensity interval to estimate GE.
RESULTS: A greater reduction in GE is seen following HIE at 100% vs 80% MAP (-3% vs 0.43%, respectively) using the BE method. BE resulted in a significantly lower GE in both T1 (20.5 1.7%) and T2 (18.2 +/-1.1%) compared to T1 and T2 Post 50%MAP (20.8 +/-1.68% P = 0.04 and 20.0 +/-1.7% P= <0.05 respectively) as well as T2 Pre50%MAP (21.2 +/-1.9% P =<0.05). There was no significant difference between T1 Pre50%MAP (20.93 +/-2.31%) and T1 BE (P =0.27). T1 Pre and Post GE were not significantly different (P = 0.51), but T2 Post GE was significantly lower than T2 Pre GE (P = 0.018). GE back extrapolated from the end of HIE was significantly correlated with Post50%MMP in T1 (r= 0.98; P = <0.05), and in T2 (r = 0.80; P = 0.001). Calculated anaerobic contribution at the end of the 4min HIE bout in both T1 and T2 was higher when using the BE method compared to assuming a constant GE from the Pre 50%MMP bout (T1 = 8.16 kj vs 6.48 kj, P = <0.05) ; T2 = 21.12 kj vs 9.36 kj, P = <0.05).
CONCLUSION: HIE acutely reduced GE during cycling. A greater anaerobic contribution to exercise at 100% MAP may contribute to this decline in efficiency and account for the lower correlation between BE GE values and those measured during Post 50%MAP. However, a greater post HIE oxygen deficit at 100%MAP compared to 80%MAP may account for the greater fall in the calculated BE values. The BE method may be a useful tool in both estimating GE during HIE and calculating aerobic and anaerobic contributions.

BOUT DURATION IN HIGH-INTENSITY INTERVAL EXERCISE AFFECTS CARDIORESPIRATORY AND METABOLIC RESPONSES, PERCEIVED EXERTION AND AFFECTIVE VALENCE

BOGDANIS, G.C.1, TSIRIGKAKIS, S.2, MOUGIOS, V.3, MASTORAKOS, G.4, VELIGEKAS, P.1

1,4NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS, GREECE; 2UNIVERSITY OF THESSALY, GREECE, 3ARISTOTLE UNIVERSITY OF THESSALONIKI, GREECE.

INTRODUCTION: Although the physiological and metabolic responses to high-intensity interval exercise (HIIE) have been largely explored over the past decade, there is relatively little information regarding the perceptual and psychological responses that may influence exercise participation and adherence (Stork et al., 2017). This study compared cardiorespiratory and metabolic responses, perceived exertion and affective valence during isoenergetic continuous and HIIE exercise with bout duration ranging from very short (10 s) to moderate (60 s).
METHODS: Eleven healthy males (age, 28 ± 6 y, mean ± SD throughout) performed four trials one week apart, in random and counterbalanced order. Each trial consisted of 20 min of cycling with equal mean power output, performed either continuously (CON) or intermittently with 10 s (HIIE10), 30 s (HIIE30), or 60 s (HIIE60) bouts, at an intensity corresponding to 100% of VO2max. The exercise-to-interval ratio for the HIIE trials was 1:1.5; thus, recovery intervals were 15, 45 and 90 s of cycling at an intensity corresponding to 15% of VO2max, respectively. Oxygen uptake (VO2), pulmonary ventilation (VE), blood lactate concentration (BL), heart rate (HR), rating of perceived exertion (RPE) and affective valence (11-point feeling scale) were measured every 5 min during exercise. Results were analyzed using one-way (mean values of trials) or 2-way ANOVA (trial x time) with repeated measures and Tukey's post-hoc test.
RESULTS: Mean VO2 was lower in CON (2.02 ± 0.38 L/min, $p < 0.001$) compared with the HIIE trials, during which VO2 was similar (approx. 67% of VO2max; 2.29 ± 0.42, 2.20 ± 0.43, 2.12 ± 0.45 L/min, for HIIE15, HIIE30 and HIIE60, respectively). HR was similar in CON, HIIE10 and HIIE30, but higher in HIIE60 (peak: 167 ± 15 beats/min, $p < 0.01$). BL at the end of exercise and mean VE were lower in CON and increasingly higher in HIIE10, HIIE30 and HIIE60 (BL, from 4.9 ± 1.6 mmol/L in CON to 12.5 ± 3.5, mmol/L in HIIE60, $p<0.001$; and VE, from 54.7 ± 11.0 L/min in CON to 74.7 ± 18.7 L/min in HIIE60, $p<0.001$). The increase in RPE during exercise was similar in CON, HIIE10 and HIIE30, reaching 13, i.e., "somewhat hard". However, RPE in HIIT60 was higher from the 10th min onwards compared with all other trials ($p < 0.01$), reaching 17 ± 3, i.e., "very hard". Affect declined during all HIIT trials ($p < 0.01$) but not during the CON trial. However, there were no significant differences among trials at the same time points.
CONCLUSION: Despite similar external power output and VO2 in trials, HR, BL, VE and RPE were higher in HIIE60. Although the decrease in affect was similar, the greater metabolic stress, cardiorespiratory stress and RPE in HIIE60 may influence exercise participation and adherence (Kilpatrick et al., 2015).

IMPACT OF HIGH INTENSITY INTERVAL TRAINING FREQUENCY ON FUTURE PHYSICAL ACTIVITY PARTICIPATION

STAVRINOU, P.S.1, BOGDANIS, G.C.2, TERZIS, G.2, GIANNAKI, C.1, HADJICHARALAMBOUS, M.1

1 UNIVERSITY OF NICOSIA, NICOSIA, CYPRUS; 2 NATIONAL & KAPODISTRIAN UNIVERSITY OF ATHENS, ATHENS, GREECE

INTRODUCTION: The potential effect of high intensity interval training (HIIT) interventions on future participation in HIIT or other forms of physical activity (PA) has rarely been investigated (Jung et al., 2015). The present study examined the impact of HIIT frequency on future PA participation in inactive adults.
METHODS: Thirty five healthy inactive adults were randomly assigned to a control (CON) and to two training groups which performed HIIT (10 x 60s cycling, ~83% Wpeak), two (HIIT-2) or three times per week (HIIT-3) for eight weeks. Following the HIIT intervention, the intention to implement HIIT in the future was evaluated. Eight weeks after cessation of training, follow-up evaluation of HIIT completion was per-

formed, using a questionnaire. PA was also estimated at baseline and at follow up using the International Physical Activity Questionnaire (IPAQ) (Hagstromer et al., 2006).
RESULTS: Following the intervention, HIIT-2 and HIIT-3 participants reported similarly higher intention to implement HIIT in the future compared to CON participants (CON: 1.1±1.9, HIIT-2: 2.6±1.1, HIIT-3: 3.3±0.8 sessions/week, p<0.05). At follow-up, HIIT-3 participants reported higher completion of HIIT compared to HIIT-2 and CON (CON: 0±0, HIIT-2: 0.9±1.3, HIIT-3: 2.2±1.4 sessions/week, p<0.05). Both training groups increased vigorous PA (HIIT-2: from 0±0 to 371±559 MET-min/wk; p<0.05 and HIIT-3: from 0±0 to 862±709 MET-min/wk; p<0.05) and total PA levels (HIIT-2: from 349±165 to 1012±505 MET-min/wk; p<0.05 and from 348±219 to 1307±871 MET-min/wk; p<0.05) at follow up compared with baseline. Furthermore, 64% and 77% of participants of HIIT-2 and HIIT-3 respectively, were classified in the moderate or high PA category, compared with being inactive at baseline.
CONCLUSION: The present study showed that performing HIIT either two or three times per week may induce high intention to implement HIIT in the future. However, the higher training frequency resulted in greater HIIT completion eight weeks following the cessation of training intervention; although both training frequencies resulted in increased PA. These results demonstrate a modification of the habitual PA patterns, of the previously inactive participants, following the HIIT program, highlighting the positive influence of HIIT in promoting sustainable PA participation.

EFFECT OF AEROBIC TRAINING-INDUCED ACCELERATION OF ADIPONECTIN SECRETION FROM LOCAL FAT CELLS ON ARTERIAL STIFFNESS IN ELDERLY

HASEGAWA, N.1,2, FUJIE, S.1,2, HORII, N.1, UCHIDA, M.1, SANADA, K.1, HAMAOKA, T.3, IEMITSU, M.1
1> RITSUMEIKAN UNIVERSITY. 2> JAPAN SOCIETY FOR THE PROMOTION OF SCIENCE. 3> TOKYO MEDICAL UNIVERSITY.

INTRODUCTION: Recent studies have showed that ectopic fat accumulation rather than whole-body fat content may be important for predicting cardiovascular disease (Lim S et al, 2014). Aerobic training (AT) elevates serum level of adiponectin, an adipokine secreted from adipocytes, concomitant with a decrease in fat accumulation. Adiponectin regulates endothelial nitric oxide synthase in endothelial cells, promoting production of nitric oxide, a vasodilator. Although adiponectin mRNA expression levels differ various local adipose tissues (Padilla J et al, 2014), it is unclear whether AT-induced acceleration of adiponectin secretion from local fat cells is involved in the reduction of arterial stiffness. This study aimed to clarify whether AT-induced changes in adiponectin production in local fat cells is associated with reduction in arterial stiffness in older adults and senescence mice.
METHODS: Human study; 42 older subjects were randomly divided into AT and control (CON) groups. Subjects in the AT group completed 8-week of aerobic training (60–70% peak oxygen uptake for 45 min, 3 days/week). Before and after the intervention, we measured carotid-femoral pulse wave velocity (cfPWV) as an indicator of arterial stiffness, and serum adiponectin concentrations using enzyme-linked immunosorbent assay method. Animal study; seventeen 38-week-old SAMP1 mice were divided into CON and AT (voluntary wheel running for 12-weeks) groups. Expression of adiponectin mRNA in epididymal, subcutaneous, perivascular and subscapular brown fat was measured by using real-time RT-PCR.
RESULTS: In the human study, AT intervention significantly decreased cfPWV and elevated plasma nitrite/nitrate (NOx) and serum adiponectin levels (each P<0.05). Furthermore, the training-induced change in plasma NOx level was negatively correlated with training-induced change in cfPWV (r=-0.40, P<0.05) and was positively correlated with the training-induced change in serum adiponectin level (r=0.41, P<0.05). By contrast, none of these parameters changed significantly in the CON group. In animal study, adiponectin mRNA expression levels of different adipose tissues were examined to identify localization of fats involved in an increase in serum adiponectin levels by AT. Adiponectin mRNA expression in epididymal and subscapular brown fats significantly elevated in AT group as compared to CON group (P<0.05), whereas no significant differences in subcutaneous and perivascular fat depots between AT and CON groups were seen.
CONCLUSION: These results suggest that AT-induced increase in the production of adiponectin from local fat cells may be associated with a reduction in arterial stiffness via elevation of nitric oxide production.

THE EFFECT OF ACUTE ORAL PHOSPHATIDIC ACID INGESTION ON MYOFIBRILLAR PROTEIN SYNTHESIS AND INTRACELLULAR SIGNALING IN OLDER MALES

SMEUNINX, B.1, NISHIMURA, Y.1, MCKENDRY, J.1, LIMB, M.2, SMITH, K.2, ATHERTON, P.J.2, BREEN, L.1
1 UNIVERSITY OF BIRMINGHAM, 2 UNIVERSITY OF NOTTINGHAM

INTRODUCTION: Age-related muscle wasting (sarcopenia) impairs physical function and increases the risk of frailty and mortality. Impaired mTORC1-mediated signaling and myofibrillar protein synthesis (MyoPS) rates are thought to be the primary mechanisms driving the progression towards sarcopenia. The purported nutraceutical phosphatidic acid (PA) has been reported to stimulate mTORC1-mediated signaling increasing muscle protein synthesis in rodents, and enhance resistance training-induced muscle remodelling in young humans. Therefore, the present study examined the effects of acute oral PA ingestion on resting and exercise induced MyoPS rates and intracellular signaling in older individuals.
METHODS: Sixteen healthy older males were randomly allocated to either consume 1.5g of PA (PA; n=8; 68.4 ± 1.8 yrs) or a rice-flour placebo (PL; n=8; 69.4 ± 3.5 yrs) over 60 min after a bout of unilateral leg resistance exercise (RE). A primed-continuous infusion of L-[ring-13C6]-phenylalanine was combined with serial muscle biopsy sampling to determine intramuscular anabolic signaling and MyoPS at rest and between 0-150 and 150-300 min post-RE.

RESULTS: Acute PA ingestion increased plasma [PA] above basal values over 180-300 min post-exercise (P = 0.02). Exercise increased MyoPS rates by 40% above basal values (0.029 ± 0.002%h-1) over 150-300 min post-exercise in PL (0.050 ± 0.006 %h-1, P = 0.001), but not PA (0.033 ± 0.004%h-1 to 0.034 ± 0.005%h-1, P = 0.83). In addition, there was a trend for a reduction in resting MyoPS rates between 150-300 min in PA (0.023 ± 0.002%h-1, P = 0.053) compared with PL (0.035 ± 0.008%h-1). Phosphorylation of p70S6K, rpS6, 4EBP1 and Akt was elevated above basal levels in the exercised leg at 150 and 300 min post-RE in PL (P < 0.05). In contrast, only p70SK phosphorylation was elevated above basal values at 150 min post-RE in PA (P = 0.047). Phosphorylation of Akt at 150 min (P < 0.001), and phosphorylation of 4EBP1, p70S6K and rpS6 at 300 min (P < 0.01) was higher in the PL exercised leg compared with corresponding PA values. Total ubiquitin conjugates in PL rest were elevated from basal values and corresponding PA values at 150 (P < 0.01) and 300 min (P < 0.01). Ubiquitin conjugates at 30kDa and LC3II protein content were elevated compared with basal values in PL exercise at 150 min. LC3II protein content was higher in PL exercise compared with corresponding PA values at 150 (P < 0.01) and 300 min (P = 0.015).
CONCLUSION: Acute oral PA ingestion significantly increased plasma concentrations in the late study phase, and coincided with a blunted MyoPS and intramuscular anabolic signaling response upon RE. Therefore, based on our acute findings, there is no clear mechanism of action to support the idea that oral PA possesses muscle anabolic properties that might effectively counteract sarcopenia.

PRESERVED SKELETAL MUSCLE MASS AND FUNCTION IN CHRONICALLY TRAINED MASTER ATHLETES COMPARED WITH AGE-MATCHED UNTRAINED OLDER INDIVIDUALS.

MCKENDRY, J., BAIG, S., LIU, B., GREIG, C., BREEN, L.

SCHOOL OF SPORT, EXERCISE & REHABILITATION SCIENCES, UNIVERSITY OF BIRMINGHAM. QUEEN ELIZABETH HOSPITAL, BIRMINGHAM. MRC- ARTHRITIS RESEARCH UK CENTRE FOR MUSCULOSKELETAL AGEING RESEARCH.

INTRODUCTION: The progressive loss of skeletal muscle mass and function with advancing age, sarcopenia, presents a significant challenge to individuals and healthcare provision. However, the relative contribution of inherent ageing and secondary, environmental influences to sarcopenia are yet to be elucidated. It is well established exercise training elicits a multitude of benefits in young and older individuals. Master athletes are a unique, older, population who maintain high physical function while remaining relatively free of age-associated comorbidities. Therefore master athletes are an ideal model in which to study ageing. Previously, studies on master athletes had not included such a comprehensive array of measures to fully characterise these exceptional individuals, and had typically been carried out in individuals below the age of 60 years.
METHODS: The aim of this study was to determine whether chronic exercise training is protective in its effects against the deleterious process of ageing. In a cross-sectional investigation of 15 young (20 ± 2.7 y, 78.9 ±13.3 kg), 12 older (69.8 ± 4.1 y, 77.5 ± 14.2 kg) and 14 master endurance athletes (67.1 ± 4.1 y, 68.7 ± 6.5 kg) we compared body composition, skeletal muscle function and morphology.
RESULTS: The older healthy controls had a significantly lower VO2max (36.7 6.5 vs. 49.3 3.6 ml.kg-1.min-1, P<0.01) and skeletal muscle index (69.8 ± 5.1 vs. 77.0 ± 4.0, P<0.05) and greater body fat percentage (26.8 5.4 vs. 19.2 4.1 %, P<0.01) than master endurance athletes. Young controls were stronger than both old controls and master endurance athletes, with a similar VO2max and a tendency to lower body fat (22.0 ± 5.5 vs. 26.8 ±5.4, P=0.58), compared with master endurance athletes. Muscle thickness was significantly greater for young controls compared with older non-exercising controls (Vastus Lateralis (Vl): 25.7 ± 3.6 vs. 17.8 ± 4.7 mm, P<0.01, Vastus Intermedius (VI): 18.6 ± 3.5 vs 13.5 ± 3.1 mm, P<0.01, Rectus Femoris (RF): 26.3 ± 3.5 vs 17.5 ± 5.0 mm, P<0.001). Master endurance athletes offset the decline in VL and VI, but not RF, muscle thickness. Type I fibre area was significantly greater for master endurance athletes compared with old controls (5179 ± 1137 vs. 3838 ± 1008 µm2, P<0.05). Type II fibre area was significantly greater for young controls compared with old controls (5509 ± 1964 vs. 3584 ± 951 µm2, P<0.01).
CONCLUSION: In summary, older, non-exercising men exhibited impairments in almost every outcome compared with young healthy individuals. In many cases chronic exercise was able to rescue this decline, demonstrating that chronic exercise training is a beneficial strategy for off-setting age-related decrements in physical function, body composition and muscle morphology.

POTENTIAL FUNCTIONAL BENEFITS OF A COMPREHENSIVE EVALUATION OF PHYSICAL ACTIVITIES FOR MIDDLE AGED AND OLDER ADULTS

MAYO, A., SENECHAL, M., BOUCHARD, D.R.

UNIVERSITY OF NEW BRUNSWICK

INTRODUCTION: Most adults do not meet the most common recommendations of 150 minutes of moderate to vigorous physical activity (PA) plus two days of resistance training (RT) a week. This recommendation excludes possible influences of other types of activities and intensities to maintain or increase physical capacities that are highly associated with independent living. The objective of this study is to explore potential functional benefits of a comprehensive evaluation of all activities completed over 24 hours for seven days.
METHODS: Data collected was from the National Health and Nutrition Examination Survey of adults 45-85 years of age. PA intensities was obtained via accelerometer, but self-reported for sleep and RT. The three PA indexes were: 1) Total Activities in a day (Total Index), 2) Resistance Training/Aerobic Training (RT/AE Index), 3) Activity Time/Sedentary Time (Activity/SED Index). The physical capacity was derived from a factor analysis using 11 questions related to activities of daily living (e.g., walking a quarter of a mile) which were answered as: no difficulty, some difficulty, much difficulty, and unable to do. Logistic regression analyses were used to test the hypothesis that the computed indexes would be significantly associated with physical capacity even when adjusting for body mass index, age, sex, ethnicity, income, education and the average of self-reported chronic conditions and then further for meeting the current PA recommendation.
RESULTS: 932 people (67.0 ± 9.6 years; 45% women) were analyzed. All indexes were included in the regression model even when adjusted for CPAG (Total Index - Beta: 1.15, CI (1.02-1.17), RT Index- Beta: 1.22, CI= (1.04-1.43), SED index- Beta: 0.58, CI= (0.47-0.71) in the full adjusted models.
CONCLUSION: This study suggests that moderate to vigorous intensity PA are not the only movements important for increasing physical capacity of older adults.

ASSOCIATION OF DIETARY PATTERNS AND PHYSICAL ACTIVITY ON CENTRAL OBESITY IN MIDDLE-AGED AND ELDERLY JAPANESE ADULTS: THE WASEDAS HEALTH STUDY

ITO, T.1, KAWAKAMI, R.1, TANISAWA, K.2,3, MIYAWAKI, R.1,4, ISHII, K.1, TORII, S.1,3, SUZUKI, K.1,3, SAKAMOTO, S.1,3, MURAOKA, I.1,3, OKA, K.1,3, HIGUCHI, H.1,3

1 WASEDA UNIVERSITY, 2 NATIONAL INSTITUTE OF HEALTH AND NUTRITION, NIBIOHN, 3 INSTITUTE OF ADVANCED ACTIVE AGING RESEARCH, WASEDA UNIVERSITY, 4 MEIJI UNIVERSITY

INTRODUCTION: Although healthy dietary patterns and physical activity are independently known to be associated with central obesity, data on the combined association of dietary patterns and physical activity on central obesity is limited. Therefore, the aim of this study was to investigate the independent and combined associations of dietary patterns and moderate-to-vigorous physical activity (MVPA) on waist circumference (WC) in middle-aged and elderly Japanese people.
METHODS: A cross-sectional study was conducted in 829 adults (534 men and 295 women), aged 40–79 years, who participated in the Waseda Alumni's Sports, Exercise, Daily Activity, Sedentariness, and Health Study (WASEDAS Health Study). Dietary patterns were derived using principal component analysis of the consumption of 52 food and beverage items, which were assessed by a validated Brief-type self-administered Diet History Questionnaire. MVPA was assessed using the Global Physical Activity Questionnaire. The dietary pattern scores and MVPA were categorized into tertiles based on sex and age (40–49 years, 50–59 years, and 60 years or older). To examine the association of each dietary pattern and MVPA on the WC, we performed multiple linear regression analysis. To examine the combined association of each dietary pattern and MVPA on the WC, we added interaction terms of dietary patterns and MVPA in the regression models.
RESULTS: Two major dietary patterns were identified: "healthy Japanese" and "seafood and alcohol". After adjustment for covariates, the healthy Japanese dietary pattern score was inversely associated with WC in men (P for trend = 0.029), but not in women (P for trend = 0.571). The seafood and alcohol dietary pattern score was not significantly associated with WC in both men and women. MVPA was inversely associated with WC in men (P for trend < 0.001), but not in women (P for trend = 0.104). There was no interaction between the healthy Japanese dietary pattern score and MVPA (P for interaction= 0.208 and 0.883 for men and women, respectively). As compared with the lowest healthy Japanese dietary group with the lowest MVPA group, the highest healthy Japanese dietary group with the highest MVPA group had significantly low WC in men (P < 0.035).
CONCLUSION: The healthy Japanese dietary pattern and MVPA were independently inversely associated with WC in middle-aged and elderly Japanese men but not in women. The healthy dietary pattern and higher MVPA together are associated with a lower WC in men.

INTERNAL LOADS, BUT NOT EXTERNAL LOADS AND FATIGUE RESPONSES, ARE SIMILAR IN YOUNG AND MIDDLE-AGED RESISTANCE TRAINED MALES DURING HIGH VOLUME SQUATTING EXERCISE

FERNANDES, J.F.T., LAMB, K., TWIST, C.

UNIVERSITY CENTRE HARTPURY

INTRODUCTION: This study compared the internal and external loads during high volume squatting exercise and the fatigue-related responses in young (n = 9; age 22.3 ± 1.7 years) and middle-aged (n = 9; age 39.9 ± 6.2 years) resistance-trained males. A secondary purpose was to determine the relationship between internal and external load variables with post-exercise impairments in muscle function
METHODS: Measures of heart rate (HR), OMNI ratings of perceived exertion (OMNI-RPE), and session RPE (internal load) and repetition peak velocity and power and volume load (external load) were recorded during 10 x 10 sets of squats performed at 60% one-repetition maximum (1RM). Markers of muscular fatigue (maximal voluntary contraction (MVC), voluntary activation (VA) and resting twitch torque of the knee extensor, peak power at 20 and 80% 1RM, and capillary blood lactate concentration) were recorded before and immediately after exercise.
RESULTS: All differences internal load variables and peak velocity between groups during exercise were unclear. Peak power and volume load were likely moderately higher (ES -0.71, CI -1.53 to 0.10) in the young compared to the middle-aged group. The unclear differences in MVC, VA and blood lactate between groups after exercise were accompanied by very likely greater decrements in resting twitch torque (ES -1.53, CI -2.34 to -0.71) and peak power at 20 (ES -1.21, CI -2.03 to -0.39) and 80% (ES -0.94, CI -1.76 to -0.12) 1RM in the middle-aged group compared to the young group. Mean HR during exercise was likely and very likely correlated with decrements in MVC (r = .45, CI .06 to .72) and 80% 1RM peak power (r = .50, CI .13 to .75), respectively, whilst OMNI-RPE was likely correlated to impairments in 20 (r = .36, CI -.05 to .66) and 80% 1RM peak power (r = .32, CI -.09 to .64, respectively). Mean peak power and volume-load were likely and very likely correlated with reductions in MVC (r = .38, CI -.03 to .68 and r = .59, CI .24 to .80, respectively) and peak power at 20 (r = .43, CI -.03 to .71 and r = .55, CI .19 to .78, respectively) and 80% 1RM (r = .35, CI -.06 to .66 and r = .50, CI .13 to .75, respectively), but peak velocity during exercise were not.
CONCLUSION: The subsequent fatigue response, for which middle-aged males can expect greater decrements in peak power, appears to be related to a higher HR, OMNI-RPE, peak power and volume-load during exercise. Practically, these findings suggest that internal, but not external, load can be monitored in a like manner between these age groups.

LOWER BODY FORCE PRODUCTION PROPERTIES AND DYNAMIC BALANCE CONTROL IN MIDDLE AGED MEN AND WOMEN

GLAD, A., HAKKARAINEN, A., LINNAMO, V., RUOTSALAINEN, K., HEIKKINEN, T., PIIRAINEN, J.M.

FACULTY OF SPORTS AND HEALTH SCIENCES, UNIVERSITY OF JYVÄSKYLÄ, FINLAND

INTRODUCTION: Balance deficiencies are significant factors in falling accidents and hospitalization in the working age population (Valonen et al. 2016). In 2013, 54% of individuals seriously injured were men and 46% were women. Of these incidents, 69% were related to poor daily functional capacity (Valonen et al. 2016). At present, standard procedures for physical performance testing for occupational health are lacking. The aim of the present study was to assess if a novel dynamic balance perturbation device would be an appropriate tool to measure daily functional capacity and if gender differences in balance control would be observed.
METHODS: 72 participants, WOMEN (n=34, 52 ± 5.5 years) and MEN (n=37, 49 ± 6.5 years), completed the study. Dynamic balance was measured with 5 sets of 16 anteroposterior perturbations each with 30 cm amplitude (SLOW: v=10 cm/s, MIDSLOW: v=13 cm/s, MID: v=16 cm/s, MIDFAST: v=19 cm/s, FAST: v=21 cm/s,) using a special perturbation device modified from Piirainen et al. (2013). Maximal centre of

pressure peak displacement (PeakD) from 8 anterior and posterior perturbations were analyzed. In addition, isometric knee extension and plantar flexion force production (maximum force, rate of force development, max RFD) were measured.
RESULTS: In posterior perturbations, MEN had lower PeakD during the MIDFAST (6.8%, p<0.01) and FAST (8.6%, p<0.01) situation than WOMEN, while in anterior perturbations MEN had lower PeakD during all five velocities from SLOW to FAST (10.8±%, p<0.01, 11.0%, p<0.01, 8.9%, p<0.01, 9.5%, p<0.01, 10.7%, p<0.01), respectively. Even though similar differences were observed in isometric knee extension (21.1%, p<0.001) and plantar flexion (23.3%, p<0.001) RFD, no significant correlations were found between PeakD and force parameters in either group.
CONCLUSION: WOMEN showed consistently weaker dynamic balance in comparison to MEN, but the differences in RFD alone do not adequately explain the differences in balance capabilities. Previously it has been shown in men that RFD correlated with dynamic balance control in elderly but not in young (Piirainen et al. 2010). It is possible that the lower RFD observed within middle-aged women compared to men is related to an increased risk of falling accidents and injuries later in life. Even though the potential of the system to measure functional capacity was observed, further investigations are needed.

CARDIORESPIRATORY RESPONSE TO A 12-WEEK EXERCISE PROGRAM COMBINING HIIT AND POWER TRAINING AND 1-YEAR FOLLOW-UP IN ELDERLY PATIENTS WITH COPD

RODRIGUEZ-LOPEZ, C.1, LOSA-REYNA, J.2,3, ALCAZAR, J.1, BALTASAR-FERNANDEZ, I.1, NAVARRO-CRUZ, R.1, GARCÍA-GARCÍA, F.J., ESPINOSA, M.J.3, ALFARO-ACHA, A.2,3, ALEGRE, L.M., ARA, I., GUADALUPE-GRAU, A.

1: GENUD-UCLM . 2. CIBERFES 3: CHT . 4. UPM .

INTRODUCTION: Moderate resistance and continuous endurance combined training are considered one of the main parts of pulmonary rehabilitation (1). HIIT and power training separately have showed good results in elderly populations with cardiopulmonary diseases (2, 3). For these reasons, we aimed to investigate cardiorespiratory response to a 12-week exercise program combining HIIT and power training in elderly patients with COPD.
METHODS: Twenty-six elderly subjects (77±7 years, 5 women) with mild COPD severity (FEV1=53±17% pred.) were randomly distributed in an exercise training group (ET; 24 sessions combining HIIT on a cycle ergometer and power training on a leg press apparatus) or a control group (CON; usual care) during 12 weeks. Pulmonary function and cardiorespiratory response were evaluated pre and post training by spirometry (FEV1, FVC, and FVC/FEV1), the six minute walk test (6MWT) and a maximal incremental exercise test on a cycle-ergometer with breath-by-breath analysis (Oxycon pro, Germany) Furthermore, oxygen uptake kinetics was assessed during warm-up of maximal incremental test (VO2Tau, constant for mono-exponential model). Magnitude based inferences analysis was performed for pre and post training comparisons. A 1-year follow-up was included in the analysis.
RESULTS: VO2peak and peak power of the incremental test (Wpeak) were improved with a moderate effect in ET [% change; ES±90%CL] (+17%; 0.6±0.5 and + 50%; 0.7±0.4 respectively) while CON showed no changes (VO2peak= +0.4%; 0.0±0.1 and Wpeak= +7.4; 0.0±0.2). 6MWT was increased in ET (3.3%; 0.2±0.2) compared with a decrease in CON (-4.7%; 0.1±0.2). Oxygen uptake kinetics was accelerated in ET whereas CON was slowed (VO2Tau= -8.9%; 0.5±0.6 vs. +4.5%; 0.10±0.60 respectively). These changes were not accompanied by any improvement in pulmonary function. After 1-year follow-up, this intervention only promoted a positive difference between groups in Wpeak and 6MWT with respect to pre-training values (ES±90%CL=1.0±0.8 and 0.8±0.8 respectively).
CONCLUSION: Twelve weeks of HIIT and power combined training could be a proper strategy to improve cardiorespiratory response on elderly patients with COPD. However, it is still not clear whether this improvement could be triggered by enhanced peripheral dysfunction, central factors or both. After 1-year follow up, ET presented residual benefits of exercise compared to usual care programs. This would support the frequently prescription of pulmonary rehabilitation programs for better COPD management.

THE EVALUATION OF PHYSICAL FITNESS PARAMETERS OF OLDER ADULTS WHO PARTICIPATED EXERCISES IN FIELD-BASED PHYSICAL ACTIVITY

SUNA, N., ODABAS, I., BULGAN, C., ERALP, F.

HALIC UNIVERSITY

INTRODUCTION: Physical fitness is a set of attributes that people have or achieve. Being physically fit has been defined as the ability to carry out daily tasks with vigor and alertness, without under fatigue and with sample energy to enjoy leisure-time pursuits and to meet unforeseen emergencies. In recent years, the increase of exercise awareness and the possibility of doing sports activities in public parks have reduced the physical inactivity levels of individuals. Controlled and deliberate exercises will prevent any injuries and health problems, especially in elderly adults. For this reason, it is important to provide follow-ups by measuring and evaluating some pyhsical parameters of these population. The purpose of this study was to investigation of the demographic characteristics, physical fitness and self-care parameters of women over 50 years of age who participated some exercise activities such as walking, running and using some fitness equipment in public park areas in Kadikoy, Istanbul.
METHODS: Thirthy-eight women (mean age 62.37±7.81years; mean height 159.38±5.47cm; mean mass 67.81±12.03kg) were participated to this study as voluntarily. They were participated to the moderate exercises three days a week. Some anthropometric parameters such as waist and hip circumference and BMI were calculated for all participants. Additionally, right and left hand grip strength were measured using a hand dynamometer; also 30sec. chair stand for lower body strength; arm curl for upper body strength; back stratch for upper body flexibility; chair sit and reach for lower body flexibility; 6min walking for aerobic endurance were assessed as physical fitness parameters. Par-Q test and self-care evaluations were also done. Descriptive statistics (mean±SD) formulated for the variables age, height, body mass and other data were analysed by using SPSS version 24 for windows (SPSS, Chicago, IL). Bivariate Correlation (Pearson r) were also used for determination of the relations between some parameters.

RESULTS: As a result of the study participants BMI values were found as 26.72±4.70kg/m2; waist to hip ratio were calculated .84±11.69cm and .103.03±8.52cm, respectively. Hand grip strength for both hand were found as 22.19±6,08kg for right hand and 20.97±6,80kg for left hand. Also, 30sec chair stand test were 25.49±9.26times; 30sec arm curl test were 24.68±9.54times; back stratch test were 4,79±6,87cm; chair sit and reach test were 14,80±11,38cm and 6min walking test were 413,42±75,86m. Meanwhile there were some relationship between BMI and waist-hip circumferences and body mass (r=,699 and r=,909); and no any relationship between physical fitness parameters and others (p>0.05).
CONCLUSION: In conclusion, participants were in moderate level of physical fitness assessments. However their body fat amount were found in risk level. Its necessary that a more systemic exercise model should be applied to decrease the amount of fatness and it should be directed to the sports activity through exercise leaders.

ASYMMETRY OF QUADRATUS FEMORIS AND PIRIFORMIS MUSCLES IN ADOLESCENT TENNIS PLAYERS WITH FEMOROACETABULAR IMPINGEMENT: A VOLUMETRIC MRI STUDY

KUX, J.1, BALIUS, R.2, ALOMAR, X.3, RUIZ-COTORRO, A.4, CALBET, J.A.L.1, SANCHIS-MOYSI, J.1
1 IUIBS ; 2 CONSELL CATALÀ DE LESPORT, 3 CLÍNICA CREU BLANCA, 4 MAPFRE CENTRE FOR TENNIS MEDICINE

INTRODUCTION: Femoroacetabular impingement (FAI) is an important problem which prevalence is increasing in young athletes participating in sports with great unilateral loads, i.e. tennis, soccer, hockey (1). Although the physiopathological mechanisms leading to FAI remain unknown, it has been hypothesized that imbalances in the muscles stabilizing the pelvis may play a role (2). The main aim was to determine if playing tennis during adolescence elicit bilateral asymmetries in quadratus femoris (QF) and piriformis (PI) muscles, and if this asymmetry is greater in tennis players (TP) with FAI.
METHODS: Thirty male TP participated in the study (15.4±2.2 years, playing frequency 5-6 days/week, at least 2 years), 15 had FAI (6 unilateral dominant leg, 6 unilateral non-dominant leg, 2 bilateral) and 15 were healthy, asymptomatic TP (CG). All TP used the two-handed backhand stroke. The volume of QL and PI was determined by MRI in the dominant (arm holding the racket) and non-dominant side. Slice thickness was 2 mm without inter-slice interval. MRI images were manually segmented. Side-to-side differences were assessed using Student's paired t-tests and differences between groups using ANCOVA with Bonferroni-Holm post hoc test. Statistical significance was set at P<0.05.
RESULTS: The FAI group had spent more time playing tennis than controls during the previous two years (218.0±62.6 vs. 174.0±48.4 min/day, respectively, P<0.05), although weekly training frequency was similar in both groups (5.1.0±1.6 vs. 5.2±0.6 days/week, respectively, P=0.9). In the FAI group, the volume of QF and PI was 9.5±16.3 and 5.7±8.8% (mean±SD) greater in the non-dominant than in the dominant side (27.9±14.9 vs 25.6±14.2 cm3 and 36.1±14.3 vs 33.7±11.9 cm3, for QF and PI, respectively, both P<0.05). In the CG, QF and PI had similar volumes in the non-dominant and dominant sides (26.4±13.4 vs. 25.6±14.5 cm3, P=0.37 and 33.7±13.0 vs 33.4±12.1 cm3, for QF and PI, respectively, P=0.79).
CONCLUSION: This study shows, for the first time, that FAI is associated with asymmetries in the hip muscles in young tennis players, likely caused by an excessive training volume and/or technical aspects of the training causing asymmetric loadings. However, the side with greater QF and PI volume did not always coincide with the hip with FAI.

KNEE VALGUS ANGLES DURING THE STANCE PHASE OF RUNNING: A LATE SWING PHASE PROBLEM?

LIU, J., TENG, H.L., POWERS, C.M.
UNIVERSITY OF SOUTHERN CALIFORNIA

INTRODUCTION: Excessive knee valgus during running has been shown to contribute to knee pain in runners [1]. In addition, female runners tend to exhibit greater amounts of knee valgus compared to their male counterparts [2-5]. While most studies have focused on stance phase kinematics, studies also have reported that females display greater knee valgus at initial contact than males [2,4]. The purpose of the current study was to determine whether late swing phase knee valgus is associated with stance phase knee valgus.
METHODS: 15 female and 10 male healthy recreational runners participated <26.7±6.4 years old>. All were heel strikers. Subjects were instructed to run at a controlled speed of 3.4 m/s along a 14-m runway using their own running shoes. Knee joint kinematics throughout the swing and stance phases of running were collected using an 11-camera motion capture system at a sampling rate of 250 Hz. Average frontal plane knee angles during the late swing phase and the peak frontal plan angles during the stance phase were calculated. Pearson correlation was used to determine the association between late swing and stance phase knee valgus. Independent sample t-tests were used to compare sex differences in knee valgus angles during these two phases. Statistical analyses were performed using SPSS , with significance level alpha=0.05.
RESULTS: Average knee valgus angles during late swing were positively associated with peak valgus angles during stance . On average, females exhibited greater average late swing knee valgus angles than males <1.19±1.75° vs -1.20±1.39°, p=0.002>. Females also exhibited greater peak stance knee valgus angles than males <2.59±1.66° vs 0.59±1.16°, p=0.003>.
CONCLUSION: Our results indicate that knee valgus during the stance phase of running is influenced in part by swing phase kinematics. Future studies should consider potential causes of abnormal knee valgus during late swing to better understand mechanisms of excessive knee valgus during the stance phase of running.

ACADEMIC OUTCOMES IN MANITOBA STUDENTS WITH SPORT-RELATED CONCUSSION OR FRACTURE INJURY

SELCI, E., RUSSELL, K., BLACK, B., COCHRANE, K., ELLIS, M.

UNIVERSITY OF MANITOBA

Background: Concussion symptoms include physical, cognitive, behavioral, and emotional deficits. A notable proportion of youth develop Persistent Post-Concussion Syndrome, which may result in difficulties in school activities and negatively impact health-related quality of life. The 2017 Concussion in Sport Group consensus statement describes a four-step Return to Learn program for students to return to school in a timely and safe manner. The objectives of this study were to compare the effects of adolescent sport-related concussion and sport-related extremity fracture on 1> academic outcomes including change in school grades and school attendance and 2> determine which specific academic accommodations were most helpful during recovery from these injuries.
Methods: A prospective cohort study was conducted to compare report-card grades, attendance, and school accommodations among students with a sport-related concussion or sport-related fracture. Students were included if they were diagnosed with an isolated sport-related concussion or fracture and presented within seven days of the injury to the Pan Am Clinic in Winnipeg, Manitoba. Grades data were extracted from students' immediate pre-injury report card and their report card after they recovered. Students completed a school attendance log book. Upon recovery, students completed an exit interview to determine how helpful they perceived their school accommodations to be during their recovery.
Results: Of 231 recruited students, 124 submitted pre- and post-injury report cards, 203 returned school attendance log books, and 190 completed the exit interview. Concussion and fracture students experienced a similar decrease in grades post-injury . Concussion students missed significantly more days of school: median of 4 versus 1 for fracture students . In total, 53.1% concussion students versus 40.3% fracture students found their school be very accommodating .
Conclusions: Students who sustain a sport-related concussion miss significantly more days of school but demonstrate similar changes in school grades post-injury compared to those with a sport-related fracture injury. Future studies are needed to identify the pre- and post-injury factors associated with poor academic functioning following concussion and identify measures that can be taken to help optimize academic outcomes in these patients.

DO FRENCH AND CHINESE REGULAR BADMINTON PLAYERS EXPERIENCE THE SAME INJURIES?

HERBAUT, A., DELANNOY, J., FOISSAC, M.

DECATHLON

INTRODUCTION: Badminton is a popular racket sport practiced worldwide by more than 200 millions of players. The injury incidence in elite and recreational players during training and competition is around 2.3–3.2 injuries/1000 badminton hours (Fahlström & Söderman, 2007). Epidemiological studies examined injuries in European and Asian badminton players but no study directly compared these 2 populations (Krøner et al., 1990; Høy et al., 1994). Therefore, the objective of this study was to examine whether differences existed between French and Chinese regular badminton players injuries distribution.
METHODS: An online questionnaire was completed by 113 French and 117 Chinese RBP. The two populations were matched for distribution of genders, ages, skill levels and badminton exposure. Chi-square tests ($\chi 2$) were conducted to determine differences in injuries distribution between the two populations.
RESULTS: A higher percentage of French players reported to have experienced at least one injury over the 5 past years compared with Chinese players (66% vs. 45%, respectively, χ^2= 10.3, p=0.001). For the upper limb, French players experienced more shoulder/arm injuries (59% vs. 32%, respectively, p<0.001) whereas Chinese players reported more wrist/hand injuries (44% vs. 12%, respectively, p=0.049). The vast majority of injuries were localized to the lower extremity both for French and Chinese (69% and 56%, respectively), with a higher prevalence for the ankle (33% and 49%, respectively), then the knee (19% and 27%, respectively).
CONCLUSION: The most common injury reported was the ankle sprain, which generally occurred during a jump landing upon backward and lateral movements (60%) or during forward lunge (26%). As more than half of the ankle sprains were moderate or severe, a particular attention should be paid to the effects of footwear and court surface characteristics on the biomechanics of badminton players.
Furthermore, the differences observed between French and Chinese RBP in terms of injuries distribution suggest differences in the employed playing techniques to perform the variety of badminton strokes. Thus, a biomechanical investigation aiming to compare French and Chinese strokes performance and movements may be of interest.

INJURY EPIDEMIOLOGY IN U13 FOOTBALL PLAYERS FROM AN ELITE ACADEMY AND A NON-ELITE CLUB: A ONE-SEASON PROSPECTIVE COMPARISON

LARRUSKAIN, J.1,2, TRASVIÑA, U.2, LEKUE, J.A.1,2, BIDAURRAZAGA-LETONA, I.2, GIL, S.M.2

1: ATHLETIC CLUB, 2: UNIVERSITY OF THE BASQUE COUNTRY

INTRODUCTION: Elite young players recruited by professional football clubs into their academies are presumably under more physical and psychosocial stress compared to their non-elite counterparts, which might predispose them to a higher injury risk and negatively impact their development and chances of becoming professional players. The aim of the study was to compare the epidemiology of injuries in young players from a professional academy and a non-elite club over one season.
METHODS: Injuries, exposure time and anthropometric data were prospectively recorded in U13 players from a professional academy (Athletic Club, n=20) and a non-elite club (Zalla Union Club, n=17) over the 2015-2016 season following the FIFA consensus. Maturity offset was calculated as Chronological age – Predicted age at peak height velocity (APHV).[1] Ratios were compared using z-tests, and the rest of variables using Mann-Whitney's U-test.

RESULTS: There were no statistically significant differences between teams in age (mean±SD, Elite vs. Non-elite: 12.4±0.4 vs. 12.4±0.3 years, p=0.78), body mass (42.8±5.8 vs. 43.3±7.8 kg, p=0.80) and height (155.8±5.2 vs. 150.6±8.4 cm, p=0.06), but the sum of 6 skinfolds was lower in elite players (48.5±15.8 vs. 68.5±19.5 mm, p<0.01). Elite players were also closer to APHV (-1.6±0.4 vs. -2.3±0.6 years, p<0.01). Both teams had a similar amount of match time (21±9 vs. 25±4 h, p=0.07), but the elite team trained considerably more (172±35 vs. 133±7 h, p<0.01). There were a total of 23 injuries in the elite team and 12 in the non-elite team. Match injury incidence was 5 times higher in elite players (26.0 vs 5.2/1000 h, p=0.04), but training (3.5 vs. 4.4/1000 h, p=0.60) and total (5.9 vs. 4.5/1000 h, p=0.43) incidence were similar between teams. Non-elite players suffered one injury of moderate severity (8-28 days), and the rest were minimal and mild (<8 days). Conversely, the elite team suffered 8 moderate and 10 severe (>28 days) injuries. There were 11 growth injuries (6 were severe) in elite players compared to only 1 in non-elite players, with an 8 times higher incidence in the elite team (p=0.05). All of this resulted in a 12 times higher injury burden in elite players (199 vs. 16 days lost/1000 h, p<0.01).
CONCLUSION: The high burden of injuries in elite U13 players, in particular growth injuries, might be due to an "early professionalization" in the elite academy with higher playing intensities, training load and psychosocial demands. However, these preliminary findings should be replicated in larger cohorts. Considering the negative impact that injuries have in player development and health, tailored preventive strategies are needed to promote safe football participation in young players.

INJURY PROFILE OF NON-CONTACT INJURIES IN U.S. MENS RUGBY-7S

MA, R., LOPEZ JR, V., WEINSTEIN, M., HUME, P., VICTORIA, C., HALEEM, S., METTRY, M., ALLEN, A.
UNIVERSITY OF MISSOURI, RUGBY RESEARCH & INJURY PREVENTION GROUP, AND HOSPITAL FOR SPECIAL SURGERY

INTRODUCTION: Rugby-7s is an Olympic global collision sport played with a high incidence of injury. There is limited injury data on Rugby-7s, including injury mechanisms in Rugby-7s. The study aims were to report men's injury incidence and nature of non-contact risk factors in U.S. Rugby-7s.
METHODS: Match injury incidence (per 1000 player-hour (ph)) and non-contact factors were catalogued using the Rugby Injury Survey & Evaluation (RISE) report methodology (Lopez et al., 2012). 26,334 U19 to elite U.S. men players (age: 10-54 years) on 2,174 teams involving 4,716 matches in 80 USA Rugby sanctioned tournaments (2010-2015) were evaluated. Medical attention (no absence from play), time-loss (players were unable to return to play the same day) injuries, and injury severity (days absent before return to training/competition) were determined. Incidence of non-contact injuries, defined as no contact with an opposing player or collision-type mechanism, were determined. Non-contact injuries were further subdivided into classic-non-contact while in play (i.e. cutting, changing direction, sprinting); or other non-contact causes influenced by another factor (i.e. slipping or trip) (Marshall, 2010). Significance was set a P<0.05.
RESULTS: Non-contact injuries occurred frequently (31%; n=446) over the study period (classic-non-contact=98%, n=403; other=2%, n=8; P<0.001). Non-contact injuries (time-loss 25%; medical attention 75%) were found at higher rates among backs (62%; 28.4/1000ph, CI:24.9-32.1) than forwards (38%; 23.2/1000ph, CI:19.7-27.2; RR:1.22, p=0.050). Non-contact injuries resulted in 48.7 mean days absence (classic-non-contact 48.1 days; other 77.0 days). Injuries overall were acute (85%) and occurred most commonly during avoiding/attempting tackling (31%) and running/open play (48% overall; from 35% in 2010, 41% in 2011, 52% in 2012, 43% in 2013, 46% in 2014, 70% in 2015). Most non-contact injuries (44%) occurred during the first two matches of the tournaments. Recurrent injuries were 33% of all injuries (9.5/1000ph, CI:8.0-11.2). Most common time-loss injuries were ankle sprains and posterior thigh muscular injuries, equivalently at 15%, 1.0/1000ph. Ankles were most commonly injured (17%, 4.9/1000ph), followed by knees (14%, 4.0/1000ph). Similar injury rates were observed among playing surfaces (grass 28.9/1000 ph; artificial 28.7/1000 ph; p<0.973
CONCLUSION: Elite Rugby-7s players may cover a total of 1,400–2,000 meters at a mean intensity of 96–120 meters·minute–1 (Higham et al., 2012). Nearly one half of the non-contact injuries in our series occurred during open running. Injury preventive measures among developing populations such as the U.S. must include conditioning for these intense running demands of Rugby-7s, which should include incorporating repeated bouts of high-intensity running with appropriate work:rest ratios (Portillo et al., 2014) and proper warm up routines. This may minimize the match thigh, knee, and ankle non-contact injuries seen in the U.S. men Rugby-7s.

BIOMECHANICAL DIFFERENCES OF CUTTING MOVEMENTS BETWEEN FOOTBALL AND AMERICAN FOOTBALL PLAYERS INTERPRETED IN RELATION TO INJURY PREVENTION

KURZ, G.1, AST, B.2, STRUTZENBERGER, G.2, STEIN, T.1, SCHWAMEDER, H.2
1 KARLSRUHE INSTITUTE OF TECHNOLOGY , GERMANY; 2 UNIVERSITY OF SALZBURG, AUSTRIA

INTRODUCTION: Tears of the anterior cruciate ligament (ACL) is one of the most critical injuries in team-sports as football (FB) and American football (AF). Cutting movements are associated with noncontact ACL-injuries. Therefore, a comprehensive understanding of the relations between cutting performance and joint biomechanics is crucial (Joseph et al., 2013; Havens et al., 2015). Especially since cuts are an essential part of training in AF (Brock et al., 2014). Less is known about the mechanics in cutting movements and how a different execution in sports may affect the knee joint loads. The aim of this study was to investigate whether knee kinetics differ between AF and FB cuts.
METHODS: Twenty-four male athletes (12 AF, 12 FB) performed three cutting movements with different cutting angles (45°, 90°, 135°, 180°) to the dominant and non-dominant foot at maximum speed. The kinematics were recorded with Vicon cameras (250 Hz) and the dynamics were measured with two AMTI force plates (1000 Hz). Knee flexion moment (FM), valgus moment (VM) and rotation moment (RM) were calculated using an inverse-dynamic model (Dynamicus 9, Härtel & Hermsdorf, 2006) and analyzed at initial contact (IC) and the maxima over the entire period of the footrest. Univariate ANOVAs with post hoc tests (Tukey HSD) were performed to compare AF and FB groups.
RESULTS: The non-dominant leg showed no differences in knee kinetics between the groups. No differences were also found in FM across all cutting conditions. RMmax values were lower in FB compared to AF (p = 0.022). At 90° and 135° FB showed lower RM at IC compared to AF (p = 0.002). In addition, FB showed lower VM at IC compared to AF (p = 0.009) and a lower VMmax than AF (p = 0.034).
CONCLUSION: Overall, AF produced higher internal rotational moments and had to accept the higher internal rotational loads in the cutting movements than FB. High rotational loads are linked with higher knee loads, which consequently, are associated with increased risks of injury. A potential explanation of the higher moments in AF might be the subject-specific movement execution, especially the direction of the Plant-step, which is in line with the deceleration direction. Further evaluations are required to get a better understanding

of the mechanics in cutting movements to develop training programs that aimed at improving performance and reducing the risk of ACL injury.

INJURY EPIDEMIOLOGY IN AUSTRALIAN PROFESSIONAL SOCCER: SEASON 2012/13- 2016/17

LU, D.1,2, JONES, M.2, KOVALCHIK, S.3, STEINWEG, J.2, GELIS, L.2, DUFFIELD, R.1,2

1: UTS , 2: FFA , 3: TA .

INTRODUCTION: The negative consequences of injuries on player health and performance in football are well reported [1]. The first step in injury prevention is exploration and understanding of the extent of injuries within a cohort [2]. Presently only one study has reported injury epidemiology in Australian professional soccer [3]. However, such findings are outdated and may not reflect the current epidemiological profile of injuries in the A-League. Therefore, this study investigated the current injury epidemiology trends in the Australian A-League by reporting injury incidence and describing the frequency of injury type, region, mechanism and number of missed matches in all clubs over the last 5 seasons (seasons 2012/13 – 2016/17).
METHODS: During regular A-League competition rounds (n=27/season) over 5 seasons, 10 physiotherapists were contractually obligated to report injury data from their respective A-League teams. Injury data was reported on a weekly basis to the national governing body for collation and statistical analysis. Injury diagnosis was overseen by the Club physiotherapist who determined if the event met the definition of "any physical complaint requiring medical attention that results in an A-League match missed". Individual injury cases were aggregated to league-based injury and missed matches count per season. Injuries were further categorized by type, region and mechanism suggested in the consensus statement on football injury definition and data collection procedures [4]. Data is presented as a rate per season and 95% confidence interval (CI).
RESULTS: Over the 5 seasons 775 injuries were reported at 154.6 (144.1-165.9) per season. Poisson regression showed injury count linearly decreased over the reported period, though a spike was observed in 2014/15 ($p<0.01$). Hamstrings (25.1(21.1-29.9)), knee (24.6(20.6-29.3)) and ankle (19.7(16.2-24)) are the most common regions of injury. Additionally, injuries were most commonly Muscle/Tendon (86.2(78.4-94.7)) and Joint/Ligament (45.8(40.2-52.1). Missed matches increased significantly in 2013/14 and 2015/16 seasons compared to 2012/13 season ($p<0.05$ and $p<0.001$, respectively).
CONCLUSION: Comparable to European football data, lower-body injuries remain critical to player health and safety. Injury incidence continues to decrease in the A-League; however, the number of missed matches due to injury has increased. Consequently, assessing the severity of injuries may be a more meaningful outcome than just the injury incidence.

SEASONAL VARIATIONS OF HEAD INJURIES IN PROFESSIONAL MALE FOOTBALL (SOCCER) – AN 11 SEASON ANALYSIS AFTER A RULE CHANGE IN 2006.

BEAUDOUIN, F.1, AUS DER FÜNTEN, K.1, TRÖß, T.1, REINSBERGER, C.2, MEYER, T.1

1 SAARLAND UNIVERSITY, 2 UNIVERSITY OF PADERBORN

INTRODUCTION: Only limited information is available on the seasonal variation of head injury rates over multiple seasons in professional male football. This study aimed to investigate the seasonal variations of head injuries and their injury mechanisms in German professional football (soccer) since a rule change in 2006 (punishing direct and deliberate elbow to head contacts).
METHODS: Based on continuously recorded data from the German football magazine 'kicker Sportmagazin®' and further media-based sources, a database of head injuries in the 1st German 'Bundesliga' was generated comprising 11 consecutive seasons (2006/07-2016/17). Injury incidence rates (IR) and 95% confidence intervals (95% CI) were calculated. Injury mechanisms were analysed from video recordings. Time trends were analysed via linear regression (Ekstrand et al. 2013; Hägglund et al. 2016).
RESULTS: 238 match head injuries occurred (IR 1.77/1000 match hours, 95% CI 1.56 to 2.01). There were no significant seasonal changes, expressed as annual average year-on-year change, in IRs over the 11-year period for total head injuries ($p=0.693$), facial/head fractures ($p=0.455$), facial/head lacerations and abrasions ($p=0.162$), and head contusions ($p=0.106$). The annual average year-on-year increase for concussion was 6.4% ($R^2=0.623$, $b=0.064$, 95% CI 0.026 to 0.101, $p=0.004$). Five predominant head injury mechanisms (incl. elbow-head blows) were identified. There were no seasonal changes in head injury mechanisms over the study period.
CONCLUSION: Total match head injuries, most of the subtypes and their injury mechanisms remained stable with no seasonal variation over 11 consecutive seasons of the German 'Bundesliga' since the rule change in 2006. However, the subcategory concussion increased slightly year-on-year over the seasons which may either be a result of increasing match dynamics or raised awareness among team physicians. Ongoing head injury surveillance remains essential. Furthermore, preventative strategies are required to decrease head injuries in professional football.

ASSESSMENT OF RECENT INJURY STATUS AND FUNCTIONAL MOVEMENT SCREENING IN YOUNG FOOTBALL PLAYERS

TARNÓCZY, Z.1, BALOGH, L.2, SZENTES-SZENDREY, A.3, PUCSOK, J.M.2

1) UNDERGROUND TRAINING CENTER, NYÍREGYHÁZA, HUNGARY (2) UNIVERSITY OF DEBRECEN, INSTITUTE OF SPORT SCIENCES, DEBRECEN, HUNGARY (3) NYÍREGYHÁZI SPARTACUS, JÓZSEF BOZSIK FOOTBALL ACADEMY, NYÍREGYHÁZA

INTRODUCTION: The Functional Movement Screening (FMS) is a widely used assessment system to evaluate current and prior injury and training status. FMS scores enable sport professionals to discover individual movement patterns through identifing possible unbalances

in certain movements executed in both sides. Fundamental core stability, mobility and strength characteristics may be identified, thus corrected with sport-specific functional movement programme (Perry, 2017).
Implementing efficient movement strategies, such core training programmes may significantly reduce the risk of injuries (Chorba et al. 2010). Use of FMS scores may improve the quality of the training programme, age, history of injuries, training status may influence the evaluation of data. (Butler, 2011).

METHODS: Youth and junior football players were volunteered to take part in our examination. A total of 45 subjects participated in our study, their age varied from 16 to 19. Three age groups: U16, U17 and U19 members of József Bozsik Football Academy were represented in our research. We were specifically interested on key areas of injuries typical to football players. We used a special questionnaire, which was developed earlier by our research team (Pucsok et al. 2014). We implemented a five to one scoring system to identify the status of injuries from healthy (5) to surgical procedure was made (1). Finally, a complete FMS testing was performed, involving all participants.
RESULTS: Beside evaluating the total FMS scores of the participants, we choosed to specifically stress on further five test batteries out of seven. We hypothesized, that in this particular population, those five test batteries provide a more accurate estimate of the injury status, thus motor performance. We were trying to establish any significant relationship between total and selected FMS scores, and the status of more recent (within two years) injuries.
In this given population, we have not found significant relationship between total FMS scores and overall scores (5 to 1) of injury status. When we were examined selected FMS scores, we were able to identify some kind of trend, although the strength of the relationship was weak, except between the scores of deep squat (DS) and injury status of the left hamstring muscle, where we found moderate negativ correlation (r=-0.54).
CONCLUSION: Because of common human error during the test procedure, individual bias may distract the evaluation of FMS scores in some extent. After reviewing the related literature, we concluded, that FMS testing combined with other traditional motor skill tests (standing long jump etc.), and pneumatic training devices (such as Keiser) may provide a better estimate for functional performance. It is critical, to identify common injury patterns in the selected sport. Ball sports such as football, basketball and volleyball are both overwhelmingly asymmetrical in nature, with a dominant-side involved in a movement (kick, throw or a serve), so similar injuries may occur.

CARBOHYDRATE MOUTH RINSE FAILS TO IMPROVE VO2MAX TEST OUTCOMES

PIRES, F.O.1, BRIETZKE, C.1, PINHEIRO, F.A.1, FRANCO-ALVARENGA, P.E.1, DE MATTOS, E.C.T.2, VERAS, K.3, RODACKI, A.L.F.2, UGRINOWITSCH, C.1

1UNIVERSITY OF SÃO PAULO, 2FEDERAL UNIVERSITY OF PARANÁ, 3UNIVERSITY OF MOGI DAS CRUZES

INTRODUCTION: The carbohydrate (CHO) mouth rinse has been accepted as an ergogenic aid to improve endurance performance in different exercise modes. The likely mechanism underpinning the CHO mouth rinse effects on endurance performance is a greater reward system-cerebral activation that attenuates neuromuscular fatigue, thus ameliorating muscle activation (Jeffers et al., 2016). To the best of our knowledge, no study has been designed yet, to verify the CHO mouth rinse effects on VO2MAX test outcomes. Therefore, the present study aimed to verify this proposal.
METHODS: Nine recreational, experienced cyclists (36.9 ± 6.4 yr, VO2MAX of 54.3 ± 9.3 ml/kg/min, WPEAK of 333.4 ± 28.6 W) performed a VO2MAX test either after a CHO or a placebo (PLA) mouth rinse. The VO2MAX test consisted of a warm-up of 5 min self-paced exercise followed by 1 min controlled-paced exercise (100 W and 70-80 rpm). Thereafter, the intensity was successively increased (25W/min) until exhaustion. In a double-blinded, randomized order, participants rinsed their mouth for 10 s with CHO or PLA (spiting it out, thereafter) during the controlled-pace warm-up. Cardiopulmonary responses were assessed throughout the VO2MAX while ratings of perceived exertion (RPE) were obtained every stage.
RESULTS: Time-to-exhaustion (p=0.24), WPEAK (p=0.45) and VO2MAX (p=0.60) were comparable between CHO and PLA conditions. There was a moment main effect on ventilatory threshold (VT) expressed as %VO2MAX (p<0.001, ES=extremely large) and %WPEAK (p<0.001, ES=extremely large), so that VT1 intensity was lower than VT2. However, neither manipulation main effect nor moment by manipulation interaction was observed The RPE increased similarly throughout the VO2MAX test in both CHO and PLA mouth rinse conditions (p=0.56, ES=moderate).
CONCLUSION: In contrast to previous results reported in different exercise models, neither CHO mouth rinse improved performance in VO2MAX test as espressed as time-to-exhaustion and WPEAK, nor CHO mouth rinse improved outcomes such as VO2MAX, VT1 and VT2. In addition, RPE increase was comparable between CHO and PLA. It has been previously proposed that the effect of CHO mouth rinse on exercise performance is centrally-regulated, thereby suggesting that CHO mouth rinse improves central drive and reduce central fatigue. However, a body of literature has argued that VO2MAX test performance is peripherally-regulated, thus highlighting that CHO mouth rinse effect on performance is likely exercise model-dependent, possible with neglected effect on peripheral-regulated (Jacobs et al., 2018) exercises performance such as a VO2MAX test.

THE EFFECTS OF GOATS MILK, COWS MILK AND AN ENERGY-MATCHED CARBOHYDRATE DRINK ON RECOVERY FROM REPEATED SPRINTING AND JUMPING IN TEAM SPORT ATHLETES

CURRISTIN, M., FITZPATRICK, P., RANKIN, P.

INSTITUTE OF TECHNOLOGY CARLOW

INTRODUCTION: Effective recovery following intense exercise is integral for any athlete to ensure subsequent performance is not comprised. The aim of this investigation was to determine the effects of cows milk and goats milk on recovery from a sprinting and jumping protocol.

METHODS: Twenty-four team sport athletes participated in an independent group investigation. Participants were randomly but equally assigned to a goats milk group (GOAT), a cows milk group (COW) or an energy-matched carbohydrate group (CHO), with 750ml of the allocated fluid consumed following a sprinting and jumping protocol. Assessment of muscle function (peak torque (PkTq), 5, 10, 20m sprint, countermovement jump (CMJ) and soreness and tiredness (visual analogue scale (VAS)), took place pre- and 24h, 48h, and 72h post-exercise.
RESULTS: Compared to CHO, GOAT had a beneficial effect on CMJ B-24h (2 v -8%; likely, small) and B-48h (-1 v -6%; possible, trivial) and COW had a beneficial effect B-24h (-4 v -8%; possible, trivial). Comparisons of GOAT and COW showed a benefit for GOAT at B-24h (2 v -4%; possible, small) but other comparisons were trivial. Comparisons of GOAT and COW to CHO for peak torque revealed trivial or unclear outcomes, though a benefit for GOAT v CHO was seen at B-48h for peak torque (180○/s) extension (-3 v -11%; possible, small) and a positive effect for peak torque (60○/s) extension B-48h (-8 v -13%; possible, trivial) and B-72h (-5 v -9%; possible, trivial). GOAT compared to CHO had a harmful effect B-24h on 5m (0 v 1%; possible trivial), 10m (-1 v 0.3%, possible, trivial), and 20m (-2 v -1%; possible, trivial) sprint time performance. Unclear and trivial effects were found for B-48h and B-72h for all sprints. In comparison to CHO, a benefit for COW was found for 5m B-24h (1 v 1%; possible, trivial), B-48h (2 v 0.4%; possible, small) and B-72h (1 v 0.4%; possible, small). Similarly, for 10m B-24h (1 v 0.4%; possible, trivial) and B-48h (1 v -0.4%; possible, trivial). Likewise, for 20m B-24h (3.5 v 0.9%; likely, small). Comparisons of GOAT to COW on sprint time performance for 5m, 10m and 20m were unclear, however there was a benefit for COW from B-48h (-2 v 4%; likely, small). GOAT v CHO had a positive effect on soreness B-24h, B-72h (possible, trivial) and B-48h (possible, small). COW v CHO had a positive effect (possible, small) on soreness B-48h and B-72h (possible, trivial). GOAT v COW had a positive effect on soreness B-24h and B-72h (possible, trivial). Comparisons of GOAT and COW to CHO for tiredness revealed a positive effect B-24h, B-72h (possible, trivial) and B-48h (likely, small). GOAT v COW showed a positive effect for GOAT B-24h and B-72 (possible, trivial).
CONCLUSION: Consumption of 750ml of goats milk and cows milk minimised losses for some muscle function variables and limited increases in muscle soreness and tiredness. Thus both are potential valuable recovery interventions for team sport athletes, though additional investigation is necessary to further elucidate responses.

EFFECT OF A PROGRESSIVE RESISTANCE TRAINING PROGRAM AND WHEY PROTEIN INTAKE ON QUALITY OF LIFE IN HUMAN IMMUNODEFICIENCY VIRUS INFECTED INDIVIDUAL RECEIVING ANTIRETROVIRAL THERAPY.

SOOKAN, T., ORMSBEE, M.J., ANTONIO, J., MAGULA, N.P., MOTALA, A.A., LALOO, U.G., MCKUNE, A.J.
UNIVERSITY OF KWAZULU NATAL

INTRODUCTION: Advances in HIV treatment in the last three decades has resulted in improved health, prolonged life and substantially reduced the risk of HIV transmission. This impact broadens to all facets of life, influencing quality of life (QOL). Progressive resistance training (PRT) combined with effective supplementation can increase muscle mass and improve physical performance in persons with HIV infection and may enhance outcomes in these patients as well as improve QOL.
METHODS: Forty HIV infected participants (40.8 ±7.7 yrs, 70.8 ±16 kgs, BMI 30.9 ±7.2 kg.m2) receiving ART (≥18 months) were randomly assigned to either a whey protein/resistance training (RT) group (n=18), placebo/PRT group (n=14) or control group (n=8). Participants received either 20g whey or placebo (maltodextrin) pre and immediately post each RT workout. Whole body RT was performed 2/week for 12 weeks. To assess QOL the WHOQOL-HIV BREF 31 was used which has six domains: Physical (1), Psychological (2), Level of Independence (3), Social Relations (4), Environment (5), and Spiritual (6). The questionnaire was completed at baseline and then at 12 weeks. The mean score of questions within each domain was used to calculate the domain score. Statistical analysis consisted of a two-way ANOVA and Sidak's multiple comparison post hoc testing. Alpha was set at $P \leq 0.05$.
RESULTS: The Physical Domain showed a significant time effect (TE) (P=0.02) with the placebo group increasing from baseline (17.69a.u.) to post (19.15a.u) (Mean difference -1.5a.u., 95% CI -2.9 to -0.05a.u.). There were no significant changes in the supplement group. The Social Relationships Domain exhibited a significant TE (P=0.02) with the placebo group increasing significantly from 14.23a.u. to 16.54a.u post (Mean difference -2.3a.u., 95% CI -3.9 to -0.7a.u.). Environment Domain showed a significant TE (P=0.002) with both placebo (15.65a.u. to 16.46a.u.; mean difference -0.8a.u., 95% CI -1.5 to -0.09a.u.) and supplement groups (14.35a.u. to 15.03a.u.; mean difference -0.7a.u., 95% CI -1.3 to -0.04a.u.) demonstrating significant increases from baseline after 12 weeks of training. The Spiritual Domain indicated significant TE (P=0.05) with the placebo group increasing from baseline (16.38a.u.) to post (17.92a.u) (Mean difference -1.5a.u., 95% CI -2.8 to -0.3a.u.). There were no significant changes in the supplement group. There were no changes in the Psychological or Level of Independence Domains for the placebo and supplement groups. There were no significant changes in the control group for any of the six domains.
CONCLUSION: Several components of QOL improved in ART treated HIV infected individuals that participated in the PRT program. Changes were predominately shown in the placebo group (Domains 1, 4, 5, 6). This can be attributed to positive social and environmental effects of exercise programmes. Exercise training is an inexpensive and efficacious strategy for improving QOL in this population with can impact other facets of their lives.

EFFECTS OF RESISTANCE EXERCISE TRAINING AND FERMENTED SOYBEANS CONSUMPTION ON GLUCOSE TOLERANCE AND MYOKINES EXPRESSION IN HIGH-FAT DIET-INDUCED OBESE MIDDLE-AGED RATS

KIM, K., AHN, N., LEE, G.
KEIMYUNG UNIVERSITY

INTRODUCTION: Soybean is widely used as an ingredient in various Korean fermented products such as Cheong-guk-jang , Doenjang , and Gochujang . Among them, fermented soybeans such as Cheonggukjang are produced by fermenting with Bacillus subtilis in a relatively short period of time during which various enzymes, microorganisms, and bioactive compounds that are not found in unfermented soybeans are produced . This study aims to help increase the living qualities of seniors who suffer from sarcopenic obesity and low immune function as a result by providing solutions from identifying the effects of 12 weeks of resistance exercise and fermented soybean consumption for obese middle-aged Wistar rats.
METHODS: Male Wistar rats aged 50 weeks were fed a high fat diet for 8 weeks to induce obesity, followed by ladder climbing exercise and soybeans treatment for 12 weeks. Subjects were randomly divided into four experimental groups: control , soybeans group , resistance exercise , and soybeans plus resistance exercise . Proteins for CON and RE group were the standard casein proteins and those for SO and SR groups were substituted with fermented soybean proteins which were consumed in the form of pallets. The exercising groups underwent high-intensity intermittent training using a ladder-climbing and weight exercise 3 days/week for a total of 12 weeks.

RESULTS: In oral glucose tolerance test, glycemic responses of SO group and SR group, a group which received both the consumption of fermented soybeans and resistance exercise training, showed significantly higher improvements compared to those of the control group and resistance exercise group . There was no difference in the amount of plantaris muscle found among groups but the myokines expression related to immune senescence was significantly low for the SO group . However, no significant differences in IL-15 which is a preventative factor for immune senescence were found among the groups.
CONCLUSION: Han et al. <2017> has reported that soy leaf extracts are effective in reducing cytokines related to inducing inflammation. Mercer et al. <2017> has reported that soy protein isolates have inhibitory effects on high-fat diet-induced hepatoma proliferation in mice during which IL-6 and TNF-α expressions related to inducing inflammation are reduced. These results lead to the idea that consumption of fermented soybeans during obesity and senescence process can help improve glucose tolerance, and prevent inflammation and increase the immune function.

HYPERTONIC, ISOTONIC, HYPOTONIC SPORTS DRINKS AND NON-CARBOHYDRATE WATER EFFECTS ON PLASMA VOLUME DECLINE DURING CONTINUOUS EXERCISE: A META-ANALYSIS

ROWLANDS, D.

MASSEY UNIVERSITY

INTRODUCTION: Reduced blood and plasma volume coupled to exercise-induced dehydration is associated with higher cardiovascular strain and impaired performance. There is considerable interest, therefore, in sports drinks that best increase plasma volume, which is the arguably the best marker of relative hydration status and physiological end-point functional change during exercise. Osmosis and solvent drag properties support hypotonic carbohydrate-electrolyte solutions as most likely to be absorbed fastest across the gut wall vs more-concentrated drinks. Faster absorption should increase relative plasma volume; the published literature, however, is inconclusive. Therefore, the purpose of this research was to meta-analyse available datasets on the effects of ingested hypertonic (>300 mOsmol·kg-1), isotonic (275–300 mOsmol·kg-1), hypotonic (<275 mOsmol·kg-1) drinks containing carbohydrate and electrolyte ([Na+] <50 mmol·L-1), and non-carbohydrate and mineral containing flavored waters and water (<90 mOsmol·kg-1) on the delta % change in plasma volume (dPV) during continuous exercise.
METHODS: A systematic literature search to 31 Jan 2018 included studies that measured dPV during continuous exercise in healthy adults in response to continually ingesting the specified drinks. The search produced 21 studies and 59 single drink treatment type contrasts, with 199 measures of dPV over 0-180 min. A random effects mixed model (SAS 9.4) with repeated-measures of time binned into <35 min, 35-60 min, and 60-180 min provided estimates of drink effects. Fixed effects were Treatment*TimeBin and continuous predictor covariates drink ingestion rate, heat index, and metabolic rate. The random effects were intercept (between-study SD, heterogeneity), within-study contrast unique identifier, Treatment*TimeBin, and the subject term StudyID. The method of setting the residual variance to unity was used to apply the weighting. Weight was 1/SE derived from the reported SD with missing values imputed using a meta-regression weighted by 2DF.
RESULTS: Weighted mean (SD) dPV were hypertonic -8.6% (2.7), isotonic -7.6% (2.1), hypotonic -6.3% (2.6), water -7.4% (2.2). Estimates (95%CI) were (higher=more effective hydration) hypertonic-isotonic -0.0% (-1.4, 1.4), hypotonic-isotonic 1.7% (0.6, 2.8), water-isotonic 1.0% (-0.2, 2.2), hypotonic-hypertonic 1.7% (0.5, 2.9), hypertonic-water -1.0% (-2.2, 0.1), hypotonic-water 0.7% (-0.2, 1.6). The smallest standardised change score (0.2SD) vs isotonic was 0.6 making the hypotonic-isotonic and hypotonic-hypertonic contrasts very likely substantial, and the hypotonic-water increase possible. Adjusting for metabolic rate accentuated outcomes (e.g. hypotonic-isotonic 2.9%, 1.4, 4.3; hypotonic-water 1.0%, 0.1, 1.9), but ingestion rate and heat index had no impact.
CONCLUSION: Hypotonic carbohydrate-electrolyte drinks ingested continually during exercise provide very likely benefits to hydration vs hypertonic and isotonic, with benefits also possible relative to non-carbohydrate waters.

ENERGY EXPENDITURE DURING PALEOLITHIC-LIKE MOVEMENT PATTERNS – A PILOT STUDY

MARKS, N.

FACULTY OF SPORT SCIENCE, RUHR-UNIVERSITÄT BOCHUM

INTRODUCTION: Mimicking a paleolithic lifestyle including a paleo diet, plentiful sleep, and exercising in nature is associated with health-improving effects for overweight and diabetic people with a high cardiovascular risk [1]. It is estimated that the physical activity of ancestral humans accounted for about 1000 kcal/d and that caloric intake was typically about 3000 kcal/d [2]. Aim of the study was to analyse energy expenditure (EE) of paleolithic-like movement patterns during a 9-days hiking trip imitating a paleolithic-like lifestyle.
METHODS: 11 healthy sport students (age: 21.7 ± 2.2 y, VO2max: 49.2 ± 8.9 ml/min/kg, BMI: 23.9 ± 2.4 kg/m²) underwent a 9-day hiking trip mimicking a paleolithic-like lifestyle in the rural area of the Carpathians (d1-d9). The diet composition consisted of food high in fat and protein and low in carbohydrates with an energy intake of approximately 1700 kcal/d. Three typical activities were analysed: gathering (GA, n=7), fishing (FI, n=2) and hunting (HU, n=2). Portable spirometry with breath-by-breath technology was used to determine maximum oxygen uptake during activities (VO2peak) and EE. Furthermore, heart rate (HR) was measured continuously. Data are presented descriptively as non-parametric values (median and range).
RESULTS: Average EE during GA, FI, and HU was 362 (244-446), 194 (140-248), and 472 (451-494) kcal/h, respectively, equivalent to approximately 4.7, 2.6, and 6.0 MET. VO2peak was 36.4 (21.5-48.0), 25.1 (20.1-30.0), and 40.9 (40.3-41.5) ml/min/kg for GA, FI, and HU, respectively. Mean HR during GA, FI, and HU was 107 (55-169), 80 (60-110), and 116 (85-171) bpm, respectively.
CONCLUSION: The three analysed activities induced an energy expenditure similar to low and moderate sporting activities. With respect to the assumed energy expenditure of ancestral humans [2] about 3 hrs of gathering, 5 hrs of fishing, or 2 hrs of hunting would sum up to the estimated energy expenditure of about 1000 kcal/d. Assuming the daily needs for these activities during stone age energy expenditure of ancestral humans might have been much higher than 1000 kcal/d. The WHO recommends a target of a physical activity level (PAL) of 1.75 (490 kcal/d more than resting PAL of 1.4) to prevent obesity and reduce cardiovascular risk in sedentary populations [1]. Concerning these recommendations on physical activities for health, they are much lower than what our ancestors consumed daily.

REPRODUCIBILITY OF FMRI MOTOR CORTEX ACTIVATION DURING HANDGRIP CONTRACTIONS

ANDRUSHKO, J.W., GOULD, L.A., RENSHAW, D.W., BOROWSKY, B., FARTHING, J.P.

UNIVERSITY OF SASKATCHEWAN

INTRODUCTION: Current methods of functional MRI analysis can be subjective beyond the statistical threshold for comparing multiple voxels when generating activation maps. Therefore, the utility of fMRI to measure robust changes in brain activation over time would benefit from a systematic approach. This study investigated the reproducibility of repeated fMRI scans involving execution of a motor task.
METHODS: Eight healthy participants (5 male; 29±7yrs; 1.72±0.07m; 79.9±16.6kg) attended two fMRI sessions at least two days apart to perform an isometric handgrip task. Three maximal voluntary contractions (MVC) were acquired first, followed by three separate scans involving handgrip contractions at three sub-maximal intensities (25, 50, & 75% MVC) in random order. Functional imaging scans were block paradigms including five blocks of 20 volumes each; with five volumes for stabilization (105 volumes total). Each block was 10 volumes of task and 10 volumes of rest. Task blocks included five handgrip contractions alternated with equal rest, and rest blocks involved no movement. Coefficient of variation (CV%) values were calculated for data acquired on each occasion for handgrip MVC force, sub-maximal target forces, corresponding voxel number and intensity values for activation in motor cortex. Between session handgrip MVC (CV=8.4%) and sub-maximal handgrip intensities (CV: 25% MVC=6.4-8.3%; 50% MVC=8.4-11.6%; 75% MVC=7.5-9.7%) were reproducible across the five blocks on repeat occasions. Two threshold methods were used to compute brain activation in motor cortex. First, a fixed threshold method (FIXED) was used with a threshold set to r=0.65. Second, a novel relative threshold method (RELATIVE) was used to normalize within session brain activation prior to comparison. The RELATIVE method determined a window of activation using the highest threshold value before brain activation disappeared and the lowest threshold value for which the map was first 'clean' (i.e. no false activation as determined by the researcher). Based on this, the 50% value between these two thresholds was used to compute the maps. Therefore, a different threshold was used for each participant, occasion, and condition.
RESULTS: For the number of voxels, the RELATIVE threshold method resulted in similar or much better reproducibility across conditions; 25% (CV: RELATIVE=14.6%; FIXED=14.3%), 50% (CV: RELATIVE=11.5%; FIXED=25.3%), and 75% (CV: RELATIVE=13.6%; FIXED=29.4%). For signal intensity, reproducibility was excellent for both methods across conditions; 25% (CV: RELATIVE=3.0%; FIXED=1.3%), 50% (CV: RELATIVE=7.0%; FIXED=2.7%), and 75% (CV: RELATIVE=3.8%; FIXED=2.2%).
CONCLUSION: The novel relative method for determining threshold for activation maps improved motor cortex voxel count reproducibility during handgrip contractions. These data are useful for determining effect size and sample size estimates for intervention studies involving repeat measures of fMRI brain activation for hand motor tasks.

PHYSICAL ACTIVITY, ACTUAL AND PERCEIVED MOTOR COMPETENCE IN 6-9 YEAR-OLD CHILDREN: A WINDOW OF OPPORTUNITY?

VENETSANOU, F., AFTHENTOPOULOU, A.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

Introduction: Motor competence (MC) and perceived motor competence (PMC) are thought as key-correlates of lifelong physical activity (PA). This study aimed at investigating the association among PA, MC, and PMC in children aged 6-9 years. Moreover, potential gender differences were explored.
Methods: Participants were 143 children (Mage=7.6 years, SD=0.9; 67 boys). Their PA was recorded by Omron HJ-720IT pedometers for seven days; MC was assessed with the Bruininks-Oseretsky Test of Motor Proficiency-Short Form (BOT-SF; Bruininks & Bruininks, 2005) and PMC with the Pictorial Scale of Perceived Movement Skill Competence for Young Children-Greek version (PMSC-GR; Venetsanou et al., 2018).
Results: According to the ANCOVAs (age as a covariate) that were applied, there were no differences between boys' and girls' MC and PMC ($p > .05$). Both were motor competent and held positive MC perceptions. Nevertheless, pedometer data revealed that gender was associated with PA ($F=29.94$, $p < .001$, $\eta 2=.20$), with boys being more active (13365+3514 steps/day) than girls (10106+1872 steps/day). Moreover, girls' PA was significantly lower ($t=2.665$, $p=.010$) than the recommended levels for their age and gender (Tudor-Locke et al., 2011). Finally, according to the correlation analyses, there was not a significant association among PA, MC and PMC either in boys or girls ($p > .05$).
Discussion: It seems that, between 6 and 9 years, the relation among PA, MC, and PMC has not been formed yet. Since this relation is thought to strengthen as children get older (Stodden et al., 2008), this age appears to be "a window of opportunity" for enhancing MC and maintaining positive PMC to achieve lifetime PA participation. Moreover, further research for other PA correlates may provide valuable evidence if children's (and especially girls') PA is to be enhanced.

DEVELOPMENT OF MOVEMENT CONTROL IN VARIOUS PATTERNS OF HOPPING IN PRESCHOOL CHILDREN

SASAKI, R., ISHIZAWA, J.

KEIO UNIVERSITY

INTRODUCTION: Early childhood is an important period for the development of fundamental movement skills, and the various locomotive movements, such as hopping, galloping, and skipping, increase with age. Hopping is a rhythmically cyclic movement requiring signifi-

cant muscle strength, multi-limb coordination, and dynamic balance in order to be performed proficiently. In this study, we clarified the developmental characteristics of motor coordination, focusing on adaptation to the restricted patterns of hopping in preschool children.
METHODS: Participants were typically developing children, 94 boys and girls aged 4-6 years. They were asked to pursue the following 4 tasks: 1. one-foot hopping, 2. alternating hopping in every three hops, 3. both feet hopping (jumping), 4. hopping with a pattern sequence with either one or two feet. In each task, they hopped forward according to the frames indicated on the floor. We filmed all their movements and analyzed the footage. We then evaluated observations of children's movements using certain criteria. We focused on the temporal and spatial control and bilateral coordination during these tasks. Mastery of the movement tasks were compared among older and younger children.
RESULTS: In task 1, about 30% older children and less than 10% younger children completed the task. In task 2, few children completed the movement sequence. In task 3, the rate of accomplishing the task was higher than the other one-foot hopping tasks in both age groups. In task 4, approximately 30% boys and 50% girls accomplished the task. However, younger children had some difficulties, and paused and faltered while executing the sequence.
CONCLUSION: Overall, the rate of accomplishing each task was higher in older than younger children. Furthermore, older girls showed more advanced performances in all tasks. The preschool years are important for learning and acquiring good hopping techniques (Gallahue et al., 2012). An adequate hopping pattern was shown at around 5 years of age, with girls showing this pattern several months earlier than boys (Seefeldt and Haubenstricker, 1982). In this study, those tasks required continuous adaptation to balance and bilateral coordination. It is considered to be difficult for younger children to execute hopping with non-dominant foot, and control rhythmic alternation of bilateral extremities.

APPROACHING PERFORMANCE CONTROL IN GYMNASTICS: ARE WELL-ESTABLISHED HANDSTAND COACHING CONCEPTS SUFFICIENT FOR MOTOR SKILL ACQUISITION?

ROHLEDER, J.

GERMAN SPORT UNIVERSITY COLOGNE

INTRODUCTION: According to the upright stance, successful postural control in human handstand performances can be modelled as a single segment inverted pendulum which is mainly controlled by wrist flexor torques. However, despite the dominant contributions of wrist torques, common handstand coaching concepts primarily focus on developing the aligned fixed body configuration. Therefore, this study challenged the effects of a sole postural training on the maintenance vs. the execution quality in handstands in competitive young gymnasts.
METHODS: Twenty-two participants (13 females, aged: 8.54 ± 1.56 years; 9 males, aged: 8.67 ± 0.87 years) were randomly assigned into two counterbalanced groups, GPT (guided postural training) and CON (control, no training intervention), each n = 11. Within one week, GPT received four standardised training sessions (T1, T2, T3 and T4) including augmented feedback and instructions addressing a straight body posture. Prior to T1 (pre-test), after T2 (mid-test) and after T4 (post-test), all participants (GPT and CON) were asked to perform five handstands focussing on a long balancing time. Standardized video recordings captured the balancing time and postural execution during the handstands that were subsequently assessed by four international-level gymnastic judges.
RESULTS: ANOVA results revealed no changes in balance time in GPT ($p > .05$), whereas divergent changes for postural execution were observed for the groups ($p < .05$) in favour of GPT. ANCOVA results showed that the impact of GPT increased with age, leading to postural changes at the expense of decreased balance abilities. Positive correlations between balance time and postural execution were revealed at all three times of measurement (pre, mid, post; each $p = .01$).
CONCLUSION: The present findings raise doubts about the benefits of sole postural training on enhanced handstand balancing abilities. Considering the importance of wrist contributions for maintaining the handstand, we attribute these findings to the continuative hypothesis that explicit information regarding the forearm work is of utterly importance for accelerated handstand acquisition processes. Furthermore, decreased balance times that were observed in older gymnasts were accompanied by short-term enhanced postural performances. Enhanced cognitive capacities compared to less-experienced gymnasts may facilitate the implementation of additional declarative knowledge, but may also impair already automated motor processes in terms of balance control. This would explain facilitated joint angle adjustments at the expense of unknown and, thus, disrupted equilibrium in handstand performances. With respect to the mutually dependences of balance and postural alignment in handstands, further motor behavioural research is needed approaching wrist-related advice in handstand acquisition.

EFFECT OF VISUAL TRAINING IN TENNIS PERFORMANCE. A RANDOMIZED CONTROLLED TRIAL

GATTI, C., LA TORRE, A., BONATO, M.

UNIVERSITÀ DEGLI STUDI DI MILANO

INTRODUCTION: Tennis is a direct opposition sport in which the result of the game is directly influenced by the interaction with the opponent. Therefore, the athlete has to respond to the different playing situations analysing in a short period of time direction, speed and rotation of the ball. "Visual training" is a training method that helps to receive and process different information optimizing the subsequent performance with extreme precision and dexterity. Therefore, the aim of the present study was to investigate how this training method could affect visual and tennis performance in junior tennis players.
METHODS: This was a randomized controlled trial in which 18 junior tennis players were recruited and randomized to either en experimental group (EG; n=10; age 15±3 years; body mass 52±11 kg; height 1.67±0.1m) that performed 30 min visual training after the warm-up or a control group (CG; age 15±3.1; body mass 53.5±12kg; height 1.7±0.1) that was involved in a standard training. Players were tested before and after 12weeks of training (3 session/week) with Motor Brain application (iOS 7.1 version, University of Udine) for off court reaction time measurement, QLIPPTM sensor for backhand, forehand and serve sweet spot and speed, and Kinovea software (Version 0.8.15, France) to evaluate the time course between split steep and shoulder rotation. Results are given as mean ± standard deviation (SD). T0 and T12 intervention intra- and intergroup differences between EG and CG were checked using two-way analysis of variants with Tukey post-hoc test.

RESULTS: No significant differences regarding off court reaction time during the two signals and four signals reaction time measured with Motor Brain application were noted. Regarding specific tennis performance improvement over baseline were noted for the time course speed between split steep and shoulder rotation for forehand (0.84±0.07 vs 0.57±0.11 sec, p=0.0008), backhand (1.02±0.12 vs 0.66±0.12 sec, p=0.001), and return of serve (0.96±0.13 vs 0.72±0.08 sec, p=0.0007). In addition an improvement over baseline values for second serve speed was noted (59.6±34.9 vs 122.6±32.8 km/h, p=0.0008). Differences were noted in post-intervention for the time course speed between split steep and shoulder rotation for forehand (0.57±0.11 vs 0.90±0.15 sec, p=0.0001), backhand (0.66±0.12 vs 0.95±0.17 sec, p=0.012), return of serve (0.72±0.08 vs 1.08±0.11 sec, p<0.0001) and second serve speed (122.6±32.8 vs 84.7±24.1 km/h, p=0.043).
CONCLUSION: Visual training improved specific tennis performance in junior tennis players. Incorporating this type of training into the workout routines may optimize precision and dexterity of tennis performance.

INFLUENCE OF AN INCREASED NUMBER OF PHYSICAL EDUCATION LESSONS ON MOTOR ABILITY AND SELF-ESTEEM

REIF, A., TSCHAN, H., WEIß, O.

UNIVERSITY OF VIENNA

Physical activity and sports can be seen as a promotor for physical and mental development and plays a significant role in shaping the personality (1). As a result, lack of physical activity especially in prepubertal age and adolescence has negative influences on their physical, mental and social well-being. Less than a fifth of Austrian students (17,4%) fulfils the physical activity recommendations (2) which amount at least 60 minutes of physical activity in moderate intensity daily (3). Previous studies demonstrated a significant relation between physical education lessons and the development of motor ability as well as self-esteem (4). Thus, the Austrian government supports the inception of an increased number of physical education (PE) lessons in schools with the intention to reach children and adolescences in all social classes and lead them to a more active and healthy lifestyle. Therefore, the aim of this study is to assess the effect of two additional PE lessons weekly on children's motor-skills and their self-esteem.
141 pupils aged 12-14 years volunteered to participate in this study. The sample comprised an observation group (n=57) with five weekly PE lessons and a control group (n=84) with three weekly PE lessons during an observation period of 1.5 years. During this period pupils were tested every 6 months. The data collection tools used were a test module for motor skills (Deutscher Motorik-Test 6-18), a tool measuring self-esteem (ALS-Test), and a questionnaire on the movement behavior outside school. A two-way analysis of variance (ANOVA) was used to detect significant differences between time and groups. An alpha-level of $P < 0.05$ was considered to be statistically significant. Preliminary results suggest a strong trend of improved motor ability in the observation group, especially in endurance (i.e. 6 min run). Furthermore, results of the questionnaire suggest that self-esteem is higher in the observation group compared to the control group. The principal findings of the study were that pupils having more than the usual hours PE tend to score higher in the Deutsche Motorik-Test and have a stronger self-esteem. These results suggest that more hours of PE have positive effects on motor skills as well as self-esteem.

DIFFERENTIAL EFFECTS OF COMBINED MOVEMENT AND STORYTELLING INTERVENTION ON MOTOR SKILLS IN SOUTH ASIAN AND WHITE CHILDREN AGED 5 -6 YEARS LIVING IN THE UK.

EYRE, E.L.J.1, DUNCAN, M.J.1, LOWTON-SMITH, S.1, HODSON, D.2, DOBELL, A.1

1: COVENTRY UNIVERSITY , 2: LEEDS TRINITY

Introduction: Early motor skill development has an important role in promoting physical activity (PA) during childhood, and across the lifespan. There is some evidence to suggest that both motor skill performance (Eyre et al., 2017) and physical activity levels are lower in children from Indian, Pakistani and Bangladeshi backgrounds (South Asian) compared to White (Eyre et al., 2013). Combined movement and storytelling interventions has shown improvements in children's motor skills compared to motor skill intervention alone (Duncan et al., 2017). However, whether children across ethnic groups benefit the same from these interventions has not been studied. This study examined the effect of a combined movement and storytelling intervention for 12 weeks on motor skills in children from South Asian backgrounds compared to White peers matched for deprivation.
Methods: Following ethics approval and parental informed consent, 46 children (27 White, 19 South Asian, 14 boys; 32 girls aged 5-6 years) from 2 schools, participated in quasi-randomised study. Schools were matched by deprivation, and children underwent a 12 week combined movement and storytelling intervention. Pre and post, 4 motor skills: run, jump, throw, and catch were assessed the Test of Gross Motor Development-2. The scores for all the skills were then summed to create a total motor competence score (0-30). Weight status was assessed using BMI.
Results: Results from a 2 (pre vs post) X 2 (group) way repeated measures ANCOVA revealed a significant time X ethnic group interaction for motor competence ($P = .013$). No interaction between time and gender, nor main effects were found. Both ethnic groups motor competence improved as a result of the intervention from baseline (White $\Delta = 4$, South Asian $\Delta = 9$). At baseline, White children had a significantly higher total motor competence score compared to South Asian children (18 ± 5 vs 15 ± 4, $P = .014$), however following the intervention there was no significant difference between these ethnic groups ($P= 0.137$, White 22 ± 5 vs South Asian 24 ± 4).
Discussion: The results of this exploratory study suggest that a) Motor competence may be developmentally delayed in South Asian children compared to deprivation matched white peers and; b) A combined movement and storytelling intervention results in beneficial changes to motor competence as well as narrowing the motor competence gap between South Asian and white children's ethnic groups.

RELATIONSHIP AMONG BIOLOGICAL MATURATION, ANTHROPOMETRY AND MOTOR ABILITY IN YOUTH ELITE SOCCER PLAYERS

ITOH, R., HIROSE, N.

WASEDA UNIVERSITY

INTRODUCTION: In youth soccer players, the differences in biological maturation affect anthropometrical and physiological development. Conversely, in a young setting, coaches evaluate a player's performance by their motor ability, e.g., speed and power. Thus, studies have reported that early-matured players, unlike late-matured players with lower motor ability (i.e., jump power), may be regarded as elite players within the same age group. Therefore, to evaluate a player's future performance, coaches should identify the motor ability influenced by the difference in players' biological maturity. Hence, we aimed to investigate the cross-sectional relationship among skeletal age (TW3), anthropometric, and motor abilities in youth elite soccer players.
METHODS: We enrolled 38 youth male soccer players (12.2±0.6 y) belonging to the J League academy club. Height, weight, body fat percentage, foot size, circumference girth (thigh/calf), and flexibility were measured. Measurements related to the 10m/50m sprint, 10m×5 shuttle run, crank test, 5-step bounding, Yo-Yo IR2, and cooper run were conducted. Further, individual radius-ulna-short bone score, evaluated using the left hand X-ray, was converted into the skeletal age (SA) using a TW3 conversion table. The participants were divided into Late, Average, and Early maturation groups as per the following criteria: SA-CA<−1 year, SA-CA=±1 year, and SA-CA>+1 year, respectively. The difference in parameters among the groups was analyzed using ANOVA and Turkey's post hoc test. Statistical significance was set at $P<0.05$.
RESULTS: The Early group participants were taller and their foot size and circumference were bigger than those of the Average group (163.8 ± 5.1 vs.151.8 ± 8.2 cm, $p<0.001$; 26.0 ± 0.9 vs. 24.8 ± 1.4 cm, $p=0.046$; 33.6 ± 1.9 vs. 31.5 ± 2.0 cm, $p=0.010$; respectively). Further, all the anthropometric parameters of the Late group (144.5 ± 5.5 cm, $p=0.028$; 23.6 ± 1.4 cm, $p=0.047$; 29.8 ± 1.4 cm, $p=0.041$; respectively) were lower than those of the Average group. Conversely, the Early group was significantly faster in the 10m (2.01 ± 0.08 vs.2.11 ± 0.05 sec, $p=0.011$) and 50m sprints (7.65 ± 0.33 vs.8.16 ± 0.30 sec, $p=0.016$) and scored higher in the 5-step bounding (10.03 ± 0.63 vs.9.13 ± 0.43 m, $p=0.006$) than the Late group; there was no difference among the groups regarding other parameters.
CONCLUSION: These results indicate that the difference in biological maturity influences the anthropometrical and physiological development, particularly muscular power. Therefore, coaches should consider maturation levels while evaluating muscular power. Conversely, endurance (Yo-Yo IR2 and cooper run) and agility (10m×5 shuttle run and crank test) were not significantly different among the three groups, implying that endurance and agility are independent of biological maturation. They may depend on other factors such as technique, coordination, and cardiopulmonary function rather than muscle power. This research may help to achieve a fair evaluation of players.

EFFECTS OF THE 12-WEEK CLIMBING-SPECIFIC HOME-BASED EXERCISE PROGRAM "HEIMSPORT" ON MOTOR FUNCTION AND LIFESTYLE IN PERSONS WITH MULTIPLE SCLEROSIS

GRAF, A., SPITZENPFEIL, P., KERN, C.

TECHNICAL UNIVERSITY OF MUNICH

INTRODUCTION: While positive effects of physical activity to limit the progression of multiple sclerosis are well-known, people with multiple sclerosis (PwMS) still tend to be less physically active than their healthy counterparts. Home-based exercise programs represent a major opportunity to encourage physical activity among PwMS. Several studies exist which include endurance and strength exercises, but no home-based exercise program for a single specific sport has been researched so far. The aim of this study was to evaluate the feasibility and effectiveness of such a home-based exercise program with a focus on climbing ("heiMSport").
METHODS: The study includes 31 PwMS (mean age 52 ± 7 years), all members in the therapeutic climbing group "MS on the Rocks". Once a week participants are enrolled to take part in therapeutic climbing lessons. The intervention group (n = 14) is encouraged to practice the home-based exercise program additional to therapeutic climbing twice a week, while the control group (n = 17) only took part in the climbing sessions. Data for motor functions (leg strength: Isomed 2000; walking speed: T25FW), physical activity (Baecke), self-efficacy (SWE), fatigue (WEIMuS) and quality of life (HAQUAMS) are collected in pre-post design after three month. Also the feasibility and effectiveness of program were explored (ZUF-8).
RESULTS: All participants were totally satisfied (100 %) with the structure of the program and the comprehensibility of the exercises. 79 % could integrate the home-based exercise program easily in their daily life. A high acceptance rate was achieved and the dropout of 8.8 % was very small. Significant improvements were seen in leg strength (p-value 0.00, ES 0.99), walking speed (p-value 0.03, ES0.64) and in self-efficacy (p-value 0.05, ES0.60). QoL, fatigue and physical activity did not change significantly.
CONCLUSION: The newly developed program heiMSport combines a regular sports activity with a home-based exercise program. The minor dropout in comparison to former studies and the high satisfaction and acceptance demonstrated the good feasibility of this program. Significant effects on motor functions and psychosocial parameters were shown. A high acceptance was achieved and the connection to their individual sports and to the therapeutic climbing group "MS on the Rocks" may be decisive. Furthermore the positive effects of individual physical activity for people with multiple sclerosis were again proved. A combined regular sports with a home-based exercise program seems to represent a more successful program to increase physical activity sustainably.

BONE MINERAL DENSITY AND ASSOCIATED GENETIC VARIANTS IN HIGH-LEVEL CAUCASIAN MARATHON RUNNERS

HERBERT, A.J.1, WILLIAMS, A.G.1, LOCKEY, S.J.1, ERSKINE, R.M.2, SALE, C.3, HENNIS, P.J.3, ANTROBUS, M.R.1, BRAZIER, J.1, HEFFERNAN, S.M.4, DAY, S.H.1, STEBBINGS, G.K.1

1:MANCHESTER METROPOLITAN UNIVERSITY , 2:LIVERPOOL JOHN MOORES UNIVERSITY , 3:NOTTINGHAM TRENT UNIVERSITY , 4: UNIVERSITY COLLEGE DUBLIN,

INTRODUCTION: Endurance runners (except those who may have low energy availability) tend to have higher total and/or loading site-specific bone mineral density (BMD) in comparison with non-athletes, most likely due to the larger volume of exercise completed. A large

genetic component also contributes to BMD, although little is known about which specific genes are involved, whether particular genotypes are sensitive to mechanical loading and the impact of such an interaction on BMD. This study investigated if high-level endurance runners possess enhanced BMD associated with an "advantageous" genetic predisposition, via a potential gene-physical activity interaction.
METHODS: Age- and weight-adjusted total BMD (TBMD) and leg BMD (LBMD) measured via Dual-energy X-ray absorptiometry of 67 high-level Caucasian marathon runners (males < 2 h 45 min, n = 37; females < 3 15 min, n = 30) was compared with 40 male and 26 female non-athletes. LRP5 rs3736228, TNFRSF11B rs4355801, VDR rs2228570, WNT16 rs3801387 and AXIN1 rs9921222 variants were then investigated singularly, and collectively, as a total genotype score (TGS) via multivariate analysis of variance in a subgroup of this cohort (male runners n = 19, controls n = 26; female runners n = 17, controls n = 14).
RESULTS: Male runners had higher TBMD (1.34 vs 1.28 g/cm2; P=0.02) and LBMD (1.53 vs 1.42 g/cm2; P=<0.01) than non-athletes. Female runners had higher LBMD than non-athletes (1.30 vs 1.22 g/cm2; P=0.02) but not TBMD (1.23 vs 1.18 g/cm2; P=0.22). An interaction (P=0.047) was observed between VDR rs2228570 genotype and group regarding LBMD in males: ff genotype runners had 0.02 g/cm2 higher LBMD than FF or Ff runners, but the FF genotype had the highest LBMD (1.45 g/cm2) amongst non-athletes. LBMD was also 0.12 g/cm2 higher in ff runners compared to ff non-athletes, whereas FF and Ff runners had 0.09 g/cm2 higher LBMD compared to their genotype-matched controls. No other interactions or variants, individually or collectively as part of a TGS, were associated with BMD (P≥0.11).
CONCLUSION: High-level female runners possess higher LBMD but not TBMD in comparison with non-athletes whereas male runners possess both higher TBMD and LBMD than non-athletes. Consistent with prior literature, we observed higher BMD in VDR rs2228570 FF genotype in non-athletes, which may be due to increased biological activity associated with the F variant. However, our preliminary data suggest that the ff genotype may be associated with enhanced LBMD in male runners via a gene-environment interaction.

INVESTIGATION OF POWER ABILITIES IN PROFESSIONAL FUTSAL PLAYERS

BERDNIKOVA, A., ZAKHAROVA, A., TARBEEVA, N.

URAL FEDERAL UNIVERSITY

Introduction: The specificity of the competitive activity in futsal involves high-intensity/high-speed and power intermittent work with variable rest intervals between player changes during the game and requires a high level of the players power capabilities. The insufficient number of research data in the field of the power abilities assessment of elite and sub-elite athletes in futsal determined the relevance of the study. Therefore, the aim was twofold – to assess the power and to test a repeated triple Wingate test in the power performance of top level futsal players.
Methods: The professional futsal club players (n=10, age 27,0±4,8 years, height 181,4 ± 7,4 cm, weight 78,8±8,4 kg, VO2max 51,6±6,6 ml/kg/min) underwent repeated (triple) Wingate test with 3 minutes rest interval between sets. Peak power (PP), average power, the time of peak power reaching (TPP) and the fatigue index in each set were under consideration.
Results: A high level of power preparedness (PP 11,74 ±0,8 W·kg-1) was determined in the tested group of athletes. The PP higher than 12 W·kg-1 was revealed in 50% of the players. 40% of futsal players showed a rapid achievement of PP (earlier than the 5th second).
Peak power was the highest in the second set in 60% of the players whereas the best values of TPP were showed in the second Wingate test by 40% of the tested athletes.
In 50% of athletes there was a gradual increase of the fatigue index during the repeated Wingate test while stable value of the fatigue index (within the 5% range) was fixed in 30% of the players that provides a high level of power endurance.
On average, the decrease in peak power and average power in the best and last approach of the Wingate test was 10.82 ± 6.55% and 14.27 ± 6.16%, respectively.
Conclusion
The achievement of the highest values of PP and average power can have place not only in the first attempt but also in the second set of the repeated Wingate test.
The assessment of power and power dynamics in three sets of Wingate test reveals a range of possible variations in the athletes' results and helps the coach to identify players' capabilities of repeatedly withstanding high intensity during attacks and counterattacks, which is extremely important for competitive activity in futsal.

BODY MASS CHANGES OF LOCAL AND INTERNATIONAL ELITE MARATHON RUNNERS IN THE TROPICS

TAN, X.R.1,2, LOW, C.C.2, LEE, J.K.W.2,3

1: NUS GRADUATE SCHOOL FOR INTEGRATIVE SCIENCES AND ENGINEERING, 2: NATIONAL UNIVERSITY OF SINGAPORE, 3: DSO NATIONAL LABORATORIES, SINGAPORE

INTRODUCTION: Prolonged exercise under a hot and humid environment leads to rapid body fluid loss due to profuse sweating. This is especially important to marathon races conducted in the tropics where the rate of sweat loss will be the fastest. The amount of dehydration accrued in elite marathon runners has yet to be directly measured in the real-world setting. Hence, we recorded the body mass changes in local runners and international elite runners after a marathon organized in a tropical country (Standard Chartered Singapore Marathon; SCSM).
METHODS: A total of 32 runners' body mass data was collected in SCSM 2017. Immediately before and after the marathon, the participants weighed themselves in their race attire. Body mass was measured to the nearest 0.01kg with an electronic balance scale (Mettler-Toledo GmBH, Giessen, Germany) placed on a flat surface. To account for the sweat retained in the clothing after the run, a set of running attire was soaked in water and weighed. The measured mass was subtracted from the post-run body mass. Any water intake by the runners after the end of marathon was estimated as accurate as possible and was included in the calculation for body mass changes. The ambient temperature and humidity were measured by a heat stress monitor before and after the marathon.
RESULTS: Valid race and body mass data was obtained from 20 runners - eight local runners (Singaporeans; SG) and 12 international elite runners (11 Kenyans and 1 Kazakhstan; INT). The runners were mixed gender (SG: 3 males, 5 females, INT: 6 males, 6 females) and their age ranged from 24 - 41 yrs old. Mean dry bulb temperature and humidity were 27.9°C and 78%. Median race timings for all runners was 160.7 mins. INT runners performed better than SG runners (155.9 mins vs 197.8 mins). Mean body mass loss and % mass loss for all runners were 2.6 kg and 4.8%. The mean body mass loss and % mass loss in SG runners were lower than the INT runners (2.0 kg vs 2.9 kg; 3.8% vs 5.5%).
CONCLUSION: While it is uncertain if the INT runners could have performed better if they opted for a more aggressive hydration plan, our data nonetheless showed that elite INT runners opted to hydrate less during a self-paced marathon as compared to SG runners.

THE INTERACTIVE EFFECTS OF SITUATIONAL VARIABLES ON TEAM PERFORMANCE IN NBA

SHAOLIANG, Z.

POLYTECHNIC UNIVERSITY OF MADRID

INTRODUCTION: Existing performance analysis has identified the effects of situational variables on sports performance at a behavioural level. However, the examination of situational variables in isolation would provide limited insight into the complex nature of team sports performance (O'Donoghue, 2009). Therefore, the aim of this study was to consider the potential interactive effects of situational variables when assessing team's performance.
METHODS: Archival data were obtained from NBA website during the 2015–2016 regular season. A total of 699 games that ended with final score differences equal to or less than 10 points were selected. The team quality was decided by final team ranking in the NBA league. Magnitude-based inferences were applied to identify differences between winning and losing teams under situational efficiency (Hopkins et al., 2009).
RESULTS: When weaker teams played against weaker teams, winning team secured more defensive rebounds (EShome=-0.62; ESaway=-0.85) and made more points inside the paint area (EShome =-0.29; ESaway=-0.32) than losing team for home and away games, respectively. When stronger teams played against weaker teams, winning teams secured more defensive rebounds (EShome =-1.07; ESaway=-0.85) and scored more points from the middle-range area (EShome =-0.73; ESaway=-0.43) than losing team for home and away games, respectively. When stronger teams played against stronger teams, winning teams secured more defensive rebounds (EShome=-0.49; ESaway=-0.69) and made more free-throws (EShome=-0.62; ESaway=-0.26) than losing team for home and away games, respectively.
CONCLUSION: The current study identified difference in team's performance between winning and losing teams under different situational variables at the NBA league. These findings were in line with (Gomez et al., 2008) demonstrating that 'defensive rebounds' were a key performance indicator to winning basketball games. In addition, our study indicated that stronger teams tend to shoot in the middle-range area or made more free-throws when playing against weaker or stronger teams, while weaker teams tend to make more points in the paint area when playing against weaker teams. It is possibly suggested that team's performance is affected by the quality of the opposition (Sampaio et al., 2010).

THE EFFECTS OF DIFFERENT UNSTABLE CORE MUSCLE TRAINING METHODS ON THE TRUNK STABILITY IN FEMALE BASKETBALL PLAYERS

LIANG, I.J., LIN, L.L., HUANG, C.C., LI, G.J.

GRADUATE INSTITUTE OF PHYSICAL EDUCATION, HEALTH & LEISURE STUDIES, NATIONAL CHENG KUNG UNIVERSITY, TAINAN, TAIWAN

INTRODUCTION: Basketball is a high speed, intense, physical game that demands exceeding strength, power, speed, balance, coordination, and dribble control. Trunk position is not only related to the performance of the physical fitness but also important for the balance and stability of the whole body (Shinkle et al., 2014). The TRX® Suspension Training has been shown to be an effective device for eliciting an increased core muscle endurance and core muscle activation. Besides, Swiss ball core muscle training can improve the core muscle strength and the neuromuscular recruitment. To our knowledge, only few studies have discussed the effects of different unstable core muscle training methods on the trunk muscle abilities. Therefore, the purpose of this study was to investigate the effects of the two training methods on the trunk stability in female basketball players.
METHODS: 34 healthy elite female basketball players (age: 14.76± 1.84yrs, BMI: 21.41± 1.96 kg/m2) were assigned to either TRX training group (n=17) or Swiss ball training group (n=17). All participants performed a progressive program consisting of 3*8 sessions twice-a-week unstable core muscle training for 8 weeks under supervision.The main outcome measures were "core muscle strength and stability test" and the performance of modified double leg lowing task (MDLL) for trunk stability. These parameters were evaluated before and after the 8-week core muscle training. Independent Sample t test was used to determine the differences of baseline data. Two way ("group" x "time") analysis of variance (ANOVA) with repeated measures on "time" was used for analyzing the effects of core muscle training on variables of trunk muscle abilities. Scheffés post-hoc comparison was used to determine the differences between groups.
RESULTS: A significant group x time interactions were found for MDLL task in TRX group (p=.021). In MDLL task, TRX group (8.6%,) increased significantly more than Swiss ball group (2.9%)(p<.05). The score of core muscle strength and stability test increased in both TRX (182%) and Swiss ball groups (168%) (p=.001), but no significant difference was observed between the two groups.
CONCLUSION: A previous study indicated that the score of MDLL task could represent the ability of maintaining the spine in neutral position (Butcher et al., 2007). The main result of this study shows that the trunk stability (score of MDLL task) in TRX was significantly higher after the 8-week training. TRX core muscle training may have a greater effect on the trunk control ability and muscle activation than Swiss ball core muscle training (Mok et al., 2015). In addition, this study also found that both TRX and Swiss ball training could increase core muscle strength and stability. In conclusion, both unstable core muscle training methods could enhance trunk control ability. Consequently, considering the goal was to improve the trunk muscle abilities, TRX training was the more preferable choice especially for the control ability.

MOVEMENT COMPETENCY IN JUNIOR ATHLETES: PILOTING AN ATHLETE PATHWAY ASSESSMENT TOOL

ROGERS, S.A.1,2, HASSMÉN, P.1, ALCOCK, A.1,2, ROBERTS, A.H.1, WARMENHOVEN, J.1, GILLEARD, W.2, WEISSENSTEINER, J.R.1

1: AUSTRALIAN INSTITUTE OF SPORT , 2: SOUTHERN CROSS UNIVERSITY

INTRODUCTION: Movement competencies form the foundations for the development and training of young aspiring athletes. Yet formal assessment of such capabilities can be overlooked within early athlete programs, arising from the wide range of assessments varying in length, difficulty, and reliability in the current literature. The aim of this study was to assess the reliability of a simple assessment tool of

four key movement patterns and subsequently evaluate its effectiveness and application to younger athletes, first entering a formal sporting system.
METHODS: Eleven junior athletes (7 male, 4 female; 15.0±1.4 years) were assessed in four movement tasks using a selection of criteria from previous reliable batteries in adolescent (Lubans et al. 2014) and adult (McKeown et al. 2014) populations. Each athlete performed two sets of four repetitions of an overhead squat, lunge, push up, and a straight-arm prone brace with alternating hand touches to the opposite shoulder. Movements were scored retrospectively via video against four criteria per movement, on a 1-3 scale. For intra-rater reliability, the same movements were scored on two occasions, three weeks apart. Athletes were reassessed under identical conditions, seven days apart, for between-day reliability. Reliability was deemed acceptable if mean difference (Mdiff) was <5%; typical error (coefficient of variation; CV) was <10% and intra-class correlation coefficient (ICC) was >0.7.
RESULTS: The composite movement scores from a possible total of 48 points, ranged from 24 to 47 points in this cohort. Assessing the same videos twice, scores were (mean±SD) 39.2±5.1 and 39.4±5.9 points. Day one and day seven performances were 38.8±5.5 and 39.2±5.1 points respectively. Both the intra-rater (Mdiff=1.0%; CV=4.7%; ICC=0.94) and between-day (Mdiff=1.0%; CV=6.4%; ICC=0.86) reliability fell within acceptable limits.
CONCLUSION: In junior athletes, this assessment appears promising in constructing a practically worthwhile measurement tool that can be integrated into a pathway program. Pilot results give a reference for the minimal detectable change in a reassessment of these movements by the same assessor. In addition, between-day reliability revealed a limited learning effect. It is useful for practitioners to screen emerging athlete's movement competency, especially prior to increases in training and competition loads, which accompany pathway transitions. Evaluating movement proficiency when athletes first enter formal development pathways, can allow informed and targeted movement training approaches, required to reduce athlete injury risk and improve holistic development outcomes.

DOES THE DEGENERATED NUCLEUS PULPOSUS OF LUMBAR INTERVERTEBRAL DISC INFLUENCE IN A GAIT PATTERN?

TAKEMURA, M.
ICHIHASHI ORTHOPEDICS CLINIC

INTRODUCTION: The degenerated nucleus pulposus (NP) of lumbar intervertebral disc (LID) is often observed to adolescent athletes with non-specific Low Back Pain (LBP). This degenerated NP is characterized by the shortness of the NP longitudinal axis and its anterior position on the LID longitudinal axis that was measured by magnetic resonance images (MRI) of spine and sacrum in sagittal plane in T2 weighted sequence (we called it the " bullet type ", see chart). The hypofunction of the LID by this degenerated NP causes the hypertonic of the back muscle and others, for example the lumbar multifidus muscle (1) then we hypothesized that the adolescents with the bullet type degenerated NP on LID are characterized by a typical gait pattern, in particular lumbar-pelvic region.
PURPOSE:
To reveal the character of NP of LID by measurement of size and position of NP (relative value [%] to an intervertebral disk) from MRI, and to detect gait kinetic patterns associated with the bullet type degenerated NP of LID.
METHODS: This study included 43 patients with LBP (Bullet type; 36 male and 7 female) from 12 to 21 years of age (male; 15.7±2.0ys, 167.4±10.3cm, 58.1±10.7kg / female; 13.7±1.9ys, 153.4±6.8cm, 48.4±6.8kg), and 17 patients without LBP (Control; 10 male and 7 female) from 15 to 30 years of age (male; 17.3±1.3ys, 171.3±4.0cm, 59.3±14.7kg / female; 16.0±0.8ys, 160.2±2.7cm, 51.8±4.8kg). They all were examined in our orthopedic clinic, and Bullet type was diagnosed degenerated NP on LID by MRI. The dynamic alignment of pelvic during gait at their usual cadence (4 steps within 10m walk, 6 times) was measured at our clinic using a motion analysis system (Vicon Nexus) which consisted of six cameras (100Hz), and 39 retro-reflective markers (Plug In Gait marker set). The dynamic alignment of pelvic, lateral tilt and rotation was compared Bullet type and Control by 2-way [inter group and sex] ANOVA.
RESULTS: The size of NP of Bullet type was short (64.4±7.1%) than Control (71.5±5.1%) ($p < 0.001$, effective size f = 0.56 [Large]). The position of NP of Bullet type was anterior (45.1±3.0%) than Control (48.6±3.5%) ($p < 0.01$, effective size f = 0.37 [Moderate]). The pelvic lateral tilt angle of Bullet type was large (7.1±2.9) than Control (5.8±1.3) ($p=.0506$, effective size f = 0.25 [Moderate]). The pelvic rotation angle of Bullet type was small (5.8±1.6) than Control (13.9±4.5) ($p<.001$, effective size f = 1.30 [Large]).
CONCLUSION: In the adolescent with the bullet type degenerated nucleus pulposus of lumbar intervertebral disc, the lateral instability and tonic rotation pattern of the spine-pelvic region in gait was characterized.

FUNCTIONAL ADAPTATIONS OF ACL RECONSTRUCTED SUBJECTS IN 90° WALKING TURNS

KRAFFT, F.C.1, STETTER, B.J.1, POTTHAST, W.2,4, ELLERMANN, A.3, FLECHTENMACHER, J.4, EBERLE, C.3, SELL, S.1,5, STEIN, T.1
1: KIT 2: GSU 3: ARCUS CLINICS, PFORZHEIM 4: ORTHO-ZENTRUM, KARLSRUHE 5: JOINT CENTER BLACK FOREST, NEUENBÜRG

INTRODUCTION: Functional adaptations in sagittal joint kinematics and kinetics in gait were detected in ACL reconstructed subjects to reduce loads to the reconstructed ACL (Gardinier et al. 2012). Manifestations of such functional adaptations could induce chronical musculoskeletal disorders and the onset of degenerative joint diseases (Zabala et al. 2013).
The purpose of this study was to examine potential functional adaptations of ACL reconstructed subjects in 90° turns by analyzing general locomotion strategies, and sagittal plane knee joint kinematics and kinetics.
METHODS: 20 subjects (32 ± 13.3 yrs.) with unilateral tears of the ACL (ACL group), reconstructed with the same technique, and 20 matched healthy controls (33.3 ± 13.4 yrs.; CG) performed 90° turns at four test sessions: T1 (6 wks. pre-reconstruction), T2 (7 wks. post reconstruction), T3 (3 mos. post-reconstruction), and T4 (6 mos. post-reconstruction). Kinetics were detected by two 3D force plates (1000Hz). Kinematics were sampled with a 3D Motion Capturing-System (200Hz). Inverse kinematics and dynamics were calculated using the full-body Dynamicus 9 model (Haertel & Hermsdorf 2006).

To understand the locomotion strategies of the ACL reconstructed subjects in the 90° turns, all subjects could freely choose the preferred locomotion strategy (spin vs. step turn). This led to a varying amount of subjects, performing the 90° turns with the same turning strategy at each test session. Thus, only descriptive statistics could be computed.
RESULTS: Analysis of the general locomotion strategy showed that the ACL group preferred the step turn technique.
In the step turns, the ACL group showed tendencies of deeper flexed knee joints and reduced knee extension movements, as well as increased knee flexion moments and decreased knee extension moments up to three (T3) and six months (T4) after reconstruction compared to the non-injured leg and the CG.
In the spin turns, the ACL group showed tendencies of deeper and prolonged knee flexion. Higher knee extension moments were found in the reconstructed trailing leg at six months (T4) post-reconstruction compared to the CG, while in the leading leg the loads appeared to be on the level of the CG. The non-injured leg, acting as leading leg, had to bear higher loads at all test sessions compared to the CG.
CONCLUSION: No adaptations were found in terms of the general locomotion strategy, as the ACL group showed a preference of the step turn strategy like the CG and healthy subjects (Hase & Stein 1999). However, because tendencies of functional kinematic and kinetic adaptations were found in the ACL group even at three and six months after reconstruction similar to those detected in straight ahead gait (Zabala et al. 2013), it was assumed that these adaptations bear the risk to manifest prospectively.

RESTING MUSCLE HARDNESS ASSESSED BY A PRESSURE METER IN RELATION TO MUSCLE STIFFNESS ASSESSED BY ULTRASOUND SHEAR WAVE ELASTOGRAPHY

MURAYAMA, M.1, INAMI, T.1, MIYAGAWA, H.2, NOSAKA, K.3, YONEDA, T.4

1: KEIO UNIV. , 2: AICHI MEDICAL UNIV, , 3: EDITH COWAN UNIV. , 4: JUNTENDO UNIV.

INTRODUCTION: Muscle hardness is often assessed by a pressure meter (PM) that measures the force against the pressure applied to the tissue, which is related to longitudinal muscle fibre tension or muscle stiffness (Murayama et al. EJAP 2012). Recently, many studies use ultrasound shear wave elastography (SWE) to evaluate muscle stiffness, but it is not known how muscle hardness assessed by PM is associated with the shear modulus (SM) measured by SWE. The present study examined the relationship between the muscle hardness measured by PM and muscle stiffness by SWE in biceps bracchi (BB), rectus femoris (RF) and gastrocnemius medialis (GM) muscles.
METHODS: Muscle hardness and stiffness in resting BB, RF and GM were assessed by PM (TK-HS100, Tokushu-keisoku, Japan) and SWE (Aixplorer, Konica Minolta, Japan) using 15 men and 3 women (age: 21.9 ± 2.3 y, height: 169.9 ± 8.2 cm, body mass: 63.1 ± 9.8 kg). For BB, the elbow joint angle was set at 0, 30 and 90° of flexion (BB0, BB30 and BB90). For RF, the hip and knee angles were set at 0°. For GM, the ankle angle was set at 30° of plantar flexion. The measurement was taken from the belly of each muscle. The displacement-force curve obtained from the PM was divided into subcutaneous and muscle components, and muscle hardness value of E (kPa) was calculated using the slope at a specific depth of the muscle component. SWE provided SM (kPa) calculated from the shear wave speed automatically. The relationship between E and SM was analysed by a Pearson's product moment.
RESULTS: The mean and SD (range) values of E for BB0, BB30, BB90, RF and GM were 18.5 ± 4.1 (13.6-27.6), 13.9 ± 8.5 (10.8-18.5), 12.5 ± 8.5 (8.7-19.6), 31.4 ± 8.5 (14.1-79.3) and 20.9 ± 4.8 (11.6-29.4), respectively, and those of SM for the corresponding muscles were 50.1 ± 11.7 (32.3-70.5), 28.7 ± 2.6 (23.4-34.2), 11.0 ± 1.3 (9.5-14.6), 12.6 ± 2.2 (9.9-17.4), and 17.3 ± 3.7 (12.7-27.3), respectively. SM of BB0 and BB30 were greater than others, but E of RF was greater than others in PM ($P<0.01$). A significant ($P<0.05$) correlation between E and SM was evident for BB0 ($r = 0.833$) and BB30 ($r = 0.497$), but no significant correlations were found for BB90 ($r = 0.009$), RF ($r = 0.033$), GM ($r = 0.060$), and all muscles combined ($r = -0.074$).
CONCLUSION: The results showed that correlations between PM and SWE were limited to BB0 and BB30 in which muscle stiffness was greater than others. The average E and SM values did not match well except for BB90. It appears that muscle hardness assessed by PM and muscle stiffness assessed by SWE are basically different, probably represent different aspects of muscle, although they are shown in the same unit (kPa). It is interesting to investigate whether the magnitude of the changes in the two parameters after an intervention (e.g., exercise) is similar.

INTRODUCTION: The foot status of children is influenced many factors such as heredity and environment. It is assumed that the Nepal geographical condition such as hill or mountain environment affect the growth status, especially the foot condition of children is very influenced by their walking habit in hill / mountain area. Additionally, The heredity status also quite different among ethnic groups (EG)(or Caste group) such as Brahman/Chhetri (B/C) and Janajati (JAN). This study was aimed to investigate foot growth characteristics of B/C and JAN children at Nepal hill area.
METHODS: The samples were 877 healthy children of B/C at urban area and JAN at rural area (393 boys and 484 girls) aged 5-16 years, higher secondary school in/around Kathmandu Valley, Nepal. Foot sole parameters, foot length, foot width, foot width/length ratio, arch type, were measured using sole photos of the children which were taken using a 2D foot scanner during 2015-2016. We also measured their height and weight. Descriptive statistics of foot sole parameters, height and weight were calculated by age, sex and ethnic groups (B/C and JAN). The difference of these statistics was compared between ethnic groups by age and sex.
RESULTS: Mean foot length of 5-yr of age was 16.5-17.0cm. It reached 20.0-21.0cm at 9-yr of age. There were no significant difference of foot length between B/C and JAN till 10-yr of age for boys and 8-yr of age for girls. However, the foot length of BC was significantly($p<0.05$) larger than that of JAN from 11-yr of age for boys and 9-yr for girls. The mean foot length at 15-yr of age was 24.6cm for B/C boys, 23.0cm for JAN boys, 22.6cm for B/C girls and 22.1cm for JAN girls. Mean foot width of 5-yr of age was 6.5-6.7cm. It reached 7.6-7.7cm at 10-yr of age. There were no significant difference of foot length between B/C and JAN except 14-yr boys and 9-yr girls. It seemed that foot growth, especially foot length was different between ethnic groups.

Regarding foot arch type, 4% of children was flat arch, 77.5% was normal arch, 12.2% was high arch and 6.3% was very high arch. There was no difference for arch type between EG (chi-square=2.28 and 6.96 for boys and girls, respectively). However, the arch construction rate was higher than Japanese (12% of flat arch children (Mimura (2010)). The results suggest that Nepalese children have a high rate of normal arch.
We found the height differences between BC for 14-yr boys and 9,12 and 13-yr girls. It seemed that growth spurt size of B/C children was larger than JAN children. The foot size differences between EG seemed to be appeared after these growth spurt.
CONCLUSION: The foot length of BC children is larger than JAN children after growth spurt. Foot arch construction rate of both B/C and JAN is higher than Japanese.
Mimura, K (2010) Motor ability and formation of foot sole contact surface used pidoscorp in elementary school. Memoirs of Osaka Kyoiku University, 58(2), 161-171 (in Japanese)

EFFECT OF TRANSCUTANEOUS VACUUM TREATMENT ON JOINT MOBILIZATION

KAYA, M.1, SHIBUTANI, T.2, TAKEMURA, M.3, KURITA, K.4, KAWAGUCHI, J.5, BANERJEE, A.6, TSUJITA, J.5

1) HYOGO UNIV. OF HEALTH SCIENCES, 2) MJ COMPANY, 3) ICHIHASHI CLINIC, 4) PHYSICAL CONDITIONING PRODUCTION, 5) INSTITUTE OF HEALTH & SPORTS MEDICAL SCIENCE, 6) AMAGASAKI EDUCATION BOARD

INTRODUCTION: Transcutaneous vacuum treatment improved gliding function, flexibility of muscle and fascia in vastus lateralis. However, the effect of transcutaneous vacuum treatment on joint mobility has not been investigated to date.
The purpose of this study was to investigate the effects of transcutaneous vacuum treatment on posterior thigh with straight leg raising angle, compared with passive static stretching of hamstrings.
METHODS: Seven volunteers who had not undergone any prior orthopedic treatment for the lower legs participated in this study.
Transcutaneous vacuum treatment (CVT) (vacuum and rolling [approximately 0.5Hz]) was applied to posterior thigh (ischial tuberosity to upper area of popliteal region) for 30 seconds 3 times with 15 second intervals between sets. Passive static stretching (PSS) of hamstrings was applied by pushing the heel using a hand held goniometer to the final angle of movement for 30 seconds 3 times with 15 second intervals between sets at supine position with knee extended.
We measured straight leg raising (SLR) angle with active and passive hip flexion before and immediately after CVT or PSS of hamstrings.
RESULTS: After PSS, the SLR angle statistically increased at active (89.9 ± 9.2 to 97.1 ± 12.4 degree) and passive (92.2 ± 11.5 to 99.0 ± 13.8 degree) hip flexion. After CVT, there was no change in SLR angle at active hip flexion (92.0 ± 9.8 to 92.9 ± 8.3 degree). However, it statistically increased at passive hip flexion (92.0 ± 11.5 to 99.1 ± 13.8 degree). There were no differences of SLR angle for passive hip flexion between PSS and CVT after treatment.
CONCLUSION: In this study, there was significant increase of SLR angle in passive hip flexion after CVT, and these changes were almost equivalent to the angle after PSS. However, despite the increase after PSS, the angle in active hip flexion after CVT did not change. These results suggest that the mechanism of change in active range of motion after transcutaneous vacuum treatment may be different from that of static stretching.

EMG ACTIVITY OF NECK AND TRUNK MUSCULATURE FOLLOWING EXPERIMENTALLY-INDUCED BREAST AUGMENTATION

KATEINA, C.

NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS

INTRODUCTION: Breast augmentation is a procedure that is been performed by many females using external inserts or surgically implanted breast implants for improving or restoring the aesthetics of their body. However, the weight of the implant that is inevitably added onto the anterior part of the female's chest may induce musculoskeletal problems, particularly in the neck and back, if the desired prosthetic is excessive (Letterman & Schurter, 1980). The purpose of the present study is to examine the effect of experimentally-induced breast augmentation on the EMG activity of neck and back musculature during execution of common movements of everyday life.
METHODS: Twenty four healthy females with each breast's volume up to 250 ml participated in the study. Breast augmentation was achieved experimentally by increasing 1.5, 3, 4.5 and 6 times the volume of each participant's breast using silicone-gel based implants with volume/weight ratio equal to one. The EMG activity of sternocleidomastoid (SCM), the upper trapezius (UT) and the thoracic and lumbar trunk extensors (TTE and LTE) was recorded before and after augmentation of the females breasts during 45 degrees of trunk flexion from the standing and sitting positions (45TFSD, 45TFST), stand-to-sit (SDST) and 180 degrees shoulder flexion (180SF).
RESULTS: Our results revealed significant differences between loading conditions with regard to TTE during 45TFSD. Marginal were the differences for TTE during SDST. The differences between loading conditions for LTE were significant during 45TFSD and during 180SF. Upper trapezius demonstrated significant differences between loading conditions during SDST and 180SF. The greatest EMG activity for TTE was obtained during 45TFSD when breasts were augmented 4.5 times or more, for TEL was obtained during 45TFSD and 180SF when breasts were augmented 4.5 and 3 times respectively and for UT during SDST and 180SF when breasts' were augmented six fold. The differences between loading conditions for SCM were not significant during all movements tested.
CONCLUSION: Neck and trunk musculature EMG activity remain unaffected for up to 3 times augmentation of the females' breasts during almost all movements tested. The increased EMG activity of TTE, LTE and UT that was obtained when the original breasts augmented by 4.5 or more times during the majority of the movements tested was probably attributed to the fact that the silicone-gel prostheses were not only heavier but also bulkier. Therefore a greater amount of activity might be necessitated for compensating a greater load that was applied at a longer distance from the chest (Kour et al. 2014).

ASSESSMENT OF SHOULDER ASYMMETRY FOR THE DESIGN OF AN UPPER LIMB EXOSKELETON

ARGUBI-WOLLESEN, A.1, SCHUBERT, T.1, MATTES, K.2

<1> HELMUT-SCHMIDT-UNIVERSITÄT HAMBURG, GERMANY; <2> UNIVERSITY OF HAMBURG, GERMANY

INTRODUCTION: Exoskeletons for the upper limbs at the workplace are used to address musculoskeletal issues by providing additional torque to the shoulder. However, data on the underlying human strength curves, especially regarding possible imbalances, are insufficient as previous research focused mostly on (a) angles of peak torque, neglecting torque distribution over the whole ROM and (b) examined primarily athletes (Challoumas et al., 2017). To adjust torque curves of an exoskeleton, the aim of this study was twofold: (1) to evalu-

ate the torque curve of maximum isokinetic shoulder flexion and extension and (2) to analyse side-to-side strength asymmetry and flex./ext. ratio for both genders.
METHODS: An Isomed2000 Dynamometer was used to assess the isokinetic concentric muscle torque for the shoulder flexion and extension for both sides in the sagittal plane (3° to 167°; arm stretched out) at 90°/s. Test subjects (N=31; women: n=15, 25.7±3.7 years, 170.8±6.7cm, 65.5±9.2 kg; men: n=16, 28.5±3.7 years, 181.4±4.9cm, 78.6±7.2 kg) remained in a supine position and completed 2 sets of 5 maximum repetitions for each side with 5 min. rest in between. The mean side-to-side strength symmetry index (SI) and unilateral flex./ext. ratio were calculated for work and peak torque and analyzed for every 55°. To control for gender differences, a one-factor anova was conducted ($p<.05$).
RESULTS: Women showed significant ($F(1,29)=5.294$, $p<.05$, $p\eta2=0.154$) higher work asymmetry at first (SIw3-58°=7.6±8.8%) and middle (SIw58-113°=13.4±12.5%) section of flexion than men (SIw3-58°=0.1±9.2% / SIw58-113°=3.6±10.4%). No significant statistical gender diffences were detected for asymmetry at peak torque (men: -0.3±11% (flexion) / 0.1±11% (extension); women: 5.8±7.4% (flexion) / 3±15.5% (extension)).
CONCLUSION: The results of flex./ext. ratio are in line with previous studies (Dehail et al., 2008) and maximum strength asymmetry was between 5% to 10%. For flexion, both genders showed highest side-to-side asymmetry at the middle section of movement (58°-113°), whereas peak torque occured in the first section (3°-58°) with lower asymmetry. The highest asymmetry during extension was observed at the third section (113°-167°), while peak torque was located at the beginning of the motion with lower asymmetry. An analysis over joint-angle sections result in a more precise evaluation of strength asymmetry than using only peak torque angles. Creators of exoskeletons should address these findings by providing adjusted torque curves.

TOWARDS AN INCREASED ECONOMY OF THE RUNNING PATTERN AFTER FIVE MINUTES OF RUNNING IN UNWEIGHTED CONDITION?

CHAVET, P.1, NICOL, C.1, SAINTON, P.1, BARTHÉLEMY-MONFORT, J.1, DE GRAAF, J.1
INSTITUTE OF MOVEMENT SCIENCES

INTRODUCTION: On lower body positive pressure (LBPP) treadmill, partial unweighting is reported as resulting in a rebounding running pattern that changes biomechanics and musculoskeletal loading in a complex manner (Farina et al., 2017). Our studies highlighted the linear relationship between the bodyweight-induced changes and many mechanical stride parameters, but also revealed muscle and SSC-phase dependent neural adjustments (Sainton et al., 2015, 2017). Interestingly, an increased unweighting from 80 to 60% bodyweight did not result in any increased economy. The present study investigated whether increasing the time spent in unweighting condition might improve the running economy.
METHODS: Eight healthy male adults run at preferred speed on LBPP treadmill. The protocol included 2 runs that consisted in 3 sequences of 5 min: at 100% bodyweight (BW), 60 or 80% BW, and 100% BW. For each running sequence, vertical ground reaction force was recorded during 3 time periods of 30 s, together with surface EMG activity from 5 major muscles of the right lower limb. Heart rate (HR) was continuously recorded and perceived exertion (RPE) repeatedly rated. The statistical analysis of the unweighting effects compared the mean values of the last 30 s at 100%BW to those at the 3 time periods of the unweighted run.
RESULTS: In both runs, the unweighting resulted in immediate and proportional increases in flight time and decreases of the active peak force and mean push-off force. These changes remained then stable up to 5 min. In contrast, HR and RPE decreased similarly in both runs. The EMG analysis revealed similar reductions of the quadriceps activity during the braking phase and an overall reduction of the lower limb muscle activity during the push-off phase, but at 80%BW only. At 60%BW, only the soleus muscle presented a delayed decreased push-off activity at 5 min.
CONCLUSION: The neuromechanical and physiological changes observed right after the unweighting transition and 3 minutes later confirmed their rapidity, but also the minimized benefits in HR, RPE and muscle activity previously reported below 70% BW (Farina et al., 2017; Sainton et al., 2015). The larger drop in force at 60%BW may thus be mostly attributed to the LBPP support. Providing more time to the runners during a first practice session was found to stabilize rather than to improve their running economy. For the rehabilitation purpose, further research is needed regarding the potential effects of repeating practice sessions to induce additional gains in running economy.

IN VIVO FASCICLE LENGTH OF THE GASTROCNEMIUS MUSCLE DURING WALKING IN SIMULATED MARTIAN GRAVITY USING TWO DIFFERENT BODY WEIGHT SUPPORT DEVICES

RICHTER, C.1,2, BRAUNSTEIN, B.1,3,4, STAEUDLE, B.1,2, ATTIAS, J.5, SUESS, A.6, WEBER, T.6, MILEVA, K.7, RITTWEGER, J.8, GREEN, D.5,6, ALBRACHT, K.1,2
1: GSU , 2: UAS , 3: CHIPS , 4: MOMENTUM , 5: KCL , 6: EAC , 7: LSBU , 8: DLR

INTRODUCTION: The effect of unloading upon locomotion is of particular interest for rehabilitative gait training as well as exploration of partial gravity environments. In rehabilitation, unloading is often achieved by lower body positive pressure whereas for spaceflight horizontal suspension combined with a subject loading system has proven to be a suitable analogue for walking in partial gravity. As the plantar flexors are anti-gravity muscles contributing significantly to vertical support and horizontal progression of the human body (Lai et al., 2015), it is important to examine the behaviour of their fascicles under unloading conditions. Therefore, the aim of this study was to compare two different body weight support systems with regard to changes in fascicle and muscle-tendon-unit (MTU) length of the gastrocnemius medialis (GM) during walking at simulated Martian gravity (0.38g).
METHODS: Eight male subjects (31.9 ± 4.7 yrs) walked at 75% of their preferred walk-to-run transition speed at 0.38g on the vertical treadmill facility (VTF) and the anti-gravity treadmill AlterG. In addition, a control condition without unloading was performed on the AlterG.

GM fascicles were scanned and measured with ultrasonography. Plantar pressure and joint kinematics were analysed to determine gait-cycle events and GM MTU length. A non-parametric multiple comparison test for dependent samples was used to test whether changes in fascicle and MTU length are significantly influenced by the different walking conditions.
RESULTS: None of the three walking conditions had a significant effect on MTU and fascicle excursion or ankle and knee joint range of motion. However, with both devices, fascicles operated at longer length in the middle of the stance phase ($p \leq 0.0179$) and maximum MTU shortening velocity was significantly lower ($p = 0.0027$) in simulated 0.38g. No differences were found when comparing the effect of VTF and AlterG on the tested parameters.
CONCLUSION: The effect of unloading on fascicle behaviour was similar on the VTF and AlterG, meaning that both devices are equally suitable for body weight supported gait training. The longer fascicles and reduced maximum MTU shortening velocity under simulated Martian gravity compared to walking without unloading, suggests that the tendon must be shorter due to the reduced body weight and hence stored less energy, which can contribute to forward progression.

THE EFFECT OF FALL HISTORY ON KINEMATIC SYNERGY DURING OBSTACLE CROSSING

YAMAGATA, M.1, TATEUCHI, H.1, SHIMIZU, I.2, ICHIHASHI, N.1
1: KYOTO UNIVERSITY, 2: FUKUI GENERAL CLINIC

INTRODUCTION: Recently, the importance of kinematic synergy stabilizing the swing foot during gait has been shown. Additionally, our earlier study revealed that fall history altered VZ during gait. Falls during obstacle crossing is a problem for older people, but no study has examined the relations between VZ and fall risk during obstacle crossing. Thus, the aim of this study was to reveal the effect of fall history on VZ during obstacle crossing using uncontrolled manifold analysis.
METHODS: Older adults with fall history and without fall history participated in this study. The fall history was evaluated with self-report of questionnaire. The participants walked on a 6-m walkway; 3 m from the start, they crossed an 8-cm tall obstacle. The kinematic data during the task was collected. The swing phase during obstacle crossing was normalized by time and divided into three phases . With UCM analysis , VZ was calculated to quantify how the limb segments stabilize the swing foot in mediolateral and vertical directions. Greater VZ implies the high stability of the swing foot. For statistical analysis, 2-way ANOVAs were performed to reveal the effect of fall history and phase on VZ in each direction. The alpha level was set at 0.05.
RESULTS: In the mediolateral direction, main effects of fall history and phase were found. VZ in fallers was significantly higher than that in nonfallers, and VZ during mid-swing was higher than that during early- and late-swing. In the vertical direction, there was an interaction between fall history and phase. VZ in mid-swing was lower than the other phases for fallers, whereas VZ was constant for nonfallers. Moreover, VZ in fallers was significantly lower than that in nonfallers only during mid-swing.
CONCLUSION: In the mediolateral direction, VZ was higher during mid-swing than the other phases, and fallers had higher VZ compared to nonfallers. Healthy younger subjects increased VZ when walking carefully in complex tasks . Fallers in this study might cross the obstacle carefully because of the fear of falling. In the vertical direction, fallers had lower VZ than nonfallers during mid-swing. The collision of the swing foot and obstacle would lead to falls, so control of the swing foot in the vertical direction is crucial in mid-swing because the vertical distance between swing foot and obstacle is smallest at this phase. Thus, the observed decrease of VZ during mid-swing might heighten risk of falls.

MO-BN06 Analysis and sports performance

MATCH PERFORMANCE PROFILES OF STRONG AND WEAK TEAMS IN THE CHINESE SOCCER SUPER LEAGUE

CHANGJING, Z.1, ALBERTO, L.2, GOMEZ, M.A.3, SHAOLIANG, Z.4
UNIVERSIDAD POLITÉCNICA DE MADRID

Introduction: Nowadays, profiling techniques applied to sports performance analysis are more focused on representing the typical performance and the spread of the performance of a single player. The usefulness of performance profiles is likely to be improved when they are extended to present and compare the technical performance of football players considering their field position or the team quality (Liu, Gomez et al. 2016). Thus, the aim of the current study was to compare the differences between strong and weak teams according to players' playing positions.
Methods: The tracking data of players was collected from the 240 matches of the 2016 CSL. Teams were classified based on their final ranking as strong (1–8) and weak teams (9–16). Magnitude-based inferences were used.
Results: Compared with weak teams, (i) center defenders from strong teams made more passes, forward passes, crosses, high intensity running and better pass, forward accuracy, but fewer shots, fouls committed and ground challenges; (ii) wide defenders from strong teams made more passes, crosses, aerial challenges, sprinting distance and higher pass accuracy, forward pass accuracy; (iii) central midfielders made more passes, crosses, shots and higher pass accuracy, forward pass accuracy, but the fewer total distance covered; (iv) wide midfielders from strong teams achieved more passes, forward passes, crosses and shots, but less total distance and high intensity running distance; (v) attacker from strong teams achieved better pass and forward pass accuracy, but fewer aerial challenges.
Discussion: The main results showed different performances profiles of football players according to playing position and team quality. In passing-related actions, defenders from strong teams had better performance than weak teams because they involve more in the attacking process (Liu, Gomez et al. 2016), which will be the main trend of football development (Bush, Barnes et al. 2015). In defending-related actions, center defenders from weak teams made more fouls committed and ground challenges and attackers made more aerial challenges, possibly because strong teams make more offense from the ground (pass) and weak teams from the cross of wide midfielders. In physical aspects, defenders from strong teams covered more sprinting distance because of more involvement in the attacking while wide midfielders covered more high intensity running distance possibly due to defending attacking from the opposing defenders. These findings could be used for talent identification or position-specific physical and technical training.

MODELLING PEAK RUNNING SPEED AS A FUNCTION OF TIME IN SOCCER GAMES - THE RELATIONSHIP BETWEEN THE MODEL´S

MAHLER, H.1, HEYDE, C.2, ROELL, M.1, GOLLHOFER, A.1, ROECKER, K.1,3

ALBERT-LUDWIGS-UNIVERSITY OF FREIBURG

INTRODUCTION: The evaluation of a soccer player´s peak running periods in games, as a function of time, can be modelled by a five-parameter algorithm and may deliver comprehensive diagnostic information of the most intense periods for players in a game [1]. The practical interpretation of the modelling parameters remains to be examined, however. The parameter "upper asymptote" characterizes a player´s peak running period performance in games within a short duration of time (<2sec). Even though a player has to produce a high number of sprints in a game, most with a length of up to 20 meters, the question arises, whether these sprints has to be produced at least once in a game with maximal intensity, due to tactical and playing position requirements [2]. Therefore, we examined, whether a players peak running speed in a 20-meter sprint field test (Speak20m) offers a prediction of the "upper asymptote" derived from games in regard to playing position.
METHODS: 95 amateur and professional male and female soccer players (177±7 cm, 72.2±9 kg, 23.9±3 y) performed individual 20-meter sprint tests, by wearing a 10 HZ GPS unit. Speed20m was assessed by the median of the fastest from 13 consecutive sprints, according to recommendations for using multiple trials to decrease signal to noise ratio [3]. Within three weeks the players also participated in between one and three official soccer games, whereby players wearing the same GPS unit. This resulted in 173 individual game observations (21 games in 8 different leagues). Following the model from Roecker et al. 2017, the algorithm allowed to calculate the "upper asymptote". Due to unbalanced data sets we used a mixed model approach with participant as random and Speed20m as a fixed factor to establish the relationship to the "upper asymptote" [4].
RESULTS: Speed20m was significantly and linearly correlated to the "upper asymptote" for all soccer players (r=.89, p<.0001, RMSE=0.34 m/s). This correlation was significant for each playing position. Highest correlations were assessed for external midfielders (r=.96, p<.0001, RMSE=0.26 m/s) the lowest for central midfielders (r=.74, p<.0001, RMSE=0.43 m/s).
CONCLUSION: On the basis of 80% variance declaration, Speak20m shows potential as a valid indicator of a player´s "upper asymptote" in a game. The results emphasize the importance for soccer players ability to sprint as fast as possible especially in a short distance perspective [2]. The relevance of Speed20m is dependent on playing position, which may be due specific tactical requirements [2]. Future studies should further investigate the "upper asymptote´s" variability from match to match and validity in training studies.

WHAT MAKES A WIMBLEDON SUCCESS?-MODELLING THE RELATIONSHIPS BETWEEN TENNIS PERFORMANCE AND MATCH RESULT

CUI, Y., LIU, H., GÓMEZ, M.Á.

A. TECHNICAL UNIVERSITY OF MADRID, MADRID, SPAIN; B. SOUTH CHINA NORMAL UNIVERSITY, GUANGZHOU, CHINA

Introduction: Performance analysis in tennis provides useful information to coaches and sport scientists on quantifying player behaviors in complex competition, helping to enhance the coaching process. Nonetheless, to better understand the relationship of tennis performance variables and match outcome, predictive models should be developed to highlight the prominent variables that contribute to the success of tennis players. Therefore, the study aimed to inspect the relationships of tennis performance variables and the match result (win/lose) via generalized mixed linear modelling within male tennis Grand Slam event.
Method
The study used the technical-tactical and movement performance statistics of 248 matches from 2015-16 Wimbledon, the only Grand Slam contested on grass surface court. Data were collected from the IBM SlamTracker of Wimbledon official website, and the inter-operator reliability of the notational data and the Hawk-eye System that tracks the movement data were validated. Twenty-one match variables related to serve and return, breakpoint, efficiency and movement performance were chosen as the predictor variables. While the match outcome (win/lose) was the dependent variable. A mixed-model reliability analysis with a random effect for player was performed to estimate between-player and within-player SD for each variable. Afterwards, the cumulative logistic-regression version of the generalized mixed linear model was employed to estimate separately the effect of each predictor variable on the odds of a player's winning a match,. The effect was estimated as the ratio of the odds of winning for a typically high value of the predictor (+1 between/within-player SD) compared with a typically low value (–1 between/within-player SD). Uncertainty in the true effects of the predictors was evaluated using non-clinical magnitude-based inference.
Results: Of all variables analyzed, there were 17 variables that had possibly to most likely positive between-player relationships with the probability of winning. A 2-SD increase in these serve, breakpoint, and movement performance related variables would lead to a 12.3% to 43.6% higher probability of victory. Meanwhile, 14 variables related to serve and return, breakpoint and movement performance showed possibly to most likely positive within-player relationships with the likelihood of winning. An increase of 2-SD in these variables would contribute to an 11.9% to 67.8% higher likelihood of winning. Interestingly, the variable net point won of total point won had a most likely negative within-player effect on winning possibility. Double faults was the only variable that had trivial between-player and within-player effect on the winning odds.
Conclusion
In Wimbledon, serving (especially aces, first and second serve points won) and breakpoint performance had critically positive effect on the probability of winning, while net success was also beneficial for winning a match, but attempting to finish the point in the net too much times would bring negative effects on player's winning odds. This indicated that player should optimize their serving strategies instead of chasing for a higher speed or a quicker-finish in the net. With the use of generalized mixed linear modelling, it is possible to identify the key performance indicators in tennis and help coaches to improve the training and match planning.

A CRITICAL REVIEW OF VIDEO ANALYSIS RESEARCH IN RUGBY UNION

DEN HOLLANDER, S., JONES, B., LAMBERT, M., HENDRICKS, S.

UNIVERSITY OF CAPE TOWN

INTRODUCTION: Video analysis research in Rugby Union has provided valuable insight into match performance. Studies in this field range from broad statistical studies of commercial databases to in-depth case-studies of specific match events. The range of studies using video analysis in rugby union makes it difficult to generalise and apply the findings to real-world settings. The methodology used in video analysis has also come under criticism related to the applicability of findings from variables analysed in isolation in a dynamic sport. To help in the application of video analysis research in rugby union, a critical review of this rugby research was performed.
METHODS: The methods of a systematic review were used in the literature search. Peer-reviewed journal articles, which analysed match footage of Rugby Union games, were included in the review. A total of 92 studies were identified. These studies were categorized into three groups based on the outcomes of the paper, physical demands, performance and injury. The studies were then categorised further into studies that identified what occurred in a match and studies that described how specific match events occurred. This allowed for more homogeneous comparisons. The studies were then reviewed using a number of polar questions related to the context of the variables included in the study, the provision of definitions for the variables, sample selection, and reference to practical application. Descriptive statistics were used to analyse the results.
RESULTS: In 50% of the studies, the variables were fully defined. Samples ranged from 4 studies analysing over 300 matches to 3 studies with samples of less than 5. 38% of performance related what type studies' samples were from one-off tournaments. One hundred percent of how type studies included at least one contextual variable in their analyses, with 86% of how type studies including 2 or more contextual variables. There was a reference to the practical application of the findings in 81% of studies.
CONCLUSION: The large range of sample sizes and the types of samples used raised concerns over the generalisability of some of the samples, and the adoption of the use of sample size calculations was recommended. We argue that the criticism that video analysis research tends towards reductionism should only be applied to studies who propose to answer how events occur. The results of the review show that the majority of studies describing how events occur in rugby matches attempted to provide context to their findings. There is a large emphasis on the practical application of the findings of video analysis research; however, the review raised concerns over the usefulness of some of the findings to coaches and practitioners. To facilitate the integration of research into practice, we suggest video analysis research follow a process, where the results of 'what' studies inform the research questions of 'how' studies, and the findings of 'how' studies provide the practical applications for coaches.

VIDEO ANALYSIS OF TACKLING SITUATIONS LEADING TO CONCUSSION IN COLLEGIATE RUGBY UNION

SUZUKI, K.1,2, NAGAI, S.3, IWAI, K.2, MIYAKAWA, S.1, TAKEMURA, M.1

1. UNIVERSITY OF TSUKUBA, 2. IBARAKI PREFECTURAL UNIVERSITY OF HEALTH SCIENCES, 3. TSUKUBA INTERNATIONAL UNIVERSITY

INTRODUCTION: In rugby union, the concussion prevention is still a current topic. However, a few researches on concussion scene have been carried out conducted based on video records. We need to clarify the tackling situations leading to concussion at various playing level in order to develop the concussion prevention for rugby union players. Therefore, the purpose of this study was to clarify the tackling characteristics leading to concussion in rugby union.
METHODS: Players from a Japanese collegiate rugby union team took part in the study. Over six playing seasons, the total number of 402 players participated in 265 matches. We identified 23 concussion events caused by tackling based on injury data and match video records. In addition, all tackles by an injured tackler in that match were including in the analysis. We defined the rest of tackles excluding the tackle leading to concussion as a control. All tackles were analyzed according 20 tackling characteristics by reference to previous researches. Tackle was divided into the three tackle-phases: pre-contact, contact and post-contact. In addition, we divided outcomes of the tackle into tackle performance outcomes and tackle result. Multiple logistic regression analysis was performed to clarify relationship between tackling characteristics and concussion.
RESULTS: In pre-contact phase, tacklers were significantly less likely to sustain concussion when ball-carrier performed a side step initiated by either leg (odds ratios (OR) 0.11, 95% CI 0.01–0.85), in comparison to when ball-carrier ran straight toward tacklers. In contact phase, Tacklers were significantly more likely to sustain concussion when they performed collision tackle (OR 84.00, 95% CI 8.27–853.11), in comparison to a shoulder tackle. Tacklers had a significantly higher likelihood of concussion when tacklers contacted with their head/neck as the first point of contact (OR 23.47, 95% CI 4.80–114.71), when compared with making initial contact with their shoulder. In post-contact phase, tacklers were significantly more likely to sustain concussion when they did not pull, grip or wrap ball-carrier by their arms (OR 3.54, 95% CI 1.23–10.20), in comparison to when they wrapped ball-carrier. In addition, tacklers were significantly more likely to sustain concussion when ball-carrier successfully penetrated the attempted tackle (OR 5.76, 95% CI 1.67–19.85), in comparison to tackle complete.
CONCLUSION: We found that the tackling characteristics before tackle were related to decrease the concussion risk. Further researches on tackle are needed to take among each tackling characteristics in view of tackle phase into consideration.

ANALYSIS OF KINEMATIC PARAMETERS OF MAE-GERI KICK DEPENDING ON THE LEVEL OF ADVANCEMENT OF COMPETITORS

BLASZCZYSZYN, M.1, SZCZESNA, A.2, BORYSIUK, Z.1, PAWLYTA, M.2,3

1 OPOLE UNIVERSITY OF TECHNOLOGY, OPOLE , POLAND 2 SILESIAN UNIVERSITY OF TECHNOLOGY, GLIWICE, POLAND 3 POLISH-JAPANESE ACADEMY OF INFORMATION TECHNOLOGY, WARSAW, POLAND

INTRODUCTION: Mae-geri, forms one of the most common types of attack both in training as well as in combat. It is a type of a front kick, characterized by a considerable speed and strength. The aim of this study was to determine kinematic differences in the movement patterns depending on the level of advancement in the kick conditions in: air (I), target (II), contact with the participant (III).
METHODS: Kinematic data was recorded using a motion tracking Vicon system with the sampling frequency of 250 Hz (Vicon®, 2010). Matlab 2016a with the BTK Toolkit library and the Mokka software were used to analyze the data. The non-parametric Mann-Whitney U-test was used for statistical analysis. Comparative analysis was performed in 26 players: G1 - 13 with advanced achivements, G2 – beginners.

RESULTS: In the comparative analysis, statistical differences were observed in : Time p=0.0387(I), p=0.0006(III), acceleration : p=2.17968E-05(I), p=0.0037(III), in angular values: neck flexion p=0.0247(I), abduction p=0.0003(I), p=5.08334E-05 (II), p=0.0005(III), external rotation p=0.0252(II), spine flexion p=0.0123(I), p=0.0002(II), p=0.0006(III), abduction p=0.0123(I), p=0.0328(II), p=0.0015(III), hip adduction p=0.0307(I), p=0.0172(II),p=0.0073(III), Max force p=0.0077(II).
CONCLUSION: Significant differences were observed in the performance of the motor model assessed in advanced and beginner riders. The key segments of the body were: head, trunk and hip. As the researchers emphasize, the effectiveness of karate techniques depends on the development of a motor model and the ability to repeat it in the shortest time and the highest acceleration (Portela et al. 2014, Witte et al. 2012). The analysis offered an observation regarding differences in the movement patterns performed by the competitors at difference levels of achievement. The authors anticipate that the flexed head and its adduction in the direction of the kicking leg in advanced competitors are related to visual control, whereas the abduction of the trunk in the opposite side of the kick leg is responsible balance control, and hip adduction with a slight rotation internal guarantees the limb setting so as perform the most effective movement pattern. In addition, the foot extension causes the opponent (target) to be pushed away.

A COMPARISON OF MARKER SET USE IN ASSESSING KINEMATIC VARIABLES IN CYCLING

JONGERIUS, N.1, WAINWRIGHT, B.1, BISSAS, A.1

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Kinematic analysis in cycling via videography is becoming increasingly popular. Accuracy of commercial systems is improving rapidly and a shift is seen from 2D to multi-camera systems. Research shows a potential increase in validity and accuracy from 2D to 3D data (Fonda et al. 2014). Factors still affecting data accuracy in 3D systems are camera quality, calibration settings, marker sets and marker placement. The quality of camera systems is continuously increasing whilst marker placement is a trainable skill. However, uncertainty exists on how the 3-point angle method typically used in such systems differs from joint angles obtained through more valid modelling methods. Such information is crucial to understand how accurate these commercial setups can become when camera quality and operator training are optimised.
METHODS: Data from 25 males were collected using a Qualisys (Sweden) system. Two marker sets were used: a 3-point angle (Trochanter Major, Lateral Femoral Epicondyle, Lateral Malleolus) and a modelling based set with extra markers on the Medial Femoral Epicondyle, Medial Malleolus and four tracking markers on the thigh and shank. Three 60s trials were captured at 250Hz for each participant and the following variables were calculated: peak knee flexion (PF), peak knee extension (PE) and mean knee angle (KA). Agreement between the two sets was tested through 95% Limits of Agreement (LoA), 95% Coefficient of Variation (CV) and Intraclass Correlation Coefficient (ICC).
RESULTS: Regarding PE, LoA, CV and ICC were 9.6°±3.9, 4.7% and 0.92 respectively. For PF, LoA were 0.8°±5.5, CV=2.6% and ICC=0.71. In terms of KA, LoA were 5.3°±4.2, whereas CV and ICC were 3.6% and 0.82 respectively.
CONCLUSION: The largest difference between sets is seen in PE, though the large systematic error could be easily corrected for. Random errors are highest for PF whilst ICCs may not provide a clear picture of the absolute error. Random errors of 4-6° need to be considered when measuring knee angles through a 3-point angle. However, modelling derived angles are also prone to some error, mainly due to marker placement, skin artefacts and individual anatomical differences, albeit to a smaller extend than in 3-point angles. Literature suggests cyclists should aim for knee angles of 25° to 35° at PE (Peveler et al. 2011). The size of random errors found in this study questions the applicability of simplified marker sets when measuring knee angle in cycling. System developers are advised to critically look at marker sets used with their systems in order to provide a more accurate alternative and apply correction factors when appropriate.

WEIGHT TRANSFER STYLES IN FULL AND PARTIAL GOLF SHOTS

OUTRAM, T., GOODMAN, S.

UNIVERSITY OF DERBY

INTRODUCTION: In full golf swings with a driver or iron, a golfer's centre of pressure pattern follows one of two distinct weight transfer styles: the "front foot" or the "reverse" (Ball and Best, 2011). Different weight transfer styles may also be important for meeting mutual requirements of submaximal speed and accuracy in partial golf shots. This could inform how a player should train and be coached. The aim of this study was to identify if skilled golfers use different weight transfer styles in partial golf shots.
METHODS: Twelve skilled golfers (handicap 3.1 ± 3.1 stokes) performed five full swings with a driver and pitching wedge to hit a ball into a net 5 m away while standing on 2 forces plates. Using ball flight data (Flightscope) from full wedge shots, 2 sub-maximal distances (75% and 50%) were identified and participants performed five partial swings to each. Centre of pressure parallel with the line of shot and relative to the feet (CPy%) was quantified at 6 swing events (Ball and Best, 2007). Weight transfer style was determined (Ball and Best, 2007) and the effect of shot type and swing style on CPy% was assessed using two-way mixed model ANOVA's.
RESULTS: In all shot conditions, both weight transfer style groups produced a large backwards shift in CPy% during the backswing. A large forwards shift in CPy% also occurred during early downswing. However, significant interactions at ball contact ($F(3, 30) = 4.51$, $p = 0.01$) and mid follow through ($F(3, 30) = 8.90$, $p = 0.00$) indicated that the reverse style was present in full golf swings. Compared with front foot players, reverse players positioned CPy% significantly closer to the back foot at ball contact (CPy% difference = driver 27%; pitching wedge 30%) and mid follow-through (CPy% difference = driver 33%; pitching wedge 32%) in full golf shots. This trend was not apparent in partial shots where all players conformed to the front foot style.

CONCLUSION: In full golf shots, skilled golfers adopted either the front foot or reverse style (Ball and Best, 2011). During partial shots, all players conformed to the front foot style suggesting that players who adopt a reverse style in full swings may use different movement strategies when shot emphasis is placed on distance control and accuracy (Okuda et al. 2010). As coaching cues will differ depending on style (Ball and Best, 2007) these findings further highlight the importance of weight transfer style identification. Future studies should examine whether reverse style players rely on different kinematic movement strategies in full shots and whether this impacts on kinematics used in partial shots.

TIME UNDER TENSION AS AN INDICATOR FOR GATE-TO-GATE RUNTIME IN ALPINE SKIING

NILSSON, R., LINDBERG, A.S., THEOS, A., FERGUSON, R., PIETERS, E., MALM, C.

SPORTS MEDICINE UNIT

INTRODUCTION: Competitive alpine skiing is a complex sport that places high demands on its practitioners (Turnbull, Kilding et al. 2009). Since the time difference between first place and lower placings is small (Hebert-Losier, Supej et al. 2014), a quantification of the performance on skis can be of utmost importance. A widely used method of determining skiing performance in alpine skiing is the use of video capture (Federolf 2012). Using video footage to identify performance indicators (PI) for alpine skiing can be problematic as analysis of video footage is subjective (Hughes and Franks 2015), thus potentially affecting the reliability of the analysis (Franks and Miller 1986). The aim of this study is to investigate whether or not time under tension (TUT) can be used to estimate gate-to-gate (G2G) runtime in competitive alpine skiing.
METHODS: Two video analysts used frame by frame method in a video analysis software. TUT and G2G were calculated in for skiers placing 1, 10 and 20 in four different WC competitions (a total of 12 different slalom runs). A linear regression calculation was conducted to predict G2G skiing performance during the last third of a run based on the TUT during the first two-thirds of the same run. Standard telecasting footage (25 fps) was used for all analyses.
RESULTS: A strong correlation was found in two races (R2 = 0.943 – 0.957) and medium correlation (R2 = 0.432 – 0.725) was found in the other two. However, none of the models reached statistical significance ($p > 0.05$).
CONCLUSION: The results of this study indicate that less TUT could be beneficial for the sport-specific performance in alpine skiing as less TUT leads to faster run time. Due to the lack of significant models, it is not possible to establish TUT as a valid PI for competitive performance. For coaches in alpine skiing, however, these results suggest that there are performance benefits to gain from focusing on technique with the intention of completing the turns as quickly as possible and minimizing the TUT.

MODELING THE PERFORMANCE STRUCTURE IN ELITE TRIATHLON: A STRUCTURAL EQUATION APPROACH

HOFFMANN, M.1, SEIDEL, I.1,2, MOELLER, T.3,4, STEIN, T.1

1: KARLSRUHE INSTITUTE OF TECHNOLOGY , 2: OLYMPIC TRAINING CENTRE LOWER SAXONY < GERMANY>, 3: GERMAN TRIATHLON UNION , 4: INSTITUTE FOR APPLIED TRAINING SCIENCE

INTRODUCTION: Triathlon as a classic endurance sport comes along with high training loads. Therefore, training science needs to provide a scientific basis for complex statements on training schedules by identifying relevant performance parameters (Hohmann & Brack, 1983). Thus, the aim of the present study was to assess the performance structure in Olympic distance triathlon of elite athletes by structural equation modelling (SEM) based on anthropometric and physiological variables measured during regular performance diagnoses.
METHODS: 19 anthropometric and 16 physiological parameters of 25 laboratory tests of eleven male elite triathletes (23.38±2.79 years) were collected at the Institute for Applied Training Science (Germany) between 2008 and 2012. After necessary preprocessing steps (e.g. normalization of race times) a SEM was developed based on theoretical considerations about the performance structure in triathlon as well as a preselection of measured parameters based on the expertise of four professional German triathlon coaches and estimated using robust maximum likelihood (MLR) estimation. Comparative Fit Index (CFI), robust Tucker-Lewis-Index (TLI), root mean square error of approximation (RMSEA) and standardized root mean square residual (SRMR) were used to evaluate the model (Schreiber et al., 2006).
RESULTS: The SEM yielded a well-fitting model (CFI=0.99, TLI=0.99, RMSEA=0.03, SRMR=0.11, DOF=7). Thereby, the most important performance parameters considered in the SEM were BMI [kg/m2], body weight [kg], maximum running pace [m/s], running pace at 3-mmol/l blood lactate [m/s] and relative VO2max [ml/min/kg].
CONCLUSION: The development of a SEM considering two anthropometric and three physiological variables provide a significant contribution to clarify the performance structure in male elite Olympic distance triathlon. While creating or optimizing training schedules, one should pay attention to the identified parameters to exploit further capacities. Regarding previous studies mainly predicting individual triathlon performance (Schabort et al., 2000; Hoffmann et al., 2017), SEMs lead to a clearer understanding of the interaction between parameters and performance. However, the present study should be regarded as a first step, since the sample size is considerably small leading to a limited generalizability of the results.

BONE MINERAL AND TISSUE COMPOSITION AMONG FEMALE ADOLESCENT ATHLETES CONTRASTING IN MECHANICAL IMPACT

VALENTE-DOS-SANTOS, J.1,2,3,4, TAVARES, O.M.5, DUARTE, J.P.1,6,7, COSTA, D.1, SOUSA-E-SILVA, P.M.1, MARTINHO, D.V.1,7,8, RAMA, L.M.1,2, FONTES-RIBEIRO, C.3,5, COELHO-E-SILVA, M.J.1,2

1: UNIVERSITY OF COIMBRA, 2: UNIVERSITY OF COIMBRA, 3: FCT, 4: ULHT, 5: POLYTECHNIC INSTITUTE OF COIMBRA, 6: FCT, 7: UNIVERSITY OF COIMBRA, 8: FCT

INTRODUCTION: Exploring the osteogenic effect of different bone-loading sports is particular relevant to understand the interaction between skeletal muscle and bone health during growth. The aim of the present study was to examine the effects of long term participation in competitive sports contrasting in mechanical loading on bone mineral content (BMC) and density (BMD) among female adolescent athletes. It was hypothesized that the distinct stimuli differently affect their skeleton.
METHODS: A total of 46 adolescent female athletes were evaluated. The high impact group included 26 volleyball players (16.20±0.77 years). The nonimpact group consisted of 20 swimmers (15.71±0.93 years). Lean soft tissue and fat tissue, BMC and BMD were assessed using dual-energy X-ray absorptiometry. Dietary intake was obtained using food frequency questionnaires. Cohen's d effect sizes and thresholds (0.2, 0.6, 1.2, 2.0, 4.0 for trivial, small, moderate, large, very large and extremely large) were used to evaluate the magnitude of the differences.
RESULTS: Volleyball group displayed moderately higher (d=0.76-1.06, p<0.05) skeletal BMC (12.4%, 13.8%, 15.1% and 15.8% respectively for whole body, subhead, trunk and lower limbs) and BMD (5.5%, 6.5%, 7.6% and 6.4%, respectively) than swimmers. Likewise, lean soft tissue at the lower limbs (d=0.72, +5.9%, p<0.05) and fat tissue for the whole body (d=0.87, +29.4%, p<0.05) and trunk (d=0.73, +28.2%, p<0.05) were also moderately greater in the volleyball players.
CONCLUSION: Youth female athletes who participate in high-intensity mechanical loading activities such as volleyball exhibit moderate gains in BMC and BMD at all skeletal sites, except at the upper limbs. The mechanical and non-mechanical stimuli associated with swimming may not be sufficient to trigger the responsiveness of bone cells.

CAN BODY MASS INDEX PREDICT THE OCCURRENCE OF MENARCHE IN ATHLETES?

TSUKAHARA, Y., NAMBA, S., KAMADA, H., YAMASAWA, F.

WASEDA UNIVERSITY

INTRODUCTION: Female athletes are in danger of the female athlete triad (FAT) and relative energy deficiency in sport (RED-S). Even though screening questionnaires and other tools have been used to identify female athletes at risk, determining factor differs in each sport or individual, which makes it harder to screen FAT and RED-S. Amenorrhea is one of the female athlete triad and earlier treatment is important especially for adolescent athletes. However, some athletes do not take it seriously and though having not reached menarche at the age of fifteen, many athletes do not go for treatment since they think it will happen soon. Low body mass index (BMI) leading to amenorrhea should be considered. However, previous studies have not shown the minimum BMI for menarche to occur in female adolescent athletes. Our purpose of this study is to elucidate the specific BMI for menarche to occur in female adolescent athletes.
METHODS: 227 national level, track and field, ninth grade female athletes at age of fifteen were enrolled in this study, including sprinters, long distance runners, hurdlers, jumpers and throwers. They filled in a questionnaire including questions regarding menarche when they participated in a national event.
RESULTS: As BMI increase, percentage of primary amenorrhea has a tendency to decrease. Cutoff point of BMI for primary amenorrhea was 17.4 by receiver operating characteristic (ROC) analysis. That for sprinters and jumpers was 17.3 and for long distance runners, 17.4.
CONCLUSION: Track and field ninth-grade female athletes are likely to reach menarche when their BMI is 17.4 or more.

MULTIDISCIPLINARY OBESITY TREATMENT PROGRAM IMPROVES BODY COMPOSITION, CARDIORESPIRATORY FITNESS AND AUTONOMIC CARDIAC FUNCTION IN ADOLESCENTS OF DIFFERENT DEGREES OF EXCESS BODY MASS

LOCATELI, J.C., LOPES, W.A., DA SILVA, D.F., SIMÕES FERRAZ, C., MENDES, V.H.S., NARDO JUNIOR, N.

STATE UNIVERSITY OF MARINGA

INTRODUCTION: Obesity negatively influences autonomic cardiac function, measured as resting heart rate variability (rHRV), even in youths (Zhou et al., 2012). Cardiorespiratory fitness and fatness play a role on autonomic function (da Silva et al., 2014); however, the combined effects of a multidisciplinary intervention on these variables are still poorly understood. Thus, we aimed to study the effects of a multidisciplinary obesity treatment program on body composition, cardiorespiratory fitness and rHRV indices according to the degree of excess body mass.
METHODS: Twenty-five adolescents were separated into two groups: overweight (OWG=11) and obese (OBG=14). A 16-week multidisciplinary intervention were performed. Weekly group meetings with the psychologists, nutritionists, and exercise professionals, as well as the three times per week water-based exercise program were held. Both pre and post intervention periods had the assessments of body fat (absolute and relative), cardiorespiratory fitness (i.e., estimated VO2max), and autonomic cardiac function (e.g., rMSSD, HF [ms² and nu], and SD1 indices). The adaptations observed were analyzed by magnitude-based practical inferences, based on Hopkins' statistics. The correlations between changes in rHRV indices and changes in body composition and VO2max were checked with Pearson's correlation.
RESULTS: Both groups enhanced parasympathetic activity (e.g., SD1) (OWG: Δ 8.5 [CI 1.7-15.3] "Likely"; OBG: Δ 11.4 [CI 4.3-18.4] "Very Likely") and cardiorespiratory fitness (OWG: Δ 2.0 [CI 1.1-2.8] "Likely"; OBG: Δ 2.4 [CI 1.5-3.3] "Almost certain") with a slightly better enhancement for the OBG (i.e., greater magnitude of change). The OWG showed greater changes in body composition (e.g., %body fat) (e.g., Δ -4.4 [CI -6.0 - -2.8] "almost certain") when compared to the OBG (Δ -3.2 [CI -4.6 - -1.8] "very likely"). Large and negative correlations were noted for percentage changes in body fat markers and percentage changes in parasympathetic indices of rHRV (i.e., rMSSD and SD1).
CONCLUSION: A multidisciplinary program improves parasympathetic activity, body composition, and cardiorespiratory fitness regardless the degree of excess body mass, with slightly better improvement in OWG for body composition and in OBG for the other variables. Changes in parasympathetic indices of rHRV were largely and negatively associated with changes in body composition (Buchheit, 2014).

RELATIONS OF FITNESS PARAMETERS AND MORPHOLOGICAL CHARACTERISTICS OF EIGHT-YEAR-OLD OBESE CHILDREN

ZIVKOVIC, D.1, DJORDJEVIC, M.2, BJELAKOVIC, L.J.1, MALOBABIC, M.3, RANDJELOVIC, N.1

UNIVERSITY OF NIS

INTRODUCTION: The global increase in childhood overweight and obesity has become a worldwide epidemic. The World Health Organization (WHO) claims that there were 41 million obese children in the world under the age of 5 and over 340 million obese children and adolescents aged between 5 and 19 in 2016. The data indicate that the prevalence of excessive nutrition and obesity has increased from 4 (1975) to over 18 percent (2016) (WHO, 2016). Gender differences were no of particular significance, and in the year the study was conducted there
METHODS: The sample of participants consisted of 273 obese children (104 girls and 169 boys), first grade students (mean age 8,26 girls and 8,34 boys) of elementary schools in Nis, Serbia. The following fitness parameters were measured: HR in load, VO2max (ml), HR in peace, bend forward - bend backward – throw test, hand taping, 20m dash with a standing start, Abalakov test and forward bend on the bench test. Morphological characteristics were determined by measuring 13 parameters of longitudinal and transversal dimensions of skeleton, volume and body weight, as well as subcutaneous fat tissue (body height, leg length, arm length, shoulder width, pelvic width, hip width, body mass, thorax volume, upper arm volume, thigh volume, upper arm skinfold, back skinfold and abdominal skinfold). For all of the data we calculated the Mean and standard deviation (SD). Canonical correlation analysis was used to determine the relations between the set of variables representing fitness parameters and the set of variables of morphological characteristics.
RESULTS: Based on the coefficients of canonical correlation analysis, it can be concluded that the spaces of morphological characteristics and fitness parameters are interconnected with two pairs of statistically significant canonical factors at the level of .01 and one pair at the level of .05. The general analysis of the relationships between the first pair of canonical factors suggests that subjects with higher circular dimensionalities of the body, accentuated adiposity and body mass tend to have poorer results in the parameters of cardiorespiratory fitness. Relations of the second pair of canonical factors indicate that subjects with higher dimensions of longitudinal and transversal dimensionality of the skeleton with higher volume and mass of the body achieve worse results in motor tasks requiring the speed of alternative movements. Relations of the third pair of canonical factors indicate that the children with more subcutaneous fatty tissue, greater body height and BMI had statistically significant lower results in Abalakov test, which measured explosive strength of the legs, higher results of HR in peace and in load, and they were slower in 20m dash with a standing start, which confirms the result of some previous studies.
CONCLUSION: It can be concluded that obesity in young school age has negative implications on the fitness parameters in obese children, and therefore on their overall growth and development.

EFFECT OF A SHORT-TERM PHYSICAL ACTIVITY INTERVENTION ON BODY COMPOSITION, BIOMARKERS AND LIFESTYLE PATTERNS IN METABOLICALLY HEALTHY OBESE CHILDREN.

ROMANCE, A.R.1, BENÍTEZ-PORRES, J.1, MOORE, J.B.2, VARGAS CANDELA, A.3, MUÑOZ MELERO, M.3, VILCHES PÉREZ, A.4, MOYA RODRÍGUEZ, P.3, BERNAL-LÓPEZ, M.R.3,4

1: UMA , 2: WFSM , 3: IBIMA , 4: CIBER .

INTRODUCTION: Despite considerable efforts the prevalence of overweight and obesity in children remains high. Visceral adiposity has been identified as a risk factor of cardiovascular disease, type 2 diabetes as well as insulin resistance (Rodicio et al., 2018; Skoczen, Wojcik, Fijorek, Siedlar, & Starzyk, 2015). The purpose of this study was to analyse the effect of a 4-months physical activity programme on visceral adipose tissue (VAT), biomarkers and lifestyle in metabolically healthy obese child population.
METHODS: Data from 131 (n=70 boys, n=61 girls) healthy children (Age: 7.8±1.4 years, BMI: 24.6±3.4 kg/m2) enrolled in primary schools were used. The Actigraph GT3X monitor device was used to assess PA. Accelerometers were set to register 60-second epoch cycles, and were programmed to assess 7 days. We selected the cut points from Pulsford et al. to determine the time spent on different intensity levels of PA and sedentary time. Blood analysis was carried out to obtain biomarkers. Total and regional body composition were estimated using dual-energy x-ray absorptiometry (DXA). Children performed 5 days of aerobic PA per week (1h). A repeated-measures T-Student test was conducted to examine temporal changes (4 months).
RESULTS: Significant changes for moderate and vigorous PA were found between both moments (Moderate PA min/d 15.3±15.5 vs. 35.5 ± 14.8, p<0.001; Vigorous PA min/d 1.2±3.1 vs. 9.1±6.3 p<0.001 respectively). Some nutritional variables at second moment were significantly lower than baseline (Energy kcal 2180.2 ± 378.1 vs. 2007.5 ± 350.0 p<0.01; Carbohydrates g/d 228.8 ± 44.1 vs. 205.4 ± 44.9 p<0.001). In contrast, a significant reduction in HDL cholesterol was seen between baseline and 4 months cut (49.4±11.3 vs. 45.9±11.6, p=0.05). There were no significant differences for the rest of biomarkers and body composition variables, VAT included.
CONCLUSION: Our results suggest that there are signs of improvement in lifestyle patterns and some biomarkers. However, 4 months of PA intervention seem to be insufficient to obtain a significant change on body composition and VAT in metabolically healthy obese children. A longer temporal follow-up is required to observe changes.

PHYSICAL ACTIVITY AND CHILDREN OVERALL HEALTH STUDY (PACH STUDY) – DESIGN AND BASELINE CHARACTERISTICS

REIHMANE, D., OZOLINA-MOLL, L., SLEZINA, L., JUSTAMENTE, I., TREIJA, E.M., RAUDENIECE, J., SILINA, L.

UNIVERSITY OF LATVIA

INTRODUCTION: Latvian Olympic Committee has developed a pilot project The Sport for All Class (SFA Class) which is exploring innovative solutions aimed at promotion of overall health of children through regular physical activities in schools outside the curriculum. To clarify whether extra school based physical education (PE)/ SFA Class) can prevent chronic cardio-metabolic diseases and facilitate emotional/psychological wellbeing in children a prospective 4 years study was designed.
METHODS: In fall (2017) 105 3rd grade students (46 boys and 59 girls) were enrolled in the study (convenience sampling); SFA class (N=56) and Control (N=49) students having 5 vs. 2 * 40 min PE lessons, respectively. During research groups 1st visit to schools corresponding baseline characteristics among others were determined: body mass index (BMI), waist circumference (WC), heart rate (HR) (3-min Kasch Pulse Recovery Test) and serum biomarkers. The Physical Activity Questionnaire for Older Children (PAQ-C) was used to determine daily activity levels. Data were analyzed with SigmaPlot12.5. Descriptive data are represented as mean ± SEM and Sperman correlation analysis was performed. Second screening is going to be 6 months later, when impact of SFA Class will be evaluated analyzing the differences between the study groups.
RESULTS: Baseline characteristics are as follows: age (9 – 10 years); BMI 17.6 ± 0.3 kg/m2; WC 60.5 ± 0.8 cm, hsC-reactive protein (CRP) 1.01 ± 0.17 mg\L, insulin resistance index (HOMA-IR) 1.70 ± 0.13, triacylgylcerides (TAG) 0.76 ± 0.04 mmol/l; leptin 4.9 ± 0.6 pg/ml; adiponectin 200 ± 18 pg/ml. PAQ-C score was 1.79 ± 0.07n (1 indicates low whereas 5 - high physical activity). HR at 3rd min of Kasch Pulse Recovery Test reached 163 ± 1 beats/min and 112 ± 2 beats/min during 1 min of recovery.
There were significant ($p < 0.05$), positive correlations in between BMI, WC, hs-CRP, HOMA-IR, TAG and leptin, except, no correlation between WC and TAG ($r = 0.17$; $p = 0.09$) was found. In addition, PAQ-C score was negatively correlated with HR ($r = -0.235$), TAG ($r = -0.206$), HOMA-IR ($r = -0.216$).
CONCLUSION: Baseline data suggests that aerobic fitness level and serum biomarkers which usually are predictors for chronic diseases in adults are in normal ranges within children in our study group. However, the PAQ-C score which shows reduced physical activity levels in children and is related to increased HR during physical activity raises concerns that inactive lifestyle could cause health problems later in adolescence. PACH-Study also evaluates cognitive functions, thus follow up data, larger study groups (enrolment of children of the same age in next fall) and comparison between them in all various aspects, will answer the question, whether extra school based PE can promote general health of children.

PHYSICAL ACTIVITY PREFERENCES IN TEN-YEAR OLD NORWEGIAN SCHOOLCHILDREN

RESALAND, G.K.

WESTERN NORWAY UNIVERSITY OF APPLIED SCIENCES

INTRODUCTION: A worrying number of children do not meet the physical activity recommendations, and physical activity levels steadily decline with age in schoolchildren. Moreover, patterns of reduced amounts of physical activity appear to persist into adulthood, which could negatively affect children's future health. As such, it is critical to intervene early to provide opportunities for increased physical activity throughout the childhood and school provide an ideal target for physical activity interventions. Most school-based interventions focus on the dose and intensity of physical activity, but few consider the type and the content of the activities that children prefer. To this end, we investigated physical activity preferences in a large sample of ten-year old Norwegian schoolchildren to provide researchers and practitioners with better tools to design interventions and programs in schools that are tailored to the preferences of the children.
METHODS: In total, 1026 ten-year-olds completed a questionnaire indicating their preferences for physical activities. We utilized principal component analysis to derive five component patterns of physical activity and studied whether gender, cardiorespiratory fitness and abdominal adiposity were associated with these patterns.
RESULTS: Combined, boys and girls reported soccer and slalom skiing as their most preferred activities. The most pronounced gender differences were for activities favored by girls: dancing, gymnastics, exercise to music and jumping rope . Only two of the activities, soccer and strength training, were significantly more preferred by boys. To better understand patterns across these activities, the five, derived component patterns of a physical activity were analyzed via linear mixed-effect models. Results showed a strong girl preference for component 2 . Also, cardiovascular fitness was negatively associated with component 3 , and positively associated with component 4 and 5 .
CONCLUSION: These results inform future school-based physical activity interventions to provide more relevant and appealing options for those children who might otherwise be missed by "one-size-fits-all" school-based physical activity interventions.

MO-PM10 Hypoxia

HOOK BREATHING AND SAO2 RECOVERY AFTER DEEP APNEA DIVES

FERNÁNDEZ, F.A., RODRÍGUEZ-ZAMORA, L., SCHAGATAY, E.

CENTRO SUPERIOR DE ESTUDIOS UNIVERSITARIOS LASALLE

INTRODUCTION: One of the main risks of deep apnea diving is hypoxic syncope at the surface (Lindholm, 2007). After diving, most freedivers perform a breathing protocol called "hook breathing" (HB), involving an interrupted exhale to build up some intrapulmonary pressure (Whinnery, 1990), said among freedivers to facilitate restitution of the basal oxygen saturation values. We examined the influence of HB on arterial oxygen saturation (SaO2) recovery, compared to normal breathing (NB) after ~30 msw dives.
METHODS: Twenty-two experienced competition male breath-hold divers participated. They performed free immersion dives (FIM), i.e. pulled down and up on a vertical line using arms only. Their mean(SD) personal best was 57(26) m. Divers performed two 30 m FIM dives, followed by HB or NB throughout recovery, at a weighted order. SaO2 and heart rate were recorded using pulse oximetry.

RESULTS: During early recovery NB resulted in a tendency for higher SaO2, but after 25 s SaO2 was slightly higher after HB. When the divers were subgrouped according to their ability to "squeeze", thus fail to reach 95% SaO2 in 2 minutes (squeezers; n=5), or not (non-squeezers; n=17), a clearly higher SaO2 resulted after HB in the squeezers (P<0.05), while non-squeezers showed no effect.
CONCLUSION: The results suggest that HB is highly efficient in "squeezers", showing delayed SaO2 recovery, while in subjects with less proneness to squeeze the effect is less evident, as NB is sufficient to recover. The proposed mechanism is that the increased pulmonary pressure created with HB will counteract the pulmonary edema developed and facilitate oxygen uptake in divers prone to squeeze.

4-WEEKS HHL TRAINING IMPROVES ROWERS CUTANEOUS MICROCIRCULATION AND ENDOTHELIAL FUNCTION

ZHIJUN, M.

SHANGHAI UNIVERSITY OF SPORT

INTRODUCTION: Sport scientists always pay attention to cardiorespiratory and hematologic system on benefit of hypoxic training, but peripheral circulation may be one of these benefit, which is one cause of improving performance. So, in order to know whether or not hypoxic training affect athletes cutaneous microcirculation, we test rowers microcirculation during 4 weeks High live-High train-Low exercise(HHL)
METHODS: Sport scientists always pay attention to cardiorespiratory and hematologic system on benefit of hypoxic training, but peripheral circulation may be one of these benefit, which is one cause of improving performance. So, in order to know whether or not hypoxic training affect athletes cutaneous microcirculation, we test rowers microcirculation during 4 weeks High live-High train-Low exercise(HHL)
RESULTS: HHL training improve rowers blood flow (9.69±3.66PU VS12.66±5.60PU) and PORH reserve capacity(4.92±1.23VS5.30±1.54) of forearm and remains for three weeks after HHL training(blood flow 10.03±5.07PU,PORH reserve capacity 5.44±1.69). Nomoxia training also increase blood flow of forearm(8.50±2.27PU VS 10.40±4.50PU), but do not increase PORH reserve capacity(5.64±1.91VS 4.93±1.92)
CONCLUSION: 4 weeks HHL training of rowers increase forearm blood flow, but no thigh. This is because thigh is main working muscle of rowers, which may be affected by training status and fatigue. And also, PORH reserve capacity is an indicator of endothelial function. In this study, we find HHL rowers increase their PORH reserve capacity, which means endothelial function is improved by hypoxia training. So, besides the traditional research of Hematologic System on hypoxia training, we find 4 weeks HHL training increase forearm blood flow and improve endothelial function. This may be one mechanism of improving performance, which need more studies to confirm.

EFFECTS OF PERIODIC HYPOBARIC HYPOXIC ENVIRONMENTS ON PHYSIOLOGICAL RESPONSES DURING UNSTEADY WORKLOAD EXERCISE

NISHIMURA, K., NAGASAKI, K.

HIROSHIMA INSTITUTE OF TECHNOLOGY

INTRODUCTION: We developed a periodic pressure-controlling system in a chamber to mimic a hypobaric hypoxic environment. The characteristics of this system varied between a decreased pressure at an altitude of 1500 m for 180 s and an increased pressure at an altitude of 0 m for 180 s. Furthermore, the relative concentration of oxygen was alternated between 20.9% and 16.9%. The present study aimed to determine the effects of periodic hypobaric hypoxic environment (PHHE) on physiological responses during unsteady workload exercise.
METHODS: This study included 15 healthy men, all of which provided written informed consents. We set developed two experimental conditions with subjects exercising in a PHHE system (periodic-condition) or at an altitude of 750 m (fixed-condition). In the periodic condition, the atmospheric pressure was changed periodically from 967 to 817 hPa (the external pressure was 1,008 hPa), while in the fixed condition, the atmospheric pressure was fixed at 892 hPa. All subjects performed a two-stage cycling exercise for 32 min. The steady-state exercise test consisted of three 4 min bouts of exercise at 20%, 60%, and 40% of the maximal oxygen intake (VO2 max), while the unsteady-workload exercise test consisted of five 4 min bouts of exercise with a gradual increase and decrease in the workload between 20% and 60% of the VO2 max. The heart rate (HR), systolic blood pressure (SBP), diastolic blood pressure (DBP), arterial oxygen saturation (SpO2), and rating of perceived exertion (RPE) were measured under both conditions. The HR maximal values, minimal values, amplitude, and phase lag (response to maximal/minimal workload) during unsteady-workload exercise were calculated. Each subject participated in the two conditions in a random order 1 week apart.
RESULTS: During exercise, HR and SBP were significantly lower in subjects under the periodic-condition compared to those under the fixed-condition, whereas the RPE was significantly higher in subjects under the periodic-condition. DBP and SpO2 did not show a significant difference between the two conditions. In addition, the phase lag and amplitude of HR did not show significant differences between the two conditions. Previous studies reported that the SpO2, HR, and SBP were significantly lower during exercise in subjects exposed to PHHE compared to those who were not. Furthermore, the brachial-ankle pulse wave velocity was significantly decreased in subjects after their exposure to PHHE. Our results show that during exercise in a PHHE, cardiocirculatory responses were decreased.
CONCLUSION: We conclude that PHHE may be an effective training method during highland stays.

TISSUE OXYGENATION RESPONSE TO DIFFERENT RELATIVE LEVELS OF BLOOD-FLOW RESTRICTION EXERCISE

FATELA, P.1,2, REIS, J.F.1,2, MENDONCA, G.V.2, INFANTE, J.2, VALAMATOS, M.J.2, ALVES, F.2, MIL-HOMENS, P.2

1 UNIVERSIDADE EUROPEIA - LAUREATE INTERNATIONAL UNIVERSITIES ; 2 UNIVERSIDADE DE LISBOA - FACULDADE DE MOTRICIDADE HUMANA

INTRODUCTION: Recently, the effect of blood-flow restricted exercise (BFRE) in tissue oxygenation has been compared with that seen in non-restricted conditions (Ganesan, 2015). Unfortunately, the acute effect of BFRE performed at different relative levels of pressure has never been investigated. Therefore, we aimed to analyse the acute response of deoxyhemoglobin (HHb) concentration and tissue oxygen saturation (TOI) to different relative levels of BFRE in the vastus lateralis (VL) muscle using near-infrared spectroscopy (NIRS).
METHODS: Fourteen healthy active men (24.8±5.4 yrs; height: 175.2±4.4 cm; body mass: 71.1±6.9 kg) were tested for unilateral knee extension exercise (20% 1RM: 4 sets of 30+15+15+15 reps, with 30-s recovery), on 4 different conditions: no-BFR (NO) or by 3 BFR levels normalized to the value of absolute vascular occlusion determined at rest (40, 60 and 80% BFR). HHb concentration and TOI were measured using a continuous-wave tissue oximeter (NIMO, Nirox srl, Brescia, Italy). The relative change in each parameter was calculated from the end of each set to the end of the respective recovery period. A two-way repeated measures ANOVA [condition (NO vs. 40 vs. 60 vs. 80% BFR) x time (rest1 vs. rest2 vs. rest3)] was used to determine the impact of each condition on HHb and TOI. Paired t tests were computed to explore differences in both parameters for each condition (NO, 40, 60 and 80% BFR).

RESULTS: HHb concentration was differently affected by all conditions in each recovery period (F=101,76; p>0.00). In each condition, there were significant differences in the changes of the HHb concentration between the end of each set and that of each recovery periods (p>0.01). Importantly, the changes in the HHb concentration values were from: -68.6 to -75.8%; -28.6 to -34.1%; -3.1 to -9.9%; and +13.2 to +17.7% for the NO, 40, 60 and 80% BFR, respectively. The TOI values were similarly affected by exercise between the NO and the 40% BFR condition and between the 60 and the 80% BFR condition (p>0.05). However, the differences in this parameter, between the end of the sets and the end of the resting periods were significant (p>0,01). TOI values changed from: +79.2 to +80.0%; +71.8 to +76.8%; +47.6 to 53.3%; and +32,2 to +39,9% in the NO condition, 40BFR, 60BFR and 80BFR, respectively.
CONCLUSION: This study demonstrates that exercising at different levels of relative blood flow restriction affects the fractional oxygen extraction during the interset recovery period. Accordingly, oxygen saturation is affected in similar fashion. However, in this parameter, the NO condition is not significantly different from a low-restricted condition (40BFR), as well as, high-restricted conditions (60 vs. 80BFR) are not different between each other. These results indicate that, when tissue oxygenation is analysed during BFRE, there may be a maximum threshold for the level of relative restriction, beyond which no further significant effect is promoted.

SALIVARY CORTISOL RESPONSE POST 15 S MAXIMAL-ANAEROBIC EXERCISE AT ALTITUDE

KRUSCHE, T., MATIAS SANTOS, V., DE MARÉES, M., SONNEBORN, M., PLATEN, P.

RUHR-UNIVERSITÄT BOCHUM

INTRODUCTION: Serum and salivary cortisol increase after psychological and physical stress. Previous studies mostly report a rise in resting and post aerobe exercise cortisol at altitude (e.g. Chen et al., 2006 & Zaccaria et al., 1998). However, little is known about the cortisol response (CR) post maximal-anaerobic exercise in hypobaric hypoxia. Therefore, the aim of the study was to analyse the effect of 15 s maximal-anaerobe exercise on rapid salivary CR.
METHODS: The CR of 9 healthy moderately trained subjects (m: n=7, f: n=2; 24±5 yrs; BMI: 23.1±2.0 kg/m2; VO2max: 52.4±5.0 ml/min/kg) was investigated before, after (d-4 and d+10; ~ sea level), and at moderate (d2; 2375 m) and high altitude (d4; 3647 m). In the morning between 9-11 am salivary cortisol levels was measured immediately before and after 15 s skipping test to maximum exertion (number of skips video-documented: SN). The CR is defined as delta values between pre- and post-exercise cortisol levels. In addition, morning heart rate variability (mRMSSD) was measured to asses' physiological stress based on sympatho-vagal activity (Thayer et al., 2011). Further, resting oxygen saturation (SaO2) and maximal capillary blood lactate accumulation after exercise (Lac max) were determined. Data are presented as median, and 1st and 3rd quartile.
RESULTS: The SN and mRMSSD remained stable at all testing times (SN: d-4 = 64 (61/70), d2 = 64 (59/67), d4 = 64 (61/69), d+10 = 68 (60/71); mRMSSD: d-4 = 93.0 (58.5/114.0), d2 = 67.5 (33.3/122.0), d4 = 67.0 (40.5/129.0), d+10 = 60.5 (32.0/95.5) ms, p>0.05, respectively). However, determined CR remained initially unchanged at 2375 m compared to d-4 and d+10 (d-4 = 0.14 (-0.26/0.94), d2 = -0.24 (-0.57/0.50), d+10 = 0.12 (-0.41/0.97) nmol/l, p>0.05), but rose significantly at 3647 m compared to d2 and d+10 (d4: 1.09 (0.14/1.99), nmol/l, p<0.05, respectively). Lac max was higher and SaO2 was lower at both altitude levels compared to sea level (Lac max: d-4 = 5.1 (4.0/6.1), d2 = 6.0 (5.7/7.8), d4 = 6.7 (5.9/8.1), d+10 = 5.9 (5.4/7.4) mmol/l; SaO2: d-4 = 98% (96%/100%), d2 = 95% (95%/98%), d4 = 91% (88%/92%), d+10 = 99% (97%/100%), p<0.05, respectively).
CONCLUSION: In conclusion, our findings are in line with previous studies of an elevated cortisol level after exercise. Hypobaric environment is known to induce lower SaO2 and physiological stress, which is reflected in higher cortisol excretion (Woods et al., 2012). This provides an explanation for a pronounced CR in high and a lack thereof in moderate altitudes. However, heart rate variability did not reflect a stress response in this particular context. Furthermore, increased Lac max values at altitude indicate metabolic changes during anaerobic exercise which may have contributed higher post-exercise cortisol levels as well.

REPEATED MAXIMAL DYNAMIC APNEAS ELICIT HIGHER SERUM ERYTHROPOIETIN CONCENTRATIONS THAN MAXIMAL STATIC APNEAS IN ELITE AND NON-DIVERS

ELIA, A.1, BARLOW, M.J.1, DEIGHTON, K.1, WILSON, O.J.1, OHARA, J.P.1

LEEDS BECKETT UNIVERSITY

INTRODUCTION: Hypoxia is a condition of reduced oxygen (O2) concentration in breathable air or blood. During static (STA) and dynamic (DYN) apneas breath-hold divers are regularly exposed to transient acute hypoxic conditions, interspersed with periods of normal breathing. Increases in serum erythropoietin (EPO) are reported to occur 30-minutes after static apnea-induced hypoxia and return to baseline five hours after. However, no data currently exist regarding the level of circulating EPO following a series of repeated maximal DYN apneas performed by either non-divers (ND) and/or elite breath-hold divers (EBHD). Therefore, this study investigated the effects of maximal STA and DYN apneas on EPO concentrations in ND and EBHD.
METHODS: 18 healthy male participants were recruited, of which 8 were EBHD (national team members) and 10 were sedentary ND. Each participant performed five maximal DYN apneas in a swimming pool with a two-minute rest between each apnea. Subsequently, within a week participants performed two sets of five maximal STA apneas with a ten-minute rest in between sets and a two-minute rest between each apnea. Peripheral oxygen saturation (SpO2) was assessed at completion of each apnea. Following completion of each apneic protocol, venous samples were drawn at 30, 90 and 180 minutes after the last apnea to assess circulating EPO levels.
RESULTS: DYN apneas induced lower SpO2 values in both groups (EBHD 62 10.45%,p=0.024; ND 85 5.8%, p=0.020) when compared with STA apneas (EBHD 76 7.44%; ND 96 1.43%), with EBHD attaining significantly lower SpO2 values during both conditions than ND (STA p=0.006; DYN p=0.0001). EBHD EPO concentrations were higher after 30 (10.82 2.5mlU/mL,p=0.017) and 180 minutes (10.87 2.1mlU/mL,p=0.024) and with a trend at 90 minutes (10.13 2.04mlU/mL,p=0.058) of DYN apneas when compared to baseline (6.85 0.9mlU/mL). ND EPO concentrations were unchanged at 30 (6.48±2.54mlU/mL,p=1), 90 (5.65±2.08mlU/mL,p=1) and 180 (6.49±2.44mlU/mL,p=1) minutes of DYN apneas when compared to baseline (6.45±3.43mlU/mL). STA apneas did not induce a significant increase in serum EPO at 30 (EBHD 6.78±1.22mlU/mL,p=1; ND 6.27±1.68mlU/mL,p=1), 90 (EBHD 6.67±2.27mlU/mL,p=1; ND 6.43±1.62mlU/mL,p=1) and 180 minutes (EBHD 7.69±2.48mlU/mL,p=1; ND 6.55±1.90mlU/mL,p=1) when compared to baseline in either group.

CONCLUSION: Serum EPO concentrations increased from baseline after the DYN protocol in the EBHD group only, whereas no changes were observed after the STA protocol for either group. These data suggest that the lower SpO2 levels attained by the EBHD during the DYN protocol lead to a greater physiological stress and that this was associated with an increase in circulating EPO.

THE EFFECTS OF GRADED REDUCTIONS IN INSPIRED OXYGEN FRACTION ON COGNITIVE FUNCTION

WILLIAMS, T.1, CORBETT, T.1, MCMORRIS, T.2, THELWELL, R.1, TIPTON, M.1, COSTELLO, J.1

1: UNIVERSITY OF PORTSMOUTH 2: UNIVERSITY OF CHICHESTER

INTRODUCTION: Whilst it is generally accepted that cognition is impaired under hypoxia, the large disparity in methodologies employed in the existing literature has made drawing definitive conclusions problematic. Moreover, it is still unclear i) at what level of hypoxia cognitive impairment begins, ii) the cognitive domain(s) that is/are affected, and iii) the mechanism(s) responsible for these deteriorations. Therefore, the aim of this study was to assess a variety of central executive and non-executive tasks and the concurrent changes in physiology over a range of simulated altitudes. It was hypothesised that there would be a linear relationship between fraction of inspired oxygen (FiO2) and cognitive performance, with non-executive tasks displaying greater resilience to hypoxia than executive tasks.
METHODS: A within participant, balanced, cross over design was employed. Twelve healthy male participants (mean [SD] 22[4] yrs, 75[9]kg, FEV1/FVC ratio 85[5] %) completed a 4-task cognitive testing battery designed to examine the cognitive domains of inhibition, selective attention (Eriksen Flanker), working memory (N-back) and simple and choice reaction time (Deary-Liewald). The battery was completed before and after 60 minutes of exposure to each of the following FiO2 values: 0.21 (sea level), 0.17 (~1600m), 0.15 (~2800m), and 0.12 (~4300m). Peripheral oxygen saturation (SpO2), cerebral oxygenation (measured via near-infrared spectroscopy), minute ventilation, mood disturbance and acute mountain sickness were also recorded.
RESULTS: As designed, SpO2 decreased as altitude increased (FiO2 0.21: 96[0] %, FiO2 0.17: 94[2] %, FiO2 0.145: 89[2] %, FiO2 12: 81[4] %, $P < 0.05$). Despite a significant reduction from baseline in cerebral oxygenation (-5.72[2.9] %, $P < 0.001$) and an increase in mood disturbance ($P = 0.049$) following exposure to FiO2 0.12, cognitive performance was maintained for both central executive and non-executive tasks across all conditions (all $P > 0.05$). Cognitive performance was not associated with cerebral oxygenation or any other physiological or perceptual measures.
CONCLUSION: These results suggest that a simulated altitude of up to ~4300m and the resultant physiological changes do not provide a sufficient stimulus to impair cognitive function at rest.

EFFECTS OF MEAN SLEEPING HEIGHT INCREMENTS OF 870 M PER NIGHT UP TO 3600 M ON SLEEP QUALITY DURING HIKING AT HIGH ALTITUDE

SCHÄFER, H.1, KRUSCHE, T.1, KÖLLING, S.2, MATIAS SANTOS, V.1, DE MARÉES, M.1, PLATEN, P.1

FACULTY OF SPORT SCIENCE, RUHR-UNIVERSITÄT BOCHUM

INTRODUCTION: Sleep is essential for regeneration and health during altitude exposure. A decrease in sleep quality (SQ) has been described in the first nights at high altitude [1,2,3]. Impaired SQ is characterized by perceived restlessness, frequent awakenings (wake after sleep onset; WASO) and reduced sleep duration, resulting in decreased sleep efficiency (SE) [2,3]. High-altitude medicine recommendations for increase in height include increments in sleeping height of not more than about 500 m per night from 3000 m. Aim of the study was to analyse the effect of high altitude exposure on SQ when sleeping height increases by 870 m per night in the first 4 days of a typical high altitude sojourn.
METHODS: 9 healthy moderately trained subjects (m: n=7, f: n=2, 23.3±3.9 yrs, BMI: 23.1±2.0 kg/m2) were investigated in a 6-day baseline window (BL: d-6 – d-1: 156 m) before a 9-day-period (d1 – d9) hiking and sleeping at moderate to high altitude. Sleeping height was 1190 m at the 1st night (d1), 2375 m at the 2nd and 3rd nights (d2 – d3) and 3647 m from 4th to 9th night (d4 – d9)), leading to a mean daily increase in sleeping height of 870 m. Daily sleep monitoring was conducted objectively with multi-sensor actigraphy (SenseWear™) and subjectively using sleep diary. Parameters included SE, wake frequency (WF) and WASO. In addition, the Lake Louise Score (LLS) and oxygen saturation (SaO2) was measured every morning. Significance was set at 0.05. Data are presented as median (M), interquartile range (IQR) and total data.
RESULTS: Objectively determined SE, WF and WASO remained unchanged compared to BL (SE: BL: M=89%, IQR=4.6; d1: M=90%, IQR=5.0; d2: M=89%, IQR=10.2; d4: M=82%, IQR=10.0; d9: M=89.2%, IQR=7.0; WF: BL: M=11.0, IQR=6.5; d1: M=7.0, IQR=5.5; d2: M=12.0, IQR=11.0; d4: M=10.0, IQR=7.0; d9: M=8.0, IQR=7.5; WASO: BL: M=30.0, IQR=19.5; d1: M=10.0, IQR=23.5; d2: M=30.0, IQR=51.0; d4: M=35.0, IQR=39.0; d9: M=12.0, IQR=25.0; $p>0.05$). In contrast, subjectively determined WF and WASO increased on d4 compared to BL (WF: BL: M=0.3, IQR=0.7; d4: M=2.0, IQR=3.0; WASO: BL: M=1.0, IQR=3.5; d4: M=10.0, IQR=17.5; $p<0.05$). Subjectively determined SE was not analysed due to missing data. The respective sleeping score item of LLS showed no differences between BL and d1, d2, d4, and d9 (BL=0, d1=0, d2=3, d4=7, d9=2; $p>0.05$). During the study one subject was diagnosed with mild acute mountain sickness on d4 (LLS=4). All subjects had SaO2 values higher than 85% throughout the sojourn (range = 85% – 99%).
CONCLUSION: Objectively determined sleep quality remained unaffected through the chosen strategy of sleeping height increase. In contrast, subjectively perceived SQ was poorer at the first night of sleeping above 3000 m. More research is needed to explore the difference between objectively and subjectively determined sleep quality at high altitude.

INFLUENCE OF MODERATE AND HIGH ALTITUDE ON GUSTATORY PERCEPTION

FRON, K., RIEMER, J., KRUSCHE, T., PLATEN, P.

FACULTY OF SPORT SCIENCE, RUHR-UNIVERSITY BOCHUM

INTRODUCTION: Nutrient intake plays an essential role for safety and performance in sports. Mountaineering at high altitude requires sufficient energy intake to guarantee physical performance and safe acting under such conditions. Previous studies showed that appetite and hunger were inhibited in hypobaric hypoxia [1]. The sensory experience of eating is an important determinant of food intake control, often attributed to the positive response associated with certain sensory cues [2]. The purpose of the study was to investigate whether gustatory thresholds (GT) are altered at moderate and high altitude.
METHODS: Gustatory detection threshold (DT) and variation threshold (VT) of 17 healthy young moderately trained subjects (m=11; w=6, age=25.0±8.1 yrs, BMI=22.8±1.5 kg/m2) were measured 4 days before (d-4:156m) and during (d2:890m, d5:3950m, d7:4550m,

d10:890m) a 7-day ascent to the top of Mt. Kilimanjaro (5895m). GT was tested with dilute aqueous solutions in several concentrations of four flavors (umami, bitter, salty, sweet) [3;4]. For umami we used a monosodium glutamate and for bitter a magnesium sulphate heptahydrate solution. Natrium chloride was used for salty and glucose for sweet solutions. 1 ml of each solution was directly given in the subject's mouth with a dropping glass. The mouth was rinsed with water between the different tests. GT was requested with a scale from 0-2 (0=no taste, 1=variation taste, 2=detected taste).
RESULTS: Mean DT of all flavors remained unchanged at all altitude conditions (d2, d5, d7, d10) compared to d-4 (umami: 2.9±1.3, 3.6±1.5, 3.4±1.4, 2.9±1.7, 2.6±1.7; bitter: 4.2±1.3, 4.4±1.3, 4.9±0.2, 4.6±1.2, 4.5±0.9; salty: 4.5±1.2, 4.6±0.9, 4.8±0.7, 4.2±1.4, 4.6±1.0; sweet: 4.2±1.3, 4.1±1.6, 4.2±1.4, 4.9±0.3, 4.6±0.9 p>0.05). Coherent to DT, mean VT also remained unchanged to d-4 at all altitude conditions (umami: 1.5±0.9, 1.6±1.0, 2.0±0.9, 2.0±1.5, 2.0±1.3; bitter: 2.4±1.5, 3.1±1.9, 3.6±1.7, 3.0±1.7, 3.1±1.5; salty: 2.2±1.5, 2.6±1.5, 2.9±1.7, 2.6±1.6, 2.5±1.6; sweet: 2.2±1.5, 1.9±1.3, 3.0±1.6, 2.6±1.7, 2.7±1.7 p>0.05).
CONCLUSION: Our data show no effect of moderate and high altitude on GT in healthy young people. The results are contradictory to recent data suggesting an impairment on gustatory perception at 1500m and 3000m [4], while animal studies showed an increase of gustatory perception under hypoxic stress [5]. In these studies, changes in GT were found during acute hypobaric hypoxia in contrast to our study with a 5-day-acclimatization. In this context, we assume that good acclimatization might prevent alterations in gustatory perception. Further studies are necessary to fully understand possible time courses of gustatory sense adaptation to high altitude.

INFLUENCE OF UPPER LIMB CIRCULATORY OCCLUSION ON CYCLE ERGOMETER TIME TRIAL PERFORMANCE IN NORMOXIA AND HYPOXIA

BELL, C., ACKERMAN, A.A., HOSKOVEC, L.C., TRIKA, S.R.J.

COLORADO STATE UNIVERSITY

INTRODUCTION: The availability of blood, and hence oxygen, to exercising muscle is an important physiological determinant of endurance performance. The purpose of this study was to investigate a novel procedure that may increase the amount of blood available to exercising limbs: upper limb circulatory occlusion. We hypothesized that upper limb circulatory occlusion would improve cycle ergometer time-trial performance and attenuate hypoxia-mediated decrements in endurance exercise.
METHODS: Following screening and habituation, 16 healthy young adults (9 male, 7 female, age: 23 ± 1 years, body mass index: 23.9 ± 0.8 kg/m^2; maximal oxygen uptake: 46 ± 2 ml/kg/min; mean ± SE) completed four randomly ordered stationary cycle ergometer time trials, equivalent to 5 km, in normoxia (fraction of inspired oxygen (FiO2)=0.21) and hypoxia (FiO2=0.15), with and without circulatory occlusion of the arms. At the start of each circulatory occlusion trial, participants raised their arms above their head for 60-seconds, and automated blood pressure cuffs were rapidly inflated to 200 mmHg before participants returned their arms to cycling position. Circulatory occlusion was confirmed by the absence of a radial pulse and the inability to measure peripheral oxygen saturation at the fingers.
RESULTS: Time trial performance was as follows: normoxia without occlusion 568.6 ± 16.4 s; normoxia with occlusion 563.3 ± 16.8 s; hypoxia without occlusion 602.3 ± 16.1 s; hypoxia with occlusion 594.4 ± 17.2 s. Two-way repeated measures analysis of variance revealed a potential main effect of occlusion (faster with occlusion P=0.082), a main effect of FiO2 (slower in hypoxia P<0.001), and no interaction (occlusion x FiO2 P=0.525).
CONCLUSION: These preliminary data suggest that upper limb circulatory occlusion may have ergogenic potential, presumably via a temporary increase in central blood volume, leading to greater blood and hence oxygen availability for the lower limbs. Noteworthy, the magnitude of improvement in time trial performance was greater than that required to determine medal positions in the track cycling pursuit (men's) events at the London and Rio Olympics (2012 and 2016, respectively).

HYPOXIA PROMOTES SKELETAL MUSCLE DIFFERENTIATION IN C2C12 SKELETAL MUSCLE CELLS.

SAKUSHIMA, K., YOSHIKAWA, M., HASHIMOTO, T.

RITSUMEIKAN UNIVERSITY

INTRODUCTION: It is well-known that mechanical stress causes muscle hypertrophy. Interestingly previous study demonstrated that muscle hypertrophy elicited by resistance exercise training in hypoxic environment was greater than that in normoxic environment (Nishimura et al., 2010). However, the effect of hypoxia on skeletal muscle morphological characteristics remains unknown. To assess this effect, we cultured C2C12 skeletal muscle cells in 10% oxygen environment and examined their morphological characteristics.
METHODS: At the onset of cell differentiation, C2C12 skeletal muscle cells were divided into two groups: Control group cultured in 20.9% oxygen environment (CON) and hypoxia group cultured in 10% oxygen environment (HYPO). After 6 days incubation, we evaluated expressions of differentiation-related proteins such as Myogenin, MyoD, Myosin heavy chain protein (MHC) using Western blotting. We also conducted immunocytochemical analyses to assess myotube diameter and Differentiation Index, an indicator of muscle differentiation (Oishi et al., 2015). As well, immunostaining of Ki67, a marker of cell proliferation, was conducted for the assessment of cell proliferation.
RESULTS: The myotube diameter in the HYPO was significantly greater than that in the CON ($p < 0.05$). The Differentiation Index was significantly higher in the HYPO than in the CON ($p<0.05$). The protein expression of myogenin was significantly higher in the HYPO than in the CON ($p < 0.05$). The number of Ki67 positive nuclear in the HYPO was significantly smaller than that in the CON ($p < 0.05$).
CONCLUSION: The findings suggest that hypoxic environment may promote skeletal muscle cell growth and hypertrophy by accelerating the cell differentiation cycle.

POOR CORRELATION BETWEEN GAINS IN VO2PEAK AND IMPROVEMENT IN METABOLIC SYNDROME AFTER 16-WEEK OF AEROBIC INTERVAL TRAINING

MORA-RODRIGUEZ, R., ORTEGA, J.F., MORALES-PALOMO, F., RAMIREZ-JIMENEZ, M.

UNIVERSITY CASTILLA-LA MANCHA

INTRODUCTION: The purpose was to examine the relationship between cardiorespiratory fitness (CRF; estimated by VO2max) and metabolic syndrome after an exercise training intervention to confirm/contradict the findings in cross-sectional observational studies.
METHODS: A group (n=155; 50% women) of middle-aged (54±8 yrs old) untrained (VO2max of 20.3±7.1 mLO2·kg-1·min-1) individuals with obesity (BMI of 32±5) and metabolic syndrome (MetS), where randomly allocated to either an aerobic exercise interval training group (AIT group; n=133) or remained sedentary (CONT group; n=22) in a 6:1 ratio. Metabolic syndrome factors were measured at baseline and after 16 weeks in AIT and CONT groups and results expressed as a summed Z-score continuous variable (MetS Z-score). Body fat, weight and exercise responses (VO2max; HRmax; POmax) were also measured. We used correlation (R Pearson) and stepwise multiple regression analysis to study associations between changes in MetS Z-score and health related outcomes.
RESULTS: At baseline, body composition, exercise responses and MetS components were similar between groups (all P>0.05). After 16 weeks of intervention AIT reduced body weight, waist circumference (-1.21±0.22 kg and -2.7±0.3 cm; P<0.001), mean arterial blood pressure and MetS Z-score (-7.06±0.77 mmHg and -0.21±0.03; P<0.001). Only in the AIT group, CRF (i.e., VO2max) increased by 16% (0.30±0.02 mLO2·min-1; P<0.001). However, in AIT, CRF was not a predictor contributing significantly to MetS Z-score (R = -0.246; β = -0.002) while changes in body weight and POmax were contributing (R=0.508; β = 0.429 and R=-0.368; β = -0.193).
CONCLUSION: This prospective exercise intervention trial disputes a causal relationship between increases in CRF with exercise training and improvements in health risk factors in obese MetS individuals. In contrast, the body weight and fat losses with exercise seem to contribute to the improvements in MetS Z-score.

CARDIOVASCULAR DISEASE RISK FACTORS IN ADOLESCENT AND YOUNG ADULT SURVIVORS OF CHILDHOOD ACUTE LYMPHOBLASTIC AND ACUTE MYELOID LEUKAEMIA.

LONG, T.M., WALLMAN, K.E., WALWYN, T.S., CHOONG, C.S., NAYLOR, L.H.

THE UNIVERSITY OF WESTERN AUSTRALIA

INTRODUCTION: Leukaemia is the most common childhood cancer [1]. Although incidence is high, worldwide 5-year survival rates for the predominant diagnoses - acute lymphoblastic (ALL) and acute myeloid (AML) leukaemia - are approaching 90% and 65%, respectively [1]. However, leukaemia therapy is highly toxic to the developing organs and systems of children and many survivors develop late-effects that significantly increase the risk of cardiovascular disease (CVD) [2]. Furthermore, poorly organised transition periods from paediatric to adult care can result in a decline in, or complete loss of, long-term monitoring of health, further exacerbating this risk [1]. As a result, death rates from CVD among the adolescent and young adult (AYA) survivor population are significantly higher than those in the healthy population [2]. Modifiable risk factors for CVD include endothelial dysfunction, hypertension, overweight and obesity, and poor aerobic fitness [2]. Early detection of such factors allows for optimal intervention and a subsequent reduction in CVD risk. Here, we implemented a battery of health assessments to determine CVD risk in a combined group of ALL and AML survivors.
METHODS: Twenty three survivors (14 ALL, 9 AML; 11 female; age 19±3 y) were compared to 17 healthy controls (9 female; age 22±2). Resting blood pressure and heart rate (HR) were taken using an electronic cuff at the conclusion of a 20 min rest period. Following this, endothelial function was assessed using the flow mediated dilation technique. Standard procedures were used to measure anthropometry, while body composition was determined using dual x-ray absorptiometry. Aerobic fitness (VO2 peak) was assessed using a modified chronotropic treadmill protocol.
RESULTS: Compared to controls, survivors had greater total percent body fat (p=0.023), central percent body fat (p=0.036) and regional percent body fat (p=0.025). This was reflected in increased amounts of total fat mass (p=0.031), central fat mass (p=0.046) and visceral adipose tissue mass (p=0.017) and volume (p=0.017). Additionally, the survivors demonstrated elevated resting HR's (p=0.038), as well as decreased peak (p=0.002) and recovery (p=0.001) HR's in the VO2 peak assessment. Ratings of perceived exertion (p=0.043), minute ventilation (p=0.000), and VO2 peak (L.min-1, p=0.05; ml.kg-1.min-1, p=0.021) were also lower compared to controls.
CONCLUSION: This study demonstrated that AYA survivors of childhood ALL and AML are at a heightened risk of CVD compared to healthy controls as a result of excessive fat mass and poor aerobic fitness. These findings highlight the importance of early intervention to reduce the risk of CVD in this population.

PHYSICAL FITNESS AND QUALITY OF LIFE IN CANCER PATIENTS

REINICKE, M.1, ELLWANGER, N.1, HOFMANN, H.1, OBERHOFFER, R.1, SCHULZ, T.1

CHAIR OF PREVENTIVE PEDIATRICS

INTRODUCTION: Cancer is the second most frequent cause of death worldwide. Advances in medicine have led to a significant increase in survival in recent years (WHO, 2017). As a result, the factor of a good quality of life (QoL) for cancer patients is becoming increasingly important. Today, it is well known that physical activity improves QoL for individuals struggling with cancer (Rogers et al., 2016). Therefore, it is of interest to find out if the QoL in cancer patients can be further increased by enhanced physical fitness. The aim of this work was to compare the physical fitness level of cancer patients with different diagnoses (breast cancer/other cancer) and therapy status (therapy/post therapy) to find out if a higher fitness level caused by increased physical activity improves QoL.
METHODS: 72 subjects with different cancer diagnoses (51.6±12.7 years) participated in this cross-sectional study (April-August 2017). Participants were enrolled via Outdoor against Cancer and Bavarian Cancer Society and interviewed about their QoL using two questionnaires (SF-36 and QLQ-C30). Physical fitness was measured with four tests: handgrip and sit-to-stand test (strength), shoulder stretch

(flexibility) and 6-min walk test (endurance). Statistical analysis was performed by Mann-Whitney-U-Test and Spearman correlation. The significance level was set at p≤.05.
RESULTS: Mental health was negatively impaired in both groups compared to normative values (p<.05). All groups achieved significantly better results in physical functioning compared to reference values for cancer patients (p<.001). QoL in patients with breast cancer was significantly better compared to other diagnoses (p=.002). The more time patients spent in physical activity the better results in physical functioning were noticeable (r=.450, p<.001).
CONCLUSION: Physical fitness is positively associated with QoL in cancer patients. All subjects showed a similar good physical functioning compared to the general population and better results than other cancer patients that was even better when they were physical active regularly. On the other hand, all subjects had an impaired mental health compared to standard values of the normative population. Further investigations need to figure out how mental health in cancer patients can be improved.

THE ASSOCIATION BETWEEN DIVERSITY OF PHYSICAL ACTIVITIES AND SELF-REPORTED MUSCULOSKELETAL PAINS

MÄKELÄ, S., AALTONEN, S., KORHONEN, T., MIKKELSSON, M., KUJALA, U., KAPRIO, J.
UNIVERSITY OF HELSINKI

The associations between diversity of sport activities and self-reported musculoskeletal pains
Mäkelä, S.1, Aaltonen, S.1, Korhonen, T.1, Mikkelsson, M.2, Kujala, U.3, Kaprio, J.1
1University of Helsinki, Finland, 2University of Tampere, Finland, 3University of Jyväskylä, Finland
Background
Low back pain (LBP) and neck-shoulder region pain (NSP) are public health problems causing large-scale disability and socio-economic burden. Cost-effective prevention is warranted, yet the widely studied risk factors, such as physical activity (PA), remain under debate. Our objective is to investigate the effect of PA on LBP and NSP from a relatively unexplored viewpoint, i.e. the association of diversity of sport activities with LBP and with NSP.
Methods: In the FinnTwin16 cohort study, twins (57% women) at the mean ages of 17 and 34 reported their participation in different leisure-time sport activities, categorized as 1, 2, 3, 4, and 5+ sport activities. In their mid-thirties, they reported the frequency of LBP (N=3361) and NSP (N=3368), categorized as seldom, monthly, or weekly. The severity of pain was not assessed. The associations of diversity of sport activities with LBP and with NSP were examined both in cross-section and longitudinally with multinomial logistic regression analyses, adjusted for multiple covariates. Due to an interaction effect between diversity of sport activities and work activity in LBP model, these analyses were conducted separately in three work activity groups. Furthermore, we conducted a conditional logistic regression model, for the twin pairs discordant for LBP (N=154) and for NSP (N=164), to explore the possible additional confounding due to familial factors.
Results: In the cross-sectional analyses, participation in 5+ sport activities, compared to single sport participation, associated with significantly less weekly LBP only among individuals with physically demanding work with OR 0.44 (95% confidence interval (CI), 0.21-0.90). For monthly LBP OR was 0.78 (CI 0.46-1.35). Yet, in the longitudinal analyses consistent participation in 5+ sport activities, compared to consistent single sport participation, in adolescence and mid-thirties related to significantly and substantially less weekly LBP in mid-thirties (OR 0.37, 95% CI 0.16-0.86).
On the contrary, no significant associations were detected between diversity of sport activities and NSP, in cross-section or longitudinally. The results of the within-pair analyses, limited by small sample size, did not replicate the results of the individual analyses.
Conclusions
Consistent diversity of sport activities from adolescence to mid-thirties may protect individuals from frequent LBP in their mid-thirties, and current diversity of sport activities can protect individuals with physically demanding work from frequent LBP. These associations may not be independent of shared familial factors.

DIFFERENTIAL EFFECTS OF RESISTANCE AND EDURANCE TRAINING ON GUT MICROBIOTA

FERNÁNDEZ-SANJURJO, M., FERNÁNDEZ, J., DÍEZ-ROBLES, S., TOMÁS-ZAPICO, C., LOMBÓ, F., FERNÁNDEZ-GARCÍA, B., VILLAR, C.J., IGLESIAS-GUTIÉRREZ, E.
UNIVERSITY OF OVIEDO

INTRODUCTION: Regular exercise shows a systemic beneficial effect on health, and it is strongly associated with a lower risk of mortality and lower incidences of chronic pathologies (1).
Several studies have described a relationship between endurance exercise and a variation on the diversity of gut microbiota (2, 3), which has been related to an improved health status and physical performance. However, the effect of resistance exercise is completely unknown.
The aim of this study was to compare the effect of resistance and endurance training on gut microbiota in mice.
