Abstract

The MERTIS (MErcury Radiometer and Thermal Infrared Spectrometer) onboard of the BepiColombo ESA/JAXA mission to Mercury will map the surface of Mercury in the wavelength range of 7-14 µm and the interpretation of these spectra a database of analog materials is needed. We analysed bulk grain size fractions of a series of analog materials relevant to the distinct terranes of Mercury in diffuse reflectance in the mid-infrared (2.5 µm to 18 µm). Mineral mixtures cover a wide range of modal amounts of forsterite, enstatite, diopside and plagioclase, the resulting spectra can be divided into three distinct groups: (1) is dominated by a single glass feature, (2) by forsterite bands, and (3) by pyroxene bands. Despite often high contents, plagioclase features, are usually 'overprinted' by forsterite and pyroxene bands.

Spectral parameter CF, an easy obtainable proxy for chemistry (SiO_2) and polymerization (SCFM) places the hermean mixtures mostly in the intermediate and basaltic range. The correlation of parameters easily obtainable in remote sensing, Mg/Si ratio, and CF, allows differing materials from high-energy evaporation processes in impacts from such formed in igneous processes.

Preliminary comparison with a spectrum covering most of the hermean surface shows some similarity with band positions of the Inter Crater Plain and Heavily Cratered Terrains (IcP-HCT) and High-Mg Northern Volcanic Plains (High-Mg NVP) mixtures, but none of our spectra is able to reproduce the remote sensing data entirely.

Key Words: Mercury, surface; Mineralogy; Infrared observations; Instrumentation; Spectroscopy

1. Introduction

The mid-infrared spectrometer MERTIS (MErcury Radiometer and Thermal Infrared Spectrometer) of BepiColombo will map the surface of Mercury in the wavelength range of 7-14 µm, with a spatial resolution of around 500 meters (Hiesinger et al., 2020). Spectral infrared features permit the direct determination of Mercury's surface mineralogy (e.g., Rothery et al., 2020), which is not possible with ground-based observations at this resolution (e.g., Sprague et al., 2009). In order to extract a more accurate, as well as spatially-resolved mineralogy from the future spectral data, laboratory studies for comparison with BepiColombo measurements are required to support spectral modelling. In order to achieve this, the IRIS laboratory in Münster and the BED laboratory in Berlin were installed to characterize a wide range of samples relevant to Mercury (e.g. Weber et al. 2018).

There are no known meteorites from Mercury (e.g., Weber et al., 2016). Hence, we rely on remote sensing observations to study the mineralogy of Mercury. Multispectral imaging with the Mercury Dual Imaging System (MDIS) and spectral reflectance measurements with the Mercury Atmospheric and Surface Composition Spectrometer (MASCS) onboard MESSENGER recognized the occurrence of graphite (Peplowski et al., 2016), sulphides (Vilas et al., 2016), and ice in polar regions (Neumann et al. 2013). Spectral measurements also show that the crust of Mercury contains Fe^{2+}-poor silicate minerals (Izenberg et al., 2014). However, spectral data from MESSENGER were insufficient to identify the mineralogy of silicate phases and their abundances. Additionally, information on the chemical composition of the hermean surface is based on data from X-ray, gamma-ray, and neutron spectrometers onboard the MESSENGER spacecraft (e.g., Peplowski et al., 2011, 2016; Nittler et al., 2020). Major element ratios obtained from the various instruments allowed the identification of several chemically different regions (the so-called 'terranes') on the hermean surface. The terranes were named the Low-Mg Northern Volcanic Plains (Low-Mg NVP), the High-Mg Northern Volcanic Plains (High-Mg

NVP), the Smooth Plains, the Inter Crater Plains and Heavily Cratered Terrains (IcP-HCT), and the High-Mg Province (Nittler et al., 2011; Peplowski et al., 2016; Weider et al., 2015; vander Kaaden et al., 2016; Peplowski and Stockstill-Cahill, 2019). Typical rock types on Mercury's surface can broadly be described as Fe-free and S-enriched komatiites, boninites, and andesites (e.g., Weider et al., 2015; Vander Kaaden et al., 2016; Peplowski and Stockstill-Cahill, 2019). Thermodynamic modeling and experimental petrology provide first order constraints on the mineralogy of such rocks, which are likely to be dominated by olivine, pyroxenes, plagioclase ± quartz, and (Mg,Ca)S sulfide (e.g., Charlier et al., 2013, Stockstill-Cahill et al., 2012; Namur & Charlier 2017; Vander Kaaden et al., 2017; Renggli et al., 2022). Data from mid-infrared spectroscopy from terrestrial telescopic observations integrating large surface regions also indicate a hermean mineralogy dominated by plagioclase and pyroxene (Donaldson-Hanna et al., 2007; Sprague et al., 1994, 2000, 2002, 2007; Sprague and Roush, 1998; Emery et al., 1998; Cooper et al., 2001).

In this study, we performed spectroscopic measurements in the mid-infrared wavelength range of analog glass and crystal mixtures relevant to Mercury's surface. The compositions of the glasses and crystals were chosen based on results from high-temperature crystallization experiments (1480-1100°C), that were equilibrated at crustal pressure (1 kbar) and reduced redox conditions (around IW-5; Namur and Charlier, 2017). The bulk compositions of these experiments are representative of the five main chemically distinct regions of the hermean surface introduced above, and the quenched products contain some of the following phases: silicate glass, plagioclase, forsterite, diopside, enstatite, quartz, FeSi metal, and sulfide (i.e., stoichiometric FeS). The samples we measured in this study are mixtures of pure endmember minerals and glass, very similar to the chemical compositions of the experimental products presented by Namur and Charlier, 2017. Synthetic glasses used in this study were previously described in detail in Morlok et al. (2021).

The overall aim of this study is to (a) provide mid-infrared reflectance spectra of hermean mineral/glass mixtures in different size fractions to allow granumeletric studies, and under varying observational geometries to accommodate for changing observational conditions in orbit, and (b) provide first spectral parameters for the comparison with future data obtained by MERTIS.

ID	mineral / features	locality (origin)

53	Enstatite	Odegardens Verk, Bamble, Norway
249	Olivine	Dreiser Weiher, Germany

Table 1: Sources of natural crystalline phases used in this study. Samples are from larger, crushed single crystals and handpicked afterwards. Spectra can be found in Figure 2f. Chemical data see Table 3.

2. Samples and Techniques

2.1. Samples

Compositional and mineralogical characteristics of five terranes are covered in this study (Peplowksi et al., 2015, Weider et al., 2015; Namur and Charlier, 2017; Denevi et al., Nittler et al., 2020). Large lava flows (~3.5 Ga) are typical of the Northern Volcanic Plains (Low-Mg and High-Mg NVP). The Low-Mg NVP is characterized by low Mg/Si ratios and a wider range of Al contents. This results in high-plagioclase abundance, together with diopside and forsterite, whereas the High-Mg NVP lavas contain a in comparison higher olivine abundance.

118 The intermediate Inter Crater Plain and Heavily Cratered Terrains (IcP-HCT), characterized by medium
119 sized craters, show high Al contents, and contrasting low Mg. This resulted in high modal amounts of
120 plagioclase.
121 3.5 to 3.9 Ga old Smooth plains cover ~40% of the hermean surface and are characterized by flat plains
122 with numerous wrinkle ridges. The chemistry shows lower Mg/Si, S/Si, and Ca/Si ratios compared to the
123 other regions, resulting in a mineralogy dominated by plagioclase, but minor mafic components. The old
124 (4.2 – 4 Ga) High-Mg Province is characterized by high Mg/Si and Ca/Si, and low Al/Si ratios. The samples
125 used in this study reflect a relatively low a a series of natural crystalline materials (Table 1). We selected
126 a series of modal (wt%) phase compositions for each surface region identified in Namur and Charlier
127 (2017) (Fig. 1). Chemical bulk compositions of the mixtures were calculated using the chemical
128 composition of the starting materials and the individual weighed phase abundances (Table 2).
129 Detailed information about the minerals labradorite, enstatite, and forsterite (IDs 28, 53, 249) used in
130 this study are given in Weber et al. (2021) and Reitze et al. (2021). ID 22 is a diopside, crushed to grain
131 sizes from 25 µm – 250 µm which shows no sign of impurity. However, in the grain size fraction from 0
132 µm – 25 µm we observe signs (<5%) of serpentinization (van der Meer et al., 1995; Daly et al., 2011).
133 However, this has only small impact on the overall bulk compositions of our samples because we used
134 low proportions of ID 22 Diopside in the mixtures.
135 The mineral samples are natural terrestrial materials. While the chemical composition of these minerals
136 is, overall, similar to minerals on Mercury, these phases formed in vastly different environments. In
137 particular, terrestrial magmatism is much more oxidized than expected for Mercury, with the latter of
138 which is characterized by redox conditions buffered by the iron-wüstite buffer (IW-7 to IW-3), whereas
139 magmatism on the Earth usually happens at redox conditions between IW-2 to IW+8 (McCubbin et al.,
140 2012; Namur et al., 2016a,b; Cartier and Wood, 2019). As a result, for example different Fe^{2+}/Fe^{3+} ratios
141 in olivine and pyroxene can be expected.

Silicate glasses were synthesized to represent the amorphous component in our mixtures. Details on the synthesis protocol can be found in Morlok et al. (2021). We produced a series of six synthetic glasses using reagent grade oxides as starting materials. Melts were kept in a gas mixing furnace for 6 h at 1450°C at the graphite-CO buffer (IW-6.7). The glasses cover the observed compositional range of the terranes (e.g., 1.6 wt% - 19.0 wt% MgO).

Size fractions for each mixture were mixed separately (<25 µm, 25 µm – 63 µm, 63 µm -125 µm, 125 µm -250 µm). This results in minor divergences from the modal starting compositions based on the laboratory experiments (see Table 2). The finest fraction (<25 µm) was chosen to represent the regolith grain size, which exhibits the important Transparency Feature (TF), a characteristic reflectance low. The other size fractions were selected to cover intensity changes related with grain sizes. Increasing grain size is correlated with increasing intensity (e.g., Salisbury, 1993; Mustard and Hayes, 1997).

For measurements, the samples were filled into aluminum sample cups, and the surface flattened with a spatula (see Mustard and Hayes, 1997 for details).

159 **2.2. Infrared Studies**

160 We used a Bruker Vertex 70v infrared spectrometer with a liquid nitrogen cooled MCT (HgCdTe) detector
161 at the IRIS laboratory in Münster. Analyses were made in the wavelength region of 2.5 µm to 18 µm in
162 low vacuum (100 Pa). For each spectrum, 512 scans were accumulated at a spectral resolution of 4 cm^{-1}
163 (20 nm at 7 µm, 80 nm at 14 µm). This spectral resolution is comparable to MERTIS onboard
164 BepiColombo (e.g., 90 nm, Hiesinger et al. 2010 and 2020). For calibration, the instrument background
165 was eliminated by ratioing the sample spectra against the spectrum of a diffuse gold standard
166 (INFRAGOLD^{TM}) measured under the same conditions. Analyses were made at 13° incidence (i) and 13°
167 emergence (e), 20° (i)/30°(e), and 30°(i)/30°(e) in order to simulate observational geometries of an
168 orbiter. The results presented in the main text were made at 20°(i) and 30°(e), results for the other
169 settings are available in the supplement. The results are presented in reflectance from 6 µm – 18 µm
170 (Fig. 2a-e), which covers the range of the MERTIS instrument (7 µm – 14 µm) but omits volatile features.
171 It also includes the Christansen Feature (CF, the Reststrahlenbands RB; the molecular vibration modes of
172 the materials), and the Transparency Feature (TF; typical for the finest <25 µm size fractions).
173 Since the aim of our study is to compare the laboratory data with future remote sensing data,
174 measurements from the laboratory have to be recalculated from reflectance to emissivity using
175 Kirchhoff's law: $\varepsilon = 1 - R$ (R = Reflectance, ε = Emission, Nicodemus, 1965). However, a prerequisite for
176 the validity of Kirchhoff's law is that the reflected light should be collected in all directions. In an ideal
177 case directional emissivity and directional hemispherical reflectance should be compared. However, we
178 used a bi-directional setup. Earlier studies showed that this approach mainly affects the reflectance
179 intensity, but not band positions. This must however be kept in mind when comparing the results in a
180 quantitative manner with emission data (Salisbury et al., 1991; Hapke, 1993; Thomson and Salisbury,
181 1993; Salisbury et al., 1994; Christensen et al., 2001). The spectra presented in this study are accessible
182 on our online database at the Institut für Planetologie in Münster (http://bc-mertis-pi.uni-muenster.de/).

190 Wollastonite content (mol.%).

191

192 **3. Results**

193 Most samples show spectral features at wavelengths shorter than 7 µm, usually at 2.7 µm – 3.0 µm,
194 3.4 µm– 4 µm, and 5 µm – 7 µm. These are volatile features due to adsorption and absorption of
195 terrestrial water and unavoidable minor contaminations of the terrestrial minerals used for the mixtures.
196

197 **3.1. Low-Mg Northern Volcanic Plains**

198 The glassy end member is represented by low Mg sample ID 174 (Morlok et al., 2021), and has the CF at
199 7.9 µm, the TF at 11.8 µm, and a single RB at 9.6 µm. The spectrum of ID 350 has the CF between 7.8 µm
200 and 8.1 µm, with several pyroxene RB at 9.4 µm, 9.9 µm, 10.2 µm, 10.5 µm – 10.6 µm and 10.8 µm. The
201 TF is located at 11.3 µm – 11.5 µm (Tab.4; Fig.2a, f). The dominance of the glassy component results in a
202 simpler spectrum with few bands for ID 349: the CF is at 7.8 µm - 7.9 µm, the TF at 11.6 µm. The
203 strongest olivine RB is at 9.4 µm -9.5 µm, with minor features at 10.2 µm and 10.5 µm - 10.6 µm (Tab.4;
204 Fig.2a, f).

205

206

207

208

3.2. High-Mg NVP

The glass-rich samples ID 355 and pure glass ID 181 have the CF at 8 µm to 8.1 µm and the TF at 11.9 µm. They have a strong RB at 9.7 µm to 9.8 µm, ID 355 also has weak olivine bands at 10.5 µm. Crystal-bearing ID 356 and ID 357 show similar pyroxene band positions, although they are different in intensities and band shapes. Their CF is between 7.8 µm and 8.2 µm (Table 4; Fig. 2b, f). Common pyroxene RBs are at 9.4 µm -9.5 µm, 10.2 µm, 10.5 µm, 10.8 µm, and 11.3 µm. At longer wavelengths, bands occur at 14.4 µm-14.5 µm, and 15.6 -15.8 µm. The TF is located at 11.4 µm.

3.3 Intra Crater Plains - Heavily Cratered Terrane (IcP-HCT)

The glass endmember, represented by high-Mg glass ID 181 (Morlok et al., 2021) has the CF at 8 µm to 8.1 µm, the TF at 11.9 µm, and a single RB at 9.8 µm. Similar to the High-Mg Province, the spectra of the IcP-HCT region (ID 351, ID 352, ID 353, ID 354) are dominated by olivine features, reflecting the forsterite modes ranging from 21 to 33 wt% (Table 4; Fig. 2c, f). The CF is located between 7.8 µm and 8.2 µm. The strongest RBs are at 9.4 µm - 9.7 µm, 10.2 µm, 10.5 µm-10.6 µm, and 11.9 µm. The TF is again a broad feature without distinct maximum. A dip at 7 µm is observed for diopside-rich samples ID 353 and ID 354.

3.4. Smooth Plains

Glass-dominated mixture ID 345 has a CF range from 7.9 to 8 µm, with an RB at 9.6 µm, 10.2 µm and 10.5-10.6 µm. The TF is located at 11.8 µm.

The-Smooth Plains samples ID 343 and ID 344 show generally similar pyroxene band positions (Table 4; Fig. 2d, f) reflecting their similar bulk composition, but with ID 344 having more pronounced, ‘sharper’ bands. The CF is between 7.8 µm and 8 µm for ID 343, and between 7.8 µm and 7.9 µm for ID 344. Significant RBs are between 9.4 µm and 9.6 µm and at 9.9 µm, 10.2 µm, 10.5 µm, 10.8 µm an 11.4°µm.

The TF is located at 11.7 µm. Various minor spectral features are found at longer wavelengths, mainly from 15.5 µm to 15.8 µm. The diopside-rich sample ID 343 shows a dip at 6.9 µm to 7 µm (or a small feature at 7.3 µm) in the finest grain size fraction.

3.5. High-Mg Province

The glassy end member ID 338 has the CF at 8.2 µm, TF at 12.1 µm and the dominating RB at 9.9 µm. As a result of the high forsterite contents (30-36 wt%), spectra of mixtures ID 346, ID347, and ID348 are quite similar (Table 2; Fig. 2e, f). The plagioclase and pyroxene contents show no significant bands in the spectra. The CF ranges from 7.8 µm to 8.6 µm, and the strongest RB is at 10.6 µm. Further common bands are found at 10.2 µm and 11.9 µm – 12 µm. ID 346 and ID 347 share further RBs at 9.4 µm and 10.8 µm. The TF is a broad feature without a clear peak. Features at longer wavelengths are seen between 15.8 µm and 16 µm. Samples ID 346 and ID 347 shows a dip at 6.9 µm in the finest grain size fractions.

4. Discussion

4.1. Interpreting the mixtures

Despite the often-complex mixtures of up to five crystalline and one amorphous phase, the resulting spectra of the mixtures can be divided into three groups (Table 3). The simplest spectra are dominated by glass, demonstrated by prominent RB from 7.9 µm – 8.3 µm. Besides the 'pure' glassy end members (ID 174, ID181, and ID 338), sample ID 355 High-Mg NVP with only minor (3 wt%) crystalline content shows barely any recognizable additional bands (Fig. 2b). In the second group, forsterite features tend to dominate (Table 3): bands near 9.4 µm to 9.5 µm, 10.2 µm, 10.6 µm, 11.9 µm, and 15.9 µm -16 µm (Fig.2c, e). In the finest size fraction (< 25 µm), the TF the 10.6 µm band is turned into a broader feature with another peak at 11.2 µm to 11.3 µm.

A third group exhibits the pyroxene RB features of diopside and enstatite near 8.9 µm to 9.1 µm, 9.4 µm - 9.5 µm, 9.9 µm, 10.2 µm, 10.4 µm - 10.8 µm, 11 µm - 11.1 µm - 11.3 µm, and 11.4 µm to 11.6 µm (Fig.2a-e). The finest grain size fractions of diopside-rich samples also show a dip at 6.9 µm to 7 µm, which is also prominent in the finest grain size fraction of the ID 22 diopside bulk material.

Although plagioclase feldspar is often a dominant component in the mixtures, its RB features tend to be subdued by the forsterite and enstatite bands. The only RB, which is visible in all samples with a high amount of plagioclase is its RB 1 as a shoulder at around 8.3 µm (e.g. 356 and 357 High-Mg NVP; Fig. 4b). This is probably caused by its flat spectrum, that is dominated by a broad RB at 8.7 µm, and particular at 9.9 µm to 10 µm and 10.5 µm to 10.6 µm, which are superimposed by the more pronounced pyroxene and olivine bands. However, further hints of significant plagioclase contents are higher intensities in the ≃10 µm to 10.5 µm range due to the strong plagioclase double-feature, which provides a generally broad feature, which serves as some kind of underlying continuum, as observed in samples ID 350 and ID 356 (Fig.2a, b). In the wavelength range around 12 µm glasses and plagioclases have overlapping TF. In earlier experiments using plagioclase (ID28) with varying degrees of Al-Si order (Reitze et al. 2021a) plagioclases with low degree of Al-Si order show a single TF, such with a higher order a double peak or

peak with shoulder, as seen in the case of the plagioclase ID28 used in this study (e.g. 350 Low-Mg NVP or 357 High-Mg NVP; Fig.2a, b).

The quartz content is too low (few wt%) to produce any recognizable RB (e.g., 2 wt.% in ID 346, 1.2 wt.% in ID 354; Fig.4b and e). This raises the question of the 'critical' concentration (i.e. detection limit) of a phase to be recognizable in a mixture. In simple mixtures of glass and a crystalline phase, minute contents of 3 wt.% olivine in ID 355 High-Mg NVP(Fig.2b) provide just enough signal to identify the mineral with features at 10.5 µm and 11.9 µm (Table 4). Contents of 9.3 wt% olivine in ID 345 Smooth Plains (Fig.2d) are easily recognizable with bands at 9.6 µm, 10.2 µm, 10.6 µm, and 11.4 µm (Table 4). However, two minor components of 8.2 wt.% olivine and 4.2 wt.% diopside in ID 349 Low-Mg NVP (Fig.4a) only allow the clear identification of the olivine 9.4-9.5 µm, 10.2 µm, 10.5 µm-10.6 µm, and 11.6 µm. Increasing number of phases will make the identification of a minute phase in the crowded range around 10 µm difficult. For the semi-quantitative identification of further components, rationing of spectral parameters could provide an alternative.

Figure 3c

Figure 3. (a) Correlation of SiO_2 abundance with CF position. Results from this study (red circles) mainly fall into the intermediate area. **(b)** Comparison of the Mg/Si ratio with the CF. The refractory glasses produced with laser-heating (Morlok et al., 2020b) is easy to distinguish from the samples with hermean and planetary compositions. **(c)** Comparison of SCFM (SiO_2, CaO, FeO, MgO) index of polymerization to CF position. Blue shaded areas and dashed line mark are from Cooper et al. (2002) for terrestrial rocks.

4.2 Correlation of Bulk Composition with Spectral Parameters

Christiansen Feature and SiO_2

The CF can be extracted even from 'noisy' spectra. Hence any correlation of the CF with other features will help to derive basic information about composition and mineralogy from remote sensing data. A classical method to correlate the average CF of all grain size fractions with chemical composition is the comparison of the SiO_2 content (wt.%) with the CF (Cooper et al., 2002). The comparison of the hermean mixtures in this study with earlier results (Fig.3a) shows that most of the mixtures fall close to the correlation line for terrestrial materials, which is the best fit for results of a range of terrestrial rocks scattering a bit due to compositional variances as indicated by the blue shaded areas (Cooper et al., 2002). Furthermore, the results fall into or very close to the field for intermediate rocks.

Christiansen Feature and Bulk Mg/Si

Absolute element abundances are difficult to determine from mid-IR remote sensing data. Hence, we use the element ratio between Mg and Si for a correlation with the CF, as ratios of chemical data of two major elements is easier to extract from the space probe data (Fig.3b). In combination with the CF it provides a set of parameters relatively easily extracted from remote sensing data.

Here, our results fall along the area of synthetic Mercury composition glasses (Morlok et al., 2017a, 2020a). The terrestrial impact glasses and the refractory glass from laser-heated melting experiments (Morlok et al., 2020b) are clearly in a separate field compared to our samples relevant to Mercury. This

separation could help to identify glassy material formed in high-velocity impacts from such produced in volcanic processes.

Christiansen Feature and SCFM

The SCFM index expresses the degree of polymerization based on the $SiO_2/SiO_2+CaO+FeO+MgO$ relation (Salisbury and Walter, 1989). Similar to earlier studies, most of the results plot systematically below the terrestrial correlation line (Fig.4c). This could be related to the varying degrees of polymerization of the mixtures, however the correlation between glass content and SCFM is very weak (R^2=0.04) The results show similarities to the intermediate, basic and basaltic terrestrial rocks (Cooper et al., 2002)

4.3. Comparison with Remote Sensing Data of Mercury

Only few mid-infrared spectra are so far available for Mercury. Owing to technical reasons they cover larger surface regions (10^4–10^6 km^2) and offer only weak spectral contrast and low signal to noise ratios (Sprague et al., 2007). Therefore, we only use as an example the spectrum with the highest signal to noise for our comparisons. The spectrum integrates a region at about 210–250° longitude and was obtained by the Mid Infrared Camera (MIRAC) at the Kitty Peak Observatory (Sprague et al., 2000).

The spectrum recalculated from emission (Fig.4) shows a CF at 8.5 µm, three strong RBs at 9.3°µm, 9.9°µm, and 11°µm. A potential TF is visible at 12.4°µm. We compare it with our results of the 0-25 µm fraction of two mixtures reproducing some of the features.

The olivine-rich 347 High-Mg Province mixture reproduces the CF of the hermean spectrum, and also has an RB at 9.4 µm, near the 9.3 µm feature of the surface spectrum. A broad feature at 11°µm overlaps with a (much narrower) band of the surface spectrum at the same position.

Plagioclase and enstatite-rich 357 High-Mg NVP mixture has a low-point at 8.5 µm, a strong RB at 9.4°µm and a minor RB at 9.9°µm. These features are similar to the CF at 8.5 µm and the second and third RB (9.3°µm and 9.9°µm) of the hermean sample.

Figure 4. Comparison of Plagioclase and enstatite-rich 357 High-Mg NVP, and olivine-rich 347 High-Mg Province mixtures with a Mercury surface spectrum (recalculated from emissivity) (Sprague et al., 2000, 2007). Shaded areas mark characteristic features of the hermean spectrum.

5. Summary & Conclusions

We mixed bulk grain size fractions of analog materials relevant to the distinct terranes of Mercury. The powdered samples were analyzed in diffuse reflectance in the mid-infrared (2 µm – 20 µm).

The resulting spectra can be divided into three groups: (1) such as dominated by a single glass feature, (2) a group with forsterite, and (3) a group dominated by pyroxene bands. Plagioclase features, even when the phase is dominating the composition, are usually 'overprinted' by forsterite and pyroxene bands.

The spectral parameter CF in comparison with chemistry (SiO_2) and polymerization (SCFM) places the hermean mixtures mostly in the intermediate and basaltic range, similar to findings based in Peplowski and Stockstill-Cahill (2019). The correlation of parameters Mg/Si ratio and CF, that are easily obtainable in remote sensing, allows to distinguish materials that were formed by high energy evaporation processes in impacts from those formed by melting processes.

Preliminary comparison with a high-quality spectrum of the hermean surface (Sprague et al., 2000) show some similarity with band positions of IcP-HCT and High-Mg NVP mixtures, but none of our spectra is able to reproduce the remote sensing data entirely. This is not unexpected since further conditions (e.g. temperature) will also affect spectral properties, and this will have to be addressed by future studies.
