ABSTRACT

Context. The observation of planets in their formation stage is a crucial but very challenging step in understanding when, how, and where planets form. PDS 70 is a young pre-main sequence star surrounded by a transition disk, in the gap of which a planetary-mass companion has recently been discovered. This discovery represents the first robust direct detection of such a young planet, possibly still at the stage of formation.

Aims. We aim to characterize the orbital and atmospheric properties of PDS 70 b, which was first identified on May 2015 in the course of the SHINE survey with SPHERE, the extreme adaptive-optics instrument at the VLT.

Methods. We obtained new deep SPHERE/IRDIS imaging and SPHERE/IFS spectroscopic observations of PDS 70 b. The astrometric baseline now covers 6 yr, which allowed us to perform an orbital analysis. For the first time, we present spectrophotometry of the young planet which covers almost the entire near-infrared range (0.96–3.8 μm). We use different atmospheric models covering a large parameter space in temperature, $\log g$, chemical composition, and cloud properties to characterize the properties of the atmosphere of PDS 70 b.

Results. PDS 70 b is most likely orbiting the star on a circular and disk coplanar orbit at ~ 22 au inside the gap of the disk. We find a range of models that can describe the spectrophotometric data reasonably well in the temperature range 1000–1600 K and $\log g$ no larger than 3.5 dex. The planet radius covers a relatively large range between 1.4 and 3.7 R_J with the larger radii being higher than expected from planet evolution models for the age of the planet of 5.4 Myr.

Conclusions. This study provides a comprehensive data set on the orbital motion of PDS 70 b, indicating a circular orbit and a motion coplanar with the disk. The first detailed spectral energy distribution of PDS 70 b indicates a temperature typical of young giant planets. The detailed atmospheric analysis indicates that a circumplanetary disk may contribute to the total planetflux.

Key words. planets and satellites: atmospheres – planets and satellites: individual: PDS 70 – techniques: spectroscopic – astrometry – methods: observational

1. Introduction

Our knowledge of the formation mechanism and evolution of planets has developed by leaps and bounds since the first detection of an exoplanet by Mayor & Queloz (1995) around the main-sequence star 51 Peg. However, constraining the formation timescales, the location of planet formation, and the physical properties of such objects remains a challenge and to date has mostly been based on indirect arguments using measured properties of protoplanetary disks. What is really needed is a detection of planets around young stars still surrounded by a disk. Modern coronagraphic angular differential imaging surveys that utilize extreme adaptive optics, such as the SPHERE INfrared survey for Exoplanets (SHINE; Chauvin et al. 2017), provide the necessary spatial resolution and sensitivity to find such young planetary systems.

In Keppler et al. (2018) we reported the first bona fide detection of a giant planet inside the gap of the transition disk

around the star PDS 70 together with the characterization of its protoplanetary disk. PDS 70 is a K7-type 5.4 Myr young pre-main sequence member of the Upper Centaurus-Lupus group (Riaud et al. 2006; Pecaute & Mamajek 2016) at a distance of distance of 113.43 ± 0.52 pc (Gaia Collaboration 2016, 2018). Our determination of the stellar parameters are explained in detail in Appendix A. The planet was detected in five epochs with VLT/SPHERE (Beuzit et al. 2008), VLT/NaCo (Lenzen et al. 2003; Rousset et al. 2003), and Gemini/NICI (Chun et al. 2008) covering a wavelength range from H to L' band. In this paper we present new deep K -band imaging and first $Y-H$ spectroscopic data with SPHERE with the goal of putting constraints on the orbital parameters and properties of PDS 70 b.

2. Observations and data reduction

2.1. Observations

We observed PDS 70 during the SPHERE/SHINE GTO program on the night of February 24, 2018. The data were taken in the IRDIFS-EXT pupil tracking mode using the

^{*} Based on observations collected at the European Organisation for Astronomical Research in the Southern Hemisphere under ESO programmes 095.C-0298, 097.C-0206, 097.C-1001, 1100.C-0481.

N_ALC_YJH_S (185 mas in diameter) apodized-Lyot coronagraph (Martinez et al. 2009; Carillet et al. 2011). We used the IRDIS (Dohlen et al. 2008) dual-band imaging camera (Vigan et al. 2010) with the K_1K_2 narrow-band filter pair ($\lambda_{K_1} = 2.110 \pm 0.102 \mu\text{m}$, $\lambda_{K_2} = 2.251 \pm 0.109 \mu\text{m}$). A spectrum covering the spectral range from Y to H band ($0.96\text{--}1.64 \mu\text{m}$, $R_\lambda = 30$) was acquired simultaneously with the IFS integral field spectrograph (Claudi et al. 2008). We set the integration time for both detectors to 96 s and acquired a total time on target of almost 2.5 h. The total field rotation is 95.7° . During the course of observation the average coherence time was 7.7 ms and a Strehl ratio of 73% was measured at $1.6 \mu\text{m}$, providing excellent observing conditions.

2.2. Data reduction

The IRDIS data were reduced as described in Keppler et al. (2018). The basic reduction steps consisted of bad-pixel correction, flat fielding, sky subtraction, distortion correction (Maire et al. 2016), and frame registration.

The IFS data were reduced with the SPHERE Data Center pipeline (Delorme et al. 2017), which uses the Data Reduction and Handling software (v0.15.0, Pavlov et al. 2008) and additional IDL routines for the IFS data reduction (Mesa et al. 2015). The modeling and subtraction of the stellar speckle pattern for both the IRDIS and IFS data set were performed with a smart Principal Component Analysis (sPCA) algorithm based on Absil et al. (2013) using the same setup as described in Keppler et al. (2018). Figure 1 shows the high-quality IRDIS combined K_1K_2 image of PDS 70. The outer disk and the planetary companion inside the gap are clearly visible. In addition, there are several disk related features present, which are described in Appendix B. For this image the data were processed with a classical ADI reduction technique (Marois et al. 2006) to minimize self-subtraction of the disk. The extraction of astrometric and contrast values was performed by injecting negative point source signals into the raw data (using the unsaturated flux measurements of PDS 70) which were varied in contrast and position based on a predefined grid created from a first initial estimate of the planet's contrast and position. For every parameter combination of the inserted negative planet the data were reduced with the same sPCA setup (maximum of 20 modes, protection angle of $0.75 \times FWHM$) and a χ^2 value within a segment of $2 \times FWHM$ and $4 \times FWHM$ around the planet's position was computed. Following Olofsson et al. (2016), the marginalized posterior probability distributions for each parameter was computed to derive final contrast and astrometric values and their corresponding uncertainties (the uncertainties correspond to the 68% confidence interval). For an independent confirmation of the extracted astrometry and photometry we used SpeCal (Galicher et al. 2018) and find the values in good agreement with each other within 1σ uncertainty.

2.3. Conversion of the planet contrasts to physical fluxes

The measured contrasts of PDS 70 b from all data sets (SPHERE, NaCo, and NICI) were converted to physical fluxes following the approach used in Vigan et al. (2016) and Samland et al. (2017), who used a synthetic spectrum calibrated by the stellar SED to convert the measured planet contrasts at specific wavelengths to physical fluxes. In our case, instead of a synthetic spectrum, which does not account for any (near-)infrared excess, we made use of the flux calibrated spectrum of PDS 70 from the SpeX spectrograph (Rayner et al. 2003), which is presented in

Fig. 1. IRDIS combined K_1K_2 image of PDS 70 using classical ADI reduction technique showing the planet inside the gap of the disk around PDS 70. The central part of the image is masked out for better display. North is up, East is to the left.

Long et al. (2018). The spectrum Long et al. (2018). The spectrum covers a wavelength the entire IFS and IRDIS data set. To obtain flux values for our data sets taken in L' band at $3.8 \mu\text{m}$, we modeled the stellar SED with simple blackbodies to account for the observed infrared excess (Hashimoto et al. 2012; Dong et al. 2012). The final SED of the planet is shown in Fig. 2. The IFS SED of the planet is shown in Fig. 2. The IFS spectrum has a steep slope and displays a few features only, mainly water values are listed in Table C.1.

3. Results

3.1. Atmospheric modeling

We performed atmospheric simulations for PDS 70 b with the self-consistent 1D radiative-convective equilibrium tool *petitCODE* (Mollière et al. 2015, 2017), which resulted in three different grids of self-luminous cloudy planetary model atmospheres (see Table 1). These grids mainly differ in the treatment of clouds: *petitCODE*(1) does not consider scattering and includes only Mg_2SiO_4 cloud opacities; *petitCODE*(2) adds scattering; *petitCODE*(3) contains four more cloud species including iron (Na_2S , KCl , Mg_2SiO_4 , Fe). Additionally, we also use the publicly available cloud-free *petitCODE* model grid (here called *petitCODE*(0); see Samland et al. 2017 for a detailed description of this grid) and the public PHOENIX BT-Settl grid (Allard 2014; Baraffe et al. 2015).

In order to compare the data to the *petitCODE* models we use the same tools as described in Samland et al. (2017), using the python MCMC code *emcee* (Foreman-Mackey et al. 2013) on N -dimensional model grids linearly interpolated at each evaluation. We assume a Gaussian likelihood function and take into account the spectral correlation of the IFS spectra (Greco & Brandt 2016). For an additional independent confirmation of the results obtained using *petitCODE*, we also used cloudy models from the Exo-REM code. The models

Fig. 2. Spectral energy distribution of PDS 70 b as a function of wavelength constructed from Y - to H -band IFS spectra (orange points), IRDIS H_2H_3 (first epoch in dark blue, second epoch in light blue), and K_1K_2 (first epoch in dark green, second epoch in light green), NaCo (red), and NICI (orange) L' -band images. Plotted are the best fits for the seven model grids smoothed to the resolution of IFS.

Table 1. Model grids used as input for MCMC exploration.

Model	T_{eff} (K)	ΔT (K)	$\log g$ \log_{10} (cgs)	$\Delta \log g$ \log_{10} (cgs)	(M/H) (dex)	$\Delta(M/H)$ (dex)	f_{sed}	Δf_{sed}	Remarks

Exo-REM(2)	1100	4.1	1.0	1	3.3	55	Yes	Yes

Notes. The last two columns indicate qualitatively whether the corresponding model is compatible with the photometric points in K and L' band, whereas all models describe the Y - to H -band data well. ^(a)Only grid value. ^(b)As derived from $\log g$ and radius.

and corresponding simulations are described in Charnay et al. (2018). Exo-REM assumes non-equilibrium chemistry, and silicate and iron clouds. For the model grid Exo-REM(1) the cloud particles are fixed at $20\mu\text{m}$ and the vertical distribution takes into account vertical mixing (with a parametrized K_{zz}) and sedimentation. The Exo-REM(2) model uses a cloud distribution with a fixed sedimentation parameter $f_{\text{sed}} = 1$ as in the model by Ackerman & Marley (2001) and *petitCODE*. Table 2 provides a compilation of the best-fit values and Fig. 2 shows the respective spectra. The values quoted correspond to the peak of the respective marginalized posterior probability distribution. The cloud-free models fail to represent the data and result in unphysical parameters. In contrast, the cloudy models provide a much better representation of the data. The results obtained by the *petitCODE* and Exo-REM models are consistent with each other. However, because of higher cloud opacities in the Exo-REM(2) models the $\log g$ values are less constrained

and the water feature at $1.4\mu\text{m}$ is less pronounced. Therefore, the resulting spectrum is closer to a blackbody and the resulting mass is less constrained. All these models indicate a relatively low temperature and surface gravity, but in some cases unrealistically high radii. Evolutionary models predict radii smaller than $2R_J$ for planetary-mass objects (Mordasini et al. 2017). The radius can be pushed toward lower values if cloud opacities are removed, for example by removing iron (*petitCODE*(2)). However, a direct comparison for the same model parameters shows that this effect is very small. In *petitCODE*(1) this is shown in an exaggerated way by artificially removing scattering from the models, which leads to a significant reduction in radius. In general, we find a wide range of models that are compatible with the current data. The parts of the spectrum most suitable for ruling out models are the possible water absorption feature at $1.4\mu\text{m}$, and the spectral behavior at longer wavelengths (K to L' band). Given the low signal-to-noise ratio in the water

Fig. 3. Multi-epoch astrometric measurements of PDS 70 b relative to PDS 70 (in blue). The plot also shows the predictions of the relative position under the hypothesis of a stationary background star for the same observing dates (in red). The gray dotted line shows one of the most likely orbital solutions based on our MCMC analysis (see text for details).

absorption feature and the large uncertainties in the L' flux, it is very challenging to draw detailed physical conclusions about the nature of the object. We emphasize that other possible explanations for the larger than expected radii from evolutionary models include the recent accretion of material, additional reddening by circumplanetary material, and significant flux contributions from a potential circumplanetary disk. The third possibility is especially interesting in the light of possible features in our reduced images that could present spiral arm structures close to the planet (Fig. 1). There also appears to be an increase in HCO^+ velocity dispersion close to the location of the planet in the ALMA data presented by Long et al. (2018).

3.2. Orbital properties of PDS 70 b

The detailed results of the relative astrometry and photometry extracted from our observation from February 2018 are listed in Table C.1 together with the earlier epochs presented in Keppler et al. (2018). A first verification of the relative position of PDS 70 b with what we could expect for a stationary background contaminant is shown in Fig. 3. The latest SPHERE observations of February 24, 2018, confirms that the companion is comoving with the central star.

To explore the possible orbital solutions of PDS 70 b, we applied the Markov chain Monte Carlo (MCMC) Bayesian analysis technique (Ford 2005, 2006) developed for β Pictoris (Chauvin et al. 2012), which is well suited for observations covering a small part of the whole orbit (for large orbital periods), as in the case of PDS 70 b. We did not initially consider any prior information on the inclination or longitude of ascending node to explore the full orbital parameter space of bound orbits. As described in Appendix A of Chauvin et al. (2012), we assume the prior distribution $p_0(x)$ to be uniform in $x = (\log P, e, \cos i, \Omega + \omega, \omega - \Omega, t_p)$ and work on a modi-

fied parameter vector $\mathbf{u}(x)$ to avoid singularities in inclination and eccentricities and to improve the convergence of the Markov chains. The results of the MCMC analysis are shown in Fig. D.1, together with the results of a classical least-squares linear method (LSLM) flagged by the red line. It shows the standard statistical distribution matrix of the orbital elements $a, e, i, \Omega, \omega,$ and t_p , where a stands for the semi-major axis, e for the eccentricity, i for the inclination, Ω the longitude of the ascending node (measured from north), ω the argument of periastron, and t_p the time for periastron passage. The results of our MCMC fit (Table D.1) indicate orbital distributions that peak at $22.2^{+6.2}_{-9.7}$ au (the uncertainties correspond to the 68% confidence interval) for the semi-major axis, $151.1^{+14.1}_{-13.6}$ for the inclination, and eccentricities compatible with low-eccentric solutions as shown by the (a, e) correlation diagram. The elements Ω and ω are poorly constrained as low-eccentric solutions are favored and as pole-on solutions are also likely possible. Time at periastron is poorly constrained. The inclination distribution clearly favors retrograde orbits ($i > 90^\circ$), which is compatible with the observed clockwise orbital motion resolved with SPHERE, NaCo, and NICI. To consider the disk geometry described by Keppler et al. (2018), we decided to explore the MCMC solutions compatible with a planet-disk coplanar configuration. We restrained the PDS 70 b solution set given by the MCMC to those solutions with orbital plane making a tilt angle less than 5° with respect to the disk midplane described by Keppler et al. (2018), i.e., $i = 180^\circ - 49.8^\circ$ and $\text{PA} = 158.6^\circ$. The results are shown in Fig. D.2 and Table D.1 together with the relative astrometry of PDS 70 b reported with 200 orbital solutions randomly drawn from our MCMC distributions in Fig. D.4. Figure D.3 shows the posterior distribution (out of Fig. D.1) of the tilt angle with the disk plane assuming $i_{\text{disk}} = 130.2^\circ$ and $\text{PA} = 158.6^\circ$. The distribution peaks around 50° , which remains consistent with a likely coplanar planet-disk configuration (or a moderate tilt angle) given the uncertainties. Given the small fraction of orbit covered by our observations, a broad range of orbital configurations are possible including coplanar solutions that could explain the formation of the broad disk cavity carved by PDS 70 b.

4. Summary and conclusions

We presented new deep SPHERE/IRDIS imaging data and, for the first time, SPHERE/IFS spectroscopy of the planetary mass companion orbiting inside the gap of the transition disk around PDS 70. With the accurate distance provided by *Gaia* DR2 we derived new estimates for the stellar mass ($0.76 \pm 0.02 M_\odot$) and age (5.4 ± 1.0 Myr). Taking into account the data sets presented in Keppler et al. (2018) we achieve an orbital coverage of 6 yr. Our MCMC Bayesian analysis favors a circular ~ 22 au wide and a disk coplanar orbit, which translates to an orbital period of 118 yr. The new imaging data show rich details in the structure of the circumstellar disk. Several arcs and potential spirals can be identified (see Fig. B.1). Determining the way these features are connected to the presence of the planet is beyond the scope of this study. With the new IFS spectroscopic data and photometric measurements from previous IRDIS, NaCo, and NICI observations we were able to construct a SED of the planet covering a wavelength range of $0.96\text{--}3.8 \mu\text{m}$. We computed three sets of cloudy model grids with the *petitCODE* and two models with Exo-REM with different treatment of clouds. These model grids and the BT-Settl grid were fitted to the planet's SED. The atmospheric analysis clearly demonstrates that cloud-free models do not provide a good fit to the data. In contrast, we find a range

of cloudy models that can describe the spectrophotometric data reasonably well, and result in a temperature range of 1000–1600 K and $\log g$ no larger than 3.5 dex. The radius varies significantly between 1.4 and 3.7 R_J based on the model assumptions and is in some cases higher than what we expect from evolutionary models. The planet’s mass derived from the best-fit values ranges from 2 to 17 M_J , which is similar to the masses derived from evolutionary models by [Keppler et al. \(2018\)](#). This paper provides the first step toward a comprehensive characterization of the orbit and atmospheric parameters of an embedded young planet. Observations with JWST and ALMA will provide additional constraints on the nature of this object, especially in the presence of a circumplanetary disk.

Appendix A: Determination of host star properties

We used a Markov chain Monte Carlo approach to find the posterior distribution for the PDS 70 host star parameters, adopting the *emcee* code (Foreman-Mackey et al. 2013). The unknown parameters are the stellar mass, age, extinction, and parallax¹, and we assumed solar metallicity. The photometric measurements used for the fit, and the independently determined effective temperature T_{eff} and radius are listed in Table A.1. We perform a simultaneous fit of all these observables. The uncertainties are treated as Gaussians and we assume no covariance between them.

We used a Gaussian prior from *Gaia* for the distance and a Gaussian prior with mean 0.01 mag and sigma 0.07 mag, truncated at $A_V = 0$ mag, for the extinction (Pecaut & Mamajek 2016). Given A_V , we computed the extinction in all the adopted bands by assuming a Cardelli et al. (1989) extinction law. We used a Chabrier (2003) initial mass function (IMF) prior on the mass and a uniform prior on the age. The stellar models adopted to compute the expected observables, given the fit parameters, are from the MIST project (Paxton et al. 2011, 2013, 2015; Dotter 2016; Choi et al. 2016). These models were extensively tested against young cluster data, and against pre-main sequence stars in multiple systems, with measured dynamical masses, and compared to other stellar evolutionary models (see Choi et al. 2016 for details). The result of the fit constrains the age of PDS 70 to 5.4 ± 1.0 Myr and its mass to $0.76 \pm 0.02 M_{\odot}$. The best-fit parameter values are given by the 50% quantile (the median) and their uncertainties are based on the 16% and 84% quantile of the marginalized posterior probability distribution. The stellar parameters are identical to the values used by Keppler et al. (2018). We note that the derived stellar age of PDS 70 is significantly younger than the median age derived for UCL with 16 ± 2 Myr and an age spread of 7 Myr by Pecaut & Mamajek (2016). For the computation of the median age Pecaut & Mamajek (2016) excluded K- and M-type stars for the reason of stellar activity which might bias the derived age. When the entire sample of stars is considered a median age of 9 ± 1 Myr is derived. The authors provide an age of 8 Myr for PDS 70 based on evolutionary models. Furthermore, the kinematic parallax for PDS 70 therein is larger by $\sim 15\%$ compared to the new *Gaia* parallax. Thus, the luminosity on which the age determination is based is underestimated and, subsequently, the age is overestimated.

Appendix B: Disk seen with IRDIS

Figure B.1 shows the IRDIS combined K_1K_2 image using classical ADI. The image shows the outer disk ring, with a radius of approximately 54 au, with the western (near) side being brighter than the eastern (far) side, as in Hashimoto et al. (2012) and Keppler et al. (2018). The image reveals a highly structured disk with several features: 1) a double ring structure along the west side, which is clearly pronounced along the northwest arc, and which is less clear but still visible along the southwest side; 2) a possible connection from the outer disk to the central region; 3,4) a possible spiral-shaped feature close to the coronagraph; and 5) two arc-like features in the gap on the southeast side of

¹ The parallax of PDS 70 is treated as an unknown parameter in our fit to the host star’s properties, together with mass, age and A_V . However we imposed a parallax prior, using *Gaia* DR2, which strongly constrains the allowed distance values. As a result, the best-fit distance value reported here from the MCMC posterior draws is identical to the value provided by the *Gaia* collaboration.

Table A.1. Stellar parameters of PDS 70.

Parameter	Unit	Value	References
Distance	pc	113.43 ± 0.52	1
T_{eff}	K	3972 ± 36	2
Radius	R_{\odot}	1.26 ± 0.15	Computed from 2
B	mag	13.494 ± 0.146	3
V	mag	12.233 ± 0.123	3
g'	mag	12.881 ± 0.136	3
r'	mag	11.696 ± 0.106	3
i'	mag	11.129 ± 0.079	3
J	mag	9.553 ± 0.024	4
H	mag	8.823 ± 0.040	4

Fig. B.1. IRDIS combined K_1K_2 image of PDS 70 using classical ADI. To increase the dynamic range of the faint disk structures, the companion’s full intensity range is not shown. The black lines indicate the structures discussed in the above text. North is up, east is to the left.

the central region. Whereas features 1 and 2 have already been tentatively seen in previous observations (see Figs. 5 and 9 in Keppler et al. 2018), our new and unprecedentedly deep data set allows us to identify extended structures well within the gap (features 3–5). Future observations at high resolution, i.e., with interferometry, will be needed to prove the existence and to investigate the nature of these features, which, if real, would provide an excellent laboratory for probing theoretical predictions of planet-disk interactions.

Appendix C: Astrometric and photometric detailed results

Table C.1. Relative astrometry and photometry of PDS 70 b as derived from the sPCA reduction.

Date	Instr.	Filter	$\Delta\alpha$ (mas)	$\Delta\delta$ (mas)	Sep. (mas)	PA (deg)	Δmag	mag_{app}	Peak S/N
2012-03-31	NICI	L'	58.7 ± 10.7	-182.7 ± 22.2	191.9 ± 21.4	162.2 ± 3.7	6.59 ± 0.42	14.50 ± 0.42	5.6

2016-05-14	IRDIS	$K1$	90.2 ± 7.3	-170.8 ± 8.6	193.2 ± 8.3	152.2 ± 2.3	7.81 ± 0.31	16.35 ± 0.31	5.5
2016-05-14	IRDIS	$K2$	95.2 ± 4.8	-175.0 ± 7.7	199.2 ± 7.1	151.5 ± 1.6	7.67 ± 0.24	16.21 ± 0.24	3.6
2016-06-01	NaCo	L'	94.5 ± 22.0	-164.4 ± 27.6	189.6 ± 26.3	150.6 ± 7.1	6.84 ± 0.62	14.75 ± 0.62	2.7
2018-02-24	IRDIS	$K1$	109.6 ± 7.9	-157.7 ± 7.9	192.1 ± 7.9	147.0 ± 2.4	8.10 ± 0.05	16.65 ± 0.06	16.3
2018-02-24	IRDIS	$K2$	110.0 ± 7.9	-157.6 ± 8.0	192.2 ± 8.0	146.8 ± 2.4	7.90 ± 0.05	16.44 ± 0.05	13.7

Notes. For completeness we list the values from the first five epochs from [Keppler et al. \(2018\)](#). The astrometric values are corrected for true north, and account for the instrument anamorphism ([Maire et al. 2016](#)). The true north correction for the IRDIS data recorded on February 24, 2018, is $-1.76^\circ \pm 0.06^\circ$. For true north values from earlier epochs, see Table 4 in [Keppler et al. \(2018\)](#).

Appendix D: Markov chain Monte Carlo results

Table D.1. MCMC solutions for the orbital parameters of PDS 70 b.

Parameter	Unit	Unrestrained solutions				Solutions for restrained i and Ω			
		Peak	Median	Lower	Upper	Peak	Median	Lower	Upper
a	au	22.2	25.1	12.5	28.4	21.2	23.8	13.3	27.0
e		0.03	0.17	0.0	0.25	0.03	0.18	0.0	0.27
i	$^\circ$	151.1	150.1	137.5	165.2	131.1	131.0	128.3	133.6
Ω	$^\circ$	-128.1	0.0	-180.0	51.0	159.6	158.4	156.2	163.9
ω	$^\circ$	-130.9	0.0	-180.0	59.9	-12.7	2.5	-144.7	52.3
t_p	yr	2041.9	2020.1	2001.4	2069.0	2009.1	2013.4	1973.1	2029.1

Notes. The left part of the table lists the values obtained without any prior information taken into account. The right part of the table lists the solution for the restrained case. The lower and upper values correspond to the 68% confidence interval.

Fig. D.1. Results of the MCMC fit of the SPHERE, NaCo, and NICI combined astrometric data of PDS 70 b reported in terms of statistical distribution matrix of the orbital elements a , e , i , Ω , ω , and t_p . The red line in the histograms and the black star in the correlation plots indicate the position of the best LSLM χ_r^2 model obtained for comparison.

Fig. D.2. Results of the MCMC fit of the SPHERE, NaCo, and NICI combined astrometric data of PDS 70 b reported in terms of statistical distribution matrix of the orbital elements a , e , i , Ω , ω , and t_p . We restrained the PDS70 b solution set given by the MCMC to solutions with orbital plane making a tilt angle of less than 5° with respect to the disk midplane described by [Keppler et al. \(2018\)](#), i.e., $i = 180^\circ - 49.8^\circ$ and PA = 158.6° .

Fig. D.3. Posterior distribution (from Fig. D.1) of the tilt angle. The distribution peaks around 50° , which remains consistent with a likely coplanar planet-disk configuration. The red line indicates the position of the best LSLM χ_r^2 model obtained for comparison.

Fig. D.4. Relative astrometry of PDS 70 b solutions drawn from the MCMC distribution for the coplanar planet-disk configuration. One of the most likely solutions from our MCMC analysis is shown as an illustration (in red).
