38 Abstract

39 Intermediate wheatgrass [IWG; *Thinopyrum intermedium* (Host) Barkworth & D.R. Dewey] is a
40 perennial grass, dual-purpose crop that can provide environmental services. In addition to the grain
41 production, assessing its forage potential is crucial. We developed models for near-infrared (NIR)
42 spectrometry prediction of the chemical composition and digestibility of IWG across various
43 experimental sites. Among these, a Belgian field was used to compare its dual production in pure
44 stands or in mixture with legumes. Good quality NIR predictions were observed, offering an efficient
45 tool to characterize the forage composition of IWG. Its forage parameters were mainly influenced by
46 the phenological stage with an increase of fibers and a decrease of protein, digestibility, and energy
47 content (NE_L) during the growing season. IWG forage at vegetative stages could be used to feed
48 lactating dairy cattle with a NE_L of 1625 kcal kg⁻¹ of DM but, its biomass was low averaging 1.8 t of DM
49 ha⁻¹. At grain maturity, biomass was higher (i.e., 5.3 t of DM ha⁻¹), representing 73 to 92 % of the total
50 biomass production, and could replace straw in high-starch dairy diets with a NE_L averaging 849 kcal
51 kg⁻¹ of DM. Although the mixture of IWG with legumes enhanced some forage parameters, its value as
52 animal feed was not improved. In mixture, we observed a tradeoff between the increase of the forage
53 yield and the reproductive potential of IWG. These insights can inform the on-going process of
54 breeding and help farmers to design relevant systems to experiment this new crop.

56 Perennial grain – *Thinopyrum intermedium* – Intermediate wheatgrass – Kernza® – Forage evaluation
57 – Legume intercropping

58 1. Introduction

59 To reconcile the objective of dedicated land to arable cropping for human food consumption and
60 grasslands area for ecological intensification, intermediate wheatgrass [IWG; *Thinopyrum intermedium*
61 subsp. *intermedium* (Host) Barkworth & D.R. Dewey] is currently proposed as a dual-use perennial
62 grass. The crop can provide both forage and grain as well as other ecosystem services thanks to its
63 year-round soil cover and its persistent root system (Crews et al., 2016; Rasche et al., 2017; Ryan et
64 al., 2018). Due to its actual low grain yield (Fagnant et al., 2024), forage valorization could be a way to

65 generate additional agricultural production to increase crop profitability (Bell et al., 2008; Larkin et al.,
66 2014; Newell & Hayes, 2017). Forage harvesting can be achieved at different time during the year
67 depending on the farmer's objectives. While grains and straws are harvested in summer, additional
68 cuts or grazing operations could be performed in fall, early-spring, or both for forage production
69 (Culman et al., 2023; Hunter et al., 2020). However, knowledge of the forage quality is essential to
70 foster an adequate use of unconventional forage resources such as *Th. intermedium* in the feeding
71 system of domestic herbivores.

72 Pasture species with high feeding value can increase farm profitability and reduce externalities through
73 the improvement of feed autonomy (Thomas et al., 2021). Chemical composition, intake, digestibility,
74 and efficiency of utilization are the main features determining the nutritive value of a given forage.
75 Notably, the fiber, lignin, and protein contents of forage tissues are associated with voluntary feed
76 intake and digestibility properties (Cherney, 2000). Deriving forage quality from multiple chemical
77 analyses is time-consuming. The near-infrared (NIR) spectrometry is successfully used since multiple
78 decades as a non-destructive alternative to lab reference methods. Nevertheless, a crucial calibration
79 step is required to relate the NIR optical measurements to the desired constituent or property used to
80 define the nutritional quality of forages (Deaville & Flinn, 2000). As for other grasses, *Th. intermedium*
81 forage quality depends on its phenological stage at harvest. Early in spring, before or at the beginning
82 of the reproductive growth, the proportion of leaves is significantly higher than that of stems and
83 represents more than 80 % of the aboveground biomass (Barriball, 2020; Fagnant et al., 2023). After
84 this stage, the proportion of stems increases until spikes are fully emerged. At grain maturity, leaves
85 only represent 13 % of the aboveground biomass, while stems and spikes are respectively 71 % and 16
86 % of it (Fagnant et al., 2023). This progressive change during the growing season is linked with an
87 increase in total aboveground biomass but is known to lead to a significant decrease in forage quality
88 (Thomas et al., 2021; Wróbel et al., 2023).

89 Agronomic management of *Th. intermedium* can help to increase the global forage yield potential in
90 terms of quantity and quality. In this way, additional forage harvesting in spring, fall or both increases
91 the total production of biomass of *Th. intermedium* compared to a unique harvest at grain maturity
92 (Hunter et al., 2020). In the study of Culman et al. (2023), harvesting forage in the spring resulted in
93 the lowest forage biomass but with the highest forage quality, fall harvest was intermediate in terms
94 biomass and quality and summer harvest maximized biomass but resulted in the lowest quality.
95 Although the forage quality at grain maturity (i.e., straw) is relatively poor, Hunter et al. (2020)
96 highlighted that the higher quantity of biomass harvested is of great interest as it provides a tangible
97 second outcome besides grains. The impact of forage harvesting, particularly the timing and frequency,
98 on grain yields also needs to be considered. As observed by Culman et al. (2023), harvesting forage in
99 the summer and fall increased grain yield as harvesting forage in the spring reduced grain yield. Besides
100 forage harvesting, the mixture of legumes with forage grasses is known to secure forage yield potential
101 (Louarn et al., 2016) and can improve forage quality. Compared to pure grass forage, protein content
102 can be reinforced, the fiber content lowered (Baumont et al., 2016) and the digestibility and therefore
103 the energy value enhanced, according to the legume species and its chemical and morphological traits.
104 For example, the digestibility of legumes such as lucerne or red clover (i.e., *Medicago sativa* L. and
105 *Trifolium pratense* L.) is generally lower than or equivalent to that of grasses. By contrast, white clover
106 (i.e., *Trifolium repens* L.) stands out for its very high digestibility, superior to that of grasses, due to its
107 notable absence of stems and lower fiber content. In addition, legume digestibility decreases less
108 rapidly over the growing cycle than that of grasses, so their nutritional value is more stable over time
109 (Baumont et al., 2016). In the study of Favre et al. (2019), the forage provided by the mixture of *Th.*
110 *intermedium* with red clover tended to have lower fiber and higher protein contents compared to a
111 *Th. intermedium* monoculture and increased forage yield. As a dual-use crop, a range of effects of the
112 legume mixtures on the grain yield of *Th. intermedium* is documented. Some experiments showed
113 lower grain yields in lucerne or red clover mixtures than monoculture (Favre et al., 2019; Mårtensson
114 et al., 2022; Pinto et al., 2022; Tautges et al., 2018). Other experiments demonstrated similar grain

115 yields in lucerne, berseem clover (*Trifolium alexandrinum* L.), kura clover (*Trifolium ambiguum* M.
 116 Bieb), sweet clover (*Melilotus officinalis* L.), and white clover mixtures than monoculture (Dick et al.,
 117 2018; Pinto et al., 2022; Reilly et al., 2022; Tautges et al., 2018). Thus, the interaction between the
 118 species within the mixture needs to be studied to favor complementary and reduce competitive
 119 relationships.

120 In this study, we aimed to develop models for near-infrared (NIR) spectrometry prediction of the
 121 chemical composition and enzymatic in vitro digestibility of *Th. intermedium* forage. Through the speed
 122 of analysis, such model should facilitate the characterization of forage nutritive value of this novel
 123 multifunctional species where efforts are still ongoing to describe and improve its dual-use
 124 productions. Secondly, using the developed prediction models, we evaluated the grain and especially
 125 the forage production of the crop, either in monoculture or in mixture with different legume species.

126 2. Materials and methods

127 2.1 Experimental sites

128 To characterize the chemical composition and enzymatic in vitro digestibility of the forage of
 129 *Thinopyrum intermedium* (intermediate wheatgrass, IWG) through near-infrared spectra models,
 130 samples from different experimental sites were used to cover a wide range of pedoclimatic conditions,
 131 agronomic managements, crop ages and phenological stages (Table 1).

132 Data collected on the BE3 experimental site in Belgium (Table 1) was used to characterize the forage
 133 production of *Th. intermedium* under a dual-use management (i.e., spring and autumn forage harvest
 134 coupled to grain and forage harvest at grain maturity). This field experiment was conducted during
 135 two successive cropping years using a complete randomized split-plot design (4 x 8 m subplots) with a
 136 forage harvest factor as the main-plot treatment and a species mixture factor as the split-plot
 137 treatment, with four replicates. The forage harvest factor compared different treatments, not studied
 138 in this study (Table S1). An autumn forage harvest was performed both years while spring harvest was
 139 only performed in the second year due to insufficient plant establishment in the first year. During these
 140 mechanical forage harvests (i.e., spring and autumn forage harvest), the aboveground biomass was
 141 cut to a height of 7 cm (i.e., above the apex height) and exported from the field. In this experiment,
 142 four treatments compared the effects of the mixture with different legumes species: I) *Th.*
 143 *intermedium* monoculture (IWG), II) *Th. intermedium* in mixture with white clover, III) *Th. intermedium*
 144 in mixture with red clover and IV) *Th. intermedium* in mixture with lucerne. Legumes were seeded in
 145 the interrow of *Th. intermedium*, but only on the half of all interrow to reduce light competition as
 146 described in Figure 1. Each subplot (i.e., 4 x 8 m) was split in two: one plot was dedicated to destructive
 147 sampling during the growing season and the other one to grain yield measurement in summer.

BBCH2. is corresponding to the autumn vegetative stage; BBCH29 to the spring vegetative stage; BBCH30 to the stem elongation stage; BBCH39 to the flag leaf stage; BBCH65 to the flowering stage and BBCH89 to the grain maturity stage.

Figure 1 : Interrow disposition in subplots between *Th. intermedium* and the different legume species in the BE3 experimental site.

149 2.2 Data collection

150 For all experimental sites, aboveground biomass was sampled during the growing season with a 50 x
151 50 cm quadrat and cut at 5 cm above soil surface. Fresh samples were weighted to obtain the fresh
152 matter and then oven-dried (72 h at 60 °C) and weighted again to obtain dry matter (DM60). Samples

153 were collected at different phenological stages, rated with the BBCH scale (Meier, 2018), from the
154 vegetative stage (BBCH2.) to the grain maturity stage (BBCH89) as mentioned in Table 1. Samples were
155 then ground to a particle size of 1 mm in a FOSS Tecator Cyclotec 1093 mill; Foss company; Hillerød;
156 Denmark.

157 The dried and ground samples were subjected to near-infrared radiation with wavelengths ranging
158 from 400 to 2498 nm by using a XDS Monochromator Type XM-1000 FOSS spectrometer; Foss
159 company; Hillerød; Denmark. The spectral data were recorded with a step of 2 nm. The spectral
160 absorbance values were recorded as $\log(1/R)$, where R is the sample reflectance.

161 2.3 Development of near-infrared spectra models

162 2.3.1 Chemical analyses

163 To develop NIRS prediction models for the chemical composition and enzymatic in vitro digestibility of
164 the forage of *Th. intermedium*, 223 samples covering the variation range within the database (Table 1)
165 were selected to undergo the chemical reference analyses.

166 The parameters described below were expressed on a dry matter basis (method 967.03; AOAC, 1990).
167 The total ash content was determined by weighing the sample fraction remaining after complete
168 calcination at 550 °C (method 942.05; AOAC, 1990). Crude protein (CP) was calculated as total Kjeldahl
169 N multiplied by 6.25 (method 981.10; AOAC, 1990). Fiber contents were analyzed with the Fibercap
170 system (Foss Electric, Bagsvaerd, Denmark). Neutral detergent fiber (NDF) and acid detergent fiber
171 (ADF, method 973.18; AOAC, 1990) contents were determined as described by Van Soest et al. (1991).
172 NDF was analyzed using Termamyl (Novo Nordisk, Bagsværd, Denmark). The acid detergent lignin
173 (ADL) was analyzed according to Van Soest (1963) and the crude cellulose (CEL) according to Weende
174 (method 978.10; AOAC, 1990). The enzymatic in vitro digestibility of organic matter (OMD_{cel}) was
175 analyzed according to De Boever et al. (1986). All analyses were performed with two replicates. Some
176 sample masses were insufficient to perform all chemical analyses, inducing a lower number of
177 observations for the OMD_{cel} parameter (i.e., 126 observations compared to more than 200
178 observations for the other chemical parameters; Table 2).

179 2.3.2 Characterization of the database

180 To identify the factors underlying the variability within the database composed of the different
181 chemical parameters and digestibility of *Th. intermedium* forage (section 2.3.1), a principal component
182 analysis (PCA) was conducted. The PCA function of R program version 4.1.2 (R Core Team, 2024) was
183 used on centered and scaled data.

184 2.3.3 Predictive models and assessment of their quality

185 All the following analyses were performed on the MatLab R2018a software. First, the NIR spectra of
186 the 223 samples were subjected to pre-processing to remove noisy regions. The SNV (Standard Normal
187 Variate) function of Matlab was firstly performed to reduce the effects of interference related to the
188 dispersion and particle size of the sample (Eylenbosch, 2018). Then, the *detrend* function was used to
189 reduce the curvature and offset of the spectra. Finally, the Savitzky-Golay algorithm was applied
190 allowing for curve smoothing and background reduction (Eylenbosch, 2018).

191 For each forage parameter (Ash, CP, NDF, ADF, ADL, CEL, OMD_{cel}), a PLS regression was performed on
192 the pre-processed spectra (shown in Figure 3) with an explanation of the variance set at 50 %. The
193 standard coefficients (i.e., β -coefficients) from the PLS regression were used to identify the most
194 significant wavelengths to explain the variability within the parameter values (Eylenbosch et al., 2018).
195 If significant wavelengths of similar sign were too close (i.e., distance set at 25 nm), only the
196 wavelength with the highest β -coefficient was kept. Finally, these wavelengths were fed into a multiple

197 linear regression to predict the different forage parameters. Of these 223 analyzed samples, 70 % were
198 randomly selected to calibrate the models. The remaining 30 % samples were used for model
199 validation as an internal validation (Table 2).

200 To evaluate the model quality, the following criteria were used: the modelling efficiency (EF; or the
201 Nash-Sutcliffe model efficiency coefficient), the standard error of calibration (SEC), the standard error
202 of prediction (SEP; i.e., when the validation is performed on a set of independent samples) and the
203 ratio of the standard deviation (RPD; i.e., standard deviation between the database reference values
204 (SD) and the SEP). To define a model as acceptable, EF value should reach at least 0.5, the SEC value
205 should be as low as possible and close to the SEP and finally, the RPD should be greater than 3
206 (Beaudoin et al., 2008; Minet et al., n.d.; Murphy et al., 2022).

207 2.4 Productivity assessment on the BE3 site

208 2.4.1 Forage productivity assessment

209 To assess the forage production of *Th. intermedium* in a dual-use management and compare the effect
210 of the mixture with different legume species, the data was collected from the BE3 experimental site
211 (Table 1). As described in section 2.2, samples of aboveground biomass were collected during the
212 growing season to quantify forage biomass (in DM) of each species separately (i.e., *Th. intermedium*,
213 white clover, red clover and lucerne). Spectral data were collected alongside to predict their forage
214 chemical composition and digestibility. Forage parameters of *Th. intermedium* were derived from the
215 predictive model described in section 2.3 as forage parameters of legumes were derived from a
216 referenced spectral database as described by Minet et al. (2018). To go further in the characterization
217 of the forage composition, the organic matter (OM) content of the samples was determined as the
218 percentage of dry matter excluding the ash content. Specifically for *Th. intermedium*, the crude fat
219 content was analyzed on 26 samples selected to capture the different phenological stages (i.e., diethyl
220 ether extraction with a Soxhlet device, method 920.39; AOAC, 1990) to assign the crude fat content at
221 each phenological stage (i.e., BBCH2. and BBCH30: 30 g kg⁻¹ of DM, BBCH39: 25 g kg⁻¹ of DM and
222 BBCH65 and BBCH89: 20 g kg⁻¹ of DM). The nonfibrous carbohydrates (NFC) content was calculated by
223 removing the crude fat, the CP and the NDF content from the OM content. Finally, from the predicted
224 forage parameters, the net energy for lactation (NE_L) of the different legume species and *Th.*
225 *intermedium* was calculated according to the Dutch feed evaluation system for ruminants (CVB, 1991).
226 Depending on the forage composition of samples (i.e., ash, fiber content, OMD_{cel} or CP), various feed
227 equations can be used to estimate NE_L values. Following the PCA analysis (see section 2.3.2 and 3.1.1),
228 the composition of *Th. intermedium* varied with the phenological stage of the crop. Different equations
229 were used to estimate the NE_L value of *Th. intermedium*: 'fresh grass' equations for the vegetative
230 stages (i.e., BBCH2. and BBCH30); 'hay' equations for the BBCH39 stage and 'straw' equations for the
231 BBCH65 and BBCH89 stages. The NE_L values of legumes were all calculated with the 'fresh grass'
232 equations.

233 The different forage parameters (i.e., OM, CP, NDF, ADF, ADL, CEL, OMD_{cel}, NE_L) of the grass-legume
234 mixture were then calculated as the weighted average of *Th. intermedium* and the legume species
235 based on their respective DM proportion of the total mixture DM.

236 2.4.2 Grain yield productivity assessment

237 From BBCH30 to BBCH89 stages, tillers and spikes, when present, were counted from the aboveground
238 biomass samples of *Th. intermedium* (as described in section 2.2.) to estimate tiller and spike density.
239 At grain maturity, plots were harvested with a trial combine harvester to obtain grain yield on a
240 cleaned, but unsorted seeds basis (i.e., a mix of hulled and dehulled seeds).

241 2.4.3 Standard statistical analysis

242 All data analyses were conducted in the R program version 4.1.2 (R Core Team, 2024). As spring forage
 243 harvest was only performed in the second year, an ANOVA was performed for each cropping year
 244 separately. Within the different ANOVA, mixed models were applied with *lmer* function from the *lme4*
 245 package. Two-way ANOVA was performed with the species mixture and the phenological stage
 246 considered as fixed effect, while replicates as random effect. Models were evaluated to ensure they
 247 met the assumptions of independence and normality of residuals through the *plotresid* function.
 248 Transformation of variables was not necessary as the assumptions were met. Following the ANOVA,
 249 pairwise comparisons among treatment means were evaluated with the *emmeans* function from the
 250 *emmeans* package with a Tukey adjustment for multiple comparisons. If a significant interaction
 251 between fixed factors within the model was observed, this was considered in the post hoc test.
 252 Statistical significance was set at 0.05. Grain yield, tiller density and spike density of *Th. intermedium*,
 253 aboveground biomass of *Th. intermedium*, legumes and the grass-legume mixture, as well as their
 254 forage parameters (i.e., OM, CP, CEL, NDF, ADF, ADL, OMD_{cel}, NE_L) were the analyzed variables.

255 3. Results

256 3.1 Prediction of *Th. intermedium* forage parameters

257 3.1.1 Database characterization

258 The performed principal component analysis is illustrated in Figure 2, OMD_{cel}, CP and fiber parameters
 259 (i.e., ADF, NDF and CEL) were relatively well represented by the first principal components (PC1),
 260 explaining 67.5 % of the variance. As expected, principal component analysis indicated that there was
 261 a clustering effect on the database through phenological stages. Globally, vegetative stages (i.e.,
 262 BBCH2., BBCH29 and BBCH30) were on the negative axis of the PC1 indicating higher OMD_{cel}, CP and
 263 lower fiber content, while late reproductive stages (i.e., BBCH65 and BBCH89) had the opposite
 264 behavior. The flag leaf stage (i.e., BBCH39) represented an intermediate situation (Figure 2).

265
 266 *Figure 2 : Principal component analysis for the consolidated dataset used to develop the NIRS predictive models: first and*
 267 *second principal component axis.*

268 Through the variability mainly induced by phenological stages, the contents expressed in g kg⁻¹ of DM
 269 obtained by standard chemical analyses ranged from 31 to 133 for Ash, from 28 to 313 for CP, from
 270 345 to 799 for NDF, from 164 to 514 for ADF, from 11 to 112 for ADL and from 144 to 528 for CEL.
 271 OMD_{cel} ranged from 28 to 93 g per 100g of DM.

272 3.1.2 NIRS models performances

273 The 223 generated spectra exhibited spectral features expected for dried forage plant samples (Figure
274 3).

275
276 Figure 3 : The 223 generated pre-processed spectra of the consolidated dataset used to develop the NIRS predictive models,
277 spectra in grey were used for calibration and spectra in blue were used for validation. As highlighted by Deaville & Flinn
278 (2000), this type of spectra has prominent absorption bands including water at 1450 and 1940 nm; aliphatic carbon -
279 hydrogen bands (lipids) at 1210, 1400, 1725 and 2310 nm; oxygen - hydrogen bands (carbohydrates) at 1600 and 2100 nm
280 and nitrogen - hydrogen bands (amide structures in protein) at 2055 and 2180 nm.

281 Performances of the PLS models developed for the NIRS prediction (Table 2) and the relationship
282 between observed and predicted values for the calibration and validation (supplementary materials –
283 Figure S1) indicated that the developed models performed quite well. Except for the ADL content,
284 modelling efficiency (EF) was always above 0.95 for calibration and 0.90 for validation, the standard
285 error of calibration (SEC) values were relatively low and close to standard error of prediction (SEP)
286 values, and the ratio of standard deviation (RPD) values were above 3. Reduced quality of prediction
287 for the ADL content was observed with lower values of EF and RPD (Table 2).

288 Table 2 : summary statistics for the calibration and validation of PLS models for the various forage parameters.

	FPLS	Calibration						Validation					
		N	Mean	SD	EF	SEC	RPD	N	Mean	SD	EF	SEP	RPD
Ash	20	156	67.2	21.4	0.95	0.50	4.30	67	66.3	22.6	0.90	0.68	3.27
CP	18	155	112.1	61.4	0.99	0.66	9.51	67	117.5	68.8	0.99	0.75	8.90
NDF	17	155	607.1	119.4	0.99	1.26	9.23	66	591.3	118.0	0.96	2.45	5.12
ADF	17	155	344.8	93.8	0.98	1.27	7.38	66	332.7	96.7	0.98	1.46	6.63

N.B.: FPLS: number of PLS factors to explain 50 % of variability; N: number of observations; Mean: mean of forage parameters, SD: standard deviation of forage parameters; EF: modelling efficiency; SEC: standard error of calibration; SEP: standard error of prediction; RPD: ratio of standard deviation. Ash, CP, NDF, ADF, ADL and CEL were expressed in g kg⁻¹ of DM and OMD_{cel} in g 100g⁻¹ of DM.

289 3.2 Forage production of *Th. intermedium* in mixture with legumes

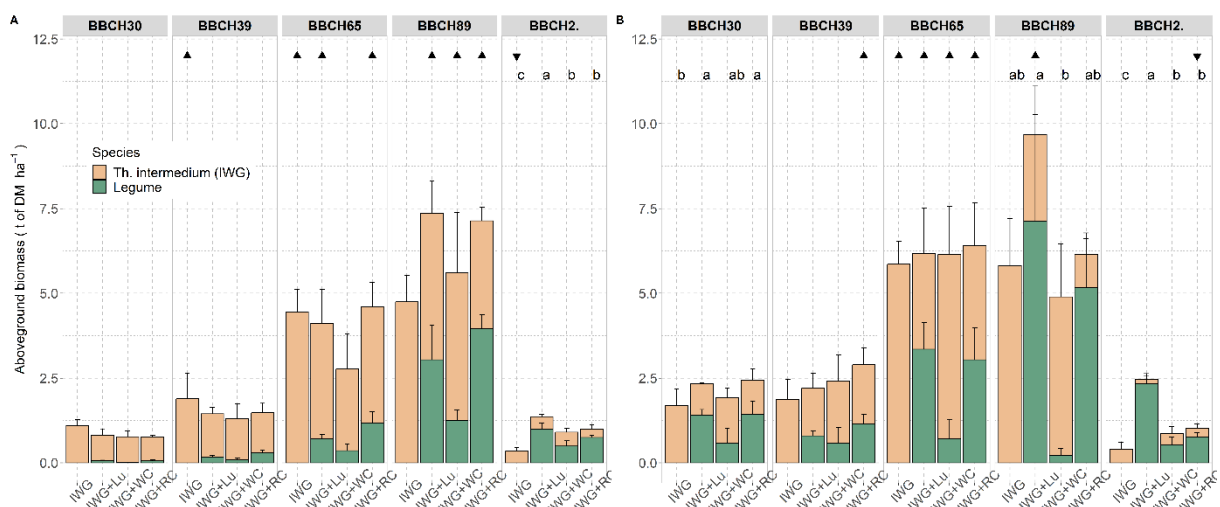

290 3.2.1 Forage quantity

291 As illustrated in Figure 4, an establishment year was observed for both *Th. intermedium* and legumes
292 through an increase of biomass from the first to the second cropping year. Particularly for legumes,
293 this establishment was marked by the increase in their relative importance (in terms of DM) in the

294 mixture over the first growing season (i.e., less than 10 % at BBCH30 compared to 23 % for white clover
 295 and more than 40 % for red clover and lucerne at BBCH89).

296 Globally, biomass production of *Th. intermedium* was low (Figure 4). Grown alone, it ranged from 4.8
 297 to 5.8 t of DM ha⁻¹ at grain maturity (i.e., BBCH89). In 2023, the spring forage harvest (only performed
 298 this year) allowed an additional exportation of biomass of 1.7 t ha⁻¹ at the beginning of the reproductive
 299 phase (i.e., BBCH30). Low autumn regrowth (i.e., 0.4 t of DM ha⁻¹ at BBCH2.) was also observed for *Th.*
 300 *intermedium*, representing lower levels compared to the biomass production at the BBCH30 stage (p
 301 < 0.001).

302 The biomass production at grain maturity and at autumn regrowth was increased (p < 0.01) when a
 303 mixture was performed, especially with lucerne and red clover, as they were the two most productive
 304 legumes (e.g., red clover reached 4 to 5.2 t of DM ha⁻¹ and lucerne reached 3 to 7.1 t of DM ha⁻¹,
 305 compared to 0.2 to 1.2 t of DM ha⁻¹ for white clover at BBCH89; Figure 4). At the autumn vegetative
 306 stage (i.e., BBCH2.), the legume mixtures increased the biomass production from 225 to 600 %
 307 compared to the production of *Th. intermedium* in monoculture. At this stage, *Th. intermedium* was
 308 completely dominated by lucerne and red clover (i.e., more than 70 % of legumes within the mixture).
 309 Indeed, a strong competition from red clover and lucerne on *Th. intermedium* was observed, especially
 310 in 2023, reducing its production (p < 0.001). The relative loss of biomass of *Th. intermedium* in mixture
 311 compared to its monoculture at grain maturity was from 0.5 to 4.8 t ha⁻¹ when associated to red clover
 312 or lucerne and from 0.4 to 1.1 t of DM ha⁻¹ when associated to white clover (Figure 4). In contrast,
 313 white clover was dominated by *Th. intermedium* and represented less than 10 % of the mixture at
 314 BBCH89 in 2023.

315 Figure 4 : Total aboveground biomass of the various species mixture treatments during the growing season of (A) 2022 and
 316 (B) 2023. Standard errors are indicated by error bars. Letters represent the results of the post hoc analysis of the effect of the
 317 species mixture for each phenological stage (i.e., each letter is assigned to a boxplot representing the species mixture
 318 treatment). Bar plot with a symbol indicates the results of the post hoc analysis of the effect of the phenological stage for each
 319 species mixture treatment; ▽ specifying a decreased value; and Δ specifying an increased value compared to the previous
 320 phenological stage, except at BBCH2, where the comparison is with the BBCH30 stage. IWG for intermediate wheatgrass - *Th.*
 321 *intermedium*, Lu for lucerne, WC for white clover and RC for red clover.
 322

323 3.2.2 Forage composition and nutritive value

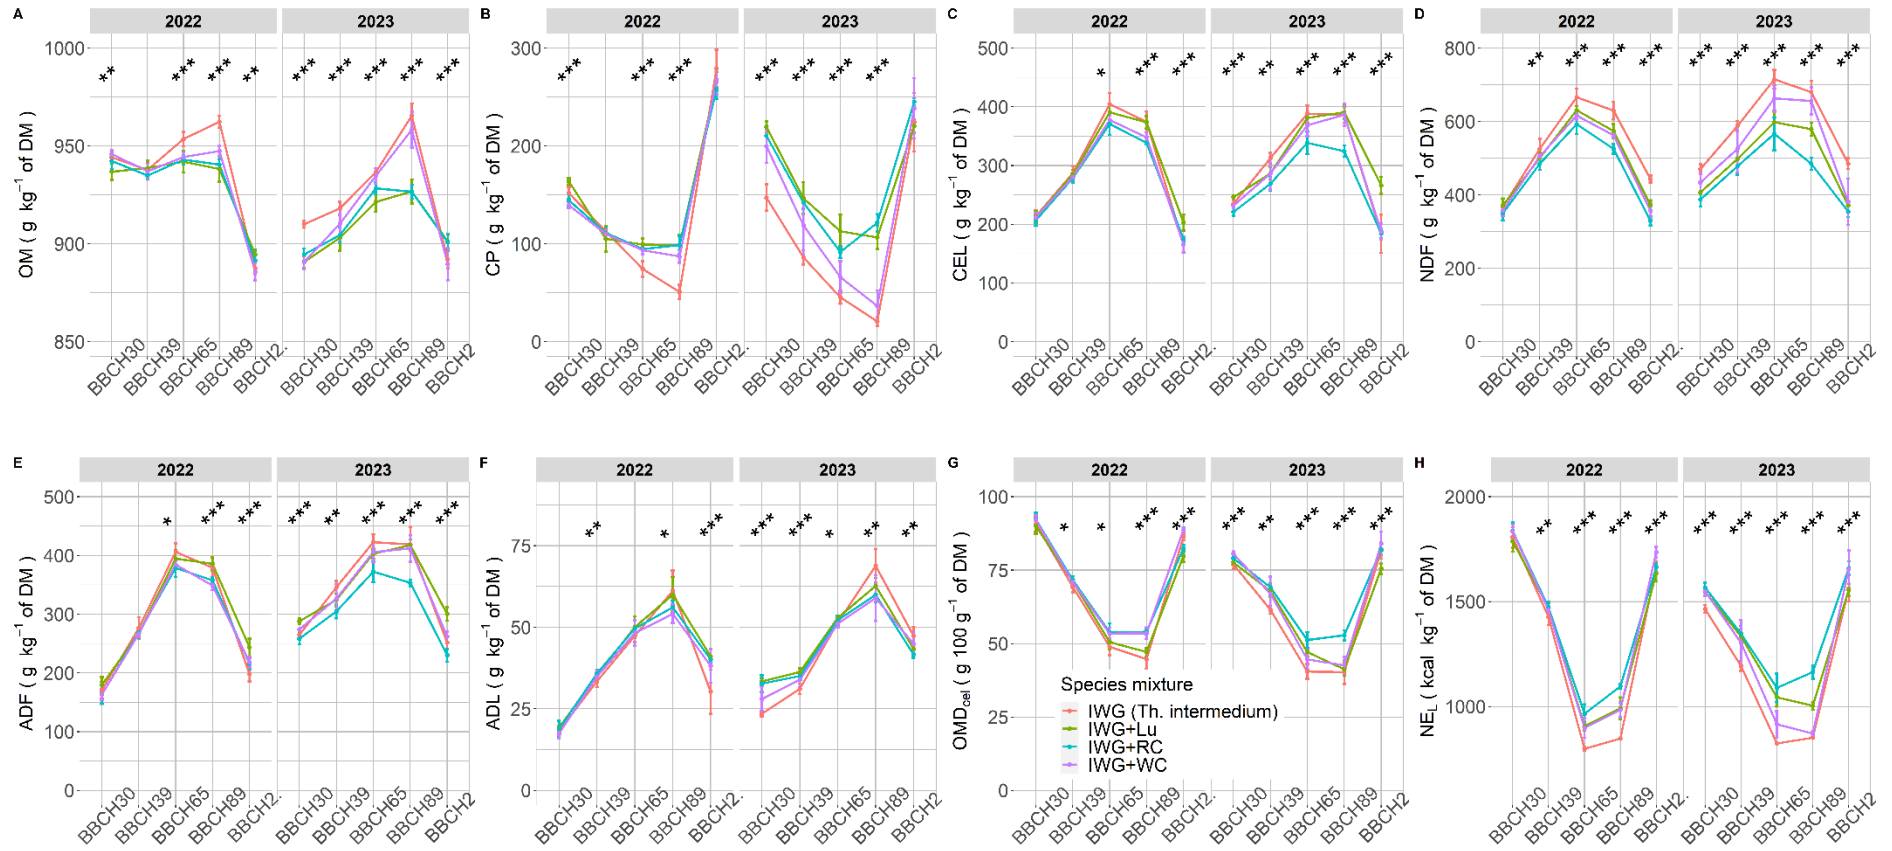

324 The forage composition of legumes is presented in supplementary materials – Table S2. Globally,
 325 lucerne had the highest content in CEL, NDF and ADF and the lowest in OMD_{cel} and NE_L. The opposite
 326 was observed with white clover, and red clover showed intermediate values (p < 0.05). The CP content
 327 of legumes didn't vary across species (Table S2).

328 Concerning organic matter (OM), it ranged from 888 to 966 g kg⁻¹ of DM (Figure 5A) and was composed
 329 from 21 to 31 % of hemicellulose (i.e., NDF minus ADF), from 16 to 40 % of cellulose (i.e., ADF minus

330 ADL), from 2 to 7 % of lignin (i.e., ADL), from 2 to 31 % of crude protein (CP) and from 2 to 3 % of crude
331 fat for *Th. intermedium* monoculture. The remaining part was represented by the nonfibrous
332 carbohydrates (NFC), ranging from 15 to 42 % of the OM. Globally, the OM increased during the
333 growing season ($p < 0.001$). When an effect of the species mixture treatments was observed, OM was
334 generally lower in mixtures compared to the monoculture ($p < 0.01$).

335 As shown by the PCA (Figure 2), the forage quality of the different mixture treatments was influenced
336 by the phenological stages. Fiber content (i.e., CEL, NDF, ADF and ADL) increased during the growing
337 season, while CP, OMD_{cel} and NE_L decreased ($p < 0.001$; Figure 5). For the monoculture of *Th.*
338 *intermedium*, the highest CEL, NDF and ADF contents were observed at the flowering stage (i.e.,
339 BBCH65; mean, in g kg⁻¹ of DM, of 396 for CEL, 690 for NDF and 415 for ADF). The highest content of
340 ADL was observed at the grain maturity stage (i.e., BBCH89; mean of 65 g kg⁻¹ of DM). Concerning CP,
341 OMD_{cel} and NE_L the highest values were observed at vegetative stages (i.e., BBCH30 and BBCH2.) with
342 a mean of 201 g kg⁻¹ of DM, 84 g per 100 g of DM and 1625 kcal kg⁻¹ of DM, respectively.

343 The forage quality was modified by legumes once they were well established (i.e., representing roughly
344 20 % of the mixture, Figure 4 and 5) at a leafy vegetative stage, as early phenological stage induced
345 the best forage quality (Table S2). Thus, red clover had globally the major impact on the forage quality
346 compared to white clover and lucerne (Figure 5). In mixture, the NDF content was reduced by about
347 87 g kg⁻¹ of DM regardless of the legume species ($p < 0.01$). At late phenological stages (i.e., BBCH65
348 and BBCH89), CEL and ADF decreased in the red clover mixture by about 43 g kg⁻¹ of DM ($p < 0.05$).
349 Focusing on the CP content, the mixture with legumes buffered the decrease over the growing season,
350 especially with red clover and lucerne ($p < 0.001$) as no effect was observed at the autumn vegetative
351 stage (i.e., BBCH2.). Concerning the OMD_{cel}, the highest increase was observed at late phenological
352 stages with the red clover mixture (e.g., maximal increase of 13 g per 100 g of DM). Finally, legumes
353 increased the energy value (NE_L) and particularly the red clover mixture (e.g., maximal increase of 313
354 kcal kg⁻¹ of DM). Focusing on *Th. intermedium* forage parameters in the mixture, the CP content was
355 the only parameters influenced by legumes at the beginning of the second year (i.e., BBCH30 and
356 BBCH39), with a maximal increase of 30 g kg⁻¹ of DM with red clover at BBCH30 (supplementary
357 materials – Figure S2).

Statistical differences (post hoc analysis) between species mixture treatment for each phenological stage are indicated by “*” with a statistical significance at $p < 0.05$, “**” with a statistical significance at $p < 0.01$, “***” with a statistical significance at $p < 0.001$. IWG for intermediate wheatgrass - *Th. intermedium*, Lu for lucerne, WC for white clover and RC for red clover.

364

365 3.3 Grain production of *Th. intermedium* in mixture with legumes

366 Overall, *Th. intermedium* grain yields were low (Figure 6) and ranged from 345 to 616 kg ha⁻¹. This was
367 partly explained by a weak establishment of the crop during the two first years with an average tiller
368 density of 260 tillers m⁻² during the entire first reproductive phase and 690 tillers m⁻² at the beginning
369 of the second reproductive phase, regardless of the species mixture treatment. This led to low spike
370 densities in the first year (i.e., ranging from 165 to 257 spikes m⁻²). In addition, the spring forage harvest
371 performed in the second year reduced the grain yield potential by about half compared to no spring
372 forage harvest (data not shown).

373 As observed in Figure 6, the mixture with a legume impacted the grain yield ($p < 0.05$) with the highest
374 grain yield obtained with *Th. intermedium* monoculture and the lowest with the mixture of *Th.*
375 *intermedium* with lucerne and red clover. Furthermore, in the second year, the mixtures with lucerne
376 and red clover led to the impossibility of harvesting grains due to lodging. Spike density was also
377 impacted by the mixture with legume ($p < 0.01$), with the highest densities obtained with the
378 monoculture (i.e., 260 and 440 spike m⁻² in the first and second year, respectively) and the lowest with
379 *Th. intermedium* associated with red clover (i.e., 165 and 56 spikes m⁻² in the first and second year,
380 respectively).

386 4. Discussion

387 4.1 NIR spectrometry prediction

388 *Th. intermedium* samples used to develop the NIR models showed a wide range of values for the
389 different forage parameters. Although the database contained various cropping sites, this variability
390 mainly reflected the ageing tissues from different phenological stages. This was also observed in
391 Culman et al. (2023) where the forage nutritive value was primarily driven by seasonal trends and to a
392 much lesser extent by stand ages. Good quality predictions were obtained for most forage parameters
393 through the different quality criteria. An exception can be mentioned with ADL with a lower quality of

394 prediction due to the weak repeatability of the chemical analysis (Table 2). As our NIR calibration was
395 based on a single species, the predictions were fairly accurate, but could involve less robustness
396 (Deville & Flinn, 2000). Although satisfactory, this initial model should be further completed with
397 additional data coming from new climatic years to broaden the database. Nevertheless, this first
398 calibration offered a fast and efficient tool to characterize the forage composition of *Th. intermedium*
399 across various pedoclimatic conditions and management practices. In addition, as present-day
400 breeding efforts on *Th. intermedium* for grain yield improvements could constrain the production of
401 vegetative tillers to the benefit of reproductive ones (Altendorf et al., 2021), this method could be
402 helpful to assess the effect of breeding advances on forage quality.

403 4.2 Forage production potential of *Th. intermedium*

404 The different forage parameters of *Th. intermedium* were in agreement with other studies on the
405 species (Table 3). Forage quality of *Th. intermedium* at vegetative stages (i.e., BBCH30 and BBCH2.)
406 was satisfactory with an energy content (NE_L) of 1625 kcal kg⁻¹ of DM (Figure 5), which was close to a
407 fresh grass (Table 3). Indeed, the various forage parameters of *Th. intermedium* were close to those of
408 common pasture grasses such as *Phleum pratense* L., *Lolium perenne* L., *Festuca pratensis* Huds.,
409 *Festuca arundinacea* Schreb. and *Dactylis glomerata* L. at the same stage (Table 3). The protein (CP)
410 content was more variable ranging from 147 to 279 g kg⁻¹ of DM and tended to be higher in autumn.
411 Consequently, this fodder could be used to feed lactating dairy cattle with an eventual proper
412 supplementation for balancing the amount of protein and energy in the diet (Cuvelier et al., 2021).
413 However, the biomass production of *Th. intermedium* at vegetative stages was weak, averaging 1.4 t
414 ha⁻¹ at the beginning of the spring (i.e., BBCH30) and 0.4 t ha⁻¹ at the autumn regrowth. Although our
415 spring production was close to other studies, the autumn production was lower, generally between 1
416 and 2 t ha⁻¹ (Culman et al., 2023; Hunter et al., 2020). The mean total production of vegetative biomass
417 averaged 1.8 t ha⁻¹ over a growing season (Figure 4). Pugliese (2017) reported that the production in
418 spring and autumn can, both, reach 4 t ha⁻¹, but only one of the two forage harvests was performed
419 over the growing season.

420 At grain maturity, the quality of *Th. intermedium* forage was relatively low with NE_L averaging 849 kcal
421 kg⁻¹ of DM (Figure 5). The fiber content of *Th. intermedium* was quite close to the reference values of
422 the different common pasture grasses previously mentioned at a flowering stage. However, the
423 OMD_{cel}, CP and NE_L values of *Th. intermedium* were close to common cereals straw (i.e., wheat, barley
424 and oat; Table 3). As already mentioned in the study of Favre et al. (2019), this crop residues could
425 replace straw in high-starch dairy diets to maintain proper rumen function and prevent acidosis
426 (Hurdebise et al., 2023). The biomass production at grain harvest averaged 5.3 t ha⁻¹ (Figure 4). This
427 was relatively low compared to the yield potential of *Th. intermedium* in our pedoclimatic conditions
428 that ranged from 7 to 16 t ha⁻¹ (Fagnant et al., 2023). It can be explained by the poor establishment of
429 the crop in the first year (i.e., only 260 tillers m⁻² during the first year) and the spring forage harvest
430 performed in the second year. As observed by Culman et al. (2023), the summer yield potential was
431 highly variable ranging from 2 to 11 t of DM ha⁻¹.

432 Over a growing season, the yield potential of *Th. intermedium* ranged from 5.2 to 7.9 t ha⁻¹ (Figure 4).
433 As observed by Pugliese (2017), when a spring, an autumn or both forage harvests are performed, this
434 yield potential varied widely, but was generally exceeding 9 t ha⁻¹ (Favre et al., 2019; Hunter et al.,
435 2020). While the biomass production *Th. intermedium* could reach that of sowed grasslands (i.e., sown
436 European grassland range from 5 to 12 t of DM ha⁻¹ y⁻¹ and up to 20 t ha⁻¹ y⁻¹; Wilkins (2000)), its forage
437 potential was limited. Indeed, most of the biomass was obtained at grain maturity (i.e., more than 70
438 % of the biomass of the year) with a forage quality comparable to cereal straw, which was of little

439 value in animal feed. In contrast, only 2 to 4 t of DM ha⁻¹, in best cases, could be valorized as good
 440 quality *Th. intermedium* fodder. Spring forage harvest represented a way to increase the proportion of
 441 good quality fodder, as it decreased the proportion of biomass harvested at grain maturity from 95 to
 442 73 % and converted the remaining percentage into valuable fodder. However, a trade-off between
 443 grain and forage harvest was observed. The spring forage harvest decreased grain yield of *Th.*
 444 *intermedium* in our second year (data not shown), as also observed in other studies (Culman et al.,
 445 2023; Hopkins et al., 2003; Zimbric et al., 2021). This could be explained by the removal of the leaf area
 446 essential for grain production and the limited accumulation of reserves after the spring harvest
 447 (Culman et al., 2023). In addition, *Th. intermedium* regrowth was not sufficient to justify an autumn
 448 forage harvest. All these insights highlighted the complexity to produce sufficient high-quality fodder
 449 in a growing season dedicated to grain production, suggesting a potential forage valorization within
 450 extensive livestock production with moderate production goals. As mentioned by Duchene et al.
 451 (2021), *Th. intermedium*, as a slow-growing species, could be more suited to harsh pedoclimatic
 452 conditions (e.g., fields at high altitudes or with low resource-availability) through its capacity to
 453 produce high levels of biomass with low resources requirements such as water or nitrogen (Clément
 454 et al., 2022; Fagnant et al., 2023).

455 *Table 3 : Forage parameters of common pastures grasses and other feedstuffs compared to Th. intermedium at different*
 456 *phenological stages found in the literature.*

N.B.: enzymatic in vitro digestibility (OMD_{ce}) is expressed in g per 100 g of DM, crude protein (CP), crude cellulose (CEL), neutral detergent fiber (NDF) and acid detergent fiber (ADF) in g per kg of DM and net energy for lactation (NE_L) in kcal per kg of DM.

457 4.3 Production potential of *Th. intermedium* grown in mixture

458 The mixture of *Th. intermedium* with legumes could improve the forage potential through quantity
 459 and, to a lesser extent, quality. We observed this positive impact when legumes represented at least
 460 20 % of the mixture. As observed in Figure 4, this proportion was not encountered before the flowering
 461 stage of the establishment year. In addition, we observed differences between legumes, with lower
 462 levels of biomass of white clover which was dominated within the mixture contrarily to red clover and
 463 lucerne. We also noticed better forage qualities of red clover and white clover compared to lucerne.
 464 Through its high biomass production and its good forage quality, red clover had the major impact on
 465 the forage quality of the mixture (Figure 4; Table S2). The positive effect of the legume mixture was
 466 mainly observed at late phenological stages, with a reduction of the fiber content (i.e., CEL, NDF, ADF)
 467 and the increase of the protein (CP) content, digestibility (OMD_{ce}) and net energy (NE_L) (Figure 5).
 468 However, at grain maturity, the production of *Th. intermedium* in mixture with legume resulted in a

469 forage with still little value in animal feed. Depending on the forage parameter compared and the
470 legume used within the mixture, the forage was comparable to common pasture grasses at a flowering
471 stage or grass seed and cereal straws that had lower forage nutritive value than a hay characterized
472 by 'poor quality' (Table 3). Concerning the forage quantity, at grain harvest, it was increased with the
473 lucerne and red clover mixtures (i.e., mean increase of 2.3 t of DM ha⁻¹; Figure 4). In autumn, due to
474 the lack of regrowth of *Th. intermedium*, a significant increase of the forage quantity was observed for
475 all the legume mixtures (i.e., mean increase of 1 t ha⁻¹; Figure 4). In the study of Favre et al. (2019) red
476 clover mixture increased forage yield around 3 t ha⁻¹ over the year and its CP content as it decreased
477 fiber content in autumn.

478 The increase of the total biomass production when *Th. intermedium* was associated to red clover or
479 lucerne came at the expense of *Th. intermedium* growth. The crop showed little competitiveness over
480 these two species with a loss of biomass compared to its monoculture at BBCH89 from 1 to 5 t ha⁻¹
481 (Figure 4). This was also reflected in grain yield component with a loss from 22 to 82 % of spike density
482 and therefore a reduction of the grain yield from 37 to 100 % (Figure 6). Indeed, the strong competition
483 of these productive forage legumes (i.e., production level always above 4 t of DM ha⁻¹; Figure 4)
484 induced an impossibility of grain harvesting due to lodging at grain maturity. It was also highlighted by
485 Tautges et al. (2018), where a reduction of the grain yield was observed when *Th. intermedium* was
486 grown in mixture with lucerne that produced from 2 to 4 t of DM ha⁻¹. As Pinto et al. (2022) observed
487 that the high level of red clover and lucerne biomass compromised the establishment of *Th.*
488 *intermedium* and its grain and forage production. On the contrary, through its low production (i.e.,
489 maximum of 1.2 t of ha⁻¹ observed at BBCH89 in 2022; Figure 4), white clover had little effect on grain
490 yield with similar spike density and limited reduction of the grain yield compared to *Th. intermedium*
491 monoculture (Figure 6). In the study of Dick et al. (2018), the mixtures with white clover and lucerne
492 didn't impact the production of *Th. intermedium* since their production of biomass didn't exceed 1 t
493 ha⁻¹. Pinto et al. (2022) suggested that the early *Th. intermedium* biomass accumulation in the
494 establishment year was essential with aggressive legume's establishment such as red clover and
495 lucerne. Thus, new agroecosystems should be designed to optimize the complementarity and stability
496 of the mixture of *Th. intermedium* with legume under a dual-use management. Some research was
497 performed to understand how to regulate the competition between *Th. intermedium* and perennial
498 legumes with agronomic management. This included forage cuttings in the interrow (Crews et al.,
499 2022), legume frost seeded in the spring on *Th. intermedium* crop planted in the previous fall
500 (Olugbenle et al., 2021; Pinto et al., 2022) or the implantation of annual legume such as berseem clover
501 (Pinto et al., 2022) to reduce competition. As suggested by Culman et al. (2023), management of the
502 crop could also be shifted from grain production to a single-purpose forage production over the
503 cropping years, enabled by the stability of the forage quantity and quality of *Th. intermedium* over
504 time. Finally, the implantation of legumes may take place after the first years of *Th. intermedium* grain
505 production to allow proper establishment of the crop and maximize the benefits of the legume
506 mixtures for forage production.

507 5. Conclusion

508 Through proper model calibrations, near-infrared spectrometry offered an efficient and easy-to-use
509 tool to predict the forage chemical composition and enzymatic in vitro digestibility of *Th. intermedium*,
510 with the need to continuously supply the database to catch the maximal variability of forage
511 constituents. *Th. intermedium* forage potential was reduced as most of the biomass harvested in a
512 dual-use perspective had poor nutritional value. The intensification of forage production through the
513 spring forage harvest or the mixture with competitive legumes came at the expense of the grain
514 production of *Th. intermedium*. Therefore, in the perspective of a dual-use management, the
515 implantation of companion legume such as white clover, in case of good stand establishment, could
516 slightly enhance the forage yield potential (i.e., increase of nutritive value and of forage quantity at
517 autumn regrowth) without hampering the grain production. More competitive legumes, like red clover

518 and lucerne, require more work to find the best varieties or innovative management options in fields.
519 All these insights can inform the on-going process of *Th. intermedium*'s breeding and help farmers to
520 design relevant systems to experiment this new crop.

521 6. Funding & Conflict of Interest

522 This research received no specific grant from any funding agency in the public, commercial, or not-
523 for-profit sectors.

524 The authors have no conflict of interests related to this publication.

525 7. Acknowledgement

526 Chloé Dufrane, Antonin Guillaume and Lucas Villé for the great work they performed during their
527 master thesis. Sylvie Mabilbe for its huge contribution to reference chemical analyses.

528 8. Author contribution

529 L.F.: Conceptualization and planning of the experiments. Writing – original draft Preparation.

530 Carrying out the samplings, data curation, formal analyses (statistical and mathematical).

531 L.F., V.D., Y.B., B.D.: Formulation of research goals and aims.

532 L.F., V.D., B.D.: Development and design of methodology. Formal analyses (statistical).

533 L.F., V.D., Y.B.: Contribution to the interpretation of result.

534 O.D.; V.D., Y.B., J.B.: Help provided for data presentation and visualization, critical review,

535 commentary and revision, validation.

536 9. Statement for Data availability

537 Data will be available on request.
